With this claim in hand, we are ready to prove Lemma 16.

Proof of Lemma 16. Let f be a continuous function satisfying $f(-x) = -f(x)$. By Lemma 8, the function g is additive. Conditioned on this event, we will show that the continuity of f implies that g is linear as well. To do so, we will argue that g is continuous at the origin and then appeal to Claim 17 to conclude that g is linear.

Let B be a ball of mass $1/2$ (with respect to $\mathcal{N}(0, I)$) centred at the origin. Let $\{p_i\}_i$ be any sequence of points with $p_i \in B$, $\|p_i\|_2 \leq 1/r$ and $p_i \to 0$. Now, let $\{x_i\}_i$ be a sequence of points such that $g(p_i) = f(p_i - x_i) + f(x_i)$ and $x_i \in B$. Such a sequence exists because, by Lemma 8 $\Pr_{x \sim \mathcal{N}(0,I)}[g(x) = f(p_i - x) + f(x)] \geq 1/2$ and so for every p_i there must exist such an x_i in B.

Let S be the ball centred at the origin with twice the radius of B. As S is compact and f is continuous, f is uniformly continuous on S. Thus for every $\xi > 0$, there exists $\zeta > 0$ such that $|f(p_i - x_i) - f(-x_i)| = |f(p_i - x_i) + f(x_i)| < \xi$ whenever $\|(p_i - x_i) + x_i\|_2 < \zeta$. Now, take a sequence $\{\xi_i\}_i$ with $\xi_i \to 0$ and consider the corresponding sequence $\{\zeta_i\}_i$. As $p_i \to 0$, for every i, there exists j such that $\|(p_j - x_j) + x_j\|_2 < \zeta_i$ which in particular implies that $|g(p_j)| = |f(p_j - x_j) + f(x_j)| < \xi_i$. Thus, $g(p_i) \to 0$, and g is continuous at the origin. By Claim 17, we can conclude that g is a linear function. ◀

Now we consider the case when $f(-x) \neq -f(x)$ for some x. Luckily, in this case we can *force* f to satisfy $f(-x) = -f(x)$. To do so, we test whether f is $\varepsilon/2$-far from satisfying this property. If it is, then we reject f, otherwise, we can replace f with a function f' guaranteed to satisfy this property, by defining

$$f'(x) := \frac{f(x) - f(-x)}{2}.$$

We then continue to work over f' rather than f. Our modified algorithm is given in Algorithm 4, which uses Algorithm 5 as a subroutine.

▷ Claim 18. If FORCENEGATIVITY$(f, \mathcal{D})$ accepts with probability at least $1/10$, then $\Pr_{x \sim \mathcal{D}}[f(x) = f'(x)] \geq 1 - \varepsilon$.

Proof. Suppose for contradiction that $\Pr_{x \sim \mathcal{D}}[f(x) = f'(x)] \leq 1 - \varepsilon$. Observe that for a point $x \in \mathbb{R}$, $f'(x) \neq f(x)$ iff $f(-x) \neq -f(x)$. Therefore, by choosing the hidden constant in N_5 to be large enough, the probability that all the sampled points x satisfy $f(x) = -f(x)$ is at most

$$\left(\Pr_{x \sim \mathcal{D}}[f(-x) = f(x)]\right)^{N_5} < (1 - \varepsilon)^{N_5} \leq \frac{1}{10},$$

which is a contradiction. ◁

Algorithm 4 Distribution-Free Linearity Tester.

Given: query access to a continuous $f\colon \mathbb{R}^n \to \mathbb{R}$, sampling access to an unknown distribution $\mathcal{D}$, and sampling access to $\mathcal{N}(0, I)$;

Reject if FORCENEGATIVITY$(f, \mathcal{D})$ returns **Reject**;
Let f' be the returned function;
Reject if TESTADDITIVITY(f') returns **Reject**;
for $N_4 := O(1/\epsilon)$ *times* **do**
    Sample $p \sim \mathcal{D}$;
    Reject if $f'(p) \neq$ QUERY-$g(f', p)$ or if QUERY-$g(f', p)$ returns **Reject**.
Accept.

Algorithm 5 Force Negativity Subroutine.

Procedure FORCENEGATIVITY$(f, \mathcal{D})$
    Given: query-Access to $f\colon \mathbb{R}^n \to \mathbb{R}$ and sampling access to an unknown distribution $\mathcal{D}$;
    for $N_5 := O(1/\epsilon)$ *times* **do**
        Sample $x \sim \mathcal{D}$;
        Reject if $f(-x) \neq -f(x)$;
    Return a function $f'\colon \mathbb{R}^n \to \mathbb{R}$ where $f'(x) := \frac{f(x)-f(-x)}{2}$;

Therefore if FORCENEGATIVITY$(f, \mathcal{D})$ accepts with probability at least $1/10$, f and f' are $\varepsilon/2$-close. Furthermore, because f is continuous and f' is the sum of continuous functions, f' is continuous as well, and so we can proceed with f' in place of f.

Proof of Theorem 2. First, observe that if f is linear then $f = f'$ and Algorithm 4 always accepts.

Now, we show that if f is ε-far from linear functions, then Algorithm 4 rejects with probability at least $2/3$. If either the TESTADDITIVITY subroutine or the FORCENEGATIVITY subroutine passes with probability at most $1/10$, we can reject f with probability at least $1 - 1/10 > 2/3$. Hence, we assume both the subroutines pass with probability at least $1/10$. Then by Lemma 18, f is $\varepsilon/2$-close to f', which means that f' is $\varepsilon/2$-far from linear. Also by Lemma 16, because f' is continuous and satisfies $f'(-x) = -f'(x)$, the function g is linear, and so f' is $\varepsilon/2$-far from g. Therefore, Algorithm 4 rejects f with probability at least $1 - 1/10 > 2/3$. ◀

5 Lower Bounds on Testing Linearity in the Sampling Model

In this section, we prove Theorem 3, that is, we show without query access, any tester requires a linear number of samples in order to test linearity and additivity over the standard Gaussian. We note that we can obtain the same lower bound for testing additivity just by replacing linearity with additivity in the proof.

By Yao's minimax principle it suffices to construct two distributions, $\mathcal{D}_{\text{yes}}$ over linear functions and $\mathcal{D}_{\text{no}}$ over functions which are (with probability 1) $1/3$-far from linear such that any deterministic n-sample algorithm cannot distinguish between them with probability at least $2/3$. Let $\delta \in \mathbb{R}^{\geq 0}$ be some parameter to be set later; we will think of δ as tiny. Instances from these two distributions are generated as follows:

- $\mathcal{D}_{\text{yes}}$: Sample $w \sim \mathcal{N}(0, I)$ and return $f(x) := \langle w, x \rangle$.
- $\mathcal{D}_{\text{no}}$: Sample $w \sim \mathcal{N}(0, I)$ and for every $x \in \mathbb{R}^n$ sample $\varepsilon_x \sim \mathcal{N}(0, \delta)$. Return $f(x) := \langle w, x \rangle + \varepsilon_x$.

The functions in the support of $\mathcal{D}_{\text{yes}}$ are linear by definition. It remains to show that the instances in the support of $\mathcal{D}_{\text{no}}$ are far from linear.

▶ **Lemma 19.** *With probability* 1 *any* $f \sim \mathcal{D}_{\text{no}}$ *is* 1/3*-far from linear.*

The proof of this lemma will hinge on the following claim.

▷ Claim 20. Let $f \sim \mathcal{D}_{\text{no}}$, for $x, y, z \sim \mathcal{N}(0, 1)$, $\Pr[f(\frac{x-y}{2}) \neq f(\frac{x-z}{2}) + f(\frac{z-y}{2})] = 1$.

Proof. Observe that $\Pr\left[f\left(\frac{x-y}{2}\right) = f\left(\frac{x-z}{2}\right) + f\left(\frac{z-y}{2}\right)\right] = \Pr\left[\varepsilon_{(x-y)/2} = \varepsilon_{(x-z)/2} + \varepsilon_{(z-y)/2}\right]$, where the probability is over $\varepsilon_{(x-y)/2}, \varepsilon_{(x-z)/2}, \varepsilon_{(z-y)/2} \sim \mathcal{N}(0, \delta)$. Define the random variable $z := \varepsilon_{(x-y)/2} - \varepsilon_{(x-z)/2} - \varepsilon_{(z-y)/2}$, and note that z is distributed according to $\mathcal{N}(0, 3\delta)$. Then

$$\Pr_{z \sim \mathcal{N}(0,3)}\left[\varepsilon_{(x-y)/2} = \varepsilon_{(x-z)/2} + \varepsilon_{(z-y)/2}\right] = \Pr_{z \sim \mathcal{N}(0,3)}[z = 0].$$

By standard arguments, we have $\Pr_{z \sim \mathcal{N}(0,3\delta)}[z = 0] = 0$. ◁

Proof of Lemma 19. Let f^* be the closest linear function to f. For a point $x \in \mathbb{R}^n$, say that $f(x)$ is *bad* if $f(x) \neq f(x^*)$. Construct the following matrix: the rows are labelled by every triple $(\frac{x-y}{2}, \frac{x-z}{2}, \frac{z-y}{2})$ and there are three columns. The entries at row $(\frac{x-y}{2}, \frac{x-z}{2}, \frac{z-y}{2})$ are $f(\frac{x-y}{2})$, $f(\frac{x-z}{2})$, and $f(\frac{z-y}{2})$. Note that because $x, y, z \sim \mathcal{N}(0, 1)$, the points $\frac{x-y}{2}, \frac{x-z}{2}, \frac{z-y}{2}$ are distributed according to $\mathcal{N}(0, 1)$.

Henceforth, we will measure mass in terms of probability mass over $\mathcal{N}(0, 1)$. By Claim 20, the probability that each row contains a bad entry is 1. Therefore, there must be some column for which the probability mass of the bad entries is at least 1/3. This implies that a mass of at least 1/3 of f must be changed to obtain f^*. Because f^* is the closest linear function to f, this implies that f is 1/3-far from linear. ◀

Having defined our distributions over linear and far-from-linear functions, it remains to argue that no algorithm receiving n samples can distinguish between them with high probability.

Proof of Theorem 3. Let $\mathcal{D}$ be the distribution that with probability 1/2 draws $f \sim \mathcal{D}_{\text{yes}}$ and otherwise draws $f \sim \mathcal{D}_{\text{no}}$. Let A be any deterministic algorithm which receives n samples $x_1, \ldots, x_n \sim \mathcal{N}(0, I)$. By Yao's minimax principle, it suffices to show that A cannot correctly distinguish which distribution of the distributions $\mathcal{D}_{\text{yes}}$ or $\mathcal{D}_{\text{no}}$ a given sample $f \sim \mathcal{D}$ comes from with probability at least 2/3. That is, we would like to show that

$$\left| \Pr_{\substack{f \sim \mathcal{D}_{\text{yes}} \\ x_1, \ldots, x_n \sim \mathcal{N}(0,I)}} [A(f(x_1), \ldots, f(x_n)) = 1] - \Pr_{\substack{f \sim \mathcal{D}_{\text{no}} \\ x_1, \ldots, x_n \sim \mathcal{N}(0,I)}} [A(f(x_1), \ldots, f(x_n)) = 1] \right| \quad (4)$$

is $o(1)$. Suppose for contradiction that an algorithm A exists that with probability at least 2/3 distinguishes these distributions.

Observe that the (4) can be bounded from above by the total variation distance between the distributions $(f^y(x_1), \ldots, f^y(x_n))$ for $f^y \sim \mathcal{D}_{\text{yes}}$, and $(f^n(x_1), \ldots, f^n(x_n))$ for $f^n \sim \mathcal{D}_{\text{no}}$, for $x_1, \ldots, x_n \sim \mathcal{N}(0, I)$, as applying the algorithm A can only make the total variation distance smaller. By the definition of $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$, this means bounding the total variation distance between $(w_y^\top x_1, \ldots, w_y^\top x_n)$ and $(w_n^\top x_1 + \varepsilon_{x_1}, \ldots, w_n^\top x_n + \varepsilon_{x_n})$, where $w_y \sim \mathcal{D}_{\text{yes}}$ and $w_n \sim \mathcal{D}_{\text{no}}$.

Now, let $X \in \mathbb{R}^n$ be the matrix whose rows are $x_1, \ldots, x_n$. Because $w_y, w_n \sim \mathcal{N}(0, I)$ and $\varepsilon_{x_i} \sim \mathcal{N}(0, \delta)$, it follows that

$$(w^\top x_1, \ldots, w^\top x_n) \sim \mathcal{N}(0, XX^\top),$$
$$(w_n^\top x_1, \ldots, w_n^\top x_n) + (\varepsilon_{x_1}, \ldots, \varepsilon_{x_n}) \sim \mathcal{N}(0, XX^\top + \delta I).$$

Therefore,

$$(4) \leq \mathrm{d_{TV}}(\mathcal{N}(0, XX^\top), \mathcal{N}(0, XX^\top + \delta I)).$$

To bound this distance we will appeal to Pinkser's inequality and Lemma 5. Thus, it will be useful to first record some facts about the covariance matrices of these distribution. First, we show that the rows of the matrix X are linearly independent with high probability.

▶ Fact 21. $\Pr_{x_1,\ldots,x_n \sim \mathcal{N}(0,1)}[\mathrm{span}(x_1, \ldots, x_n) = \mathbb{R}^n] = 1.$

It follows that the covariance matrices of these two distributions are positive definite with high probability.

▷ Claim 22. With probability 1 the matrices $XX^\top$ and $XX^\top + \delta I$ are positive definite.

Proof. That $XX^\top \succ 0$ is immediate from Fact 21, which implies that rows of X are linearly independent with probability 1. Let $\lambda_1, \ldots, \lambda_n$ be the eigenvalues of $XX^\top$. To prove that $XX^\top + \delta I \succ 0$ note that adding δI simply adds δ to each of the eigenvalues. Thus, the eigenvalues of $XX^\top + \delta I$ are all positive. ◁

With these facts in hand we turn to bounding the total variation distance between $\mathcal{N}(0, XX^\top)$ and $\mathcal{N}(0, XX^\top + \delta I)$. Denote by $\Sigma_{\mathrm{yes}} := XX^\top$ and $\Sigma_{\mathrm{no}} := XX^\top + \delta I$. By Pinkser's inequality (Theorem 4) and Lemma 5,

$$\mathrm{d_{TV}}\left(\mathcal{N}(0, XX^\top), \mathcal{N}(0, XX^\top + \delta I)\right) \leq \sqrt{\frac{1}{4}\left(\log\left(\frac{\det \Sigma_{\mathrm{yes}}}{\det \Sigma_{\mathrm{no}}}\right) + \mathrm{tr}\left(\Sigma_{\mathrm{yes}}^{-1}\Sigma_{\mathrm{no}}\right) - n\right)}.$$

We will bound each of these terms separately.

Bounding the Determinant

For simplicity of notation, we will bound the inverse of $\det(\Sigma_{\mathrm{yes}})/\det(\Sigma_{\mathrm{NO}})$ below. We have

$$\begin{aligned}\frac{\det \Sigma_{\mathrm{no}}}{\det \Sigma_{\mathrm{yes}}} &= \frac{\det(XX^\top + \delta I)}{\det(XX^\top)} \\ &= \det\left(XX^\top\left(XX^\top\right)^{-1} + \delta\left(XX^\top\right)^{-1}\right) \\ &= \det\left(I + \delta\left(XX^\top\right)^{-1}\right).\end{aligned}$$

▷ Claim 23. If A is a diagonalizable matrix with eigenvalues $\lambda_1, \ldots, \lambda_n$ then $\det(A + I) = \prod_{i=1}^n (\lambda_i + 1)$.

Applying this claim, we have $\det(I + \delta(XX^\top)^{-1}) = (\delta\lambda_1^{-1} + 1)\ldots(\delta\lambda_n^{-1} + 1)$, where $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of $XX^\top$. By Claim 22 the matrix $XX^\top$ is positive definite and so $\lambda_i > 0$ for all i. Therefore, $(\delta\lambda_i^{-1} + 1) > 1$ for all i, and we can conclude that $\det \Sigma_{\mathrm{n}}/\det \Sigma_{\mathrm{yes}} > 1$. Thus we can upper bound $\det \Sigma_{\mathrm{yes}}/\det \Sigma_{\mathrm{no}}$ by 1.

Bounding the Trace

Next, we bound

$$\begin{aligned}\operatorname{tr}\left(\Sigma_{\text{yes}}^{-1}\Sigma_{\text{no}}\right) &= \operatorname{tr}\left(\left(XX^\top\right)^{-1}(XX^\top+\delta I)\right)\\ &= \operatorname{tr}\left(I+\delta\left(X^\top\right)^{-1}X^{-1}\right)\\ &\leq \operatorname{tr}(I)+\delta\operatorname{tr}\left(\left(X^\top\right)^{-1}X^{-1}\right)\\ &= n+\delta\sum_{i,j}\left(X_{i,j}^{-1}\right)^2\\ &\leq n+\delta n^2\cdot\lambda_{\max}(X^{-1})^2,\end{aligned}$$

where $\lambda_{\max}$ is the largest eigenvalue of X^{-1}. Noting that the eigenvalues of X^{-1} are the inverse of the eigenvalues of X, we have $\operatorname{tr}\left(\Sigma_{\text{yes}}^{-1}\Sigma_{\text{no}}\right) \leq n+\delta n^2/\lambda_{\min}(X)^2$. Setting $\delta := C\lambda_{\min}(X)^2/n^2$ for some tiny $C>0$ to be set later, we can conclude that $\operatorname{tr}\left(\Sigma_{\text{yes}}^{-1}\Sigma_{\text{no}}\right) \leq n+C$.

Completing the proof

Putting our previous bounds together we conclude that

$$\mathrm{d}_{\mathrm{TV}}\left(\mathcal{N}(0,XX^\top),\mathcal{N}(0,XX^\top+\delta I)\right) \leq \sqrt{\frac{1}{4}\left(\log(1)+n+C-n\right)} = \frac{1}{2}C^{1/2}.$$

By our previous argument we have

$$(4) \leq \mathrm{d}_{\mathrm{TV}}\left(\mathcal{N}(0,XX^\top),\mathcal{N}(0,XX^\top+\delta I)\right) \leq \frac{1}{2}C^{1/2}.$$

Setting $C<(2/3)^2$ contradicts our assumption of the existence of an algorithm A which distinguishes a sample drawn from $\mathcal{D}_{\text{yes}}$ from one drawn from $\mathcal{D}_{\text{no}}$ with probability at least $2/3$, completing the proof. ◀

Finally, observe that the same proof goes through for testing additivity as well. Indeed, $\mathcal{D}_{\text{yes}}$ is supported on additive functions, while $\mathcal{D}_{\text{no}}$ is supported on functions which are far from additive with probability 1.

▶ **Corollary 24.** *Any sampler for additivity of functions $f\colon \mathbb{R}^n \to \mathbb{R}$ requires $\Omega(n)$ samples when $\mathcal{D}=\mathcal{N}(0,I)$.*

Abstract

We study input compression in a biologically inspired model of neural computation. We demonstrate that a network consisting of a random projection step (implemented via random synaptic connectivity) followed by a sparsification step (implemented via winner-take-all competition) can reduce well-separated high-dimensional input vectors to well-separated low-dimensional vectors. By augmenting our network with a third module, we can efficiently map each input (along with any small perturbations of the input) to a unique *representative neuron*, solving a neural clustering problem.

Both the size of our network and its processing time, i.e., the time it takes the network to compute the compressed output given a presented input, are independent of the (potentially large) dimension of the input patterns and depend only on the number of distinct inputs that the network must encode and the pairwise relative Hamming distance between these inputs. The first two steps of our construction mirror known biological networks, for example, in the fruit fly olfactory system [9, 29, 17]. Our analysis helps provide a theoretical understanding of these networks and lay a foundation for how random compression and input memorization may be implemented in biological neural networks.

Technically, a contribution in our network design is the implementation of a *short-term* memory. Our network can be given a desired *memory time* t_m as an input parameter and satisfies the following with high probability: any pattern presented several times within a time window of t_m rounds will be mapped to a single representative output neuron. However, a pattern not presented for $c \cdot t_m$ rounds for some constant $c > 1$ will be "forgotten", and its representative output neuron will be released, to accommodate newly introduced patterns.

1 Introduction

In this work we study brain-like networks that receive potentially complex and high-dimensional inputs (e.g., from sensory neurons representing odors, faces, or sounds) and encode these inputs in a very compressed way. Specifically, we consider networks with n input neurons and k output neurons, where n may be very large. When presented with up to k sufficiently different but otherwise arbitrary input patterns, the goal of the network is

to represent the inputs in such a way that they can be recognized when presented again: each input should be uniquely mapped to a single *representative output neuron* that fires if that input pattern is reintroduced. Further, any small perturbations of a presented input should be recognized by the same representative neuron. We call the above problem the *neural clustering problem*.

Clustering, input memorization, and compression are fundamental problems in biological neural networks. Our work is also inspired by the important *novelty detection* problem [25, 41]. Novelty detection requires detecting inputs that differ significantly from previously seen inputs. It is easy to see that this problem can be solved with a neural clustering network, in which all sufficiently far inputs are mapped to different representative neurons and all sufficiently close inputs are mapped to the same neuron. A novel input is detected whenever a new representative neuron is assigned. The novelty detection problem has been considered recently in the fruit fly olfactory system [16], where it is believed to be solved using a random projection based method. The high level structure of this method closely resembles the initial stages of our clustering algorithm, and we see a major contribution of our work as providing a theoretical understanding of how random projection can be implemented in biologically inspired neural networks. For further discussion about the connection to fruit fly novelty detection see Section 1.2.

1.1 Our Results

We study the neural clustering problem in a biologically inspired model of *stochastic spiking neural networks* (stochastic SNNs), which was previously defined in [33, 34, 35]. In these networks, computation proceeds in discrete rounds with each neuron either firing (spiking) in a round or remaining silent. Each neuron spikes randomly, with probability determined by its membrane potential. This potential is induced by spikes from neighboring neurons, which can have either an excitatory or inhibitory effect (increasing or decreasing the potential). In general, the input to an SNN is a stream of binary vectors, corresponding to spikes of the input neurons. In our setting we will consider a single binary vector as the input pattern and assume that each input vector is presented for a certain number of consecutive rounds before changing. This allows the network time to stabilize to the correct output associated with the given input.

We demonstrate that clustering can be solved efficiently in these networks, where the cost is measured by (i) the number of *auxiliary neurons*, besides the input and output neurons, that are required to solve the clustering task and (ii) the number of rounds required to converge to the correct output for a given input, which corresponds to the number of rounds for which the input must be presented for before moving to the next input.

In the clustering problem, we consider a (potentially large) set of n-length patterns that are clustered around k base patterns. It is then required to map all patterns in the same cluster to a unique output in $[k]$.

Clustering with Output Reassignment. We also want our network to be reusable, with a *memory duration* t_m that is given as an input parameter. Instead of considering a single infinite input stream with at most k distinct patterns (or clusters of patterns), our memory module allows one having many distinct patterns, as long as their presentation times are sufficiently spaced out. That is, in any window of $\Theta(t_m)$ rounds, the network is presented at most k distinct patterns. To handle distinct patterns in each $\Theta(t_m)$-round window, the network must *forget* patterns that have not been introduced for a while and release their allocated outputs so that they can be assigned to new inputs. Specifically, for some fixed

constant c, our network remembers a pattern (its cluster) for at least t_m rounds and at most $c \cdot t_m$ round. The output of any pattern not introduced for $c \cdot t_m$ rounds is released with high probability and can be reassigned to represent another input.

The Neural Clustering Problem. We now formally define the neural clustering problem, which is parametrized by several parameters: the input dimension n, the number of distinct input patterns k, the memory duration t_m, a bound on the relative distance of input patterns Δ, and the allowed failure probability δ. We require that every pattern introduced as input, remains the input pattern for at least $t_p = \text{poly}(k, 1/\Delta, \log(1/\delta))$ (i.e., independent of n) consecutive rounds. The t_p parameter is the processing time or mapping time, i.e., the time it takes for the network to converge to the output neuron. Throughout, we will assume that all patterns have p non-zero entries. We conjecture that this assumption can be easily removed however keep it to simplify our arguments.

Define the *relative Hamming distance* between two inputs $\overline{X}_i, \overline{X}_j \in \{0,1\}^n$ to be:

$$\mathcal{RD}(\overline{X}_i, \overline{X}_j) = \frac{||\overline{X}_i - \overline{X}_j||_1}{\max\{||\overline{X}_i||_1, ||\overline{X}_j||_1\}} \ .$$

In the basic clustering problem, the network is introduced to a possibly large number of distinct patterns that are *clustered* around k-centers. That is, in every window of t_m rounds, the patterns introduced are clustered around a base-set of k patterns $\overline{X}_1, \ldots, \overline{X}_k \in \{0,1\}^n$ such that the relative difference between each pair in the base-set is at least Δ, and any other pattern introduced is sufficiently close to one of the patterns in the base-set (with relative distance $\leq \Delta/\alpha$ for some $\alpha = \tilde{O}(1)$). In the clustering problem the network maps *similar* patterns to the same unique output q_i for $i \in [k]$ (i.e., the cluster name) and *non-similar* patterns to distinct names. Formally:

▶ **Definition 1** (Clustering Input Condition). *An infinite input sequence $\overline{Z}_1, \overline{Z}_2, \ldots$ is a well-behaved clustering input sequence with input size n, output size k, memory duration t_m, relative distance parameter Δ, closeness parameter α, and input persistence time t_p if:*

- *For any set of t_m rounds $T = \{t, t+1, ..., t+(t_m-1)\}$ there exist $\overline{X}_1, \overline{X}_2, ..., \overline{X}_k \in \{0,1\}^n$ such that $\mathcal{RD}(\overline{X}_i, \overline{X}_j) \geq \Delta$ for all $i \neq j$ and for all $i \in T$, $\mathcal{RD}(\overline{Z}_i, \overline{X}_j) \leq \Delta/\alpha$ for some $j \in [k]$.*
- *If $\overline{Z}_i \neq \overline{Z}_{i-1}$, then $\overline{Z}_i = \overline{Z}_{i+1} = ... = \overline{Z}_{i+t_p}$.*

▶ **Definition 2** (Clustering Network). *A network $\mathcal{N}$ solves the clustering problem for input size n, output size k, memory duration t_m, relative distance parameter Δ, closeness parameter α, input duration t_p, and failure probability δ if, on a well-behaved input sequence for the same parameters (Definition 1), on any fixed window of t_m rounds, with probability $\geq 1 - \delta$:*

- *Each input pattern $\overline{Z}$ is* mapped *to some output q_j for $j \in [k]$. That is, whenever the input changes to $\overline{Z}$ round i (so $\overline{Z}_{i-1} \neq \overline{Z}$ but $\overline{Z}_i = \overline{Z}$), there is a unique output neuron q_j that fires at round $i + t_p$ and continues to fire as long as the input remains fixed to $\overline{Z}$.*
- *Any pair of far patterns $\overline{Z}, \overline{Z}'$ with $\mathcal{RD}(\overline{Z}, \overline{Z}') \geq \Delta$ introduced within the t_m time window are mapped to different outputs.*
- *Any pair of closed-patterns $\overline{Z}, \overline{Z}'$ with $\mathcal{RD}(\overline{Z}, \overline{Z}') \leq \Delta/\alpha$ introduced within the same t_m time window will be mapped to the same output neuron.*

Our goal is to design a clustering network that uses small number of auxiliary neurons and requires small input persistence time t_p. We show the following theorem.

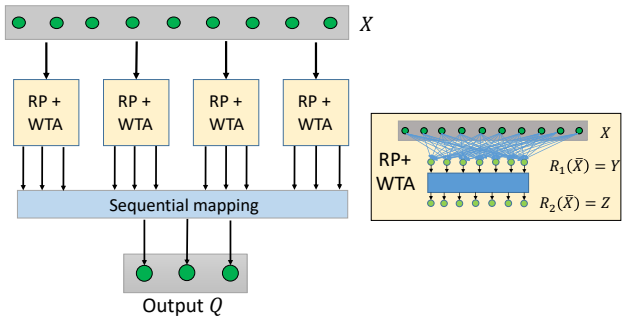

Figure 1 High level illustration of the clustering network. Right: The input pattern $\bar{X} \in \{0,1\}^n$ is mapped to an intermediate sparser vector in two steps: random projection and WTA sparsification. Left: In the clustering network, the input $\bar{X}$ is mapped by applying $O(\log(k/\delta))$ parallel repetitions of the random projection + WTA mapping. As a result, $\bar{X}$ is mapped to a vector $\bar{Z}$ with $O(\frac{\log(k/\delta)}{\Delta})$ neurons. This vector is mapped to the output unit vector in $\{0,1\}^k$ via a sequential mapping module.

▶ **Theorem 3.** *For any parameters n, k, t_m, δ and Δ, there is a network $\mathcal{N}$ with $O\left(\frac{\log(1/\Delta)^3 \log(t_m/\delta) \log(1/\delta)}{\Delta^{3/2}}\right)$ auxiliary neurons that solves the clustering problem with these parameters, input persistence time $t_p = O\left(\frac{\log(1/\Delta)^2 \log(t_m/\delta)}{\Delta}\right)$ and closeness parameter $\alpha = O(\log(1/\Delta)^4)$.*

Note that the number of auxiliary neurons and the convergence time of Theorem 3 are *independent of the input dimension n*, which may potentially be very large. The spiking neural network construction that achieves Theorem 3 involves in three steps. The first two steps reduce the input from n neurons to $m \ll n$ neurons, while approximately preserving the relative distances between inputs. These steps use a biologically inspired construction that mirrors circuits seen, for example, in the fruit fly olfactory system [9, 29, 17]. In particular the first step maps the input to a set of intermediate neurons via random projection, and the second step sparsifies the outputs of these intermediate neurons to yield a sparse code representing the input. The final *sequential mapping* step then solves the clustering problem given these m intermediate neurons as inputs, avoiding the high cost of directly solving the problem on the n-dimensional input. See Figure 1 for an illustration.

1.2 Comparison to Previous Work

1.2.1 Broader Agenda: Algorithmic Theory for Brain Networks

Understanding how the brain works, as a computational device, is a central challenge of modern neuroscience and artificial intelligence. Different research communities tackle this problem in different ways, ranging from studies that examine neural network structure as a clue to computational function [43, 3], to functional imaging that studies neural activation patterns [40, 31], to theoretical work on simplified models of neural computation [23, 36], to the engineering of complex neural-inspired machine learning architectures [21, 27]. This paper joins a recent line of work [44, 37, 45, 38, 33, 30, 46, 34, 28, 32, 39, 10, 22] that approach this problem using techniques from *distributed computing theory and other branches of theoretical computer science.* The ultimate goal of this research direction is to develop an *algorithmic theory for brain networks*, based on stochastic graph-based neural network models. To understand neural behavior from a theory of computing point of view, we design networks

to solve abstract problems that are inspired by tasks that seem to be solved in actual brains. We believe that the rigorous analysis of such networks in terms of static costs (e.g., the number of neurons), and dynamic costs (e.g., the time to converge to a solution) will lead to a better understanding of how these tasks may be performed in biological neural networks.

1.2.2 Connections to Sparse Recovery

Our work is closely related to sparse recovery (compressed sensing), where the goal is to map high-dimensional but sparse vectors (with dimension n and $s \ll n$ nonzero entries) into a much lower dimensional space, such that the vectors can be uniquely identified and efficiently recovered [19]. We can see that this goal is essentially identical to that of our first two network layers, before the sequential mapping step. Two different s-sparse binary vectors have relative hamming distance $\geq 1/s$. Additionally there are $k = O(n^s)$ s-sparse binary vectors in n dimensions. Thus, as a Corollary of Lemma 12, our first two layers can uniquely compress all such vectors with high probability into dimension $m = \tilde{O}\left(\frac{\log k}{\Delta^{1/2}}\right) = O(s^{3/2} \log n)$.

It is known that optimal sparse recovery reducing the dimension to $O(s \log n)$ can be achieved using random projections [13]. However, unlike in our setting, these random projections have real valued outputs, which cannot be directly represented by binary spiking neurons. The case when output of the random projection is thresholded to be a binary value has been studied extensively, under the name "one-bit compressed sensing" [6]. In this setting, it is known that dimension $\tilde{\Theta}\left(s^2 \log n\right)$ can be achieved and is required for general sparse recovery [1]. If the input vectors are restricted to be binary (as in our case), dimension $O(s^{3/2} \log n)$ is possible [24, 1]. Our results match this bound up to logarithmic factors.

1.2.3 Connections to Fruit Fly Novelty Detection via Bloom Filters

Recently, Dasgupta et al. [16] demonstrated that the fruit fly olfactory circuit implements a variant of a classic Bloom filter [5] to assess the novelty of odors. A bloom filter is a data structure that maintains a set of items, allowing for membership queries, with the possibility of occasional false positives. The filter has m bits and r random hash functions mapping the input space to integers in $1, ..., m$. When an item is inserted, it is hashed using these r functions and the bits corresponding to the hashed values are set to 1. A membership query is answered by hashing the input in question and checking that all r bits corresponding to its hashed values are set to 1.

Such a filter can be used to implement novelty detection – a novel pattern is detected whenever an insertion operation sets a new bit to 1 or an membership query returns false. Dasgupta et al. [16] demonstrate that a such a scheme is used in the fly olfactory circuit. The hashing step consists of a random projection followed by winner-take-all sparsification, which maps each input into a r-sparse binary vector. The r entries of this vector represent the r hash function outputs. This step closely resembles the first two layers of our clustering network.

Our third layer operates differently than a bloom filter, associating each sparsified intermediate vector to with unique output via sequential mapping rather than simply marking the bits corresponding to its entries. However, it can implement the same functionality (and correspondingly can implement novelty detection). Specifically, to implement insertion and deletion operations we can make the following modifications to the sequential mapping sub-network:

- The input layer contains an extra neuron that is set to 1 if the operation is insertion, and 0 if the operation is a membership query.
- In the sequential mapping step the output layer fires only if this extra neuron fires. In this way, new outputs will only be mapped during insertion operations and not membership queries.
- For query operations, we add an output neuron that fires only if there exists an index $j \in [k]$ for which many memory modules m_{ji}, as well as an association neuron a_{ji} fire.
- Novelty detection can be implemented via an additional output neuron that responds when an insertion causes a new output to be mapped or when a query operation returns false.

2 Computational Model and Preliminaries

We start by defining our model of stochastic spiking neural networks.

Network Structure. A *Spiking Neural Network* (SNN) $\mathcal{N} = \langle X, Q, A, w, b\rangle$ consists of n input neurons $X = \{x_1, \ldots, x_n\}$, m output neurons $Q = \{q_1, \ldots, q_m\}$, and ℓ auxiliary neurons $A = \{a_1, ..., a_\ell\}$. The directed, weighted synaptic connections between X, Q, and A are described by the weight function $w : [X \cup Q \cup A] \times [X \cup Q \cup A] \to \mathbb{R}$. A weight $w(u, v) = 0$ indicates that a connection is not present between neurons u and v. Finally, for any neuron v, $\beta(v) \in \mathbb{R}_{\geq 0}$ is the activation bias – as we will see, roughly, v's membrane potential must reach $\beta(v)$ for a spike to occur with good probability.

The in-degree of every input neuron x_i is zero. That is, $w(u, x) = 0$ for all $u \in [X \cup Q \cup A]$ and $x \in X$. Additionally, each neuron is either *inhibitory* or *excitatory*: if v is inhibitory, then $w(v, u) \leq 0$ for every u, and if v is excitatory, then $w(v, u) \geq 0$ for every u.

Neuron Chains. In our implementation, we make use of *chains* of neurons to create a delay in a response. For a neuron u, and integer ℓ, let $C_\ell(u)$ be a directed path of length ℓ starting with u. All neurons on the chain are excitatory. We then say that a chain $C_\ell(u)$ is connected to v if each neuron $w \in C_\ell(u)$ has an outgoing edge to v.

The SNN Model. An SNN evolves in discrete, synchronous rounds as a Markov chain. The firing probability of every neuron at time t depends on the firing status of its neighbors at time $t - 1$, via a standard sigmoid function, with details given below. For each neuron u, and each time $t \geq 0$, let $u^t = 1$ if u fires (i.e., generates a spike) at time t. Let u^0 denote the initial firing state of the neuron. Our results will specify the initial input firing states $x_j^0 = 1$ and assume that $u^0 = 0$ for all $u \in [Q \cup A]$. The firing state of each input neuron x_j in each round is the input to the network, and our results will specify to which sequences of input firing patterns they apply.

For each non-input neuron u and every $t \geq 1$, let $\text{pot}(u, t)$ denote the membrane potential at round t and $p(u, t)$ denote the corresponding firing probability ($\Pr[u^t = 1]$). These values are calculated as:

$$\text{pot}(u,t) = \sum_{v \in X \cup Q \cup A} w_{v,u} \cdot v^{t-1} - \beta(u) \text{ and } p(u,t) = \frac{1}{1 + e^{-\text{pot}(u,t)/\lambda}} \tag{1}$$

where $\lambda > 0$ is a *temperature parameter*, which determines the steepness of the sigmoid. It is easy to see that λ does not affect the computational power of the network. A network can be made to work with any λ simply by scaling the synapse weights and biases appropriately.

For simplicity we assume throughout that $\lambda = \frac{1}{\Omega(\log(n \cdot k \cdot \Delta \cdot t_m \cdot 1/\delta))}$, where $n, k, \delta, \Delta, t_m$ are the parameters of the clustering problem, defined in Section 1.1. Thus by (1), if $\text{pot}(u,t) \geq 1$, then $u^t = 1$ w.h.p. and if $\text{pot}(u,t) \leq -1$, $u^t = 0$ w.h.p. , where w.h.p. denotes with probability at least $1 - (1/\delta \cdot n \cdot k \cdot \Delta \cdot t_m)^{-c}$ for some constant c.

The remainder of the paper is devoted to proving Theorem 3. Our analysis considers the three stages of the network in sequence: random projection, sparsification, and sequential mapping to the final outputs.

3 Layer 1: Random Projection

The goal of this step is to reduce the input size from n input neurons to $m \ll n$ neurons while ensuring that the relative distance between any two n-length input vectors is approximately preserved after the mapping. In this way, we can solve the clustering problem working with the much smaller m neuron representation instead of the original n neuron input. While there are many ways in which distance may be preserved, we consider one in particular, based on the membrane potentials induced on the intermediate neurons by the inputs:

▶ **Definition 4** (Distance Preserving Dimensionality Reduction). *Consider $\overline{X}_1, \ldots, \overline{X}_k \in \{0,1\}^n$ with $\mathcal{RD}(\overline{X}_i, \overline{X}_j) \geq \Delta$ for $i \neq j$. Consider a network $\mathcal{N}$ mapping n input neurons to m intermediate neurons, which are split into b buckets each containing m/b neurons. $\mathcal{N}$ is distance preserving for $\overline{X}_1, \ldots, \overline{X}_k$ if, for any two $\overline{X}_i, \overline{X}_j$, and any round t, in the large majority of buckets, the identity of the neuron that in round $t+1$* has the highest membrane potential below a fixed threshold τ *is different if $\overline{X}_i$ is presented at round t than if $\overline{X}_j$ were presented.*[1]

Our network satisfies Definition 4 with parameters $m = \tilde{O}\left(\frac{1}{\sqrt{\Delta}}\right)$ and $b = \tilde{O}(1)$. We implement the dimensionality reduction step via *random projection*. We note that random projection has been studied extensively as a dimensionality reduction tool in computer science, with applications in data analysis [4, 7, 12], fast linear algebraic computation [42, 11], and sparse recovery [8]. See [47] for a survey. In neuroscience, it is thought that random projection may play a key role in neural dimensionality reduction [20, 2]. Random projection for example, underlies sparse coding of inputs in the fruit fly olfactory circuit [9, 17]. Random connections have also been studied in theoretical models for memory formation, in which inputs are mapped to representative output neurons [45, 38, 28].

We start with describing the construction and then analyzing its properties. The main outputs of this section are Corollaries 9 and 11 which show that, with high probability, the identities of the neurons with maximum membrane potential below some threshold τ in each bucket of the intermediate layer share little overlap for far inputs (with relative distance $\geq \Delta$) and significant overlap for close inputs (with relative distance $\leq \Delta/\alpha$ for $\alpha = O(\log(1/\Delta)^4)$). That is, the network satisfies the distance preserving dimensionality reduction guarantee of Definition 4 for far inputs, along with an analogous guarantee for close inputs.

Our mapping can be understood as an example of *local sensitive hashing* [18, 15, 17]. In each bucket, the input is hashed to the identity of the maximum potential neuron below τ in that bucket. Near inputs have many hash collisions, and thus there is significant overlap in the identities of the mapped neurons. Far input have fewer collisions and thus less overlap.

[1] We formally define how the membrane potential is calculated in Section 2. "Large majority" will be a constant fraction of the buckets significantly larger than 1/2, which will be specified in our bounds.

Layer Description. The random projection layer consists of $m \cdot \ell$ intermediate auxiliary neurons for $m = \Theta\left(\frac{\log(1/\Delta)}{\sqrt{\Delta}}\right)$ and $\ell = \Theta(\log(t_m/\delta))$. The layer is subdivided into ℓ buckets $b_1, ..., b_\ell$ containing m neurons each. Each input neuron has an excitatory connection to each neuron in the intermediate layer with weight sampled as a Chi-squared random variable (with one degree of freedom). We denote this random weight matrix connecting the two layers by $\mathrm{A} \in \mathbb{R}^{m\cdot\ell\times n}$. For $b \in 1, ..., \ell$, we let $\mathrm{A}_b \in \mathbb{R}^{m\times n}$ denote the rows of A corresponding to the intermediate neurons in bucket b. In typical applications of random projection, the entries of A are most commonly either Gaussian or Rademacher random variable. Here we use Chi-squared random variables as they are non-negative, a requirement in our setting where the outgoing edge weights from each neuron (corresponding to the entries in A) must be either all positive or all negative.

Layer Analysis. When the input neurons X fire with input pattern $\overline{X}_i \in \{0,1\}^n$ at time t, by (1) the vector of membrane potentials of the intermediate neurons at time $t+1$ is given by $\mathrm{A}\,\overline{X}_i \in \mathbb{R}^{m\times\ell}$. Our analysis will focus on the properties of this vector of potentials, which can be viewed as a real valued compressed representation of the input $\overline{X}_i$. Later, we will show how these properties lead to desirable properties of the spiking patterns of the intermediate neurons.

For technical reasons, we will not focus on the actual largest entry of $A_b\overline{X}_i$, but on the *largest entry bounded by some fixed threshold* τ which can still be identified via a minor modification to a traditional WTA circuit. We begin with a preliminary lemma showing that a Chi-squared distribution (the distribution of each entry in $A_b\overline{X}_i$) is roughly uniform around its mean. We give a proof in Appendix A.

▶ **Lemma 5** (Chi-squared uniformity). *Let $\mathcal{D}_p$ be the Chi-squared distribution with p degrees of freedom. For any c with $1 \le c < p^{1/2}$ there are constants c_ℓ, c_u (depending on c) such that, for any interval $[r_1, r_2] \subseteq \left[p - cp^{1/2}, p + cp^{1/2}\right]$, we have: $\frac{c_\ell(r_2-r_1)}{p^{1/2}} \le \Pr_{x\sim\mathcal{D}_p}[x \in [r_1, r_2]] \le \frac{c_u(r_2-r_1)}{p^{1/2}}$. That is, $\mathcal{D}_p$ is roughly uniform on the range $\left[p - cp^{1/2}, p + cp^{1/2}\right]$.*

We also use the fact that the Chi-squared distribution decays far from its mean, which follows from standard sub-exponential concentration bounds.

▶ **Lemma 6** (Chi-squared decay). *Let $\mathcal{D}_p$ be the Chi-squared distribution with p degrees of freedom. For any $c \le 1$ there is a constant c_1 (depending on c) such that:*

$$\Pr_{x\sim\mathcal{D}_p}\left[x \notin [p - c_1p^{1/2}, p + c_1p^{1/2}]\right] \le c.$$

Using the near-uniform distribution property of Lemma 5, we can show that with good probability, for every compressed vector $\mathrm{A}_b\,\overline{X}_i \in \mathbb{R}^m$ the gap between the two largest entries (bounded by the threshold) is $\Omega(p^{1/2}/m)$ – since there are m entries roughly uniformly distributed in a range of size $O(p^{1/2})$. This gap will be necessary for the neuron with the largest membrane potential (and hence the highest firing probability) to be reliably identified in the second sparsification layer of our network. We remark that in non-neural applications of random projection such a gap would not be necessary: the largest entry in the bucket can be typically be identified exactly.

The complete proof is given in Appendix A.

▶ **Lemma 7** (Sufficient Gap). *Consider our construction with bucket size $m = c_1$. Let $\overline{X} \in \{0,1\}^n$ be any input vector with $\|\overline{X}\| = p$ for $p \geq 5$. Let $\tau = p + 2p^{1/2}$ and for any $b \in [\ell]$ define:*

$$i_{1,b}(\overline{X}) = \underset{i\in[m]:[A_b\overline{X}](i)\leq\tau}{\arg\max} [A_b\overline{X}](i) \quad \text{and} \quad i_{2,b}(\overline{X}) = \underset{i\in[m]\setminus i_{1,b}(\overline{X}):[A_b\overline{X}](i)\leq\tau}{\arg\max} [A_b\overline{X}](i),$$

where we set $i_{1,b}(\overline{X}), i_{2,b}(\overline{X}) = 0$ in the case that no index satisfies the constraint. For sufficiently large constants c_1, c_2, with probability $\geq 99/100$ over the random choice of A_b, $i_{1,b}(\overline{X}) \neq 0$, $[\mathrm{A}_b\,\overline{X}](i_{1,b}(\overline{X})) \geq p$, and either $[\mathrm{A}_b\,\overline{X}](i_{1,b}(\overline{X})) - [\mathrm{A}_b\,\overline{X}](i_{2,b}(\overline{X})) \geq \frac{p^{1/2}}{c_2 m}$ or $i_{2,b}(\overline{X}) = 0$.

Along with Lemma 7 we prove that, with good probability, the neuron with the maximum potential below τ in each bucket differs for any two far inputs.

▶ **Lemma 8** (Low Collision Probability – Far Inputs). *Let $\overline{X}_1, \overline{X}_2 \in \{0,1\}^n$ be two vectors with $\|\overline{X}_1\| = \|\overline{X}_2\| = p$ [2] and $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \geq \Delta$. Assume that $p \geq c$ for some sufficiently large constant c. Consider our construction with bucket size $m = \frac{c_1 \log(1/\Delta)}{\sqrt{\Delta}}$. Then for sufficiently large constants c_1, c_2, for any $b \in [\ell]$, defining $i_{1,b}(\cdot)$ and $i_{2,b}(\cdot)$ as in Lemma 7, with probability ≥ 0.9165:*

- *$i_{1,b}(\overline{X}_1) \neq i_{1,b}(\overline{X}_2)$.*
- *For both $j = 1, 2$: $i_{1,b}(\overline{X}_j) \neq 0$, $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) \geq p$, and $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) - [A_b\overline{X}_j](i_{2,b}(\overline{X}_j)) \geq \frac{p^{1/2}}{c_2 \cdot m}$ or $i_{2,b}(\overline{X}_j) = 0$.*

See Appendix A for the complete proof of Lemma 8. Intuitively, if $\overline{X}_1$ and $\overline{X}_2$ each have Hamming weight p and relative distance Δ they differ on $\Omega(\Delta p)$ entries. If *just the shared entries* of these vectors fired as inputs, by Lemma 5 each intermediate neuron in the bucket of size m would have its potential distributed roughly uniformly in a range of width $O([(1-\Delta)p]^{1/2}) = O(p^{1/2})$. On average these potentials would be spaced out by $O(p^{1/2}/m)$. By setting $m = \tilde{O}(1/\sqrt{\Delta})$ we have average spacing $\tilde{O}(\Delta^{1/2}p^{1/2})$. This is a small enough spacing, so that when we consider the $\Omega(\Delta p)$ non-shared neurons in the inputs, their contribution to the potential will be large enough to significantly reorder the potentials of the intermediate neurons, so that the neuron with maximum potential is unlikely to be the same for the two different inputs.

From Lemma 8 we can show that our network satisfies the distance preserving dimensionality reduction guarantee of Definition 4, along with the additional condition that the gap between the membrane potentials of the neurons with the largest potentials under $\tau = p + 2p^{1/2}$ is sufficiently large, so that these neurons can be distinguished reliably in the second sparsification layer:

▶ **Corollary 9** (Overall Success – Far Inputs). *For $m = O\left(\frac{\log(1/\Delta)}{\sqrt{\Delta}}\right)$, and $\ell = O(\log(t_m/\delta))$, for any window of t_m rounds, with probability $\geq 1-\delta$, for all pairs of inputs $\overline{X}_1, \overline{X}_2$ presented during these rounds with $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \geq \Delta$, on at least $91/100 \cdot \ell$ of the ℓ buckets, letting $\tau = p + 2p^{1/2}$ and defining $i_{1,b}(\cdot)$ and $i_{2,b}(\cdot)$ as in Lemma 7:*

- *$i_{1,b}(\overline{X}_1) \neq i_{1,b}(\overline{X}_2)$*
- *For both $j = 1, 2$: $i_{1,b}(\overline{X}_j) \neq 0$, $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) \geq p$, and $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) - [A_b\overline{X}_j](i_{2,b}(\overline{X}_j)) = \Omega\left(\frac{p^{1/2}}{m}\right)$ or $i_{2,b}(\overline{X}_j) = 0$.*

[2] When $\overline{X}$ is binary we often drop the subscript and just use $\|\overline{X}\|$ to denote the ℓ_1 norm which is equal to the number of nonzero entries, $|\operatorname{supp}(\overline{X})|$.

Proof. By Lemma 8 and a Chernoff bound, since $\ell = \Theta(\log(t_m/\delta)) = \Theta(\log(t_m^2/\delta))$, for any fixed pair of inputs with $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \geq \Delta$, the conditions hold on at least $91/100 \cdot \ell$ buckets with probability $\geq 1 - \delta/t_m^2$. The corollary follows since at most t_m inputs can be presented in t_m rounds, and so we can union bound over at most t_m^2 pairs of far inputs. ◀

We can give a complementary statement to Lemma 8: if $\overline{X}_1$ and $\overline{X}_2$ are close to each other, it is relatively likely that the index of the largest value of $\mathrm{A}_b\,\overline{X}_1$ and $\mathrm{A}_b\,\overline{X}_2$ are the same. We defer the proof to Appendix A.

▶ **Lemma 10** (High Collision Probability – Close Inputs). *Let $\overline{X}_1, \overline{X}_2 \in \{0,1\}^n$ be two vectors with $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \leq \Delta/\alpha$. Consider our construction with bucket size $m = \frac{c_1 \log(1/\Delta)}{\sqrt{\Delta}}$. Then for sufficiently large constants c_1, c_2 and $\alpha = O(\log(1/\Delta)^4)$, for any $b \in [\ell]$, defining $i_{1,b}(\cdot)$ and $i_{2,b}(\cdot)$ as in Lemma 7, with probability ≥ 0.97:*

- *$i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2)$.*
- *For both $j = 1, 2$: $i_{1,b}(\overline{X}_j) \neq 0$, $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) \geq p$, and $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) - [A_b\overline{X}_j](i_{2,b}(\overline{X}_j)) \geq \frac{p^{1/2}}{c_2 \cdot m}$ or $i_{2,b}(\overline{X}_j) = 0$.*

Lemma 10 yields an analogous corollary to Corollary 9, which follows via a Chernoff bound and a union bound over at most t_m^2 pairs of close inputs that may be presented over t_m rounds.

▶ **Corollary 11** (Overall Success – Close Inputs). *For $m = O\left(\frac{\log(1/\Delta)}{\sqrt{\Delta}}\right)$, $\ell = O(\log(t_m/\delta))$, and $\alpha = O(\log(1/\Delta)^4)$, for any window of t_m rounds, with probability $\geq 1 - \delta$, for all pairs of inputs $\overline{X}_1, \overline{X}_2$ presented during these rounds with $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \leq \Delta/\alpha$, on at least $96/100 \cdot \ell$ of the ℓ buckets, letting $\tau = p + 2p^{1/2}$ and defining $i_{1,b}(\cdot)$ and $i_{2,b}(\cdot)$ as in Lemma 7:*

- *$i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2)$*
- *For both $j = 1, 2$: $i_{1,b}(\overline{X}_j) \neq 0$, $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) \geq p$, and $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) - [A_b\overline{X}_j](i_{2,b}(\overline{X}_j)) = \Omega\left(\frac{p^{1/2}}{m}\right)$ or $i_{2,b}(\overline{X}_j) = 0$.*

4 Layer 2: Sparsification via Winner Takes All

Corollaries 9 and 11 show that the random projection step preserves significant information about input distance, encoded in the membrane potentials of the intermediate neurons, which correspond to the entries of $\mathrm{A}\,\overline{X}$ when the network is given input $\overline{X}$. These membrane potentials cause the intermediate neurons to fire randomly, as Bernoulli processes with different rates. The goal of our second layer is to convert this random behavior to a uniquely identifying sparse code for each input. We achieve this through a winner-takes-all (WTA) based sparsification process, which is thought to play a major role in neural computation [26, 14, 37]. A separate winner-take-all instance is applied to each bucket, "selecting" the neuron with the highest membrane potential below τ by inducing its corresponding neuron in the sparsification layer to fire with high probability while all other neurons in the bucket do not fire.Let $\overline{Y} \in \mathbb{R}^m$ denote the vector of membrane potentials of a single bucket of the intermediate layer: $\overline{Y} = \mathrm{A}_b\,\overline{X}$. Our WTA layer maps each $\overline{Y}$ into a binary unit-vector $\overline{Z}$ of the same length, in which the only firing neuron corresponds to the neuron with the largest potential in $\overline{Y}$ that is bounded by the threshold parameter τ. As explained in Section 3, the random projection step produces $\ell = O(\log(t_m/\delta))$ random compressed vectors, one for each of the ℓ buckets. Each such copy is an input to an independent WTA circuit and thus, in this section, we focus on our construction restricted to just a single bucket, bearing in mind that in fact our network consists of ℓ repetitions of this module.

The first part of the WTA circuit is devoted to *reading*: the circuit collects firing statistics for a period of $T = \tilde{O}(m^2)$ rounds to obtain a good estimate of the neuron in the bucket that 1) has potential $\leq \tau$ and 2) has the largest firing rate. This neuron corresponds to the neuron with the highest potential in $\overline{Y}$ bounded by τ. This is done by augmenting each neuron i in the bucket with a directed chain H_i of neurons of length T. The j^{th} neuron in the chain triggers the firing of the $(j+1)^{th}$ neuron with high probability. As a result, after T rounds, the number of firing neurons in the chain H_i is equal to the number of times i fired within the last T rounds, with high probability. We thus refer to this H_i chain as the *history* chain of the i^{th} neuron in the bucket. The second part of the circuit first excludes all neurons with potential $\geq \tau$ and then applies a standard WTA circuit to pick the neuron remaining that fires the most in this T-length time interval. See Fig. 2 for an illustration of the overall clustering network and the WTA module. The main result of this section is as follows.

▶ **Lemma 12.** *For every pair of input patterns $\overline{X}_i, \overline{X}_j$ presented over a period of t_m rounds, with probability at least $1-\delta$ the following hold:*

(I) *If $\mathcal{RD}(\overline{X}_i, \overline{X}_j) \geq \Delta$, then $\text{supp}(\overline{Z}_i) \setminus \text{supp}(\overline{Z}_j) \geq 0.9 \cdot \ell$.*

(II) *If $\mathcal{RD}(\overline{X}_i, \overline{X}_j) \leq \Delta/\alpha$, then $\text{supp}(\overline{Z}_i) \cap \text{supp}(\overline{Z}_j) \geq 0.9 \cdot \ell$.*

We first give a detailed description of the specification step via WTA (see Figure 2). We focus on a single bucket, bearing in mind that in fact our network consists of ℓ repetitions of this module.

Reading via History Chain. Every neuron $i \in \{1, \ldots, m\}$ in the bucket is connected to a chain H_i of length $T = \Theta(\log(1/\delta) \cdot m^2)$ of neurons where the j^{th} neuron in this chain fires in round t with high probability iff its incoming neighbor on that chain fires in round $t-1$. This is done by setting the bias value of each neuron to 1 and the edge weights to be $1/2$. As a result we get that the number of firing neurons in this chain equals to the number of times i fires within the last T rounds with high probability.

Omitting the Neurons Exceeding the Threshold Value. For every neuron $i \in \{1, \ldots, m\}$ we introduce an inhibitor copy r_i that has the same incoming weights as i and therefore also has the same potential. We set the bias of r_i such that with high probability it fires iff its potential exceeds the threshold value τ. We then connect r_i to all neurons in the chain H_i with large negative weight. As a result, if the potential of neuron i exceeds τ with high probability all neurons in H_i will not fire.

Selecting the Maximum Firing Rate with Pairwise Comparisons. For every ordered pair of neurons $i, j \in [1, m]$, we have a designated (threshold gate) neuron $y_{i,j}$ that fires iff the i^{th} neuron in the bucket fires more than the j^{th} neuron within the last T rounds. To accomplish this, each of the neurons in the chain H_i (respectively, H_j) is connected to $y_{i,j}$ with a positive (respectively, negative) edge weight of ± 1. Hence, the total weighted sum incoming to $y_{i,j}$ is exactly the difference between $R(i)$ and $R(j)$ where $\overline{R}(i), \overline{R}(j)$ are the number of times that the i^{th} and j^{th} neurons fired in the last T rounds. We set the bias of $y_{i,j}$ such that it fires with high probability iff $\overline{R}(i) - \overline{R}(j) \geq 1$. The i^{th} output neuron in $\overline{Z}$ computes the AND-gate of the threshold-gates $y_{i,1}, \ldots, y_{i,m}$. That is, z_i fires in round t only if every $y_{i,1}, \ldots, y_{i,m}$ fired in round $t-1$. The AND-gate can be implemented by setting the incoming edge weight from each $y_{i,j}$ to z_i to be $1/m$, and the bias of $\overline{Z}_i$ to $1 - 1/(2m)$.

Analysis. The requirement from the WTA module is that the firing frequency vector $\overline{R}$ has its largest entry in the same position as the largest entry of $\overline{Y}$ that is $\leq \tau$. If this is the case, the WTA circuit indeed selects the neuron corresponding to the largest firing rate $\leq \tau$, and the only entry in the support of $\overline{Z}$ is the one corresponding to this entry. For the largest entry in $\overline{R}$ to reflect the largest entry in $\overline{Y} \leq \tau$ with probability $\geq 1-\delta$, the gap between the largest and second largest firing rates must be $\Omega\left(\sqrt{\log(1/\delta)/T}\right)$. Using the gap condition of Corollary 9 we will show that this gap is $\Omega(1/m)$, letting us set $T = O(\log(1/\delta) \cdot m^2)$. The desired gap is achieved in a large fraction of the buckets, this implies that the WTA picks the maximal entry in most of the buckets as well.

▷ Claim 13. Let $\overline{Y}$ be a vector with $i = \arg\max_{j:\overline{Y}(j)\leq\tau} \overline{Y}(j)$ and $\overline{Y}(i) - \overline{Y}(j) = \Omega(p^{1/2}/m)$ for every[3] $j \neq i$ with $\overline{Y}(j) \leq \tau$. Then in the output vector $\overline{Z}$, $\overline{Z}(i) = 1$ and $\overline{Z}(j) = 0$ for every $j \neq i$ with probability at least 99/100. If $\overline{Y}$ is first introduced in round t, the desired output vector $\overline{Z}$ fires in round $t + T + 2$ w.h.p.

The proof of Claim 13 and the complete proof of Lemma 12 is given in Appendix B.

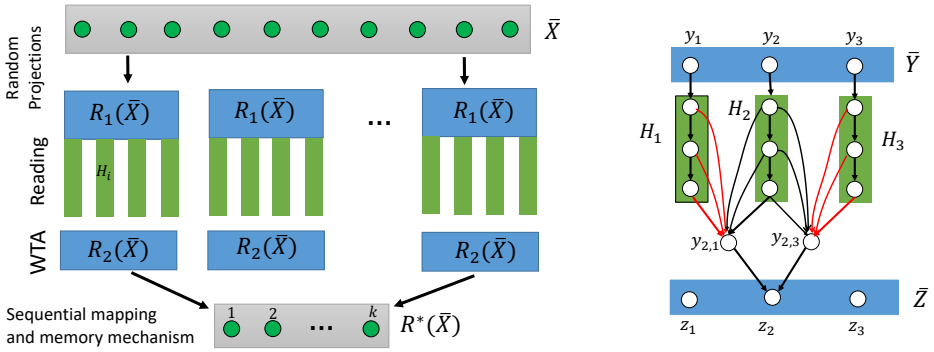

Figure 2 Left: Overall network description, the input pattern $\overline{X}$ is mapped to unique output neuron in $[1, k]$ via three main steps. Right: Description of the WTA circuit. For clarity we only show the connections for the second output neuron, but same holds for all k output neurons. Every input neuron i in $\overline{Y}$ is connected to a history chain H_i of length T that is used to collect firing statistics. For each pair of input neurons i, j, there is a threshold gate $q_{i,j}$ that fires only if i fired at least $T/2m$ more times than j within T rounds. Each history neuron in H_i, H_j is connected with weight 1 (respectively -1) to $q_{i,j}$ and the bias of $q_{i,j}$ is $T/2m$. Finally, each output neuron q_i computes the AND gate of $q_{i,1}, \ldots, q_{i,m}$, i.e., fires only if all these gates fire in the previous round. As a result a winner q_i is selected only if $y_i - y_j = \Omega(1/m)$ for every $j \neq i$.

5 Layer 3: Sequential Mapping

We conclude by discussing the final sequential mapping layer of our network, which maps the *binary* patterns $\overline{Z}_i$ of length $r = O(\ell \cdot m)$ to a single output neuron. The inputs to the third layer are the r neurons $Z = \{z_1, z_2, \ldots, z_r\}$ and its outputs are the k output neurons $Q = \{q_1, q_2, \ldots, q_k\}$. The r-length patterns will be mapped to their unique output neuron in a sequential manner, where at each given round, a newly introduced pattern will be mapped to the available output with the smallest index. The mapping will satisfy the following properties: (1) patterns $\overline{Z}_i, \overline{Z}_j$ that correspond to *far* input patterns $\overline{X}_i, \overline{X}_j$ respectively will be mapped to distinct outputs, (2) patterns $\overline{Z}_i, \overline{Z}_j$ that correspond to *close* input patterns

[3] This required gap is based on Lemma 7/Corollary 9.

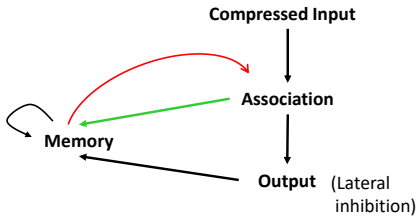

Figure 3 Schematic description.

presented within the same time window of $\Theta(t_m)$ rounds will be mapped to the same outputs. Recall that t_m is the memory duration which is a parameter of the network. A key component in our network is the *memory module* that remembers the association between each previously introduced pattern and its selected output for $\Theta(t_m)$ rounds. Roughly speaking, our network has two intermediate layers: an *association* layer and a *memory* layer (see Figure 3), which we describe below.

We first describe the construction by considering the case where a new pattern $\overline{Z}$ is introduced (and no close pattern to it was introduced before). When $\overline{Z}$ is presented to the network for the first time, it activates the association layer which contains r neurons $a_{i,1}, \ldots, a_{i,r}$ for each output q_i. Let $\text{supp}(\overline{Z})$ be the non-zero entries of $\overline{Z}$. Since[4] $|\text{supp}(\overline{Z})| \leq \ell$ it can activate at most $\ell \cdot k$ many neurons $a_{i,j}$ for every $j \in \text{supp}(\overline{Z})$ and $i \in \{1, \ldots, k\}$. Every output q_i is connected to its association neurons $a_{i,1}, \ldots, a_{i,r}$ and fires only if *many* of them fire.

Our construction will make sure that the number of active *association* neurons of a *taken* output (i.e., output already mapped to other pattern, far from $\overline{Z}$) will be small, which will prevent the firing of these outputs when a far pattern is presented. This will be provided due to the *memory module* appended to each output q_i which remembers the pattern (in fact the cluster of patterns) that were mapped to q_i in the *past*. For each j in the support of the pattern associated with q_i, the memory module corresponding to q_i and z_j inhibits all other association neurons associated with q_i, while activating the association a_{ij}. This association will be remembered – by the memory module – for at least $c_1 \cdot t_m$ rounds and at most $c_2 \cdot t_m$ rounds, for $c_1 < c_2$ with high probability.

For every available output q_i, all its association neurons $a_{i,j}$ for $j \in \text{supp}(\overline{Z})$ will start firing once $\overline{Z}$ is presented, which will in turn activate q_i. To select exactly one output neuron among all the available ones, the output layer is connected via a lateral inhibition, where every neuron q_i inhibits all q_j for $j \geq i + 1$.

Overall, our sequential mapping module satisfies:

▶ **Theorem 14** (The Sequential Mapping Module). *There exists a sequential mapping module with r input neurons, $\widetilde{\Theta}(r \cdot k)$ auxiliary neurons, and k output neurons that for every pattern $\overline{Z}$ that is introduced in round t satisfy the following with probability $1 - \delta$:*

(1) *The pattern $\overline{Z}$ is mapped to one of the outputs $q_1, \ldots, q_k$ in round $t + 6$.*

(2) *Any pair of* close *patterns $\overline{Z}, \overline{Z}'$ introduced within a span of $c_1 \cdot t_m$ rounds are mapped to the same output neuron.*

(3) *Any pair of far patterns $\overline{Z}, \overline{Z}'$ introduced within a span of $c_1 \cdot t_m$ rounds are mapped to different output neurons.*

In addition, if a pattern $\overline{Z}$ (or a pattern close to it) is not introduced for t_m rounds, then its unique mapped output q_j is released after $c \cdot t_m$ rounds, for some constant $c \geq 1$.

[4] As the WTA module picks at most one winning entry in each of the ℓ buckets.

5.1 Complete Network Description of the Sequential Mapping

Next we precisely describe the neurons and edge weights of the sequential mapping sub-network.

The association layer. For each neuron z_i in the input layer, and each neuron q_j in the output layer, we introduce an *association neuron* denoted as $a_{j,i}$. The neuron $a_{j,i}$ has positive and negative incoming edges from the memory modules that is described in the next paragraph. It also has a *positive* incoming edge from the neuron z_i with weight $w(z_i, a_{j,i}) = 2\ell$, and bias $\beta(a_{j,i}) = (19/10)\ell - 1$. We set the connections to this neuron in a way that guarantees it fires only if z_i fired in the previous round, and no other (far) pattern is already mapped to q_j.

The memory modules. For each neuron z_i in the input layer and output neuron q_j we introduce a *memory of association* module $M_{j,i}$ which remembers the association of neuron z_i and q_j. The memory module $M_{j,i}$ contains $c \cdot \log(\frac{1}{\delta'})$ excitatory neurons denoted as $M^+_{j,i}$ where $\delta' = \delta/\ell$ and c is chosen to be a sufficiently large constant. For every $m \in M^+_{j,i}$ we introduce a *feedback* neuron f_m which starts exciting m once the memory module is being activated.In addition, we introduce a delay chain $C^M_j = C_5(q_j)$ that starts at the output q_j and ends at each of the neurons $m \in M^+_{j,i}$. Finally, the memory module contains two head neurons, an excitatory neuron $m^+_{j,i}$ and an inhibitory neuron $m^-_{j,i}$.

Each excitatory neuron $m \in M^+_{j,i}$ has positive incoming edges from $a_{j,i}, q_j, C^M_j$, as well as from the corresponding feedback neuron f_m with the following weights and bias

$$w(a_{j,i}, m) = 2\lambda, \quad \forall u \in C^M_j \quad w(u, m) = 2 \ , \ w(f_m, m) = \lambda \cdot (\chi + 2) + 9 \quad \beta(m) = 9 + 2 \cdot \lambda \ ,$$

where $\chi = \log(t_m - 1)$. Note that if the feedback neuron f_m fired in the previous round, the memory neuron m fires with probability at least $\frac{1}{1+e^{-\chi}} = 1 - 1/t_m$. The feedback neuron f_m for $m \in M^+_{j,i}$ has *positive* incoming edges from m and $m^+_{j,i}$ with weights $w(m, f_m) = 2$, $w(m^+_{j,i}, f_m) = 2$, and bias $\beta(f_m) = 3$. Hence, w.h.p. f_m fires iff m and $m^+_{j,i}$ fired in the previous round. The excitatory head neuron $m^+_{j,i}$ has *positive* incoming edges from all $m \in M^+_{j,i}$ with weights $w(m, m^+_{j,i}) = 2$ and bias $\beta(m^+_{j,i}) = c \cdot \log(1/\delta') + 1$. The head neuron $m^-_{j,i}$ is an inhibitory copy of $m^+_{j,i}$ with the same incoming edges, bias and potential function.

Each association neuron $a_{j,i}$ has a *positive* incoming edge from the head memory neuron $m^+_{j,i}$ with weight $w(m^+_{j,i}, a_{j,i}) = \ell$. In addition, $a_{j,i}$ has *negative* incoming edges from the inhibitory memory neurons $m^-_{j,i'}$ for every $i' = \{1, 2, \ldots k\} \setminus \{i\}$ with weights $w(m^-_{j,i'}, a_{j,i}) = -1$. Note that w.h.p. $a_{j,i}$ fires in round t only if $z_i = 1$ in round $t - 1$. In case where there are at least $1/10\ell$ memory modules $m_{j,i'}$ that inhibit $a_{j,i}$, it fires only if its own memory module, namely, $M_{j,i}$ is active. To prevent a situation of partial memory where only part of the memory modules associated with a pattern are released, if at most 0.9ℓ of the memory modules $M_{j,1}, \ldots, M_{j,r}$ are active, we activate the inhibition of these firing modules. For that purpose, for every output q_j, we introduce 3 *deletion* neurons d^1_j, d^2_j, d^3_j. The neurons d^1_j, d^2_j detect this situation and the inhibitor d^3_j kills the partial memory. The deletion neuron d^1_j has incoming edges from all head neurons $m^+_{j,i}$ for $i = 1 \ldots r$ with weights $w(m^+_{j,i}, d^1_j) = 2$ and bias $\beta(d^1_j) = 1$. Hence, w.h.p. d^1_j fires in round t iff at least one memory module fired in round $t - 1$. The second deletion neuron has incoming edges from all the inhibitor head neurons $m^-_{j,i}$ for $i = 1 \ldots r$ with weights $w(m^-_{j,i}, d^2_j) = -1$ and bias $\beta(d^2_j) = -0.9\ell + 1$. Thus, w.h.p. d^2_j fires in round t iff at most 0.9ℓ memory module fired in round $t - 1$. The third deletion neuron d^3_j has incoming edges from d^1_j and d^2_j with weights $w(d^1_j, d^3_j) = w(d^2_j, d^3_j) = 2$ and bias $\beta(d^3_j) = 3$. Hence, d^3_j fires in round t iff d^1_j and d^2_j fired in round $t - 1$. In addition, the head neurons $m^+_{j,i}, m^-_{j,i}$ have a *negative* incoming edge from d^3_j with weight $w(d^3_j, m^+_{j,i}) = w(d^3_j, m^-_{j,i}) = -2c \log(1/\delta')$.

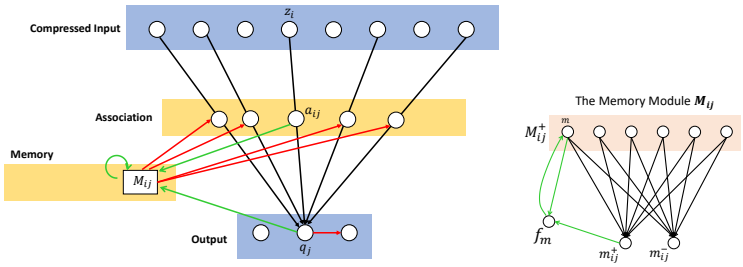

Figure 4 Left: an illustration of the network. The green edges correspond to edges with positive weight where the red edges correspond to negative weights. For simplicity we omitted the history and deletion neurons as well as the rest on the association and memory modules. Right: The memory module and the feedback loop mechanism.

History neurons. If an input pattern $\overline{Z}$ is already mapped to an output neuron, our goal is to map every pattern close to $\overline{Z}$ to the same output. To make sure that close patterns $\overline{Z}, \overline{Z}'$ are indeed mapped to the same output, for each output neuron q_j we introduce an inhibitory *history* neuron h_j. The role of the history neuron is to take care of a situation where a pattern $\overline{Z}$ is mapped to output q_j, but when a close pattern $\overline{Z}'$ is presented later on, an output q_i for $i < j$ is free. Recall that in our construction, each pattern is mapped to the first available output. To do that, the network parameters of the history neurons are defined as follows. Each history neuron h_j has *positive* incoming edges from all associated excitatory memory neurons $m^+_{j,i}$ for $i = 1 \dots r$ with weights $w(m^+_{j,i}, h_j) = 1$. In addition, it has a *positive* incoming edge from the output neuron q_j with weight $w(q_j, h_j) = \ell$ and bias $\beta(h_j) = -(3/2)\ell - 1$. Thus, the history neuron h_j fires if the output neuron q_j fired and at least a large fraction of the memory modules corresponding to q_j are active (the latter indicates that q_j is indeed taken). The history neuron h_j then inhibits all the preceding output neurons $q_1, \dots, q_{j-1}$, preventing the input pattern from being mapped to a different output.

The output layer. The output layer Q consists of excitatory neurons. In order to map the input pattern sequentially, for each $q_j \in Q$ we introduce an inhibitor output neuron q_j^- which inhibits the output neurons $q_{j'}$ for $j' \in \{j+1, \dots, k\}$. The neuron q_j is connected to q_j^- via a delay chain of length 3 denoted as $C_j^I = C_3(q_j)$. The neuron q_j^- has incoming edges from C_j^I with weights 2, and a negative bias of $\beta(q_j^-) = 5$. Hence, w.h.p. q_j^- fires iff q_j fired for 3 consecutive rounds.

Each output neuron q_j has *positive* incoming edges from the association neuron $a_{j,i}$ for every $i = \{1, 2, \dots k\}$. In addition, q_j has *negative* incoming edges from all preceding neurons q_i^- for $i < j$ and all successive history neurons h_i where $i > j$. The weights and bias are given by

$$w(a_{j,i}, q_j) = 2 \;\; \forall i \in [r], \quad w(q_i^-, q_j) = -3\ell \;\; \forall i < j, \quad w(h_i, q_j) = -3\ell \;\; \forall i > j, \quad \beta(q_j) = \ell - 1$$

Note that q_j fires in round t only if at least $(1/2)\ell$ association neurons fired in round $t-1$, and no history or inhibitor output neuron inhibit it.

As in previous sections, we assume that before the first round no neuron fires (i.e $v^0 = 0$ for every neuron v in the network). Figure 4 illustrates the structure of the network and Figure 5 demonstrates the network flow with two inputs.

5.2 Network Dynamics

Before providing the detailed analysis of the network, we give a more detailed description of the network behavior in the two orthogonal cases: mapping close patterns to the same output and mapping far patterns to distinct outputs.

Introduction of a New Pattern $\overline{X}_j$. A pattern $\overline{X}_j$ is introduced in round t where $q_1, \ldots, q_{j-1}$ are already allocated. We will describe how $\overline{X}_j$ is mapped to q_j. First, in Step (1), $\overline{X}_j$ is mapped to a vector $\overline{Y}_j = R_1(\overline{X}_j)$. In Step (2), $\overline{Y}_j$ is mapped to a *binary* vector $\overline{Z}_j$ which is the input to the sequential mapping sub-network. Let t' be the time in which $\overline{Z}_j$ fires. This will cause the firing of the association layer in the following manner. Let $\overline{X}_1, \ldots, \overline{X}_{j-1}$ be the patterns mapped to $q_1, \ldots, q_{j-1}$.

- For every allocated neuron q_i, $i \leq j-1$, and every entry $i_1 \in \text{supp}(Z_j) \setminus \text{supp}(Z_i)$, their association neuron a_{i,i_1} is inhibited by the memory modules M_{i,i_2} for every $i_2 \in \text{supp}(Z_i)$.
- Thus, for every allocated neuron q_i, when introducing Z_j, at most $|\text{supp}(Z_i) \cap \text{supp}(Z_j)| \leq 0.1 \cdot \ell$ association neurons $a_{i,j'}$ are active.
- Since an output q_i fires only if at least $1/2\ell$ association neurons are active, q_i would not fire.
- For every free output q_i for $i \in \{j, \ldots, k\}$, all the association neurons a_{i,i_1} for every $i_1 \in \text{supp}(Z_j)$ are now active. Hence, in the next round, all $q_j, \ldots, q_k$ fire.
- Since we have a lateral inhibition, q_j inhibits[5] all other q_i for $i \in \{j+1, \ldots, k\}$.
- Only at the point where $q_{j+1}, \ldots, q_k$ are inhibited, the memory modules M_{j,i_1} of the winner output q_j start being active, for every $i_1 \in \text{supp}(Z_j)$. This memory module continues firing from that point on for $\Theta(t_m)$ rounds, even when X_j is not introduced.
- Each activated module M_{j,i_1} for every $i_1 \in \text{supp}(Z_j)$ inhibits each of the other association neurons a_{j,i_2} for every $i_2 \neq i_1$. In addition, each M_{j,i_1} excites its own association neuron a_{j,i_1} for $i_1 \in \text{supp}(Z_j)$, thus canceling the inhibition from the other M_{j,i_2} modules. As a result, the only inhibited association neurons are a_{j,i_2} for $i_2 \notin \text{supp}(Z_j)$.

Re-Introduction of a Close-Pattern $\overline{X}_j$. We now consider the situation where $\overline{X}_j$ is introduced in round t, and a close-pattern $\overline{X}_{j'}$ was introduced in the past (e.g., in a window of $\Theta(t_m)$ rounds). We would like to show that $\overline{X}_j$ will be mapped to the exact same output neuron $q_{j'}$ as $\overline{X}_{j'}$.

- For every allocated neuron q_i and every entry $i_1 \in \text{supp}(Z_j) \setminus \text{supp}(Z_i)$, their association neuron a_{i,i_1} is inhibited by the memory modules M_{i,i_2} for every $i_2 \in \text{supp}(Z_i)$.
- Thus, for every allocated neuron q_i for $i \neq j'$, when introducing Z_j, at most $|\text{supp}(Z_i) \cap \text{supp}(Z_j)| \leq 0.1 \cdot \ell$ association neurons a_{i,i_1} are active. As a result, q_{i_1} will not fire.
- In contrast, for the desired output neuron $q_{j'}$, only $|\text{supp}(Z_j) \setminus \text{supp}(Z_{j'})|$ association neurons are inhibited, while the remaining ones, namely, a_{j',i_1} for $i_1 \in \text{supp}(Z_j) \cap \text{supp}(Z_{j'})$ are active. Since $|\text{supp}(Z_j) \cap \text{supp}(Z_{j'})|$ is sufficiently large, $q_{j'}$ will fire.
- Due to lateral inhibition of $q_{j'}$, all other free outputs $q_{i'}$ for $i' \geq j'+1$ will not fire.
- It remains to show that all other *free* outputs q_i for $i \leq j'-1$ will not be active. Recall that these outputs have a lateral inhibition on $q_{j'}$ that starts inhibiting $q_{j'}$ within a small number of rounds since the activation of q_i. It is therefore important to neutralize these outputs before their inhibition on $q_{j'}$ comes into play. Indeed this is the reason for introducing the delay to the lateral inhibition mechanism.

[5] In fact, its inhibitor copy will do this inhibition.

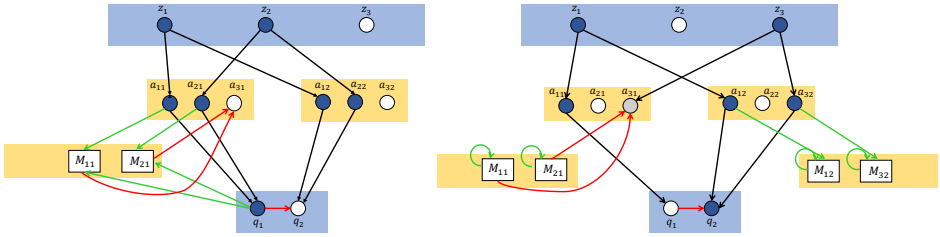

Figure 5 Left: network's state where first pattern $(1,1,0)$ is presented. Since all outputs are free at that point, the pattern is mapped to the first output q_1, which activates all its memory modules. Right: network description when the second input $(1,0,1)$ is presented. Because the memory modules $M_{1,1}$ and $M_{1,2}$ are active, the association neuron $a_{1,3}$ is inhibited and this q_1 will not fire. As a result, $(1,0,1)$ is mapped to q_2, activating corresponding memory modules $M_{2,1}$ and $M_{2,3}$.

- To indicate the fact that $q_{j'}$ was already allocated to a pattern close to X_j, we have a history neuron $h_{j'}$ that works as follows. It gets input from all the memory modules of $q_{j'}$, as well as from $q_{j'}$ itself. Since the close patterns X_j and $X_{j'}$ have many entries in common, sufficiently many memory modules of $q_{j'}$ will activate $h_{j'}$. For a free output q_i for $i \leq j'-1$, the memory modules of q_i are not active and hence the history neuron would not be active.
- The history neuron $h_{j'}$ then inhibits all prior outputs q_i for $i \leq j'-1$ just before their lateral inhibition chain affects $q_{j'}$. In addition, the inhibition on q_i also occurs before the memory modules of q_i start being active. That is, since we want to remember only the association to the correct output $q_{j'}$, we delay the activation of the memory model. The latter starts only after $q_{j'}$ fires for a consecutive constant number of rounds.

5.2.1 Correctness

The following definitions are useful in our context.

▶ **Definition 15.** *A pattern $\overline{Z}$ is* mapped *to an output neuron q_j in round t if when presenting $\overline{Z}$ to the sequential mapping network in round $t-1$, q_j is the only firing output neuron in round t.*

▶ **Definition 16.** *$M_{j,i}$ is* active *in round t, if its head neurons $m^+_{j,i}$, $m^-_{j,i}$ fired in round t.*

In order to prove the main Theorem 14, we start by establishing useful auxiliary claims and observations.

▶ **Observation 17.** *For every output neuron q_j if the number of active memory modules M_{ij} in round t is between 1 and 0.9ℓ, then w.h.p. there are no active memory modules in round $t+3$.*

Proof. For output neuron q_j if the number of active memory modules M_{ij} in round t is at least 1 w.h.p. the deletion neuron d^1_j fires in round $t+1$. If the number of active memory modules M_{ij} is also less than 0.9ℓ then w.h.p. d^2_j fires in round $t+1$ and therefore d^3_j fires in round $t+2$, inhibiting all memory modules M_{ij} for $i=1,\ldots,r$. ◀

▶ **Observation 18.** *Given that the deletion neurons of output q_j did not fire in round $t-1$, w.h.p. a memory module $M_{j,i}$ is active in round t iff at least $(c/2)\log(1/\delta')$ neurons $m \in M^+_{j,i}$ fired in round $t-1$.*

Proof. Recall that a memory module $M_{j,i}$ is *active* in round t if the excitatory neuron $m^+_{j,i}$ fired. The potential function of $m^+_{j,i}$ is given by

$$pot(m^+_{j,i}, t) = \sum_{m \in M^+_{j,i}} 2 \cdot m^{t-1} - 2c\log(1/\delta')(d^3_j)^{t-1} - c\log(1/\delta') + 1 \ .$$

If at least $\frac{c}{2}\log(1/\delta')$ neurons in $M^+_{j,i}$ fired in round $t-1$, the potential of $m^+_{j,i}$ in round t is at least 1 and the probability that $m^+_{j,i}$ fire in round t is at least $\frac{1}{1+e^{-1/\lambda}} \geq 1 - \Theta(\frac{\delta}{n \cdot k \cdot \Delta \cdot t_m \cdot \log 1/\delta})$. On the other hand, if less than $\frac{c}{2}\log(1/\delta')$ neurons in $M^+_{j,i}$ fired, the potential of $m^+_{j,i}$ is at most -1 and the probability that $m^+_{j,i}$ fired in round t is at most $\frac{1}{1+e^{1/\lambda}} \leq \Theta(\frac{\delta}{n \cdot k \cdot \Delta \cdot t_m \cdot \log 1/\delta})$. ◀

▷ Claim 19. If $\overline{Z}_1, \overline{Z}_2$ are close and $\overline{Z}_2, \overline{Z}_3$ are close, then $\overline{Z}_1, \overline{Z}_3$ are close.

Proof. Let $\overline{X}_1, \overline{X}_2, \overline{X}_3$ be the corresponding input patterns, where $\overline{Z}_i = R_2(\overline{X}_i)$ for $i \in \{1, 2, 3\}$. By the definition of the clustering instance, every pair of patterns $\overline{X}_i, \overline{X}_j$ are either with relative distance at least $\Delta/2$ (i.e., if these patterns belong to different clusters), or have relative distance at most Δ/α (i.e., if they belong to the same cluster) for $\alpha = \Omega(\log(1/\Delta))$.

By Lemma 12, input patterns $\overline{X}_i, \overline{X}_j$ that belong to different (resp., same) clusters are mapped to far (resp., close) vectors $\overline{Z}_i, \overline{Z}_j$. We therefore have that $\overline{X}_1, \overline{X}_2$ are in the same cluster, and also $\overline{X}_2, \overline{X}_3$ are in the same cluster, concluding that $\overline{X}_1, \overline{X}_2, \overline{X}_3$ are all in the same cluster. ◁

▷ Claim 20. For every $j \in [k]$ and $i \in [\ell]$ w.h.p. the memory module $M_{j,i}$ is active in round t given that it was not active in round $t-3$, only if C^M_j and $a_{j,i}$ fired in round $t-2$.

Proof. By Observation 18 $M_{j,i}$ is activated in round t only if at least $(c/2)\log(1/\delta')$ neurons $m \in M^+_{j,i}$ fire in round $t-1$. Since $M_{j,i}$ was not active in round $t-3$ all feedback neurons f_m for $m \in M^t_{j,i}$ was not active in round $t-2$ and the potential of each $m \in M^+_{j,i}$ in round $t-1$ is $\sum_{u \in C^M_j} 2 \cdot (u)^{t-2} + 2\lambda \cdot (a_{ij})^{t-2} - 9 - 2\lambda$. Hence, if C^M_j and $a_{j,i}$ fired in round $t-2$, in the next round the potential of each $m \in M^+_{j,i}$ is at least 1 and m fires in round $t-1$ with probability at least $1 - \Theta(\frac{\delta}{n \cdot k \cdot \Delta \cdot t_m \cdot \log 1/\delta})$. Thus, by Chernoff bound w.h.p. at least $(c/2)\log(1/\delta')$ neurons $m \in M^+_{j,i}$ fired in round $t-1$.

On the other hand if C^M_j and $a_{j,i}$ did not fire together in round $t-2$, the potential of every $m \in M^t_{j,i}$ in round $t-1$ is at most -2λ and m fires with probability at most $\frac{1}{1+e^2}$. Using Chernoff bound and choosing c to be sufficiently large, we conclude that $(c/2)\log(1/\delta')$ neurons $m \in M^+_{j,i}$ fire in round $t-1$ with probability at most δ'. ◁

▶ **Observation 21.** *For every output q_j at each round w.h.p. the number of memory modules $M_{j,i}$ that are active is at most ℓ.*

Proof. Since every pattern has at most ℓ non zero entries, in each round at most ℓ association neurons $a_{j,i}$ fire. By Claim 20, at each round at most ℓ memory modules $M_{j,i}$ are activated for the first time. If in round $t-3$ more then 0.1ℓ memory modules were active, the only association neurons firing in round $t-2$ correspond to the activated memory modules and therefore w.h.p. no new modules are activated in round t. Else, by Observation 17 w.h.p. the deletion neuron d^3_j kills the active memory modules and no memory module is active in round t. ◀

Using the same arguments, since the deletion neurons erase the partial memory, we can also conclude that for every output neuron all its active memory modules correspond to the same input pattern.

▶ **Observation 22.** *For each output neuron q_i in each round if it has active memory modules, there exists an input pattern $\overline{Z}$ s.t if $M_{i,j}$ is active then $j \in \text{supp}(\overline{Z})$.*

▷ Claim 23. If $\overline{Z}$ is mapped to q_j in round t, with probability greater than $1-\delta$ at least 0.8ℓ memory modules $M_{j,i}$ where $i \in \text{supp}(\overline{Z})$ are active for $c_1 \cdot t_m$ consecutive round starting from round $t+8$.

Proof. Let $\overline{Z}$ be a pattern mapped to q_j in round t. Recall that we assume persistence and therefore w.h.p. $\overline{Z}$ is also mapped to q_j in rounds $t+1$ to $t+8$.

- First we argue that at least 0.8ℓ of the association neurons $a_{j,i}$ for $i \in \text{sup}(\overline{Z})$ fire in round $t+6$. From Observation 17 either there where no memory modules corresponding to q_j active before $\overline{Z}$ was introduces or at least 0.9ℓ [6]. If there where no memory modules active, all association neurons $a_{j,i}$ for $i \in \text{sup}(\overline{Z})$ fire starting round $t+1$ ahead as long as $\overline{Z}$ persist. Otherwise, since q_j fired in round $t+7$, we conclude that at least 0.5ℓ association neurons $a_{j,i}$ fired in round $t+6$. The association neurons that fired are from the support of $\overline{Z}$ and together with Observation 22 we conclude that the pattern previously mapped to q_j is close to $\overline{Z}$ and at least 0.8ℓ association neurons fired in rounds $t+6$ (due to Lemma 12).
- For $i \in sup(\overline{Z})$ for which a_{ij} fired in rounds $t+6$, we now calculate the probability that M_{ij} is active in round $t+8$. By Observation 18 its enough to calculate the probability that at least $(c/2)\log(1/\delta')$ neurons $m \in M^+_{j,i}$ fired in round $t+7$. The potential function of every $m \in M^+_{j,i}$ is given by

$$\text{pot}(m,t) = \sum_{u \in C^M_j} 2 \cdot (u)^{t-1} + 2\lambda \cdot (a_{ij})^{t-1} + (9 + \lambda \cdot (2+\chi)) \cdot (f_m)^{t-1} - 9 - 2\lambda \ .$$

  Since q_j fires in rounds t to $t+7$, the delay chain C^M_j fired in round $t+6$, and the probability m fires in round $t+7$ is at least $1 - \Theta(\frac{\delta}{n \cdot k \cdot \Delta \cdot t_m \cdot \log 1/\delta})$. Using Chernoff bound with probability greater than $1-\delta/3\ell$ at least $\frac{c\log(1/\delta')}{2}$ neurons in $M_{j,i}$ fire in round $t+7$ and the head memory neuron $m^+_{j,i}$ fires in round $t+8$.
- Next we calculate the probability that $m \in M^+_{j,i}$ fires $c_1 t_m$ consecutive rounds starting round $t+8$ given that $m^+_{j,i}$ fires in round $t+8$. Since $m^+_{j,i}$ fired in round $t+8$, for every $m \in M^+_{j,i}$ that fired in round $t+8$, the feedback neuron f_m is activated in round $t+9$ and m fires in round $t+10$ with probability at least $1-1/t_m$. Hence, the probability $m \in M^+_{j,i}$ fires in rounds $t+8$, $t+9$ and $c_1 t_m$ consecutive rounds is at least $(1-\Theta(\frac{\delta}{n \cdot k \cdot \Delta \cdot t_m \cdot \log 1/\delta}))^2 \cdot (\frac{1}{e^{c_1}})$. We chose c_1 such that this is greater than $1/2$. Thus, using Chernoff bound and a large enough c (depending on c_1) the probability that at least $\frac{c\log(1/\delta')}{2}$ neurons $m \in M^+_{j,i}$ fire in rounds $t+8$, $t+9$ and then for $c_1 t_m$ consecutive rounds is at least $1-\delta'/3 = 1-\delta/3\ell$.
- Summing things up, the probability $M_{j,i}$ is active for $c_1 \cdot t_m$ consecutive rounds from round $t+8$ ahead is at least the probability that $m^+_{j,i}$ fired in round $t+8$ and $\frac{c\log(1/\delta')}{2}$ neurons in $M^+_{j,i}$ fires $c_1 t_m$ consecutive rounds starting round $t+8$. By union bound this probability is greater than

$$1 - 3 \cdot (\delta/3\ell) = 1 - \delta/\ell.$$

Thus, we conclude that the probability all 0.8ℓ modules $M_{j,i}$ s.t $a_{j,i}$ fired in round $t+6$ are active for $c_1 \cdot t_m$ consecutive rounds is greater than $1-\delta$. ◁

We are now ready to prove the correctness of the sequential mapping step.

[6] up too ± 3 rounds, but since we assume persistence its ok.

Proof of Theorem 14

Proof. We start by proving the 3 main properties of the network. Given a pattern $\overline{Z}$ introduced in round t we will show:

(1) $\overline{Z}$ is mapped to one of the outputs $q_1, \ldots, q_k$ in round $t+6$

(2) For any pattern $\overline{Z}'$ which is *close* to $\overline{Z}$ and was introduced within a span of $c_1 \cdot t_m$ rounds from t, $\overline{Z}$ and $\overline{Z}'$ are mapped to the same output neuron.

(3) For any pattern $\overline{Z}'$ which is *far* from $\overline{Z}$ and was introduced within a span of $c_1 \cdot t_m$ rounds from t, $\overline{Z}$ and $\overline{Z}'$ are mapped to a different output neuron.

By induction on the order of arrival of the patterns. Let $\overline{Z}$ be the first pattern arrived in round 0. We show that $\overline{Z}$ is mapped to the first (available) neuron q_1 in round 6. For every $i \in \sup(\overline{Z})$ the potential function of the association neuron $a_{1,i}$ is given by:

$$pot(a_{1,i}, t) = 2\ell(z_i)^{t-1} + \ell(m^+_{1,i})^{t-1} - \sum_{j \neq i}(m^-_{1,j})^{t-1} - (19/10)\ell - 1 \ .$$

Since $\overline{Z}$ is the first pattern seen, no neuron has fired in round zero and $\mathrm{pot}(a_{1,i}, 1) = (1/10)\ell - 1 > 1$, and w.h.p. each $a_{1,i}$ for $i \in \sup(\overline{Z})$ fires in round 1.

Since q_1 is the first output, no preceding output neuron inhibits it, and its potential is:

$$\mathrm{pot}(q_1, t) = \sum_{i=1}^{r}(2 \cdot a_{1,i})^{t-1} - \sum_{i=2}^{k} 3\ell h_i - \ell + 1 \ .$$

By Claim 13, w.h.p. each input pattern $\overline{Z}$ (to the sequential mapping network) has at least 0.98ℓ non-zero entries (and at most ℓ). Therefore, at least 0.98ℓ association neurons $a_{1,i}$ excite q_1 in round 2. Recall that the history neurons h_i fire only if at least $1/2$ of the corresponding memory modules are active in the previous round. Hence w.h.p. in round 1, no history neuron fires.

We conclude that q_1 fires in round 2 w.h.p. By Claim 20 every memory module $M_{i,j}$ becomes active only after having q_i firing for 5 consecutive rounds (due to the delay chain C^M_i). For that reason, no memory module fires before round 5. Since the memory neurons are not active, $a_{1,i}$ keeps firing in rounds 1 to 6, and q_1 keeps firing in rounds 2 to 7. Since q_1 is connected to q^-_1 via a delay chain C^I_1 of length 3, starting round 5 (and as long as q_1 fires), the inhibitor q^-_1 inhibits all other output neuron q_i for $i \geq 2$. Thus, for every $i \geq 2$ the potential of q_i in round 6 is at most $\ell - 2\ell - 1/2\ell + 1 < -1$. As a result, for $i \geq 2$ neuron q_i does not fire starting round 6.

We next argue that at this point, no memory modules are yet active and consequently the history neurons are inactive as well. This is due to the fact that the delay in the inhibition of q_i by q_1 is *shorter* then the delay chain C^M_i that starts at q_i and ends at the memory modules. Thus q_i is inhibited before its memory modules are activated. We conclude that if $\overline{Z}$ is observed, starting from round 6, the output neuron q_1 is the only active output neuron, and $\overline{Z}$ is *mapped* to q_1.

Assume the claim holds for the first $i-1$ presented patterns, we next consider the i^{th} pattern $\overline{Z}$ presented in round t.

- We first show that for every $\overline{Z}'$ that is far from $\overline{Z}$ introduced in round $t' \in [t - c_1 \cdot t_m, t-1]$, the pattern $\overline{Z}$ will be mapped to a different output. By the induction assumption, $\overline{Z}'$ is mapped in round $t'+6$ to some output neuron, q_j. Since $\overline{Z}'$ was introduced within $c_1 \cdot t_m$ rounds, by Claim 23 at least 0.8ℓ many memory modules $M_{j,i}$ for $i \in \sup(\overline{Z}')$ are active it round t.

Let $\overline{X}$, $\overline{X}'$ be the inputs corresponding to $\overline{Z}$ and $\overline{Z}'$ respectively. From Lemma 12, $\|\sup(\overline{Z}) \cap \sup(\overline{Z'})\| \leq 0.1\ell$. By Observation 21, the number of active memory modules $M_{j,i}$ in round t is at most ℓ. Thus, the number of active memory modules $M_{j,i}$ in round t for $i \in \sup(\overline{Z})$ is at most $0.2\ell + 0.1\ell = 0.3\ell$.

For every association neuron $a_{j,i}$ whose memory module $M_{j,i}$ is inactive in round t, there are at least 0.8ℓ memory modules that inhibit it. Therefore its potential is $2\ell - 8/10\ell - (19/10)\ell + 1 < -1$, and w.h.p. it does not fire in round $t+1$. Overall, at most 0.3ℓ association neurons $a_{j,i}$ start firing from round $t+1$ and as long as the pattern persists. We conclude that q_j will stop firing from round $t+2$.

- Next we show that two close patterns $\overline{Z}'$ and $\overline{Z}$, introduced within a span of $c_1 \cdot t_m$ rounds are mapped to the same output. First note that by Claim 19, all patterns that are close to $\overline{Z}$ are close to each other. Hence, by the induction assumption, all patterns close to $\overline{Z}$ introduced within the last $c_1 t_m$ rounds were mapped to the same output. We now consider a pattern $\overline{Z}'$ close to $\overline{Z}$ introduced in round $t' \in [t - c_1 \cdot t_m, t - 10]$. By the induction assumption, the pattern $\overline{Z}'$ was mapped to output q_j in round $t' + 6$. By claim 23, 0.8ℓ many memory modules $M_{j,i}$ are active in round $t' + 7 < t$ onward (i.e., for $\Theta(t_m)$ rounds). Combining with Lemma 12 because $\overline{Z}$ is close to $\overline{Z}'$, at least 0.7ℓ many memory modules $M_{j,i}$, $i \in \sup(\overline{Z})$ are active in round t. Since there are at most ℓ many active memory modules associated with q_j in round t, the potential of the association neuron $a_{j,i}$ for which the memory neuron is active in round $t+1$ is at least $2\ell + \ell - (\ell - 1) - 1.9\ell - 1 = 0.1\ell > 1$. We have that at least 0.7ℓ many association neuron $a_{j,i}$ fire in round $t+1$, leading to the firing of q_j in round $t+2$.

  Next, because at least 0.8ℓ memory modules $M_{j,i}$ are active from round $t+3$ ahead, the history neuron h_j fires, and by that inhibits all output neurons q_i for $i \leq j-1$ starting from round $t+4$. Recall that every inhibitor neuron q_i^- for $i \leq j-1$ starts firing only after the delay chain C_i^I fired, i.e. after 3 rounds that q_i fired. Hence the history neuron h_j inhibits every q_i for $i \leq j-1$, just before q_i^- starts firing. We next show that no other q_i fires for $i \geq j+1$. This holds since q_j^- inhibits any such q_i in round $t+6$ via the delay chain C_j^I. Finally, we show that q_j continues firing as long the pattern persists. Because at least 0.5ℓ of the association neurons $a_{j,i}$ are firing, and no preceding inhibitor q_i^- is currently firing (thanks to the history neuron h_j), it remains to show that no other history neuron h_i for $i \neq j$ inhibits q_j. By the induction assumption, all patterns close to $\overline{Z}$ were mapped to q_j. Hence if for some other output q_i for $i \neq j$, at least 0.5ℓ of its associated memory modules are active, by Observation 17 at least 0.9ℓ memory modules are active. Since the pattern $\overline{Z}''$ that was mapped to q_i is far from $\overline{Z}$, we have that at most 0.2ℓ many memory modules $M_{i,i'}$ for $i' \in sup(\overline{Z})$ are active, thus q_i does not fire and consequently h_i does not fire.
- We now consider the case of a newly presented pattern, i.e., no close pattern to it has been presented in the last $\Theta(t_m)$ rounds. We will show that in such a case, $\overline{Z}$ will be mapped to the left-most available output q_j, where by available we mean that no memory module $M_{j,i}$ is active in round t. Let $q_{i_1}, q_{i_2} \ldots q_{i_s}$ be the available output neurons in round t. Hence all the association neurons $a_{i_1,i}$ for $i \in \sup(\overline{Z})$ start firing in round $t+1$. This is because no memory module $M_{i_1,j}$ is active. Thus, in round $t+2$ the output neuron q_{i_1} starts firing. As for the unavailable neurons q_j, by Observation 17 at least 0.9ℓ memory modules M_{ji} are active and by Observation 22 they are associated with a pattern $\overline{Z''}$ which was mapped to q_j. The pattern $\overline{Z''}$ is far from $\overline{Z}$ ($\overline{Z}$ is a new pattern) and therefore at most 0.2ℓ memory module $M_{j,i}$ for $i \in \sup(\overline{Z})$ are active in round t. Hence, at most 0.2ℓ association neurons $a_{j,i}$ fire starting round $t+1$ and w.h.p. q_j will

not fire starting round $t+2$ (and also no history neuron inhibits q_{i_1}). Since we assume persistence, and due to the delay in the activation of the memory modules, q_{i_1} fires also in rounds $t+3$ and $t+4$, and in round $t+5$ the inhibitor $q^-_{i_1}$ starts firing, inhibiting all the successive output neurons q_j for $j \geq i_1+1$.

In order to finish the proof of Theorem 14 we will prove th following Lemma.

▶ **Lemma 24** (Reset, Clearance of Memory). *Let $\overline{Z}$ be a pattern last introduced in round t and mapped to q_j. If no close pattern $\overline{Z}'$ is introduced in rounds $[t, t+c_2 \cdot t_m]$, then q_j is released in some round $\tau \leq t+c_2 t_m$, i.e., all memory modules $M_{j,i}$ stop firing with probability greater than $1-\delta$.*

Proof. Let $\overline{Z}$ be a pattern last introduced in round t and mapped to q_j. By Observation 17 if in some round τ there are less than 0.9ℓ memory modules corresponding to q_j firing, after 3 round 0 memory modules are active and w.h.p. q_j is released. As long as there are at least 0.9ℓ memory modules firing, since all patterns introduced in rounds t to $t+c_2 t_m$ are far from $\overline{Z}$ by the same arguments used in Lemma 14 starting from round $t+1$ less than 0.5ℓ association neurons associated with q_j fire and q_j will not fire for $c_2 t_m$ consecutive rounds starting from round $t+2$ (as long as it is not already released). Thus, from round $t+7$ ahead w.h.p. all neurons in the delay chain C^M_j do not fire.

Therefore, the probability neuron $m \in M^+_{j,i}$ fires in round $\tau \in [t+8, t+c_2 t_m]$ given that f_m did not fire in round $\tau-1$ is at most $\Theta(\frac{\delta}{\log 1/\delta \cdot n \cdot k \cdot \Delta \cdot t_m})$. Moreover, by union bound the probability that there exists a neuron $m \in M^+_{j,i}$ that fired in some round $\tau \in [t+8, t+c_2 t_m]$ given that f_m did not fire in round $\tau-1$ is at most $\delta/2\ell$.

Next we calculate the probability at least half of the neurons $m \in M^+_{j,i}$ fire for $c_2 t_m$ consecutive rounds. Because the delay chain C^M_j do not fire starting round $t+7$ the potential of each neuron $m \in M^+_{j,i}$ in round $t' \in [t+7, t+c_2 t_m]$ is bounded by $\lambda \cdot (\chi+2) = \lambda(\log(t_m-1)+2)$. Hence, the probability $m \in M^+_{j,i}$ fires in round t' is at most $1 - \frac{1}{e^2(t_m-1)+1} < 1 - \frac{1}{e^2 t_m}$. We conclude that the probability a neuron $m \in M^+_{j,i}$ fires for $c_2 t_m$ consecutive rounds is at most e^{c_2/e^2} which for $c_2 > e^2 log(3)$ is less than $1/3$. Using Chernoff bound and a sufficient large c (constant depending on c_2) the probability that at least $(c/2)\log(1/\delta')$ neurons in $M^+_{j,i}$ fire for $c_2 \cdot t_m$ consecutive rounds starting round $t+7$ is at most $\delta/2\ell$.

If $m^+_{j,i}$ fires for $c_2 t_m$ consecutive rounds starting round $t+8$, be Observation 18 at each round at least $1/2$ of the neurons in $M^+_{j,i}$ fired. Given that no neuron $m \in M^+_{j,i}$ fires in round $\tau \in [t+8, t+c_2 t_m]$ unless f_m fired in round $\tau-1$, the head neuron $m^+_{j,i}$ fires for $c_2 t_m$ consecutive rounds only if at least $1/2$ of the neurons in $M^+_{j,i}$ fires for $c_2 t_m$ consecutive rounds. Thus we conclude that $m^+_{j,i}$ fired for $c_2 t_m$ consecutive rounds starting round $t+8$ with probability at most $\delta/(2\ell) + \delta/(2\ell) = \delta/\ell$. Note that by Observation 21 at most ℓ memory neurons M_{ij} are active at each round and using union bound we conclude that with probability at least $1-\delta$ the output neuron q_j is release in round $\tau < t+c_2 t_m$ ◀

This concludes Theorem 14 and therefore also Theorem 3. ◀

A Additional Proofs: Random Projection

We first prove Lemma 5, that a Chi-squared distribution is nearly uniform within a constant number of standard deviations from its mean.

▶ **Lemma 5.** *Let $\mathcal{D}_p$ be the Chi-squared distribution with p degrees of freedom. For any c with $1 \leq c < p^{1/2}$ there are constants c_ℓ, c_u (depending on c) such that, for any interval $[r_1, r_2] \subseteq \left[p - cp^{1/2}, p + cp^{1/2}\right]$, we have:*

$$\frac{c_\ell(r_2 - r_1)}{p^{1/2}} \leq \Pr_{x \sim \mathcal{D}_p}[x \in [r_1, r_2]] \leq \frac{c_u(r_2 - r_1)}{p^{1/2}}$$

That is, $\mathcal{D}_p$ is roughly uniform on the range $\left[p - cp^{1/2}, p + cp^{1/2}\right]$.

Proof. It is well known that $\mathcal{D}_p$ has mean p, density $d(x) = \frac{1}{2^{p/2}\Gamma(p/2)} x^{p/2-1} e^{-x/2}$. Since we assume $p^{1/2} > c \geq 1$ we have $p \geq 2$ and the distribution has mode $p - 2$. Additionally, we have $p - cp^{1/2} > 0$. So for $x \in \left[p - cp^{1/2}, p + cp^{1/2}\right]$ we can bound:

$$d(x) \leq d(p-2) = \frac{1}{2^{p/2}\Gamma(p/2)}(p-2)^{p/2-1}e^{-p/2+1} \leq \frac{1}{\Gamma(p/2)} \cdot \left(\frac{p}{2e}\right)^{p/2-1}$$

By Stirling's approximation, $\Gamma(p/2) \geq \sqrt{\frac{2\pi}{p/2}}\left(\frac{p}{2e}\right)^{p/2}$ which gives:

$$d(x) \leq \sqrt{\frac{p}{4\pi}} \cdot \frac{2e}{p} = \frac{e}{\sqrt{\pi} \cdot p^{1/2}}. \tag{2}$$

On the other side, since $p - cp^{1/2} > 0$, and since the density of the Chi-squared distribution is monotonically decreasing as x moves further from the mode $p - 2$ either left or right:

$$d(x) \geq \min(d(p - cp^{1/2}), d(p + cp^{1/2})). \tag{3}$$

We lower bound each term in the minimum.

$$\begin{aligned} d(p - cp^{1/2}) &= \frac{1}{2^{p/2}\Gamma(p/2)}(p - cp^{1/2})^{p/2-1}e^{-p/2+(c/2)p^{1/2}} \\ &= \frac{1}{2\Gamma(p/2)}\left(\frac{p}{2e}\right)^{p/2-1} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{p/2-1} \cdot e^{(c/2)p^{1/2}-1} \end{aligned}$$

Again using Stirling's approximation, and a similar argument to the proof of (2), for some constant c_1, $\frac{1}{2\Gamma(p/2)}\left(\frac{p}{2e}\right)^{p/2-1}$ is lower bounded by $\frac{c_1}{p^{1/2}}$. Thus,

$$\begin{aligned} d(p - cp^{1/2}) &\geq \frac{c_1}{p^{1/2}} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{p/2-1} \cdot e^{(c/2)p^{1/2}-1} \\ &\geq \frac{c_1}{p^{1/2}} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{\left(\frac{p^{1/2}}{c}-1\right)\cdot(c/2)p^{1/2}} \cdot e^{(c/2)p^{1/2}-1} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{(c/2)p^{1/2}-1} \\ &\geq \frac{c_1}{p^{1/2}} \frac{1}{e^{(c/2)p^{1/2}}} \cdot e^{(c/2)p^{1/2}-1} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{(c/2)p^{1/2}-1} \\ &\geq \frac{c_1}{ep^{1/2}} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{\left(\frac{p^{1/2}}{c}-1\right)\cdot(c^2/2)+(c^2/2-1)} \\ &\geq \frac{c_1 \cdot e^{c^2/2}}{ep^{1/2}} \cdot \left(1 - \frac{c}{p^{1/2}}\right)^{c^2/2-1} \geq \frac{c'}{p^{1/2}} \end{aligned} \tag{4}$$

for some constant c' that depends on c. We give a similar bound for $p + cp^{1/2}$.

$$\begin{aligned} d(p+cp^{1/2}) &= \frac{1}{2\Gamma(p/2)}\left(\frac{p}{2e}\right)^{p/2-1}\cdot\left(1+\frac{c}{p^{1/2}}\right)^{-p/2-1}\cdot e^{(c/2)p^{1/2}-1} \\ &\geq \frac{c_1}{p^{1/2}}\cdot\left(1+\frac{c}{p^{1/2}}\right)^{-p/2-1}\cdot e^{(c/2)p^{1/2}-1} \\ &= \frac{c_1}{p^{1/2}}\cdot\left(1+\frac{c}{p^{1/2}}\right)^{-\frac{p^{1/2}}{c}\cdot(c/2)p^{1/2}}\cdot e^{(c/2)p^{1/2}-1}\cdot\left(1+\frac{c}{p^{1/2}}\right)^{-1} \\ &\geq \frac{c}{ep^{1/2}}\cdot\left(1+\frac{c}{p^{1/2}}\right)^{-1} \geq \frac{c'}{p^{1/2}} \end{aligned} \tag{5}$$

for some c'. Combining (4) and (5) with (3) and (2) gives that there exist constants c_ℓ, c_u such that for all $x \in [p - cp^{1/2}, p + cp^{1/2}]$,

$$\frac{c_\ell}{p^{1/2}} \leq d(x) \leq \frac{c_u}{p^{1/2}}.$$

Thus for any r_1, r_2:

$$\frac{c_\ell(r_2 - r_1)}{p^{1/2}} \leq \Pr_{x\sim\mathcal{D}_p}[x \in [r_1, r_2]] \leq \frac{c_u(r_2 - r_1)}{p^{1/2}},$$

completing the lemma. ◀

We next give a complete proof of Lemma 7.

A.1 Proof of Lemma 7

Since each $[A_b\overline{X}](i)$ is a Chi-squared random variable with p degrees of freedom, which has median $\leq p$, each $[A_b\overline{X}](i)$ is upper bounded by $p \leq \tau = p + 2p^{1/2}$ with probability $\geq 1/2$. Thus, by Lemma 5 applied with $c = 2$, conditioned on $[A_b\overline{X}](i) \leq p + 2p^{1/2}$, there is some c_ℓ with:

$$\Pr\left[[A_b\overline{X}](i) \in \left[p, p + 2p^{1/2}\right] \middle| [A_b\overline{X}](i) \leq p + 2p^{1/2}\right] \geq \frac{c_\ell \cdot 2p^{1/2}}{p^{1/2}} = 2c_\ell.$$

Thus, for large enough constant c_1 and $m = c_1$, with probability at least $\frac{199}{200}$, we have $i_{1,b}(\overline{X}) \neq 0$ and $[A_b\overline{X}](i_{1,b}(\overline{X})) \geq p$. Call this event $\mathcal{E}_1$. Condition on the event that $\mathcal{E}_1$ occurs and, in particular, that $[A_b\overline{X}](i_{1,b}(\overline{X})) = x$ for any $x \in [p, p + 2p^{1/2}]$. Call this event $\mathcal{E}_{1,x}$. Then for all $j \neq i_{1,b}(\overline{X})$, $[A_b\overline{X}](j)$ is an independent Chi-squared random variable with p degrees of freedom conditioned on either 1) $[A_b\overline{X}](j) \leq x$ or 2) $[A_b\overline{X}](j) \geq p + 2p^{1/2}$. Since $[A_b\overline{X}](j) \leq p \leq x$ with probability at least $1/2$, this conditioning at most doubles the density at any one value. Thus, by Lemma 5,

$$\Pr\left[[A_b\overline{X}](j) \in \left[x - \frac{p^{1/2}}{c_2 m}, x\right] \middle| \mathcal{E}_{1,x}\right] \leq \frac{2c_u \cdot \frac{p^{1/2}}{c_2 m}}{p^{1/2}}.$$

By a union bound, we thus have:

$$\Pr\left[\exists j :\ [A_b\overline{X}](j) \in \left[x - \frac{p^{1/2}}{c_2 m}, x\right] \middle| \mathcal{E}_{1,x}\right] \leq \frac{2c_u \cdot \frac{p^{1/2}}{c_2}}{p^{1/2}} = \frac{2c_u}{c_2}.$$

Setting c_2 sufficiently large ensures that this quantity is bounded by $\frac{1}{200}$. Thus, by a union bound with the probability that $\mathcal{E}_1$ occurs, with probability $\geq \frac{99}{100}$: $i_{1,b}(\overline{X}) \neq 0$ and 2) no $[A_b\overline{X}](j)$ falls in $\left[x - \frac{p^{1/2}}{mc_2}, x\right] = \left[[A_b\overline{X}](i_{1,b}(\overline{X})) - \frac{p^{1/2}}{mc_2}, [A_b\overline{X}](i_{1,b}(\overline{X}))\right]$. This completes the proof.

A.2 Proof of Lemma 8

We first use the relative distance assumption to give a basic claim:

▷ Claim 25. Write $\overline{X}_1, \overline{X}_2$ as $\overline{X}_1 = \chi + \delta_1$ and $\overline{X}_2 = \chi + \delta_2$ where $\chi \in \{0,1\}^n$ is the common vector with $\chi(i) = 1$ iff $\overline{X}_1(i) = \overline{X}_2(i) = 1$. Note that since $\|X_1\| = \|X_2\| = p$ we have $\|\delta_1\| = \|\delta_2\|$. Letting $\Delta = \mathcal{RD}(\overline{X}_1, \overline{X}_2)$,

$$\frac{\|\delta_1\|}{p} = \frac{\Delta}{2}.$$

Proof. We can write:

$$\Delta = \mathcal{RD}(\overline{X}_1, \overline{X}_2) = \frac{\|\overline{X}_1 - \overline{X}_2\|}{p} = \frac{\|\delta_1 - \delta_2\|}{p} = \frac{\|\delta_1\| + \|\delta_2\|}{p}.$$

The claim follows since $\|\delta_1\| = \|\delta_2\|$. ◁

▷ Claim 26. For $i \in [2]$ and $j \in [m] \cup 0$ let $\mathcal{E}_j$ be the event that $j = i_{1,b}(\overline{X}_1)$. With probability $\geq 999/1000$ over the choice of $\mathrm{A}_b\,\chi$, for all j we have:

$$\Pr[\mathcal{E}_j \;\mid\; \mathrm{A}_b\,\chi] \leq \frac{1}{16}.$$

Proof. Let $\Delta = \mathcal{RD}(\overline{X}_1, \overline{X}_2)$ and assume for simplicity that $\Delta \leq 1$ (we will latter see that it is easy to remove this assumption). By Claim 25, $\|\delta_1\| = \|\delta_2\| \leq \frac{p}{2}$ and thus $\|\chi\| \geq \frac{p}{2}$. For a constant c_3 (to be set later) sub-divide the range $\left[\|\chi\| - c_3 p^{1/2}, \|\chi\| + c_3 p^{1/2}\right]$ into $\frac{1}{\Delta^{1/2}}$ subranges of width:

$$2c_3 p^{1/2}\Delta^{1/2} = 2\sqrt{2}c_3\|\delta_1\|^{1/2},$$

where the equality follows from Claim 25. By Lemma 5 (applied with the constant c in the Lemma set to c_3) for any $i \in [m]$, $[A_b\chi](i)$ falls into each range with probability $\Theta(c_3 \cdot \Delta^{1/2})$. Thus, by a standard Chernoff bound, for $m = \frac{c_1 \log 1/\Delta}{\sqrt{\Delta}}$ for sufficiently large c_1, with probability $1999/2000$ over the choice of A_b, at least c_4 indices of $A_b\chi$ fall within each bucket where c_4 is a constant to be set later. Note that c_1 depends on c_3, c_4. Call the event that c_4 indices fall into each bucket $\mathcal{E}_{full-buckets}$. Additionally, as argued in Lemma 7, for sufficiently large m, the maximum value $[A_b\bar{X}_1](i_{1,b}(\bar{X}_1))$ below $p + p^{1/2}$ satisfies $[A_b\bar{X}_1](i_{1,b}(\bar{X}_1)) \geq p$ with probability at least $1999/2000$. Thus, with probability $1999/2000$ over the choice of A_b,

$$\Pr\left[[A_b\bar{X}_1](i_{1,b}(\bar{X}_1)) \geq p \middle| A_b\chi\right] \geq 1999/2000. \tag{6}$$

Let $\mathcal{E}_{good}$ be the event that both $\mathcal{E}_{full-buckets}$ and (6) hold. $\mathcal{E}_{good}$ holds with probability $\geq 999/1000$ over the choice of A_b. First note that conditioning on $\mathcal{E}_{good}$, $\Pr[\mathcal{E}_0 \big|\, \mathrm{A}_b\,\chi] \leq \frac{1}{2000}$, easily giving the claim for $j = 0$. We now consider $j \in [m]$. We consider any bucket,

$$R = \left\{j : [A_b\chi](j) \in \left[r, r + 2\sqrt{2}c_3\|\delta_1\|^{1/2}\right]\right\},$$

where r is be some integer multiple of $2\sqrt{2}c_3\|\delta_1\|^{1/2}$. Roughly, since each index in R has a very similar value in $A_b\chi$, each has nearly the same likelihood of being the largest entry in A_bX_1 below $\tau = p + 2p^{1/2}$. Since $\mathcal{E}_{full-buckets}$ occurs, there are at least c_4 of these indices

and thus if c_4 is large, none has very high probability of being the largest entry. Formally, we will show that, assuming $\mathcal{E}_{good}$ holds, for each $j \in R$,

$$\Pr[\mathcal{E}_j \mid \mathrm{A}_b\, \chi] \leq \frac{1}{16}. \tag{7}$$

Since this bound holds for all buckets in the range $[\|\chi\| - c_3 p^{1/2}, \|\chi\| + c_3 p^{1/2}]$, it will give the claim after arguing that no index with $A_b\chi$ falling outside this range is likely to have $\mathcal{E}(1, j)$ occur either.

Indices in Buckets. Each entry of $A_b\delta_1$ is identically distributed as an independent Chi-squared random variable with $\|\delta_1\|$ degrees of freedom. Additionally, $A_b\delta_1$ is independent of $A_b\chi$ since δ_1 and χ have disjoint supports. Consider $j \in R$ with $\Pr[[A_b\bar{X}_1](j) \geq \tau \big| A_b\chi] \geq 15/16$. In this case, since $\mathcal{E}(1, j)$ can only hold if $[A_b\bar{X}_1](j) \leq \tau$, (7) trivially holds.

Next consider $j \in R$ with $\Pr[[A_b\bar{X}_1](j) \geq \tau \big| A_b\chi] \leq 15/16$. By Lemma 6 there is some c with:

$$\Pr\left[[A_b\delta_1](j) \geq \|\delta_1\| + c\|\delta_1\|^{1/2}\right] = \frac{1}{64},$$

or equivalently since $[A_b\overline{X}_1](j) = [A_b\chi](j) + [A_b\delta_1](j)$:

$$\Pr\left[[A_b\overline{X}_1](j) \geq [A_b\chi](j) + \|\delta_1\| + c\|\delta_1\|^{1/2} \big| A_b\chi\right] = \frac{1}{64},$$

Setting $r_2 = \min\left([A_b\chi](j) + \|\delta_1\| + c\|\delta_1\|^{1/2}, \tau\right)$ we thus have that

$$\Pr[[A_b\overline{X}_1](j) \in [r_2, \tau] \big| A_b\chi] \leq \frac{1}{64}. \tag{8}$$

Additionally, by Lemma 5 there is some r_1 with $r_2 - r_1 = \Theta(\|\delta_1\|^{1/2})$ such that:

$$\Pr\left[[A_b\overline{X}_1](j) \in [r_1, r_2] \big| A_b\chi\right] = \frac{1}{32}.$$

Since for all $j' \in R$, $|[A_b\chi](j) - [A_b\chi](j')| \leq 2\sqrt{2}c_3\|\delta_1\|^{1/2} = O(\|\delta_1\|^{1/2})$ we have $r_2 = [A_b\chi](j') + O(\|\delta_1\|^{1/2})$ and thus again by Lemma 5, for all $j' \in R$:

$$\Pr\left[[A_b\overline{X}_1](j') \in [r_1, r_2] \big| A_b\chi\right] = \Omega(1).$$

If we set the constant c_4 large enough, since assuming $\mathcal{E}_{good}$, $|R| \geq c_4$ we have:

$$\Pr\left[\exists\, j' \in R \setminus j :\ [A_b\overline{X}_1](j') \in [r_1, r_2] \big| A_b\chi\right] \geq \frac{31}{32}.$$

If this event holds, we can only have $\mathcal{E}(1, j)$ occur if $[A_b\overline{X}_1](j)$ falls in $[r_2, \tau]$, which by (8) occurs with probability $\leq \frac{1}{64}$ conditioned on $A_b\chi$. Thus by a union bound we have:

$$\Pr[\mathcal{E}_j \mid \mathrm{A}_b\, \chi] \leq \frac{1}{16},$$

giving (7) in this case.

Indices Outside Buckets. We now consider indices not falling in any bucket: that is, j with $[A_b\chi](j) \leq \|\chi\| - c_3 p^{1/2}$ or $[A_b\chi](j) \geq \|\chi\| + c_3 p^{1/2}$. For the later, to have $\mathcal{E}_b(1,j)$ occur we must have $[A_b\overline{X}_1](j) \leq \tau = p + 2p^{1/2}$ and thus $[A_b\delta_1](j) \leq \|\delta_1\| - (c_3 - 2)p^{1/2} \leq \|\delta_1\| - (c_3 - 2)\sqrt{2}\|\delta_1\|$. By Lemma 6, this occurs with probability $< 1/16$ for all $\|\delta_1\|$ as long as we set c_3 large enough. Similarly, for j with $[A_b\chi](j) \leq \|\chi\| - c_3 p^{1/2}$, with probability $\geq 15/16$, we will have $[A_b\delta_1](j) \leq \|\delta_1\| + c_3 p^{1/2}$ and thus $[A_b\overline{X}_1](j) \leq p$. Since assuming $\mathcal{E}_{good}$, the maximum value of $A_b\overline{X}_1$ bounded by $\leq \tau$ is $\geq p$, if $[A_b\overline{X}_1](j) \leq p$, $\mathcal{E}_b(1,j)$ will not occur. Thus completes the argument in this case, giving that for all j with $[A_b\chi](j) \leq \|\chi\| - c_3 p^{1/2}$ or $[A_b\chi](j) \geq \|\chi\| + c_3 p^{1/2}$, $\Pr[\mathcal{E}_b(1,j) \mid \mathrm{A}_b\,\chi] \leq \frac{1}{16}$.

Removing Bound on Δ. Finally, we note that we can remove the assumption that $\Delta \leq 1$. If $\Delta \geq 1$ we can simply have χ encompass some of the non-shared entries in $\overline{X}_1$ until $\|\chi\| \geq \frac{p}{2}$ and $\|\delta_1\| \leq \frac{p}{2}$ as desired. The bound will go through as argued up to constants, since we will still have $\frac{\|\delta\|_1}{p} = \Theta(\Delta)$ as in Claim 25 (note that we always have $\Delta \leq 2$). ◁

We can now complete the proof of Lemma 8. We have:

$$\begin{aligned}\Pr[i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2) \mid \mathrm{A}_b\,\chi] &= \sum_{j=0}^{m} \Pr\left[i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2) = j \mid \mathrm{A}_b\,\chi\right] \\ &= \sum_{j=0}^{m} \Pr\left[i_{1,b}(\overline{X}_1) = j \mid \mathrm{A}_b\,\chi\right] \cdot \Pr\left[i_{1,b}(\overline{X}_2) = j | \,\mathrm{A}_b\,\chi\right] \end{aligned} \tag{9}$$

where the second line follows from the fact that $\mathrm{A}_b\,\overline{X}_1$ and $\mathrm{A}\,\overline{X}_2$ are independent conditioned on $\mathrm{A}_b\,\chi$ since δ_1, δ_2 are disjoint vectors. By Claim 26, with probability $\geq 999/1000$ over the choice of $\mathrm{A}_b\,\chi$ we can bound (9) by:

$$\Pr[i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2) \mid \mathrm{A}_b\,\chi] \leq \sum_{j=0}^{m} \Pr\left[i_{1,b}(\overline{X}_2) = j \mid \mathrm{A}_b\,\chi\right] \cdot 1/16 = 1/16 \tag{10}$$

where the last line follows simply since $\sum_{j=0}^{m} \Pr\left[i_{1,b}(\overline{X}_2) = j \mid \mathrm{A}_b\,\chi\right] = 1$. Since (10) holds with probability $\geq 999/1000$ over the choice of $\mathrm{A}_b\,\chi$, overall $\Pr[i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2)] \leq 1/16 + 1/1000$.

Applying Claim 7 and a union bound gives that $i_{1,b}(\overline{X}_1) \neq i_{1,b}(\overline{X}_2)$ and the gaps between the largest and second largest entries of $\mathrm{A}_b\,\overline{X}_1$ and $\mathrm{A}_b\,\overline{X}_2$ (bounded by τ) are both at least $\geq \frac{p^{1/2}}{c_2 \cdot m}$ (or there is at most one such entry), and $[\mathrm{A}_b\,\overline{X}_1](i_1(\overline{X}_1)), [\mathrm{A}_b\,\overline{X}_2](i_1(\overline{X}_2)) \geq p$ with probability $\geq 1 - (1/16 + 1/1000) - 2/100 = .9165$, giving the lemma.

A.3 Proof of Lemma 10

We now give the deferred proof of Lemma 10, which shows that two close inputs are likely to have the same intermediate neuron with the maximum potential $\leq \tau$ in each bucket. We restate the lemma below.

▶ **Lemma 10.** *Let $\overline{X}_1, \overline{X}_2 \in \{0,1\}^n$ be two vectors with $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \leq \Delta/\alpha$. Consider our construction with bucket size $m = \frac{c_1 \log(1/\Delta)}{\sqrt{\Delta}}$. Then for sufficiently large constants c_1, c_2 and $\alpha = O(\log(1/\Delta)^4)$, for any $b \in [\ell]$, defining $i_{1,b}(\cdot)$ and $i_{2,b}(\cdot)$ as in Lemma 7, with probability ≥ 0.97:*

- $i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2)$.
- *For both $j = 1, 2$: $i_{1,b}(\overline{X}_j) \neq 0$, $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) \geq p$, and $[A_b\overline{X}_j](i_{1,b}(\overline{X}_j)) - [A_b\overline{X}_j](i_{2,b}(\overline{X}_j)) \geq \frac{p^{1/2}}{c_2 \cdot m}$ or $i_{2,b}(\overline{X}_j) = 0$.*

Proof. By Lemma 7, with probability $\geq 99/100$, for all $i \in [m] \setminus i_{1,b}(\overline{X}_1)$ with $[\mathrm{A}_b\, \overline{X}_1](i) \leq \tau$:

$$[\mathrm{A}_b\, \overline{X}_1](i_{1,b}(\overline{X}_1)) - [\mathrm{A}_b\, \overline{X}_1](i) = \Omega\left(\frac{p^{1/2}}{m}\right), \tag{11}$$

By a similar argument, with probability $\geq 99/100$, for all $i \in [m]$,

$$|\tau - (\mathrm{A}_b\, \overline{X}_1)_i| = \Omega\left(\frac{p^{1/2}}{m}\right). \tag{12}$$

Additionally, by standard sub-exponential concentration (as used in Lemma 6) with probability $\geq 99/100$, for both $j = 1, 2$ and all $i \in m$ we have $[\mathrm{A}_b\, \delta_j](i) \in \|\delta_i\| \pm O(\log m \cdot \|\delta_i\|^{1/2})$. Note that $\log m = O(\log(1/\Delta))$. Additionally, by Claim 25, since $\mathcal{RD}(\overline{X}_1, \overline{X}_2) \leq \Delta/\alpha$ for $\alpha = O(\log(1/\Delta)^4)$, we have for both $i = 1, 2$, $\frac{\|\delta_i\|}{p} \leq \frac{\Delta}{2\alpha} = O\left(\frac{\Delta}{\log(1/\Delta)^4}\right)$. This gives that

$$O(\log m \cdot \|\delta_1\|^{1/2}) = O\left(\frac{\Delta^{1/2} p^{1/2}}{\log(1/\Delta)}\right) = O\left(\frac{p^{1/2}}{m}\right).$$

So for both $j = 1, 2$ and all $i \in m$, $(\mathrm{A}_b\, \delta_j)_i \in \|\delta_i\| \pm O\left(\frac{p^{1/2}}{m}\right)$. So by (11) we have for all $i \neq i_{1,b}(\overline{X}_1)$ with $[\mathrm{A}_b\, \overline{X}_1](i) \leq \tau$:

$$[\mathrm{A}_b\, \overline{X}_2](i_{1,b}(\overline{X}_1)) - [\mathrm{A}_b\, \overline{X}_1](i) =$$
$$[\mathrm{A}_b\, \overline{X}_1](i_{1,b}(\overline{X}_1)) - [\mathrm{A}_b\, \delta_1](i_{1,b}(\overline{X}_1)) + [\mathrm{A}_b\, \delta_2](i_{1,b}(\overline{X}_1)) - [\mathrm{A}_b\, \overline{X}_1](i) = \Omega\left(\frac{p^{1/2}}{m}\right).$$

By (12) we also have,

$$[\mathrm{A}_b\, \overline{X}_2](i_{1,b}(\overline{X}_1)) = [\mathrm{A}_b\, \overline{X}_1](i_{1,b}(\overline{X}_1)) - [\mathrm{A}_b\, \delta_1)](i_{1,b}(\overline{X}_1)) + [\mathrm{A}_b\, \delta_2](i_{1,b}(\overline{X}_1)) \leq \tau.$$

and similarly, for all $i \neq i_{1,b}(\overline{X}_1)$ with $[\mathrm{A}_b\, \overline{X}_1](i) \geq \tau$:

$$[\mathrm{A}_b\, \overline{X}_2](i) \geq \tau.$$

That is, $i_{1,b}(\overline{X}_1)$ is the largest entry of $\mathrm{A}_b\, \overline{X}_2$ under τ, and thus $i_{1,b}(\overline{X}_1) = i_{1,b}(\overline{X}_2)$.

Applying Lemma 7 and a union bound gives the second claim with overall probability $1 - 1/100 - 1/100 - 1/100 = 97/100$. ◀

B Detailed Analysis of the Sparsification Step via WTA

Proof of Claim 13

Proof. Let $i = \arg\max_{j:\overline{Y}(j) \leq \tau} \overline{Y}(j)$. For every neuron $j \in \{1, \ldots, m\}$ in the input vector $\overline{Y}$, let $\overline{R}(j)$ be the random variable that counts the number of rounds in which j fires in a window of $T = \Theta(m^2 \log m)$ rounds. By the construction described above in which all j with $\overline{Y}(j) \geq \tau$ are inhibited with very strong weight, $\overline{R}(j) = 0$ w.h.p. for all such j. Thus we focus on j with $\overline{Y}(j) \leq \tau$. We show that if $\overline{Y}(i) - \overline{Y}(j) = \Omega\left(\frac{p^{1/2}}{m}\right)$ for $j \neq i$, then $\overline{R}(i) \gg \overline{R}(j)$ with probability at least $1 - \Theta(1/m)$.

First, let $\overline{P}$ be the vector of firing probabilities of each intermediate neuron induced by the potentials in $\overline{Y}$ (ignoring the entries that have been zero'd out since $\overline{Y}(j) \geq \tau$). By (1) we have $\overline{P}(i) = \frac{1}{1+e^{-\overline{Y}(i)}}$. Letting $s(x) = 1/(1 + e^{-x})$, we have $s'(x) \in \left[\frac{1}{2}, \frac{3}{4}\right]$ for $x \in [0, 1]$

and can see that if $\overline{Y}(i) - \overline{Y}(j) = \Omega(1/m)$, then also $s(\overline{Y}(i)) - s(\overline{Y}(j)) = \Omega(1/m)$. That is, a gap of $\Omega(1/m)$ between $\overline{Y}(i)$ and $\overline{Y}(j)$ translates to a gap of $\Omega(1/m)$ between the firing probabilities $\overline{P}(i)$ and $\overline{P}(j)$. To ensure that $\overline{Y}(i), \overline{Y}(j)$ are in $[0,1]$ we can simply rescale the weights of the random connection matrix A by $\frac{1}{2p}$ and shift them by p by adding a bias of p to each intermediate neuron. By Corollary 9, before this shift and scaling, $\overline{Y}(i) \in [p, p + 2p^{1/2}]$, so afterwards, $\overline{Y}(i) \in [0,1]$. For all $j \neq i$, since by Corollary 9 we had $\overline{Y}(i) - \overline{Y}(j) = \Omega\left(\frac{p^{1/2}}{m}\right)$ we still have $\overline{Y}(i) - \overline{Y}(j) = \Omega\left(\frac{1}{m}\right)$ as required and thus $\overline{P}(i) - \overline{P}(j) = \Omega\left(\frac{1}{m}\right)$.

By Chernoff bound, with probability of at least $1 - c/m$,

$$\overline{R}(i) \geq T \cdot \overline{P}(i) - \sqrt{T \cdot \overline{P}(i) \cdot c \log m} \quad \text{and} \quad \overline{R}(j) \leq T \cdot \overline{P}(j) + \sqrt{T \cdot \overline{P}(j) \cdot c \log m)} \ .$$

Hence, with probability $1 - 2c/m$ we get that

$$\begin{aligned} \overline{R}(i) - \overline{R}(j) &\geq T \cdot (\overline{P}(i) - \overline{P}(j)) - \sqrt{T \cdot \overline{P}(i) \cdot c \log m)} - \sqrt{T \cdot \overline{P}(j) \cdot c \log m.} \\ &\geq T \cdot (\overline{P}(i) - \overline{P}(j)) - 2\sqrt{T \cdot \overline{P}(i) \cdot \log m} = \Omega(T/m) - O(\sqrt{T \cdot \log m}) \\ &= \Omega(T/m) \ , \end{aligned}$$

by taking $T = c' \cdot m^2 \log m$ for a sufficiently large constant c'.

Since the incoming weight of each neuron $y_{i,j}$ is $\overline{R}(i) - \overline{R}(j) = \omega(1)$, we get that $y_{i,j}$ fires with probability of $1 - \Theta(1/m)$. By doing a union bound over all $m - 1$ neurons, and taking large enough constants, we get that with probability at least $99/100$, all neurons $y_{i,j}$ fire for every $j \neq i$. Hence, z_i is the only firing neuron in $\overline{Z}$. ◀

Recall that in Step (1), every input vector $\overline{X}_i$ is projected into ℓ vectors $\overline{Y}_{i,b} = \mathrm{A}_b \cdot \overline{X}_i$ for every $b \in \{1, \ldots, m\}$. On each such vector $\overline{Y}_{i,b}$ we apply the WTA circuit and get a vector $\overline{Z}_{i,b}$. Let $\overline{Z}_i = \overline{Z}_{i,1} \circ \overline{Z}_{i,2} \circ \ldots \circ \overline{Z}_{i,\ell}$ for $\ell = O(\log(t_m/\delta))$, where $\circ$ denotes vector concatenation.

We conclude this section by showing that the relative gap between input patterns $\overline{X}_i, \overline{X}_j$ is reflected in their output vectors of the WTA circuit. By combining Claim 13 with Cor. 9 and 11, we prove Lemma 12 which completes the correctness of Step (II).

Proof of Lemma 12

Proof. First observe that for every input $\overline{X}_i$, there are at most ℓ non-zero entries in $\overline{Z}_i$ since the threshold gates fire only if there is a sufficient gap in the firing rates. (I) For a fixed pair $\overline{X}_i, \overline{X}_j$ of far patterns, let $B_{i,j}$ be the set of all buckets b where $\arg\max_{r \in [m]: \overline{Y}_{i,b}(r) \leq \tau} \overline{Y}_{i,b}(r) \neq \arg\max_{r \in [m]: \overline{Y}_{j,b}(r) \leq \tau} \overline{Y}_{j,b}(r)$ and the gap between largest and second largest entries in both vectors $\overline{Y}_{i,b}$ and $\overline{Y}_{j,b}$ is $\Omega(p^{1/2}/m)$. By Cor. 9, with probability $1 - \delta$, for every pair of far patterns $\overline{X}_i, \overline{X}_j$, $|B_{i,j}| \geq 0.9 \cdot \ell$.

By Claim 13, if $\overline{Y}_{i,b}$ has a desired gap between the largest entry and other entries then, with probability $p = 99/100$, $\overline{Z}_{i,b}$ has exactly one winning entry corresponding to $\arg\max(\overline{Y}_{i,b})$. In expectation the vectors $\overline{Z}_{i,b}$ differ in $p \cdot |B_{i,j}|$ buckets. Thus by applying Chernoff bound overall k^2 pairs, in 0.9ℓ of the buckets, the WTA picks a distinct winner for the $\overline{X}_i$ and $\overline{X}_j$ patterns. Thus, $\mathrm{supp}(\overline{Z}_i) \setminus \mathrm{supp}(\overline{Z}_j) \geq 0.9\ell$.

(II) For a fixed pair $\overline{X}_i, \overline{X}_j$ of close patterns, let $B_{i,j}$ be the set of all buckets b where $\arg\max_{r \in [m]: \overline{Y}_{i,b}(r) \leq \tau} \overline{Y}_{i,b}(r) = \arg\max_{r \in [m]: \overline{Y}_{j,b}(r) \leq \tau} \overline{Y}_{j,b}(r)$ and the gap between largest and second largest entries in both vectors $\overline{Y}_{i,b}$ and $\overline{Y}_{j,b}$ is $\Omega(p^{1/2}/m)$. By Cor. 11 with probability $1 - \delta$, for every pair of close patterns $\overline{X}_i, \overline{X}_j$, $|B_{i,j}| \geq 0.91 \cdot \ell$. By applying Claim 13 and Chernoff bound overall k^2 pairs, in at least $0.9 \cdot \ell$ of the buckets, the selected winner is the same with probability of $1 - \delta$, implying that $\mathrm{supp}(\overline{Z}_i) \cap \mathrm{supp}(\overline{Z}_j) \geq 0.9 \cdot \ell$. ◀

Signed Tropical Convexity

Abstract

We establish a new notion of tropical convexity for signed tropical numbers. We provide several equivalent descriptions involving balance relations and intersections of open halfspaces as well as the image of a union of polytopes over Puiseux series and hyperoperations. Along the way, we deduce a new Farkas' lemma and Fourier-Motzkin elimination without the non-negativity restriction on the variables. This leads to a Minkowski-Weyl theorem for polytopes over the signed tropical numbers.

Acknowledgements We thank Daniel Dadush for insisting on balanced numbers and for inspiring discussions on the tropical Fourier-Motzkin elimination. We thank Xavier Allamigeon as well as Stéphane Gaubert for communicating their related work. We are grateful to Matthias Schymura for helping to get an intuition for the unintuitive line segments. Furthermore, we thank Mateusz Skomra and an anonymous referee for pointing out the NP-completeness stated in Theorem 4.21.

1 Introduction

Tropical convexity is an important notion with applications in several branches of mathematics. It arises from the usual definition of convexity by replacing $+$ with max and $\cdot$ with $+$. This notion has been studied for several years involving different approaches from extremal algebra [36], idempotent semirings [18], max-algebra [16], convex analysis [15], discrete geometry [20], matroid theory [22]. So far, it was mainly studied in $\mathbb{T}_{\max} = \mathbb{R} \cup \{-\infty\}$. Indeed, this is essentially a restriction to the tropical non-negative orthant, as $r \geq -\infty$ for all $r \in \mathbb{T}_{\max}$, where $-\infty$ is the tropical zero element. We remedy this restriction by introducing a notion of tropical convexity involving all orthants. We give our main points of motivation for our generalization.

Mean payoff games are equivalent to feasibility of a tropical linear inequalities

$$\bigoplus_{j \in J_i} a_{ij} + x_j \geq \bigoplus_{j \in [n] \setminus J_i} a_{ij} + x_j \quad \forall j \in [m] \ , \tag{1}$$

where $a_i, x \in \mathbb{T}_{\max}^n$, for $i \in [n]$, see [3]. This problem is in NP ∩ co-NP, but no polynomial-time algorithm is known [26]. Furthermore, the latter feasibility problem is intimately related to the feasibility problem for classical linear inequality systems [33, 6]. This connection has recently lead to a construction showing that certain interior point methods are not strongly polynomial [7]. The tropical linear feasibility problem is also a special scheduling problem [31] and it can be considered as a particular disjunctive programming problem [13].

In the context of mean payoff games, signs can be used to represent the two sides of the inequality (1). This system can be concisely written as $A \odot x \geq \mathbb{0}, x \geq \mathbb{0}$, where $\mathbb{0}$ represents the vector of $-\infty$'s, and $A \in \mathbb{T}_{\pm}^{m \times n}$ is a matrix with $A_{ij} = a_{ij}$ if $j \in J_i$ and $A_{ij} = \ominus a_{ij}$ if $j \notin J_i$. Here, $\ominus a_{ij}$ represents a tropically negative number (note that 5 and -5 are tropically positive, while $\ominus 5$ and $\ominus -5$ are tropically negative).

Our main motivation is to extend some of the basic concepts and tools from convex geometry and polyhedral combinatorics to signed tropical numbers. Significant work has been done already in this direction, however, some fundamentals are still missing: in particular, a satisfactory notion of convexity for signed tropical numbers has not been given prior to this work.

Such an investigation is motivated both by algorithmic questions as well as in the context of recent developments in tropical geometry. Solving mean payoff games in polynomial time is a major open question. Developing tropical versions of polyhedral combinatorics tools may lead to new approaches to tackle this problem. For example, there is a relatively recent class of polynomial-time algorithms for linear programming are naturally formulated as deciding if the origin is in the convex hull of a set of points, see, e.g., [17]. Our convexity notion provides an analogous formulation for the tropical linear feasibility problem in terms of the signed convex hull of the coefficient vectors.

Signed tropical numbers have been used in important recent results in tropical geometry, for example, in the tropicalization of the simplex method [6]. The study of real tropicalization of semialgebraic sets [27] follows a similar spirit. Another approach to extend from $\mathbb{T}_{\max}^d$ involving signs is to deduce the structure of a variety by "unfolding" it from the positive orthant into the other orthants, which is formalized by the patchworking introduced in [34] that has several applications in algebraic geometry.

Furthermore, separation theorems like Farkas' lemma for linear programming have their easiest formulation in terms of separation from the origin leading to powerful generalizations to oriented matroids, see [11]. Our approach allows to formulate an analogous theory for tropical linear programming. This gives new possibilities for studying tropical normal fans and tropical hyperplane arrangements.

Arithmetic operations can be naturally extended from $\mathbb{T}_{\max}$ to the set of signed tropical numbers $\mathbb{T}_{\pm}$. There is however a critical case of degeneracy, namely, adding a positive and a negative number of the same absolute value. In the context of the formulation (1), this corresponds to allowing the same variable x_j on both sides with the same a_{ij} term. Introducing *balanced numbers* are a standard way to carry out such additions: $5 \oplus (\ominus 5) = \bullet 5$, thus obtaining the *symmetrized semiring*. Unfortunately, it is not possible to order this structure, and hence, it is desirable to study the geometry restricted to the signed numbers $\mathbb{T}_{\pm}$.

1.1 Our Contributions

Tropical convexity has been well-studied for $\mathbb{T}_{\max}$ (see [6]). Balanced numbers constitute an important challenge in extending this notion to signed tropical numbers. Consider for example the points $(1, 1)$ and $(\ominus 1, \ominus 1)$ in $\mathbb{T}_{\pm}^2$. It is natural to include all points (a, a) and $(\ominus a, \ominus a)$ for $a \leq 1$ as well as $(-\infty, -\infty)$ as the convex combinations of these points. Our convexity notion will additionally include every point of the form (a, b), $(\ominus a, \ominus b)$, $(\ominus a, b)$, and $(a, \ominus b)$ for $a, b \leq 1$; thus, the convex combination of these two points in $\mathbb{T}_{\pm}^2$ will be a rectangle rather than a line segment. We obtain these combinations by "resolving" the balanced combination $(\bullet 1, \bullet 1)$ of these two points.

Our definition of signed tropical convexity (Definition 3.1) just arises from the usual definition of tropical convexity by replacing equality "=" with the balance relation "$\bowtie$" first introduced in [1]. We provide multiple arguments justifying why this is the right

definition. A standard way to introduce the tropical semiring is via Puiseux lifts. It turns out (Theorem 3.14) that this construction yields the tropicalization of the union of all possible lifts. This notion of signed tropical convexity also comes up naturally in the context of hyperoperations (Section 3.3). Instead of balanced numbers, hyperoperations have a multi-valued addition of signed numbers. Defining convexity for hyperoperations coincides with our notion. However, the advantage of using balanced numbers is to maintain a finite representation for computations.

Certain properties of the signed tropical convex hull are surprising and, compared to usual convexity, harder to deal with. For example, in contrast to the classical notion, there is no unique minimal generating set of a convex set: the convex hulls of the points $\{(1,1),(\ominus 1,\ominus 1)\}$ and of $\{(1,\ominus 1),(\ominus 1,1)\}$ coincide. The duality of signed tropical convex hulls and tropical linear inequality systems is reflected in the dual notions of non-negative kernel (22) and open tropical cones (23). We formalize a new version of Farkas' lemma (Theorem 4.6) for signed tropically convex sets. We deduce it in a geometric way from new versions of Fourier-Motzkin elimination for signed numbers (Theorem 4.14 and Corollary 4.15).

There is a curious difference between open and closed signed tropical halfspaces in our framework. Whereas open halfspaces are always convex, closed halfspaces are typically not. In fact, even signed tropical hyperplanes are convex in very special cases only (Example 3.8). Whereas we show that the convex hull of a set of points coincides with the intersection of all open halfspaces containing these points (Theorem 5.1), the analogous statement is not true for closed tropical halfspaces (Remark 5.3).

Nevertheless, we can derive a Minkowski-Weyl theorem (Theorem 5.4): for every finite set of points, their convex hull can be obtained as the intersection of finitely many closed halfspaces, and conversely, if the intersection of a finite set of closed halfspaces is convex (which is not always the case), it can be obtained as the convex hull of a finite set of points. The proof of the first direction is based on a version of Fourier-Motzkin elimination for non-strict inequalities. However, the elimination procedure may create balanced coefficients that have to be resolved by signed numbers. Such a transformation can be easily obtained for the case of strict inequalities (Theorem 4.12), but becomes rather challenging in the non-strict case. In fact, our proof (Proposition 5.7) only shows existence, but does not even yield a finite algorithm.

Finally, we relate our notion to the known concept of tropical convexity over $\mathbb{T}_{\geq 0}$. We show that the signed tropical convex hull can be obtained as the union of unsigned hulls in each orthant (Theorem 6.4).

1.2 Related Work

Our notion of signed tropical convexity heavily relies on the concept of the symmetrized tropical semiring $\mathbb{S}$, which goes back to [1], and was further developed in [4, 32], among others. Signed numbers arise in the context of tropical convexity in [6], however only as coefficients for an inequality system. The technically difficult aspects are the necessary properties of equality and order relations. While [4] also developed different notions replacing orders or equalities, they do not provide all necessary concepts to deal with the new notion of tropical convexity. The relations $\bowtie$, $\vDash$ and $>$ we use also appear in the context of hyperfields in [27], where images of semi-algebraic sets are studied. The duality of the tropical analog of polar cones in [23] can be considered as a predecessor of our duality in Section 4.1. Infeasibility certificates for linear inequality systems were deduced from the duality of mean payoff games in [25, 9]. A tropical version of Fourier-Motzkin elimination was established in [8]. The latter results rely on the (tropical) non-negativity of the variables and cannot be transferred directly to our setting, as we discuss also in Remark 4.18 and Remark 4.7. The tropicalizations of

polytopes [21] or more general semialgebraic sets [27] leads to the image of a single object. However, our construction naturally leads to the tropicalization of a union of polytopes arising as the convex hull of lifts of points. This is in some sense dual to the representation established in [27], where all satisfied equations and inequalities are needed to describe the tropicalization of a single object. Parallel to our work, similar structures for signed numbers are developed in [5, 2].

2 Signed Numbers and Orderings

We introduce the necessary terminology for our purposes. For a recent comprehensive introduction to signed numbers and the symmetrized semiring, see [4].

2.1 Signed Numbers

We define the signed tropical numbers $\mathbb{T}_\pm$ by glueing two copies of $(\mathbb{R} \cup \{-\infty\})$ at $-\infty$. One copy is declared the *non-negative tropical numbers* $\mathbb{T}_{\geq \mathbb{0}}$ (this is often denoted by $\mathbb{T}_{\max}$ in the literature), the other copy forms the *non-positive tropical numbers* $\mathbb{T}_{\leq \mathbb{0}}$. Most of the time, we denote $-\infty$ by $\mathbb{0}$ as it is the tropical zero element. The elements in $\mathbb{T}_{\leq \mathbb{0}} \setminus \{\mathbb{0}\}$ are marked by the symbol $\ominus$. The signed tropical numbers $\mathbb{T}_\pm$ have a natural norm $|\,.\,|$ which maps each element of $\mathbb{T}_{\geq \mathbb{0}}$ to itself and removes the sign of an element in $\mathbb{T}_{\leq \mathbb{0}}$. This gives rise to the order

$$x \leq y \qquad \Leftrightarrow \qquad \begin{cases} x \in \mathbb{T}_{\leq \mathbb{0}} \text{ and } y \in \mathbb{T}_{\geq \mathbb{0}} \\ x \leq y \text{ for } x, y \in \mathbb{T}_{\geq \mathbb{0}} \\ |x| \geq |y| \text{ for } x, y \in \mathbb{T}_{\leq \mathbb{0}} \end{cases} . \tag{2}$$

Furthermore, we obtain the strict order $x < y \Leftrightarrow x \leq y \wedge x \neq y$. The tropical signed space $\mathbb{T}_\pm^d$ is the union of 2^d orthants which are copies of $\mathbb{T}_{\geq \mathbb{0}}^d$ glued along their boundary.

2.2 Balanced Numbers

To develop the technical tools for dealing with signed numbers, we use the *symmetrized semiring* $\mathbb{S}$ which forms a semiring containing $\mathbb{T}_\pm$, introduced in [1]. This semiring is constructed with a third copy of $\mathbb{R} \cup \{\mathbb{0}\}$ by glueing again at $\mathbb{0}$. We denote the third copy, the *balanced numbers*, by $\mathbb{T}_\bullet$ and mark the elements by the symbol $\bullet$. Unfortunately, the symmetrized semiring $\mathbb{S}$ cannot be ordered. We extend the norm $|\,.\,|$ in such a way that it removes the $\bullet$ from an element in $\mathbb{T}_\bullet$ and leaves the corresponding element in $\mathbb{T}_{\geq \mathbb{0}}$. The complementary map tsgn from $\mathbb{S}$ to $\{\oplus, \ominus, \bullet, \mathbb{0}\}$ remembers only in which of the sets an elements lies: positive tropical numbers $\mathbb{T}_{>\mathbb{0}} = \mathbb{T}_{\geq \mathbb{0}} \setminus \{\mathbb{0}\}$, negative tropical numbers $\mathbb{T}_{<\mathbb{0}} = \mathbb{T}_{\leq \mathbb{0}} \setminus \{\mathbb{0}\}$, balanced non-zero tropical numbers $\mathbb{T}_\bullet \setminus \{\mathbb{0}\}$ or the tropical zero $\{\mathbb{0}\}$.

Next, we define the binary operations of the semiring. For $x, y \in \mathbb{S}$, we define the addition by

$$x \oplus y = \begin{cases} \operatorname{argmax}_{x,y}(|x|, |y|) & \text{if } |\chi| = 1 \\ \bullet \operatorname{argmax}_{x,y}(|x|, |y|) & \text{else} \end{cases} . \tag{3}$$

where $\chi = \{\operatorname{tsgn}(\xi) \mid \xi \in (\operatorname{argmax}(|x|, |y|))\}$. Note that we omit the sign for elements in $\mathbb{T}_{\geq \mathbb{0}}$. For the multiplication we set

$$x \odot y = (\operatorname{tsgn}(x) * \operatorname{tsgn}(y))\,(|x| + |y|) \ , \tag{4}$$

where the $*$-multiplication table is the usual multiplication of $\{-1, 1, 0\}$ for $\{\ominus, \oplus, \bullet\}$ with the additional specialty that multiplication with $\mathbb{0}$ yields $\mathbb{0}$.

The operations $\oplus$ and $\odot$ extend to vectors and matrices componentwise. Observe that the operations agree with the usual max-tropical operations on $\mathbb{T}_{\geq \mathbb{0}}$.

We can also consider $\ominus$ as a unary selfmap of the semiring; to this extent, we set

$$\ominus x = \begin{cases} \ominus x & \text{if } x \in \mathbb{T}_{>\mathbb{0}} \\ |x| & \text{if } x \in \mathbb{T}_{<\mathbb{0}} \\ x & \text{if } x \in \mathbb{T}_{\bullet} \end{cases} .$$

The map $\ominus \colon \mathbb{S} \to \mathbb{S}$ is a semiring homomorphism. In particular, this justifies to write $a \ominus b$ for $a \oplus (\ominus b)$.

Furthermore, the absolute value fulfills $|a \oplus b| = |a| \oplus |b|$ by definition of the addition.

▶ **Example 2.1.** Using the definitions, we see that -5 is positive, $\ominus 6$ and $\ominus -6$ are negative, $\bullet 3$ is balanced. Furthermore, the absolute value of -5 is $|-5| = -5$, of $\ominus 6$ is $|\ominus 6| = 6$, and $|\bullet 3| = 3$. Some simple sums are $3 \oplus (\ominus 3) = \bullet 3$, $-3 \oplus 5 = 5$, $-3 \oplus (\ominus 5) = \ominus 5$, $\bullet 2 \oplus 4 = 4$, $\bullet - 3 \oplus \ominus - 5 = \bullet - 3$. Finally some simple products are $\bullet 3 \odot 5 = \bullet 8$, $\ominus 4 \odot -6 = \ominus - 2$, $\ominus 1 \odot \ominus 1 = 2$, $\bullet 3 \odot \mathbb{0} = \mathbb{0}$, $\ominus 4 \odot \mathbb{0} = \mathbb{0}$.

2.3 Extending the Order

As already mentioned, the semiring $\mathbb{S}$ cannot be ordered in a consistent way with respect to its binary operations. However, we will equip it with some binary relations, which partly fulfill the tasks of an order. They occur under a different terminology in [27]; see 3.3.

2.3.1 Signed Order

Even if $\mathbb{S}$ cannot be ordered totally, we can extend the ordering from $\mathbb{T}_{\pm}$ partially by setting

$$x > y \quad \Leftrightarrow \quad x \ominus y \in \mathbb{T}_{>\mathbb{0}} \ . \tag{5}$$

This is equivalent to

$$x > y \quad \Leftrightarrow \quad \begin{cases} x > y & \text{for } x, y \in \mathbb{T}_{\pm}, \text{ see (2)} \\ x > |y| & \text{for } x \in \mathbb{T}_{\pm}, y \in \mathbb{T}_{\bullet} \\ \ominus |x| > y & \text{with } x \in \mathbb{T}_{\bullet}, y \in \mathbb{T}_{\pm} \end{cases} . \tag{6}$$

Note that there are pairs in $\mathbb{T}_{\pm} \times \mathbb{T}_{\bullet}$ and in $\mathbb{T}_{\bullet} \times \mathbb{T}_{\pm}$ which are not comparable. In particular, the signed numbers

$$\{x \in \mathbb{T}_{\pm} \mid x \not< a \text{ and } x \not> a\} \ ,$$

which are incomparable to $a \in \mathbb{T}_{\bullet}$ via "$<$", form the interval

$$\mathcal{U}(a) := [\ominus |a|, |a|] := \{x \in \mathbb{T}_{\pm} \mid \ominus |a| \leq x \leq |a|\} \ . \tag{7}$$

We also denote the set incomparable to a signed element $a \in \mathbb{T}_{\pm}$, which is only the singleton $\{a\}$, by $\mathcal{U}(a)$. We extend this to vectors by setting $\mathcal{U}(v) = \prod_{i \in [d]} \mathcal{U}(v_i)$. Note that also no pair in $\mathbb{T}_{\bullet} \times \mathbb{T}_{\bullet}$ is comparable.

The relation (6) gives rise to a non-strict relation

$$x \geq y \quad \Leftrightarrow \quad x > y \text{ or } x = y \ . \tag{8}$$

which turns out to be a partial order in Corollary 4.9.

Observe that the ordering is compatible with the reflection map, in the sense that

$$x \geq y \qquad \Leftrightarrow \qquad \ominus y \geq \ominus x \ . \tag{9}$$

A useful property of strict inequalities is that they can be added together.

▶ **Lemma 2.2.** *For $a, b, c, d \in \mathbb{S}$, we have the implication*

$$a < b \text{ and } c < d \qquad \Rightarrow \qquad a \oplus c < b \oplus d \ . \tag{10}$$

Proof. By definition, we first get $b \ominus a > \mathbb{0}$ and $d \ominus c > \mathbb{0}$. As addition is closed in $\mathbb{T}_{>\mathbb{0}}$, this yields $b \ominus a \oplus d \ominus c > \mathbb{0}$. The claim follows from (5). ◀

▶ Remark 2.3. In general, the strict and non-strict partial order "$<$" and "$\leq$" on $\mathbb{S}$ is not compatible with addition. The inequality $3 < 4$ does not imply $3 \oplus 5 < 4 \oplus 5$, and $3 \leq 4$ does not imply $\ominus 4 = 3 \ominus 4 \leq 4 \ominus 4 = \bullet 4$. This is the main motivation for introducing the relation "$\vDash$" below, which is not an ordering (as it lacks transitivity) but it is compatible with the addition.

An advantage of strict inequalities is the validity of

$$a \oplus b > c \Leftrightarrow a > c \ominus b \ .$$

The analogous reformulation

$$a \oplus b \geq c \Leftrightarrow a \geq c \ominus b \ .$$

is wrong in general. For example, $2 \oplus 5 \geq 5$ but 2 is incomparable with $5 \ominus 5 = \bullet 5$. However, such reformulations hold for the relation "$\vDash$", which we show in Lemma 2.6(a).

2.3.2 Balanced Relations

The balance relation "Δ" was introduced in [1]; we will use the notation $\bowtie$ in this paper. We define

$$x \bowtie y \quad \Leftrightarrow \quad x \ominus y \in \mathbb{T}_\bullet \ .$$

The following characterizations are immediate from the definitions. For more properties of $\bowtie$, we refer to [1, §IV].

▶ **Lemma 2.4.** *Let $a, b \in \mathbb{S}$.*
(a) *$a \bowtie b$ is equivalent to $(a \in \mathbb{T}_\bullet, |a| \geq |b|) \vee (b \in \mathbb{T}_\bullet, |b| \geq |a|) \vee (a = b)$.*
(b) *If $b \in \mathbb{T}_\pm$, then $a \bowtie b$ is equivalent to $b \in \mathcal{U}(a)$.*

▶ Remark 2.5. Note that $\bowtie$ is *not* an equivalence relation, as the example

$$1 \bowtie \bullet 6, \quad \bullet 6 \bowtie 3, \quad \text{but } 1 \not\bowtie 3$$

shows.

We introduce the binary relation

$$x \vDash y \qquad \Leftrightarrow \quad x > y \text{ or } x \bowtie y \quad \Leftrightarrow \qquad x \ominus y \in \mathbb{T}_{\geq \mathbb{0}} \cup \mathbb{T}_\bullet \ . \tag{11}$$

Note that $a \bowtie b$ is equivalent to $(a \vDash b) \vee (a \dashv b)$. Remark 2.5 shows that $\vDash$ is *not* a partial order.

Recall from Remark 2.3 that bringing terms to the other side of a non-strict inequality with "$\geq$" is not valid in general. The next lemma shows, among other simple properties, that "$\vDash$" is compatible with the semiring operations; the proof is deferred to the Appendix.

▶ **Lemma 2.6.** *Let* $a, b, c, d \in \mathbb{S}$.
(a) $a \oplus c \vDash b \Leftrightarrow a \vDash b \ominus c$
(b) $a \vDash b \quad \wedge \quad c \vDash d \quad \Rightarrow \quad a \oplus c \vDash b \oplus d$.
(c) *If* $c \in \mathbb{T}_{\pm}$, *then* $b \vDash c$ *and* $c \vDash a$ *imply* $b \vDash a$.
(d) $a \vDash b$ *implies* $c \odot a \oplus d \vDash c \odot b \oplus d$ *for* $c \in \mathbb{T}_{\geq \mathbb{0}}$ *and* $c \odot b \oplus d \vDash c \odot a \oplus d$ *for* $c \in \mathbb{T}_{\leq \mathbb{0}}$.

3 Tropical Convexity of Signed Numbers

3.1 Signed Tropical Convex Combinations

Let us recall the notation that for a matrix $A \in \mathbb{T}_{\geq \mathbb{0}}^{d \times n}$, and a vector $x \in \mathbb{T}_{\geq \mathbb{0}}^{n}$, we denote by $A \odot x \in \mathbb{T}_{\geq \mathbb{0}}^{n}$ the tropical matrix product. The *tropical convex hull* $\operatorname{tconv}(A)$ of the columns of a matrix $A \in \mathbb{T}_{\geq \mathbb{0}}^{d \times n}$, studied in [15, 18, 20], is defined as

$$\operatorname{tconv}(A) = \left\{ A \odot x \;\middle|\; x \in \mathbb{T}_{\geq \mathbb{0}}^{n}, \bigoplus_{j \in [n]} x_j = 0 \right\} \subseteq \mathbb{T}_{\geq \mathbb{0}}^{d} \ . \tag{12}$$

In this definition it is essential that all columns of A lie in the non-negative orthant $\mathbb{T}_{\geq \mathbb{0}}^{d}$. For general matrices in $\mathbb{T}_{\pm}^{d \times n}$, the product $A \odot x$ may contain balanced entries. We now extend the notion of the tropical convex hull to $\mathbb{T}_{\pm}^{d}$. Note that we switch freely between a matrix and its set of columns.

▶ **Definition 3.1** (Inner hull). *The* (signed) tropical convex hull *of the columns of the matrix* $A \in \mathbb{T}_{\pm}^{d \times n}$ *is defined as*

$$\operatorname{tconv}(A) = \left\{ z \in \mathbb{T}_{\pm}^{d} \;\middle|\; z \bowtie A \odot x, x \in \mathbb{T}_{\geq \mathbb{0}}^{n}, \bigoplus_{j \in [n]} x_j = 0 \right\} \subseteq \mathbb{T}_{\pm}^{d} \ . \tag{13}$$

Such a set is a (signed) tropical polytope. *The tropical convex hull of an arbitrary set* $M \subseteq \mathbb{T}_{\pm}^{d}$ *is the union*

$$\operatorname{tconv}(M) = \bigcup_{V \subseteq M, V \text{ finite}} \operatorname{tconv}(V) \ .$$

A subset $M \subseteq \mathbb{T}_{\pm}^{d}$ *is* tropically convex *if* $M = \operatorname{tconv}(M)$.
This hull construction generalizes (12) because if $A \in \mathbb{T}_{\geq \mathbb{0}}^{d \times n}$ then $A \odot x \in \mathbb{T}_{\pm}^{d}$. In this case, Lemma 2.4(a) implies that $z \bowtie A \odot x$ holds only for $z = A \odot x$.

Using Lemma 2.4(b), we can write (13) equivalently as

$$\operatorname{tconv}(A) = \bigcup \left\{ \mathcal{U}(A \odot x) \;\middle|\; x \in \mathbb{T}_{\geq \mathbb{0}}^{n}, \bigoplus_{j \in [n]} x_j = 0 \right\} \subseteq \mathbb{T}_{\pm}^{d} \ . \tag{14}$$

▶ **Example 3.2.** The combinations of the tropical convex hull depicted in Figure 1, where balanced numbers occur, can be calculated via

$$(-3) \odot \begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} \ominus 1 \\ \ominus 0 \end{pmatrix} = \begin{pmatrix} \ominus 1 \\ \bullet 0 \end{pmatrix} , \qquad (-2) \odot \begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} \ominus 1 \\ \ominus 0 \end{pmatrix} = \begin{pmatrix} \bullet 1 \\ 1 \end{pmatrix}$$

$$\begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus (-1) \odot \begin{pmatrix} \ominus 4 \\ \ominus 2 \end{pmatrix} = \begin{pmatrix} \bullet 3 \\ 3 \end{pmatrix} , \qquad (-1) \odot \begin{pmatrix} 3 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} \ominus 4 \\ \ominus 2 \end{pmatrix} = \begin{pmatrix} \ominus 4 \\ \bullet 2 \end{pmatrix} \ .$$

A more precise way, how these points can be used to determine the signed tropical convex hull, via the tropical convex hull of the intersection with each orthant is given in Theorem 6.4.

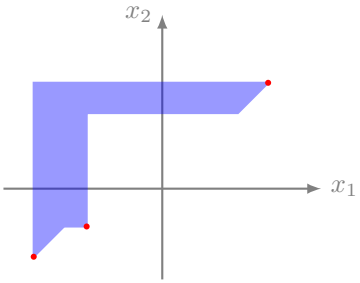

Figure 1 The signed tropically convex hull of $\{(3,3),(\ominus 1,\ominus 0),(\ominus 4,\ominus 2)\}$. We omit labels for the axes as the origin is $(-\infty,-\infty)$ and therefore infinitely far away.

▶ Remark 3.3. There is no unique minimal generating set in the usual sense as one can see from $\operatorname{tconv}((0,0),(\ominus 0,\ominus 0)) = \operatorname{tconv}((0,\ominus 0),(\ominus 0,0))$.

We now derive some elementary properties of this convexity notion. The following are immediate from the definition, as (14) is just a componentwise construction.

▶ **Proposition 3.4.**
(a) *The intersection of tropically convex sets is tropically convex.*
(b) *The coordinate projection of tropically convex sets is tropically convex.*

Next, we show that convexity follows already by showing the containment of line segments (Proposition 3.6), and that tconv(.) is a closure operator, i.e., the convex hull of a set is a tropically convex set (Proposition 3.7). The following technical lemma will be needed for these proofs. The next three proofs are deferred to the Appendix.

▶ **Lemma 3.5.**
(a) *Let $a \in \mathbb{S}$, $b \in \mathbb{T}_{\pm}$, and $z \in \mathcal{U}(a \oplus b)$. Then there exists an $a' \in \mathcal{U}(a)$ such that $z \in \mathcal{U}(a' \oplus b)$.*
(b) *If $a \in \mathcal{U}(x)$, $b \in \mathcal{U}(y)$, and $c \in \mathbb{T}_{\pm}$, then $\mathcal{U}(c \odot a \oplus b) \subseteq \mathcal{U}(c \odot x \oplus y)$.*

▶ **Proposition 3.6.** *An arbitrary subset $M \subseteq \mathbb{T}_{\pm}^d$ is tropically convex if and only if the tropical convex hull $\operatorname{tconv}(\{p,q\})$ is contained in M for all $p,q \in M$.*

▶ **Proposition 3.7.** *For any matrix $A \in \mathbb{T}_{\pm}^{d\times n}$, the convex hull $\operatorname{tconv}(A)$ is tropically convex. Consequently, $\operatorname{tconv}(\operatorname{tconv}(A)) = \operatorname{tconv}(A)$.*

▶ **Example 3.8.** A *(signed) tropical hyperplane* is of the form

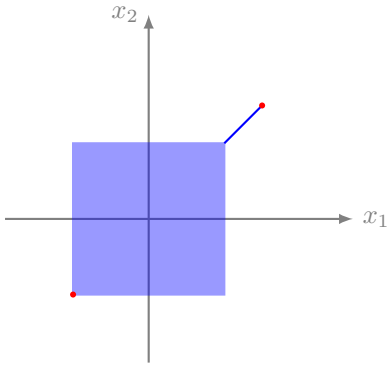
$$\operatorname{Hyp}(a) = \left\{ x \in \mathbb{T}_{\pm}^d \;\middle|\; a \odot x \in \mathbb{T}_{\bullet}^d \right\} \quad .$$

It is easy to see that this set is tropically convex if $|\operatorname{supp}(a)| = 1$, where $\operatorname{supp}(a) = \{i \in [d] \mid a_i \neq \mathbb{0}\}$. Therefore, using Proposition 3.4(a), we see that for a subset $I \subseteq [d]$ and a point $b \in \mathbb{T}_{\pm}^d$, the set

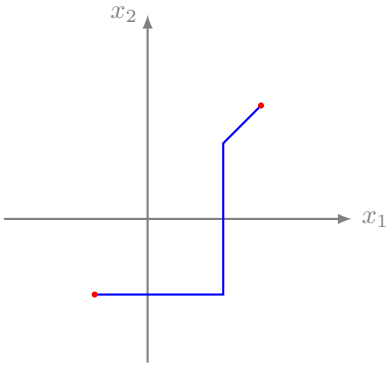
$$\left\{ z \in \mathbb{T}_{\pm}^d \;\middle|\; z_i = b_i \text{ for all } i \in I \right\}$$

is tropically convex.

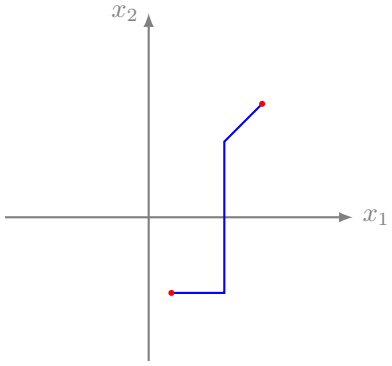
On the other hand, if $|\operatorname{supp}(a)| > 1$, then $\operatorname{Hyp}(a)$ is *not* tropically convex. To see this, let us assume that $\operatorname{supp}(a) \supseteq \{1,2\}$. Then $p = (\ominus a_2, a_1, \mathbb{0}, \ldots, \mathbb{0}), q = (a_2, \ominus a_1, \mathbb{0}, \ldots, \mathbb{0}) \in \operatorname{Hyp}(a)$. Because of $p \oplus q = (\bullet a_2, \bullet a_1, \mathbb{0}, \ldots, \mathbb{0})$, the point $(a_2, a_1, \mathbb{0}, \ldots, \mathbb{0})$ is contained in $\operatorname{tconv}(p,q)$. However, it is not an element of $\operatorname{Hyp}(a)$.



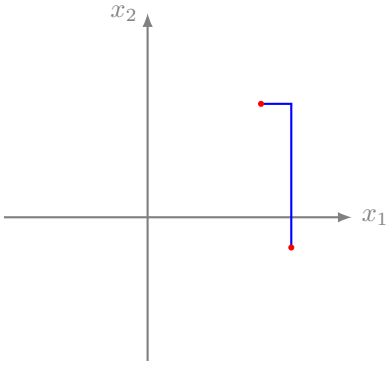
(a) $\mathrm{tconv}((0,0),(\ominus-2,\ominus-2))$.



(b) $\mathrm{tconv}((0,0),(\ominus-3,\ominus-2))$.



(c) $\mathrm{tconv}((0,0),(-3,\ominus-1))$.



(d) $\mathrm{tconv}((0,0),(2,\ominus-1))$.

Figure 2 Several tropical line segments in the plane.

▶ **Example 3.9.** For a vector $(a_0,a_1,\dots,a_d)\in\mathbb{T}_\pm^{d+1}$ we define the *open signed (affine) tropical halfspace*

$$\mathcal{H}^+(a)=\left\{x\in\mathbb{T}_\pm^d \;\middle|\; a\odot\begin{pmatrix}0\\x\end{pmatrix}>\mathbb{O}\right\}\ . \tag{15}$$

An open signed tropical halfspace is tropically convex. Let $c\in\mathbb{T}_\pm^d, c_0\in\mathbb{T}_\pm$, $p,q\in\mathbb{T}_\pm^d$ and $\lambda,\mu\in\mathbb{T}_{\leq\mathbb{O}}$ with $\lambda\oplus\mu=0$. For p and q contained in the halfspace, we have $c\odot p\oplus c_0>\mathbb{O}$ and $c\odot q\oplus c_0>\mathbb{O}$, and by Lemma 2.2,

$$c\odot(\lambda\odot p\oplus\mu\odot q)\oplus c_0=\lambda\odot(c\odot p\oplus c_0)\oplus\mu\odot(c\odot q\oplus c_0)>\mathbb{O}\ . \tag{16}$$

If $\lambda\odot p\oplus\mu\odot q$ has a balanced component $b\in\mathbb{T}_\bullet$, then the value of $c\odot(\lambda\odot p\oplus\mu\odot q)\oplus c_0$ cannot depend on this component as it is positive. Hence, we can replace that component by an element in $\mathcal{U}(b)$ and preserve the inequality (16).

▶ Remark 3.10. Let $\mathbb{P}\subset\mathbb{T}_\pm^{d\times d}$ be the set of permutation matrices with 0 as one and $\mathbb{O}$ as zero, and let $\mathbb{D}\subset\mathbb{T}_\pm^{d\times d}$ be the set of matrices with diagonal entries from $\mathbb{T}_\pm$ and $\mathbb{O}$ else. Their union generates the multiplicative *group of signed tropical transformations* $\mathbb{ST}$. This group is the natural group of transformations which leaves the combinatorial structure of a subset of $\mathbb{T}_\pm^d$ unchanged. It provides a useful tool to simplify technical constructions.

▶ **Example 3.11.** We want to describe the line segment $\mathrm{tconv}(p,q)$ for two points $p,q\in\mathbb{T}_\pm^d$. By suitable scaling with elements from $\mathbb{ST}$, we can assume that $p=(0,\dots,0)$, and that the entries of q are ordered by increasing absolute value.

Analogous to the description in [20], one obtains a piecewise-linear structure where the breakpoints are determined by the absolute values of the components of q. As an additional phenomenon, the line segments flip to another orthant at each tropically negative entry of q. If the sign changes in ℓ coordinates at once, the line segment has dimension ℓ. We visualize several examples for the two-dimensional case in Figure 2.

▶ **Definition 3.12** (Conic hull). *The* signed tropical conic hull *of the columns of A is*

$$\operatorname{tcone}(A) = \bigcup_{\lambda \in \mathbb{T}^n_{\geq \mathbb{0}}} \mathcal{U}(A \odot \lambda) \ . \tag{17}$$

The definition together with Proposition 3.7 yields the following.

▶ **Corollary 3.13.** *The conic hull of a subset of $\mathbb{T}^d_\pm$ is tropically convex.*

3.2 Image of Puiseux Lifts

The aim of this section is to relate our concept of convexity over $\mathbb{T}_\pm$ to convexity over $\mathbb{R}$. To achieve this, we move to another ordered field, the field of real Puiseux series $\mathbb{K} = \mathbb{R}\{\{t\}\}$. This has proven to be a helpful concept in the study of tropical numbers with signs, see [35, 6, 27]. It is formed by formal Laurent series with exponents in $\mathbb{R}$ and coefficients in $\mathbb{R}$. The exponent sequence is strictly decreasing and it has no accumulation point. This ordered field is equipped with a non-archimedean valuation val which maps all non-zero elements to their leading exponent and zero to $\mathbb{0} = -\infty$. Additionally, the map $\operatorname{sgn}\colon \mathbb{K} \to \{\ominus, \mathbb{0}, \oplus\}$ yields the sign of an element. This gives rise to the *signed valuation* $\operatorname{sval}\colon \mathbb{K} \to \mathbb{T}_\pm$ which maps an element $k \in \mathbb{K}$ to $\operatorname{sgn}(k)\operatorname{val}(k)$. It is enough to think of Puiseux series as polynomials in t with arbitrary exponents and coefficients in $\mathbb{R}$.

The *tropicalization* of structured sets over $\mathbb{K}$, i.e., the study of the image of a subset of $\mathbb{K}^d$ is a technique which is widely used in tropical geometry. We introduced a concept purely on the tropical side. We will see in Theorem 3.14, that signed tropically convex sets are not the image of the valuation of a single convex hull but of a whole union, ranging over the fibers of tropical points.

In some sense, this is complementary to the main result in [27]. While they consider semialgebraic sets over $\mathbb{K}$ in general, polytopes, i.e., the convex hull of finitely many points in $\mathbb{K}^d$, can be considered as a special case. They show that one has to tropicalize all semialgebraic relations fulfilled by a set to describe its image under the signed valuation map.

Recall that for our concept of tropical convexity over $\mathbb{T}_\pm$ the image of a single polytope under the signed valuation may not be tropically convex as the Example B.1 shows. It is subject to further work to study the special case of polytopes (as semialgebraic sets) from [27] and to see which properties such a notion of signed tropical polytopes could provide.

Note that the next statement is valid for more general fields with a non-trivial non-archimedean valuation val which is surjective onto $\mathbb{T}_{\geq \mathbb{0}}$. The proof is given in the Appendix.

▶ **Theorem 3.14.** *The signed hull* $\operatorname{tconv}(A)$ *is the union of the signed valuations for all possible lifts*

$$\operatorname{tconv} A = \bigcup_{\operatorname{sval}(\mathbf{A})=A} \operatorname{sval}(\operatorname{conv}(\mathbf{A})) \ .$$

▶ Remark 3.15. Theorem 3.14 generalizes [21, Proposition 2.1], since val is a semiring homomorphism from $\mathbb{K}_{\geq 0}$ to $\mathbb{T}_{\max} = \mathbb{T}_{\geq \mathbb{0}}$.

▶ **Corollary 3.16.** *The tropical convex hull is the union of the convex hulls of the lifts, i.e.,*

$$\operatorname{tconv}(A) = \operatorname{sval}(\operatorname{conv}(\operatorname{sval}^{-1}(A))) \ .$$

3.3 Convex Hull from Hyperoperation

As we shall see in Proposition 3.17, our signed tropical convex hull from Definition 3.1 is a natural generalization of the classical convex hull as image of a simplex to hyperoperations. In recent years, hyperfields found their way into matroid theory due to the work [12] building on [30] and [35]. While hyperfields have been used in tropical geometry [27] from an algebraic point of view, they were not used to describe intrinsically defined geometric objects before.

We introduce the necessary notions for hyperfields to define a signed convex hull and compare our binary operations with hyperfield operations (20). Let us briefly introduce the *real plus-tropical hyperfield* $\mathbb{H}$, see [35]. It has the multiplicative group $(\mathbb{T}_\pm, \odot)$ and its additive hyperoperation on $\mathbb{T}_\pm$ is given by

$$x \boxplus y = \begin{cases} \operatorname{argmax}_{x,y}(|x|,|y|) & \text{if } \chi \subseteq \{+,\mathbb{0}\} \text{ or } \chi = \{-\} \\ [\ominus|x|, |x|] & \text{else} \quad . \end{cases} \tag{18}$$

We see that the latter addition for non-balanced numbers $x, y \in \mathbb{T}_\pm$ differs from the Definition in (3) in that it has a multi-valued result in the powerset of $\mathbb{T}_\pm$. A balanced outcome $z \in \mathbb{T}_\bullet$ is replaced with the interval $\mathcal{U}(z) = [-|z|, |z|]$. One can extend the operations again componentwise and use the symbol $\boxdot$ for the product of two matrices or vectors. In particular, the operation $\boxdot$ agrees with $\odot$ on $\mathbb{T}_\pm$. The addition is set-valued in $\mathbb{H}$ if and only if it would be balanced in $\mathbb{S}$. It agrees with $\oplus$ on $\mathbb{T}_{\geq \mathbb{0}}$.

We recall the order relations used in [27] for the multiplicative real tropical hyperfield. Note that they use the multiplication $\odot =$"$\cdot$" instead of our approach with "+".

A polynomial over the real tropical hyperfield is a formal expression

$$F(x) = \boxplus_{d_1,\dots,d_n \in \mathbb{Z}} c_{d_1,\dots,d_n} x_1^{d_1} \cdots x_n^{d_n}$$

which can be evaluated at an element $\zeta \in \mathbb{H}^n$. This yields a subset

$$F(\zeta) = \boxplus_{d_1,\dots,d_n \in \mathbb{Z}} c_{d_1,\dots,d_n} \zeta_1^{d_1} \cdots \zeta_n^{d_n} \subseteq \mathbb{H}^n \quad . \tag{19}$$

Note that we mainly deal with linear polynomials, where the exponent vector $(d_1, \dots, d_n) \in \mathbb{Z}^d$ is just a unit vector.

One can define the sets

$$\begin{aligned} \{F = 0\} &:= \{(x_1,\dots,x_n) \in \mathbb{T}_\pm^n \colon \mathbb{0} \in F(x_1,\dots,x_n)\} \\ \{F \geq 0\} &:= \{(x_1,\dots,x_n) \in \mathbb{T}_\pm^n \colon F(x_1,\dots,x_n) \cap \mathbb{T}_{\geq \mathbb{0}} \neq \emptyset\} \\ \{F > 0\} &:= \{(x_1,\dots,x_n) \in \mathbb{T}_\pm^n \colon F(x_1,\dots,x_n) \in \mathbb{T}_{>\mathbb{0}}\} \quad . \end{aligned} \tag{20}$$

Observe that $F = 0$ is indeed equivalent to $F \geq 0 \wedge -F \leq 0$ due to the structure of the set (19). Translating (20) to the symmetrized semiring $\mathbb{S}$ yields the relations "$\bowtie$", "$\vDash$" and "$>$".

To motivate the next construction, we consider a tropical polytope generated by $V \in \mathbb{T}_{\geq \mathbb{0}}^{d \times k}$ as the image of the tropical standard simplex in the sense that

$$\operatorname{tconv}(V) = \{V \odot \lambda \mid \bigoplus_{\ell \in [k]} \lambda_\ell = 0\} \quad .$$

For a matrix $A \in \mathbb{T}_\pm^{d \times n}$, we define the *balanced image* of the tropical standard simplex $\Delta_n = \{\lambda \mid \bigoplus_{\ell \in [n]} \lambda_\ell = 0\}$ by

$$A \odot \Delta_n := \left\{ A \odot x \;\middle|\; \bigoplus_{j \in [n]} x_j = 0, x \geq \mathbb{0} \right\} \subset \mathbb{S}^d \quad . \tag{21}$$

With this notion, one can write $\operatorname{tconv}(A) = \bigcup_{z \in A \odot \Delta_d} \mathcal{U}(z)$.

By using the hyperoperations in $\mathbb{H}$, we can naturally consider the image of the tropical standard simplex $\Delta_k = \{\lambda \mid \bigoplus_{\ell \in [k]} \lambda_\ell = 0\}$ with respect to matrix multiplication by $V \in \mathbb{T}_\pm^{d \times k}$ as a subset of $\mathbb{T}_\pm^d$.

▶ **Proposition 3.17.**

$$V \boxdot \Delta_d = \operatorname{tconv}(V) \ .$$

Proof. This follows directly by the definition of the set-valued addition in (18) from (13) with $\mathcal{U}(z) = [\ominus|z|, |z|]$ for $z \in \mathbb{T}_\bullet$. ◀

In Appendix B, we compare our convexity notion to $\mathbb{B}$-convexity studied in the literature [15], as well as a cancellative sum construction used in [14].

4 Farkas' Lemma and Fourier-Motzkin Elimination

4.1 Convexity and Tropical Linear Feasibility

For a matrix $A = (a_{ij}) \in \mathbb{T}_\pm^{d \times n}$, we define the *non-negative kernel*

$$\ker_+(A) = \left\{ x \in \mathbb{T}^n_{\geq \mathbb{O}} \setminus \{\mathbb{O}\} \;\middle|\; A \odot x \bowtie \mathbb{O} \right\} \tag{22}$$

This corresponds to the classical definition of a polyhedral cone in the form $Ax = 0, x \geq 0, x \neq 0$. We replace "$=$" by "$\bowtie$" and "$\geq$" by "$\vDash$". In terms of the non-negative kernel, we can express containment in the convex hull as follows.

▶ **Proposition 4.1.** *For $A \in \mathbb{T}_\pm^{d \times n}$ and $b \in \mathbb{T}_\pm^d$ we have*

$$b \in \operatorname{tconv}(A) \Leftrightarrow \mathit{ker}_+ \begin{pmatrix} A & \ominus b \\ 0 & \ominus 0 \end{pmatrix} \neq \emptyset \ .$$

▶ **Corollary 4.2.** *The origin $\mathbb{O}$ is in the convex hull $\operatorname{tconv}(A)$ if and only if the non-negative kernel $\mathit{ker}_+(A)$ is not empty.*

Proof. Setting $b = \mathbb{O}$ in Proposition 4.1 implies the equivalence with the definition from (22). ◀

We now define the *open tropical cone* as the dual to the non-negative kernel (22).

$$\operatorname{sep}_+(A) = \{y \in \mathbb{T}_\pm^d \mid y^\top \odot A > \mathbb{O}\} \ . \tag{23}$$

The name is motivated by the use of the elements of $\operatorname{sep}_+(A)$ as separators of the columns of A from the origin. Note that the condition "$> \mathbb{O}$", in particular, means that the product "$y^\top \odot A$" is comparable with $\mathbb{O}$ and, equivalently, is in $\mathbb{T}_{>\mathbb{O}}$.

We can also define $\ker_+(A)$ and $\operatorname{sep}_+(A)$ for $A \in \mathbb{S}^{d \times n}$. However, this does not provide a wider class of objects. This follows by replacing a balanced number by $\mathbb{O}$ in $\ker_+(A)$ and applying Theorem 4.12 for $\operatorname{sep}_+(A)$. We still extend the definition to these more general matrices, as it will lead to simplified arguments.

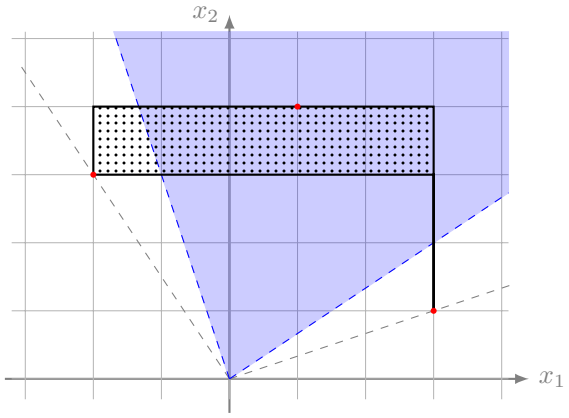


Figure 3 An open tropical cone visualized with the operations "$\oplus$" = "max" and "$\odot$" = "$\cdot$".

▶ **Example 4.3.** In the next example we work with the semiring $(\mathbb{R}_{\geq 0}, \max, \cdot)$, as it provides a more natural picture of the behaviour around the origin in the different orthants. Instead of the semiring defined on $\mathbb{R} \cup \{-\infty\}$ with operations "max" and "+", one can isomorphically use the semiring $\mathbb{R}_{>0} \cup \{0\}$ with "max" and "$\cdot$". The exponentiation map

$$\exp\colon \mathbb{R} \cup \{-\infty\} \to \mathbb{R}_{>0} \cup \{0\}$$

yields an isomorphism between these two semirings. One can further extend this mapping to $\mathbb{T}_{\pm}$ by setting

$$x \mapsto \qquad \operatorname{tsgn}(x) \exp(|x|) \ .$$

Note that the image of $\mathbb{S}$ involves a balanced version of positive numbers as it decomposes into the union $\mathbb{R}_{>0} \cup \mathbb{R}_{<0} \cup \bullet\mathbb{R}_{>0} \cup \{0\}$.

The dotted black shape in Figure 3 depicts the $(\max, \cdot)$-convex hull of the columns of the matrix $A = \begin{pmatrix} 3 & 1 & -2 \\ 1 & 4 & 3 \end{pmatrix}$. The combinations, where balanced numbers occur, are

$$\frac{1}{2} \cdot \begin{pmatrix} -2 \\ 3 \end{pmatrix} \oplus \begin{pmatrix} 1 \\ 4 \end{pmatrix} = \begin{pmatrix} \bullet 1 \\ 4 \end{pmatrix} \quad \text{and} \quad \frac{2}{3} \cdot \begin{pmatrix} 3 \\ 1 \end{pmatrix} \oplus \begin{pmatrix} -2 \\ 3 \end{pmatrix} = \begin{pmatrix} \bullet 2 \\ 3 \end{pmatrix} \ .$$

The blue shaded area is $\operatorname{sep}_+(A)$. The configuration visualizes Theorem 4.4, as $\operatorname{sep}_+(A)$ is not empty and the $(\max, \cdot)$-convex hull of A does not contain the origin.

Let us now show that weak duality holds between the non-negative kernel and the open tropical cone:

▶ **Theorem 4.4** (Weak duality). *For a matrix $A \in \mathbb{T}_{\pm}^{d \times n}$ at least one of the sets $\ker_+(A)$ and $\operatorname{sep}_+(A)$ is empty. Equivalently, for an arbitrary vector $y \in \mathbb{T}_{\pm}^{d}$ and a non-negative vector $x \in \mathbb{T}_{\geq \mathbb{0}}^{n} \setminus \{\mathbb{0}\}$ at most one of $A \odot x \in \mathbb{T}_{\bullet}^{d}$ and $y^{\top} \odot A > \mathbb{0}$ can hold.*

Proof. The claim follows from the fact that $\mathbb{T}_{\bullet}$ is a left- and right-ideal of $\mathbb{S}$, see [4, Definition 2.6]. This means that for $x \in \ker_+(A)$, the product $y^{\top} \odot A \odot x$ is in $\mathbb{T}_{\bullet}$ while $y^{\top} \odot A > \mathbb{0} \Rightarrow y^{\top} \odot A \odot x > \mathbb{0}$. ◀

▶ Remark 4.5. We give a direct proof of the former statement. We consider the product $y^\top \odot A \odot x$. Scaling the rows of A by arbitrary numbers in $\mathbb{T}_\pm$ does not change whether $x \in \ker_+(A)$, just as scaling the columns of A by a non-negative number in $\mathbb{T}_{\geq \mathbb{0}}$ does not change whether $y \in \operatorname{sep}_+(A)$. Hence, we can assume that x and y only have the entries 0 or $\mathbb{0}$. Let a_{pq} be the entry of A with maximal absolute value. For $x \in \ker_+(A)$, there is an index $r \in [n]$ such that $a_{pr} = \ominus a_{pq}$. We can assume that $a_{pq} > \mathbb{0} > a_{pr}$. From this we conclude that $y \notin \operatorname{sep}_+(A)$ since the rth column of $y^\top \odot A$ cannot be positive.

The key result of this section will be showing the appropriate version of Farkas' lemma. The proof will follow via Fourier-Motzkin elimination.

▶ **Theorem 4.6** (Farkas' lemma)**.** *For a matrix $A \in \mathbb{T}_\pm^{d\times n}$ exactly one of the sets $ker_+(A)$ and $sep_+(A)$ is nonempty.*

▶ Remark 4.7. Theorem 4.6 is similar to [25, Corollary 3.12]. Through a suitable replacement of the balanced coefficients and a careful analysis of the occuring signs, Theorem 4.6 may be deduced from [25]. Note however, that we allow for unconstrained variables in the definition of $\operatorname{sep}_+(A)$ which is not directly covered by [25, Corollary 3.12].

4.2 Technical Properties of the Order Relations

The next lemma is a version of transitivity and it is a preparation for the elimination of a variable in a system of inequalities in Section 4.3. The proofs of the next two propositions are given in the Appendix.

▶ **Proposition 4.8.** *Let $A, B \subset \mathbb{S}$ be two finite sets. There is an element $c \in \mathbb{S}$ with*

$$c \ominus a > \mathbb{0} \text{ and } b \ominus c > \mathbb{0} \text{ for all } a \in A, b \in B \tag{24}$$

if and only if

$$b \ominus a > \mathbb{0} \text{ for all } (a, b) \in A \times B \ . \tag{25}$$

Furthermore, the element c can chosen to be signed.

▶ **Corollary 4.9.** *The non-strict relation $x \geq y$ defined in* (8) *is a partial order.*

Proof. Reflexivity and antisymmetry follow directly from (8) and (6). Proposition 4.8 implies transitivity. ◀

▶ **Proposition 4.10.** *Let $A, B \subset \mathbb{S}$ be two finite sets. There is an element $c \in \mathbb{T}_\pm$ with*

$$c \ominus a \vDash \mathbb{0} \text{ and } b \ominus c \vDash \mathbb{0} \text{ for all } a \in A, b \in B \tag{26}$$

if and only if

$$b \ominus a \vDash \mathbb{0} \text{ for all } (a, b) \in A \times B \ . \tag{27}$$

To deal with geometric objects in $\mathbb{T}_\pm^d$, we will use balanced numbers because this allows for explicit calculations in the semiring $\mathbb{S}$. However, as we are only interested in the signed part of the sets. We provide a first tool to resolve balanced numbers in inequalities. While this is for strict inequalities, Proposition 5.7 provides a tool for the relation $\vDash$.

▶ **Lemma 4.11.** *For $a, b \in \mathbb{S}$, we have an equivalence of*
(1) *$a \ominus a \oplus b > \mathbb{0}$*
(2) *$a \oplus b > \mathbb{0}$ and $\ominus a \oplus b > \mathbb{0}$*
(3) *For all $c \in [\ominus|a|, |a|] = \mathcal{U}(a \ominus a)$, it holds $c \oplus b > \mathbb{0}$.*

Proof. The condition (3) clearly implies (2), as the latter is just a special case. The implication from (2) to (1) follows by adding up the positive values in (2). For the direction from (1) to (3), we use that $a \ominus a$ is balanced and, hence, incomparable. Therefore, we have $b > |a|$. Because of $|a| = |\ominus a| = |a \ominus a|$, the claim follows. ◀

Given a matrix $A \in \mathbb{S}^{d\times n}$, let us construct the matrix $B = \xi(A) \in \mathbb{T}_{\pm}^{d'\times n}$ for $d \le d' \le 2d$ as follows. We include in B all the columns of A that do not contain any balanced elements. For every column a_{*j} that contains some balanced elements, we include two columns a' and a'' in B, such that whenever $a_{ij} = \bullet\alpha$ is a balanced entry, then we set $a'_i = \oplus\alpha$ and $a''_i = \ominus\alpha$. For all other $i \in [d]$, we set $a'_i = a''_i = a_{ij}$.

▶ **Theorem 4.12.** *For every matrix $A \in \mathbb{S}^{d\times n}$, $sep_+(A) = sep_+(\xi(A))$.*

Proof. Recalling Definition 23, we see that it is enough to consider the transition from A to B column by column. An inequality arising from A (after potentially reordering entries) is of the form $y^\top \odot (u, v) > \mathbb{0}$ with $u \in \mathbb{T}_{\pm}^k$ and $v \in \mathbb{T}_{\bullet}^{d-k}$ for some $k \le d$. It either remains the same in B if it has no balanced entry or it gets transformed to two inequalities. Regrouping the summands by balanced and signed numbers, we deduce the claim from the equivalence of (1) and (3) in Lemma 4.11. ◀

4.3 Fourier-Motzkin Elimination

We derive three versions of Fourier-Motzkin elimination, which will be useful for deriving further description of signed tropically convex sets in Section 5 and 6. As the elimination process produces balanced coefficients for the inequalities, it is convenient to have an elimination procedure which can directly deal with those (Theorem 4.14). We also need to derive explicit inequalities with signed coefficients (Corollary 4.15) to describe the dual convex hull in Section 6. The version with non-strict inequalities (Theorem 4.19) will be used in constructing an exterior description by closed tropical halfspaces (Theorem 5.4).

For a subset M of $\mathbb{T}_{\pm}^d$, we define its coordinate projection $\rho_i(M)$ with $i \in [d]$ by

$$\rho_i(M) = \{(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_d) \mid (x_1, \dots, x_d) \in M\} \ . \tag{28}$$

We fix a matrix $A = (a_{ij}) \in \mathbb{S}^{d\times n}$. The non-negative matrix $S^{(i)}$ in the group of signed tropical transformations from Remark 3.10 with the sequence $(-|a_{ij}|)_j \in \mathbb{T}^n_{\ge \mathbb{0}}$ as diagonal scales the rows of A such that the ith row of $A \odot S$ has only entries with absolute value 0 or $\mathbb{0}$. As S is non-negative, we directly obtain from the definitions in Section 4.1 the following.

▶ **Lemma 4.13.** *There is a matrix $S^{(i)} \in \mathbb{D} \subset \mathbb{T}_{\pm}^{d\times d}$ such that the entries in the ith row of $A \odot S^{(i)}$ have absolute value 0 or $\mathbb{0}$, and $ker_+(A \odot S^{(i)}) = ker_+(A)$, $sep_+(A \odot S^{(i)}) = sep_+(A)$ and $\left\{ y \in \mathbb{T}_{\pm}^d \;\middle|\; y^\top \odot A \vDash \mathbb{0} \right\} = \left\{ y \in \mathbb{T}_{\pm}^d \;\middle|\; y^\top \odot S^{(i)} \odot A \vDash \mathbb{0} \right\}$.*

We define several sets partitioning $[n]$ based on the sign of the entries in the ith row of A by

$$\begin{aligned} J^+ &= \{j \in [n] \mid a_{ij} > \mathbb{0}\}\,, & J^- &= \{j \in [n] \mid a_{ij} < \mathbb{0}\} \\ J^\bullet &= \{j \in [n] \mid a_{ij} \in \mathbb{T}_\bullet \setminus \{\mathbb{0}\}\}\,, & J^0 &= \{j \in [n] \mid a_{ij} = \mathbb{0}\} \ . \end{aligned} \tag{29}$$

Furthermore, we define $T^{(i)} = (t_{j,p}) \in \{0, \mathbb{0}\}^{n \times ((J^+ \cup J^\bullet) \times (J^\bullet \cup J^-) \cup J^0)}$ as the incidence matrix

$$t_{j,p} = \begin{cases} 0 & j = k \text{ or } j = \ell \text{ for } p = (k,\ell) \in (J^+ \cup J^\bullet) \times (J^\bullet \cup J^-) \\ 0 & j = p \text{ for } p \in J^0 \\ \mathbb{0} & \text{else} \end{cases} . \tag{30}$$

We denote by A_{-i} the matrix obtained from A by removing the last row.

4.3.1 Strict Inequalities

▶ **Theorem 4.14** (Fourier–Motzkin for strict inequalities with balanced numbers)**.** *The ith coordinate projection of the open tropical cone $\rho_i(sep_+(A))$ for the matrix $A \in \mathbb{S}^{d \times n}$ is the open tropical cone $sep_+(A_{-i} \odot S^{(i)} \odot T^{(i)})$.*

Proof. By using an appropriate scaling matrix $S^{(i)}$, we can assume by Lemma 4.13 that the absolute value of each entry in the ith row of A is either 0 or $\mathbb{0}$ and that this does not affect $\rho_i(\mathrm{sep}_+(A))$.

To simplify notation, we additionally assume that $i = d$. Using Lemma 4.11 and ordering the inequalities according to the partition from (29), we get the system

$$\begin{aligned} y_d \oplus (y_1, \dots, y_{d-1}) \odot (a_{1,j}, \dots, a_{d-1,j})^\top &> \mathbb{0} \text{ for } j \in J^+ \cup J^\bullet \\ \ominus y_d \oplus (y_1, \dots, y_{d-1}) \odot (a_{1,j}, \dots, a_{d-1,j})^\top &> \mathbb{0} \text{ for } j \in J^- \cup J^\bullet \end{aligned} \tag{31}$$

Proposition 4.8 implies that (31) has a solution $(y_1, \dots, y_{d-1}, y_d) \in \mathbb{T}_\pm^d$ if and only if

$$(y_1, \dots, y_{d-1}) \odot A_{-d} \odot T > \mathbb{0} \tag{32}$$

has a solution $(y_1, \dots, y_{d-1}) \in \mathbb{T}_\pm^{d-1}$. ◀

We can resolve the balanced entries which can occur in the product with $T^{(i)}$ by means of Theorem 4.12.

▶ **Corollary 4.15** (Fourier–Motzkin for strict inequalities with signed numbers)**.** *The ith coordinate projection of the open tropical cone $\rho_i(sep_+(A))$ is $sep_+\left(\xi(A_{-i} \odot S^{(i)} \odot T^{(i)})\right)$.*

▶ **Example 4.16.** We use the matrix

$$A = \begin{pmatrix} 3 & \ominus 1 & \ominus 4 \\ 3 & \ominus 0 & \ominus 2 \end{pmatrix} ,$$

from Figure 1.

Eliminating the first row yields

$$\begin{pmatrix} 3 & \ominus 0 & \ominus 2 \end{pmatrix} \odot \begin{pmatrix} -3 & \mathbb{0} & \mathbb{0} \\ \mathbb{0} & -1 & \mathbb{0} \\ \mathbb{0} & \mathbb{0} & -4 \end{pmatrix} \odot \begin{pmatrix} 0 & 0 \\ 0 & \mathbb{0} \\ \mathbb{0} & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \end{pmatrix}$$

This shows that $\mathrm{sep}_+^+(A)$ is not empty (as all entries of the remaining matrix are positive signed numbers), which can also be seen in Figure 1 using the duality in Theorem 4.6.

▶ Remark 4.17. The crucial difference to classical Fourier–Motzkin elimination happens in the treatment of balanced numbers occuring in the calculation. While classically in each step several variables could be eliminated at the same time we have to deal with their balanced left-overs. For strict inequalities, Lemma 4.11 provides a tool to resolve them by introducing two inequalities instead of one. We will see how to resolve them for non-strict inequalities in Proposition 5.7.

▶ Remark 4.18. The classical technique of Fourier-Motzkin for polytopes, see e.g. [19] has already been successfully adapted to tropical linear inequality systems in [8]. In the latter work, an algorithmic scheme to determine a projection of a tropical inequality system is described. In our Theorem 4.14, we do not have the non-negatively constrained variables but allow arbitrary elements of $\mathbb{T}_{\pm}$. Classically, one can represent an unconstrained variable as the difference of a pair of non-negative variables. Applying this technique to a system of the form $y^\top \odot A > \mathbb{0}$ with unconstrained $y \in \mathbb{T}_{\pm}^n$ for a matrix $A \in \mathbb{T}_{\pm}^{d\times n}$ yields the system

$$(u^\top, v^\top) \odot \begin{pmatrix} A \\ \ominus A \end{pmatrix} \; > \; \mathbb{0} \text{ with } u, v \in \mathbb{T}^d_{\geq \mathbb{0}} \; . \tag{33}$$

Reordering terms with coefficients in $\mathbb{T}_{<\mathbb{0}}$ to the other side of the inequality yields a system which allows to apply [8, Theorem 11]. However, the differences of non-negative variables are harder to resolve as there is no cancellation but it results in balanced entries. This makes our direct approach more tractable for unconstrained variables. Furthermore, we are also interested in the structure of the resulting inequalities in Section 5, whence our approach is more suitable for this setting.

The elimination procedure derived in the last section allows to prove the desired separation in $\mathbb{T}_{\pm}^d$.

Proof of Theorem 4.6. At first, we show the claim for $d = 1$. The set $\operatorname{sep}_+(A)$ is non-empty if and only if either all entries are positive or all entries are negative. Otherwise, we can select a balanced entry or a pair of entries with opposite sign by multiplication from the right.

If $\operatorname{sep}_+(A)$ is not empty, then Theorem 4.4 tells us that $\ker_+(A)$ is empty. So, we assume that $\operatorname{sep}_+(A)$ is empty. As the scaling of the columns of A does not change the sets $\operatorname{sep}_+(A)$ or $\ker_+(A)$, we can assume that the absolute value of the entries in the last row of A is 0 or $\mathbb{0}$. Let T be the matrix from (30). Then Theorem 4.14 shows that $\operatorname{sep}_+(A_{-d} \odot T)$ is empty. By induction, there is an element z in $\ker_+(A_{-d} \odot T)$. We show that $T \odot z \in \ker_+(A)$. By definition of T, the elements in the dth row of $A \odot T$ are all in $\mathbb{T}_\bullet$. This implies that the dth row of $A \odot T \odot z$ is in $\mathbb{T}_\bullet$. Additionally, the choice of z yields $A_{-d} \odot T \odot z \in \mathbb{T}_\bullet^{d-1}$. This finishes the proof. ◀

4.3.2 Non-strict Inequalities

While we mainly considered the strict inequalities as separators from the origin, in light of Theorem 4.6, we develop the elimination theory for non-strict inequalities with a view towards the representation of convex sets as intersection of closed halfspaces in Theorem 5.4. Therefore, we add another coordinate to treat affine halfspaces, which only occurred in Example 3.9 so far. Next, we derive the analogous statement to Theorem 4.14 for the relation "$\vDash$" instead of "$>$".

Note that this is substantially more subtle than the case of strict inequalities. We require the coefficient matrix of the inequalities to consist of signed numbers only. However, as each elimination step can result in balanced coefficients, we again need a method to resolve those. While this was rather easy for strict inequalities as shown in Theorem 4.12, we need to develop a more technical and less explicit machinery in Proposition 5.7.

We recall the matrices $S^{(i)}$ from Lemma 4.13 and $T^{(i)}$ from (30) with d replaced by $d+1$ and $J^\bullet = \emptyset$.

▶ **Theorem 4.19** (Fourier–Motzkin for non-strict inequalities with signed numbers). *The ith coordinate projection of the set*

$$\left\{ y \in \mathbb{T}_\pm^d \;\middle|\; (0, y^\top) \odot A \vDash \mathbb{0} \right\} \tag{34}$$

for $A \in \mathbb{T}_\pm^{(d+1)\times n}$ is the set

$$\left\{ z \in \mathbb{T}_\pm^{d-1} \;\middle|\; (0, z^\top) \odot A_{-i} \odot S^{(i)} \odot T^{(i)} \vDash \mathbb{0} \right\} \quad . \tag{35}$$

Proof. Using Lemma 4.13, we can assume that the absolute value of each entry in the ith row of A is either 0 or $\mathbb{0}$ by using an appropriate scaling matrix $S^{(i)}$.

To simplify notation, we additionally assume that $i = d$. Ordering the inequalities according to the distinction from (29), we get the system

$$\begin{aligned} y_d \oplus (0, y_1, \dots, y_{d-1}) \odot (a_{0,j}, a_{1,j}, \dots, a_{d-1,j})^\top &\vDash \mathbb{0} \text{ for } j \in J^+ \\ \ominus y_d \oplus (0, y_1, \dots, y_{d-1}) \odot (a_{0,j}, a_{1,j}, \dots, a_{d-1,j})^\top &\vDash \mathbb{0} \text{ for } j \in J^- \end{aligned} \tag{36}$$

Proposition 4.10 implies that (36) has a solution $(0, y_1, \dots, y_{d-1}, y_d) \in \mathbb{T}_\pm^{d+1}$ if and only if

$$(0, y_1, \dots, y_{d-1}) \odot A_{-d} \odot S^{(d)} \odot T^{(d)} \vDash \mathbb{0} \tag{37}$$

has a solution $(0, y_1, \dots, y_{d-1}) \in \mathbb{T}_\pm^d$. ◀

▶ **Example 4.20.** We will see how to obtain an exterior description by closed halfspaces in Theorem 5.4. To determine the exterior description of the one dimensional line segment from $\ominus 0$ to 1 in $\mathbb{T}_\pm$, one can eliminate x_1 and x_2 from the system

$$\ominus 0 \odot x_1 \oplus 1 \odot x_2 \ominus z \vDash \mathbb{0} \tag{38a}$$
$$0 \odot x_1 \ominus 1 \odot x_2 \oplus z \vDash \mathbb{0} \tag{38b}$$
$$0 \odot x_1 \oplus 0 \odot x_2 \ominus 0 \vDash \mathbb{0} \tag{38c}$$
$$\ominus 0 \odot x_1 \ominus 0 \odot x_2 \oplus 0 \vDash \mathbb{0} \tag{38d}$$
$$0 \odot x_1 \vDash \mathbb{0} \tag{38e}$$
$$0 \odot x_2 \vDash \mathbb{0} \tag{38f}$$

Eliminating x_1 yields

$$\bullet 1 \odot x_2 \bullet z \vDash \mathbb{0} \qquad \text{from (38a)\&(38b)} \tag{39a}$$
$$1 \odot x_2 \ominus z \ominus 0 \vDash \mathbb{0} \qquad \text{from (38a)\&(38c)} \tag{39b}$$
$$1 \odot x_2 \ominus z \vDash \mathbb{0} \qquad \text{from (38a)\&(38e)} \tag{39c}$$
$$\ominus 1 \odot x_2 \oplus z \oplus 0 \vDash \mathbb{0} \qquad \text{from (38d)\&(38b)} \tag{39d}$$
$$\bullet 0 \odot x_2 \bullet 0 \vDash \mathbb{0} \qquad \text{from (38d)\&(38c)} \tag{39e}$$
$$\ominus 0 \odot x_2 \oplus 0 \vDash \mathbb{0} \qquad \text{from (38d)\&(38e)} \tag{39f}$$
$$0 \odot x_2 \vDash \mathbb{0} \qquad \text{from (38f)} \tag{39g}$$

From further elimination of x_2 we get by ignoring redundant inequalities of (39)

$$\bullet z \bullet 0 \vDash \mathbb{0} \qquad \text{from (39b)\&(39d)} \tag{40a}$$
$$\ominus(-1) \odot z \oplus 0 \vDash \mathbb{0} \qquad \text{from (39b)\&(39f)} \tag{40b}$$
$$(-1) \odot z \oplus (-1) \vDash \mathbb{0} \qquad \text{from (39g)\&(39d)} \tag{40c}$$
$$0 \vDash \mathbb{0} \qquad \text{from (39g)\&(39f)} \tag{40d}$$

This yields the exterior description $z \vDash \ominus 0$ and $z \vDash \ominus 1$.

4.4 On the Complexity of Signed Tropical Inequality Systems

For (regular) linear programs, solving all standard forms such as $Ax = b$, $x \geq 0$ or $Ax \leq b$ are polynomial-time equivalent. For example, consider a system in the second form with $A \in \mathbb{R}^{m \times n}, b \in \mathbb{R}^m$. By using variables $x', x'' \in \mathbb{R}^n$ and $s \in \mathbb{R}^m$, we can write a system in the first form as $(A, -A, I_m)(x', x'', s) = b$, $(x', x'', s) \geq 0$. From a feasible solution (x', x'', s), we can recover a feasible solution $x = x' - x''$ to the original system.

The situation for tropical LP is different. Consider systems of the form $A \odot x \bowtie b$, $x \geq \mathbb{0}$, $x \in \mathbb{T}^d_\pm$ and $A \odot x \trianglerighteq b$, $x \in \mathbb{T}^d_\pm$; in both cases, we need to find a nonzero solution. The first system asks for $\ker_+ \begin{pmatrix} A & \ominus b \\ 0 & \ominus 0 \end{pmatrix} \neq \emptyset$, and is essentially equivalent to solving mean payoff games (1). Deciding whether this system is feasible is in the complexity class NP∩coNP; this can be seen from Farkas' lemma (Theorem 4.6), and an additional argument showing that if one of the respective systems is feasible, there is a solution of bit complexity bounded in the bit complexity of the input.

It turns out that systems of the form $A \odot x \trianglerighteq b$, $x \in \mathbb{T}^d_\pm$ actually describe a more general problem. We thank Mateusz Skomra for making the connection with the negative cycles in mixed graphs [10] and an anonymous referee for pointing us to a reduction leading to [29] as well as a hinting towrads a direct proof which we give here.

▶ **Theorem 4.21.** *The feasibility problem for systems of the form $A \odot x \trianglerighteq b$, $x \in \mathbb{T}^d_\pm$ is NP-complete.*

Proof. We give a reduction from SAT. For this, we fix an arbitrary SAT formula $\mathcal{F}$ in conjunctive normal form on d variables. To each clause $(l_1 \vee \cdots \vee l_k)$, composed of the literals $l_1, \ldots, l_k$, we associate an inequality $\sigma_1 \odot x_1 \oplus \cdots \oplus \sigma_k \odot x_k \vDash 0$ where σ_i is 0 or $\ominus 0$ depending if the corresponding literal in the clause is positive or negative. This yields a linear inequality system where the number of inequalities equals the number of clauses in the formula.

For a satisfying assignment $s \in \{\texttt{True}, \texttt{False}\}^d$, we construct a vector $x \in \{0, \ominus 0\}^d$ by replacing `True` with 0 and `False` with $\ominus 0$. As at least one literal yields `True` for the assignment s, each inequality becomes $0 \vDash 0$ or $\bullet 0 \vDash 0$, which are both true.

On the other hand, let $x \in \mathbb{T}^d_\pm$ be a solution of the associated tropical linear inequality system. We claim that then also $(\operatorname{tsgn}(x_1)\, 0, \ldots, \operatorname{tsgn}(x_d)\, 0)$ is a solution. Indeed, at least one term $\sigma_i \odot x_i$ of each inequality $\sigma_1 \odot x_1 \oplus \cdots \oplus \sigma_k \odot x_k \vDash 0$ has to be 0 or bigger (with respect to $\geq$). Hence, we can just set the absolute value of that component to 0 without changing the validity of the inequality. Each component which does not contribute to any of the left hand sides can take any value in the interval $[\ominus 0, 0]$ without violating any of the inequalities. Now, we can again use the correspondence between $(0, \ominus 0)$ and $(\texttt{True}, \texttt{False})$ to construct a satisfying assignment for $\mathcal{F}$.

Note that the problem is in NP as a solution can be checked to fulfill the inequalities in polynomial time. Hence, the problem is NP-complete. ◀

Recall that we do not obtain a variant of Farkas' lemma for the system $A \odot x \operatorname{\rotatebox[origin=c]{180}{$\vDash$}} b$, $x \in \mathbb{T}_{\pm}^d$ via the above Fourier-Motzkin elimination. The construction analogous to the classical case would transform it to $(A, \ominus A, I_m) \odot (x', x'', s) \bowtie b$, $(x', x'', s) \geq \mathbb{0}$. However, the solution $x = x' \ominus x''$ may contain balanced entries, and it may not be possible to resolve these entries to get a feasible solution.

▶ **Example 4.22.** We consider the system

$$\begin{pmatrix} 0 & 0 \\ \ominus 0 & 0 \\ 0 & \ominus 0 \\ \ominus 0 & \ominus 0 \end{pmatrix} \odot \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \operatorname{\rotatebox[origin=c]{180}{$\vDash$}} \begin{pmatrix} \ominus 0 \\ \ominus 0 \\ \ominus 0 \\ \ominus 0 \end{pmatrix} .$$

It does not have a signed solution. However the extended system

$$\begin{pmatrix} 0 & 0 & \ominus 0 & \ominus 0 & 0 & \mathbb{0} & \mathbb{0} & \mathbb{0} \\ \ominus 0 & 0 & 0 & \ominus 0 & \mathbb{0} & 0 & \mathbb{0} & \mathbb{0} \\ 0 & \ominus 0 & \ominus 0 & 0 & \mathbb{0} & \mathbb{0} & 0 & \mathbb{0} \\ \ominus 0 & \ominus 0 & 0 & 0 & \mathbb{0} & \mathbb{0} & \mathbb{0} & 0 \end{pmatrix} \odot \begin{pmatrix} x_1' \\ x_2' \\ x_1'' \\ x_2'' \\ s_1 \\ s_2 \\ s_3 \\ s_4 \end{pmatrix} \bowtie \begin{pmatrix} \ominus 0 \\ \ominus 0 \\ \ominus 0 \\ \ominus 0 \end{pmatrix} , \qquad x', x'', s \geq \mathbb{0}$$

has the solution $(0, 0, 0, 0, 0, 0, 0, 0)$.

Note that one can use [29, Theorem 1.2] to show that also systems of the form $A \odot x \bowtie b$, $x \in \mathbb{T}_{\pm}^d$ are NP-complete. This is in stark contrast to the intuition from classical equations. While systems of linear equations with the usual arithmetic are solvable in strongly polynomial time, it gets harder when we add non-negativity constraints. The latter is just linear programming and, hence, solvable in weakly polynomial time. Adding a non-negativity constraint to the system of balances above yields a tropical linear programming which is in NP ∩ co-NP.

5 Description by Halfspaces

An important property of classical polytopes is the duality between the representation as convex hull and as intersection of finitely many halfspaces. This is more subtle for tropical polytopes over $\mathbb{T}_{\pm}$. While we establish a description as intersection of open tropical halfspaces (Theorem 5.1) containing a set of points, we need additional properties to formulate a Minkowski-Weyl theorem (Theorem 5.4). All proofs are deferred to Section 5.1.

We saw already in Examples 3.9 that open halfspaces are convex. The *outer hull* of a set $M \subseteq \mathbb{T}_{\pm}^d$ is the intersection of its containing open halfspaces

$$\bigcap_{M \subseteq \mathcal{H}^+(a)} \mathcal{H}^+(a) \ . \tag{41}$$

This construction yields the same as our key Definition 3.1.

▶ **Theorem 5.1.** *The outer and the inner hull of a matrix $A \in \mathbb{T}_{\pm}^{d \times n}$ coincide, i. e.,* $\operatorname{tconv}(A) = \bigcap_{A \subseteq \mathcal{H}^+(v)} \mathcal{H}^+(v)$*, where we identify A with the set of its columns.*

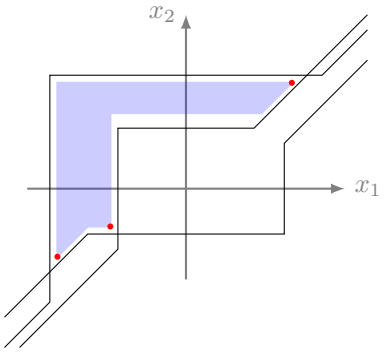

Figure 4 Approximation of a triangle by open halfspaces.

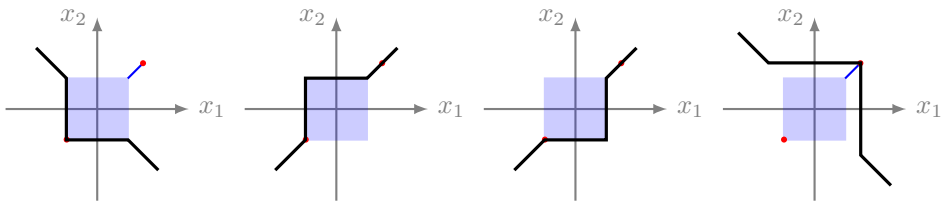

Figure 5 Exterior description of $\operatorname{tconv}((\ominus 1, \ominus 1), (2, 2))$ by closed halfspaces.

As the latter does not give a finite description, one is usually more interested in closed halfspaces. For a vector $(a_0, a_1, \dots, a_d) \in \mathbb{T}_{\pm}^{d+1}$, we define a *closed (signed) tropical halfspace* by

$$\overline{\mathcal{H}}^{+}(a) = \left\{ x \in \mathbb{T}_{\pm}^{d} \;\middle|\; a \odot \begin{pmatrix} 0 \\ x \end{pmatrix} \in \mathbb{T}_{\geq \mathbb{0}} \cup \mathbb{T}_{\bullet} \right\} . \tag{42}$$

▶ **Lemma 5.2.** *The closed signed tropical halfspace $\overline{\mathcal{H}}^{+}(a)$ is the topological closure of the open signed halfspace $\mathcal{H}^{+}(a)$.*

Observe that the former statement is wrong for inequalities with balanced numbers as coefficients.

▶ Remark 5.3. Closed tropical halfspaces are not as suitable for the hull construction in Equation (41) as open tropical halfspaces. The inner hull of $M = \{(\ominus 1, 1), (1, \ominus 1)\}$ should contain the origin $\mathbb{0}$. However, the closed halfspace $x_1 \oplus x_2 \geq \ominus 0$ contains those two points but not the origin. Taking the analogous intersection as in (41) with closed tropical halfspaces for M yields again M. Note that this is the same as the intersection of the balanced image $M \odot \Delta_2$ with $\mathbb{T}_{\pm}^{2}$.

Example 3.8 shows that such a closed signed tropical halfspace is in general not tropically convex. However, a finite intersection of such halfspaces can be tropically convex, as Figure 5 shows.

Hence, to arrive at a Minkowski-Weyl theorem for tropical polytopes over $\mathbb{T}_{\pm}$, one has to adapt the condition in the characterization of finite intersections of closed tropical halfspaces.

▶ **Theorem 5.4.** *For each finite set $V \subset \mathbb{T}_{\pm}^{d}$, there are finitely many closed tropical halfspaces H such that $\operatorname{tconv}(V)$ is the intersection of the halfspaces.*

For each finite set H of closed halfspaces, whose intersection M is tropically convex, there is a finite set of points $V \in \mathbb{T}_{\pm}^{d}$ such that $M = \operatorname{tconv}(V)$.

▶ **Corollary 5.5.** *A tropically convex set is the intersection of its containing closed halfspaces.*

▶ Remark 5.6. The crucial difference with Theorem 5.1 is that for open tropical halfspaces the generators are enough, while for closed tropical halfspaces, we have to take the whole set into account.

5.1 Proofs

To prove that the inner hull and the outer hull coincide, we mainly have to use the separation results from Section 4.

Proof of Theorem 5.1. The inclusion $\operatorname{tconv}(A) \subseteq \bigcap_{A \subseteq \mathcal{H}^+(v)} \mathcal{H}^+(v)$ follows by combining Proposition 3.4.a and Example 3.9.

For the other inclusion, assume that there is a point

$$z \in \bigcap_{A \subseteq \mathcal{H}^+(v)} \mathcal{H}^+(v) \setminus \operatorname{tconv}(A) \ .$$

By Proposition 4.1, we get that $\ker_+(B) = \emptyset$, where

$$B = \begin{pmatrix} 0 & \ominus 0 \\ A & \ominus z \end{pmatrix} \ .$$

Theorem 4.6 implies that $\operatorname{sep}_+(B) \neq \emptyset$. Hence, there is a separator $(u_0, \bar{u}) = (u_0, u_1, \dots, u_d) \in \mathbb{T}_\pm^{d+1}$ with $u_0 \oplus \bar{u}^\top \odot a^{(j)} > \mathbb{O}$ for all columns $a^{(j)}$ of A, and $\ominus u_0 \oplus \ominus \bar{u}^\top \odot z > \mathbb{O} \Leftrightarrow u_0 \oplus \bar{u}^\top \odot z < \mathbb{O}$. This means that the columns of A lie in the halfspace $\mathcal{H}^+(u)$ but z does not. This contradicts the choice of z in $\bigcap_{A \subseteq \mathcal{H}^+(v)} \mathcal{H}^+(v)$. ◀

Showing that a closed tropical halfspace is obtained as the closure of an open tropical halfspace follows from a simple limit argument. We use the notation $[d]_0 = \{0, 1, 2, \dots, d\}$.

Proof of Lemma 5.2. Let $z \in \mathbb{T}^d_{\geq \mathbb{O}}$ be an element of $\overline{\mathcal{H}^+}(a) \setminus \mathcal{H}^+(a)$. Set

$$J = \operatorname{argmax} \{ |c_j \odot z_j| \mid j \in [d]_0 \} \ ,$$

where $z_0 = 0$, and let $\ell \in J$ with $c_\ell \odot z_\ell > \mathbb{O}$. Denoting the kth unit vector $(0, \dots, 0, 1, 0, \dots, 0)$ in $\mathbb{R}^d$ by e_k for $k \in [d]$ and $e_0 = (-1, \dots, -1)$, we define a sequence

$$y^{(m)} = z + \frac{1}{m} \cdot e_\ell \ .$$

The sequence converges to z but each element of the sequence is an element of $\mathcal{H}^+(a)$. ◀

We will use the Fourier-Motzkin version for the relation "$\vDash$" (Theorem 4.19) to deduce an exterior description of a tropical polytope. However, the system describing the projection in (35) may contain balanced coefficients. We address this issue in the next statement. It is an existence argument statement that a balanced coefficient can be replaced by a signed coefficient, see also Figure 6.

▶ **Proposition 5.7** (Resolving balanced coefficients)**.** *Let M be a tropically convex set and $c = (c_0, c_1, \dots, c_d) \in \mathbb{S}^d$ with $c_i \in \mathbb{T}_\bullet$ for some $i \in [d]_0$ such that*

$$M \subseteq H(c) = \left\{ x \in \mathbb{T}^d_\pm \;\middle|\; c \odot \begin{pmatrix} 0 \\ x \end{pmatrix} \vDash \mathbb{O} \right\} \ .$$

Then there is an element $b \in \mathcal{U}(c_i)$ such that M is contained in

$$\left\{ x \in \mathbb{T}^d_\pm \;\middle|\; (c_0, \dots, c_{i-1}, b, c_{i+1}, \dots, c_d) \odot \begin{pmatrix} 0 \\ x \end{pmatrix} \vDash \mathbb{O} \right\} \ .$$

Proof. If $i = 0$, then we can set $b = |c_i|$.

Assuming without loss of generality that $i = d$, we set $c_{-d} = (c_0, c_1, \dots, c_{d-1})$. Fix $u \in \mathbb{T}_{\pm}^{d-1}, v \in \mathbb{T}_{\pm}$ such that $(u, v) \in M$. We define $w = w(u) = c_{-d} \odot \begin{pmatrix} 0 \\ u \end{pmatrix}$.

If $v \in \mathbb{T}_{<\mathbb{0}}$, then

$$\lambda(u, v) = \operatorname{argmax} \{ \lambda \in \mathcal{U}(c_d) \mid w \oplus \lambda \odot v \vDash \mathbb{0} \} \quad . \tag{43}$$

Let

$$\underline{\lambda} = \min \{ \lambda(u, v) \mid (u, v) \in M, v < \mathbb{0} \} \quad . \tag{44}$$

If $v \in \mathbb{T}_{>\mathbb{0}}$, then

$$\lambda(u, v) = \operatorname{argmin} \{ \lambda \in \mathcal{U}(c_d) \mid w \oplus \lambda \odot v \vDash \mathbb{0} \} \quad . \tag{45}$$

Let

$$\overline{\lambda} = \max \{ \lambda(u, v) \mid (u, v) \in M, v > \mathbb{0} \} \quad . \tag{46}$$

We derive a contradiction to the convexity of M, if $\overline{\lambda} > \underline{\lambda}$.

Let (p, q) and (r, s) attain $\underline{\lambda}$ and $\overline{\lambda}$, respectively. In particular, we have $q < \mathbb{0}$ and $s > \mathbb{0}$. The inequality $\overline{\lambda} > \underline{\lambda}$ implies that $\overline{\lambda} > \ominus|c_d|$ and that $\underline{\lambda} < |c_d|$. We can assume that $w(p)$ and $w(r)$ are signed numbers, as we otherwise can replace them by their absolute value without changing the admissible values of λ in (43) and (45).

Now, the construction of $\underline{\lambda}$ in (43) implies that $w(p) = \ominus\underline{\lambda} \odot q$ and (45) yields $w(r) = \ominus\overline{\lambda} \odot s$. This implies

$$w(r) \odot s^{\odot -1} = \ominus\overline{\lambda} < \ominus\underline{\lambda} = w(p) \odot q^{\odot -1} \quad . \tag{47}$$

We consider the point in the convex combination of (p, q) and (r, s) given by

$$z = (\ominus q^{\odot -1} \oplus s^{\odot -1})^{\odot -1} \odot (\ominus q^{\odot -1} \odot p \oplus s^{\odot -1} \odot r, \mathbb{0}) \quad .$$

Then

$$\begin{aligned} c \odot \begin{pmatrix} 0 \\ z \end{pmatrix} &= c \odot \begin{pmatrix} 0 \\ (\ominus q^{\odot -1} \oplus s^{\odot -1})^{\odot -1} \odot (\ominus q^{\odot -1} \odot p \oplus s^{\odot -1} \odot r) \\ \mathbb{0} \end{pmatrix} = \\ &= (\ominus q^{\odot -1} \oplus s^{\odot -1})^{\odot -1} \odot \begin{pmatrix} \ominus q^{\odot -1} \odot c_{-d} \odot \begin{pmatrix} 0 \\ p \end{pmatrix} \oplus s^{\odot -1} \odot c_{-d} \odot \begin{pmatrix} 0 \\ r \end{pmatrix} \\ \mathbb{0} \end{pmatrix} = \\ &= (\ominus q^{\odot -1} \oplus s^{\odot -1})^{\odot -1} \odot \begin{pmatrix} \ominus q^{\odot -1} \odot w(p) \oplus s^{\odot -1} \odot w(r) \\ \mathbb{0} \end{pmatrix} \end{aligned}$$

By (47), this implies $c \odot \begin{pmatrix} 0 \\ z \end{pmatrix} < \mathbb{0}$. As M is convex, this yields $z \in M \subseteq H(c)$, a contradiction.

So, we can conclude that $\overline{\lambda} \leq \underline{\lambda}$. Fix any b in the interval $[\overline{\lambda}, \underline{\lambda}] \neq \emptyset$. Let $(u, v) \in M$ with $v < \mathbb{0}$. Then

$$(c_{-d}, b) \odot \begin{pmatrix} 0 \\ u \\ v \end{pmatrix} = w(u) \oplus b \odot v \vDash w(u) \oplus \underline{\lambda} \odot v \vDash w(u) \oplus \lambda(u, v) \odot v \vDash \mathbb{0} \quad ,$$

where we use $b \leq \underline{\lambda}$, (44) and Lemma 2.6.d. The proof for $v > \mathbb{0}$ goes analogously. ◀

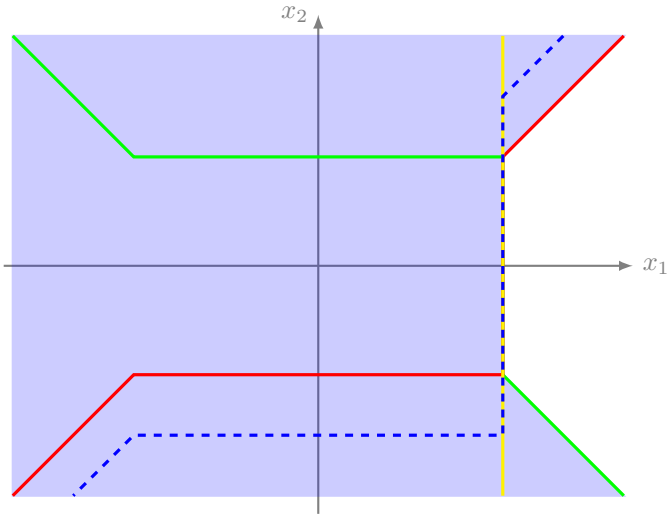

Figure 6 Finding a containing halfspace without balanced coefficients.

▶ **Example 5.8.** A pathological example for the last statement arises from resolving the tautological relation $\bullet(-1) \odot x \oplus \bullet(-1) \odot y \oplus \bullet 0 \vDash \mathbb{0}$. One obtains the chain of relations

$$\begin{aligned} \bullet(-1) \odot x \oplus \bullet(-1) \odot y \oplus \bullet 0 \vDash \mathbb{0} &\Leftrightarrow \\ \bullet(-1) \odot x \oplus \bullet(-1) \odot y \oplus 0 \vDash \mathbb{0} &\Leftrightarrow \\ \bullet(-1) \odot x \oplus \mathbb{0} \odot y \oplus 0 \vDash \mathbb{0} &\Leftrightarrow \\ \mathbb{0} \odot x \oplus \mathbb{0} \odot y \oplus 0 \vDash \mathbb{0} \ . & \end{aligned}$$

▶ Remark 5.9. Indeed, any value of $b \in \mathcal{U}(c_d)$ in the former proof could occur as Figure 6 shows. Any part of the dashed line without opposite (with respect to the origin) points is a tropical line segment.

▶ **Example 5.10.** The shaded area in Figure 6 shows the feasible region

$$\left\{ (x,y) \in \mathbb{T}_{\pm}^2 \;\middle|\; \ominus(-1) \odot x_1 \oplus (\bullet 2) \odot x_2 \oplus 0 \vDash \mathbb{0} \right\} \ .$$

The red line marks the inequality $\ominus(-1) \odot x_1 \oplus 2 \odot x_2 \oplus 0 \vDash \mathbb{0}$, while the green line marks the inequality $\ominus(-1) \odot x_1 \oplus (\ominus 2) \odot x_2 \oplus 0 \vDash \mathbb{0}$. The yellow line corresponds to the inequality $\ominus(-1) \odot x_1 \oplus 0 \vDash \mathbb{0}$. The blue dashed line interpolates between these three possible extreme closed halfspaces contained in the feasible region.

Our proof of Theorem 5.4 is based on eliminating variables from the canonical exterior description (13). For using those halfspaces, we need to show the additional requirement of tropical convexity for their intersection.

▶ **Lemma 5.11.** *The set*

$$\left\{ (x,z) \in \mathbb{T}_{\pm}^{n+d} \;\middle|\; A \odot x \bowtie z,\ x \geq \mathbb{0} \right\} \tag{48}$$

is tropically convex.

Proof. It is enough to show that, for fixed $a \in \mathbb{T}_{\pm}^n$, the set

$$H = \left\{ (x,z) \in \mathbb{T}_{\pm}^{n+1} \;\middle|\; a \odot x \bowtie z,\ x \geq \mathbb{0} \right\}$$

is tropically convex, then the claim follows from Proposition 3.4(a). Let $(p,q),(r,s) \in H$, and $\lambda \in \mathbb{T}_{\geq \mathbb{0}}$, $\lambda \leq 0$. We need to show that $\mathcal{U}(p \oplus \lambda \odot r, q \oplus \lambda \odot s) \subseteq H$.

Note that since $p, r \geq \mathbb{0}$, we have $p \oplus \lambda \odot r \in \mathbb{T}_{\pm}$ and therefore $\mathcal{U}(p \oplus \lambda \odot r) = \{p \oplus \lambda \odot r\}$. By Lemma 2.4(b), we have that $q \in \mathcal{U}(a \odot p)$ and $s \in \mathcal{U}(a \odot r)$. Using Lemma 3.5(b), we see that

$$\mathcal{U}(q \oplus \lambda \odot s) \subseteq \mathcal{U}((a \odot p) \oplus \lambda \odot (a \odot r)) = \mathcal{U}(a \odot (p \oplus \lambda \odot r)) \ ,$$

completing the proof. ◀

Proof of Theorem 5.4. Equation (13) provides a description by halfspaces involving additional variables. The convex hull of V is the set of those $z \in \mathbb{T}_{\pm}^d$ for which there is an $x \in \mathbb{T}_{\pm}^n$ with

$$\begin{pmatrix} A & \ominus \boldsymbol{I}_d & \mathbb{0} \\ \ominus A & \boldsymbol{I}_d & \mathbb{0} \\ 0 & \mathbb{0}_d & \ominus 0 \\ \ominus 0 & \mathbb{0}_d & 0 \\ \boldsymbol{I}_n & \mathbb{0}_d & \mathbb{0} \end{pmatrix} \odot \begin{pmatrix} x \\ z \\ 0 \end{pmatrix} \vDash \mathbb{0} \ , \tag{49}$$

where $\boldsymbol{I}$ is a tropical identity matrix with 0 on the diagonal and $\mathbb{0}$ elsewhere.

By Lemma 5.11 and the tropical convexity of $\left\{ x \in \mathbb{T}_{\pm}^n \;\middle|\; \bigoplus_{j \in [n]} x_j = 0, x \geq \mathbb{0} \right\}$, the set of $(x,z) \in \mathbb{T}_{\pm}^{n+d}$ fulfilling (49) is the intersection of tropically convex sets and, by Proposition 3.4(a), tropically convex as well.

Hence, we can use Theorem 4.19 to successively project out the x-variables. As the inequalities arising from a projection may contain balanced coefficients, we use Proposition 5.7 to replace them by signed coefficients. This yields a description of $\operatorname{tconv}(A)$ by non-strict inequalities. Here, we use that resolving a balanced coefficient in an inequality leads to a tighter constraint.

If the intersection of closed tropical halfspaces M is tropically convex, then its intersection with any orthant is tropically convex. By the tropical Minkowski-Weyl theorem in the non-negative orthant [24], each of the parts in the orthants are finitely generated. Taking the tropical convex hull of the union of all these generators yields M, as M is tropically convex. ◀

6 Connection with Tropical Convexity in $\mathbb{T}_{\max}$

The intersection of a signed tropically convex set with an orthant is just a tropically convex set over $\mathbb{T}_{\max}$. This allows to study signed tropical convex sets through the existing theory of unsigned tropically convex sets with the hull (12) in each orthant of $\mathbb{T}_{\pm}^d$. The proofs of the main statements are deferred to Section 6.1; these are based on the duality between the non-negative kernels and open tropical cones.

We fix a (finite) set $M \subseteq \mathbb{T}_{\pm}^d$ and interpret M as a matrix whose columns list the points. We will augment M by iteratively intersecting line segments between points in M with the coordinate hyperplanes to get a matrix $\zeta(M)$.

To make the construction of $\zeta(M)$ formal, we start with a slight modification of (30). We fix $A = (a_{ij}) \in \mathbb{T}_{\pm}^{d \times n}$ and a row index $i \in [d]$.

For two columns u and v of A with $u_i > \mathbb{O}$ and $v_i < \mathbb{O}$, we set

$$\begin{aligned}\lambda^+(u,v) &= \ominus v_i^{\odot -1} \odot (u_i^{\odot -1} \oplus \ominus v_i^{\odot -1})^{\odot -1} \text{ and}\\ \lambda^-(u,v) &= u_i^{\odot -1} \odot (u_i^{\odot -1} \oplus \ominus v_i^{\odot -1})^{\odot -1} \ .\end{aligned} \tag{50}$$

These scalars fulfill $\lambda^+(u,v) \oplus \lambda^-(u,v) = 0$ and $\lambda^+(u,v), \lambda^-(u,v) \geq \mathbb{O}$.

we define $T^{(i)} = (t_{j,p}) \in \{0, \mathbb{O}\}^{n \times ((J^+ \cup J^\bullet) \times (J^\bullet \cup J^-) \cup J^0)}$, using the decomposition from (29) for A, as the incidence matrix

$$t_{j,p} = \begin{cases} \lambda^+(a^{(k)}, a^{(\ell)}) & j = k \text{ for } p = (k,\ell) \in (J^+ \cup J^\bullet) \times (J^\bullet \cup J^-) \\ \lambda^-(a^{(k)}, a^{(\ell)}) & j = \ell \text{ for } p = (k,\ell) \in (J^+ \cup J^\bullet) \times (J^\bullet \cup J^-) \\ 0 & j = p \text{ for } p \in J^0 \\ \mathbb{O} & \text{else} \end{cases} \ . \tag{51}$$

In Theorem 4.14, we could also have used the matrix from (51) instead of multiplying with both $S^{(i)}$ and $T^{(i)}$. This is technically slightly more complicated but has the advantage that the resulting columns of the product with A are tropical convex combinations of the original columns. This motivates the following.

▶ **Definition 6.1.** *The matrix $\zeta_i(A)$ is the* ith elimination matrix *of A and it arises from $\xi(A \odot T)$ by replacing the ith row with $\mathbb{O}$.*

This allows to describe generators for the intersection of a tropical convex hull with a coordinate hyperplane $H_i := \left\{ x \in \mathbb{T}_\pm^d \;\middle|\; x_i = \mathbb{O} \right\}$ for $i \in [d]$.

▶ **Proposition 6.2.** *The intersection $\operatorname{tconv}(A) \cap H_i$ is generated by $\zeta_i(A)$.*

Additionally, we get generators for the intersection with an orthant.

▶ **Proposition 6.3.** *The intersection $\operatorname{tconv}(A) \cap \mathbb{T}^d_{\geq \mathbb{O}}$ is generated by*

$$\left(A \cup \bigcup_{i \in [d]} (\operatorname{tconv}(A) \cap H_i) \right) \cap \mathbb{T}^d_{\geq \mathbb{O}} \ .$$

Now, we have to combine all possible ways of descending in a chain of intersections of coordinate hyperplanes. Each permutation σ in the symmetric group on d elements S_d gives rise to a sequence of matrices $\zeta_{\sigma(1)}(M)$, $\zeta_{\sigma(2)}(\zeta_{\sigma(1)}(M))$ until $\zeta_{\sigma(d)}(\dots(\zeta_{\sigma(2)}(\zeta_{\sigma(1)}(M)))\dots)$. We denote the concatenation of these d matrices by $\zeta_\sigma(M)$. The concatenation of the matrices for all $\sigma \in S_d$ forms the matrix $\zeta(M)$.

▶ **Theorem 6.4.** *The convex hull $\operatorname{tconv}(M)$ of M is the union*

$$\bigcup_{O \text{ closed orthant of } \mathbb{T}^d_\pm} \operatorname{tconv}(O \cap \zeta(M)) \ . \tag{52}$$

Proof. By Proposition 6.3, we know that $\operatorname{tconv}(M)$ is generated by the projections on the boundary of the orthants and the generators in the interior. Iteratively applying Proposition 6.2 to the intersection of coordinate hyperplanes yields the claim. ◀

▶ **Example 6.5.** Looking at the points from Example 3.2, we see how we can determine the tropical convex hull of $\{(3,3), (\ominus 1, \ominus 0), (\ominus 4, \ominus 2)\}$. It is the union of the tropical convex hulls

$$\begin{aligned}&\operatorname{tconv}\left(\{(3,3),(\mathbb{O},3),(\mathbb{O},1)\}\right), \quad \operatorname{tconv}\left(\{(\ominus 1,0),(\mathbb{O},1),(\mathbb{O},3),(\ominus 4,\mathbb{O})\}\right)\\ &\operatorname{tconv}\left(\{(\ominus 1,\ominus 0),(\ominus 4,\ominus 2),(\ominus 1,\mathbb{O}),(\ominus 4,\mathbb{O})\}\right) \ .\end{aligned}$$

On the other hand, to get the tropical convex hull $\operatorname{tconv}((0,0),(\ominus-2,\ominus-2))$ in Figure 2a, one needs actual multi-valued cancellation.

We get

$$\zeta_1\left(\begin{pmatrix}0\\0\end{pmatrix},\begin{pmatrix}\ominus-2\\\ominus-2\end{pmatrix}\right)=\left\{\begin{pmatrix}\mathbb{O}\\-2\end{pmatrix},\begin{pmatrix}0\\\ominus-2\end{pmatrix}\right\} \text{ and}$$
$$\zeta_2\left(\begin{pmatrix}0\\0\end{pmatrix},\begin{pmatrix}\ominus-2\\\ominus-2\end{pmatrix}\right)=\left\{\begin{pmatrix}-2\\\mathbb{O}\end{pmatrix},\begin{pmatrix}\ominus-2\\\mathbb{O}\end{pmatrix}\right\}.$$

From applying $\zeta_1(\zeta_2(.))$, we additionally obtain $\{(\mathbb{O},\mathbb{O})\}$.

For the positive orthant, this yields the generators $\{(\mathbb{O},\mathbb{O}),(\mathbb{O},-2),(-2,\mathbb{O}),(0,0)\}$. The other orthants are derived analogously.

▶ **Corollary 6.6.** *Tropically convex sets are contractible.*

Proof. The space $\mathbb{T}_{\pm}^d$ inherits the topology of $\mathbb{R}^d$ via the map $\operatorname{slog}\colon x\mapsto \operatorname{sgn}(x)\log(|x|)$, where the origin is mapped to the all-$\mathbb{O}$-point. As tropically convex sets in all orthants are contractible [20, Theorem 2], we can contract to the boundary of the orthants. The claim follows by induction on the dimension d. ◀

For the definition of the covector decomposition in $(\mathbb{R}\cup\{-\infty\})^d$ and its connection with regular subdivisions of $\Delta_d\times\Delta_n$ we refer the reader to [28].

▶ **Corollary 6.7** (Covector decomposition)**.** *The combinatorics of the tropically convex hull of a matrix $A\in\mathbb{T}_{\pm}^{d\times n}$ can be described by 2^d regular subdivisions of $\Delta_d\times\Delta_n$.*

6.1 Proofs

Proof of Proposition 6.2. Using the construction in (51) and the fact that $\ominus|z|,|z|\in\mathcal{U}(z)$ for $z\in\mathbb{T}_\bullet$, the inclusion $\zeta_i(A)\subseteq\operatorname{tconv}(A)\cap H_i$ follows from Definition 3.1. Example 3.8 and Proposition 3.4.a imply that $\operatorname{tconv}(\zeta_i(A))\subseteq\operatorname{tconv}(A)\cap H_i$.

For the other inclusion, assume that there is a point $z\in\operatorname{tconv}(A)$ with $z_i=\mathbb{O}$ which is not contained in $\operatorname{tconv}(\zeta_i(A))$. By Proposition 4.1, this implies that

$$\ker_+\begin{pmatrix}0&\ominus 0\\ \zeta_i(A)&\ominus z\end{pmatrix}=\emptyset\ .$$

The Farkas Lemma 4.6 implies that

$$\operatorname{sep}_+\begin{pmatrix}0&\ominus 0\\ \zeta_i(A)&\ominus z\end{pmatrix}\neq\emptyset\ .$$

Furthermore, we get

$$\operatorname{sep}_+(\zeta_i\begin{pmatrix}0&\ominus 0\\ A&\ominus z\end{pmatrix})\neq\emptyset$$

as, because of $z_i=\mathbb{O}$, the last column is unchanged by ζ_i and the first row remains the same due to the definition of $\lambda^+(u,v)$ and $\lambda^-(u,v)$ for (50).

However, by Corollary 4.15, then also

$$\operatorname{sep}_+\begin{pmatrix}0&\ominus 0\\ A&\ominus z\end{pmatrix}\neq\emptyset\ .$$

Using again the Farkas Lemma 4.6, this implies $z\notin\operatorname{tconv}(A)$, a contradiction. ◀

To derive the next claim, we start with a more precise description of a signed tropical line segment. There is a natural bijection between $\Delta_2 = \left\{ (\nu, \mu) \in \mathbb{T}^2_{\geq \mathbb{0}} \;\middle|\; \max(\nu, \mu) = 0 \right\}$ and $\overline{\mathbb{T}} = \mathbb{R} \cup \{-\infty, \infty\}$ given by

$$(\nu, \mu) \mapsto \mu - \nu \ .$$

We denote the inverse image of an element $\eta \in \overline{\mathbb{T}}$ with respect to this map by $\Psi(\eta)$. This leads to a parametrization of a tropical line segment for $a, b \in \mathbb{T}^d_{\pm}$ via $\operatorname{tconv}(a, b) = \left\{ L_\eta(a, b) \;\middle|\; \eta \in \overline{\mathbb{T}} \right\}$ where $L_\eta(a, b) = \Psi(\eta)_0 \odot a \oplus \Psi(\eta)_1 \odot b$. Note that $L_{-\infty}(a, b) = a$ and $L_\infty(a, b) = b$.

Proof of Proposition 6.3. Let $z \in \operatorname{tconv}(A) \cap \mathbb{T}^d_{\geq \mathbb{0}}$ be an element of $\mathcal{U}(A \odot \lambda)$ with $\lambda \in \Delta_d$. We consider the tropical line segments from z to the columns of A. For a fixed column $a^{(j)}$ of A with $a^{(j)} \notin \mathbb{T}^d_{\geq \mathbb{0}}$, there is a minimal $\eta \in \overline{\mathbb{T}}$ such that a component of $L_\eta(z, a^{(j)})$ is balanced.

Intermediate claim I: All entries of $L_\eta(z, a^{(j)})$ are either balanced or in $\mathbb{T}_{\geq \mathbb{0}}$. For an arbitrary row $i \in [d]$, the expression $\Psi(\eta)_1 \odot z_i \oplus \Psi(\eta)_2 \odot a^{(j)}_i$ is in $\mathbb{T}_{\geq \mathbb{0}}$ for $\eta = -\infty$. The claim now follows from the piecewise definition of the addition in terms of the absolute values.

Using Proposition 3.6, we see that the point $b^{(j)}$ obtained from $L_\eta(z, a^{(j)})$ by replacing all balanced entries with $\mathbb{0}$ is in $\operatorname{tconv}(A) \cap \mathbb{T}^d_{\geq \mathbb{0}}$. For $a^{(j)} \in \mathbb{T}^d_{\geq \mathbb{0}}$ we set $b^{(j)} = a^{(j)}$.

Intermediate claim II: The point z is in the convex hull of $\left\{ b^{(j)} \;\middle|\; j \in [n] \right\}$. It is enough to show that

$$\ker_+\left(\begin{pmatrix} 0 & \dots & 0 & 0 & \ominus 0 \\ a^{(1)} & \dots & a^{(n-1)} & b^{(n)} & \ominus z \end{pmatrix}\right) \neq \emptyset$$

because than we can iteratively replace the columns $a^{(i)}$ by $b^{(i)}$. Let $b^{(1)} \in \nu \odot z \oplus \mu \odot a^{(1)}$. Pick an element x scaled such that $x_1 = \mu$. Then

$$\begin{pmatrix} \nu & \mathbb{0} & \dots & \mathbb{0} & \ominus \nu \\ \nu \odot z & \mathbb{0} & \dots & \mathbb{0} & \nu \odot \ominus z \end{pmatrix} \oplus \begin{pmatrix} 0 & 0 & \dots & 0 & \ominus 0 \\ a^{(1)} & a^{(2)} & \dots & a^{(n)} & \ominus z \end{pmatrix} \odot x$$

is in $\mathbb{T}^d_\bullet$. Therefore $(0, \dots, 0)$ is in the non-negative kernel of

$$\begin{pmatrix} \nu \oplus x_1 & x_2 & \dots & x_n & \ominus(\nu \oplus x_{n+1}) \\ \nu \odot z \oplus x_1 \odot a^{(1)} & x_2 \odot a^{(2)} & \dots & x_n \odot a^{(n)} & (\nu \oplus x_{n+1}) \odot (\ominus z) \end{pmatrix} = \begin{pmatrix} 0 & x_2 & \dots & x_n & \ominus(\nu \oplus x_{n+1}) \\ \nu \odot z \oplus \mu \odot a^{(1)} & x_2 \odot a^{(2)} & \dots & x_n \odot a^{(n)} & (\nu \oplus x_{n+1}) \odot (\ominus z) \end{pmatrix} \tag{53}$$

For fixed $i \in [d]$, if $\nu \odot z_i \oplus \mu \odot a^{(1)}_i$ is not balanced or the maximum absolute value is attained somewhere else in the row, we can replace it by $b^{(1)}_i$ and $(0, \dots, 0)$ is still in the non-negative kernel.

Otherwise, $\ominus \nu \odot z_i = \mu \odot a^{(1)}_i$ and $\nu \oplus x_{n+1} = \nu$. But $(0, \dots, 0)$ is also in the non-negative kernel of

$$\begin{pmatrix} \mu & x_2 & \dots & x_n & \ominus x_{n+1} \\ \mu \odot a^{(1)} & x_2 \odot a^{(2)} & \dots & x_n \odot a^{(n)} & x_{n+1} \odot (\ominus z) \end{pmatrix} \ .$$

Since $\mu \odot a^{(1)}_i = \ominus \nu \odot z_i$ has the same sign as $\ominus x_{n+1} \odot z_i$ and we have $\nu \geq x_{n+1}$, there has to be an $\ell \in [n]$ such that $x_\ell \odot a^{(\ell)}_i = \ominus \mu \odot a^{(1)}_i = \nu \odot z_i$. Therefore, we can replace $\nu \odot z_i \oplus x_1 \odot a^{(1)}$ by $\mathbb{0}$ and $(0, \dots, 0)$ remains in the non-negative kernel.

Therefore, $(0, x_2, \dots, x_n, (\nu \oplus x_{n+1}))$ is in the non-negative kernel of

$$\begin{pmatrix} 0 & 0 & \dots & 0 & \ominus 0 \\ b^{(1)} & a^{(2)} & \dots & a^{(n)} & \ominus z \end{pmatrix} .$$

This finishes the proof of claim II. ◀

A Missing Proofs

▶ **Lemma 2.6.** *Let* $a, b, c, d \in \mathbb{S}$.

(a) $a \oplus c \vDash b \Leftrightarrow a \vDash b \ominus c$

(b) $a \vDash b \quad \wedge \quad c \vDash d \quad \Rightarrow \quad a \oplus c \vDash b \oplus d$.

(c) *If* $c \in \mathbb{T}_{\pm}$, *then* $b \vDash c$ *and* $c \vDash a$ *imply* $b \vDash a$.

(d) $a \vDash b$ *implies* $c \odot a \oplus d \vDash c \odot b \oplus d$ *for* $c \in \mathbb{T}_{\geq \mathbb{0}}$ *and* $c \odot b \oplus d \vDash c \odot a \oplus d$ *for* $c \in \mathbb{T}_{\leq \mathbb{0}}$.

Proof.

(a) The claim follows directly from the definition and the properties of the semiring $\mathbb{S}$.

(b) Using the definition, we obtain $a \ominus b, c \ominus d \in \mathbb{T}_{\geq \mathbb{0}} \cup \mathbb{T}_{\bullet}$. This implies already $a \oplus c \ominus b \ominus d \in \mathbb{T}_{\geq \mathbb{0}} \cup \mathbb{T}_{\bullet}$.

(c) For a contradiction, assume $b \nvDash a$, that is, $b \ominus a \in \mathbb{T}_{<\mathbb{0}}$.

Case I: $|b| > |a|$. In this case, $b \in \mathbb{T}_{<0}$. Since $b \ominus c \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_\bullet$, it follows that $c \in \mathbb{T}_{<0}$ and $|c| \geq |b|$, using $c \in \mathbb{T}_\pm$. We now get a contradiction to $c \ominus a \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_\bullet$, since $|c| \geq |b| > |a|$.

Case 2: $|a| > |b|$. This case follows by an analogous argument. With $a \in \mathbb{T}_{>0}$, the condition $c \ominus a \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_\bullet$ implies $c \in \mathbb{T}_{>0}$ and $|c| \geq |a| > |b|$. This contradicts $b \ominus c \in \mathbb{T}_{\geq 0} \cup \mathbb{T}_\bullet$.

Case 3: $|a| = |b|$. In this case, we must have $b \in \mathbb{T}_{<0}$ and $a \in \mathbb{T}_{>0}$. We thus obtain $c \in \mathbb{T}_{<0}$ as in case I, but also $c \in \mathbb{T}_{>0}$ as in case II, a contradiction.

(d) The expression $c \odot (a \ominus b) = c \odot a \ominus c \odot b$ is in $\mathbb{T}_{\geq 0}$ for $c \in \mathbb{T}_{\geq 0}$ and in $\mathbb{T}_{\leq 0}$ for $c \in \mathbb{T}_{\leq 0}$. Now, the statement follows from (b) with $d \vDash d$. ◀

▶ **Lemma 3.5.**

(a) *Let $a \in \mathbb{S}$, $b \in \mathbb{T}_\pm$, and $z \in \mathcal{U}(a \oplus b)$. Then there exists an $a' \in \mathcal{U}(a)$ such that $z \in \mathcal{U}(a' \oplus b)$.*

(b) *If $a \in \mathcal{U}(x)$, $b \in \mathcal{U}(y)$, and $c \in \mathbb{T}_\pm$, then $\mathcal{U}(c \odot a \oplus b) \subseteq \mathcal{U}(c \odot x \oplus y)$.*

Proof.

(a) If $a \in \mathbb{T}_\pm$, then $a' = a$ satisfies the requirements. For the rest of the proof, we assume $a \in \mathbb{T}_\bullet$. If $|b| > |a|$, then we can set $a' = |a|$. In this case, $a' \oplus b = a \oplus b = b \in \mathbb{T}_\pm$. Consider now the case $|a| \geq |b|$, which implies $a \oplus b = a$. Then $z \in \mathcal{U}(a \oplus b)$ if and only if $|z| \leq |a|$. For $|a| \geq |z| > |b|$, we set $a' = z$. If $|a| \geq |b| \geq |z|$, then we set $a' = \ominus b$. In both cases it is easy to see that $z \in \mathcal{U}(a' \oplus b)$.

(b) Note that $|a| \leq |x|$ and $|b| \leq |y|$, and consequently, $|c \odot a \oplus b| \leq |c \odot x \oplus y|$. If $c \odot x \oplus y$ is balanced, then the claim follows: $\mathcal{U}(c \odot x \oplus y)$ contains all $r \in \mathbb{T}_\pm$ with $|r| \leq |c \odot x \oplus y|$; this holds for all $r \in \mathcal{U}(c \odot a \oplus b)$.

Hence, assume that $c \odot x \oplus y$ is not balanced. In particular, x or y is not balanced. If both $x, y \in \mathbb{T}_\pm$, then $a = x$ and $b = y$ and thus the claim is immediate. The remaining case is when exactly one of x and y is balanced. Let us assume $y \in \mathbb{T}_\pm$; the case $x \in \mathbb{T}_\pm$ follows similarly. Now we have $b = y$, and we must also have $|y| > |c \odot x|$ as otherwise $c \odot x \oplus y$ would be balanced. Consequently, $c \odot x \oplus y = y$. On the other hand, $|a| \leq |x|$ and $b = y$ imply $|c \odot a| < |b|$, and therefore $c \odot a \oplus b = y$, and the claim follows. ◀

▶ **Proposition 3.6.** *An arbitrary subset $M \subseteq \mathbb{T}_\pm^d$ is tropically convex if and only if the tropical convex hull $\operatorname{tconv}(\{p, q\})$ is contained in M for all $p, q \in M$.*

Proof. For a tropically convex set, the tropical convex hull of all two-element subsets is contained by definition. In the converse direction, we show by induction on n that if we select any n vectors from M as the columns of a matrix $A \in \mathbb{T}_\pm^{d \times n}$, then $\mathcal{U}(A \odot x) \subseteq M$ for any $x \in \mathbb{T}_{\geq 0}^n$, $\bigoplus_{j \in [n]} x_j = 0$. The case $n = 2$ follows by the assumption; consider now $n \geq 3$ and assume that the claim holds for $n - 1$.

Let $z \in \mathcal{U}(A \odot x)$. Without loss of generality, we can assume that $x_1 = 0$. We set $s = \bigoplus_{\ell=1}^{n-1} x_\ell \odot a^{(\ell)} \in \mathbb{S}^d$, where $a^{(\ell)}$ is the ℓ-th column of A. We let $q = a^{(n)}$. Then, $A \odot x = s \oplus x_n \odot q$.

We can apply Lemma 3.5(a) to each component of z, s, and $x_n \odot q$. Thus, we obtain a vector $p \in \mathcal{U}(s)$ such that $z \in \mathcal{U}(p \oplus x_n \odot q)$. By induction, $p \in M$, and thus $z \in \operatorname{tconv}(\{p, q\}) \subseteq M$ by the assumption. This completes the proof. ◀

▶ **Proposition 3.7.** *For any matrix $A \in \mathbb{T}_\pm^{d \times n}$, the convex hull $\operatorname{tconv}(A)$ is tropically convex. Consequently, $\operatorname{tconv}(\operatorname{tconv}(A)) = \operatorname{tconv}(A)$.*

Proof. Using Proposition 3.6, it suffices to show that if $p, q \in \operatorname{tconv}(A)$, $\lambda \in \mathbb{T}_{\geq \mathbb{0}}$, $\lambda \leq 0$, then $\mathcal{U}(p \oplus \lambda \odot q) \subseteq \operatorname{tconv}(A)$.

Let $x, y \in \mathbb{T}^n_{\geq \mathbb{0}}$, $\bigoplus_{j\in[n]} x_j = 0$, $\bigoplus_{j\in[n]} y_j = 0$ such that $p \in \mathcal{U}(A \odot x)$ and $q \in \mathcal{U}(A \odot y)$. We let $z = x \oplus \lambda \odot q$; clearly, $z \in \mathbb{T}^n_{\geq \mathbb{0}}$ and $\bigoplus_{j\in[n]} z_j = 0$. From Lemma 3.5(b), we obtain that

$$\mathcal{U}(p \oplus \lambda \odot q) \subseteq \mathcal{U}\left((A \odot x) \oplus \lambda \odot (A \odot y)\right) = \mathcal{U}(A \odot z) \subseteq \operatorname{tconv}(A) \ . \qquad \blacktriangleleft$$

▶ **Proposition 4.1.** *For $A \in \mathbb{T}^{d\times n}_{\pm}$ and $b \in \mathbb{T}^d_{\pm}$ we have*

$$b \in \operatorname{tconv}(A) \Leftrightarrow \mathit{ker}_+ \begin{pmatrix} A & \ominus b \\ 0 & \ominus 0 \end{pmatrix} \neq \emptyset \ .$$

Proof. The condition $b \in \operatorname{tconv}(A)$ is equivalent to the existence of an element $x \in \mathbb{T}^n_{\geq \mathbb{0}}$ with $\bigoplus_{j\in[n]} x_j = 0$ and $A \odot x \bowtie b$.

Let (x, t) be a vector in the non-negative kernel, where $x \in \mathbb{T}^n_{\geq \mathbb{0}}$ and $t \in \mathbb{T}_{\geq \mathbb{0}}$ denotes the last component. First, we claim that $t \neq \mathbb{0}$. Indeed, $t = \mathbb{0}$ would yield $\bigoplus_{j\in[n]} x_j \bowtie \mathbb{0}$, which implies $x_j = \mathbb{0}$ for all $j \in [n]$. Thus, we obtain $(x, t) = \mathbb{0}$, a contradiction. Since $t \neq \mathbb{0}$, we can scale (x, t) such that $t = 0$. In this case, the definition of the kernel gives $A \odot x \ominus b \bowtie \mathbb{0}$ and $\bigoplus_{j\in[n]} x_j \ominus 0 \bowtie \mathbb{0}$. The latter inequality yields $\bigoplus_{j\in[n]} x_j = 0$. This is the same as the combination witnessing $b \in \operatorname{tconv}(A)$ as above. $\blacktriangleleft$

▶ **Theorem 3.14.** *The signed hull* $\operatorname{tconv}(A)$ *is the union of the signed valuations for all possible lifts*

$$\operatorname{tconv} A = \bigcup_{\operatorname{sval}(\mathbf{A})=A} \operatorname{sval}(\operatorname{conv}(\mathbf{A})) \ .$$

Proof. We start with the inclusion "$\supseteq$". Let $A \in \mathbb{T}^{d\times n}_{\pm}$ and fix a lift $\mathbf{A}$ of A, this means a matrix $\mathbf{A} \in \mathbb{K}^{d\times n}$ with $\operatorname{sval}(\mathbf{A}) = A$. For a vector $\lambda \in \mathbb{K}_{\geq 0}$ with $\sum_{j=1}^n \lambda_i = 1$ the valuation $x = \operatorname{sval}(\lambda)$ is in $\mathbb{T}^n_{\geq \mathbb{0}}$ and fulfills $\bigoplus_{j=1}^n x_i = 0$. We want to show that $b = \operatorname{sval}(\lambda_1 \cdot \mathbf{a^{(1)}} + \cdots + \lambda_n \cdot \mathbf{a^{(n)}}) \in \operatorname{tconv} A$. For each $i \in [d]$, let $c_i = \max\left\{ |\operatorname{sval}(\lambda_j \cdot \mathbf{a_i^{(j)}})| \;\middle|\; j \in [n] \right\}$. Furthermore, we define $p = A \odot x = \bigoplus_{j\in[n]} x_j \odot a^{(j)} = \bigoplus_{j\in[n]} \operatorname{sval}(\lambda_j \cdot \mathbf{a^{(j)}})$. We fix an $i \in [d]$ and we want to show that $b_i \in \mathcal{U}(p_i)$. Note that $|p_i| = c_i$. If p_i is not balanced, we already have $b_i = p_i$. Otherwise, we get $|b_i| \leq c_i$ and consequently $b_i \in [\ominus c_i, c_i]$. This finishes the proof of the inclusion "$\supseteq$".

For the other direction, we fix $b \in \mathcal{U}(A \odot x)$ for some $x \in \mathbb{T}^n_{\geq \mathbb{0}}, \bigoplus_{j\in[n]} x_j = 0$. We define

$$\lambda_j = t^{x_j} \cdot \left(\sum_{k\in[n]} t^{x_k} \right)^{-1} \qquad \text{for each } j \in [n] \ .$$

With this, we get $\lambda \geq 0$ and $\sum_{k\in[n]} \lambda_k = 1$.

For each row $i \in [d]$, we denote by J_i^+ the set of indices of the positive elements in the set $\operatorname{argmax}\left\{ a_j^{(i)} \odot x_j \;\middle|\; j \in [n] \right\}$, and by J_i^- analogously for negative elements.

We set ℓ_i to be an arbitrary index in $\operatorname{argmin}\{|J_i^+|, |J_i^-|\}$, and define

$$\mathbf{a_i^{(j)}} = \begin{cases} \operatorname{tsgn}(a_{ij}) t^{|a_{ij}|} + \alpha_i & \text{for } j = \ell_i \\ \operatorname{tsgn}(a_{ij}) t^{|a_{ij}|} & \text{else} \end{cases} ,$$

where

$$\alpha_i = \frac{1}{\lambda_{\ell_i}} \left(- \sum_{k \in [d]} \operatorname{tsgn}(a_{ik}) t^{|a_{ik}|+x_k} + \operatorname{tsgn}(b_i) t^{|b_i|} \right) \quad .$$

Note that $|b_i| \leq |a_{i\ell_i}| + x_{\ell_i}$ and $|a_{ij}| + x_j - x_{\ell_i} \leq |a_{i\ell_i}|$ for all $j \in [n]$. Therefore, $\operatorname{sval}(\mathbf{a_i^{(j)}}) = a_{ij}$ for all $i \in [d]$ and $j \in [n]$. Furthermore, we get

$$\begin{aligned} \mathbf{a_i} \cdot \lambda &= \sum_{k \in [d] \setminus \{\ell_i\}} \lambda_k \mathbf{a_i^{(k)}} + \lambda_{\ell_i} \mathbf{a_i^{(\ell_i)}} \\ &= \sum_{k \in [d]} \operatorname{tsgn}(a_{ik}) t^{|a_{ik}|+x_k} - \sum_{k \in [d]} \operatorname{tsgn}(a_{ik}) t^{|a_{ik}|+x_k} + \operatorname{tsgn}(b_i) t^{|b_i|} \\ &= \operatorname{tsgn}(b_i) t^{|b_i|} \quad . \end{aligned}$$

Hence, we have $\operatorname{sval}(\mathbf{a_i} \cdot \lambda) = b_i$ for all $i \in [d]$. This concludes the proof. ◀

▶ **Proposition 4.8.** *Let $A, B \subset \mathbb{S}$ be two finite sets. There is an element $c \in \mathbb{S}$ with*

$$c \ominus a > \mathbb{0} \text{ and } b \ominus c > \mathbb{0} \text{ for all } a \in A, b \in B \tag{24}$$

if and only if

$$b \ominus a > \mathbb{0} \text{ for all } (a, b) \in A \times B \quad . \tag{25}$$

Furthermore, the element c can chosen to be signed.

Proof. For each pair $(a, b) \in A \times B$, we add the inequalities in (24) using Lemma 2.2 and obtain $b \ominus a \oplus c \ominus c > \mathbb{0}$. This implies $b \ominus a > |c| \geq \mathbb{0}$ and, hence, (25).

For the other direction, note that $A \subset \mathbb{T}_\pm$ or $B \subset \mathbb{T}_\pm$, as two balanced elements are not comparable by ">". Because of the symmetry (9), we can assume that $B \subset \mathbb{T}_\pm$. Let β denote the minimum of B. Furthermore, we define α as the maximum of $A \cap \mathbb{T}_\pm$ and $\{|a| \mid a \in A \cap \mathbb{T}_\bullet\}$, where either of these two sets could also be empty. We obtain from (25) that $\beta > \alpha$, where we use that $b > a \Leftrightarrow b > |a|$ for $a \in \mathbb{T}_\bullet$. An arbitrary element c with $\alpha < c < \beta$ fulfills (24). As the elements in B are totally ordered, the claim for the inequalities involving B follows immediately. Distinguishing the balanced and signed elements yields the claim for the inequalities involving A. ◀

▶ **Proposition 4.10.** *Let $A, B \subset \mathbb{S}$ be two finite sets. There is an element $c \in \mathbb{T}_\pm$ with*

$$c \ominus a \vDash \mathbb{0} \text{ and } b \ominus c \vDash \mathbb{0} \text{ for all } a \in A, b \in B \tag{26}$$

if and only if

$$b \ominus a \vDash \mathbb{0} \text{ for all } (a, b) \in A \times B \quad . \tag{27}$$

Proof. The first direction from (26) to (27) follows from Lemma 2.6(a) and 2.6(c) because of $c \in \mathbb{T}_\pm$.

For the other direction, let

$$\begin{aligned} \alpha_0 &= \operatorname{argmin} \{ |a| \mid a \in A \cap \mathbb{T}_\bullet \} \quad , \\ \alpha_1 &= \max \{ a \mid a \in A \cap \mathbb{T}_\pm \} \quad , \\ \beta_0 &= \operatorname{argmin} \{ |b| \mid b \in B \cap \mathbb{T}_\bullet \} \quad , \\ \beta_1 &= \min \{ b \mid b \in B \cap \mathbb{T}_\pm \} \quad , \end{aligned} \tag{54}$$

with respect to the ordering "$\geq$". By construction, we get from (27) the relation $\beta_1 \ominus \alpha_1 \vDash \mathbb{0}$, which yields $\beta_1 \geq \alpha_1$. Furthermore, we obtain $\beta_1 \ominus \alpha_0 \vDash \mathbb{0}$ implying $\beta_1 \geq \ominus|\alpha_0|$ and $\beta_0 \ominus \alpha_1 \vDash \mathbb{0}$ implying $|\beta_0| \geq \alpha_1$. We conclude that

$$\underline{\beta} := \min(|\beta_0|, \beta_1) \geq \max(\ominus|\alpha_0|, \alpha_1) =: \overline{\alpha} \ ,$$

using also the trivial inequality $|\beta_0| \geq \ominus|\alpha_0|$. Let γ be an arbitrary element in the interval

$$\left\{ x \in \mathbb{T}_\pm \;\middle|\; \underline{\beta} \geq x \geq \overline{\alpha} \right\} \neq \emptyset.$$

By checking all possibilities arising from the list in (54), we see that the element γ fulfills $b \ominus \gamma \vDash \mathbb{0}$ and $\gamma \ominus a \vDash \mathbb{0}$ for all $a \in A, b \in B$. ◀

B Other Notions of Tropical Convexity

Parallel to the development of tropical convexity, the more general notion of $\mathbb{B}$-convexity was developed starting with [15]. The notion of $\mathbb{B}$-convexity boils down to convexity defined over the semiring $\mathbb{R}_{\geq 0}$ with operations "$\oplus$" = "max" and "$\odot$" = "$\cdot$", see [15, Theorem 2.1.1]. Taking logarithms transforms these operations to "$\oplus$" = "max" and "$\odot$" = "$+$" on $\mathbb{R} \cup \{-\infty\}$. This gives rise to a transferred version of $\mathbb{B}$-convexity on $\mathbb{T}_\pm$ by considering the images of $\mathbb{B}$-convex sets in $\mathbb{R}^d$ under the map $\operatorname{slog}\colon x \mapsto \operatorname{sgn}(x)\log(|x|)$.

The following example shows that our notion of signed tropical convexity is an even more restrictive notion than $\mathbb{B}$-convexity and $\mathbb{B}^\sharp$-convex [14].

▶ **Example B.1.** The tropical convex hull of $A = \{(\ominus 2, \ominus 1), (2, 1)\}$ is the set

$$[\ominus 2, 2] \times [\ominus 1, 1] \ .$$

However, the set $\operatorname{Co}^r(A)$ is

$$L = \{\, (2 \odot \lambda, \lambda) \mid \lambda \in [\ominus 1, 1] \} \ .$$

for all $r \in \mathbb{N}$. In particular, also $\operatorname{Co}^\infty(A)$ equals L. This implies that $\mathbb{B}(L) = L$. We depict both in Figure 7. Hence, $\operatorname{tconv}(A)$ strictly contains $\mathbb{B}(A)$. Furthermore, [14, Corollary 4.2.4] shows that L is also $\mathbb{B}^\sharp$-convex.

Interestingly, the set L is also the image under the signed valuation of the set

$$\operatorname{conv}\left(\begin{pmatrix} -t^2 \\ -t \end{pmatrix}, \begin{pmatrix} t^2 \\ t \end{pmatrix} \right) \ .$$

Here, we mean the convex hull over the Puiseux series $R\{\!\{t\}\!\}$. So L is the tropicalization of a single line segment while our hull construction yields the union of line segments whose spanning points tropicalize to A, as we saw in Section 3.2. For example, we get the set $\{\ominus 2\} \times [\ominus 1, 1] \cup [\ominus 2, 2] \times \{1\}$ as the tropicalization of $\operatorname{conv}\left(\begin{pmatrix} -2t^2 \\ -t \end{pmatrix}, \begin{pmatrix} t^2 \\ 2t \end{pmatrix} \right)$.

▶ Remark B.2. It is tempting to define a *cancellative sum* for two numbers $a, b \in \mathbb{T}_\pm$ by

$$a \overline{\oplus} b = \begin{cases} a & |a| > |b| \\ b & |b| > |a| \\ a & a = b \\ \mathbb{0} & a = \ominus b \end{cases} \ .$$

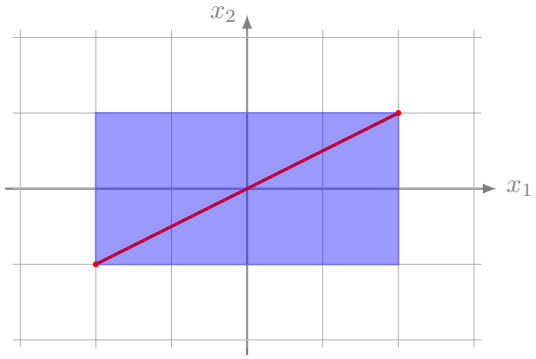

Figure 7 Distinction between $\mathbb{B}$-convex line and tropical line segment through the origin.

This can be extended componentwise to $\mathbb{T}_{\pm}^{d}$.

An iterative version of this construction is used in [14]. A conceptional drawback of the cancellative sum is that it is not associative, as the example

$$0 \,\overline{\oplus}(\ominus 0 \,\overline{\oplus}\, -1) = 0 \,\overline{\oplus} \ominus 0 = \mathbb{0} \neq -1 = \mathbb{0} \,\overline{\oplus}\, -1 = (0 \,\overline{\oplus} \ominus 0) \,\overline{\oplus}\, -1$$

shows.

▶ Remark B.3. Recall that Theorem 6.4 gave a way to determine the whole tropical convex hull from the tropical convex hull in each orthant. For sufficiently generic matrices, one can use the cancellative sum from Remark B.2. If there are no antipodal points, no balanced coefficients arise in the elimination and the map ξ used for Theorem 4.12 is just the identity. Hence, the iterative construction of a single intersection point with a coordinate hyperplane suffices.

Distributional Property Testing in a Quantum World

Abstract

A fundamental problem in statistics and learning theory is to test properties of distributions. We show that quantum computers can solve such problems with significant speed-ups. We also introduce a novel access model for quantum distributions, enabling the coherent preparation of quantum samples, and propose a general framework that can naturally handle both classical and quantum distributions in a unified manner. Our framework generalizes and improves previous quantum algorithms for testing closeness between unknown distributions, testing independence between two distributions, and estimating the Shannon / von Neumann entropy of distributions. For classical distributions our algorithms significantly improve the precision dependence of some earlier results. We also show that in our framework procedures for classical distributions can be directly lifted to the more general case of quantum distributions, and thus obtain the first speed-ups for testing properties of density operators that can be accessed coherently rather than only via sampling.

1 Introduction

Distributional property testing is a fundamental problem in theoretical computer science (see, e.g. [22]) aiming at determining properties of probability distributions with the least number of independent samples. It has intimate connections and applications to statistics, learning theory, and algorithm design.

The merit of distributional property testing mainly comes from the fact that the testing of many properties admits *sublinear* algorithms. For instance, given the ability to take samples from a discrete distribution p on $[n] := \{1, \ldots, n\}$, it requires $\Theta(n/\epsilon^2)$ samples to "learn" p,

i.e., to construct a distribution q on $[n]$ such that $\|p-q\|_1 \leq \epsilon$ with success probability at least $2/3$ ($\|\cdot\|_1$ being ℓ^1-distance). However, testing whether $p=q$ or $\|p-q\|_1 > \epsilon$ requires only $\Theta(\max\{\frac{n^{2/3}}{\epsilon^{4/3}}, \frac{n^{1/2}}{\epsilon^2}\})$ samples from p and q [19], which is sublinear in n and significantly smaller than the complexity of learning the entire distributions. See Section 1.4 for more examples and discussions.

In this paper, we study the impact of quantum computation on distributional property testing problems. We are motivated by the emerging topic of "quantum property testing" (see the survey of [30]) which focuses on investigating the quantum advantage in testing classical statistical properties. Quantum speed-ups have already been established for a few specific problems such as testing closeness between distributions [13, 29], testing identity to known distributions [18], estimating entropies [27], etc. In this paper we propose a generic approach for quantum distributional property testing, and illustrate its power on a few examples. This is our attempt to make progress on the question:

Can quantum computers test properties of distributions systematically and more efficiently?

1.1 Problem statements

Throughout the paper, we denote probability distributions on $[n]$ by p and q; their ℓ^α-distance is defined as $\|p-q\|_\alpha := (\sum_{i=1}^n |p_i - q_i|^\alpha)^{\frac{1}{\alpha}}$. Similarly, we denote $n \times n$ density operators[1] (i.e., quantum distributions) by ρ and σ; their ℓ^α-distance is defined via the corresponding Schatten norm.

Input models. To formulate the problems we address, we define classical and quantum access models for distributions on $[n]$. We begin with the very natural model of sampling.

▶ **Definition 1** (Sampling). *A classical distribution $(p_i)_{i=1}^n$ is accessible via* classical sampling *if we can request independent samples from the distribution, i.e., get a random $i \in [n]$ with probability p_i. A quantum distribution $\rho \in \mathbb{C}^{n\times n}$ is accessible via* quantum sampling *if we can request independent copies of the state ρ.*

Now we define a coherent analogue of the above sampling model. To our knowledge this type of query-access was only studied by a few earlier works [29, 24] and only in the special case of classical distributions. The motivation for this input model is the following: we can think about a density operator as the outcome of some physical process modeled by some black-box. Suppose that the black-box can generate samples on demand. Unlike in the classical (randomized) setting, in a quantum scenario in principle it is always possible to reverse every computational / physical process – including this black-box. If reversion is not feasible, then we get the plain sampling model; however if it is possible to reverse the (quantum) black-box then we get the purified query access model that we describe. For example, if a quantum computer produces the samples via, say, a Monte Carlo method, then the process is easily reversible. However, if the samples come from some source "outside the lab", then reversing the process might not be possible. Therefore, both input models (purified quantum query access and sampling access) are well-motivated. The surprising fact is that this subtle difference in the input models gives rise to significantly different complexities, as we show later for several problems.

[1] For readers less familiar with quantum computing, a density operator (=quantum distribution) $\rho \in \mathbb{C}^{n\times n}$ is a positive semidefinite matrix with $\mathrm{Tr}[\rho] = 1$. Please refer to the textbook [31] for more information.

▶ **Definition 2** (Purified quantum query-access). *A density operator $\rho \in \mathbb{C}^{n\times n}$, has* purified quantum query-access *if we have access to a unitary oracle U_ρ (and its inverse) acting as*[2]

$$U_\rho|0\rangle_A|0\rangle_B = |\psi_\rho\rangle_{AB} = \sum_{i=1}^{n} \sqrt{p_i}|\phi_i\rangle_A|\psi_i\rangle_B, \text{ (where } \langle\phi_i|\phi_j\rangle = \langle\psi_i|\psi_j\rangle = \text{(Kronecker) } \delta_{ij})$$

such that $\mathrm{Tr}_A(|\psi_\rho\rangle\langle\psi_\rho|) = \rho$. If $|\psi_i\rangle = |i\rangle$, then $\rho = \sum_i^n p_i|i\rangle\langle i|$ is a diagonal density operator which can be identified with the classical distribution p, so we can simply write U_p instead of U_ρ. With a slight abuse of notation sometimes we will concisely write $|\rho\rangle$ instead of $|\psi_\rho\rangle$.

We also define an even stronger input model that is considered in a series of earlier works, see, e.g., [13, 18, 27, 15].

▶ **Definition 3** (Classical distribution with discrete query-access). *A classical distribution $(p_i)_{i=1}^n$, has* discrete query-access *if we have classical / quantum query-access to a function $f\colon S \to [n]$ such that for all $i \in [n]$, $p_i = |\{s \in [S] : f(s) = i\}|/|S|$. (Typically the interesting regime is when $|S| \gg n$.) In the quantum case a query oracle is a unitary operator O acting on $\mathbb{C}^{|S|} \otimes \mathbb{C}^n$ as*

$$\mathrm{O}\colon |s, 0\rangle \leftrightarrow |s, f(s)\rangle \text{ for all } s \in S.$$

Note that if one first creates a uniform superposition over S and then makes a query, then the above oracle turns into a purified query oracle to a classical distribution as in Definition 2. Therefore all lower bounds that are proven in this model also apply to the purified query-access oracles. In fact all algorithms that the authors are aware of do this conversion, so they effectively work in the purified query-access model. Moreover, we conjecture that the two input models are equivalent when $|S| \gg n$. For this reason we only work with the purified query-access model in this work.

Another strengthening of the purified query-access model for classical distributions is when we assume access to a unitary (and its inverse) acting as $|0\rangle \mapsto \sum_{i=1}^n \sqrt{p_i}|i\rangle$. A very similar input model was thoroughly studied by [4].

▶ **Definition 4** (Classical distribution with pure-state preparation access). *A classical distribution $(p_i)_{i=1}^n$, is accessible via* pure state preparation oracle *if we have access to a unitary oracle U_{pure} (and its inverse) acting as*

$$U_{\mathrm{pure}}\colon |0\rangle \mapsto \sum_{i=1}^{n} \sqrt{p_i}|i\rangle.$$

This is strictly stronger[3] than the purified query-access model. In order to simulate purified queries we can first do a pure state query and then copy $|i\rangle$ to a second fresh ancillary

[2] $|\psi\rangle \in \mathbb{C}^n$ denotes a "ket" vector and $\langle\psi| = (|\psi\rangle)^\dagger$ stands for its conjugate transpose, called "bra" in Dirac notation; $|i\rangle = \vec{e}_i$ is the i^{th} basis vector. An ℓ^2-normalized $|\psi\rangle$ is called a pure state, and corresponds to density operator $|\psi\rangle\langle\psi|$. For $A = \mathbb{C}^k, B = \mathbb{C}^n$ and $|\phi\rangle \in A\otimes B$ we denote by $\mathrm{Tr}[|\phi\rangle\langle\phi|]_A \in B\otimes B^* = \mathbb{C}^{n\times n}$ the partial trace over A.

[3] This can be seen in various ways. We give an argument in the spirit of distributional property testing. Closeness of two unknown distributions p, q can be tolerantly tested in the squared Hellinger distance $H(p,q)^2 = \frac{1}{2}\left\|\sqrt{p} - \sqrt{q}\right\|_2^2$ to precision ϵ in query complexity $\mathcal{O}\left(1/\sqrt{\epsilon}\right)$ in the model of Definition 4 using amplitude estimation. On the other hand the classical sample complexity of testing equality to ϵ precision in this metric is $\widetilde{\Theta}(\min(n^{2/3}/\epsilon^{4/3}, n^{3/4}/\epsilon))$, as shown in [20]. The results of Chailloux [16] imply that this query complexity improves at most cubically in the model of Definition 2, showing that the input model of Definition 4 is strictly stronger.

register using, e.g., some CNOT gates. Finally, for completeness we mention that one could also consider a model similar to the above where one can only request samples of pure states of the form $\sum_{i=1}^{n} \sqrt{p_i}|i\rangle$, as studied for example in [6, 5].

We will mostly focus on the first two input models and will only use the latter strengthenings of the purified query-access model for invoking and proving lower bounds.

Property testing problems. We study three distributional properties: ℓ^α-closeness testing, independence testing, and entropy estimation. In the classical literature these are well-studied properties, and the corresponding testers motivate general algorithms for testing properties of discrete distributions [20, 1].

For brevity we only give the definitions for classical distributions; similar definitions apply to quantum density matrices if we replace vector norms by the corresponding Schatten norms.

▶ **Definition 5** (ℓ^α-closeness testing). *Given $\epsilon > 0$ and two probability distributions p, q on $[n]$,* ℓ^α-closeness testing *is to decide whether $p = q$ or $\|p-q\|_\alpha \geq \epsilon$ with success probability at least $\frac{2}{3}$. Tolerant testing: decide whether $\|p-q\|_\alpha \leq 0.99\epsilon$ or $\|p-q\|_\alpha \geq \epsilon$ with success probability at least $\frac{2}{3}$.*

▶ **Definition 6** (Independence testing). *Given $\epsilon > 0$ and a probability distribution p on $[n] \times [m]$ with $n \geq m$,* independence testing *is to decide, with success probability at least $\frac{2}{3}$, whether p is a product distribution or p is ϵ-far in ℓ^1-norm from any product distribution on $[n] \times [m]$.*

▶ **Definition 7** (Entropy estimation). *Given $\epsilon > 0$ and a density operator $\rho \in \mathbb{C}^{n \times n}$,* entropy estimation *is to estimate the Shannon / von Neumann entropy $H(\rho) = -\mathrm{Tr}[\rho \log(\rho)]$ within additive ϵ-precision with success probability at least $\frac{2}{3}$.*

1.2 New results

We give a systematic study of distributional property testing for classical / quantum distributions, and obtain the following results for the purified quantum query model of Definition 2:

- Entropy estimation of classical / quantum distributions costs $\widetilde{\mathcal{O}}\left(\frac{\sqrt{n}}{\epsilon^{1.5}}\right)$ and $\widetilde{\mathcal{O}}\left(\frac{n}{\epsilon^{1.5}}\right)$ queries respectively,[4] as we prove in Theorem 12 and Theorem 13.
- Tolerant ℓ^2-closeness testing of classical / quantum distributions costs $\tilde{\Theta}\left(\frac{1}{\epsilon}\right)$ and $\mathcal{O}\left(\min\left(\frac{\sqrt{n}}{\epsilon}, \frac{1}{\epsilon^2}\right)\right)$ queries respectively, as we prove in Theorem 14 and Theorem 15.
- ℓ^1-closeness testing of classical / quantum distributions costs $\widetilde{\mathcal{O}}\left(\frac{\sqrt{n}}{\epsilon}\right)$ and $\mathcal{O}\left(\frac{n}{\epsilon}\right)$ queries respectively, as we prove in Corollary 17.
- Independence testing of classical / quantum distributions costs $\widetilde{\mathcal{O}}\left(\frac{\sqrt{nm}}{\epsilon}\right)$ and $\mathcal{O}\left(\frac{nm}{\epsilon}\right)$ queries respectively, as we prove in Corollary 18.

For context, we compare our results with previous classical and quantum results in Table 1 and Table 2. (Note that all of our results are gate efficient, because they are based on singular value transformation and amplitude estimation, both of which have gate-efficient implementations.)

---

[4] Throughout the paper, we use $\widetilde{\mathcal{O}}$ to omit poly-logarithmic factors in $\mathcal{O}$, i.e., $\widetilde{\mathcal{O}}(T) = \mathcal{O}(T \,\mathrm{poly}(\log T))$.
[5] Recent results of [16] imply that in this model quantum speed-ups are at most cubic.

Table 1 Summary of sample and query complexity results. Our new bounds are printed in **bold**. For classical distributions with quantum query-access[5] we prove (almost) matching upper and lower bounds for ℓ^2-testing, and improve the previous best complexity $\widetilde{\mathcal{O}}\left(\sqrt{n}/\epsilon^{2.5}\right)$ for ℓ^1-testing by [29] and $\widetilde{\mathcal{O}}\left(\sqrt{n}/\epsilon^{2}\right)$ for Shannon entropy estimation by [27]. We are not aware of prior work on testing quantum distributions with purified query-access.

Classical distribution sampling	$\Theta\left(\max\left\{\frac{n^{2/3}}{\epsilon^{4/3}}, \frac{n^{1/2}}{\epsilon^2}\right\}\right)$ [19]	$\Theta\left(\frac{1}{\epsilon^2}\right)$ [19]	$\Theta\left(\frac{n}{\epsilon \log n} + \frac{\log^2 n}{\epsilon^2}\right)$ [25, 42]
Classical distribution with purified query-access	$\widetilde{\boldsymbol{\mathcal{O}}}\left(\frac{\sqrt{n}}{\epsilon}\right)$	$\widetilde{\boldsymbol{\Theta}}\left(\frac{1}{\epsilon}\right)$	$\widetilde{\boldsymbol{\mathcal{O}}}\left(\frac{\sqrt{n}}{\epsilon^{1.5}}\right)$; $\tilde{\Omega}(\sqrt{n})$ [15]
Quantum state with purified query-access	$\boldsymbol{\mathcal{O}}\left(\frac{n}{\epsilon}\right)$	$\boldsymbol{\mathcal{O}}\left(\mathbf{min}\left(\frac{\sqrt{n}}{\epsilon}, \frac{1}{\epsilon^2}\right)\right)$	$\widetilde{\boldsymbol{\mathcal{O}}}\left(\frac{n}{\epsilon^{1.5}}\right)$
Quantum state sampling	$\Theta\left(\frac{n}{\epsilon^2}\right)$ [7]	$\Theta\left(\frac{1}{\epsilon^2}\right)$ [7]	$\mathcal{O}\left(\frac{n^2}{\epsilon^2}\right)$, $\Omega\left(\frac{n^2}{\epsilon}\right)$ [3]

As we show our quantum algorithms for classical distributional property testing problems with purified access can be naturally lifted to the case of quantum distributions, incurring an overhead of $\approx \sqrt{n}$, which is manifested in the complexities of Table 1.

Table 2 Complexities of Shannon / von Neumann entropy estimation with constant precision. It seems that the n-dependence is roughly quadratically higher for quantum distributions, while coherent quantum access gives a quadratic advantage for both classical and quantum distributions. This suggests that our entropy estimation algorithm has essentially optimal n-dependence for density operators with purified access, however we do not have a matching lower bound yet.

	Sample complexity	(Purified) Query complexity
Classical	$\Theta\left(\frac{n}{\log n}\right)$ [40]	$\widetilde{\Theta}\left(\sqrt{n}\right)$ [27, 15]
Quantum	$\Theta\left(n^2\right)$ [3]	$\widetilde{\boldsymbol{\mathcal{O}}}(\boldsymbol{n})$

1.3 New techniques

The motivating idea behind our approach is that if we can prepare a purification of a quantum distribution / density operator ρ, then we can construct a unitary U, which has this density operator in the top-left corner, using only two queries to U_ρ. This observation is due to [28]. We call such a unitary a *block-encoding* of ρ:

$$U = \begin{bmatrix} \rho & \cdot \\ \cdot & \cdot \end{bmatrix} \quad \Longleftrightarrow \quad \rho = \left(\langle 0|^{\otimes a} \otimes I\right) U \left(|0\rangle^{\otimes a} \otimes I\right).$$

One can think of a block-encoding as a post-selective implementation of the linear map ρ: given an input state $|\psi\rangle$, applying the unitary U to the state $|0\rangle^{\otimes a}|\psi\rangle$, measuring the first a-qubit register and post-selecting on the $|0\rangle^{\otimes a}$ outcome, we get a state $\propto \rho|\psi\rangle$ in the second register. Block-encodings are easy to work with, for example given a block-encoding of ρ and σ we can easily construct a block-encoding of $(\rho - \sigma)/2$, see for example in the work of [17].

Example application to ℓ^3-testing. The problem is to decide whether $\rho = \sigma$ or $\|\rho - \sigma\|_3 \geq \epsilon$, with query complexity $\mathcal{O}\left(\epsilon^{-\frac{3}{2}}\right)$. The first idea is that if we can prepare a purification of ρ and σ, then we can also prepare a purification of $(\rho + \sigma)/2$ by setting a qubit to the state

$(|0\rangle + |1\rangle)/\sqrt{2}$, and then controlled on the $|0\rangle$ or $|1\rangle$ value of the qubit run the process that samples from ρ or σ, respectively. The second idea is to combine the block-encodings of ρ and σ to apply the map $\frac{\rho-\sigma}{2}$ to the purification of $(\rho+\sigma)/2$, to get

$$\left|\frac{\rho+\sigma}{2}\right\rangle \mapsto \left(\frac{\rho-\sigma}{2}\otimes I\right)\left|\frac{\rho+\sigma}{2}\right\rangle|0\rangle + \ldots|1\rangle.$$

Finally, apply amplitude estimation with setting $M = \Theta(\epsilon^{-\frac{3}{2}})$. This works since if $\|\rho-\sigma\|_3 \geq \epsilon$, then the $|0\rangle$ ancilla state has probability $\mathrm{Tr}\big[(\rho-\sigma)^2(\rho+\sigma)\big]/8 \geq \mathrm{Tr}\big[|\rho-\sigma|^3\big]/8 \geq \epsilon^3/8$.

Working with singular values. The above is a promising approach because it directly makes the density operator in question operationally accessible. However, it turns out that using this simple block-encodings is often suboptimal for distribution testing, because a query in some sense gives access to the square-root of ρ, whereas this unitary has ρ itself in the top-left corner. Since the problems often heavily depend on smaller eigenvalues of ρ, the square root of ρ is more desirable since it has quadratically larger singular/eigenvalues.

One of our main technical contributions is to use a new type of block-encoding, which is a unitary matrix having a certain block proportional to a matrix A such that $A^\dagger A = \rho$, i.e., we use a "square-root" of the (quantum) distribution ρ (in the case of classical distributions rho is a diagonal matrix with the probabilities as diagonal entries). This new technique allows us to develop a unified approach for distributional property testing, which we consider one of our major contributions. It is this new perspective that enables us to derive several results in a relatively short paper. Once we establish this methodology the results are relatively easy to derive in a systematic way, both for classical and quantum distributions.

Therefore, we show how to efficiently construct a unitary matrix whose top-left corner contains a matrix with singular values $\sqrt{p_1}, \ldots, \sqrt{p_n}$, given purified access to a classical distribution p. To be more precise, we define a slight generalization of block-encodings called *projected unitary encodings*, which represent a matrix A in the form of $\Pi U \widetilde{\Pi}$, where $\Pi, \widetilde{\Pi}$ are orthogonal projectors and U is a unitary matrix. One can think about U in a projected unitary encoding as a post-selective implementation of the map $A\colon \mathrm{img}\left(\widetilde{\Pi}\right) \to \mathrm{img}(\Pi)$. Take for example $U := (U_p \otimes I)$, $\Pi := (\sum_{i=1}^n I \otimes |i\rangle\langle i| \otimes |i\rangle\langle i|)$, and $\widetilde{\Pi} := (|0\rangle\langle 0| \otimes |0\rangle\langle 0| \otimes I)$. As we show in Appendix A these operators form a projected unitary encoding of

$$A = \Pi U \widetilde{\Pi} = \sum_{i=1}^{n} \sqrt{p_i}|\phi_i\rangle\langle 0| \otimes |i\rangle\langle 0| \otimes |i\rangle\langle i|. \tag{1}$$

We can use a similar trick for a general density operator ρ too. However, there is a major difficulty which arises from the fact that we do not a prioiri know the diagonalizing basis of ρ. Therefore we use slightly different operators. Let W be a unitary,[6] mapping $|0\rangle|0\rangle \mapsto \sum_{j=1}^n \frac{|j\rangle|j\rangle}{\sqrt{n}}$. Let $U' := \big(I \otimes U_\rho^\dagger\big)\big(W^\dagger \otimes I\big)$, $\Pi' := (I \otimes |0\rangle\langle 0| \otimes |0\rangle\langle 0|)$ and $\widetilde{\Pi}$ as above. As we show in Appendix A these operators form a projected unitary encoding of

$$A' = \Pi' U' \widetilde{\Pi} = \sum_{i=1}^{n} \sqrt{\frac{p_i}{n}}|\phi_i'\rangle\langle 0| \otimes |0\rangle\langle 0| \otimes |0\rangle\langle \psi_i|, \tag{2}$$

where $\sum_{j=1}^n \frac{|\phi_j'\rangle|\phi_j\rangle}{\sqrt{n}} = \sum_{j=1}^n \frac{|j\rangle|j\rangle}{\sqrt{n}}$ is the Schmidt decomposition of the maximally entangled state under the basis $(|\phi_1\rangle, \ldots, |\phi_n\rangle)$.

[6] This unitary is easy to implement, e.g., by using a few Hadamard and CNOT gates.

As we can see, the case of general density operators is less efficient, it only gives operational access to the "square root" of ρ/n. We note that for (approximately) transforming a block-encoding of $A/\sqrt{n}$ to a block-encoding of $A/\mathcal{O}(1)$ it is necessary and sufficient to use the block-encoding of $A/\sqrt{n}$ about $\sqrt{n}$ times [21, Theorems 3&17]. This is essentially the reason for the $\approx\sqrt{n}$ overhead in our quantum algorithms for quantum distributions in Table 1. If the $1/\sqrt{n}$ factor could be directly improved, that would speed up our von Neumann entropy estimation algorithm Theorem 13, which seems unlikely, cf. Table 2. This suggests that it is impossible to obtain a more efficient block-encoding in the general case.

General recipe. We summarize our recipe to distributional property testing as follows.

1. Construct quantum circuit / unitary matrix operationally representing the distribution.
2. Transform the singular values of the corresponding matrix according to a desired function.
3. Apply the resulting map to the purification of the distribution, or another suitable state.
4. Estimate the amplitude of the flagged output state and conclude.

The above general scheme describes our approach to the problems we discuss in this paper. Sometimes it is useful to divide the probabilities / singular values into bins, and fine-tune the algorithm by using the approximate knowledge of the size of the singular values. This divide-and-conquer strategy is at the core of our improved tolerant ℓ^2-closeness tester of Theorem 14.

1.4 Related works on distributional property testing

Classical algorithms. Many distributional property testing problems fall into the category of *closeness testing*, where we are given the ability to take independent samples from two unknown distributions p and q with cardinality n, and the goal is to determine whether they are the same versus significantly different. For ℓ^1*-closeness testing*, which is about testing whether $p=q$ or $\|p-q\|_1\geq\epsilon$, [10] first gave a sublinear algorithm using $\tilde{O}(n^{2/3}/\epsilon^{8/3})$ samples to p and q. The follow-up work by [19] determined the optimal sample complexity as $\Theta(\max\{\frac{n^{2/3}}{\epsilon^{4/3}},\frac{n^{1/2}}{\epsilon^2}\})$; the same paper also gave a tight bound $\Theta(\frac{1}{\epsilon^2})$ for ℓ^2*-closeness testing*.

Besides closeness testing, a similar problem is *identity* testing where one of the distributions, say q, is known and we are given independent samples from the other distribution p. For ℓ^1 *identity testing*, it is known that the sample complexity can be smaller than that of ℓ^1-closeness testing, which was proved by [9] to be $\tilde{O}(\sqrt{n}/\epsilon^4)$ and then [37] gave the tight bound $\Theta(\sqrt{n}/\epsilon^2)$. More recently, Ref. [20] proposed a modular reduction-based approach for distributional property testing problems, which recovered all closeness and identity testing results above. Furthermore, they also studied *independence testing* (see also the previous studies by [9, 26, 2]), i.e., whether a distribution on $[n]\times[m]$ $(n\geq m)$ is a product distribution or at least ϵ-far in ℓ^1-distance from any product distribution, and determined the optimal bound $\Theta(\max\{\frac{n^{2/3}m^{1/3}}{\epsilon^{4/3}},\frac{(nm)^{1/2}}{\epsilon^2}\})$.

Apart from the relationship between distributions, properties of a single distribution also have been extensively studied. One of the most important properties is *Shannon entropy* [39] because it measures for example compressibility. The sample complexity of estimating $H(p)$ within additive error ϵ has been intensively studied [8, 35, 36]; in particular, [40, 41] gave an explicit algorithm for entropy estimation using $\Theta(\frac{n}{\epsilon\log n})$ samples when $\epsilon=\Omega(n^{-0.03})$ and $\epsilon=O(1)$; for the general case [25] and [42] gave the optimal estimator with $\Theta\left(\frac{n}{\epsilon\log n}+\frac{(\log n)^2}{\epsilon^2}\right)$ samples.

Quantum algorithms. The first paper on distributional property testing by quantum algorithms was by [13], which considered classical distributions with discrete quantum query-access (see Definition 3); it gives a quantum query complexity upper bound $O(\sqrt{n}/\epsilon^6)$ for ℓ^1-closeness testing and $O(n^{1/3}/\epsilon^{4/3})$ for identity testing to the uniform distribution on $[n]$. Subsequently, [18] gave an algorithm for identity testing (to an arbitrary known distribution) with $\widetilde{\mathcal{O}}\big(n^{1/3}/\epsilon^5\big)$ queries, and [29] improved the ϵ-dependence of ℓ^1-closeness testing to $\widetilde{\mathcal{O}}\big(\sqrt{n}/\epsilon^{2.5}\big)$. More recently, [27] studied entropy estimation under this model, and gave a quantum algorithm for Shannon entropy estimation with $\widetilde{\mathcal{O}}\big(\sqrt{n}/\epsilon^2\big)$ queries and also sublinear quantum algorithms for estimating Rényi entropies ([38]).

Another type of quantum property testing results ([32, 33, 34, 3, 7, 23]) concern *density matrices*, where the ℓ^1-distance becomes the trace distance and the Shannon entropy becomes the von Neumann entropy. To be more specific, for n-dimensional density matrices, the number of samples needed for ℓ^1 and ℓ^2-closeness testing are $\Theta(n/\epsilon^2)$ and $\Theta(1/\epsilon^2)$ ([7]), respectively. In addition [3] gave upper and lower bounds $\mathcal{O}\big(n^2/\epsilon^2\big), \Omega\big(n^2/\epsilon\big)$ for estimating the von Neumann entropy of an n-dimensional density matrix with accuracy ϵ.

1.5 Organization of the paper

The rest of the paper is organized as follows. In Section 2 we introduce two important quantum algorithmic techniques, amplitude estimation and singular value transformation. We give entropy estimators of classical and quantum distributions in Section 3. In Section 4 we give an (essentially) optimal quantum algorithm for tolerantly testing ℓ^2-closeness of classical distributions, and another efficient tolerant ℓ^2-closeness tester for quantum distributions. Proof details of projected encodings, polynomial approximations for singular value transformation, and corollaries about ℓ^1-closeness and independence testing are deferred to Appendix A, B, and C respectively.

2 Preliminaries

2.1 Amplitude estimation

Classically, given i.i.d. samples of a Bernoulli random variable X with $\mathbb{E}[X] = p$, it takes $\Theta(1/\epsilon^2)$ samples to estimate p within ϵ with high success probability. Quantumly, if we are given a unitary U such that

$$U|0\rangle|0\rangle = \sqrt{p}|0\rangle|\phi\rangle + |0^\perp\rangle, \quad \text{where } \||\phi\rangle\| = 1 \text{ and } (\langle 0| \otimes I)|0^\perp\rangle = 0, \tag{3}$$

then if measure the output state, we get 0 in the first register with probability p. Given access to U we can estimate the value of p quadratically more efficiently than what is possible by sampling:

▶ **Theorem 8** ([12, Theorem 12]). *Given U satisfying (3), the amplitude estimation algorithm outputs $\tilde{p}$ such that $\tilde{p} \in [0, 1]$ and*

$$|\tilde{p} - p| \leq \frac{2\pi\sqrt{p(1-p)}}{M} + \frac{\pi^2}{M^2} \tag{4}$$

with success probability at least $8/\pi^2$, using M calls to U and $U^\dagger$.

In particular, if we take $M = \left\lceil 2\pi\left(\frac{2\sqrt{p}}{\epsilon} + \frac{1}{\sqrt{\epsilon}}\right)\right\rceil = \Theta\left(\frac{\sqrt{p}}{\epsilon} + \frac{1}{\sqrt{\epsilon}}\right)$ in (4), we have

$$|\tilde{p} - p| \leq \frac{2\pi\sqrt{p(1-p)}}{2\pi}\epsilon + \frac{\pi^2}{4\pi^2}\epsilon^2 \leq \frac{\epsilon}{2} + \frac{\epsilon}{4} \leq \epsilon.$$

Therefore, using only $\Theta(1/\epsilon)$ implementations of U and $U^\dagger$, we could get an ϵ-additive approximation of p with success probability at least $8/\pi^2$, which is a quadratic speed-up compared to the classical sample complexity $\Theta(1/\epsilon^2)$. The success probability can be boosted to $1-\nu$ by executing the algorithm for $\Theta(\log 1/\nu)$ times and taking the median of the estimates.

2.2 Quantum singular value transformation

Singular value decomposition (SVD) is one of the most important tools in linear algebra, generalizing eigen-decomposition of Hermitian matrices. Recently, [21] proposed *quantum singular value transformation* which turns out to be very useful for property testing. Mathematically, it is defined as follows:

▶ **Definition 9** (Singular value transformation). *Let $f:\mathbb{R}\to\mathbb{C}$ be an even or odd function. Let $A\in\mathbb{C}^{\tilde{d}\times d}$ have the following singular value decomposition*

$$A=\sum_{i=1}^{d_{\min}}\varsigma_i|\tilde{\psi}_i\rangle\langle\psi_i|,$$

where $d_{\min}:=\min(d,\tilde{d})$. For the function f we define the singular value transform *of A as*

$$f^{(SV)}(A):=\begin{cases}\sum_{i=1}^{d_{\min}}f(\varsigma_i)|\tilde{\psi}_i\rangle\langle\psi_i| & \text{if } f \text{ is odd, and}\\ \sum_{i=1}^{d}f(\varsigma_i)|\psi_i\rangle\langle\psi_i| & \text{if } f \text{ is even, where for } i\in[d]\setminus[d_{\min}] \text{ we define } \varsigma_i:=0.\end{cases}$$

Quantum singular value transformation by real polynomials can be efficiently implemented on a quantum computer as follows:

▶ **Theorem 10** ([21, Corollary 18]). *Let $\mathcal{H}_U$ be a finite-dimensional Hilbert space and let $U,\Pi,\widetilde{\Pi}\in\mathrm{End}(\mathcal{H}_U)$ be linear operators on $\mathcal{H}_U$ such that U is a unitary, and $\Pi,\widetilde{\Pi}$ are orthogonal projectors. Suppose that $P=\sum_{k=0}^{n}a_kx^k\in\mathbb{R}[x]$ is a degree-n polynomial such that*

- *$a_k\neq 0$ only if $k\equiv n \mod 2$, and*
- *for all $x\in[-1,1]$: $|P(x)|\leq 1$.*

Then there exist $\Phi\in\mathbb{R}^n$, such that

$$P^{(SV)}\Big(\widetilde{\Pi}U\Pi\Big)=\begin{cases}\Big(\langle+|\otimes\widetilde{\Pi}\Big)\Big(|0\rangle\langle 0|\otimes U_\Phi+|1\rangle\langle 1|\otimes U_{-\Phi}\Big)\Big(|+\rangle\otimes\Pi\Big) & \text{if } n \text{ is odd, and}\\ \Big(\langle+|\otimes\Pi\Big)\Big(|0\rangle\langle 0|\otimes U_\Phi+|1\rangle\langle 1|\otimes U_{-\Phi}\Big)\Big(|+\rangle\otimes\Pi\Big) & \text{if } n \text{ is even,}\end{cases}$$

where $U_\Phi=e^{i\phi_1(2\widetilde{\Pi}-I)}U\prod_{j=1}^{(n-1)/2}\Big(e^{i\phi_{2j}(2\Pi-I)}U^\dagger e^{i\phi_{2j+1}(2\widetilde{\Pi}-I)}U\Big)$.[7]

Thus for an even or odd polynomial P of degree n, we can apply singular value transformation of the matrix $\widetilde{\Pi}U\Pi$ with n uses of U, $U^\dagger$ and the same number of controlled reflections $I-2\Pi, I-2\widetilde{\Pi}$.

To apply singular value transformation corresponding to our problems, we need low-degree polynomial approximations to the following functions, which we construct in Appendix B.

[7] This is the mathematical form for odd n; even n is defined similarly.

▶ **Lemma 11.** (Polynomial approximations) *Let $\beta \in (0,1]$, $\eta \in (0, \frac{1}{2}]$ and $t \geq 1$. There exists polynomials $\tilde{P}, \tilde{Q}, \tilde{S}$ such that*

- $\forall x \in [\frac{1}{t}, 1]\colon |\tilde{P}(x) - \frac{1}{2tx}| \leq \eta$, *and* $\forall x \in [-1,1]\colon -1 \leq \tilde{P}(x) = \tilde{P}(-x) \leq 1$,
- $\forall x \in [-\frac{1-\beta}{t}, \frac{1-\beta}{t}]\colon |\tilde{Q}(x) - tx| \leq \eta \cdot (tx)$, *and* $\forall x \in [-1,1]\colon \tilde{Q}(x) = -\tilde{Q}(-x) \leq 1$,
- $\forall x \in [\beta, 1]\colon |\tilde{S}(x) - \frac{\ln(1/x)}{2\ln(2/\beta)}| \leq \eta$, *and* $\forall x \in [-1,1]\colon -1 \leq \tilde{S}(x) = \tilde{S}(-x) \leq 1$,

moreover $\deg(\tilde{P}) = \mathcal{O}\Big(t \log\Big(\frac{1}{\eta}\Big)\Big)$, $\deg(\tilde{Q}) = \mathcal{O}\Big(\frac{t}{\beta} \log\Big(\frac{1}{\eta}\Big)\Big)$, *and* $\deg(\tilde{S}) = \mathcal{O}\Big(\frac{1}{\beta} \log\Big(\frac{1}{\eta}\Big)\Big)$.

3 Entropy estimation

3.1 Classical distributions with purified quantum query-access

Recall that we introduced purified quantum query-access in Definition 2. In particular, for a classical distribution p on $[n]$, we are given a unitary U_p acting on $\mathbb{C}^{n \times n}$ such that

$$U_p|0\rangle_A|0\rangle_B = |\psi_p\rangle = \sum_{i=1}^{n} \sqrt{p_i}|\phi_i\rangle_A|i\rangle_B. \tag{5}$$

We use U_p and $U_p^\dagger$ to estimate the Shannon entropy $H(p)$:

▶ **Theorem 12.** *For any $0 < \epsilon < 1$, we can estimate $H(p)$ with accuracy ϵ with success probability at least $2/3$ using $\mathcal{O}\Big(\frac{\sqrt{n}}{\epsilon^{1.5}} \log^{1.5}\big(\frac{n}{\epsilon}\big) \log\Big(\frac{\log n}{\epsilon}\Big)\Big)$ calls to U_p and $U_p^\dagger$.*

Proof. The general idea is to first construct a unitary matrix that has a specific matrix block with singular values $\sqrt{p_1}, \ldots, \sqrt{p_n}$. We use the construction of Eq. (1) and apply singular value transformation (Theorem 10) by a polynomial $\tilde{S}$ constructed in Lemma 11, setting $\eta = \frac{\epsilon}{24\ln(2/\beta)}$ and $\beta = \sqrt{\Delta}$ for $\Delta = \frac{\epsilon}{12n\ln(n/\epsilon)}$. Notice that this Δ satisfies

$$\Delta\Big(\ln\Big(\frac{1}{\Delta}\Big) + 4\ln\Big(\frac{2}{\beta}\Big)\Big) = \frac{\epsilon}{12n\ln(n/\epsilon)} \cdot \ln\frac{16(4n\ln\frac{n}{\epsilon})^3}{\epsilon^3} \leq \frac{\epsilon}{12n\ln(n/\epsilon)} \cdot \ln\frac{n^6}{\epsilon^6} = \frac{\epsilon}{2n}, \tag{6}$$

provided that $\frac{n}{\epsilon} \geq 152$. Note that the polynomial $\tilde{S}$ satisfies both conditions in Theorem 10. Applying the singular value transformed version of the operator (1) to the state $|\psi_p\rangle$ gives

$$|\widetilde{\Psi_p}\rangle = \sum_{i=1}^{n} \sqrt{p_i}\tilde{S}(\sqrt{p_i})|\phi_i\rangle_A|i\rangle_B|0\rangle + \ldots|1\rangle. \tag{7}$$

Preparing $|\widetilde{\Psi_p}\rangle$ costs $\deg\tilde{S} = \mathcal{O}\Big(\frac{1}{\beta}\log\Big(\frac{1}{\eta}\Big)\Big) = \mathcal{O}\Big(\sqrt{\frac{n}{\epsilon}\log\big(\frac{n}{\epsilon}\big)}\log\Big(\frac{\log n}{\epsilon}\Big)\Big)$ uses of U_p and $U_p^\dagger$ and the same number of controlled reflections through $\Pi, \widetilde{\Pi}$. Furthermore, Lemma 11 implies that for all i such that $p_i \geq \Delta$,

$$\Big|\frac{p_i\ln(1/p_i)}{4\ln(2/\beta)} - p_i\tilde{S}(\sqrt{p_i})\Big| = p_i \cdot \Big|\frac{\ln(1/\sqrt{p_i})}{2\ln(2/\beta)} - \tilde{S}(\sqrt{p_i})\Big| \leq \eta p_i. \tag{8}$$

For all i such that $p_i < \Delta$, we have

$$\Big|\frac{p_i\ln(1/p_i)}{4\ln(2/\beta)} - p_i\tilde{S}(\sqrt{p_i})\Big| \leq \frac{p_i\ln(1/p_i)}{4\ln(2/\beta)} + p_i \leq \frac{\Delta(\ln(\frac{1}{\Delta}) + 4\ln(2/\beta))}{4\ln(2/\beta)} \leq \frac{\epsilon}{8n\ln(2/\beta)}, \tag{9}$$

where the first inequality comes from the fact that $|\tilde{S}(x)| \leq 1$ for all $x \in [-1,1]$, the second inequality comes from the monotonicity of $x(\ln(1/x) + 4\ln(2/\beta))$ on $(0, \frac{1}{\Delta}]$, and the third inequality comes from (6). As a result of (5), (8), and (9), we have

$$\left|\left(\langle\psi_p|\otimes\langle 0|\right)|\widetilde{\Psi_p}\rangle - \frac{H(p)}{4\ln(2/\beta)}\right| = \left|p_i\tilde{S}(\sqrt{p_i}) - \sum_{i=1}^{n}\frac{p_i\log(1/p_i)}{4\ln(2/\beta)}\right|$$
$$\leq \sum_{i\colon p_i<\Delta}\frac{\epsilon}{8n\ln(2/\beta)} + \sum_{i\colon p_i\geq\Delta}\eta p_i$$
$$\leq \frac{\epsilon}{8\ln(2/\beta)} + \frac{\epsilon}{24\ln(2/\beta)} = \frac{\epsilon}{6\ln(2/\beta)}.$$

Therefore, $|4\ln(2/\beta)(\langle\psi_p|\otimes\langle 0|)|\widetilde{\Psi_p}\rangle - H(p)| \leq 2\epsilon/3$. By Theorem 8, we can use $\Theta(\ln(1/\beta)/\epsilon)$ applications of the unitaries (and their inverses) that implement $|\psi_p\rangle$ and $|\widetilde{\Psi_p}\rangle$ to estimate $(\langle\psi_p|\otimes\langle 0|)|\widetilde{\Psi_p}\rangle$ within additive error $\frac{\epsilon}{12\ln(2/\beta)}$. In total, this estimates $H(p)$ within additive error $\frac{\epsilon}{12\ln(2/\beta)}\cdot 4\ln(2/\beta)+\frac{2\epsilon}{3} = \epsilon$ with success probability at least $8/\pi^2$. The total complexity of the algorithm is

$$\mathcal{O}\left(\frac{\ln(1/\beta)}{\epsilon}\right)\cdot\mathcal{O}\left(\sqrt{\frac{n}{\epsilon}\log\left(\frac{n}{\epsilon}\right)}\log\left(\frac{\log n}{\epsilon}\right)\right) = \mathcal{O}\left(\frac{\sqrt{n}}{\epsilon^{1.5}}\log^{1.5}\left(\frac{n}{\epsilon}\right)\log\left(\frac{\log n}{\epsilon}\right)\right). \quad \blacktriangleleft$$

3.2 Density matrices with purified quantum query-access

For a density matrix ρ, we also assume the purified quantum query-access in Definition 2, i.e., a unitary oracle U_ρ acting as $U_\rho|0\rangle_A|0\rangle_B = |\rho\rangle = \sum_{i=1}^{n}\sqrt{p_i}|\phi_i\rangle_A|\psi_i\rangle_B$. We use U_ρ and $U_\rho^\dagger$ to estimate the von-Neumann entropy $H(\rho) = -\mathrm{Tr}[\rho\log\rho]$:

▶ **Theorem 13.** *For any $0<\epsilon<1$, we can estimate $H(p)$ with accuracy ϵ with success probability at least $2/3$ using $\widetilde{\mathcal{O}}\left(\frac{n}{\epsilon^{1.5}}\right)$ calls to U_ρ and $U_\rho^\dagger$.*

Proof. We use the construction of Eq. (2). The proof is essentially the same as that of Theorem 12 proceeding by constructing singular value transformation via Theorem 10, with the only difference that all probabilities are rescaled by a factor of $1/\sqrt{n}$ in (2); as a result, the number of calls to U_ρ and $U_\rho^\dagger$ is blown up to $\widetilde{\mathcal{O}}\left(\sqrt{n}\cdot\frac{\sqrt{n}}{\epsilon^{1.5}}\right) = \widetilde{\mathcal{O}}\left(\frac{n}{\epsilon^{1.5}}\right)$. ◀

4 Tolerant testers for ℓ^2-closeness with purified query-access

First we give an ℓ^2-closeness tester for unknown classical distributions p, q.

▶ **Theorem 14.** *Given purified quantum query-access for classical distributions p, q as in Definition 2, for any $\nu, \epsilon \in (0,1)$ the quantum query complexity of distinguishing the cases $\|p-q\|_2 \geq \epsilon$ and $\|p-q\|_2 \leq (1-\nu)\epsilon$ with success probability at least $2/3$ is*

$$\mathcal{O}\left(\frac{1}{\nu\epsilon}\log^3\left(\frac{1}{\nu\epsilon}\right)\log\log\left(\frac{1}{\nu\epsilon}\right)\right).$$

Proof. The main idea is to first bin the x elements based on the approximate value of $p(x)+q(x)$, then apply fine-tuned algorithms exploiting the knowledge of the approximate value of $p(x)+q(x)$.

Using amplitude estimation for any $k\in\mathbb{N}$ we can construct an algorithm $\mathcal{A}_k$ that for any input x with $p(x)+q(x)\geq 2^{-k}$ outputs "greater" with probability at least $2/3$, and for any x with $p(x)+q(x)\leq 2^{-k-1}$ outputs "smaller" and uses $\mathcal{O}\left(2^{\frac{k}{2}}\right)$ queries to U_p and U_q. Using $\mathcal{O}\left(\log(\frac{1}{\nu\epsilon})\right)$ repetitions we can boost the success probability to $1-\mathcal{O}(\mathrm{poly}(\nu\epsilon))$. Since our

algorithm only needs to succeed with constant probability, and will use these subroutines at most $\frac{1}{\mathrm{poly}(\nu\epsilon)}$ times, we can ignore the small failure probability. Therefore in the rest of the proof we assume without loss of generality, that $\mathcal{A}_k$ that solves perfectly the above question with (query) complexity $\mathcal{O}\Big(2^{\frac{k}{2}}\log(\frac{1}{\nu\epsilon}))\Big)$.

Algorithm 1 Estimating $\log_2(p(x)+q(x))$.

input $x \in [n]$, $\theta \in (0,1)$
for $k \in K := \left\{-1, 0, 1, 2, \ldots, \left\lceil \log_2\left(\frac{1}{\theta}\right)\right\rceil\right\}$ **do**
    Run algorithm $\mathcal{A}_k$ on $|x\rangle$ **if** output is "greater" **then return** k
return "less than θ"

For any x with $p(x)+q(x)\geq\theta$, Algorithm 1 outputs a k such that $p(x)+q(x)\in(2^{-k-1},2^{-k+1})$. However, note that this labeling is probabilistic; let us denote by $s_k(x)$ the probability that x is labeled by k. Observe that $s_k(x)=0$ unless $k\in\left\{\left\lfloor\log_2\left(\frac{1}{p(x)+q(x)}\right)\right\rfloor,\left\lceil\log_2\left(\frac{1}{p(x)+q(x)}\right)\right\rceil\right\}$ (otherwise the return is either "greater" or "less than"). Now let us express $\|p-q\|_2^2$ in terms of this "soft-selection" function $s(x)$.

$$\begin{aligned}\|p-q\|_2^2 &= \sum_x |p(x)-q(x)|^2 \\ &= \sum_x\sum_{k\in K} s_k(x)|p(x)-q(x)|^2+\eta && (\eta\in[0,2\theta)) \\ &= \sum_{k\in K} 2^{9-k}\sum_x s_k(x)\frac{p(x)+q(x)}{2}\frac{2^{-k-2}}{p(x)+q(x)}\left(\frac{p(x)-q(x)}{2^{-k+3}}\right)^2+\eta, && (10)\end{aligned}$$

where the bound on η follows from the observation that

$$\eta\leq\sum_{x\colon p(x)+q(x)<\theta}|p(x)-q(x)|^2\leq\sum_{x\colon p(x)+q(x)<\theta}(p(x)+q(x))^2<\theta\sum_{x\colon p(x)+q(x)<\theta}p(x)+q(x)<2\theta.$$

If for all $k\in K$ we have a $2^{k-9}\frac{\theta}{|K|}$-precise estimate of

$$\sum_x s_k(x)\frac{p(x)+q(x)}{2}\frac{2^{-k-2}}{p(x)+q(x)}\left(\frac{p(x)-q(x)}{2^{-k+3}}\right)^2, \qquad (11)$$

then we get a 3θ-precise estimate of $\|p-q\|_2^2$. In particular setting $\theta:=\nu\epsilon^2/6$, this solves the tolerant testing problem, since if $\|p-q\|\geq\epsilon$ then $\|p-q\|^2\geq\epsilon^2$, on the other hand if $\|p-q\|\leq(1-\nu)\epsilon$ then $\|p-q\|^2\leq(1-\nu)^2\epsilon^2\leq(1-\nu)\epsilon^2=\epsilon^2-\nu\epsilon^2$.

Now we describe how to construct a quantum algorithm that sets the first output qubit to $|0\rangle$ with probability (11). Start with preparing a purification of the distribution of $\frac{p(x)+q(x)}{2}$, then set the label of x to k with probability $s_k(x)$ using Algorithm 1 terminating it after using $\mathcal{A}_k$. Then separately apply the maps $\sqrt{\frac{2^{-k-2}}{p(x)+q(x)}}$ and $\frac{p(x)-q(x)}{2^{-k-3}}$ to the state.

Note that we do not need to apply the above transformations exactly, it is enough if apply them with precision say $2^{k-11}\frac{\theta}{|K|}$. We analyze the complexity of (approximately) implementing the above sketched algorithm. To implement the map $\sqrt{\frac{2^{-k-2}}{p(x)+q(x)}}$, we use the unitary of Eq. (1), and transform the singular values by the polynomial $\tilde{P}$ from Lemma 11 using Theorem 10. In order to implement the map $\frac{p(x)-q(x)}{2^{-k-2}}$, we again use the unitary of Eq. (1), but now separately for p and q. We amplify both the singular values $\sqrt{p(x)}$ and $\sqrt{q(x)}$

by a factor $\sqrt{2^{k-2}}$ using the polynomial $\tilde{Q}$ from Lemma 11 in Theorem 10. Then we create a block-encoding[8] of both and $2^{k-2}p(x)$ and $2^{k-2}q(x)$ and then combine them to get a block-encoding of $\frac{p(x)-q(x)}{2^{-k-3}}$. In both cases the query complexity of $\mathcal{O}(\theta/|K|)$-precisely implementing the transformations is $\mathcal{O}\big(2^{k/2}\log(|K|/\theta)\big) = \mathcal{O}\big(2^{k/2}\log(1/\theta)\big)$. Since computing the label k also costs $\mathcal{O}\big(2^{k/2}\log(1/(\nu\epsilon))\big)$, this is the overall complexity so far. Finally we estimate the probability of the first qubit being set to $|0\rangle$ with setting $M = \mathcal{O}\big(|K|2^{-k/2}/(\nu\epsilon)\big)$ in Theorem 8, and boost the success probability to $1-\mathcal{O}(1/|K|)$ with $\mathcal{O}(\log(|K|))$ repetitions. Thus for any $k \in K$ the overall complexity of estimating Eq. (11) with sufficient precision has (query) complexity $\mathcal{O}\Big(\frac{|K|}{\nu\epsilon}\log\big(\frac{1}{\nu\epsilon}\big)\log(|K|)\Big) = \mathcal{O}\big(\frac{1}{\nu\epsilon}\log^2\big(\frac{1}{\nu\epsilon}\big)\log\log\big(\frac{1}{\nu\epsilon}\big)\big)$. Therefore estimating $\|p-q\|_2^2$ to precision $\nu\epsilon^2/6$ with high probability has (query) complexity

$$\mathcal{O}\left(\frac{1}{\nu\epsilon}\log^3\left(\frac{1}{\nu\epsilon}\right)\log\log\left(\frac{1}{\nu\epsilon}\right)\right). \qquad \blacktriangleleft$$

It is easy to see an $\Omega\big(\frac{1}{\epsilon}\big)$ lower bound on the above problem even in the strongest quantum pure state input model Definition 4. Indeed, consider the case $n=2, q=(\frac{1}{2},\frac{1}{2})$ (the uniform distribution on $\{1,2\}$) and we want to test whether $p=q$ or $\|p-q\|_2 \geq \epsilon$. This is equivalent to test whether $p_1 = \frac{1}{2}$ or $|p_1 - \frac{1}{2}| \geq \frac{\epsilon}{\sqrt{2}}$; due to the optimality of amplitude estimation in Theorem 8, this task requires $\Omega(\frac{1}{\epsilon})$ quantum queries to the unitary U preparing the state $\sqrt{p_1}|1\rangle + \sqrt{p_2}|2\rangle$.

Now we prove the result below on (tolerant) ℓ^2-closeness testing for quantum distributions:

▶ **Theorem 15.** *Given $\epsilon, \nu \in (0,1)$ and two density operators $\rho, \sigma \in \mathbb{C}^{n\times n}$ with purified quantum query-access to U_ρ and U_σ as in Definition 2, it takes $\mathcal{O}\Big(\min\Big(\frac{\sqrt{n}}{\epsilon}, \frac{1}{\epsilon^2}\Big)\frac{1}{\nu}\Big)$ queries to $U_\rho, U_\rho^\dagger, U_\sigma, U_\sigma^\dagger$ to decide whether $\|\rho-\sigma\|_2 \geq \epsilon$ or $\|\rho-\sigma\|_2 \leq (1-\nu)\epsilon$, with success probability at least $2/3$.*

Proof. We can combine the block-encodings of ρ and σ to apply the map $\frac{\rho-\sigma}{2}$ to the maximally entangled state $\sum_{j=1}^n \frac{|j\rangle|j\rangle}{\sqrt{n}}$, which gives

$$\sum_{j=1}^n \frac{|j\rangle|j\rangle}{\sqrt{n}} \to \left(\frac{\rho-\sigma}{2}\otimes I\right)\sum_{j=1}^n \frac{|j\rangle|j\rangle}{\sqrt{n}}|0\rangle + \ldots|1\rangle.$$

The probability of measuring the $|0\rangle$ ancilla state is

$$\sum_{i,j=1}^n \frac{\langle i|\langle i|}{\sqrt{n}}\left(\frac{(\rho-\sigma)^2}{4}\otimes I\right)\frac{|j\rangle|j\rangle}{\sqrt{n}} = \frac{1}{4n}\sum_{i=1}^n \langle i|(\rho-\sigma)^2|i\rangle = \frac{1}{4n}\mathrm{Tr}[(\rho-\sigma)^2].$$

Thus it suffices to apply amplitude estimation with $M = \Theta\Big(\frac{\sqrt{n}}{\nu\epsilon}\Big)$ calls to $U_\rho, U_\rho^\dagger, U_\sigma, U_\sigma^\dagger$.

On the other hand, we can estimate $\|\rho-\sigma\|_2^2$ by observing that $\|\rho-\sigma\|_2^2 = \mathrm{Tr}\big[(\rho-\sigma)^2\big]$ $= \mathrm{Tr}\big[\rho^2\big] - 2\mathrm{Tr}[\rho\sigma] + \mathrm{Tr}\big[\sigma^2\big]$. Since the success probability of the SWAP test ([14]) on input states ρ, σ is $\frac{1}{2}(1+\mathrm{Tr}[\rho\sigma])$, we can individually estimate the latter quantities with precision $\mathcal{O}\big(\nu\epsilon^2\big)$ using amplitude estimation (Theorem 8) with $\mathcal{O}\big(\frac{1}{\nu\epsilon^2}\big)$ queries to $U_\rho, U_\rho^\dagger, U_\sigma, U_\sigma^\dagger$. As a result, we could decide whether $\|\rho-\sigma\|_2 \geq \epsilon$ or $\|\rho-\sigma\|_2 \leq (1-\nu)\epsilon$ using $\mathcal{O}\big(\frac{1}{\nu\epsilon^2}\big)$ queries.

The result of Theorem 15 hence follows by taking the minimum of the two complexities. ◀

[8] If we have a projected unitary encoding of $\Pi U\widetilde{\Pi} = A = \sum_i \varsigma_i|\psi_i\rangle\langle 0,i|$ with $\widetilde{\Pi} = |0\rangle\langle 0|\otimes I$, we can immediately turn it into a block-encoding of $A^\dagger A = \sum_i \varsigma_i^2|i\rangle\langle i|$ by e.g. applying Theorem 10 with the polynomial x^2.

5 Future work and open questions

Our paper raises a couple of natural open questions for future work, including:

- For which other distributional property testing problems can we get faster and simpler quantum algorithms using the presented methodology?
- Can we prove quantum lower bounds that match our upper bounds? For instance, can we prove an $\Omega\left(\frac{n}{\epsilon}\right)$ lower bound on estimating the von Neumann entropy in the purified quantum query-access model for density operators?
- Is there a lower bound technique which naturally fits our purified quantum query input model?
- Can we prove the conjecture that the purified and discrete query input models are equivalent for classical distributions, with respect to the query complexity of (distributional) property testing problems? For some recent progress in this direction see [11].

A Projected unitary encodings used for singular value transformation

First we handle the case of classical distributions. Let U_p be a purified quantum oracle of a classical distribution p as in Definition 2, and let $U := (U_p \otimes I)$, also let $\Pi := (\sum_{i=1}^{n} I \otimes |i\rangle\langle i| \otimes |i\rangle\langle i|)$, $\widetilde{\Pi} := (|0\rangle\langle 0| \otimes |0\rangle\langle 0| \otimes I)$, then

$$\begin{aligned}\Pi U \widetilde{\Pi} = \Pi (U_p \otimes I)\widetilde{\Pi} &= \Big(\sum_{i=1}^{n} I \otimes |i\rangle\langle i| \otimes |i\rangle\langle i|\Big)(U_p \otimes I)\big(|0\rangle\langle 0| \otimes |0\rangle\langle 0| \otimes I\big) \\ &= \sum_{i=1}^{n} \Big((I \otimes |i\rangle\langle i|) U_p (|0\rangle\langle 0| \otimes |0\rangle\langle 0|)\Big) \otimes |i\rangle\langle i|\end{aligned}$$

$$\ldots = \sum_{i=1}^{n} \Big((I \otimes |i\rangle\langle i|) \sum_{j=1}^{n} \sqrt{p_j} |\phi_j\rangle|j\rangle\langle 0|\langle 0| \Big) \otimes |i\rangle\langle i|$$
$$= \sum_{i=1}^{n} \sqrt{p_i} |\phi_i\rangle\langle 0| \otimes |i\rangle\langle 0| \otimes |i\rangle\langle i|.$$

Now we turn to quantum distributions where we do not know the diagonalizing basis of the density operator ρ. Let U_ρ be a purified quantum oracle of a quantum distribution ρ as in Definition 2, and W a unitary, mapping $|0\rangle|0\rangle \mapsto \sum_{j=1}^{n} \frac{|j\rangle|j\rangle}{\sqrt{n}}$. Let $U' := \big(I \otimes U_\rho^\dagger\big)\big(W^\dagger \otimes I\big)$, $\Pi' := (I \otimes |0\rangle\langle 0| \otimes |0\rangle\langle 0|)$ and $\widetilde{\Pi}$ as above, then

$$\begin{aligned}
\Pi' U' \widetilde{\Pi} &= \Pi' \big(I \otimes U_\rho^\dagger\big)\big(W^\dagger \otimes I\big)\widetilde{\Pi} \\
&= \big(I \otimes (|0\rangle\langle 0| \otimes |0\rangle\langle 0| U_\rho^\dagger)\big) \left(\left(\sum_{j=1}^{n} \frac{|j\rangle|j\rangle}{\sqrt{n}} \right) \langle 0|\langle 0| \otimes I \right) \\
&= \left(I \otimes \sum_{i=1}^{n} \sqrt{p_i} |0\rangle|0\rangle\langle \phi_i|\langle \psi_i| \right) \left(\left(\sum_{j=1}^{n} \frac{|\phi'_j\rangle|\phi_j\rangle}{\sqrt{n}} \right) \langle 0|\langle 0| \otimes I \right) \\
&= \sum_{i=1}^{n} \sqrt{\frac{p_i}{n}} |\phi'_i\rangle|0\rangle|0\rangle\langle 0|\langle 0|\langle \psi_i|,
\end{aligned}$$

where $\sum_{j=1}^{n} \frac{|\phi'_j\rangle|\phi_j\rangle}{\sqrt{n}} = \sum_{j=1}^{n} \frac{|j\rangle|j\rangle}{\sqrt{n}}$ is the Schmidt decomposition of the maximally entangled state under the basis $(|\phi_1\rangle, \ldots, |\phi_n\rangle)$.

B Polynomial approximations for singular value transformation

We use the following result based on local Taylor series:

▶ **Lemma 16** ([21, Corollary 66]). *Let $x_0 \in [-1, 1]$, $r \in (0, 2]$, $\nu \in (0, r]$ and let $f\colon [-x_0 - r - \nu, x_0 + r + \nu] \to \mathbb{C}$ and be such that $f(x_0 + x) = \sum_{\ell=0}^{\infty} a_\ell x^\ell$ for all $x \in [-r - \nu, r + \nu]$. Suppose $B > 0$ is such that $\sum_{\ell=0}^{\infty} (r + \nu)^\ell |a_\ell| \leq B$. Let $\epsilon \in \big(0, \frac{1}{2B}\big]$, then there is an efficiently computable polynomial $P \in \mathbb{C}[x]$ of degree $\mathcal{O}\big(\frac{1}{\nu} \log\big(\frac{B}{\epsilon}\big)\big)$ such that*[9]

$$\begin{aligned}
\|f(x) - P(x)\|_{[x_0 - r, x_0 + r]} &\leq \epsilon \\
\|P(x)\|_{[-1,1]} &\leq \epsilon + \|f(x)\|_{[x_0 - r - \nu/2, x_0 + r + \nu/2]} \leq \epsilon + B \\
\|P(x)\|_{[-1,1] \setminus [x_0 - r - \nu/2, x_0 + r + \nu/2]} &\leq \epsilon.
\end{aligned}$$

We can use the above result to construct the following useful polynomial approximations.

▶ **Lemma 11.** (Polynomial approximations) *Let $\beta \in (0, 1]$, $\eta \in (0, \frac{1}{2}]$ and $t \geq 1$. There exists polynomials $\tilde{P}, \tilde{Q}, \tilde{S}$ such that*

- $\forall x \in [\frac{1}{t}, 1]\colon |\tilde{P}(x) - \frac{1}{2tx}| \leq \eta$, *and* $\forall x \in [-1, 1]\colon -1 \leq \tilde{P}(x) = \tilde{P}(-x) \leq 1$,
- $\forall x \in [-\frac{1-\beta}{t}, \frac{1-\beta}{t}]\colon |\tilde{Q}(x) - tx| \leq \eta \cdot (tx)$, *and* $\forall x \in [-1, 1]\colon \tilde{Q}(x) = -\tilde{Q}(-x) \leq 1$,
- $\forall x \in [\beta, 1]\colon |\tilde{S}(x) - \frac{\ln(1/x)}{2\ln(2/\beta)}| \leq \eta$, *and* $\forall x \in [-1, 1]\colon -1 \leq \tilde{S}(x) = \tilde{S}(-x) \leq 1$,

moreover $\deg(\tilde{P}) = \mathcal{O}\Big(t \log\Big(\frac{1}{\eta}\Big)\Big)$, $\deg(\tilde{Q}) = \mathcal{O}\Big(\frac{t}{\beta} \log\Big(\frac{1}{\eta}\Big)\Big)$, *and* $\deg(\tilde{S}) = \mathcal{O}\Big(\frac{1}{\beta} \log\Big(\frac{1}{\eta}\Big)\Big)$.

[9] For a function $g\colon \mathbb{R} \to \mathbb{C}$, and an interval $[a, b] \subseteq \mathbb{R}$, we define $\|g\|_{[a,b]} := \max_{x \in [a,b]} |g(x)|$.

Proof. For the construction of the $\tilde{P}$ and $\tilde{Q}$ polynomials see Corollary 67 and Theorem 30 of [21], respectively. It remains to construct the polynomial $\tilde{S}$ above.

Denote $f(x) = \frac{\ln(1/x)}{2\ln(2/\beta)}$; by taking $\epsilon = \eta/2$, $x_0 = 1$, $r = 1-\beta$, $\nu = \frac{\beta}{2}$, and $B = \frac{1}{2}$ in Corollary 16, we have a polynomial $S \in \mathbb{C}[x]$ of degree $\mathcal{O}\big(\frac{1}{\nu}\log(\frac{B}{\epsilon})\big) = \mathcal{O}\Big(\frac{1}{\beta}\log(\frac{1}{\eta})\Big)$ such that

$$\|f(x) - S(x)\|_{[\beta,2-\beta]} \le \eta/2 \tag{12}$$

$$\|S(x)\|_{[-1,1]} \le B + \eta/2 \le (1+\eta)/2 \tag{13}$$

$$\|S(x)\|_{[-1,\frac{\beta}{2}]} \le \eta/2. \tag{14}$$

Note that $B = \frac{1}{2}$ is valid because the Taylor series of $f(x)$ at $x = 1$ is $\frac{1}{2\ln(2/\beta)}\sum_{l=1}^{\infty}\frac{(-1)^l x^l}{l}$, and as a result we could take

$$\begin{aligned} B = \frac{1}{2\ln(2/\beta)}\sum_{l=1}^{\infty}\frac{(1-\beta/2)^l}{l} &= -\frac{1}{2\ln(2/\beta)}\sum_{l=1}^{\infty}\frac{(-1)^{l-1}}{l}(-1+\beta/2)^l \\ &= -\frac{1}{2\ln(2/\beta)}\ln\frac{\beta}{2} = \frac{1}{2}. \end{aligned}$$

However, S is not an even polynomial in general; we instead take $\tilde{S}(x) = S(x) + S(-x)$ for all $x \in [-1,1]$. Then by (12) and (14) we have

$$\big\|f(x) - \tilde{S}(x)\big\|_{[\beta,1]} \le \big\|f(x) - \tilde{S}(x)\big\|_{[\beta,1]} + \big\|\tilde{S}(-x)\big\|_{[\beta,1]} \le \frac{\eta}{2} + \frac{\eta}{2} = \eta. \tag{15}$$

Furthermore, $\tilde{S}$ is an even polynomial such that $\deg(\tilde{S}) = \mathcal{O}\Big(\frac{1}{\beta}\log(\frac{1}{\eta})\Big)$; hence (13) and (14) imply

$$\big\|\tilde{S}(x)\big\|_{[-1,1]} = \big\|\tilde{S}(x)\big\|_{[0,1]} \le \|S(x)\|_{[0,1]} + \|S(x)\|_{[-1,0]} \le \frac{1+\eta}{2} + \frac{\eta}{2} \le 1$$

given $\eta \le 1/2$. (Finally we can take the real part of $\tilde{S}(x)$ if it has some complex coefficients.) ◀

C Corollaries of our ℓ^2-closeness testing results

C.1 ℓ^1-closeness testing with purified query-access

▶ **Corollary 17.** *Given $\epsilon > 0$ and two distributions p, q on the domain $[n]$ with purified quantum query-access via U_p and U_q as in Definition 2, it takes $\widetilde{\mathcal{O}}\Big(\frac{\sqrt{n}}{\epsilon}\Big)$ queries to $U_p, U_p^\dagger, U_q, U_q^\dagger$ to decide whether $p = q$ or $\|p-q\|_1 \ge \epsilon$ with success probability at least $2/3$. Similarly for density operators $\rho, \sigma \in \mathbb{C}^{n\times n}$ with purified quantum query-access via U_ρ and U_σ, it takes $\mathcal{O}\big(\frac{n}{\epsilon}\big)$ queries to $U_\rho, U_\rho^\dagger, U_\sigma, U_\sigma^\dagger$ to decide whether $\rho = \sigma$ or $\|\rho-\sigma\|_1 \ge \epsilon$ with success probability at least $2/3$.*

Proof. By the Cauchy-Schwartz inequality we have $\|p-q\|_2 \ge \frac{1}{\sqrt{n}}\|p-q\|_1$, therefore Theorem 14 implies our claim by taking $\epsilon \leftarrow \epsilon/\sqrt{n}$ therein. Similarly, Theorem 15 implies our claim for quantum distributions ρ and σ. ◀

C.2 Independence testing with purified query-access

▶ **Corollary 18.** *Given $\epsilon > 0$ and a classical distribution p on $[n] \times [m]$ with the purified quantum query-access via U_p as in Definition 2, it takes $\widetilde{\mathcal{O}}\left(\frac{\sqrt{nm}}{\epsilon}\right)$ queries to $U_p, U_p^\dagger$ to decide whether p is a product distribution on $[n] \times [m]$ or p is ϵ-far in ℓ^1-norm from any product distribution on $[n] \times [m]$ with success probability at least $2/3$.*

Proof. We define p_A to be the margin of p on the first marginal space, i.e., $p_A(i) = \sum_{j=1}^m p(i,j)$ for all $i \in [n]$. We similarly define p_B to be the margin of p on the second marginal space, i.e., $p_B(j) = \sum_{i=1}^n p(i,j)$ for all $j \in [m]$. Assume the quantum oracle U_p from Definition 2 acts as

$$U_p|0\rangle_A|0\rangle_B|0\rangle_C = \sum_{i=1}^n \sum_{j=1}^m \sqrt{p(i,j)}|i\rangle_A|j\rangle_B|\psi_{i,j}\rangle_C;$$

if we denote $|\phi_i\rangle = \sum_{j=1}^m \frac{\sqrt{p(i,j)}}{\sqrt{p_A(i)}}|j\rangle|\psi_{i,j}\rangle$ for all $i \in [n]$ and $|\varphi_j\rangle = \sum_{i=1}^n \frac{\sqrt{p(i,j)}}{\sqrt{p_B(j)}}|i\rangle|\psi_{i,j}\rangle$ for all $j \in [m]$, then we have

$$U_p|0\rangle_A|0\rangle_B|0\rangle_C = \sum_{i=1}^n \sqrt{p_A(i)}|i\rangle_A|\phi_i\rangle_{B,C} = \sum_{j=1}^m \sqrt{p_B(j)}|j\rangle_B|\varphi_j\rangle_{A,C}.$$

As a result,

$$(U_p \otimes U_p)(|0\rangle^{\otimes 6}) = \sum_{i=1}^n \sum_{j=1}^m \sqrt{p_A(i)}\sqrt{p_B(j)}|i\rangle|j\rangle|\phi_i\rangle|\varphi_j\rangle;$$

in other words, one purified quantum query to the distribution $p_A \times p_B$ can be implemented by two queries to U_p.

If p is a product distribution on $[n] \times [m]$, then $p = p_A \times p_B$; if p is ϵ-far in ℓ^1-norm from any product distribution on $[n] \times [m]$, then $\|p - p_A \times p_B\|_1 \geq \epsilon$. Therefore, the problem of independence testing reduces to ℓ^1-closeness testing for distributions on $[n] \times [m]$, and hence Corollary 18 follows from Corollary 17. ◀

Similarly, Corollary 17 implies that the quantum query complexity of testing independence of quantum distributions is $\mathcal{O}\left(\frac{nm}{\epsilon}\right)$.

On Local Testability in the Non-Signaling Setting

Abstract

Non-signaling strategies are a generalization of quantum strategies that have been studied in physics for decades, and have recently found applications in theoretical computer science. These applications motivate the study of local-to-global phenomena for *non-signaling functions*.

We prove that low-degree testing in the non-signaling setting is possible, assuming that the locality of the non-signaling function exceeds a threshold. We additionally show that if the locality is below the threshold then the test fails spectacularly, in that there exists a non-signaling function which passes the test with probability 1 and yet is maximally far from being low-degree.

Along the way, we present general results about the local testability of linear codes in the non-signaling setting. These include formulating natural definitions that capture the condition that a non-signaling function "belongs" to a given code, and characterizing the sets of local constraints that imply membership in the code. We prove these results by formulating a logical inference system for linear constraints on non-signaling functions that is complete and sound.

1 Introduction

Locally testable codes (LTCs) are error correcting codes in which one can verify whether a given string belongs to the code by reading only a few (randomly chosen) bits from the string. Goldreich and Sudan [6] have described LTCs as the "combinatorial counterparts of the complexity theoretic notion of PCPs", motivating the standalone study of these objects.

In this work we study local testability for *non-signaling strategies*, which are a class of non-local strategies that generalize quantum strategies, capturing the maximum amount of "non-local correlation" that can occur under the assumption that spatially-isolated parties cannot communicate instantaneously. Non-signaling strategies have been studied in physics for decades [14, 10, 12], in order to better understand quantum entanglement. Recently they have gained attention in computer science due to their applications to hardness of approximation [8] and delegation of computation [7, 9]. PCPs sound against non-signaling strategies (nsPCPs) underlie these applications, which motivates the study of local testability in the non-signaling setting.

Given an integer n, a field $\mathbb{F}$, and a locality parameter $k \leq n$, the object that we study is a *k-non-signaling function* $\mathcal{F}\colon [n] \to \mathbb{F}$, which extends the notion of a function $f\colon [n] \to \mathbb{F}$ as follows.[1]

▶ **Definition 1.** *A **k-non-signaling function** $\mathcal{F}\colon [n] \to \mathbb{F}$ is a collection $\{\mathcal{F}_S\}_{S\subseteq[n]:|S|\leq k}$ where each $\mathcal{F}_S$ is a distribution over local functions $g\colon S \to \mathbb{F}$, and for any two subsets $R \subseteq S \subseteq [n]$ with $|S| \leq k$ it holds that the distribution $\mathcal{F}_R$ and the marginal distribution $\mathcal{F}_S|_R$ are equal.[2] (The set of all such $\mathcal{F}$ are the solutions to the k-relaxation in the Sherali–Adams hierarchy [16].)*

The evaluation of $\mathcal{F}$ on a set S is a single sample $g\colon S \to \mathbb{F}$ from the distribution $\mathcal{F}_S$. Intuitively, a k-non-signaling function is like a quantum function: evaluation is probabilistic and only happens once, just like quantum measurement; and $\mathcal{F}$ can only be evaluated on at most k points simultaneously, which is similar to the uncertainty principle. As k approaches n, $\mathcal{F}$ behaves more like a classical function and, when $k = n$, $\mathcal{F}$ is a distribution over functions $f\colon [n] \to \mathbb{F}$.

Local testability of non-signaling functions may sound like an oxymoron, because non-signaling functions, at least superficially, are collections of local distributions with no global structure that we can talk about. Yet prior work has shown that local-to-global phenomena *are possible*.

For example, [4] shows that any non-signaling function passing the linearity test [3] with high probability is well-approximated by a *quasi-distribution* supported on linear functions. This result was later used in [5] to show that the exponential-length constant-query PCP of [2] is sound against non-signaling strategies.

The results obtained in [4, 5] naturally raise the question of whether local testability in the non-signaling setting is possible for other codes, like those based on low-degree polynomials. After all, both linearity testing and low-degree testing do work in the quantum setting [11].

Recall that, in the classical setting, local testability plays a central role in PCP constructions, many of which can be described as having two main components.

- *Property testing:* check with few queries whether or not the given proof π belongs to a code $\mathbf{C}$.
- *Checking computation:* given that π is a codeword in $\mathbf{C}$ (or at least is close to a codeword), check with few queries whether or not π proves the desired statement.

This modular approach has enabled the study of local testability as a natural standalone goal, which in turn has led to improved PCP constructions.

---

[1] There are two distinct definitions of a non-signaling strategy, depending on whether the strategy is meant to represent isolated parties or a function. The former is used for MIPs [7, 9], while the latter is used for PCPs and property testing [7, 9, 4, 5]. We use the latter definition, although equivalent statements of all our results will hold when adopting the former definition (see the appendix in [4]).

[2] A common relaxation of this condition requires that these two distributions are only statistically (or computationally) close. While we consider the standard definition, we note that this is without loss of generality as [4] shows that every statistically (or computationally) non-signaling strategy is close to an (exact) non-signaling strategy.

Inspired by this state of affairs, we initiate the study of locally testable codes in general in the non-signaling setting, focusing specifically on the case of low-degree testing. We believe that, similarly to the classical setting, understanding local testability against non-signaling strategies will enable researchers to construct more efficient non-signaling PCPs.

1.1 Low-degree testing against non-signaling functions

We show that a simple low-degree test, the *evenly-spaced points test*, tests proximity to degree-d non-signaling functions when $k \geq O(d^2)$, and *fails* to test proximity when $k \leq O(d^2)$.

The evenly-spaced points test. Let $m, d \in \mathbb{N}$ and p be a prime with $p \geq d+2$. Given a function $f\colon \mathbb{F}_p^m \to \mathbb{F}_p$, the degree-$d$ evenly-spaced points test: (1) samples a random point $x \in \mathbb{F}_p^m$ and slope $h \in \mathbb{F}_p^m \setminus \{0^m\}$, (2) checks that $\sum_{i=0}^{d+1} c_i f(x+ih) = 0$, where $c_i = (-1)^i \binom{d+1}{i}$. It is well-known that if f passes the degree-d evenly-spaced points test with high probability, then f is close to (the evaluation of) an m-variate polynomial of total degree at most d [15]. Below we ask whether the test is also sound in the non-signaling setting.

Suppose that a k-non-signaling function $\mathcal{F}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ passes the evenly-spaced points test with high probability. Can we deduce any global low-degree structure about $\mathcal{F}$?

In more detail, the probabilistic experiment that we consider is this: first we sample x and h according to the distribution of the evenly-spaced points test, and let the query set S be $\{x + ih : i \in \{0, \ldots, d+1\}\}$; then we sample a local function $g\colon S \to \mathbb{F}_p$ according to the distribution $\mathcal{F}_S$; and finally we check that $\sum_{i=0}^{d+1} c_i g(x+ih) = 0$.

The answer to the above question will, in general, depend on the locality parameter k of $\mathcal{F}$. At minimum, we need $k \geq d+2$ for otherwise we cannot even run the evenly-spaced points test (k is the maximum number of simultaneous queries to $\mathcal{F}$). At the other extreme, when k has the maximum value ($k = p^m$) then we are back to the classical case because $\mathcal{F}$ is now a distribution over functions $f\colon \mathbb{F}_p^m \to \mathbb{F}_p$; hence if $\mathcal{F}$ passes the test with high probability then (one can verify that) with high probability a function f sampled according $\mathcal{F}$ is close to low-degree. In fact, even when $k \geq O(d^m)$, we are in a trivial case, as one can query $\mathcal{F}$ on an interpolating set, a "cube of $(d+1)^m$ points".

We are thus interested in whether or not the test works for *non-trivial* values of k, namely when $O(d) \leq k < O(d^m)$, and thus we will assume that $m \geq 2$. In this regime, k is large enough to run the test, and yet is small enough so that one cannot query an interpolating set. Our first result shows that the test succeeds in the non-signaling setting when $k \geq O(d^2)$. This is a non-signaling analogue of the evenly-spaced points test, similar to how [4] gives a non-signaling analogue of the linearity test of [3].

▶ **Theorem 2** (informal). *Let $\mathcal{F}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a k-non-signaling function that passes the degree-d evenly-spaced points test with high probability, where $k \geq (d+2)^2$. Then $\mathcal{F}$ has a global individual degree-d structure.*

One drawback of the above theorem is that the conclusion only asserts that $\mathcal{F}$ has an individual degree-d structure, when one would like to conclude that $\mathcal{F}$ has a total degree-d structure. We discuss the difficulty of extending the result to total degree-d in Remark 13.

Our second result shows that the test fails when $k \leq O(d^2)$, and moreover it fails *even when the test passes with probability* 1, namely, it fails in the worst possible sense.

▶ **Theorem 3** (informal). *For every k with $2d+2 \leq k < \frac{3}{16}(d+2)^2$, there exists a k-non-signaling function that passes the evenly-spaced points test with probability 1, and yet is $(1-\frac{1}{p})$-far from all degree-d k-non-signaling functions.*

Theorem 3 is surprising, as it reveals that in the non-signaling setting, there is a regime of k in which the low-degree test fails. This stands in sharp contrast to the fact that for linearity testing, there is *no regime* of k in which non-signaling linearity test fails. Our results thus suggest that low-degree testing is a qualitatively different task, as it has a regime of k where a natural test fails.

Theorem 3 also shows that in the case of bivariate testing when $m = 2$, there is (up to constants) no non-trivial value of k where the test succeeds. This is counterintuitive, as bivariate testing is a natural test for which we would expect some guarantee to hold (regardless of how weak), at the very least when the test passes with probability 1.

Other low-degree tests. We note that Theorem 3 generalizes to *any* low-degree test over an arbitrary finite field $\mathbb{F}$ that (1) works by checking constraints that lie along a line, and (2) has perfect completeness.

Beyond low-degree testing. Our theorems on low-degree testing come from applying more general results that we prove about the structure of local characterizations for *any linear code*, in the non-signaling setting. We view our general results on local characterizations as a significant technical contribution within this paper, and we now discuss them.

1.2 Local characterizations and linear proofs

Local characterizations are fundamental to the study of locally testable codes [15]. They express membership in a given linear code via a set of low-weight constraints, and they naturally induce a canonical tester: sample a random low-weight constraint and check if the given word satisfies it. In order to prove the negative result in Theorem 3, we do not need to consider distributions on constraints, but instead we only need to study how constraints express code membership, via *exact* local characterizations [15]. Below we describe one of our main technical contributions, which informally consists of establishing necessary and sufficient conditions for when a constraint set is a local characterization for a code, in the non-signaling setting. We begin by recalling known facts about local characterizations in the classical setting, and then proceed to the non-signaling setting.

The classical setting. A *constraint set* $T \subseteq \mathbb{F}^n$ for a linear code $\mathbf{C} \subseteq \mathbb{F}^n$ is a subset of its dual code $\mathbf{C}^\perp$. A constraint set T is a *ℓ-local characterization* of $\mathbf{C}$ if every $\alpha \in T$ has at most ℓ non-zero entries, and the condition "$\langle \alpha, f \rangle = 0$ for every $\alpha \in T$" implies that $f \in \mathbf{C}$ (and conversely).

For example, the set $\{e_x + e_y - e_{x+y} : x, y \in \{0,1\}^n\}$ where e_x is the x-th standard basis vector in $\{0,1\}^{\{0,1\}^n}$ is a 3-local characterization of the Hadamard code, because $f(x) + f(y) - f(x+y) = 0$ for every $x, y \in \{0,1\}^n$ implies that f is a linear function, and conversely. As another example, the Reed–Muller code containing all polynomials $f \colon \mathbb{F}^m \to \mathbb{F}$ in m variables of total degree at most d has a $(d+2)$-local characterization T, where T contains a constraint α for each subset S of $\mathbb{F}^m$ of size $d+2$ that is contained in a line.

There is a simple condition that is both necessary and sufficient for a constraint set T to be a local characterization for $\mathbf{C}$: the span of T equals $\mathbf{C}^\perp$. In this work it is useful to view this condition instead through the lens of mathematical logic, as follows. Given a constraint set T and $\alpha \in \mathbb{F}^n$, we define the notion of a linear proof.

▶ **Definition 4** (Linear proof). *We write $T \vdash \alpha$ (T proves α) if there exists a sequence $(\alpha_0{:=}0^n, \alpha_1, \ldots, \alpha_{r-1}, \alpha_r{:=}\alpha)$ with each $\alpha_i \in \mathbb{F}^n$ such that, for every $i \in [r]$, one of the following holds:*

- *$\exists\, j < i$ and $b \in \mathbb{F}$ such that $\alpha_i = b\alpha_j$,*
- *$\exists\, j < i$ and $\gamma \in T$ such that $\alpha_i = \alpha_j + \gamma$,*
- *$\exists\, j_1, j_2 < i$ such that $\alpha_i = \alpha_{j_1} + \alpha_{j_2}$.*

As an example, suppose that $\alpha = \sum_{i=1}^{r} b_i\gamma_i$ with each $b_i \in \mathbb{F}$ and $\gamma_i \in T$. Then the sequence $(0^n, \gamma_1, b_1\gamma_1, \ldots, \gamma_r, b_r\gamma_r, \alpha_1, \ldots, \alpha_r)$, where each α_i is the partial sum $b_1\gamma_1 + \cdots + b_i\gamma_i$, gives a linear proof that $\alpha \in \mathrm{span}(T)$.

One can immediately see that $T \vdash \alpha$ if and only if $\alpha \in \mathrm{span}(T)$. In particular, we have the following lemma.

▶ **Lemma 5.** *Linear proofs are (i) complete: if $\langle \gamma, f\rangle = 0$ for every $\gamma \in T$ implies $\langle \alpha, f\rangle = 0$, then $T \vdash \alpha$; and (ii) sound: if $\langle \gamma, f\rangle = 0$ for every $\gamma \in T$ and $T \vdash \alpha$, then $\langle \alpha, f\rangle = 0$. In particular, a constraint set T is a local characterization of a linear code $\mathbf{C}$ if and only if $T \vdash \mathbf{C}^{\perp}$.*

Our goal is to establish a non-signaling analogue of Lemma 5.

A motivating example. We illustrate via an example why a statement like Lemma 5 is non-trivial in the non-signaling setting. Let $n \in \mathbb{N}$ be even, and let $T = \{1^n - e_i : i \in [n]\} \subseteq \{0,1\}^n$, i.e. T contains every vector that is 1 in all but one of the coordinates, where it is 0. Classically, one can check that T is a $(n-1)$-local characterization of the code $\mathbf{C} = \{0^n\}$, as if $f \in \{0,1\}^n$ satisfies $\langle \alpha, f\rangle = 0$ for every $\alpha \in T$ (equivalently, $\sum_{\ell \neq i} f(\ell) = 0$ for every $i \in [n]$), then we must have $f = 0^n$, since n is even. This is because $T \vdash e_i$, and so f must satisfy $f(i) = \langle e_i, f\rangle = 0$.

However, there exist $(n-1)$-non-signaling functions that satisfy every constraint in T and yet are not identically 0; the non-signaling function which outputs uniformly random bits with parity 0 on every set of size exactly $n-1$ is one such example. In particular, T is not a $(n-1)$-local characterization of $\mathbf{C}$. To see why, let us examine where the classical argument that $f(i) = 0$ fails for $(n-1)$-non-signaling functions. Recall that an $(n-1)$-non-signaling function can only be evaluated simultaneously at $n-1$ points. Thus, while one can classically argue, for example, that $f(i) + f(j) = 0$ via the argument that $\sum_{\ell \neq i} f(\ell) = 0$ and $\sum_{\ell \neq j} f(\ell) = 0$ implies that $f(i) + f(j) = \sum_{\ell \neq i} f(\ell) + \sum_{\ell \neq j} f(\ell) = 0$, this reasoning is no longer valid in the non-signaling setting because it requires f to be simultaneously defined at every $i \in [n]$, which is $n > k = n-1$ points. In particular, any proof that $\langle e_i, f\rangle = 0$ from T requires f to be simultaneously defined on all n points, so this logical reasoning is not valid in the non-signaling setting.

An equivalence for non-signaling functions. We prove an analogous equivalence in the non-signaling setting, which informally states that a suitable notion of local characterization for any linear code is equivalent to being able to prove all low weight elements of $\mathbf{C}^{\perp}$ using *local* proofs. This equivalence is a strict generalization of Lemma 5. The example above can thus be viewed as a case where a low weight element of $\mathbf{C}^{\perp}$ (namely, e_i) has no local proof from a particular T.

We begin by formulating a notion of local characterization that works for constraint sets applied to non-signaling functions rather than (classical) functions. There are two main qualitative differences with the classical case. First, the definition depends on the locality parameter k because we need to specify the locality of the non-signaling functions that we

consider. Second, the requirement that a non-signaling function "belongs" to a code $\mathbf{C}$ is expressed via a property that we call $\mathbf{C}$-*explainability*, on which we comment after the definition.

▶ **Definition 6** (informal). *A constraint set $T \subseteq \mathbf{C}^\perp$ is a* **ℓ-local characterization** *for $(\mathbf{C}, k)$ if every $\alpha \in T$ has at most ℓ non-zero entries, and the set of k-non-signaling functions that satisfy every $\alpha \in T$ with probability 1 equals the set of k-non-signaling functions that are "$\mathbf{C}$-explainable".*

The term "$\mathbf{C}$-explainable" refers to the condition that the given non-signaling function is, with probability 1, consistent with the restriction of some codeword in $\mathbf{C}$. This condition is motivated by non-trivial properties of the Fourier spectrum of non-signaling functions that we discuss later on (see Section 2.5). For now, it suffices to say that if a non-signaling function $\mathcal{F}$ is $\mathbf{C}$-explainable then $\mathcal{F}$ satisfies natural *global* properties that extend code membership to the non-signaling setting.

We remark that Definition 6 reduces to the classical notion of local characterization when setting $k := n$. We now introduce the notion of local linear proofs that we use in our equivalence.

▶ **Definition 7** (k-local linear proof). *Given a constraint set T and $\alpha \in \mathbb{F}^n$, we write $T \vdash_k \alpha$ if there exists a sequence $(\alpha_0{:=}0^n, \alpha_1, \ldots, \alpha_{r-1}, \alpha_r{:=}\alpha)$ with each $\alpha_i \in \mathbb{F}^n$ such that, for every $i \in [r]$, one of the following holds:*

- *$\exists\, j < i$ and $b \in \mathbb{F}$ such that $\alpha_i = b\alpha_j$*
- *$\exists\, j < i$ and $\gamma \in T$ such that $|\mathrm{supp}(\alpha_j) \cup \mathrm{supp}(\gamma)| \leq k$ and $\alpha_i = \alpha_j + \gamma$*
- *$\exists\, j_1, j_2 < i$ such that $|\mathrm{supp}(\alpha_{j_1}) \cup \mathrm{supp}(\alpha_{j_2})| \leq k$ and $\alpha_i = \alpha_{j_1} + \alpha_{j_2}$.*

Above, $\mathrm{supp}(\alpha)$ denotes the set of indices $i \in [n]$ where $\alpha_i \neq 0$, and $\mathrm{wt}(\alpha)$ is the size of $\mathrm{supp}(\alpha)$. Notice that Definition 7 is nearly identical to Definition 4: the only change is the addition of the restriction on the support size in the second and third bullets.

The motivation behind Definition 7 is the following fact: if $T \vdash_k \alpha$ then any k-non-signaling function that satisfies every constraint in T must satisfy α as well. Definition 7 thus captures a notion of constraint propagation for non-signaling functions. The restriction on the support size in the second and third bullets is there because querying a k-non-signaling function on more than k points simultaneously is undefined.

We now state our main technical contribution in this section, a non-signaling analogue of Lemma 5.

▶ **Theorem 8** (informal). *k-local linear proofs are complete and sound for k-non-signaling functions. In particular, a constraint set T is a ℓ-local characterization for $(\mathbf{C}, k)$ if and only if $T \vdash_k \alpha$ for every $\alpha \in \mathbf{C}^\perp$ with $\mathrm{wt}(\alpha) \leq k$.*

Proving that k-local linear proofs are sound is straightforward; the interesting component of Theorem 8 is showing that k-local linear proofs are complete. We do this by showing that for every T there exists a k-non-signaling function that satisfies every α where $T \vdash_k \alpha$, and violates every α where $T \nvdash_k \alpha$ with probability $1 - \frac{1}{|\mathbb{F}|}$.

When $k = n$ in Theorem 8 we recover the classical statement (Lemma 5). This is because when $k = n$, $T \vdash_k \alpha$ if and only if $T \vdash \alpha$. However, when $k < n$, the equivalence is qualitatively different from its classical analogue. While Lemma 5 essentially captures a simple linear algebraic statement (the constraints span the dual code), Theorem 8 is a non-trivial statement that *does not involve linear spaces*. This is because the requirement $T \vdash_k \alpha$ depends on k in a way that breaks linearity, as exhibited by our motivating example earlier.

1.3 Roadmap

In Section 2 we provide an overview of the proofs of our results. Then, in Section 3 and Section 4 we formally define non-signaling functions, quasi-distributions, and discuss the relationship between them using Fourier analysis. In Section 5 we discuss what it means for a non-signaling function to "belong" to a given linear code. In Section 6 we prove that the non-signaling low-degree test works (Theorem 2). In Section 7 we prove an equivalence between local characterizations for non-signaling linear codes and local linear proofs (Theorem 8). We conclude in Section 8, by using Theorem 8 to show that the non-signaling low-degree test fails for small locality (Theorem 3).

2 Techniques

We outline the techniques used to prove our results. We begin by explaining the Fourier structure of non-signaling functions in Section 2.1. This structure is fundamental to the proofs of our results. We then outline the proof of Theorem 2 in Section 2.2. In Section 2.3 we outline our proof of the relationship between local characterizations and local linear proofs. In Section 2.4 we use the techniques and main theorem from Section 2.3 to show Theorem 3, that any low-degree lines test fails for non-signaling functions when $k \leq O(d^2)$. Finally, in Section 2.5 we justify our definition of "**C**-explainability".

Notation. A k-non-signaling function $\mathcal{F}$ is defined by local distributions $\mathcal{F}_S$ for each $S \subseteq [n]$ with $|S| \leq k$. Because of this, when studying non-signaling functions we naturally encounter situations where we only consider subsets of a domain containing at most k elements, or vectors in $\mathbb{F}^n$ of weight at most k. We introduce notation to make referring to these notions more convenient. For a subset $S \subseteq [n]$ we write $S \subseteq [n]_{\leq k}$ if $|S| \leq k$. For a vector $\alpha \in \mathbb{F}^n$, we let $\mathrm{supp}(\alpha) = \{i \in [n] : \alpha_i \neq 0\}$ and $\mathrm{wt}(\alpha) = |\mathrm{supp}(\alpha)|$. For a set of vectors $R \subseteq \mathbb{F}^n$, we let $R_{\leq k} \subseteq R$ denote the subset $\{\alpha \in R : \mathrm{wt}(\alpha) \leq k\}$. In particular, $\mathbb{F}^n_{\leq k}$ denotes the set $\{\alpha \in \mathbb{F}^n : \mathrm{wt}(\alpha) \leq k\}$. For a subset $S \subseteq [n]$, we use similar notation and let $R_{\subseteq S} = \{\alpha \in R : \mathrm{supp}(\alpha) \subseteq S\}$.

2.1 The Fourier structure of non-signaling functions

We make frequent use of Fourier analysis to state and establish properties of non-signaling functions. Below we recall basic facts about Fourier analysis, explain their application to quasi-distributions, and state an equivalence between non-signaling functions and quasi-distributions. This equivalence motivates a definition for the Fourier spectrum of a non-signaling function.

Refresher on Fourier analysis. Let $\mathbb{F}$ be the finite field of size q with characteristic p, and $\mathbb{F}_p$ the prime subfield of $\mathbb{F}$. The inner product of $F_1, F_2 \colon \mathbb{F}^n \to \mathbb{C}$ is $\langle F_1, F_2 \rangle := \frac{1}{q^n} \sum_{f \in \mathbb{F}^n} \overline{F_1(f)} F_2(f)$. The *character* corresponding to $\alpha \in \mathbb{F}^n$ is the function $\chi_\alpha \colon \mathbb{F}^n \to \mathbb{C}$ defined as $\chi_\alpha(f) := \omega^{\mathrm{Tr}(\langle \alpha, f \rangle)}$ where: $\mathrm{Tr} \colon \mathbb{F} \to \mathbb{F}_p$ is the trace map; $\langle \alpha, f \rangle$ is the inner product $\sum_{i=1}^n \alpha_i f_i$; $\omega = e^{2\pi i/p}$ is a primitive complex p-th root of unity; and ω^j is defined by thinking of $j \in \mathbb{F}_p$ as an integer in $\{0, 1, \ldots, p-1\}$. The characters $\{\chi_\alpha\}_{\alpha \in \mathbb{F}^n}$ form an orthonormal basis of the space of all functions $F \colon \mathbb{F}^n \to \mathbb{C}$, so every function $F \colon \mathbb{F}^n \to \mathbb{C}$ can be written as

$$F(\cdot) = \sum_{\alpha \in \mathbb{F}^n} \widehat{F}(\alpha) \chi_\alpha(\cdot) \ , \text{ where } \widehat{F}(\alpha) := \langle \chi_\alpha, F \rangle \ .$$

The values $\{\widehat{F}(\alpha)\}_{\alpha \in \mathbb{F}^n}$ are called the *Fourier coefficients* of F.

Quasi-distributions. A *quasi-distribution* $\mathcal{Q}$ over functions $f\colon [n] \to \mathbb{F}$ is a distribution where the probability weights are complex numbers that "add up" to real probabilities. More formally, a quasi-distribution is a function $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ where $\sum_{f\in\mathbb{F}^n} \mathcal{Q}(f) = 1$. (We abuse notation and identify a function $f\colon [n] \to \mathbb{F}$ with the vector in $\mathbb{F}^n$ corresponding to its evaluation table.) We say that $\mathcal{Q}$ is *k-local* if the marginals $\mathcal{Q}|_S$ for each $S \subseteq [n]_{\leq k}$ are distributions, namely, if for each $S \subseteq [n]_{\leq k}$ and $g\colon S \to \mathbb{F}$ it holds that $\sum_{f\in\mathbb{F}^n : f|_S = g} \mathcal{Q}(f)$ is a non-negative real number. We can decompose a quasi-distribution $\mathcal{Q}$ according to the Fourier basis: we can write $\mathcal{Q}(f) = \sum_{\alpha\in\mathbb{F}^n} \widehat{\mathcal{Q}}(\alpha)\chi_\alpha(f)$, where $\{\chi_\alpha\}_{\alpha\in\mathbb{F}^n}$ are the characters and $\{\widehat{\mathcal{Q}}(\alpha)\}_{\alpha\in\mathbb{F}^n}$ are the Fourier coefficients of $\mathcal{Q}$.

Equivalence lemma. The following lemma shows that k-local quasi-distributions and k-non-signaling functions are equivalent, and exposes the Fourier structure of non-signaling functions.

▶ **Lemma 9.** *A quasi-distribution $\mathcal{Q}$ is equivalent to a k-non-signaling function $\mathcal{F}$ if and only if for every $\alpha \in \mathbb{F}^n_{\leq k}$ it holds that $\widehat{\mathcal{Q}}(\alpha) = \frac{1}{q^n}\sum_{j\in\mathbb{F}_p} \omega^{-j} \Pr[\mathrm{Tr}(\langle\alpha,\mathcal{F}\rangle) = j]$, where the random variable $\langle\alpha,\mathcal{F}\rangle$ has the probability distribution given by*

$$\left\{\Pr[\langle\alpha,\mathcal{F}\rangle = b] := \Pr_{f\leftarrow\mathcal{F}_{\mathrm{supp}(\alpha)}}\left[\textstyle\sum_{i\in\mathrm{supp}(\alpha)} \alpha_i f(i) = b\right]\right\}_{b\in\mathbb{F}} .$$

The foregoing lemma motivates defining the Fourier coefficients of a k-non-signaling function $\mathcal{F}$ as follows: for every $\alpha \in \mathbb{F}^n$ with $\mathrm{wt}(\alpha) \leq k$ we define

$$\widehat{\mathcal{F}}(\alpha) := \frac{1}{q^n}\sum_{j\in\mathbb{F}_p} \omega^{-j} \Pr[\mathrm{Tr}(\langle\alpha,\mathcal{F}\rangle) = j] .$$

For more details on the above, including the proof of our Equivalence Lemma, see Section 4.

2.2 Low-degree testing

We outline the proof of Theorem 2. As a simple case, we first state and prove the theorem in the zero error case (when test passes with probability 1), and then we briefly explain how to extend the proof to the robust case (when the test passes with probability $1 - \varepsilon$).

The zero error case. Let $\mathbf{C}$ be the set of all m-variate polynomials of *individual* degree d. Formally, we first show the following.

▶ **Theorem 10** (formal version of Theorem 2, zero error case)**.** *Let $m, d \in \mathbb{N}$ and p be a prime with $p \geq d + 2$. Let $\mathcal{F}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a k-non-signaling function, and suppose that $\mathcal{F}$ passes the degree-d evenly-spaced points test with probability 1. Then $\mathcal{F}$ (viewed as a $\lfloor k/(d+2)\rfloor$-non-signaling function) is $\mathbf{C}$-explainable.*

In the language of Section 1.2, Theorem 10 shows that T, the set of linear constraints checked by the degree-d evenly spaced points test, is a $(d+2)$-local characterization of $\mathbf{C}$.

Theorem 10 is a non-signaling analogue of the following classical fact: if $f\colon \mathbb{F}_p^m \to \mathbb{F}_p$ passes the evenly-spaced points test with probability 1, then f is a polynomial of total degree d. (Note that in Theorem 10 we only conclude that $\mathcal{F}$ has individual degree d. We remark on the difference after the proof.) Our proof of Theorem 10 can be interpreted as taking a local proof of the aforementioned classical fact, and lifting it to the non-signaling setting.

Concretely, let us consider the following simple classical statement.

▶ **Theorem 11** (folklore). *Let $f\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a function such that, for every line L, f agrees with a univariate degree-d polynomial on L. Then for every $S \subseteq \mathbb{F}_p^m$, there exists a degree-$d$ function g such that $g|_S = f|_S$.*

There are multiple known proofs of Theorem 11. To demonstrate the challenges in the non-signaling setting, we first outline a standard classical proof of Theorem 11 that will not generalize to the non-signaling setting. The proof uses the following lemma.

▶ **Lemma 12.** *Suppose that $f\colon \mathbb{F}_p^m \to \mathbb{F}_p$ is a polynomial where $\deg(f) = d < p$. Then there exists a line L in $\mathbb{F}_p^m$ such that $f|_L$ is a univariate polynomial of degree exactly d.*

The above lemma is shown by considering the function $f(a + tb)$ where $a, b \in \mathbb{F}_p^m$, and arguing that the coefficient of t^d in $f(a + tb)$ is a non-zero polynomial in the variables a, b, and hence does not vanish for all $a, b \in \mathbb{F}_p^m$. Thus, there exists a line $L(t) = a + tb$ for which the coefficient of t^d is non-zero, and therefore $f|_L$ has degree exactly d.

With the above lemma, one can prove Theorem 11 as follows. Suppose that f is a polynomial of degree $d' > d$. Then by the lemma there exists a line L such that $f|_L$ has degree $d' > d$, contradicting the fact that $f|_L$ has degree at most d.[3]

The above proof is a good example of a proof that will *not* extend to the non-signaling setting. This is because the proof of Lemma 12 is "global", in the sense that arguing about the polynomial coefficients of f requires "knowing" $f(a)$ for $\Omega(d^m)$ points $a \in \mathbb{F}_p^m$, as this is the minimum number of evaluations of f needed for all polynomial coefficients of f to be fixed. As indicated by Section 1.2, the types of classical proofs that will extend to the non-signaling setting are those with small locality, i.e. ones that require looking at $f(a)$ for only a small number of a at a time. This implies that the above proof will not work for k-non-signaling functions when $k \leq O(d^m)$, i.e., when k is a non-trivial value.

We instead present the following local proof of Theorem 11. Since this proof has small locality it will extend to the non-signaling setting, and thus imply Theorem 10.

Let $S \subseteq \mathbb{F}_p^m$. We wish to show that $f|_S = g|_S$ for some $g \in \mathbf{C}$. Let $S_0 = \emptyset$, and for each $i \in [m]$ define $S_i \subseteq \mathbb{F}_p^i$ to be the projection of S to the first i coordinates, so S_i is the set of all $(a_1, \ldots, a_i) \in \mathbb{F}_p^i$ such that $(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) \in S$ for some $(b_{i+1}, \ldots, b_m) \in \mathbb{F}_p^{m-i}$. Note that $S_m = S$.

We prove by induction that for every $i \in [m]$ and every $b_{i+1}, \ldots, b_m \in \mathbb{F}_p$ there exists an individual degree-d polynomial $g_i\colon \mathbb{F}_p^i \to \mathbb{F}_p$ such that $f|_{S_i \times \{(b_{i+1}, \ldots, b_m)\}} = g_i|_{S_i}$. This proves Theorem 11, as $S_m = S$. The base case ($i = 1$) holds since f looks degree-d on every line, so in particular f is degree-d on the line $\mathbb{F}_p \times \{(b_2, \ldots, b_m)\}$, which contains S_1.

We now argue the induction step. Suppose that the induction hypothesis holds for $i - 1$ and every $b_i, \ldots, b_m \in \mathbb{F}_p$. The induction hypothesis implies that for each $j \in \{0, \ldots, d\}$, there exists an individual degree-d polynomial $g_{i-1}^{(j)}\colon \mathbb{F}_p^{i-1} \to \mathbb{F}_p$ such that $g_{i-1}^{(j)}|_{S_{i-1}} = f|_{S_{i-1} \times \{j\} \times \{(b_{i+1}, \ldots, b_m)\}}$. Let $g_i\colon \mathbb{F}_p^i \to \mathbb{F}_p$ be defined by interpolating the $g_{i-1}^{(j)}$'s along the i-th axis, i.e. $g_i(x_1, \ldots, x_i) := \sum_{j=0}^{d} \delta_j(x_i) \cdot g_{i-1}^{(j)}(x_1, \ldots, x_{i-1})$ where $\delta_j(y)$ is the unique degree-d univariate polynomial that is 1 if $y = j$ and 0 otherwise. We then argue that f agrees with g_i on $S_{i-1} \times \mathbb{F}_p$. This is because f agrees with g_i on $S_{i-1} \times \{0, \ldots, d\}$ (since here $g_i = g_{i-1}^{(j)} = f$ by the induction hypothesis), and therefore agrees with g_i on $S_{i-1} \times \mathbb{F}_p$ by polynomial interpolation, since f looks degree-d on any axis-parallel line along the i-th axis.

[3] The argument as stated does not quite work, as the lemma only holds when $d' < p$. Here, we ignore this technicality to simplify the presentation of the argument.

The above proof can be adapted to an $|S|(d+2)$-local proof (as stated above, it is $|S|p$-local). We thus conclude that if a k-non-signaling function $\mathcal{F}$ looks degree-d on every line L, then it also looks individual degree-d on every S where $|S|(d+2) \leq k$, i.e., $\mathcal{F}$ (viewed as a $\lfloor k/(d+2) \rfloor$-non-signaling function) is $\mathbf{C}$-explainable.

In the aforementioned argument, we have crucially required that $\mathcal{F}$ looks low-degree along *every* line, rather than merely on sets of evenly-spaced points, which are the only constraints checked by the test. Thus, we must show that if $\mathcal{F}$ passes the degree-d evenly-spaced points test with probability 1, then $\mathcal{F}$ looks degree-d on arbitrary subsets of any line. This last step can be viewed as the following. Let T be the set of constraints checked by the evenly-spaced test, and let T' be the set of all low-weight line constraints (weight at most $k-d-2$) satisfied by degree-d polynomials. We show that $T \vdash_k T'$, so $\mathcal{F}$ (by Theorem 8) must also satisfy all constraints in T', and thus looks degree-d on arbitrary subsets of lines, which concludes the proof of Theorem 10.

▶ Remark 13 (total degree vs. individual degree). Theorem 2 only concludes that $\mathcal{F}$ has an individual degree-d structure, when one might expect to conclude that it has a *total* degree-d structure, as it passes the evenly-spaced points test along *random lines*. Indeed, this is the conclusion in the classical setting. The difficulty in establishing such a result comes from Lemma 12. The classical analysis of the low-degree test proceeds by induction, initially concluding that $f\colon \mathbb{F}^m \to \mathbb{F}$ is a polynomial that is degree-d in x_m and total degree-d in all the other variables, and hence is a total degree-$2d$ polynomial. Then, by using Lemma 12 one concludes that in fact f has total degree-d, not $2d$. A non-signaling analogue of Lemma 12 would allow us to conclude a total degree-d structure. However, as explained earlier the classical proof of Lemma 12 is not local, so it does not lift to a non-signaling one. Exploring whether or not the gap between total and individual degree is necessary in the non-signaling setting is thus an intriguing open question.

The robust case. We now explain how to adapt the above proof to the robust case. Our goal now is to show that $\mathcal{F}$ is close to a $\mathbf{C}$-explainable non-signaling function, where the distance between two k-non-signaling functions $\mathcal{F}$ and $\mathcal{G}$ is defined as

$$\Delta_k(\mathcal{F},\mathcal{G}) = \max_{S\subseteq[n],|S|\leq k} \Delta_{\mathrm{TV}}(\mathcal{F}_S,\mathcal{G}_S) \ ,$$

where Δ_{TV} is the total variation distance between distributions [4]. As in the case of linearity testing in [4], this is impossible, as the definition of distance requires that $\mathcal{F}$ be close to $\mathbf{C}$-explainable on all sets $S \subseteq \mathbb{F}_p^m$ with $|S| \leq k$. In particular, if $\mathcal{F}$ looks low-degree on all lines but one, then $\mathcal{F}$ will be very far from $\mathbf{C}$-explainable. Following [4], we instead show that an appropriately defined self-correction of $\mathcal{F}$, denoted by $\hat{\mathcal{F}}$, is close to $\mathbf{C}$-explainable. Informally, $\hat{\mathcal{F}}(x)$ is defined by querying $\mathcal{F}$ on a random evenly-spaced line L passing through x, and then setting $\hat{\mathcal{F}}(x)$ to be the value at x obtained by locally decoding $\mathcal{F}$ along L. $\hat{\mathcal{F}}$ is a $\hat{k}$-non-signaling function, where $\hat{k} = k/(d+1)$.

We prove Theorem 2 via the following four steps:

1. Average to worst case reduction: we show that if $\mathcal{F}$ passes the evenly-spaced points test with high probability, then $\hat{\mathcal{F}}$ looks low-degree on *every* set of evenly-spaced set of points contained in a line L with high probability.
2. From evenly-spaced points to arbitrary subsets of a line: we show that if $\hat{\mathcal{F}}$ looks low-degree on every set of evenly-spaced set of points contained in a line, then $\hat{\mathcal{F}}$ looks low-degree on every subset of every line L.

3. Robust local characterization: we show that T, the set of constraints where the support of the constraint is contained in some line L, is a robust local characterization of $\mathbf{C}$, i.e. that if $\hat{\mathcal{F}}$ satisfies every $\alpha \in T$ with high probability, then $\hat{\mathcal{F}}$ satisfies every $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$ with high probability, where $k' = \hat{k}/(d+2)$.
4. Finishing the proof: we show that if $\hat{\mathcal{F}}$ satisfies every $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$ with high probability, then $\hat{\mathcal{F}}$ is close to a $\mathbf{C}$-explainable non-signaling function.

We have already discussed the proofs of the second and third steps in the zero error case. In the robust case, the main difference is that we now pay some small error in union bounds every time we use the fact that $\hat{\mathcal{F}}$ looks low-degree along an evenly-spaced line.

The first step follows from our non-trivial definition of $\hat{\mathcal{F}}$. Naively, one might define $\hat{\mathcal{F}}$ for each x by locally decoding its value from $\mathcal{F}$ along a random evenly-spaced line containing x. This does not work. Instead, we decode its value along the line $L_x(t) = x + iw_x$, where the slopes (the w_x's) are correlated so that $w_{x+y} = w_x + w_y - w_{0^n}$. These correlations, combined with the fact that $L(t)$ looks random for each x, allows us to show that $\hat{\mathcal{F}}$ looks low-degree on every evenly-spaced set of points.

The final step follows abstractly from the more general statements we show for all linear codes, and relies on our characterization of the Fourier spectrum of $\mathbf{C}$-explainable non-signaling functions.

2.3 Local characterizations and linear proofs

We outline the proof of Theorem 8; we assume familiarity with the notions introduced in Section 1.2. We begin by formally defining local characterizations.

Local characterizations. We say that a k-non-signaling function $\mathcal{F}$ is $\mathbf{C}$-*explainable* if for every $S \subseteq [n]_{\leq k}$, with probability 1 the function $f\colon S \to \mathbb{F}$ sampled from $\mathcal{F}_S$ is in $\mathbf{C}|_S$. (See Section 2.5 for a discussion of this definition.) Recall from Definition 6 that a subset $T \subseteq \mathbf{C}^{\perp}$ is an ℓ-local characterization of $(\mathbf{C}, k)$ if every $\alpha \in T$ has $\mathrm{wt}(\alpha) \leq \ell$ and the set of k-non-signaling functions $\mathcal{F}$ where $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in T$ equals the set of $\mathbf{C}$-explainable k-non-signaling functions.

Outline of the proof. The proof of Theorem 8 has two directions: completeness and soundness. For soundness, we show that if $T \vdash_k \alpha$, then for any k-non-signaling function $\mathcal{F}$ where $\langle \gamma, \mathcal{F} \rangle = 0$ holds with probability 1 for every $\gamma \in T$, it also holds that $\langle \alpha, \mathcal{F} \rangle = 0$ with probability 1. Intuitively, this means that any k-non-signaling function satisfying every constraint in T must satisfy α as well, and therefore shows that our definition of "proof" makes sense. The proof of this direction is straightforward, and can be found in Section 7.1.

To show completeness, we explicitly construct a k-non-signaling function $\mathcal{F}$ that satisfies every constraint α where $T \vdash_k \alpha$ with probability 1, and satisfies every other constraint α with probability $\frac{1}{|\mathbb{F}|}$. Our construction of $\mathcal{F}$ makes crucial use of the notion of a *local subspace* that we introduce.

▶ **Definition 14.** *A* **k-local subspace** *$\mathcal{V}$ is a subset of $\mathbb{F}^n_{\leq k}$ that looks like a subspace when restricted to local views of size at most k, i.e., $\mathcal{V}_{\subseteq S}$ is a linear subspace in $\mathbb{F}^n$ for every $S \subseteq [n]_{\leq k}$.*

We show that for any k-local subspace $\mathcal{V}$ there is a k-non-signaling function $\mathcal{F}$ where $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathcal{V}$ and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathbb{F}|}$ otherwise. We then show that the set of α's provable from T, which is $\{\alpha \in \mathbb{F}^n_{\leq k} : T \vdash_k \alpha\}$, is a k-local subspace. This latter step is straightforward, and the proof is in Section 7.3. We now discuss the first step, which is non-trivial.

Non-signaling functions from local subspaces. Given a k-local subspace $\mathcal{V}$, we argue that there is a k-non-signaling function $\mathcal{F}$ where $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathcal{V}$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathbb{F}|}$ for every $\alpha \notin \mathcal{V}$. We construct $\mathcal{F} = \{\mathcal{F}_S\}_{S \subseteq [n] : |S| \leq k}$ by specifying its local distributions $\mathcal{F}_S$.

A distribution over functions $f \colon S \to \mathbb{F}$ is a function that maps each f to a non-negative real number such that the total sum is 1. With this viewpoint, we first define $\mathcal{F}_S$ as a *function* that maps each $f \colon S \to \mathbb{F}$ to a complex number. Then, we show that the total sum is 1 and that each f is mapped to a non-negative real number, so that the function $\mathcal{F}_S$ is indeed a distribution.

We define the function $\mathcal{F}_S \colon \mathbb{F}^S \to \mathbb{C}$ by specifying its Fourier coefficients:

$$\widehat{\mathcal{F}_S}(\alpha) := \begin{cases} \frac{1}{q^{|S|}} & \text{if } \alpha \in \mathcal{V} \\ 0 & \text{if } \alpha \notin \mathcal{V} \end{cases} ,$$

These "local" Fourier coefficients should *not* be confused with the Fourier coefficients of $\mathcal{F}$ that are defined in Section 2.1. In fact, at this point the non-signaling function $\mathcal{F}$ is not yet defined.

This completely specifies $\mathcal{F}_S$ as a function $\mathbb{F}^S \to \mathbb{C}$. We show that since $\mathcal{V}$ is a k-local subspace, $\mathcal{F}_S$ is in fact a distribution. First, $\sum_{f \in \mathbb{F}^S} \mathcal{F}_S(f) = 1$ because $\widehat{\mathcal{F}_S}(0^S) = 1/q^{|S|}$ since $\mathcal{V}$ is a k-local subspace, and thus must contain 0^n. Hence, it suffices to show that $\mathcal{F}_S(f) \in \mathbb{R}_{\geq 0}$ for each $f \in \mathbb{F}^S$. For each $f \in \mathbb{F}^S$ we have

$$\mathcal{F}_S(f) = \sum_{\alpha \in \mathbb{F}^S} \widehat{\mathcal{F}_S}(\alpha) \chi_\alpha(f) = \sum_{\alpha \in \mathcal{V}_{\subseteq S}} \widehat{\mathcal{F}_S}(\alpha) \chi_\alpha(f) ,$$

since we have defined $\mathcal{F}_S$ in this way using its Fourier coefficients. There are two cases: either $\langle \alpha, f \rangle = 0$ for every $\alpha \in \mathcal{V}_{\subseteq S}$, in which case the sum is $|\mathcal{V}_{\subseteq S}|/q^{|S|}$, or $\langle \alpha, f \rangle \neq 0$ for some $\alpha \in \mathcal{V}_{\subseteq S}$. In the latter case, we use the fact that $\mathcal{V}_{\subseteq S}$ is a linear subspace to show that the sum is 0. In either case, we conclude that $\mathcal{F}_S(f)$ is a non-negative real number, and therefore that $\mathcal{F}_S$ is a distribution.

Next, we argue that the collection of local distributions $\{\mathcal{F}_S\}_{S \subseteq [n]_{\leq k}}$ is indeed non-signaling. This follows from a lemma that we prove that shows that a collection of local distributions is non-signaling if and only if the Fourier coefficients of the local distributions (after removing the normalization factors) are the same. Thus the k-non-signaling function $\mathcal{F}$ is well-defined.

Finally, we show that $\mathcal{F}$ satisfies the desired properties. This follows from our definition of each $\mathcal{F}_S$, as the construction implies that the Fourier coefficients of $\mathcal{F}$ satisfy:

$$\widehat{\mathcal{F}}(\alpha) := \begin{cases} \frac{1}{q^n} & \text{if } \alpha \in \mathcal{V} \\ 0 & \text{if } \alpha \notin \mathcal{V} \end{cases} .$$

This corresponds to having $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathcal{V}$, and the random variable $\langle \alpha, \mathcal{F} \rangle$ having the uniform distribution when $\alpha \notin \mathcal{V}$, which completes the proof.

2.4 Low-degree testing fails for small locality

We discuss how to prove Theorem 3. We let $\mathbf{C}$ denote the linear code of polynomials $f \colon \mathbb{F}^m \to \mathbb{F}$ of total degree-d, and let T be the set of all $\alpha \in \mathbf{C}^\perp$ whose support is contained in a line in $\mathbb{F}^m$. Note that for any low-degree test that only checks line constraints and has perfect completeness, if we let T_0 be the set of constraints checked by this test, we will have $T_0 \subseteq T$.

The main combinatorial quantity that we use in our proof is the *rank* of an element $\alpha \in \mathbf{C}^\perp$, defined as

$$\mathsf{rank}_T(\alpha) := \min_{T' \subseteq T : \alpha \in \mathrm{span}(T')} |T'| \ .$$

Note that $\mathsf{rank}_T(\alpha)$ is a non-negative integer, as $\mathrm{span}(T) = \mathbf{C}^\perp$.

We now sketch the proof of Theorem 3 in three steps.

(1) Interval Cut Lemma. We show a generic lemma about the relationship between rank and provability from T. Informally, we show that in order for T to prove α of rank at least r, T must also prove some β of "intermediate" rank. Formally, we show that if there is an interval $[r/2, r)$ such that every β with rank in this interval is *not* provable from T, then every α of rank at least r is also not provable from T. We prove this *Interval Cut Lemma* via the fact that rank_T is subadditive, that is, $\mathsf{rank}_T(\alpha + \beta) \leq \mathsf{rank}_T(\alpha) + \mathsf{rank}_T(\beta)$. Subadditivity implies that for every interval $[r/2, r)$, in order to prove a constraint of rank $\geq r$ from constraints of rank $< r/2$ there must be an intermediate constraint β with rank in $[r/2, r)$ bridging the gap.

(2) Two combinatorial facts. We prove two combinatorial facts about the dual code of $\mathbf{C}$.

- There exists $\alpha^* \in \mathbf{C}^\perp$ where $\mathrm{wt}(\alpha) = 2d+2$ and $\mathrm{supp}(\alpha) \subseteq \{(a, a^2, 0^{m-2}) : a \in \mathbb{F}\} \subseteq \mathbb{F}^m$, i.e., $\mathrm{supp}(\alpha)$ is contained along the curve $x_1^2 - x_2 = 0$ embedded on the plane $x_3 = x_4 = \cdots = x_m = 0$ of $\mathbb{F}^m$.
  Proof sketch. If f is an m-variate polynomial of total degree d then $f(t, t^2, 0, \ldots, 0)$ is a polynomial of degree $\leq 2d$ in t. Thus, there is an element $\alpha^* \in \mathbf{C}^\perp$ supported on this curve of weight $2d+2$ that checks some linear constraint. This shows the existence of the desired α^*.
- For every $\beta \in \mathbf{C}^\perp$ with $\mathsf{rank}_T(\beta) \in \{(d+2)/4, \ldots, (d+2)/2\}$ it holds that $\mathrm{wt}(\beta) \geq \frac{3}{16}(d+2)^2$.
  Proof sketch. Any β of rank r is the sum of *exactly* r line constraints, where each constraint is on a *distinct* line. Each new constraint adds at least $d+2$ weight to β, ignoring the weight that is removed by cancellation. The amount of cancellation is at most the number of intersection points, which is not too large when r is in $\{(d+2)/4, \ldots, (d+2)/2\}$, thus implying that $\mathrm{wt}(\beta) \geq \frac{3}{16}(d+2)^2$.

(3) Completing the proof. Theorem 3 follows from the Interval Cut Lemma, the two combinatorial facts, and Theorem 8. Any $\beta \in \mathbf{C}^\perp$ with rank in $[(d+2)/4, (d+2)/2)$ has weight $\geq \frac{3}{16}(d+2)^2$, and thus is *not* provable when $k < \frac{3}{16}(d+2)^2$. Since α^* has weight $2d+2$ and is supported only on the diagonal, it has rank $\geq d+1$, as each line constraint increases the number of points on the curve by at most 2, by Bézout's theorem. The Interval Cut Lemma implies that α^* is also not provable. The non-signaling function constructed in the proof of Theorem 8 thus passes the random lines test with probability 1 yet satisfies α^* with probability only $1/|\mathbb{F}|$. But, α^* must be satisfied with probability 1 by any non-signaling function that is "locally low-degree", which completes the proof.

2.5 Fourier spectrum of non-signaling linear codes

We have so far adopted the definition that a k-non-signaling function $\mathcal{F}$ is "in" a linear code $\mathbf{C} \subseteq \mathbb{F}^n$ if a function $f \colon S \to \mathbb{F}$ sampled from $\mathcal{F}_S$ is in $\mathbf{C}|_S$ with probability 1 for every $S \subseteq [n]_{\leq k}$. Indeed, we use this "$\mathbf{C}$-explainability" to define the notion of a *local characterization* (see Definition 6).

We now provide thorough justification for this choice. We view the definitions and results below as a conceptual contribution that sheds light on basic properties of non-signaling functions.

In the classical setting, a function $f\colon [n] \to \mathbb{F}$ "looks like" a codeword of $\mathbf{C}$ if, well, it equals some codeword in $\mathbf{C}$. The issue at hand is that, in the non-signaling setting, it is not immediately clear what it means for a non-signaling function $\mathcal{F}$ to be "in" $\mathbf{C}$ because $\mathcal{F}$ is a collection of local distributions. Below are two natural ways to capture this notion.

▶ **Definition 15** (informal). *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function.*

- *We say that $\mathcal{F}$ is* **C-supported** *if it is equivalent to a k-local quasi-distribution $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ that is supported on $\mathbf{C}$, namely, $\mathcal{Q}(f) = 0$ for all $f \notin \mathbf{C}$.*[4]
- *We say that $\mathcal{F}$ is* **C-explainable** *if, for all $S \subseteq [n]_{\leq k}$, the distribution $\mathcal{F}_S$ is supported on $\mathbf{C}|_S$. In other words, the output of $\mathcal{F}$ is always consistent with the restriction of some codeword in $\mathbf{C}$.*

The first definition is motivated by our Equivalence Lemma (Lemma 9), and imposes a "global" property on the non-signaling function. The second definition, implied by the first one, instead takes a "local" approach, imposing consistency with relevant restrictions of the code.

In the following lemma, we quantify the difference between the notions of "**C**-supported" and "**C**-explainable" by characterizing the Fourier spectrum in each case. For convenience, we denote by $\mathbf{C}^{\perp}_{\leq k}$ the set $\{\alpha \in \mathbf{C}^{\perp} : \mathrm{wt}(\alpha) \leq k\}$, which are the constraints with at most k non-zero entries.

▶ **Lemma 16** (informal). *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function.*

- *$\mathcal{F}$ is $\mathbf{C}$-supported $\leftrightarrow$ the Fourier coefficients $\{\widehat{\mathcal{F}}(\alpha)\}_{\alpha \in \mathbb{F}^n_{\leq k}}$ are constant on each coset of $\mathbf{C}^{\perp}$.*
- *$\mathcal{F}$ is $\mathbf{C}$-explainable $\leftrightarrow$ the Fourier coefficient $\widehat{\mathcal{F}}(\alpha)$ equals $\frac{1}{q^n}$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k}$.*

We additionally prove that the foregoing structure is robust to errors: $\mathcal{F}$ is close to being $\mathbf{C}$-supported if and only if its Fourier coefficients are almost constant on every coset of $\mathbf{C}^{\perp}$; moreover $\mathcal{F}$ is close to being $\mathbf{C}$-explainable if and only if $\widehat{\mathcal{F}}(\alpha)$ is close to $\frac{1}{q^n}$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k}$.

One may interpret Lemma 16 as "bad news" because it shows that the notions of "**C**-supported" and "**C**-explainable" are in fact *distinct*. Which one is the correct one to use? From the perspective of local testability, we may regard "**C**-supported" as more desirable, because it requires a global structure to hold. We prove that, fortunately, the two notions are equivalent up to a small change in parameters, reinforcing our belief that we have identified the right notions.

▶ **Lemma 17** (informal). *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function.*

- *If $\mathcal{F}$ is $\mathbf{C}$-supported, then $\mathcal{F}$ is $\mathbf{C}$-explainable.*
- *If $\mathcal{F}$ is $\mathbf{C}$-explainable, then $\mathcal{F}$ (viewed as a $k/2$-non-signaling function) is $\mathbf{C}$-supported.*

In light of the above, it suffices to study non-signaling functions that are **C**-explainable. We have used this notion in our results on local characterizations (see Definition 6), as it is more natural in this setting: the set of **C**-explainable k-non-signaling functions are precisely those that are consistent with the set of constraints $\mathbf{C}^{\perp}_{\leq k}$.

[4] When $\mathbf{C}$ is the Hadamard code, this definition equals the notion of a *linear* non-signaling function from [4].

Detailed definitions and proofs can be found in Section 5. Below we provide proof sketches for Lemmas 16 and 17. The Fourier structure of non-signaling functions, discussed in Section 2.1, underlies all of these proofs.

2.5.1 Fourier spectrum of a C-supported function

We outline the proof of the first item of Lemma 16. A k-non-signaling function $\mathcal{F}$ that is $\mathbf{C}$-supported is by definition equivalent to a quasi-distribution $\mathcal{Q}$ supported on $\mathbf{C}$. We explain why all such non-signaling functions have Fourier coefficients that are constant on cosets of $\mathbf{C}^\perp$, that is, $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{F}}(\alpha')$ for every $\alpha, \alpha' \in \mathbb{F}^n_{\leq k}$ with $\alpha - \alpha' \in \mathbf{C}^\perp$. We compare the following two affine spaces:

$$V_1 = \left\{ \mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C} \text{ s.t. } \sum_{f \in \mathbf{C}} \mathcal{Q}(f) = 1 \text{ and } \mathcal{Q}(f) = 0 \ \forall f \notin \mathbf{C} \right\} ,$$

$$V_2 = \left\{ \mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C} \text{ s.t. } \widehat{\mathcal{Q}}(0^n) = \frac{1}{q^n} \text{ and } \widehat{\mathcal{Q}}(\alpha) = \widehat{\mathcal{Q}}(\alpha + \gamma) \ \forall \alpha \in \mathbb{F}^n, \gamma \in \mathbf{C}^\perp \right\} .$$

The affine space V_1 corresponds to quasi-distributions that are supported on $\mathbf{C}$, while V_2 corresponds to quasi-distributions whose Fourier coefficients satisfy the desired characterization. It suffices to prove that $V_1 = V_2$. First we show that $\dim(V_1) = \dim(V_2)$, and then that $V_1 \subseteq V_2$.

The dimension of V_1 is $|\mathbf{C}| - 1$ because the $|\mathbf{C}|$ free terms are subject to a single linear constraint. The dimension of V_2 is $q^n/\left|\mathbf{C}^\perp\right| - 1$ because the Fourier coefficients are constant on each coset of $\mathbf{C}^\perp$, and on each coset they may have an arbitrary value; the one exception is the coset $\mathbf{C}^\perp$, where the Fourier coefficients must be $\frac{1}{q^n}$. Recalling that $q^n = |\mathbf{C}| \cdot \left|\mathbf{C}^\perp\right|$, we deduce that $\dim(V_1) = \dim(V_2)$.

Next we show that $V_1 \subseteq V_2$. For any $\mathcal{Q} \in V_1$ and $\alpha \in \mathbb{F}^n$ we have by definition

$$\widehat{\mathcal{Q}}(\alpha) := \frac{1}{q^n} \cdot \sum_{f \in \mathbb{F}^n} \mathcal{Q}(f) \cdot \omega^{-\mathrm{Tr}(\langle \alpha, f \rangle)} .$$

Since $\mathcal{Q} \in V_1$, any function f in the support of $\mathcal{Q}$ must be in $\mathbf{C}$. Therefore, for any $\gamma \in \mathbf{C}^\perp$ have $\langle \gamma, f \rangle = 0$, so that $\omega^{\mathrm{Tr}(\langle \gamma, f \rangle)} = \omega^{\mathrm{Tr}(0)} = 1$. This implies that $\widehat{\mathcal{Q}}(\alpha) = \widehat{\mathcal{Q}}(\alpha + \gamma)$. Intuitively, when we shift α by γ the sum remains unchanged because each term in the sum is multiplied by $\omega^{-\mathrm{Tr}(\langle \gamma, f \rangle)} = 1$. Thus $V_1 \subseteq V_2$. Since $\dim(V_1) = \dim(V_2)$ and $V_1 \subseteq V_2$, we conclude that $V_1 = V_2$.

2.5.2 Fourier spectrum of a C-explainable function

We outline the proof of the second item of Lemma 16. The characterization of $\mathbf{C}$-explainable functions relies on the fact that the Fourier coefficient $\widehat{\mathcal{F}}(\alpha)$ is related to the distribution of the random variable $\langle \alpha, \mathcal{F} \rangle$, i.e., the distribution $(\Pr[\langle \alpha, \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$. This intuition can be quantified via (a generalization of) the DFT matrix $M \in \mathbb{C}^{q \times q}$, which is the matrix defined as $M_{a,b} := \omega^{-\mathrm{Tr}(ab)}$ (entries are indexed by $\mathbb{F}$); M is invertible and $\frac{1}{\sqrt{q}} M$ is unitary.

Recall that the Fourier coefficients of $\mathcal{F}$ are defined as follows:

$$\forall\, \alpha \in \mathbb{F}^n_{\leq k} \quad \widehat{\mathcal{F}}(\alpha) := \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] .$$

Letting $v := (\Pr[\langle \alpha, \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$, expanding the definitions shows that $Mv = (q^n \widehat{\mathcal{F}}(a\alpha))_{a \in \mathbb{F}}$. The linear transformation M thus quantifies the relation between the distribution $(\Pr[\langle \alpha, \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$ and the Fourier coefficients $(q^n \widehat{\mathcal{F}}(a\alpha))_{a \in \mathbb{F}}$.

Now, given a k-non-signaling function $\mathcal{F}$, we first show that $\mathcal{F}$ is $\mathbf{C}$-explainable if and only if $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k}$. This follows from the fact that any local function $g \colon S \to \mathbb{F}$ that satisfies every $\alpha \in \mathbf{C}^{\perp}_{\subseteq S}$ can be extended into a codeword $f \in \mathbf{C}$. Using the matrix M, we can relate the condition that $\mathcal{F}$ satisfies every $\alpha \in \mathbf{C}^{\perp}_{\leq k}$ with probability 1 to its Fourier spectrum. Specifically, we have that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ if and only if $(q^n \widehat{\mathcal{F}}(a\alpha))_{a \in \mathbb{F}} = M(1, 0, \ldots, 0)^{\top}$. Since $M(1, 0, \ldots, 0)^{\top} = (1, \ldots, 1)^{\top}$, we get that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ if and only if $\widehat{\mathcal{F}}(a\alpha) = \frac{1}{q^n}$ for every $a \in \mathbb{F}$, completing the proof.

2.5.3 The relationship between C-supported and C-explainable

We outline the proof of Lemma 17. First note that Lemma 16 immediately implies that a $\mathbf{C}$-supported k-non-signaling function $\mathcal{F}$ is $\mathbf{C}$-explainable, because if $\mathcal{F}$ is $\mathbf{C}$-supported then $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{F}}(0^n) = \frac{1}{q^n}$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k}$, implying that $\mathcal{F}$ is $\mathbf{C}$-explainable.

Conversely, if $\mathcal{F}$ is $\mathbf{C}$-explainable, then for any $\alpha, \alpha' \in \mathbb{F}^n_{\leq k/2}$ with $\alpha - \alpha' \in \mathbf{C}^{\perp}$ we get that for any $b \in \mathbb{F}$,

$$\Pr[\langle \alpha, \mathcal{F} \rangle = b] = \Pr[\langle \alpha', \mathcal{F} \rangle + \langle \alpha - \alpha', \mathcal{F} \rangle = b] = \Pr[\langle \alpha', \mathcal{F} \rangle = b] \ ,$$

since $\Pr[\langle \alpha - \alpha', \mathcal{F} \rangle = 0] = 1$ as $\alpha - \alpha' \in \mathbf{C}^{\perp}$ and $\mathcal{F}$ is $\mathbf{C}$-explainable. This shows that the vectors $(\Pr[\langle \alpha, \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$ and $(\Pr[\langle \alpha', \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$ are equal, which implies that the Fourier coefficients $\widehat{\mathcal{F}}(\alpha)$ and $\widehat{\mathcal{F}}(\alpha')$ are equal. By Lemma 16, this completes the proof. Note that we crucially need $\mathrm{wt}(\alpha), \mathrm{wt}(\alpha') \leq k/2$ so that $\mathrm{wt}(\alpha - \alpha') \leq k$, as otherwise $\Pr[\langle \alpha - \alpha', \mathcal{F} \rangle = 0]$ is undefined.

3 Preliminaries

Throughout this paper we let $n \in \mathbb{N}$ be an arbitrary positive integer, and $k \in \mathbb{N}$ a positive integer that is at most n. We use $\mathbb{F}$ to denote the finite field of size q with characteristic p, and $\mathbb{F}_p$ to denote the prime subfield of $\mathbb{F}$. We often abuse notation and identify a function $f \colon [n] \to \mathbb{F}$ with its evaluation table in $\mathbb{F}^n$. For a vector $\alpha \in \mathbb{F}^n$ we let $\mathrm{supp}(\alpha) := \{i \in [n] : \alpha_i \neq 0\}$, and we let $\mathrm{wt}(\alpha) := |\mathrm{supp}(\alpha)|$. For a set of vectors $R \subseteq \mathbb{F}^n$, we let $R_{\leq \ell} \subseteq R$ denote the subset $\{\alpha \in R : \mathrm{wt}(\alpha) \leq \ell\}$. In particular, $\mathbb{F}^n_{\leq k}$ contains all vectors $\alpha \in \mathbb{F}^n$ of weight at most k. For a subset $S \subseteq [n]$, we let $R_{\subseteq S} = \{\alpha \in R : \mathrm{supp}(\alpha) \subseteq S\}$; we also write $S \subseteq [n]_{\leq \ell}$ if $|S| \leq \ell$.

3.1 Non-signaling functions

We define *non-signaling functions* and *quasi-distributions*, and introduce useful notation for them. The definitions are almost identical to those in [4], but extended to any finite field.

▶ **Definition 18.** *A* **k-non-signaling function** $\mathcal{F} \colon [n] \to \mathbb{F}$ *is a collection* $\mathcal{F} = \{\mathcal{F}_S\}_{S \subseteq [n]_{\leq k}}$ *where (i) each* $\mathcal{F}_S$ *is a distribution over functions* $f \colon S \to \mathbb{F}$*, and (ii) for every two subsets* S *and* R *each of size at most* k*, the restrictions of* $\mathcal{F}_S$ *and* $\mathcal{F}_R$ *to* $S \cap R$ *are equal as distributions.*

Note that any function $f \colon [n] \to \mathbb{F}$ induces a n-non-signaling function by setting $\mathcal{F}_S$ to be the distribution that outputs $f|_S$ with probability 1. More generally, any distribution $\mathcal{D}$ over functions $f \colon [n] \to \mathbb{F}$ induces a corresponding n-non-signaling function by defining $\mathcal{F}_S$ to be the distribution that samples $f \leftarrow \mathcal{D}$ and outputs $f|_S$.

Given a set $S \subseteq [n]_{\leq k}$ and function $g \in \mathbb{F}^S$, we define

$$\Pr\left[\, \mathcal{F}(S) = g \,\right] := \Pr[\, g \leftarrow \mathcal{F}_S \,] \ .$$

The non-signaling property in this notation is the following: for every two subsets $S, R \subseteq [n]_{\leq k}$ and every string $g \in \mathbb{F}^{S \cap T}$, $\Pr[\mathcal{F}(S)|_{S\cap T} = g] = \Pr[\mathcal{F}(T)|_{S\cap T} = g]$, where the probability is over the randomness of $\mathcal{F}$.

We extend the above notation to every $E \subseteq \mathbb{F}^S$ in the natural way by defining $\Pr[\mathcal{F}(S) \in E]$ to be $\Pr_{f \leftarrow \mathcal{F}_S}[f \in E]$. We highlight the case when E is an "inner product event", as we will encounter this case frequently.

▶ **Definition 19.** *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function. For $\alpha \in \mathbb{F}^n_{\leq k}$ and $b \in \mathbb{F}$, we define*

$$\Pr[\langle \alpha, \mathcal{F} \rangle = b] := \Pr_{f \leftarrow \mathcal{F}_{\mathrm{supp}(\alpha)}} \left[\sum_{i \in \mathrm{supp}(\alpha)} \alpha_i f(i) = b \right] .$$

Similarly, we define $\Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] := \sum_{b \in \mathbb{F}: \mathrm{Tr}(b) = j} \Pr[\langle \alpha, \mathcal{F} \rangle = b]$ for every $j \in \mathbb{F}_p$.

The probability above is well-defined since $\mathrm{wt}(\alpha) \leq k$, and so we query $\mathcal{F}$ on at most k points.

Since $\mathcal{F}$ is non-signaling, $\Pr[\langle \alpha, \mathcal{F} \rangle = b] = \Pr_{f \leftarrow \mathcal{F}_S}[\sum_{i \in S} \alpha_i f(i)]$ for any set $S \supseteq \mathrm{supp}(\alpha)$. The intuition behind the above definition is that the inner product $\langle \alpha, g \rangle$ for any $g\colon [n] \to \mathbb{F}$ can be computed only given $g|_{\mathrm{supp}(\alpha)}$, namely, given g restricted to a set of size at most k.

3.2 Quasi-distributions

A quasi-distribution extends the notion of a probability distribution by allowing probabilities to be complex, and is the main tool that we use to analyze non-signaling functions.

▶ **Definition 20.**

- *A* **quasi-distribution** *is a function $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ where $\sum_{f \in \mathbb{F}^n} \mathcal{Q}(f) = 1$.*
- *For a set of functions $R \subseteq \mathbb{F}^n$, we say that $\mathcal{Q}$ is* **supported** *on R if $\{f \in \mathbb{F}^n : \mathcal{Q}(f) \neq 0\} \subseteq R$.*
- *For a positive integer ℓ, we say that $\mathcal{Q}$ is* **ℓ-local** *if the marginals $\mathcal{Q}|_S$ for each $S \subseteq [n]_{\leq \ell}$ are distributions ($\sum_{f \in \mathbb{F}^n : f|_S = g} \mathcal{Q}(f)$ is a non-negative real number for each $S \subseteq [n]_{\leq \ell}$ and $g\colon S \to \mathbb{F}$).*

If $\mathcal{Q}$ is ℓ-local, then for every subset $S \subseteq [n]_{\leq \ell}$, we may view $\mathcal{Q}|_S$ as a probability distribution over $\mathbb{F}^S$. If $\mathcal{Q}$ is ℓ-local then it is s-local for every $s \in \{0, 1, \ldots, \ell\}$.

▶ **Definition 21.** *Given a quasi-distribution $\mathcal{Q}$, a subset $S \subseteq [n]$, and $g \in \mathbb{F}^S$, we define the* **quasi-probability** *of the event "$\mathcal{Q}(S) = g$" to be the following complex number*

$$\widetilde{\Pr}[\mathcal{Q}(S) = g] := \sum_{f \in \mathbb{F}^n : f|_S = g} \mathcal{Q}(f) .$$

(The tilde above Pr *denotes that quasi-probabilities are not necessarily non-negative real numbers.)*

Given a subset $E \subseteq \mathbb{F}^S$, we similarly define $\widetilde{\Pr}[\mathcal{Q}(S) \in E] := \sum_{f \in \mathbb{F}^n : f|_S \in E} \mathcal{Q}(f)$.

As for non-signaling functions, we highlight the case when E is an inner product event.

▶ **Definition 22.** *Let $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ be a quasi-distribution. For $\alpha \in \mathbb{F}^n$ and $b \in \mathbb{F}$, we define*

$$\widetilde{\Pr}[\langle \alpha, \mathcal{Q} \rangle = b] := \sum_{f \in \mathbb{F}^n : \langle \alpha, f \rangle = b} \mathcal{Q}(f) .$$

Similarly, we define $\widetilde{\Pr}[\mathrm{Tr}(\langle \alpha, \mathcal{Q} \rangle) = j] := \sum_{b \in \mathbb{F}: \mathrm{Tr}(b) = j} \widetilde{\Pr}[\langle \alpha, \mathcal{Q} \rangle = b]$ for every $j \in \mathbb{F}_p$.

▶ **Definition 23** (statistical distance). *Given a finite domain $[n]$ and an integer $\ell \in \{1,\ldots,|D|\}$, the* **$\Delta_\ell$-distance** *between two quasi-distributions $\mathcal{Q}$ and $\mathcal{Q}'$ is*

$$\Delta_\ell(\mathcal{Q},\mathcal{Q}') := \max_{S\subseteq[n]_{\leq\ell}} \Delta(\mathcal{Q}|_S,\mathcal{Q}'|_S) \ ,$$

where $\Delta(\mathcal{Q}|_S,\mathcal{Q}'|_S) := \max_{E\subseteq\mathbb{F}^S} \left|\widetilde{\Pr}[\mathcal{Q}(S)\in E] - \widetilde{\Pr}[\mathcal{Q}'(S)\in E]\right|$.

We say that $\mathcal{Q}$ and $\mathcal{Q}'$ are **ε-close in the Δ_ℓ-distance** *if $\Delta_\ell(\mathcal{Q},\mathcal{Q}') \leq \varepsilon$; else, they are ε-far.*

▶ Remark 24 (distance for non-signaling functions). The definition of Δ_ℓ-distance naturally extends to defining distances between k-non-signaling functions, as well as between quasi-distributions and k-non-signaling functions, provided that $\ell \leq k$.

The notion above generalizes the standard notion of statistical (total variation) distance: if $\mathcal{Q}$ and $\mathcal{Q}'$ are *distributions* then their Δ_n-distance equals their statistical distance. Also note that if $\mathcal{Q}$ and $\mathcal{Q}'$ are ℓ-local quasi-distributions then their Δ_ℓ-distance equals the maximum statistical distance, across all subsets $S \subseteq [n]$ with $|S| \leq \ell$, between the two *distributions* $\mathcal{Q}|_S$ and $\mathcal{Q}'|_S$ – in particular this means that any experiment that queries exactly one set of size at most ℓ cannot distinguish between the two quasi-distributions with probability greater than $\Delta_\ell(\mathcal{Q},\mathcal{Q}')$.

We stress that $\Delta_\ell(\mathcal{Q},\mathcal{Q}') = 0$ does *not* necessarily mean that $\mathcal{Q} = \mathcal{Q}'$! In fact, it is possible to have $\Delta_\ell(\mathcal{Q},\mathcal{Q}') = 0$ while $\sum_{f\in U} |\mathcal{Q}(f) - \mathcal{Q}'(f)|$ is arbitrarily large. We also remark that the Δ_ℓ-distance is not necessarily upper bounded by 1, and is in general unbounded.

▶ **Definition 25** (approximate locality). *Given a finite domain $[n]$, an integer $\ell \in \{1,\ldots,n\}$, and a real number $\varepsilon \geq 0$, a quasi-distribution $\mathcal{Q}$ over U_n is* **(ℓ,ε)-local** *if, for every subset $S \subseteq [n]_{\leq\ell}$ and every event $E \subseteq \{0,1\}^S$,*

$$\min_{x\in[0,1]} \left\{\left|\widetilde{\Pr}[\mathcal{Q}(S)\in E] - x\right|\right\} \in [0,\varepsilon] \ .$$

Approximate locality generalizes the notion of (exact) locality as in Definition 20. Below, we state a lemma that if$\mathcal{Q}$ is (ℓ,ε)-local and is supported over a linear code $\mathbf{C}$, then there is an ℓ-local $\mathcal{Q}'$ over $\mathbf{C}$ that is close to $\mathcal{Q}$. The proof idea is similar to that of "smoothening" almost-feasible solutions to Sherali–Adams relaxations into feasible ones [13].

▶ **Lemma 26.** *If $\mathcal{Q}$ is a (ℓ,ε)-local quasi-distribution over $\mathbf{C}$, then there is an ℓ-local quasi-distribution $\mathcal{Q}'$ over $\mathbf{C}$ such that $\Delta_\ell(\mathcal{Q},\mathcal{Q}') < q^\ell\varepsilon$.*

We omit the proof of Lemma 26 as it is identical to the proof of lemma 7.8 in [4], just replacing the field $\mathbb{F}_2 = \{0,1\}$ with a general field $\mathbb{F}$.

4 Fourier analysis of non-signaling functions

We prove statements about the Fourier structure of non-signaling functions, and prove the Equivalence Lemma. In Section 4.1 we recall basic facts about Fourier analysis of functions over finite fields. In Section 4.2 we relate Fourier coefficients to probabilities and quasi-probabilities. In Section 4.3 we prove that non-signaling functions and quasi-distributions are equivalent notions.

4.1 Fourier analysis of functions over finite fields

We consider functions of the type $F\colon \mathbb{F}^n \to \mathbb{C}$. For two such functions F_1 and F_2, we define their inner product as $\langle F_1, F_2\rangle := \frac{1}{q^n}\sum_{x\in\mathbb{F}^n} \overline{F_1(x)}F_2(x)$. For every $\alpha \in \mathbb{F}^n$, we define the *character* $\chi_\alpha\colon \mathbb{F}^n \to \mathbb{C}$ as $\chi_\alpha(x) := \omega^{\mathrm{Tr}(\langle\alpha,x\rangle)}$ where: (1) $\mathrm{Tr}\colon \mathbb{F} \to \mathbb{F}_p$ is the trace map; (2) $\langle\alpha, x\rangle$ is the inner product $\sum_{i=1}^n \alpha_i x_i$; (3) $\omega = e^{2\pi i/p}$ is a primitive complex p-th root of unity; and (4) ω^j is defined by thinking of $j \in \mathbb{F}_p$ as an integer in $\mathbb{Z}$. The functions $\{\chi_\alpha\}_{\alpha\in\mathbb{F}^n}$ form an orthonormal basis of the space of all functions $f\colon \mathbb{F}^n \to \mathbb{C}$, so every function $F\colon \mathbb{F}^n \to \mathbb{C}$ can be written as

$$F(\cdot) = \sum_{\alpha\in\mathbb{F}^n} \widehat{F}(\alpha)\chi_\alpha(\cdot) \ , \text{ where } \widehat{F}(\alpha) := \langle\chi_\alpha, F\rangle \ .$$

The values $\{\widehat{F}(\alpha)\}_{\alpha\in\mathbb{F}^n}$ are the *Fourier coefficients* of F. We recall and prove a few useful identifies.

Parseval's identity. For every two functions $F, G\colon \mathbb{F}^n \to \mathbb{C}$,

$$\langle F, G\rangle = \frac{1}{q^n}\sum_{x\in\mathbb{F}^n} \overline{F(x)}G(x) = \sum_{\alpha\in\mathbb{F}^n} \overline{\widehat{F}(\alpha)}\widehat{G}(\alpha) \ .$$

Proof.

$$\frac{1}{q^n}\sum_{x\in\mathbb{F}^n} \overline{F(x)}G(x) = \frac{1}{q^n}\sum_{x\in\mathbb{F}^n} \overline{\left(\sum_{\alpha\in\mathbb{F}^n} \widehat{F}(\alpha)\chi_\alpha(x)\right)}\left(\sum_{\beta\in\mathbb{F}^n} \widehat{G}(\beta)\chi_\beta(x)\right)$$
$$= \sum_{\alpha\in\mathbb{F}^n}\sum_{\beta\in\mathbb{F}^n} \overline{\widehat{F}(\alpha)}\widehat{G}(\beta)\langle\chi_\alpha,\chi_\beta\rangle = \sum_{\alpha\in\mathbb{F}^n} \overline{\widehat{F}(\alpha)}\widehat{G}(\alpha) \ ,$$

since $\{\chi_\alpha\}_{\alpha\in\mathbb{F}^n}$ are orthonormal. ◀

Plancherel's identity. As a corollary of the above,

$$\frac{1}{q^n}\sum_{x\in\mathbb{F}^n} |F(x)|^2 = \sum_{\alpha\in\mathbb{F}^n} |\widehat{F}(\alpha)|^2 \ .$$

The case of indicator functions. When analyzing non-signaling functions and quasi-distributions we will apply the above identities in the case where F is an indicator function $\mathbf{1}_E$ for a set $E \subseteq \mathbb{F}^n$. In this case, by Plancherel's identity we have that $|E|/q^n = \sum_{\alpha\in\mathbb{F}^n} |\widehat{\mathbf{1}_E}(\alpha)|^2$. In particular, by the Cauchy–Schwarz inequality, this implies that

$$\|\widehat{\mathbf{1}_E}\|_1 = \sum_{\alpha\in\mathbb{F}^n} |\widehat{\mathbf{1}_E}(\alpha)| \le \sqrt{\sum_{\alpha\in\mathbb{F}^n} |\widehat{\mathbf{1}_E}(\alpha)|^2}\cdot\sqrt{\sum_{\alpha\in\mathbb{F}^n} 1} \le \sqrt{|E|/q^n}\cdot q^{n/2} = \sqrt{|E|} \ .$$

If we let $F(x) = \mathbf{1}_E(x)$, then Parseval's identity becomes the following lemma.

▶ **Lemma 27.** *Let $G\colon \mathbb{F}^n \to \mathbb{C}$ be a function and $E \subseteq \mathbb{F}^n$. Then*

$$\frac{1}{q^n}\sum_{x\in E} G(x) = \frac{1}{q^n}\sum_{\alpha\in\mathbb{F}^n} \overline{\widehat{\mathbf{1}_E}(\alpha)}\sum_{x\in\mathbb{F}^n} G(x)\omega^{-\mathrm{Tr}(\langle\alpha,x\rangle)} = \sum_{\alpha\in\mathbb{F}^n} \overline{\widehat{\mathbf{1}_E}(\alpha)}\widehat{G}(\alpha) \ .$$

4.2 Relating the Fourier spectrum to the probabilities of events

A quasi-distribution $\mathcal{Q}$ is a function $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ that maps a function $f\colon [n] \to \mathbb{F}$ (identified with the corresponding vector $\mathbb{F}^n$) to $\mathcal{Q}(f)$. We can write $\mathcal{Q}(\cdot) = \sum_{\alpha\in\mathbb{F}^n} \widehat{\mathcal{Q}}(\alpha)\chi_\alpha(\cdot)$, where $\{\chi_\alpha\}_{\alpha\in\mathbb{F}^n}$ are the characters and $\{\widehat{\mathcal{Q}}(\alpha)\}_{\alpha\in\mathbb{F}^n}$ are $\mathcal{Q}$'s Fourier coefficients. For $S \subseteq [n]$ and $\alpha \in \mathbb{F}^S$, we abuse notation and use $\widehat{\mathcal{Q}}(\alpha)$ to refer to $\widehat{\mathcal{Q}}(\beta)$ where $\beta \in \mathbb{F}^n$ has $\beta_i = \alpha_i$ for all $i \in S$ and 0 otherwise.

The lemma below relates the inner product quasi-probabilities defined in Definition 22 to the Fourier coefficients of $\mathcal{Q}$.

▶ **Lemma 28.** *Let $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ be a quasi-distribution. For every $\alpha \in \mathbb{F}^n$,*

$$\widehat{\mathcal{Q}}(\alpha) = \frac{1}{q^n}\sum_{j\in\mathbb{F}_p} \omega^{-j}\widetilde{\Pr}[\mathrm{Tr}(\langle\alpha,\mathcal{Q}\rangle) = j] \ .$$

Proof of Lemma 28. By definition,

$$\begin{aligned}\widehat{\mathcal{Q}}(\alpha) = \langle\chi_\alpha,\mathcal{Q}(\cdot)\rangle &= \frac{1}{q^n}\sum_f \overline{\chi_\alpha(f)}\mathcal{Q}(f) = \frac{1}{q^n}\sum_{j\in\mathbb{F}_p}\omega^{-j}\sum_{f:\chi_\alpha(f)=\omega^j}\mathcal{Q}(f)\\ &= \frac{1}{q^n}\sum_{j\in\mathbb{F}_p}\omega^{-j}\sum_{f:\mathrm{Tr}(\langle\alpha,f\rangle)=j}\mathcal{Q}(f) = \frac{1}{q^n}\sum_{j\in\mathbb{F}_p}\omega^{-j}\widetilde{\Pr}[\mathrm{Tr}(\langle\alpha,\mathcal{Q}\rangle) = j] \ . \end{aligned}$$ ◀

The above lemma implies that the Fourier coefficients $(\widehat{\mathcal{Q}}(a\alpha))_{a\in\mathbb{F}}$ are determined by the quasi-probabilities $(\Pr[\langle\alpha,\mathcal{Q}\rangle = b])_{b\in\mathbb{F}}$, as the quasi-probabilities $(\Pr[\langle\alpha,\mathcal{Q}\rangle = b])_{b\in\mathbb{F}}$ determine the quasi-probabilities $(\Pr[\langle a\alpha,\mathcal{Q}\rangle = b])_{b\in\mathbb{F}}$ for every $a \in \mathbb{F}$. In fact, there is a linear transformation M that maps $(\Pr[\langle\alpha,\mathcal{Q}\rangle = b])_{b\in\mathbb{F}}$ to $(q^n\widehat{\mathcal{Q}}(a\alpha))_{a\in\mathbb{F}}$. Below, we state a well-known lemma about M.

▶ **Lemma 29.** *Let $M \in \mathbb{C}^{q\times q}$ be the matrix defined as $M_{a,b} := \omega^{-\mathrm{Tr}(ab)}$ (entries are indexed by $\mathbb{F}$). Then M is invertible and $\frac{1}{\sqrt{q}}M$ is unitary (namely, $M^\dagger \cdot M = qI$). In particular, for every vector $(v_b)_{b\in\mathbb{F}}$ with values in $\mathbb{C}$, the map $(v_b)_{b\in\mathbb{F}} \mapsto (\sum_{b\in\mathbb{F}}\omega^{-\mathrm{Tr}(ab)}v_b)_{a\in\mathbb{F}}$ is a bijection.*

We additionally prove the following lemma, which relates the Fourier spectrum of the quasi-distribution $\mathcal{Q}|_S$ to the Fourier spectrum of $\mathcal{Q}$.

▶ **Lemma 30.** *Let $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ be a quasi-distribution. Let $S \subseteq [n]$, and let $\mathcal{Q}|_S$ denote the restriction of $\mathcal{Q}$ to S, namely, $\mathcal{Q}|_S$ is the quasi-distribution from $\mathbb{F}^S$ to $\mathbb{C}$ where $\mathcal{Q}|_S(g) := \sum_{f:f|_S=g}\mathcal{Q}(f)$. Then for every $\alpha \in \mathbb{F}^S$ it holds that $q^{|S|}\widehat{\mathcal{Q}|_S}(\alpha) = q^n\widehat{\mathcal{Q}}(\alpha)$.*[5]

Proof of Lemma 30.

$$q^{|S|}\widehat{\mathcal{Q}|_S}(\alpha) = \sum_{g\in\mathbb{F}^S}\mathcal{Q}|_S(g)\omega^{-\mathrm{Tr}(\langle\alpha,g\rangle)} = \sum_{f\in\mathbb{F}^n}\mathcal{Q}(f)\omega^{-\mathrm{Tr}(\langle\alpha,f\rangle)} = q^n\widehat{\mathcal{Q}}(\alpha) \ .$$ ◀

If $\mathcal{F}\colon [n] \to \mathbb{F}$ is a k-non-signaling function, then for any $\alpha \in \mathbb{F}^n_{\le k}$ and $b \in \mathbb{F}$ we have defined $\Pr[\langle\alpha,\mathcal{F}\rangle = b]$ in Definition 19 to be $\Pr_{f\leftarrow\mathcal{F}_{\mathrm{supp}(\alpha)}}[\langle\alpha,f\rangle = b]$. Note that the probability is well-defined since $\mathrm{wt}(\alpha) \le k$ (so we query $\mathcal{F}$ on at most k points). Also note that Lemma 28 implies that, for every $\alpha \in \mathbb{F}^n_{\le k}$, we can define the Fourier coefficient $\widehat{\mathcal{F}}(\alpha)$ of $\mathcal{F}$ as

$$\widehat{\mathcal{F}}(\alpha) := \frac{1}{q^n}\sum_{j\in\mathbb{F}_p}\omega^{-j}\Pr[\mathrm{Tr}(\langle\alpha,\mathcal{F}\rangle) = j] \ .$$

[5] The vector α in $\widehat{\mathcal{Q}}(\alpha)$ is treated as a element in $\mathbb{F}^n$ with $\alpha_j = 0$ for all $j \notin S$

With the above definitions, we can prove the following two corollaries of Lemma 27. The first is for non-signaling functions, and the second is for quasi-distributions.

▶ **Corollary 31.** *For any k-non-signaling function $\mathcal{F}\colon [n] \to \mathbb{F}$, set $S \subseteq [n]$, and event $E \subseteq \mathbb{F}^S$,*

$$\Pr[\mathcal{F}(S) \in E] = \sum_{\alpha \in \mathbb{F}^S} \overline{\widehat{\mathbf{1}_E}(\alpha)} \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] = q^n \sum_{\alpha \in \mathbb{F}^S} \overline{\widehat{\mathbf{1}_E}(\alpha)} \widehat{\mathcal{F}}(\alpha) \ .$$

Proof. Apply Lemma 27 with $G\colon \mathbb{F}^S \to \mathbb{C}$ defined as $G(x) := \Pr[\mathcal{F}_S(i) = x_i \ \forall i \in S]$. ◀

▶ **Corollary 32.** *For any quasi-distribution $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$, set $S \subseteq [n]$, and event $E \subseteq \mathbb{F}^S$,*

$$\widetilde{\Pr}[\mathcal{Q}(S) \in E] = \sum_{f\colon f(S) \in E} \mathcal{Q}(f) = \sum_{\alpha \in \mathbb{F}^S} \overline{\widehat{\mathbf{1}_E}(\alpha)} \sum_{j \in \mathbb{F}_p} \omega^{-j} \widetilde{\Pr}[\mathrm{Tr}(\langle \alpha, \mathcal{Q} \rangle) = j] = q^n \sum_{\alpha \in \mathbb{F}^S} \overline{\widehat{\mathbf{1}_E}(\alpha)} \widehat{\mathcal{Q}}(\alpha) \ .$$

Proof. Apply Lemma 27 to the function $G\colon \mathbb{F}^S \to \mathbb{C}$ that is the quasi-distribution $\mathcal{Q}|_S$. Then observe that for every $\alpha \in \mathbb{F}^S$, $q^{|S|} \widehat{\mathcal{Q}|_S}(\alpha) = q^n \widehat{\mathcal{Q}}(\alpha)$ by Lemma 30. ◀

The above two lemmas allow us to bound the distance between a k-non-signaling function $\mathcal{F}$ and a quasi-distribution $\mathcal{Q}$ in terms of their Fourier spectra.

▶ **Lemma 33.** *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function and $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ a quasi-distribution. For any set $S \subseteq [n]_{\leq k}$ and event $E \subseteq \mathbb{F}^S$,*

$$\left| \Pr[\mathcal{F}(S) \in E] - \widetilde{\Pr}[\mathcal{Q}(S) \in E] \right| \leq q^n \sum_{\alpha \in \mathbb{F}^S} \left| \widehat{\mathbf{1}_E}(\alpha) \right| \left| \widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{Q}}(\alpha) \right| \ .$$

In particular, $\Delta_k(\mathcal{Q}, \mathcal{F}) \leq q^{n+k/2} \max_{\alpha \in \mathbb{F}^n_{\leq k}} |\widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{Q}}(\alpha)|$.

▶ **Corollary 34.** *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function and $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ a quasi-distribution. Then $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$ if and only if $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{Q}}(\alpha)$ for every $\alpha \in \mathbb{F}^n_{\leq k}$.*

Proof of Lemma 33. The first equation follows immediately from Corollary 31 and Corollary 32. For the second part of the lemma,

$$\begin{aligned}
\Delta_k(\mathcal{Q}, \mathcal{F}) &\leq \max_{S \subseteq [n]_{\leq k}} \max_{E \subseteq \mathbb{F}^S} q^n \sum_{\alpha \in \mathbb{F}^S} \left| \overline{\widehat{\mathbf{1}_E}(\alpha)} \right| \left| \widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{Q}}(\alpha) \right| \\
&\leq q^n \max_{S \subseteq [n]_{\leq k}} \left(\left(\max_{E \subseteq \mathbb{F}^S} \sum_{\alpha \in \mathbb{F}^S} \left| \widehat{\mathbf{1}_E}(\alpha) \right| \right) \max_{\alpha \in \mathbb{F}^S} \left| \widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{Q}}(\alpha) \right| \right) \\
&\leq q^n \left(\max_{S \subseteq [n]_{\leq k}} q^{|S|/2} \right) \max_{\alpha \in \mathbb{F}^n_{\leq k}} \left| \widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{Q}}(\alpha) \right| \\
&\leq q^{n+k/2} \max_{\alpha \in \mathbb{F}^n_{\leq k}} \left| \widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{Q}}(\alpha) \right| \ .
\end{aligned}$$ ◀

Proof of Corollary 34. If $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{Q}}(\alpha)$ for every $\alpha \in \mathbb{F}^n_{\leq k}$, then by Lemma 33 it follows that $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$. Conversely, if $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$, then for every $\alpha \in \mathbb{F}^n_{\leq k}$ and $j \in \mathbb{F}_p$ it holds that $\widetilde{\Pr}[\mathrm{Tr}(\langle \alpha, \mathcal{Q} \rangle) = j] = \Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j]$, as these are both events. This implies that $q^n \widehat{\mathcal{Q}}(\alpha) = \sum_{j \in \mathbb{F}_p} \omega^{-j} \widetilde{\Pr}[\mathrm{Tr}(\langle \alpha, \mathcal{Q} \rangle) = j] = \sum_{j \in \mathbb{F}_p} \omega^{-j} \Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] = q^n \widehat{\mathcal{F}}(\alpha)$. ◀

Suppose that we are given a collection of local distributions $(\mathcal{F}_S)_{S \subseteq [n]_{\leq k}}$, namely, $\mathcal{F}_S$ is a distribution over functions $f\colon S \to \mathbb{F}$. We can think of each local distribution $\mathcal{F}_S$ as a function $\mathcal{F}_S\colon \mathbb{F}^S \to \mathbb{C}$, and in this way define for each local distribution $\mathcal{F}_S$ the Fourier coefficients $\widehat{\mathcal{F}_S}(\alpha)$ for each $\alpha \in \mathbb{F}^n_{\subseteq S}$. In the following lemma, we characterize when $(\mathcal{F}_S)_{S \subseteq [n]_{\leq k}}$ is k-non-signaling in terms of the Fourier spectra of the local distributions.

▶ **Lemma 35.** *Let $(\mathcal{F}_S)_{S\subseteq[n]_{\leq k}}$ be a collection of local distributions. Then $(\mathcal{F}_S)_{S\subseteq[n]_{\leq k}}$ is a k-non-signaling function if and only if $q^{|S|}\widehat{\mathcal{F}_S}(\alpha) = q^{|R|}\widehat{\mathcal{F}_R}(\alpha)$ for every $S \subseteq [n]_{\leq k}$, $R \subseteq S$, and $\alpha \in \mathbb{F}^n_{\subseteq R}$.*

Proof. Suppose $(\mathcal{F}_S)_{S\subseteq[n]_{\leq k}}$ is a k-non-signaling function. Fix $S \subseteq [n]_{\leq k}$, $R \subseteq S$, and $\alpha \in \mathbb{F}^n_{\subseteq R}$. Since the collection of local distributions is k-non-signaling we have that $\mathcal{F}_S|_R = \mathcal{F}_R$. Therefore by Lemma 30 we have that $q^{|S|}\widehat{\mathcal{F}_S}(\alpha) = q^{|R|}\widehat{\mathcal{F}_R}(\alpha)$.

Now, fix $S \subseteq [n]_{\leq k}$ and $R \subseteq S$. Applying Corollary 32 to the distributions $\mathcal{F}_S$ and $\mathcal{F}_R$, we see that if $q^{|S|}\widehat{\mathcal{F}_S}(\alpha) = q^{|R|}\widehat{\mathcal{F}_R}(\alpha)$ for every $\alpha \in \mathbb{F}^n_{\subseteq R}$, then $\mathcal{F}_S|_R \equiv \mathcal{F}_R$. Hence, $(\mathcal{F}_S)_{S\subseteq[n]_{\leq k}}$ is k-non-signaling. ◀

4.3 Equivalence between non-signaling functions and quasi-distributions

We show that k-non-signaling functions and k-local quasi-distributions are equivalent. Every k-local quasi-distribution $\mathcal{Q}$ induces a k-non-signaling function $\mathcal{F}$ (Proposition 36). Conversely, every k-non-signaling function $\mathcal{F}$ can be described by a k-local quasi-distribution $\mathcal{Q}$ (Proposition 37). In fact, the set of such quasi-distributions is an affine subspace of co-dimension $\sum_{i=0}^{k}\binom{n}{i}\cdot(q-1)^i$ in $\mathbb{C}^{q^n}$. The first direction of the equivalence is elementary; the other direction is the interesting one.

The aforementioned result is a special case of a result of Abramsky and Brandenburger [1] that establishes an equivalence between *non-signaling empirical models* (a general notion of non-signaling experiments in the language of sheaf theory) and quasi-distributions over *global sections*. Our result strengthens this equivalence by giving an explicit characterization of the affine subspace of quasi-distributions describing a non-signaling function, by leveraging Fourier-analytic tools. This also extends to any finite field $\mathbb{F}$ the equivalence lemma for $\mathbb{F}_2$ presented in [4].[6]

▶ **Proposition 36.** *For every k-local quasi-distribution $\mathcal{Q}$ over functions $f\colon [n] \to \mathbb{F}$ there exists a k-non-signaling function $\mathcal{F}\colon [n] \to \mathbb{F}$ such that $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$.*

Proof. For every subset $S \subseteq [n]_{\leq k}$, define $\mathcal{F}_S$ to be the distribution over functions $f\colon S \to \mathbb{F}$ where $\Pr[\mathcal{F}_S \text{ outputs } f] := \widetilde{\Pr}[\mathcal{Q}(S) = f(S)]$, namely, such that $\mathcal{F}_S \equiv \mathcal{Q}|_S$. Note that $\mathcal{F}_S$ is a distribution because $\mathcal{Q}$ is k-local, so the relevant probabilities are in $[0,1]$ and sum to 1. The definition immediately implies that $\Pr[\mathcal{F}(S) = g] = \widetilde{\Pr}[\mathcal{Q}(S) = g]$ for every string $g \in \mathbb{F}^S$, and so $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$. We are left to argue that $\mathcal{F} = \{\mathcal{F}_S\}_{S\subseteq[n]_{\leq k}}$ is k-non-signaling. Let $S \subseteq [n]_{\leq k}$, and let $R \subseteq S$. By definition of $\mathcal{F}$ and Lemma 30 we have that for every $\alpha \in \mathbb{F}^R$, $q^{|S|}\widehat{\mathcal{F}_S}(\alpha) = q^{|S|}\widehat{\mathcal{Q}|_S}(\alpha) = q^{|R|}\widehat{\mathcal{Q}|_R}(\alpha) = q^{|R|}\widehat{\mathcal{F}_R}(\alpha)$. By Lemma 35, it follows that $\mathcal{F}$ is k-non-signaling. ◀

▶ **Proposition 37.** *For every k-non-signaling function $\mathcal{F}\colon [n] \to \mathbb{F}$, there exists a k-local quasi-distribution $\mathcal{Q}$ over functions $f\colon [n] \to \mathbb{F}$ such that $\Delta_k(\mathcal{F}, \mathcal{Q}) = 0$. Moreover, the set of such $\mathcal{Q}$'s (viewed as vectors in $\mathbb{C}^{q^n}$) is the affine subspace of co-dimension $\sum_{i=0}^{k}\binom{n}{i}\cdot(q-1)^i$ in $\mathbb{C}^{q^n}$ given by $\mathcal{Q}_0 + \operatorname{span}\{\chi_\alpha : \alpha \in \mathbb{F}^n, \operatorname{wt}(\alpha) > k\}$, where $\mathcal{Q}_0$ is any solution.*

[6] The characterization further extends to functions taking values in any finite alphabet Σ (not necessarily a field) by adding an abelian group structure to Σ (for example, by identifying Σ with $\mathbb{Z}/|\Sigma|\mathbb{Z}$), and then using analogous tools from Fourier analysis over finite abelian groups.

Proof. Let $\mathcal{Q}$ be a quasi-distribution over functions $f\colon [n] \to \mathbb{F}$. By Corollary 34, it holds that $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$ if and only if $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{Q}}(\alpha)$ for all $\alpha \in \mathbb{F}^n_{\leq k}$.

Let $\mathcal{Q}_0$ be the quasi-distribution with Fourier coefficients $\widehat{\mathcal{Q}}(\alpha) := \widehat{\mathcal{F}}(\alpha)$ for all α of weight at most k and $\widehat{\mathcal{Q}}(\alpha) := 0$ otherwise. Consider the affine subspace $\mathcal{Q}_0 + \mathrm{span}\{\chi_\alpha : \alpha \in \mathbb{F}^n, \mathrm{wt}(\alpha) > k\}$. By Corollary 34, every quasi-distribution $\mathcal{Q}$ in the affine subspace satisfies $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$. We note that this affine subspace has dimension $\sum_{i=0}^{k} \binom{n}{i} \cdot (q-1)^i$.

Conversely, suppose that $\mathcal{Q}$ satisfies $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$. Then by Corollary 34 it holds that $\widehat{\mathcal{Q}}(\alpha) = \widehat{\mathcal{F}}(\alpha)$ for all $\alpha \in \mathbb{F}^n_{\leq k}$, which implies that $\mathcal{Q}$ is in the aforementioned affine subspace. Hence, the affine subspace contains all $\mathcal{Q}$ such that $\Delta_k(\mathcal{Q}, \mathcal{F}) = 0$. ◀

5 Non-signaling linear codes

We wish to define what it means for a non-signaling function $\mathcal{F}\colon [n] \to \mathbb{F}$ to be "in" a linear code $\mathbf{C} \subseteq \mathbb{F}^n$. We introduce two natural definitions for the above goal. The first definition is motivated by the equivalence between non-signaling functions and quasi-distributions established in Section 4.3. The second definition is motivated by a notion of local consistency.

For each of the two definitions, we *characterize* the Fourier spectrum of non-signaling strategies that satisfy the definition, in the exact and in the robust case. Also, we prove a strong relationship between the two definitions, showing that they are *equivalent* (up to a small loss in parameters). The compelling structure that we uncover supports our choice of definitions.

For this section, we remind the reader that a linear code $\mathbf{C}$ over $\mathbb{F}$ with block length n is a linear subspace of $\mathbb{F}^n$. We equivalently also view $\mathbf{C}$ as a linear subspace of the set of all functions $f\colon [n] \to \mathbb{F}$. The dual code of $\mathbf{C}$ is the linear subspace $\mathbf{C}^\perp := \{\alpha : \langle \alpha, f \rangle = 0 \ \forall f \in \mathbf{C}\} \subseteq \mathbb{F}^n$.

5.1 Quasi-distributions supported on linear codes

The equivalence between non-signaling functions and quasi-distributions in Section 4.3 suggests a natural way to capture when a non-signaling function is "in" a given linear code.

▶ **Definition 38.** *Given a k-non-signaling strategy $\mathcal{F}\colon [n] \to \mathbb{F}$, code $\mathbf{C} \subseteq \mathbb{F}^n$ and parameter $k' \leq k$, we say that $\mathcal{F}$ is* **$(\mathbf{C}, k')$-supported** *if there exists a k'-local quasi-distribution $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ supported on $\mathbf{C}$ such that $\Delta_{k'}(\mathcal{Q}, \mathcal{F}) = 0$.*

In light of the characterization of the Fourier spectra of quasi-distributions equivalent to a given non-signaling function in Section 4.3, it is natural to ask if the Fourier spectrum of a quasi-distribution supported on $\mathbf{C}$ has a special structure. In the following lemma, we characterize the Fourier spectrum of quasi-distributions supported on a given linear code $\mathbf{C}$. Informally, we show that the condition "Fourier coefficients are constants on cosets of $\mathbf{C}^\perp$" is necessary and sufficient.

▶ **Lemma 39.** *Let $\mathbf{C} \subseteq \mathbb{F}^n$ be a linear code. A quasi-distribution $\mathcal{Q}\colon \mathbb{F}^n \to \mathbb{C}$ is supported on $\mathbf{C}$ if and only if $\widehat{\mathcal{Q}}(\alpha) = \widehat{\mathcal{Q}}(\alpha')$ for all $\alpha, \alpha' \in \mathbb{F}^n$ such that $\alpha - \alpha' \in \mathbf{C}^\perp$.*

The foregoing statement immediately gives us a corollary about non-signaling functions.

▶ **Corollary 40.** *A k-non-signaling strategy $\mathcal{F}\colon [n] \to \mathbb{F}$ is $(\mathbf{C}, k')$-supported if and only if for all $\alpha, \alpha' \in \mathbb{F}^n_{\leq k}$ such that $\alpha - \alpha' \in \mathbf{C}^\perp$ it holds that $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{F}}(\alpha')$.*

Next, we wish to study the Fourier spectrum of a quasi-distribution $\mathcal{Q}$ that is merely *close* to being supported on $\mathbf{C}$. For this case, we give the following "robust" version of Lemma 39.

▶ **Lemma 41.** *Let $\mathbf{C} \subseteq \mathbb{F}^n$ be a linear code, and let $\mathcal{Q}$ be a quasi-distribution.*

- *Suppose that there exists a quasi-distribution $\mathcal{Q}'$ supported on $\mathbf{C}$ such that $\Delta_k(\mathcal{Q}, \mathcal{Q}') \leq \delta$. Then for all $\alpha, \alpha' \in \mathbb{F}^n_{\leq k}$ and $\alpha - \alpha' \in \mathbf{C}^\perp$ it holds that $\left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}(\alpha')\right| \leq \frac{2\delta}{q^n}$.*
- *Conversely, suppose that for all $\alpha, \alpha' \in \mathbb{F}^n_{\leq k}$ and $\alpha - \alpha' \in \mathbf{C}^\perp$ it holds that $\left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}(\alpha')\right| \leq \frac{2\delta}{q^n}$. Then there exists a quasi-distribution $\mathcal{Q}'$ supported on $\mathbf{C}$ such that $\Delta_k(\mathcal{Q}, \mathcal{Q}') \leq q^{k/2} \cdot 2\delta$.*

We note that in Lemma 41, neither quasi-distribution is required to be local.

5.1.1 Proof of Lemma 39

Define the affine spaces

$$V_1 = \left\{ \mathcal{Q} \colon \mathbb{F}^n \to \mathbb{C} \text{ s.t. } \sum_{f \in \mathbf{C}} \mathcal{Q}(f) = 1 \text{ and } \mathcal{Q}(f) = 0 \ \forall f \notin \mathbf{C} \right\} ,$$

$$V_2 = \left\{ \mathcal{Q} \colon \mathbb{F}^n \to \mathbb{C} \text{ s.t. } \widehat{\mathcal{Q}}(0^n) = \frac{1}{q^n} \text{ and } \widehat{\mathcal{Q}}(\alpha) = \widehat{\mathcal{Q}}(\alpha + \gamma) \ \forall \alpha \in \mathbb{F}^n, \gamma \in \mathbf{C}^\perp \right\} .$$

It suffices to prove that $V_1 = V_2$. First we show that $\dim(V_1) = \dim(V_2)$. The dimension of V_1 is $|\mathbf{C}| - 1$ because the $|\mathbf{C}|$ free terms are subject to a single linear constraint. The dimension of V_2 is $q^n / \left|\mathbf{C}^\perp\right| - 1$ because the Fourier coefficients are constant on each coset of $\mathbf{C}^\perp$, and on each coset they can take on an arbitrary value; the one exception is the coset $\mathbf{C}^\perp$, on which the Fourier coefficients must be $\frac{1}{q^n}$. Recalling that $q^n = |\mathbf{C}| \cdot |\mathbf{C}^\perp|$, we deduce that $\dim(V_1) = \dim(V_2)$.

Next we show that $V_1 \subseteq V_2$. Fix $\mathcal{Q} \in V_1$. Since $\sum_f \mathcal{Q}(f) = 1$, we have $\widehat{\mathcal{Q}}(0^n) = \frac{1}{q^n} \sum_f \mathcal{Q}(f) \cdot \omega^0 = \frac{1}{q^n}$. Moreover, for any $\alpha \in \mathbb{F}^n$ and $\gamma \in \mathbf{C}^\perp$,

$$\widehat{\mathcal{Q}}(\alpha + \gamma) = \frac{1}{q^n} \cdot \sum_f \mathcal{Q}(f) \cdot \omega^{-\mathrm{Tr}(\langle \alpha + \gamma f \rangle)} = \frac{1}{q^n} \cdot \sum_f \mathcal{Q}(f) \cdot \omega^{-\mathrm{Tr}(\langle \alpha, f \rangle)} \cdot \omega^{-\mathrm{Tr}(\langle \gamma, f \rangle)} .$$

Since $\mathcal{Q} \in V_1$, if $\mathcal{Q}(f) \neq 0$ then $f \in \mathbf{C}$ and hence $\omega^{\mathrm{Tr}(\langle \gamma, f \rangle)} = \omega^{\mathrm{Tr}(0)} = 1$. Therefore,

$$\widehat{\mathcal{Q}}(\alpha + \gamma) = \frac{1}{q^n} \cdot \sum_f \mathcal{Q}(f) \cdot \omega^{-\mathrm{Tr}(\langle \alpha, f \rangle)} = \widehat{\mathcal{Q}}(\alpha) .$$

Thus $V_1 \subseteq V_2$. Since $\dim(V_1) = \dim(V_2)$ and $V_1 \subseteq V_2$, we conclude that $V_1 = V_2$.

5.1.2 Proof of Lemma 41

Suppose $\mathcal{Q} \colon \mathbb{F}^n \to \mathbb{C}$ is a quasi-distribution such that there exists a quasi-distribution $\mathcal{Q}'$ supported on $\mathbf{C}$ with $\Delta_k(\mathcal{Q}, \mathcal{Q}') \leq \delta$. Fix $\alpha \in \mathbb{F}^n_{\leq k}$, so that $S = \mathrm{supp}(\alpha)$ has $|S| \leq k$. Since $\Delta_k(\mathcal{Q}, \mathcal{Q}') \leq \delta$, we have that $\sum_{g \in \mathbb{F}^S} \left|\widetilde{\Pr}[\mathcal{Q}(S) = g] - \widetilde{\Pr}[\mathcal{Q}'(S) = g]\right| \leq \delta$. Therefore,

$$\begin{aligned}
\left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}'(\alpha)\right| &\leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \left|\omega^{-j}\right| \left|\widetilde{\Pr}[\mathrm{Tr}(\langle \alpha, \mathcal{Q} \rangle) = j] - \widetilde{\Pr}[\mathrm{Tr}(\langle \alpha, \mathcal{Q}' \rangle) = j]\right| \\
&= \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \sum_{g \in \mathbb{F}^S : \mathrm{Tr}(\langle \alpha, g \rangle) = j} \left|\widetilde{\Pr}[\mathcal{Q}(S) = g] - \widetilde{\Pr}[\mathcal{Q}'(S) = g]\right| \\
&\leq \frac{1}{q^n} \sum_{g \in \mathbb{F}^S} \left|\widetilde{\Pr}[\mathcal{Q}(S) = g] - \widetilde{\Pr}[\mathcal{Q}'(S) = g]\right| \leq \frac{\delta}{q^n} .
\end{aligned}$$

By Lemma 39, we know that for every $\alpha, \alpha' \in \mathbb{F}^n$ such that $\alpha - \alpha' \in \mathbf{C}^\perp$ it holds that $\left|\widehat{\mathcal{Q}}'(\alpha) - \widehat{\mathcal{Q}}'(\alpha')\right| = 0$. Hence, for every $\alpha, \alpha' \in \mathbb{F}^n_{\leq k}$ such that $\alpha - \alpha' \in \mathbf{C}^\perp$ it holds that

$$\begin{aligned}\left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}(\alpha')\right| &\leq \left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}'(\alpha)\right| + \left|\widehat{\mathcal{Q}}'(\alpha) - \widehat{\mathcal{Q}}'(\alpha')\right| + \left|\widehat{\mathcal{Q}}'(\alpha') - \widehat{\mathcal{Q}}(\alpha')\right| \\ &\leq \frac{\delta}{q^n} + 0 + \frac{\delta}{q^n} = \frac{2\delta}{q^n} \ .\end{aligned}$$

Now, suppose that $\mathcal{Q}$ is a quasi-distribution such that $\left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}(\alpha')\right| \leq \frac{2\delta}{q^n}$ for all $\alpha, \alpha' \in \mathbb{F}^n_{\leq k}$ such that $\alpha - \alpha' \in \mathbf{C}^\perp$. For each $\alpha \in \mathbb{F}^n$, let γ_α be an element of the coset $\alpha + \mathbf{C}^\perp$ of minimal weight (ties are broken arbitrarily). Define $\mathcal{Q}'$ to be the quasi-distribution where $\widehat{\mathcal{Q}}'(\alpha) := \widehat{\mathcal{Q}}(\gamma_\alpha)$ if $\mathrm{wt}(\gamma_\alpha) \leq k$ and 0 otherwise. By construction, for any $\alpha, \alpha' \in \mathbb{F}^n$ such that $\alpha - \alpha' \in \mathbf{C}^\perp$ it holds that $\widehat{\mathcal{Q}}'(\alpha) = \widehat{\mathcal{Q}}'(\alpha')$, so $\mathcal{Q}'$ is supported on $\mathbf{C}$ by Lemma 39. Let $\alpha \in \mathbb{F}^n_{\leq k}$. By construction, we know that $\left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}'(\alpha)\right| \leq \left|\widehat{\mathcal{Q}}(\alpha) - \widehat{\mathcal{Q}}(\gamma_\alpha)\right| + \left|\widehat{\mathcal{Q}}(\gamma_\alpha) - \widehat{\mathcal{Q}}'(\alpha)\right| \leq \frac{2\delta}{q^n} + 0 = \frac{2\delta}{q^n}$, since $\alpha - \gamma_\alpha \in \mathbf{C}^\perp$ and $\mathrm{wt}(\gamma_\alpha) \leq \mathrm{wt}(\alpha) \leq k$. Therefore, by Lemma 33 we have that $\Delta_k(\mathcal{Q}, \mathcal{Q}') \leq q^{k/2} \cdot 2\delta$.

5.2 Locally-explainable non-signaling functions

We introduce another natural definition that captures when a non-signaling function $\mathcal{F}$ is "in" a given linear code $\mathbf{C} \subseteq \mathbb{F}^n$. This time we take the perspective of local consistency, namely, we shall require that the output of $\mathcal{F}$ is always consistent with a codeword in $\mathbf{C}$.

▶ **Definition 42.** *Given a k-non-signaling strategy $\mathcal{F}\colon [n] \to \mathbb{F}$, code $\mathbf{C} \subseteq \mathbb{F}^n$, and parameter $k' \leq k$, we say that $\mathcal{F}$ is* **$(\mathbf{C}, k')$-explainable** *if for every set $S \subseteq [n]_{\leq k'}$ it holds that $\Pr[\mathcal{F}(S) \in \mathbf{C}|_S] = 1$.*

Note that $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable if and only if $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathbf{C}^\perp_{\leq k'}$. The non-trivial direction of the equivalence is implied by the following lemma.

▶ **Lemma 43.** *Let $\mathbf{C} \subseteq \mathbb{F}^n$ be a linear code, $S \subseteq [n]_{\leq k}$, and $g\colon S \to \mathbb{F}$. If $\langle \alpha, g \rangle = 0$ for every $\alpha \in \mathbf{C}^\perp_{\subseteq S}$, then there is a codeword $f \in \mathbf{C}$ such that $f|_S = g$.*

Proof. Since $\mathbf{C} \subseteq \mathbb{F}^n$ is a linear code, there is a *pivotal set* $P \subseteq [n]$ of size $|P| = \dim(\mathbf{C})$ such that for all $y\colon P \to \mathbb{F}$ there is a unique codeword $f \in \mathbf{C}$ satisfying $f|_P = y$. Such P need not be unique.

Let $P^* \subseteq [n]$ be a pivotal set such that $|P^* \cap S|$ is maximal, and let $P_S := P^* \cap S$. Define $f'\colon P^* \to \mathbb{F}$ by letting $f'(i) = g(i)$ for all $i \in P_S$, and letting $f'(j)$ be arbitrary for all $j \in P^* \setminus P_S$. Since P^* is a pivotal set, there exists a unique $f \in \mathbf{C}$ such that $f|_{P^*} = f'$.

It remains to show that $f|_S = g$. Let $i \in S$. If $i \in P_S$, then $f(i) = f'(i) = g(i)$, as required. Suppose that $i \notin P_S$. Since P^* is maximal, there exists $\alpha \in \mathbf{C}^\perp$ such that $\alpha_i = 1$ and $\mathrm{supp}(\alpha) \subseteq P_S \cup \{i\} \subseteq S$. Indeed, if no such α exists then for any codeword $h \in \mathbf{C}$, $h(i)$ is not determined by $\{h(j) : j \in P_S\}$. Hence, the set $P_S \cup \{i\}$ can be extended into a pivotal set for $\mathbf{C}$, which contradicts the maximality of P^*. Therefore, such an α exists. Since $\langle \alpha, f \rangle = 0$ and $\langle \alpha, g \rangle = 0$, we get that $0 = \langle \alpha, f \rangle - \langle \alpha, g \rangle = f(i) + \sum_{j \in P_S} \alpha_j f(j) - g(i) - \sum_{j \in P_S} \alpha_j g(j) = f(i) + \sum_{j \in P_S} \alpha_j g(j) - g(i) - \sum_{j \in P_S} \alpha_j g(j) = f(i) - g(i)$, and therefore $f(i) = g(i)$. We conclude that $f|_S = g$, as required. ◀

We provide a characterization of the Fourier spectrum of $\mathbf{C}$-explainable non-signaling functions, both in the exact and in the robust cases, as captured by the respective lemmas below. Both lemmas make crucial use of Lemma 29.

▶ **Lemma 44.** *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function. Then $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable if and only if $\widehat{\mathcal{F}}(\alpha) = \frac{1}{q^n}$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$.*

Proof. We know that $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable if and only if for every $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$ it holds that $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] = 1$. By Lemma 29, we know that $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] = 1$ if and only if $\widehat{\mathcal{F}}(a\alpha) = \frac{1}{q^n}$ for every $a \in \mathbb{F}$, as M is invertible and maps the distribution $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] = 1$ and $\Pr[\langle \alpha, \mathcal{F}\rangle = b] = 0$ for all other b to the vector 1^q. We conclude the proof by noting that if $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$ then $a\alpha \in \mathbf{C}^{\perp}_{\leq k'}$ for any $a \in \mathbb{F}$. ◀

▶ **Lemma 45.** *Let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function, and let $\alpha \in \mathbb{F}^n_{\leq k}$.*

- *If $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] \geq 1 - \varepsilon$, then $|\widehat{\mathcal{F}}(a\alpha) - \frac{1}{q^n}| \leq \frac{2\varepsilon}{q^n}$ for every $a \in \mathbb{F}$.*
- *If $|\widehat{\mathcal{F}}(a\alpha) - \frac{1}{q^n}| \leq \frac{\varepsilon}{q^n}$ for every $a \in \mathbb{F}$, then $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] \geq 1 - \varepsilon$.*

Proof. Suppose that $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] \geq 1 - \varepsilon$. This immediately implies that, for every $a \in \mathbb{F}$, $\Pr[\langle a\alpha, \mathcal{F}\rangle = 0] \geq 1 - \varepsilon$. Therefore,

$$\begin{aligned}
\left|q^n \widehat{\mathcal{F}}(a\alpha) - 1\right| &= \left|-1 + \sum_{b \in \mathbb{F}} \omega^{-\mathrm{Tr}(ab)} \Pr[\langle a\alpha, \mathcal{F}\rangle = b]\right| \\
&\leq |-1 + \Pr[\langle a\alpha, \mathcal{F}\rangle = 0]| + \sum_{b \neq 0} |\omega^{-\mathrm{Tr}(ab)}||\Pr[\langle a\alpha, \mathcal{F}\rangle = b]| \\
&\leq \varepsilon + \sum_{b \neq 0} \Pr[\langle a\alpha, \mathcal{F}\rangle = b] \\
&= \varepsilon + (1 - \Pr[\langle a\alpha, \mathcal{F}\rangle = 0]) \leq 2\varepsilon \ .
\end{aligned}$$

This proves the first direction.

For the second direction, let $v \in \mathbb{C}^q$ be the vector where $v_b = \Pr[\langle \alpha, \mathcal{F}\rangle = b]$ and let $w \in \mathbb{C}^q$ be the vector where $w_a = q^n \widehat{\mathcal{F}}(a\alpha)$. Note that $Mv = w$, where M is the matrix from Lemma 29. Suppose that $|\widehat{\mathcal{F}}(a\alpha) - \frac{1}{q^n}| \leq \frac{\varepsilon}{q^n}$ for every $a \in \mathbb{F}$, so that $|w_a - 1| \leq \varepsilon$ for every $a \in \mathbb{F}$. Then, we have that $\|w - 1^q\|^2_{\ell_2} \leq q\varepsilon^2$, so that $\|w - 1^q\|_{\ell_2} \leq \varepsilon\sqrt{q}$. Let $u \in \mathbb{C}^q$ be the vector where $u_0 = 1$ and $u_b = 0$ for all other $b \in \mathbb{F}$. Observe that $Mu = 1^q$. Since $\frac{1}{\sqrt{q}} M$ is unitary, we have that $\|\frac{1}{\sqrt{q}} M(v - u)\|_{\ell_2} = \|\frac{1}{\sqrt{q}}(w - 1^q)\|_{\ell_2} \leq \frac{1}{\sqrt{q}} \cdot \varepsilon\sqrt{q} = \varepsilon$. Therefore, $|v_b - u_b| \leq \varepsilon$ for all $b \in \mathbb{F}$. In particular, $|v_0 - 1| \leq \varepsilon$, so that $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] \geq 1 - \varepsilon$. ◀

5.3 The relationship between the two definitions

We have given two natural definitions of what it means for a non-signaling function to be in a linear code. Which of the two definitions is more "correct"? Lemma 39 and Lemma 44 show that Definition 38 implies Definition 42, in the sense that if $\mathcal{F}$ is $(\mathbf{C}, k')$-supported then $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable. We prove that, conversely, Definition 42 implies Definition 38 up to a factor of 2 in the locality k'. We conclude that the two definitions are essentially equivalent.

▶ **Lemma 46.** *Let $\mathbf{C} \subseteq \mathbb{F}^n$ be a linear code, and let $\mathcal{F}\colon [n] \to \mathbb{F}$ be a k-non-signaling function.*

- *If $\mathcal{F}$ is $(\mathbf{C}, k')$-supported then $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable.*
- *If $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable then $\mathcal{F}$ is $(\mathbf{C}, k'/2)$-supported.*

▶ Remark 47. For specific choices of $\mathbf{C}$ one can achieve stronger versions of the above lemma. For example, when $\mathbf{C}$ is the Hadamard code (all linear functions), one can prove the lemma with $k' - 1$ in place of $k'/2$. Also, *some* gap in locality is necessary: taking again $\mathbf{C}$ to be the Hadamard code, there exists a non-signaling function $\mathcal{F}$ that is $(\mathbf{C}, k)$-explainable and $(\mathbf{C}, k-1)$-supported but *not* $(\mathbf{C}, k)$-supported. (The foregoing statements are shown implicitly in [4].)

Proof. Lemma 39 and Lemma 44 imply the first direction, as any $(\mathbf{C}, k')$-supported k-non-signaling function $\mathcal{F}$ satisfies $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{F}}(0^n) = \frac{1}{q^n}$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$, implying that $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable.

We now prove the second direction. Fix $\alpha \in \mathbf{C}^{\perp}_{\leq k'}$, and let $S := \{i \in [n] : \alpha_i \neq 0\}$. Note that $|S| \leq k'$ since $|S| = \mathrm{wt}(\alpha)$. We first show that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$. Indeed, since $\mathcal{F}$ is $(\mathbf{C}, k')$-explainable, we have that

$$\begin{aligned}\Pr[\langle \alpha, \mathcal{F} \rangle = 0] &\geq \Pr[\langle \alpha, \mathcal{F} \rangle = 0 \wedge \exists\, f \in \mathbf{C} \text{ s.t. } \mathcal{F}(S) = f|_S] \\ &= \Pr[\langle \alpha, f \rangle = 0 \wedge \exists\, f \in \mathbf{C} \text{ s.t. } \mathcal{F}(S) = f|_S] \\ &= \Pr[\exists\, f \in \mathbf{C} \text{ s.t. } \mathcal{F}(S) = f|_S] = 1 \ ,\end{aligned}$$

and so $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$.

Now, for any $\alpha, \alpha' \in \mathbb{F}^n_{\leq k'/2}$ with $\alpha - \alpha' \in \mathbf{C}^{\perp}$ we get that for any $b \in \mathbb{F}$,

$$\Pr[\langle \alpha, \mathcal{F} \rangle = b] = \Pr[\langle \alpha', \mathcal{F} \rangle + \langle \alpha - \alpha', \mathcal{F} \rangle = b] = \Pr[\langle \alpha', \mathcal{F} \rangle = b] \ ,$$

since $\Pr[\langle \alpha - \alpha', \mathcal{F} \rangle = 0] = 1$ as $\alpha - \alpha' \in \mathbf{C}^{\perp}$ with $\mathrm{wt}(\alpha - \alpha') \leq k'$. This shows that the vectors $(\Pr[\langle \alpha, \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$ and $(\Pr[\langle \alpha', \mathcal{F} \rangle = b])_{b \in \mathbb{F}}$ are the same. Thus, $\widehat{\mathcal{F}}(\alpha) = \widehat{\mathcal{F}}(\alpha')$, by the definition of $\mathcal{F}$'s Fourier coefficients. By Lemma 39, it follows that $\mathcal{F}$ is $(\mathbf{C}, k'/2)$-supported. ◀

6 Low-degree testing

In this section, we prove Theorem 2. Throughout this section, we let $m, d, k \in \mathbb{N}$ be parameters, and p be a prime where $p \geq d+2$. Let $\mathsf{RS}^{\otimes m}[\mathbb{F}_p, d]$ denote the code of polynomials from $\mathbb{F}_p^m$ to $\mathbb{F}_p$ of individual degree at most d in each variable. We let $\mathcal{F} \colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a k-non-signaling function. For a subset $S \subseteq \mathbb{F}_p$ and $a \in S$, we let $\delta_{a,S}(x) = \frac{\prod_{a' \in S \setminus \{a\}} (x - a')}{\prod_{a' \in S \setminus \{a\}} (a - a')}$ be the degree $|S| - 1$ polynomial satisfying $\delta_a(x) = \begin{cases} 1 & \text{if } x = a \ , \\ 0 & \text{if } x \in S \setminus \{a\} \ . \end{cases}$

We begin by recalling the degree-d evenly-spaced points test.

▶ **Definition 48** (Evenly-spaced points test)**.** *Given a function $f \colon \mathbb{F}_p^m \to \mathbb{F}_p$, the degree-$d$ evenly-spaced points test:*

1. *samples a random point $x \in \mathbb{F}_p^m$ and slope $h \in \mathbb{F}_p^m \setminus \{0^m\}$,*
2. *checks that $\sum_{i=0}^{d+1} c_i f(x + ih) = 0$, where $c_i = (-1)^i \binom{d+1}{i}$.*

▶ **Definition 49** (Evenly-spaced self-correction)**.** *The evenly-spaced self-correction of $\mathcal{F}$, denoted $\hat{\mathcal{F}}$, is a $\lfloor k/(d+1) \rfloor$-non-signaling function defined as follows. Let $w_0, w_1, \ldots, w_m \in \mathbb{F}_p^m$ be independent uniformly random vectors in $\mathbb{F}_p^m$, and for each $x \in \mathbb{F}_p^m$ let $w_x = w_0 + \sum_{i=1}^m x_i w_i$. For an input set S and $g \colon S \to \mathbb{F}_p$, the distribution of $\hat{\mathcal{F}}(S)$ correction is defined as*

$$\Pr[\hat{\mathcal{F}}(S) = g] = \Pr_{w_0, \ldots, w_m, \mathcal{F}}[-\sum_{j=1}^{d+1} c_j \mathcal{F}(x + j w_x) = g(x) \ \forall x \in S] \ .$$

Our main theorem is the following.

▶ **Theorem 50** (Formal version of Theorem 2)**.** *Let p be a prime, and let $m, d \in \mathbb{N}$ with $p \geq d+2$. Let $\mathcal{F} \colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a k-non-signaling function. Suppose that $\mathcal{F}$ passes the degree-d evenly-spaced points test with probability $1 - \varepsilon$. Then there exists a k'-non-signaling function $\mathcal{G} \colon \mathbb{F}_p^m \to \mathbb{F}_p$ that is $(\mathsf{RS}^{\otimes m}[\mathbb{F}_p, d], k')$-supported such that $\Delta_{k'}(\hat{\mathcal{F}}, \mathcal{G}) \leq O(p^{3k'/2}(d+1)^m \varepsilon)$, where $k' = \lfloor \frac{k}{2(d+1)(d+2)} \rfloor - 3$.*

When $\varepsilon = 0$, the theorem can be simplified considerably to the statement below.

▶ **Theorem 51** (Formal version of Theorem 2, zero error case)**.** *Let p be a prime, and let $m, d \in \mathbb{N}$ with $p \geq d+2$. Let $\mathcal{F}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a k-non-signaling function. Suppose that $\mathcal{F}$ passes the degree-d evenly-spaced points test with probability 1. Then $\mathcal{F}$ is $(\mathsf{RS}^{\otimes m}[\mathbb{F}_p, d], \lfloor k/(d+2) \rfloor - 1)$-supported.*

We prove Theorem 50 via the following statements, each proved in one of the following sections.

▶ **Lemma 52** (Average to worst case)**.** *Suppose that $\mathcal{F}$ passes the degree-d evenly-spaced points test with probability $1-\varepsilon$, i.e. that $\Pr_{h \neq 0^m, x, \mathcal{F}}[\sum_{i=0}^{d+1} c_i \mathcal{F}(x+ih) = 0] \geq 1-\varepsilon$. Then for every $x, h \in \mathbb{F}_p^m$ with $h \neq 0^m$ it holds that $\Pr_{\hat{\mathcal{F}}}[\sum_{i=0}^{d+1} c_i \hat{\mathcal{F}}(x+ih) = 0] \geq 1-(d+1)\varepsilon$.*

▶ **Lemma 53** (Evenly-spaced points to axis-parallel lines)**.** *Let $\hat{\mathcal{F}}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a $\hat{k}$-non-signaling function, with $\hat{k} \geq 2d+3$. Suppose that for every $x, h \in \mathbb{F}_p^m$ with $h \neq 0^m$ it holds that $\Pr_{\hat{\mathcal{F}}}[\sum_{i=0}^{d+1} c_i \hat{\mathcal{F}}(x+ih) = 0] \geq 1-\varepsilon$. Then for every $b_1, \ldots, b_m \in \mathbb{F}_p$, $i \in [m]$, and $S \subseteq \mathbb{F}_p \setminus \{b_i\}$ of size $|S| = d+1 \leq \hat{k}-d-2$ it holds that*

$$\Pr_{\hat{\mathcal{F}}}[\hat{\mathcal{F}}(b_1, \ldots, b_m) = \sum_{a \in S} \delta_{a,S}(b_i) \cdot \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, a, b_{i+1}, \ldots, b_m)] \geq 1 - p\varepsilon \ .$$

▶ **Lemma 54** (Robust local characterization)**.** *Let $\hat{\mathcal{F}}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a $\hat{k}$-non-signaling function, and suppose that for every $i \in [m]$, $b_1, \ldots, b_m \in \mathbb{F}_p$, and $S' \subseteq \mathbb{F}_p \setminus \{b_i\}$ of size $|S'| = d+1$ it holds that*

$$\Pr_{\hat{\mathcal{F}}}[\hat{\mathcal{F}}(b_1, \ldots, b_m) = \sum_{a \in S'} \delta_{a,S'}(b_i) \cdot \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, a, b_{i+1}, \ldots, b_m)] \geq 1 - \varepsilon \ .$$

Then for every $S \subseteq \mathbb{F}_p^m$ with $|S| \leq \lfloor \hat{k}/(d+2) \rfloor$ it holds that $\Pr[\hat{\mathcal{F}}(S) \in \mathsf{RS}^{\otimes m}[\mathbb{F}_p, d]\big|_S] \geq 1 - 2|S| \cdot (d+1)^{m-1}\varepsilon$.

▶ **Lemma 55.** *Let $\hat{\mathcal{F}}\colon \mathbb{F}_p^m \to \mathbb{F}_p$ be a $\hat{k}$-non-signaling function, and let $k' \leq \hat{k}$. Suppose that for every $S \subseteq \mathbb{F}_p^m$ with $|S| \leq k'$ it holds that $\Pr[\hat{\mathcal{F}}(S) \in \mathsf{RS}^{\otimes m}[\mathbb{F}_p, d]\big|_S] \geq 1-\varepsilon$. Then there exists a $k'/2$-non-signaling function $\mathcal{G}$ that is $(\mathsf{RS}^{\otimes m}[\mathbb{F}_p, d], k'/2)$-supported and $\Delta_{k'/2}(\mathcal{F}, \mathcal{G}) \leq (p^{k'/2}+1) \cdot p^{k'/4} \cdot 2\varepsilon$.*

6.1 Step 1: Average to worst case reduction

We prove Lemma 52. Fix $x, h \in \mathbb{F}_p^m$ with $h \neq 0^m$. Observe that $w_{x+ih} = w_x + i(w_h - w_0)$. Therefore

$$\begin{aligned}
&\Pr_{\hat{\mathcal{F}}}[\sum_{i=0}^{d+1} c_i \hat{\mathcal{F}}(x+ih) = 0] = \Pr_{w_0, \ldots, w_m, \mathcal{F}}[\sum_{i=0}^{d+1} c_i \sum_{j=1}^{d+1} -c_j \mathcal{F}(x+ih+jw_{x+ih}) = 0] \\
&\Pr_{w_0, \ldots, w_m, \mathcal{F}}[\sum_{j=1}^{d+1} -c_j \sum_{i=0}^{d+1} c_i \mathcal{F}(x+ih+jw_x+ij(w_h-w_0)) = 0] \\
&\geq \Pr_{w_0, \ldots, w_m, \mathcal{F}}[\sum_{i=0}^{d+1} c_i \mathcal{F}(x+jw_x+i(h+j(w_h-w_0))) = 0 \ \forall j \in [d+1]] \\
&\geq 1-(d+1)\varepsilon \ ,
\end{aligned}$$

where last inequality is by union bound, using the fact that for $j \neq 0$ the vectors $x + jw_x$ and $h + j(w_h - w_0)$ are independent and uniformly random vectors in $\mathbb{F}_p^m$. Indeed, for $h \neq 0^m$ the vector $h + j(w_h - w_0)$ is equal to $h + \sum_{i=1}^m jh_i w_i$, and hence is uniformly random, and $x + jw_x$ is equal to $x + jw_0 + \sum_{i=1}^m jx_i w_i$, which is also uniformly random and independent of $h + j(w_h - w_0)$ because the term w_0 is independent of all other w_i's.

6.2 Step 2: From evenly-spaced points to axis-parallel lines

We prove Lemma 53. Note that by the assumption for every $x \in \mathbb{F}_p^m$ and $h = e_i$ it holds that $\Pr_{\hat{\mathcal{F}}}[\sum_{\ell=0}^{d+1} c_\ell \hat{\mathcal{F}}(x + \ell e_i) = 0] \geq 1 - \varepsilon$. Fix $i \in [m]$, $b_1, \ldots, b_{i-1}, b_{i+1}, \ldots b_m \in \mathbb{F}_p$, and $S \subseteq \mathbb{F}_p$ of size $|S| = d + 2$. We claim that

$$\Pr[\exists\, g \in \mathsf{RS}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, s, b_{i+1}, \ldots b_m) \equiv g(s)\ \forall s \in S] \geq 1 - p\varepsilon\ . \tag{1}$$

This clearly implies Lemma 53.

In order to prove Equation (1), let us order the elements of S as $s_1 \leq s_2 \leq \cdots \leq s_{d+2}$ by treating s_i's as integers in $\{0, 1, 2, \ldots, p-1\} \subseteq \mathbb{N}$. For each $j \in \mathbb{F}_p$ define the interval $I_j = \{j, j+1, j+2, \ldots, j+d+1\}$, and denote $Q_j = \{s \in S : s \leq j + d + 2\} \cup I_j$. We claim that with high probability $\hat{\mathcal{F}}$ on the points corresponding to Q_j agrees with some univariate polynomial. Specifically, we prove the following claim.

▷ Claim 56. For each $j = 0, 1 \ldots, p-1$ it holds that

$$\Pr[\exists\, g \in \mathsf{RS}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) \equiv g(\ell)\ \forall \ell \in Q_j] \geq 1 - (j+1)\varepsilon\ .$$

It is clear that the statement of Claim 56 for $j = p - 1$ implies Equation (1), and hence proves Lemma 53.

Proof of Claim 56. The proof is by induction in j. For the base case of $j = 0$ we query $\hat{\mathcal{F}}$ on the set I_0. By the assumption of the lemma we have

$$\Pr_{\hat{\mathcal{F}}}[\exists\, g \in \mathsf{RS}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) = \ell\ \forall \ell \in I_0] \geq 1 - \varepsilon\ ,$$

and the claim hold since for $j = 0$ we have $Q_0 = I_0$.

For the induction step suppose that the statement of the claim holds for $j - 1$, i.e., with probability $1 - j\varepsilon$ there exists a univariate polynomial g of degree d that agrees with $\hat{\mathcal{F}}$ on Q_{j-1}. Note that the set $Q'_{j-1} = Q_{j-1} \setminus \{j-1\}$ contains the $d+1$ consecutive points $\{j, j+1, \ldots, j+d\}$, and these points uniquely define the polynomial g of degree d. Therefore

$$\Pr[\exists\, g \in \mathsf{RS}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) \equiv g(\ell)\ \forall \ell \in Q'_{j-1}] \geq 1 - j\varepsilon\ .$$

On the other hand, by the assumption that $\hat{\mathcal{F}}$ satisfies evenly-spaced constraints with probability $\geq 1 - \varepsilon$ we have

$$\Pr[\exists\, g' \in \mathsf{RS}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) \equiv g'(\ell)\ \forall \ell \in I_j] \geq 1 - \varepsilon\ .$$

Note that the above statement requires that $p \geq d + 2$, as passing the evenly-spaced points test along a line corresponds to being a univariate polynomial only when $p \geq d + 2$.

Query $\hat{\mathcal{F}}$ on the set $Q'_{j-1} \cup I_j$. By union bound, the above events both hold with probability $\geq 1 - (j+1)\varepsilon$, so that there exists $g, g' \in \mathsf{RS}[\mathbb{F}_p, d]$ such that $\hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) = g(\ell)$ for all $\ell \in Q'_{j-1}$ and $\hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) = g'(\ell)$ for all $\ell \in I_j$. However, since Q'_{j-1} intersects I_j on $d+1$ points it must be the case that $g = g'$. Hence, $\hat{\mathcal{F}}(b_1, \ldots, b_{i-1}, \ell, b_{i+1}, \ldots b_m) = g(\ell)$ for all $\ell \in Q'_{j-1} \cup I_j$. Since $Q_j \subseteq Q'_{j-1} \cup I_j$, this proves the induction step. Since $\left|Q'_{j-1} \cup I_j\right| \leq |S| + d + 2$ and $|Q_j| \leq |S| + d + 2$, it follows that this is valid for all S with $|S| \leq \hat{k} - d - 2$, which completes the proof of Claim 56. ◁

6.3 Step 3: A robust local characterization of low-degree polynomials

We prove Lemma 54. We begin by introducing some notation. For each $i \in [m]$ define $S_i \subseteq \mathbb{F}_p^i$ to be the projection of S to the first i coordinates, i.e. that

$$S_i := \{(a_1, \ldots, a_i) \in \mathbb{F}_p^i : \exists\, b_{i+1}, \ldots b_m \in \mathbb{F}_p \text{ s.t. } (a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) \in S\} \ .$$

Note that $S_m = S$. For any set $R \subseteq \mathbb{F}_p^i$ and $b_{i+1}, \ldots, b_m \in \mathbb{F}_p$, we define the extension of R as

$$R^{(b_{i+1},\ldots,b_m)} := R \times \{(b_{i+1}, \ldots, b_m)\} \ .$$

We prove by induction that for every $i \in [m]$ and every $b_{i+1}, \ldots, b_m \in \mathbb{F}_p$ it holds that

$$\Pr[\exists\, g_i \in \mathsf{RS}^{\otimes i}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) = g_i(a_1, \ldots, a_i)\ \forall (a_1, \ldots, a_i) \in S_i] \geq 1 - \varepsilon_i \ , \tag{2}$$

where $\varepsilon_i = |S| \sum_{j=1}^{i} (d+1)^{j-1} \varepsilon$. Note that the above probability is well-defined since we query $\hat{\mathcal{F}}$ on the set $S_i^{(b_{i+1},\ldots,b_m)}$, which contains at most $|S| \leq k' \leq k$ points. Equation (2) proves Lemma 54, as $S_m = S$ and $\varepsilon_m \leq |S| \cdot (\sum_{j=1}^{m} (d+1)^{j-1}) \cdot \varepsilon \leq \frac{(d+1)^m - 1}{d} \cdot |S| \varepsilon \leq 2(d+1)^{m-1} |S| \varepsilon$.

We first show the base case: $i = 1$. Let $R \subseteq S_1$ be a subset of size $\min(d+1, |S_1|)$. Query $\hat{\mathcal{F}}$ on $S_1^{(b_2,\ldots,b_m)}$, and let $g_1 \in \mathsf{RS}^{\otimes 1}[\mathbb{F}_p, d]$ be the univariate polynomial $g_1(x) = \sum_{a \in R} \delta_{a,R}(x) \cdot \hat{\mathcal{F}}(a, b_2, \ldots, b_m)$. Then,

$$\Pr[\exists\, g_1 \in \mathsf{RS}^{\otimes 1}[\mathbb{F}_p, d] \text{ s.t. } \hat{\mathcal{F}}(a_1, b_2, \ldots, b_m) = g_1(a_1) \text{ for all } a_1 \in S_1] \geq 1 - |S_1| \varepsilon = 1 - \varepsilon_1 \ .$$

This is because if $a_1 \in R$, then $\hat{\mathcal{F}}(a, b_2, \ldots, b_m) = g_1(a)$ is trivially true by definition of g_1, and if $a_1 \in S_1 \setminus R$ then this is true because

$$\hat{\mathcal{F}}(a_1, b_2, \ldots, b_m) = \sum_{a \in R} \delta_{a,R}(a_1) \cdot \hat{\mathcal{F}}(a, b_2, \ldots, b_m) = g_1(a_1) \ ,$$

with probability $1 - \varepsilon$, by the assumption on $\hat{\mathcal{F}}$.

We now show the induction step. Suppose that Equation (2) holds for $i-1$ and every $b_i, \ldots, b_m \in \mathbb{F}_p$. Let $R_i = S_i \cup (S_{i-1} \times \{0, \ldots, d\})$. Fix $b_{i+1}, \ldots, b_m \in \mathbb{F}_p$, and query $\hat{\mathcal{F}}$ on $R_i^{(b_{i+1},\ldots,b_m)}$. Note that this is well-defined since $\left|R_i^{(b_{i+1},\ldots,b_m)}\right| \leq |S_i| + (d+1)|S_{i-1}| \leq (d+2)|S| \leq (d+2)k' \leq k$.

We have that $S_{i-1} \times \{0, \ldots, d\} \subseteq R_i$, and so for every $j \in \{0, \ldots, d\}$, the induction hypothesis implies (by setting $b_i = j$) that with probability at least $1 - \varepsilon_{i-1}$ there exists $g_{i-1}^{(j)} \in \mathsf{RS}^{\otimes i-1}[\mathbb{F}_p, d]$ such that $\hat{\mathcal{F}}(a_1, \ldots, a_{i-1}, j, b_{i+1}, \ldots, b_m) = g_{i-1}^{(j)}(a_1, \ldots, a_{i-1})$ for every $(a_1, \ldots, a_{i-1}) \in S_{i-1}$.

For $j \in \{0, \ldots, d\}$, let $\delta_j(x) := \delta_{j,\{0,\ldots,d\}}(x)$. Let $g_i \in \mathsf{RS}^{\otimes i}[\mathbb{F}_p, d]$ be defined as $g_i(x_1, \ldots, x_i) = \sum_{j=0}^{d} \delta_j(x_i) \cdot g_{i-1}^{(j)}(x_1, \ldots, x_{i-1})$. We show that

$$\Pr[\hat{\mathcal{F}}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) = g_i(a_1, \ldots, a_i) \text{ for all } (a_1, \ldots, a_i) \in S_i] \geq 1 - \varepsilon_i \ .$$

Indeed, note that for any $(a_1, \ldots, a_i) \in S_i$ we have $(a_1, \ldots, a_{i-1}) \in S_{i-1}$, and so with probability $1 - (d+1)\varepsilon_{i-1}$ all the $g_{i-1}^{(j)}$'s exist, and so we have that for all $(a_1, \ldots, a_i) \in S_i$ it holds that

$$g_i(a_1, \ldots, a_i) = \sum_{j=0}^{d} \delta_j(a_i) \cdot g_{i-1}^{(j)}(a_1, \ldots, a_{i-1}) = \sum_{j=0}^{d} \delta_j(a_i) \cdot \hat{\mathcal{F}}(a_1, \ldots, a_{i-1}, j, b_{i+1}, \ldots, b_m)$$

By the assumption on $\hat{\mathcal{F}}$, we have

$$\Pr[\sum_{j=0}^{d} \delta_j(a_i) \cdot \hat{\mathcal{F}}(a_1, \ldots, a_{i-1}, j, b_{i+1}, \ldots, b_m) \\ = \hat{\mathcal{F}}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m) \ \forall (a_1, \ldots, a_i) \in S_i] \geq 1 - |S_i|\varepsilon \ .$$

Combining the two equations shows that $g_i(a_1, \ldots, a_i) = \hat{\mathcal{F}}(a_1, \ldots, a_i, b_{i+1}, \ldots, b_m)$ with probability $1 - (d+1)\varepsilon_{i-1} - |S_i|\varepsilon \geq 1 - (d+1)\varepsilon_{i-1} - |S|\varepsilon = 1 - \varepsilon_i$, as required, completing the proof.

6.4 Step 4: Completing the proof

The following generic lemma immediately implies Lemma 55.

▶ **Lemma 57.** *Let $\mathbf{C} \subseteq \mathbb{F}^n$ be a linear code, and let $\mathcal{F}$ be a k-non-signaling function. Suppose that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] \geq 1 - \varepsilon$ for every $\alpha \in \mathbf{C}^{\perp}_{\leq k}$. Then there exists a $k/2$-non-signaling function $\mathcal{G}$ that is $(\mathbf{C}, k/2)$-supported such that $\Delta_{k/2}(\mathcal{F}, \mathcal{G}) \leq (q^{k/2} + 1) \cdot q^{k/4} \cdot 2\varepsilon$.*

Proof. Let $\alpha, \alpha' \in \mathbb{F}^n_{\leq k/2}$ such that $\alpha - \alpha' \in \mathbf{C}^{\perp}$. Then

$$\left|\widehat{\mathcal{F}}(\alpha) - \widehat{\mathcal{F}}(\alpha')\right| = \left|\frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \omega^{-j} (\Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] - \Pr[\mathrm{Tr}(\langle \alpha', \mathcal{F} \rangle) = j])\right| \\ \leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \left|\omega^{-j}\right| \left|\Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j] - \Pr[\mathrm{Tr}(\langle \alpha', \mathcal{F} \rangle) = j]\right| \\ \leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \left|\Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j \wedge \langle \alpha - \alpha', \mathcal{F} \rangle \neq 0] - \Pr[\mathrm{Tr}(\langle \alpha', \mathcal{F} \rangle) = j \wedge \langle \alpha - \alpha', \mathcal{F} \rangle \neq 0]\right| \\ \leq \frac{1}{q^n} \sum_{j \in \mathbb{F}_p} \left(\left|\Pr[\mathrm{Tr}(\langle \alpha, \mathcal{F} \rangle) = j \wedge \langle \alpha - \alpha', \mathcal{F} \rangle \neq 0]\right| + \left|\Pr[\mathrm{Tr}(\langle \alpha', \mathcal{F} \rangle) = j \wedge \langle \alpha - \alpha', \mathcal{F} \rangle \neq 0]\right|\right) \\ \leq \frac{2}{q^n} \cdot \Pr[\langle \alpha - \alpha', \mathcal{F} \rangle \neq 0] \leq \frac{2\varepsilon}{q^n} \ ,$$

since $\alpha - \alpha' \in \mathbf{C}^{\perp}$ and $\mathrm{wt}(\alpha - \alpha') \leq k$. By Lemma 41, there exists a quasi-distribution $\mathcal{Q}$ supported on $\mathbf{C}$ such that $\Delta_{k/2}(\mathcal{F}, \mathcal{Q}) \leq q^{k/4} \cdot 2\varepsilon$. By Lemma 26, there exists a quasi-distribution $\mathcal{Q}'$ supported on $\mathbf{C}$ such that $\Delta_{k/2}(\mathcal{Q}, \mathcal{Q}') \leq q^{k/2} \cdot q^{k/4} \cdot 2\varepsilon$. Letting $\mathcal{G}$ be the $k/2$-non-signaling function corresponding to $\mathcal{Q}'$ completes the proof. ◀

7 Local characterizations and linear proofs

We prove Theorem 8 in this section. For this section, we let $k' \leq k$ be an integer. We let $\mathbf{C} \subseteq \mathbb{F}^n$ be a linear code, and $T \subseteq \mathbb{F}^n$ be a set of constraints. Given a k-non-signaling function $\mathcal{F}$, we say that $\mathcal{F}$ satisfies a constraint $\alpha \in \mathbb{F}^n_{\leq k}$ if $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$.

▶ **Definition 58.** *We let* $\mathsf{Consistent}(T, k)$ *denote the set of k-non-signaling functions $\mathcal{F}$ where $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in T$. That is,* $\mathsf{Consistent}(T, k)$ *is the set of k-non-signaling functions that are consistent with T.*

We note that by Lemma 44, $\mathsf{Consistent}(\mathbf{C}^{\perp}_{\leq k'}, k)$ is the set of k-non-signaling functions that are $(\mathbf{C}, k')$-explainable.

With the above definition, the definition of local characterization can be rephrased as follows.

▶ **Definition 59.** *For $\ell \le k' \le k$, a set of constraints $T \subseteq \mathbf{C}^{\perp}_{\le \ell}$ is a ℓ-local characterization of $(\mathbf{C}, k', k)$ if* $\mathsf{Consistent}(T, k)$ *equals the set of k-non-signaling functions that are $(\mathbf{C}, k')$-explainable, i.e. that* $\mathsf{Consistent}(T, k) = \mathsf{Consistent}(\mathbf{C}^{\perp}_{\le k'}, k)$.

In this language, [4] shows that $T = \{e_x + e_y - e_{x+y} : x, y \in \{0,1\}^n\}$ is a 3-local characterization of $(\mathbf{C}, k-1, k)$, where $\mathbf{C}$ is the Hadamard code.

We briefly recall the definition of a k-local linear proof introduced in Section 1.2.

▶ **Definition 60** (k-local linear proof)**.** *Given a constraint set T and $\alpha \in \mathbb{F}^n$, we write $T \vdash_k \alpha$ if there exists a sequence $(\alpha_0{:=}0^n, \alpha_1, \ldots, \alpha_{r-1}, \alpha_r{:=}\alpha)$ with each $\alpha_i \in \mathbb{F}^n$ such that, for every $i \in [r]$, one of the following holds:*

- *$\exists\, j < i$ and $b \in \mathbb{F}$ such that $\alpha_i = b\alpha_j$*
- *$\exists\, j < i$ and $\gamma \in T$ such that $|\mathrm{supp}(\alpha_j) \cup \mathrm{supp}(\gamma)| \le k$ and $\alpha_i = \alpha_j + \gamma$*
- *$\exists\, j_1, j_2 < i$ such that $|\mathrm{supp}(\alpha_{j_1}) \cup \mathrm{supp}(\alpha_{j_2})| \le k$ and $\alpha_i = \alpha_{j_1} + \alpha_{j_2}$.*

Theorem 8 is stated formally as the theorem below.

▶ **Theorem 61** (Formal version of Theorem 8)**.** *k-local linear proofs are complete and sound for k-non-signaling functions. In particular, for $\ell \le k' \le k$, a set of constraints $T \subseteq \mathbf{C}^{\perp}_{\le \ell}$ is a ℓ-local characterization of $(\mathbf{C}, k', k)$ if and only if $T \vdash_k \mathbf{C}^{\perp}_{\le k'}$.*

The proof of Theorem 61 relies on the notion of a k-local subspace, which we define below.

▶ **Definition 62.** *A k-local subspace $\mathcal{V}$ is a subset of $\mathbb{F}^n_{\le k}$ where $\mathcal{V}_{\subseteq S} \subseteq \mathbb{F}^n$ is a linear subspace for every $S \subseteq [n]_{\le k}$.*

We prove Theorem 61 by showing the following three lemmas.

▶ **Lemma 63** (Soundness)**.** *If $T \vdash_k \alpha$, then* $\mathsf{Consistent}(T, k) = \mathsf{Consistent}(T \cup \{\alpha\}, k)$.

▶ **Lemma 64.** *For every k-local subspace $\mathcal{V} \subseteq \mathbb{F}^n_{\le k}$, there exists a k-non-signaling function $\mathcal{F}$ such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathcal{V}$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathbb{F}|}$ otherwise.*

▶ **Lemma 65.** *$\{\alpha \in \mathbb{F}^n : T \vdash_k \alpha\} \subseteq \mathbb{F}^n_{\le k}$ is a k-local subspace.*

The following corollary follows immediately from Lemma 64 and Lemma 65.

▶ **Corollary 66** (Strong completeness)**.** *There exists a k-non-signaling function such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every α where $T \vdash_k \alpha$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathbb{F}|}$ otherwise.*

Proof of Theorem 61. Completeness and soundness are shown in Corollary 66 and Lemma 63. It remains to show the equivalence for local characterizations.

Suppose that $T \vdash_k \mathbf{C}^{\perp}_{\le k'}$. Then by Lemma 63 we have that $\mathsf{Consistent}(T, k)$ and $\mathsf{Consistent}(T \cup \mathbf{C}^{\perp}_{\le k'}, k)$ are equal. Since $T \subseteq \mathbf{C}^{\perp}_{\le \ell}$ and $\ell \le k'$, we get that $T \subseteq \mathbf{C}^{\perp}_{\le k'}$. Hence, $\mathsf{Consistent}(T, k) = \mathsf{Consistent}(T \cup \mathbf{C}^{\perp}_{\le k'}, k) = \mathsf{Consistent}(\mathbf{C}^{\perp}_{\le k'}, k)$, as required.

Conversely, suppose that T is an ℓ-local characterization of $(\mathbf{C}, k', k)$. By Lemma 64 and Lemma 65, there exists a k-non-signaling function $\mathcal{F}$ such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in \mathbb{F}^n_{\le k}$ such that $T \vdash_k \alpha$, and $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = \frac{1}{|\mathbb{F}|}$ otherwise. Since $T \vdash_k \alpha$ for every $\alpha \in T$, it follows that $\mathcal{F} \in \mathsf{Consistent}(T, k)$, which implies that $\mathcal{F} \in \mathsf{Consistent}(\mathbf{C}^{\perp}_{\le k'}, k)$ as T is an ℓ-local characterization of $(\mathbf{C}, k', k)$. This implies that $T \vdash_k \alpha$ for all $\alpha \in \mathbf{C}^{\perp}_{\le k'}$, since for all such α it holds that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$, and thus $T \vdash_k \alpha$. Hence, $T \vdash_k \mathbf{C}^{\perp}_{\le k'}$, as required. ◀

7.1 Proof of Lemma 63

It is clear that from the definition that $\mathsf{Consistent}(T,k) \supseteq \mathsf{Consistent}(T \cup \{\alpha\},k)$ for all $\alpha \in \mathbb{F}^n$. Below we prove the containment in the other direction. Suppose that $T \vdash_k \alpha$, and let $(\alpha_0 = 0^n, \alpha_1, \ldots, \alpha_r = \alpha)$ be a k-local proof of α from T. Let $\mathcal{F} \in \mathsf{Consistent}(T,k)$, that is, $\mathcal{F}$ is a k-non-signaling function such that $\forall \gamma \in T$, $\Pr[\langle \gamma, \mathcal{F}\rangle = 0] = 1$. We prove by induction that for $i \in [r]$ it holds that $\Pr[\langle \alpha_i, \mathcal{F}\rangle = 0] = 1$.

For the base case of $i = 0$ it must be the case that $\alpha_0 = 0^n$. Therefore, $\Pr[\langle \alpha_0, \mathcal{F}\rangle = 0] = 1$. For the induction step let $i \geq 1$, and consider the following three cases.

1. There exists $j < i$ and $b \in \mathbb{F} \setminus \{0^n\}$ such that $\alpha_i = b\alpha_j$. Then,

$$\Pr[\langle \alpha_i, \mathcal{F}\rangle = 0] = \Pr[b\langle \alpha_j, \mathcal{F}\rangle = 0] = \Pr[\langle \alpha_j, \mathcal{F}\rangle = 0] = 1 \ ,$$

   where the last equality uses the induction hypothesis.
2. There exist $j < i$ and $\gamma \in T$ such that $\alpha_i = \alpha_j + \gamma$ with $|\mathrm{supp}(\alpha_j) \cup \mathrm{supp}(\gamma)| \leq k$. Since $\mathcal{F} \in \mathsf{Consistent}(T,k)$ we have that $\Pr[\langle \gamma, \mathcal{F}\rangle = 0] = 1$, as $\gamma \in T$. Therefore,

$$\Pr[\langle \alpha_i, \mathcal{F}\rangle = 0] = \Pr[\langle \alpha_j, \mathcal{F}\rangle + \langle \gamma, \mathcal{F}\rangle = 0] \geq \Pr[\langle \alpha_j, \mathcal{F}\rangle = 0 \wedge \langle \gamma, \mathcal{F}\rangle = 0] = 1 \ ,$$

   as required. Note that $\Pr[\langle \alpha_j, \mathcal{F}\rangle = 0 \wedge \langle \gamma, \mathcal{F}\rangle = 0]$ is well-defined because we have $|\mathrm{supp}(\alpha_{j_1}) \cup \mathrm{supp}(\gamma)| \leq k$.
3. There exist $j_1, j_2 < i$ such that $\alpha_i = \alpha_{j_1} + \alpha_{j_2}$ and $|\mathrm{supp}(\alpha_{j_1}) \cup \mathrm{supp}(\alpha_{j_2})| \leq k$. By the induction hypothesis we know that $\Pr[\langle \alpha_{j_1}, \mathcal{F}\rangle = 0] = 1$ and $\Pr[\langle \alpha_{j_2}, \mathcal{F}\rangle = 0] = 1$. Thus,

$$\Pr[\langle \alpha_i, \mathcal{F}\rangle = 0] = \Pr[\langle \alpha_{j_1}, \mathcal{F}\rangle + \langle \alpha_{j_2}, \mathcal{F}\rangle = 0] \geq \Pr[\langle \alpha_{j_1}, \mathcal{F}\rangle = 0 \wedge \langle \alpha_{j_2}, \mathcal{F}\rangle = 0] = 1 \ ,$$

   and therefore $\Pr[\langle \alpha_i, \mathcal{F}\rangle = 0] = 1$. Again, we require $|\mathrm{supp}(\alpha_{j_1}) \cup \mathrm{supp}(\alpha_{j_2})| \leq k$ in order for the last probability to be well-defined.

In particular, this implies that $\Pr[\langle \alpha, \mathcal{F}\rangle = 0] = \Pr[\langle \alpha_r, \mathcal{F}\rangle = 0] = 1$, and hence $\mathcal{F} \in \mathsf{Consistent}(T \cup \{\alpha\},k)$. Therefore $\mathsf{Consistent}(T,k) \subseteq \mathsf{Consistent}(T \cup \{\alpha\},k)$, which completes the proof of Lemma 63.

7.2 Proof of Lemma 64

We define $\mathcal{F}$ specifying its local distributions $\mathcal{F}_S$ for each $S \subseteq [n]_{\leq k}$. We define the function $\mathcal{F}_S \colon \mathbb{F}^S \to \mathbb{C}$ by specifying its (local) Fourier coefficients as follows. We set the Fourier coefficient $\widehat{\mathcal{F}_S}(\alpha)$ to be $\frac{1}{q^{|S|}}$ if $\alpha \in \mathcal{V}$, and 0 otherwise.

We now show that each $\mathcal{F}_S$ is a distribution. For any $f \colon S \to \mathbb{F}$ we have

$$\mathcal{F}_S(f) = \sum_{\alpha \in \mathbb{F}^S} \widehat{\mathcal{F}_S}(\alpha)\chi_\alpha(f) = \sum_{\alpha \in \mathcal{V}_{\subseteq S}} \frac{1}{q^{|S|}}\chi_\alpha(f) = \frac{1}{q^{|S|}} \sum_{\alpha \in \mathcal{V}_{\subseteq S}} \omega^{\mathrm{Tr}(\langle \alpha, f\rangle)} \ .$$

For each $b \in \mathbb{F}$, let $\mathcal{V}_b \subseteq \mathcal{V}_{\subseteq S}$ be the set of $\alpha \in \mathcal{V}_{\subseteq S}$ where $\langle \alpha, f\rangle = b$. Let $\pi \colon \mathcal{V}_{\subseteq S} \to \mathbb{F}$ be the map where $\pi(\alpha) = \langle \alpha, f\rangle$. Since $\mathcal{V}_{\subseteq S}$ is a subspace, π is a homomorphism. It follows that either $\mathcal{V}_0 = \mathcal{V}_{\subseteq S}$ or $|\mathcal{V}_b| = |\mathcal{V}_0|$ for every $b \in \mathbb{F}$. In the first case, $\sum_{\alpha \in \mathcal{V}_{\subseteq S}} \omega^{\mathrm{Tr}(\langle \alpha, f\rangle)} = |\mathcal{V}_{\subseteq S}| \geq 0$. In the second case,

$$\sum_{\alpha \in \mathcal{V}_{\subseteq S}} \omega^{\mathrm{Tr}(\langle \alpha, f\rangle)} = \sum_{b \in \mathbb{F}} \sum_{\alpha \in \mathcal{V}_b} \omega^{\mathrm{Tr}(b)} = \sum_{b \in \mathbb{F}} |\mathcal{V}_b| \omega^{\mathrm{Tr}(b)} = |\mathcal{V}_0| \sum_{b \in \mathbb{F}} \omega^{\mathrm{Tr}(b)} = 0 \ .$$

This implies that in either case, $\mathcal{F}_S(f) \geq 0$, and so $\mathcal{F}_S$ is a distribution.

We now show that the collection of local distributions $\{\mathcal{F}_S\}_{S\subseteq[n]_{\leq k}}$ is indeed non-signaling. This follows from Lemma 35. If $\alpha \in \mathcal{V}$ then we have that $q^{|S|}\widehat{\mathcal{F}_S}(\alpha) = 1 = q^{|R|}\widehat{\mathcal{F}_R}(\alpha)$ for every $S, R \in [n]_{\leq k}$ such that $\mathrm{supp}(\alpha) \subseteq S \cap R$, and otherwise we have $q^{|S|}\widehat{\mathcal{F}_S}(\alpha) = 0 = q^{|R|}\widehat{\mathcal{F}_R}(\alpha)$. Thus, the collection of local distributions is a k-non-signaling function $\mathcal{F}$.

It remains to show that $\mathcal{F}$ satisfies the desired property. Observe that for every α, $q^n\widehat{\mathcal{F}}(\alpha) = q^{|\mathrm{supp}(\alpha)|}\widehat{\mathcal{F}}_{\mathrm{supp}(\alpha)}(\alpha) = 1$ if $\alpha \in \mathcal{V}$, and otherwise $\widehat{\mathcal{F}}(\alpha) = 0$. By Lemma 29 it follows that $\mathcal{F}$ has the desired properties.

7.3 Proof of Lemma 65

Let $\mathcal{V} = \{\alpha \in \mathbb{F}^n : T \vdash_k \alpha\}$. We show that $\mathcal{V}$ is a k-local subspace. Let $S \subseteq [n]_{\leq k}$. We need to show that $\mathcal{V}_{\subseteq S}$ is a linear subspace of $\mathbb{F}^n$. We first observe that 0^n is always in the set, as $T \vdash_k 0^n$ always.

Let $\alpha \in \mathcal{V}_{\subseteq S}$ and let $b \in \mathbb{F} \setminus \{0\}$. Then we have that $T \vdash_k \alpha$ which implies that $T \vdash_k b\alpha$. Since $\mathrm{supp}(b\alpha) = \mathrm{supp}(\alpha) \subseteq S$, it follows that $b\alpha \in \mathcal{V}_{\subseteq S}$.

Let $\alpha, \beta \in \mathcal{V}_{\subseteq S}$. Then, since $|\mathrm{supp}(\alpha) \cup \mathrm{supp}(\beta)| \leq |S| \leq k$ we have that $(\alpha, \beta, \alpha+\beta)$ is a hyperedge in Γ_k. Thus, since $T \vdash_k \{\alpha, \beta\}$ it follows that $T \vdash_k \alpha + \beta$. Since $\mathrm{supp}(\alpha+\beta) \subseteq \mathrm{supp}(\alpha) \cup \mathrm{supp}(\beta) \subseteq S$, it follows that $\alpha + \beta \in \mathcal{V}_{\subseteq S}$.

We have thus shown that $\mathcal{V}_{\subseteq S}$ is a linear subspace of $\mathbb{F}^n$, which completes the proof.

8 Low-degree testing fails for small locality

In this section, we prove Theorem 3. The proof relies heavily on Theorem 8.

We let $\mathbf{C}$ be the linear code of m-variate polynomials $P\colon \mathbb{F}^m \to \mathbb{F}$ of total degree at most d, with $m \geq 2$, and let T be the set of α's in $\mathbf{C}^\perp$ where the $\mathrm{supp}(\alpha)$ is contained in exactly one line.

We define the *rank* of an element in $\mathbf{C}^\perp$ to be

$$\mathsf{rank}_T(\alpha) := \min_{T' \subseteq T : \alpha \in \mathrm{span}(T')} |T'| \ .$$

Note that since $\mathrm{span}(T) = \mathbf{C}^\perp$, the rank of α is well-defined for all $\alpha \in \mathbf{C}^\perp$.

We let T_0 denote the subset of T that only contains elements whose support is *evenly-spaced* along a line and has weight $d+2$. With this notation, the non-signaling evenly-spaced test (i) samples $\alpha \leftarrow T_0$ uniformly at random, and (ii) checks that $\langle \alpha, \mathcal{F} \rangle = 0$.

The main theorem we prove is stated below, and is the formal statement of Theorem 3.

▶ **Theorem 67** (Formal version of Theorem 3). *For every k with $2d+2 \leq k < \frac{3}{16}(d+2)^2$, there exists a k-non-signaling function such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in T_{\leq k}$, and yet $\Delta_{2d+2}(\mathcal{F}, \mathcal{F}') \geq (1 - \frac{1}{|\mathbb{F}|})$ for every $(2d+2)$-non-signaling function $\mathcal{F}'$ that is $(\mathbf{C}, 2d+2)$-explainable.*

We begin the proof of Theorem 67 by showing the following lemma. This lemma follows from earlier statements, and outlines a sufficient condition to prove Theorem 67

▶ **Lemma 68.** *Suppose that there exists $\alpha^* \in \mathbf{C}^\perp$ with $\mathrm{wt}(\alpha^*) = 2d+2$ such that for every $k < \frac{3}{16}(d+2)^2$ it holds that $T \not\vdash_k \alpha^*$. Then for every k with $2d+2 \leq k < \frac{3}{16}(d+2)^2$ there exists a k-non-signaling function $\mathcal{F}$ such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in T_{\leq k}$, and yet $\Delta_{2d+2}(\mathcal{F}, \mathcal{F}') \geq 1 - \frac{1}{|\mathbb{F}|}$ for every $(2d+2)$-non-signaling function $\mathcal{F}'$ that is $(\mathbf{C}, 2d+2)$-explainable.*

Proof. Applying Corollary 66, for every k with $2d+2 \leq k < \frac{3}{16}(d+2)^2$, we get that there exists a k-non-signaling function $\mathcal{F}$ such that $\Pr[\langle \alpha, \mathcal{F} \rangle = 0] = 1$ for every $\alpha \in T_{\leq k}$ and $\Pr[\langle \alpha^*, \mathcal{F} \rangle = 0] = \frac{1}{|\mathbb{F}|}$. Let $\mathcal{F}'$ be a $(2d+2)$-non-signaling function that is $(\mathbf{C}, 2d+2)$-explainable. Since for every $S \subseteq \mathbb{F}^m$ with $|S| \leq 2d+2$ we have that $\Pr[\mathcal{F}'(S) \in \mathbf{C}|_S] = 1$ and $\alpha^* \in \mathbf{C}^\perp$ has $\mathrm{wt}(\alpha^*) = 2d+2$, it follows that $\Pr[\langle \alpha^*, \mathcal{F}' \rangle = 0] = 1$. Therefore, $\Delta_{2d+2}(\mathcal{F}, \mathcal{F}') \geq |\Pr[\langle \alpha^*, \mathcal{F} \rangle = 0] - \Pr[\langle \alpha^*, \mathcal{F}' \rangle = 0]| = 1 - \frac{1}{|\mathbb{F}|}$. ◀

By Lemma 68 it suffices to find such an α^*. We let $\alpha^* \in \mathbf{C}^\perp$ be any constraint where $\mathrm{supp}(\alpha)$ has size $2d+2$ and is contained on the curve $x_1^2 - x_2 = 0$ embedded on the plane $x_3 = x_4 = \cdots = x_m = 0$ in $\mathbb{F}^m$. We note that α^* is one of the constraints that checks that $P(t, t^2, 0, \ldots, 0)$ is a univariate polynomial of degree at most $2d$ in t.

We show that α^* satisfies the desired properties in two main lemmas. We first show the following generic lemma, which gives us a way to prove that $T \nvdash_k \alpha^*$.

▶ **Lemma 69** (Interval cut Lemma). *Fix $\alpha \in \mathbf{C}^\perp$. Suppose that there exists $r \in \mathbb{R}$ with $2 \leq r \leq \mathsf{rank}_T(\alpha)$ such that for every $\beta \in \mathbf{C}^\perp$ with $\mathsf{rank}_T(\beta) \in [r/2, r)$ it holds that $T \nvdash_k \beta$. Then $T \nvdash_k \alpha$.*

We then show that every $\beta \in \mathbf{C}^\perp$ of rank in $[(d+2)/4, (d+2)/2)$ must have large weight, implying that they are not provable from T when k is small.

▶ **Lemma 70.** *For every $\beta \in \mathbf{C}^\perp$ with $\mathsf{rank}_T(\beta) \in [(d+2)/4, (d+2)/2)$ it holds that $\mathrm{wt}(\beta) \geq \frac{3}{16}(d+2)^2$. In particular, if $k < \frac{3}{16}(d+2)^2$ then $T \nvdash_k \beta$.*

With the above two lemmas, we now finish the proof of Theorem 67.

Proof of Theorem 67. Let $k < \frac{3}{16}(d+2)^2$. We first show that $\mathsf{rank}_T(\alpha^*) \geq d+1$. Since the curve $x_1^2 - x_2 = 0$ is irreducible in $\mathbb{F}[x_1, x_2, \ldots, x_m]$, any line L intersects the curve on at most 2 distinct points. It follows that $\mathsf{rank}_T(\alpha^*) \geq (2d+2)/2 = d+1$, as any constraint $\beta \in T$ can only have at most 2 points on the curve $x_1^2 - x_2 = 0$.

Since $k < \frac{3}{16}(d+2)^2$, Lemma 70 implies that $T \nvdash_k \beta$ for every β with $\mathsf{rank}_T(\beta) \in [(d+2)/4, (d+2)/2)$. Thus, by Lemma 69 it follows that $T \nvdash_k \alpha^*$. Hence, α^* satisfies the assumptions of Lemma 68, and so applying Lemma 68 completes the proof of Theorem 67. ◀

Next we turn to the proofs of Lemma 69 and Lemma 70.

Proof of Lemma 69. First, observe that by definition of rank, $\mathsf{rank}_T(\alpha_1 + \alpha_2) \leq \mathsf{rank}_T(\alpha_1) + \mathsf{rank}_T(\alpha_2)$. By the assumption of the lemma, there exists $r \in \mathbb{R}$ with $2 \leq r \leq \mathsf{rank}_T(\alpha)$ such that for every $\beta \in \mathbf{C}^\perp$ with $\mathsf{rank}_T(\beta) \in [r/2, r)$ it holds that $T \nvdash_k \beta$. We need to show that $T \nvdash_k \alpha$.

Suppose toward a contradiction that $T \vdash_k \alpha$. Then there exists a path $(\alpha_1, \ldots, \alpha_t = \alpha)$ in $\Gamma_k(\mathbf{C}^\perp, T)$ from 0^n to α. Let S_1 be the set of α_i's such that $\mathsf{rank}_T(\alpha_i) < r/2$, and let S_2 be the set of α_i's such that $\mathsf{rank}_T(\alpha_i) \geq r$. Note that $S_1 \cup S_2 = \{\alpha_1, \ldots, \alpha_t\}$, as otherwise there would exist some i such that α_i has rank in $[r/2, r)$, which would contradict the assumption that $T \vdash_k \alpha_i$ for all $i \in [t]$.

Since $\mathsf{rank}_T(\alpha) \geq r$ it follows that $\alpha \in S_2$, and hence $S_2 \neq \emptyset$. Let ℓ be the smallest index such that $\alpha_\ell \in S_2$. We have that $\alpha_\ell \neq 0^n$ since $\alpha_\ell \in S_2$, and there does not exist $i < \ell$ and $b \in \mathbb{F} \setminus \{0\}$ such that $\alpha_\ell = b\alpha_i$, as then $\mathsf{rank}_T(\alpha_i) = \mathsf{rank}_T(\alpha_\ell) \geq r$, thus contradicting the minimality of ℓ. Suppose that there exists $i < \ell$ and $\gamma \in T$ such that $\alpha_\ell = \alpha_i + \gamma$. By the minimality of ℓ, we must have that $\alpha_i \in S_1$, and hence $r \leq \mathsf{rank}_T(\alpha_\ell) \leq \mathsf{rank}_T(\alpha_i) + \mathsf{rank}_T(\gamma) < r/2 + 1 \leq r/2 + r/2 = r$, which is also a contradiction. Therefore, there must either exist $j_1, j_2 < \ell$ such that $\alpha_\ell = \alpha_{j_1} + \alpha_{j_2}$. By the minimality of ℓ, we must

have that $\alpha_{j_1}, \alpha_{j_2} \in S_1$, and hence $r \leq \mathsf{rank}_T(\alpha_\ell) \leq \mathsf{rank}_T(\alpha_{j_1}) + \mathsf{rank}_T(\alpha_{j_1}) < r/2 + r/2 = r$, which is, again, a contradiction. In all cases we have reached a contradiction to the assumption that $T \vdash_k \alpha$, which completes the proof of Lemma 69. ◀

▶ Remark 71. We note that in the foregoing proof we only required that rank_T is subadditive, i.e., that $\mathsf{rank}_T(\alpha_1 + \alpha_2) \leq \mathsf{rank}_T(\alpha_1) + \mathsf{rank}_T(\alpha_2)$, $\mathsf{rank}_T(\alpha) = 1$ for every $\alpha \in T$, and $\mathsf{rank}_T(0^n) = 0$. Thus, the Interval Cut Lemma holds for any such subadditive function.

Proof of Lemma 70. Let $\beta \in \mathbf{C}^\perp$ be such that $\mathsf{rank}_T(\beta) = r \in [(d+2)/4, (d+2)/2)$. Then there exist lines $L_1, \ldots, L_r$ such that $\beta = \sum_{i=1}^{r} \beta_i$ where $\mathrm{supp}(\beta_i) \subseteq L_i$. The L_i's must be distinct, as otherwise we could add two constraints contained in the same line and we would then get $\mathsf{rank}_T(\beta) < r$. We have that $\mathrm{wt}(\beta_i) \geq d+2$ for each i. Hence, $\mathrm{wt}(\beta) \geq r(d+2) - 2\binom{r}{2}$, since each β_i contributes at least $d+2$ to the weight, and there are at most $\binom{r}{2}$ intersection points as each of the r lines is distinct. The function $f(r) = r(d+2) - r^2$ for $r \in [\frac{d+2}{4}, \frac{d+2}{2})$ is minimized when $r = \frac{d+2}{4}$, and hence $\mathrm{wt}(\beta) \geq r(d+2) - r^2 \geq \frac{3}{16}(d+2)^2$, which completes the proof. ◀

Abstract

Consider an algorithm performing a computation on a *huge random object* (for example a random graph or a "long" random walk). Is it necessary to generate the entire object prior to the computation, or is it possible to provide query access to the object and sample it incrementally "on-the-fly" (as requested by the algorithm)? Such an *implementation* should emulate the random object by answering queries in a manner consistent with an instance of the random object sampled from the true distribution (or close to it). This paradigm is useful when the algorithm is sub-linear and thus, sampling the entire object up front would ruin its efficiency.

Our first set of results focus on undirected graphs with independent edge probabilities, i.e. each edge is chosen as an independent Bernoulli random variable. We provide a general implementation for this model under certain assumptions. Then, we use this to obtain the first efficient local implementations for the Erdös-Rényi $G(n, p)$ model for *all* values of p, and the Stochastic Block model. As in previous local-access implementations for random graphs, we support VERTEX-PAIR and NEXT-NEIGHBOR queries. In addition, we introduce a new RANDOM-NEIGHBOR query. Next, we give the first local-access implementation for ALL-NEIGHBORS queries in the (sparse and directed) Kleinberg's Small-World model. Our implementations require no pre-processing time, and answer each query using $\mathcal{O}(\text{poly}(\log n))$ time, random bits, and additional space.

Next, we show how to implement random Catalan objects, specifically focusing on Dyck paths (balanced random walks on the integer line that are always non-negative). Here, we support HEIGHT queries to find the location of the walk, and FIRST-RETURN queries to find the time when the walk returns to a specified location. This in turn can be used to implement NEXT-NEIGHBOR queries on random rooted ordered trees, and MATCHING-BRACKET queries on random well bracketed expressions (the Dyck language).

Finally, we introduce two features to define a new model that: (1) allows multiple independent (and even simultaneous) instantiations of the same implementation, to be consistent with each other without the need for communication, (2) allows us to generate a richer class of random objects that do not have a succinct description. Specifically, we study uniformly random *valid* q-colorings of an input graph G with maximum degree Δ. This is in contrast to prior work in the area, where the relevant random objects are defined as a distribution with $\mathcal{O}(1)$ parameters (for example, n and p in the $G(n, p)$ model). The distribution over valid colorings is instead specified via a "huge" input (the underlying graph G), that is far too large to be read by a sub-linear time algorithm. Instead, our implementation accesses G through local neighborhood probes, and is able to answer queries to the color of any given vertex in sub-linear time for $q \geq 9\Delta$, in a manner that is consistent with a specific random valid coloring of G. Furthermore, the implementation is memory-less, and can maintain consistency with non-communicating copies of itself.

1 Introduction

Consider an algorithm performing a computation on a *huge random object* (for example a huge random graph or a "long" random walk). Is it necessary to generate the entire object prior to the computation, or is it possible to provide local query access to the object and generate it incrementally "on-the-fly" (as requested by the algorithm)? Such an *implementation* would ideally emulate the random object by answering appropriate queries, in a manner that is consistent with a specific instance of the random object, sampled from the true distribution. This paradigm is useful when we wish to simulate a sub-linear algorithm on a random object, since sampling the entire object up front would ruin its efficiency.

In this work, we focus on generating huge random objects in a number of new settings, including basic random graph models that were not previously considered, Catalan objects, and random colorings of graphs. One emerging theme that we develop further is to provide access to random objects through more complex yet natural queries. For example, consider an implementation for Erdös-Rényi $G(n, p)$ random graphs, where the simplest query $\textsc{Vertex-Pair}(u, v)$ would ask about the existence of edge (u, v), which can be answered trivially by flipping a coin with bias p (thus revealing a single entry in the adjacency matrix). However, many applications involving non-dense graphs would benefit from *adjacency list* access, which we provide through $\textsc{Next-Neighbor}$ and $\textsc{Random-Neighbor}$ queries[1]

The problem of sampling partial information about huge random objects was pioneered in [26, 24, 25], through the implementation of *indistinguishable* pseudo-random objects of exponential size. Further work in [41, 18] considers the implementation of different random graph models. [18] introduced the study of $\textsc{Next-Neighbor}$ queries which provide efficient access to the adjacency list representation. In addition to supporting $\textsc{Vertex-Pair}$ and $\textsc{Next-Neighbor}$, we also introduce and implement a new $\textsc{Random-Neighbor}$ query for undirected graphs with independent edge probabilities.

Finally, we define a new model that allows us to generate a richer class of random objects that do not have a succinct description. Specifically, we study uniformly random *valid* q-colorings of an input graph G with max degree Δ. This is in contrast to prior work in the area, where random objects are defined as a distribution with $\mathcal{O}(1)$ parameters (for example, n and p in the $G(n, p)$ model). The distribution over valid colorings is instead specified via a "huge" input (the underlying graph G), that is too large to be read by a sub-linear time algorithm. Instead, our implementation accesses G using local neighborhood probes.

This new model can be compared to *Local Computation Algorithms*, which also implement query access to a consistent valid solution, and read their input using local probes. Inspired by this connection, we extend our model to support *memory-less* implementations. This allows multiple independent (possibly simultaneous) instantiations to agree on the same

[1] $\textsc{Vertex-Pair}(u, v)$ returns whether u and v are adjacent, $\textsc{Next-Neighbor}(v)$ returns a new neighbor of v each time it is invoked (until none is left), and $\textsc{Random-Neighbor}(v)$ returns a uniform random neighbor of v (if v is not isolated).

random object, without any communication. We show how to implement local access to color of any given node in a random coloring, using sub-linear resources. Unlike LCAs which can generate an *arbitrary* valid solution, our model requires a uniformly random one.

Random Graphs (Section 3 and Section E)

Random graphs are one of the most well studied types of random object. We consider the problem of implementing local access to a number of fundamental random graph models, through natural queries, including VERTEX-PAIR, NEXT-NEIGHBOR, and a newly introduced RANDOM-NEIGHBOR query[1], using polylogarithmic resources per query. Our results on random graphs are summarized in Table 1.

Undirected Random Graphs with Independent Edge Probabilities. We implement the aforementioned queries for the generic class of *undirected graphs* with *independent edge probabilities* $\{p_{uv}\}_{u,v\in V}$, where p_{uv} denotes the probability that there is an edge between u and v. Under reasonable assumptions on the ability to compute certain values pertaining to consecutive edge probabilities, our implementations support VERTEX-PAIR, NEXT-NEIGHBOR, and RANDOM-NEIGHBOR queries[1], using $\mathcal{O}(\text{poly}(\log n))$ time, space, and random bits. Note that in this setting, VERTEX-PAIR queries are trivial by themselves, since the existence of an edge depends on an independent random variable. However, maintaining all three types of queries simultaneously is much harder. As in [18] (and unlike many of the implementations presented in [24, 26]), our techniques allow unlimited queries, and the generated random objects are sampled from the true distribution (rather than just being indistinguishable). In particular, our construction yields local-access implementations for the Erdös-Rényi $G(n,p)$ model (for *all* values of p), and the Stochastic Block model with random community assignment.

Table 1 (Local access implementations for random graphs): All the implementations in this table use polylogarithimc time, additional space and random bits per query. A ✗ in the ALL-NEIGHBORS column indicates that the graphs in this model may have un-bounded degree, and it is therefore impossible to sample ALL-NEIGHBORS efficiently. A ?? entry indicates a sampling problem with no known efficient solution.

While VERTEX-PAIR and NEXT-NEIGHBOR queries have been considered in prior work [18, 24, 41], we provide the first implementations of these in non-sparse random graph models. Prior results for implementing queries to $G(n,p)$ focused on the sparse case where $p = \log^{\mathcal{O}(1)} n/n$ [41]. The dense case where $p = \Theta(1)$ is also relatively simple because most of the adjacency matrix is filled, and neighbor queries can be answered by performing $\Theta(1)$ VERTEX-PAIR queries until an edge is found. The case of general p is more involved, and

was not considered previously. For example, when $p = 1/\sqrt{n}$, each vertex has high degree $\mathcal{O}(\sqrt{n})$ but most of the adjacency matrix is empty, thus making it difficult to generate a neighbor efficiently. NEXT-NEIGHBOR queries were introduced in [18] in order to access the neighborhoods of vertices in non-sparse graphs in *lexicographic order*. This query however, does not allow us to efficiently explore graphs in some natural ways, such as via random walks, since the initially returned neighbors are biased by the lexicographic ordering. We address this deficiency by introducing a new RANDOM-NEIGHBOR query, which would be useful, for instance, in sub-linear algorithms that employ random walk processes. We provide the first implementation of all three queries in *non-sparse graphs* as follows:

▶ **Theorem 1.** *Given a random graph model defined by the probability matrix $\{p_{uv}\}_{u,v\in[n]}$, and assuming that we can compute the the quantities $\prod_{u=a}^{b}(1-p_{vu})$ and $\sum_{u=a}^{b} p_{vu}$ in $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ time, there exists an implementation for this model that supports local access through* RANDOM-NEIGHBOR*,* VERTEX-PAIR*, and* NEXT-NEIGHBOR *queries using $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ running time, additional space, and random bits per query.*

We show that these assumptions can be realized in Erdös-Rényi random graphs and the Stochastic Block Model. SBM presents additional challenges for assigning community labels to vertices (Section 2.1.1).

▶ **Corollary 2.** *There exists an algorithm that implements local access to a Erdös-Rényi $G(n,p)$ random graph, through* VERTEX-PAIR*,* NEXT-NEIGHBOR*, and* RANDOM-NEIGHBOR *queries, while using $\mathcal{O}(\log^3 n)$ time, $\mathcal{O}(\log^3 n)$ random bits, and $\mathcal{O}(\log^2 n)$ additional space per query with high probability.*

▶ **Corollary 3.** *There exists an algorithm that implements local access to a random graph from the n-vertex Stochastic Block Model with r randomly-assigned communities, through* VERTEX-PAIR*,* NEXT-NEIGHBOR*, and* RANDOM-NEIGHBOR *queries, using $O(r\,\mathrm{poly}(\log n))$ time, random bits, and space per query w.h.p.*

We remark that while we are able to generate Erdös-Rényi random graphs on-the-fly supporting all three types of queries, our construction still only requires $\widetilde{\mathcal{O}}(m+n)$ time and space to generate a complete $G(n,p)$ graph, which is optimal up to logarithmic factors.

▶ **Corollary 4.** *The final algorithm in Section 3 can generate a complete random graph from the Erdös-Rényi $G(n,p)$ model using overall $\widetilde{\mathcal{O}}(n+m)$ time, random bits and space, which is $\widetilde{\mathcal{O}}(pn^2)$ in expectation. This is optimal up to $\mathcal{O}(\mathrm{poly}(\log n))$ factors.*

Directed Random Graphs – The Small World Model (Section E). We consider local-access implementations for directed graphs through Kleinberg's Small World model, where the probabilities are based on distances in a 2-dimensional grid. This model was introduced in [31] to capture the geographical structure of real world networks, in addition to reproducing observed properties of short routing paths and low diameter. We implement ALL-NEIGHBORS queries for the Small World model, using $\mathcal{O}(\mathrm{poly}(\log n))$ time, space and random bits. Since such graphs are sparse, the other queries follow directly.

▶ **Theorem 5.** *There exists an algorithm that implements* ALL-NEIGHBORS *queries for a random graph from Kleinberg's Small World model, where probability of including each directed non-grid edge (u,v) in the graph is $c/(\mathtt{DIST}(u,v))^2$, where the range of allowed values of c is $\log^{\pm\mathcal{O}(1)} n$ and* DIST *denotes the Manhattan distance, using $O(\log^2 n)$ time and random words per query with high probability.*

Catalan Objects (Section 4)

Catalan objects capture a well studied combinatorial property and admit numerous interpretations that include well bracketed expressions, rooted trees and binary trees, Dyck languages etc. In this paper, we focus on the Dyck path interpretation and implement local access to a uniformly random instance of a Dyck path. Since Dyck paths have natural bijections to other Catalan objects, we can use our Dyck Path implementation to obtain implementations of these random Catalan objects.

A Dyck path is defined as a sequence of n upward $(+1)$ steps, and n downward (-1) steps, with the added constraint that the *sum of any prefix of the sequence is non-negative*. A *random* Dyck path may be viewed as a constrained one dimensional balanced random walk. A natural query on Dyck paths is $\textsc{Height}(t)$ which returns the position of the walk after t steps (equivalently, sum of the first t sequence elements). $\textsc{Height}$ queries correspond to $\textsc{Depth}$ queries on rooted trees and bracketed expressions (Section 4.1).

We also introduce and support $\textsc{First-Return}$ queries, where $\textsc{First-Return}(t)$ returns the first time when the random walk returns to the same *height* as it was at time t, as long as $\textsc{Height}(t+1) = \textsc{Height}(t)+1$ (Section 4.1 presents the rationale for this definition). This allows us to support more involved queries that are widely used; for example, $\textsc{First-Return}$ queries are equivalent to finding the next child of a node in a random rooted tree, and also to finding a matching closing bracket in random bracketed expressions.

$\textsc{Height}$ queries for unconstrained random walks follow trivially from the implementation of interval summable functions in [26, 23]. However, the added non-negativity constraint introduces intricate non-local dependencies on the distribution of positions. We show how to overcome these challenges, and support both queries using $\mathcal{O}(\text{poly}(\log n))$ resources.

▶ **Theorem 6.** *There is an algorithm using $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ resources per query that provides access to a uniformly random Dyck path of length $2n$ by implementing the following queries:*

- $\textsc{Height}(t)$ *returns the position of the walk after t steps.*
- $\textsc{First-Return}(t)$*: If* $\textsc{Height}(t+1) > \textsc{Height}(t)$*, then* $\textsc{First-Return}(t)$ *returns the smallest index t', such that $t' > t$ and* $\textsc{Height}(t') = \textsc{Height}(t)$ *(i.e. the first time the Dyck path returns to the same height). Otherwise, if* $\textsc{Height}(t+1) < \textsc{Height}(t)$*, then* $\textsc{First-Return}(t)$ *is not defined.*

Random Coloring of Graphs – A New Model (Section 5)

So far, all the results in this area have focused on random objects with a small description size; for instance, the $G(n,p)$ model is described with only two parameters n and p. We introduce a new model for implementing random objects with *huge input description*; that is, the distribution is specified as a uniformly random solution to a huge combinatorial problem. The challenge is that now our algorithms cannot read the entire description in sub-linear time.

In this model, we implement query access to random q-colorings of a given huge graph G with maximum degree Δ. A random coloring is generated by proposing $\mathcal{O}(n \log n)$ color updates and accepting the ones that do not create a conflict (Glauber dynamics). This is an inherently sequential process with the acceptance of a particular proposal depending on all preceding neighboring proposals. Moreover, unlike the previously considered random objects, this one has no succinct representation, and we can only uncover the proper distribution by probing the underlying graph (in the manner of *local computation algorithms* [48, 5]). Unlike LCAs which can return an *arbitrary* valid solution, we also have to make sure that we return a solution from the correct distribution. We are able to construct an efficient oracle that returns the final color of a vertex using only a sub-linear number of probes when $q \geq 9\Delta$.

This implementation also has the feature that multiple independent instances of the algorithm having access to the same random bits, will respond to queries in a manner consistent with each other; they will generate exactly the same coloring, regardless of the queries asked. Since these implementations are memory-less, the resulting coloring is *oblivious* to the order of queries, and only depends on common random bits,

▶ **Theorem 7.** *Given neighborhood query access to a graph G with n nodes, maximum degree Δ, and $q = 2\alpha\Delta \geq 9\Delta$ colors, we can generate the color of any given node from a distribution of color assignments that is ϵ-close (in L_1 distance) to the uniform distribution over all valid colorings of G, in a consistent manner, using only $\mathcal{O}((n/\epsilon)^{3.06/\alpha}\Delta\log(n/\epsilon))$ time, probes, and public random bits per query.*

1.1 Related Work

The problem of computing local information of huge random objects was pioneered in [24, 26]. Further work of [41] considers the implementation of sparse $G(n,p)$ graphs from the Erdös-Rényi model [17], with $p = O(\text{poly}(\log n)/n)$, by implementing ALL-NEIGHBORS queries. While these implementations use polylogarithmic resources over their entire execution, they generate graphs that are only guaranteed to *appear random* to algorithms that inspect a *limited portion* of the generated graph.

In [18], the authors construct an oracle for the implementation of recursive trees, and BA preferential attachment graphs. Unlike prior work, their implementation allows for an arbitrary number of queries. Although the graphs in this model are generated via a sequential process, the oracle is able to locally generate arbitrary portions of it and answer queries in polylogarithmic time. Though preferential attachment graphs are sparse, they contain vertices of high degree, thus [18] provides access to the adjacency list through NEXT-NEIGHBOR queries. For additional related work, see Section G.

1.2 Applications

One motivation for implementing local access to huge random objects is so that we can simulate sub-linear time algorithms on them. The standard paradigm of generating the entire (input) object a priori is wasteful, because sub-linear algorithms only inspect a small fraction of the generated input. For example, the greedy routing algorithm on Kleinberg's small world networks [31] only uses $\mathcal{O}(\log^2 n)$ probes to the underlying network. Using our implementation, one can execute this algorithm on a random small world instance in $\mathcal{O}(\text{poly}(\log n))$ time, without incurring the $\mathcal{O}(n)$ prior-sampling overhead, by generating only those parts of the graph that are accessed by the routing algorithm.

Local access implementations may also be used to design parallel generators for random objects. The model in Definition 10 is particularly suited to parallelization; different processors/machines can generate parts of the random object independently, using a *read-only* shared memory containing public random bits.

2 Model and Overview of our Techniques

We begin by formalizing our model of *local-access implementations*, inspired by [18], but we add some aspects that were not addressed in earlier models. First, we define families of random objects.

▶ **Definition 8.** *A **random object family** maps a description* Π *to a distribution* X^Π *over the set* $\mathbb{X}^\Pi$*.*

For example, the *family* of Erdös-Rényi graphs maps $\Pi = (n, p)$ to a distribution over $\mathbb{X}^\Pi$, which is the set of all possible n-vertex graphs, where the probability assigned to any graph containing m edges in the distribution X^Π is exactly $p^m \cdot (1-p)^{\binom{n}{2}-m}$.

▶ **Definition 9.** *Given a **random object family** $\{(\mathsf{X}^\Pi, \mathbb{X}^\Pi)\}$ parameterized by* Π*, a* local access implementation *of a family of query functions $\langle F_1, F_2, \cdots \rangle$ where $F_i : \mathbb{X}^\Pi \to \{0,1\}$, provides an oracle $\mathcal{M}$ with an internal state for storing a partially generated random object. Given a description Π and a query F_i, the oracle returns the value $\mathcal{M}(\Pi, F_i)$, and updates its internal state, while satisfying the following:*

- ***Consistency:** There must be a single $X \in \mathbb{X}^\Pi$, such that for all queries F_i presented to the oracle, the returned value $\mathcal{M}(\Pi, F_i)$ equals the true value $F_i(X)$.*
- ***Distribution equivalence:** The random object $X \in \mathbb{X}^\Pi$ consistent with the responses $\{F_i(X)\}$ must be sampled from some distribution $\hat{\mathsf{X}}^\Pi$ that is ϵ-close to the desired distribution X^Π in L_1-distance. In this work, we focus on supporting $\epsilon = n^{-c}$ for any desired constant $c > 0$.*
- ***Performance:** The computation time, and random bits required to answer a single query must be sub-linear in $|X|$ with high probability, without any initialization overhead.*

In particular, we allow queries to be made adversarially and non-deterministically. The adversary has full knowledge of the algorithm's behavior and its past random bits.

For example, in the $G(n,p)$ family with description $\Pi = (n,p)$, we can define `Vertex-Pair` query functions $\{F_{(u,v)}\}_{u,v\in[n]}$. So, given a graph $G \in \mathbb{X}^\Pi$, the query $F_{(u,v)}(G) = 1$ if and only if $(u,v) \in G$.

In prior work [18, 26, 41] as well as some of our results, the input description Π is of small size (typically $\mathcal{O}(\log n)$), and the oracle $\mathcal{M}$ can read all of Π (for example, $\Pi = (n,p)$ in $G(n,p)$).

Distributions with Huge Description Size. We initiate the study of **random object families** where the description Π is too large to be read by a sub-linear time algorithm. In this setting, the oracle from Definition 9 cannot read the entire input Π, and instead accesses it through local probes. For instance, consider the **random object family** that maps a graph G to the uniform distribution over valid colorings of G. Here, the description Π includes the entire graph G, which is too large to be read by a sub-linear time algorithm. In this case, the oracle can query the underlying graph using neighborhood probes. The number of such probes used to answer a single query must be sub-linear in the input size.

Supporting Independent Query Oracles: Memory-less Implementations

The model in Definition 9 only supports sequential queries, since the response to a future query may depend on the changes in internal state caused by past queries. In some applications, we may want to have multiple independent query oracles whose responses are all consistent with each other. One way to achieve this is to restrict our attention to *memory-less* implementations; ones without any internal state. An important implication of being memory-less is that the responses to each query is oblivious to the order of queries being asked. In fact, the lack of internal state implies that independent implementations that use the same random bits and the same input description must respond to queries in the same way. Thus, instead of using the internal state to maintain consistency, memory-less implementations are given access to the same public random oracle.

For the problem of sampling a random graph coloring, we present an implementation that is memory-less and also accesses the input description through local probes, as elaborated in the following model:

▶ **Definition 10.** *Given a* ***random object family*** $\{(\mathsf{X}^\Pi, \mathbb{X}^\Pi)\}$ *parameterized by input* Π*, a* local access implementation *of a family of query functions* $\langle F_1, F_2, \cdots \rangle$*, provides an oracle* $\mathcal{M}$ *with the following properties.* $\mathcal{M}$ *has query access to the input description* Π*, and a tape of public random bits* $\mathbf{R}$*. Upon being queried with* Π *and* F_i*, the oracle uses sub-linear resources to return the value* $\mathcal{M}(\Pi, \mathbf{R}, F_i)$*, which must equal* $F_i(X)$ *for a specific* $X \in \mathbb{X}^\Pi$*, where the choice of* X *depends only on* $\mathbf{R}$*, and the distribution of* X *(over* $\mathbf{R}$*) is* $\frac{1}{n^c}$*-close to the distribution over* $\mathbb{X}^\Pi$*, for any given constant* c*. Thus, different instances of* $\mathcal{M}$ *with the same description* Π *and the same random bits* $\mathbf{R}$*, must agree on the choice of* X *that is consistent with all answered queries regardless of the order and content of queries that were actually asked.*

We can contrast Definition 10 with the one for *Local Computation Algorithms* [48, 5] which also allow query access to *some* valid solution by reading the input through local probes. The additional challenge in our setting is that we also have to make sure that we return a uniformly random solution, rather than an arbitrary one. We also note that the memory-less property may be achieved for small description size **random object families**. For instance, our implementation for the directed small world model admits such a memory-less implementation using public random bits.

2.1 Undirected Graphs

We consider the generic class of *undirected graphs* with *independent edge probabilities* $\{p_{uv}\}_{u,v \in V}$, (where p_{uv} denotes the probability that there is an edge between u and v), from which the results can be applied to Erdös-Rényi random graphs and the Stochastic Block Model. Throughout, we identify our vertices via their unique IDs from 1 to n, namely $V = [n]$. In this model, `Vertex-Pair` queries by themselves can be implemented trivially, since the existence of any edge (u, v) is an independent Bernoulli random variable, but it becomes harder to maintain consistency when implementing them in conjunction with the other queries. Inspired by [18], we provide an implementation of `next-neighbor` queries, which return the neighbors of any given vertex one by one in lexicographic order. Finally, we introduce a new query: `Random-Neighbor` that returns a uniformly random neighbor of any given vertex. This would be useful for any algorithm that performs random walks. `Random-Neighbor` queries in non-sparse graphs present particularly interesting challenges that are outlined below.

`Next-Neighbor` Queries

In Erdös-Rényi graphs, the (lexicographically) next neighbor of a vertex can be recovered by generating consecutive entries of the adjacency matrix until a neighbor is found, which takes roughly $\Omega(1/p_{uv})$ time. For small edge probabilities $p_{uv} = o(1)$, this implementation is inefficient, and we show how to improve the runtime to $\mathcal{O}(\text{poly}(\log n))$. Our main technique is to sample the number of "non-neighbors" preceding the next neighbor. To do this, we assume that we can estimate the "skip" probabilities $F(v, a, b) = \prod_{u=a}^{b}(1 - p_{vu})$, where $F(v, a, b)$ is the probability that v has no neighbors in the range $[a, b]$. We later show how to compute this quantity efficiently for $G(n, p)$ and the Stochastic Block Model.

This strategy of *skip-sampling* is also used in [18]. However, in our work, the main difficulty arises from the fact that our graph is undirected, and thus we must "inform" all (potentially $\Theta(n)$) non-neighbors once we decide on the query vertex's next neighbor. Concretely, if u' is sampled as the next neighbor of v after its previous neighbor u, we must maintain consistency in subsequent steps by ensuring that none of the vertices in the range (u, u') return v as a neighbor. This update will become even more complicated as we handle Random-Neighbor queries, where we may generate non-neighbors at random locations.

In Section 3.1, we present a randomized implementation (Algorithm 1) that supports Next-Neighbor queries efficiently, but has a complicated performance analysis. We remark that this approach may be extended to support Vertex-Pair queries (Section A) with superior performance (if we do not support Random-Neighbor queries), and also to provide deterministic resource usage guarantee (Section C).

Random-Neighbor Queries

We implement Random-Neighbor queries (Section 3.2) using $\text{poly}(\log n)$ resources. The ability to do so is surprising since: (1) Sampling the degree of vertex, may not be viable for *sub-linear* implementations, because this quantity alone imposes dependence on the existence of *all* of its potential incident edges and consequently on the rest of the graph (since it is undirected). Thus, our implementation needs to return a random neighbor, with probability reciprocal to the query vertex's degree, without resorting to *determining* its degree. (2) Even without committing to the degrees, answers to Random-Neighbor queries affect the conditional probabilities of the remaining adjacencies in a global and non-trivial manner.[2]

We formulate an approach which samples many consecutive edges simultaneously, in such a way that the conditional probabilities of the unsampled edges remain independent and "well-behaved" during subsequent queries. For each vertex v, we divide the potential neighbors of v into consecutive ranges $\{B_v^{(i)}\}$ called blocks, so that each $B_v^{(i)}$ contains $\Theta(1)$ neighbors in expectation (i.e. $\sum_{u \in B_i} p_{vu} = \Theta(1)$). The subroutine of Next-Neighbor is applied to sample the neighbors within a block in expected $\widetilde{\mathcal{O}}(1)$ time. We can now obtain a neighbor of v by picking a random neighbor from a random block, but this introduces a bias because all blocks may not have the same number of neighbors. We remove this bias by rejecting samples from block $B_v^{(i)}$ with probability proportional to the number of neighbors in $B_v^{(i)}$.

2.1.1 Applications to Random Graph Models

We now consider the application of our construction above to actual random graph models, where we must realize the assumption that $\prod_{u=a}^{b}(1 - p_{vu})$ and $\sum_{u=a}^{b} p_{vu}$ can be computed efficiently. For the Erdös-Rényi $G(n, p)$ model, these quantities have simple closed-form expressions. Thus, we obtain implementations of Vertex-Pair, Next-Neighbor, and Random-Neighbor queries, using polylogarithmic resources per query, for *arbitrary* values of p, We remark that, while $\Omega(n + m) = \Omega(pn^2)$ time and space is clearly necessary to generate and represent a full random graph, our implementation supports local-access via all three types of queries, and yet can generate a full graph in $\widetilde{O}(n + m)$ time and space (Corollary 4).

[2] Consider a $G(n, p)$ graph with small p, say $p = 1/\sqrt{n}$, such that vertices will have $\tilde{\mathcal{O}}(\sqrt{n})$ neighbors with high probability. After $\tilde{\mathcal{O}}(\sqrt{n})$ Random-Neighbor queries, we will have uncovered all the neighbors (w.h.p.), so that the conditional probability of the remaining $\Theta(n)$ edges should now be close to zero.

We also generalize our construction to implement the Stochastic Block Model. In this model, the vertex set is partitioned into r *communities* $\{C_1, \ldots, C_r\}$. The probability that an edge exists between $u \in C_i$ and $v \in C_j$ is p_{ij}. A naive solution would be to simply assign communities to contiguous (by index) blocks of vertices, which would easily allow us to calculate the relevant sums/products of probabilities on continuous ranges of indices, with some additional case analysis to check when we are at a community boundary. However, this setup is unrealistic, and not particularly useful in the context of the Stochastic Block model. As communities in the observed data are generally unknown a priori, and significant research has been devoted to designing efficient algorithms for community detection and recovery, these studies generally consider the *random community assignment* condition for the purpose of designing and analyzing algorithms [40]. Thus, we construct implementations where the community assignments are sampled from some given distribution R, or from a collection of specified community sizes $\langle |C_1|, \ldots, |C_r| \rangle$. The main difficulty here is to obtain a uniformly sampled assignment of vertices to communities on-the-fly.

Since the probabilities of potential edges now depend on the communities of their endpoints, we can't obtain closed form expressions for the relevant sums and products of probabilities. However, we observe that it suffices to efficiently count the number of vertices of each community in any range of contiguous vertex indices. We then design a data structure extending a construction of [26], which maintains these counts for ranges of vertices, and determines the partition of their counts only on an as-needed basis. This extension results in an efficient technique to sample counts from the *multivariate hypergeometric distribution* (Section D) which may be of independent interest. For r communities, this yields an implementation with $\mathcal{O}(r \cdot \mathrm{poly}(\log n))$ overhead in required resources for each operation.

2.2 Directed Graphs

Lastly, we consider Kleinberg's Small World model ([31, 37]) in Section E. While small world models are proposed to capture properties of observed data such as small shortest-path distances and large clustering coefficients [55], this important special case of Kleinberg's model, defined on two-dimensional grids, demonstrates the underlying geographical structures of networks.

In this model, each vertex is identified via its 2D coordinate $v = (v_x, v_y) \in [\sqrt{n}]^2$. Defining the Manhattan distance as $\textsc{dist}(u, v) = |u_x - v_x| + |u_y - v_y|$, the probability that each directed edge (u, v) exists is $c/(\textsc{dist}(u, v))^2$. A common choice for c is given by normalizing the distribution such that the expected out-degree of each vertex is 1 ($c = \Theta(1/\log n)$). We can also support a range of values of $c = \log^{\pm\Theta(1)} n$. Since the degree of each vertex in this model is $\mathcal{O}(\log n)$ with high probability, we implement `All-Neighbor` queries, which in turn can emulate `Vertex-Pair`, `Next-Neighbor` and `Random-Neighbor` queries. In contrast to our previous cases, this model imposes an underlying two-dimensional structure of the vertex set, which governs the distance function as well as complicates the individual edge probabilities.

We implement `All-Neighbors` queries in the small world model by listing all neighbors from closest to furthest away from the queried vertex, using $\mathrm{poly}(\log n)$ resources per query. The main challenge is to sample for the next closest neighbor, when the probabilities are a function of the Manhattan distance on the lattice. Rather than sampling for a neighbor directly, we partition the nodes based on their distance from v (there are $\Theta(d)$ vertices at distance d). We first choose the next smallest distance partition with a neighbor using rejection sampling techniques (Lemma 11) on the appropriate distribution. In the second step, we generate all the neighbors within that partition using *skip-sampling*.

2.3 Random Catalan Objects

Many important combinatorial objects can be interpreted as Catalan objects. One such interpretation is a Dyck path; a one dimensional random walk on the line with n up and n down steps, starting from the origin, with the constraint that the height is always non-negative. We implement $\textsc{Height}(t)$, which returns the position of the walk at time t, and $\textsc{First-Return}(t)$, which returns the first time when the random walk returns to the same position as it was at time t. These queries are natural for several types of Catalan objects. As noted previously, we can use standard bijections to translate the Dyck path query implementations into natural queries for *bracketed expressions* and *ordered rooted trees*. Specifically, `Height` values in Dyck paths are equivalent to *depth* in bracket expressions and trees. The `First-Return` queries are more involved, and are equivalent to finding the *matching bracket* in bracket expressions, and alternately to finding the *next child* of a node in an ordered rooted tree (see Section 4.1).

Over the course of the execution, our algorithm will determine the height of a random Dyck path at many different positions $\{x_1, x_2, \cdots, x_m\}$ (with $x_i < x_{i+1}$), both directly as a result of user given `Height` queries, and indirectly through recursive calls to `Height`. These positions divide the sequence into contiguous *intervals* $[x_i, x_{i+1}]$, where the height of the endpoints y_i, y_{i+1} have been determined, but none of the intermediate heights are known. The important observation is that the unknown section of the path within an *interval* is entirely determined by the positions and heights of the endpoints, and in particular is completely independent of all other *intervals*. So, each interval $[x_i, x_{i+1}]$ along with corresponding heights $\{y_i, y_{i+1}\}$, represents a generalized Dyck problem with U up steps, D down steps, and a constraint that the path never dips more than y_i units below the starting height.

`Height` Queries

General $\textsc{Height}(x)$ queries can then be answered by recursively halving the *interval* containing x, by repeatedly sampling the height at the midpoint, until the height of position x is sampled. We start by implementing a subroutine that given an *interval* $[x_i, x_{i+1}]$ of length $2B$, containing $2U$ up and $2D$ down steps, determines the number of up steps $U' = U + d$ assigned to the first half of the *interval* (we parameterize U' with d in order to make the analysis cleaner). Note that this is equivalent to answering the query $\textsc{Height}(x_i + B)$. This is done by sampling the parameter d from a distribution $\{p_d\}$ where $p_d \equiv S_{left}(d) \cdot S_{right}(d)/S_{total}$. Here, $S_{left}(d)$ (respectively $S_{right}(d)$) is the number of possible paths in the left (resp. right) half of the *interval* when $U + d$ up steps and $D - d$ down steps are assigned to the first half, and S_{total} is the number of possible paths in the original $2B$-interval.

The problem of determining the number of up steps in the first half of the *interval* was solved for the unconstrained case (where the sequence is just a random permutation of up and down steps) in [26]. Adding the non-negativity constraint introduces further difficulties as the distribution over d has a CDF that is difficult to compute. We construct a different distribution $\{q_d\}$ that approximates $\{p_d\}$ pointwise to a factor of $\mathcal{O}(\log n)$ and has an efficiently computable CDF. This allows us to sample from $\{q_d\}$ and leverage rejection sampling techniques (see Lemma 11 in Section 2.5) to obtain samples from $\{p_d\}$.

`First-Return` Queries

Note that $\textsc{First-Return}(x)$ is only of interest when the first step after position x is upwards (i.e. $\textsc{Height}(x+1) > \textsc{Height}(x)$), since this situation is important for complex queries to random bracketed expressions and random rooted trees. Section 4.1 details the rationale

for this definition based on bijections between these objects. FIRST-RETURN queries are challenging because we need to find the *interval* containing the first return to HEIGHT(x). Since there could be up to $\Theta(n)$ intervals, it is inefficient to iterate through all of them. To circumvent this problem, we allow each interval $[x_i, x_{i+1}]$ to sample and maintain its own boundary constraint k_i instead of using the global non-negativity constraint. This implies that the path within the interval $[x_i, x_{i+1}]$ never reaches the height $y_i - k_i$ or lower. Additionally, we maintain a crucial invariant that states that this boundary is achieved by the endpoint of lower height i.e. $\min(y_i, y_{i+1})$. If the invariant holds, we can find the interval containing FIRST-RETURN(x) by finding the smallest determined position $x_j > x$ whose sampled height $y_j \leq$ HEIGHT(x), and considering the interval $[x_{j-1}, x_j]$ preceding x_j. We use an interval tree to update and query for the known heights.

Unfortunately, every HEIGHT query creates new intervals by sub-dividing existing ones, potentially breaking the invariant. We re-establish the invariant for $[x_i, x_{i+1}]$ by generating a "mandatory boundary" h (a boundary constraint with the added restriction that some position within the interval *must* touch the boundary), and then sampling a position $x_{mid} \in [x_i, x_{i+1}]$ such that HEIGHT(x_{mid}) $= h$ (Figure 6). This creates new intervals $[x_i, x_{mid}]$ and $[x_{mid}, x_{i+1}]$, both of which have a boundary constraint at h.

The first step of sampling the *mandatory boundary* is performed by binary searching on the possible boundary locations using an appropriate CDF (Section 4.4.2). To find an intermediate position touching this boundary, we parameterize the position with d, and find the distribution $\{p_d\}$ associated with the various possibilities. Since we cannot directly sample from this complicated distribution, we define a *piecewise continuous* probability distribution $\hat{q}(\delta)$ such that $\hat{q}(\delta)$ approximates $p_{\lfloor \delta \rfloor}$ (Section 4.4.3). We then use this to define a discrete distribution $\{q_d\}$ where $q_d = \int_d^{d+1} \hat{q}(\delta)$, where we can efficiently compute the CDF of $\{q_d\}$ by integrating the piecewise continuous $\hat{q}(\delta)$. The challenge here is to construct an appropriate $\hat{q}(\delta)$ that only has $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ continuous pieces. This allows us to again use the rejection sampling technique (Lemma 11) to indirectly obtain a sample from $\{p_d\}$.

2.4 Random Coloring of a Graph

Finally, we introduce a new model (Definition 10) for implementing huge random objects, where the distribution is specified as a uniformly random solution to a huge combinatorial problem. In this new setting, we will implement local query access to random q-colorings of a given huge graph G of size n with maximum degree Δ. Since the implementation has to run in sub-linear time, it is not possible to read the entire input G during a single query execution.

`Color` Queries

Given a graph G with maximum degree Δ, and the number of colors $q \geq 9\Delta$, we are able to construct an efficient implementation for COLOR(v) that returns the final color of v in a uniformly random q-coloring of G using only a sub-linear number of probes. Random colorings of a graph are sampled using $\mathcal{O}(n \log n)$ iterations of a Markov chain [22]. Each step of the chain proposes a random color update for a random vertex, and accepts the update if it does not create a conflict. This is an inherently sequential process, with the acceptance of a particular proposal depending on all preceding neighboring proposals.

To make the runtime analysis simpler, we define a modified version of Glauber Dynamics that proceeds in $\mathcal{O}(\log n)$ epochs. In each epoch, all of the n vertices propose a random color and update themselves if their proposals do not conflict with any of their neighbors. This Markov chain is a special case of the one presented in [20] for distributed graph coloring, and mixes in $\mathcal{O}(\log n)$ epochs when $q \geq 9\Delta$. In order to implement the query COLOR(v), it suffices

to implement $\textsc{Accepted}(v, t)$ that indicates whether the proposal for v was accepted in the t^{th} epoch. This depends on the prior colors of the potentially Δ neighbors of v. Determining the prior colors of all the neighbors w using recursive calls would result in Δ invocations of $\textsc{Accepted}(w, t-1)$ (at the preceding epoch $t-1$). Naively, this gives a bound of Δ^t on the number of invocations. We can prune the recursions by only considering neighbors who proposed the color c during *some* past epoch. This reduces the expected number of recursive calls to $t\Delta/q$, since there are $t\Delta$ potential proposals and each one is c with probability $1/q$. If q is larger than $t\Delta$, the number of recursive calls is less than 1, which gives a sub-linear bound on the total number of resulting invocations. Since the number of epochs t can be as large as $\Theta(\log n)$, this strategy will only work when $q = \Omega(\Delta \log n)$.

The improvement to $q = \Omega(\Delta)$ follows from the observation that for a neighbor w that proposed color c at epoch t', the recursive call corresponding to w can directly jump to epoch t'. If the conflicting color c was indeed accepted at that epoch, we then step *forwards* through epochs $t'+1, t'+2, \cdots$, to check whether c was overwritten by some future accepted proposal. This strategy dramatically reduces the recursive sub-problem size (given by the epoch number t'), and furthermore we show that we do not have to step through too many future epochs in order to check whether c was overwritten. This allows us to bound the runtime by $\widetilde{\mathcal{O}}\left(t\Delta(n/\epsilon)^{6.12\Delta/q}\right)$, where the overall coloring is sampled from a distribution that is ϵ-close to uniform (see Definition 10).

One requirement for our strategy is the ability to access a *valid initial coloring* (the initial state of the Markov Chain) through local probes, in addition to local probes to the underlying graph structure. This assumption can be removed by using a result of [10], that presents an LCA for $\Delta+1$ graph coloring using $\Delta^{\mathcal{O}(1)} \log n$ graph probes. Alternately, we can assign random initial colors to the vertices, which may result in an *invalid* final coloring. However, the Markov Chain will transform the initial invalid coloring into a valid one with high probability.

2.5 Basic Tools for Efficient Sampling

In this section, we describe the main techniques used to sample from a distribution $\{p_i\}_{i\in[n]}$, which differs based on the type of access to $\{p_i\}$ provided to the algorithm. If the algorithm is given cumulative distribution function (CDF) access to $\{p_i\}$, then it is well known that via $\mathcal{O}(\log n)$ CDF evaluations, one can sample according to a distribution that is at most n^{-c} far from $\{p_i\}$ in L_1 distance.

Sampling can be more challenging when when we can only access the probability distribution function (PDF) of $\{p_i\}$, The approach that we use in this work is to construct an auxiliary distribution $\{q_i\}$ such that: (1) $\{q_i\}$ has an efficiently computable CDF, and (2) q_i approximates p_i pointwise to within a polylogarithmic multiplicative factor for "most" of the support of $\{p_i\}$. The following Lemma inspired by [26] formalizes this concept.

▶ **Lemma 11.** *Let $\{p_i\}_{i\in[n]}$ and $\{q_i\}_{i\in[n]}$ be distributions on $[n]$ satisfying the following conditions:*

1. *There is a $\log^{\mathcal{O}(1)} n$ time algorithm to approximate p_i and q_i up to a multiplicative $\left(1 \pm \frac{1}{n^c}\right)$ factor.*
2. *We can generate an index i according to a distribution $\{\hat{q}_i\}$, where $\hat{q}_i$ is a $\left(1 \pm \frac{1}{n^c}\right)$ multiplicative approximation to q_i.*
3. *There exists a poly$(\log n)$-time recognizable set S such that*
   - $1 - \sum_{i\in S} p_i < \frac{1}{n^c}$
   - *For every $i \in S$, it holds that $p_i \le \log^{\mathcal{O}(1)} n \cdot q_i$*

Then, with high probability we can use only $\log^{\mathcal{O}(1)} n$ samples from $\{\hat{q}_i\}$ to generate an index i according to a distribution that is $\mathcal{O}\left(\frac{1}{n^c}\right)$-close to $\{p_i\}$ in L_1 distance.

Proof. We begin by setting an upper bound $U = \log^{\mathcal{O}(1)} n$ on p_i/q_i for all $i \in S$. The sampling proceeds in iterations, such that in each iteration we obtain an index i according to the distribution $\{\hat{q}_i\}$. If $i \notin S$, this index is returned with probability $\tilde{p}_i/U\tilde{q}_i$, where $\tilde{p}_i$ and $\tilde{q}_i$ are the $\left(1 \pm \frac{1}{n^c}\right)$ multiplicative approximations to p_i and q_i, Otherwise, we repeat this process until some output is returned.

The probability of returning index $i \in S$ in a particular iteration is $\hat{q}_i \cdot (\tilde{p}_i/U\tilde{q}_i)$, which is in turn a $\left(1 \pm \frac{1}{n^c}\right)$ multiplicative approximation to p_i/U. Hence, the probability of success in a single iteration is roughly $1/U$, and therefore we only need $\mathcal{O}(U \log n) = \log^{\mathcal{O}(1)} n$ iterations (and the same number of samples from $\{\hat{q}_i\}$) in order to succeed with high probability. The resulting distribution of indices approximates $\{p_i\}$ pointwise on the domain S, up to a factor of $\left(1 \pm \frac{1}{n^c}\right)$. Since the remainder of the domain contains at most $\frac{1}{n^c}$ probability mass, the output distribution is $\mathcal{O}\left(\frac{1}{n^c}\right)$ close to $\{p_i\}$ in L_1 distance. ◀

3 Local-Access Implementations for Random Undirected Graphs

In this section, we provide an efficient local access implementations for random undirected graphs when the probabilities $p_{uv} = \mathbb{P}[(u, v) \in E]$ are given, and we can efficiently approximate the following quantities: (1) the probability that there is no edge between a vertex u and a range of consecutive vertices $[a, b]$, namely $\prod_{u=a}^{b}(1 - p_{vu})$, and (2) the sum of the edge probabilities (i.e., the expected number of edges) between u and vertices from $[a, b]$, namely $\sum_{u=a}^{b} p_{vu}$. In Section 1.2, we provide subroutines for computing these values for the Erdös-Rényi model and the Stochastic Block model. We also begin by assuming perfect-precision arithmetic, which we relax in Section B.1.

First, consider the adjacency matrix $\mathbf{A}$ of G, where each entry $\mathbf{A}[u][v]$ can exist in three possible states: $\mathbf{A}[u][v] = 1$ or 0 if the algorithm has determined that $\{u, v\} \in E$ or $\{u, v\} \notin E$ respectively, and $\mathbf{A}[u][v] = \phi$ if whether $\{u, v\} \in E$ or not will be determined by future random choices (in fact, the marginal probability of $\mathbb{P}[(u, v) \in E]$ conditioned on all prior samples is still p_{uv}). Our implementation also maintains the vector **last** (used in the same sense as [18]), where $\mathbf{last}[v]$ records the neighbor of v returned in the last call NEXT-NEIGHBOR(v), or $\mathbf{last}[v] = 0$ if no such call has been invoked. All cells of $\mathbf{A}$ and **last** are initialized to ϕ and 0, respectively.

We use the Bernoulli random variable $X_{uv} \sim \mathsf{Bern}(p_{uv})$ when sampling the value of $\mathbf{A}[u][v] = \phi$. For the sake of analysis, we will frequently view our random process as if the *entire* table of random variables X_{uv} has been sampled *up-front*, and the algorithm simply "uncovers" these variables instead of making coin-flips. Thus, every cell $\mathbf{A}[u][v]$ is originally ϕ, but will eventually take the value X_{uv}.

Obstacles for maintaining A explicitly. Consider a naive implemention that fills out the cells of $\mathbf{A}$ one-by-one as required by each query; equivalently, we perform VERTEX-PAIR queries on successive vertices until a neighbor is found. There are two problems with this approach. Firstly, the algorithm only finds a neighbor, for a RANDOM-NEIGHBOR or NEXT-NEIGHBOR query, with probability p_{uv}: for $G(n, p)$ this requires $1/p$ iterations, which is already infeasible for $p = o(1/\text{poly}(\log n))$. Secondly, the algorithm may generate a large number of non-neighbors in the process, possibly in random or arbitrary locations.

3.1 `Next-Neighbor` Queries via Run-of-0's Sampling

We implement NEXT-NEIGHBOR(v) by sampling for the first index $u > \mathbf{last}[v]$ such that $X_{vu} = 1$, from a sequence of Bernoulli RVs $\{X_{v,u}\}_{u>\mathbf{last}[v]}$. To do so, we sample a consecutive "run" of 0's with probability $\prod_{u=\mathbf{last}[v]+1}^{u'}(1-p_{vu})$: this is the probability that there is no edge between a vertex v and any $u \in (\mathbf{last}[v], u']$, which can be computed efficiently by our assumption. The problem is that, some entries $\mathbf{A}[v][u]$'s in this run may have already been determined (to be 1 or 0) by queries NEXT-NEIGHBOR(u) for $u > \mathbf{last}[v]$. To mitigate this issue, we give a succinct data structure that determines the value of $\mathbf{A}[v][u]$ for $u > \mathbf{last}[v]$ and, more generally, captures the state $\mathbf{A}$, in Section 3.1.1. Using this data structure, we ensure that our sampled run does not skip over any 1. Next, for the sampled index u of the first occurrence of 1, we check against this data structure to see if $\mathbf{A}[v][u]$ is already assigned to 0, in which case we re-sample for a new candidate $u' > u$. Section 3.1.2 discusses the subtlety of this issue.

We note that we do not yet try to handle other types of queries here yet. We also do not formally bound the number of re-sampling iterations of this approach here, because the argument is not needed by our final algorithm. Yet, we remark that $O(\log n)$ iterations suffice with high probability, even if the queries are adversarial. This method can be extended to support VERTEX-PAIR queries (but unfortunately not RANDOM-NEIGHBOR queries). See Section A for full details.

3.1.1 Data structure

From the definition of X_{uv}, NEXT-NEIGHBOR(v) is given by $\min\{u > \mathbf{last}[v] : X_{vu} = 1\}$. Let $P_v = \{u : \mathbf{A}[v][u] = 1\}$ be the set of known neighbors of v, and $w_v = \min\{(P_v \cap (\mathbf{last}[v], n])\}$ be its first known neighbor not yet reported by a NEXT-NEIGHBOR(v) query, or equivalently, the next occurrence of 1 in v's row on $\mathbf{A}$ after $\mathbf{last}[v]$. If there is no known neighbor of v after $\mathbf{last}[v]$, we set $w_v = n + 1$. Consequently, $\mathbf{A}[v][u] \in \{\phi, 0\}$ for all $u \in (\mathbf{last}[v], w_v)$, so NEXT-NEIGHBOR($v$) is either the index u of the first occurrence of $X_{vu} = 1$ in this range, or w_v if no such index exists.

We keep track of $\mathbf{last}[v]$ in a dictionary, to avoid any initialization overhead. Each P_v is maintained as an ordered set, which is also instantiated when it becomes non-empty. When NEXT-NEIGHBOR(v) returns u, we add v to P_u and u to P_v. We do not attempt to maintain $\mathbf{A}$ explicitly, as updating it requires replacing up to $\Theta(n)$ ϕ's to 0's for a single NEXT-NEIGHBOR query in the worst case. Instead, we argue that $\mathbf{last}$ and P_v's provide a succinct representation of $\mathbf{A}$ via the following observation.

▶ **Lemma 12.** *The data structures* $\mathbf{last}$ *and* P_v*'s together provide a succinct representation of* $\mathbf{A}$ *when only* NEXT-NEIGHBOR *queries are allowed. In particular,* $\mathbf{A}[v][u] = 1$ *if and only if* $u \in P_v$*. Otherwise,* $\mathbf{A}[v][u] = 0$ *when* $u < \mathbf{last}[v]$ *or* $v < \mathbf{last}[u]$*. In all remaining cases,* $\mathbf{A}[v][u] = \phi$*.*

Proof. The condition for $\mathbf{A}[v][u] = 1$ clearly holds by constuction. Otherwise, observe that $\mathbf{A}[v][u]$ becomes *decided* (i.e. its value is changed from ϕ to 0) during the first call to NEXT-NEIGHBOR(v) that returns a value $u' > u$ thereby setting $\mathbf{last}[v] = u' \implies u < \mathbf{last}[v]$, or vice versa. ◀

3.1.2 Queries and Updates

We now present Algorithm 1, and discuss the correctness of its sampling process. The argument here is rather subtle and relies on viewing the process as an "uncovering" of the table of RVs X_{uv} (introduced in Section 3). Consider the following strategy to find

Algorithm 1 Sampling NEXT-NEIGHBOR.

```
1:  procedure NEXT-NEIGHBOR(v)
2:      u ← last[v]
3:      w_v ← min{(P_v ∩ (u, n]) ∪ {n + 1}}
4:      repeat
5:          sample F ~ F(v, u, w_v)
6:          u ← F
7:      until u = w_v or last[u] < v
8:      if u ≠ w_v
9:          P_v ← P_v ∩ {u}
10:         P_u ← P_u ∩ {v}
11:     last[v] ← u
12:     return u
```

NEXT-NEIGHBOR(v) in the range $(\mathbf{last}[v], w_v)$. Suppose that we generate a sequence of $w_v - \mathbf{last}[v] - 1$ independent coin-tosses, where the i^{th} coin C_{vu} corresponding to $u = \mathbf{last}[v]+i$ has bias p_{vu}, regardless of whether X_{vu} is decided or not. Then, we use the sequence $\langle C_{vu}\rangle$ to assign values to *undecided* random variables X_{vu}. The main observation here is that, the *decided* random variables $X_{vu} = 0$ do not need coin-flips, and the corresponding coin result C_{vu} can be discarded. Thus, we generate coin-flips until we encounter some u satisfying both $C_{vu} = 1$ and $\mathbf{A}[v][u] = \phi$.

Let $\mathsf{F}(v, a, b)$ denote the probability distribution of the occurrence u of the first coin-flip $C_{vu} = 1$ among the neighbors in (a, b). More specifically, $F \sim \mathsf{F}(v, a, b)$ represents the event that $C_{v,a+1} = \cdots = C_{v,F-1} = 0$ and $C_{v,F} = 1$, which happens with probability $\mathbb{P}[F = f] = \prod_{u=a+1}^{f-1}(1 - p_{vu}) \cdot p_{vf}$. For convenience, let $F = b$ denote the event where all $C_{vu} = 0$. Our algorithm samples $F_1 \sim \mathsf{F}(v, \mathbf{last}[v], w_v)$ to find the first occurrence of $C_{v,F_1} = 1$, then samples $F_2 \sim \mathsf{F}(v, F_1, w_v)$ to find the second occurrence $C_{v,F_2} = 1$, and so on. These values $\{F_i\}$ are iterated as u in Algorithm 1. This process generates u satisfying $C_{vu} = 1$ in increasing order, until we find one that also satisfies $\mathbf{A}[u][v] = \phi$ (this outcome is captured by the condition $\mathbf{last}[u] < v$), or until the next generated u is equal to w_v. Note that once the process terminates at some u, we make no implications on the results of any uninspected coin-flips after C_{vu}.

Obstacles for extending beyond `Next-Neighbor` queries. There are two main issues that prevent this method from supporting RANDOM-NEIGHBOR queries. Firstly, while one might consider applying NEXT-NEIGHBOR starting from some random location u to find the minimum $u' \geq u$ where $\mathbf{A}[v][u'] = 1$, the probability of choosing u' will depend on the probabilities p_{vu}'s, and is generally not uniform. Secondly, in Section 3.1.1, we observe that $\mathbf{last}[v]$ and P_v together provide a succinct representation of $\mathbf{A}[v][u] = 0$ only for contiguous cells $\mathbf{A}[v][u]$ where $u \leq \mathbf{last}[v]$ or $v \leq \mathbf{last}[u]$: they cannot handle 0 anywhere else. Unfortunately, in order to support RANDOM-NEIGHBOR queries, we will likely need to assign $\mathbf{A}[v][u]$ to 0 in random locations beyond $\mathbf{last}[v]$ or $\mathbf{last}[u]$, which cannot be captured by the current data structure. Specifically, to speed-up the sampling process for small p_{vu}'s, we must generate many random non-neighbors at once, but we cannot afford to spend time linear in the number of created 0's to update our data structure. We remedy these issues via the following approach.

3.2 Final Implementation Using Blocks

We begin this section by focusing first on RANDOM-NEIGHBOR queries, then extend the construction to the remaining queries. In order to handle RANDOM-NEIGHBOR(v), we divide the neighbors of v into *blocks* $\mathbf{B}_v = \{B_v^{(1)}, B_v^{(2)}, \ldots, B_v^{(i)}, \ldots\}$, so that each block contains, in expectation, roughly the same number of neighbors of v. We implement RANDOM-NEIGHBOR(v) by randomly selecting a block $B_v^{(i)}$, filling in entries $\mathbf{A}[v][u]$ for $u \in B_v^{(i)}$ with 1's and 0's, and then reporting a random neighbor from this block. As the block size may be large when the probabilities are small, instead of using a linear scan, our FILL subroutine will be implemented using the "run-of-0s" sampling from Algorithm 1 (see Section 3.1). Since the number of iterations required by this subroutine is roughly proportional to the number of neighbors, we choose to allocate a constant number of neighbors in expectation to each block: with constant probability the block contains some neighbors, and with high probability it has at most $O(\log n)$ neighbors.

As the actual number of neighbors appearing in each block will be different, we balance out these discrepancies by performing *rejection sampling*. This equalizes the probability of choosing any neighbor implicitly, without the knowledge of $\deg(v)$. Leveraging the fact that the maximum number of neighbors in any block is $\mathcal{O}(\log n)$, we show not only that the probability of success in the rejection sampling process is at least $1/\mathrm{poly}(\log n)$, but the number of iterations required by NEXT-NEIGHBOR is also bounded by $\mathrm{poly}(\log n)$, achieving the overall $\mathrm{poly}(\log n)$ complexities. Here, we will extensively rely on the assumption that the expected number of neighbors for consecutive vertices, $\sum_{u=a}^{b} p_{vu}$, can be approximated efficiently.

3.2.1 Partitioning and Filling the Blocks

We fix a sufficiently large constant L, and assign the vertex u to the $\lceil \sum_{i=1}^{u} p_{vi}/L \rceil^{\text{th}}$ block of v. Essentially, each block represents a contiguous range of vertices, where the expected number of neighbors of v in the block is $\approx L$ (for example, in $G(n,p)$, each block contains $\approx L/p$ vertices). We define $\Gamma^{(i)}(v) = \Gamma(v) \cap B_v^{(i)}$, the neighbors appearing in block $B_v^{(i)}$. Our construction ensures that $L - 1 < \mathbb{E}\left[|\Gamma^{(i)}(v)|\right] < L + 1$ for every $i < |\mathbf{B}_v|$ (i.e., the condition holds for all blocks except possibly the last one).

Now, we show that with high probability, all the block sizes $|\Gamma^{(i)}(v)| = \mathcal{O}(\log n)$, and at least a 1/3-fraction of the blocks are non-empty (i.e., $|\Gamma^{(i)}(v)| > 0$), via the following lemmas (proven in Section B).

▶ **Lemma 13.** *With high probability, the number of neighbors in every block, $|\Gamma^{(i)}(v)|$, is at most $\mathcal{O}(\log n)$.*

▶ **Lemma 14.** *With high probability, for every v such that $|\mathbf{B}_v| = \Omega(\log n)$ (i.e., $\mathbb{E} = \Omega(\log n)$), at least a 1/3-fraction of the blocks $\{B_v^{(i)}\}_{i \in [|\mathbf{B}_v|]}$ are non-empty.*

We consider blocks to be in two possible states – filled or unfilled. Initially, all blocks are considered unfilled. In our algorithm we will maintain, for each block $B_v^{(i)}$, the set $P_v^{(i)}$ of known neighbors of u in block $B_v^{(i)}$; this is a refinement of the set P_v in Section 3.1. We define the behaviors of the procedure FILL(v,i) as follows. When invoked on an unfilled block $B_v^{(i)}$, FILL(v,i) decides whether each vertex $u \in B_v^{(i)}$ is a neighbor of v (implicitly setting $\mathbf{A}[v][u]$ to 1 or 0) unless X_{vu} is already decided; in other words, update $P_v^{(i)}$ to $\Gamma^{(i)}(v)$. Then $B_v^{(i)}$ is marked as filled. We postpone the description of our implementation of FILL to Section 3.3, instead using it as a black box.

3.2.2 Putting it all together: `Random-Neighbor` queries

Algorithm 2 Block sampling.

procedure RANDOM-NEIGHBOR(v)
  while True
    sample $B_v^{(i)} \sim_{\mathcal{U}} \mathbf{B}_v$ u.a.r.
    if $B_v^{(i)}$ is not *filled*
      FILL(v, i)
    with probability $\frac{|P_v^{(i)}|}{M}$
      return $u \sim_{\mathcal{U}} P_v^{(i)}$ u.a.r

Consider Algorithm 2 for sampling a random neighbor via rejection sampling. For simplicity, throughout the analysis, we assume $|\mathbf{B}_v| = \Omega(\log n)$; otherwise, invoke FILL$(v, i)$ for all $i \in [|\mathbf{B}_v|]$ to obtain the entire neighbor list $\Gamma(v)$.

To obtain a random neighbor, we first choose a block $B_v^{(i)}$ uniformly at random, and invoke FILL(v, i) if the block is *unfilled*. Then, we *accept* the sampled block for generating our random neighbor with probability proportional to $|P_v^{(i)}|$. More specifically, if $M = \Theta(\log n)$ is an upper bound on the maximum number of neighbors in any block (see Lemma 13), we accept block $B_v^{(i)}$ with probability $|P_v^{(i)}|/M$, which is well-defined (i.e., does not exceed 1) with high probability. Note that if $P_v^{(i)} = \emptyset$, we sample another block. If we choose to accept $B_v^{(i)}$, we return a random neighbor from $P_v^{(i)}$. Otherwise, *reject* this block and repeat the process again.

Since the returned vertex is always a member of $P_v^{(i)}$, a valid neighbor is always returned. We now show that the algorithm correctly samples a uniformly random neighbor and bound the number of iterations required for the rejection sampling process.

▶ **Lemma 15.** *Algorithm 2 returns a uniformly random neighbor of vertex v.*

Proof. It suffices to show that the probability that any neighbor in $\Gamma(v)$ is return with uniform positive probability, within the same iteration. Fixing a single iteration and consider a vertex $u \in P_v^{(i)}$, we compute the probability that u is accepted. The probability that $B_v^{(i)} i$ is chosen is $1/|\mathbf{B}_v|$, the probability that $B_v^{(i)}$ is accepted is $|P_v^{(i)}|/M$, and the probability that u is chosen among $P_v^{(i)}$ is $1/|P_v^{(i)}|$. Hence, the overall probability of returning u in a single iteration of the loop is $1/(|\mathbf{B}_v| \cdot M)$, which is positive and independent of u. Therefore, each vertex is returned with the same probability. ◀

▶ **Lemma 16.** *Algorithm 2 terminates in $\mathcal{O}(\log n)$ iterations in expectation, or $\mathcal{O}(\log^2 n)$ iterations w.h.p.*

Proof. Using Lemma 14, we conclude that the probability of choosing a non-empty block is at least $1/3$. Since $M = \Theta(\log n)$ by Lemma 13, the success probability of each iteration is at least $1/(3M) = \Omega(1/\log n)$, Thus, the number of iterations required is $O(\log^2 n)$ with high probability. ◀

3.3 Implementation of `Fill`

Lastly, we describe the implementation of the FILL procedure, employing the approach of skipping non-neighbors, as developed for Algorithm 1. We aim to simulate the following process: perform coin-tosses C_{vu} with probability p_{vu} for every $u \in B_v^{(i)}$ and update $\mathbf{A}[v][u]$'s

Algorithm 3 Filling a block.

```
procedure FILL(v, i)
    (a, b) ← B_v^(i)
    while a < b
        sample u ~ F(v, a, b)
        B_u^(j) ← block containing v
        if B_u^(j) is not filled
            P_v^(i) ← P_v^(i) ∪ {u}
            P_u^(j) ← P_u^(j) ∪ {v}
        a ← u
    mark B_u^(j) as filled
```

according to these coin-flips unless they are decided (i.e., $\mathbf{A}[v][u] \neq \phi$). We directly generate a sequence of u's where the coins $C_{vu} = 1$, then add u to P_v and vice versa if X_{vu} has not previously been decided. Thus, once $B_v^{(i)}$ is filled, we will obtain $P_v^{(i)} = \Gamma^{(i)}(v)$ as desired.

As discussed in Section 3.1, while we have recorded all occurrences of $\mathbf{A}[v][u] = 1$ in $P_v^{(i)}$, we need an efficient way of checking whether $\mathbf{A}[v][u] = 0$ or ϕ. In Algorithm 1, **last** serves this purpose by showing that $\mathbf{A}[v][u]$ for all $u \leq \mathbf{last}[v]$ are decided as shown in Lemma 12. Here instead, we maintain a single bit marking whether each block is filled or unfilled: a filled block implies that $\mathbf{A}[v][u]$ for all $u \in B_v^{(i)}$ are decided. The block structure along with the mark bits, unlike **last**, is capable of handling intermittent ranges of intervals, which is sufficient for our purpose, as shown in the following lemma. This yields the implementation of Algorithm 3 for the FILL procedure fulfilling the requirement previously given in Section 3.2.1.

▶ **Lemma 17.** *The data structures $P_v^{(i)}$'s and the block marking bits together provide a succinct representation of $\mathbf{A}$ as long as modifications to $\mathbf{A}$ are performed solely by the* FILL *operation in Algorithm 3. In particular, let $u \in B_v^{(i)}$ and $v \in B_u^{(j)}$. Then, $\mathbf{A}[v][u] = 1$ if and only if $u \in P_v^{(i)}$. Otherwise, $\mathbf{A}[v][u] = 0$ when at least one of $B_v^{(i)}$ or $B_u^{(j)}$ is marked as* filled. *In all remaining cases, $\mathbf{A}[v][u] = \phi$.*

Proof. The condition for $\mathbf{A}[v][u] = 1$ still holds by construction. Otherwise, observe that $\mathbf{A}[v][u]$ becomes decided precisely during a FILL(v, i) or a FILL(u, j) operation, which thereby marks one of the corresponding blocks as filled. ◀

Note that $P_v^{(i)}$'s, maintained by our implementation, are initially empty but may not still be empty at the beginning of the FILL function call. These $P_v^{(i)}$'s are again instantiated and stored in a dictionary once they become non-empty. Further, observe that the coin-flips are simulated independently of the state of $P_v^{(i)}$, so the number of iterations of Algorithm 3 is the same as the number of coins $C_{vu} = 1$ which is, in expectation, a constant (namely $\sum_{u \in B_v^{(i)}} \mathbb{P}[C_{vu} = 1] = \sum_{u \in B_v^{(i)}} p_{vu} \leq L + 1$).

By tracking the resource required by Algorithm 3 we obtain the following lemma; note that "additional space" refers to the enduring memory that the implementation must allocate and keep even after the execution, not its computation memory. The $\log n$ factors in our complexities are required to perform binary-search for the range of $B_v^{(i)}$, or for the value u from the CDF of $\mathsf{F}(u, a, b)$, and to maintain the ordered sets $P_v^{(i)}$ and $P_u^{(j)}$.

▶ **Lemma 18.** *Each execution of Algorithm 3 (the* FILL *operation) on an* unfilled *block $B_v^{(i)}$, in expectation:*

- *terminates within $\mathcal{O}(1)$ iterations (of its* **repeat** *loop);*
- *computes $\mathcal{O}(\log n)$ quantities of $\prod_{u \in [a,b]}(1 - p_{vu})$ and $\sum_{u \in [a,b]} p_{vu}$ each;*
- *uses an additional $\mathcal{O}(\log n)$ time, $\mathcal{O}(1)$ random $\log n$-bit words, and $\mathcal{O}(1)$ additional space.*

Observe that the number of iterations required by Algorithm 3 only depends on its random coin-flips and independent of the state of the algorithm. Combining with Lemma 16, we finally obtain polylogarithimc resource bound for our implementation of RANDOM-NEIGHBOR.

▶ **Corollary 19.** *Each execution of Algorithm 2 (the* RANDOM-NEIGHBOR *query), with high probability,*

- *terminates within* $\mathcal{O}(\log^2 n)$ *iterations (of its* **repeat** *loop);*
- *computes* $\mathcal{O}(\log^3 n)$ *quantities of* $\prod_{u\in[a,b]}(1-p_{vu})$ *and* $\sum_{u\in[a,b]} p_{vu}$ *each;*
- *uses an additional* $\mathcal{O}(\log^3 n)$ *time,* $\mathcal{O}(\log^2 n)$ *random words, and* $\mathcal{O}(1)$ *additional space.*

Supporting Other Query Types along with `Random-Neighbor`

- VERTEX-PAIR(u,v): We simply need to make sure that Lemma 17 holds, so we first apply FILL(u, j) on block $B_u^{(j)}$ containing v (if needed), then answer accordingly.
- NEXT-NEIGHBOR(v): We maintain **last**, and keep invoking FILL until we find a neighbor. Recall that by Lemma 14, the probability that a particular block is empty is a small constant. Then with high probability, there exists no $\omega(\log n)$ *consecutive* empty blocks $B_v^{(i)}$'s for any vertex v, and thus NEXT-NEIGHBOR only invokes up to $\mathcal{O}(\log n)$ calls to FILL.

We summarize the results so far with through the following theorem.

▶ **Theorem 1.** *Given a random graph model defined by the probability matrix* $\{p_{uv}\}_{u,v\in[n]}$*, and assuming that we can compute the the quantities* $\prod_{u=a}^{b}(1-p_{vu})$ *and* $\sum_{u=a}^{b} p_{vu}$ *in* $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ *time, there exists an implementation for this model that supports local access through* RANDOM-NEIGHBOR*,* VERTEX-PAIR*, and* NEXT-NEIGHBOR *queries using* $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ *running time, additional space, and random bits per query.*

We have also been implicitly assuming perfect-precision arithmetic and we relax this assumption in Section B.1. In the following Section 3.4, we show applications of Theorem 1 to the $G(n,p)$ model, and the Stochastic Block model under random community assignment, by providing formulas and by constructing data structures for computing the quantities specified in Theorem 1.

3.4 Applications to Erdös-Rényi Model and Stochastic Block Model

In this section we demonstrate the application of our techniques to two well known, and widely studied models of random graphs. That is, as required by Theorem 1, we must provide a method for computing the quantities $\prod_{u=a}^{b}(1-p_{vu})$ and $\sum_{u=a}^{b} p_{vu}$ of the desired random graph families in logarithmic time, space and random bits. Our first implementation focuses on the well known Erdös-Rényi model – $G(n,p)$: in this case, $p_{vu} = p$ is uniform and our quantities admit closed-form formulas.

Next, we focus on the Stochastic Block model with randomly-assigned communities. Our implementation assigns each vertex to a community in $\{C_1, \ldots, C_r\}$ identically and independently at random, according to some given distribution R over the communities. We formulate a method of sampling community assignments locally. This essentially allows us to sample from the *multivariate hypergeometric distribution*, using $\text{poly}(\log n)$ random bits, which may be of independent interest. We remark that, as our first step, we sample for the number of vertices of each community. That is, our construction can alternatively support the community assignment where the number of vertices of each community is given, under the assumption that the *partition* of the vertex set into communities is chosen uniformly at random.

3.4.1 Erdös-Rényi Model

As $p_{vu} = p$ for all edges $\{u, v\}$ in the Erdös-Rényi $G(n, p)$ model, we have the closed-form formulas $\prod_{u=a}^{b}(1-p_{vu}) = (1-p)^{b-a+1}$ and $\sum_{u=a}^{b} p_{vu} = (b-a+1)p$, which can be computed in constant time according to our assumption, yielding the following corollary.

▶ **Corollary 2.** *There exists an algorithm that implements local access to a Erdös-Rényi $G(n, p)$ random graph, through* Vertex-Pair, Next-Neighbor, *and* Random-Neighbor *queries, while using $\mathcal{O}(\log^3 n)$ time, $\mathcal{O}(\log^3 n)$ random bits, and $\mathcal{O}(\log^2 n)$ additional space per query with high probability.*

We remark that there exists an alternative approach that picks $F \sim \mathsf{F}(v, a, b)$ directly via a closed-form formula $a + \lceil \frac{\log U}{\log(1-p)} \rceil$ where U is drawn uniformly from $[0, 1)$, rather than binary-searching for U in its CDF. Such an approach may save some $\mathrm{poly}(\log n)$ factors in the resources, given the prefect-precision arithmetic assumption. This usage of the log function requires $\Omega(n)$-bit precision, which is not applicable to our computation model.

While we are able to generate our random graph on-the-fly supporting all three types of queries, our construction still only requires $\mathcal{O}(m + n)$ space ($\log n$-bit words) in total at any state; that is, we keep $\mathcal{O}(n)$ words for **last**, $\mathcal{O}(1)$ words per neighbor in P_v's, and one marking bit for each block (where there can be up to $m + n$ blocks in total). Hence, our memory usage is nearly optimal for the $G(n, p)$ model:

▶ **Corollary 4.** *The final algorithm in Section 3 can generate a complete random graph from the Erdös-Rényi $G(n, p)$ model using overall $\widetilde{\mathcal{O}}(n + m)$ time, random bits and space, which is $\widetilde{\mathcal{O}}(pn^2)$ in expectation. This is optimal up to $\mathcal{O}(\mathrm{poly}(\log n))$ factors.*

3.4.2 Stochastic Block model

In the Stochastic Block model, each vertex is assigned to some community C_i, $i \in [r]$. By partitioning the product by communities, we may rewrite the desired formulas, for $v \in C_i$, as $\prod_{u=a}^{b}(1 - p_{vu}) = \prod_{j=1}^{r}(1 - p_{ij})^{|[a,b]\cap C_j|}$ and $\sum_{u=a}^{b} p_{vu} = \sum_{j=1}^{r} |[a, b] \cap C_j| \cdot p_{ij}$. Thus, it suffices to design a data structure that is able to efficiently count the number of occurrences of vertices of each community in any contiguous range (namely the value $|[a, b] \cap C_j|$ for each $j \in [r]$), where the vertices are assigned communities according to a given distribution R. To this end, we use the following lemma, yielding an implementation for the Stochastic Block model using $O(r\,\mathrm{poly}(\log n))$ resources per query.

▶ **Theorem 20.** *There exists a data structure that samples a community for each vertex independently at random from R with $\frac{1}{\mathrm{poly}(n)}$ error in the L_1-distance, and supports queries that ask for the number of occurrences of vertices of each community in any contiguous range, using $O(r\,\mathrm{poly}(\log n))$ time, random bits, and additional space per query. Further, this data structure may be implemented in such a way that requires no overhead for initialization.*

▶ **Corollary 3.** *There exists an algorithm that implements local access to a random graph from the n-vertex Stochastic Block Model with r randomly-assigned communities, through* Vertex-Pair, Next-Neighbor, *and* Random-Neighbor *queries, using $O(r\,\mathrm{poly}(\log n))$ time, random bits, and space per query w.h.p.*

We provide the full details of the construction in Section D. Our construction extends a similar implementation in the work of [26] which only supports $r = 2$. The overall data structure is a balanced binary tree, where the root corresponds to the entire range of indices $[n]$, and the children of each vertex correspond to the first and second half of the parent's range.

Each node[3] holds the number of vertices of each community in its range. The tree initially contains only the root, with the number of vertices of each community $\langle |C_1|, |C_2|, \cdots, |C_r| \rangle$ sampled according to the multinomial distribution (for n samples from the distribution R). The children are generated top-down on an as-needed basis according to the given queries. The technical difficulties arise when generating the children, where one needs to sample the counts assigned to either child from the correct marginal distribution. We show how to sample such a count from the *multivariate hypergeometric distribution*, below in Theorem 21 (proven in Section D).

▶ **Theorem 21.** *Given B marbles of r different colors, such that there are C_i marbles of color i, there exists an algorithm that samples $\langle s_1, s_2, \cdots, s_r \rangle$, the number of marbles of each color appearing when drawing l marbles from the urn without replacement, in $O(r \cdot \mathrm{poly}(\log B))$ time and random words.*

Proof of Theorem 20. Recall that R denotes the given distribution over integers $[r]$ (namely, the random distribution of communities for each vertex). Our algorithm generates and maintains random variables $X_1, \ldots, X_n$ (denoting the community assignment), each of which is drawn independently from R. Given a pair (a, b), it uses Theorem 20 to sample the vector $\mathbf{C}(a, b) = \langle c_1, \ldots, c_r \rangle$, where c_k counts the number of variables in $\{X_a, \ldots, X_b\}$ that take on the value k.

We maintain a complete binary tree whose leaves corresponds to indices from $[n]$. Each node represents a range and stores the vector $\mathbf{C}$ for the corresponding range. The root represents the entire range $[n]$, which is then halved in each level. Initially the root samples $\mathbf{C}(1, n)$ from the multinomial distribution according to R (see e.g., Section 3.4.1 of [32]). Then, the children are generated on-the-fly as described above. Thus, each query can be processed within $O(r \,\mathrm{poly}(\log n))$ time, yielding Theorem 20. ◀

Then, by embedding the information stored by the data structure into the state (as in the proof of Lemma 51), we obtain the desired Corollary 3.

4 Implementing Random Catalan Objects

In the previous Section 3.4.2 on the Stochastic Block Model, we considered random sequences of colored marbles. Next, we focus on an important variant of these sequences as Catalan objects, which impose a global constraint on the types of allowable sequences. Specifically, consider a sequence of n white and n black marbles, such that every *prefix* of the sequence has at least as many white marbles as black ones. Our goal will be to support queries to a uniformly random instance of such an object.

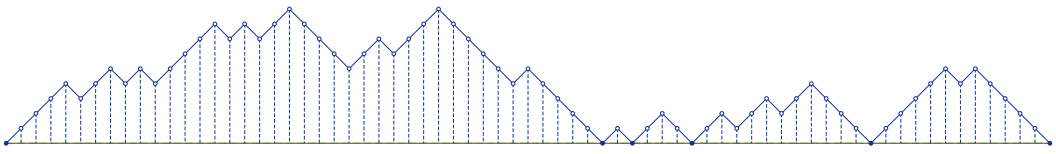

Figure 1 Simple Dyck path with $n = 35$ up and down steps.

[3] For clarity, "vertex" is only used in the sampled graph, and "node" is only used in the internal data structures.

One interpretation of Catalan objects is given by Dyck paths (Figure 1). A Dyck path is essentially a $2n$ step *balanced* one-dimensional walk with exactly n up and down steps. In Figure 1, each step moves one unit along the positive x-axis (time) and one unit up or down the positive y-axis (position). The prefix constraint implies that the y-coordinate of any point on the walk is ≥ 0 i.e. the walk never crosses the x-axis. The number of possible Dyck paths (see Theorem 62) is the n^{th} Catalan number $C_n = \frac{1}{n+1} \cdot \binom{2n}{n}$. Many important combinatorial objects occur in Catalan families of which these are an example.

We will approach the problem of partially sampling Catalan objects through Dyck paths. This, in turn, will allow us to implement access other random Catalan objects such as rooted trees, and bracketed expressions. Specifically, we will want to answer the following queries:

- DIRECTION(t): Returns the value of the t^{th} step in the Dyck path (whether the step is up or down).
- HEIGHT(t): Returns the y-position of the path after t steps (the number of up steps minus the number of down steps among the first t steps). Since a DIRECTION(t) query can be simulated using the queries HEIGHT(t) and HEIGHT($t-1$), we will not explicitly discuss the DIRECTION queries in what follows.
- FIRST-RETURN(t): If the $(t+1)^{th}$ step is upwards i.e. HEIGHT($t+1$) = HEIGHT(t) + 1, it returns the smallest index $t' > t$ such that HEIGHT(t') = HEIGHT(t). While it may not be clear why this query is important, it will be useful for querying bracketed expressions and random trees. (see Section 4.1).

4.1 Bijections to other Catalan objects

The HEIGHT query is natural for Dyck paths, but the FIRST-RETURN query is important in exploring other Catalan objects. For instance, consider a random well bracketed expression; equivalently an uniform distribution over the Dyck language. One can construct a trivial bijection between Dyck paths and words in this language by replacing up and down steps with opening and closing brackets respectively (Figure 2). The HEIGHT query corresponds to asking for the nesting depth at a certain position in the word, and FIRST-RETURN(x) returns the position after the matched closing bracket for the step $(x \to x+1)$.

There is also a natural bijection between Dyck paths and ordered rooted trees (Figure 2), by viewing the Dyck path as a transcript of the tree's DFS traversal. Starting with the root, for each "up-step" we move to a new child of the current node, and for each "down-step", we backtrack towards the root. Thus, the HEIGHT query returns the depth of a node. Also, since the Dyck path is a DFS transcript of the tree, a FIRST-RETURN query on the path can be used to find successive children of a tree node (each return produces the *next child*). For instance, in Figure 2, we can invoke FIRST-RETURN thrice starting at the first *yellow path position* to reveal the corresponding three children of the *yellow tree node*.

By definition, FIRST-RETURN(x) is meaningful only when the step from x to $x+1$ is upwards, i.e. when HEIGHT($x+1$) = HEIGHT(x)+1. We can also implement a REVERSE-FIRST-RETURN query, which is just a standard FIRST-RETURN query on the reversed Dyck path (consider a reversal of the green dashed arrows in Figure 2). The reversal implies that REVERSE-FIRST-RETURN(x) is only meaningful when HEIGHT($x-1$) = HEIGHT(x) + 1. In terms of bijections, REVERSE-FIRST-RETURN is equivalent to finding a matching opening bracket in bracketed expressions, and a PREVIOUS-CHILD query in rooted trees. We show how to implement this query in Section 4.4.7. In the case where the height at x is larger than both the heights at $x-1$ and $x+1$ (boxed nodes in Figure 2), there is no meaningful "first return" from the context of the bijections. Specifically, these nodes correspond to leaf nodes in rooted trees, or to a terminal nesting level in the bracket expression.

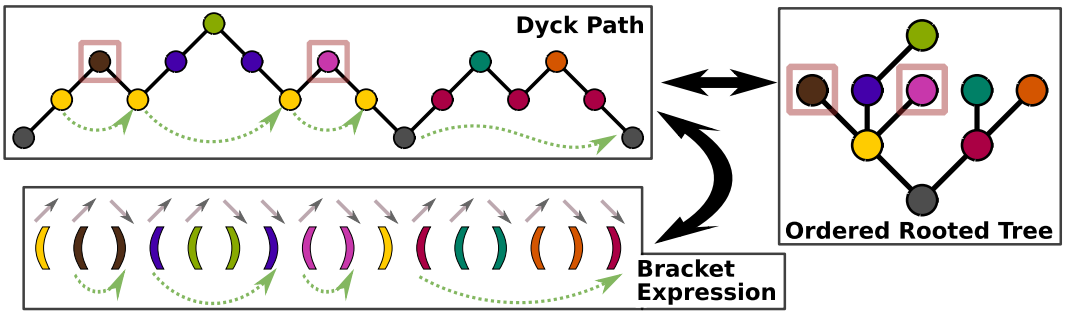

Figure 2 Bijections from Dyck paths to bracketed expressions and ordered rooted trees. Note that the color coded *positions* on the path correspond to tree nodes, and the path itself is a DFS traversal of the tree. The bijection to bracketed expressions proceeds by directly replacing up and down steps with opening and closing brackets respectively (we color the brackets with the *higher* endpoint of the corresponding step). Green dashed arrows show successive FIRST-RETURN queries on the path. Using the bijection, this is equivalent to revealing three child sub-trees in order from left to right for the corresponding tree node, and also to finding matching brackets in bracketed expressions. FIRST-RETURN is not defined for the red boxed nodes in either forward or reverse direction, since this position corresponds to a leaf node in the tree, or to a terminal nesting level in the bracket expression.

Moving forwards, we will focus on Dyck paths for the sake of simplicity.

4.2 Catalan Trapezoids and Generalized Dyck Paths

In order to implement local access to random Dyck paths, we will need to analyze more general Catalan objects. Specifically, we consider a sequence of U up-steps and D down-steps, such that any prefix of the sequence containing U' up and D' down steps satisfies $U' - D' \geq 1 - k$. This means that we start our Dyck path at a height of $k - 1$, and we are never allowed to cross below zero (Figure 3). Note that the case $k = 1$ corresponds to the standard description of Dyck paths, as mentioned previously (Figure 1).

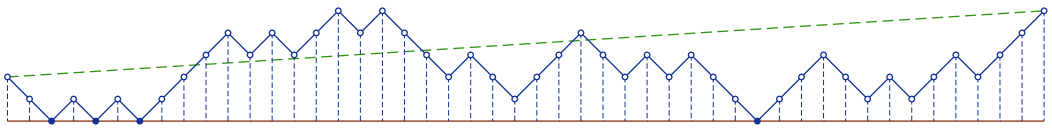

Figure 3 Generalized Dyck path with $U = 25$, $D = 22$ and $k = 3$. Note that the boundary is $k - 1 = 2$ units below the starting height.

We will denote the set of such *generalized Dyck paths* as $\mathbb{C}_k(U, D)$ and the number of paths as $C_k(U, D) = |\mathbb{C}_k(U, D)|$, which is an entry in the *Catalan Trapezoid* of order k [47]. We also use $\mathsf{C}_k(U, D)$ to denote the uniform distribution over $\mathbb{C}_k(n, m)$. Now, we state a result from [47] without proof:

$$C_k(U,D) = \begin{cases} \binom{U+D}{D} & 0 \leq D < k \\ \binom{U+D}{D} - \binom{U+D}{D-k} & k \leq D \leq U + k - 1 \\ 0 & D > U + k - 1 \end{cases} \tag{1}$$

For $k = 1$ and $n = m$, these represent the vanilla Catalan numbers i.e. $C_n = C_1(n, n)$ (number of simple Dyck paths). Our goal is to sample from the distribution $\mathsf{C}_1(n, n)$.

Consider the situation after a sequence of HEIGHT queries to the Dyck path at various locations $\langle x_1, x_2, \cdots, x_m \rangle$, such that the corresponding heights were sampled to be $\langle y_1, y_2, \cdots, y_m \rangle$. These revealed locations partition the path into disjoint *intervals* $[x_i, x_{i+1}]$, where the heights of the endpoints of each interval have been determined (as $y_i = \textsc{Height}(x_i)$). We notice that these intervals can be generated independently of each other. Specifically, the path within the interval $[x_i, x_{i+1}]$ will be sampled from $\mathsf{C}_k(U, D)$, where $k - 1 = y_i$, $U + D = x_{i+1} - x_i$, and $U - D = y_{i+1} - y_i$. Moreover, since the heights of the endpoints y_i and y_{i+1} are known, this choice is independent of any samples outside the interval. Next, in Section 4.3, we will show how one can determine heights within such an interval, and in Section 4.4 we will move on to the more complicated FIRST-RETURN queries.

4.3 Implementing Height queries

We implement $\textsc{Height}(t)$ by showing how to efficiently determine the height of the path at the midpoint of an existing interval $[x_i, x_{i+1}]$ (with corresponding endpoint heights y_i, y_{i+1}), which results in two sub-intervals that are half the size. Next, we extend this strategy to determine the heights of arbitrary positions by recursively sub-dividing the relevant interval (binary search). If the interval in question has odd length, we sample a single step from an endpoint, and proceed with a shortened even length interval. Sampling a single step is easy since there are only two outcomes (see proof of Theorem 28).

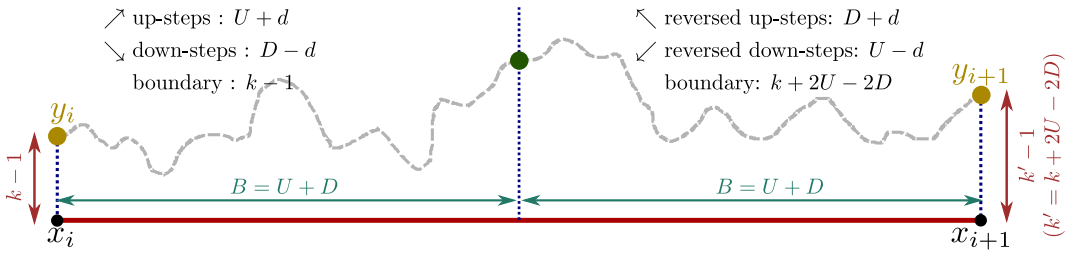

Figure 4 The $2B$-interval is split into two equal parts resulting in two separate Dyck problems. The green node (center) is the sampled height of the midpoint parameterized by the value of d. The path considered in both sub-intervals starts at a yellow node (left and right edges) and ends at the green node. From this perspective, the path on the right is reversed with up and down steps being swapped. A possible path is shown in gray.

Our general recursive step is as follows. We consider an interval of length $2B$ comprising of $2U$ up-steps and $2D$ down-steps where the sum of any prefix cannot be less than $k - 1$ i.e. the path within this interval should be sampled from $\mathsf{C}_k(2U, 2D)$. In order to make the analysis simpler, we have assumed that the number of up and down steps are both even. The case of sampling according to $\mathsf{C}_k(2U + 1, 2D + 1)$ works similarly with slightly different formulae. Without loss of generality, we assume that $D \leq U$; if this were not the case, we could simply flip the interval, swap the up and down steps, and modify the prefix constraint to $k' = k + 2U - 2D$ (Figure 4). This ensures that the overall path in the interval is non-decreasing in height, which will simpify our analysis.

We determine the height of the path $B = U + D$ steps into the interval at the midpoint (see Figure 4). This is equivalent to finding the number of up or down steps that get assigned to the first half of the interval. We parameterize the possibilities by d and define p_d to be the probability that exactly $U + d$ up-steps and $D - d$ down steps get assigned to the first half (with the remaining $U - d$ up steps and $D + d$ down steps being assigned to the second half).

$$p_d = \frac{S_{left}(d) \cdot S_{right}(d)}{S_{total}(d)} \tag{2}$$

Here, $S_{left}(d)$ denotes the number of possible paths in the first half (using $U + d$ up steps) and $S_{right}(d)$ denotes the number of possible paths in the second half (using $U - d$ up steps). Note that all of these paths have to respect the k-boundary constraint (cannot dip more than $k - 1$ units below the starting height), where $k = y_i + 1$. Moving forwards, we will drop the d when referring to the path counts. We (conceptually) flip the second half of the interval, such that the corresponding path begins from the end of the $2B$-interval and terminates at the midpoint (Figure 4). This results in a different starting point, and the prefix/boundary constraint will also be different. Hence, we define $k' = k + 2U - 2D$ to represent the new boundary constraint (since the final height of the $2B$-interval is $k' - 1$). Finally, S_{total} is the total number of possible paths in the $2B$ interval.

We cannot directly sample from this complicated distribution $\{p_d\}$. Instead, we use the rejection sampling strategy from Lemma 11. An important point to note is that in order to apply this lemma, we must be able to approximate the p_d values. However, we cannot naively use the formula from Equation 2, since the values of $\{S_{left}, S_{right}, S_{total}\}$ are too large to compute explicitly. Lemma 67 in Section F.3 shows how to indirectly compute the probabilty approximations. We also use the following lemma to bound the deviation of the path with high probability. A proof is presented in Section F.2.

▶ **Lemma 22.** *Consider a contiguous* sub-path *of a simple Dyck path of length* $2n$ *where the sub-path is of length* $2B$ *comprising of* U *up-steps and* D *down-steps (with* $U + D = 2B$*). Then there exists a constant* c *such that the quantities* $|B - U|$, $|B - D|$, *and* $|U - D|$ *are all* $< c\sqrt{B \log n}$ *with probability at least* $1 - 1/n^2$ *for every possible sub-path.*

This lemma allows us to ignore potential midpoint heights that cause a deviation greater than $c\sqrt{B \log n}$. A direct implication is that with high probability, the correctly sampled value for d will be $\mathcal{O}(\sqrt{B \log n})$. In other words, the height of the midpoint takes on one of only $\mathcal{O}(\sqrt{B \log n})$ distinct values with high probability. This immediately suggests a $\widetilde{\mathcal{O}}(\sqrt{B})$ time algorithm for determining the midpoint height, by explicitly computing the probabilities of each of these potential heights, and directly sampling from the resulting distribution. However, we can go further and obtain a $\mathcal{O}(poly(\log n))$ time algorithm.

4.3.1 The Simple Case: Far Boundary

We first consider the case when the boundary constraint is far away from the starting point, i.e. k is large. The following lemma (proof in Section F.2) shows that in this case, we can safely *ignore* the constraint. Intuitively, this is because the boundary is so far away, that with high probability, we do not hit it even if we choose a random *unconstrained* path.

▶ **Lemma 23.** *Given a Dyck path sampling problem of length* B *with* U *up,* D *down steps, and a boundary at* k*, there exists a constant* c *such that if* $k > c\sqrt{B \log n}$*, then the distribution of paths sampled without a boundary* $\mathsf{C}_\infty(U, D)$ *is* $\mathcal{O}(1/n^2)$*-close in* L_1 *distance to the distribution of Dyck paths* $\mathsf{C}_k(U + D)$*.*

By Lemma 23, the problem of sampling from $C_k(2U, 2D)$ reduces to sampling from the hypergeometric distribution $C_\infty(2U, 2D)$ when $k > \mathcal{O}(\sqrt{B \log n})$ i.e. the probabilities p_d can be approximated by:

$$q_d = \frac{\binom{B}{D-d} \cdot \binom{B}{D+d}}{\binom{2B}{2D}}$$

This problem of sampling from the hypergeometric distribution is implemented using $\mathcal{O}(poly(\log n))$ resources in [26] (see Lemma 54 in Section D). We also used this result earlier in the paper in order to find the community assignments in the Stochastic Block Model (Section 3.4.2).

4.3.2 The Difficult Case: Intervals Close to Zero

The difficult case is when $k = \mathcal{O}(\sqrt{B \log n})$, and the previous approximation due to Lemma 23 no longer works. In this case, we cannot just ignore the boundary constraint, and instead we have to analyze the true probability distribution given by p_d. We obtain an expression for p_d by substituting the formula for generalized Catalan numbers as follows: (Equation 1) into Equation 2.

$$S_{left} = C_k(U + d, D - d) \qquad S_{right} = C_{k'}(U - d, D + d) \qquad S_{total} = C_k(2U, 2D) \tag{3}$$

Since the right interval is flipped in our analysis, this changes the prefix/boundary constraint, and hence, the expression for S_{right} uses $k' = k + 2U - 2D$. This also implies that $k' = \mathcal{O}(\sqrt{B \log n})$ (using Lemma 22). We can now use Equation 2 to evaluate the probabilties $p_d = S_{left} \cdot S_{right}/S_{total}$. Recall that S_{left} and S_{right} are the number of possible paths in the left and right half of the interval, when exactly $U + d$ up steps are assigned to the first half, and S_{total} is the total number of possible paths in the interval.

We will invoke the rejection sampling technique (Lemma 11), by constructing a different distribution q_d that approximates p_d up to logarithmic factors over the vast majority of its support (we ignore all $|d| > \Theta(\sqrt{B \log n})$ since the associated probability mass is negligible by Lemma 22). In order to perform rejection sampling, we also need good approximations of p_d, which is acheved by Lemma 67 in Section F.3. Next, we define an appropriate q_d that approximates p_d and also has an *efficiently computable CDF*. Surprisingly, as in Section 4.3.1, we will be able to use the hypergeometric distribution for q_d,

$$q_d \equiv \frac{\binom{B}{D-d} \cdot \binom{B}{D+d}}{\binom{2B}{2D}} = \frac{\binom{B}{D-d} \cdot \binom{B}{U-d}}{\binom{2B}{2D}}$$

However, the argument for why this q_d is a good approximation to p_d is far less straightforward.

First, we consider the case where $k \cdot k' \leq 2U + 1$. In this case, we use loose bounds for $S_{left} < \binom{B}{D-d}$ and $S_{right} < \binom{B}{U-d}$. These are true because $\binom{B}{D-d}$ and $\binom{B}{U-d}$ are the total number of *unconstrained* paths in the left and right half respectively, and adding the boundary constraint can only reduce the number of paths. We also prove the following lemma in Section F.4 to bound the value of S_{total}.

▶ **Lemma 24.** *When $kk' > 2U + 1$, $S_{total} > \frac{1}{2} \cdot \binom{2B}{2D}$.*

Combining the three bounds, we conclude that $p_d < \frac{1}{2} q_d$. Intuitively, in this case the Dyck boundary is far away, and therefore the number of possible paths is only a constant factor away from the number of unconstrained paths (see Section 4.3.1). The case where the boundaries are closer (i.e. $k \cdot k' \leq 2U + 1$) is trickier, since the individual counts need not be close to the corresponding binomial counts. However, in this case we can still ensure that the sampling probability is within poly-logarithmic factors of the binomial sampling probability. We use the following lemmas to bound S_{left} and S_{right} (proofs in Section F.4).

▶ **Lemma 25.** *$S_{left} \leq c_1 \frac{k \cdot \sqrt{\log n}}{\sqrt{B}} \cdot \binom{B}{D-d}$ for some constant c_1.*

▶ **Lemma 26.** *$S_{right} \leq c_2 \frac{k' \cdot \sqrt{\log n}}{\sqrt{B}} \cdot \binom{B}{U-d}$ for some constant c_2.*

Finally, we obtain a diferent bound on S_{total} for the *near boundary* case.

▶ **Lemma 27.** *When $kk' \leq 2U + 1$, $S_{total} \geq c_3 \frac{k \cdot k'}{B} \cdot \binom{2B}{2D}$ for some constant c_3.*

Multiplying these inequalities together allows us to bound $p_d = S_{left} \cdot S_{right}/S_{total} \leq \Theta(q_d \log n)$, implying $p_d/q_d \leq \Theta(\log n)$. Consequently, we can leverage Lemma 11 to obtain a sample from $\{p_d\}$ using $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ samples from $\{q_d\}$, thus determining the height of the Dyck path at the midpoint of the interval.

▶ **Theorem 28.** *Given an interval $[x_i, x_{i+1}]$ (and the associated endpoint heights y_i, y_{i+1}) in a Dyck path of length $2n$, with the guarantee that no position between x_i and x_{i+1} has been sampled yet, there is an algorithm that returns the height of the path at the midpoint of x_i and x_{i+1} (or next to the midpoint if $x_{i+1} - x_i$ is odd). Moreover, this algorithm only uses $\mathcal{O}(poly(\log n))$ resources.*

Proof. If $x_{i+1} - x_i$ is even, we can set $B = (x_{i+1} - x_i)/2$. Otherwise, we first sample a single step from x_i to $x_i + 1$, and then set $B = (x_{i+1} - x_i - 1)/2$. Since there are only two possibilities for a single step, we can explicitly approximate the corresponding probabilities using the strategy outlined in the proof of Lemma 67 (see Section F.3), and then sample accordingly. This allows us to apply the rejection sampling from Lemma 11 using $\{q_d\}$ to obtain samples from $\{p_d\}$ as defined above. ◀

▶ **Theorem 29.** *There is an algorithm that provides sample access to a Dyck path of length $2n$, by answering queries of the form* HEIGHT(x) *with the correctly sampled height of the Dyck path at position x using only $\mathcal{O}(poly(\log n))$ resources per query.*

Proof. The algorithm maintains a successor-predecessor data structure (e.g. Van Emde Boas tree) to store all positions x that have already been determined. Each newly determined position is added to this structure. Given a query HEIGHT(x), the algorithm first finds the successor and predecessor (say a and b) of x among the already queried positions. This provides us the guarantee required to apply Theorem 28, which allows us to query the height at the midpoint of a and b. We then binary search by updating either the successor or predecessor of x and repeat until we determine the height of position x. ◀

4.4 Supporting "First Return" Queries

In this section, we discuss more complex queries to a Dyck path. Specifically, we implement FIRST-RETURN(x) to allow the user to query the next time the path returns to HEIGHT(x). The utility of this kind of query is illustrated through bijections to other random Catalan objects in Section 4.1. An important detail here is that if the first step from x to $x + 1$ is a down-step, there is no well defined FIRST-RETURN.

4.4.1 Maintaining a Boundary Invariant

Notice that after performing a set of HEIGHT queries $\langle x_1, x_2, \cdots, x_m \rangle$ to the Dyck path, many different positions are revealed (possibly in adversarial locations). This partitions the path into at most $m + 1$ disjoint and independent *intervals* with known boundary conditions. The first step towards finding the FIRST-RETURN from position t would be to locate the *interval* where the first return occurs. Even if we had an efficient technique to filter intervals, we would want to avoid considering all $\Theta(m)$ intervals to find the correct one. In addition, the fact that a specific interval *does not* contain the first return implies dependencies for all subsequent samples.

We resolve these difficulties by maintaining a new invariant. Consider all positions whose heights have have already been determined, either directly as a result of user given HEIGHT queries, or indirectly due to recursive HEIGHT calls; $\langle x_1, x_2, \cdots, x_m \rangle$ in increasing order i.e. $x_i < x_{i+1}$. Let the corresponding heights be $\langle y_1, y_2, \cdots, y_m \rangle$ i.e. HEIGHT$(x_i) = y_i$.

▶ **Invariant 30.** *For any interval $[x_i, x_{i+1}]$ where the heights of the endpoints have been determined to be y_i and y_{i+1}, and every other height in the interval has yet to determined, the section of the Dyck path between positions x_i and x_{i+1} is constrained to lie above $min(y_i, y_{i+1})$.*

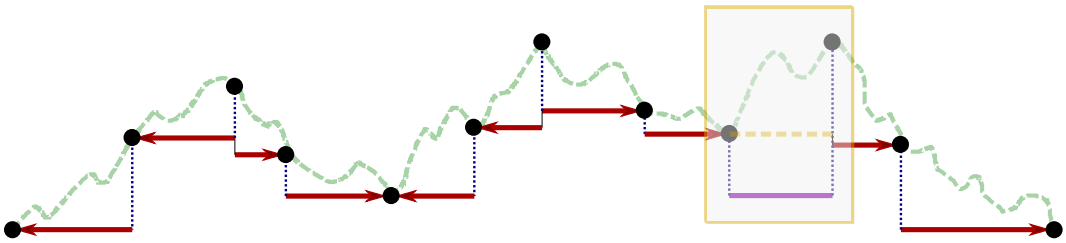

Figure 5 The set of intervals formed by a set of height samples. Each interval also has its own boundary constraint (red). Invariant 30 implies that each boundary must coincide with one of the interval endpoints. Note that the only interval which violates the invariant is the third last one (shown in yellow box).

How can one maintain such an invariant? After determining the height of a particular position x_i as y_i (with $x_{i-1} < x_i < x_{i+1}$), the invariant is potentially broken on either side of x_i. We re-establish the invariant by determining the height of an additional point on either side (see Section 4.4.6 for details). Specifically, we use the following *two step strategy* to find the additional point for some violating interval $[x_i, x_{i+1}]$ (example violation in Figure 5):

1. Sample the lowest height h achieved by the walk between x_i and x_{i+1} according to the uniform distribution over all possible paths that respect the current boundary constraint (see Section 4.4.2).
2. Find an intermediate position x such that $x_i < x < x_{i+1}$ and $\textsc{Height}(x) = h$ (see Section 4.4.3).

The newly determined position x produces two sub-intervals $[x_i, x]$ and $[x, x_{i+1}]$. Since $h = \textsc{Height}(x)$ has been determined to be the minimum height in the overall range $[x_i, x_{i+1}]$, the invariant is preserved in the new intervals (see Figure 6). Lemma 37 in Section 4.4.5 shows how this invariant can help us efficiently search for the interval containing the first return.

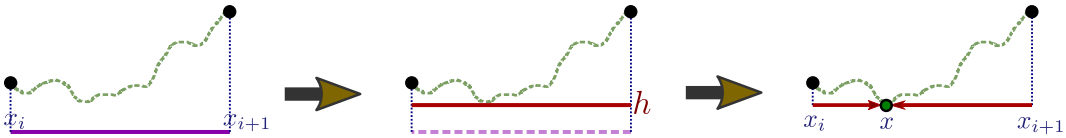

Figure 6 An interval $[x_i, x_{i+1}]$ that violates the invariant is "fixed" by first sampling the lowest height h achieved within the interval, and then generating a position $x \in [x_i, x_{i+1}]$ such that $Height(x) = h$.

4.4.2 Sampling the Lowest Achievable Height: Mandatory Boundary

First, we need to sample the lowest height h of the walk between x_i and x_{i+1} (with corresponding heights y_i and y_{i+1}). We will refer to h as the *"mandatory boundary"* in this interval; i.e. no height in the interval may be lower than the boundary, but at least one point *must* touch the boundary (have height h). We assume that $y_i \leq y_{i+1}$ without loss of generality; if this is not the case, swap x_i and x_{i+1} and consider the reversed path. Say this interval defines a generalized Dyck problem with U up steps, D down steps, and a boundary that is $k - 1$ units below y_i.

Given any two boundaries k_{lower} and k_{upper} on this interval (with $k_{lower} < k_{upper} \leq y_i$), we can count the number of possible generalized Dyck paths that violate the k_{upper} boundary but *not* the k_{lower} boundary as follows (see Figure 7):

$$P_{k_{lower}}^{k_{upper}} = C_{k_{lower}}(U, D) - C_{k_{upper}}(U, D)$$

We define the current lower and upper boundaries as $k_{low} = k, k_{up} = 0$, and set $k_{mid} =$

Algorithm 4 Finding the Mandatory boundary.

```
1:  function MANDATORY-BOUNDARY(U, D, k)
2:      k_low ← k
3:      k_up ← 0
4:      while k_low < k_up − 1
5:          k_mid ← ⌊(k_low + k_up)/2⌋
6:          P_total ← C_{k_low}(U, D) − C_{k_up}(U, D)
7:          P_{k_low}^{k_mid} ← C_{k_low}(U, D) − C_{k_mid}(U, D)
8:          with probability P_{k_low}^{k_mid} / P_total
9:              k_up ← k_mid
10:         else
11:             k_low ← k_mid
12:     return k_low
```

$(k_{low} + k_{up})/2$. Since we can compute the quantities $P_{k_{mid}}^{k_{up}}$, $P_{k_{low}}^{k_{mid}}$, and $P_{total} = P_{k_{low}}^{k_{up}}$, we can sample a single bit to decide if the *"lower boundary"* should move up or if the *"upper boundary"* should move down. We then repeat this binary search until we find $k' = k_{low} = k_{up} - 1$ and k' becomes the *"mandatory boundary"* (i.e. the walk reaches the height exactly $k' - 1$ units below y_i but no lower.

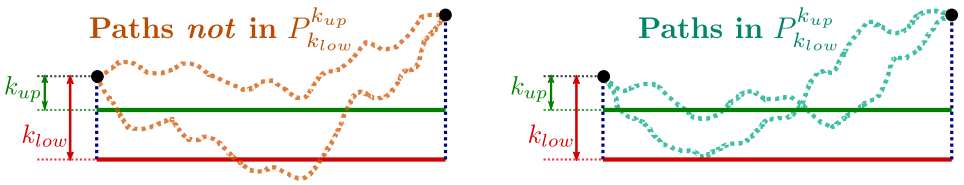

Figure 7 $P_{k_{low}}^{k_{up}}$ counts all the paths that dip at least k_{up} units below the starting point, but **do not** dip k_{low} units below the starting point. k_{mid} would lie halfway between these boundaries.

4.4.3 Determining First Position that Touches the *"Mandatory Boundary"*

Now that we have a "*mandatory boundary*" k, we just need to generate a position $x \in [x_i, x_{i+1}]$ with $\textsc{Height}(x) = y_i - k + 1$, according to the uniform distribution over all paths that touch, but do not violate the boundary at k. In fact, we will do something stronger by determining the *first* time the walk touches the boundary after x_i. As before, we assume that this interval contains U up steps and D down steps.

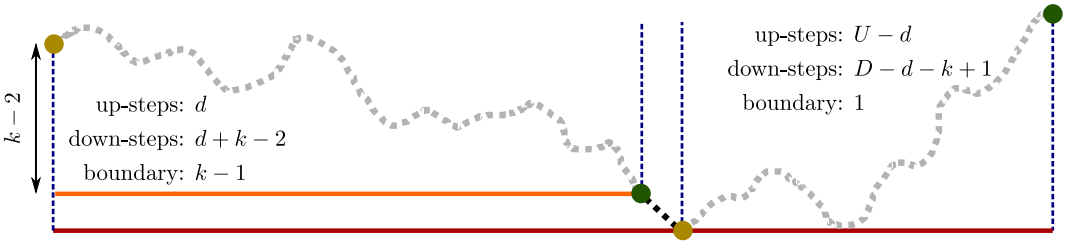

Figure 8 Zooming into the error in Figure 5. We generate a position x (yellow) on the boundary (red), such that the section of the path to the left of x never approaches the red boundary (it respects the orange boundary).

We will parameterize the position x the number of up-steps d between x_i and x (See Figure 8). implying that $x = x_i + 2d + k - 1$. Given a specific d, we want to compute the number of valid paths that result in d up-steps before the first approach to the boundary. Note that unlike Section 4.3, d is used here to parameterize the (horizontal) x-position of the desired point. We will calculate the probability p_d associated with a particular position by counting the total number of paths to the left and right of the first approach and multiplying them together.

As in Section 4.3.2, we define S_{left} to be the number of paths in the sub-interval before the first approach (left side of Figure 8), S_{right} to be the number of paths following the first approach, and S_{total} to be the total number of paths that touch the "mandatory boundary" at k (note that these quantities are functions of U, D, k and d, but we drop the parameters for the sake of clarity):

$$S_{left} = C_k(d, d+k-2) \quad S_{right} = C_1(U-d, D-d-k+1) \quad S_{total} = C_k(U, D) - C_{k-1}(U, D)$$

Our goal is to generate d from the distribution $\{p_d\}$ where $p_d = S_{left} \cdot S_{right}/S_{total}$. The application of Lemma 11 requires us to approximate $\{p_d\}$ with a "well behaved" $\{q_d\}$ (one whose CDF can be efficiently estimated). Since q_d only needs to approximate p_d up to $\text{poly}(\log n)$ factors, we focus on obtaining $\text{poly}(\log n)$ approximations to the path counts $\{S_{left}, S_{right}, S_{total}\}$. Using Equation 1, we obtain approximations for S_{left} and S_{right} (Lemma 31 and Lemma 32 with proofs in Section F.5).

▶ **Lemma 31.** *If $d > \log^4 n$, then $S_{left}(d) = \Theta\left(\frac{2^{2d+k}}{\sqrt{d}} e^{-r_{left}(d)} \cdot \frac{k-1}{d+k-1}\right)$ where $r_{left}(d) = \frac{(k-2)^2}{2(2d+k-2)}$. Furthermore, $r_{left}(d) = \mathcal{O}(\log^2 n)$.*

▶ **Lemma 32.** *If $U + D - 2d - k > \log^4 n$, then $S_{right}(d) = \Theta\left(\frac{2^{U+D-2d-k}}{\sqrt{U+d-2d-k}} e^{-r_{right}(d)} \cdot \frac{U-D+k}{U-d+1}\right)$ where $r_{right}(d) = \frac{(U-D-k-1)^2}{4(U+D-2d-k+1)}$. Furthermore, $r_{right}(d) = \mathcal{O}(\log^2 n)$.*

Our general strategy will be to integrate continuous versions of these approximations in order to obtain a CDF of some approximating distribution. Unfortunately, the continuous approximation functions obtained do not admit closed form integrals. The main culprit is the exponential term in both expressions. We tackle this issue by noticing that the values of the exponents are bounded by $\mathcal{O}(\log^2 n)$ over the majority of the range of d. Within this range of d values, the exponential term may be further simplified by taking a piecewise constant approximation, where each of the pieces corresponds to a fixed value of the *floor of the corresponding exponent*. This technique is elaborated in Section 4.4.4.

We start by considering the *"problematic"* values of d that are outside the range of the two preceding lemmas. These values are the ones where $d < \log^4 n$ or $2d > U + D - k - \log^4 n$. Since d is the number of up steps in the left sub-interval, $d \geq 0$. Further, since the length of the right sub-interval nust be non-negative (see Figure 8), we get $U + D - 2d - k + 1 \geq 0$. Thus, we define the *"problematic"* set:

$$\mathcal{R} = \left\{ d \;\middle|\; 0 \leq d < \log^4 n \textbf{ or } -1 < 2d - U - D + k < \log^4 n \right\} \tag{4}$$

Clearly, we can bound the size of this set as $|\mathcal{R}| = \mathcal{O}(\log^4 n)$. An immediate consequence of Lemma 31 and Lemma 32 is the following.

▶ **Corollary 33.** *When $d \notin \mathcal{R}$, $S_{left}(d) \cdot S_{right}(d) = \Theta\left(\frac{2^{U+D}}{\sqrt{d(U+D-2d-k)}} \cdot e^{-r(d)} \cdot \frac{k-1}{d+k-1} \cdot \frac{U-D+k}{U-d+1}\right)$ where $r(d) = \mathcal{O}(\log^2 n)$.*

4.4.4 Estimating the CDF

We use these observations to construct a suitable $\{q_d\}$ that can be used to invoke the rejection sampling lemma (Lemma 11). We will achieve this by constructing a piecewise continuous function $\hat{q}$, such that $\hat{q}(\delta)$ approximates $p_{\lfloor \delta \rfloor}$, and then use the integral of $\hat{q}$ to define the discrete distribution $\{q_d\}$. As stated in the previous section, we can leverage the fact that when $d \notin \mathcal{R}$, the floor of the exponent $\lfloor r(d) \rfloor$ only takes $\mathcal{O}(\log^2 n)$ distinct values (consequence of Corollary 33). Since the "problematic" set $\mathcal{R}$ only has $\mathcal{O}(\log^4 n)$ values, we can also deal with these remaining values by simply creating $|\mathcal{R}|$ additional continuous pieces in the function $\hat{q}$. We begin by rewriting $p_d = \Theta\left(\mathcal{K} \cdot f(d) \cdot e^{-r(d)}\right)$ where:

$$\mathcal{K} = \frac{2^{U+D}}{S_{total}} = \frac{2^{U+D}}{C_k(U,D) - C_{k-1}(U,D)} \qquad f(d) = \frac{(k-1)(U-D+k)}{\sqrt{d(U+D-2d-k)}(d+k-1)(U-d+1)} \tag{5}$$

Notice that $\mathcal{K}$ is a constant and $f(d)$ is a function whose integral has a closed form. Using the fact that $r(d) = \mathcal{O}(\log^2 n)$ (Corollary 33), and $|\mathcal{R}| = \mathcal{O}(\log^4 n)$, we obtain the following lemma:

▶ **Lemma 34.** *Given the piecewise continuous function*

$$\hat{q}(\delta) = \begin{cases} p_{\lfloor \delta \rfloor} & \text{if } \lfloor \delta \rfloor \in \mathcal{R} \\ \mathcal{K} \cdot f(\delta) \cdot exp\left(-\lfloor r(\lfloor \delta \rfloor) \rfloor\right) & \text{if } \lfloor \delta \rfloor \notin \mathcal{R} \end{cases} \qquad \Longrightarrow \qquad p_d = \Theta\left(\int_d^{d+1} \hat{q}(\delta)\right)$$

Furthermore, $\hat{q}(\delta)$ has $\mathcal{O}(\log^4 n)$ continuous pieces.

Proof. For $d \in \mathcal{R}$, the integral trivially evaluates to exactly p_d. For $d \notin \mathcal{R}$, it suffices to show that $p_d = \Theta\left(\hat{q}(\delta)\right)$ for all $\delta \in [d, d+1)$. We already know that $p_d = \Theta\left(\mathcal{K} \cdot f(d) \cdot e^{-r(d)}\right)$. Moreover, for any $\delta \in [d, d+1)$, the exponential term $e^{-\lfloor r(\lfloor \delta \rfloor) \rfloor}$ in $\hat{q}(\delta)$ is within a factor of e of the original $e^{-r(\lfloor \delta \rfloor)}$ term.

For all $\mathcal{O}(\log^4 n)$ values $d \in \mathcal{R}$, $\hat{q}(\delta)$ is constant on the interval $[d, d+1]$. Since $r(d) = \mathcal{O}(\log^2 n)$ by Corollary 33, the exponential term $e^{-\lfloor r(\lfloor \delta \rfloor) \rfloor}$ in $\hat{q}(\delta)$ taken on at most $\mathcal{O}(\log^2 n)$ values. Thus, $\hat{q}$ is continuous for a range of δ correspoding to a fixed value of $\lfloor r(\lfloor \delta \rfloor) \rfloor$, and so, we conclude that $\hat{q}$ is piecewise continuous with $\mathcal{O}(\log^2 n)$ pieces. ◀

Now, we have everything in place to define the distribution $\{q_d\}$ that we will be sampling from. Specifically, we will define q_d and it's CDF Q_d as follows ($\mathcal{N}$ is the normalizing factor):

$$q_d = \left(\int_d^{d+1} \hat{q}(\delta)\right) \cdot \frac{1}{\mathcal{N}} \qquad Q_d = \left(\int_0^{d+1} \hat{q}(\delta)\right) \cdot \frac{1}{\mathcal{N}} \qquad \text{where } \mathcal{N} = \int_0^{d_{max}+1} \hat{q}(\delta) \tag{6}$$

To show that these can be computed efficiently, it suffices to show that any integral of $\hat{q}(\delta)$ can be efficiently evaluated. This follows from the fact that $\hat{q}$ is piecewise continuous with $\mathcal{O}(\log^4)$ pieces (Lemma 34), each of which has a closed form integral (since $f(d)$ defined in Equation 5 has an integral).

▶ **Lemma 35.** *Given the function $\hat{q}_d$ defined in Lemma 34, it is possible to approximate the integral $\int_{d_1}^{d_2+1} \hat{q}(\delta)$ to a multiplicative factor of $\left(1 \pm \frac{1}{n^2}\right)$, in $\mathrm{poly}(\log n)$ time for any valid $d_1, d_2 \in \mathbb{Z}$ (the bounds must be such that $d_i \geq 0$ and $U + D - 2d_i - k + 1 \geq 0$).*

Proof. We will compute the integral by splitting it up into $\mathcal{O}(\log^4 n)$ continuous pieces and then approximating the integral over each piece. The pieces corresponding to values of $d \in \mathcal{R}$ can be explicitly computed as $\int_d^{d+1} \hat{q}(\delta) = p_d$ (recall that we can compute p_d using Lemma 67 from Section F.3).

The more interesting pieces are over the range of δ where $\lfloor \delta \rfloor \notin \mathcal{R}$. Such a piece is given by a continuous range of values $[\delta_{min}, \delta_{max}] \subseteq [d_1, d_2 + 1]$, such that for any $\delta \in [\delta_{min}, \delta_{max}]$, the value of $\lfloor r(\lfloor \delta \rfloor) \rfloor$ is a constant E. We begin the calculation of $\hat{q}(\delta) = \mathcal{K} \cdot f(\delta) \cdot exp(-E)$, by first computing a $\left(1 \pm 1/n^3\right)$ multiplicative approximation to $\ln \mathcal{K} = (U + D) \ln 2 - \ln S_{total}$, using the strategy in Lemma 67 (Section F.3). Since $f(\delta)$ has a closed form integral (Equation 5), we can also compute $F = \int_{\delta_{min}}^{\delta_{max}} f(\delta)$. Using the fact that the exponent is constant over the range $[\delta_{min}, \delta_{max}]$, we can write the logarithm of the integral as:

$$\ln \left(\int_{d_{min}}^{d_{max}} \hat{q}(\delta) \right) = \ln \left(\mathcal{K} \cdot e^{-E} \cdot F \cdot \right) = (U + D) \cdot \ln 2 - \ln S_{total} + \ln F - E$$

If this value is smaller than $-3 \ln n$, we can safely ignore it since it contrbuted less than $1/n^3$ to the probability mass. On the flipside, the logarithm is guaranteed to be bounded by $\mathcal{O}(1)$. This upper bound is a result of the fact that $\int \hat{q}(\delta) = \mathcal{O}(\sum p_d) = \mathcal{O}(1)$, where both the sum and the integral are taken over the entire *valid* range of d. This means that we can exponentiate to obtain the true value of the piecewise integral up to a multiplicative approximation of $(1 \pm 1/n^3)$. Adding the integrals of all the $\mathcal{O}(\log^4 n)$ pieces together produces the final desired value of the integral. ◀

Now, we are finally ready to use Lemma 11 to sample d from the distribution $\{p_d\}$, using the efficient sampling procedure for $\{q_d\}$. The only other requirement is the ability to approximate the p_d values, which follows from Lemma 67.

▶ **Theorem 36.** *Given a sub-interval $[x_i, x_{i+1}]$ of a random Dyck path of length $2n$, such that the only determined heights in the interval are $y_i = \textsc{Height}(x_i)$ and $y_{i+1} = \textsc{Height}(x_{i+1})$, and a mandatory boundary constraint at k, there exists an algorithm that generates a point x within the interval such that $\textsc{Height}(x) = y_i - k + 1$, using $\mathrm{poly}(\log n)$ time, random bits, and additional space.*

4.4.5 Finding the Correct Interval: `First-Return` Query

As before, consider all positions that have been queried already $\langle x_1, x_2, \cdots, x_m \rangle$ (in increasing order) along with their corresponding heights $\langle y_1, y_2, \cdots, y_m \rangle$. We wish to find the first return to height y_i after x_i (where $y_i = \textsc{Height}(x_i)$). Our strategy begins by using Invariant 30 to find the interval $\mathcal{I} = [x_k, x_{k+1}]$ containing $\textsc{First-Return}(x_i)$.

▶ **Lemma 37.** *Assuming that Invariant 30 holds, the interval $(x_{j-1}, x_j]$ containing $\textsc{First-Return}(x_i)$ is obtained by setting j to be either the smallest index $f > i$ such that $y_f \leq y_i$ or setting $j - 1 = i$.*

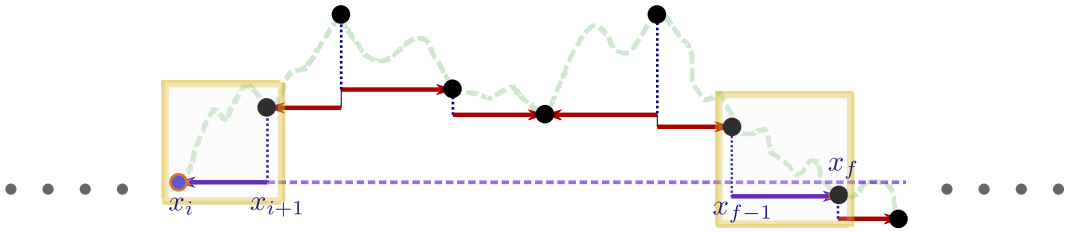

Figure 9 There are only two possible intervals (yellow boxes) that could contain $\textsc{First-Return}(x_i)$; either the interval adjacent to x_i, or the interval $[x_{f-1}, x_f]$, where f is the smallest index such that $y_f < x_i$.

Proof. We assume the contrary i.e. there exists some $k \neq f$ and $k \neq i+1$ such that the correct interval is $(x_{k-1}, x_k]$. Since $y_f < y_i$, the position of first return to y_i happens in the range $(x_i, x_f]$. So, the only possibility is $i+1 < k \leq f-1$. By the definition of y_f, we know that both y_k and y_{k-1} are strictly larger than y_i. Invariant 30 implies that the boundary for this interval $(y_{k-1}, y_k]$ is at $\min(y_{k-1}, y_k) > y_i$. So, it is not possible for the first return to be in this interval. ◀

The good news is that there are only two intervals that we need to worry about, one of which is just the adjacent one $[x_i, x_{i+1}]$. The problem of finding the other interval that may contain the first return boils down to finding the smallest index $f > i$ such that $y_f \leq y_i$. To this end, we define $M_{[a,b]}$ as the minimum determined height in the range of positions $[a, b]$.

One solution is to maintain a range tree $\mathbf{R}$ [14] over the range $[2n]$. Assuming that $2n = 2^l$, we can view $\mathbf{R}$ as a complete binary tree with depth r. Every non-leaf node is denoted by $\mathbf{R}_{[a,b]}$, and corresponds to a range $[a, b] \subseteq [2n]$ that is the union of the ranges of its children. Each $\mathbf{R}_{[a,b]}$ stores the value $M_{[a,b]}$ which is is the minimum determined height in the range of positions $[a, b]$, or ∞ if none of the heights have been revealed. The leaf nodes are denoted as $\{\mathbf{R}_i\}_{i\in[2n]}$, and correspond to the singleton range corresponding to position $i \in [2n]$. Note that a node at depth l' will correspond to a range of size $2^{l-l'}$, with the root being associated with the entire range $[2n]$.

We say that the range $[a, b]$ is *canonical* if it corresponds to a range of some $\mathbf{R}_{[a,b]}$ in $\mathbf{R}$. By the property of range trees, any arbitrary range can be decomposed into a disjoint union of $O(\log n)$ canonical ranges. We implement $\mathbf{R}$ to support the following operations:

- $\textsc{Update}(x, y)$: Update the height of the position x to y.
  This update affects all ranges $[a_i, b_i]$ containing x. So, for each $[a_i, b_i]$ we set $M_{[a_i,b_i]} = \min\left(M_{[a_i,b_i]}, y\right)$.
- $\textsc{Query}(a, b)$: Return the minimum boundary height in the range $[a, b]$.
  We decompose $[a, b]$ into $\mathcal{O}(\log n)$ *canonical* ranges $\langle r_1, r_2, \cdots\rangle$, and return the minimum of all the M_{r_i} values as $M_{[a,b]}$ (since $[a, b]$ is the union of all r_i).

Now, we can binary search for f by guessing a value f' and checking if $\textsc{Query}(x_i, x_{f'}) \leq y_i$. Overall, this requires $\mathcal{O}(\log n)$ calls to $\textsc{Query}$, each of which makes $\mathcal{O}(\log n)$ probes to the range tree. To avoid an initialization overhead, we only create the node $\mathbf{R}_{[a,b]}$ during the first $\textsc{Update}$ affecting a position $x \in [a, b]$. Since a call to $\textsc{Update}$ can create at most $\mathcal{O}(\log n)$ new nodes in $\mathbf{R}$, the additional space required for each $\textsc{Height}$ or $\textsc{First-Return}$ query is still bounded.

▶ **Theorem 38.** *There is an algorithm using $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ resources per query that provides access to a random Dyck path of length $2n$, by answering queries of the form $\textsc{First-Return}(x_i)$ with the correctly sampled smallest position $x' > x_i$, where the Dyck path first returns to $\textsc{Height}(x_i)$.*

Proof. In order to make the presentation simpler, we ensure that the next determined position after x_i is x_i+1 (in other words $x_{i+1} = x_i+1$). This can be done by invoking $\textsc{Height}(x_i+1)$, if needed. If $\textsc{Height}(x_i+1) = y_{i+1} < y_i$, we can terminate because $\textsc{First-Return}(x_i)$ is not defined. Otherwise, we notice that in this setting, the first return cannot lie in the adjacent interval $[x_i, x_{i+1}] = [x_i, x_i+1]$.

Hence, we proceed to finding the smallest value f such that $y_f \le y_i$, by using the range tree data structure described above. Since $\textsc{Height}(x_{f-1}) > y_i \le \textsc{Height}(x_f)$ by definition, the interval $(x_{f-1}, x_f]$ must contain at least one position at height y_i. We determine the height at the midpoint of this interval, and then fix the potential violation of Invariant 30 by finding another point along with its height. This essentially breaks up the interval $[x_{f-1}, x_f]$ into $\mathcal{O}(1)$ sub-intervals, each at most half the size of the original. Based on the newly revealed heights, we again find the (newly created) sub-interval containing the first return in $\mathcal{O}(1)$ time. We repeat up to $\mathcal{O}(\log n)$ times, reducing the size of the intervals in consideration, until the position of the first return is revealed. ◀

4.4.6 Maintaining `Height` Queries under Invariant 30

Finally, we show that the boundary constraints introduced in order to maintain Invariant 30 do not interfere with the implementation of $\textsc{Height}$ queries. As before, we consider the currently revealed heights $\langle y_1, y_2, \cdots, y_m\rangle$, along with the corresponding positions $\langle x_1, x_2, \cdots, x_m\rangle$ (in increasing order). Say that we are now presented with a query $\textsc{Height}(x)$, where $x_i < x < x_{i+1}$. As in Section 4.3, we swap x_i and x_{i+1} if necessary in order to ensure that $y_i < y_{i+1}$. Due to Invariant 30, we know that the lowest achievable height in the interval $[x_i, x_{i+1}]$ is y_i, i.e. the boundary constraint for the left half becomes $k = 1$ instead of $k = y_i + 1$, since the constrained boundary is at height y_i. Similarly, the boundary constraint for the right half becomes $k' = 2U - 2D + 1$.

The algorithm for determining the height at the midpoint x_{mid} of $[x_i, x_{i+1}]$ can proceed as described in Section 4.3. Of course, in this scenario, the boundary is never far away, and therefore we should always use the strategy in Section 4.3.2. The second step is to re-establish Invariant 30 in the newly created sub-interval $[x_{mid}, x_{i+1}]$[4], using the two step strategy from Section 4.4.1. This involves determining the height of one additional point $x' \in [x_{mid}, x_{i+1}]$. Finally, we can continue with the height sampling algorithm from Theorem 29, by recursively halving one of the newly created intervals (the one containing x). Figure 10 illustrates the aforementioned three steps.

Hence, we can combine results from Theorem 29 and Theorem 38 to obtain the following:

▶ **Theorem 6.** *There is an algorithm using $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ resources per query that provides access to a uniformly random Dyck path of length $2n$ by implementing the following queries:*

- $\textsc{Height}(t)$ *returns the position of the walk after t steps.*
- $\textsc{First-Return}(t)$*: If* $\textsc{Height}(t+1) > \textsc{Height}(t)$*, then* $\textsc{First-Return}(t)$ *returns the smallest index t', such that $t' > t$ and* $\textsc{Height}(t') = \textsc{Height}(t)$ *(i.e. the first time the Dyck path returns to the same height). Otherwise, if* $\textsc{Height}(t+1) < \textsc{Height}(t)$*, then* $\textsc{First-Return}(t)$ *is not defined.*

[4] Note that the invariant is not broken for the $[x_i, x_{mid}]$ sub-interval since $y_i + 1$ was the original boundary constraint. In general, the invariant will be automatically preserved for one of the sub-intervals; the side corresponding to $\min(y_i, y_{i+1})$.

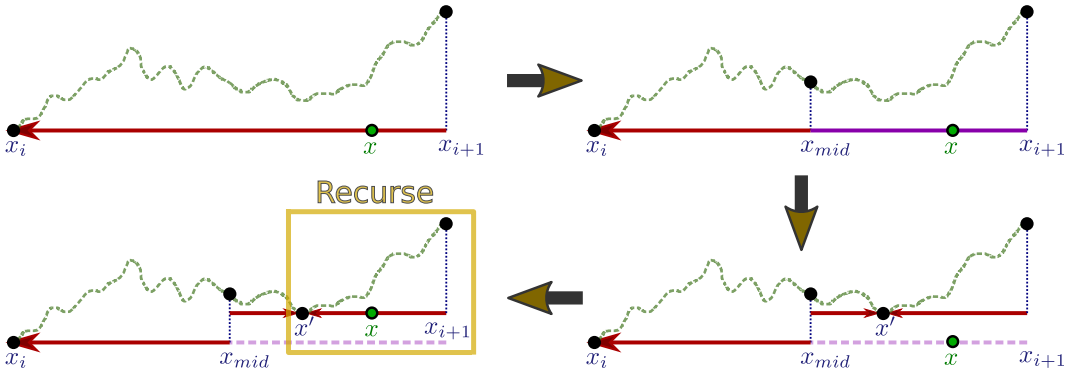

Figure 10 Performing HEIGHT queries while maintaining Invariant 30. The first step is to determine the height at the midpoint x_{mid} of an existing interval $[x_i, x_{i+1}]$ that contains x. Next, we re-establish Invariant 30 by sampling an additional point x' within the violating interval Finally, we recurse on the appropriate sub-interval (yellow box).

4.4.7 Reverse-First-Return Queries

For the sake of completeness, we also sketch how to implement a REVERSE-FIRST-RETURN query, which is just a standard FIRST-RETURN query on the reversed Dyck path. This type of query was motivated in Section 4.1, and can be applied to positions x where $\textsc{Height}(x-1) = \textsc{Height}(x) + 1$.

Note that Invariant 30 remains unchanged as it is symmetric to reversal of the Dyck path. Specifically, the invariant on a particular interval does not change if we swap the endpoints of the interval. First, we can find the correct interval containing $\textsc{Reverse-First-Return}(x)$, by using an analog of Lemma 37.

▶ **Lemma 39.** *Assuming Invariant 30, the interval* $[x_j, x_{j+1})$ *containing* $\textsc{Reverse-First-Return}(x_i)$ *is obtained by setting* j *to be either the largest index* $f < i$ *such that* $y_f \leq y_i$ *or setting* $j + 1 = i$.

Since the range tree defined in Section 4.4.5 allows us to query the minimum in arbitrary contiguous ranges, we can also use it to find the appropriate f for Lemma 39 through binary search. Once we have found an interval that is known to contain the REVERSE-FIRST-RETURN, we can follow the strategy from the proof of Theorem 38; recursively sub-dividing the relevant interval and finding the newly created sub-interval that contains the return, until we converge on the correct return position.

5 Random Coloring of a Graph

A *valid* q-coloring of a graph $G = (V, E)$ is a vector of colors $\mathbf{X} \in [q]^V$, such that for all $(u, v) \in E$, $\mathbf{X}_u \neq \mathbf{X}_v$. We present a sub-linear time algorithm to provide local access to a uniformly random valid q-coloring of an input graph. Specifically, we implement $\textsc{Color}(v)$, which returns the color $\mathbf{X}_v$ of node v, where $\mathbf{X}$ is a uniformly random valid coloring. The implementation can access the input graph G through a sub-linear number of *neighborhood queries*. A neighborhood query of the form $\textsc{All-Neighbors}(v)$ returns a list of neighbors of v. The implementation can also access a tape of public random bits $\mathbf{R}$.

Moreover, multiple independent instances of COLOR that are given access to the same public tape of random bits $\mathbf{R}$, should output color values consistent with a single $\mathbf{X}$, regardless of the order and content of the queries received. Unlike our previous results, the choice of

$\mathbf{X}$ only depends on $\mathbf{R}$, and the COLOR implementations do not need to use any additional memory to maintain consistency. For a formal description of this model, see Definition 10. This model is essentially a generalization of *Local Computation Algorithms* [48]. Given a computation problem with input x and a set of valid outputs $F(x)$, LCAs provide query access to some $y \in F(x)$ using only a sub-linear number of probes to x. This makes it feasible to consider sub-linear algorithms for problems where the output size is super-linear. Our model has the additional restriction that the output must be drawn uniformly at random from $F(x)$, rather than just being an arbitrary member. Since the number of possible outputs ($|F(x)|$) may be exponential, it is not possible to encode all the requisite random bits in sub-linear space. Therefore, we use a source of public randomness $\mathbf{R}$.

Sequential Algorithm for Random Coloring

We consider graphs with max degree Δ, and $q = \Theta(\Delta)$, since this is the regime where this problem is feasible [22]. In the sequential setting, [22] used the technique of path coupling to show that for $q > 2\Delta$, one can sample an uniformly random coloring by using a simple Markov chain. The Markov chain proceeds in T steps. The state of the chain at time t is given by $\mathbf{X}^t \in [q]^{|V|}$. Specifically, the color of vertex v at step t is $\mathbf{X}^t_v$. In each step of the Markov process, a vertex and a color are sampled uniformly at random i.e. a pair $(v, c) \sim_{\mathcal{U}} V \times [q]$. Subsequently, if the recoloring of vertex v with color c does not result in a conflict with v's neighbors, i.e. $c \notin \{\mathbf{X}^t_u : u \in \Gamma(v)\}$, then the vertex is recolored i.e. $\mathbf{X}^{t+1}_v \leftarrow c$. After running this chain for $T = \mathcal{O}(n \log(n/\epsilon))$ steps, the Markov chain is mixed, implying that the distribution of resulting colors is ϵ close to the uniform distribution in L_1 distance.

5.1 Modified Glauber Dynamics based on a Distributed Algorithm

Now we define a modified Markov chain as a special case of the *Local Glauber Dynamics* presented in [20]. The modified Markov chain proceeds in epochs. We denote the initial coloring of the graph by the vector $\mathbf{X}^0$ and the state of the coloring after the k^{th} epoch by $\mathbf{X}^k$. In the k^{th} epoch, every node attempts to recolor itself simultaneously in a conservative manner, as described below:

- Sample $|V|$ colors $\langle c_1, c_2, \cdots, c_n \rangle$ from $[q]$, where c_v is the color proposed by vertex v.
- For each vertex v, we set $\mathbf{X}^k_v$ to c_v, if and only if for all neighbors w of v, $\mathbf{X}^{k-1}_w \neq c_v$ and $c_w \neq c_v$. Specifically, a vertex v is recolored if and only if its proposed color c_v does not conflict with any of it's neighbors current colors (at the end of the previous epoch), or their current proposals.

This procedure is a special case of the *Local Glauber Dynamics*, which was presented in [20] as a distributed algorithm for sampling a random coloring.[5] In the distributed setting, our epochs correspond to synchronous rounds, where many vertices recolor themselves simultaneously.

In order to bound the mixing time of this Markov chain, [20] uses the standard technique of *path coupling*, introduced in [8]. The argument begins by considering two initial states of the Markov Chains, say two colorings $\mathbf{X}^0$ and $\mathbf{Y}^0$, that differ at only one vertex. Formally, we can define the distance between two colorings $d(\mathbf{X}, \mathbf{Y})$ as the number of vertices v such

[5] Note that [20] also uses a marking probability γ, which indicates the likelihood of any vertex participating in a given round. For our purposes, it suffices to set $\gamma = 1$.

that $\mathbf{X}_v \neq \mathbf{Y}_v$, which results in the condition $d(\mathbf{X}^0, \mathbf{Y}^0) = 1$. A *coupling* is a joint evolution rule for a pair of states $(\mathbf{X}^0, \mathbf{Y}^0) \to (\mathbf{X}^1, \mathbf{Y}^1)$, such that both of the individual evolutions $(\mathbf{X}^0 \to \mathbf{X}^1)$ and $(\mathbf{Y}^0 \to \mathbf{Y}^1)$ have the same transition probabilities as the original Markov Chain. We can directly use the result from the coupling defined in [20].

▶ **Lemma 40.** *If $q = 2\alpha\Delta$, then there exists a coupling $(\mathbf{X}^0, \mathbf{Y}^0) \to (\mathbf{X}^1, \mathbf{Y}^1)$, such that if $d(\mathbf{X}^0, \mathbf{Y}^0) = 1$, then $\mathbb{E}[d(\mathbf{X}^1, \mathbf{Y}^1)] \leq 1 - \left(1 - \frac{1}{2\alpha}\right) e^{-3/\alpha} + \frac{1/2\alpha}{1-1/\alpha}$*

▶ **Corollary 41.** *If $q \geq 9\Delta$ and $d(\mathbf{X}^0, \mathbf{Y}^0) = 1$, then $\mathbb{E}[d(\mathbf{X}^1, \mathbf{Y}^1)] < \frac{1}{e^{1/3}}$*

The *path coupling* lemma from [8] uses a coupling on adjacent states to bound the mixing time.

▶ **Lemma 42** (Simplified Path Coupling from [8])**.** *If there exists a coupling $(\mathbf{X}^0, \mathbf{Y}^0) \to (\mathbf{X}^1, \mathbf{Y}^1)$ defined for states where $d(\mathbf{X}^0, \mathbf{Y}^0) = 1$, such that $\mathbb{E}[d(\mathbf{X}^1, \mathbf{Y}^1) \mid \mathbf{X}^0, \mathbf{Y}^0] \leq \beta$ (for $\beta < 1$), then, the mixing time $\tau_{mix}(\epsilon) = \mathcal{O}(\ln(n\epsilon^{-1})/\ln \beta^{-1})$.*

▶ **Corollary 43.** *If $q \geq 9\Delta$, then the chain is mixed after $\tau_{mix}(\epsilon) = 3\left(\ln n + \ln(\frac{1}{\epsilon})\right)$ epochs.*

5.1.1 Naive Reduction from Distributed Algorithms

Using the technique of Parnas and Ron [46], one can modify a distributed algorithm for a graph problem to construct a Local Computation Algorithm for the same problem. Specifically, given a k-round distributed algorithm on a network of max degree Δ, we can simulate the behaviour and outcome of a single node v by simulating the full algorithm on the k-neighborhood of v. The simulation only requires us to probe this k-neighborhood, which contains $\mathcal{O}(\Delta^k)$ nodes. However, the aforementioned distributed algorithm for Glauber Dynamics used $\mathcal{O}(\log n)$ rounds, implying a probe complexity of $\Delta^{\mathcal{O}(\log n)}$, which is super-linear. We show how to reduce the probe complexity by appropriately pruning the k-neighborhood.

5.2 Local Coloring Algorithm

Given query access to the adjacency matrix of a graph G with maximum degree Δ and a vertex v, the algorithm has to output the color assigned to v after running $t = \mathcal{O}(\ln n)$ epochs of *Modified Glauber Dynamics*. We want to be able to answer such queries in sub-linear time, without simulating the entire Markov Chain. We will define the number of colors as $q = 2\alpha\Delta$ where $\alpha > 1$.

The proposals at each epoch are a vector of color samples $\mathbf{C}^t \sim_{\mathcal{U}} [q]^n$, where $\mathbf{C}^t_v$ is the color proposed by v in the t^{th} epoch. Since each of these $\mathbf{C}^t_v$ values are independent uniform samples from $[q]$, instances of our algorithm will be able to access them in a consistent manner using the public random bits $\mathbf{R}$.

We also use $\mathbf{X}^t$ to denote the final vector of vertex colors at the end of the t^{th} epoch. Finally, we define indicator variables $\boldsymbol{\chi}^t_v$ to indicate whether the color $\mathbf{C}^t_v$ proposed by vertex v was accepted at the t^{th} epoch: $\boldsymbol{\chi}^t_v = 1$ if and only if for all neighbors $w \in \Gamma(v)$, we satisfy the condition $\mathbf{C}^t_v \neq \mathbf{X}^{t-1}_w$ and $\mathbf{C}^t_v \neq \mathbf{C}^t_w$ (i.e. the proposed color does not conflict with any neighboring proposal or any neighbor's color from the preceding epoch). So, the color of a vertex v after the t^{th} epoch $\mathbf{X}^t_v$ is set to be $\mathbf{C}^i_v$ where $i \leq t$ is the largest index such that $\boldsymbol{\chi}^i_v = 1$. While the proposals $\mathbf{C}^t_v$ can simply be read off the public random tape $\mathbf{R}$, it is not clear how we can determine the $\boldsymbol{\chi}^t_v$ values efficiently. Computing $\mathbf{X}^t_v$ is quite simple if we know the values $\boldsymbol{\chi}^i_v$ for all $i \leq t$. So, we focus our attention on the query $\textsc{Accepted}(v, t)$ that returns $\boldsymbol{\chi}^t_v$.

5.2.1 Local Access to an Initial Valid Coloring

One caveat that we have not addressed is how we should initialize the Markov Chain. The starting state can be any valid coloring of G, but we have to be able to access the initial colors of requisite vertices in sub-linear time. One option is to simply assume that we have oracle access to an arbitrary valid coloring. We can also invoke a result from [10] that provides a *Local Computation Algorithm* for $(\Delta+1)$-coloring of a graph. Specifically, they provide local access to the color of any vertex using $\mathcal{O}(\Delta^{\mathcal{O}(1)}\log n)$ queries to the underlying graph, such that the returned colors are consistent with some valid coloring. Integrating their routine into our algorithm incurs a multiplicative poly(Δ) overhead for each query.

Another option is to (uniformly) randomly intialize the colors of the vertex independently of its neighbors. Although the initial coloring may be invalid, one can show that with high probability, the final coloring after running the Markov Chain is valid. The intuitive reasoning is that each vertex attempts to recolor itself $\mathcal{O}(\log n)$ times, and each attempt suceeds with constant probabiltity at least $1-1/\alpha$ (Lemma 44). Furthermore, we can union bound to claim that *all* the vertices get re-colored at least once with high probability. After a vertex is re-colored once, it can no longer be in conflict with any of its neighbor's colors, and therefore we obtain a final coloring that is valid. For the sake of simplicity, we will assume that our algorithm can access the initial colors of any vertex v through a public $\mathbf{C}_v^0$.

5.2.2 Naive Coloring Implementations

Our general strategy to determine $\boldsymbol{\chi}_v^t$ will be to check for all neighbors w of v, whether w causes a conflict with v's proposed color in the t^{th} epoch. One naive way to achieve this, is to iterate backwards from epoch t, querying to find out whether w's proposal was accepted, until the most recent accepted proposal (latest epoch $t' < t$ such that $\boldsymbol{\chi}_w^{t'} = 1$) is found. At this point, if $\mathbf{C}_w^{t'} = \mathbf{C}_v^t$, then the current color of w conflicts with v's proposal. Otherwise there is no conflict, and we can proceed to the next neighbor. However, this process potentially makes Δ recursive calls to a sub-problem that is only slightly smaller i.e. $T(t) \leq \Delta \cdot T(t-1)$. This leads to a running time upper bound of Δ^t which is superlinear for the desired number of epochs $t = \Omega(\log n)$ (the mixing time).

We can prune the number of recursive calls by only processing the neighbors w which actually proposed the color $\mathbf{C}_v^t$ during *some* epoch. In this case, the expected number of neighbors that have to be probed recursively is less than $t\Delta/q$ (since the total number of neighbor proposals over t epochs is at most $t\Delta$, and there are q possible colors). So, the overall runtime is upper bounded by $(t\Delta/q)^t$. For this algorithm, if we allow $q > t\Delta = \Omega(\Delta \log n)$ colors, the runtime becomes sub-linear. So, we can use this simple algorithm only when q is sufficiently large. However, we want a sub-linear time algorithm for $q = \mathcal{O}(\Delta)$.

5.2.3 A Sub-linear Time Algorithm for $q = \mathcal{O}(\Delta)$

The expected number of neighbors that need to be checked recursively can always be $t\Delta/q$ in the worst case. The crucial observation is that even though these recursive calls seem unavoidable, we can aim to reduce the size of the recursive sub-problem, and thus bound the number of levels of recursion.

Algorithm 5 shows our final procedure for generating $\boldsymbol{\chi}_v^t$, where $c = \mathbf{C}_v^t$ is v's proposal at epoch t. We iterate through all neighbors w of v, checking for conflicts (Line 3). The condition $c \neq \mathbf{C}_w^t$ can be checked by reading $\mathbf{C}_w^t$ off the public random tape (Line 4). If no conflict is seen, we proceed to check whether $c \neq \mathbf{X}_w^{t-1}$.

Algorithm 5 Checking if proposal is accepted.

```
1:  procedure ACCEPTED(v, t)
2:      c ← C_v^t                          ▷ Find the current proposal using the public random bits
3:      for w ← Γ(v)                       ▷ Iterate through the neighbors, checking for conflicts
4:          if C_w^t = c                   ▷ Check for conflict with neighbor's current proposal
5:              return 0
6:          for t' ← [t, t−1, t−2, ··· , 1, 0]   ▷ Check for conflict with neighbor's prior state
7:              if C_w^{t'} = c and ACCEPTED(w, t')   ▷ Potential conflict with neighbor's color
8:                  overwritten ← false    ▷ Check if color c is overwritten by a future proposal
9:                  for t̃ ← [t'+1, t'+2, t'+3, ··· , t−1]
10:                     if ACCEPTED(w, t̃)
11:                         overwritten ← true
12:                         break
13:                 if not overwritten
14:                     return 0           ▷ Conflict! This proposal is not accepted
15:                 break
16:     return 1                           ▷ No conflicts! This proposal is accepted
```

To achieve this, we iterate through all the epochs in reverse order (line 6) to check whether the color c was ever proposed for vertex w. If not, we can ignore w. Otherwise let's say that the most recent proposal for c was at epoch t' i.e. $\mathbf{C}_w^{t'} = c$. Now, we directly "jump" to the $(t')^{th}$ epoch and recursively check if this proposal was accepted (line 7). If the proposal $\mathbf{C}_w^{t'}$ was not accepted, we keep iterating back in time until we find the next most recent epoch when c was proposed by w, or until we run out of epochs. When we find the most recent epoch t' in which c was accepted i.e. $\boldsymbol{\chi}_w^{t'} = 1$, we successively consider epochs $t'+1, t'+2, t'+3, \cdots, t-1$, to see whether, the color c was overwritten (line 9) by an accepted proposal in a future epoch. This is done by recursively invoking $\textsc{Accepted}(w, t'+i)$ in order to compute $\boldsymbol{\chi}_w^{t'+i}$ (line 10). If at any of these subsequent iterations, we see that a different proposal was accepted (thus overwriting the color c), then neighbor w does not cause a conflict, and we can move on to the next neighbor. Otherwise, we have seen that $\boldsymbol{\chi}_w^{t'} = 1$ (color c was accepted) and every subsequent proposal until the current epoch t was rejected; this implies that color c *survived* as the color of neighbor w, i.e. $\mathbf{X}_w^{t-1} = c$. This leads to a conflict with v's current proposal for color c (line 14) and hence $\boldsymbol{\chi}_v^t = 0$. If we exhaust all the neighbors and don't find any conflicts (line 16) then $\boldsymbol{\chi}_v^t = 1$.

Now we analyze the runtime of $\textsc{Accepted}$ by constructing and solving a recurrence relation. We will use the following lemma to evaluate the expectation of products of relevant random variables.

▶ **Lemma 44.** *The probability that any given proposal is rejected* $\mathbb{P}[\boldsymbol{\chi}_v^t = 0]$ *is at most* $1/\alpha$. *Moreover, this upper bound holds even if we condition on all the values in* $\mathbf{C}$ *except* $\mathbf{C}_v^t$.

Proof. A rejection can occur due to a conflict with at most 2Δ possible values in $\{\mathbf{C}_w^t, \mathbf{X}_w^{t-1} | w \in \Gamma(v)\}$. Since there are $2\alpha\Delta$ colors, the rejection probability is at most $1/\alpha$. ◀

▶ **Definition 45.** *We define* T_t *to be a random variable indicating the number of recursive calls performed during the execution of* $\textsc{Accepted}(v, t)$ *while computing a single* $\boldsymbol{\chi}_v^t$.

▶ **Definition 46.** *We define $W^t_{t'}$ to be a random variable indicating the number of calls to* ACCEPTED *that are required, to check whether a color c assigned at epoch t' was overwritten at some epoch before t.*

Using $\mathcal{B}(p)$ to denote the Bernoulli random variable with bias p, we obtain an expression for $W^t_{t'}$ (using $\leq$ to denote stochastic dominance).

$$W^t_{t'} \leq \left[T_{t'+1} + \mathcal{B}\left(\frac{1}{\alpha}\right) \cdot T_{t'+2} + \mathcal{B}\left(\frac{1}{\alpha^2}\right) \cdot T_{t'+3} + \cdots + \mathcal{B}\left(\frac{1}{\alpha^{t-t'-2}}\right) \cdot T_{t-1} \right] \tag{7}$$

The above Equation 7 conservatively assumes that the call to ACCEPTED$(v, t'+1)$ in line 10 is always invoked (resulting in $T_{t'+1}$ invocations of ACCEPTED). However, the next call to ACCEPTED$(v, t'+2)$ occurs only if the previous one was not accepted, which happens with probability $\leq 1/\alpha$ (Lemma 44). This produces the $\mathcal{B}(1/\alpha) \cdot T_{t'+2}$ term in the expression. In general, ACCEPTED$(v, t'+i)$ is only invoked if the preceding $i-1$ calls to ACCEPTED all returned 0. This event happens with probability at most $1/\alpha^{i-1}$.

Next, we prove our main lemma that bounds the number of recursive calls to ACCEPTED.

▶ **Lemma 47.** *Given graph G and $q = 2\alpha\Delta$ colors, for $\alpha > 4.5$, the expected number of recursive calls to the procedure* ACCEPTED *while computing a single $\boldsymbol{\chi}^t_v =$* ACCEPTED(v, t) *is $\mathbb{E}[T_t] = \mathcal{O}\left(e^{1.02t/\alpha}\right)$.*

Proof. We start by constructing a recurrence for the expected number of calls to ACCEPTED used by the algorithm. When checking a single neighbor w, the algorithm iterates through all the epochs t' such that $\mathbf{C}^{t'}_w = c$ (in reality, only the last occurence matters, but we are looking for an upper bound). If such a t' is found (which happens with probability $1/q$ independently for each trial), there is a recursive call to ACCEPTED(w, t'), which in turn results in $T_{t'}$ recursive calls to ACCEPTED. If we find that $\boldsymbol{\chi}^{t'}_w = 1$ (i.e. w was colored to c at epoch t'), we will need to proceed to check whether the color was subsequently overwritten, which requires an additional $W^t_{t'}$ calls to ACCEPTED. Summing up over all neighbors and epochs, we obtain the following bound:

$$T_t \leq \sum_{w \in \Gamma(v)} \sum_{t'=1}^{t} \mathbb{P}\left[\mathbf{C}^{t'}_w = c\right] \cdot \left[T_{t'} + W^t_{t'}\right] \tag{8}$$

$$\leq \Delta \cdot \sum_{t'=1}^{t} \mathcal{B}\left(\frac{1}{q}\right) \cdot \left[T_{t'} + T_{t'+1} + \mathcal{B}\left(\frac{1}{\alpha}\right) \cdot T_{t'+2} + \mathcal{B}\left(\frac{1}{\alpha^2}\right) \cdot T_{t'+3} + \cdots \right.$$

$$\left. \cdots + \mathcal{B}\left(\frac{1}{\alpha^{t-t'-2}}\right) \cdot T_{t-1} \right] \tag{9}$$

$$\leq \Delta \cdot \mathcal{B}\left(\frac{1}{q}\right) \cdot \left[\sum_{t'=1}^{t-1} T_{t'} + \sum_{t'=1}^{t-1} T_{t'} \cdot \left(1 + \mathcal{B}\left(\frac{1}{\alpha}\right) + \mathcal{B}\left(\frac{1}{\alpha^2}\right) + \cdots\right) \right] \tag{10}$$

In the last step, we just grouped together all the terms corresponding to the same epoch (note that we include additional terms since it's an upper bound). Using Lemma 44 and the fact that $\mathbb{P}[\mathbf{C}^{t'}_w = c]$ is independent of all other events, we can write a recurrence for the expected number of probes.

$$\mathbb{E}[T_t] \leq \Delta \cdot \frac{1}{2\alpha\Delta} \left[\sum_{t'=1}^{t-1} T_{t'} + \sum_{t'=1}^{t-1} T_{t'} \cdot \left(1 + \frac{1}{\alpha} + \frac{1}{\alpha^2} + \cdots\right) \right] \leq \frac{1}{2\alpha} \cdot \sum_{t'=1}^{t-1} T_{t'} \cdot \left[1 + \frac{\alpha}{\alpha - 1}\right] \tag{11}$$

Now, we make the assumption that $\mathbb{E}[T_{t'}] \leq e^{kt/\alpha}$, and show that this satisfies the expectation recurrence for the desired value of k. First, we sum the geometric series:

$$\sum_{t'=1}^{t-1} \mathbb{E}[T_{t'}] = \sum_{t'=1}^{t-1} e^{kt'/\alpha} < \frac{e^{kt/\alpha} - 1}{e^{k/\alpha} - 1} < \frac{e^{kt/\alpha}}{e^{k/\alpha} - 1}$$

The expectation recurrence to be satisfied then becomes:

$$\mathbb{E}[T_t] \leq \frac{1}{2\alpha} \cdot \frac{e^{kt/\alpha}}{e^{k/\alpha} - 1} \cdot \left[1 + \frac{\alpha}{\alpha - 1}\right] = e^{kt/\alpha} \cdot \frac{2\alpha - 1}{2\alpha(\alpha - 1)(e^{k/\alpha} - 1)} = e^{kt/\alpha} \cdot f(\alpha, k)$$

We notice that for $k = 1.02$ and $\alpha > 4.5$, $f(\alpha) < 1$. This can easily be verified by checking that $f(\alpha, 1.02)$ decreases monotonically with α in the range $\alpha > 4.5$. Thus, our recurrence is satisfied for $k = 1.02$, and therefore the expected number of calls is $\mathcal{O}(e^{1.02t/\alpha})$. ◀

▶ **Theorem 7.** *Given neighborhood query access to a graph G with n nodes, maximum degree Δ, and $q = 2\alpha\Delta \geq 9\Delta$ colors, we can generate the color of any given node from a distribution of color assignments that is ϵ-close (in L_1 distance) to the uniform distribution over all valid colorings of G, in a consistent manner, using only $\mathcal{O}((n/\epsilon)^{3.06/\alpha}\Delta \log(n/\epsilon))$ time, probes, and public random bits per query.*

Proof. Since $q \geq 9\Delta$, we can use Corollary 43 to obtain $\tau_{mix}(\epsilon) \leq 3(\ln n + \ln 1/\epsilon)$. Also, since $\alpha > 4.5$, we can invoke Lemma 47 to conclude that the number of calls to ACCEPTED is $\mathcal{O}(n^{3.06/\alpha}\epsilon^{-3.06/\alpha})$. Finally, we note that each call to ACCEPTED(v, t) potentially reads $\mathcal{O}(t\Delta)$ color proposals from the public random tape, while iterating through all $\leq \Delta$ neighbors of v in all t epochs. Since $t \leq 3\ln(n/\epsilon)$, this implies that the algorithm uses $\mathcal{O}((n/\epsilon)^{3.06/\alpha}\Delta \log(n/\epsilon))$ time and random bits, which is sub-linear for $\alpha > 3.06$. ◀

6 Open Problems

There are many interesting directions to pursue in this area. Below, we provide a few examples of random objects that may admit local access implementations.

Small Description Size

- Provide a local access implementation of degree queries for undirected random graphs, even for $G(n, p)$. How about i^{th} neighbor queries?
- For simple models such as $G(n, p)$, provide a local access implementation of a RANDOM-TRIANGLE(v) query, that returns a uniformly random triangle containing vertex v.
- Provide a memory-less local access implementation of basic queries for undirected random graphs.
- Given an ordered graph such as a lattice, provide an implementation to locally access a random perfect matching. Interesting special cases of this problem include random domino and lozenge tilings.

Huge Description Size

- Provide a faster local access implementation for sampling the color of a specified vertex in a random q-coloring of a bounded degree graph G.
- Improve the local access implementation for sampling the color of a specified vertex in a random q-coloring of G, by supporting smaller values of q (smaller than 9Δ). We remark that this problem in particular should be feasible, by simulating a faster mixing Markov chain. The important question is whether you can you get down to $q = 2\Delta$?

- Given query access to an input graph G and starting vertex v, provide a local access implementation for sampling the location of a random walk starting at v after t steps. This may be feasible in certain restricted classes of graphs.
- Given query access to an input DNF formula, provide an implementation to access the truth value of a single variable in a uniformly random satisfying assignment.

A Further Analysis and Extensions of Algorithm 1: Sampling `Next-Neighbor` without Blocks

A.1 Performance Guarantee

This section is devoted to showing the following lemma that bounds the required resources per query of Algorithm 1. We note that we only require efficient computation of $\prod_{u\in[a,b]}(1-p_{vu})$ (and not $\sum_{u\in[a,b]} p_{vu}$), and that for the $G(n,p)$ model, the resources required for such computation is asymptotically negligible.

▶ **Theorem 48.** *Each execution of Algorithm 1 (the* NEXT-NEIGHBOR *query), with high probability,*

- *terminates within* $\mathcal{O}(\log n)$ *iterations (of its* **repeat** *loop);*
- *computes* $\mathcal{O}(\log^2 n)$ *quantities of* $\prod_{u\in[a,b]}(1-p_{vu})$*;*
- *aside from the above computations, uses* $\mathcal{O}(\log^2 n)$ *time,* $\mathcal{O}(\log n)$ *random* N*-bit words, and* $\mathcal{O}(\log n)$ *additional space.*

Proof. We focus on the number of iterations as the remaining results follow trivially. This proof is rather involved and thus is divided into several steps.

Specifying random choices

The performance of the algorithm depends on not only the random variables X_{vu}'s, but also the unused coins C_{vu}'s. We characterize the two collections of Bernoulli variables $\{X_{vu}\}$ and $\{Y_{vu}\}$ that cover all random choices made by Algorithm 1 as follows.

- Each X_{vu} (same as X_{uv}) represents the result for the *first* coin-toss corresponding to cells $\mathbf{A}[v][u]$ and $\mathbf{A}[u][v]$, which is the coin-toss obtained when X_{vu} becomes decided: either C_{vu} during a NEXT-NEIGHBOR(v) call when $\mathbf{A}[v][u]=\phi$, or C_{vu} during a NEXT-NEIGHBOR(u) call when $\mathbf{A}[u][v]=\phi$, whichever occurs first. This description of X_{vu} respects our invariant that, if the generation process is executed to completion, we will have $\mathbf{A}[v][u]=X_{vu}$ in all entries.
- Each Y_{vu} represents the result for the *second* coin-toss corresponding to cell $\mathbf{A}[v][u]$, which is the coin-toss C_{vu} obtained during a NEXT-NEIGHBOR(v) call when X_{vu} is already decided. In other words, $\{Y_{vu}\}$'s are the coin-tosses that should have been skipped but still performed in Algorithm 1 (if they have indeed been generated). Unlike the previous case, Y_{vu} and Y_{uv} are two independent random variables: they may be generated during a NEXT-NEIGHBOR(v) call and a NEXT-NEIGHBOR(u) call, respectively.

As mentioned earlier, we allow any sequence of probabilities p_{vu} in our proof. The success probabilities of these indicators are therefore given by $\mathbb{P}[X_{vu}=1]=\mathbb{P}[Y_{vu}=1]=p_{vu}$.

Characterizing iterations

Suppose that we compute NEXT-NEIGHBOR(v) and obtain an answer u. Then $X_{v,\mathbf{last}[v]+1}=\cdots=X_{v,u-1}=0$ as none of $u'\in(\mathbf{last}[v],u)$ is a neighbor of v. The vertices considered in the loop of Algorithm 1 that do not result in the answer u, are $u'\in(\mathbf{last}[v],u)$ satisfying $\mathbf{A}[v][u']=0$ and $Y_{v,u'}=1$; we call the iteration corresponding to such a u' a *failed iteration*. Observe that if $X_{v,u'}=0$ but is undecided ($\mathbf{A}[v][u']=\phi$), then the iteration is not failed, even if $Y_{v,u'}=1$ (in which case, $X_{v,u'}$ takes the value of $C_{v,u'}$ while $Y_{v,u'}$ is never used). Thus we assume the worst-case scenario where all $X_{v,u'}$ are revealed: $\mathbf{A}[v][u']=X_{v,u'}=0$ for all $u'\in(\mathbf{last}[v],u)$. The number of failed iterations in this case stochastically dominates those in all other cases.[6]

[6]There exists an adversary who can enforce this worst case. Namely, an adversary that first makes NEXT-NEIGHBOR queries to learn all neighbors of every vertex except for v, thereby filling out the whole $\mathbf{A}$ in the process. The claimed worst case then occurs as this adversary now repeatedly makes NEXT-NEIGHBOR queries on v. In particular, a committee of n adversaries, each of which is tasked to perform this series of calls corresponding to each v, can always expose this worst case.

Then, the upper bound on the number of failed iterations of a call NEXT-NEIGHBOR(v) is given by the maximum number of cells $Y_{v,u'} = 1$ of $u' \in (\mathbf{last}[v], u)$, over any $u \in (\mathbf{last}[v], n]$ satisfying $X_{v,\mathbf{last}[v]+1} = \cdots = X_{vu} = 0$. Informally, we are asking "of all consecutive cells of 0's in a single row of $\{X_{vu}\}$-table, what is the largest number of cells of 1's in the corresponding cells of $\{Y_{vu}\}$-table?"

Bounding the number of iterations required for a fixed pair $(v, \mathrm{last}[v])$

We now proceed to bounding the number of iterations required over a sampled pair of $\{X_{vu}\}$ and $\{Y_{vu}\}$, from any probability distribution. For simplicity we renumber our indices and drop the index $(v, \mathbf{last}[v])$ as follows. Let $p_1, \ldots, p_L \in [0, 1]$ denote the probabilities corresponding to the cells $\mathbf{A}[v][\mathbf{last}[v] + 1 \ldots n]$ (where $L = n - \mathbf{last}[v]$), then let $X_1, \ldots, X_L$ and $Y_1, \ldots, Y_L$ be the random variables corresponding to the same cells on $\mathbf{A}$.

For $i = 1, \ldots, L$, define the random variable Z_i in terms of X_i and Y_i so that

- $Z_i = 2$ if $X_i = 0$ and $Y_i = 1$, which occurs with probability $p_i(1 - p_i)$.
  This represents the event where i is not a neighbor, and the iteration fails.
- $Z_i = 1$ if $X_i = Y_i = 0$, which occurs with probability $(1 - p_i)^2$.
  This represents the event where i is not a neighbor, and the iteration does not fail.
- $Z_i = 0$ if $X_i = 1$, which occurs with probability p_i.
  This represents the event where i is a neighbor.

For $\ell \in [L]$, define the random variable $M_\ell := \prod_{i=1}^{\ell} Z_i$, and $M_0 = 1$ for convenience. If $X_i = 1$ for some $i \in [1, \ell]$, then $Z_i = 0$ and $M_\ell = 0$. Otherwise, $\log M_\ell$ counts the number of indices $i \in [\ell]$ with $Y_i = 1$, the number of failed iterations. Therefore, $\log(\max_{\ell \in \{0,\ldots,L\}} M_\ell)$ gives the number of failed iterations this NEXT-NEIGHBOR(v) call.

To bound M_ℓ, observe that for any $\ell \in [L]$, $\mathbb{E}[Z_\ell] = 2p_\ell(1 - p_\ell) + (1 - p_\ell)^2 = 1 - p_\ell^2 \leq 1$ regardless of the probability $p_\ell \in [0, 1]$. Then, $\mathbb{E}[M_\ell] = \mathbb{E}[\prod_{i=1}^{\ell} Z_i] = \prod_{i=1}^{\ell} \mathbb{E}[Z_i] \leq 1$ because Z_ℓ's are all independent. By Markov's inequality, for any (integer) $r \geq 0$, $\Pr[\log M_\ell > r] = \Pr[M_\ell > 2^r] < 2^{-r}$. By the union bound, the probability that more than r failed iterations are encountered is $\Pr[\log(\max_{\ell \in \{0,\ldots,L\}} M_\ell) > r] < L \cdot 2^{-r} \leq n \cdot 2^{-r}$.

Establishing the overall performance guarantee

So far we have deduced that, for each pair of a vertex v and its $\mathbf{last}[v]$, the probability that the call NEXT-NEIGHBOR(v) encounters more than r failed iterations is less that $n \cdot 2^{-r}$, which is at most n^{-c-2} for any desired constant c by choosing a sufficiently large $r = \Theta(\log n)$. As Algorithm 1 may need to support up to $\Theta(n^2)$ NEXT-NEIGHBOR calls, one corresponding to each pair $(v, \mathbf{last}[v])$, the probability that it ever encounters more than $O(\log n)$ failed iterations to answer a single NEXT-NEIGHBOR query is at most n^{-c}. That is, with high probability, $O(\log n)$ iterations are required per NEXT-NEIGHBOR call, which concludes the proof of Theorem 48. ◀

A.2 Supporting Vertex-Pair Queries

We extend our implementation (Algorithm 1) to support the VERTEX-PAIR queries: given a pair of vertices (u, v), decide whether there exists an edge $\{u, v\}$ in the generated graph. To answer a VERTEX-PAIR query, we must first check whether the value X_{uv} for $\{u, v\}$ has already been assigned, in which case we answer accordingly. Otherwise, we must make a coin-flip with the corresponding bias p_{uv} to assign X_{uv}, deciding whether $\{u, v\}$ exists in the generated graph. If we maintained the full $\mathbf{A}$, we would have been able to simply set $\mathbf{A}[u][v]$ and $\mathbf{A}[v][u]$ to this new value. However, our more efficient Algorithm 1 that represents $\mathbf{A}$ compactly via $\mathbf{last}$ and P_v's cannot record arbitrary modifications to $\mathbf{A}$.

Observe that if we were to apply the trivial implementation of VERTEX-PAIR, then by Lemma 12, **last** and P_v's will only fail capture the state $\mathbf{A}[v][u] = 0$ when $u > \mathbf{last}[v]$ and $v > \mathbf{last}[u]$. Fortunately, unlike NEXT-NEIGHBOR queries, a VERTEX-PAIR query can only set one cell $\mathbf{A}[v][u]$ to 0 per query, and thus we may afford to store these changes explicitly.[7] To this end, we define the set $Q = \{\{u, v\} : X_{uv}$ is assigned to 0 during a VERTEX-PAIR query$\}$, maintained as a hash table. Updating Q during VERTEX-PAIR queries is trivial: we simply add $\{u, v\}$ to Q before we finish processing the query if we set $\mathbf{A}[u][v] = 0$. Conversely, we need to add u to P_v and add v to P_u if the VERTEX-PAIR query sets $\mathbf{A}[u][v] = 1$ as usual, yielding the following observation. It is straightforward to verify that each VERTEX-PAIR query requires $O(\log n)$ time, $O(1)$ random N-bit word, and $O(1)$ additional space per query.

▶ **Lemma 49.** *The data structures* **last**, P_v*'s and* Q *together provide a succinct representation of* $\mathbf{A}$ *when* NEXT-NEIGHBOR *queries (modified Algorithm 1) and* VERTEX-PAIR *queries are allowed. In particular,* $\mathbf{A}[v][u] = 1$ *if and only if* $u \in P_v$*. Otherwise,* $\mathbf{A}[v][u] = 0$ *if* $u < \mathbf{last}[v]$*,* $v < \mathbf{last}[u]$*, or* $\{v, u\} \in Q$*. In all remaining cases,* $\mathbf{A}[v][u] = \phi$*.*

We now explain other necessary changes to Algorithm 1. In the implementation of NEXT-NEIGHBOR, an iteration is not failed when the chosen X_{vu} is still undecided: $\mathbf{A}[v][u]$ must still be ϕ. Since X_{vu} may also be assigned to 0 via a VERTEX-PAIR(v, u) query, we must also consider an iteration where $\{v, u\} \in Q$ failed. That is, we now require one additional condition $\{v, u\} \notin Q$ for termination (which only takes $O(1)$ time to verify per iteration). As for the analysis, aside from handling the fact that X_{vu} may also become decided during a VERTEX-PAIR call, and allowing the states of the algorithm to support VERTEX-PAIR queries, all of the remaining analysis for correctness and performance guarantee still holds.

Therefore, we have established that our augmentation to Algorithm 1 still maintains all of its (asymptotic) performance guarantees for NEXT-NEIGHBOR queries, and supports VERTEX-PAIR queries with complexities as specified above, concluding the following corollary. We remark that, as we do not aim to support RANDOM-NEIGHBOR queries, this simple algorithm here provides significant improvement over the performance of RANDOM-NEIGHBOR queries (given in Corollary 19).

▶ **Corollary 50.** *Algorithm 1 can be modified to allow an implementation of* VERTEX-PAIR *query as explained above, such that the resource usages per query still asymptotically follow those of Theorem 48.*

B Omitted Details from Section 3: Undirected Random Graph Implementations

B.1 Removing the Perfect-Precision Arithmetic Assumption

In this section we remove the prefect-precision arithmetic assumption. Instead, we only assume that it is possible to compute $\prod_{u=a}^{b}(1 - p_{vu})$ and $\sum_{u=a}^{b} p_{vu}$ to N-bit precision, as well as drawing a random N-bit word, using polylogarithmic resources. Here we will focus on proving that the family of the random graph we generate via our procedures is statistically close to that of the desired distribution. The main technicality of this lemma arises from the fact that, not only the implementation is randomized, but the agent interacting with the implementation may choose their queries arbitrarily (or adversarially): our proof must handle any sequence of random choices the implementation makes, and any sequence of queries the agent may make.

[7] The disadvantage of this approach is that the implementation may allocate more than $\Theta(m)$ space over the entire graph generation process, if VERTEX-PAIR queries generate many of these 0's.

Observe that the distribution of the graphs constructed by our implementation is governed entirely by the samples u drawn from $\mathsf{F}(v,a,b)$ in Algorithm 3. By our assumption, the CDF of any $\mathsf{F}(v,a,b)$ can be efficiently computed from $\prod_{u=a}^{u'}(1-p_{vu})$, and thus sampling with $\frac{1}{\mathrm{poly}(n)}$ error in the L_1-distance requires a random N-bit word and a binary-search in $\mathcal{O}(\log(b-a+1)) = \mathcal{O}(\log n)$ iterations. Using this crucial fact, we prove our lemma that removes the perfect-precision arithmetic assumption.

▶ **Lemma 51.** *If Algorithm 3 (the* FILL *operation) is repeatedly invoked to construct a graph G by drawing the value u for at most S times in total, each of which comes from some distribution $\mathsf{F}'(v,a,b)$ that is ϵ-close in L_1-distance to the correct distribution $\mathsf{F}(v,a,b)$ that perfectly generates the desired distribution G over all graphs, then the distribution G' of the generated graph G is (ϵS)-close to G in the L_1-distance.*

Proof. For simplicity, assume that the algorithm generates the graph to completion according to a sequence of up to n^2 distinct blocks $\mathcal{B} = \langle B_{v_1}^{(u_1)}, B_{v_2}^{(u_2)}, \ldots\rangle$, where each $B_{v_i}^{(u_i)}$ specifies the unfilled block in which any query instigates a FILL function call. Define an *internal state* of our implementation as the triplet $s = (k, u, \mathbf{A})$, representing that the algorithm is currently processing the k^{th} FILL, in the iteration (the **repeat** loop of Algorithm 3) with value u, and have generated $\mathbf{A}$ so far. Let $t_{\mathbf{A}}$ denote the *terminal state* after processing all queries and having generated the graph $G_{\mathbf{A}}$ represented by $\mathbf{A}$. We note that $\mathbf{A}$ is used here in the analysis but not explicitly maintained; further, it reflects the changes in every iteration: as u is updated during each iteration of FILL, the cells $\mathbf{A}[v][u'] = \phi$ for $u' < u$ (within that block) that has been skipped are also updated to 0.

Let $\mathcal{S}$ denote the set of all (internal and terminal) states. For each state s, the implementation samples u from the corresponding $\mathsf{F}'(v,a,b)$ where $\|\mathsf{F}(v,a,b) - \mathsf{F}'(v,a,b)\|_1 \le \epsilon = \frac{1}{\mathrm{poly}(n)}$, then moves to a new state according to u. In other words, there is an induced pair of collection of distributions over the states: $(\mathcal{T}, \mathcal{T}')$ where $\mathcal{T} = \{\mathsf{T}_s\}_{s\in\mathcal{S}}, \mathcal{T}' = \{\mathsf{T}'_s\}_{s\in\mathcal{S}}$, such that $\mathsf{T}_s(s')$ and $\mathsf{T}'_s(s')$ denote the probability that the algorithm advances from s to s' by using a sample from the correct $\mathsf{F}(v,a,b)$ and from the approximated $\mathsf{F}'(v,a,b)$, respectively. Consequently, $\|\mathsf{T}_s - \mathsf{T}'_s\|_1 \le \epsilon$ for every $s \in \mathcal{S}$.

The implementation begins with the initial (internal) state $s_0 = (1, 0, \mathbf{A}_\phi)$ where all cells of $\mathbf{A}_\phi$ are ϕ's, goes through at most $S = O(n^3)$ other states (as there are up to n^2 values of k and $O(n)$ values of u), and reach some terminal state $t_{\mathbf{A}}$, generating the entire graph in the process. Let $\pi = \langle s_0^\pi = s_0, s_1^\pi, \ldots, s_{\ell(\pi)}^\pi = t_{\mathbf{A}}\rangle$ for some $\mathbf{A}$ denote a sequence ("path") of up to $S+1$ states the algorithm proceeds through, where $\ell(\pi)$ denote the number of transitions it undergoes. For simplicity, let $T_{t_{\mathbf{A}}}(t_{\mathbf{A}}) = 1$, and $T_{t_{\mathbf{A}}}(s) = 0$ for all state $s \neq t_{\mathbf{A}}$, so that the terminal state can be repeated and we may assume $\ell(\pi) = S$ for every π. Then, for the correct transition probabilities described as $\mathcal{T}$, each π occurs with probability $q(\pi) = \prod_{i=1}^{S} \mathsf{T}_{s_{i-1}}(s_i)$, and thus $\mathsf{G}(G_{\mathbf{A}}) = \sum_{\pi: s_S^\pi = t_{\mathbf{A}}} q(\pi)$.

Let $\mathcal{T}^{\min} = \{\mathsf{T}_s^{\min}\}_{s\in\mathcal{S}}$ where $\mathsf{T}_s^{\min}(s') = \min\{\mathsf{T}_s(s'), \mathsf{T}'_s(s')\}$, and note that each $\mathsf{T}_s^{\min}$ is not necessarily a probability distribution. Then, $\sum_{s'} \mathsf{T}_s^{\min}(s') = 1 - \|\mathsf{T}_s - \mathsf{T}'_s\|_1 \ge 1 - \epsilon$. Define $q', q^{\min}, \mathsf{G}'(G_{\mathbf{A}}), \mathsf{G}^{\min}(G_{\mathbf{A}})$ analogously, and observe that $q^{\min}(\pi) \le \min\{q(\pi), q'(\pi)\}$ for every π, so $\mathsf{G}^{\min}(G_{\mathbf{A}}) \le \min\{\mathsf{G}(G_{\mathbf{A}}), \mathsf{G}'(G_{\mathbf{A}})\}$ for every $G_{\mathbf{A}}$ as well. In other words, $q^{\min}(\pi)$ lower bounds the probability that the algorithm, drawing samples from the correct distributions or the approximated distributions, proceeds through states of π; consequently, $\mathsf{G}^{\min}(G_{\mathbf{A}})$ lower bounds the probability that the algorithm generates the graph $G_{\mathbf{A}}$.

Next, consider the probability that the algorithm proceeds through the prefix $\pi_i = \langle s_0^\pi, \ldots, s_i^\pi \rangle$ of π. Observe that for $i \geq 1$,

$$\sum_\pi q^{\min}(\pi_i) = \sum_\pi q^{\min}(\pi_{i-1}) \cdot \mathsf{T}^{\min}_{s^\pi_{i-1}}(s^\pi_i) = \sum_{s,s'} \sum_{\pi : s^\pi_{i-1}=s, s^\pi_i = s'} q^{\min}(\pi_{i-1}) \cdot \mathsf{T}^{\min}_s(s')$$
$$= \sum_{s'} \mathsf{T}^{\min}_s(s') \cdot \sum_s \sum_{\pi : s^\pi_{i-1}=s} q^{\min}(\pi_{i-1}) \geq (1-\epsilon) \sum_\pi q^{\min}(\pi_{i-1}).$$

Roughly speaking, at least a factor of $1-\epsilon$ of the "agreement" between the distributions over states according to $\mathcal{T}$ and $\mathcal{T}'$ is necessarily conserved after a single sampling process. As $\sum_\pi q^{\min}(\pi_0) = 1$ because the algorithm begins with $s_0 = (1, 0, \mathbf{A}_\phi)$, by an inductive argument we have $\sum_\pi q^{\min}(\pi) = \sum_\pi q^{\min}(\pi_S) \geq (1-\epsilon)^S \geq 1 - \epsilon S$. Hence, $\sum_{G_\mathbf{A}} \min\{\mathsf{G}(G_\mathbf{A}), \mathsf{G}'(G_\mathbf{A})\} \geq \sum_{G_\mathbf{A}} \mathsf{G}^{\min}(G_\mathbf{A}) \geq 1 - \epsilon S$, implying that $\|\mathsf{G} - \mathsf{G}'\|_1 \leq \epsilon S$, as desired. In particular, by substituting $\epsilon = \frac{1}{\mathrm{poly}(n)}$ and $S = O(n^3)$, we have shown that Algorithm 3 only creates a $\frac{1}{\mathrm{poly}(n)}$ error in the L_1-distance. ◀

We remark that RANDOM-NEIGHBOR queries also require that the returned edge is drawn from a distribution that is close to a uniform one, but this requirement applies only *per query* rather then over the entire execution of the generator. Hence, the error due to the selection of a random neighbor may be handled separately from the error for generating the random graph; its guarantee follows straightforwardly from a similar analysis.

B.2 Bounding Block Sizes

▶ **Lemma 13.** *With high probability, the number of neighbors in every block, $|\Gamma^{(i)}(v)|$, is at most $\mathcal{O}(\log n)$.*

Proof. Fix a block $B_v^{(i)}$, and consider the Bernoulli RVs $\{X_{vu}\}_{u \in B_v^{(i)}}$. The expected number of neighbors in this block is $\mathbb{E}\left[|\Gamma^{(i)}(v)|\right] = \mathbb{E}\left[\sum_{u \in B_v^{(i)}} X_{vu}\right] < L + 1$. Via the Chernoff bound,

$$\mathbb{P}\left[|\Gamma^{(i)}(v)| > (1 + 3c \log n) \cdot L\right] \leq e^{-\frac{3c \log n \cdot L}{3}} = n^{-\Theta(c)}$$

for any constant $c > 0$. ◀

▶ **Lemma 14.** *With high probability, for every v such that $|\mathbf{B}_v| = \Omega(\log n)$ (i.e., $\mathbb{E} = \Omega(\log n)$), at least a 1/3-fraction of the blocks $\{B_v^{(i)}\}_{i \in [|\mathbf{B}_v|]}$ are non-empty.*

Proof. For $i < |B_v|$, since $\mathbb{E}\left[|\Gamma^{(i)}(v)|\right] = \mathbb{E}\left[\sum_{u \in B_v^{(i)}} X_{vu}\right] > L - 1$, we bound the probability that $B_v^{(i)}$ is empty:

$$\mathbb{P}[B_v^{(i)} \text{ is empty}] = \prod_{u \in B_v^{(i)}} (1 - p_{vu}) \leq e^{-\sum_{u \in B_v^{(i)}} p_{vu}} \leq e^{1-L} = c$$

for any arbitrary small constant c given sufficienty large constant L. Let T_i be the indicator for the event that $B_v^{(i)}$ is *not* empty, so $\mathbb{E}1 - c$. By the Chernoff bound, the probability that less than $|B_v|/3$ blocks are non-empty is

$$\mathbb{P}\left[\sum_{i \in [|B_v|]} T_i < \tfrac{|B_v|}{3}\right] < \mathbb{P}\left[\sum_{i \in [|B_v|-1]} T_i < \tfrac{|B_v - 1|}{2}\right] \leq e^{-\Theta(|B_v|-1)} = n^{-\Omega(1)}$$

as $|B_v| = \Omega(\log n)$ by assumption. ◀

C Next-Neighbor Implementation with Deterministic Performance Guarantee

In this section, we construct data structures that allow us to sample for the next neighbor directly by considering only the cells $\mathbf{A}[v][u] = \phi$ in the Erdös-Rényi model and the Stochastic Block model. This provides poly$(\log n)$ *worst-case* performance guarantee for implementations supporting only the Next-Neighbor queries. We may again extend this data structure to support Vertex-Pair queries, however, at the cost of providing poly$(\log n)$ *amortized* performance guarantee instead.

In what follows, we first focus on the $G(n, p)$ model, starting with Next-Neighbor queries (Section C.1) then extend to Vertex-Pair queries (Section C.2. We then explain how this result may be generalized to support the Stochastic Block model with random community assignment in Section C.3.

C.1 Data structure for next-neighbor queries in the Erdös-Rényi model

Algorithm 6 Alternate implementation.

procedure Next-Neighbor(v)
  $w \leftarrow \min K_v$, or $n+1$ if $K_v = \emptyset$
  $t \leftarrow$ count(v)
  sample $F \sim$ ExactF(p, t)
  if $F \leq t$
    $u \leftarrow$ pick(v, F)
    $K_u \leftarrow K_u \cup \{v\}$
  else
    $u \leftarrow w$
    if $u \neq n+1$
      $K_v \leftarrow K_v \setminus \{u\}$
  update(v, u)
  last$[v] \leftarrow u$
  return u

Recall that Next-Neighbor(v) is given by $\min\{u > \mathbf{last}[v] : X_{vu} = 1\}$ (or $n+1$ if no satisfying u exists). To aid in computing this quantity, we define:

$$K_v = \{u \in (\mathbf{last}[v], n] : \mathbf{A}[v][u] = 1\},$$
$$w_v = \min K_v, \text{ or } n+1 \text{ if } K_v = \emptyset,$$
$$T_v = \{u \in (\mathbf{last}[v], w_v) : \mathbf{A}[v][u] = \phi\}.$$

The ordered set K_v is only defined for ease of presentation: it is equivalent to $(\mathbf{last}[v], n] \cap P_v$, recording the known neighbors of v after **last**$[v]$ (i.e., those that have not been returned as an answer by any Next-Neighbor(v) query yet). The quantity w_v remains unchanged but is simply restated in terms of K_v. T_v specifies the list of candidates u for Next-Neighbor(v) with $\mathbf{A}[v][u] = \phi$; in particular, all candidates u's, such that the corresponding RVs $X_{vu} = 0$ are decided, are explicitly excluded from T_v.

Unlike the approach of Algorithm 1 that simulates coin-flips even for decided X_{vu}'s, here we only flip undecided coins for the indices in T_v: we have $|T_v|$ Bernoulli trials to simulate. Let F be the random variable denoting the first index of a successful trial out of

$|T_v|$ coin-flips, or $|T_v|+1$ if all fail; denote the distribution of F by $\mathsf{ExactF}(p, |T|)$. The CDF of F is given by $\mathbb{P}[F = f] = 1-(1-p)^f$ for $f \le |T_v|$ (i.e., there is some success trial in the first f trials), and $\mathbb{P}[F = |T_v|+1] = 1$. Thus, we must design a data structure that can compute w_v, compute $|T_v|$, find the F^{th} minimum value in T_v, and update $\mathbf{A}[v][u]$ for the F lowest values $u \in T_v$ accordingly.

Let $k = \lceil \log n \rceil$. We create a range tree, where each node itself contains a balanced binary search tree (BBST), storing **last** values of its corresponding range. Formally, for $i \in [0, n/2^j)$ and $j \in [0, k]$, the i^{th} node of the j^{th} level of the range tree, stores $\mathbf{last}[v]$ for every $v \in (i \cdot 2^{k-j}, (i+1) \cdot 2^{k-j}]$. Denote the range tree by $\mathbf{R}$, and each BBST corresponding to the range $[a, b]$ by $\mathbf{B}_{[a,b]}$. We say that the range $[a, b]$ is *canonical* if it corresponds to a range of some $\mathbf{B}_{[a,b]}$ in $\mathbf{R}$.

Again, to allow fast initialization, we make the following adjustments from the given formalization above: (1) values $\mathbf{last}[v] = 0$ are never stored in any $\mathbf{B}_{[a,b]}$, and (2) each $\mathbf{B}_{[a,b]}$ is created on-the-fly during the first occasion it becomes non-empty. Further, we augment each $\mathbf{B}_{[a,b]}$ so that each of its node maintains the size of the subtree rooted at that node: this allows us to count, in $O(\log n)$ time, the number of entries in $\mathbf{B}_{[a,b]}$ that is no smaller than a given threshold.

Observe that each v is included in exactly one $\mathbf{B}_{[a,b]}$ per level in $\mathbf{R}$, so $k+1 = O(\log n)$ copies of $\mathbf{last}[v]$ are stored throughout $\mathbf{R}$. Moreover, by the property of range trees, any interval can be decomposed into a disjoint union of $O(\log n)$ canonical ranges. From these properties we implement the data structure $\mathbf{R}$ to support the following operations. (Note that $\mathbf{R}$ is initially an empty tree, so initialization is trivial.)

- `COUNT`(v): compute $|T_v|$.
  We break $(\mathbf{last}[v], w_v)$ into $O(\log n)$ disjoint canonical ranges $[a_i, b_i]$'s each corresponding to some $\mathbf{B}_{[a_i,b_i]}$, then compute $t_{[a_i,b_i]} = |\{u \in [a_i, b_i] : \mathbf{last}[u] < v\}|$, and return $\sum_i t_{[a_i,b_i]}$. The value $t_{[a_i,b_i]}$ is obtained by counting the entries of $\mathbf{B}_{[a_i,b_i]}$ that is at least v, then subtract it from $b_i - a_i + 1$; we cannot count entries less than v because $\mathbf{last}[u] = 0$ are not stored.
- `PICK`(v, F): find the F^{th} minimum value in T_v (assuming $F \le |T_v|$).
  We again break $(\mathbf{last}[v], w_v)$ into $O(\log n)$ canonical ranges $[a_i, b_i]$'s, compute $t_{[a_i,b_i]}$'s, and identify the canonical range $[a^*, b^*]$ containing the i^{th} smallest element (i.e., $[a_i, b_i]$ with the smallest b satisfying $\sum_{j \le i} t_{[a_j,b_j]} \ge F$ assuming ranges are sorted). Binary-search in $[a^*, b^*]$ to find exactly the i^{th} smallest element of T. This is accomplished by traversing $\mathbf{R}$ starting from the range $[a^*, b^*]$ down to a leaf, at each step computing the children's $T_{[a,b]}$'s and deciding which child's range contains the desired element.
- `UPDATE`(v, u): simulate coin-flips, assigning $X_{vu} \leftarrow 1$, and $X_{v,u'} \leftarrow 0$ for $u' \in (\mathbf{last}[v], u) \cap T_v$.
  This is done implicitly by handling the change $\mathbf{last}[v] \leftarrow u$: for each BBST $\mathbf{B}_{[a,b]}$ where $v \in [a, b]$, remove the old value of $\mathbf{last}[v]$ and insert u instead.

It is straightforward to verify that all operations require at most $O(\log^2 n)$ time and $O(\log n)$ additional space per call. The overall implementation is given in Algorithm 6, using the same asymptotic time and additional space. Recall also that sampling $F \sim \mathsf{ExactF}(p, t)$ requires $O(\log n)$ time and one N-bit random word for the $G(n, p)$ model.

C.2 Data structure for `Vertex-Pair` queries in the Erdös-Rényi model

Recall that we define Q in Algorithm 1 as the set of pairs (u, v) where X_{uv} is assigned to 0 during a `VERTEX-PAIR` query, allowing us to check for modifications of $\mathbf{A}$ not captured by $\mathbf{last}[v]$ and K_v. Here in Algorithm 6, rather than checking, we need to be able to count such entries. Thus, we instead create a BBST Q'_v for each v defined as:

$Q'_v = \{u : u > \textbf{last}[v], v > \textbf{last}[u],$ and X_{uv} is assigned to 0 during a VERTEX-PAIR query$\}$.

This definition differs from that of Q in Section A.2 in two aspects. First, we ensure that each $\mathbf{A}[v][u] = 0$ is recorded by either **last** (via Lemma 12) or Q'_v (explicitly), but *not both*. In particular, if u were to stay in Q'_v when $\textbf{last}[v]$ increases beyond u, we would have double-counted these entries 0 not only recorded by Q'_v but also implied by $\textbf{last}[v]$ and K_v. By having a BBST for each Q'_v, we can compute the number of 0's that must be excluded from T_v, which cannot be determined via $\textbf{last}[v]$ and K_v alone: we subtract these from any counting process done in the data structure $\mathbf{R}$.

Second, we maintain Q'_v separately for each v as an ordered set, so that we may identify non-neighbors of v within a specific range – this allows us to remove non-neighbors in specific range, ensuring that the first aspect holds. More specifically, when we increase $\textbf{last}[v]$, we must go through the data structure Q'_v and remove all $u < \textbf{last}[v]$, and for each such u, also remove v from Q'_u. There can be as many as linear number of such u, but the number of removals is trivially bounded by the number of insertions, yielding an amortized time performance guarantee in the following theorem. Aside from the deterministic guarantee, unsurprisingly, the required amount of random words for this algorithm is lower than that of the algorithm from Section A (given in Theorem 48 and Corollary 50).

▶ **Theorem 52.** *Consider the Erdös-Rényi $G(n, p)$ model. For* NEXT-NEIGHBOR *queries only, Algorithm 6 is an implementation that answers each query using $O(\log^2 n)$ time, $O(\log n)$ additional space, and one N-bit random word. For* NEXT-NEIGHBOR *and* VERTEX PAIR *queries,an extension of Algorithm 6 answers each query using $O(\log^2 n)$ amortized time, $O(\log n)$ additional space, and one N-bit random word.*

C.3 Data structure for the Stochastic Block model

We employ the data structure for generating and counting the number of vertices of each community in a specified range from Section 3.4.2. We create r different copies of the data structure $\mathbf{R}$ and Q'_v, one for each community, so that we may implement the required operations separately for each color, including using the COUNT subroutine to sample $F \sim$ ExactF via the corresponding CDF, and picking the next neighbor according to F. Recall that since we do not store $\textbf{last}[v] = 0$ in $\mathbf{R}$, and we only add an entry to K_v, P_v or Q'_v after drawing the corresponding X_{uv}, the communities of the endpoints, which cover all elements stored in these data structures, must have already been determined. Thus, we obtain the following corollary for the Stochastic Block model.

▶ **Corollary 53.** *Consider the Stochastic Block model with randomly-assigned communities. For* NEXT-NEIGHBOR *queries only, Algorithm 6 is an implementation that answers each query using $O(r \operatorname{poly}(\log n))$ time, random words, and additional space per query. For* NEXT-NEIGHBOR *and* VERTEX-PAIR *queries, Algorithm 6 answers each query using $O(r \operatorname{poly}(\log n))$ amortized time, $O(r \operatorname{poly}(\log n))$ random words, and $O(r \operatorname{poly}(\log n))$ additional space per query additional space, and one N-bit random word.*

D Sampling from the Multivariate Hypergeometric Distribution

Consider the following random experiment. Suppose that we have an urn containing $B \leq n$ marbles (representing vertices), each occupies one of the r possible colors (representing communities) represented by an integer from $[r]$. The number of marbles of each color in the

urn is known: there are C_k indistinguishable marbles of color $k \in [r]$, where $C_1 + \cdots + C_r = B$. Consider the process of drawing $\ell \leq B$ marbles from this urn *without replacement*. We would like to sample how many marbles of each color we draw.

More formally, let $\mathbf{C} = \langle c_1, \ldots, c_r \rangle$, then we would like to (approximately) sample a vector $\mathbf{S}_\ell^{\mathbf{C}}$ of r non-negative integers such that

$$\Pr[\mathbf{S}_\ell^{\mathbf{C}} = \langle s_1, \ldots, s_r \rangle] = \frac{\binom{C_1}{s_1} \cdot \binom{C_2}{s_2} \cdots \binom{C_r}{s_r}}{\binom{B}{C_1 + C_2 + \cdots + C_r}}$$

where the distribution is supported by all vectors satisfying $s_k \in \{0, \ldots, C_k\}$ for all $k \in [r]$ and $\sum_{k=1}^{r} s_k = \ell$. This distribution is referred to as the *multivariate hypergeometric distribution*.

The sample $\mathbf{S}_\ell^{\mathbf{C}}$ above may be generated easily by simulating the drawing process, but this may take $\Omega(\ell)$ iterations, which have linear dependency in n in the worst case: $\ell = \Theta(B) = \Theta(n)$. Instead, we aim to generate such a sample in $O(r \operatorname{poly}(\log n))$ time with high probability. We first make use of the following procedure from [26].

▶ **Lemma 54.** *Suppose that there are T marbles of color 1 and $B - T$ marbles of color 2 in an urn, where $B \leq n$ is even. There exists an algorithm that samples $\langle s_1, s_2 \rangle$, the number of marbles of each color appearing when drawing $B/2$ marbles from the urn without replacement, in $O(\operatorname{poly}(\log n))$ time and random words. Specifically, the probability of sampling a specific pair $\langle s_1, s_2 \rangle$ where $s_1 + s_2 = T$ is approximately $\binom{B/2}{s_1}\binom{B/2}{T-s_1}/\binom{B}{T}$ with error of at most n^{-c} for any constant $c > 0$.*

In other words, the claim here only applies to the two-color case, where we sample the number of marbles when drawing exactly half of the marbles from the entire urn ($r = 2$ and $\ell = B/2$). First we generalize this claim to handle any desired number of drawn marbles ℓ (while keeping $r = 2$).

▶ **Lemma 55.** *Given C_1 marbles of color 1 and $C_2 = B - C_1$ marbles of color 2, there exists an algorithm that samples $\langle s_1, s_2 \rangle$, the number of marbles of each color appearing when drawing ℓ marbles from the urn without replacement, in $O(\operatorname{poly}(\log B))$ time and random words.*

Proof. For the base case where $B = 1$, we trivially have $\mathbf{S}_1^{\mathbf{C}} = \mathbf{C}_1$ and $\mathbf{S}_0^{\mathbf{C}} = \mathbf{C}_2$. Otherwise, for even B, we apply the following procedure.

- If $\ell \leq B/2$, generate $\mathbf{C}' = \mathbf{S}_{B/2}^{\mathbf{C}}$ using Lemma 54.
  - If $\ell = B/2$ then we are done.
  - Else, for $\ell < B/2$ we recursively generate $\mathbf{S}_\ell^{\mathbf{C}'}$.
- Else, for $\ell > B/2$, we generate $\mathbf{S}_{B-\ell}^{\mathbf{C}'}$ as above, then output $\mathbf{C} - \mathbf{S}_{B-\ell}^{\mathbf{C}'}$.

On the other hand, for odd B, we simply simulate drawing a single random marble from the urn before applying the above procedure on the remaining $B - 1$ marbles in the urn. That is, this process halves the domain size B in each step, requiring $\log B$ iterations to sample $\mathbf{S}_\ell^{\mathbf{C}}$. ◀

Lastly we generalize to support larger r.

▶ **Theorem 21.** *Given B marbles of r different colors, such that there are C_i marbles of color i, there exists an algorithm that samples $\langle s_1, s_2, \cdots, s_r \rangle$, the number of marbles of each color appearing when drawing l marbles from the urn without replacement, in $O(r \cdot \operatorname{poly}(\log B))$ time and random words.*

Proof. Observe that we may reduce $r > 2$ to the two-color case by sampling the number of marbles of the first color, collapsing the rest of the colors together. Namely, define a pair $\mathbf{D} = \langle C_1, C_2 + \cdots + C_r \rangle$, then generate $\mathbf{S}_\ell^{\mathbf{D}} = \langle s_1, s_2 + \ldots + s_r \rangle$ via the above procedure. At this point we have obtained the first entry s_1 of the desired $\mathbf{S}_\ell^{\mathbf{C}}$. So it remains to generate the number of marbles of each color from the remaining $r - 1$ colors in $\ell - s_1$ remaining draws. In total, we may generate $\mathbf{S}_\ell^{\mathbf{C}}$ by performing r iterations of the two-colored case. The error in the L_1-distance may be established similarly to the proof of Lemma 51. ◀

▶ **Theorem 56.** *Given B marbles of r different colors in $[r]$, such that there are C_i marbles of color i and a parameter $k \le r$, there exists an algorithm that samples $s_1 + s_2 + \cdots + s_k$, the number of marbles among the first k colors appearing when drawing ℓ marbles from the urn without replacement, in $O(\mathrm{poly}(\log B))$ time and random words.*

Proof. Since we don't have to find the individual counts, we can be more efficient by grouping half the colors together at each step. Formally, we define a pair $\mathbf{D} = \langle D_1, D_2 \rangle$ where $D_1 = C_1 + C_2 + \cdots + C_{r/2}$ and $D_2 = C_{r/2+1} + \cdots + C_{r-1} + C_r$. We then generate $\langle D_1', D_2' \rangle = \mathbf{S}_\ell^{\mathbf{D}}$.

- If $k < r/2$, we recursively solve the problem with the first $r/2$ colors, $B \leftarrow D_1'$, and the original value of k.
- If $k > r/2$, we recurse on the last $r/2$ colors, B set to D_2', and k set to $k - r/2$. In this case, we add D_1' to the returned value.
- Otherwise, $k = r/2$ and we can return D_1'.

The number of recursive calls is $\mathcal{O}(\log r) = \mathcal{O}(\log B)$ (since $r \le B$). So, the overall runtime is $\mathcal{O}(\mathrm{poly}(\log B))$. ◀

E Local-Access Implementations for Random Directed Graphs

In this section, we consider Kleinberg's Small-World model [31, 37] where the probability that a *directed* edge (u, v) exists is $\min\{c/(\textsc{dist}(u, v))^2, 1\}$. Here, $\textsc{dist}(u, v)$ is the Manhattan distance between u and v on a $\sqrt{n} \times \sqrt{n}$ grid. We begin with the case where $c = 1$, then generalize to different values of $c = \log^{\pm\Theta(1)}(n)$. We aim to support ALL-NEIGHBORS queries using $\mathrm{poly}(\log n)$ resources. This returns the entire list of out-neighbors of v.

E.1 Implementation for $c = 1$

Observe that since the graphs we consider here are directed, the answers to the ALL-NEIGHBOR queries are all independent: each vertex may determine its out-neighbors independently. Given a vertex v, we consider a partition of all the other vertices of the graph into sets $\{\Gamma_1^v, \Gamma_2^v, \ldots\}$ by distance: $\Gamma_k^v = \{u : \textsc{dist}(v, u) = k\}$ contains all vertices at a distance k from vertex v. Observe that $|\Gamma_k^v| \le 4k = O(k)$. Then, the expected number of edges from v to vertices in Γ_k^v is therefore $|\Gamma_k^v| \cdot 1/k^2 = O(1/k)$. Hence, the expected degree of v is at most $\sum_{k=1}^{2(\sqrt{n}-1)} O(1/k) = O(\log n)$. It is straightforward to verify that this bound holds with high probability (use Hoeffding's inequality). Since the degree of v is small, in this model we can afford to perform ALL-NEIGHBORS queries instead of NEXT-NEIGHBOR queries using an additional $\mathrm{poly}(\log n)$ resources.

Nonetheless, internally in our implementation, we generate our neighbors one-by-one similarly to how we process NEXT-NEIGHBOR queries. We perform our sampling in two phases. In the first phase, we compute a distance d, such that the next neighbor closest to v is at distance d. We maintain $\mathbf{last}[v]$ to be the last computed distance. In the second phase, we

generate all neighbors of v at distance d, under the assumption that there must be at least one such neighbor. For simplicity, we generate these neighbors as if there are *full* $4d$ vertices at distance d from v: some generated neighbors may lie outside our $\sqrt{n} \times \sqrt{n}$ grid, which are simply discarded. As the running time of our implementation is proportional to the number of implementation neighbors, then by the bound on the number of neighbors, this assumption does not asymptotically worsen the performance of the implementation.

E.1.1 Phase 1: Generate the distance D

Let $a = \mathbf{last}[v] + 1$, and let $\mathsf{D}(a)$ to denote the probability distribution of the distance where the next closest neighbor of v is located, or $\perp$ if there is no neighbor at distance at most $2(\sqrt{n} - 1)$. That is, if $D \sim \mathsf{D}(a)$ is drawn, then we proceed to Phase 2 to generate all neighbors at distance D. We repeat the process by sampling the next distance from $\mathsf{D}(a + D)$ and so on until we obtain $\perp$, at which point we return our answers and terminate.

To generate the next distance, we perform a binary search: we must evaluate the CDF of $\mathsf{D}(a)$. The CDF is given by $\mathbb{P}[D \le d]$ where $D \sim \mathsf{D}(a)$, the probability that there is *some* neighbor at distance at most d. As usual, we compute the probability of the negation: there is *no* neighbor at distance at most d. Recall that each distance i has exactly $|\Gamma_i^v| = 4i$ vertices, and the probability of a vertex $u \in \Gamma_i^v$ is not a neighbor is exactly $1 - 1/i^2$. So, the probability that there is no neighbor at distance i is $(1 - 1/i^2)^{4i}$. Thus, for $D \sim \mathsf{D}(a)$ and $d \le 2(\sqrt{n} - 1)$,

$$\mathbb{P}[D \le d] = 1 - \prod_{i=a}^{d} \left(1 - \frac{1}{i^2}\right) = 1 - \prod_{i=a}^{d} \left(\frac{(i-1)(i+1)}{i^2}\right)^{4i} = 1 - \left(\frac{(a-1)^a}{a^{a-1}} \cdot \frac{(d+1)^d}{d^{d+1}}\right)^4$$

where the product enjoys telescoping as the denominator $(i^2)^{4i}$ cancels with $(i^2)^{4(i-1)}$ and $(i^2)^{4(i+1)}$ in the numerators of the previous and the next term, respectively. This gives us a closed form for the CDF, which we can compute with 2^{-N} additive error in constant time (by our computation model assumption). Thus, we may generate the distance $D \sim \mathsf{D}(a)$ using $O(\log n)$ time and one random N-bit word.

E.1.2 Phase 2: Sampling neighbors at distance D

After sampling a distance D, we now have to generate all the neighbors at distance D. We label the vertices in Γ_D^v with unique indices in $\{1, \ldots, 4D\}$. Note that now each of the $4D$ vertices in Γ_D^v is a neighbor with probability $1/D^2$. However, by Phase 1, this is conditioned on the fact that there is at least one neighbor among the vertices in Γ_D^v, which may be difficult to generate when $1/D^2$ is very small. We can emulate this naïvely by repeatedly sampling a "block", composing of the $4D$ vertices in Γ_D^v, by deciding whether each vertex is a neighbor of v with uniform probability $1/D^2$ (i.e., $4D$ identical independent Bernoulli trials), and then discarding the entire block if it contains no neighbor. We repeat this process until we finally generate one block that contains at least one neighbor, and use this block as our output.

For the purpose of making the sampling process more efficient, we view this process differently. Let us imagine that we are given an infinite sequence of independent Bernoulli variables, each with bias $1/D^2$. We then divide the sequence into contiguous blocks of length $4D$ each. Our task is to find the *first* occurrence of success (a neighbor), then report the whole block hosting this variable.

This first occurrence of a successful Bernoulli trial is given by sampling from the geometric distribution, $X \sim \mathsf{Geo}(1/D^2)$. Since the vertices in each block are labeled by $1, \ldots, 4D$, then this first occurrence has label $X' = X \bmod 4D$. By sampling $X \sim \mathsf{Geo}(1/D^2)$, the first X'

Bernoulli variables of this block is also implicitly determined. Namely, the vertices of labels $1, \ldots, X' - 1$ are non-neighbors, and that of label X' is a neighbor. The sampling for the remaining $4D - X'$ vertices can then be performed in the same fashion we generate next neighbors in the $G(n, p)$ case: repeatedly find the next neighbor by sampling from $\mathsf{Geo}(1/D^2)$, until the index of the next neighbor falls beyond this block.

Thus at this point, we have generated all neighbors in Γ_D^v. We can then update $\mathbf{last}[v] \leftarrow D$ and continue the process of larger distances. Sampling each neighbor takes $O(\log n)$ time and one random N-bit word; the resources spent sampling the distances is also bounded by that of the neighbors. As there are $O(\log n)$ neighbors with high probability, we obtain the following theorem.

▶ **Theorem 57.** *There exists an algorithm that generates a random graph from Kleinberg's Small World model, where probability of including each directed edge (u, v) in the graph is $1/(\textsc{dist}(u, v))^2$ where $\textsc{dist}$ denote the Manhattan distance, using $O(\log^2 n)$ time and random $\log n$-bit words per $\textsc{All-Neighbors}$ query with high probability.*

E.2 Implementation for $c \neq 1$

Observe that to support different values of c in the probability function $c/(\textsc{dist}(u, v))^2$, we do not have a closed-form formula for computing the CDF for Phase 1, whereas the process for Phase 2 remains unchanged. To handle the change in the probability distribution Phase 1, we consider the following, more general problem. Suppose that we have a process P that, one-by-one, provide occurrences of successes from the sequence of independent Bernoulli trials with success probabilities $\langle p_1, p_2, \ldots \rangle$. We show how to construct a process $\mathcal{P}^c$ that provide occurrences of successes from Bernoulli trials with success probabilities $\langle c \cdot p_1, c \cdot p_2, \ldots \rangle$ (truncated down to 1 as needed). For our application, we assume that c is given in N-bit precision, there are $O(n)$ Bernoulli trials, and we aim for an error of $\frac{1}{\mathrm{poly}(n)}$ in the L_1-distance.

E.2.1 Case $c < 1$

We use rejection sampling in order to construct a new Bernoulli process.

▶ **Lemma 58.** *Given a process $\mathcal{P}$ outputting the indices of successful Bernoulli trials with bias $\langle p_i \rangle$, there exists a process $\mathcal{P}^c$ outputting the indices of successful Bernoulli trials with bias $\langle c \cdot p_i \rangle$ where $c < 1$, using one additional N-bit word overhead for each answer of $\mathcal{P}$.*

Proof. Consider the following rejection sampling process to simulate the Bernoulli trials. In addition to each Bernoulli variable X_i with bias p_i, we generate another coin-flip C_i with bias c. Set $Y_i = X_i \cdot C_i$, then $\mathbb{P}[Y_i = 1] = \mathbb{P}[X_i = 1] \cdot \mathbb{P}[C_i] = c \cdot p_i$, as desired. That is, we keep a success of a Bernoulli trial with probability c, or reject it with probability $1 - c$.

Now, we are already given the process $\mathcal{P}$ that "handles" X_i's, generating a sequence of indices i with $X_i = 1$. The new process $\mathcal{P}^c$ then only needs to handle the C_i's. Namely, for each i reported as success by $\mathcal{P}$, $\mathcal{P}^c$ flips a coin C_i to see if it should also report i, or discard it. As a result, $\mathcal{P}^c$ can generate the indices of successful Bernoulli trials using only one random N-bit word overhead for each answer from $\mathcal{P}$. ◀

Applying this reduction to the distance sampling in Phase 1, we obtain the following corollary.

▶ **Corollary 59.** *There exists an algorithm that generates a random graph from Kleinberg's Small World model with edge probabilities $c/(\textsc{dist}(u, v))^2$ where $c < 1$, using $O(\log^2 n)$ time and random $\log n$-bit words per $\textsc{All-Neighbors}$ query with high probability.*

E.2.2 Case $c > 1$

Since we aim to sample with larger probabilities, we instead consider making $k \cdot c$ independent copies of each process $\mathcal{P}$, where $k > 1$ is a positive integer. Intuitively, we hope that the probability that one of these process returns an index i will be at least $c \cdot p_i$, so that we may perform rejection sampling to decide whether to keep i or not. Unfortunately such a process cannot handle the case where $c \cdot p_i$ is large, notably when $c \cdot p_i > 1$ is truncated down to 1, while there is always a possibility that none of the processes return i.

▶ **Lemma 60.** *Let $k > 1$ be a constant integer. Given a process $\mathcal{P}$ outputting the indices of successful Bernoulli trials with bias $\langle p_i \rangle$, there exists a process $\mathcal{P}^c$ outputting the indices of successful Bernoulli trials with bias $\langle \min\{c \cdot p_i, 1\} \rangle$ where $c > 1$ and $c \cdot p_i \leq 1 - \frac{1}{k}$ for every i, using one additional N-bit word overhead for each answer of $k \cdot c$ independent copies of $\mathcal{P}$.*

Proof. By applying the following form of Bernoulli's inequality, we have

$$(1 - p_i)^{k \cdot c} \leq 1 - \frac{k \cdot c \cdot p_i}{1 + (k \cdot c - 1) \cdot p_i} = 1 - \frac{k \cdot c \cdot p_i}{1 + k \cdot c \cdot p_i - p_i} \leq 1 - \frac{k \cdot c \cdot p_i}{1 + (k - 1)} = 1 - c \cdot p_i$$

That is, the probability that at least one of the implementations report an index i is $1 - (1 - p_i)^{k \cdot c} \geq c \cdot p_i$, as required. Then, the process $\mathcal{P}^c$ simply reports i with probability $(c \cdot p_i)/(1 - (1 - p_i)^{k \cdot c})$ or discard i otherwise. Again, we only require N-bit of precision for each computation, and thus one random N-bit word suffices. ◀

In Phase 1, we may apply this reduction only when the condition $c \cdot p_i \leq 1 - \frac{1}{k}$ is satisfied. For lower value of $p_i = 1/D^2$, namely for distance $D < \sqrt{c/(1 - 1/k)} = O(\sqrt{c})$, we may afford to generate the Bernoulli trials one-by-one as c is $\mathrm{poly}(\log n)$. We also note that the degree of each vertex is clearly bounded by $O(\log n)$ with high probability, as its expectation is scaled up by at most a factor of c. Thus, we obtain the following corollary.

▶ **Corollary 61.** *There exists an algorithm that generates a random graph from Kleinberg's Small World model with edge probabilities $c/(\texttt{DIST}(u, v))^2$ where $c = \mathrm{poly}(\log n)$, using $O(\log^2 n)$ time and random words per* ALL-NEIGHBORS *query with high probability.*

F Omitted Proofs for the Dyck Path Implementation

▶ **Theorem 62.** *There are $\frac{1}{n+1}\binom{2n}{n}$ Dyck paths for length $2n$ (construction from [53]).*

Proof from [53]. Consider all possible sequences containing $n+1$ up-steps and n down-steps with the restriction that the first step is an up-step. We say that two sequences belong to the same *class* if they are cyclic shifts of each other. Because of the restriction, the total number of sequences is $\binom{2n}{n}$ and each class is of size $n + 1$. Now, within each class, exactly one of the sequences is such that the prefix sums are *strictly greater* than zero. From such a sequence, we can obtain a Dyck sequence by deleting the first up-step. Similarly, we can start with a Dyck sequence, add an initial up-step and consider all $n + 1$ cyclic shifts to obtain a *class*. This bijection shows that the number of Dyck paths is $\frac{1}{n+1}\binom{2n}{n}$. ◀

F.1 Approximating Close-to-Central Binomial Coefficients

We start with Stirling's approximation which states that

$$m! = \sqrt{2\pi m}\left(\frac{m}{e}\right)^m \left(1 + \mathcal{O}\left(\frac{1}{m}\right)\right)$$

We will also use the logarithm approximation when a better approximation is required:

$$\log(m!) = m\log m - m + \frac{1}{2}\log(2\pi m) + \frac{1}{12m} - \frac{1}{360m^3} + \frac{1}{1260m^5} - \cdots \tag{12}$$

This immediately gives us an asymptotic formula for the central binomial coefficient as:

▶ **Lemma 63.** *The central binomial coefficient can be approximated as:*

$$\binom{n}{n/2} = \sqrt{\frac{2}{\pi n}}2^n\left(1+\mathcal{O}\left(\frac{1}{n}\right)\right)$$

Now, we consider a "off-center" Binomial coefficient $\binom{n}{k}$ where $k = \frac{n+c\sqrt{n}}{2}$.

▶ **Lemma 64.**

$$\binom{n}{k} = \binom{n}{n/2}e^{-c^2/2}exp\left(\mathcal{O}(c^3/\sqrt{n})\right)$$

Proof from [52]. We consider the ratio: $R = \binom{n}{k}/\binom{n}{n/2}$:

$$R = \frac{\binom{n}{k}}{\binom{n}{n/2}} = \frac{(n/2)!(n/2)!}{k!(n-k)!} = \prod_{i=1}^{c\sqrt{n}/2}\frac{n/2-i+1}{n/2+i} \tag{13}$$

$$\implies \log R = \sum_{i=1}^{c\sqrt{n}/2}\log\left(\frac{n/2-i+1}{n/2+i}\right) \tag{14}$$

$$= \sum_{i=1}^{c\sqrt{n}/2} -\frac{4i}{n} + \mathcal{O}\left(\frac{i^2}{n^2}\right) = -\frac{c^2 n}{2n} + \mathcal{O}\left(\frac{(c\sqrt{n})^3}{n^2}\right) = -\frac{c^2}{2} + \mathcal{O}\left(\frac{c^3}{\sqrt{n}}\right) \tag{15}$$

$$\implies \binom{n}{k} = \binom{n}{n/2}e^{-c^2/2}exp\left(\mathcal{O}(c^3/\sqrt{n})\right) \tag{16}$$

◀

F.2 Dyck Path Boundaries and Deviations

▶ **Lemma 65.** *Given a random walk of length $2n$ with exactly n up and down steps, consider a contiguous* sub-path *of length $2B$ that comprises of U up-steps and D down-steps i.e. $U + D = 2B$. Both $|B - U|$ and $|B - D|$ are $\mathcal{O}(\sqrt{B\log n})$ with probability at least $1 - 1/n^4$.*

Proof. We consider the random walk as a sequence of unbiased random variables $\{X_i\}_{i=1}^{2n} \in \{0,1\}^{2n}$ with the constraint $\sum_{i=1}^{2n} X_i = n$. Here, 1 corresponds to an up-step and 0 corresponds to a down step. Because of the constraint, X_i, X_j are negatively correlated for $i \neq j$ which allows us to apply Chernoff bounds. Now we consider a sub-path of length $2B$ and let U denote the sum of the X_is associated with this subpath. Using Chernoff bound with $\mathbb{E}[X] = B$, we get:

$$\mathbb{P}\left[|U-B| < 3\sqrt{B\log n}\right] = \mathbb{P}\left[|U-B| < 3\frac{\sqrt{\log n}}{\sqrt{B}}B\right] < e^{-\frac{9\log n}{3}} = \frac{1}{n^3}$$

Since U and D are symmetric, the same argument applies. ◀

▶ **Corollary 66.** *With high probability, every contiguous sub-path of length $2B$ (with U up and D down steps such that $U + D = 2B$) in the random walk satisfies the property that $|B - U|$ and $|B - D|$ are upper bounded by $c\sqrt{B\log n}$ w.h.p. $1 - 1/n^2$ (for some constant c).*

Proof. We can simply apply Lemma 65 and union bound over all n^2 possible contiguous sub-paths. ◀

▶ **Lemma 22.** *Consider a contiguous* sub-path *of a simple Dyck path of length $2n$ where the sub-path is of length $2B$ comprising of U up-steps and D down-steps (with $U + D = 2B$). Then there exists a constant c such that the quantities $|B - U|$, $|B - D|$, and $|U - D|$ are all $< c\sqrt{B \log n}$ with probability at least $1 - 1/n^2$ for every possible sub-path.*

Proof. As a consequence of Theorem 62, we can sample a Dyck path by first sampling a *balanced* random walk with n up steps and n down steps and adding an initial up step. We can then find the corresponding Dyck path by taking the unique cyclic shift that satisfies the Dyck constraint (after removing the initial up-step). Any interval in a cyclic shift is the union of at most two intervals in the original sequence. This affects the bound only by a constant factor. So, we can simply use Corollary 66 to finish the proof. Notice that since $|U - D| \leq |B - U| + |B - D|$, $|U - D| = \mathcal{O}(\sqrt{B \log n})$ comes for free. ◀

▶ **Lemma 23.** *Given a Dyck path sampling problem of length B with U up, D down steps, and a boundary at k, there exists a constant c such that if $k > c\sqrt{B \log n}$, then the distribution of paths sampled without a boundary $\mathsf{C}_\infty(U, D)$ is $\mathcal{O}(1/n^2)$-close in L_1 distance to the distribution of Dyck paths $\mathsf{C}_k(U + D)$.*

Proof. We use $\mathcal{D}$ and $\mathcal{R}$ to denote the set of all valid Dyck paths and all random sequences respectively. Clearly, $\mathcal{D} \subseteq \mathcal{R}$. Since the random walk/sequence distribution is uniform on $\mathcal{R}$, and by Corollary 66 we see that at least $1 - 1/n^2$ fraction of the elements of $\mathcal{R}$ do not violate the boundary constraint. Therefore, $|\mathcal{D}| \geq (1 - 1/n^2)|\mathcal{R}|$, and so the L_1 distance between the uniform distributions on $\mathcal{D}$ and $\mathcal{R}$ is $\mathcal{O}(1/n^2)$. ◀

F.3 Estimating the Sampling Probabilities

▶ **Lemma 67.** *Given a Dyck sub-path problem within a global Dyck path of size $2n$ and a probability expression of the form $p_d = \frac{S_{left} \cdot S_{right}}{S_{total}}$, there exists a* $\text{poly}(\log n)$ *time oracle that returns a $\left(1 \pm 1/n^2\right)$ multiplicative approximation to p_d if $p_d = \Omega(1/n^2)$ and returns* 0 *otherwise.*

Proof. We first compute a $1 + 1/n^3$ multiplicative approximation to $\ln p_d$. Using $\mathcal{O}(\log n)$ terms of the series in Equation 12, it is possible to estimate the logarithm of a factorial up to $1/n^c$ additive error. So, we can use the series expansion from Equation 12 up to $\mathcal{O}(\log n)$ terms. The additive error can also be cast as multiplicative since factorials are large positive integers.

The probability p_d can be written as an arithmetic expression involving sums and products of a constant number of factorial terms. Given a $1 \pm 1/n^c$ multiplicative approximation to $l_a = \ln a$ and $l_a = \ln b$, we wish to approximate $\ln(ab)$ and $\ln(a + b)$. The former is trivial since $\ln(ab) = l_a + l_b$. For the latter, we assume $a > b$ and use the identity $\ln(a + b) = \ln a + \ln(1 + b/a)$ to note that it suffices to approximate $\ln(1 + b/a)$. We define $\widetilde{l_a} = l_a \cdot (1 \pm \mathcal{O}(1/n^c))$ and $\widetilde{l_b} = l_b \cdot (1 \pm \mathcal{O}(1/n^c))$. In case $\widetilde{l_b} - \widetilde{l_a} < -c \ln n \implies b/a < 1/n^c$, we approximate $\ln(a + b)$ by $\ln a$ since $\ln(1 + b/a) = \mathcal{O}(1/n^c)$ in this case.

Otherwise, we notice that $\max(a, b) = \mathcal{O}\left((n!)^2\right) \implies \max(l_a, l_b) = o(n^3) \implies l_a - l_b = o(n^3)$. This is true because if we write out the expression for $p_d = S_{left} \cdot S_{right}/S_{total}$ in terms of sums and products of factorials, the largest possible value will be a product of at most two terms that are present in the numerator/denominator of a binomial term (see the expression

for generalized Catalan numbers in Equation 1). Hence, the claim $\max(a,b) = \mathcal{O}\left((n!)^2\right)$ follows from the fact that the numerators/denominators of the relevant binomial coefficient in Equation 1 are at most $n!$. Using this fact, we obtain the following:

$$1 + e^{\widetilde{l}_b - \widetilde{l}_a} = 1 + \frac{b}{a} \cdot e^{\mathcal{O}\left(\frac{l_b - l_a}{n^c}\right)} = 1 + \frac{b}{a} \cdot \left(1 \pm \mathcal{O}\left(\frac{1}{n^{c-3}}\right)\right) = \left(1 + \frac{b}{a}\right) \cdot \left(1 \pm \mathcal{O}\left(\frac{1}{n^{c-3}}\right)\right)$$

In other words, the value of c decreases every time we have a sum operation. Since there are only a constant number of such arithmetic operations in the expression for p_d, we can set c to be a high enough constant when approximating the factorials, cewhich allows us to obtain the desired $1 \pm 1/n^3$ multiplicative approximation to $\ln p_d$. If $\ln p_d < -3 \ln n$, we approximate $p_d = 0$. Otherwise, we can exponentiate the approximation to obtain $\widetilde{p}_d = p_d \cdot e^{-\mathcal{O}(\ln n / n^3)} = p_d \left(1 \pm \mathcal{O}(1/n^2)\right)$. ◀

F.4 Omitted Proofs from Section 4.3: Sampling the Height

▶ **Lemma 68.** *For $x < 1$ and $k \geq 1$, we claim that $1 - kx < (1-x)^k < 1 - kx + \frac{k(k-1)}{2}x^2$*

▶ **Lemma 25.** *$S_{left} \leq c_1 \frac{k \cdot \sqrt{\log n}}{\sqrt{B}} \cdot \binom{B}{D-d}$ for some constant c_1.*

Proof. This involves some simple manipulations.

$$S_{left} = \binom{B}{D-d} - \binom{B}{D-d-k} \tag{17}$$

$$= \binom{B}{D-d} \cdot \left[1 - \frac{(D-d)(D-d-1)\cdots(D-d-k+1)}{(B-D-d+k)(B-D-d+k-1)\cdots(B-D-d+1)}\right] \tag{18}$$

$$\leq \binom{B}{D-d} \cdot \left[1 - \left(\frac{D-d-k+1}{B-D+d+k}\right)^k\right] \tag{19}$$

$$\leq \binom{B}{D-d} \cdot \left[1 - \left(\frac{U+d+k-(U-D+d+k-1)}{U+d+k}\right)^k\right] \tag{20}$$

$$\leq \binom{B}{D-d} \cdot \left[1 - \left(\frac{U+d+k-\mathcal{O}(\sqrt{B\log n})}{U+d+k}\right)^k\right] \tag{21}$$

$$\leq \Theta\left(\frac{k\sqrt{\log n}}{\sqrt{B}}\right) \cdot \binom{B}{D-d} \tag{22}$$

◀

▶ **Lemma 26.** *$S_{right} \leq c_2 \frac{k' \cdot \sqrt{logn}}{\sqrt{B}} \cdot \binom{B}{U-d}$ for some constant c_2.*

Proof.

$$S_{right} = \binom{B}{U-d} - \binom{B}{U-d-k'} \tag{23}$$

$$= \binom{B}{U-d} \cdot \left[1 - \frac{(U-d)(U-d-1)\cdots(U-d-k'+1)}{(B-U-d+k')(B-U-d+k'-1)\cdots(B-U-d+1)}\right] \tag{24}$$

$$\dots \leq \binom{B}{U-d} \cdot \left[1 - \left(\frac{U-d-k'+1}{B-U+d+k'}\right)^{k'}\right] \tag{25}$$

$$\leq \binom{B}{U-d} \cdot \left[1 - \left(\frac{2D-U-d-k+1}{2U-D+k+d}\right)^{k'}\right] \tag{26}$$

$$\leq \binom{B}{U-d} \cdot \left[1 - \left(\frac{U+k+d-(2U-2D+2d+2k-1)}{U+k+d}\right)^{k'}\right] \tag{27}$$

$$\leq \binom{B}{U-d} \cdot \left[1 - \left(\frac{U+k+d-\mathcal{O}(\sqrt{B\log n})}{U+k+d}\right)^{k'}\right] \tag{28}$$

$$\leq \Theta\left(\frac{k'\sqrt{\log n}}{\sqrt{B}}\right) \cdot \binom{B}{U-d} \tag{29}$$

◀

▶ **Lemma 69.** $S_{tot} \geq \binom{2B}{2D} \cdot \left[1 - \left(1 - \frac{k'}{2U+1}\right)^{k}\right]$.

Proof.

$$S_{tot} = \binom{2B}{2D} - \binom{2B}{2D-k} \tag{30}$$

$$= \binom{2B}{2D} \cdot \left[1 - \frac{(2D)(2D-1)\cdots(2D-k+1)}{(2B-2D+k)(2B-2D+k-1)\cdots(2B-2D+1)}\right] \tag{31}$$

$$\geq \binom{2B}{2D} \cdot \left[1 - \left(\frac{2D-k+1}{2B-2D+1}\right)^{k}\right] \tag{32}$$

$$\geq \binom{2B}{2D} \cdot \left[1 - \left(\frac{2U-(2U-2D+k-1)}{2U+1}\right)^{k}\right] \tag{33}$$

$$\geq \binom{2B}{2D} \cdot \left[1 - \left(\frac{(2U+1)-k'}{2U+1}\right)^{k}\right] \tag{34}$$

$$\geq \binom{2B}{2D} \cdot \left[1 - \left(1 - \frac{k'}{2U+1}\right)^{k}\right] \tag{35}$$

$$\tag{36}$$

◀

▶ **Lemma 24.** *When $kk' > 2U+1$, $S_{total} > \frac{1}{2} \cdot \binom{2B}{2D}$.*

Proof. When $kk' > 2U+1 \implies k > \frac{2U+1}{k'}$, we will show that the above expression is greater than $\frac{1}{2}\binom{2B}{2D}$. Defining $\nu = \frac{2U+1}{k'} > 1$, we see that $(1-\frac{1}{\nu})^k \leq (1-\frac{1}{\nu})^{\nu}$. Since this is an increasing function of ν and since the limit of this function is $\frac{1}{e}$, we conclude that

$$1 - \left(1 - \frac{k'}{2U+1}\right)^{k} > \frac{1}{2}$$

◀

▶ **Lemma 27.** *When $kk' \leq 2U+1$, $S_{total} \geq c_3 \frac{k \cdot k'}{B} \cdot \binom{2B}{2D}$ for some constant c_3.*

Proof. Now we bound the term $1 - \left(1 - \frac{k'}{2U+1}\right)^k$, given that $kk' \leq 2U+1 \implies \frac{kk'}{2U+1} \leq 1$. Using Bernoulli's inequality, we know that $(1-x)^n \leq 1/(1+nx)$ for $x \in [0,1]$ and $n \in \mathbb{N}$. Since the term $k'/(2U+1)$ is positive and ≤ 1 (since $kk' \leq 2U+1$), we can apply this as follows:

$$1 - \left(1 - \frac{k'}{2U+1}\right)^k \tag{37}$$

$$\geq 1 - \frac{1}{1 + \frac{kk'}{2U+1}} = \frac{\frac{kk'}{2U+1}}{1 + \frac{kk'}{2U+1}} = \frac{kk'}{2U+1} \cdot \frac{1}{1 + \frac{kk'}{2U+1}} \tag{38}$$

$$\geq \frac{kk'}{2U+1} \cdot \frac{1}{2} \qquad \left(\text{Since } \frac{kk'}{2U+1} \leq 1\right) \tag{39}$$

$$\geq \frac{kk'}{\Theta(B)} \tag{40}$$

F.5 Omitted Proofs from Section 4.4: `First-Return` Queries

▶ **Lemma 31.** *If $d > \log^4 n$, then $S_{left}(d) = \Theta\left(\frac{2^{2d+k}}{\sqrt{d}} e^{-r_{left}(d)} \cdot \frac{k-1}{d+k-1}\right)$ where $r_{left}(d) = \frac{(k-2)^2}{2(2d+k-2)}$. Furthermore, $r_{left}(d) = \mathcal{O}(\log^2 n)$.*

Proof. In what follows, we will drop constant factors: Refer to Figure 8 for the setup. The left section of the path reaches one unit above the boundary (the next step would make it touch the boundary). The number of up-steps on the left side is d and therefore the number of down steps must be $d+k-2$. This inclues d down steps to cancel out the upwards movement, and $k-2$ more to get to one unit above the boundary. The boundary for this section is $k' = k-1$. This gives us:

$$S_{left}(d) = \binom{2d+k-2}{d} - \binom{2d+k-2}{d-1} \tag{41}$$

$$= \binom{2d+k-2}{d}\left[1 - \frac{d}{d+k-1}\right] = \binom{2d+k-2}{d}\frac{k-1}{d+k-1} \tag{42}$$

Now, letting $z = 2d+k-2$, we can write $d = \frac{z-(k-2)}{2} = \frac{z - \frac{k-2}{\sqrt{z}}\sqrt{z}}{2}$. Using Lemma 22, we see that $\frac{k-2}{\sqrt{z}}$ should be $\mathcal{O}(\sqrt{\log n})$. If this is not the case, we can simply return 0 because the probability associated with this value of d is negligible. Since $z > \log^4 n$, we can apply Lemma 64 to get:

$$S_{left}(d) = \Theta\left(\binom{z}{z/2} e^{\frac{(k-2)^2}{2z}} \frac{k-1}{d+k-1}\right) = \Theta\left(\frac{2^{2d+k}}{\sqrt{d}} e^{\frac{(k-2)^2}{2(2d+k-2)}} \frac{k-1}{d+k-1}\right)$$ ◀

▶ **Lemma 32.** *If $U+D-2d-k > \log^4 n$, then $S_{right}(d) = \Theta\left(\frac{2^{U+D-2d-k}}{\sqrt{U+d-2d-k}} e^{-r_{right}(d)} \cdot \frac{U-D+k}{U-d+1}\right)$ where $r_{right}(d) = \frac{(U-D-k-1)^2}{4(U+D-2d-k+1)}$. Furthermore, $r_{right}(d) = \mathcal{O}(\log^2 n)$.*

Proof. The right section of the path starts from the original boundary. Consequently, the boundary for this section is at $k' = 1$. The number of up-steps on the right side is $U - d$ and the number of down steps is $D - d - k + 1$. This gives us:

$$S_{right}(d) = \binom{U + D - 2d - k + 1}{U - d} - \binom{U + D - 2d - k + 1}{U - d + 1} \tag{43}$$

$$= \binom{U + D - 2d - k + 1}{U - d} \left[1 - \frac{D - d - k - 1}{U - d + 1}\right] \tag{44}$$

$$= \binom{U + D - 2d - k + 1}{U - d} \frac{U - D + k}{U - d + 1} \tag{45}$$

Now, letting $z = U + D - 2d - k + 1$, we can write $U - d = \frac{z+(U-D+k-1)}{2} = \frac{z+\frac{U-D+k-1}{\sqrt{z}}\sqrt{z}}{2}$. Using Lemma 22, we see that $\frac{k-2}{\sqrt{z}}$ should be $\mathcal{O}(\sqrt{\log n})$. If this is not the case, we can simply return 0 because the probability associated with this value of d is negligible. Since $z > \log^4 n$, we can apply Lemma 64 to get:

$$S_{right}(d) = \Theta\left(\binom{z}{z/2} e^{\frac{(U-D+k-1)^2}{2z}} \frac{U - D + k}{U - d + 1}\right) \tag{46}$$

$$= \Theta\left(\frac{2^{U+D-2d-k}}{\sqrt{U + D - 2d - k}} e^{\frac{(U-D+k-1)^2}{2(U+D-2d-k+1)}} \frac{U - D + k}{U - d + 1}\right) \tag{47}$$

Random graph models

The Erdös-Rényi model, given in [17], is one of the most simple theoretical random graph model, yet more specialized models are required to capture properties of real-world data. The Stochastic Block model (or the planted partition model) was proposed in [29] originally for modeling social networks; nonetheless, it has proven to be an useful general statistical model in numerous fields, including recommender systems [33, 49], medicine [51], social networks [21, 44], molecular biology [11, 36], genetics [9, 30, 13], and image segmentation [50]. Canonical problems for this model are the community detection and community recovery problems: some recent works include [12, 40, 3, 2]; see e.g., [1] for survey of recent results. The study of Small-World networks is originated in [55] has frequently been observed, and proven to be important for the modeling of many real world graphs such as social networks [15, 54], brain neurons [6], among many others. Kleinberg's model on the simple lattice topology (as considered in this paper) imposes a geographical that allows navigations, yielding important results such as routing algorithms (decentralized search) [31, 37]. See also e.g., [43] and Chapter 20 of [16].

Generation of random graphs

The problem of local-access implementation of random graphs has been considered in the aforementioned work [24, 41, 18], as well as in [35] that locally generates out-going edges on bipartite graphs while minimizing the maximum in-degree. The problem of generating full graph instances for random graph models have been frequently considered in many models of computations, such as sequential algorithms [39, 7, 45, 38], and the parallel computation model [4].

Query models

In the study of sub-linear time graph algorithms where reading the entire input is infeasible, it is necessary to specify how the algorithm may access the input graph, normally by defining the type of queries that the algorithm may ask about the input graph; the allowed types of queries can greatly affect the performance of the algorithms. While Next-Neighbor query is only recently considered in [18], there are other query models providing a neighbor of a vertex, such as asking for an entry in the adjacency-list representation [28], or traversing to a random neighbor. On the other hand, the Vertex-Pair query is common in the study of dense graphs as accessing the adjacency matrix representation [27]. The All-Neighbors query has recently been explicitly considered in local algorithms [19].

Other constructions of huge pseudorandom functions that are permutations or random hash functions were given in [34, 42, 35].

Monotone Probability Distributions over the Boolean Cube Can Be Learned with Sublinear Samples

Abstract

A probability distribution over the Boolean cube is **monotone** if flipping the value of a coordinate from zero to one can only increase the probability of an element. Given samples of an unknown monotone distribution over the Boolean cube, we give (to our knowledge) the first algorithm that learns an approximation of the distribution in statistical distance using a number of samples that is sublinear in the domain.

To do this, we develop a structural lemma describing monotone probability distributions. The structural lemma has further implications to the sample complexity of basic testing tasks for analyzing monotone probability distributions over the Boolean cube: We use it to give nontrivial upper bounds on the tasks of estimating the distance of a monotone distribution to uniform and of estimating the support size of a monotone distribution. In the setting of monotone probability distributions over the Boolean cube, our algorithms are the first to have sample complexity lower than known lower bounds for the same testing tasks on arbitrary (not necessarily monotone) probability distributions.

One further consequence of our learning algorithm is an improved sample complexity for the task of testing whether a distribution on the Boolean cube is monotone.

1 Introduction

1.1 Learning Monotone Distributions

Data generated from probability distributions is ubiquitous, and algorithms for understanding such data are of fundamental importance. In particular, a fundamental task is to *learn* an approximation to the probability distribution underlying the data. For probability distributions over huge discrete domains, the sample complexity and run-time bounds for the learning task can be prohibitive. In particular, learning an arbitrary probability distribution on a universe of N_{universe} elements up to sufficiently small constant total variation distance

requires $\Omega(N_{\text{universe}})$ samples. However, when the probability distribution is known to belong to a more structured class of distributions, much better results are possible (cf. [16, 19, 22, 21, 20, 24, 13, 12, 6, 10, 25, 23, 15, 28]) – for example, learning an unknown Poisson binomial distribution up to variation distance ϵ can be achieved with only $\tilde{O}(1/\epsilon^3)$ samples and $\tilde{O}(\log(N_{\text{universe}})/\epsilon^3)$ run-time [13].

A fundamental class of probability distributions is the class of multidimensional monotone probability distributions, which broadly satisfy the following properties:

- The elements of the probability distribution have n different features.
- For every element, an increase in the value of one of the features can only increase its probability.

This basic class of distributions is of great interest because many commonly studied distributions are either monotone or can be approximated by a combination of monotone distributions. Furthermore, often the tools developed for monotone distributions are useful for other classes of distributions: for example, in the one dimensional setting, [12] use tools developed for testing monotone distributions in order to learn k-modal distributions. In [8], tools developed for testing properties of monotone distributions by [4] are used to develop testers for many other classes of distributions.

For the case of only one feature, or equivalently for monotone probability distributions over the totally ordered set $[k]$, a sample-efficient algorithm is known for learning the unknown distribution up total variation distance ϵ with $O(\log(k)/\epsilon^3)$ samples [6, 12]. In [1] it was also shown that an unknown probability distribution over $[k]^n$ can be learned up to χ^2 distance ϵ^2 with $O((n \log k/\epsilon^2)^n/\epsilon^2)$ samples (note that for constant ϵ, this sample complexity is non-trivial only when k is sufficiently large). Overall, the cases considered in the literature specialize on the regime when all the dimensions have a wide range that grows with n. Here we focus on a contrasting case, where each feature has only two possible values, 0 and 1, thus specializing on the Boolean cube:

▶ **Definition 1.** *A probability distribution ρ over $\{0,1\}^n$ is **monotone** if whenever for $x, y \in \{0,1\}^n$ we have that $x \preceq y$ (which means that for all i $x_i \leq y_i$), then we have that $\rho(x) \leq \rho(y)$.*

When studying multi-dimensional objects, focusing on the specific case of the Boolean cube is a common research theme, because the ideas and techniques developed for the Boolean cube are often applicable in the general case. A lower bound of $\Omega(2^{0.15n})$ for learning monotone probability distributions over the Boolean cube (up to sufficiently small constant variation distance) can be inferred from an entropy testing lower bound in [29, page 39] and an argument in [32] (see Claim 17 in Preliminaries). Though the dramatic exponential improvement as in [6, 12] for the totally ordered set is thereby impossible, this still leaves open the possibility of a sublinear sample algorithm for the Boolean cube.

We give, to the best of our knowledge, the first sublinear sample algorithm for learning a monotone probability distribution over the Boolean cube:

▶ **Theorem 2.** *For every positive ϵ, such that $0 < \epsilon \leq 1$ and for all sufficiently large n, there exists an algorithm, which given $\frac{2^n}{2^{\Theta_\epsilon(n^{1/5})}}$ samples from an unknown monotone probability distribution ρ over $\{0,1\}^n$, can reliably return a description of an estimate probability distribution $\hat{\rho}$, such that $d_{TV}(\rho, \hat{\rho}) \leq \epsilon$. The algorithm runs in time $O\left(2^{n+O_\epsilon(n^{1/5}\log n)}\right)$.*

Our algorithm relies on a new structural lemma describing monotone probability distributions on the Boolean cube, as described in Section 1.3. These structural insights also allow us to get improved sample complexity for certain testing tasks on monotone distributions – namely, estimating the closeness of a distribution to uniformity and the support size of the distribution, as presented in Section 1.2.

Theorem 2, together with the L_1 distance tester in [31], can be applied to give the best known sample complexity for testing whether a distribution is monotone. Specifically, one can test whether an unknown distribution ρ over the Boolean cube is monotone or ϵ-far from monotone with $O(\frac{2^n}{n\epsilon^2})$ samples as shown in Claim 18 in Preliminaries. Note that this does not follow from [32] directly, because monotonicity is not a symmetric property. The best previously known algorithm for testing monotonicity over the Boolean cube was presented in [5], requiring $\tilde{O}\left(\frac{2^n}{(n/\log n)^{1/4}}\text{poly}(1/\epsilon)\right)$ samples. The best sample complexity lower bound for testing monotonicity over $\{0,1\}^n$ is $\Omega(2^{(1-\Theta(\sqrt{\epsilon})+o(1))\cdot n})$, as presented in [3]. For the domain $[k]^n$, a monotonicity testing algorithm that requires $O\left(k^{n/2}/\epsilon^2 + \left(\frac{n\log k}{\epsilon^2}\right)^n \cdot \frac{1}{\epsilon^2}\right)$ samples is given and shown to be optimal in [1] (note that this is inapplicable to the Boolean setting, because this sample bound is non-trivial only for sufficiently large k).

1.2 Testing properties of monotone distributions

In addition to learning a distribution, several other basic tasks aimed at understanding distributions have received attention. These include estimating the entropy of a distribution, the size of the support and whether the distribution has certain "shape" properties (monotonicity, convexity, monotone hazard rate, etc.). For arbitrary probability distributions over huge domains, the sample complexity and run-time bounds for the above tasks can be prohibitive, provably requiring $\Omega\left(\frac{N_{\text{universe}}}{\log(N_{\text{universe}})}\right)$ samples. This is true in particular for the properties of support size, entropy and the distance to the uniform distribution [27, 32, 30, 33, 34].

This state of affairs motivates going beyond worst-case analysis and considering common classes of structured probability distributions, a direction that has been considered by many and with a large variety of results (cf. [4, 9, 24, 29, 14, 18]). Some specific examples include: In [4] it is shown that testing whether a monotone distribution is uniform requires only $\Theta(\log^3(N_{\text{universe}})/\epsilon^3)$ samples, in contrast to the $\Theta(\sqrt{N_{\text{universe}}}/\epsilon^2)$ samples required for testing arbitrary distributions for uniformity [26, 11, 17]. The situation is analogous for the tasks of testing whether two distributions given by samples are either the same or far, and testing whether a constant dimensional distribution is independent, which require only polylogarithmic samples if the unknown distributions are promised to be monotone on a total order [4].

Algorithms for testing properties of monotone probability distributions over the Boolean cube were studied in [29, 2]. It was shown that, given samples from a probability distribution over $\{0,1\}^n$ that is promised to be monotone, distinguishing the uniform distribution over $\{0,1\}^n$ from one that is ϵ-far from uniform can be done using only $O\left(\frac{n}{\epsilon^2}\right)$ samples, which is nearly optimal. In contrast, a number of other testing problems cannot have such dramatic improvements when the distribution is known to be monotone: for example in [29] it was shown that for sufficiently small constant ϵ the estimation of entropy up to an additive error of ϵn requires $2^{\Omega(n)}$ samples. However, no nontrivial[1] upper bounds on the sample complexity of any other computational tasks for monotone probability distributions over the Boolean cube are known.

[1] i.e. using monotonicity in an essential way and going beyond the bounds known for arbitrary probability distributions.

1.2.1 Estimating support size

We consider the task of additively estimating the support size of an unknown monotone probability distribution over the Boolean cube. The following assumption is standard in support size estimation:

▶ **Definition 3.** *A probability distribution over a universe of size $N_{universe}$ is called **well-behaved** (in context of support size estimation) if for every x in the set, the probability of x is either zero or at least $1/N_{universe}$.*

The purpose of this definition is to rule out pathological cases in which there are items that are in the support, yet have probability very close to zero. We henceforth adapt this definition to probability distributions over $\{0,1\}^n$, where we have $N_{\text{universe}} = 2^n$. We prove the following theorem:

▶ **Theorem 4.** *For every positive ϵ, the following is true: for all sufficiently large n, there exists an algorithm, which given $\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$ samples from an unknown well-behaved monotone probability distribution ρ over $\{0,1\}^n$, can reliably[2] approximate the support size of ρ with an additive error of up to ϵ. The algorithm runs in time $O_\epsilon\left(\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}\right)$*

We contrast this result to the results of [27, 30, 31, 32, 34] that show that one needs $\Omega(N_{\text{universe}}/\log(N_{\text{universe}}))$ samples to estimate the support size of an arbitrary distribution up to a sufficiently small constant, which equals to $\Omega(2^n/n)$ for a universe of size 2^n, such as the Boolean cube.

1.2.2 Estimating distance to uniformity

We now consider the task of additively estimating the distance from an unknown monotone probability distribution over the Boolean cube to the uniform distribution. We prove the following theorem:

▶ **Theorem 5.** *For every positive ϵ, the following is true: for all sufficiently large n, there exists an algorithm, which given $\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$ samples from an unknown monotone probability distribution ρ over $\{0,1\}^n$, can reliably approximate the distance between ρ and the uniform distribution over $\{0,1\}^n$ with an additive error of up to ϵ. The algorithm runs in time $O\left(2^{n+O_\epsilon(\sqrt{n}\log n)}\right)$.*

We, again, contrast this result to the results of [30, 31, 32] that show that one needs $\Omega(N_{\text{universe}}/\log(N_{\text{universe}}))$ samples to estimate the distance of an arbitrary distribution to the uniform distribution, which equals to $\Omega(2^n/n)$ for a universe of size 2^n, such as the Boolean cube.

We also have the following sample complexity lower bound on this task, which we prove using the sub-cube decomposition technique of [29]:

▶ **Theorem 6.** *For infinitely many positive integers n, there exist two probability distributions Δ_{Close} and Δ_{Far} over monotone distributions over $\{0,1\}^n$, satisfying:*

1. *Every distribution in Δ_{Far} is $1/2$-far from the uniform distribution.*
2. *Any algorithm that takes only $o\left(2^{\frac{n^{0.5-0.01}}{2}}\right)$ samples from a probability distribution, fails to reliably distinguish between Δ_{Close} and Δ_{Far}.*
3. *Every distribution in Δ_{Close} is $o(1)$-close to the uniform distribution.*

[2] By **reliably** we henceforth mean that the probability of success is at least $2/3$.

▶ Remark 7. In our construction, the distribution Δ_{Close} consists of only one probability distribution. Additionally, the constant 0.01 can be made arbitrarily small.

Recall that in [29, 2] it was shown that, given samples from a probability distribution over the Boolean cube that is promised to be monotone, distinguishing the uniform distribution from one that is ϵ-far from uniform can be done using only $O\left(\frac{n}{\epsilon^2}\right)$ samples. Yet, as the theorem above shows, the **tolerant** version of this problem, which requires one to distinguish a distribution that is $o(1)$-close to the uniform from a distribution that is $1/2$-far from uniform, requires $\Omega\left(2^{\frac{n^{0.5-0.01}}{2}}\right)$ samples, which is dramatically greater.

1.3 Technical overview

1.3.1 Structural results

Our analysis applies and builds upon the main structural lemma in [7]. To state it, recall that a **DNF** is a Boolean function that is formed as an OR of ANDs, and it is monotone if there are no negations. Each AND is referred to as a **clause**, with the number of variables in the AND is referred to as the **width** of the clause. Their structural lemma shows that each monotone function can be approximated by a DNF with only a constant number of distinct clause widths. Specifically:

▶ **Lemma 8** (Main Lemma in [7], abridged and restated)**.** *For every positive ϵ, for all sufficiently large n, let f be a monotone Boolean function over the domain $\{0,1\}^n$. There is a function $g = g_1 \vee ... \vee g_t$ with the following properties: (i) $t \leq 2/\epsilon$ (ii) each g_i is a monotone DNF with terms of width exactly k_i (iii) g disagrees with f at no more than $\epsilon \cdot 2^n$ elements of $\{0,1\}^n$ (iv) $g(x) \leq f(x)$ for all x in $\{0,1\}^n$.*

For Theorem 4, we use the lemma above on the indicator function of the support of the probability distribution, which allows us to prove the correctness of our algorithm. For the problems of learning and estimating the distance to uniform, we go a step further and prove an analogous structural lemma for *monotone probability distributions*.

There are some crucial differences between monotone Boolean functions in the setting of Boolean function approximation and monotone probability distributions in our setting. First of all, the basic properties of the two objects are different: a Boolean function always has one of the two values (zero or one), which is usually not the case for a probability distribution, but a probability distribution, summed over $\{0,1\}^n$, has to equal one. Secondly, the relevant notions of a function f_2 being well-approximated by a function f_1 are different: for Boolean functions we bound the fraction of points on which f_1 and f_2 disagree, whereas for monotone probability distributions we would like to bound the L_1 distance between f_1 and f_2.

To overcome these differences, we generalize to the setting of non-Boolean functions the main concept used in the proof of Lemma 8: the concept of a **minterm** of a monotone Boolean function. In [7] the minterm of a monotone Boolean function f is defined as follows:

$$\text{minterm}_f(x) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } f(x) = 1 \text{ and for all } y \prec x,\ f(y) = 0 \\ 0 & \text{otherwise} \end{cases}$$

Using this language, the function g in Lemma 8 can be characterized as a function, for which:

$$\sum_{h=0}^{n} \mathbf{1}_{\exists\, x \in \{0,1\}^n:\, ||x||=h \,\wedge\, \text{minterm}_g(x) \neq 0} \leq \frac{2}{\epsilon} \tag{1}$$

We introduce the notion of monotone **slack** that generalizes the notion of a minterm to non-Boolean functions:

$$\text{slack}_f(x) \stackrel{\text{def}}{=} f(x) - \max_{y \prec x} f(y) = f(x) - \max_{y \preceq x \text{ and } ||y||=||x||-1} f(y)$$

With such a definition at hand, one could hope to prove that every monotone probability distribution ρ is well-approximated in the L_1 norm by a monotone function f, for which $\sum_{h=0}^{n} \mathbf{1}_{\exists\, x \in \{0,1\}^n:\, ||x||=h \,\wedge\, \text{slack}_f(x) \neq 0}$ is bounded by a constant independent of n. We were not able to prove such a theorem, and instead we bound a related quantity that can be thought of as the weighted analogue of the expression in Equation 1: $\sum_{h=0}^{n} R_h \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n:\, ||x||=h \,\wedge\, \text{slack}_f(x) \neq 0}$, where the R_h are positive weights that can be chosen arbitrarily, as long as they satisfy a certain technical condition that ensures that not too many of these weights are too large. Precisely, our main lemma is:

▶ **Lemma 9** (Main Structural Lemma). *For all positive ζ, for all sufficiently large n, the following is true: Let ρ be a monotone probability distribution over $\{0,1\}^n$. Suppose, for each h between 0 and n we are given a positive value R_h, and it is the case that: $\sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}}{\sum_{j=h}^{n} \binom{n}{j}} \leq \zeta$*

Then, there exists a positive monotone function f, mapping $\{0,1\}^n$ to positive real numbers, satisfying:

1. *For all x, it is the case that $\rho(x) \geq f(x)$.*
2. *It is the case that: $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \zeta$*
3. *It is the case that: $\sum_{h=0}^{n} R_h \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n:\, ||x||=h \,\wedge\, slack_f(x) \neq 0} \leq 1$*

Now, as a corollary, we present a simple special case (proven to be so in Subsection 3.1) that not only illustrates the power of Lemma 9, but also is sufficient for our proof of Theorem 5:

▶ **Corollary 10.** *Let ρ be a monotone probability distribution over $\{0,1\}^n$ and let h_0 be an integer for which:*

$$\frac{\epsilon}{4} \leq \Pr_{x \sim \{0,1\}^n}[||x|| \geq h_0] \leq \frac{\epsilon}{2}$$

Then, there exists a positive monotone function $f : \{0,1\}^n \to R$ satisfying:

1. *For all x, it is the case that $\rho(x) \geq f(x)$.*
2. *It is the case that: $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \frac{\epsilon}{4}$.*
3. *There exists a set of values $\{k_1, ..., k_t\}$ (ordered in an increasing order) with $t \leq \frac{16}{\epsilon^2}$, satisfying that if for some x in $\{0,1\}^n$ we have $||x|| < h_0$ and $slack_f(x) \neq 0$, then $||x|| = k_i$ for some i.*

For Theorem 2, however, we use the full power of Lemma 9.

1.3.2 Algorithmic ideas

Here we present an informal overview of the ideas involved in the design and analysis of our algorithms. Throughout we omit details and technicalities. As already mentioned, our algorithms for Theorems 4, 5 and 2 use respectively Lemma 8, Corollary 10 and Lemma 9 as their structural core. Here we present the algorithmic ideas in the order of increasing technical sophistication.

1.3.2.1 Support size estimation (Theorem 4)

The idea behind our support size estimation algorithm is as follows: if we received x as a sample, then not only x has to be in the support of ρ, but every y, satisfying $x \preceq y$ is in the support of ρ. For all such y, we say that y is **covered** by x. Our algorithms estimates the support size of ρ through estimating the number of all such y that are covered by at least one of the samples.

This algorithm can be made computationally efficient by standard methods in randomized algorithms, and the only non-trivial step is to show that $\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$ samples suffice. To show this, we first apply Lemma 8 to the indicator function of the support of ρ (which we from now on call the support function of ρ). This gives us a Boolean function g that approximates well the support function of ρ and has zero slack everywhere, except for a small number of levels[3] of $\{0,1\}^n$. For simplicity, assume that the support function of ρ itself has this property, and there are only a small number of levels of the Boolean cube on which the support function of ρ can have non-zero slack, which we call the **slacky** levels.

Now, we divide the elements of $\{0,1\}^n$ (which we also call **points**) into **good**[4] points and **bad** points, with the former defined as all the points sufficiently close to a slacky level, and the latter defined as all the other points. Clearly, a given level of $\{0,1\}^n$ consists either fully from good points or fully from bad points, so we also refer to levels as good or bad.

We argue that if a point y in the support of ρ is a good point, then it is likely to be covered by one of the samples, because there is a large number of values x in the support of ρ, for which $y \preceq x$.

We conclude by bounding the number of elements in the support of ρ that are bad, by using the fact that there cannot be too many slacky levels.

1.3.2.2 Estimation of distance to uniform (Theorem 5)

To estimate the distance of a monotone distribution to uniform, we pick a value h_0 as in Corollary 10 and break down the value of the total variation distance from ρ to uniform into contributions from two disjoint components: (i) $\{x \in \{0,1\}^n \text{ s.t. } ||x|| \geq h_0\}$ and (ii) all the other points of $\{0,1\}^n$. In other words, we use h_0 as the cutoff value for the Hamming weight, to separate $\{0,1\}^n$ into components (i) and (ii). The first contribution is straightforward to estimate simply through estimating how likely a random sample x from ρ is to have $||x|| \geq h_0$, because it is straightforward to prove that if one redistributes the probability mass of ρ in $\{x \in \{0,1\}^n \text{ s.t. } ||x|| \geq h_0\}$, while keeping the total amount of probability mass in this set fixed, the total variation distance between ρ and the uniform distribution cannot change by more than $O_\epsilon(1)$.

For any element x of the component (ii), we prepare an estimate of $\rho(x)$, which we call $\hat{\phi}(x)$. Our approach here is somewhat similar to the one for our support size estimation algorithm. In the case of support size estimation, we only registered whether x was covered by a sample from ρ or not. In this case, we actually need an estimate on $\rho(x)$ (as opposed to $\mathbf{1}_{\rho(x)\neq 0}$) which we obtain by studying the pattern of all the samples covering x. More precisely, suppose we draw N_2 samples from the distribution, which form a multiset S_2. We extract the estimate $\hat{\phi}(x)$ from the pattern of samples as follows:

$$\hat{\phi}(x) := \frac{1}{2^L} \cdot \frac{\max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \left| \left\{ z \in S_2 : y \preceq z \preceq x \right\} \right|}{N_2}$$

[3] i.e. subsets of $\{0,1\}^n$ that have the same Hamming weight.

[4] We later re-define these notions in order to adapt them for the technical details we ignore in the introduction.

Here L is a parameter equal to $\Theta_\epsilon(\sqrt{n})$. We then estimate the contribution of set (ii) as $\sum_{x\in\{0,1\}^n:\ ||x||\geq h_0} \left|\hat{\phi}(x) - 1/2^n\right|$.

We show the correctness of our algorithm as follows. We use a tail bound to show that $\hat{\phi}(x)$ concentrates sufficiently closely to the value: .

$$\phi(x) \stackrel{\text{def}}{=} \frac{1}{2^L} \cdot \max_{y \text{ s.t. } y\preceq x \text{ and } ||x||-||y||=L} \Pr_{z\sim\rho}[y \preceq z \preceq x] =$$

$$\frac{1}{2^L} \cdot \max_{y \text{ s.t. } y\preceq x \text{ and } ||x||-||y||=L} \sum_{z \text{ s.t. } y\preceq z\preceq x} \rho(z)$$

Then, we apply Corollary 10, which implies that ρ is approximated well by a function f and a certain set of constraints on the slack of f holds.

Now for the sake of simplicity (analogously to the case of support size estimation), assume that ρ itself satisfies the condition that below the threshold h_0 there are at most $O_\epsilon(1)$ levels of $\{0,1\}^n$ on which there are points x with non-zero $\text{slack}_\rho(x)$ (in reality it is merely well-approximated by such a function). We now can (analogously to the case of support size estimation) introduce the concepts of **slacky** levels as levels on which ρ has non-zero slack, and **good** levels, which are below h_0 and farther than L from all **slacky** levels of ρ. Now, one can prove that for x on a good level the value of $\phi(x)$ equals precisely to $\rho(x)$, for the following reasons: First of all the inequality:

$$\max_{y \text{ s.t. } y\preceq x \text{ and } ||x||-||y||=L} \rho(y) \leq \phi(x) \leq \rho(x)$$

follows immediately from the monotonicity of ρ and the definition of ϕ. Secondly, if ρ has no slack on the levels between $||x||$ and $||x|| - L$ (inclusive), then from the definition of slack it follows immediately using induction on L that:

$$\max_{y \text{ s.t. } y\preceq x \text{ and } ||x||-||y||=L} \rho(y) = \rho(x)$$

Therefore, it has to be the case that $\rho(x) = \phi(x)$.

Finally, we bound the contribution to the L_1 distance between $\hat{\phi}$ and ρ of all the levels below h_0 that are not good (which we again call the **bad** levels). We do this by upper-bounding the number of bad levels, and then upper bounding the total probability mass on a single level below h_0.

1.3.2.3 Learning a monotone probability distribution (Theorem 2)

As we saw, our algorithm for the estimation of the distance to the uniform distribution contained a component that learned in L_1 distance the restriction of ρ on the levels below the cutoff h_0. The main challenge here is to extend these ideas to levels above h_0. To this, we make the following changes to our setup:

- Instead of having one fixed constant L defining whether a point is close to a slacky level, we make this value level-dependent. In other words, for every h we define L_h, and then after drawing N samples, which form a multiset S, we compute:

$$\hat{\phi}(x) := \frac{1}{2^{\lfloor L_{||x||}\rfloor}} \cdot \frac{\max_{y \text{ s.t. } y\preceq x \text{ and } ||y||-||x||=\lfloor L_{||x||}\rfloor} \left|\left\{z \in S : y \preceq z \preceq x\right\}\right|}{N}$$

- Instead of using Corollary 10, we use the the full power of Lemma 9. This, again gives us a function f that approximates ρ closely and has a restriction on its slacky levels.

Finally, we pick values of L_h in the algorithm and R_h in the analysis so we balance (i) The random error from the deviation of $\hat{\phi}(x)$ from its expectation and (ii) The systematic error introduced by the slacky levels of f and the levels close to them. As a result, we find that $\frac{2^n}{2^{\Theta(n^{1/5})}}$ samples suffice.

2 Preliminaries

We use the following basic definitions and notation:

▶ **Definition 11.** *For $x \in \{0,1\}^n$, its **Hamming weight** is denoted as $||x||$ and is equal to $\sum_i x_i$.*

▶ **Definition 12.** *For a function $f : \{0,1\}^n \to R$, we define the **average value on level** k (with $0 \le k \le n$) as: $\mu_f(k) = \frac{1}{\binom{n}{k}} \sum_{x \in \{0,1\}^n : ||x|| = k} f(x)$. We also refer to average value on level k for a probability distribution ρ, which we denote $\mu_\rho(k)$. By this we mean the average value on level k of the density function of ρ.*

▶ **Definition 13.** *For a monotone function $f : \{0,1\}^n \to R$, we define the **monotone slack** $slack_f(x)$ at point $x \in \{0,1\}^n$ as follows: $slack_f(x) \stackrel{\text{def}}{=} f(x) - \max_{y \prec x} f(y) = f(x) - \max_{y \preceq x \text{ and } ||y|| = ||x|| - 1} f(y)$. We also stipulate that $slack_f(0^n) = f(0^n)$.*

▶ **Definition 14.** *The **total variation distance** between two probability distributions ρ_1 and ρ_2 is defined as:*
$d_{TV}(\rho_1, \rho_2) \stackrel{\text{def}}{=} \frac{1}{2} \sum_x |\rho_1(x) - \rho_2(x)|$.

The following are well-known facts, which were also used in [7]:

▶ **Fact 15.** *For a monotone function $f : \{0,1\}^n \to R$, for all k_1, k_2 satisfying $0 \le k_1 \le k_2 \le n$, it is the case that $\mu_f(k_1) \le \mu_f(k_2)$.*

▶ **Fact 16.** *For all k, it is the case that $\binom{n}{k} \le \frac{2}{\sqrt{n}} \cdot 2^n$.*

Now, we justify two claims we made in the introduction:

▷ Claim 17. For sufficiently small ϵ_0, for all sufficiently large n, any algorithm that learns an unknown monotone probability distribution over $\{0,1\}^n$ requires at least $\Omega(2^{0.15n})$ samples from the distribution.

Proof. From the argument in [32, pages 1937-1938] it follows that if two probability distributions are ϵ-close in total variation distance, then their entropy values are within $2\log(N_{\text{universe}})\epsilon = 2\epsilon n$. Therefore, the task of estimating the entropy of an unknown monotone probability up to an additive error $2\epsilon n$ is not harder than learning it to withing total variation distance ϵ. But in [29, page 39] it is shown that at least $\sqrt{T}/10$ samples are required for the task of distinguishing whether the unknown monotone probability distribution has entropy at least $0.81n$ or at most $n/2 + \log T$. Picking $T = 2^{0.3n}$ gives us the desired learning lower bound. ◁

▷ Claim 18. Given Theorem 2, one can test whether an unknown distribution ρ over the Boolean cube is monotone or ϵ-far from monotone with $O(\frac{2^n}{n\epsilon^2})$ samples.

Proof. This can be done in the following way: (1) Use our learning algorithm with an error parameter $\epsilon/4$. This gives us a description of a distribution $\hat{\rho}$, which is $\epsilon/4$-close to ρ if ρ is monotone. (2) Estimate, using the estimator of [31], the total variation distance between

ρ and $\hat{\rho}$ up to $\epsilon/4$. If the result is closer to ϵ than to zero, output NO. (3) Compute the total variation distance between $\hat{\rho}$ and the closest monotone probability distribution. If this distance estimate is closer to ϵ than to zero, output NO, otherwise output YES. For constant ϵ, the sample complexity is dominated by step (3), which is $O(\frac{2^n}{\epsilon^2 n})$. It is easy to see that a monotone probability distribution will pass this test, whereas a distribution that is ϵ-far from monotone will fail either step (2) or step (3). ◁

3 Learning monotone probability distributions

Algorithm 1 Algorithm for learning a monotone probability distribution over the Boolean cube (given sample access from a distribution ρ, which is monotone over $\{0,1\}^n$).

1. Set $A := \frac{1}{2n} \cdot e^{\frac{1}{2000} \cdot n^{1/5}}$. For all $h \geq n/2$, set $L_h := \max\left(\log\left(2nA \cdot \frac{\binom{n}{h}}{2^n}\right), 0\right)$
   Similarly, for all h, satisfying $n/2 > h \geq 0$, set: $L_h := L_{n/2} = \log\left(2nA \cdot \frac{\binom{n}{n/2}}{2^n}\right)$.
2. Set $N := \frac{2^n}{A} \cdot \frac{192}{\epsilon^2} \cdot (n + 9\sqrt{n} + 4)$
   Draw N samples from the probability distribution ρ and denote the multiset of these samples as S.
3. For all x in $\{0,1\}^n$, if $||x|| < 9\sqrt{n}$, then set $\hat{\phi}(x) = 0$, otherwise compute:
$$\hat{\phi}(x) := \frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \frac{\max_{y \text{ s.t. } y \preceq x \text{ and } ||y|| - ||x|| = \lfloor L_{||x||} \rfloor} \left| \left\{ z \in S : y \preceq z \preceq x \right\} \right|}{N}$$
   Do this by first making a look-up table, which given arbitrary $z \in \{0,1\}^n$ returns the number of times z was encountered in S. Then, use this look-up table to compute the necessary values of $|\{z \in S : y \preceq z \preceq x\}|$ by querying all these values of z in the lookup table and summing the results up.
4. For all x in $\{0,1\}^n$, compute the following: $\hat{\rho}(x) = \hat{\phi}(x) + \frac{1}{2^n}\left(1 - \sum_{y \in \{0,1\}^n} \hat{\phi}(y)\right)$
5. Output the value table of $\hat{\rho}$.

In this section we prove our upper-bound on the sample complexity of learning an unknown monotone probability distribution over the Boolean cube. We restate the theorem:

▶ **Theorem 2.** *For every positive ϵ, such that $0 < \epsilon \leq 1$ and for all sufficiently large n, there exists an algorithm, which given $\frac{2^n}{2^{\Theta_\epsilon(n^{1/5})}}$ samples from an unknown monotone probability distribution ρ over $\{0,1\}^n$, can reliably return a description of an estimate probability distribution $\hat{\rho}$, such that $d_{TV}(\rho, \hat{\rho}) \leq \epsilon$. The algorithm runs in time $O\left(2^{n + O_\epsilon(n^{1/5} \log n)}\right)$.*

Proof. We present the algorithm as Algorithm 1. The number of samples drawn from ρ is $N = \frac{2^n}{2^{\Theta_\epsilon(n^{1/5})}}$. The run-time, in turn, is dominated by computing the values of $\hat{\phi}$ in step (3), in which the construction of the lookup table takes $O(n \cdot 2^n)$ time, and the time spent computing each $\hat{\phi}(x)$ can be upper bounded by the product of: (i) the number of pairs (y, z) that simultaneously satisfy $y \preceq z \preceq x$ and $||y|| - ||x|| = L_{||x||}$, which can be upper-bounded by $O(n^{L_{||x||}} \cdot 2^{L_{||x||}})$ and (ii) the time it takes to look up a given z in the lookup table, which can be upper-bounded by $O(n)$. Overall, this gives us a run-time upper bound of $O(2^{n + O_\epsilon(n^{1/5} \log n)})$.

Now, the only thing to prove is correctness. Here is our main claim:

▷ Claim 19. If the following conditions are the case:

a) As a function of h, L_h is non-increasing.

b) For all h, we have that $L_h \leq 9\sqrt{n}$.

c)

$$\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} \leq \frac{1}{2}$$

d)

$$\sum_{h=9\sqrt{n}}^{n} L_h \cdot \left(\begin{cases} \frac{400}{n^{2.5}} & \text{if } h \leq n/2 - \sqrt{n\ln(n)} \\ \frac{40000}{n} & \text{if } n/2 - \sqrt{n\ln(n)} < h < n/2 + \sqrt{n} \\ 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right) \leq \frac{\epsilon^2}{20000}$$

Then, with probability at least $2/3$, it is the case that $\sum_{x\in\{0,1\}^n \text{ s.t. } 9\sqrt{n}\leq||x||} \left|\hat{\phi}(x) - \rho(x)\right| \leq \frac{\epsilon}{2}$.

We verify in Appendix A, subsection 7.1, that L_h indeed satisfy the conditions above. In fact, the values of L_h and A were chosen specifically to satisfy the constraints above. We prove Claim 19 in Section 3.2, after we develop our main structural lemma in Section 3.1.

We now bound the contribution to the L_1 distance between $\hat{\phi}$ to ρ that comes from points of Hamming weight less than $9\sqrt{n}$. Since $\sum_{x\in\{0,1\}^n} \rho(x) = 1$ and ρ is monotone, then whenever $||x|| \leq n/2$ we have $\rho(x) \leq 1/2^{n/2}$. Therefore, for sufficiently large n we have:

$$\sum_{x\in\{0,1\}^n \text{ s.t. } ||x||<9\sqrt{n}} \left|\hat{\phi}(x) - \rho(x)\right| = \sum_{x\in\{0,1\}^n \text{ s.t. } ||x||<9\sqrt{n}} \rho(x) \leq \frac{n^{9\sqrt{n}}}{2^{n/2}} \leq \frac{\epsilon}{2}$$

Combining this with the bound in Claim 19 we get:

$$\sum_{x\in\{0,1\}^n} \left|\hat{\phi}(x) - \rho(x)\right| \leq \epsilon$$

Overall, we have:

$$2 \cdot d_{\mathrm{TV}}(\rho, \hat{\rho}) = \sum_{x\in\{0,1\}^n} \left|\hat{\rho}(x) - \rho(x)\right| =$$

$$\sum_{x\in\{0,1\}^n} \left|\hat{\phi}(x) - \rho(x) + \frac{1}{2^n}\left(1 - \sum_{y\in\{0,1\}^n} \hat{\phi}(y)\right)\right| \leq$$

$$\sum_{x\in\{0,1\}^n} \left|\hat{\phi}(x) - \rho(x)\right| + \left|1 - \sum_{y\in\{0,1\}^n} \hat{\phi}(y)\right| =$$

$$\sum_{x\in\{0,1\}^n} \left|\hat{\phi}(x) - \rho(x)\right| + \left|\sum_{x\in\{0,1\}^n} \rho(x) - \hat{\phi}(x)\right| \leq 2 \cdot \sum_{x\in\{0,1\}^n} \left|\hat{\phi}(x) - \rho(x)\right| \leq 2 \cdot \epsilon$$

Thus, with probability at least $2/3$, we have $d_{\mathrm{TV}}(\rho, \hat{\rho}) \leq \epsilon$. ◀

3.1 Main lemma

Here we prove the following structural lemma. The lemma, as well as its proof are inspired by the main structural lemma of [7] (i.e. Lemma 8). Recall that the slack of a monotone function was given in Definition 13.

▶ **Lemma 9** (Main Structural Lemma). *For all positive ζ, for all sufficiently large n, the following is true: Let ρ be a monotone probability distribution over $\{0,1\}^n$. Suppose, for each h between 0 and n we are given a positive value R_h, and it is the case that:* $\sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}}{\sum_{j=h}^{n}\binom{n}{j}} \leq \zeta$

Then, there exists a positive monotone function f, mapping $\{0,1\}^n$ to positive real numbers, satisfying:

1. *For all x, it is the case that $\rho(x) \geq f(x)$.*
2. *It is the case that: $\sum_{x\in\{0,1\}^n} \rho(x) - f(x) \leq \zeta$*
3. *It is the case that: $\sum_{h=0}^{n} R_h \cdot \mathbf{1}_{\exists\, x\in\{0,1\}^n:\, ||x||=h \,\wedge\, slack_f(x)\neq 0} \leq 1$*

Proof. We use the following process to obtain f:

a) Set $f^* = \rho$.

b) For $h = 0$ to n:

- If it is the case that:

$$\frac{1}{\binom{n}{h}} \cdot \sum_{x\in\{0,1\}^n \text{ s.t. } ||x||=h} \text{slack}_{f^*}(x) < R_h \cdot \frac{1}{\sum_{j=h}^{n}\binom{n}{h}} \tag{2}$$

  Then, for all x in $\{0,1\}^n$, satisfying $||x|| = h$ set: $f^*(x) := f^*(x) - \text{slack}_{f^*}(x)$.

c) Set $f = f^*$ and output f.

By inspection, f^* remains monotone and positive at every iteration of the process. Therefore, f is also monotone and positive.

Property (1) in the Lemma is true, because at every step of the process, values of f^* only decrease.

To see why Property (2) is the case, note that the value $\sum_{x\in\{0,1\}^n} \rho(x) - f(x)$ is zero in the beginning of the process, and at a step h it either stays the same or decreases by at most $R_h \cdot \frac{\binom{n}{h}}{\sum_{j=h}^{n}\binom{n}{j}}$. Therefore we can upper-bound:

$$\sum_{x\in\{0,1\}^n} \rho(x) - f(x) \leq \sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}}{\sum_{j=h}^{n}\binom{n}{j}} \leq \zeta$$

Now, the only thing left to prove is that property (3) holds.

From the definition of monotone slack, it follows that modifying the value of a function on points of Hamming weight j does not affect the slack on any point with Hamming weight lower than j. Therefore, the value $\frac{1}{\binom{n}{j}} \cdot \sum_{x\in\{0,1\}^n \text{ s.t. } ||x||=j} \text{slack}_{f^*}(x)$ will not change as f^* changes after the jth iteration. Therefore, this value will be equal to $\frac{1}{\binom{n}{j}} \cdot \sum_{x\in\{0,1\}^n \text{ s.t. } ||x||=j} \text{slack}_{f}(x)$. Thus, the value of $\frac{1}{\binom{n}{j}} \cdot \sum_{x\in\{0,1\}^n \text{ s.t. } ||x||=j} \text{slack}_{f}(x)$ is either zero or at least $R_h \cdot \frac{1}{\sum_{j=h}^{n}\binom{n}{h}}$.

Now, we need the following generalization of Fact 15:

▶ **Observation 20.** *Let f be an arbitrary monotone function $\{0,1\}^n \to R$. Then, for any k in $[0, n-1]$ it is the case that:*

$$\mu_f(k+1) \geq \mu_f(k) + \frac{1}{\binom{n}{k+1}} \cdot \sum_{x\in\{0,1\}^n \text{ s.t. } ||x||=k+1} slack_f(x)$$

Proof. For all x with $||x|| = k+1$ we have that:

$$f(x) = \text{slack}_f(x) + \max_{y \in \{0,1\}^n \text{ s.t. } ||y||=k \text{ and } y \preceq x} f(y)$$

We have that:

$$\max_{y \in \{0,1\}^n \text{ s.t. } ||y||=k \text{ and } y \preceq x} f(y) \geq \mathbb{E}_{y \sim \{0,1\}^n \text{ conditioned on } ||y||=k \text{ and } y \preceq x}[f(y)]$$

Therefore:

$$f(x) \geq \text{slack}_f(x) + \mathbb{E}_{y \sim \{0,1\}^n \text{ conditioned on } ||y||=k \text{ and } y \preceq x}[f(y)]$$

Averaging the both sides, we get:

$$\mu_f(k+1) \geq \frac{1}{\binom{n}{k+1}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=k+1} \text{slack}_f(x) +$$

$$\mathbb{E}_{x \sim \{0,1\}^n \text{ conditioned on } ||x||=k+1} \mathbb{E}_{y \sim \{0,1\}^n \text{ conditioned on } ||y||=k \text{ and } y \preceq x}[f(y)] =$$

$$\frac{1}{\binom{n}{k+1}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=k+1} \text{slack}_f(x) + \mathbb{E}_{y \sim \{0,1\}^n \text{ conditioned on } ||y||=k}[f(y)] =$$

$$\frac{1}{\binom{n}{k+1}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=k+1} \text{slack}_f(x) + \mu_f(k) \quad (3)$$

Above, the penultimate equality followed from a simple probabilistic fact: if one picks a random n-bit string of Hamming weight $k+1$ and then sets to zero a random bit that equals to one, this is equivalent to picking a random n-bit string of weight k. ◀

Using the Observation 20 repeatedly and recalling that in Definition 13 we defined $\text{slack}_f(0^n) = f(0^n)$, we get that for all h:

$$\mu_f(h) \geq \mu_f(0) + \sum_{k=1}^{h} \frac{1}{\binom{n}{k}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=k} \text{slack}_f(x) =$$

$$\sum_{k=0}^{h} \frac{1}{\binom{n}{k}} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } ||x||=k} \text{slack}_f(x) \geq \sum_{k=0}^{h} R_k \cdot \frac{1}{\sum_{j=k}^{n} \binom{n}{j}} \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n :\, ||x||=k \,\wedge\, \text{slack}_f(x) \neq 0}$$

Summing this up over all h and changing the order of summations, we get:

$$1 = \sum_{x \in \{0,1\}^n} \rho(x) \geq \sum_{x \in \{0,1\}^n} f(x) = \sum_{h=0}^{n} \binom{n}{h} \mu_f(h) \geq$$

$$\sum_{h=0}^{n} \binom{n}{h} \sum_{k=0}^{h} R_k \cdot \frac{1}{\sum_{j=k}^{n} \binom{n}{j}} \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n :\, ||x||=k \,\wedge\, \text{slack}_f(x) \neq 0} =$$

$$\sum_{k=0}^{n} \sum_{h=k}^{n} \binom{n}{h} R_k \cdot \frac{1}{\sum_{j=k}^{n} \binom{n}{j}} \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n :\, ||x||=k \,\wedge\, \text{slack}_f(x) \neq 0} =$$

$$\sum_{k=0}^{n} R_k \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n :\, ||x||=k \,\wedge\, \text{slack}_f(x) \neq 0}$$

This finishes the proof of the lemma. ◀

Now, we prove the following corollary:

▶ **Corollary 10.** *Let ρ be a monotone probability distribution over $\{0,1\}^n$ and let h_0 be an integer for which:*

$$\frac{\epsilon}{4} \leq \Pr_{x \sim \{0,1\}^n}[||x|| \geq h_0] \leq \frac{\epsilon}{2}$$

Then, there exists a positive monotone function $f : \{0,1\}^n \to R$ satisfying:

1. *For all x, it is the case that $\rho(x) \geq f(x)$.*
2. *It is the case that: $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \frac{\epsilon}{4}$.*
3. *There exists a set of values $\{k_1, ..., k_t\}$ (ordered in an increasing order) with $t \leq \frac{16}{\epsilon^2}$, satisfying that if for some x in $\{0,1\}^n$ we have $||x|| < h_0$ and $slack_f(x) \neq 0$, then $||x|| = k_i$ for some i.*

Proof. We use Lemma 9, setting $\zeta = \epsilon/4$ and

$$R_h = \begin{cases} \frac{\epsilon^2}{16} & \text{if } h \leq h_0 \\ 0 & \text{otherwise} \end{cases}$$

We verify the precondition to Lemma 9, by using that $\sum_{x \in \{0,1\}^n} \rho(x) - f(x) \leq \frac{\epsilon}{4}$:

$$\sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}}{\sum_{j=h}^{n} \binom{n}{j}} = \sum_{h=0}^{h_0} \frac{\epsilon^2}{16} \cdot \frac{\binom{n}{h}}{\sum_{j=h}^{n} \binom{n}{j}} \leq \sum_{h=0}^{h_0} \frac{\epsilon^2}{16} \cdot \frac{\binom{n}{h}}{\sum_{j=h_0}^{n} \binom{n}{j}} \leq$$

$$\sum_{h=0}^{h_0} \frac{\epsilon^2}{16} \cdot \frac{\binom{n}{h}}{2^n \cdot \epsilon/4} = \frac{\epsilon}{4} \cdot \sum_{h=0}^{h_0} \frac{\binom{n}{h}}{2^n} \leq \frac{\epsilon}{4}$$

Now, we simply check that properties (1), (2) and (3) of the Lemma directly imply the properties (1), (2) and (3) of the Corollary respectively. This completes the proof. ◀

To use Lemma 9, we need an upper bound on the value of $\frac{\binom{n}{h}}{\sum_{j \geq h}^{n} \binom{n}{j}}$. The following claim provides such an upper bound:

▷ Claim 21. For all sufficiently large n, for all h, satisfying $0 \leq h \leq n$, it is the case that:

$$\frac{\binom{n}{h}}{\sum_{j \geq h}^{n} \binom{n}{j}} \leq \left(\begin{cases} \frac{2}{n^2} & \text{if } h \leq n/2 - \sqrt{n \ln(n)} \\ \frac{200}{\sqrt{n}} & \text{if } n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h - n/2}{n} & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right)$$

Proof. See Appendix A, Subsection 7.2 ◁

3.2 Proof of Claim 19

For all x in $\{0,1\}^n$, satisfying $9\sqrt{n} \leq ||x||$, we define the following quantity:

$$\phi(x) \stackrel{\text{def}}{=} \frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x|| - ||y|| = \lfloor L_{||x||} \rfloor} \Pr_{z \sim \rho}[y \preceq z \preceq x] =$$

$$\frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x|| - ||y|| = \lfloor L_{||x||} \rfloor} \sum_{z \text{ s.t. } y \preceq z \preceq x} \rho(z) \quad (4)$$

Observe that since for every such x and y there are $2^{\lfloor L_{||x||} \rfloor}$ values of z satisfying $y \preceq z \preceq x$, and ρ is a monotone probability distribution, it has to be the case that $\phi(x) \leq \rho(x)$ for all x on which $\phi(x)$ is defined.

More interestingly, we will be claiming that ϕ is (in terms of L_1 distance) a good approximation to ρ, but first we will show that $\hat{\phi}$ is a good approximation to ϕ, assuming that the values L_h are not too small:

▷ Claim 22. If it is the case that $\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} \leq \frac{1}{2}$, then, with probability at least $7/8$, it is the case that:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{4} \tag{5}$$

Proof. See Appendix A, Subsection 7.3, for the proof, which follows using tail bounds. ◁

Now, we apply Lemma 9 to ρ, with value $\zeta := \epsilon/100$. For now, we postpone setting the values of R_h, which we will do later in our derivation (of course, we will then check that the required constraint is indeed satisfied by these values).

This gives a positive monotone function f that satisfies the three conditions of Lemma 9. We separate all the values of x in $\{0,1\}^n$ for which $9\sqrt{n} \leq ||x||$ into two kinds: **good** and **bad**. We say that x is **bad** if there is some y for which $0 \leq ||x|| - ||y|| < \lfloor L_{||x||} \rfloor$ and $\text{slack}_f(y)$ is non-zero. Otherwise, x if **good**. Clearly, for a given Hamming weight value, wither every point with this Hamming weight is good, or every such point is bad.

We can write:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} |\phi(x) - f(x)| = \sum_{\text{good } x} |\phi(x) - f(x)| + \sum_{\text{bad } x} |\phi(x) - f(x)| \tag{6}$$

Now, we bound the two terms above separately. If x is good, then it is the case that for all y satisfying $||x|| - \lfloor L_{||x||} \rfloor < ||y|| \leq ||x||$ we have $\text{slack}_f(x) = 0$, and therefore $f(y) = \max_{y' \in \{0,1\}^n \text{ s. t. } y' \preceq y \text{ and } ||y|| - ||y'|| = 1} f(y')$. Using this relation recursively, we obtain that:

$$f(x) = \max_{y \in \{0,1\}^n \text{ s. t. } y \preceq x \text{ and } ||x|| - ||y|| = \lfloor L_{||x||} \rfloor} f(y)$$

Therefore, since f is monotone, we obtain that:

$$f(x) = \frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x|| - ||y|| = \lfloor L_{||x||} \rfloor} \sum_{z \text{ s.t. } y \preceq z \preceq x} f(z)$$

By Lemma 9, it is the case $\rho(x) \geq f(x)$. This, together with the equation above and Equation 4 implies:

$$\phi(x) \geq f(x)$$

But we also know that $\rho(x) \geq \phi(x)$. Therefore:

$$\sum_{\text{good } x} |\phi(x) - f(x)| \leq \sum_{\text{good } x} |\rho(x) - f(x)| \leq \frac{\epsilon}{4} \tag{7}$$

Where the last inequality follows from Lemma 9.

Now, we bound the contribution of bad points. Since $\phi(x) \leq \rho(x)$, $f(x) \leq \rho(x)$ and recalling the definition of a bad point, we get:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{\text{bad } x} \max(\phi(x), f(x)) \leq \sum_{\text{bad } x} \rho(x) \leq \sum_{h_2=9\sqrt{n}}^{n} \mu_\rho(h_2) \cdot \binom{n}{h_2} \cdot \mathbf{1}_{\exists\, x\in\{0,1\}^n:\, \left(h_2 - \lfloor L_{h_2} \rfloor < ||x|| \leq h_2\right) \wedge \text{slack}_f(x) \neq 0} \quad (8)$$

Since Lemma 9 gives us a bound on a weighed sum of indicator variables of the form $\mathbf{1}_{\exists\, x\in\{0,1\}^n:\, ||x||=h \wedge \text{slack}_f(x)\neq 0}$, we would like to upper-bound the expression above by such a weighted sum. To do this, to every Hamming weight value h that has a point x with non-zero $\text{slack}_f(x)$ (we call such Hamming weight value h **slacky**) we "charge" every value h_2, for which points of Hamming weight h_2 are rendered bad because h is slacky. This will happen only if $h_2 \geq h$ and $h_2 - \lfloor L_{h_2} \rfloor < h$. But since $\lfloor L_{h_2} \rfloor$ can only decrease as h_2 increases, the latter can happen only if $h_2 - \lfloor L_h \rfloor < h$. Therefore:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} \left(\sum_{h_2=h}^{h+\lfloor L_h \rfloor - 1} \mu_\rho(h_2) \cdot \binom{n}{h_2} \right) \cdot \mathbf{1}_{\exists\, x\in\{0,1\}^n:\, ||x||=h \wedge \text{slack}_f(x)\neq 0} \quad (9)$$

Now, to upper-bound $\mu_\rho(h_2)$, we need the following claim:

▷ Claim 23. For any monotone probability distribution ρ it is the case that for all h:

$$\mu_\rho(h) \leq \frac{1}{\sum_{j=h}^{n} \binom{n}{j}}$$

Proof. This follows immediately from Fact 15 and that $\sum_{x\in\{0,1\}^n} \rho(x) = 1$. ◁

Claim 23, Equation 8 and Claim 21 together imply:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} \left(\sum_{h_2=h}^{h+\lfloor L_h \rfloor - 1} \frac{\binom{n}{h_2}}{\sum_{j=h_2}^{n} \binom{n}{j}} \right) \mathbf{1}_{\left(\substack{\exists\, x\in\{0,1\}^n: \\ ||x||=h \wedge \text{slack}_f(x)\neq 0}\right)} \leq$$

$$\sum_{h=0}^{n} \left(\sum_{h_2=h}^{h+\lfloor L_h \rfloor - 1} \left(\begin{cases} \frac{200}{\sqrt{n}} & \text{if } h_2 < n/2 + \sqrt{n} \\ 200 \cdot \frac{h_2 - n/2}{n} & \text{if } h_2 \geq n/2 + \sqrt{n} \end{cases} \right) \right) \mathbf{1}_{\left(\substack{\exists\, x\in\{0,1\}^n: \\ ||x||=h \wedge \text{slack}_f(x)\neq 0}\right)} \leq$$

$$\sum_{h=0}^{n} L_h \cdot \left(\begin{cases} \frac{200}{\sqrt{n}} & \text{if } h + L_h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h + L_h - n/2}{n} & \text{if } h + L_h \geq n/2 + \sqrt{n} \end{cases} \right) \mathbf{1}_{\left(\substack{\exists\, x\in\{0,1\}^n: \\ ||x||=h \wedge \text{slack}_f(x)\neq 0}\right)} \quad (10)$$

Now, we claim that:

$$\left(\begin{cases} \frac{200}{\sqrt{n}} & \text{if } h + L_h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h + L_h - n/2}{n} & \text{if } h + L_h \geq n/2 + \sqrt{n} \end{cases} \right) \leq 10 \cdot \left(\begin{cases} \frac{200}{\sqrt{n}} & \text{if } h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h - n/2}{n} & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right) \quad (11)$$

This follows by considering three cases (i) $h + L_h < n/2 + \sqrt{n}$, in which case this is equivalent to $\frac{200}{\sqrt{n}} \leq \frac{2000}{\sqrt{n}}$, which is trivially true. (ii) $h \geq n/2 + \sqrt{n}$, in which case since $L_h \leq 9\sqrt{n}$, we have that $\frac{h + L_h - n/2}{n} \leq 10 \cdot \frac{h - n/2}{n}$ (iii) $h + L_h \geq n/2 + \sqrt{n}$, but $h < n/2 + \sqrt{n}$, in which case since $L_h \leq 9\sqrt{n}$, we have that $\frac{h + L_h - n/2}{n} \leq \frac{\sqrt{n} + L_h}{n} \leq 10\sqrt{n}$.

Combining Equations 10 and 11, we get:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq$$
$$\sum_{h=0}^{n} L_h \cdot 10 \cdot \left(\begin{cases} \frac{200}{\sqrt{n}} & \text{if } h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h-n/2}{n} & \text{otherwise} \end{cases} \right) \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n \colon ||x|| = h \,\wedge\, \text{slack}_f(x) \neq 0} \quad (12)$$

Recall that we postponed setting the values of R_h. The equation above motivates us to set:

$$R_h := \frac{200}{\epsilon} \cdot L_h \cdot \left(\begin{cases} \frac{200}{\sqrt{n}} & \text{if } h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h-n/2}{n} & \text{otherwise} \end{cases} \right)$$

Now, we check the constraint on R_h in Lemma 9. Using Claim 21 and the premise of Claim 19:

$$\sum_{h=0}^{n} R_h \cdot \frac{\binom{n}{h}}{\sum_{j \geq h}^{n} \binom{n}{j}} \leq \sum_{h=0}^{n} R_h \cdot \left(\begin{cases} \frac{2}{n^2} & \text{if } h \leq n/2 - \sqrt{n \ln(n)} \\ \frac{200}{\sqrt{n}} & \text{if } n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h-n/2}{n} & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right) =$$
$$\frac{200}{\epsilon} \cdot \sum_{h=0}^{n} L_h \cdot \left(\begin{cases} \frac{400}{n^{2.5}} & \text{if } h \leq n/2 - \sqrt{n \ln(n)} \\ \frac{40000}{n} & \text{if } n/2 - \sqrt{n \ln(n)} < h < n/2 + \sqrt{n} \\ 40000 \cdot \left(\frac{h-n/2}{n} \right)^2 & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right) \leq \frac{\epsilon}{100} = \zeta$$

Therefore, Lemma 9, together with Equation 12 implies that:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{h=0}^{n} \frac{\epsilon}{20} \cdot R_h \cdot \mathbf{1}_{\exists\, x \in \{0,1\}^n \colon ||x|| = h \,\wedge\, \text{slack}_f(x) \neq 0} \leq \frac{\epsilon}{20}$$

Now, using triangle inequality and then combining the inequality above with Equations 28, 6 and 7 we get:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \rho(x) \right| \leq$$
$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \phi(x) \right| + \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \phi(x) - \rho(x) \right| \leq$$
$$\frac{\epsilon}{4} + \frac{\epsilon}{100} + \frac{\epsilon}{20} \leq \frac{\epsilon}{2} \quad (13)$$

4 Estimating the distance to uniform

In this section we prove our upper-bound on the sample complexity of estimating the distance from uniform of an unknown monotone probability distribution over the Boolean cube. We restate the theorem:

▶ **Theorem 5.** *For every positive ϵ, the following is true: for all sufficiently large n, there exists an algorithm, which given $\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$ samples from an unknown monotone probability distribution ρ over $\{0,1\}^n$, can reliably approximate the distance between ρ and the uniform distribution over $\{0,1\}^n$ with an additive error of up to ϵ. The algorithm runs in time $O\left(2^{n+O_\epsilon(\sqrt{n}\log n)}\right)$.*

Algorithm 2 Algorithm for the estimation of distance to uniform efficiently (given sample access from a distribution ρ, which is monotone over $\{0,1\}^n$).

1. Pick set h_0 to be an integer for which it is the case that:

$$\frac{\epsilon}{4} \leq \Pr_{x \sim \{0,1\}^n}[||x|| \geq h_0] \leq \frac{\epsilon}{2} \tag{14}$$

   Do this by going through every integer candidate $h_{\text{candidate}}$ in the interval and computing the fraction of points x in $\{0,1\}$ for which $||x|| \geq h_{\text{candidate}}$. Finally, pick h_0 to be one of $h_{\text{candidate}}$ for which the relation above holds.
2. Set $N_1 := \frac{32 \ln 2}{\epsilon^2}$. Draw N_1 samples from the probability distribution ρ and denote the multiset of these samples as S_1.
3. Set:

$$\hat{d}_1 := \frac{1}{2} \cdot \frac{\left|\left\{z \in S_1 : ||z|| \geq h_0\right\}\right|}{N_1}$$

4. Set $L := \left\lfloor \frac{\sqrt{n}\epsilon^4}{512} \right\rfloor$.
5. Set

$$N_2 := \frac{2^n}{2^L} \cdot \frac{192}{\epsilon^2} \cdot \left(n \ln 2 + L \ln n + 4 \ln 2\right)$$

   Draw N_2 samples from the probability distribution ρ and denote the multiset of these samples as S_2.
6. For all x, satisfying $L \leq ||x|| < h_0$, compute:

$$\hat{\phi}(x) := \frac{1}{2^L} \cdot \frac{\max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \left|\left\{z \in S_2 : y \preceq z \preceq x\right\}\right|}{N_2}$$

   Do this by first making a look-up table, which given arbitrary $z \in \{0,1\}^n$ returns the number of times z was encountered in S_2. Then, use this look-up table to compute the necessary values of $|\{z \in S_2 : y \preceq z \preceq x\}|$ by querying all these values of z in the lookup table and summing the results up.
7. Compute the following:

$$\hat{d}_2 := \frac{1}{2} \cdot \sum_{x \text{ s.t. } L \leq ||x|| < h_0} \left|\hat{\phi}(x) - \frac{1}{2^n}\right|$$

8. Output $\hat{d}_1 + \hat{d}_2$.

Proof. We present the algorithm as Algorithm 2. The number of samples drawn from ρ is $N_1 + N_2 = \frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$. The run-time, in turn, is dominated[5] by computing the values of $\hat{\phi}$ in step (6), in which the construction of the lookup table takes $O(n \cdot 2^n)$ time and the time spent computing each $\hat{\phi}(x)$ can be upper bounded by the product of: (i) the number of pairs (y, z) that simultaneously satisfy $y \preceq z \preceq x$ and $||x|| - ||y|| = L$, which can be upper-bounded by $O(n^L \cdot 2^L)$ and (ii) the time it takes to look up a given z in the lookup table, which can be upper-bounded by $O(n)$. Overall, this gives us a run-time upper bound of $O(2^{n+O_\epsilon(\sqrt{n}\log n)})$.

Now, the only thing left to prove is correctness. First of all, it is not a priori clear that there exists a value of h_0 satisfying Equation 14 (in Algorithm 2). This is true for the following reason: imagine changing $h_{\text{candidate}}$ from n to 0 by decrementing it in steps of one. Then $\Pr_{x\in\{0,1\}^n}[||x|| \geq h_{\text{candidate}}]$ will increase from $\frac{1}{2^n}$ to 1 and by Fact 16 it will not increase by more than $\frac{2}{\sqrt{n}}$ at any given step. For sufficiently large n we have $\frac{2}{\sqrt{n}} < \frac{\epsilon}{4}$. Then it is impossible to skip over the interval between $\frac{\epsilon}{4}$ and $\frac{\epsilon}{2}$ in just one step of length at most $\frac{2}{\sqrt{n}}$, and therefore Equation 14 (in Algorithm 2) will be the case for some value of $h_{\text{candidate}}$.

We decompose the total variation distance between ρ and the uniform distribution into three terms:

$$\frac{1}{2}\cdot\sum_{x\in\{0,1\}^n}\left|\rho(x)-\frac{1}{2^n}\right| = \frac{1}{2}\cdot\sum_{\substack{x\in\{0,1\}^n \text{ s.t.}\\ ||x||\geq h_0}}\left|\rho(x)-\frac{1}{2^n}\right| + \frac{1}{2}\cdot\sum_{\substack{x\in\{0,1\}^n \text{ s.t.}\\ L\leq||x||<h_0}}\left|\rho(x)-\frac{1}{2^n}\right| + \frac{1}{2}\cdot\sum_{\substack{x\in\{0,1\}^n \text{ s.t.}\\ ||x||<L}}\left|\rho(x)-\frac{1}{2^n}\right| \tag{15}$$

We argue that the first term is well approximated by $\hat{d}_1$, the second term is well approximated by $\hat{d}_2$, and the third term is negligible. As the reader will see, out of these three terms, the middle term is the least trivial to prove guarantees for.

We will first handle the first term: From the triangle inequality, Hoeffding's bound and Equation 14 (in Algorithm 2) it follows immediately that with probability at least 7/8 it is the case that:

$$\left|\hat{d}_1 - \frac{1}{2}\cdot\sum_{x\in\{0,1\}^n \text{ s.t. } ||x||\geq h_0}\left|\rho(x)-\frac{1}{2^n}\right|\right| \leq \left|\hat{d}_1 - \frac{1}{2}\cdot\sum_{x\in\{0,1\}^n \text{ s.t. } ||x||\geq h_0}\rho(x)\right| + \frac{1}{2}\cdot\sum_{x\in\{0,1\}^n \text{ s.t. } ||x||\geq h_0}\frac{1}{2^n} \leq \frac{\epsilon}{8}+\frac{\epsilon}{4} = \frac{3\epsilon}{8} \tag{16}$$

Now, we use the two following facts: (i) Since $\sum_x \rho(x) = 1$ and ρ is monotone, for every x with $||x|| \leq L$ it should be the case that $\rho(x) \leq \frac{1}{2^{n-L}}$. (ii) The number of different values of x in $\{0,1\}^n$ for which $||x|| \leq L$ can be upper bounded by n^L. We get for sufficiently large n:

$$\frac{1}{2}\cdot\sum_{x\in\{0,1\}^n \text{ s.t. } ||x||<L}\left|\rho(x)-\frac{1}{2^n}\right| \leq \frac{1}{2}\cdot\sum_{x\in\{0,1\}^n \text{ s.t. } ||x||<L}\left(\frac{1}{2^n}+\rho(x)\right) \leq \frac{1}{2}\cdot n^L\cdot\left(\frac{1}{2^n}+\frac{1}{2^{n-L}}\right) = o(1) \leq \frac{\epsilon}{8} \tag{17}$$

[5] Step 1 requires only $2^n\text{poly}(n)$ time, which is less than what step (6) requires. By inspection, other steps require even less run-time. Incidentally, the task in step 1 can be done much faster by randomized sampling, but since this is not the run-time bottleneck, we use this direct approach for the sake of simplicity.

The rest of this section will be dedicated to proving the following claim:

▷ Claim 24. With probability at least 7/8 it is the case that:

$$\left|\hat{d}_2 - \frac{1}{2} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left|\rho(x) - \frac{1}{2^n}\right|\right| \leq \frac{\epsilon}{2} \tag{18}$$

Once this is proven, it follows by a union bound that with probability at least 3/4 both Equations 16 and 18 will be the case. This, together with Equation 17, when substituted into Equation 15 will imply that:

$$\left| \sum_{x \in \{0,1\}^n} \left|\rho(x) - \frac{1}{2^n}\right| - (\hat{d}_1 + \hat{d}_2)\right| \leq \epsilon$$

This will imply the correctness of our algorithm. ◀

4.1 Proof of Claim 24

For all x in $\{0,1\}^n$, satisfying $L \leq ||x|| < h_0$, we define the following quantity:

$$\phi(x) \stackrel{\text{def}}{=} \frac{1}{2^L} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \Pr_{z \sim \rho}[y \preceq z \preceq x] = \frac{1}{2^L} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y||=L} \sum_{z \text{ s.t. } y \preceq z \preceq x} \rho(z) \tag{19}$$

Observe that since for every such x and y there are 2^L values of z satisfying $y \preceq z \preceq x$, and ρ is a monotone probability distribution, it has to be the case that $\phi(x) \leq \rho(x)$ for all x on which $\phi(x)$ is defined.

We will be claiming that $\phi(x)$ is (in terms of L_1 distance) a good approximation to $\rho(x)$, but first we will show that $\hat{\phi}(x)$ is a good approximation to $\phi(x)$:

▷ Claim 25. With probability at least 7/8, it is the case that:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left|\hat{\phi}(x) - \phi(x)\right| \leq \frac{\epsilon}{4} \tag{20}$$

Proof. We claim that for any pair (x, y), such that ϕ is defined on x and $||x|| - ||y|| = L$, with probability at least $1 - \frac{1}{8 \cdot 2^n \cdot n^L}$ the following holds:

$$\frac{1}{2^L}\left|\Pr_{z \sim \rho}[y \preceq z \preceq x] - \frac{|\{z \in S : y \preceq z \preceq x\}|}{N_2}\right| \leq \frac{\epsilon}{8} \cdot \max\left(\frac{1}{2^n}, \frac{1}{2^L}\Pr_{z \sim \rho}[y \preceq z \preceq x]\right) \tag{21}$$

We use Chernoff's bound to prove this as follows. Denote by q the value $\Pr_{z \sim \rho}[y \preceq z \preceq x]$. If $q \geq \frac{2^L}{2^n}$ then by Chernoff's bound we have:

$$\Pr\left[\left||\{z \in S : y \preceq z \preceq x\}| - qN_2\right| \geq \frac{\epsilon}{8}qN_2\right] \leq 2\exp\left(-\frac{1}{3}\left(\frac{\epsilon}{8}\right)^2 qN_2\right) \leq 2\exp\left(-\frac{1}{3}\left(\frac{\epsilon}{8}\right)^2 \frac{2^L}{2^n} \cdot N_2\right) = \frac{1}{8 \cdot 2^n \cdot n^L}$$

Otherwise, if we have $q < \frac{2^L}{2^n}$, then by Chernoff's bound:

$$\Pr\left[\left||\{z \in S : y \preceq z \preceq x\}| - qN_2\right| \geq \frac{\epsilon}{8} \cdot \frac{2^L}{2^n} \cdot N_2\right] \leq 2\exp\left(-\frac{1}{3}\left(\frac{\epsilon}{8} \cdot \frac{2^L}{2^n} \cdot \frac{1}{q}\right)^2 qN_2\right) \leq$$
$$2\exp\left(-\frac{1}{3}\left(\frac{\epsilon}{8}\right)^2 \frac{2^L}{2^n} \cdot N_2\right) = \frac{1}{8 \cdot 2^n \cdot n^L}$$

Now, by taking a union bound, it follows that with probability 7/8 for all such pairs (x, y) Equation 21 will be the case. For all x on which ϕ is defined it then will be the case that:

$$\left|\hat{\phi}(x) - \phi(x)\right| \leq \frac{\epsilon}{8} \cdot \max\left(\frac{1}{2^n}, \phi(x)\right)$$

Summing this for all x in the domain of ϕ we get:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left|\hat{\phi}(x) - \phi(x)\right| \leq \frac{\epsilon}{8} \cdot \left(2^n \cdot \frac{1}{2^n} + \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \phi(x)\right) \leq$$
$$\frac{\epsilon}{8} \cdot \left(1 + \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \rho(x)\right) \leq \frac{\epsilon}{4}$$

◁

Now, we apply Corollary 10 to ρ. This gives a positive monotone function f that satisfies the three conditions of Corollary 10. We separate all the values of x in $\{0,1\}^n$ for which $L \leq ||x|| < h_0$ into two kinds: **good** and **bad**. Recall that by Corollary 10 an element x of $\{0,1\}^n$ for which $L \leq ||x|| < h_0$ can have $\text{slack}_f(x) \neq 0$ only if $||x|| = k_i$ for some i between 1 and t. We say that x is **bad** if there is some k_i for which $0 \leq ||x|| - k_i \leq L$. Otherwise, x if **good**.

We can write:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\phi(x) - f(x)| = \sum_{\text{good } x} |\phi(x) - f(x)| + \sum_{\text{bad } x} |\phi(x) - f(x)| \tag{22}$$

Now, we bound the two terms above separately. If x is good, then it is the case that for all z satisfying $||x|| - L \leq ||z|| \leq ||x||$ we have $\text{slack}_f(x) = 0$, and therefore $f(z) = \max_{z' \in \{0,1\}^n \text{ s. t. } z' \preceq z \text{ and } ||z|| - ||z'|| = 1} f(z')$. Using this relation recursively, we obtain that:

$$f(x) = \max_{z \in \{0,1\}^n \text{ s. t. } z \preceq x \text{ and } ||x|| - ||z|| = L} f(z)$$

Therefore, since f is monotone, we obtain that:

$$f(x) = \frac{1}{2^L} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x|| - ||y|| = L} \sum_{z \text{ s.t. } y \preceq z \preceq x} f(z)$$

By Corollary 10, it is the case $\rho(x) \geq f(x)$. This, together with the equation above and Equation 19 implies:

$$\phi(x) \geq f(x)$$

But we also know that $\rho(x) \geq \phi(x)$. Therefore:

$$\sum_{\text{good } x} |\phi(x) - f(x)| \leq \sum_{\text{good } x} |\rho(x) - f(x)| \leq \frac{\epsilon}{4} \tag{23}$$

Where the last inequality follows from Corollary 10.

Now, we bound the contribution of bad points.

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \sum_{\text{bad } x} \max(\phi(x), f(x)) \leq \sum_{\text{bad } x} \rho(x) = \sum_{k \in [L, h_0] \text{ s.t. for some } k_i\text{: } |k - k_i| \leq L} \mu_\rho(k) \cdot \binom{n}{k}$$

Now, by Claim 23 we have $\mu_\rho(k) \leq \frac{1}{2^n} \cdot \frac{4}{\epsilon}$ and by Fact 16 we have that $\binom{n}{k} \leq \frac{2}{\sqrt{n}} \cdot 2^n$. Combining these two facts with the inequality above we get:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \left(\frac{1}{2^n} \cdot \frac{4}{\epsilon}\right) \cdot \left(\frac{2}{\sqrt{n}} \cdot 2^n\right) \cdot (L \cdot t) = \frac{4}{\epsilon} \cdot \frac{2}{\sqrt{n}} \cdot L \cdot t$$

Substituting the value of L and the upper bound on t from Corollary 10 we get:

$$\sum_{\text{bad } x} |\phi(x) - f(x)| \leq \frac{4}{\epsilon} \cdot \frac{2}{\sqrt{n}} \cdot \frac{\epsilon^4 \sqrt{n}}{512} \cdot \frac{16}{\epsilon^2} = \frac{\epsilon}{4}$$

Combining this with Equations 22 and 23 we get:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\phi(x) - f(x)| \leq \frac{\epsilon}{2} \tag{24}$$

Overall, we have:

$$\left| \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\rho(x) - 1/2^n| - \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - 1/2^n| \right| \leq$$
$$\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - \rho(x)| \leq \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - \phi(x)| +$$
$$\sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\phi(x) - f(x)| + \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |f(x) - \rho(x)|$$

This three terms can be bound using respectively Equation 20, Corollary 10 and Equation 24. This gives us:

$$\left| 2 \cdot \hat{d}_2 - \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} \left| \rho(x) - \frac{1}{2^n} \right| \right| =$$
$$\left| \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\rho(x) - 1/2^n| - \sum_{x \in \{0,1\}^n \text{ s.t. } L \leq ||x|| < h_0} |\hat{\phi}(x) - 1/2^n| \right| \leq \epsilon$$

Therefore, with probability at least 7/8 Equation 18 holds, which proves Claim 24 and completes the proof of correctness.

5 Estimating the support size

In this section we prove our upper-bound on the sample complexity of estimating the support size of an unknown monotone probability distribution over the Boolean cube. Recall that a probability distribution ρ is **well-behaved** if for every x either $\rho(x) = 0$ or $\rho(x) \geq 1/2^n$. We restate the theorem:

▶ **Theorem 4.** *For every positive ϵ, the following is true: for all sufficiently large n, there exists an algorithm, which given $\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$ samples from an unknown well-behaved monotone probability distribution ρ over $\{0,1\}^n$, can reliably[6] approximate the support size of ρ with an additive error of up to ϵ. The algorithm runs in time $O_\epsilon\left(\frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}\right)$*

Proof. The algorithm we use is listed as Algorithm 3.

Algorithm 3 Algorithm for the estimation of support size (given sample access from the distribution).

1. Set
$$M_1 = \frac{2^n}{2^{\frac{\epsilon^2}{64}\sqrt{n}}}\left(\ln\frac{32}{\epsilon}+1\right)$$
2. Take M_1 samples from the probability distributions. Call the set of these samples S_1.
3. Set
$$M_2 = \frac{32\ln 2}{\epsilon^2}$$
4. Pick M_2 elements of $\{0,1\}^n$ uniformly at random. Call these samples S_2.
5. We say that a point y is **covered** if in S_1 there exists at least one z, so that $z \preceq y$. One can check if a point y is covered by going through all the M_1 elements in S_1. Using this checking procedure, compute the fraction $\hat{\eta}$ of the elements in S_2 that are covered.
6. Output $\hat{\eta}$.

Clearly, the sample complexity is:

$$O\left(\frac{2^n}{2^{\frac{\epsilon^2}{64}\sqrt{n}}}\left(\ln\frac{32}{\epsilon}+1\right)\right) = \frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$$

In turn, the run-time is:

$$O\left(\frac{2^n}{2^{\frac{\epsilon^2}{64}\sqrt{n}}}\left(\ln\frac{32}{\epsilon}+1\right)\cdot\frac{32\ln 2}{\epsilon^2}\right) = \frac{2^n}{2^{\Theta_\epsilon(\sqrt{n})}}$$

Now, all is left to prove is correctness.

Let η denote the fraction of elements in $\{0,1\}^n$ that are covered by our samples in S_1. Then, a random element of $\{0,1\}^n$ is covered with probability η. Therefore, by the Hoeffding bound it follows that:

$$\Pr_{S_2}\left[|\hat{\eta}-\eta| > \frac{\epsilon}{4}\right] \leq 2\exp\left(-2\left(\frac{\epsilon}{4}\right)^2 M_2\right) = \frac{1}{8} \tag{25}$$

The last equality follows by substituting the value of M_2.

[6] By **reliably** we henceforth mean that the probability of success is at least 2/3.

Since ρ is monotone, it has to be the case that every point that is covered is in the support of ρ. Hence, the support size of ρ is at least $\eta \cdot 2^n$.

Now, all we need to show is that $\eta \cdot 2^n$ is not likely to be much smaller than the support size of ρ. We call a point x in the support of ρ **good** if there are at least $2^{\frac{\epsilon^2}{64}\sqrt{n}}$ points y each of which satisfying: (i) y belongs to the support of ρ. (ii) $x \preceq y$. If a point in the support of ρ is not good, then it is **bad**. We will show that the bad points are few, while a lot of the good points are likely to be covered.

Let f_{support} be defined as follows:

$$f_{\text{support}} \stackrel{\text{def}}{=} \begin{cases} 1 \text{ if } \rho(x) \neq 0 \\ 0 \text{ otherwise} \end{cases}$$

In other words, f_{support} is the indicator function of the support of ρ. Since ρ is a monotone probability distribution, f_{support} is a monotone function. Therefore, applying Lemma 8, there exists a function $g = g_1 \vee ... \vee g_t$ that $\epsilon/4$-approximates f_{support}, where $t \leq 8/\epsilon$ and each g_i is a monotone DNF with terms of width exactly k_i. Additionally, $g(x) \leq f(x)$ for all x in $\{0,1\}^n$

▷ Claim 26. For all i, g_i contains at most $\frac{\epsilon^2}{32} \cdot 2^n$ bad points.

Proof. Recall that g_i is k_i-regular, and therefore every point x on which $g_i(x) = 1$ needs to have Hamming weight $||x|| \geq k_i$.

▷ Claim 27. If x satisfies $g_i(x) = 1$ and $||x|| \geq k_i + \frac{\epsilon^2}{64}\sqrt{n}$, then x has to be good

Proof. Since g_i is a DNF and $g_i(x) = 1$ then x satisfies at least one of the terms of g_i. If there are more than one, arbitrarily pick one of them. Let this term be

$$t(y) = \bigwedge_{j \in H_1} y_j$$

The width of this AND has to be k_i, therefore $|H| = k_i$. Since $||x|| \geq k_i + \frac{\epsilon^2}{64}\sqrt{n}$, there must be $\frac{\epsilon^2}{64}\sqrt{n}$ values of j for which $x_j = 1$ but j is not in H_1. Denote the set of these values of j as H_2.

Now, consider an element $y \in \{0,1\}^n$ satisfying the criteria:

- For all j in H_1, $y_j = 1$.
- For all j neither in H_1 nor in H_2, $y_j = 0$.

Clearly, $t(y) = 1$, which implies $g_i(y) = 1$, $g(y) = 1$, and $f_{\text{support}}(y) = 1$. Also, for all j, we have $y_j \leq x_j$, and therefore $y \preceq x$. Finally, for all j in H_2 the value of y_j can be set arbitrarily to zero or one, and therefore there are $2^{|H_2|}$ such points, which is at least $2^{\frac{\epsilon^2}{64}\sqrt{n}}$. Therefore, x is a good point. ◁

Thus, we can upper-bound the number of bad points x on which $g_i(x) = 1$ by:

$$\left|\left\{x \in \{0,1\}^n : g(x) = 1 \text{ and } k_i + \frac{\epsilon^2}{64}\sqrt{n} > \sum_j x_j \geq k_i\right\}\right| \leq$$

$$\left|\left\{x \in \{0,1\}^n : k_i + \frac{\epsilon^2}{64}\sqrt{n} > \sum_j x_j \geq k_i\right\}\right| = \sum_{j=k_i}^{k_i + \frac{\epsilon^2}{64}\sqrt{n} - 1} \binom{n}{j} \leq \frac{\epsilon^2}{64}\sqrt{n}\binom{n}{n/2}$$

By Fact 16, for sufficiently large n, it is the case that $\binom{n}{n/2} \leq 2 \cdot \frac{2^n}{\sqrt{n}}$. This implies that the expression above is upper-bounded by $\frac{\epsilon^2}{32} \cdot 2^n$, which completes the proof of this claim. ◁

Since $g = g_1 \vee ... \vee g_t(x)$, our claim implies the following:

$$\left|\left\{x : g(x) = 1 \text{ and } x \text{ is bad}\right\}\right| \leq \sum_{i=1}^{t} \left|\left\{x : g_i(x) = 1 \text{ and } x \text{ is bad}\right\}\right| \leq$$
$$t \cdot \frac{\epsilon^2}{32} \cdot 2^n \leq \frac{8}{\epsilon} \cdot \frac{\epsilon^2}{32} \cdot 2^n = \frac{\epsilon}{4} \cdot 2^n$$

In addition, there could be at most $\frac{\epsilon}{4} \cdot 2^n$ bad points among the points on which f_{support} and g disagree. Thus, in total, there are at most $\frac{\epsilon}{2} \cdot 2^n$ bad points.

Finally, we need to argue that it is likely that many of the good points get covered:

▷ Claim 28. Suppose there are G good points. Then, with probability at least $7/8$ it will be the case that at least $1 - \epsilon/4$ fraction of these good points are covered.

Proof. For every good point x there exist least $2^{\frac{\epsilon^2}{64}\sqrt{n}}$ values of y for which i) $x \preceq y$ and ii) y is in the support of ρ. Since $x \preceq y$, if y is ever picked from the distribution, then x will be covered. Since y is in the support of ρ, and ρ is well-behaved, we have $\rho(y) \geq \frac{1}{2^n}$. Together, these imply that the probability that a random sample from ρ covers x is at least $\frac{2^{\frac{\epsilon^2}{64}\sqrt{n}}}{2^n}$. Hence, the probability that any of the M_1 i.i.d. samples taken from ρ does not cover x is at most:

$$\left(1 - \frac{2^{\frac{\epsilon^2}{64}\sqrt{n}}}{2^n}\right)^{M_1} = \left(1 - \frac{2^{\frac{\epsilon^2}{64}\sqrt{n}}}{2^n}\right)^{\frac{2^n}{2^{\frac{\epsilon^2}{64}\sqrt{n}}}\left(\ln\frac{32}{\epsilon}+1\right)} \leq \frac{1}{e^{\ln\frac{32}{\epsilon}}} = \frac{\epsilon}{32}$$

Let C denote a random variable, whose value equals to the number of the good points (out of total G) covered after taking M_1 i.i.d. samples from ρ.

The value of C has to satisfy these two constraints: (i) It has to be between 0 and G (ii) By linearity of expectation, $E[C] \geq (1 - \frac{\epsilon}{32})G$. Thus, to finish the proof of the Lemma, it is sufficient to show the following claim:

▷ Claim 29. If, for some fixed G, a random variable C is supported on $[0, G]$ and $E[C] \geq (1 - \frac{\epsilon}{32})G$, then $\Pr[C \geq (1 - \epsilon/4)G] \geq 7/8$.

Proof. This is immediate from Markov's inequality for the random variable $G - C$. ◁

◁

Now, we put it all together. Suppose that the bad events we previously identified do not happen. In particular, we know that with probability at least $7/8$ we have:

$$\left|\hat{\eta} - \eta\right| \leq \frac{\epsilon}{4}$$

Additionally, we also know that with probability at least $7/8$ it is the case that:

$$\left|\frac{\left|\left\{x : \substack{f_{\text{support}}(x)=1 \text{ and} \\ x \text{ is good and covered}}\right\}\right|}{2^n} - \frac{\left|\left\{x : \substack{f_{\text{support}}(x)=1 \text{ and} \\ x \text{ is good}}\right\}\right|}{2^n}\right| \leq$$
$$\frac{\epsilon}{4} \cdot \frac{|\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good}\}|}{2^n}$$

By union bound, the probability that none of this bad events happens is at least 3/4, which we will henceforth assume. Using the inequalities above together with the fact that the fraction of bad points is at most $\epsilon/2$ we get:

$$\left|\hat{\eta} - \frac{|\{x : f_{\text{support}}(x) = 1\}|}{2^n}\right| \leq \left|\hat{\eta} - \eta\right| + \left|\eta - \frac{|\{x : f_{\text{support}}(x) = 1\}|}{2^n}\right| =$$
$$\left|\hat{\eta} - \eta\right| + \left|\frac{|\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is covered}\}|}{2^n} - \frac{|\{x : f_{\text{support}}(x) = 1\}|}{2^n}\right| \leq \left|\hat{\eta} - \eta\right| +$$
$$\left|\frac{\left|\left\{x : \begin{smallmatrix} f_{\text{support}}(x)=1 \text{ and} \\ x \text{ is good and covered} \end{smallmatrix}\right\}\right|}{2^n} - \frac{\left|\left\{x : \begin{smallmatrix} f_{\text{support}}(x)=1 \text{ and} \\ x \text{ is good} \end{smallmatrix}\right\}\right|}{2^n}\right| +$$
$$\frac{|\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is bad}\}|}{2^n} \leq \frac{\epsilon}{4} + \frac{\epsilon}{4} \cdot \frac{|\{x : f_{\text{support}}(x) = 1 \text{ and } x \text{ is good}\}|}{2^n} + \frac{\epsilon}{2} \leq$$
$$\frac{\epsilon}{4} + \frac{\epsilon}{4} + \frac{\epsilon}{2} = \epsilon$$

This completes the proof of correctness. ◀

6 A lower bound on tolerant testing of uniformity

In this section we prove a sample complexity lower bound on the problem of tolerantly testing the uniformity of an unknown monotone probability distribution over $\{0,1\}^n$: the task of distinguishing a distribution that is $o(1)$-close to uniform from a distribution that is sufficiently far from uniform. Recall the theorem:

▶ **Theorem 6.** *For infinitely many positive integers n, there exist two probability distributions Δ_{Close} and Δ_{Far} over monotone distributions over $\{0,1\}^n$, satisfying:*

1. *Every distribution in Δ_{Far} is $1/2$-far from the uniform distribution.*
2. *Any algorithm that takes only $o\left(2^{\frac{n^{0.5-0.01}}{2}}\right)$ samples from a probability distribution, fails to reliably distinguish between Δ_{Close} and Δ_{Far}.*
3. *Every distribution in Δ_{Close} is $o(1)$-close to the uniform distribution.*

Proof. A basic building block of our construction is the following:

▶ **Definition 30.** *For a member of the Boolean cube x, the **subcube distribution** S_x is the probability distribution that picks y uniformly, subject to $y \succeq x$.*

All our distributions will be mixtures of such subcube distributions. For all the mixtures we will use, each subcube in the mixture is given the same weight. This method involving subcube distributions was used in [29] to prove property testing lower bounds for monotone probability distributions.

We construct Δ_{Close} to have only one member, which is equal to the uniform mixture of S_x for all $\binom{n}{n^{0.5-0.01}}$ values of x with Hamming weight $n^{0.5-0.01}$.

We define a random member of Δ_{Far} to be the uniform mixture of $\frac{1}{2}2^{n^{0.5-0.01}}$ subcube distributions S_{x_j}, where each of the x_j is picked randomly among all the members of the Boolean cube with Hamming weight $n^{0.5-0.01}$.

We show that any member of Δ_{Far} is sufficiently far from uniform by upper-bounding the size of its support (i.e. the number of elements that have non-zero probability). Each of the subcube distributions has a support size of $2^{n-n^{0.5-0.01}}$. The support size of a mixture of distributions is at most the sum of the supports sizes of the respective distributions.

Therefore, the support size of a member of Δ_{Far} is at most:

$$2^{n-n^{0.5-0.01}} \cdot \frac{1}{2} 2^{n^{0.5-0.01}} = \frac{1}{2} 2^n$$

This is sufficient to conclude that any member of Δ_{Far} is 1/2-far from uniform.

A random member D_1 of Δ_{Far} and the sole member D_2 of Δ_{Close} cannot be reliably distinguished using only $o\left(2^{\frac{n^{0.5-0.01}}{2}}\right)$ samples. This follows by the argument used in [29]: Because of the number of samples, with probability at least 0.99, the samples drawn from a random distribution from D_1 will all be from different subcube distributions. Also with probability at least 0.99, this will also be true for the sole distribution of D_2. If both of these things happen (which is the case with probability at least 0.98), the samples will be statistically indistinguishable. Thus, no tester can distinguish between D_1 and D_2 with an advantage greater than 0.02.

Finally, we need to prove that D_2 is $o(1)$-close to the uniform distribution. Here, the proof goes as follows. Both D_2 and the uniform distribution are symmetric with respect to a change of indices. This implies that the distance between these probability distributions equals to the distance between random variables R_2 and R_1, where R_1 is distributed as the Hamming weight of a random sample from D_2, whereas R_2 is distributed as the Hamming weight of uniformly random element of the Boolean cube. It is not hard to see that R_1 and R_2 are distributed according to binomial distributions with slightly different parameters. Now, the problem is equivalent to proving that the two following probability distributions are $o(1)$-close in total variation distance:

- A sum of n i.i.d. uniform random variables from $\{0,1\}$.
- A sum of $n - n^{0.5-0.01}$ i.i.d. uniform random variables from $\{0,1\}$.

It is convenient to first bound the variation distance between 1) the sum of k i.i.d. uniform random variables from $\{0,1\}$ and 2) $k+1$ i.i.d. uniform random variables from $\{0,1\}$, where k. We write the total variation distance as:

$$\frac{1}{2^k} + \sum_{i=1}^{k-1} \left| \frac{1}{2^k}\binom{k}{i} - \frac{1}{2^{k-1}}\binom{k-1}{i} \right| = \frac{1}{2^k}\left(1 + \sum_{i=1}^{k-1} \left| \binom{k-1}{i} - \binom{k-1}{i-1} \right| = \right) =$$

$$\frac{1}{2^k}\left(1 + \sum_{i=1}^{(k-1)/2} \left(\binom{k-1}{i} - \binom{k-1}{i-1} \right) + \sum_{i=(k-1)/2}^{k-1} \left(\binom{k-1}{i-1} - \binom{k-1}{i} \right)\right) =$$

$$\frac{1}{2^k}\left(1 + \binom{k-1}{(k-1)/2} - 1 + \binom{k-1}{(k-1)/2} - 1\right) = O\left(\frac{1}{\sqrt{k}}\right)$$

We telescoped the sums, and used the inequality that for all k, we have that $\binom{k}{k/2} \leq O\left(\frac{2^k}{\sqrt{k}}\right)$. For simplicity, we assumed above that $k-1$ is even, the odd case can be handled analogously. Thus, we have an upper bound of $O(1/\sqrt{k})$ on the total variation distance.

Using this, together with the triangle inequality for total variation distance, we bound the variation distance between 1) the sum of n i.i.d. uniform random variables from $\{0,1\}$ and 2) the sum of $n - n^{0.5-0.01}$ i.i.d. uniform random variables from $\{0,1\}$ by

$$O\left(\frac{n^{0.5-0.01}}{n^{0.5}}\right) = o(1).$$

This finishes the proof. ◀

7 Appendix A

7.1 Verifying the conditions on L_h

Recall that we defined A and L_h as follows:

- $A := \frac{1}{2n} \cdot e^{\frac{1}{2000} \cdot n^{1/5}}$
- For all $h \geq n/2$, we set $L_h := \max\left(\log\left(2nA \cdot \frac{\binom{n}{h}}{2^n}\right), 0\right)$
- For all h, satisfying $n/2 > h \geq 9\sqrt{n}$, we set: $L_h := L_{n/2} = \log\left(2nA \cdot \frac{\binom{n}{n/2}}{2^n}\right)$.

Here we prove that these values of A and L_h satisfy the following four conditions:

a) As a function of h, L_h is non-increasing.

b) For all h, we have that $L_h \leq 9\sqrt{n}$.

c)

$$\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} \leq \frac{1}{2}$$

d)

$$\sum_{h=9\sqrt{n}}^{n} L_h \cdot \left(\begin{cases} \frac{400}{n^{2.5}} & \text{if } h \leq n/2 - \sqrt{n\ln(n)} \\ \frac{40000}{n} & \text{if } n/2 - \sqrt{n\ln(n)} < h < n/2 + \sqrt{n} \\ 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right) \leq \frac{\epsilon^2}{20000}$$

We will need the following standard fact can be proven, for example, by comparing $\sum_{i=0}^{N} i^k$ and $\int_{i=0}^{N} i^k \, di$:

▶ **Fact 31.** *For any positive constant k and for sufficiently large n, it is the case that:* $\sum_{i=0}^{n} i^k = (1 + o(1)) \, \frac{n^{k+1}}{k+1}$.

The truth of conditions (a) and (b) follows immediately by inspection. In fact a statement stronger than (b) is the case: for sufficiently large n we have $L_h \leq \log(n \cdot A) \leq 2 \cdot n^{1/5}$. Regarding condition (c), we have:

$$\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} =$$

$$\frac{A}{2^n} \left(\sum_{h=9\sqrt{n}}^{n/2} \binom{n}{h} \frac{1}{2nA} \cdot \frac{2^n}{\binom{n}{n/2}} + \sum_{h=n/2}^{n} \binom{n}{h} \cdot \min\left(\frac{1}{2nA} \cdot \frac{2^n}{\binom{n}{h}}, 1\right) \right) \leq \sum_{h=9\sqrt{n}}^{n} \frac{1}{2n} \leq \frac{1}{2}$$

Finally, recall that for all h, we have $L_h \leq 2 \cdot n^{1/5}$. For sufficiently large n, we have:

$$\sum_{h=9\sqrt{n}}^{n} L_h \cdot \left(\begin{cases} \frac{400}{n^{2.5}} & \text{if } h \leq n/2 - \sqrt{n\ln(n)} \\ \frac{40000}{n} & \text{if } n/2 - \sqrt{n\ln(n)} < h < n/2 + \sqrt{n} \\ 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 & \text{if } h \geq n/2 + \sqrt{n} \end{cases} \right) \leq$$

$$\sum_{h=9\sqrt{n}}^{n/2-\sqrt{n\ln n}} 2 \cdot n^{1/5} \cdot \frac{400}{n^{2.5}} + \sum_{h=n/2-\sqrt{n\ln n}}^{n+\sqrt{n}} 2 \cdot n^{1/5} \cdot \frac{40000}{n} + \sum_{h=n/2+\sqrt{n}}^{n} 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 \cdot L_h \leq$$

$$\frac{\epsilon^2}{40000} + \sum_{h=n/2+\sqrt{n}}^{n} 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 \cdot L_h \quad (26)$$

We now bound the last term using Hoeffding's inequality to bound the value of $\binom{n}{h}$, making a change of variables with $i := \frac{n-h}{2}$ and then using Fact 31 to bound the resulting summation. Precisely, we have the following chain of inequalities (some of which are only true for sufficiently large n):

$$\sum_{h=n/2+\sqrt{n}}^{n} 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 \cdot L_h \leq$$

$$\sum_{h=n/2}^{n} 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 \cdot \max\left(\log\left(2nA \cdot \frac{\binom{n}{h}}{2^n}\right), 0\right) \leq$$

$$\sum_{h=n/2}^{n} 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 \cdot \max\left(\log\left(2nA \cdot \exp\left(-2\frac{(h-n/2)^2}{n}\right)\right), 0\right) =$$

$$\sum_{i=0}^{\sqrt{\frac{n}{2}\ln(2nA)}} \frac{40000}{\ln 2} \cdot \left(\frac{i}{n}\right)^2 \left(\ln(2nA) - 2 \cdot \frac{i^2}{n}\right) =$$

$$\frac{40000}{\ln 2} \cdot \left((1+o(1)) \frac{\left(\sqrt{\frac{n}{2}\ln(2nA)}\right)^3}{3n^2} \ln(2nA) - (1+o(1))\, 2 \cdot \frac{\left(\sqrt{\frac{n}{2}\ln(2nA)}\right)^5}{5n^3}\right)$$

Finally, simplifying and substituting the value of A we get:

$$\sum_{h=n/2+\sqrt{n}}^{n} 40000 \cdot \left(\frac{h-n/2}{n}\right)^2 \cdot L_h \leq (1+o(1)) \cdot \frac{40000}{\ln 2} \cdot \frac{\sqrt{2}}{30\sqrt{n}} \left(\ln(2nA)\right)^{5/2} \leq \frac{\epsilon^2}{40000}$$

Condition (d) is verified by combining Equation 26 with the equation above.

7.2 Proof of Claim 21

Here we prove that for all sufficiently large n, for all h, satisfying $0 \leq h \leq n$, it is the case that:

$$\frac{\binom{n}{h}}{\sum_{j\geq h}^{n}\binom{n}{j}} \leq \left(\begin{cases} \frac{2}{n^2} & \text{if } h \leq n/2 - \sqrt{n\ln(n)} \\ \frac{200}{\sqrt{n}} & \text{if } n/2 - \sqrt{n\ln(n)} < h < n/2 + \sqrt{n} \\ 200 \cdot \frac{h-n/2}{n} & \text{if } h \geq n/2 + \sqrt{n} \end{cases}\right)$$

We first handle the case when $h \geq n/2 + \sqrt{n}$. If, furthermore, $h > 11n/20$, then it is sufficient to prove that $\frac{\binom{n}{h}}{\sum_{j\geq h}^{n}\binom{n}{j}} \leq 10$, which is trivially true. Thus, we now assume that $h \leq 11n/20$

It is the case that:

$$\frac{\binom{n}{k}}{\binom{n}{k-1}} = \frac{1 - \frac{k-n/2-1}{n/2}}{1 + \frac{k-n/2}{n/2}} \tag{27}$$

Therefore, we can write:

$$\frac{\sum_{j\geq h}^{n}\binom{n}{j}}{\binom{n}{h}} = \sum_{j=h}^{n} \prod_{k=h+1}^{j} \frac{1 - \frac{k-n/2-1}{n/2}}{1 + \frac{k-n/2}{n/2}}$$

Since $n/2+\sqrt{n} \leq h \leq 11n/20$, for sufficiently large n we have that $h+\frac{1}{4}\cdot\frac{n}{h-n/2} \leq n$. Using this, we can truncate the sum above, and then lower-bound the result by the product of the smallest summand with the total number of summands, getting:

$$\frac{\sum_{j\geq h}^{n}\binom{n}{j}}{\binom{n}{h}} \geq \sum_{j=h}^{h+\frac{1}{4}\cdot\frac{n}{h-n/2}} \prod_{k=h+1}^{j} \frac{1-\frac{k-n/2-1}{n/2}}{1+\frac{k-n/2}{n/2}} \geq \frac{1}{4}\cdot\frac{n}{h-n/2}\cdot \prod_{k=h+1}^{h+\frac{1}{4}\cdot\frac{n}{h-n/2}} \frac{1-\frac{k-n/2-1}{n/2}}{1+\frac{k-n/2}{n/2}}$$

Now, we analogously lower-bound the product by lower-bounding each of the factors, and then use the fact that since $h \geq n/2+\sqrt{n}$, it is the case that $\frac{n}{h-n/2} \leq h-n/2$. We get:

$$\frac{\sum_{j\geq h}^{n}\binom{n}{j}}{\binom{n}{h}} \geq \frac{1}{4}\cdot\frac{n}{h-n/2}\cdot\left(\frac{1-\frac{h+\frac{1}{4}\cdot\frac{n}{h-n/2}-n/2-1}{n/2}}{1+\frac{h+\frac{1}{4}\cdot\frac{n}{h-n/2}-n/2}{n/2}}\right)^{\frac{1}{4}\cdot\frac{n}{h-n/2}} \geq$$

$$\frac{1}{4}\cdot\frac{n}{h-n/2}\cdot\left(\frac{1-1.25\frac{h-n/2}{n/2}}{1+1.25\frac{h-n/2}{n/2}}\right)^{\frac{1}{4}\cdot\frac{n}{h-n/2}}$$

Finally, we use the fact that for all w between zero and one we have that $\frac{1}{1+w} = 1-w+w^2-... \geq 1-w$. We get:

$$\frac{\sum_{j\geq h}^{n}\binom{n}{j}}{\binom{n}{h}} \geq \frac{1}{4}\cdot\frac{n}{h-n/2}\cdot\left(1-1.25\frac{h-n/2}{n/2}\right)^{\frac{1}{2}\cdot\frac{2n}{h-n/2}}$$

Now, recall that for any value w between zero and one, we have that $\ln(1-w) = -\sum_{i=1}^{\infty}\frac{w^i}{i} \geq -\sum_{i=1}^{\infty} w^i = -\frac{w}{1-w}$. Using this, and recalling that $h \leq 11n/20$, we get that:

$$\ln\left(1-1.25\frac{h-n/2}{n/2}\right) \geq -\frac{1.25\frac{h-n/2}{n/2}}{1-1.25\frac{h-n/2}{n/2}} \geq -\frac{1.25\frac{h-n/2}{n/2}}{1-1.25\frac{11n/20-n/2}{n/2}} = -\frac{20}{7}\frac{h-n/2}{n}$$

Combining the two previous equations together we get:

$$\frac{\sum_{j\geq h}^{n}\binom{n}{j}}{\binom{n}{h}} \geq \frac{1}{4}\cdot\frac{n}{h-n/2}\cdot\exp\left(-\frac{20}{7}\frac{h-n/2}{n}\cdot\frac{1}{2}\cdot\frac{n}{h-n/2}\right) \geq \frac{1}{200}\cdot\frac{n}{h-n/2}$$

This completes the proof in the case $h \geq n/2+\sqrt{n}$.

Given our bound in the range $h \geq n/2+\sqrt{n}$, to show the desired bound in the range $n/2-\sqrt{n\ln(n)} < h < n/2+\sqrt{n}$ it is sufficient to show that $\frac{\binom{n}{h}}{\sum_{j\geq h}^{n}\binom{n}{j}}$ is non-decreasing, as a function of h. If $h < n/2$, this follows immediately, because, as a function of h, the numerator is non-decreasing, whereas the denominator is decreasing. If $h \geq n/2$, then using Equation 27, we get:

$$\frac{\sum_{j\geq h+1}^{n}\binom{n}{j}}{\binom{n}{h+1}} = \frac{1+\frac{h+1-n/2}{n/2}}{1-\frac{h-n/2}{n/2}}\cdot\frac{1}{\binom{n}{h}}\cdot\sum_{j\geq h+1}^{n}\frac{1-\frac{j-n/2-1}{n/2}}{1+\frac{j-n/2}{n/2}}\binom{n}{j-1} \leq$$

$$\frac{1}{\binom{n}{h}}\cdot\sum_{j\geq h+1}^{n}\binom{n}{j-1} \leq \frac{1}{\binom{n}{h}}\cdot\sum_{j\geq h+1}^{n+1}\binom{n}{j-1} = \frac{\sum_{j\geq h}^{n}\binom{n}{j}}{\binom{n}{h}}$$

Which implies that $\frac{\binom{n}{h+1}}{\sum_{j\geq h+1}^{n}\binom{n}{j}} \geq \frac{\binom{n}{h}}{\sum_{j\geq h}^{n}\binom{n}{j}}$

Finally, for the range $h \leq n/2-\sqrt{n\ln(n)}$ we can use Hoeffding's bound:

$$\frac{\binom{n}{h}}{\sum_{j\geq h}^{n}\binom{n}{j}} \leq \frac{\binom{n}{h}}{\frac{1}{2}\cdot 2^n} \leq 2\cdot\Pr_{x\sim\{0,1\}^n}\left[x \leq n/2-\sqrt{n\ln(n)}\right] \leq 2\cdot\exp\left(-2\ln n\right) = \frac{2}{n^2}$$

7.3 Proof fo Claim 22

Recall that:

$$N \stackrel{\text{def}}{=} \frac{2^n}{A} \cdot \frac{192}{\epsilon^2} \cdot (n + 9\sqrt{n} + 4)$$

Our algorithm for learning a monotone probability distribution drew N samples from the probability distribution ρ and the resulting multiset of samples was denoted as S. For all x in $\{0,1\}^n$, if $||x|| < 9\sqrt{n}$, we set $\hat{\phi}(x) = 0$, otherwise we set:

$$\hat{\phi}(x) := \frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \frac{\max_{y \text{ s.t. } y \preceq x \text{ and } ||y||-||x|| = \lfloor L_{||x||} \rfloor} \left| \left\{ z \in S : y \preceq z \preceq x \right\} \right|}{N}$$

Where L_h is a specific value associated to each value of h. We also defined for all x with $x \geq 9\sqrt{n}$ the value:

$$\phi(x) \stackrel{\text{def}}{=} \frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y|| = \lfloor L_{||x||} \rfloor} \Pr_{z \sim \rho}[y \preceq z \preceq x] =$$
$$\frac{1}{2^{\lfloor L_{||x||} \rfloor}} \cdot \max_{y \text{ s.t. } y \preceq x \text{ and } ||x||-||y|| = \lfloor L_{||x||} \rfloor} \sum_{z \text{ s.t. } y \preceq z \preceq x} \rho(z)$$

Here we prove that if it is the case that $\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} \leq \frac{1}{2}$, then, with probability at least $7/8$, it is the case that:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{4}$$

We claim that for any pair (x, y), such that ϕ is defined on x and $||x|| - ||y|| = \lfloor L_{||x||} \rfloor$, with probability at least $1 - \frac{1}{8 \cdot 2^n \cdot n^{9\sqrt{n}}}$ the following holds:

$$\left| \Pr_{z \sim \rho}[y \preceq z \preceq x] - \frac{|\{z \in S : y \preceq z \preceq x\}|}{N} \right| \leq \frac{\epsilon}{8} \cdot \max\left(\frac{A}{2^n}, \Pr_{z \sim \rho}[y \preceq z \preceq x] \right) \tag{28}$$

We use Chernoff's bound to prove this as follows. Denote by q the value $\Pr_{z \sim \rho}[y \preceq z \preceq x]$. If $q \geq \frac{A}{2^n}$ then by Chernoff's bound we have:

$$\Pr\left[\left| |\{z \in S : y \preceq z \preceq x\}| - qN \right| \geq \frac{\epsilon}{8} qN \right] \leq$$
$$2 \exp\left(-\frac{1}{3} \left(\frac{\epsilon}{8} \right)^2 qN \right) \leq 2 \exp\left(-\frac{1}{3} \left(\frac{\epsilon}{8} \right)^2 \frac{A}{2^n} \cdot N \right) = \frac{1}{8 \cdot 2^n \cdot n^{9\sqrt{n}}}$$

Otherwise, if we have $q < \frac{A}{2^n}$, then by Chernoff's bound:

$$\Pr\left[\left| |\{z \in S : y \preceq z \preceq x\}| - qN \right| \geq \frac{\epsilon}{8} \cdot \frac{A}{2^n} \cdot N \right] \leq 2 \exp\left(-\frac{1}{3} \left(\frac{\epsilon}{8} \cdot \frac{A}{2^n} \cdot \frac{1}{q} \right)^2 qN \right) \leq$$
$$2 \exp\left(-\frac{1}{3} \left(\frac{\epsilon}{8} \right)^2 \frac{A}{2^n} \cdot N \right) = \frac{1}{8 \cdot 2^n \cdot n^{9\sqrt{n}}}$$

Now, by taking a union bound, it follows that with probability $7/8$ for all such pairs (x, y) Equation 28 will be the case. Recalling the definition of ϕ, for all x on which ϕ is defined it then will be the case that:

$$\left| \hat{\phi}(x) - \phi(x) \right| \leq \frac{\epsilon}{8} \cdot \max\left(\frac{1}{2^{\lfloor L_{||x||} \rfloor}} \frac{A}{2^n}, \phi(x) \right)$$

Now, we sum this for all x in the domain of ϕ and use the fact that $\lfloor L_h \rfloor \geq L_h + 1$, and then use that $\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} \leq \frac{1}{2}$. We get:

$$\sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \left| \hat{\phi}(x) - \phi(x) \right| \leq$$

$$\frac{\epsilon}{8} \cdot \left(\frac{1}{2^n} \cdot \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \frac{A}{2^{\lfloor L_{||x||} \rfloor}} + \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \phi(x) \right) =$$

$$\frac{\epsilon}{8} \cdot \left(\frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{\lfloor L_h \rfloor}} + \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \phi(x) \right) \leq$$

$$\frac{\epsilon}{8} \cdot \left(2 \cdot \frac{1}{2^n} \cdot \sum_{h=9\sqrt{n}}^{n} \binom{n}{h} \cdot \frac{A}{2^{L_h}} + \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \phi(x) \right) \leq$$

$$\frac{\epsilon}{8} \cdot \left(1 + \sum_{x \in \{0,1\}^n \text{ s.t. } 9\sqrt{n} \leq ||x||} \rho(x) \right) \leq \frac{\epsilon}{4}$$

Sample Complexity Bounds for Influence Maximization

Abstract

Influence maximization (IM) is the problem of finding for a given $s \geq 1$ a set S of $|S| = s$ nodes in a network with maximum influence. With stochastic diffusion models, the influence of a set S of seed nodes is defined as the expectation of its *reachability* over *simulations*, where each simulation specifies a deterministic reachability function. Two well-studied special cases are the *Independent Cascade (IC)* and the *Linear Threshold* (LT) models of Kempe, Kleinberg, and Tardos [31]. The influence function in stochastic diffusion is unbiasedly estimated by averaging reachability values over i.i.d. simulations. We study the IM *sample complexity*: the number of simulations needed to determine a $(1-\epsilon)$-approximate maximizer with confidence $1-\delta$. Our main result is a surprising upper bound of $O(s\tau\epsilon^{-2}\ln\frac{n}{\delta})$ for a broad class of models that includes IC and LT models and their mixtures, where n is the number of nodes and τ is the number of diffusion steps. Generally $\tau \ll n$, so this significantly improves over the generic upper bound of $O(sn\epsilon^{-2}\ln\frac{n}{\delta})$. Our sample complexity bounds are derived from novel upper bounds on the variance of the reachability that allow for small relative error for influential sets and additive error when influence is small. Moreover, we provide a data-adaptive method that can detect and utilize fewer simulations on models where it suffices. Finally, we provide an efficient greedy design that computes an $(1-1/e-\epsilon)$-approximate maximizer from simulations and applies to any submodular stochastic diffusion model that satisfies the variance bounds.

1 Introduction

Models for the spread of information among networked entities were studied for decades in sociology and economics [26, 20, 29]. A diffusion process is initiated from a seed set of nodes (entities) and progresses in steps: Initially, only the seed nodes are activated. In each step additional nodes may become active based on the current set of active nodes. The progression can be deterministic or stochastic. The t-stepped influence of a seed set S of nodes is then defined as its expected reachability (total number of active nodes) in t steps.

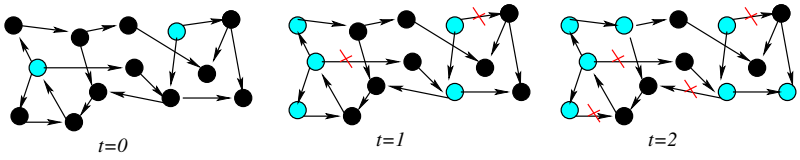

Figure 1 A 2-step diffusion from two seed nodes in a live-edge model.

Influence maximization (IM) is the problem of finding a set S of nodes of specified cardinality $|S| = s$ and maximum *influence*. The IM problem was formulated nearly two decades ago by Richardson and Domingos [17, 40] and inspired by the application of viral marketing. In a seminal paper, Kempe, Klienberg, and Tardos [31] studied stochastic diffusion models and introduced two elegant special cases, the *Independent Cascade (IC)* and *Generalized Threshold (GT)* diffusion models. Their work sparked extensive followup research and large scale implementations [35, 7, 30, 39]. Currently IM is applied in multiple domains with linked entities for tasks as varied as diversity-maximization (the most representative subset of the population) and sensor placement that maximize coverage [32, 4, 34].

We consider *stochastic diffusion models (SDM)* $\mathcal{G}(V)$ over $|V| = n$ nodes that are specified by a distribution $\boldsymbol{\phi} \sim \mathcal{G}$ over sets $\boldsymbol{\phi} := \{\phi_v\}_{v \in V}$ of monotone non-decreasing boolean *activation functions*

$$\phi_v : 2^{V \setminus \{v\}} \to \{0, 1\}.$$

A diffusion process starts with a seed set $S \subset V$ of nodes and $\boldsymbol{\phi} \sim \mathcal{G}$. At step 0 we activate the seed nodes $\texttt{Reach}^0(\boldsymbol{\phi}, S) := S$. The diffusion then proceeds deterministically: At step $t > 0$ all active nodes remain active and we activate any inactive node v where $\phi_v(\texttt{Reach}^{t-1}(\boldsymbol{\phi}, S)) = 1$:

$$\texttt{Reach}^{t+1}(\boldsymbol{\phi}, S) := \{v \in V \mid \phi_v(\texttt{Reach}^t(\boldsymbol{\phi}, S)) = 1\}.$$

The *τ-steps reachability set* of a seed set S is the random variable $\texttt{Reach}^\tau(\boldsymbol{\phi}, S)$ for $\boldsymbol{\phi} \sim \mathcal{G}$ and respectively the τ-steps *reachability*, $\texttt{R}^\tau(S)$, is the random variable that is the number of active nodes $|\texttt{Reach}^\tau(\boldsymbol{\phi}, S)|$ for $\boldsymbol{\phi} \sim \mathcal{G}$. Finally, the influence value of S is defined to be the expectation

$$\texttt{I}^\tau(S) := \mathrm{E}[\texttt{R}^\tau(S)] = \mathrm{E}_{\boldsymbol{\phi} \sim \mathcal{G}}[|\texttt{Reach}^\tau(\boldsymbol{\phi}, S)|].$$

We refer to the case where the diffusion is allowed to progress until there is no growth as *unrestricted* diffusion and this corresponds to $\tau = n - 1$. The influence $\texttt{I}^\tau(S)$ is a monotone set function. We say that an SDM is *submodular* when the influence function is submodular and that it is *independent* if the activation functions ϕ_v of different nodes are independent random variables. The IM problem for seed set size s and τ steps is to find

$$\arg \max_{S : |S| \le k} \texttt{I}^\tau(S).$$

The reader might be more familiar with well-studied special cases of this general formulation. *Live-edge* diffusion models $\mathcal{G}(V, \mathcal{E})$ are specified by a graph $(V, \mathcal{E})$ with $|V| = n$ nodes and $|\mathcal{E}| = m$ directed edges and a distribution $E \sim \mathcal{G}$ over subsets $E \subset \mathcal{E}$ of "live" edges. When expressed as an SDM, the activation functions that correspond to E have $\phi_v(T) = 1$ if and only if there is an edge from a node in T to v in the graph (V, E). Live-edge models are always submodular: This because $|\texttt{Reach}^\tau(E, S)|$, which is the number of nodes reachable

from S in (V, E) by paths of length at most τ, is a coverage function and hence monotone and submodular. Therefore, so is the influence function $\mathtt{I}^{\tau}(S)$, which is an expectation of a distribution over coverage functions. A live-edge model is independent if we only have dependencies between incoming edges to the same node. The Independent Cascade (IC) model is the special case of an independent live-edge model where all edges $e \in \mathcal{E}$ are independent Bernoulli random variables selected with probabilities p_e ($e \in \mathcal{E}$).

Another well-studied class are *generalized threshold* (GT) models [31, 35]. A GT model $\mathcal{G}(V, \boldsymbol{f})$ is specified by a set $\boldsymbol{f} := \{f_v\}_{v \in V}$ of monotone functions $f_v : 2^V \rightarrow [0, 1]$. The randomization is specified by a set of threshold values $\boldsymbol{\theta} \sim \mathcal{G}$ where $\boldsymbol{\theta} := \{\theta_v\}_{v \in V}$. The corresponding activation functions to $\boldsymbol{\theta}$ are

$$\phi_v(T) := \text{Indicator}(\theta_v \leq f_v(T)).$$

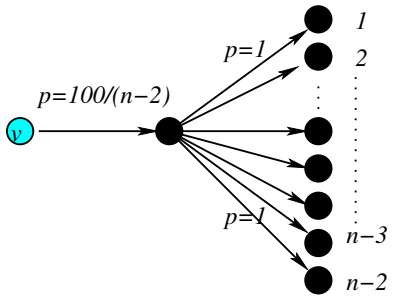
An important subclass are *Independent GT (IGT)* where we require that $\boldsymbol{f}$ are submodular and nodes $v \in V$ have independent threshold values $\theta_v \sim U[0, 1]$. Mossel and Roch [35, 36] proved that IGT models are submodular, which is surprising because the functions $|\mathtt{Reach}^{\tau}(\boldsymbol{\phi}, S)|$ are generally not submodular. Their proof was provided for unrestricted diffusion but extends to the case where we stop the process after τ steps. Finally, Linear threshold (LT) models [26, 31] are a special case of IGT where we have an underlying directed graph and each edge (u, v) is associated with a fixed weight value $b_{uv} \geq 0$ so that for all $v \in V$ $\sum_u b_{uv} \leq 1$ and the functions are defined as the sums $f_v(A) := \sum_{u \in A \cap N(v)} b_{uv}$. Kempe et al showed [31] that each LT model is equivalent to an independent live-edge model.

One of the challenges brought on by the IM formulation is computational efficiency. Kempe et al [31] noted that the IM problem generalizes the classic Max Cover problem even with $\tau = 1$ and a live-edge model with a fixed set of live edges ($p_e = 1$ for all $e \in \mathcal{E}$). Therefore, IM inherits Max Cover's hardness of approximation for ratio better than $1 - (1 - 1/s)^s \geq 1 - 1/e$ [21] for a cover with s sets. On the positive, with submodular models, an approximation ratio of $1 - (1 - 1/s)^s$ can be achieved by the first s nodes of a greedy sequence generated by sequentially adding a node with maximum marginal value [37]. A challenge of applying Greedy with stochastic models, however, is that even point-wise evaluation of the influence function can be computationally intensive. Exact evaluation even for IC models [6] and LT models [8] is #P hard . As for approximation, Kempe et al proposed to work with *averaging oracles*

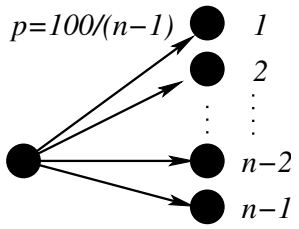
$$\hat{\mathsf{A}}^{\tau}(T) := \frac{1}{\ell} \sum_{i=1}^{\ell} |\mathtt{Reach}^{\tau}(\boldsymbol{\phi}_i, T)|$$

that average the reachability values obtained from a set $\{\boldsymbol{\phi}_i\}_{i=1}^{\ell}$ of i.i.d. simulations. Recall that in the general SDM formulation, a simulation is specified by a set $\boldsymbol{\phi}$ of node activation functions. For live-edge models, a simulation is simply a set of concurrently live edges E. In GT models, a simulation is specified by a set of thresholds $\boldsymbol{\theta}$.

Averaging oracles, which we focus on here, have several appealing properties: First, it is robust compared to estimators tailored to models that satisfy specific assumptions (see related work section) in that for any diffusion model $\mathcal{G}$, also with complex and unknown dependencies (between activation functions of different nodes or between edges in live-edge models), for any set S, $\hat{\mathsf{A}}(S)$ is an unbiased estimate of the exact influence value $\mathtt{I}^{\tau}(S)$ and estimates are accurate as long as the variance of $\mathtt{R}^{\tau}(S)$ is "sufficiently" small. Second, the oracle is constructed directly from simulations and does not require learning or inferring the underlying diffusion model that generated the data [41, 24, 23, 18]. Therefore, the results are not sensitive to modeling assumptions and learning accuracy [9, 27]. Moreover, estimation of



(a) Family of n node graphs. Node v has influence $\mathtt{I}^{\tau=2}(v) = 100$ but variance $\approx 100n$.



(b) Star graphs with n nodes where all edges have marginal probabilities $100/(n-1)$. The center node has influence value 101 and all other nodes have influence 1.

Figure 2 Example live-edge models.

model parameters even for IC models can require a large number of simulations: Consider the family of IC models depicted in the example in Figure 2b where tiny edge probabilities that require many simulations to estimate are critical for IM accuracy. Finally, when the reachability functions $\mathtt{Reach}^\tau(\phi, T)$ are monotone and submodular (as is the case with live-edge models), so is their average $\hat{\mathsf{A}}$, and hence the oracle optimum can be approximated by the greedy algorithm. Prior work addressed the efficiency of working with averaging oracles by improving the efficiency of greedy maximization [32, 25] and applied sketches [10] to efficiently estimate $\hat{\mathsf{A}}(S)$ values [7, 14].

The fundamental question we study here is the *sample complexity* of IM, that is, the number of i.i.d. simulations needed to recover an approximate maximizer of the influence function $\mathtt{I}^\tau$. Formally, for parameters (ϵ, δ), identify a seed set T of size s so that $\Pr\left[\mathtt{I}^\tau(T) \geq (1-\epsilon)\mathrm{OPT}_s^\tau\right] \geq 1-\delta$, where $\mathrm{OPT}_s^\tau := \max_{S||S|\leq s} \mathtt{I}^\tau(S)$ is the exact maximum. Note that the recovery itself is generally computationally hard and the sample complexity only considers the information we can glean from a set of simulations.

Kempe et al provided an upper bound of

$$O\left(\epsilon^{-2} sn \log \frac{n}{\delta}\right) \tag{1}$$

on the sample complexity of the harder *Uniform Relative-Error Estimation (UREE)* problem where for a given (ϵ, δ) we bound the number of simulations so that with probability $1-\delta$, for all subsets S such that $|S| \leq s$, $\hat{\mathsf{A}}(S)$ approximates $\mathtt{I}^\tau(S)$ within relative error of ϵ. The sample complexity of UREE upper bounds that of IM because the oracle maximizer $\arg\max_{S||S|\leq s} \hat{\mathsf{A}}(S)$ must be an approximate maximizer. We provide the argument for the bound (1) here because it is basic and broadly applies to all SDMs: The reachability values $\mathtt{Reach}^\tau(\phi, S)$, and hence their expectation, $\mathtt{I}^\tau(S)$ have values in $[1, n]$. Using the multiplicative Chernoff bound (with values divided by n) we obtain that $O(\epsilon^{-2} n \ln \delta^{-1})$ simulations guarantee a relative error of ϵ with probability at least $(1-\delta)$ for the estimate of any particular set S. Interestingly, this sample complexity bound is tight for point-wise influence estimation even for IC models: The example family of models in Figure 2a is such that $\tau = 2$ and $\Omega(\epsilon^{-2} n)$ simulations are required for estimating the influence value of a single node. The UREE sample complexity bound (1) follows from applying a union bound over all $\binom{n}{s} = O(n^s)$ subsets.

The generic upper bound has prohibitive linear dependence on the number of nodes n (that the example in Figure 2a shows is unavoidable for UREE even for IC models). A simple example shows that we can not hope for an umbrella improvement for IM: Consider the star

graph family of Figure 2b when edges are dependent so that either all edges are live or none is. Clearly $n/100$ simulations are necessary to detect a 1-step approximate maximizer (which must be the actual maximizer). The remaining hope is that we can obtain stronger bounds on the IM sample complexity for models with weaker or no dependencies such as IC and IGT models. This question eluded researchers for nearly two decades.

1.1 Contributions and Overview

We study the sample complexity of influence maximization from averaging oracles computed from i.i.d. simulations. One of our main contributions is an upper bound of

$$O\left(\epsilon^{-2} s\tau \log \frac{n}{\delta}\right) \tag{2}$$

on the IM sample complexity of independent strongly submodular SDMs. Informally, strong submodularity means that the influence function of any "reduced" model (model derived from original one by setting a subset $T \subset V$ of nodes as active) is submodular. The IC and IGT models are special cases of strongly submodular independent SDMs.

Interestingly, we provide similar sample complexity bounds for natural families of models that are not independent: Mixtures of small number of strongly submodular SDMs and what we call *b-dependence* live-edge models that allow for positive dependence of small groups of edges with a shared tail node.

Our bound improves over prior work by replacing the prohibitive linear dependence in the number of nodes n in (1) with the typically much smaller value τ. While on worst-case instances unrestricted diffusions may require $\Omega(n)$ steps, understanding the sample complexity in terms of τ is important: First, IM with explicit step limits [5, 33, 22, 19, 15], is studied for applications where activation time matters. Moreover, due to the "small world" phenomenon [44], in "natural" settings we can expect most activations (even with unrestricted diffusions) to occur within a small number of steps. In the latter case, unrestricted influence values are approximated well by corresponding step-limited influence with $\tau \ll n$.

Our improvement is surprising as generally a linear-in-n number of simulations is necessary for estimating influence values of some nodes or to estimate essential model parameters (for example, the edge probabilities in IC models), and this is the case even when τ is very small. This shows that the maximization problem is in an information sense inherently easier and can circumvent these barriers.

We overview our results and implications – complete proofs can be found in the appendix. We review related work in Section 2 and place it in the context of our results. In Section 3 we formulate quality measures for influence oracles and relate unrestricted and step-limited influence. In particular, we observe that for IM it suffices that the oracle provides good estimates (within a small relative error) of larger influence values. This allows us to circumvent the lower bound for point-wise relative-error estimates shown in Example 2a.

In Section 4 we state our main technical result that for independent strongly submodular SDMs, upper bounds the variance of the reachability of set T $\mathsf{Var}[\mathtt{R}^{\tau}(T)]$ by $\tau \mathtt{I}^{\tau}(T) \max_{v \in V \setminus T} \mathtt{I}^{\tau-1}(v)$. This variance upper bound facilitates estimates with small relative error for sets with larger influence values and additive error for sets with small influence values. We also provide a family of IC models that shows that the linear dependence on τ in the variance bound is necessary. We derive similar variance bounds to mixtures of strongly submodular independent SDMs and b-dependence models. All our subsequent sample complexity bounds apply generically to any SDM (submodular/independent or not) that satisfies variance bounds of this form. In Section 5 we review *averaging oracles* and bound the sample

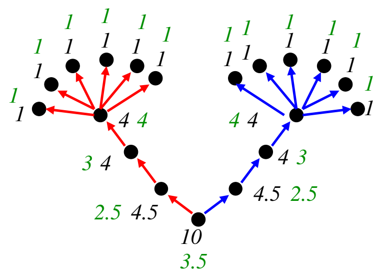


Figure 3 Dependent SDM Example. A live-edge model where with probability $\frac{1}{2}$ all red edges are active and otherwise all blue edges are active. The influence values $\mathtt{I}^4(v)$ are shown in black. Simulation averages and RR samples with full simulations provide unbiased estimates of influence values $\mathrm{E}[\hat{\mathtt{I}}^4(v)] = \mathtt{I}^4(v)$. However, "efficient" RRS, which works with the marginal edge probabilities ($p_e = \frac{1}{2}$) or with decomposed simulations is biased, with $\mathrm{E}[\hat{\mathtt{I}}^4(v)]$ shown in green. We can see that the bias induces large errors and also yields an erroneous maximizer.

complexity using variance upper bounds. In section 6 we present our *median-of-averages* oracle that amplifies the confidence guarantees of the averaging oracle and facilitates a tighter sample complexity bound. In Section 7 we provide a data-adaptive framework that provides guarantees while avoiding the worst-case sample complexity upper bounds on models when a smaller number of simulations suffices. In Section 8 we consider computational efficiency and present a greedy maximization algorithm based on our median-of-averages oracles that returns a $(1-(1-1/s)^s - \epsilon$ approximate maximizer with probability $1-\delta$. The design generically applies to any SDM with a submodular influence function that satisfies the variance bounds.

2 Related work

We focus here on influence estimates obtained from averages of i.i.d. simulations of a SDM. We note that alternative approaches can be more effective for specific families of models. Most notably for IC models, state of the art large-scale greedy approximate maximization algorithms [43, 42, 38, 28] are not based on simulation averages. The estimates are also obtained by building a sample that reflects the influence of each but instead they use a finer building block of i.i.d. *Reverse Reachability (RR) searches*. The random RR search method was proposed in [10] to estimate size of reachability sets in graphs and Borg et al [3] adapted it to IC models.

The method is applicable in principle with any live-edge model: A basic RR search is conducted by selecting a node $v \in V$ uniformly at random and performing a BFS search on reversed edges that is pruned at length τ. The search "flips" edges as their head node is reached according to conditional distribution on $\mathcal{G}$. The index number of the RR search is then added to the sample set of each node that is "reached" by the search. Influence of a subset S can then be unbiasedly estimated from the cardinality of the union of the samples of nodes $v \in S$ and the greedy algorithm can be applied to the sets of samples for approximate maximization. To obtain an approximate influence maximizer we need to perform RR searches until some node has a sample of size $O\left(\epsilon^{-2} s \log(n/\delta)\right)$. In the worst case, this requires $O\left(\epsilon^{-2} sn \log(n/\delta)\right)$ RR searches. For general live-edge models, an independent RR search can always be obtained from a simulation $E \sim \mathcal{G}$ by randomly drawing a node and performing a reverse search from it using edges E. The same simulation, however, can not

generally be reused to generate multiple independent RR searches. This way of obtaining RR searches works for general live-edge models (with arbitrary dependencies) but requires $O(\epsilon^{-2}ns\log(n/\delta))$ simulations, which does not improve over the generic upper bound (1).

The appeal of the RR searches method is that it can be implemented very efficiently for independent live-edge (including IC or LT) models. The total work performed requires only $O(\epsilon^{-2}ms(\log(n/\delta)))$ "edge flips" that can be easily performed using specified edge probabilities p_e for IC models. Moreover, the basic building block of RR searches are local simulations of sets of incoming edges of specified nodes and the full computation requires at most $O(\epsilon^{-2}s\log(n/\delta))$ local simulations for each node. When we have full simulations generated by an independent live-edge model these "local" simulations are independent and the required number of "local simulations" can be obtained by decomposing $O(\epsilon^{-2}s\log(n/\delta))$ full simulations. But the caveat is that this approach breaks the coherence of simulations, as we construct each RR search from components taken from multiple simulations. These "efficient" implementations (i.e. based on decomposed simulations or edge flips according to marginal probabilities) may "catastrophically fail" when dependencies exist: The influence estimates obtained are biased and cause large errors even when the variance is low. Figure 3 shows an example of a simple mixture model (of two degenerate IC models) where "efficient" RRS has large error due to bias but averages of few simulations provide accurate estimates. To summarize, with RRS, the implementation that works with full simulations is robust to dependencies but is inefficient and the efficient implementation breaks ungracefully even with light dependencies. To conclude, both basic approaches to approximate IM, simulation averages and RRS offer distinct advantages: Simulation averages are robust in that they remain unbiased and are accurate on any SDM, including dependent ones, for which the variance is sufficiently small whereas RRS offers more efficiency for purely independent live-edge models.

3 Preliminaries

We consider stochastic diffusion models $\mathcal{G}(V)$ as outlined in the introduction. We denote by $\texttt{Reach}^\tau(\boldsymbol{\phi}, T)$ the τ-steps reachability set of T when we use a specific set $\boldsymbol{\phi}$ of activation functions. We will use the notation $\texttt{Reach}^\tau(T)$ (with the parameter $\boldsymbol{\phi}$ omitted) for the random variable $\texttt{Reach}^\tau(\boldsymbol{\phi}, T)$ obtained when we draw $\boldsymbol{\phi} \sim \mathcal{G}$ according to the model.

3.1 Utility Functions

For simplicity, the discussion in the introduction took the utility of a reachable set to be the number of reachable nodes $\texttt{VReach}^\tau(\boldsymbol{\phi}, T) := |\texttt{Reach}^\tau(\boldsymbol{\phi}, T)|$. Generally, we can consider *utility functions* $H : 2^V \to \Re_+$ that are nonnegative monotone non-decreasing with $H(\emptyset) = 0$:

$$\texttt{VReach}^\tau(\boldsymbol{\phi}, T) := H(\texttt{Reach}^\tau(\boldsymbol{\phi}, T)). \tag{3}$$

Submodular utility is particularly natural and studied by Mossel and Roch [35]. Additive utility is the special case where nodes have nonnegative weights $w : V \to \mathcal{R}^+$ and

$$\texttt{VReach}^\tau(\boldsymbol{\phi}, T) := \sum_{v \in \texttt{Reach}^\tau(\boldsymbol{\phi}, T)} w(v). \tag{4}$$

We consider a diffusion model $\mathcal{G}(V, H)$ together with a utility function H. The random variable $\mathtt{R}^{\tau}_{\mathcal{G}}(T)$ is the utility of the reachable set, that is, $\mathtt{VReach}^{\tau}(\boldsymbol{\phi}, T)$ when $\boldsymbol{\phi} \sim \mathcal{G}$. The influence function is then the expected utility of the reachable set

$$\mathtt{I}^{\tau}(T) := \mathrm{E}[\mathtt{R}^{\tau}(T)] = \mathrm{E}_{\boldsymbol{\phi}\sim\mathcal{G}}\mathtt{VReach}^{\tau}(\boldsymbol{\phi}, T) \ .$$

We denote the maximum influence value of a subset of cardinality s by $\mathrm{OPT}^{\tau}_{s} := \max_{S:|S|\leq s} \mathtt{I}^{\tau}(S)$.

It follows from the definition that for any SDM $\mathcal{G}(V, H)$ with utility H, the influence $\mathtt{I}^{\tau}(T)$ is monotone non-decreasing in τ and in the set T and the optimum values OPT^{τ}_{s} are non-decreasing in τ and s. Generally, influence functions $\mathtt{I}^{\tau}(T)$ of SDMs may not be submodular even when utility is additive. The influence function is known to be submodular for live-edge and for IGT models [35] with submodular utility.

3.2 Reduced Models

We work with the following notion of model reduction. Let $\mathcal{G}(V, H)$ be an independent SDM with submodular utility. For a set of nodes $T \subset V$, we define the *reduced model* $\mathcal{G}'(V', H')$ of $\mathcal{G}$ with respect to T: The reduced model contains the nodes $V' = V \setminus T$. The activation function $\phi'_v \sim \mathcal{G}'$ for $v \in V \setminus T$ are obtained by drawing $\phi_v \sim \mathcal{G}$ conditioned on $\phi_v(T) = 0$ and take

$$\text{for all } S \subset V \setminus (T \cup \{v\}),\ \phi'_v(S) := \phi_v(S \cup T)$$

(Note that since we have independent SDM we can separately consider the distribution of activation functions of each node). The utility in $\mathcal{G}'$ is the marginal utility in $\mathcal{G}$ with respect to T:

$$\text{for all } S \subset V \setminus T,\ H'(S) := H(S \cup T) - H(T).$$

The reduced model $\mathcal{G}'(V', H')$ is also an independent SDM with submodular utility: Activation functions $\boldsymbol{\phi}' \sim \mathcal{G}'$ are independent and monotone and the utility is monotone with $H'(\emptyset) = 0$ and submodular.

3.3 Strongly Submodular SDM

We say that an independent SDM $\mathcal{G}(V, H)$ is *strongly submodular* if the utility function H is submodular and the influence function $\mathtt{I}^{\tau}_{\mathcal{G}'}$ is submodular with any reduced model $\mathcal{G}'$ and step limit $\tau \geq 0$. IC and IGT models are strongly submodular SDMs (see Theorem 19).

The variance and thus sample complexity upper bounds that we present in the sequel apply to any strongly submodular SDM. We will also provide bounds for some dependent families of models. One family is a slight generalization of IC models that we refer to as *b-dependence*. Here edges are partitioned into disjoint groups, where each group contains at most b edges emanating from the same node. The edges in a group must be either all live or none live (are positively dependent).

3.4 Relating Step-Limited and Unrestricted Influence

When unrestricted diffusion from a seed set S is such that most activations occur within τ steps, the unrestricted influence $\mathtt{I}(S)$ is approximated well by τ-step influence $\mathtt{I}^{\tau}(S)$. We can also relate unrestricted influence with small expected steps-to-activation to step-limited

influence: For a seed set S, node v, and length d, we denote by $p(S,v,d)$ the probability that node v is activated in a diffusion from S in step d. For additive utility functions (4) by definition, $\mathtt{I}^\tau(S) = \sum_{v\in V} w(v) \sum_{d\leq \tau} p(S,v,d)$. The *expected length of an activation path* from S (in unrestricted diffusion) is:

$$\overline{D}(S) := \frac{\sum_{v\in V} w(v) \sum_{d\leq n} d \cdot p(S,v,d)}{\mathtt{I}(S)} \ . \tag{5}$$

The following lemma is an immediate consequence of Markov's inequality and shows that τ-stepped influence with $\tau = O(\overline{D}(S))$ approximates well the unrestricted influence:

▶ **Lemma 1.** *For all S and $\epsilon > 0$, $I^{\overline{D}(S)\epsilon^{-1}}(S) \geq (1-\epsilon) I(S)$.*

3.5 Influence Oracles

We say that a set function $\hat{F}$ is an *ϵ-approximation* of another set function F *at a point* T if $\left|\hat{F}(T) - F(T)\right| \leq \epsilon \max\{F(T), \mathrm{OPT}_1(F)\}$, where $\mathrm{OPT}_s(F) := \max_{S||S|\leq s} F(S)$. That is, the estimate $\hat{F}$ has a small relative error for sets T with $F(T) \geq \mathrm{OPT}_1(F)$ and a small absolute error of $\epsilon\mathrm{OPT}_1(F)$ for sets T with $F(T) \leq \mathrm{OPT}_1(F)$. We say that $\hat{F}$ provides a *uniform* ϵ-approximation for all subsets T in a collection C if $\hat{F}$ is an ϵ-approximation for all $T \in C$.

An *influence oracle*, $\hat{\mathtt{I}}^\tau$, is a randomized data structure that is constructed from a set of i.i.d. simulations of a model. The influence oracle, $\hat{\mathtt{I}}^\tau$, defines a set function (we use the same name $\hat{\mathtt{I}}^\tau$ for the set function) that for any input query set $T \subset V$, returns a value $\hat{\mathtt{I}}^\tau(T)$. For $\epsilon < 1$ and $\delta < 1$ we say that an oracle provides (ϵ,δ) *approximation guarantees with respect to I^τ* if for any set T it is an ϵ-approximation with probability at least $1-\delta$. That is

$$\forall T \text{ such that} \mathtt{I}^\tau(T) \geq \mathrm{OPT}_1^\tau, \Pr\left[\frac{\left|\hat{\mathtt{I}}^\tau(T) - \mathtt{I}^\tau(T)\right|}{\mathtt{I}^\tau(T)} \geq \epsilon\right] \leq \delta \ . \tag{6}$$

$$\forall T \text{such that } \mathtt{I}^\tau(T) \leq \mathrm{OPT}_1^\tau, \Pr\left[\left|\hat{I}^\tau(T) - \mathtt{I}^\tau(T)\right| \geq \epsilon \mathrm{OPT}_1^\tau\right] \leq \delta \ . \tag{7}$$

where $\mathrm{OPT}_1^\tau := \mathrm{OPT}_1(I^\tau)$. Example 2a shows that this type of requirement is what we can hope for with an oracle that is constructed from a small number of simulations.

The (ϵ,δ) requirements are *for each* particular set T. If we are interested in stronger guarantees that with probability $(1-\delta)$ the approximation uniformly holds *for all* sets in a collection $\mathcal{C}$, we can use an oracle that provides $(\epsilon, \delta_A = \delta/|\mathcal{C}|)$ guarantees. The ϵ-approximation guarantee for all sets in $\mathcal{C}$ then follow using a union bound argument: The probability that all $|\mathcal{C}|$ sets are approximated correctly is at most $|\mathcal{C}|\delta_A \leq \delta$.

4 Variance Bounds

We consider upper bounds on the variance $\mathsf{Var}\left[\mathtt{R}^\tau(T)\right]$ of the reachability of a set of nodes T that have the following particular form

$$\mathsf{Var}[\mathtt{R}^\tau(T)] \leq c\mathtt{I}^\tau(T) \max\{\mathtt{I}^\tau(T), \max_{v\in V} \mathtt{I}^\tau(v)\} \tag{8}$$

for some $c \geq 1$. The sample complexity bounds we present in the sequel apply to any SDM that satisfies these bounds. In the remaining part of this section we state our variance upper bound for strongly submodular SDMs and extensions and a tight worst-case lower bound for IC models.

4.1 Variance Upper Bound

The following key theorem facilitates our main results. We show that any strongly submodular SDM satisfy the bound (8) with $c = \tau$. The proof is technical and provided in Appendix A.

▶ **Theorem 2** (Variance Upper Bound Lemma). *Let $\mathcal{G}(V, H)$ be a strongly submodular SDM. Then for any step limit $\tau \geq 0$ and a set $T \subset V$ of nodes we have*

$$\mathsf{Var}[R^{\tau}(T)] \leq \tau I^{\tau}(T) \max_{v \in V \setminus T} I^{\tau-1}(v).$$

Some natural dependent SDMs have a variance bound of the form (8): (See Appendix F for proofs.)

▶ **Corollary 3.** *IC models with τ-steps and b-dependence satisfy the bound (8) with $c = 2b\tau$. Any mixture of τ-steps strongly submodular SDMs where each model has probability at least p satisfy the bound (8) with $c = (\tau + 1)/p$.*

4.2 Variance Lower Bound

We provide a family of IC models for which this variance upper bound is asymptotically tight. This shows that the dependence of the variance bound on τ is necessary.

▶ **Theorem 4** (Variance Lower Bound). *For any $\tau > 0$ there is an IC model $\mathcal{G}^{\tau} = (V, \mathcal{E})$ with a node $v \in V$ of maximum influence such that $\mathsf{Var}[R^{\tau}(v)] \geq \frac{1}{12}\tau I^{\tau}(v)^2$.*

Our family of models $\mathcal{G}^{\tau} = (V, \mathcal{E})$ are such that $(V, \mathcal{E})$ is a complete directed binary tree of depth $\tau \geq 1$ rooted at $v \in V$ with all edges directed away from the root and $p_e = 1/2$ for all $e \in \mathcal{E}$. We show (details in Appendix B) that:

$$\mathtt{I}^{\tau}(v) = \tau$$
$$\mathsf{Var}[\mathtt{R}^{\tau}(v)] = \frac{1}{12}\tau(\tau - 1)(2\tau - 1).$$

5 The Averaging Oracle

The *averaging oracle* uses i.i.d. simulations $\{\boldsymbol{\phi}_i\}_{i=1}^{\ell}$. For a query T it returns the average utility of the reachability set of T: $\hat{\mathsf{A}}^{\tau}(T) = \mathsf{Ave}_{i \in [\ell]} \mathtt{VReach}^{\tau}(\boldsymbol{\phi}_i, T) := \frac{1}{\ell}\sum_{i=1}^{\ell} \mathtt{VReach}^{\tau}(\boldsymbol{\phi}_i, T)$. We quantify the approximation guarantees of an averaging oracle in terms of a variance bound of the form (8).

▶ **Lemma 5.** *Consider an SDM that for some $c \geq 1$ satisfies a variance bound of the form (8). Then for any $\epsilon, \delta < 1$, an averaging oracle constructed from $\ell \geq \epsilon^{-2}\delta^{-1}c$ i.i.d. simulations provides (ϵ, δ) guarantees.*

In particular for strongly submodular SDMs, we use the variance bound in Theorem 2 and obtain these approximation guarantees using $\ell \geq \epsilon^{-2}\delta^{-1}\tau$ i.i.d. simulations.

Proof. Using variance properties of the average of i.i.d. random variables, we get that for any query T

$$\mathsf{Var}[\hat{\mathsf{A}}^{\tau}(T)] = \frac{1}{\ell}\mathsf{Var}[\mathtt{R}^{\tau}(T)] \leq \frac{1}{\ell}c\mathtt{I}^{\tau}(T)\max\{\mathtt{I}^{\tau}(T), \mathrm{OPT}_1^{\tau}\} .$$

The claims follow using Chebyshev's inequality that states that for any random variable X and M, $\Pr[|X - \mathrm{E}[X]| \geq \epsilon M] \leq \epsilon^{-2}\mathsf{Var}[X]/M^2$. We apply it to the random variable $\hat{\mathsf{A}}^{\tau}(T)$ that has expectation $I^{\tau}(T)$ and plug in the variance bound. To establish (6) we use $M = \mathtt{I}^{\tau}(T)$ and to establish (7) we use $M = \mathrm{OPT}_1^{\tau}$. ◀

5.1 Sketched Averaging Oracle

For live-edge models with additive utility (4), the query efficiency of the averaging oracle can be improved with off-the-shelf use of τ-step combined reachability sketches [10, 14, 15, 11]. The sketching is according to a sketch-size parameter k that also determines the sketches computation time and accuracy of the estimates that sketches provide. A sketch of size $O(k)$ is computed for each node v so that for any set of nodes S, $\sum_{i=1}^{r} \mathtt{VReach}^{\tau}(E_i, S)$ can be efficiently estimated from the sketches of the nodes $v \in S$. The computation of the sketches from an arbitrary set of simulations $\{E_i\}$ uses at most $\sum_i |E_i| + k \sum_v \max_i d_v(E_i)$ edge traversals, where $d_v(E_i)$ is the maximum in-degree of node v over simulations $\{E_i\}$. In the case of an IC model, the expected number of traversals is $(k+\ell)\sum_e p_e$. Sketching with general node weights can be handled as in [11]. The estimates obtained from the sketches are unbiased with coefficient of variation $1/\sqrt{k-2}$ and are concentrated: Sketches of size $k = O(\epsilon^{-2}\log(\delta^{-1}))$ provide estimates with relative error ϵ with probability $1-\delta$.

6 Confidence Amplification: The Median-of-Averages Oracle

The statistical guarantees we provide for our averaging oracle are derived from variance bounds. The limitation is that the number of simulations we need to provide (ϵ, δ) guarantees is linear in δ^{-1} and therefore the number of simulations we need to provide uniform guarantees (via a union bound argument) grows linearly with the number of subsets. In order to find an approximate optimizer, we would like to have a uniform ϵ-approximation for all the $\binom{n}{s}$ subsets of size at most s but doing so with an averaging oracle would require too many simulations. We adapt to our setting a classic confidence amplification technique [1] to construct an oracle where the number of simulations grows logarithmically in the confidence parameter δ^{-1}.

A *median-of-averages* oracle is specified by a number r of *pools* with ℓ simulations in each pool. The oracle is therefore constructed from $r\ell$ i.i.d. simulations $\boldsymbol{\phi}_{ij}$ for $i \in [r]$ and $j \in [\ell]$.

The simulations of each pool are used in an averaging oracle that for the ith pool ($i \in [r]$) returns the estimates $\hat{\mathsf{A}}_i^{\tau}(T)$. The median-of-averages oracle returns the median value of these r estimates

$$\widehat{\mathsf{mA}}^{\tau}(T) := \operatorname*{Median}_{i\in[r]} \hat{\mathsf{A}}_i^{\tau}(T) = \operatorname*{Median}_{i\in[r]} \operatorname*{Ave}_{j\in[\ell]} \mathtt{VReach}^{\tau}(\boldsymbol{\phi}_{ij}, T) \ . \tag{9}$$

We establish that when the i.i.d simulations are from a model that has variance bound (8) for some $c \geq 1$, the median-of-averages oracle provides (ϵ, δ) approximation guarantees using $112\epsilon^{-2}c\ln\delta^{-1}$ i.i.d. simulations.

▶ **Lemma 6.** *Consider an SDM that for some $c \geq 1$ satisfies the variance bound (8). Then for every ϵ and δ, a median-average oracle $\widehat{\mathsf{mA}}$ organized with $r = 28\ln\delta^{-1}$ pools of $\ell = 4\epsilon^{-2}c$ simulations in each provides (ϵ, δ) approximation guarantees.*

Proof. An averaging oracle with ℓ simulations provides (ϵ, δ_A) approximation guarantees for $\delta_A = 1/4$. Therefore, the probability of correct estimate for any subset is at least $3/4$. We now consider the estimates $\hat{\mathsf{A}}_j$ obtained from the r pools when sorted in increasing order. The estimates that are not correct (too low or too high) will be at the prefix and suffix of the sorted order. The expected number of correct estimates is at least $\mu \geq \frac{3}{4}r$. The probability that the median estimate is not correct is bounded by the probability that number of correct estimates is $\leq r/2$, which is $\leq \frac{2}{3}\mu$. From multiplicative Chernoff bounds, the probability of a sum of Bernoulli random variables beings below $(1-\epsilon')\mu$ is at most $e^{-\epsilon'^2\mu/(2+\epsilon')}$. Using $\epsilon' = 1/3$ we have $\epsilon'^2\mu/(2+\epsilon') = \frac{1}{9}\frac{3}{4}\frac{3}{7}28\ln\delta^{-1} = \ln\delta^{-1}$. ◀

As a corollary, we obtain a sample complexity bound for influence maximization from variance bounds:

▶ **Theorem 7.** *Consider an SDM that satisfies the variance bound* (8) *for some* $c \geq 1$. *Then for any* $\epsilon < 1$ *and* $\delta < 1$, *using* $112\epsilon^{-2}cs \ln \frac{n}{\delta}$ *i.i.d. simulations, we can construct a median-of-averages oracle* $\widehat{mA}$ *such that the oracle optimum*

$$T := \arg \max_{S||S|\leq s} \widehat{mA}(S)$$

satisfies

$$\Pr\left[I^{\tau}(T) \geq (1-2\epsilon)\mathrm{OPT}_s^{\tau}\right] \geq 1-\delta \ .$$

Proof. We construct our median-of-averages oracle with $\ell = 4\epsilon^{-2}c$ and $r = 28 \ln \delta_{MA}^{-1}$ where $\delta_{MA} = \delta/\binom{n}{s}$. From Lemma 6 using a union bound over the $\binom{n}{s}$ sets we obtain that with probability $1-\delta$ the oracle provides a uniform ϵ-approximation for all subsets of size at most s. Let S be a set with maximum influence $\mathtt{I}(S) = \mathrm{OPT}_s^{\tau}$ and let T be the oracle optimum. We have

$$\mathtt{I}(T) \geq (1-\epsilon)\widehat{\mathsf{mA}}(T) \geq (1-\epsilon)\widehat{\mathsf{mA}}(S) \geq (1-\epsilon)^2\mathtt{I}(S) \geq (1-2\epsilon)\mathrm{OPT}_s^{\tau} \ .$$

We comment that the $(1-2\epsilon)$ ratio is not tight and we can obtain a bound closer to $(1-\epsilon)$. This because the particular set S to be approximated more tightly by the oracle (that uses enough simulations to support a union bound). ◀

7 Optimization with Adaptive Sample Size

The bound on the number of simulations we derived in Theorem 7 (through a median-of-averages oracle) and also the naive bound (1) (for the averaging oracle) are worst-case. This is obtained by using enough simulations to have the oracle provide a uniform ϵ-approximation with probability at least $1-\delta$ on any problem instance. To obtain the uniform approximation we applied a union bound over $\binom{n}{s}$ subsets that resulted in an increase in the number of required simulations by an $s \log n$ factor over the base (ϵ, δ) approximation guarantees.

On real data sets a much smaller number of simulations than this worst-case often suffices. We are interested in algorithms that adapt to such data and return a seed set of approximate maximum influence using a respectively smaller number of simulations and while providing statistical guarantees on the quality of the end result. To do so, we apply an adaptive optimization framework [12] (some example applications are [14, 38, 16, 13]). This framework consists of a "wrapper" that take as inputs oracle constructions from simulations and a base algorithm that performs an optimization over an oracle. The wrapper invokes the algorithm on oracles constructed using an increasing number of simulations until a validation condition on the quality of the result is met. The details are provided in Appendix E. We denote by $r(\epsilon, \delta)$ the number of simulations that provides (ϵ, δ) guarantees and we obtain the following results:

▶ **Theorem 8.** *Suppose that on our data the averaging (respectively, median-of-averages) oracle* $\hat{I}$ *has the property that with* r *simulations, with probability at least* $1-\delta$, *the oracle optimum* $T := \arg\max_{S||S|\leq s} \hat{I}(S)$ *satisfies*

$$I^{\tau}(T) \geq (1-\epsilon)\mathrm{OPT}_s^{\tau}.$$

Then with probability at least $1-5\delta$*, when using*

$$2\max\{r, r(\epsilon,\delta)\} + O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta} + \ln\left(\ln\ln\frac{n}{\delta} + \ln s\right)\right)\right)$$

simulations with the median-of-averages oracle and

$$2\max\{r, r(\epsilon,\delta)\} + O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta} + \ln\left(\ln\ln\frac{n}{\delta} + \ln n\right)\right)\right)$$

simulations with the averaging oracle, the wrapper outputs a set T *such that* $\mathcal{I}^{\tau}(T) \geq (1-5\epsilon)\mathrm{OPT}^{\tau}_{s}$*.*

The wrapper can also be used with a base algorithm that is an approximation algorithm. For live-edge models, our averaging oracle is monotone and submodular and hence we can apply greedy to efficiently compute a set with approximation ratio at least $1-1/e$ (with respect to the oracle). If we use greedy as our base algorithm we obtain the following:

▶ **Theorem 9.** *If the averaging oracle* $\hat{A}$ *is submodular and has the property that with* $\geq r$ *simulations, with probability at least* $1-\delta$*, it provides a uniform* ϵ*-approximation for all subsets of size at most* s*, then with*

$$2\max\{r, r(\epsilon,\delta)\} + O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta} + \ln\left(\ln\ln\frac{n}{\delta} + \ln n\right)\right)\right)$$

simulations we can find in polynomial time a $(1-(1-1/s)^s)(1-5\epsilon)$ *approximate solution with confidence* $1-5\delta$*.*

8 Approximate Greedy Maximization

In this section we consider the computational efficiency of maximization over our oracle $\hat{\mathtt{I}}$ that approximates a monotone submodular influence function $\mathtt{I}^{\tau}$. The maximization problem is computationally hard: The brute force method evaluates $\hat{\mathtt{I}}(S)$ on all $\binom{n}{s}$ subsets S of size s in order to find the oracle maximizer. An efficient algorithm for approximate maximization of a monotone submodular function $\hat{F}$ is greedy that sequentially builds a seed set S by adding a node u with maximum marginal contribution $\arg\max_{u\in V}(\hat{F}(S\cup\{u\}) - \hat{F}(S))$ at each step. To implement greedy we only need to evaluate at each step the function on a linear number of subsets $\hat{F}(S\cup\{u\})$ for $u\in V$ and thus overall we do sn evaluations of $\hat{F}$ on subsets. With a monotone and submodular $\hat{F}$, for any $s\geq 1$ the subset T that consists of the first s nodes in a greedy sequence satisfies [37]:

$$\hat{F}(T) \geq (1-(1-1/s)^s)\max_{S||S|\leq s}\hat{F}(S) \geq (1-1/e)\mathrm{OPT}_s(\hat{F})\ .$$

If our functions $\hat{F}$ provides a uniform ϵ-approximation of another function F for all subsets of size at most s, then $F(T)\geq(1-(1-1/s)^s)(1-2\epsilon)\mathrm{OPT}_s(F)$ (See the proof of 7).

The averaging oracle is monotone and submodular [31] when reachability functions are as in live-edge models. Unfortunately our median-of-averages oracle which facilitates tighter bounds on the number of simulations is monotone but may not be submodular even for models where the averaging oracle is submodular. Generally when this is the case, greedy may fail (as highlighted in recent work by Balkanski et al [2]).

Fortunately, greedy is effective on a function $\hat{F}$ that is monotone but not necessarily submodular as long as $\hat{F}$ "closely approximates" a monotone submodular F in that marginal contributions of the form

$$F(u\mid S) := F(S\cup\{u\}) - F(S)$$

are approximated well by $\hat{F}(u\mid S)$ [14]. We apply this to establish the following lemma:

▶ **Lemma 10.** *The greedy algorithm applied to a function $\hat{F}$ that is monotone and provides a uniform ϵ_A-approximation of a monotone submodular function F where $\epsilon_A = \frac{\epsilon(1-\epsilon)}{14s}$ returns a set T such that $F(T) \geq (1-(1-1/s)^s)(1-\epsilon)\mathrm{OPT}_s(F)$.*

Our proof of Lemma 10 generally applies to an approximate oracle $\hat{F}$ of any monotone submodular function F and is presented in Appendix C. For approximate IM we obtain the following as a corollary:

▶ **Theorem 11.** *Consider a submodular SDM $\mathcal{G}(V,H)$ that for some $c \geq 1$ satisfies the variance bound* (8)*. Consider a median-of-averages oracle constructed with $O(\epsilon^{-2}s^3 c \ln \frac{n}{\delta})$ simulations of $\mathcal{G}$ arranged as $r = O(s \ln \frac{n}{\delta})$ pools with $\ell = O(\epsilon^{-2}s^2 c)$ simulations each. Then with probability $1-\delta$, the set T that contains the first s nodes returned by greedy on the oracle satisfies $\mathcal{I}^\tau(T) \geq (1-(1-1/s)^s)(1-\epsilon)\mathrm{OPT}_s^\tau$.*

Proof. From Lemma 6, with appropriate constants, this configuration provides us with $(\epsilon/(14s), \delta)$ approximation guarantees. From Lemma 10 greedy provides the stated approximation ratio. ◀

Greedy on the median-of-averages oracle can be implemented generically for any SDM $\mathcal{G}$ by explicitly maintaining the reachability sets $\texttt{Reach}(\boldsymbol{\phi}_{ij}, \{v\} \cup S)$ for all nodes $v \in V$ in each simulation $\boldsymbol{\phi}_{ij}$ as the greedy selects nodes into the seed set S. For each step, we compute the oracle value (see (9)) and select v for which the value for $\{v\} \cup S$ is maximized:

$$\arg\max_{v \in V \setminus S} \widehat{\mathsf{mA}}^\tau(\{v\} \cup S).$$

We obtain approximation guarantees, however, only when the conditions of monotone submodular influence function and variance bounds are satisfied. For specific families of models, we can consider tailored efficient implementations that incrementally maintain reachability sets and values.

For live-edge models with additive utility (4) we consider an implementation of greedy on a median-of-averages oracle. This can be done by explicit maintenance of reachability sets or by using sketches [10, 14, 15, 11] (see Section 5.1). We obtain the following bounds (proof is deferred to Appendix Section D).

▶ **Theorem 12.** *Let $\mathcal{G}$ be a live-edge model with an additive utility function* (4) *that satifies the variance bound* (8)*. Then greedy on median-of-averages oracle can be implemented with explicit reachability sets in time*

$$O(\epsilon^{-2}s^3 c \ln\left(\frac{n}{\delta}\right)\overline{m}n)\ , \tag{10}$$

where $\overline{m}$ is the average number of edges per simulation (For an IC model, $c = \tau$ and $\mathrm{E}[\overline{m}] = \sum_{e\in\mathcal{E}} p_e$). When using sketches, the time bound is

$$O(\epsilon^{-2}s^3 \ln\frac{n}{\delta}(c\overline{m} + s(m^* + ns)\ln n)), \tag{11}$$

where $m^* = \sum_v \max_{ij} d_v(E_{ij})$. For an IC model, $c = \tau$ and $m^* = \sum_e p_e$ in expectation.

Conclusion

We explore the "sample complexity" of IM on stochastic diffusion models and show that an approximate maximizer (within a small relative error) can be recovered from a small number of simulations as long as the variance is appropriately bounded. We establish the variance

bound for the large class of strongly submodular stochastic diffusion models. This includes IC models (where edges are drawn independently) and IGT models (where node thresholds are drawn independently) and natural extensions that allow for some dependencies. Our sample complexity bound significantly improves over the previous bounds by replacing the linear dependence in the number of nodes by a logarithmic dependence on the number of nodes and linear dependence on the length of the activation paths (which are usually very short). An interesting question for future work is to address the gap between the sample complexity and the larger number of simulations currently needed for greedy maximization.

A Variance Upper Bound: Proof of Theorem 2

In this section we prove Theorem 2 which upper bounds the variance in strongly submodular SDMs. We start by bounding the variance in a more basic setting of a submodular function over a random subset in Section A.1 (Theorem 14). This will be an ingredient in our main proof provided in Section A.3.

We will be using the following basic tools:

▶ **Lemma 13.** *If X, Y are two random variables on the same probability space and the variance of Y is finite, then:*

$$\mathrm{E}[Y] = \mathrm{E}[\mathrm{E}[Y|X]] \quad \textit{(total expectation)}$$

$$\mathsf{Var}[Y] = \mathrm{E}[\mathsf{Var}[Y|X]] + \mathsf{Var}[\mathrm{E}[Y|X]] \quad \textit{(total variance)}$$

where $\mathrm{E}[Y|X]$ is a random variable that gets the expectation of Y conditioned the value of X and $\mathsf{Var}[Y|X]$ is a random variable that gets the variance of Y conditioned the value of X.

When X is a Bernoulli random variable $X \sim Ber(p)$ then Lemma 13 gives that

$$\mathsf{Var}[Y] = \mathrm{E}[\mathsf{Var}[Y|X]] + \mathsf{Var}[\mathrm{E}[Y|X]] = p\mathrm{V}_1 + (1-p)V_0 + p(1-p)(\mathrm{E}_1 - \mathrm{E}_0)^2.$$

where $\mathrm{V}_0 = \mathsf{Var}[Y|X=0]$, $\mathrm{V}_1 = \mathsf{Var}[Y|X=1]$, $\mathrm{E}_0 = \mathrm{E}[Y|X=0]$, and $\mathrm{E}_1 = \mathrm{E}[Y|X=1]$.

A.1 Submodular Monotone Functions on Random Subsets

Let $S = \{a_i\}_{1<i\leq t}$ be a set with t elements and let $P = \{p_i\}_{1<i\leq t}$ be a set of t probabilities such that p_i is associated with the element a_i. Let X be a random subset of S that contains a_i with probability p_i independently for each $i = 1, ..., t$. That is

$$\forall A \in 2^S : \Pr[X = A] = \prod_{a_i \in A} p_i \prod_{a_i \notin A} (1 - p_i).$$

We say that X is a *random subset of S using probabilities P*.

A *submodular monotone function* f over S is a function with the following properties:

1. $f : 2^S \to R^+$
2. For every $A, B \subset S$ with $A \subset B$ and for every $x \in S \setminus B$ we have that $f(A \cup x) - f(A) \geq f(B \cup x) - f(B)$
3. $A \subset B \Rightarrow f(A) \leq f(B)$

For any singelton $\{a\} \in S$ we write $f(a)$ instead of $f(\{a\})$. Let $\mathtt{M}_f = \max_i f(a_i) - f(\emptyset)$. Our purpose in this subsection is to establish the following:

▶ **Theorem 14.** *Let X be a random subset of S using probabilities P and let f be a submodular monotone function. Then*

$$\mathsf{Var}[f(X)] \leq \mathtt{M}_f \mathrm{E}\left[f(X) - f(\emptyset)\right].$$

We give the following additional definitions and lemmas before proving this theorem.

Let $S_{-i} = S \setminus \{a_i\}$ and let $P_{-i} = P \setminus \{p_i\}$. We define X_{-i} to be a random subset of S_{-i} using the probabilities P_{-i}. Let f_i^0, f_i^1 be submodular functions over S_{-i} defined by $f_i^0(A) = f(A)$ and $f_i^1(A) = f(A \cup \{a_i\})$. Let

$$\mathrm{E}_i^1 = \mathrm{E}[f_i^1(X_{-i})] = \sum_{A \in 2^{S \setminus \{a_i\}}} \Pr[X_{-i} = A] f_i^1(A).$$

and

$$\mathrm{E}_i^0 = \mathrm{E}[f_i^0(X_{-i})] = \sum_{A \in 2^{S \setminus \{a_i\}}} \Pr[X_{-i} = A] f_i^0(A).$$

By our definitions $\mathrm{E}[f(X_{-i})] = \mathrm{E}_i^0$ and from total expectation (Lemma 13), $\mathrm{E}[f(X)] = p_i \mathrm{E}_i^1 + (1 - p_i)\mathrm{E}_i^0$.

▶ **Lemma 15.** *let f be a submodular monotone function over S and X a random subset of S using probabilities P. Then,*

$$\forall i : \mathrm{E}_i^1 - \mathrm{E}_i^0 \leq f(a_i) - f(\emptyset) \leq \mathtt{M}_f.$$

Proof. Since X is obtained by drawing the elements in S independently it follows that

$$\mathrm{E}_i^1 - \mathrm{E}_i^0 = \sum_{A \in 2^{S_{-i}}} \Pr[X_{-i} = A] \big[f(A \cup \{a_i\}) - f(A) \big] \underbrace{\leq}_{\text{submodularity}}$$

$$\sum_{A \in 2^{S \setminus a_i}} \Pr[X_{-i} = A] \big[f(a_i) - f(\emptyset) \big] \leq f(a_i) - f(\emptyset) \leq \mathtt{M}_f.$$ ◀

▶ **Lemma 16.** *for any submodular monotone function f over S and for any index i we have that $\mathtt{M}_{f_i^0} \leq \mathtt{M}_f$ and $\mathtt{M}_{f_i^1} \leq \mathtt{M}_f$.*

Proof. The first inequality follows immediately from our definition since

$$\mathtt{M}_{f_i^0} = \max_{j \neq i} f_i^0(a_j) - f_i^0(\emptyset) = \max_{j \neq i} f(a_j) - f(\emptyset) \leq \mathtt{M}_f.$$

For the second inequality we use submodularity as follows

$$\mathtt{M}_{f_i^1} = \max_{j \neq i} f_i^1(a_j) - f_i^1(\emptyset) = \max_{j \neq i} f(\{a_j \cup a_i\}) - f(a_i) \underbrace{\leq}_{\text{sub-modularity}} \max_j f(a_j) - f(\emptyset) = \mathtt{M}_f.$$

◀

We are now ready for the proof of Theorem 14.

Proof of Theorem 14. The proof is by induction on the size of S.
Base case. Let $S = \{a_1\}, P = \{p_1\}$ we have that

$$\mathrm{E}[f(X)] = p_1 f(a_1) + (1 - p_1) f(\emptyset),$$

and

$$\begin{aligned} \mathsf{Var}[f(X)] &= \mathrm{E}[f(X)^2] - \mathrm{E}^2[f(X)] = p_1 f^2(a_1) + (1 - p_1) f^2(\emptyset) - \big[p_1 f(a_1) + (1 - p_1) f(\emptyset) \big]^2 \\ &= p_1(1 - p_1) \big[f(a_1) - f(\emptyset) \big]^2 \leq \mathtt{M}_f p_1 (1 - p_1) \big[f(a_1) - f(\emptyset) \big]. \end{aligned}$$

It is left to prove that $\mathrm{E}\left[f(X)-f(\emptyset)\right] \geq p_1(1-p_1)\left[f(a_1)-f(\emptyset)\right]$, and indeed we have that

$$\mathrm{E}\left[f(X)-f(\emptyset)\right] = p_1\left[f(a_1)-f(\emptyset)\right] \geq p_1(1-p_1)\left[f(a_1)-f(\emptyset)\right].$$

Inductive Step. Assume the lemma holds for sets of size ℓ and any submodular function f and probabilities P. For a set S with $\ell+1$ elements and a submodular function f over S. Let $j \leq i$ be an arbitrary index.
From the total variance formula in Lemma 13 we know that

$$\mathsf{Var}[f(X)] = p_j \mathrm{V}_j^1 + (1-p_j)\mathrm{V}_j^0 + p_j(1-p_j)\left[\mathrm{E}_j^1 - \mathrm{E}_j^0\right]^2 \ , \tag{12}$$

where $\mathrm{E}_j^1 = \mathrm{E}[f_j^1(X_{-j})]$, $\mathrm{E}_j^0 = \mathrm{E}[f_j^0(X_{-j})]$, $\mathrm{V}_j^1 = \mathsf{Var}[f_j^1(X_{-j})]$, and $\mathrm{V}_j^0 = \mathsf{Var}[f_j^0(X_{-j})]$. By applying the induction hypothesis to S_{-j} with probabilities P_{-j} and $|S_{-j}| = \ell$ and f_j^0 and f_j^1 we get that

$$\mathrm{V}_j^0 \leq \mathtt{M}_{f_j^0}\left[\mathrm{E}_j^0 - f_j^0(\emptyset)\right] \underbrace{\leq}_{\text{Lemma 16}} \mathtt{M}_f\left[\mathrm{E}_j^0 - f(\emptyset)\right],$$

and

$$\mathrm{V}_j^1 \leq \mathtt{M}_{f_j^1}\left[\mathrm{E}_j^1 - f_j^1(\emptyset)\right] \underbrace{\leq}_{\text{Lemma 16}} \mathtt{M}_f\left[\mathrm{E}_j^1 - f(a_j)\right].$$

Substituting these bounds in Equation (12) we get that

$$\begin{aligned}
\mathsf{Var}[f(X)] &\leq p_j \mathtt{M}_f\left[\mathrm{E}_j^1 - f(a_j)\right] + (1-p_j)\mathtt{M}_f\left[\mathrm{E}_j^0 - f(\emptyset)\right] + p_j(1-p_j)\left[\mathrm{E}_j^1 - \mathrm{E}_j^0\right]^2 \\
&= \mathtt{M}_f\left[p_j\mathrm{E}_j^1 + (1-p_j)\mathrm{E}_j^0 - f(\emptyset)\right] + p_j(1-p_j)\left[\mathrm{E}_j^1 - \mathrm{E}_j^0\right]^2 - p_j\mathtt{M}_f\left[f(a_j) - f(\emptyset)\right] \\
&\underbrace{=}_{\text{total expectation}} \mathtt{M}_f\left[\mathrm{E}[f(X)] - f(\emptyset)\right] + p_j(1-p_j)\left[\mathrm{E}_j^1 - \mathrm{E}_j^0\right]^2 - p_j\mathtt{M}_f\left[f(a_j) - f(\emptyset)\right] \\
&\underbrace{\leq}_{\text{Lemma 15}} \mathtt{M}_f\left[\mathrm{E}[f(X)] - f(\emptyset)\right] + p_j\mathtt{M}_f\left[f(a_j) - f(\emptyset)\right]\left[(1-p_j) - 1\right] \\
&\leq \mathtt{M}_f[\mathrm{E}[f(X)] - f(\emptyset)].
\end{aligned}$$

◀

A.2 Properties of Reduced Diffusion Models

We establish some properties of reduced independent SDMs that are needed for our upper bound.

We first show that influence values of nodes in a reduced model can only be lower than respective values in the original model:

▶ **Lemma 17.** *Let $\mathcal{G}'(V \setminus T, H')$ be a reduction of a model $\mathcal{G}(V,H)$.*

For all $v \in V \setminus T$ and $t \geq 0$, $\mathcal{I}^t_{\mathcal{G}'}(v) \leq \mathcal{I}^t_{\mathcal{G}}(v)$. (13)

Proof. Note that $\mathcal{G}'$ is obtained from $\mathcal{G}$ by removing nodes. Therefore respective reachability sets given $\boldsymbol{\phi}$ are such that those in $\mathcal{G}'$ can only be subsets of those in $\mathcal{G}$:

$$\mathtt{Reach}_{\mathcal{G}'}(v, \boldsymbol{\phi}') \subset \mathtt{Reach}_{\mathcal{G}}(v, \boldsymbol{\phi}).$$

Then from monotonicity and submodularity of H we get

$$H'(\mathtt{Reach}_{\mathcal{G}'}(v, \boldsymbol{\phi}')) \leq H'(\mathtt{Reach}_{\mathcal{G}}(v, \boldsymbol{\phi})) \leq H(\mathtt{Reach}_{\mathcal{G}}(v, \boldsymbol{\phi})).$$

(second inequality follows from monotonicity and submodularity of H so that for all $A \subset V \setminus T$, $H'(A) \leq H(A)$.) Therefore,

$$\mathtt{I}^t_{\mathcal{G}'}(v) = \mathrm{E}[\mathtt{VReach}^t_{\mathcal{G}'}(v)] \leq \mathrm{E}[\mathtt{VReach}^t_{\mathcal{G}}(v)] = \mathtt{I}^t_{\mathcal{G}}(v). \quad \blacktriangleleft$$

A convenient property is that reduction preserves strong monotone submodularity:

▶ **Lemma 18.** *A reduction of a strongly monotone submodular model is also strongly monotone submodular.*

Proof. A reduced model with respsect to T_2 of a reduced model of $\mathcal{G}$ with respect to T_1 is a reduced model of $\mathcal{G}$ with respect to $T_1 \cup T_2$. Also note that the reduced utility function H' is also monotone and submodular. ◀

We next show that IC or IGT models with submodular utility are closed under reduction:

▶ **Theorem 19.** *IC and IGT models with submodular utility are strongly submodular SDMs.*

Proof. We first show that IC/IGT models are independent SDMs. In the introduction we expressed IC and IGT models as SDMs: A live-edge model is expressed as an SDM using $\phi_v(T) = 1$ if and only if there is an edge from a node in T to v. The model is independent if for all v the edges incoming to v are independent of all other edges. In IC models all edges are independent and hence IC models are independent SDMs. Recall (from the Introduction) that an IGT model is expressed as an SDM using $\phi_v(T) := \mathrm{Indicator}(\theta_v \leq f_v(T))$. In an IGT model the thresholds θ_v are independent random variables, and hence ϕ_v are independent. Hence, an IGT model is an independent SDM. Submodularity of influence when utlity is submodular is established for IC models in [31] and for IGT models in [35].

Reduction of any model preserves submodularity of the utility and in particular this holds for reduced IC/IGT models. What remains to show is that a reduced IC/IGT model is also an IC/IGT model (respectively). This would conclude the proof of strong submodularity since any IC and IGT models with submodular utility has a submodular influence functions.

To establish this remaining claim we consider IC/IGT models and express the reduction in terms of the activation functions as one in terms of the respective family of models.

We first consider IC models. The reduced IC model $\mathcal{G}'(V \setminus T, \mathcal{E} \setminus (V \times T \cup T \times V)$ is obtained from $\mathcal{G}(V)$ by deleting the nodes T and their incident edges and keeping p_e on remaining edges. This is clearly an IC model. It remains to show that this is equivalent to the reduction of the distribution of activation functions. The conditioning that $\phi_v(T) = 0$ is equivalent to live-edge set E with no edges from T to V. For such edge set for any $S \subset V \setminus (T \cup \{v\})$ we have $\phi'_v(S) = \phi_v(S \cup T) = \phi_v(S)$ which corresponds to E having at least one edge from S to v. From independence of edges, the conditional distribution is also independent and retains the same inclusion probabilities.

We next consider IGT models. The reduction $\mathcal{G}'(V \setminus T, \{f'_v\})$ in terms of activation functions distribution is equivalent to functions is equivalent to modifying the functions so that

$$f'_v(S) := f_v(S \cup T) - f_v(T).$$

The reduced model is clearly an IGT model. The conditioning that $\phi_v(T) = 0$ means that $\theta_v > f_v(T)$. Therefore, the conditional distribution of θ_v provided it was not activated in the first step is uniform on $[f_v(T), 1]$. The probability that $\theta_v > f_v(S \cup T)$ given this conditioning is equal to the probability that $\theta'_v > f_v(S \cup T) - f_v(T) = f'_v(S)$. ◀

A.3 Upper Bound on the Variance in Strongly Submodular SDM

Let $\mathcal{G}(V,H)$ be a τ-stepped diffusion model. We denote by $\mathtt{M}^{\tau}_{\mathcal{G}}(\bar{T})$ the maximum influence of a single node in $\mathcal{G}$ that is not included in T:

$$\mathtt{M}^{\tau}_{\mathcal{G}}(\bar{T}) = \max_{v \in V \setminus T} \mathtt{I}^{\tau}_{\mathcal{G}}(v)$$

As before, we omit $\mathcal{G}$ if it can be understood from the context. We prove the following theorem which is a restatement of Theorem 2.

▶ **Theorem 20.** *Let $\mathcal{G}(V,H)$ be a strongly submodular SDM. Then for any $\tau \geq 0$ and a set of nodes $T \subset V$:*

$$\mathsf{Var}[R^{\tau}(T)] \leq \tau M^{\tau-1}(\bar{T}) I^{\tau}(T).$$

The remaining part of this Subsection contains the proof of the Theorem.

Let T be a set of nodes, and let

$$N(T) = \{v \in V \setminus T \mid \Pr[\phi_v(T) = 1] > 0\}$$

be the nodes that have nonzero probability to be activated if T is active. For the special case of IC models, $N(T) = \{v \notin T \mid \exists (u,v) \in \mathcal{E}, u \in T\}$ is the set of outgoing neighbors of T.

We first consider the case where $N(T)$ is empty. In this case, $\mathtt{Reach}^{\tau}(T) = T$ for all $\tau \geq 0$. Therefore, $\mathsf{Var}[\mathtt{R}^{\tau}(T)] = 0$, $\mathtt{I}^{\tau}(T) = H(T) \geq 0$, and $\mathtt{M}^{\tau-1}(\bar{T}) = 0$ and the claim holds.

We now assume that $N(T)$ is not empty and give a proof by induction on τ.

A.3.1 Base case ($\tau = 1$)

Let

$$p_v := \Pr[\phi_v(T) = 1]$$

be the probability that node v is activated in step 1 provided that the set of nodes T was active at step 0. From independence of the model, the events of activating different nodes $v \in N(T)$ at step 1 are independent. We have that the set of nodes that is active at step 1 is a random subset S of $N(T)$ with probabilities $\{p_v\}$ as defined in Subsection A.1. Moreover, from monotonicity and submodularity of H, the function $f(S) := H(T \cup S) - H(T)$ is monotone and submodular with $f(\emptyset) = 0$. We can therefore apply Theorem 14 to bound the variance of $f(S)$:

$$\mathsf{Var}[f(S)] \leq M_f \mathrm{E}[f(S)]. \tag{14}$$

We now note that

$$\mathrm{E}[f(S)] = \mathrm{E}[H(T \cup S)] - H(T) = \mathtt{I}^1(T) - I^0(T)$$

and

$$\mathsf{Var}[f(S)] = \mathsf{Var}[H(T \cup S)] = \mathsf{Var}[\mathtt{R}^1(T)].$$

For all $v \in N(T)$ we have $f(v) = H(T \cup \{v\}) - H(T) \leq H(v) = \mathtt{I}^0(v)$. Therefore

$$M_f := \max_{v \in N(T)} f(v) \leq \max_{v \in N(T)} \mathtt{I}^0(v) = M^0(\bar{T}).$$

Substituting in (14) we obtain the claim

$$\mathsf{Var}[\mathtt{R}^1(T)] \leq M^0(\bar{T}) \mathtt{I}^1(T).$$

A.3.2 Inductive step

We define $\texttt{Reach}^t_{\mathcal{G}}(T \mid A)$ to be the random variable that is the t-steps reachability of T in a diffusion on $\mathcal{G}$ seeded with T that is conditioned on the event that exactly the nodes $A \subset N(T)$ (and no other nodes) are activated in step 1. Equivalently, we condition on $\boldsymbol{\phi}$ such that for $v \setminus (T \cup A)$, $\phi_v(T) = 0$ and for $v \in A$, $\phi_v(T) = 1$. We respectively define $\texttt{R}^t_{\mathcal{G}}(T \mid A)$ to be the random variable $H(\texttt{Reach}^t_{\mathcal{G}}(T \mid A))$. From definition, we have

$$\texttt{I}^t_{\mathcal{G}}(T) = \sum_{A \subset N(T)} \Pr[\texttt{Reach}^1_{\mathcal{G}}(T) = A \cup T] \mathrm{E}[\texttt{R}^t_{\mathcal{G}}(T \mid A)] = \mathrm{E}_A \mathrm{E}[\texttt{R}^t_{\mathcal{G}}(T \mid A)] \ . \tag{15}$$

We consider the reduced model $\mathcal{G}'$ of $\mathcal{G}$ with respect to T and show that the conditioned $t \geq 1$ steps diffusion from T in $\mathcal{G}$ is equivalent to the unconditioned $t-1$ steps diffusion from A in $\mathcal{G}'$:

▶ **Lemma 21.** *For any $A \subset N(T)$ and $t \geq 1$, the random variables $\texttt{Reach}^{t-1}_{\mathcal{G}'}(A)$ and $\texttt{Reach}^t_{\mathcal{G}}(T|A) \setminus \{T\}$ have identical distribution overs subsets. The random variables $\texttt{R}^{t-1}_{\mathcal{G}'}(A)$ and $\texttt{R}^t_{\mathcal{G}}(T|A) - H(T)$ have identical distributions over values.*

Proof. We first consider $t = 1$. For a draw of conditioned activation functions we have $\texttt{Reach}^1_{\mathcal{G}}(T|A) = T \cup A$. By definition, we also have $\texttt{Reach}^0_{\mathcal{G}'}(A) = A$ and the claim holds.

We next consider $t > 1$. We first observe that in both situations, (i) the reduced model $\mathcal{G}'$ when seeded with A and (ii) the conditioned diffusion in $\mathcal{G}$ seeded with T such that the nodes A are activated in the first step, the progression is determined only by the activation functions on the nodes $V \setminus (T \cup A)$.

We next argue that the distribution of activation functions projected on the nodes $V \setminus (T \cup A)$ is the same in both situations. From independence of $\mathcal{G}$ it suffices to consider separately the activation functions of each node. From definition of a reduced model, we draw for each $v \in V \setminus T$, $\phi_v \sim \mathcal{G}$ conditioned on $\phi_v(T) = 0$. This is exactly what we get for the conditioned diffusion in $\mathcal{G}$.

We can thus match the supports (sets of activations functions) in both situations so that $\boldsymbol{\phi}$ and $\boldsymbol{\phi}'$ are matched when the projections on $V \setminus (T \cup A)$ is the same. The starting points are at steps 0 of the reduced model and step 1 of the conditioned process is A, the progression of new activations is thus the same. Therefore, for any step $t \geq 1$,

$$\texttt{Reach}^t_{\mathcal{G}}(T \mid A, \boldsymbol{\phi}) \setminus T = \texttt{Reach}^{t-1}_{\mathcal{G}'}(A, \boldsymbol{\phi}')$$

and the first claim follows.

For the second claim, note that $\texttt{R}^t_{\mathcal{G}}(T|A) = H(\texttt{Reach}^t_{\mathcal{G}}(T|A))$ and thus

$$\texttt{R}^{t-1}_{\mathcal{G}'}(A) = H'(\texttt{Reach}^{t-1}_{\mathcal{G}'}(A)) = H(\texttt{Reach}^{t-1}_{\mathcal{G}'}(A) \cup T) - H(T) = H(\texttt{Reach}^t_{\mathcal{G}}(T|A)) - H(T)$$

where the equalities are those of distributions. ◀

As immediate corollaries we can relate expectations and variance of as follows:

$$\begin{aligned} \texttt{I}^{\tau-1}_{\mathcal{G}'}(A) &= \mathrm{E}[\texttt{R}^{\tau-1}_{\mathcal{G}'}(A)] = \mathrm{E}[H'(\texttt{Reach}^{\tau-1}_{\mathcal{G}'}(A))] = \mathrm{E}\left[H(\texttt{Reach}^{\tau}_{\mathcal{G}}(T|A))\right] - H(T) \\ &= \mathrm{E}[\texttt{R}^{\tau-1}_{\mathcal{G}}(T|A)] - H(T). \end{aligned} \tag{16}$$

$$\begin{aligned} \mathsf{Var}[\texttt{R}^{\tau-1}_{\mathcal{G}'}(A)] &= \mathsf{Var}[H'(\texttt{Reach}^{\tau-1}_{\mathcal{G}'}(A))] = \mathsf{Var}[H'(\texttt{Reach}^{\tau}_{\mathcal{G}}(T|A) \setminus \{T\})] \\ &= \mathsf{Var}[H(\texttt{Reach}^{\tau}_{\mathcal{G}}(T|A)) - H(T)] = \mathsf{Var}[H(\texttt{Reach}^{\tau}_{\mathcal{G}}(T|A))] = \mathsf{Var}[\texttt{R}^{\tau}_{\mathcal{G}}(T|A)] \ . \end{aligned} \tag{17}$$

A.3.2.1 Total Variance

We define the random variable A to be the subset of $N(T)$ which is activated after the first step. Note that A is a random subset of $N(T)$ using probabilities p_v for $v \in N(T)$ as defined in Section A.1. By the total variance formula we get that

$$\mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] = \mathsf{Var}_A[\mathrm{E}[\mathtt{R}^{\tau}_{\mathcal{G}}(T|A)]] + \mathrm{E}_A[\mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T|A)]]. \tag{18}$$

We bound the total variance by separately bounding the two terms.

A.3.2.2 Bound on the first term of the total variance

We consider the reduced model $\mathcal{G}'$ with respect to T and a restriction of the influence function $\mathtt{I}^{\tau-1}_{\mathcal{G}'}$ to the domain that is subsets $A \subseteq N(T)$:

$$f(A) := \mathtt{I}^{\tau-1}_{\mathcal{G}'}(A).$$

From Lemma 21, this function represents the expected marginal utility value of nodes which are not in T that are activated after τ steps if we activate T at step 0 and the set A at step 1.

We first observe that f is monotone and submodular. This because strong monotone submodularity of our model implies that the reduced model is also strongly monotone and submodular, and a restriction of a monotone and submodular function is also monotone and submodular. We establish two helpful properties of f. First,

$$f(\emptyset) = 0\ , \tag{19}$$

which holds for any influence function. Second, using Lemma 17 we obtain

$$\max_{v \in N(T)} f(v) \underbrace{\leq}_{(13)} \max_{v \in N(T)} \mathtt{I}^{\tau-1}_{\mathcal{G}}(v) \leq \mathtt{M}^{\tau-1}(\bar{T})\ . \tag{20}$$

We are now ready to bound the first term of the total variance (18). Our monotone submodular function f and the random subset A using probabilities p_v satisfy the conditions of Theorem 14.

$$\mathsf{Var}_A[\mathrm{E}[\mathtt{R}^{\tau}(T|A)]] = \mathsf{Var}_A[f(A) + H(T)] = \mathsf{Var}_A[f(A)] \underbrace{\leq}_{\text{Theorem 14}} (\max_{v \in N(T)} f(v))\mathrm{E}_A\left[f(A) - f(\emptyset)\right]$$
$$\underbrace{\leq}_{(19),\ (20)} \mathtt{M}^{\tau-1}(\bar{T})\mathrm{E}_A\left[\mathrm{E}[\mathtt{R}^{\tau}(T|A) - H(T)]\right] = \mathtt{M}^{\tau-1}(\bar{T})\left(\mathtt{I}^{\tau}_{\mathcal{G}}(T) - H(T)\right) \tag{21}$$

A.3.2.3 Bound on the second term of the total variance

We next bound the second term of (18) which is the expectation of the variance conditioned on A:

$$
\begin{aligned}
\mathrm{E}_A[\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid A)]] &= \sum_{S \subset N(T)} \Pr[A = S]\, \mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S)] \\
&= \sum_{S \subset N(T)} \Pr[A = S] \mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S) - H(T)] \frac{\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S)]}{\mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S) - H(T)]} \\
&\leq \max_{S \subset N(T)} \frac{\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S)]}{\mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S) - H(T)]} \sum_{S \subset N(T)} \Pr[A = S] \mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S) - H(T)] \\
&= \mathrm{E}_A\left[\mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid A) - H(T)]\right] \max_{S \subset N(T)} \frac{\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S)]}{\mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}}(T \mid S) - H(T)]} \\
&\underbrace{=}_{(15),(16),(17)} (\mathtt{I}^\tau_{\mathcal{G}}(T) - H(T)) \max_{S \subset N(T)} \frac{\mathsf{Var}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S)]}{\mathtt{I}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S)]} \\
&= (\mathtt{I}^\tau_{\mathcal{G}}(T) - H(T)) \frac{\mathsf{Var}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S')]}{\mathtt{I}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S')]} \qquad (22)
\end{aligned}
$$

Where we take

$$S' = \arg \max_{S \subset N(T)} \frac{\mathsf{Var}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S)]}{\mathtt{I}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S)]}$$

to be the subset that maximizes the ratio.

Using the induction hypothesis on $(\tau-1)$-stepped influence we get

$$\mathsf{Var}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S')] \leq (\tau-1)\mathtt{M}^{\tau-2}_{\mathcal{G}'}(\bar{S'})\mathtt{I}[\mathtt{R}^{\tau-1}_{\mathcal{G}'}(S')]. \qquad (23)$$

We now relate the maximum influence of nodes in the original and reduced models:

$$\mathtt{M}^{\tau-2}_{\mathcal{G}'}(\bar{S'}) = \max_{v \in V \setminus (T \cup S')} \mathtt{I}^{\tau-2}_{\mathcal{G}'}(v) \underbrace{\leq}_{(13)} \max_{v \in V \setminus (T \cup S')} \mathtt{I}^{\tau-2}_{\mathcal{G}}(v) \leq \mathtt{M}^{\tau-2}_{\mathcal{G}}(\overline{T \cup S'}) \leq \mathtt{M}^{\tau-1}_{\mathcal{G}}(\bar{T}). \qquad (24)$$

From (22) using (23) and (24) we obtain

$$\mathrm{E}_A[\mathsf{Var}[\mathtt{R}^\tau(T|A)]] \underbrace{\leq}_{(23)} \left(\mathtt{I}^\tau_{\mathcal{G}}(T) - H(T)\right)(\tau-1)\mathtt{M}^{\tau-2}_{\mathcal{G}'}(\bar{S'}) \underbrace{\leq}_{(24)} \left(\mathtt{I}^\tau_{\mathcal{G}}(T) - H(T)\right)(\tau-1)\mathtt{M}^{\tau-1}_{\mathcal{G}}(\bar{T})\,. \qquad (25)$$

A.3.2.4 Combining the bounds of the first and second terms

The claim of the Theorem follows using total variance (18) and the bounds on the first term (21) and second term (25).

B Variance lower bound construction

▶ **Lemma 22.** *Let $\mathcal{G}$ be complete binary tree where each edge has probability $\frac{1}{2}$ and let $h(u)$ be the height of the node u. Then, $\mathcal{I}^\tau(u) = h(u)$ and $\mathsf{Var}[R^\tau(u)] = \frac{1}{2}\sum_{i=0}^{h(u)-1} i^2 = \frac{(h(u)-1)h(u)(2h(u)-1)}{12}$.*

Proof. By induction on the height of the of the node.

Base step ($h(u) = 1$). It is clear that $\mathtt{I}^1(u) = 1$ and $\mathsf{Var}\left[\mathtt{R}^1(u)\right] = 0$ since u is a leaf.

Inductive step. u has two neighbors and each is reached with probability $\frac{1}{2}$. Let v_1 and v_2 be the neighbors of u and let X_1, X_2 be random variables that indicate if $(u, v_1), (u, v_2)$ were activated respectively. The variables X_1, X_2 are Bernoulli random variables with $p = \frac{1}{2}$, hence, $\mathrm{E}[X_1] = \mathrm{E}[X_2] = \frac{1}{2}$ and $\mathsf{Var}[X_1] = \mathsf{Var}[X_2] = \frac{1}{4}$. Since the graph is a tree, the reachabilities of v_1 and v_2 are independent random variables, so we can simply write:

$$\mathtt{R}^\tau(u) = 1 + X_1\mathtt{R}^{\tau-1}(v_1) + X_2\mathtt{R}^{\tau-1}(v_2)$$

The variable $\mathtt{R}^{\tau-1}(v_1)$ and $\mathtt{R}^{\tau-1}(v_2)$ are identical and $X_1, \mathtt{R}^{\tau-1}(v_1)$ and $X_2, \mathtt{R}^{\tau-1}(v_2)$ are independent random variables, Thus,

$$\mathtt{I}^\tau(u) = \mathrm{E}[\mathtt{R}^\tau(u)] = 1 + \mathrm{E}[X_1]\mathrm{E}[\mathtt{R}^{\tau-1}(v_1)] + \mathrm{E}[X_2]\mathrm{E}[\mathtt{R}^{\tau-1}(v_2)] = 1 + 2\frac{1}{2}\mathrm{E}[\mathtt{R}^{\tau-1}(v_1)]$$

$$\underbrace{=}_{\text{induction's hypothesis}} 1 + h(u) - 1 = h(u)$$

The computation of the variance is similar:

$$\mathsf{Var}[\mathtt{R}^\tau(u)] = \mathsf{Var}[X_1\mathtt{R}^{\tau-1}(v_1)] + \mathsf{Var}[X_2\mathtt{R}^{\tau-1}(v_2)] = 2\,\mathsf{Var}[X_1\mathtt{R}^{\tau-1}(v_1)]$$

For two independent random variables A, B holds that: $\mathsf{Var}[AB] = \mathsf{Var}[A]\,\mathsf{Var}[B] + \mathsf{Var}[A]\mathrm{E}^2[A] + \mathsf{Var}[B]\mathrm{E}^2[B]$, we have that:

$$\mathsf{Var}[\mathtt{R}^\tau(u)] = 2\left(\mathsf{Var}[X_1]\,\mathsf{Var}[\mathtt{R}^{\tau-1}(v_1)] + \mathsf{Var}[X_1]\mathrm{E}^2[\mathtt{R}^{\tau-1}(v_1)] + \mathsf{Var}[\mathtt{R}^{\tau-1}(v_1)]\mathrm{E}^2[X_1]\right)$$

$$= 2\left(\frac{1}{2}\,\mathsf{Var}[\mathtt{R}^{\tau-1}(v_1)] + \frac{1}{4}\mathrm{E}^2[\mathtt{R}^{\tau-1}(v_1)]\right) = \mathsf{Var}[\mathtt{R}^{\tau-1}(v_1)] + \frac{1}{2}(h(u)-1)^2$$

$$\underbrace{=}_{\text{induction's hypothesis}} \frac{1}{2}\sum_{i=0}^{h(u)-1} i^2 = \frac{(h(u)-1)h(u)(2h(u)-1)}{12}.$$

◀

▶ **Theorem 23.** *There is a model $\mathcal{G}$ and a set of nodes T such that $\frac{\mathsf{Var}[\mathtt{R}^\tau(T)]}{\mathtt{M}^\tau(T)\mathtt{I}^\tau(T)} \geq \frac{\tau}{12}$.*

Proof. Lemma 22 shows that for every node $u \in \mathcal{G}$, $\mathtt{I}^\tau(u) = h(u)$ and $\mathsf{Var}[\mathtt{R}^\tau(u)] = \frac{(h(u)-1)h(u)(2h(u)-1)}{12}$. It follows that the root r has the largest influence $\mathtt{I}^\tau(r) = \tau$ and $\mathsf{Var}[\mathtt{R}^\tau(u)] = \frac{(\tau-1)t(2\tau-1)}{12}$, Furthermore $\mathtt{M}^\tau(\bar{r}) = \tau - 1$ since the nodes of the largest influence in $V \setminus r$ are the children of r. We conclude that:

$$\frac{\mathsf{Var}[\mathtt{R}^\tau(r)]}{\mathtt{M}^\tau(\bar{r})\mathtt{I}^\tau(r)} = \frac{(\tau-1)\tau(2\tau-1)}{\tau(\tau-1)12} = \frac{2\tau-1}{12} \underbrace{\geq}_{\tau\geq 1} \frac{\tau}{12}.$$

◀

C Greedy Optimization with an Approximately Submodular Oracle

In this section we present the proof of Lemma 10. We show that our approximation guarantees imply that the application of greedy on $\hat{F}$ generates a sequence that is an approximate greedy sequence (in the sense of Lemma 24) with respect to F.

We first state a helpful Lemma [14] that establishes that it suffices that $\hat{F}(u \mid S)$ to approximate the marginal contributions

$$F(u \mid S) := F(S \cup \{u\}) - F(S)$$

.

▶ **Lemma 24** ([14]). *Given a monotone submodular function F, an approximate greedy algorithm that for some $\epsilon \in [0,1)$ selects at each step an element u such that $F(u \mid S) \geq (1-\epsilon)\max_v F(v \mid S)$ has approximation ratio $\geq (1-(1-1/s)^s)(1-\epsilon)$.*

Proof. It is easy to see that the approximation ratio of ϵ-approximate greedy is $1-(1-(1-\epsilon)/s)^s$. It therefore suffices to establish that this expression is larger than $(1-(1-1/s)^s)(1-\epsilon)$ for $\epsilon \in [0,1]$. Equivalently, we need to show that for all $s \geq 2$ and $x \in [0,1]$

$$(1-(1-x)/s)^s - (1-x)(1-1/s)^s - x \leq 0 \ .$$

This follows from equality holding for $x=0$ and $x=1$ and the function being concave up (second derivative is positive). ◀

Proof of Lemma 10. Consider a monotone non-negative $\hat{F}$ that is a uniform ϵ_A-approximation of a monotone non-negative F with $\epsilon_A = \frac{\epsilon(1-\epsilon)}{14s}$. By definition of ϵ-approximation (see Section 3.5), $\left|\hat{F}(T) - F(T)\right| \geq \epsilon_A \max\{F(T), \mathrm{OPT}_1(F)\}$ for all S with $|S| \leq s$. Therefore,

$$\text{if } F(S) \geq (1-\epsilon)\mathrm{OPT}_1(F) \text{ then } \frac{\left|\hat{F}(S) - F(S)\right|}{F(S)} \leq \frac{\epsilon}{14s} \tag{26}$$

$$\text{if } F(S) \leq (1-\epsilon)\mathrm{OPT}_1(F) \text{ then } \hat{F}(S) \leq \left(1-\frac{\epsilon}{2}\right)\mathrm{OPT}_1(F) \ . \tag{27}$$

Inequality (26) follows immediately when $F(S) \geq \mathrm{OPT}_1(F)$ because the relative error is at most $\epsilon_A \leq \frac{\epsilon}{14s}$. For $(1-\epsilon)\mathrm{OPT}_1(F) \leq F(S) < \mathrm{OPT}_1(F)$ we have absolute error being at most $\epsilon_A \mathrm{OPT}_1(S)$ which is a relative error of at most $\epsilon_A/(1-\epsilon) \leq \frac{\epsilon}{14s}$. Inequality (27) follows from the absolute error being at most $\epsilon_A \mathrm{OPT}_1(F)$ and $\epsilon_A \leq \epsilon/2$.

We establish that these conditions imply that greedy on $\hat{F}$ on the prefix of the greedy sequence where $F(S) \leq \frac{3}{4}\mathrm{OPT}_s(F)$ is actually approximate greedy (as in the conditions of Lemma 24) with respect to F. Note that $1-(1-1/s)^s \geq 3/4$ for $s \geq 2$ and thus the prefix restriction does not limit generality. The claim will then follow from Lemma 24.

For $s=1$, it follows from Equations (26) and (27) , that the first element of a greedy sequence with respect to $\hat{F}$, $\arg\max_u \hat{F}(u)$, satisfies $\hat{F}(u) \geq (1-\frac{\epsilon}{14})\mathrm{OPT}_1(F)$. Therefore from the second iteration and on, we have a set S for which the relative error bounds in Equation (26)) applies.

We consider the marginal contributions $F(u \mid S)$ for any node u. We have

$$\begin{aligned} |\hat{F}(S) - F(S)| &\leq \frac{\epsilon}{14s}F(S) \\ |\hat{F}(S\cup\{u\}) - F(S\cup\{u\})| &\leq \frac{\epsilon}{14s}F(S\cup\{u\}) = \frac{\epsilon}{14s}(F(S)+F(u \mid S)) \ . \end{aligned}$$

We use these inequalities to bound the absolute error of (any) marginal influence estimate by

$$\begin{aligned} \left|\hat{F}(u \mid S) - F(u \mid S)\right| &= \left|\hat{F}(S\cup\{u\}) - \hat{F}(S) - F(S\cup\{u\}) + F(S)\right| \\ &\leq \left|\hat{F}(S\cup\{u\}) - F(S\cup\{u\}\right| + \left|\hat{F}(S) - F(S)\right| \\ &\leq \frac{\epsilon}{7s}F(S) + \frac{\epsilon}{14s}F(u \mid S) \ . \end{aligned} \tag{28}$$

We now consider the node $v = \arg\max_{u\in V} F(u \mid S)$ with maximum marginal contribution to S with respect to F and its contribution value

$$\Delta := F(v \mid S) \geq \frac{1}{s}(\mathrm{OPT}_s - F(s)) \ .$$

Thus, when $F(S) \leq \frac{3}{4}\mathrm{OPT}_s$,

$$\Delta \geq \frac{1}{3s}F(S). \tag{29}$$

By applying (28) to v we get that

$$\hat{F}(v \mid S) \geq \Delta - \frac{\epsilon}{7s}F(S) - \frac{\epsilon}{14s}\Delta$$

Therefore the node $v' = \arg\max_v \hat{F}(v' \mid S)$ with maximum marginal contribution according to $\hat{F}$ satisfies

$$\hat{F}(v' \mid S) \geq \hat{F}(v \mid S) \geq \Delta - \frac{\epsilon}{7s}F(S) - \frac{\epsilon}{14s}\Delta.$$

By using (28) again, substituting (29), and using that fact that $s \geq 2$:

$$F(v' \mid S) \geq \Delta - 2\frac{\epsilon}{7s}F(S) - 2\frac{\epsilon}{14s}\Delta \tag{30}$$

$$\geq \Delta - \epsilon\Delta(\frac{1}{7s} + \frac{6}{7}) \geq \Delta\,(1-\epsilon)\ . \tag{31}$$

Therefore, the greedy sequence according to $\hat{F}$ is an approximate greedy sequence according to F and satisfies the conditions of Lemma 24. Therefore the resulting sequence yields an approximation ratio at least $(1-(1-1/s)^s)(1-\epsilon)$. ◀

D Greedy for Live-Edge Models

Proof of Theorem 12. For the first bound, we explicitly maintain for each node $u \in V$, for each pool, the reachability set of u in the simulations of the pool (and its cardinality). The dominant term in the cost of computation is performing a BFS from each node in each of the $r\ell$ simulations that is truncated at distance τ. The total computation time is

$$O(r\ell\overline{m}n) = O(\epsilon^{-2}s^3 c \ln\left(\frac{n}{\delta}\right)\overline{m}n)\ , \tag{32}$$

where

$$\overline{m} = \frac{1}{\ell r}\sum_{i=1}^{r}\sum_{j=1}^{\ell}|E_{ij}|$$

is the average number of edges per simulation. For an IC model, $\mathrm{E}[\overline{m}] = \sum_{e\in\mathcal{E}} p_e$. When a node u is selected into the seed set we remove all nodes in its reachability set from the reachability sets of all other nodes. The removal cost can be "charged" to the initial reachability computation.

The dependence of the computation time on the graph size can be improved by using combined reachability sketches [10, 14, 15, 11] instead of maintaining the reachability sets explicitly (see Section 5.1). The sketch size needed in order to provide the required accuracy of $O(\epsilon/s)$ (as in Theorem 10) uniformly for all subsets of size at most s is $k = O(\epsilon^{-2}s^3 \ln n)$. We compute a sketch for each node in each of the r pools, so in total we have rn node sketches. The construction time of these sketches has a term $\sum_{ij}|E_{ij}| = r\ell\overline{m}$ linear in the total size of simulations and a term for sketch constructions which is a product of the number of pools r and the construction time for each pool. The per-pool construction time is as described in Section 5.1 and is bounded by k (sketch size) visits for each node, each involving reverse

traversals of incoming edges of the node in some simulation. The per-pool construction time for an IC model is $O(k(n + \sum_e p_e))$ in expectation. The time with arbitrary simulations for pool i is $O(k(n + \sum_v \max_j d_v(E_{ij})))$. In total over all pools, the construction time is dominated by $O(r(\ell\overline{m} + k(n + m^*))$, where $m^* = \sum_v \max_{ij} d_v(E_{ij})$ for arbitrary simulations and $m^* = \sum_e p_e$ for simulations generated by an IC model.

The sketches improve the computation time of greedy. Each iteration of greedy uses the (precomputed) union sketch of the current seed set S in each pool. It then examines the sketches of each $v \in V$ to compute the estimate of the averaging oracle $\hat{\mathsf{A}}(S \cup \{v\})$ in each pool. This operations takes $O(knr)$ in total for the iteration. Therefore s iterations of greedy maximization takes $O(knrs)$ using the sketches. Combining the construction cost of the sketches using $r = O(s \ln \frac{n}{\delta})$ and $\ell = O(\epsilon^{-2} s^2 c)$ and the greedy implementation over the sketches we obtain a total bound on the computation time of

$$\begin{aligned} O(r\ell\overline{m} + kr(m^* + ns)) &= O(r(\ell\overline{m} + k(m^* + ns))) \\ &= O(s \ln \frac{n}{\delta}(\epsilon^{-2} s^2 c\overline{m} + \epsilon^{-2} s^3 (m^* + ns) \ln n) \\ &= O(\epsilon^{-2} s^3 \ln \frac{n}{\delta}(c\overline{m} + s(m^* + ns) \ln n)) \ . \end{aligned}$$ ◀

E Optimization with Adaptive Sample Size

The pseudocode for our wrapper is provided in Algorithm 1. The inputs to the wrapper are a base algorithm $\mathcal{A}$ and two constructions of oracles from sets of simulations. The first construction produces an oracle, $\hat{F}_v$, that we use for validation. The second construction produces oracles, $\hat{F}_x$, that are provided as input to $\mathcal{A}$ to perform the optimization. The oracles provide an approximation of our influence function $\mathtt{I}^\tau(S)$ with non-uniform guarantees. For specified (ϵ, δ) we use the expressions $r_v(\epsilon, \delta)$ or $r_x(\epsilon, \delta)$ for the number of simulations required to obtain (ϵ, δ) guarantees (in the sense of Section 3.5). This gives us a relation between ϵ, δ, and a number of simulations. When constructing an oracle with a given number of simulations r and a specified ϵ, we can determine the confidence δ we have from ϵ and r. The oracles that we consider have the property that for a fixed ϵ, δ decreases at least linearly with the number of simulations. (i.e., when we double the number of simulations δ decreases by at least a factor of 2.)

The wrapper first determines an upper bound ($\lceil \log_2 M/r_x(\epsilon, \delta) \rceil$) on the maximum number of iterations it performs (based on the initial number and the simulation budget) and constructs a validation oracle that provides guarantees for a small number of sets (queries) which equals this maximum number of iterations. It then starts with a set $\mathcal{R}$ of $r_x(\epsilon, \delta)$ simulations that suffice for the oracle $\hat{F}_x$ to provide (non-uniform) (ϵ, δ) approximation guarantees. The wrapper repeats the following: It constructs an "optimization" oracle $\hat{F}_x$ using the set of simulations $\mathcal{R}$ and applies $\mathcal{A}$ over $\hat{F}_x$ to obtain a set T. The wrapper terminates when $\hat{F}_v(T)$ is close to $\hat{F}_x(T)$ or when our simulation budget of M is exceeded. Otherwise, we double the number of simulations in our set $\mathcal{R}$ and repeat.

The wrapped algorithm $\mathcal{A}$ can be an exact or approximate optimizer. It is applied to the oracle function and therefore its quality guarantees are with respect to how well the oracle value $\hat{F}_x(T)$ of the output set T approximates the oracle optimum $\max_{S||S|\leq s} \hat{F}_x(S)$. The wrapper extends the approximation guarantees that $\mathcal{A}$ provides (with respect to the oracle) to a guarantee with respect to the influence function while avoiding the worst-case number of simulations needed for a uniform approximation.

We first establish some basic properties.

Algorithm 1 Optimization Wrapper.

Input: (i) Two oracle constructions from simulations: $\hat{F}_v$ (validation) and $\hat{F}_x$ (optimization) that with $r_v(\epsilon,\delta)$ (resp., $r_x(\epsilon,\delta)$) simulations provide (ϵ,δ) guarantees. (ii) An optimization algorithm $\mathcal{A}$ that applies to the optimization oracle $\hat{F}_x$ and returns a subset. (iii) M: Bound on maximum number of simulations. (iv) Parameters $\epsilon > 0$ and $\delta > 0$.

$r \leftarrow r_x(\epsilon,\delta)$ `// #simulations for` $\hat{F}_x$ `to provide` (ϵ,δ) `guarantees`

`// Build validation oracle`

$\delta_v \leftarrow \frac{\delta}{\lceil \log_2 M/r \rceil}$; $r_v \leftarrow r_v(\epsilon,\delta_v)$ `// #simulations for validation oracle`

$\hat{F}_v \leftarrow$ validation oracle from r_v i.i.d simulations that provides (ϵ,δ_v) guarantees

$\mathcal{R} \leftarrow \perp$ `// Initialize set of i.i.d simulations for optimization`

repeat

  Add r fresh i.i.d simulations to set $\mathcal{R}$

  $\hat{F}_x \leftarrow$ optimization oracle from simulations $\mathcal{R}$ that provides $(\epsilon,*)$ guarantees `// * determined by` $|\mathcal{R}|$

  $T \leftarrow \mathcal{A}(\hat{F}_x)$ `// Optimize over the oracle`

  if $\hat{F}_v(T) \geq \frac{(1-2\epsilon)}{1+\epsilon}\hat{F}_x(T)$ **then**

    return T, $\hat{F}_v(T)$

  else

    $r \leftarrow 2r$

until $|\mathcal{R}| + r_v > M$

▶ **Lemma 25.** *Let S be a set with maximum influence (with $I^\tau(S) = \mathrm{OPT}_s^\tau$). With probability at least $1-2\delta$, all the optimization oracles $\hat{F}_x$ constructed by the wrapper have $(1-\epsilon)\mathrm{OPT}_s^\tau \leq \hat{F}_x(S) \leq (1+\epsilon)\mathrm{OPT}_s^\tau$.*

Proof. The probability that $(1-\epsilon)\mathrm{OPT}_s^\tau \leq \hat{F}_x(S) \leq (1+\epsilon)\mathrm{OPT}_s^\tau$ fails for the first oracle is at most δ. The number of $\hat{F}_x$ uses simulations doubles in each iteration and all our constructions are such that the confidence parameter δ decreases at least linearly with the number of simulations. We therefore obtain that the sequence of failure probabilities for $(1-\epsilon)\mathrm{OPT}_s^\tau \leq \hat{F}_x(S) \leq (1+\epsilon)\mathrm{OPT}_s^\tau$ is geometric and sums up to at most 2δ. ◀

As an immediate corollary we obtain:

▶ **Corollary 26.** *Under the conditions of Lemma 25, the oracle optimum in all iterations satisfies*

$$\max_{T||T|\leq s} \hat{F}_x(T) \geq (1-\epsilon)\mathrm{OPT}_s^\tau \ .$$

The following is immediate from the construction of the validation oracle.

▶ **Lemma 27.** *With probability at least $1-\delta$, the validation oracle has relative error at most ϵ on all tests in which the input set T is such that $I^\tau(T) \geq \mathrm{OPT}_1^\tau$ and absolute error at most $\epsilon\mathrm{OPT}_1^\tau$ otherwise.*

Proof. The wrapper performs at most $\lceil \log_2 M/r \rceil$ iterations before it stops, in each iteration the validation oracle fails to provide an ϵ-approximation with probability at most δ_v. Therefore, by union bound, the probability that the algorithm fails to provide an ϵ-approximation in at least one round is at most $\delta_v \lceil \log_2 M/r \rceil \leq \delta$. ◀

▶ **Lemma 28.** *Assume that our data and our optimization oracle with r or more simulations, are such that with probability at least $1-\delta$, the optimum of the oracle is an approximate optimizer, that is:*

$$(1+\epsilon)\mathrm{OPT}_s^\tau \geq \max_{S||S|\leq s} \hat{F}_x(S) \geq (1-\epsilon)\mathrm{OPT}_s^\tau \tag{33}$$

$$\mathcal{I}^\tau(\arg\max_{S||S|\leq s} \hat{F}_x(S)) \geq (1-\epsilon)\mathrm{OPT}_s^\tau \tag{34}$$

and assume that the algorithm $\mathcal{A}$ returns the oracle optimum. Then with probability at least $1-5\delta$, the wrapper terminates after at most $2\max\{r, r_x(\epsilon,\delta)\} + r_v$ simulations and returns T such that $\mathcal{I}^\tau(T) \geq (1-5\epsilon)\mathrm{OPT}_s^\tau$.

Proof. First we show that the wrapper returns a set T with the required properties with probability at most $1-3\delta$ and then we show that the number of iterations the wrapper does before it stops is smaller than M with probability of at most $1-2\delta$.

From Lemma 25, with probability at least $1-2\delta$ in all iterations $\mathcal{A}$ returns T for which $\hat{F}_x(T) \geq (1-\epsilon)\mathrm{OPT}_s^\tau$. The validation succeeds only if $\hat{F}_v(T) \geq \frac{(1-2\epsilon)}{1+\epsilon}\hat{F}_x(T) \geq \frac{(1-\epsilon)(1-2\epsilon)}{1+\epsilon}\mathrm{OPT}_s^\tau$. From Lemma 27 with probability at least $1-\delta$ in all iterations we have

$$\hat{F}_v(T) \leq \max\{(1+\epsilon)\mathtt{I}^\tau(T), \mathtt{I}^\tau(T) + \epsilon\mathrm{OPT}_1^\tau\} .$$

Therefore, with probability $1-3\delta$ the set T returned by the wrapper satisfies

$$\frac{(1-\epsilon)(1-2\epsilon)}{1+\epsilon}\mathrm{OPT}_s^\tau \leq \max\{(1+\epsilon)\mathtt{I}^\tau(T), \mathtt{I}^\tau(T) + \epsilon\mathrm{OPT}_1^\tau\} .$$

If $(1+\epsilon)\mathtt{I}^\tau(T) > \mathtt{I}^\tau(T) + \epsilon\mathrm{OPT}_1^\tau$ then $\mathtt{I}^\tau(T) \geq \frac{(1-\epsilon)(1-2\epsilon)}{(1+\epsilon)^2}\mathrm{OPT}_s^\tau \geq (1-5\epsilon)\mathrm{OPT}_s^\tau$. Otherwise, we have that $\mathtt{I}^\tau(T) \geq \left(\frac{(1-\epsilon)(1-2\epsilon)}{1+\epsilon} - \epsilon\right)\mathrm{OPT}_s^\tau \geq (1-5\epsilon)\mathrm{OPT}_s^\tau$.

We have to show that with probability at least $1-2\delta$ within $2\max\{r, r_x(\epsilon,\delta)\} + r_v$ simulations the wrapper returns such a set T to finish the proof. Consider the first iteration where $|\mathcal{R}| \geq r$. By Equations (33) and (34) with probability at least $1-\delta$ we have that $\mathtt{I}^\tau(T) \geq (1-\epsilon)\mathrm{OPT}_s^\tau$ and $(1+\epsilon)\mathrm{OPT}_s^\tau \geq \hat{F}_x(T) \geq (1-\epsilon)\mathrm{OPT}_s^\tau$ .By Lemma 27 we have that with probability at least $1-\delta$, the validation oracle satisfies that $\hat{F}_v(T) \geq (1-\epsilon)\mathtt{I}^\tau(T)$ or $\hat{F}_v(T) \geq \mathtt{I}^\tau(T) - \epsilon\mathrm{OPT}_s^1 \geq \mathtt{I}^\tau(T) - \epsilon\mathrm{OPT}_s^\tau$. By the last two statements we have that with probability of at least $1-2\delta$:

$$\hat{F}_v(T) \geq (1-\epsilon)\mathtt{I}^\tau(T) \geq (1-\epsilon)^2\mathrm{OPT}_s^\tau \geq (1-2\epsilon)\mathrm{OPT}_s^\tau \geq \frac{(1-2\epsilon)}{1+\epsilon}\hat{F}_x(T)$$

or

$$\hat{F}_v(T) \geq \mathtt{I}^\tau(T) - \epsilon\mathrm{OPT}_s^\tau \geq (1-2\epsilon)\mathrm{OPT}_s^\tau \geq \frac{(1-2\epsilon)}{1+\epsilon}\hat{F}_x(T). \qquad \blacktriangleleft$$

Theorem 8, which we restate below to provide reading fluency, now follows as a corollary.

▶ **Theorem 29** (Theorem 8)**.** *Suppose that on our data the averaging (respectively, median-of-averages) oracle $\hat{F}$ has the property that with r simulations, with probability at least $1-\delta$, the oracle optimum $T := \arg\max_{S||S|\leq s} \hat{F}(S)$ satisfies*

$$\mathcal{I}^\tau(T) \quad \geq \quad (1-\epsilon)\mathrm{OPT}_s^\tau.$$

Then with probability at least $1-5\delta$*, when using* $2\max\{r, r(\epsilon,\delta)\} + O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta}+\ln\left(\ln\ln\frac{n}{\delta}+\ln s\right)\right)\right)$ *simulations with the median-of-averages oracle and* $2\max\{r, r(\epsilon,\delta)\} + O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta}+\ln\left(\ln\ln\frac{n}{\delta}+\ln n\right)\right)\right)$ *simulations with the averaging oracle, the wrapper outputs a set* T *such that* $\mathcal{I}^\tau(T) \geq (1-5\epsilon)\mathrm{OPT}_s^\tau$*.*

Proof of Theorem 8. We analyze here the number of simulations required using the averaging oracles and the median-of-averages oracles, in both cases we use median-of-averages oracles for validation. In both cases $r_v = r(\epsilon,\delta_v) = O\left(\epsilon^{-2}c\log\frac{1}{\delta_v}\right)$, where $\delta_v = \frac{\delta}{\lceil\log_2\frac{M}{r_x}\rceil}$. By Lemma 28 the number of simulations is at most $2\max\{r, r_x(\epsilon,\delta)\} + r_v$. M and r_x get different values for each oracle.

Median-of-averages oracles analysis. We have that $r_x = O(\epsilon^{-2}c\ln\delta^{-1})$ by Lemma 6 and we set $M = O(\epsilon^{-2}cs\ln\frac{n}{\delta})$ by Theorem 7. Simple calculation shows that:

$$\frac{1}{\delta_v} = \frac{\lceil\ln\frac{s\ln\frac{n}{\delta}}{\ln\frac{1}{\delta}}\rceil}{\delta} \leq \frac{1}{\delta}\left(\ln s + \ln\left(\ln\frac{n}{\delta}\right)\right).$$

Therefore,

$$r_v = O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta}+\ln\left(\ln\ln\frac{n}{\delta}+\ln s\right)\right)\right).$$

Averaging oracles analysis. We have $r_x = O(\epsilon^{-2}c\delta^{-1})$ and we set $M = O\left(\epsilon^{-2}sn\ln\frac{n}{\delta}\right)$ according to the respective worst-case guarantees on the number of simulations specified in (1). A simple calculations shows:

$$\frac{1}{\delta_v} = \frac{\lceil\ln\frac{\delta sn\ln\frac{n}{\delta}}{c}\rceil}{\delta} \leq \frac{1}{\delta}\left(\ln\ln\frac{n}{\delta} + 2\ln n\right)$$

Therefore,

$$r_v = O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta}+\ln\left(\ln\ln\frac{n}{\delta}+\ln n\right)\right)\right). \quad \blacktriangleleft$$

We next consider cases where the algorithm $\mathcal{A}$ is approximate (may not return the oracle optimizer). We assume in these cases that the optimization oracles $\hat{F}_x$ when constructed with a given number of simulations provide, with high probability, uniform ϵ-approximation for all $\binom{n}{s}$ subsets of cardinality at most s:

$$\forall T \text{ such that } |T|<s,\ \left|\hat{F}(T) - \mathtt{I}^\tau(T)\right| \leq \epsilon\max\{\mathtt{I}^\tau(T), \mathrm{OPT}_1^\tau\}.$$

We first show that a very weak assumption on $\mathcal{A}$ suffices to guarantee termination with good probability.

▶ **Lemma 30.** *If the optimization oracle* $\hat{F}_x$ *when constructed with* r *or more simulations provides uniform* ϵ*-approximation with probability at least* $1-\delta$*, and the algorithm* $\mathcal{A}$ *returns* T *such that* $\hat{F}_x(T) \geq (1-\epsilon)\mathrm{OPT}_1^\tau$*. Then with probability at least* $1-2\delta$ *the wrapper will terminate after using at most* $2\max\{r, r_x(\epsilon,\delta)\} + r_v$ *simulations.*

Proof. Consider the first iteration where $\hat{F}_x$ is constructed using at least r simulations. Let T be the set that $\mathcal{A}$ returns at this iteration. Since $\hat{F}_x$ provides uniform ϵ-approximation we have that $\hat{F}_x(T) \leq (1+\epsilon)\mathtt{I}^\tau(T)$ with probability at least $1-\delta$. Combining this with our assumption we get that $\mathtt{I}^\tau(T) \geq \mathrm{OPT}_1^\tau$ and by Lemma 27 we have that with probability at least $1-\delta$ if $\mathtt{I}^\tau(T) \geq \mathrm{OPT}_1^\tau$ then $\hat{F}(T) \geq (1-\epsilon)\mathtt{I}^\tau(T)$ and if $\frac{1-\epsilon}{1+\epsilon}\mathrm{OPT}_1^\tau \leq \mathtt{I}^\tau(T) \leq \mathrm{OPT}_1^\tau$ then $\hat{F}_v(T) \geq \mathtt{I}^\tau(T) - \epsilon\mathrm{OPT}_1^\tau \geq \mathtt{I}^\tau(T) - \frac{\epsilon(1+\epsilon)}{1-\epsilon}\mathtt{I}^\tau(T)$. Combining we obtain that $\hat{F}_v(T) \geq \frac{1-2\epsilon}{1+\epsilon}\hat{F}_x(T)$, and thus the validation condition holds. ◀

We next consider algorithms $\mathcal{A}$ that guarantees some approximation ratio ρ.

▶ **Theorem 31.** *Suppose that our optimization oracle when constructed with r or more simulations provides uniform ϵ-approximation with probability at least $1-\delta$. Assume now that the algorithm $\mathcal{A}$ returns a set T such that*

$$\hat{F}_x(T) \geq \rho \max_{S||S|\leq s} \hat{F}_x(S) \ .$$

Then, the set T returned by our wrapper satisfies $\mathtt{I}^\tau(T) \geq \rho(1-5\epsilon)\mathrm{OPT}_s^\tau$ with probability of at least $(1-3\delta)$.

Proof. Consider an optimal set S (with $\mathtt{I}^\tau(S) = \mathrm{OPT}_s^\tau$). By Lemma 25 with probability at least $1-2\delta$ all our oracles have $(1-\epsilon)\mathrm{OPT}_s^\tau \leq \hat{F}_x(S) \leq (1+\epsilon)\mathrm{OPT}_s^\tau$ are within $(1\pm\epsilon)\mathrm{OPT}_s^\tau$. By the assumption, the sets T returned by $\mathcal{A}$ in all iterations have $\hat{F}_x(T) \geq \rho \max_{S||S|\leq s} \hat{F}_x(S) \geq \rho(1-\epsilon)\mathrm{OPT}_s^\tau$. When the wrapper stops we have that $\hat{F}_x(T) \leq \frac{1+\epsilon}{1-2\epsilon}\hat{F}_v(T)$ and by Lemma 27 we have with probability at least $1-\delta$ that $\hat{F}_v(T) \leq \max\{(1+\epsilon)\mathtt{I}^\tau(T), \mathtt{I}^\tau(T) + \epsilon\mathrm{OPT}_1^\tau\}$.

Combining, we have that with probability at least $1-3\delta$,

$$\rho(1-\epsilon)\mathrm{OPT}_s^\tau \leq \rho\hat{F}_x(S) \leq \hat{F}_x(T) \leq \frac{1+\epsilon}{1-2\epsilon}\hat{F}_v(T) \leq \frac{1+\epsilon}{1-2\epsilon}\max\{(1-\epsilon)\mathtt{I}^\tau(T), \mathtt{I}^\tau(T) + \epsilon\mathrm{OPT}_s^\tau\}.$$

Now, a simple calculation shows that $\mathtt{I}^\tau(T) \geq \rho(1-5\epsilon)\mathrm{OPT}_s^\tau$. ◀

We can prove now Theorem 9 (restated for reading fluency):

▶ **Theorem 32** (Theorem 9). *If the averaging oracle $\hat{A}$ has the property that with $\geq r$ simulations, with probability at least $1-\delta$, it provides a uniform ϵ-approximation for all subsets of size at most s, then with $2\max\{r, r(\epsilon,\delta)\} + O\left(\epsilon^{-2}c\left(\ln\frac{1}{\delta} + \ln\left(\ln\ln\frac{n}{\delta} + \ln n\right)\right)\right)$ simulations we can find in polynomial time a $(1-(1-1/s)^s)(1-5\epsilon)$ approximate solution with confidence $1-5\delta$.*

Proof. The averaging oracle is monotone and submodular [31] and therefore greedy can efficiently recover a set T such that $\hat{F}_x(T) \geq (1-(1-1/s)^s)\max_{S||S|\leq S}\hat{F}_x(S)$.

By Lemma 30, the wrapper terminates using at most $2\max\{r, r_x(\epsilon,\delta)\} + r_v$ with probably at least $1-2\delta$. Applying Theorem 31 with $\rho = (1-(1-1/s)^s)$, we get that $\mathtt{I}^\tau(T) \geq (1-(1-1/s)^s)(1-5\epsilon)\mathrm{OPT}_s^\tau$ with probability at least $1-3\delta$. Hence, with probability at least $1-5\delta$ the wrapper applied with greedy finds $(1-(1-1/s)^s)(1-5\epsilon)$-approximate solution using $2\max\{r, r_x(\epsilon,\delta)\} + r_v$ simulations. ◀

F Variance Bounds for Dependent Models

In this section we provide a proof for Corollary 3. We consider a natural extensions of IC models, b-dependence, that allow for some dependencies between edges and mixtures of IC and IGT models. For these extensions, we establish upper bounds of the form (8) on the variance of the reachability of a set of nodes.

We bound the variance by constructing for each dependent model a corresponding IC model and then apply the variance upper bound established in Section A for IC models.

For mixture models we provide a generic derivation that bounds the variance of the mixture by variance of components.

F.1 b-Dependence Models

The first family we consider are *b-dependence* models, which we define as follows. We assume that all edges with the same tail node are partitioned into disjoint groups where each group is of size at most b. The edges of each group B are either all active together with probability p_B or none is active with probability $1 - p_B$. The special case where all groups are of size 1 corresponds to an IC model (where all edges are independent).

▶ **Theorem 33.** *Let $\mathcal{G}$ be a b-dependence model for some $b \geq 1$. For every set T we have that:*

$$\mathit{Var}[R^{\tau}_{\mathcal{G}}(T)] \leq 2b\tau I^{\tau}_{\mathcal{G}}(T) \max_{v \in V \setminus T} I^{\tau}_{\mathcal{G}}(v)$$

Proof. We construct an IC model $\mathcal{G}'$ from the given b-dependence model $\mathcal{G}$. The model $\mathcal{G}'$ is defined over the set of nodes V of $\mathcal{G}$ together with an additional set D of dummy nodes. The construction has the properties that 2τ-step influence in $\mathcal{G}'$ from a set of nodes $T \subseteq V$ is equal to τ-stepped influence of T in $\mathcal{G}$. Furthermore, the variances of the sizes of the 2τ-step reachbility of T in $\mathcal{G}'$ is the same as the variance of the τ step reachability of T in $\mathcal{G}$. The influence of each dummy node in $\mathcal{G}'$ is at most $b \max_{v \in V} \mathtt{I}^{\tau}(v)$. The claim follows from these properties and Theorem 2.

Here is a formal description of our reduction.

We start by putting in $\mathcal{G}'$ the set V of the nodes of $\mathcal{G}$. Then for every group $B = \{(u, v_1), (u, v_2), ..., (u, v_\ell)\}$ in $\mathcal{G}$ we do the following:

1. Add a new dummy node v_B to $\mathcal{G}'$, and add to $\mathcal{G}'$ the edge (u, v_B) and give it the probability p_B. We assign weight 0 to v_B so that it does not contribute to the reachability of any set of nodes.
2. we create edges (v_B, v_i) for every $1 \leq i \leq \ell$, each such edge has probability 1.

Let $T \subset V$ be a set of nodes in $\mathcal{G}$. It follows from our construction that for any set of nodes $B \subset V$ the probability that $\mathtt{R}^{2\tau}_{\mathcal{G}'}(T) = B$ is the same as the probability that $\mathtt{R}^{\tau}_{\mathcal{G}}(T) = B$. This implies that for any $T \subseteq V$

$$\mathtt{I}^{2\tau}_{\mathcal{G}'}(T) = \mathtt{I}^{\tau}_{\mathcal{G}}(T) \ ,$$

and

$$\mathsf{Var}[\mathtt{R}^{2\tau}_{\mathcal{G}'}(T)] = \mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] \ .$$

Each dummy node is connected to at most k original nodes, hence, $\mathtt{I}^{2\tau}_{\mathcal{G}'}(v)$ is bounded by $b \max_{v \in V} \mathtt{I}^{2\tau}_{\mathcal{G}'}(v)$. By Theorem 20 it follows that for every set of nodes T in $\mathcal{G}'$:

$$\mathsf{Var}[\mathtt{R}^{2\tau}_{\mathcal{G}'}(T)] \leq 2\tau \mathtt{I}^{2\tau}_{\mathcal{G}'}(T) \max_{v \in V \setminus T} \mathtt{I}^{2\tau}_{\mathcal{G}'}(v).$$

Combining all these observations together, we get that

$$\mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] \leq 2b\tau \mathtt{I}^{\tau}_{\mathcal{G}}(T) \max_{v \in V \setminus T} \mathtt{I}^{\tau}_{\mathcal{G}}(v) \qquad \blacktriangleleft$$

This Theorem can be generalized to more complex dependencies. For example it holds for any distribution on subsets of the outgoing edges from each node that we can realize by a distribution on disjoint subsets where we draw each subset with certain probability, and take the union of the subset which we draw.

F.2 Mixture of IC and IGT Models

The second family of dependent models we consider is a mixture of IC and IGT models.

Consider a set of models $\mathcal{G}_i(V)$ for $i \in [r]$ and respective probabilities p_i such that $\sum_{i=1}^{r} p_i = 1$. We define a mixture model $\mathcal{G}(V)$ as follows. To draw $\boldsymbol{\phi} \sim \mathcal{G}$, we first draw $i \in [r]$ according to probabilities p_i and then return $\boldsymbol{\phi} \sim \mathcal{G}_i$.

We provide two proofs for the variance bound of the mixture. The first is direct and applies to any mixture of models that satisfies the variance bound of Theorem 2), and in particular to mixtures of strongly submodular SDMs. The second proof is specific to live-edge models and based on a reduction to an IC model.

▶ **Theorem 34.** *Consider a model $\mathcal{G}$ that is a mixture of r models $\mathcal{G}_i$ with probabilities p_i that satisfy the variance bound of Theorem 2. Then for all $T \subset V$,*

$$\mathit{Var}[R^{\tau}_{\mathcal{G}}(T)] \leq \frac{\tau+1}{\min_i p_i} I^{\tau}_{\mathcal{G}}(T) \max_{v \in V} I^{\tau}_{\mathcal{G}}(v)$$

Proof. We first relate the influence of T in the mixture model to the influence of T in the components.

$$\mathtt{I}^{\tau}_{\mathcal{G}}(T) = \mathrm{E}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] = \sum_{i=1}^{r} p_i \mathrm{E}[\mathtt{R}^{\tau}_{\mathcal{G}_i}(T)] = \sum_{i=1}^{r} p_i \mathtt{I}^{\tau}_{\mathcal{G}_i}(T) \ . \tag{35}$$

This holds to any set T and any τ. Therefore we also obtain the inequality

$$\mathtt{M}^{\tau}_{\mathcal{G}}(\bar{T}) = \max_{v \in V \setminus T} I^{\tau}_{\mathcal{G}}(v) = \max_{v \in V \setminus T} \sum_{i=1}^{r} p_i \mathtt{I}^{\tau}_{\mathcal{G}_i}(v) \leq \sum_{i=1}^{r} p_i \max_{v \in V \setminus T} \mathtt{I}^{\tau}_{\mathcal{G}_i}(v) = \sum_{i=1}^{r} p_i \mathtt{M}^{\tau}_{\mathcal{G}_i}(\bar{T}) \ . \tag{36}$$

It also follows that we can bound the influence values on the component by the respective ones in the mixture: $\mathtt{I}^{\tau}_{\mathcal{G}_i}(T) \leq \frac{1}{p_i} \mathtt{I}^{\tau}_{\mathcal{G}}(T)$ and thus

$$\max_i \mathtt{I}^{\tau}_{\mathcal{G}_i}(T) \quad \leq \quad \frac{1}{\min_i p_i} \mathtt{I}^{\tau}_{\mathcal{G}}(T) \tag{37}$$

$$\max_i \mathtt{M}^{\tau}_{\mathcal{G}_i}(\overline{T}) \quad \leq \quad \frac{1}{\min_i p_i} \mathtt{M}^{\tau}_{\mathcal{G}}(\overline{T}) \ . \tag{38}$$

The random variable $\mathtt{R}^{\tau}_{\mathcal{G}}(T)$ can be expressed as a sum of of r products of random variables:

$$\mathtt{R}^{\tau}_{\mathcal{G}}(T) = \sum_{i=1}^{r} X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T) \ ,$$

where X_i are Bernoulli with probabilities p_i. The random variables $\{\mathtt{R}^{\tau}_{\mathcal{G}_i}(T)\}$ are independent of each other and also are independent from (the joint distribution of) $\{X_i\}$. The variables $\{X_i\}$ have negative dependence as $\sum_i X_i = 1$ and thus the products $X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T)$ are also negatively dependent and thus

$$\mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] \leq \sum_i \mathsf{Var}[X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T)] \ .$$

We will instead bound the variance of a surrogate random variable

$$Y = \sum_i X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T)$$

that has the same sum of products but with the variables $\{X_i\}$ being independent of each other and hence the products are also independent. We have

$$\mathsf{Var}[Y] = \sum_i \mathsf{Var}[X_i \mathtt{R}^\tau_{\mathcal{G}_i}(T)] \geq \mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}}(T)] \tag{39}$$

We next express the variance of each product using variance properties of the product of two independent random variables. For $i \in [r]$:

$$\begin{aligned}
\mathsf{Var}[X_i \mathtt{R}^\tau_{\mathcal{G}_i}(T)] &= \mathsf{Var}[X_i]\,\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)] + \mathrm{E}[X_i]^2\,\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)]^2 + \mathsf{Var}[X_i]\mathrm{E}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)]^2 \\
&= p_i(1-p_i)\,\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)] + p_i^2\,\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)] + p_i(1-p_i)\mathtt{I}^\tau_{\mathcal{G}_i}(T)^2 \\
&= p_i\,\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)] + p_i(1-p_i)\mathtt{I}^\tau_{\mathcal{G}_i}(T)^2 \ .
\end{aligned}$$

Therefore, invoking Theorem 2 to bound the variance for each IC model $\mathcal{G}_i$ and then using (37) and (38) and finally using (35) and (36) we get

$$\begin{aligned}
\mathsf{Var}[Y] &= \sum_{i=1}^r p_i \left(\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)] + p_i(1-p_i)\mathtt{I}^\tau_{\mathcal{G}_i}(T)^2\right) \\
&\leq \sum_{i=1}^r p_i\,\mathsf{Var}[\mathtt{R}^\tau_{\mathcal{G}_i}(T)] + \sum_{i=1}^r p_i \mathtt{I}^\tau_{\mathcal{G}_i}(T)^2 \\
&\underbrace{\leq}_{\text{Theorem 2}} \sum_{i=1}^r p_i \tau \mathtt{M}^{\tau-1}_{\mathcal{G}_i}(\bar{T})\mathtt{I}^\tau_{\mathcal{G}_i}(T) + \sum_{i=1}^r p_i \mathtt{I}^\tau_{\mathcal{G}_i}(T)^2 \\
&\underbrace{\leq}_{(37),\ (38)} \frac{\tau}{\min_i p_i}\mathtt{I}^\tau_{\mathcal{G}}(T)\sum_{i=1}^r p_i \mathtt{M}^{\tau-1}_{\mathcal{G}_i}(\bar{T}) + \frac{1}{\min_i p_i}\mathtt{I}^\tau_{\mathcal{G}}(T)\sum_{i=1}^r p_i \mathtt{I}^\tau_{\mathcal{G}_i}(T) \\
&\underbrace{\leq}_{(35)\ ,\ (36)} \frac{1}{\min_i p_i}\mathtt{I}^\tau_{\mathcal{G}}(T)\left(\tau \mathtt{M}^{\tau-1}_{\mathcal{G}}(\bar{T}) + \mathtt{I}^\tau_{\mathcal{G}}(T)\right) \leq \frac{\tau+1}{\min_i p_i}\mathtt{I}^\tau_{\mathcal{G}}(T)\max_{v\in V}\mathtt{I}^\tau_{\mathcal{G}}(v)
\end{aligned}$$

◀

We next give a different proof (of a slightly different bound) for live-edge models using a reduction to an IC model. Consider a set of τ-steps models $\mathcal{G}_i(V, \mathcal{E}_i)$ for $i \in [r]$ and respective probabilities p_i such that $\sum_{i=1}^r p_i = 1$. We define a mixture model $\mathcal{G}(V, \bigcup_i \mathcal{E}_i)$ as follows. To draw $E \sim \mathcal{G}$, we first draw $i \in [r]$ according to probabilities p_i and then return $E \sim \mathcal{G}_i$.

▶ **Theorem 35.** *Consider a model $\mathcal{G}$ that is a mixture of r IC models $\mathcal{G}_i$ with probabilities p_i. Then for all $T \subset V$,*

$$\mathit{Var}[R^\tau_{\mathcal{G}}(T)] \leq \frac{\tau+1}{\min_i p_i} I^\tau_{\mathcal{G}}(T)\max\{I^\tau_{\mathcal{G}}(T), \max_{v\in V} I^\tau_{\mathcal{G}}(v)\}$$

Proof. We first argue that we can assume without loss of generality that T is a single node and $\bigcup_i \mathcal{E}_i$ does not contain edges that are incoming to T. We can transform a general case $\mathcal{G}$ and T to this form by contracting all nodes in T into a single node and deleting all edges that are incoming to T. We then retain the same conditional distribution on the remaining edges. Note that this transformation preserves the distribution of $\mathtt{R}^\tau_{\mathcal{G}}(T)$ and hence also its expectation and variance. The influence values $I^\tau_{\mathcal{G}}(v)$ of nodes $v \in V \setminus T$ can only decrease. Finally, the transformed model is also a mixture of correspondingly transformed IC models, where in each such model the distribution of $\mathtt{R}^\tau_{\mathcal{G}_i}(T)$ remains the same and influence values $I^\tau_{\mathcal{G}_i}(v)$ can only decrease. It follows that the claimed variance bound for the transformed model implies the same bound for the original model.

We construct a new IC model $\mathcal{G}'$ with respect to (a single node) T as follows. The new model has nodes $V' = \{v\} \cup \bigcup_i V_i$, where each V_i is a map of V. We create an instantiation of each of our IC models $\mathcal{G}_i$ with set of nodes V_i and edges $\mathcal{E}_i$ with the probabilities as in the model $\mathcal{G}_i$. The new IC model $\mathcal{G}'$ has a root node v with weight 0 and for each $i \in [r]$, there is an edge (v, T_i) with probability p_i, where T_i is the image of T in the copy of $\mathcal{G}_i$. We can see that

$$I^{\tau+1}_{\mathcal{G}'}(v) = \mathtt{I}^{\tau}_{\mathcal{G}}(T) = \sum_{i=1}^{r} p_i \mathtt{I}^{\tau}_{\mathcal{G}_i}(T) \ , \tag{40}$$

that is, the $\tau + 1$ steps influence of v in the constructed IC model $\mathcal{G}'$ is equal to the τ steps influence of T in the mixture model $\mathcal{G}$.

We next consider the variance of the random variables $\mathtt{R}^{\tau}_{\mathcal{G}}(T)$ and $\mathtt{R}^{\tau+1}_{\mathcal{G}'}(v)$. Both these random variables are a sum of r products of random variables:

$$\sum_{i=1}^{r} X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T) \ ,$$

where X_i are Bernoulli with probabilities p_i. In both cases the random variables $\{\mathtt{R}^{\tau}_{\mathcal{G}_i}(T)\}$ are independent of each other and also are independent from (the joint distribution of) $\{X_i\}$. But in the case of $\mathtt{R}^{\tau+1}_{\mathcal{G}'}(v)$ the random variables X_i are independent and hence also the products are independent and in the case of $\mathtt{R}^{\tau}_{\mathcal{G}}(T)$, the variables $\{X_i\}$ have negative dependence as $\sum_i X_i = 1$ and thus the products $X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T)$ are also negatively dependent. Therefore,

$$\mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] \leq \mathsf{Var}[\mathtt{R}^{\tau+1}_{\mathcal{G}'}(v)] = \sum_i \mathsf{Var}[X_i \mathtt{R}^{\tau}_{\mathcal{G}_i}(T)] \ . \tag{41}$$

Finally, we bound $\mathtt{M}^{\tau}_{\mathcal{G}'}(\bar{v})$ by considering the maximum influence of a node other than v in the constructed model $\mathcal{G}'$. For T_i we have

$$\mathtt{I}^{\tau}_{\mathcal{G}'}(T_i) = \mathtt{I}^{\tau}_{\mathcal{G}_i}(T) \leq \frac{1}{p_i} \mathtt{I}^{\tau}_{\mathcal{G}}(T) \ , \tag{42}$$

where the last inequality follows from (40). We next consider nodes $z_i \in V_i$ that is a map of a node $z \in V$.

$$\mathtt{I}^{\tau}_{\mathcal{G}'}(z_i) = \mathtt{I}^{\tau}_{\mathcal{G}_i}(z) \leq \frac{1}{p_i} \mathtt{I}^{\tau}_{\mathcal{G}}(z) \ . \tag{43}$$

The last inequality follows because for any node $z \in v$ we have $\mathtt{I}^{\tau}_{\mathcal{G}}(z) = \sum_{i=1}^{r} p_i I^{\tau}_{\mathcal{G}_i}(z)$. Combining (42) and (43) we get

$$\begin{aligned} \mathtt{M}^{\tau}_{\mathcal{G}'}(\bar{v}) &= \max_{u \in V' \setminus \{v\}} \mathtt{I}^{\tau}_{\mathcal{G}'}(u) \leq \max_{u \in V} \max_i \mathtt{I}^{\tau}_{\mathcal{G}_i}(u) \leq \max_{u \in V} \frac{1}{\min_i p_i} \mathtt{I}^{\tau}_{\mathcal{G}}(u) \\ &= \frac{1}{\min_i p_i} \max\{I^{\tau}_{\mathcal{G}}(T), \max_{z \in V} \mathtt{I}^{\tau}_{\mathcal{G}}(z)\} \ . \end{aligned} \tag{44}$$

To conclude, we invoke Theorem 2 for the IC model $\mathcal{G}'$:

$$\mathsf{Var}[\mathtt{R}^{\tau}_{\mathcal{G}}(T)] \underbrace{\leq}_{(41)} \mathsf{Var}[\mathtt{R}^{\tau+1}_{\mathcal{G}'}(v)] \underbrace{\leq}_{\text{Theorem 2}} (\tau+1) I^{\tau+1}_{\mathcal{G}'}(v) \mathtt{M}^{\tau}_{\mathcal{G}'}(\bar{v}) \ .$$

We then apply inequalities (44) and the equality (40) to obtain the claim. ◀

On Oblivious Amplification of Coin-Tossing Protocols

Nir Bitansky[1]

Abstract

We consider the problem of amplifying two-party coin-tossing protocols: given a protocol where it is possible to bias the common output by at most ρ, we aim to obtain a new protocol where the output can be biased by at most $\rho^\star < \rho$. We rule out the existence of a natural type of amplifiers called *oblivious amplifiers* for every $\rho^\star < \rho$. Such amplifiers ignore the way that the underlying ρ-bias protocol works and can only invoke an oracle that provides ρ-bias bits.

We provide two proofs of this impossibility. The first is by a reduction to the impossibility of deterministic randomness extraction from Santha-Vazirani sources. The second is a direct proof that is more general and also rules outs certain types of asymmetric amplification. In addition, it gives yet another proof for the Santha-Vazirani impossibility.

1 Introduction

Hardness amplification is a foundational problem in cryptography: given a cryptographic primitive that is *weakly secure* in some sense, we would like to make it *strongly secure*. Two famous examples of such amplification procedures are Yao's amplification of weak one-way functions into strong ones and Yao's Xor lemma for amplifying unpredictability [17]. Other examples of primitives with known amplification procedures include public-key encryption [5, 11], oblivious transfer [4, 16], commitments [4, 8] and cryptographic arguments [6].

Coin-Tossing Protocols

We consider amplification of coin-tossing protocols [3]. Such protocols allow two parties to jointly toss an unbiased coin, such that even if one party is malicious and diverges from the protocol, it cannot significantly bias the outcome. Concretely, a *ρ-bias coin-tossing protocol* is such that a cheating party cannot force the common outcome to be any specific bit b with probability greater than $1/2 + \rho$.

[1] Member of the Check Point Institute of Information Security.

It is common knowledge that coin-tossing protocols against unbounded (or even PSPACE) adversaries cannot have bias $\rho < 1/2$. Accordingly, the common definition addresses efficient adversaries. Here coin-tossing protocols with negligible bias have been long known assuming one-way functions [3, 9, 13]. In fact, a long line of work shows that one-way functions are, in fact, necessary provided that the bias is at most $\rho < 1/2 - \Omega(1)$ [10, 12, 7, 2]. Whether one-way functions are necessary for any non-trivial bias $\rho < 1/2 - 1/\text{poly}(n)$ (or even for some $\rho = 1/2 - o(1)$) remains an open problem.

Amplifying Coin Tossing

A coin-tossing amplifier should take a coin-tossing protocol π with (non-trivial) bias $\rho < 1/2$ and transform it into a new coin-tossing protocol $\pi^\star$ with smaller bias $\rho^\star < \rho$. One specific way for obtaining coin-tossing amplifiers is to first derive from the protocol π a one-way function f_π, and then construct optimal coin tossing from f_π. Indeed, following the known results mentioned above this would work for any

$$\text{negl}(n) < \rho^\star < \rho < 1/2 - \Omega(1) \ .$$

In this work, we ask whether there exist "more direct" amplification procedures, which we call *oblivious amplifiers*. Such amplifiers completely ignore the way that the underlying protocol π works, they only obtain oracle access to the result – the adversary can adaptively bias the resulting bit of each oracle invocation as long as the bias is bounded by ρ. The amplifier is required to satisfy an information theoretic guarantee: *unbounded* attackers cannot bias the common output of the new protocol π^* by more than $\rho^* < \rho$. Addressing unbounded attackers is a natural choice as we wish to avoid computational assumptions (certainly, one-way functions, which would trivialize the problem).

We find the model of oblivious amplifiers quite natural and similar to other settings, such as Yao's Xor lemma [17], where amplifiers satisfy an information theoretic guarantee. In particular, constructing such amplifiers seems like a natural route toward fully understanding the complexity of coin tossing. In particular, the existence of such efficient amplifiers for

$$\rho^\star \leq 1/2 - \Omega(1) < 1/2 - 1/\text{poly}(n) \leq \rho$$

would completely resolve the question, showing that any non-trivial coin tossing is equivalent to one-way functions.

1.1 Results

We show that oblivious coin-tossing amplifiers do not exist.

▶ **Theorem 1** (Informal). *There do not exist oblivious coin-tossing amplifiers for any $\rho^* < \rho$.*

Our theorem can further be extended to rule out oblivious amplification of *weak coin tossing* [2] that essentially requires that one side cannot bias toward 0 and the other cannot bias toward 1. (See Remark 6.)

A More General Lower Bound

We give two proofs of the above theorem. The first is by a simple reduction to the impossibility of *deterministic randomness extraction from Santha-Vazirani sources* [15]. We also give a direct proof that provides a more general lower bound. In particular, we quantify the tradeoff between improving the potential bias caused by specific party A toward a specific bit b, at

the account of making it worst for other party B and bit $1-b$. This also rules out oblivious amplification for asymmetric notions of coin tossing where we allow different bounds on the bias for the two parties. The tradeoff is explained in the technical overview below and expressed in Figure 2.

The alternative proof also gives yet another proof of the Santha-Vazirani impossibility for deterministic extraction (in addition to several existing proofs [15, 14, 1]).

1.2 Technical Overview

We now give a brief overview of our proofs.

Modeling Protocols as Trees

We model any possible amplifier protocol $\pi^\star$ as a full binary tree. The correspondence is natural: the root corresponds to the beginning of the protocol before any message is sent. Every inner node in the tree is either

- Controlled by one of the two parties A or B, meaning that it is this party's turn to send a message, without loss of generality, a single bit.
- Representing an oracle call to the underlying protocol π resulting in a common bit.

Whenever a message is sent or an oracle call is made, we move in accordance to the left or right child, until reaching a leaf labeled by the common outcome of the protocol. Here the execution ends.

Each node is associated with some (honest) distribution on the next bit to be sent or produced by the oracle. The adversary can gain control over the nodes representing one of the parties and arbitrarily fix their distributions. For any oracle node, the adversary can fix an arbitrary distribution provided that it has bias at most ρ. Note that every node corresponds to some partial execution of the protocol, represented by the path from the root to this node, and the adversarial response is adaptively fixed according to this path. (See illustration in Figure 1.)

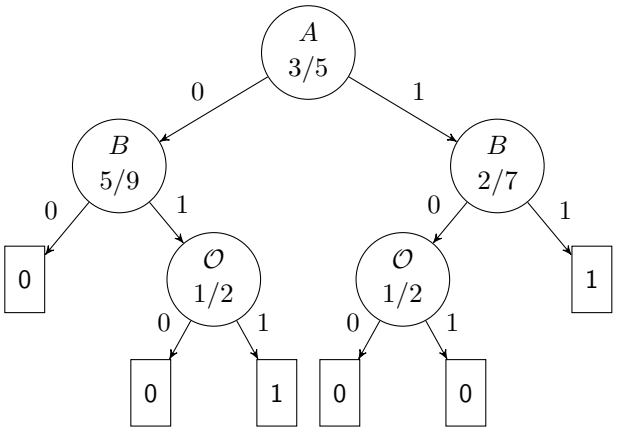

Figure 1 An example of a protocol represented by a tree. Each node specifies which party should send a bit as well as the distribution of this bit (when the party is honest). Alternatively, the parties may invoke the oracle and obtain a joint bit. The adversary may take control of one of the parties and arbitrarily replace its distributions; it can also replace the oracle call distributions provided that they remain ρ-biased.

The above model does not explicitly capture protocols where honest parties may store private coins through the interaction. However, we can transform any private-coin protocol to a protocol in the above model by considering parties that do not explicitly keep private randomness; instead, in every node they resample their private randomness conditioned on the execution transcript so far and answer according to that string. The transformation has no effect on the distribution of transcript and in particular on the outcome bit. However, the transformation may make the new protocol inefficient. This is not an issue as our lower bound will in fact hold for inefficient protocols as well.

A Reduction to Deterministic Santha-Vazirani Extractors

In their seminal work, Santha and Vazirani considered the problem of extracting a statistically uniform bit from a sequence of biased random bits $\mathbf{X} = X_1, \ldots, X_n$ such that X_i has bounded bias ρ conditioned on any fixing of $X_1, \ldots, X_{i-1}$. Such random sources $\mathbf{X}$ are called Santha-Vazirani Sources. They proved that there exist no deterministic extractors for such sources, namely, for any deterministic Boolean function E, there exists a Santha-Vazirani source such that $E(\mathbf{X})$ is far from uniform. In fact, they proved that $E(\mathbf{X})$ is ρ-biased.

Indeed, this bares similarity to the setting of oblivious coin-tossing amplification where the ρ-biased input bits naturally correspond to oracle calls to π. The gap between the two models is that a coin-tossing oblivious amplifier further allows interaction between two *randomized* parties. To bridge this gap, we prove that any oblivious amplifier can be turned into a non-interactive oblivious amplifier.

To convey the basic idea, imagine that we have an amplifier tree where the root belongs to party A (namely, it sends the first message). We argue that at least one of its left or right subtrees also has bias at most $\rho^\star$, and thus we can reduce one round of interaction. In fact, *both* subtrees must be such that an adversary controlling A can bias the outcome by at most $\rho^\star$, or else an adversary controlling A in the original protocol could have simply always chosen the worse subtree in order to bias the outcome by more than $\rho^\star$. We then observe that at least one of the subtrees must be such that an adversary controlling B cannot bias by more than $\rho^\star$. Indeed, the bias caused by an adversary controlling B in the original protocol is just a convex combination of the its bias in the two corresponding subtrees.

The Second Proof and a More General Lower Bound

Our second proof of the theorem pours more light on the tradeoff between how much each party can bias the protocol towards a specific bit. We first give a correspondence between protocols and points on the plane. For a protocol π, let x_π be the maximum probability a malicious A^* (controlling A) can force output 0 and y_π be the maximum probability a malicious B^* can force output 1. We assign the protocol π coordinates (x_π, y_π). Considering the tree representing the protocol π, the point in the plane corresponding to the protocol π is determined by the points corresponding to its children themselves as protocols, as well as the operation at its root. (This is roughly done following a similar argument to the one used above, where we either take the maximum of two subtrees, or a convex combination thereof.)

Our basic Theorem 1 and its proof show that all points corresponding to protocols lie outside the axis-aligned square given by $x = 0$, $y = 0$, $x = 0.5 + \rho$, $y = 0.5 + \rho$. Our more general analysis, shows a more accurate picture – all points lie above a certain piecewise linear f (See Figure 2). In a bit more detail, we prove by induction on the depth of the tree that the point corresponding to every protocol lies above the function f, by showing closure of points above f to each of the operations that may appear at the root, and also

that protocol leaves (the base case) lie above f. When considering a non-leaf protocol, we get from the induction that the sub-protocols rooted at its children lie above f, and since the set of points above f is closed under the operation at the protocols' root, the point corresponding to the protocol itself also lies above f.

This more general result shows that we cannot hope to improve the x_π-value of the oracle without strictly hurting its y_π-value, and furthermore gives some lower bound $g(\Delta_x)$, for every $0 \leq \Delta_x \leq x_\pi$, on how much y_π must increase in order to reduce x_π by Δ_x.

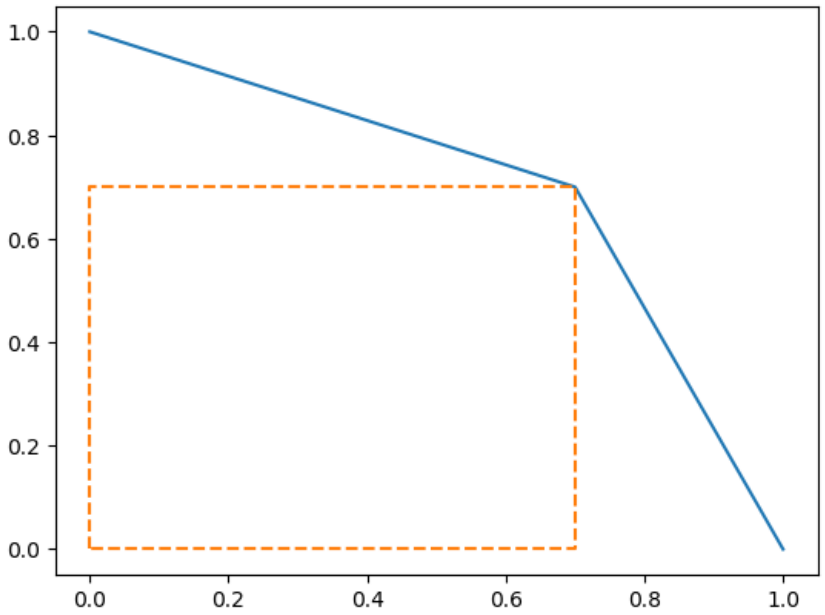

Figure 2 For the sake of this illustration, we set $\rho = 0.2$. The X-axis represents the ability of a malicious A^* to bias the common output toward 0, and the Y-axis represents the ability of a malicious B^* to bias the common output toward 1. While our basic Theorem 1 argues that all protocols lie outside the dotted square, our more general theorem shows that they in fact lie above the piece-wise linear function represented by the continuous line.

Organization

In Section 2, we define the relevant notion of oblivious amplifiers and their correspondence to trees. In Section 3, we prove the main impossibility result by a reduction to the impossibility of deterministic Santha-Vazirani extraction. In Section 4, we give our alternative (direct) proof leading to a more general lower bound.

2 Definitions

Throughout the paper, we denote by $Ber(p)$ the Bernoulli distribution with parameter p, namely, the value 1 gets probability p and 0 gets $1 - p$.

▶ **Definition 2** (Common-output two-party protocol with oracle access to ρ-biased bits)**.** *We model a common-output two-party protocol with oracle access to ρ-biased bits using full binary trees such that:*

- *Every leaf is labeled with either "0" or "1", which represent the common output of the protocol upon reaching that leaf.*
- *Every inner node v is labeled with "(P_v, q_v)" where*
  1. *$P_v \in \{A, B, \mathcal{O}\}$ represents whether it is A's turn to speak, B's turn to speak, or an oracle call.*
  2. *In an honest execution, the bit sent after reaching that node should be distributed according to $Ber(q_v)$. If $P_v = \mathcal{O}$ then q_v must be 0.5, otherwise q_v may be an arbitrary probability.*

Execution. *An execution of the protocol follows a path along the tree, starting at the root and going left/right in accordance to the bits sent, when 0 means left and 1 means right, until reaching a leaf which determines the common output of that execution.*

Adversarial behavior. *A malicious party can ignore q_v when it is their turn to speak and send an arbitrarily distributed bit instead. Also, whenever the oracle is called, the malicious party may change the output distribution of that call from $Ber(0.5)$ to $Ber(q_v)$ for any q_v such that $|q_v - 0.5| \leq \rho$. Note that q_v may depend on all the bits sent up to that call*

▶ **Definition 3.** *Given a protocol π, A^* an adversarial behavior of A and $b \in \{0,1\}$, we denote by $\pi(A^*, b)$ the probability of π's output being b when executed with A^* and an honest B. Next, define $Opt(\pi, A^*, b) := \max_{A^*} \pi(A^*, b)$, where the maximum is taken over all adversarial behaviors A^* of A. $\pi(B^*, b)$ and $Opt(\pi, B^*, b)$ are defined symmetrically for B.*

▶ **Definition 4** ((α, β)-oblivious coin-tossing amplifier)**.** *A common-output two-party protocol π with oracle access to α-biased bits is an (α, β)-oblivious coin-tossing amplifier if*

$$\max_{P^*, b} Opt(\pi, P^*, b) \leq 0.5 + \beta \ ,$$

where $P^* \in \{A^*, B^*\}$ and $b \in \{0, 1\}$. In addition, we require that the expected output of π over an honest execution is 0.5.

▶ Remark 5. Actually, for the lower bound, we do not use the fact that the expected output of π over an honest execution is 0.5. We note that bounded biases already makes coin-tossing protocols non-trivial.

▶ Remark 6. We may also consider the notion of (α, β)-oblivious weak coin-tossing amplifiers, which aim to produce a β-bias weak coin tossing (CT) protocol instead of standard β-CT. In the weak CT setting, we know in advance that A^* aims to bias the result toward 0 while B^* aims to bias the result toward 1. We only need to bound their ability to bias the output in their chosen direction. The difference is in the requirement

$$\max_{P^*, b} Opt(\pi, P^*, b) \leq 0.5 + \beta \ ,$$

which is replaced with

$$\max\{Opt(\pi, A^*, 0), Opt(\pi, B^*, 1)\} \leq 0.5 + \beta \ .$$

3 Impossibility of Oblivious Amplifiers

In this section, we state and prove our main result regarding the impossibility of non-trivial oblivious coin-tossing amplifiers.

▶ **Theorem 7** (main). *For every common-output two-party protocol π with oracle access to ρ-biased bits, either $Opt(\pi, A^*, 0) \geq 0.5 + \rho$ or $Opt(\pi, B^*, 1) \geq 0.5 + \rho$. In particular, there do not exist (α, β)-oblivious coin-tossing amplifier, for any $\beta < \alpha$.*

Toward proving the theorem, we first analyze in Section 3.1 the best possible (unbounded) attacks. Then in Section 3.2, we give the reduction to the impossibility of deterministic extraction from Santha-Vazirani sources.

3.1 The Optimal Attacks

Let π be a common-output two-party protocol with oracle access to ρ-biased bits, and denote its root by r. Also, denote by π_0 and π_1 the protocols rooted at the left and right children of r. The best strategy of a malicious A^* to make the protocol π output 0 is to bias the first bit b as much as possible towards $\arg\max_{z\in\{0,1\}} Opt(\pi_z, A^*, 0)$, and after b is sent continue to recursively apply the best strategy at the resulting child. The best strategy of a malicious B^* to make the protocol π output 1 is symmetrical. Thus, we have that:

- If r is labeled with "A, p", then A can completely bias the bit while B cannot change its distribution at all, so

$$Opt(\pi, A^*, 0) = \max_{z\in\{0,1\}} Opt(\pi_z, A^*, 0)$$
$$Opt(\pi, B^*, 1) = \mathbb{E}_{z\sim Ber(p)}\left[Opt(\pi_z, B^*, 1)\right]$$

- If r is labeled with "B, p", then B can completely bias the bit while A cannot change its distribution at all, so

$$Opt(\pi, A^*, 0) = \mathbb{E}_{z\sim Ber(p)}\left[Opt(\pi_z, A^*, 0)\right]$$
$$Opt(\pi, B^*, 1) = \max_{z\in\{0,1\}} Opt(\pi_z, B^*, 1)$$

- If r is labeled with "$\mathcal{O}$", then both A and B can bias the bit by at most ρ, so

$$Opt(\pi, A^*, 0) = (0.5-\rho)\cdot \min_{z\in\{0,1\}} Opt_z(\pi, A^*, 0) + (0.5+\rho)\cdot \max_{z\in\{0,1\}} Opt(\pi_z, A^*, 0)$$
$$Opt(\pi, B^*, 1) = (0.5-\rho)\cdot \min_{z\in\{0,1\}} Opt(\pi_z, B^*, 1) + (0.5+\rho)\cdot \max_{z\in\{0,1\}} Opt(\pi_z, B^*, 1)$$

- If r is a leaf labeled with "0", then

$$Opt(\pi, A^*, 0) = 1$$
$$Opt(\pi, B^*, 1) = 0$$

- If r is a leaf labeled with "1", then

$$Opt(\pi, A^*, 0) = 0$$
$$Opt(\pi, B^*, 1) = 1$$

3.2 Reduction to Deterministic Santha-Vazirani Extraction

The following theorem states that allowing interaction does not help in creating more secure protocols, in the sense that it does not allow us to generate a better protocol, in either $Opt(\pi, A^*, 0)$ or $Opt(\pi, B^*, 1)$, than protocols already existing without interaction.

▶ **Theorem 8.** *For every common-output two-party protocol π with oracle access to ρ-biased bits, there exists a common-output two-party protocol π' with oracle access to ρ-biased bits, with no inner nodes labeled by either "A, p" or "B, p", and such that $Opt(\pi', A^*, 0) \leq Opt(\pi, A^*, 0)$ and $Opt(\pi', B^*, 1) \leq Opt(\pi, B^*, 1)$*

In other words, allowing interaction does not help in producing protocols where it is harder for A^* to cheat towards 0 or for B^* to cheat towards 1.

Proof. We show how given any protocol π with "A, p"/"B, p" turns, we can strictly reduce its number of "A, p"/"B, p" turns without increasing its cheating probabilities $Opt(\pi, A^*, 0)$ and $Opt(\pi, B^*, 1)$. In essence, we show that for every inner node labeled with "A, p"/"B, p" there exists a child such that replacing the subtree rooted at that node with the subtree rooted at its child results a protocol that is only harder to cheat in, for both A^* towards 0 and B^* towards 1. In more detail: First, we pick some arbitrary inner node of π labeled with either "A, p" or "B, p". Denote this node by N, and its left and right children by N_0 and N_1, respectively. If N is labeled by "A, p" we choose $z := \arg\min_{b\in\{0,1\}} Opt(N_b, B^*, 1)$, otherwise choose $z := \arg\min_{b\in\{0,1\}} Opt(N_b, A^*, 0)$. We take π and replace in it the subtree rooted at N with the subtree rooted at N_z. Essentially, we fixed the bit sent at node N to always be z, instead of letting A/B choose it. We make two observations:

1. Both $Opt(N_z, A^*, 0) \leq Opt(N, A^*, 0)$ and $Opt(N_z, B^*, 1) \leq Opt(N, B^*, 1)$.
   To see this, assume w.l.o.g that N is labeled with "A, p" (symmetrical argument for "B, p"). We have that $Opt(N, A^*, 0) = \max_{b\in\{0,1\}} Opt(N_b, A^*, 0)$ and in particular $Opt(N, A^*, 0) \geq Opt(N_z, A^*, 0)$. Also, since we have that
   $$Opt(N, B^*, 1) = \mathbb{E}_{b\sim Ber(p)} [Opt(N_b, B^*, 1)]$$
   and we chose $z := \arg\min_{b\in\{0,1\}} Opt(N_b, B^*, 1)$ in case N is labeled with "A, p", then $Opt(N, B^*, 1) \geq Opt(N_z, B^*, 1)$.
   In other words, at N_z it is both harder for A^* to cheat towards 0 and for B^* to cheat towards 1.
2. Let π and T be protocols, N be some node of π, and π' be the protocol resulted by replacing in π the subtree rooted at N with T. If $Opt(T, A^*, 0) \leq Opt(N, A^*, 0)$ then $Opt(\pi', A^*, 0) \leq Opt(\pi, A^*, 0)$ and similarly if $Opt(T, B^*, 1) \leq Opt(N, B^*, 1)$ then $Opt(\pi', B^*, 1) \leq Opt(\pi, B^*, 1)$. The reason for this is that the value $Opt(R, A^*, 0)$ of an inner node R, for all three operations ("A, p","B, p","$\mathcal{O}$"), is a monotone function of the values $Opt(R_0, A^*, 0), Opt(R_1, A^*, 0)$ of its children. By not increasing the $(A^*, 0)$-value of some node, you cannot increase the $(A^*, 0)$-value of its father, which in turn will not increase the $(A^*, 0)$-value of its father and so on.
   In other words, by taking a protocol and replacing the sub-protocol run at some partial transcript with another sub-protocol where it is not easier for A^*/B^* to cheat towards 0/1, we result a protocol where it is not easier for A^*/B^* to cheat towards 0/1.

Combining these observations, we reach the conclusion that by taking a protocol and repeatedly getting rid of its "A, p"/"B, p" nodes by replacing the subtree rooted at them with the subtree rooted at a correctly chosen child of theirs, we can get rid of all the "A, p"/"B, p" turns without increasing the cheating probabilities of A^* towards 0 and of B^* towards 1. ◀

▶ **Definition 9** (SV Source)**.** *For $0 \leq \rho \leq 0.5$, a source $X = X_1, \ldots, X_n$ of length n (A random variable taking values in $\{0,1\}^n$) is a Santha-Vazirani (SV) source with bias ρ if for every $i \in [n]$ and every $x_1, \ldots, x_{i-1} \in \{0,1\}$, the bias of X_i conditioned on $X_1 = x_1, \ldots, X_{i-1} = x_{i-1}$ is at most ρ. That is,*

$$|\mathbb{E}[X_i | X_1 = x_1, \ldots, X_{i-1} = x_{i-1}] - 0.5| \leq \rho \ .$$

▶ **Theorem 10** ([15], [14]). *For every function $f : \{0,1\}^n \to \{0,1\}$ and every $0 \leq \rho \leq 0.5$ there exists an SV source $X = X_1, \ldots, X_n$ of length n and bias ρ such that $f(X)$ has bias at least ρ.*

We remark that this version of the statement is taken from Reingold, Vadhan and Wigderson [14], and that differently from them we refer to the bias as the distance from 0.5 and not double that amount.

The following theorem implies that there are no non-trivial oblivious coin-tossing amplifiers comprised solely of oracle calls.

▶ **Theorem 11.** *For every common-output two-party protocol π with oracle access to ρ-biased bits and no inner nodes labeled by either "A, p" or "B, p", either $Opt(\pi, A^*, 0) \geq 0.5 + \rho$ or $Opt(\pi, B^*, 1) \geq 0.5 + \rho$*

In fact, in a protocol with no "A, p"/"B, p" turns there is no longer a difference between A and B so either $Opt(\pi, A^*, 0) = Opt(\pi, B^*, 0) \geq 0.5 + \rho$ or $Opt(\pi, A^*, 1) = Opt(\pi, B^*, 1) \geq 0.5 + \rho$

Proof. Let n be an upper bound on the number of oracle calls made by π in any execution. We can think w.l.o.g of π as always making exactly n oracle calls, with results denoted by $o_1, \ldots, o_n$, and then outputting $f(o_1, \ldots, o_n)$ for some function f. The impossibility result of deterministic extraction from Santha-Vazirani sources, Theorem 10, guarantees that there exists an SV source $X = X_1, \ldots, X_n$ of length n and bias ρ such that $f(X)$ has bias at least ρ. Therefore, if the malicious party can make sure the oracle calls' output distribution is X, they can succeed in biasing the output of π by at least ρ. (If it is towards 0 then $Opt(\pi, A^*, 0) \geq 0.5 + \rho$ and if it is towards 1 then $Opt(\pi, B^*, 1) \geq 0.5 + \rho$). The malicious party can make sure the oracle calls' output distribution is X by doing it bit-by-bit: After $0 \leq i \leq n - 1$ calls with results $x_1, \ldots, x_i$ they ask the next oracle call to be distributed according to $X_{i+1} | X_1 = x_1, \ldots, X_i = x_i$, and their request from the ρ-biased bit oracle is legal by the definition of SV sources with bias ρ. ◀

Combining Theorem 8 and Theorem 11, Theorem 7 follows.

4 A More General Lower Bound

In this section, we give a direct proof by induction which gives some insight on the possible relations between $Opt(\pi, A^*, 0)$ and $Opt(\pi, B^*, 1)$ and the trade-offs we can get between them.

We correspond every protocol with a point on the plane using $Opt(\pi, A^*, 0)$ as the x-coordinate and $Opt(\pi, B^*, 1)$ as the y-coordinate. Our main theorem translates into showing that all protocol points lie outside or on the axis-aligned square with boundaries $x = 0.5 + \rho, x = 0$ and $y = 0.5 + \rho, y = 0$, but still inside of the first (i.e., $(+,+)$) quadrant (the second part is obvious from the definition). The area outside the square (but still inside the first quadrant) is not closed under the oracle-call operation (defined later), and thus the naïve induction attempt fails. Instead, we will strengthen the induction hypothesis into showing that all points lie above $f := \min\left(1 - \frac{0.5-\rho}{0.5+\rho} \cdot x, \frac{0.5+\rho}{0.5-\rho} - \frac{0.5+\rho}{0.5-\rho} \cdot x\right)$, which is both closed under all operations (now the induction works) and lies above the square (so it implies what we want, and more). See Figure 2 for a graphic representation of the square and f.

▶ **Theorem 12.** *For every common-output two-party protocol π with oracle access to ρ-biased bits, we have that* $Opt(\pi, B^*, 1) \geq \min(1 - \frac{0.5-\rho}{0.5+\rho} \cdot Opt(\pi, A^*, 0),\ \frac{0.5+\rho}{0.5-\rho} - \frac{0.5+\rho}{0.5-\rho} \cdot Opt(\pi, A^*, 0))$

Equivalently, if we take ℓ_1 to be the line between $(0, 1)$ and $(0.5 + \rho, 0.5 + \rho)$

$$\text{so } \ell_1 \text{ is } y = 1 - \frac{0.5 - \rho}{0.5 + \rho} \cdot x$$

and ℓ_2 to be the line between $(0.5 + \rho, 0.5 + \rho)$ and $(1, 0)$

$$\text{so } \ell_2 \text{ is } y = \frac{0.5 + \rho}{0.5 - \rho} - \frac{0.5 + \rho}{0.5 - \rho} \cdot x$$

then the point $(Opt(\pi, A^*, 0), Opt(\pi, B^*, 1))$ lies above (not strictly) at least one of ℓ_1, ℓ_2.

▶ **Corollary 13.** *Theorem 7 follows.*

Proof. Since both ℓ_1 and ℓ_2 are strictly decreasing (negative slope) and pass through the point $(0.5 + \rho, 0.5 + \rho)$, then $x < 0.5+\rho$ implies $\ell_1(x), \ell_2(x) > 0.5+\rho$. Thus $Opt(\pi, A^*, 0) < 0.5+\rho$ implies $Opt(\pi, B^*, 1) \geq \min\left(\ell_1(Opt(\pi, A^*, 0)), \ell_2(Opt(\pi, A^*, 0))\right) > 0.5 + \rho$ ◀

Proof of Theorem 12. Proof by induction on the depth.
Leaves labeled with "0" lie on ℓ_2 and leaves labeled with "1" lie on ℓ_1.
If π is not a leaf, denote its root by r, by π_0 and π_1 the protocols rooted at the left and right children of r, and let $f := \min(\ell_1, \ell_2)$. Also, denote

$$\begin{aligned} x_0, y_0 &= Opt(\pi_0, A^*, 0), Opt(\pi_0, B^*, 1) \\ x_1, y_1 &= Opt(\pi_1, A^*, 0), Opt(\pi_1, B^*, 1) \\ x', y' &= Opt(\pi, A^*, 0), Opt(\pi, B^*, 1) \end{aligned}$$

We assume (induction hypothesis) that $y_0 \geq f(x_0)$, $y_1 \geq f(x_1)$ and want to show that $y' \geq f(x')$. There are three types of operations to consider:

- If r is labeled with "A, p"

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} \max(x_0, x_1) \\ (1-p) \cdot y_0 + p \cdot y_1 \end{pmatrix}$$

- If r is labeled with "B, p"

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} (1-p) \cdot x_0 + p \cdot x_1 \\ \max(y_0, y_1) \end{pmatrix}$$

- If r is labeled with "$\mathcal{O}$"

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} (0.5-\rho) \cdot \min(x_0, x_1) + (0.5+\rho) \cdot \max(x_0, x_1) \\ (0.5-\rho) \cdot \min(y_0, y_1) + (0.5+\rho) \cdot \max(y_0, y_1) \end{pmatrix}$$

We may assume without loss of generality that the points $(x_0, y_0), (x_1, y_1)$ lie on f and not strictly above it, namely, that $y_0 = f(x_0)$, $y_1 = f(x_1)$. This is true because y' is non-decreasing in y_0, y_1 in all three operations, so if $y' \geq f(x')$ for $y_0 = f(x_0)$, $y_1 = f(x_1)$, then we also have that $y' \geq f(x')$ for any $y_0 \geq f(x_0)$, $y_1 \geq f(x_1)$.
(Note that $f(x')$ is unaffected by changes to y_0, y_1)

Let $(x_0, y_0), (x_1, y_1)$ be any two points on f. Since ℓ_1 and ℓ_2 are decreasing, f is also decreasing. Let $i = \arg\max_{z \in \{0,1\}} x_z$, so we have that $x_i > x_{1-i}$ and $y_i < y_{1-i}$.

- The first operation gives us $(x', y') = (x_i, (1-p)\cdot y_0 + p \cdot y_1)$, and since

$$y' = (1-p)\cdot y_0 + p \cdot y_1 > y_i = \min_{z\in\{0,1\}} y_z$$

for every $0 < p < 1$, we have $y' > y_i = f(x_i) = f(x')$.
- The second operation gives us $(x', y') = ((1-p)\cdot x_0 + p \cdot x_1, y_{1-i})$, and since

$$x' = (1-p)\cdot x_0 + p \cdot x_1 > x_{1-i} = \min_{z\in\{0,1\}} x_z$$

for every $0 < p < 1$, we have $f(x') < f(x_{1-i}) = y_{1-i} = y'$.
- The third operation gives us

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} (0.5-\rho)\cdot x_{1-i} + (0.5+\rho)\cdot x_i \\ (0.5-\rho)\cdot y_i + (0.5+\rho)\cdot y_{1-i} \end{pmatrix}$$

We separate into two cases:

1. Both (x_0, y_0) and (x_1, y_1) lie on either ℓ_1 or ℓ_2. Denote this common line by ℓ. Notice that every convex combination of $(x_0, y_0), (x_1, y_1)$ also lies on ℓ, and in particular

$$\begin{pmatrix} x_{0.5+\rho} \\ y_{0.5+\rho} \end{pmatrix} = (0.5-\rho)\cdot\begin{pmatrix} x_0 \\ y_0 \end{pmatrix} + (0.5+\rho)\begin{pmatrix} x_1 \\ y_1 \end{pmatrix} = \begin{pmatrix} (0.5-\rho)\cdot x_0 + (0.5+\rho)\cdot x_1 \\ (0.5-\rho)\cdot y_0 + (0.5+\rho)\cdot y_1 \end{pmatrix}$$

lies on ℓ. Since $x_{1-i} = \min(x_0, x_1)$ and $x_i = \max(x_0, x_1)$, we have that

$$x' = (0.5-\rho)\cdot x_{1-i} + (0.5+\rho)\cdot x_i \geq (0.5-\rho)\cdot x_0 + (0.5+\rho)\cdot x_1 = x_{0.5+\rho}$$

Since $y_i = \min(y_0, y_1)$ and $y_{1-i} = \max(y_0, y_1)$, we have that

$$y' = (0.5-\rho)\cdot y_i + (0.5+\rho)\cdot y_{1-i} \geq (0.5-\rho)\cdot y_0 + (0.5+\rho)\cdot y_1 = y_{0.5+\rho}$$

Overall, we conclude that $f(x') \leq \ell(x') \leq \ell(x_{0.5+\rho}) = y_{0.5+\rho} \leq y'$.
2. One of $(x_0, y_0), (x_1, y_1)$ lies on ℓ_1 and the other lies on ℓ_2. The lines ℓ_1, ℓ_2 intersect at $(0.5+\rho, 0.5+\rho)$ and the slope of ℓ_2 is steeper, so we can conclude that

$$f(x) = \min(\ell_1, \ell_2) = \begin{cases} \ell_1(x) & x \leq 0.5+\rho \\ \ell_2(x) & x > 0.5+\rho \end{cases}$$

and that $x_{1-i} < 0.5+\rho < x_i$. We have that

$$\begin{aligned} y' &= (0.5-\rho)\cdot y_i + (0.5+\rho)\cdot y_{1-i} = (0.5-\rho)\cdot \ell_2(x_i) + (0.5+\rho)\cdot \ell_1(x_{1-i}) = \\ &= (0.5-\rho)\cdot\left(\frac{0.5+\rho}{0.5-\rho} - \frac{0.5+\rho}{0.5-\rho}\cdot x_i\right) + (0.5+\rho)\cdot\left(1 - \frac{0.5-\rho}{0.5+\rho}\cdot x_{1-i}\right) = \\ &= 0.5+\rho-(0.5+\rho)\cdot x_i + 0.5+\rho-(0.5-\rho)\cdot x_{1-i} = \\ &= 1+2\rho-((0.5+\rho)\cdot x_i + (0.5-\rho)\cdot x_{1-i}) = 1+2\rho-x' \end{aligned}$$

Therefore, the point (x', y') lies on the line $y = 1+2\rho-x$ which we will denote by ℓ. Notice that ℓ also passes through $(0.5+\rho, 0.5+\rho)$, and that the slope of ℓ is steeper than that of ℓ_1 but more moderate than that of ℓ_2, and thus $\ell_1 \leq \ell$ for $x \leq 0.5+\rho$, and $\ell_2 \leq \ell$ for $x \geq 0.5+\rho$, and overall $f(x) \leq \ell(x)$. This implies that $f(x') \leq \ell(x') = y'$. ◀

Abstract

We give a new proof of the "transfer theorem" underlying adaptive data analysis: that any mechanism for answering adaptively chosen statistical queries that is differentially private and sample-accurate is also accurate out-of-sample. Our new proof is elementary and gives structural insights that we expect will be useful elsewhere. We show: 1) that differential privacy ensures that the expectation of any query on the *conditional distribution* on datasets induced by the transcript of the interaction is close to its expectation on the data distribution, and 2) sample accuracy on its own ensures that any query answer produced by the mechanism is close to the expectation of the query on the conditional distribution. This second claim follows from a thought experiment in which we imagine that the dataset is resampled from the conditional distribution after the mechanism has committed to its answers. The transfer theorem then follows by summing these two bounds, and in particular, avoids the "monitor argument" used to derive high probability bounds in prior work.

An upshot of our new proof technique is that the concrete bounds we obtain are substantially better than the best previously known bounds, even though the improvements are in the constants, rather than the asymptotics (which are known to be tight). As we show, our new bounds outperform the naive "sample-splitting" baseline at dramatically smaller dataset sizes compared to the previous state of the art, bringing techniques from this literature closer to practicality.

1 Introduction

Many data analysis pipelines are *adaptive*: the choice of which analysis to run next depends on the outcome of previous analyses. Common examples include variable selection for regression problems and hyper-parameter optimization in large-scale machine learning problems: in both cases, common practice involves repeatedly evaluating a series of models on the same dataset. Unfortunately, this kind of adaptive re-use of data invalidates many traditional methods of avoiding over-fitting and false discovery, and has been blamed in part for the recent flood of non-reproducible findings in the empirical sciences [14].

There is a simple way around this problem: don't re-use data. This idea suggests a baseline called *data splitting*: to perform k analyses on a dataset, randomly partition the dataset into k disjoint parts, and perform each analysis on a fresh part. The standard "holdout method" is the special case of $k = 2$. Unfortunately, this natural baseline makes poor use of data: in particular, the data requirements of this method grow *linearly* with the number of analyses k to be performed.

A recent literature starting with Dwork et al. [6] shows how to give a significant asymptotic improvement over this baseline via a connection to differential privacy: rather than computing and reporting exact sample quantities, perturb these quantities with noise. This line of work established a powerful *transfer theorem*, that informally says that any analysis that is simultaneously differentially private and accurate *in-sample* will also be accurate *out-of-sample*. The best analysis of this technique shows that for a broad class of analyses and a target accuracy goal, the data requirements grow only with $\sqrt{k}$ – a quadratic improvement over the baseline [1]. Moreover, it is known that in the worst case, this cannot be improved asymptotically [15, 23]. Unfortunately, thus far this literature has had little impact on practice. One major reason for this is that although the more sophisticated techniques from this literature give asymptotic improvements over the sample-splitting baseline, the concrete bounds do not actually improve on the baseline until the dataset is enormous. This remains true even after optimizing the constants that arise from the arguments of Dwork et al. [6] or Bassily et al. [1], and appears to be a fundamental limitation of their proof techniques [20]. In this paper, we give a new proof of the transfer theorem connecting differential privacy and in-sample accuracy to out-of-sample accuracy. Our proof is based on a simple insight that arises from imagining a "resampling" experiment, and in particular yields an improved concrete bound that beats the sample-splitting baseline at dramatically smaller data set sizes n compared to prior work. In fact, at reasonable dataset sizes, the magnitude of the improvement arising from our new theorem is significantly larger than the improvement between the bounds of Bassily et al. [1] and Dwork et al. [6]: see Figure 1.

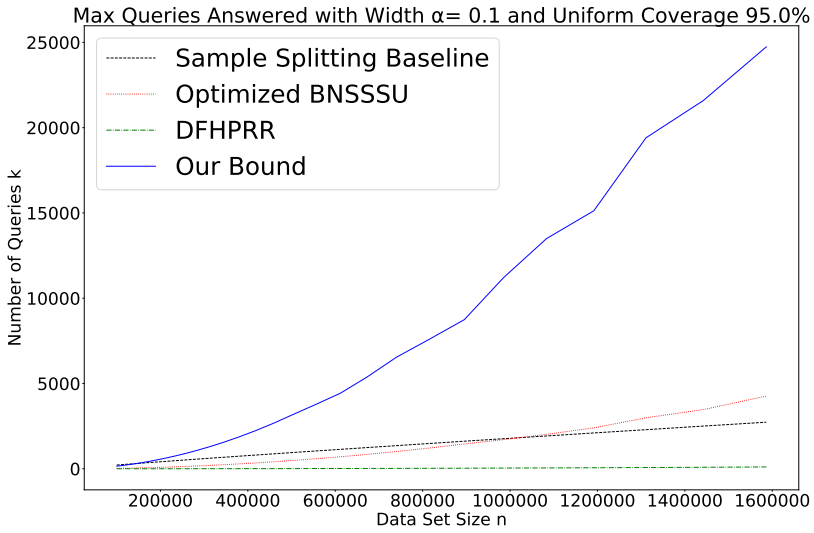

Figure 1 A comparison of the number of adaptive linear queries that can be answered using the Gaussian mechanism as analyzed by our transfer theorem (Theorem 9), the numerically optimized variant of the bound from Bassily et al. [1] (Optimized BNSSSU) as derived in [20], and the original transfer theorem from Dwork et al. [6] (DFHPRR). We plot for each dataset size n, the number of queries k that can be answered while guaranteeing confidence intervals around the answer that have width $\alpha = 0.1$ and uniform coverage probability $1 - \beta = 0.95$. We compare with the naive sample splitting baseline that simply splits the dataset into k pieces and answers each query with the empirical answer on a fresh piece.

1.1 Proof Techniques

Prior Work

Consider an unknown data distribution $\mathcal{P}$ over a data-domain $\mathcal{X}$, and a dataset $S \sim \mathcal{P}^n$ consisting of n i.i.d. draws from $\mathcal{P}$. It is a folklore observation (attributed to Frank McSherry) that if a predicate $q : \mathcal{X} \to [0, 1]$ is selected by an ϵ-differentially private algorithm M acting on S, then it will generalize *in expectation* (or *have low bias*) in the sense that $|\mathbb{E}_{q \sim M(S)}[\mathbb{E}_{x \sim \mathcal{P}}[q(x)] - \frac{1}{n}\sum_{x \in S} q(x)]| \approx \epsilon$. But bounds on bias are not enough to yield tight confidence intervals, and so prior work has focused on strengthening the above observation into a high probability bound. For small ϵ, the optimal bound has the asymptotic form: $\Pr_{q \sim M(S)}[|\mathbb{E}_{x \sim \mathcal{P}}[q(x)] - \frac{1}{n}\sum_{x \in S} q(x)| \geq \epsilon] \leq e^{-O(\epsilon^2 n)}$ [1]. Note that this bound does not refer to the *estimated answers* supplied to the data analyst: it says only that a differentially private data analyst is unlikely to be able to find a query whose average value on the dataset differs substantially from its expectation. Pairing this with a simultaneous high probability bound on the *in-sample accuracy* of a mechanism – that it supplies answers a such that with high probability the empirical error is small: $\Pr_{a \sim M(S)}[|a - \frac{1}{n}\sum_{x \in S} q(x)| \geq \alpha] \leq \beta$ – yields a bound on out-of-sample accuracy via the triangle inequality.

Dwork et al. [6] proved their high probability bound via a direct computation on the *moments* of empirical query values, but this technique was unable to achieve the optimal rate. Bassily et al. [1] proved a bound with the optimal rate by introducing the ingenious *monitor technique*. This important technique has subsequently found other uses [24, 19, 13], but is a heavy hammer that seems unavoidably to yield large constant overhead, even after numeric optimization [20].

Our Approach

We take a fundamentally different approach by directly providing high probability bounds on the out-of-sample accuracy $|a - \mathbb{E}_{x\sim\mathcal{P}}[q(x)]|$ of mechanisms that are both differentially private and accurate in-sample. Our elementary approach is motivated by the following thought experiment: in actuality, the dataset S is fixed before any interaction with M begins. However, imagine that after the entire interaction with M is complete, the dataset S is *resampled* from the conditional distribution $\mathcal{Q}$ on datasets *conditioned* on the output of M. This thought experiment doesn't alter the joint distribution on datasets and outputs, and so any in-sample accuracy guarantees that M has continue to hold under this hypothetical re-sampling experiment. But because the empirical value of the queries on the re-sampled dataset are likely to be close to their expected value over the conditional distribution $\mathcal{Q}$, the only way the mechanism can promise to be sample-accurate with high probability is if it provides answers that are *close to their expected value over the conditional distribution with high probability.*

This focuses attention on the conditional distribution on datasets induced by differentially private transcripts. But it is not hard to show that a consequence of differential privacy is that the conditional expectation of any query must be close to its expectation over the data distribution with high probability. In contrast to prior work, this argument directly leverages high-probability in-sample accuracy guarantees of a private mechanism to derive high-probability out-of-sample guarantees, without the need for additional machinery like the monitor argument of Bassily et al. [1].

1.2 Further Related Work

The study of "adaptive data analysis" was initiated by Dwork et al. [6, 5] who provided upper bounds via a connection to differential privacy, and Hardt and Ullman [15] who provided lower bounds via a connection to fingerprinting codes. The upper bounds were subsequently strengthened by Bassily et al. [1], and the lower bounds by Steinke and Ullman [23] to be (essentially) matching, asymptotically. The upper bounds were optimized by Rogers et al. [20], which we use in our comparisons. Subsequent work proved transfer theorems related to other quantities like description length bounds [4] and compression schemes [3], and expanded the types of analyses whose generalization properties we could reason about via a connection to a quantity called approximate max information [4, 21]. Feldman and Steinke [11, 12] give improved methods that could guarantee out-of-sample accuracy bounds that depended on query variance. Neel and Roth [17] extend the transfer theorems from this literature to the related problem of adaptive data gathering, which was identified by Nie et al. [18]. Ligett and Shenfeld [16] give an algorithmic stability notion they call *local statistical stability* (also defined with respect to a conditional data distribution) that they show asymptotically characterizes the ability of mechanisms to offer high probability out-of-sample generalization guarantees for linear queries. A related line of work initiated by Russo and Zou [22] and extended by Xu and Raginsky [25] starts with weaker assumptions on the mechanism (mutual information bounds), and derives weaker conclusions (bounds on bias, rather than high probability generalization guarantees).

A more recent line of work aims at mitigating the fact that the worst-case bounds deriving from transfer theorems do not give non-trivial guarantees on reasonably sized datasets. Zrnic and Hardt [26] show that better bounds can be derived under the assumption that the data analyst is restricted in various ways to not be fully adaptive. Feldman et al. [10] show that overfitting by a classifier because of test-set re-use is mitigated in multi-label prediction

problems, compared to binary prediction problems. Rogers et al. [20] give a method for certifying the correctness of heuristically guessed confidence intervals, which they show often out-perform the theoretical guarantees by orders of magnitude.

Finally, Elder [9, 8] proposes a Bayesian reformulation of the adaptive data analysis problem. In the model of [9], the data distribution $\mathcal{P}$ is assumed to itself be drawn from a prior that is commonly known to the data analyst and mechanism. In contrast, we work in the standard adversarial setting originally introduced by Dwork et al. [6] in which the mechanism must offer guarantees for worst case data distributions and analysts, and focus our attention on conditional distributions purely as a proof technique.

2 Preliminaries

Let $\mathcal{X}$ be an abstract data domain, and let $\mathcal{P}$ be an arbitrary distribution over $\mathcal{X}$. A dataset of size n is a collection of n data records: $S = \{S_i\}_{i=1}^n \in \mathcal{X}^n$. We study datasets sampled *i.i.d.* from $\mathcal{P}$: $S \sim \mathcal{P}^n$. We will write S to denote the random variable and $\boldsymbol{x}$ for realizations of this random variable. A linear query is a function $q : \mathcal{X}^* \to [0, 1]$ that takes the following empirical average form when acting on a data set $S \in \mathcal{X}^n$:

$$q(S) = \frac{1}{n}\sum_{i=1}^{n} q(S_i).$$

We will be interested in estimating the expectations of linear queries over $\mathcal{P}$. Abusing notation, given a distribution $\mathcal{D}$ over datasets, we write $q(\mathcal{D})$ to denote the expectation of q over datasets drawn from $\mathcal{D}$, and write $S_i \sim S$ to denote a datapoint sampled uniformly at random from a dataset S. Note that for linear queries we have:

$$q(\mathcal{D}) = \mathop{\mathbb{E}}_{S\sim\mathcal{D}}[q(S)] = \mathop{\mathbb{E}}_{S\sim\mathcal{D},S_i\sim S}[q(S_i)]$$

We note that for linear queries, when the dataset distribution $\mathcal{D} = \mathcal{P}^n$, we have $q(\mathcal{P}^n) = \mathbb{E}_{x\sim\mathcal{P}}[q(x)]$, which we write as $q(\mathcal{P})$ when the notation is clear from context. However, the more general definition will be useful because we will need to evaluate the expectation of q over other (non-product) distributions over datasets in our arguments, and we will generalize beyond linear queries in Appendices A.1 and A.2.

Given a family of queries Q, a statistical estimator is a (possibly stateful) randomized algorithm $M : \mathcal{X}^n \times Q^* \to \mathbb{R}^*$ parameterized by a dataset S that interactively takes as input a stream of queries $q_i \in Q$, and provides answers $a_i \in \mathbb{R}$. An analyst is an arbitrary randomized algorithm $\mathcal{A} : \mathbb{R}^* \to Q^*$ that generates a stream of queries and receives a stream of answers (which can inform the next queries it generates). When an analyst interacts with a statistical estimator, they generate a transcript of their interaction $\pi \in \mathbf{\Pi}$ where $\mathbf{\Pi} = (Q \times \mathbb{R})^*$ is the space of all transcripts. Throughout we write Π to denote the transcript's random variable and π for its realizations.

The interaction is summarized in Algorithm 1, and we write $\text{Interact}(M, \mathcal{A}; S)$ to refer to it. When M and $\mathcal{A}$ are clear from context, we will abbreviate this notation and write simply $I(S)$. When we refer to an indexed query q_j, this is implicitly a function of the transcript π. Given a transcript $\pi \in \mathbf{\Pi}$, write $\mathcal{Q}_\pi$ to denote the conditional distribution on datasets conditional on $\Pi = \pi$: $\mathcal{Q}_\pi = (\mathcal{P}^n)|\text{Interact}(M, \mathcal{A}; S) = \pi$. Note that $\mathcal{Q}_\pi$ will no longer generally be a product distribution. We will be interested in evaluating uniform accuracy bounds, which control the worst-case error over all queries:

Algorithm 1 Interact$(M, \mathcal{A}; S)$: An Analyst Interacting with a Statistical Estimator to Generate a Transcript.

Input: A statistical estimator M, an analyst $\mathcal{A}$, and a dataset $S \in \mathcal{X}^n$.
for $t = 1$ *to* k **do**
  The analyst generates a query $q_t \leftarrow \mathcal{A}(a_1, \ldots, a_{t-1})$ and sends it to the statistical estimator;
  The statistical estimator generates an answer $a_t \leftarrow M(S; q_t)$;
return $\Pi = ((q_1, a_1), \ldots, (q_k, a_k))$.

▶ **Definition 1** (Accuracy). *M satisfies (α, β)-sample accuracy if for every data analyst $\mathcal{A}$ and every data distribution $\mathcal{P}$,*

$$\Pr_{S\sim\mathcal{P}^n, \Pi\sim Interact(M,\mathcal{A};S)}[\max_j |q_j(S) - a_j| \geq \alpha] \leq \beta.$$

We say M satisfies (α, β)-distributional accuracy if for every data analyst $\mathcal{A}$ and every data distribution $\mathcal{P}$,

$$\Pr_{S\sim\mathcal{P}^n, \Pi\sim Interact(M,\mathcal{A};S)}[\max_j |q_j(\mathcal{P}^n) - a_j| \geq \alpha] \leq \beta.$$

We will be interested in interactions I that satisfy *differential privacy.*

▶ **Definition 2** (Differential Privacy [7]). *Two datasets $S, S' \in \mathcal{X}^n$ are neighbors if they differ in at most one coordinate. An interaction Interact$(M, \cdot; \cdot)$ satisfies (ϵ, δ)-differential privacy if for all data analysts $\mathcal{A}$, pairs of neighboring datasets $S, S' \in \mathcal{X}^n$, and for all events $E \subseteq \mathbf{\Pi}$:*

$$\Pr_{\Pi\sim Interact(M,\mathcal{A};S)}[\Pi \in E] \leq e^\epsilon \cdot \Pr_{\Pi\sim Interact(M,\mathcal{A};S')}[\Pi \in E] + \delta.$$

If Interact$(M, \cdot; \cdot)$ satisfies (ϵ, δ)-differential privacy, we will also say that M satisfies (ϵ, δ)-differential privacy.

We introduce a novel quantity that will be crucial to our argument: it captures the effect of the transcript on the change in the expectation of a query contained in the transcript.

▶ **Definition 3.** *An interaction Interact$(M, \mathcal{A}; \cdot)$ is called (ϵ, δ)-posterior stable if for every data distribution $\mathcal{P}$:*

$$\Pr_{S\sim\mathcal{P}^n, \Pi\sim Interact(M,\mathcal{A};S)}[\max_j |q_j(\mathcal{P}^n) - q_j(\mathcal{Q}_\Pi)| \geq \epsilon] \leq \delta.$$

3 An Elementary Proof of the Transfer Theorem

3.1 A General Transfer Theorem

In this section we prove a general transfer theorem for sample accurate mechanisms with low posterior stability. In Section 3.2 we prove that differentially private mechanisms have low posterior stability.

▶ **Theorem 4** (General Transfer Theorem). *Suppose that Interact$(M, \mathcal{A}; \cdot)$ is an (α, β)-sample accurate, (ϵ, δ)-posterior stable interaction. Then for every $c > 0$ it also satisfies:*

$$\Pr_{S\sim\mathcal{P}^n, \Pi\sim Interact(M,\mathcal{A};S)}[\max_j |a_j - q_j(\mathcal{P})| > \alpha + c + \epsilon] \leq \frac{\beta}{c} + \delta$$

i.e. it is (α', β')-distributionally accurate for $\alpha' = \alpha + c + \epsilon$ and $\beta' = \frac{\beta}{c} + \delta$.

The theorem follows easily from a change in perspective driven by an elementary observation. Imagine that *after* the interaction is run and results in a transcript π, the dataset S is *resampled* from its conditional distribution $\mathcal{Q}_\pi$. This does not change the joint distribution on datasets and transcripts. This simple claim is formalized below: its elementary proof appears in Appendix B.

▶ **Lemma 5** (Resampling Lemma). *Let $E \subseteq \mathcal{X}^n \times \mathbf{\Pi}$ be any event. Then:*

$$\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}[(S,\Pi)\in E] = \Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S),S'\sim\mathcal{Q}_\Pi}[(S',\Pi)\in E]$$

The change in perspective suggested by the resampling lemma makes it easy to see why the following must be true: any sample-accurate mechanism must in fact be accurate with respect to the conditional distribution it induces. This is because if it can first commit to answers, and guarantee that they are sample-accurate *after* the dataset is resampled from the conditional, the answers it committed to must have been close to the conditional means, because it is likely that the empirical answers on the resampled dataset will be. This argument is generic and does not use differential privacy.

▶ **Lemma 6.** *Suppose that M is (α,β)-sample accurate. Then for every $c>0$ it also satisfies:*

$$\Pr_{S\sim\mathcal{P}^n,\,\Pi\sim Interact(M,\mathcal{A};S)}[\max_j |a_j - q_j(\mathcal{Q}_\Pi)| > \alpha + c] \le \frac{\beta}{c}$$

Proof. Denote by $j^*(\pi) = \arg\max_j |a_j - q_j(\mathcal{Q}_\pi)|$. Given $\alpha \ge 0$ and $c>0$, and expanding the definition of $q_{j^*(\Pi)}(\mathcal{Q}_\Pi)$ we get:

$$\begin{aligned}
&\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[a_{j^*(\Pi)} - q_{j^*(\Pi)}(\mathcal{Q}_\Pi) > \alpha + c\right] \\
&\quad= \Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[\mathop{\mathbb{E}}_{S'\sim\mathcal{Q}_\Pi}\left[a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha\right] > c\right] \\
&\quad\le \Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[\mathop{\mathbb{E}}_{S'\sim\mathcal{Q}_\Pi}\left[\max\left\{a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha, 0\right\}\right] > c\right] \\
&\quad\overset{(1)}{\le} \frac{1}{c}\mathop{\mathbb{E}}_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[\mathop{\mathbb{E}}_{S'\sim\mathcal{Q}_\Pi}\left[\max\left\{a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha, 0\right\}\right]\right] \\
&\quad\overset{(2)}{\le} \frac{1}{c}\mathop{\mathbb{E}}_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[\Pr_{S'\sim\mathcal{Q}_\Pi}\left[a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha > 0\right]\right] \\
&\quad= \frac{1}{c}\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S),S'\sim\mathcal{Q}_\Pi}\left[a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') > \alpha\right] \\
&\quad\overset{(3)}{=} \frac{1}{c}\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[a_{j^*(\Pi)} - q_{j^*(\Pi)}(S) > \alpha\right]
\end{aligned}$$

Here, inequality (1) follows from Markov's inequality, inequality (2) follows from the fact that $a_{j^*(\Pi)} - q_{j^*(\Pi)}(S') - \alpha \le 1$, and equality 3 follows from the Resampling Lemma (Lemma 5). Repeating this argument for $q_{j^*(\Pi)}(Q_\Pi) - a_{j^*(\Pi)}$ yields a symmetric bound, so by combining the two with the guarantee of (α,β)-sample accuracy we get,

$$\begin{aligned}
\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[\left|a_{j^*(\Pi)} - q_{j^*(\Pi)}(Q_\Pi)\right| > \alpha + c\right] &\le \frac{1}{c}\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}\left[\left|a_{j^*(\Pi)} - q_{j^*(\Pi)}(S)\right| > \alpha\right] \\
&\le \frac{\beta}{c}
\end{aligned}$$

◀

Because sample accuracy implies accuracy with respect to the conditional distribution, together with a bound on posterior stability, the transfer theorem follows immediately:

Proof of Theorem 4. By the triangle inequality:

$$\max_j |a_j - q_j(\mathcal{P})| \leq \max_i |a_i - q_i(\mathcal{Q}_\Pi)| + \max_l |q_l(\mathcal{Q}_\Pi) - q_l(\mathcal{P})|.$$

Lemma 6 bounds the first term by $\alpha + c$ with probability $1 - \frac{\beta}{c}$ over Π, and the definition of posterior stability bounds the second term by ϵ with probability $1 - \delta$ over Π, which concludes the proof. ◀

3.2 A Transfer Theorem for Differential Privacy

In this section we prove a transfer theorem for differentially private mechanisms by demonstrating that they have low posterior stability and applying our general transfer theorem.

We here show that differentially private mechanisms have low posterior stability for linear queries. In the Appendix we extend this argument to low-sensitivity and optimization queries.

▶ **Lemma 7.** *If M is (ϵ, δ)-differentially private, then for any data distribution $\mathcal{P}$, any analyst $\mathcal{A}$, and any constant $c > 0$:*

$$\Pr_{S \sim \mathcal{P}^n, \Pi \sim Interact(M, \mathcal{A}; S)} \left[\max_j |q_j(\mathcal{Q}_\Pi) - q_j(\mathcal{P})| > (e^\epsilon - 1) + 2c \right] \leq \frac{\delta}{c}$$

i.e. it is (ϵ', δ')-posterior stable for every data analyst $\mathcal{A}$, where $\epsilon' = e^\epsilon - 1 + 2c$ and $\delta' = \frac{\delta}{c}$.

Proof. Given a transcript $\pi \in \mathbf{\Pi}$, let $j^*(\pi) \in \arg\max_j |q_j(\mathcal{Q}_\pi) - q_j(\mathcal{P})|$. Define for an $\alpha > 0$:

$$\mathbf{\Pi}_\alpha = \left\{ \pi \in \mathbf{\Pi} | \, q_{j^*(\pi)}(\mathcal{Q}_\pi) - q_{j^*(\pi)}(\mathcal{P}) > \alpha \right\}$$

$$\mathcal{X}^+(\pi) = \left\{ x \in \mathcal{X} | \, \Pr_{S \sim \mathcal{Q}_\pi, S_i \sim S} [S_i = x] > \Pr_{S_i \sim \mathcal{P}} [S_i = x] \right\}$$

$$B^+_\alpha = \bigcup_{\pi \in \mathbf{\Pi}_\alpha} \left(\mathcal{X}^+(\pi) \times \{\pi\} \right)$$

$$\mathbf{\Pi}^+_\alpha(x) = \left\{ \pi \in \mathbf{\Pi} | \, (x, \pi) \in B^+_\alpha \right\}$$

Fix any α. Suppose that $\Pr\left[\left| q_{j^*(\Pi)}(\mathcal{Q}_\Pi) - q_{j^*(\Pi)}(\mathcal{P}) \right| > \alpha \right] > \frac{\delta}{c}$. We must have that either $\Pr\left[q_{j^*(\Pi)}(\mathcal{Q}_\Pi) - q_{j^*(\Pi)}(\mathcal{P}) > \alpha \right] > \frac{\delta}{2c}$ or $\Pr\left[q_{j^*(\Pi)}(\mathcal{P}) - q_{j^*(\Pi)}(\mathcal{Q}_\Pi) > \alpha \right] > \frac{\delta}{2c}$. Without loss of generality, assume

$$\Pr\left[q_{j^*(\Pi)}(\mathcal{Q}_\Pi) - q_{j^*(\Pi)}(\mathcal{P}) > \alpha \right] = \Pr\left[\Pi \in \mathbf{\Pi}_\alpha \right] > \frac{\delta}{2c} \tag{1}$$

Let S_i be the random variable obtained by first sampling $S \sim \mathcal{P}^n$ and then sampling $S_i \in S$ uniformly at random. We compare the probability measure of B^+_α under the joint distribution on S_i and Π with its corresponding measure under the product distribution of S_i and Π:

$$
\begin{aligned}
&\Pr_{(S_i,\Pi)}\left[(S_i,\Pi)\in B_\alpha^+\right]-\Pr_{S_i\otimes\Pi}\left[(S_i,\Pi)\in B_\alpha^+\right]\\
&\quad=\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr[\Pi=\pi]\sum_{x\in\mathcal{X}^+(\pi)}\left(\Pr[S_i=x|\Pi=\pi]-\Pr[S_i=x]\right)\\
&\quad\geq\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr[\Pi=\pi]\sum_{x\in\mathcal{X}^+(\pi)}q_{j^*(\pi)}(x)\left(\Pr[S_i=x|\Pi=\pi]-\Pr[S_i=x]\right)\\
&\quad\geq\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr[\Pi=\pi]\sum_{x\in\mathcal{X}}q_{j^*(\pi)}(x)\left(\Pr[S_i=x|\Pi=\pi]-\Pr[S_i=x]\right)\\
&\quad=\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr[\Pi=\pi]\left(q_{j^*(\pi)}(\mathcal{Q}_\pi)-q_{j^*(\pi)}(\mathcal{P})\right)\\
&\quad>\alpha\cdot\Pr\left[\Pi\in\mathbf{\Pi}_\alpha\right]
\end{aligned}
$$

On the other hand, using the definition of (ϵ,δ)-differential privacy (See Lemma 21 for the elementary derivation of the first inequality):

$$
\begin{aligned}
&\Pr_{(S_i,\Pi)}\left[(S_i,\Pi)\in B_\alpha^+\right]-\Pr_{S_i\otimes\Pi}\left[(S_i,\Pi)\in B_\alpha^+\right]\\
&\quad=\sum_{x\in\mathcal{X}}\Pr[S_i=x]\left(\Pr\left[\Pi\in\mathbf{\Pi}_\alpha^+(x)|S_i=x\right]-\Pr\left[\Pi\in\mathbf{\Pi}_\alpha^+(x)\right]\right)\\
&\quad\leq\sum_{x\in\mathcal{X}}\Pr[S_i=x]\left((e^\epsilon-1)\Pr\left[\Pi\in\mathbf{\Pi}_\alpha^+(x)\right]+\delta\right)\\
&\quad=(e^\epsilon-1)\Pr_{S_i\otimes\Pi}\left[(S_i,\Pi)\in B_\alpha^+\right]+\delta\\
&\quad\leq(e^\epsilon-1)\Pr\left[\Pi\in\mathbf{\Pi}_\alpha\right]+\delta\\
&\quad<(e^\epsilon-1)\Pr\left[\Pi\in\mathbf{\Pi}_\alpha\right]+2c\Pr\left[\Pi\in\mathbf{\Pi}_\alpha\right]\quad\text{(by Equation (1))}\\
&\quad=\left((e^\epsilon-1)+2c\right)\cdot\Pr\left[\Pi\in\mathbf{\Pi}_\alpha\right]
\end{aligned}
$$

This is a contradiction for $\alpha\geq(e^\epsilon-1)+2c$. ◀

▶ Remark 8. Note

1. Since differential privacy is closed under post processing, this claim can be generalized beyond queries contained in the transcript to any query generated as function of the transcript.
2. In the case of $(\epsilon,0)$-differential privacy, choosing $c=0$, the claim holds for every query with probability 1.

Combined with our general transfer theorem (Theorem 4), this directly yields a transfer theorem for differential privacy:

▶ **Theorem 9** (Transfer Theorem for (ϵ,δ)-Differential Privacy)**.** *Suppose that M is (ϵ,δ)-differentially private and (α,β)-sample accurate for linear queries. Then for every analyst $\mathcal{A}$ and $c,d>0$ it also satisfies:*

$$
\Pr_{S\sim\mathcal{P}^n,\,\Pi\sim Interact(M,\mathcal{A};S)}[\max_j|a_j-q_j(\mathcal{P})|>\alpha+(e^\epsilon-1)+c+2d]\leq\frac{\beta}{c}+\frac{\delta}{d}
$$

i.e. it is (α',β')-distributionally accurate for $\alpha'=\alpha+(e^\epsilon-1)+c+2d$ and $\beta'=\frac{\beta}{c}+\frac{\delta}{d}$.

▶ Remark 10. As we will see in Section 4, the Gaussian mechanism (and many other differentially private mechanisms) has a sample accuracy bound that depends only on the square root of the log of both $1/\beta$ and $1/\delta$. Thus, despite the Markov-like term $\beta' = \frac{\beta}{c} + \frac{\delta}{d}$ in the above transfer theorem, together with the sample accuracy bounds of the Gaussian mechanism, it yields Chernoff-like concentration.

Our technique extends easily to reason about arbitrary low sensitivity queries and minimization queries. See Appendix A.1 and A.2 for more details.

4 Applications: The Gaussian Mechanism

We now apply our new transfer theorem to derive the concrete bounds that we plotted in Figure 1. The Gaussian mechanism is extremely simple and has only a single parameter σ: for each query q_i that arrives, the Gaussian mechanism returns the answer $a_i \sim \mathcal{N}(q_i(S), \sigma^2)$ where $\mathcal{N}(q_i(S), \sigma^2)$ denotes the Gaussian distribution with mean $q_i(S)$ and standard deviation σ. First, we recall the differential privacy properties of the Gaussian mechanism.

▶ **Theorem 11** ([2]). *When used to answer k linear queries, for every $0 < \delta < 1$, the Gaussian mechanism with parameter σ satisfies (ϵ, δ)-differential privacy for:*

$$\epsilon = \frac{k}{2n^2\sigma^2} + \sqrt{2\frac{k}{n^2\sigma^2}\log\left(\sqrt{\pi \cdot \frac{k}{2n^2\sigma^2}}/\delta\right)}$$

It is also easy to see that the sample-accuracy of the Gaussian mechanism is characterized by the CDF of the Gaussian distribution:

▶ **Lemma 12.** *For any $0 < \beta < 1$, the Gaussian mechanism with parameter σ is (α_G, β)-sample accurate for:*

$$\alpha_G = \sqrt{2}\sigma \cdot \mathrm{erfc}^{-1}\left(2 - 2\left(1 - \frac{\beta}{2}\right)^{1/k}\right) < \sqrt{2}\sigma \cdot \mathrm{erfc}^{-1}\left(\frac{\beta}{k}\right) < \sqrt{2}\sigma\sqrt{\log\left(\frac{\sqrt{2}k}{\pi\beta}\right)}.$$

Above, $\mathrm{erfc}(x) = 1 - \mathrm{erf}(x)$ is the complementary error function.

Proof. For a query q_j, write $a_j = q_j(S) + Z_j$ where $Z_j \sim \mathcal{N}(0, \sigma^2)$. The sample error is $\max_j |a_j - q_j(S)| = \max_j |Z_j|$. We have that $\Pr[\max_j |Z_j| \geq \alpha] \leq \Pr[\max_j Z_j \geq \alpha] + \Pr[\min_j Z_j \leq -\alpha]$. α_G is the value that solves the equation $\Pr[\max_j Z_j \geq \alpha] = \Pr[\min_j Z_j \leq -\alpha] = \beta/2$ ◀

With these quantities in hand, we can now apply Theorem 9 to derive distributional accuracy bounds for the Gaussian mechanism:

▶ **Theorem 13.** *Fix a desired confidence parameter $0 < \beta < 1$. When σ is set optimally, the Gaussian mechanism can be used to answer k linear queries while satisfying (α, β)-distributional accuracy, where α is the solution to the following unconstrained minimization problem:*

$$\alpha = \min_{\sigma,\delta>0}\left\{\sqrt{2}\sigma \cdot \mathrm{erfc}^{-1}\left(\frac{\delta}{k}\right) + e^{\frac{k}{2n^2\sigma^2} + \sqrt{2\frac{k}{n^2\sigma^2}\log\left(\sqrt{\pi\cdot\frac{k}{2n^2\sigma^2}}/\delta\right)}} - 1 + 6\left(\frac{\delta}{\beta}\right)\right\}$$

Proof. Using Theorem 9 and fixing $\beta' = \delta$ and $c = d$, we have that an (α', β')-sample accurate, (ϵ, δ)-differentially private mechanism is (α, β)-distributionally accurate for $\alpha = \alpha' + (e^\epsilon - 1) + 3c$ and $\beta = \frac{2\delta}{c}$ where c can be an arbitrary parameter. For any fixed value of β, we can take $c = \frac{2\delta}{\beta}$, and see that we obtain (α, β)-distributional accuracy where $\alpha = \alpha' + (e^\epsilon - 1) + 6\,(\delta/\beta)$. The theorem then follows from plugging in the privacy bound from Theorem 11, the sample accuracy bound from Theorem 12, and optimizing over the free variables σ and δ. ◀

5 Discussion

We have given a new proof of the transfer theorem for differential privacy that has several appealing properties. Besides being simpler than previous arguments, it achieves substantially better concrete bounds than previous transfer theorems, and uncovers new structural insights about the role of differential privacy and sample accuracy. In particular, sample accuracy serves to guarantee that the reported answers are close to their conditional means, and differential privacy serves to guarantee that the conditional means are close to their true answers. This focuses attention on the conditional data distribution as a key quantity of interest, which we expect will be fruitful in future work. In particular, it may shed light on what makes certain data analysts overfit less than worst-case bounds would suggest: because they choose queries whose conditional means are closer to the prior than the worst-case query.

There seems to be one remaining place to look for improvement in our transfer theorem: Lemmas 6 and 7 both exhibit a Markov-like tradeoff between a parameter c and β and δ respectively. Although the dependence on β and δ in our ultimate bounds is only root-logarithmic, it would still yield an improvement if this Markov-like dependence could be replaced with a Chernoff-like dependence. It *is* possible to do this for the β parameter: we give an alternative (and even simpler) proof of the transfer theorem for $(\epsilon, 0)$-differential privacy which shows that conditional distributions induced by private mechanisms exhibit Chernoff-like concentration, in Appendix D. But the only way we know to extend this argument to (ϵ, δ)-differential privacy requires dividing δ by a factor of n, which yields a final theorem that is inferior to Theorem 9.

A Extensions

A.1 Low Sensitivity Queries

Our technique extends easily to reason about arbitrary *low sensitivity* queries. We only need to generalize our lemma about posterior stability.

▶ **Definition 14.** *A query $q : \mathcal{X}^n \to \mathbb{R}$ is called Δ-sensitive if for all pairs of neighbouring datasets $S, S' \in \mathcal{X}^n$: $|q(S) - q(S')| \leq \Delta$. Note that linear queries are $(1/n)$-sensitive.*

▶ **Lemma 15.** *If M is an (ϵ, δ)-differentially private mechanism for answering Δ-sensitive queries, then for any data distribution $\mathcal{P}$, analyst $\mathcal{A}$, and any constant $c > 0$:*

$$\Pr_{S\sim\mathcal{P}^n, \Pi\sim Interact(M,\mathcal{A};S))}\left[\max_j |q_j(\mathcal{Q}_\Pi) - q_j(\mathcal{P}^n)| > (e^\epsilon - 1 + 4c)n\Delta\right] \leq \frac{\delta}{c}$$

i.e. it is $(\epsilon', \frac{\delta}{c})$-posterior stable for every $\mathcal{A}$, where $\epsilon' = (e^\epsilon - 1 + 4c)n\Delta$.

Proof. We introduce a useful bit of notation: $\bar{q}\left(\boldsymbol{x}_{\leq i}\right) = \mathop{\mathbb{E}}_{S'\sim\mathcal{P}^{n-i}}\left[q\left(\left(\boldsymbol{x}_{\leq i}, S'\right)\right)\right]$. Notice that $\bar{q}\left(\boldsymbol{x}_{\leq 0}\right) = q\left(\mathcal{P}^n\right)$ and $\bar{q}\left(\boldsymbol{x}_{\leq n}\right) = q\left(\boldsymbol{x}\right)$. Given a transcript $\pi \in \mathbf{\Pi}$, let $j^*(\pi) \in \arg\max_j |q_j(\mathcal{Q}_\pi) - q_j(\mathcal{P}^n)|$. Denote for any $\alpha \geq 0$

$$\mathbf{\Pi}_\alpha = \left\{\pi \in \mathbf{\Pi} \,|\, q_{j^*(\pi)}\left(\mathcal{Q}_\pi\right) - q_{j^*(\pi)}\left(\mathcal{P}^n\right) > \alpha\right\}$$

and for any $z \in [0, 2\Delta]$ denote

$$\mathbf{\Pi}_{\alpha,z}\left(\boldsymbol{x}_{\leq i}\right) = \left\{\pi \in \mathbf{\Pi}_\alpha \,|\, \bar{q}_{j^*(\pi)}\left(\boldsymbol{x}_{\leq i}\right) - \bar{q}_{j^*(\pi)}\left(\boldsymbol{x}_{\leq i-1}\right) > z - \Delta\right\}$$

From the definition of differential privacy:

$$\begin{aligned}
& \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\sum_{\pi\in\mathbf{\Pi}_\alpha} \Pr_{\Pi\sim I(S)}\left[\Pi = \pi\right]\left(\bar{q}_{j^*(\pi)}\left(S_{\leq i}\right) - \bar{q}_{j^*(\pi)}\left(S_{\leq i-1}\right) + \Delta\right)\right] \\
= & \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\int_0^{2\Delta} \Pr_{\Pi\sim I(S)}\left[\Pi \in \mathbf{\Pi}_{\alpha,z}\left(S_{\leq i}\right)\right] dz\right] \\
\leq & \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n, Y\sim\mathcal{P}}\left[\int_0^{2\Delta}\left(e^\epsilon \Pr_{\Pi\sim I(S^{i\leftarrow Y})}\left[\Pi \in \mathbf{\Pi}_{\alpha,z}\left(S_{\leq i}\right)\right] + \delta\right) dz\right] \\
= & \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n, Y\sim\mathcal{P}}\left[e^\epsilon \sum_{\pi\in\mathbf{\Pi}_\alpha} \Pr_{\Pi\sim I(S^{i\leftarrow Y})}\left[\Pi = \pi\right]\left(\bar{q}_{j^*(\pi)}\left(S_{\leq i}\right) - \bar{q}_{j^*(\pi)}\left(S_{\leq i-1}\right) + \Delta\right) + 2\Delta\delta\right] \\
= & \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n, Y\sim\mathcal{P}}\left[e^\epsilon \sum_{\pi\in\mathbf{\Pi}_\alpha} \Pr_{\Pi\sim I(S)}\left[\Pi = \pi\right]\left(\bar{q}_{j^*(\pi)}\left(S^{i\leftarrow Y}_{\leq i}\right) - \bar{q}_{j^*(\pi)}\left(S_{\leq i-1}\right) + \Delta\right) + 2\Delta\delta\right]
\end{aligned}$$

where $S^{i\leftarrow Y} = (S_1, \ldots, S_{i-1}, Y, S_{i+1}, \ldots, S_n)$, and the last equality follows from the observation that (S, Y) and $(S^{i\leftarrow Y}, S_i)$ are identically distributed. Since $Y \sim \mathcal{P}$, independently from Π, we get that $\mathbb{E}_{Y\sim\mathcal{P}}\left[\bar{q}_{j^*(\pi)}\left(S^{i\leftarrow Y}_{\leq i}\right)\right] = \bar{q}_{j^*(\pi)}\left(S_{\leq i-1}\right)$, so

$$\begin{aligned}
& \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\sum_{\pi\in\mathbf{\Pi}_\alpha} \Pr_{\Pi\sim I(S)}\left[\Pi = \pi\right]\left(\bar{q}_{j^*(\pi)}\left(S_{\leq i}\right) - \bar{q}_{j^*(\pi)}\left(S_{\leq i-1}\right) + \Delta\right)\right] \\
\leq & \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\left(e^\epsilon \Pr_{\Pi\sim I(S)}\left[\Pi \in \mathbf{\Pi}_\alpha\right] + 2\delta\right)\Delta\right] \\
= & \left(e^\epsilon \Pr\left[\Pi \in \mathbf{\Pi}_\alpha\right] + 2\delta\right)\Delta
\end{aligned}$$

Subtracting $\Delta \Pr[\Pi \in \Pi_\alpha]$ from both sides we get

$$\mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr_{\Pi\sim I(S)}[\Pi=\pi]\left(\bar{q}_{j^*(\pi)}(S_{\le i})-\bar{q}_{j^*(\pi)}(S_{\le i-1})\right)\right] \le ((e^\epsilon-1)\Pr[\Pi\in\mathbf{\Pi}_\alpha]+2\delta)\Delta \tag{2}$$

We now chooose $\alpha = (e^\epsilon - 1 + 4c)\, n\Delta$. Suppose that $\Pr\left[\left|q_{j^*(\Pi)}(\mathcal{Q}_\Pi) - q_{j^*(\Pi)}(\mathcal{P}^n)\right| > \alpha\right] > \frac{\delta}{c}$. We must have that either $\Pr\left[q_{j^*(\Pi)}(\mathcal{Q}_\Pi) - q_{j^*(\Pi)}(\mathcal{P}^n) > \alpha\right] > \frac{\delta}{2c}$ or $\Pr\left[q_{j^*(\Pi)}(\mathcal{P}^n) - q_{j^*(\Pi)}(\mathcal{Q}_\Pi) > \alpha\right] > \frac{\delta}{2c}$. Without loss of generality, assume

$$\Pr\left[q_{j^*(\Pi)}(\mathcal{Q}_\Pi) - q_{j^*(\Pi)}(\mathcal{P}^n) > \alpha\right] = \Pr[\Pi\in\mathbf{\Pi}_\alpha] > \frac{\delta}{2c} \tag{3}$$

But this leads to a contradiction, since

$$\begin{aligned}
&\Pr[\Pi\in\mathbf{\Pi}_\alpha]\,(e^\epsilon-1+4c)\,n\Delta \\
&< \sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr[\Pi=\pi]\left(q_{j^*(\pi)}(\mathcal{Q}_\pi)-q_{j^*(\pi)}(\mathcal{P}^n)\right) \\
&= \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr_{\Pi\sim I(S)}[\Pi=\pi]\left(q_{j^*(\pi)}(S)-q_{j^*(\pi)}(\mathcal{P}^n)\right)\right] \\
&= \sum_{i=1}^{n}\mathop{\mathbb{E}}_{S\sim\mathcal{P}^n}\left[\sum_{\pi\in\mathbf{\Pi}_\alpha}\Pr_{\Pi\sim I(S)}[\Pi=\pi]\left(\bar{q}_{j^*(\pi)}(S_{\le i})-\bar{q}_{j^*(\pi)}(S_{\le i-1})\right)\right] \\
&\le ((e^\epsilon-1)\Pr[\Pi\in\mathbf{\Pi}_\alpha]+2\delta)\,n\Delta \quad \text{(by Equation (2))} \\
&< \Pr[\Pi\in\mathbf{\Pi}_\alpha]\,(e^\epsilon-1+4c)\,n\Delta \quad \text{(by Equation (3))}
\end{aligned}$$

◀

We can combine this Lemma with Lemma 6 (which holds for any query type) to get our transfer theorem:

▶ **Theorem 16** (Transfer Theorem for Low Sensitivity Queries). *Suppose that M is (ϵ,δ)-differentially private and (α,β)-sample accurate for Δ-sensitive queries. Then for every analyst $\mathcal{A}$, $c,d>0$ it also satisfies:*

$$\Pr_{S\sim\mathcal{P}^n,\,\Pi\sim Interact(M,\mathcal{A};S)}\left[\max_j |a_j - q_j(\mathcal{P}^n)| > \alpha + c + (e^\epsilon-1+4d)n\Delta\right] \le \frac{\beta}{c}+\frac{\delta}{d}$$

i.e. it is (α',β')-distributionally accurate for $\alpha' = \alpha + c + (e^\epsilon-1+4d)n\Delta$ and $\beta' = \frac{\beta}{c}+\frac{\delta}{d}$.

A.2 Minimization Queries

▶ **Definition 17.** *Minimization queries are specified by a loss function $L : \mathcal{X}^n \times \Theta \to [0,1]$ where Θ is generally known as the "parameter space". An answer to a minimization query L is a parameter $\theta\in\Theta$. We work with Δ-sensitive minimization queries: for all pairs of neighbouring datasets $S, S'\in\mathcal{X}^n$ and all $\theta\in\Theta$, $|L(S,\theta) - L(S',\theta)| \le \Delta$.*

A mechanism M is (α,β)-sample accurate for minimization queries if for every data analyst $\mathcal{A}$ and every dataset $S\in\mathcal{X}^n$:

$$\Pr_{\Pi\sim Interact(M,\mathcal{A};S)}\left[\max_j\left|L_j(S,\theta_j) - \min_{\theta\in\Theta}L_j(S,\theta)\right| \ge \alpha\right] \le \beta$$

We say that M satisfies (α,β)-distributional accuracy for minimization queries if for every data analyst $\mathcal{A}$ and every data distribution $\mathcal{P}$:

$$\Pr_{S\sim\mathcal{P}^n,\Pi\sim Interact(M,A;S)}\left[\max_j\left|\mathop{\mathbb{E}}_{S'\sim\mathcal{P}^n}\left[L_j(S',\theta_j) - \min_{\theta\in\Theta}L_j(S',\theta)\right]\right| \ge \alpha\right] \le \beta$$

▶ Remark 18. Note that

$$\mathop{\mathbb{E}}_{S'\sim\mathcal{P}^n}[L_j(S',\theta_j)] - \min_{\theta\in\Theta}\mathop{\mathbb{E}}_{S'\sim\mathcal{P}^n}[L_j(S',\theta)] \leq \mathop{\mathbb{E}}_{S'\sim\mathcal{P}^n}\left[L_j(S',\theta_j) - \min_{\theta\in\Theta} L_j(S',\theta)\right]$$

So as long as the RHS is bounded, the LHS is bounded too.

▶ Remark 19. For a given Δ-sensitive minimization query L_j and an answer θ_j, define:

$$q_j(S) := L_j(S,\theta_j) - \min_{\theta\in\Theta} L_j(S,\theta) \quad \text{and} \quad a_j := 0$$

Note several things:

1. If L_j is Δ-sensitive, then q_j is 2Δ-sensitive.
2. The mapping from a minimization query transcript $\pi = ((L_1,\theta_1),\ldots,(L_k,\theta_k))$ to the 2Δ-sensitive query transcript $\pi' = ((q_1,a_1),\ldots,(q_k,a_k))$ as defined above is a dataset-independent post-processing $\pi' = f(\pi)$.
3. π satisfies an (α,β)-accuracy guarantee if and only if π' does.

With the above observation, the transfer theorem for minimization queries immediately follows by Lemma 15 and Lemma 6.

▶ **Theorem 20** (Transfer Theorem for Minimization Queries). *Suppose that M is (ϵ,δ)-differentially private and (α,β)-sample accurate for Δ-sensitive minimization queries. Then for every analyst $\mathcal{A}$ and $c,d>0$ it also satisfies:*

$$\Pr\left[\max_j \left|\mathop{\mathbb{E}}_{S'\sim\mathcal{P}^n}\left[L_j(S',\theta_j) - \min_{\theta\in\Theta} L_j(S',\theta)\right]\right| > \alpha + c + 2(e^\epsilon - 1 + 4d)n\Delta\right] \leq \frac{\beta}{c} + \frac{\delta}{d}$$

i.e. it is (α',β')-distributionally accurate for $\alpha' = \alpha + c + 2(e^\epsilon - 1 + 4d)n\Delta$ and $\beta' = \frac{\beta}{c} + \frac{\delta}{d}$.

B Details from Section 3.1

Proof of Lemma 5. This follows from the expansion of the definition, and an application of Bayes Rule.

$$\begin{aligned}
&\Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S),S'\sim\mathcal{Q}_\Pi}[(S',\Pi)\in E]\\
&= \sum_{\boldsymbol{x}}\sum_{\pi}\sum_{\boldsymbol{x}'} \Pr[S=\boldsymbol{x}]\Pr[\Pi=\pi|S=\boldsymbol{x}]\Pr_{S'\sim\mathcal{Q}_\pi}[S'=\boldsymbol{x}']\mathbb{1}[(\boldsymbol{x}',\pi)\in E]\\
&= \sum_{\pi}\sum_{\boldsymbol{x}'} \Pr[\Pi=\pi]\Pr_{S'\sim\mathcal{Q}_\pi}[S'=\boldsymbol{x}']\mathbb{1}[(\boldsymbol{x}',\pi)\in E]\\
&= \sum_{\pi}\sum_{\boldsymbol{x}'} \Pr[\Pi=\pi]\Pr[S=\boldsymbol{x}'|\Pi=\pi]\mathbb{1}[(\boldsymbol{x}',\pi)\in E]\\
&= \sum_{\pi}\sum_{\boldsymbol{x}'} \Pr[\Pi=\pi]\frac{\Pr[\Pi=\pi|S=\boldsymbol{x}']\cdot\Pr[S=\boldsymbol{x}']}{\Pr[\Pi=\pi]}\mathbb{1}[(\boldsymbol{x}',\pi)\in E]\\
&= \Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}[(S,\Pi)\in E]
\end{aligned}$$

◀

C Details from Section 3.2

▶ **Lemma 21.** *If M is (ϵ,δ)-differentially private, then for any event E and datapoint x:*

$$\Pr_{S\sim\mathcal{P}^n,S_i\sim S,\Pi\sim I(S)}[\Pi\in E|S_i=x] \leq e^\epsilon \Pr_{S\sim\mathcal{P}^n,\Pi\sim I(S)}[\Pi\in E] + \delta$$

Proof. This follows from expanding the definitions.

$$\begin{aligned}
\Pr_{S\sim\mathcal{P}^n, S_i\sim S, \Pi\sim I(S)}[\Pi \in E | S_i = x] &= \frac{1}{n}\sum_{i=1}^{n} \Pr_{S\sim\mathcal{P}^n, \Pi\sim I(S)}[\Pi \in E | S_i = x] \\
&= \frac{1}{n}\sum_{i=1}^{n}\sum_{\boldsymbol{x}\in\mathcal{X}^n} \Pr_{S\sim\mathcal{P}^n}[S = \boldsymbol{x}] \cdot \Pr[\Pi \in E | S = (\boldsymbol{x}_{-i}, x)] \\
&\leq \frac{1}{n}\sum_{i=1}^{n}\sum_{\boldsymbol{x}\in\mathcal{X}^n} \Pr_{S\sim\mathcal{P}^n}[S = \boldsymbol{x}] \cdot (e^{\epsilon}\Pr[\Pi \in E | S = \boldsymbol{x}] + \delta) \\
&= e^{\epsilon} \Pr_{S\sim\mathcal{P}^n, \Pi\sim I(S)}[\Pi \in E] + \delta
\end{aligned}$$

where the inequality follows from the definition of differential privacy. ◀

D An (even) Simpler and Better Proof for ϵ-Differential Privacy

In this section we give an *even simpler* proof of an *even better* transfer theorem for $(\epsilon, 0)$-differential privacy. Rather than using Markov's inequality as we did in the proof of Lemma 6, we can directly show that conditional distributions induced by differentially private mechanisms exhibit Chernoff-like concentration.

▶ **Lemma 22.** *If M is $(\epsilon, 0)$-differentially private, then for any data distribution $\mathcal{P}$, any transcript $\pi \in \mathbf{\Pi}$, any linear query q, and any $\eta > 0$:*

$$\Pr_{S\sim\mathcal{Q}_\pi}\left[|q(S) - q(\mathcal{P})| \geq (e^{\epsilon} - 1) + \sqrt{\frac{2\ln(2/\eta)}{n}}\right] \leq \eta$$

Proof. Define the random variables $V_i = q(S_i) - \mathbb{E}[q(S_i)|S_{<i}]$, and let $X_i = \frac{1}{n}\sum_{j=1}^{i} V_j$. Then the sequence $0 = X_0, X_1, \ldots, X_n$ forms a martingale and $|X_i - X_{i-1}| = \frac{1}{n}|V_i| \leq \frac{1}{n}$. We can therefore apply Azuma's inequality to conclude that:

$$\Pr\left[\left|\frac{1}{n}\sum_{i=1}^{n} q(S_i) - \frac{1}{n}\sum_{i=1}^{n}\mathbb{E}[q(S_i)|S_{<i}]\right| \geq t\right] \leq 2\exp\left(\frac{-t^2 n}{2}\right) \tag{4}$$

Now fix any realization $\boldsymbol{x}$, and consider each term: $\mathbb{E}[q(S_i)|S_{<i} = \boldsymbol{x}_{<i}]$. We have:

$$\begin{aligned}
\mathop{\mathbb{E}}_{S\sim\mathcal{Q}_\pi}[q(S_i)|S_{<i} = \boldsymbol{x}_{<i}] &= \sum_x q(x) \cdot \Pr_{S\sim\mathcal{P}^n}[S_i = x | \Pi = \pi, S_{<i} = \boldsymbol{x}_{<i}] \\
&= \sum_x q(x) \cdot \frac{\Pr_{S\sim\mathcal{P}^n}[\Pi = \pi | S_i = x, S_{<i} = \boldsymbol{x}_{<i}] \cdot \Pr_{S\sim\mathcal{P}^n}[S_i = x]}{\Pr[\Pi = \pi | S_{<i} = \boldsymbol{x}_{<i}]} \\
&\leq e^{\epsilon} \cdot \sum_x q(x) \cdot \Pr_{S\sim\mathcal{P}^n}[S_i = x] \\
&= e^{\epsilon} q(\mathcal{P})
\end{aligned}$$

where the inequality follows from the definition of $(\epsilon, 0)$-differential privacy. Symmetrically, we can show that $\mathbb{E}_{S\sim\mathcal{Q}_\pi}[q(S_i)|S_{<i} = \boldsymbol{x}_{<i}] \geq e^{-\epsilon} q(\mathcal{P})$. Therefore we have that:

$$e^{-\epsilon} q(\mathcal{P}) \leq \frac{1}{n}\sum_{i=1}^{n}\mathbb{E}[q(S_i)|S_{<i}] \leq e^{\epsilon} q(\mathcal{P}).$$

Combining this with Equation 4 gives us that for any $\eta > 0$, with probability $1 - \eta$ when $S \sim \mathcal{Q}_\pi$:

$$q(S) \leq e^{\epsilon} q(\mathcal{P}) + \sqrt{\frac{2\ln(2/\eta)}{n}} \quad \text{and} \quad q(S) \geq e^{-\epsilon} q(\mathcal{P}) - \sqrt{\frac{2\ln(2/\eta)}{n}}$$ ◀

A transfer theorem follows immediately from lemma 22.

▶ **Theorem 23.** *Suppose that M is $(\epsilon, 0)$-differentially private and (α, β)-sample accurate. Then for any $\eta > 0$ it is (α', β')-distributionally accurate for $\alpha' = \alpha + (e^\epsilon - 1) + \sqrt{\frac{2\ln(2/\eta)}{n}}$ and $\beta' = \beta + \eta$.*

Proof. For a given π, let $j^*(\pi) = \arg\max_j |a_j - q_j(\mathcal{P})|$. By the triangle inequality we have:

$$\begin{aligned}|a_{j^*(\Pi)} - q_{j^*(\Pi)}(\mathcal{P})| &\leq |a_{j^*(\Pi)} - q_{j^*(\Pi)}(S)| + |q_{j^*(\Pi)}(S) - q_{j^*(\Pi)}(\mathcal{P})| \\ &\leq \max_j |a_j - q_j(S)| + |q_{j^*(\Pi)}(S) - q_{j^*(\Pi)}(\mathcal{P})|\end{aligned}$$

By the definition of (α, β)-sample accuracy, we have that with probability $1 - \beta$, $\max_j |a_j - q_j(S)| \leq \alpha$. The Resampling Lemma (Lemma 5) gives us that:

$$\begin{aligned}&\Pr_{S\sim\mathcal{P}^n,\, \Pi\sim I(S)}\left[|q_{j^*(\Pi)}(S) - q_{j^*(\Pi)}(\mathcal{P})| \geq (e^\epsilon - 1) + \sqrt{\frac{2\ln(2/\eta)}{n}}\right] \\ &= \Pr_{S\sim\mathcal{P}^n,\, \Pi\sim I(S),\, S'\sim\mathcal{Q}_\Pi}\left[|q_{j^*(\Pi)}(S') - q_{j^*(\Pi)}(\mathcal{P})| \geq (e^\epsilon - 1) + \sqrt{\frac{2\ln(2/\eta)}{n}}\right] \\ &= \mathop{\mathbb{E}}_{S\sim\mathcal{P}^n,\, \Pi\sim I(S)}\left[\Pr_{S'\sim\mathcal{Q}_\Pi}\left[|q_{j^*(\Pi)}(S') - q_{j^*(\Pi)}(\mathcal{P})| \geq (e^\epsilon - 1) + \sqrt{\frac{2\ln(2/\eta)}{n}}\right]\right] \\ &\leq \eta\end{aligned}$$

Because Lemma 22 guarantees us that for *every* π,

$$\Pr_{S'\sim\mathcal{Q}_\pi}\left[|q_{j^*(\pi)}(S') - q_{j^*(\pi)}(\mathcal{P})| \geq (e^\epsilon - 1) + \sqrt{\frac{2\ln(2/\eta)}{n}}\right] \leq \eta.$$

The theorem then follows from a union bound. ◀

Robust Algorithms for the Secretary Problem

Abstract

In classical secretary problems, a sequence of n elements arrive in a uniformly random order, and we want to choose a single item, or a set of size K. The random order model allows us to escape from the strong lower bounds for the adversarial order setting, and excellent algorithms are known in this setting. However, one worrying aspect of these results is that the algorithms overfit to the model: they are not very robust. Indeed, if a few "outlier" arrivals are adversarially placed in the arrival sequence, the algorithms perform poorly. E.g., Dynkin's popular $1/e$-secretary algorithm is sensitive to even a single adversarial arrival: if the adversary gives one large bid at the beginning of the stream, the algorithm does not select any element at all.

We investigate a robust version of the secretary problem. In the *Byzantine Secretary* model, we have two kinds of elements: green (good) and red (rogue). The values of all elements are chosen by the adversary. The green elements arrive at times uniformly randomly drawn from $[0, 1]$. The red elements, however, arrive at adversarially chosen times. Naturally, the algorithm does not see these colors: how well can it solve secretary problems?

We show that selecting the highest value red set, or the single largest green element is not possible with even a small fraction of red items. However, on the positive side, we show that these are the only bad cases, by giving algorithms which get value comparable to the value of the optimal green set *minus the largest green item*. (This benchmark reminds us of regret minimization and digital auctions, where we subtract an additive term depending on the "scale" of the problem.) Specifically, we give an algorithm to pick K elements, which gets within $(1 - \varepsilon)$ factor of the above benchmark, as long as $K \geq \text{poly}(\varepsilon^{-1} \log n)$. We extend this to the knapsack secretary problem, for large knapsack size K.

For the single-item case, an analogous benchmark is the value of the second-largest green item. For value-maximization, we give a $\text{poly} \log^* n$-competitive algorithm, using a multi-layered bucketing scheme that adaptively refines our estimates of second-max over time. For probability-maximization, we show the *existence* of a good randomized algorithm, using the minimax principle.

We hope that this work will spur further research on robust algorithms for the secretary problem, and for other problems in sequential decision-making, where the existing algorithms are not robust and often tend to overfit to the model.

Acknowledgements We thank Thomas Kesselheim and Marco Molinaro for sharing their model and thoughts on robust secretary problems with us; these have directly inspired our model.

1 Introduction

In sequential decision-making, we have to serve a sequence of requests *online*, i.e., we must serve each request before seeing the next one. E.g., in online auctions and advertising, given a sequence of arriving buyers, we want to choose a high bidder. Equivalently, given a sequence of n numbers, we want to choose the highest of these. The worst-case bounds for this problem are bleak: choosing a random buyer is the best we can do. So we make (hopefully reasonable) stochastic assumptions about the input stream, and give algorithms that work well under those assumptions.

A popular assumption is that the values/bids are chosen by an adversary, but presented to the algorithm in a uniformly random order. This gives the *secretary* or the *random-order model*, under which we can get much better results. E.g., Dynkin's secretary algorithm that selects the first prefix-maximum bidder after discarding the first $1/e$-fraction of the bids, selects the highest bid with probability $1/e$ [13]. The underlying idea – of fixing one or more thresholds after seeing some prefix of the elements – can be generalized to solve classes of packing linear programs near-optimally [8, 9, 25, 21], and to get $O(\log \log n)$-competitive algorithms for matroids [28, 16] in the random-order model.

However, the assumption that we see the elements in a uniformly random order is quite strong, and most current algorithms are not robust to small perturbations to the model. E.g., Dynkin's algorithm is sensitive to even a single adversarial corruption: if the adversary gives one large bid at the beginning of the stream, the algorithm does not select any buyer at all, even if the rest of the stream is perfectly random! Many other algorithms in the secretary model suffer from similar deficiencies, which suggests that we may be over-fitting to the assumptions of the model.

We propose the *Byzantine secretary model*, where the goal is to design algorithms robust to outliers and adversarial changes. The use of the term "Byzantine" parallels its use in distributed systems, where some of the input is well-behaved while the rest is arbitrarily corrupted by an adversary. Alternatively, our model can be called *semi-random* or *robust*: these other terms are used in the literature which inspires our work. Indeed, there is much interest currently in designing stochastic algorithms that are robust to adversarial noise (see [10, 34, 29, 3, 34, 11, 12, 14, 30] and references therein). Our work seeks to extend robustness to online problems. Our work is also related in spirit to investigations into how much randomness in the stream is necessary and sufficient to get competitive algorithms [5, 23].

1.1 Our Model

In the secretary problem, n elements arrive one-by-one. Each item has a value that is revealed upon its arrival, which happens at a time chosen independently and *uniformly at random* in $[0, 1]$. (We choose the continuous time model, instead of the *uniformly random* arrival order model, since the independence allows us to get clean proofs.) When we see an item, we must either *select* it or discard it before we see the next item. Our decisions are *irrevocable*. We can select at most K elements, where $K = 1$ for the classical version of the problem. We typically want to maximize the expected total value of the selected elements where the value of a set is simply the sum of values of individual elements. (For the single-item case we may also want to maximize the probability of selecting the highest-value item, which is called the *ordinal case*.) Given its generality and wide applicability, this model and its extensions are widely studied; see §1.3.

The difference between the classical and Byzantine secretary models is in how the sequence is generated. In both models, the adversary chooses the values of all n elements. In the classical model, these are then permuted in a random order (say by choosing the arrival times independently and uniformly at random (u.a.r.) from $[0, 1]$). In the Byzantine model, the elements are divided into two groups: the *green (or good)* elements/items G, and the *red (or rogue/bad)* elements/items R. This partition and the colors are not visible to the algorithm. Now elements in G arrive at independently chosen u.a.r. times between $[0, 1]$, but those in R arrive at times chosen by the adversary. Faced with this sequence, the algorithm must select some subset of elements (say, having size at most K, or more generally belonging to some down-closed family). The precise order of actions is important:

- First, the adversary chooses values of elements in $R \cup G$, and the arrival times of elements in R.
- Then each element $e \in G$ is independently assigned a uniformly random arrival time $t_e \sim U[0, 1]$.

Hence the adversary is powerful and strategic, and can "stuff" the sequence with values in an order that fools our algorithms the most. The green elements are non-strategic (hence are in random order) and beyond the adversary's control. When an element is presented, the algorithm does not see the color (green vs. red): it just sees the value and the time of arrival. We assume that the algorithm knows $n := |R| + |G|$, but not $|R|$ or $|G|$; see Appendix B on how to relax this assumption. The green elements are denoted $G = \{g_{\max} = g_1, g_2, \ldots, g_{|G|}\}$ in non-increasing order of values.

What results can we hope to get in this model? Here are two cautionary examples:

- Since the red elements behave completely arbitrarily, the adversary can give non-zero values to only the reds, and plant a bad example for the adversarial order using them. Hence, we cannot hope to get the value of the optimal red set in general, and should aim to get value only from the greens.
- Moreover, suppose essentially all the value among the greens is concentrated in a single item $g_{\max}$. Here's a bad example: the adversary gives a sequence of increasing reds, all having value much smaller than $g_{\max}$, but values which are very far from each other. When the algorithm does see the green item, it will not be able to distinguish it from the next red, and hence will fail. This is formalized in Observation 19. Hence, to succeed, the green value must be spread among more than one item.

Given these examples, here is the "leave-one-out" benchmark we propose:

$$\boxed{V^* := \text{value of the best feasible green set from } G \setminus g_{\max}.} \tag{1}$$

This benchmark is at least as strong as the following guarantee:

$$(\text{value of best feasible green set from } G) \; - v(g_{\max}). \tag{2}$$

The advantage of (1) over (2) is that V^* is interesting even when we want to select a single item, since it asks for value v_{g_2} or higher.

We draw two parallels to other commonly used benchmarks. Firstly, the perspective (2) suggests the regret-type guarantees, where we seek the best solution in hindsight, minus the "scale of the problem instance". The value of $g_{\max}$ is the scale of the instance here. Secondly, think of the benchmark (1) as assuming the existence of at least two high bids, then the second-largest element is almost as good a benchmark as the top element. This is a commonly used assumption, e.g., in digital goods auctions [4].

Finally, if we really care about a benchmark that includes $g_{\max}$, our main results for selecting multiple items (Theorem 1 and Theorem 2) continue to hold, under the (mild?) assumption that the algorithm starts with a polynomial approximation to $v(g_{\max})$.

1.2 Our Results

We first consider the setting where we want to select at most K elements to maximize the expected total value. In order to get within $(1+\varepsilon)$ factor of the benchmark V^* defined in (1), we need to assume that we have a "large budget", i.e., we are selecting a sufficiently large number of elements. Indeed, having a larger budget K allows us to make some mistakes and yet get a good expected value.

▶ **Theorem 1** (Uniform Matroids). *There is an algorithm for Byzantine secretary on uniform matroids of rank $K \geq \text{poly}(\varepsilon^{-1} \log n)$ that is $(1+\varepsilon)$-competitive with the benchmark V^*.*

For the standard version of the problem, i.e. without any red elements, [26] gave an algorithm that achieves the same competitiveness when $K \geq \Omega(1/\varepsilon^2)$. The algorithm from [26] uses a single threshold, that it updates dynamically; we extend this idea to having several thresholds/budgets that "cascade down" over time; we sketch the main ideas in §2.2. In fact, we give a more general result – an algorithm for the *knapsack* setting where each element has a size in $[0, 1]$, and the total size of elements we can select is at most K. (The uniform-matroids case corresponds to all sizes being one.) Whereas the main intuition remain unchanged, the presence of non-uniform sizes requires a little more care.

▶ **Theorem 2** (Knapsack). *There is an algorithm for Byzantine secretary on knapsacks with size at least $K \geq \text{poly}(\varepsilon^{-1} \log n)$ (and elements of at most unit size) that is $(1+\varepsilon)$-competitive with the benchmark V^*.*

As mentioned earlier, under mild assumptions the guarantee in Theorem 2 can be extended against the stronger benchmark that includes $g_{\max}$. Formally, assuming the algorithm starts with a $\text{poly}(m)$-approximation to the value of $g_{\max}$, we get a $(1+\varepsilon)$-competitive algorithm for $K \geq \text{poly}(\varepsilon^{-1} \log(mn))$ against the stronger benchmark.

Selecting a Single Item. What if we want to select a single item, to maximize its expected value? Note that the benchmark V^* is now the value of g_2, the second-largest green item. Our main result for this setting is the following, where $\log^* n$ denotes the iterated logarithm:

▶ **Theorem 3** (Value Maximization Single-Item). *There is a randomized algorithm for the value-maximization (single-item) Byzantine secretary problem which gets an expected value at least $(\log^* n)^{-2} \cdot V^*$.*

Interestingly, our result is unaffected by the corruption level, and works even if just two elements $g_{\max}, g_2$ are green, and every other item is red. This is in contrast to many other robustness models where the algorithm's performance decays with the fraction of bad elements [14, 3, 12, 30]. Moreover, our algorithms do not depend on the fraction of bad items. Intuitively, we obtain such strong guarantees because the adversary has no incentive to present too many bad elements with large values, as otherwise an algorithm that selects a random element would have a good performance.

In the classical setting, the proofs for the value-maximization proceed via showing that the best item itself is chosen with constant probability. Indeed, in that setting, the competitiveness of value-maximization and probability-maximization versions is the same. We do not know of such a result in the Byzantine model. However, we can show a non-trivial performance for the probability-maximization (ordinal) problem:

▶ **Theorem 4** (Ordinal Single-item Algorithm). *There is a randomized algorithm for the ordinal Byzantine secretary which selects an element of value at least the second-largest green item with probability* $\Omega(1/\log^2 n)$.

Other Settings. Finally, we consider some other constraint sets given by matroids. In (simple) partition matroids, the universe U is partitioned into r groups, and the goal is to select one item from each group to maximize the total value. If we were to set the benchmark to be the sum of second-largest green items from each group, we can just run the single-item algorithm from Theorem 1 on each group independently. But our benchmark V^* is much higher: among the items $g_2, \ldots, g_{|G|}$, the set V^* selects the largest one from each group. Hence, we need to get the largest green item from $r-1$ groups! Still, we do much better than random guessing.

▶ **Theorem 5** (Partition Matroids). *There is an algorithm for Byzantine secretary on partition matroids that is* $O(\log\log n)^2$*-competitive with the benchmark* V^*.

Finally, we record a simple but useful logarithmic competitive ratio for arbitrary matroids (proof in §6.2), showing how to extend the corresponding result from [1] for the non-robust case.

▶ **Observation 6** (General Matroids). *There is an algorithm for Byzantine secretary on general matroids that is* $O(\log n)$*-competitive with the benchmark* V^*.

Our results show how to get robust algorithms for the widely-studied secretary problems, and we hope it will generate futher interest in robust algorithm design. Interesting next directions include improving the quantitative bounds in our results (which are almost certainly not optimal), and understanding tradeoffs between competitiveness and robustness.

1.3 Related Work

The secretary problem has a long history, see [17] for a discussion. The papers [1, 28, 16] studied generalizations of the secretary problem to matroids, [20, 27, 24, 22] studied extensions to matchings, and [38, 39] studied extensions to arbitrary packing constraints. More generally, the random-order model has been considered, both as a tool to speed up algorithms (see [6, 41]), and to go beyond the worst-case in online algorithms (see [32, 18, 19]). E.g., we can solve *linear programs* online if the columns of the constraint matrix arrive in a random order [8, 9, 25, 21], and its entries are small compared to the bounds. In online algorithms, the random-order model provides one way of modeling benign nature, as opposed to an adversary hand-crafting a worst-case input sequence; this model is at least as general as i.i.d. draws from an unknown distribution.

Both the random-order model and the Byzantine model are *semi-random* models [2, 15], with different levels of power to the adversary. Other restrictions of the random-order model have been studied, via lower-bounding the entropy of the input stream, to ensure the permutations are "random enough" [5, 23]. These papers give sufficient conditions for the classical algorithms to perform well, whereas we take the dual approach of permitting outliers and then asking for new robust algorithms. There are works (e.g., [31, 33, 35]) that give algorithms which have a worst-case adversarial bound, and which work better when the input is purely stochastic; most of these do not study the performance on mixed arrival sequences. One exception is the work [14] who study online matching for mixed arrivals, under the assumption that the "magnitude of noise" is bounded. Another exception is a recent (unpublished) work of Kesselheim and Molinaro, who define a robust K-secretary problem similar to ours. They assume the corruptions have a bursty pattern, and get $1 - f(K)$-competitive algorithms. Our model is directly inspired by theirs.

2 Preliminaries and Techniques

By $[a \dots b]$ we denote the set of integers $\{a, a+1, \dots, b-1, b\}$. The *universe* $U := R \cup G$ consists of *red/corrupted* elements R and *greed/good* elements G. Let $v(e)$ denote the value of element e: in the *ordinal* case $v(e)$ merely defines a total ordering on the elements, whereas in the *value-maximization* case $v(e) \in \mathbb{R}_{\geq 0}$. Similarly, let $v(\mathcal{A})$ be the random variable denoting the value of the elements selected by algorithm $\mathcal{A}$. Let $t_e \in [0, 1]$ be the arrival time of element e. Let $R = \{r_1, r_2, \dots, r_{|R|}\}$ and $G = \{g_{\max}, g_2, g_3, \dots, g_{|G|}\}$; the elements in each set are ordered in non-increasing values. Let V^* be the benchmark to which we compare our algorithm. Note that V^* is some function of $G \setminus \{g_{\max}\}$, depending on the setting. We sometimes refer to elements $\{e \in U \mid v(e) \geq v(g_2)\}$ as *big*.

2.1 Two Useful Subroutines

Here are two useful subroutines.

Select a Random Element. The subroutine is simple: *select an element uniformly at random*. The algorithm can implement this in an online fashion since it knows the total number of elements n. An important property of this subroutine is that, in the value case, if any element in U has value at least nV^*, this subroutine gets at least V^* in expectation since this highest value element is selected with probability $1/n$.

Two-Checkpoints Secretary. The subroutine is defined on two checkpoints $T_1, T_2 \in [0, 1]$, and let $\mathbb{I} := [T_1, T_2]$ be the interval between them. The subroutine ignores the input up to time T_1, observes it during $\mathbb{I}$ by setting threshold τ to be the highest value seen in the interval $\mathbb{I}$, i.e., $\tau \leftarrow \max\{v(e) \mid t_e \in \mathbb{I}\}$. Finally, during $\langle T_2, 1]$ the subroutine selects the first element e with value $v(e) \geq \tau$.

We use the subroutine in the single-item setting where the goal is to find a "big" element, i.e., an element with value at least $v(g_2)$. Suppose that there are no big red elements in $\mathbb{I}$. Now, if g_2 lands in $\mathbb{I}$, and also $g_{\max}$ lands in $\langle T_2, 1]$, we surely select some element with value at least g_2. Indeed, if there are no big items, threshold $\tau \leftarrow g_2$, and because $g_{\max}$ lands after $\mathbb{I}$, it or some other element will be selected. Hence, with probability $\Pr[t_{g_2} \in \mathbb{I}] \Pr[t_{g_{\max}} \in \langle T_2, 1]] = (T_2 - T_1) \cdot (1 - T_2)$, we select an element of value at least $v(g_2)$.

2.2 Our Techniques

A common theme of our approaches is to prove a "good-or-learnable" lemma for each problem. Our algorithms begin by putting down a small number of *checkpoints* $\{T_i\}_i$ to partition the time horizon $[0, 1]$ – and the arriving items – into disjoint *intervals* $\{\mathbb{I}_i\}_i$. We maintain *thresholds* in each interval to decide whether to select the next element. Now a "good-or-learnable" lemma says that either the setting of the thresholds in the current interval $\mathbb{I}_i$ will give us a "good" performance, or we can "learn" that this is not the case and update the thresholds for the next interval $\mathbb{I}_{i+1}$. Next we give details for each of our problems.

Uniform Matroid Value Maximization (§3). Recall that here we want to pick K elements (in particular, all elements have size 1, unlike the knapsack case where sizes are in the range $[0, 1]$). For simplicity, suppose the algorithm knows that the benchmark V^* lies in $[1, n]$; we remove this assumption later. We define $O(\varepsilon^{-1} \log n)$ levels, where level $\ell \geq 0$ corresponds to values in the range $[n/(1+\varepsilon)^{\ell+1}, n/(1+\varepsilon)^{\ell})$. For each interval $\mathbb{I}_i$ and level ℓ, we maintain a budget $B_{\ell,i}$. Within this interval $\mathbb{I}_i$, we select the next arriving element having a value in some level ℓ only if the budget $B_{\ell,i}$ has not been used up. How should we set these budgets? If there are $1/\delta$ intervals of equal size, we expect to select δK elements in this interval. So we have a total of δK budget to distribute among the various levels. We start off optimistically, giving all the budget to the highest-value level. Now this budget gradually *cascades* from a level ℓ to the next (lower-value) level $\ell + 1$, if level ℓ is not selecting elements at a "good enough" rate. The intuition is that for the "heavy" levels (i.e., those that contain many elements from the benchmark-achieving set S^*), we will roughly see the right number of them arriving in each interval. This allows us to prove a good-or-learnable lemma, that either we select elements at a "good enough" rate in the current interval, or this is not the case and we "learn" that the budgets should cascade to lower value levels. There are many details to be handled: e.g., this reasoning is only possible for levels with many benchmark elements, and so we need to define a dedicated budget to handle the "light" levels.

Single-Item Value-Maximization (§5). We want to maximize the expected value of the selected element, compared to $V^* := v(g_2)$, the value of the second-max green. With some small constant probability our algorithm selects a uniformly random element. This allows us to assume that every element has value less than nV^*, as otherwise the expected value of a random guess is $\Omega(V^*)$. We now describe how applying the above "good-or-learnable" paradigm in a natural way guarantees an expected value of $\Omega(V^*/\log n)$. Running the two-checkpoint secretary (with constant probability) during $T_1 = 0, T_2 = 1/2$ we know that it gets value $\Omega(V^*)$ and we are done, or failing that, there exist a red element of value at least V^* in $[0, 1/2]$. But then we can use this red element (highest value in the first half) to get a factor n estimate on the value of V^*. So by grouping elements into buckets if their values are within a factor 2, and randomly guessing the bucket that contains $v(g_2)$, gives us an expected value of $\Omega(V^*/\log n)$. To obtain the stronger factor of $\operatorname{poly}\log^* n$ in Theorem 3, we now define $\log^* n$ checkpoints. We prove a "good-or-learnable" lemma that either selecting a random element from one of the current buckets has a good value, or we can learn a tighter estimate on V^* and reduce the number of buckets.

Ordinal Single-Item Secretary (§4). We now want to maximize the probability of selecting an element whose value is as large as the green second-max; this is more challenging than value-maximization since there is no notion of values for bucketing. Our approach is crucially different. Indeed, we use the *minimax principle* in the "hard" direction: we give an algorithm

that does well when the input distribution is *known to the algorithm* (i.e., where the algorithm can adapt to the distribution), and hence infer the existence of a (randomized) algorithm that does well on worst-case inputs.

The known-distribution algorithm uses $O(\log n)$ intervals. Again, we can guarantee there is a "big" (larger than g_2) red element within each interval, as otherwise running Dynkin's algorithm on a random interval with a small probability already gives a "good" approximation. This implies that even if the algorithm "learns" a good estimate of the second-max just before the last interval, it will win. This is because the algorithm can set this estimate of second-max as a threshold, and it wins by selecting the big red element of the last interval. Finally, to learn a good estimate on the second-max, we again prove a "good-or-learnable" lemma. Its proof crucially relies on the algorithm knowing the arrival distribution, since that allows us to set "median" of the conditional distribution as a threshold.

Other Results (§6). We also give $O(\log \log n)^2$-competitive algorithms for Partition matroids, where the difficulty is that we cannot afford to lose the max-green element in every part. Our idea is to only lose one element globally to get a very rough scale of the problem, and then exploit this scale in every part. We also show why other potential benchmarks are too optimistic in §A, and how to relax the assumption that n is known in §B. See those sections for details.

3 Knapsack Byzantine Secretary

Consider a knapsack of size K; for all the results in this section we assume that $K \geq \text{poly}(\varepsilon^{-1} \log n)$. Each arriving element e has a size $s(e) \in [0, 1]$ and a value $v(e) \geq 0$. Let $g_{\max}, g_2, g_3, \ldots,$ denote the green elements G with decreasing values and let

$$V^* := \max \left\{ \textstyle\sum_{e \in S} v(e) \mid S \subseteq G \setminus g_{\max} \text{ and } \sum_{e \in S} s(e) \leq K \right\} \tag{3}$$

be the value of the benchmark solution, i.e., the optimal solution obtained after discarding the top green element $g_{\max}$. Let S^* be the set of green elements corresponding to this benchmark.

In §3.1 we give a $(1 + \varepsilon)$-competitive algorithm assuming we have a factor $\text{poly}(n)$-approximation to the benchmark value V^*. (In fact, given this $\text{poly}(n)$-approximation, we can even get within a $(1 + \varepsilon)$-factor of the optimal set *including* $g_{\max}$.) Then in §3.2 we remove the assumption, but now our value is only comparable to V^* (i.e., excluding $g_{\max}$).

Intuition. The main idea of the regular (non-robust) multiple-secretary problem (where we pick at most K items) is to observe a small ε fraction of the input, estimate the value of the K^{th} largest element, and then select elements with value exceeding this estimate. (A better algorithm revises these estimates over time, but let us ignore this optimization for now.) In the Byzantine case, there may be an arbitrary number of red items, so strategies that try to estimate some statistics (like the K^{th} largest) to use for the rest of the algorithm are susceptible to adversarial attacks.

For now, suppose we know that all items of S^* have values in $[1, n^c]$ for some constant c. The density of an item to be its value divided by its size. We define $O(\log n)$ *density levels*, where elements in the same level have roughly the same density, so our algorithm does not distinguish between them. The main idea of our algorithm is to use *cascading budgets*. At the beginning we allocate all our budget to picking only the highest-density level items. If we find that we are not picking items at a rate that is "good enough", we re-allocate parts of

our budget to lower-density levels. The hope is that if the benchmark solution S^* selects many elements from a certain density level, we can get a good estimate of the "right" rate at which to pick up items from this level. Moreover, since our budgets trickle from higher to lower densities, the only way the adversary can confuse us is by giving dense red elements, in which case we will select them.

Such an idea works only for the value levels that contain many elements of S^*. For the remaining value levels, we allocate *dedicated budgets* whose sole purpose is to pick a "few" elements from that level, irrespective of whether they are from S^*. By making the total number of levels logarithmic, we argue that the total amount of dedicated budgets is only $o(K)$, so it does not affect the analysis for the cascading budget.

3.1 An Algorithm Assuming a Polynomial Approximation

Suppose we know the benchmark V^* to within a polynomial factor: by rescaling, assume that V^* lies in the range $[1 \dots n^c]$ for some constant c. This allows us to simplify the instance structure as follows: Firstly, we can pick all elements of size at most $1/n$, since the total space usage is at most $n \cdot 1/n = 1$ (recall, $K \geq \text{poly}(\varepsilon^{-1} \log n)$). Next, we can ignore all elements with value less than $1/n^2$ because their total value is at most $1/n \ll 1 \leq V^*$. If the *density* of an element is defined to be the ratio $v(e)/s(e)$, then all remaining elements have density between n^{c+1} and n^{-2}. The main result of this section is the following:

▶ **Lemma 7.** *If V^* lies between 1 and n^c for some constant c, each element has size at least $1/n$ and value at least $1/n^2$, and $K \geq \text{poly}(\varepsilon^{-1} \log n)$, then there exists a $(1 + O(\varepsilon))$-competitive algorithm.*

The idea of our algorithm is to partition the input into $1/\delta$ disjoint pieces (δ is a small parameter that will be chosen later) and try to solve $1/\delta$ "similar-looking" instances of the knapsack problem, each with a knapsack of size δK.

The Algorithm. Define *checkpoints* $T_i := \delta i$ and corresponding intervals $\mathbb{I}_i := \langle T_{i-1}, T_i]$ for all $i \in [1 \dots 1/\delta]$. Define $L := (1 + \frac{c+3}{\varepsilon} \log n)$ *density levels* as follows: for each integer $\ell \in [0 \dots L)$, density value $\rho_\ell := n^{c+1}/(1+\varepsilon)^\ell$. Now density level ℓ corresponds to all densities lying in the range $(\rho_{\ell+1}, \rho_\ell]$. Note that densities decrease as ℓ increases. We later show that the setting of parameters $K \geq \Omega\big(\frac{L^2 \log L/\varepsilon}{\varepsilon^4}\big)$ and $1/\delta = \Omega(L/\varepsilon)$ suffices.

We maintain two kinds of *budgets*:

- *Cascading budgets*: We maintain a budget $B_{\ell,i}$ for each density level ℓ and each interval $\mathbb{I}_i$. For the first interval $\mathbb{I}_1$, define $B_{0,1} := \delta K$, and $B_{\ell,1} := 0$ for $\ell > 0$. For the subsequent intervals, we will set $B_{\ell,i}$ in an online way as described later.
- *Dedicated budgets*: We maintain a dedicated budget $\widetilde{B}_\ell := H$ for each density level ℓ; we will later show that setting $H := \Omega\big(\frac{L \log L/\varepsilon}{\varepsilon^3}\big)$ suffices.

Suppose we are in the interval $\mathbb{I}_i$, and the arriving element e has density $v(e)/s(e)$ in level ℓ.

1. If the remaining cascading budget $B_{\ell',i}$ of one of the density levels $\ell' \geq \ell$ is positive then select e. For the smallest $\ell' \geq \ell$ satisfying this condition, update $B_{\ell',i} \leftarrow B_{\ell',i} - s(e)$.
2. Else, if the remaining dedicated budget $\widetilde{B}_\ell$ for level ℓ is positive, select e and update $\widetilde{B}_\ell \leftarrow \widetilde{B}_\ell - s(e)$.

Finally, for $i > 1$, we define the cascading budgets $B_{\ell,i}$ for this interval $\mathbb{I}_i$ based on how much of the budgets at levels ℓ and $\ell - 1$ are consumed in the previous interval $\mathbb{I}_{i-1}$ as follows. The amount of budget $B_{\ell-1,i-1}$ at level $\ell - 1$ that is not consumed in interval $\mathbb{I}_{i-1}$ is moved to level ℓ (which has lower density), and the budget that gets consumed in $\mathbb{I}_{i-1}$ is restored

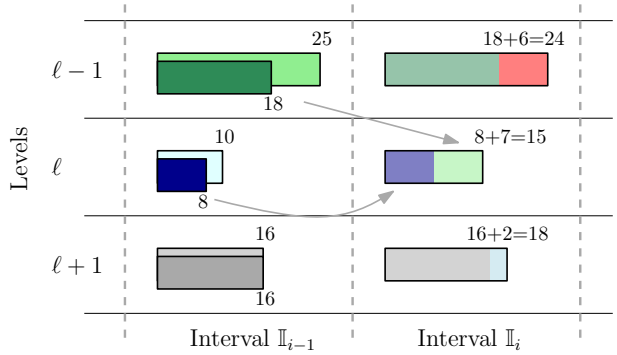

Figure 1 The bars for $\mathbb{I}_{i-1}$ show the budget, and (in darker colors) the amount consumed. The consumed budget (in dark blue) at level ℓ in interval $\mathbb{I}_{i-1}$ is restored at level ℓ in $\mathbb{I}_i$; the unconsumed budget at level $\ell-1$ in interval $\mathbb{I}_{i-1}$ is then added to it.

at level ℓ (see Figure 1). Formally, if $C_{\ell,i-1}$ is the amount of *consumed* cascading budget for level ℓ in interval $\mathbb{I}_{i-1}$ and $R_{\ell,i-1}$ is the amount of *remaining* budget at level ℓ at the end of interval $i-1$ (i.e., the value of $B_{\ell,i-1}$ at the time corresponding to the end of $\mathbb{I}_{i-1}$), then we define the initial budget for level ℓ at the start of interval i to be

$$B_{\ell,i} := C_{\ell,i-1} + R_{\ell-1,i-1}.$$

It is easy to see that we can compute these cascading budgets online.

A Note about Budget Violations. The total budget, summed over both categories and over all the intervals for the cascading budgets, is $K' := ((1/\delta)\cdot\delta K) + L\,H > K$. If we use up all this budget, we would violate the knapsack capacity. Moreover, we select an element as long as the corresponding budget is positive, and hence may exceed each budget by the size of the last element. However, since $K' \le (1+\varepsilon)K$ and K is much larger than individual element sizes, the violations is a small fraction of K, so we can *reject* each element originally selected by the algorithm with some small probability (e.g., $p = 2\varepsilon$) to guarantee that the non-rejected selected elements have size at most K with high probability (i.e., at least $1 - 1/n^c$, for an arbitrary constant $c > 0$). Henceforth, we will not worry about violating the budget.

The Analysis. Recall the benchmark V^* from (3), and let S^* be a set that achieves this value. All the elements have value in $[1/n^2, n^c]$ and size at least $[1/n, 1]$, so each element $e \in S^*$ has a corresponding density level $\ell(e) \in [0\ldots L)$ based on its density $v(e)/s(e)$. We need the notion of "heavy" and "light" levels. For any level $\ell \in [0\ldots L)$, define s^*_ℓ to be the total size of elements in S^* with density level ℓ:

$$s^*_\ell := \textstyle\sum_{e\in S^*:\ell(e)=\ell} s(e). \tag{4}$$

We say a level ℓ is *heavy* if $s^*_\ell \ge H$, else level ℓ is *light*. We refer to (green) elements of S^* at a heavy (resp., light) level as heavy-green (resp., light-green) elements. Note that elements not in S^* (some are red and others green) are left unclassified. If H is sufficiently large, a concentration-of-measure argument using the uniformly random arrival times for green items shows that each heavy level receives $(1-\varepsilon)\delta H$ size during each interval with high probability. The idea of the proof is to argue that the cascading budget never "skips" a heavy level, and hence we get almost all the value of the heavy levels.

To avoid double-counting the values of the light levels, we separately account for the algorithm's value attained (a) on light levels using the dedicated budget or on light-green elements using the cascading budget, and (b) for elements that are not light-green (incl.

red elements) using the cascading budget. Note that (a) and (b) are disjoint, hence their contributions can be added up. We show that (a) exceeds the value of S^* restricted to the light levels, while (b) exceeds $(1-\varepsilon)$ times the value of of S^* on the heavy levels. This is sufficient to prove our result. We start by arguing the former claim.

▷ Claim 8 (Light-Green Elements). The sum of values of elements selected using the dedicated budget at light levels, and of light-green elements selected using the cascading budget, is at least $\sum_{\ell \text{ light}} s^*_\ell \cdot \rho_{\ell+1}$.

Proof. Our algorithm attempts to select each light-green element in S^* using the cascading budget, or failing that, by the dedicated budget at its density level. The only case in which a light-green element $e \in S^*$ is dropped is if all the dedicated budget at its level $\ell(e)$ has been exhausted. But this means the algorithm has already collected at least $s^*_\ell \cdot \rho_{\ell+1}$ from the dedicated budget at this light level ℓ. ◁

Next, to prove that (b) exceeds the value on heavy levels (up to $1-\varepsilon$), we need the following property of the cascading budget on the heavy levels.

▷ Claim 9. For all intervals $\mathbb{I}_i$ and levels ℓ, w.h.p. we have that if $B_{\ell,i} > 0$ then every heavy level $\ell' < \ell$ satisfies $B_{\ell',i} \geq \delta s^*_{\ell'} \cdot (1-\varepsilon)$.

Proof. For a heavy level ℓ', the expected size of heavy-green elements from S^* falling in any interval is $\delta s^*_{\ell'} \geq \delta H$. If $\delta H \geq \frac{\Omega(\log(L/(\delta\varepsilon)))}{\varepsilon^2}$ then with probability $1-\varepsilon$ we get that for each interval i and each heavy level ℓ', the total size of elements from S^* lying at level ℓ' and arriving in interval $\mathbb{I}_i$ is at least $\delta s^*_{\ell'} \cdot (1-\varepsilon)$, by a concentration bound. Henceforth, let us condition on this event happening for all heavy levels ℓ'.

Now if the cascading budget $B_{\ell,i} > 0$, this budget must have gradually come from levels $\ell' < \ell$ of higher densities. But this means $B_{\ell',i} \geq \delta s^*_{\ell'} \cdot (1-\varepsilon)$ because otherwise the cascading budget would never move to level $\ell'+1$, since level ℓ' receives at least $\delta s^*_{\ell'} \cdot (1-\varepsilon)$ size of elements in every interval. ◁

For a level τ let $h^*_{[0,\tau\rangle} := \sum_{\ell' \text{heavy},\ \ell'<\tau} s^*_{\ell'}$ denote the total size of items in S^* restricted to heavy levels from $[0,\tau\rangle$. Similarly, let $h^{\mathcal{A}}_{[0,\tau\rangle}$ be the total size of non-light-green items collected by the algorithm in levels $[0,\tau\rangle$ and charged against the cascading budget.

▷ Claim 10. For all levels τ we have that $h^{\mathcal{A}}_{[0,\tau\rangle} \geq (1-O(\varepsilon))h^*_{[0,\tau\rangle}$.

Proof. Let t be the smallest index of an interval where $B_{\tau,t+1} > 0$. We partition the intervals into two groups: $\mathbb{I}_1, \mathbb{I}_2, \ldots, \mathbb{I}_t$ and $\mathbb{I}_{t+1}, \ldots, \mathbb{I}_{1/\delta}$. From Claim 9 we can conclude that for *each interval* in the latter group, the algorithm collects a total size of at least $\sum_{\ell \text{ heavy},\ \ell<\tau}(1-\varepsilon)\,\delta\, s^*_\ell = (1-\varepsilon)\,\delta\, h^*_{[0,\tau\rangle}$ from levels $[0,\tau\rangle$. Hence the total contribution over all the intervals of the latter group is $(\frac{1}{\delta} - t)(1-\varepsilon)\,\delta\, h^*_{[0,\tau\rangle} = (1-t\delta)(1-\varepsilon)\,h^*_{[0,\tau\rangle}$.

We now consider the group $\mathbb{I}_1, \ldots, \mathbb{I}_t$. Let C_i, R_i and Q_i be the total size of the consumed non-light-green, remaining budget, and consumed light-green elements charged to the cascading budget in interval i with levels $[0,\tau\rangle$. By definition, the total size of all light-green elements is at most LH, giving $\sum_{i=1}^t Q_i \leq LH$. Furthermore, since the full cascading budget is contained in $[0,\tau\rangle$, the algorithm construction guarantees $C_i + R_i + Q_i = \delta K$. Finally, we argue that $\sum_{i=1}^t R_i \leq \delta KL$: consider an infinitesimally small part dB of the budget. At the end of each interval, dB is either used to consume an element or it "moves" from level ℓ to $\ell+1$, which can happen at most L times. Since the total amount of budget per interval is $\int dB = \delta K$, the total sum is at most δKL.

This lower-bounds the total size contribution of the group $\mathbb{I}_{t+1}, \ldots, \mathbb{I}_{1/\delta}$.

$$\begin{aligned}\sum_{i=1}^{t} C_i &= t\delta K - \sum_{i=1}^{t} R_i - \sum_{i=1}^{t} Q_i \quad \geq \quad t\delta K - \delta K L - LH \quad \geq \quad (t\delta - \varepsilon - \varepsilon)K \\ &\geq (t\delta - O(\varepsilon))\, h^*_{[0,\tau\rangle},\end{aligned}$$

where we use $K \geq h^*_{[0,\tau\rangle}$ (since the total size of elements in S^* is at most K), $\delta L \leq \varepsilon$, and $LH \leq \varepsilon K$. Combining contributions from both groups we get:

$$\begin{aligned}(1-t\delta)(1-\varepsilon)\, h^*_{[0,\tau\rangle} + (t\delta - O(\varepsilon))\, h^*_{[0,\tau\rangle} &= [(1-\varepsilon) - t\delta(1-\varepsilon) + t\delta - O(\varepsilon)]\ h^*_{[0,\tau\rangle} \\ &= (1 - O(\varepsilon))\ h^*_{[0,\tau\rangle}.\end{aligned}$$

Hence, we conclude that $h^{\mathcal{A}}_{[0,\tau\rangle} \geq (1 - O(\varepsilon))\, h^*_{[0,\tau\rangle}$. ◁

Using the above claims we now prove Lemma 7.

Proof of Lemma 7. Our fine-grained discretization of densities gives us that

$$V^* \leq (1+\varepsilon)\Bigg(\sum_{\ell \text{ light}} s^*_\ell \rho_{\ell+1} + \sum_{\ell \text{ heavy}} s^*_\ell \rho_{\ell+1}\Bigg). \tag{5}$$

From Claim 8, our algorithm accrues value at least $\sum_{\ell \text{ light}} s^*_\ell \cdot \rho_{\ell+1}$ due to the elements from light levels that were charged to the dedicated budget and light-green elements charged to the cascading budget. It is therefore sufficient to prove a similar bound on the value accrued on non-light-green elements charged to the cascading budget with respect to $\sum_{\ell \text{ heavy}} s^*_\ell \cdot \rho_{\ell+1}$, which we deduce from Claim 10.

Let $\ell'(x)$ be defined as the largest level ℓ' where $\rho_{\ell'} \geq x$, then

$$\begin{aligned}\sum_{\ell \text{ heavy}} s^*_\ell \rho_{\ell+1} &= \int_0^\infty \sum_{\ell \text{ heavy},\ \rho_{\ell+1} \geq x} s^*_\ell \, dx \quad = \quad \int_0^\infty h^*_{[0,\ell'(x)\rangle}\, dx \\ &\leq (1 + O(\varepsilon)) \int_0^\infty h^{\mathcal{A}}_{[0,\ell'(x)\rangle}\, dx,\end{aligned}$$

where the last inequality uses Claim 10. Notice the right-hand side is the value of non-light-green elements charged against the cascading budget. Thus, this part of the algorithm's value exceeds (up to $1 - O(\varepsilon)$) the value of heavy levels of S^*, finalizing our proof. ◀

3.2 An Algorithm for the General Case

To remove the assumption that we know a polynomial approximation to V^*, the idea is to ignore the first ε fraction of the arrivals, and use the maximum value in this interval to get a poly(n) approximation to the benchmark. This strategy is easily seen to work if there are $\Omega(1/\varepsilon)$ elements with a non-negligible contribution to V^*. For the other case where most of the value in V^* comes from a small number of elements, we separately reserve some of the budget, and run a collection of algorithms to catch these elements when they arrive.

Formally, we define $(1/\varepsilon)$ *checkpoints* $T_i := i\varepsilon$ and corresponding intervals $\mathbb{I}_i := \langle T_{i-1}, T_i]$ for all $i \in [1 \ldots (1/\varepsilon)]$. We run the following three algorithms in parallel, and select the union of elements selected by them.

(i) Select one of the n elements uniformly at random; i.e., run Select-Random-Element from §2.1.

(ii) Ignore elements that arrive in times $[0, \varepsilon)$, and let $\hat{v}$ denote the highest of their values. Run the algorithm from §3.1 during time $[1/\varepsilon, 1]$, assuming that $V^* \in [\hat{v}/n^2, \hat{v}\, n^2]$.

(iii) At every checkpoint T_i, consider the largest value $\hat{v}_i$ seen until then. Define $L := \frac{10}{\varepsilon} \log n$ *value levels* as follows: for $\ell \in (-L/2 \dots L/2)$ and $\tau_\ell := \hat{v}_i/(1+\varepsilon)^\ell$, define level $\ell(i)$ as corresponding to values in $(\tau_{\ell(i)+1}, \tau_{\ell(i)}]$. For each of these levels ℓ, keep $D := \frac{10}{\varepsilon} \log \frac{1}{\varepsilon}$ dedicated slots, and select any element having this value level and arriving after T_i, as long as there is an empty slot in its level.

The total space used by the there algorithms is at most

$$1 + K + (1/\varepsilon) \cdot L \cdot D \quad = \quad K + O\Big(\frac{\log n \log {}^1\!/_\varepsilon}{\varepsilon^3}\Big) \quad \leq \quad (1+\varepsilon)K,$$

where the last inequality holds because $K \geq \Omega\big(\frac{L^2 \log(L/\varepsilon)}{\varepsilon^4}\big)$ from the size condition from §3.1. We can now fit this into our knapsack of size K w.h.p. by sub-sampling each selected element with probability $(1 - O(\varepsilon))$. To complete the proof of Theorem 2, we need to show that we get expected value $(1 - O(\varepsilon))V^*$.

Proof of Theorem 2. The proof considers several cases. Firstly, if there is any single element with value more than $n \cdot V^*$, then the algorithm in Step (i) will select it with probability $1/n$, proving the claim. Hence, all elements have value at most nV^*.

Now suppose at least $D = \frac{10}{\varepsilon} \log \frac{1}{\varepsilon}$ elements in S^* (recall S^* has total value V^*) have individual values at least V^*/n^2. In this case, at least one of these D elements arrives in the interval $[0, \varepsilon)$ with probability $1 - \varepsilon$, and that element gives us the desired n^2-approximation to V^*. Moreover, the expected value of elements in S^* arriving in times $[\varepsilon, 1]$ is at least $(1 - O(\varepsilon))\, V^*$, even conditioning on one of them arriving in $[0, \varepsilon)$.

Finally, consider the case where $D' \leq D$ elements of S^* have value more than V^*/n^2. The idea of the algorithm in Step (iii) is to use the earliest arriving of these D' elements, or the element $g_{\max}$, to get a rough estimate of V^*, and from thereon use the dedicated slots to select the remaining elements. Indeed, if the first of these elements arrive in interval $\mathbb{I}_i$, the threshold $\hat{v}_i$ lies in $[V^*/n^2, nV^*]$ (since we did not satisfy the first case above). Now the value levels and dedicated budgets set up at the end of this interval would pick the rest of these D' elements – except those that fall in this same interval $\mathbb{I}_i$. We argue that each of the remaining D' elements has at least $(1 - \varepsilon)$ probability of not being in $\mathbb{I}_i$, which gives us an expected value of $(1 - O(\varepsilon))V^*$ in this case as well. This is true because the expected number of these $1 + D'$ elements (including $g_{\max}$) that land in any interval that contains at least one of them is at most $1 + \varepsilon D'$ (even after we condition on the first arrival, each remaining element has ε chance of falling in this interval). Since any such interval has the same chance of being the first interval $\mathbb{I}_i$, and these $1 + D'$ elements have the same distribution, the expected number of additional elements in $\mathbb{I}_i$ is $\varepsilon D'$. ◀

This completes the proof of Theorem 2 for the knapsack case, where the size K of the knapsack is large enough compared to the largest size of any element. This generalizes the multiple-secretary problem, where all items have unit size. We have not optimized the value of K that suffices, opting for modularity and simplicity. It can certainly be improved further, though getting an algorithm that works under the assumption that $K \geq O(1/\varepsilon^2)$, like in the non-robust case, may require new ideas.

4 Single-Item Ordinal Case

In this section we give a proof of Theorem 4, showing that there exists an algorithm which selects an element with value no smaller than g_2, with probability at least $\Omega(1/\log^2 n)$. Our proof for this theorem is non-constructive and uses (the hard direction of) the Minimax

Theorem; hence we can currently only show the *existence* of this algorithm, and not give a compact description for it. Our main technical lemma furnishes an algorithm which, given a known (general) probability distribution $\mathcal{B}$ over input instances, selects a big element with probability at least $\Omega(1/\log^2 n)$. Consequently, we use the Minimax Lemma to deduce that the known-distribution case is equivalent to the worst-case input setting and recover the analogous result.

Since our algorithms crucially argue about the input distribution $\mathcal{B}$ and rely on the Minimax, we need to formally define these terms and establish notation connecting the Byzantine secretary problem with two-player zero-sum games. Suppose we want to maximize the probability of selecting a big element and to this end we choose an algorithm $\mathcal{A}$, while the adversary chooses a distribution $\mathcal{B}$ over the input instances and there is an (infinite) payoff matrix K prescribing the outcomes. Its rows are indexed by different algorithms, and columns by input instances. Formally, a *"pure" input instance* is represented as an $|R|$-tuple of numbers in $[0,1]$, representing the arrival times t_e of the red elements; and a permutation $\pi \in S_n$ over U representing the total ordering of all values in $U = R \cup G$. Recall that the green elements G choose their arrival times independently and uniformly at random in $[0,1]$, hence their t_e's are not part of the input. A *"mixed" input instance* is a probability distribution $\mathcal{B}$ over pure instances $[0,1]^{|R|} \times S_n$.

While we do not need the full formal specifications of algorithms, we will mention that a "mixed" algorithm $\mathcal{A}$ is a distribution over deterministic algorithms. An algorithm $\mathcal{A}$ on an input instance I gets a payoff of $K(\mathcal{A}, I) := \Pr[v(\mathcal{A}) \geq v(g_2) \mid I]$ where the probability is taken over the assignment of random arrival times to elements in G and the distribution of deterministic algorithms $\mathcal{A}$. The following Lemma states that for each $\mathcal{B}$ there is an algorithm (that depends on $\mathcal{B}$) that selects a big elements with probability $\Omega(1/\log^2 n)$. We prove the result in §4.1 and §4.2.

▶ **Lemma 11** (Known Distribution Ordinal Single-Item Algorithm). *Given a distribution over input instances $\mathcal{B}$, there exists an algorithm $\mathcal{A}$ that has an expected payoff of $\Omega(1/\log^2 n)$.*

To deduce the general case from the known distribution setting, we use a minimax lemma for two-player games. We postpone the details to Appendix C and simply state the final result here.

▶ **Theorem 4** (Ordinal Single-item Algorithm). *There is a randomized algorithm for the ordinal Byzantine secretary which selects an element of value at least the second-largest green item with probability $\Omega(1/\log^2 n)$.*

4.1 The Algorithm when $\mathcal{B}$ is Known

In this section we give the algorithm for Lemma 11. We start with some preliminary notation. For each element e, let t_e denote the time at which it appears. Furthermore, for $t \in [0,1]$, let $\mathcal{K}(t)$ denote the information seen by the algorithm up to and including time t, consisting of arrival times and relative values of elements appearing before t.

We define $\log n + 1$ time *checkpoints* as follows: set the initial checkpoint $T_0 := \frac{1}{4}$, and then subsequent checkpoints $T_i := \frac{1}{4} + \frac{i}{2 \cdot \log n}$ for all $i \in [1 \dots \log n]$. Note that the last checkpoint is $T_{\log n} = \frac{3}{4}$. Now the corresponding intervals are

$$\mathbb{I}_0 := [0, 1/4] \quad , \quad \mathbb{I}_i := \langle T_{i-1}, T_i] \ \forall\, i \in [1 \dots \log n], \quad \text{and} \quad \mathbb{I}_{\log n+1} := \langle 3/4, 1]. \tag{6}$$

Let $m_i := \max\{v(e) \mid e \in R \text{ and } t_e \in \mathbb{I}_i\}$ be the maximum value among the red elements that land in interval $\mathbb{I}_i$, and let $\mathcal{H} := \{m_i > v(g_2) \text{ for all } i \in [1 \dots \log n]\}$ be the event where the maximum value red item in all intervals is larger than the target g_2, i.e., is "big". We

call this event $\mathcal{H}$ the *hard cases* and $\mathcal{H}^c$ the *easy cases*; we will show the Two Checkpoints Secretary (from §2.1) achieves $\Omega(1/\log^2 n)$ winning probability for all input instances in $\mathcal{H}^c$. Finally, define

$$p_e^i := \Pr_{\mathcal{B}}[e = g_2 \mid \mathcal{H} \text{ and } \mathcal{K}(T_i)],$$

i.e., p_e^i is the probability that e is the second-highest green element conditioned on the information seen until checkpoint T_i and the current instance being hard. Importantly, the algorithm can compute p_e^i at T_i.

Now to solve the hard cases, at each checkpoint T_i the algorithm computes sets S_i satisfying $S_{i+1} \subseteq S_i$. These sets represent elements which are candidates for the second-max. In other words, at time T_i there is reasonable probability that second-max is in S_i. We start with defining $S_0 \leftarrow \{e \in U \mid t_e \in \mathbb{I}_0\}$, the elements the algorithm saw before T_0. For $i \geq 0$, let c_i denote the *center* of S_i, i.e., the element of S_i such that there are exactly $\lfloor |S_i|/2 \rfloor$ elements smaller than it. Define $p^i(X) := \sum_{e \in X} p_e^i$ for a set X and index $i \geq 0$. Given S_{i-1}, we determine S_i as follows:

- Define $\mathsf{bot}_{i-1} \leftarrow \{e \in S_{i-1} \mid v(e) \leq v(c_{i-1})\}$, and note that $\mathsf{bot}_{i-1} \subseteq S_{i-1}$.
- If $p^i(\mathsf{bot}_{i-1}) = p^{i-1}(S_{i-1})$ then $S_i \leftarrow \mathsf{bot}_{i-1}$, else $S_i \leftarrow S_{i-1} \setminus \mathsf{bot}_{i-1}$.

Our algorithm runs one of the following three algorithms uniformly at random:

(i) Select a random $i \in [1 \dots \log n]$, define $\tau \leftarrow \max\{v(e) \mid t_e \in \mathbb{I}_i\}$ and select the first element larger than τ. I.e., run Two Checkpoints Secretary (from §2.1) with the checkpoints being the ends of interval $\mathbb{I}_i$.

(ii) Select a random $i \in [0 \dots \log n]$, read input until checkpoint T_i, define $\tau \leftarrow v(c_i)$ and select the first element larger than it.

(iii) Compute the sets S_i until $|S_k| \leq 10$ for some k: then define τ to be the value of a random element in S_k, and select the first element larger than it.

4.2 The Analysis

In this section we prove Lemma 11. Let us give some intuition. We can assume we have a hard case, else the first algorithm achieves $\Omega(1/\log^2 n)$ winning probability. For the other two algorithms, let us condition on g_2 falling in the first interval $\mathbb{I}_0$, and then exploit the fact that there is a big red element in every interval $\mathbb{I}_i$. It may be useful to imagine that we are trying to guess, at each checkpoint, which of the elements in the past were actually g_2. If we could do this, we would set a threshold at its value, and select the first subsequent element bigger than the threshold – and since there is a $1/4$ chance that $g_{\max}$ would fall in $\mathbb{I}_{\log n+1}$, we'd succeed! Of course, since there are red elements all around, guessing g_2 is not straightforward.

So suppose we are at checkpoint T_k, and suppose there is a reasonable probability that $v(g_2) \leq v(c_{k-1})$, but also still some nonzero probability that $v(g_2) > v(c_{k-1})$. In such a scenario, we claim that trying to choose an element in the interval $\mathbb{I}_k$ larger than c_{k-1} will give us a reasonable probability of success. Indeed, we claim there would have been at least one red element in $\mathbb{I}_k$ bigger than c_{k-1} (since there is still a non-zero probability that $v(g_2) > v(c_{k-1})$ even at the end of the interval $\mathbb{I}_k$, and since the case is hard), and $v(g_2) \leq v(c_{k-1})$ with reasonable probability. Of course, we only know this at the end of the interval, but the algorithm can randomly guess k with $\Omega(1/\log n)$ probability. Finally, if there is no such checkpoint, then in every interval we reduce the size of set $|S_i|$ by half while suffering a small loss in $p(S_i)$. In this case, both $|S_{\log n}| = O(1)$ and $p(S_{\log n}) = \Omega(1)$, so the third algorithm can guess g_2 with constant probability and select an element larger than it in the last interval.

Formal Analysis. Let ALG be 1 if $v(\mathcal{A}) \geq v(g_2)$ and 0 otherwise, where $\mathcal{A}$ is the algorithm from the last section. Suppose we're in an easy case, i.e., there is an interval $\mathbb{I}_s$ such that all red elements in this interval are smaller than g_2. Now if the first algorithm is chosen, suppose it selects the interval $\mathbb{I}_s$, suppose g_2 lands in $\mathbb{I}_s$, and $g_{\max}$ lands in $\mathbb{I}_{\log n+1}$. Then the algorithm surely selects an element greater than g_2, and it has expected value:

$$\mathbb{E}[\text{ALG}] \geq \tfrac{1}{3} \cdot \tfrac{1}{\log n} \cdot \tfrac{1}{2 \log n} \cdot \tfrac{1}{4} = \Omega\left(\tfrac{1}{\log^2 n}\right).$$

Henceforth we can assume the case is hard, and hence each interval I_i contains a red element bigger than g_2. We condition on the event that g_2 appears in $\mathbb{I}_0$, which happens with constant probability. Define

$$k^* := \min\left\{i \in [1 \dots \log n] \mid \tfrac{1}{\log n} \leq \tfrac{p^i(\mathsf{bot}_{i-1})}{p^{i-1}(S_{i-1})} < 1\right\},$$

and set $k^* = \log n + 1$ if the above set is empty.

▷ Claim 12. For all $i < k^*$, the probability $p^i(S_i) = \Omega(1)$.

Proof. By definition, $p^0(S_0) = 1$. By our definition of the sets S_i, we know that if $p^i(\mathsf{bot}_{i-1}) = p^{i-1}(S_{i-1})$ then $p^i(S_i) = p^{i-1}(S_{i-1})$. Else since $i < k^*$, we have

$$p^i(S_i) = p^{i-1}(S_{i-1}) - p^i(\mathsf{bot}_{i-1}) \leq p^{i-1}(S_{i-1})(1 - \tfrac{1}{\log n}).$$

Hence, $p^i(S_i) \geq (1 - \frac{1}{\log n})^{\log n} = \Omega(1)$, proving the claim. ◁

Now there are two cases, depending on the value of k^*. Suppose $k^* \leq \log n$. Condition on the event that the second algorithm is chosen, that it chooses the $i^{th} = (k^* - 1)^{th}$ checkpoint, and that $v(g_2) \leq v(c_i)$. By our choice of k^*, we get that $v(g_2) \leq \tau = v(c_i)$ with probability at least $p^i(S_i) \cdot \frac{1}{\log n}$, and by Claim 12 this is $\Omega(\frac{1}{\log n})$. Since the case we are considering is hard and $\Pr[v(g_2) > v(c_i) \mid \mathcal{H} \text{ and } \mathcal{K}(T_{i+1})] > 0$, there is a red element larger than $v(c_i) = \tau$ appearing in $\mathbb{I}_i$. Thus the algorithm will always select an element in this interval. The correct interval is chosen with probability $\frac{1}{\log n}$, so the algorithm's value is

$$\mathbb{E}[\text{ALG}] = \tfrac{1}{3} \cdot \tfrac{1}{\log n} \cdot \Omega\big(\tfrac{1}{\log n}\big) = \Omega\big(\tfrac{1}{\log^2 n}\big).$$

The other case is when $k^* = \log n + 1$. By definition $|S_0| \leq n$ and $|S_i| \leq \lceil |S_{i-1}|/2 \rceil$. Therefore $|S_{\log n}| \leq 10$. Let us condition on the event that the third algorithm is chosen, that $g_{\max}$ appears in $\mathbb{I}_{\log n+1}$, and that the algorithm guesses g_2 correctly. The probability of this event is at least

$$\tfrac{1}{3} \cdot \tfrac{1}{4} \cdot p^{\log n}(S_{\log n}) \cdot \tfrac{1}{10} = \Omega(1).$$

where we use Claim 12 to bound the probability $p^{\log n}(S_{\log n})$. In this event, the algorithm selects an element larger than g_2 and has expected value $\mathbb{E}[\text{ALG}] = \Omega(1)$.

Putting all these cases together, we get that our algorithm selects an element with value at least $v(g_2)$ with probability at least $\Omega((\log n)^{-2})$. This finishes the proof of Lemma 11, and hence of Theorem 4. It remains an intriguing open question to get a direct algorithm that achieves similar guarantees.

5 Single-Item Value-Maximization

In this section, we give an algorithm for the problem of selecting an item to maximize the expected *value*, instead of maximizing the probability of selecting the second-largest green item (the ordinal problem considered in §4). In the classical secretary problem, both problems are well known to be equivalent, with Dynkin's algorithm giving a tight $1/e$ bound for both. But in the Byzantine case the problems thus far appear to have different levels of complexity: in §6.2 we present a simple $O(\log n)$-competitive algorithm for the value-maximization byzantine secretary problem, which is already better than the $\operatorname{poly}\log n$-competitive of §4. We now substantially improve it to give a $\operatorname{poly}\log^* n$-competitive ratio.

▶ **Theorem 3** (Value Maximization Single-Item). *There is a randomized algorithm for the value-maximization (single-item) Byzantine secretary problem which gets an expected value at least* $(\log^* n)^{-2} \cdot V^*$.

In the rest of this section, let $V^* := v(g_2)$ denote the benchmark, the value of the second-largest green element. The high level idea of our algorithm is to partition the input into $O(\log^* n)$ intervals and argue that every interval contains a red element of value $v_i > V^*$, as otherwise Dynkin's algorithm will be successful. Moreover, this v_i cannot be much larger than V^*, as otherwise we can just select a random element. This implies we can use the largest value in each interval to find a good estimate of V^*, and eventually set it as a threshold in the last interval to select a large value element.

5.1 The Algorithm

Define $\log^{(i)} n$ to be the *iterated logarithm* function: $\log^{(0)} n = n$ and $\log^{(i+1)} n = \log(\log^{(i)} n)$. We define $\log^* n + 1$ time *checkpoints* as follows: the initial checkpoint $T_0 = \frac{1}{2}$, and then subsequent checkpoints $T_i = \frac{1}{2} + \frac{i}{4 \cdot \log^* n}$ for all $i \in [1, \ldots, \log^* n]$. Note that the last checkpoint is $T_{\log^* n} = \frac{3}{4}$. Now the intervals are

$$\mathbb{I}_0 := [0, T_0] \quad , \quad \mathbb{I}_i := \langle T_{i-1}, T_i] \; \forall \, i \in [1 \ldots \log^* n], \quad \text{and} \quad \mathbb{I}_{\log^* n + 1} := \langle T_{\log^* n}, 1]. \tag{7}$$

Our algorithm runs one of the following three algorithms chosen uniformly at random.

- **(i)** Select one of the n elements uniformly at random; i.e., run Select-Random-Element from §2.1.
- **(ii)** Select a random interval $i \in [1 \ldots \log^* n]$ and run Dynkin's secretary algorithm on $\mathbb{I}_i$. Formally, run Two-Checkpoints-Secretary (from §2.1) with the interval being $[T_{i-1}, \frac{1}{2}(T_{i-1} + T_i)]$.
- **(iii)** Select a random index $i \in [0 \ldots \log^* n]$ and observe the maximum value during the interval $\mathbb{I}_i$; let this maximum value be v_i. Choose a uniformly random $s \in [0 \ldots 2 \log^{(i)} n]$. Select the first element arriving after T_i that has value at least $\tau := (v_i \log^{(i)} n)/2^s$.

5.2 The Analysis

To prove Theorem 3, assume WLOG that there are only two green elements $g_{\max}$ and g_2, and every other element is red (otherwise, we can condition on the arrival times of all other green elements). Let v_i be the value of the highest red element in $\mathbb{I}_i$, i.e., excluding $g_{\max}$ and g_2.

Proof of Theorem 3. We assume $\log^{(i)} n$ is an integer for all i; this is true with a constant factor loss. For sake of a contradiction, assume that the algorithm in §5.1 does not get expected value $\Omega((\log^* n)^{-2}V^*)$. Under this assumption, we first show that every interval contains a red element of value at least V^*.

▷ Claim 13. For all $j \in [1 \dots \log^* n]$ we have $v_j \geq V^*$.

Proof. Suppose this is not the case. Let $\mathcal{E}_1$ be the event that the following three things happen simultaneously: that we select Algorithm ii in §5.1 with random variable $i = j$, that the second-highest green element g_2 falls in the interval $[T_{i-1}, \frac{1}{2}(T_{i-1}+T_i)\rangle$, and that the highest green element $g_{\max}$ falls in $\mathbb{I}_{\log^* n+1}$. Note that $\Pr[\mathcal{E}_1] = \frac{1}{3\log^* n} \cdot \frac{1}{4\log^* n} \cdot \frac{1}{4} = \Omega((\log^* n)^{-2})$. Conditioned on this event $\mathcal{E}_1$, our algorithm (or specifically, Algorithm ii on the interval $\mathbb{I}_j$) gets a value at least $v(g_2) = V^*$. Hence the algorithm has expected valuation $\Omega\big((\log^* n)^{-2}V^*\big)$, which is a contradiction to our assumption on its performance. ◁

We now prove that these red elements with large values cannot be much larger than V^*.

▶ **Lemma 14.** *For all $j \in [1 \dots \log^* n]$ we have $v_j \leq V^* \cdot \log^{(j-1)} n$.*

Proof. We prove this lemma by induction. The base case $j = 1$ says $v_1 \leq nV^*$, i.e., the highest observed value in $\mathbb{I}_1 = [T_0, T_1\rangle$ is at most nV^*. Suppose this is not the case – there exists a red element e in $\mathbb{I}_1$ with value at least nV^*. Let $\mathcal{E}_1$ be the event that we select Algorithm i in §5.1 (i.e., Select-Random-Element) and that it selects e. Since $\Pr[\mathcal{E}_1] = \Omega(\frac{1}{n})$, we have a contradiction that the expected valuation is $\Omega(V^*)$.

Now suppose the statement is true until $j \geq 1$. We prove the inductive step $j+1$. Suppose not, i.e., $v_{j+1} > V^* \log^{(j)} n$. Let $\mathcal{E}_2$ be the event that we select Algorithm iii in §5.1 with parameter $i = j$ and that the random $s \in [0 \dots 2\log^{(j)} n]$ is such that $\frac{v_j}{2^{s+1}} \leq V^* < \frac{v_j}{2^s}$ (it exists by induction hypothesis). This implies threshold $\tau := \frac{v_j \log^{(j)} n}{2^s}$ is between $\frac{1}{2}V^* \log^{(j)} n$ and $V^* \log^{(j)} n$. Note $\Pr[\mathcal{E}_2] \geq \frac{1}{3} \cdot \frac{1}{\log^* n} \cdot \frac{1}{2\log^{(j)} n}$. Since event $\mathcal{E}_2$ implies the algorithm gets value at least $\tau \geq \frac{1}{2}V^* \log^{(j)} n$ (because $v_{j+1} > \tau$), its expected value is $\Omega((\log^* n)^{-1}V^*)$, a contradiction. ◀

Now by Claim 13 and Lemma 14, we have $v_j \in [V^*, V^* \cdot \log^{(j)} n]$ for all $j \in [1 \dots \log^* n]$. We still get a contradiction. Let $\mathcal{E}_3$ be the event that the following three things happen simultaneously: that we select Algorithm iii in §5.1 with $i = \log^* n$, that the highest green element $g_{\max}$ is in interval $\mathbb{I}_{\log^* n+1}$, and that we select s in Algorithm iii such that $\tau := (v_{\log^* n} \log^{(j)} n)/(2^s)$ is between $\frac{1}{2}V^*$ and V^*. Note $\Pr[\mathcal{E}_3] \geq \frac{1}{3\log^* n} \cdot \frac{1}{4} \cdot \frac{1}{2\log^* n}$. Since the event $\mathcal{E}_2$ implies the algorithm gets value at least $\tau \geq \frac{1}{2}V^*$ (because $g_{\max}$ is in $\mathbb{I}_{\log^* n+1}$), its expected value is $\Omega((\log^* n)^{-2}V^*)$. Thus, we have a contradiction in every case, which means our assumption is incorrect and the algorithm has expected value $\Omega((\log^* n)^{-2}V^*)$. ◀

6 Value Maximization for Matroids

In this section we discuss multiple-choice Byzantine secretary algorithms in the matroid setting.

▶ **Definition 15** (Byzantine secretary problem on matroids). *Let $\mathcal{M}$ be a matroid over $U = R \cup G$, where elements in $G = \{g_{\max}, g_2, \dots, g_{|G|}\}$ arrive uniformly at random in $[0, 1]$. When an element $e \in U$ arrives, the algorithm must irrevocably select or ignore e, while ensuring that the set of selected elements forms an independent set in $\mathcal{M}$. The leave-one-out benchmark V^* is the highest-value independent subset of $G \setminus \{g_{\max}\}$.*

The knapsack results imply $(1-\varepsilon)$-competitiveness for uniform matroids as long as the rank r is large enough; we now consider other matroids.

6.1 $O(\log\log n)^2$-competitiveness for Partition Matroids

A partition matroid is where the elements of the universe are partitioned into parts $\{P_1, P_2, \ldots\}$. Given some integers $r_1, r_2, \ldots$, a subset of elements is independent if for every i it contains at most r_i element from part P_i.

▶ **Theorem 5** (Partition Matroids). *There is an algorithm for Byzantine secretary on partition matroids that is $O(\log\log n)^2$-competitive with the benchmark V^*.*

We prove Theorem 5 for simple partition matroids where all $r_i = 1$, i.e., we can select at most one element in each part. This is without loss of generality (up to $O(1)$ approximation) because we can randomly partition each part P_i further into r_i parts and run the simple partition matroid algorithm.

Recall that our single item $\operatorname{poly}\log^* n$ algorithm from §5 no longer works for partition matroids. This is because besides one part we want to get the highest green element in all the other parts. Formally, Claim 13 where we use Dynkin's secretary algorithm in the proof of Theorem 3 fails because it needs at least two green elements. So we need to overcome the lower bound to getting the highest-value green element $v(g_1)$ in Observation 19. We achieve this and design an $O(\log\log n)^2$-approximation algorithm by making an assumption that the algorithm starts with a polynomial approximation to $v(g_1)$. Although in general this is a strong assumption, it turns out that for partition matroids this assumption is w.l.o.g. because the algorithm may lose the highest green element in one of the parts.

6.1.1 The Algorithm

We define $\log\log n + 1$ time *checkpoints* as follows: the initial checkpoint $T_0 = \frac{1}{2}$, and then subsequent checkpoints $T_i = \frac{1}{2} + \frac{i}{2\cdot\log\log n}$ for all $i \in [1 \ldots \log\log n]$. Now the corresponding intervals are

$$\mathbb{I}_0 := [0, T_0] \quad \text{and} \quad \mathbb{I}_i = \langle T_{i-1}, T_i] \quad \forall\, i \in [1 \ldots \log\log n] \tag{8}$$

Let v_0 denote the value of the max element seen by the algorithm in $\mathbb{I}_0$.

Now for every part P of the partition matroid, we execute the following algorithm separately. Let v_i for $i \in [1 \ldots \log\log n]$ denote the value of the max element seen by the algorithm *in part* P during interval $\mathbb{I}_i$. Let V^* denote the element of our benchmark in P. Notice that $v_i \in P$ and V^* cannot be the overall highest green element as we exclude it. We define $4\log^{1/i} n$ levels for $\mathbb{I}_i$ where *level* j for $j \in [1 \ldots 4\log^{1/i} n]$ is given by elements with values in

$$\Big[\frac{v_{i-1}\cdot\log^{1/i} n}{2^j}, \frac{v_{i-1}\cdot\log^{1/i} n}{2^{j-1}}\Big].$$

We run one of the following algorithms uniformly at random.

(a) Select an element uniformly at random as discussed in §2.1.
(b) For every part P, select a random interval $i \in [1 \ldots \log\log n]$ and select a random level $j \in [4\log^{1/i} n]$. Select the first element above $\frac{v_{i-1}\cdot\log^{1/i} n}{2^j}$ in P.
(c) For every part P, select a random interval $i \in [1 \ldots \log\log n]$ and if there is an element with value more than $2^{\log^{1/i} n}$ times the max of all the already seen elements in $\mathbb{I}_i$, selects it with constant probability, say $1/100$.

6.1.2 The Analysis

Since with constant probability our algorithm selects one of the n elements uniformly at random (Algorithm a), we can assume that $v_0 \le n^2 \cdot V^*$. We always condition on the event that $g_{\max}$ arrives in the interval $\mathbb{I}_0$, which happens with constant probability and implies $v_0 \ge v(g_{\max})$. Moreover, we ignore parts P where V^* is below $v(g_{\max})/n^2$ because they do not contribute significantly to the benchmark. So from now assume

$$V^*/n^2 \le v_0 \le n^2 \cdot V^*.$$

We design an algorithm that gets value $\Omega(V^*/(\log\log n)^2)$ in each part P, which implies Theorem 5 by linearity of expectation over parts.

Let $v_i^{(\text{red})} \in P$ for $i \in [1 \dots \log\log n]$ denote the value of the max red element that the adversary presents in $\mathbb{I}_i$.

▷ Claim 16. If there exists an $i \in [1 \dots \log\log n]$ with $v_i^{(\text{red})} > V^* \cdot \log^{1/i} n$ then the expected value of the algorithm is $\Omega(V^*/\log\log n)$.

Proof. With constant probability, our algorithm selects a random interval i and selects a random level element in it (Algorithm b). Since w.p. $1/\log\log n$ it selects this i, and w.p. $\frac{1}{4}\log^{1/i} n$ it selects the random level of $v_i^{(\text{red})}$ in $\mathbb{I}_i$, the algorithm has expected value at least

$$\frac{1}{\log\log n} \cdot \frac{1}{4\log^{1/i} n} \cdot v_i^{(\text{red})} \ge \frac{1}{4\log\log n} \cdot V^*. \qquad \triangleleft$$

By the last claim we can assume for all $i \in [1 \dots \log\log n]$, we have $v_i^{(\text{red})} \le V^* \cdot \log^{1/i} n$.

▷ Claim 17. If there exists an $i \in [1 \dots \log\log n]$ with $v_i^{(\text{red})} < V^*/2^{\log^{1/i} n}$ then the expected value of the algorithm is $\Omega(V^*/(\log\log n)^2)$.

Proof. With constant probability the algorithm guesses one of the intervals i and if there is an element with value more than $2^{\log^{1/i} n}$ times the max of all the already seen elements in $\mathbb{I}_i$, selects it with constant probability (Algorithm c). With $1/\log\log n$ probability the algorithm selects this particular i and with $1/\log\log n$ probability V^* appears in this interval with value at least $2^{\log^{1/i} n}$ times the max seen element in this interval. Notice there can be at most $O\left(\frac{4\log^{1/i} n}{\log^{1/i} n}\right) = O(1)$ elements with such large jumps in value in this interval. In this case our algorithm selects V^* with constant probability. $\triangleleft$

Finally, we are only left with the case where for all $i \in [1 \dots \log\log n]$ value $\frac{V^*}{2^{\log^{1/i} n}} \le v_i^{(\text{red})} \le V^* \cdot \log^{1/i} n$, which we handle using Algorithm b.

▷ Claim 18. If for all $i \in [1 \dots \log\log n]$ we have

$$\frac{V^*}{2^{\log^{1/i} n}} \le v_i^{(\text{red})} \le V^* \cdot \log^{1/i} n$$

then the expected value of the algorithm is $\Omega(V^*/(\log\log n)^2)$.

Proof. Consider Algorithm b. It selects $i = \log\log n - 1$ w.p. $1/\log\log n$. Moreover, suppose V^* appears in $\mathbb{I}_{\log\log n - 1}$. Now since there are only a constant number of levels in this interval, our algorithm selects an element of value at least V^* with constant probability. $\triangleleft$

We have shown that in every case the algorithm has expected value $\Omega(V^*/(\log\log n)^2)$ for any fixed part P. This implies Theorem 5 by linearity of expectation over parts.

6.2 $O(\log n)$-approx for General Matroids

▶ **Observation 6** (General Matroids). *There is an algorithm for Byzantine secretary on general matroids that is $O(\log n)$-competitive with the benchmark V^*.*

Proof. Notice that no element can have weight more than nr times the second max-element because w.p. $1/n$ our algorithm selects one of the n elements uniformly at random. Given this, condition on the event that the max element with value v lands in the first half of the input. Define $2\log(nr)$ exponentially separated levels as follows:

$$[\frac{v}{2^{\log(nr)}}, \frac{v}{2^{\log(nr)-1}}\rangle, [\frac{v}{2^{\log(nr)-1}}, \frac{v}{2^{\log(nr)-2}}\rangle, \ldots, [\frac{v}{2}, v\rangle, \ldots, [v2^{\log(nr)-1}, v2^{\log(nr)}\rangle.$$

Since at least one of these intervals contains at least $2\log(nr)$ fraction of OPT, we can guess that interval and run a greedy algorithm, i.e., accept any element with value in that interval or above if it is independent. ◀

7 Conclusion

In this paper we defined a robust model for the secretary problem, one where some of the elements can arrive at adversarially chosen times, whereas the others arrive at random times. For this setting, we argue that a natural is the optimal solution on all but the highest-valued green item (or even simpler, the optimal solution on the green items, minus the single highest-value item). This benchmark reflects the fact that we cannot hope to compete with the red (adversarial) items, and also cannot do well if all the green value is concentrated in a single green item.

We show that for the case where we want to pick K items, or if we have a knapsack of size K, we can get within $(1-\varepsilon)$ of this benchmark, assuming K is large enough. We can also get non-trivial results for the single-item case, where our benchmark is now the second-highest valued green item. In the ordinal setting where we only see the relative order of arriving elements and the goal is to maximize the probability of getting an element whose value is above the benchmark, we use the minimax principle to show existence of an $O(\log^2 n)$-approximation algorithm in §4. In the value maximization setting, we give an $O(\log^* n)^2$-approximation algorithm in §5. We also show $O(\log\log n)$-competitiveness for partition matroids.

The results above suggest many question. Can we improve the lower bound on the size required for $(1-\varepsilon)$-competitiveness? Can we get a constant-competitive algorithm for the single-item case? For the probability-maximization problem, our proof only shows the existence of an algorithm; can we make this constructive? More generally, many of the algorithms for secretary problems seem to overfit to the model, at least in the presence of small adversarial changes: how can we make our algorithms robust?

A Hard Benchmarks

We show that for the benchmark $V^* := v(g_{max})$, every algorithm has an approximation of at most $O(1/n)$.

▶ **Observation 19** (Lower Bound for $g_{\max}$)**.** *Any randomized algorithm for the single-item Byzantine secretary problem cannot select the highest-value good/green item with probability larger than* $1/(|R|+1)$.

Proof. We use Yao's minimax lemma, so it is enough to construct an input distribution $\mathcal{B}$ for which no deterministic algorithm can achieve an approximation better than $\frac{1}{|R|+1}$. The distribution is as follows. The red elements arrive at random times, that is $(t_{r_1}, t_{r_2}, ...t_{r_{|R|}}) \sim U[0,1]^{|R|}$. The linear ordering among the elements is set such that the red elements are strictly increasing according to their arrival time, or formally: $t_{r_i} > t_{r_j} \implies v(r_i) > v(r_j)$. The maximum element is green and all the other green elements are smaller than all red elements. Formally: $v(g_{max}) > v(r_1) > v(r_2)... > v(r_{|R|}) > v(g_2) > v(g_3) \ldots > v(g_{|G|})$. This fully defines the input distribution.

All the arrival times are distinct with probability 1. Let $\mathcal{K}(t)$ denote the information seen by the algorithm up to and including time t. Partition the probability space according to $S := \{t_{g_{max}}, t_{r_1}, t_{r_2}, ...t_{r_{|R|}}\}$ and $L := (t_{g_2}, t_{g_3}, ...t_{g_{|G|}})$. Let $s_1 < s_2 < ... < s_{|R|+1}$ be the elements of S. Let $M_i := \{t_{g_{max}} = s_i\}$. By definition, we have $Pr[M_i|S,L] = \frac{1}{|R|+1}$. Note that, since the red items arrive in increasing order of value and the green item has maximum value, we have $Pr[M_i|S,L,\mathcal{K}(t)] = Pr[M_j|S,L,\mathcal{K}(t)]$ for all $t \le s_i, s_j$. Therefore, $Pr[M_i|S,L,\mathcal{K}(s_i)] \le \frac{1}{|R|+2-i}$. In other words, there is no way to distinguish the maximum green element from the red elements before it is too late, that is at the time of the green element's arrival. Thus, by a simple inductive argument, the proof is finished. ◀

Using techniques presented in [7], we can extend this result to the value case as well.

B Relaxing the Assumption that n is Known

In this section we extend our results to some settings where n is unknown. Most importantly, observe that all of the results in this paper hold even if n is *known only up to a constant factor* with at most a constant factor degradation in the quality of the result. As a simple example, note that picking a uniformly random element from an n-element sequence when the assumed number of elements is $\tilde{n} \in [n, 2n]$ will select an element $x \in U$ with probability $p_x \in [\frac{1}{2n}, \frac{1}{n}]$, leading to a degradation in the result by a factor of at most 2, which we typically ignore in this paper.

This still leaves us open to the possibility that we do not even know the scale of n. Surprisingly, it is still possible to "guess" $\tilde{n}$ while only incurring a loss of $\widetilde{O}(\log n)$ in the quality, even if there is no prior known upper limit on n.[1] The following claim formalizes this result.

▷ Claim 20. There exists a distribution X over the integers such that for every $n \ge 1$ the probability that the sampled number $\tilde{n} \sim X$ is within a constant factor of n, is at least $1/\widetilde{O}(\log n)$.

[1] By $\widetilde{O}(f(n))$ we mean $f(n) \cdot \text{poly}(\log f(n))$.

Proof. Consider the sequence $a_k := \frac{1}{k(\log_2 k)(\log_2 \log_2 k)^2}$ defined for $k \geq 2$. It is well-known that this sequence converges, i.e., $\sum_{k=2}^{\infty} a_k = O(1)$. A simple way to see this is by noting that a non-negative decreasing sequence $(A_k)_k$ converges if and only if $(2^k A_{2^k})_k$ converges [40, Thm 3.27].

Let $\sum_k^\infty A_k \sim \sum_k^\infty B_k$ be the equivalence relation denoting that $(A_k)_k$ and $(B_k)_k$ either both converge or both diverge. Then the above fact implies that $\sum_k^\infty \frac{1}{k \log_2 k (\log_2 \log_2 k)^2} \sim \sum_k^\infty \frac{1}{k(\log_2 k)^2} \sim \sum_k^\infty \frac{1}{k^2}$, where the last sequence clearly converges.

We can assume without loss of generality that $n \geq 100$ by handling those cases separately. The strategy for guessing the estimate $\tilde{n}$ is now immediate: we sample $\tilde{n}$ from $\mathbb{Z}_{\geq 2}$ according to the distribution $\Pr[\tilde{n} = k] = a_k/Z$ where $Z := \sum_{k=100}^{\infty} a_k = O(1)$. We observe that $\Pr[\tilde{n} \in \langle 2^{k-1} \dots 2^k]] \geq \frac{1}{2} 2^k a_{2^k}/Z = \widetilde{\Omega}(1/k)$. Let k' be the unique index such that $n \in \langle 2^{k'-1} \dots 2^{k'}]$, hence $k' = \Theta(\log n)$. Then $\Pr[\tilde{n} \in \langle 2^{k'} \dots 2^{k'+1}]] = \widetilde{\Omega}(1/k') = \widetilde{\Omega}(1/\log n)$. But also in that case we have that $n \in [\tilde{n}/4, \tilde{n}]$ and we are done. ◁

Finally, consider an important case where the fraction of red elements is bounded away from $1 - \Omega(1)$. This is a reasonable assumption for most applications, e.g., online auctions, where we do not expect that most of the arrivals will be chosen by an adversary. By simply observing the first half of the sequence, i.e., $[0, 1/2\rangle$, we can typically estimate n up to a constant while degrading the expected output of our algorithms by at most a constant factor.

▷ Claim 21. If there is a constant $\varepsilon < 1$ such that the fraction of red elements $\frac{|R|}{|R|+|G|} \leq \varepsilon$ then we can estimate n up to a constant factor by time $t = 1/2$.

Proof. We run a simple preprocessing step to estimate n up to a constant factor by $t = 1/2$. Notice that the expected number of green elements to arrive in the interval $[0, 1/2\rangle$ is $0.5 \cdot |G| = 0.5 \cdot n(1 - \varepsilon) = \Omega(n)$. Since by simple Chernoff bounds this means that w.h.p. we see $\Omega(n)$ elements in the first half, we run a simple algorithm that does not select any element till $t = 1/2$, and then use the number of elements that arrive in $[0, 1/2\rangle$ as an estimate of n. ◁

C Minimax

In this section we argue that an α-payoff (i.e., the probability of selecting the second-max element or better is at least α) known distribution algorithm for the ordinal single-item Byzantine secretary implies an α-payoff algorithm for the general, worst-case input, setting. This can be directly modeled as a two-player game where player A chooses an algorithm $\mathcal{A}$ and player B chooses a distribution over the input instances $\mathcal{B}$. Our coveted result would go along the lines of

$$\sup_{\mathcal{A}} \inf_{\mathcal{B}} K(a, b) = \inf_{\mathcal{B}} \sup_{\mathcal{A}} K(\mathcal{A}, \mathcal{B}),$$

where $K(\mathcal{A}, \mathcal{B})$ denotes the payoff when we run algorithm $\mathcal{A}$ on the input distribution $\mathcal{B}$. The left-hand side denotes the worst-case input setting, while the right-hand side denotes the known distribution setting.

The main challenge in proving such a claim stems from the infiniteness of the set of algorithms and set of input distributions. Indeed, if one makes no finiteness assumption for either A or B, the Minimax property can fail even for relatively well-behaved two-player games [37]. On the other hand if both A and B would be finite, then the result would follow from the classic Von Neumann's Minimax [36].

▶ **Fact 22** (Von Neumann's Minimax). *Let A and B be finite sets. Denote by $\mathcal{D}(A)$ and $\mathcal{D}(B)$ distributions over A and B, respectively. Then for any matrix of values $K : A \times B \to \mathbb{R}$ it holds that*

$$\max_{a\in\mathcal{D}(A)} \min_{b\in\mathcal{D}(B)} K(a,b) = \min_{b\in\mathcal{D}(B)} \max_{a\in\mathcal{D}(A)} K(a,b). \tag{9}$$

The infiniteness of the sets stems from the arrival times being in the infinite set $[0,1]$. To solve this issue, we slightly modify our algorithm by discretizing $[0,1]$. Let $N = n^3, \mathcal{T} := \{\frac{0}{N}, \frac{1}{N}, \frac{2}{N}, \ldots, \frac{N}{N}\}$ and $\Phi : [0,1] \to \mathcal{T}, \Phi(t) := \lfloor N \cdot t \rfloor / N$ be the discretizing function. We modify our algorithm in the following way: apply Φ to the input distribution $\mathcal{B}$, as well as to every arrival time. Note that the elements are presented to the algorithm exactly as before, it just *pretends* they arrive in discrete time steps. We can assume $\Phi(t_e) \neq \Phi(t_g)$ for every $e \in U, g \in G, e \neq g$ (otherwise, we say the algorithm loses), since this happens with at most $n^2/N = o(1)$ probability. Using completely analoguous techniques as in Section 4 we can show this algorithm is $\Omega(1/\log^2 n)$-competitive.

We note that a randomized algorithm is simply a distribution over deterministic algorithms. Hence our second goal is to argue that the number of distinct deterministic algorithms is finite (i.e., bounded by a function of n). To this end we have to specify how we represent them with at least some formality. We identify a deterministic algorithm $\mathcal{A}$ with a function that gets evaluated each time a new element arrives; its parameter is the information history $\mathcal{K}(t)$ (t being the current time) represented in any appropriate format; its output is $\{\bot, \top\}$ representing whether to select the current element. For concreteness, the information history consists of (t_e, π_e) for every element e that arrived before the function call, where $t_e \in \mathcal{T}$ is the discretized arrival time (after applying Φ) and $\pi_e \in [0 \ldots n-1]$ is the relative value order of e with respect to prior arrived elements. The number of distinct histories is bounded by $((N+1)n)^n$, a function of n; therefore the set of deterministic algorithms, i.e., functions from the history to $\{\bot, \top\}$, is also bounded.

We remember that an input distribution is simply a distribution over "pure" inputs. Note that the payoff of a deterministic algorithm for a specific input depends only on the following: $\Phi(t_r)$ for every red element; $\pi \in S_n$, the permutation representing the total order among the elements; and $\pi_t \in S_{|R|}$, the permutation denoting the order in which the red elements arrive (since red elements can have the same discretized arrival time, but an arbitrary order in which they are presented to the algorithm). The above discretization makes the number of pure inputs at most $(n!)^2 \cdot (N+1)^n$, i.e., bounded by a function of n. The reader can refresh their memory about the representation of pure inputs by reviewing the introduction to Section 4.

Finally, for our discretized algorithm, we proved that the set of pure inputs with different payoffs, as well as the number of deterministic algorithms is bounded by a function of n. Therefore, for a fixed n, both numbers are finite. We invoke the Von Neumann's Minimax (Fact 22) to conclude that the best result in the known distribution setting and worst-case input setting are equivalent, recovering the following theorem.

▶ **Theorem 4** (Ordinal Single-item Algorithm). *There is a randomized algorithm for the ordinal Byzantine secretary which selects an element of value at least the second-largest green item with probability $\Omega(1/\log^2 n)$.*

Universal Communication, Universal Graphs, and Graph Labeling

Nathaniel Harms
University of Waterloo, Canada
https://cs.uwaterloo.ca/~nharms
nharms@uwaterloo.ca

Abstract

We introduce a communication model called *universal SMP*, in which Alice and Bob receive a function f belonging to a family $\mathcal{F}$, and inputs x and y. Alice and Bob use shared randomness to send a message to a third party who cannot see f, x, y, or the shared randomness, and must decide $f(x, y)$. Our main application of universal SMP is to relate communication complexity to graph labeling, where the goal is to give a short label to each vertex in a graph, so that adjacency or other functions of two vertices x and y can be determined from the labels $\ell(x), \ell(y)$. We give a universal SMP protocol using $O(k^2)$ bits of communication for deciding whether two vertices have distance at most k in distributive lattices (generalizing the k-Hamming Distance problem in communication complexity), and explain how this implies a $O(k^2 \log n)$ labeling scheme for deciding $\mathsf{dist}(x, y) \leq k$ on distributive lattices with size n; in contrast, we show that a universal SMP protocol for determining $\mathsf{dist}(x, y) \leq 2$ in modular lattices (a superset of distributive lattices) has super-constant $\Omega(n^{1/4})$ communication cost. On the other hand, we demonstrate that many graph families known to have efficient adjacency labeling schemes, such as trees, low-arboricity graphs, and planar graphs, admit constant-cost communication protocols for adjacency. Trees also have an $O(k)$ protocol for deciding $\mathsf{dist}(x, y) \leq k$ and planar graphs have an $O(1)$ protocol for $\mathsf{dist}(x, y) \leq 2$, which implies a new $O(\log n)$ labeling scheme for the same problem on planar graphs.

1 Introduction

In the simultaneous message passing (SMP) model of communication, introduced by Yao [34], Alice and Bob separately receive inputs x and y to a function f. They send messages $a(x), b(y)$ to a third party, called the referee, who knows f and must output $f(x, y)$ (with high probability) using the messages $a(x), b(y)$. But what if the referee *doesn't* know f? Can they still compute $f(x, y)$? Yes: Alice can include in her message a description of f, and then

the referee knows it; however, if f is restricted, they can sometimes do much better. Here is a simple example: the players receive vertices $x, y \in \{1, \ldots, n\}$ in a graph G of maximum degree 2, and want to decide if (x, y) is an edge in G. Sharing a source of randomness, Alice and Bob randomly label each vertex of G with a number up to 200; Alice sends the label of both neighbors of x and Bob sends the label of y. The referee says *yes* if one of Alice's labels matches the label of y, *no* otherwise. They will be correct with probability at least 99/100, and the referee never needs to learn G. This is also an example where the referee can decide many problems using only one strategy. In this work we will see that more interesting families of graphs, such as trees, planar graphs, and distributive lattices, also exhibit these phenomena, even when we wish to compute *distances* instead of just adjacency.

To study this, we introduce the *universal SMP* model, which operates as follows. Fix some family $\mathcal{F}$ of functions. Alice and Bob receive a function $f \in \mathcal{F}$ and inputs x, y, and they use shared randomness to each send one message to the referee. The referee knows the family $\mathcal{F}$ and the size of the inputs, but doesn't know f, x, y or the shared randomness, and must compute $f(x, y)$ with high probability. By choosing the family $\mathcal{F}$ to be the singleton family, one sees that this model includes standard SMP. As in the earlier example, we will be studying communication problems on graphs, but this is not a significant restriction: every Boolean-valued communication problem f is equivalent to determining adjacency in some graph (use f as the adjacency matrix), so we will treat $\mathcal{F}$ as a family of graphs.

A surprising but intuitive application of universal SMP is that it connects two apparently disjoint areas of study: communication complexity and graph labeling. For a graph family $\mathcal{F}$, the graph labeling problem (introduced by Kannan, Naor, and Rudich [23]) asks how to assign the shortest possible labels $\ell(v)$ to each vertex v of a graph $G \in \mathcal{F}$, so that the adjacency (or some other function [29]) of vertices x, y can be computed from $\ell(x), \ell(y)$ by a decoder that knows $\mathcal{F}$. We observe the following principle (Theorem 1.1):

If there is a (randomized) universal SMP protocol for the graph family $\mathcal{F}$ with communication cost c, then there is a labeling scheme for graphs $G \in \mathcal{F}$ with labels of size $O(c \log n)$, where n is the number of vertices.

Common variants of graph labeling are *distance labeling* [15], where the goal is to compute $\mathsf{dist}(x, y)$ from the labels, and *small-distance* labeling, where the goal is to compute $\mathsf{dist}(x, y)$ if it is at most k and output "$> k$" otherwise [24, 2]. This is similar to the well-studied k-Hamming Distance problem in communication complexity, where the players must decide if their vertices x, y have distance at most k in the Boolean hypercube graph. A natural generalization of the Boolean hypercube is the family of distributive lattices (which also include, for example, the hypergrids). We demonstrate that techniques from communication complexity can be used to obtain new graph labelings, by adapting the k-Hamming Distance protocol of Huang et al. [21] to the universal SMP model, achieving an $O(k^2)$ protocol for computing $\mathsf{dist}(x, y) \leq k$ and the corresponding k-distance labeling scheme with label size $O(k^2 \log n)$. It is interesting to note that, in contrast to the standard application of communication complexity as a method for obtaining lower bounds, we are using it to obtain upper bounds.

Generalizing in another direction, we ask: for which graphs other than the Boolean hypercube can we obtain efficient communication protocols for k-distance? For constant k, k-Hamming Distance can be computed with communication cost $O(1)$; which other graphs admit a constant-cost protocol? To approach this question, we observe that many (but not all) graph families known to have efficient $O(\log n)$ adjacency labeling schemes also admit an $O(1)$ universal SMP protocol for adjacency. Commonly studied families in the adjacency and distance labeling literature are trees [23, 24, 2, 5, 3] and planar graphs [23, 15, 14, 16, 6]. We

study the k-distance problem on these families and find that trees admit an $O(k)$ protocol, while planar graphs admit an $O(1)$ protocol for 2-distance; this implies a new labeling scheme for planar graphs.

Further motivation for the universal SMP model comes from *universal graphs*. Introduced by Rado [30], an induced-universal graph U for a set $\mathcal{F}$ is one that contains each $G \in \mathcal{F}$ as an induced subgraph. An efficient adjacency labeling scheme for a set $\mathcal{F}$ implies a small induced-universal graph for that set [23]. Deterministic universal SMP protocols are equivalent to universal graphs (Theorem 1.7), and we introduce *probabilistic universal graphs* as the analogous objects for randomized univeral SMP protocols. We think probabilistic universal graphs are worthy of study alongside universal graphs, especially since many non-trivial families admit one of *constant-size*.

The universal SMP model is also related to a recent line of work studying communication between parties with imperfect knowledge of each other's "context". The most relevant incarnation of this idea is the recent work [18, 17], who study the 2-way communication model where Alice and Bob receive functions f and g respectively, with inputs x and y, and must compute $f(x, y)$ under the guarantee that f and g are close in some metric. In other words, one party does not have full knowledge of the function to be computed. The universal SMP model provides a framework for studying a similar problem in the SMP setting, where the players know the function but the referee does not; the similarity is especially clear when we define the family $\mathcal{F}$ to be all graphs of distance δ to a reference graph G in some metric (we discuss this situation in more detail at the end of the paper). This could model, for example, a situation where the clients of a service operate in a shared environment but the server does not; or, a situation in which the clients want to keep their shared environment secret from the server, and their inputs secret from each other. This suggests a possible application to privacy and security. A relevant example is private proximity testing (e.g. [27]), where two clients should be notified by the server when they are at distance at most k from each other, without revealing to each other or the server their exact locations.

The Discussion at the end of the paper highlights some interesting questions and open problems related to universal SMP.

1.1 Results

A universal SMP protocol *decides k-distance* for a family $\mathcal{F}$ if for all graphs $G \in \mathcal{F}$ and vertices x, y, the protocol will correctly decide if $\mathsf{dist}(x, y) \leq k$, with high probability. A labeling scheme decides k-distance if $\mathsf{dist}(x, y) \leq k$ can be decided from the labels of x, y. Below, the variable n always refers to the number of vertices in the input graph.

Implicit graph representations. The main principle connecting communication and graph labeling is:

▶ **Theorem 1.1.** *Any graph family $\mathcal{F}$ with universal SMP cost m has an adjacency labeling scheme with labels of size $O(m \log n)$. In particular, if the universal SMP cost for $\mathcal{F}$ is $O(1)$ then $\mathcal{F}$ has an $O(\log n)$ adjacency labeling scheme.*

Adjacency labeling schemes of size $O(\log n)$ are of special interest because $\log n$ is the minimum number of bits required to label each vertex uniquely, and they correspond to *implicit graph representations*, as defined by Kannan, Naor, and Rudich [23] (we omit their requirement that the encoding and decoding be computable in polynomial-time). Section 2.3 elaborates further. To obtain implicit representations, we can relax our requirements:

▶ **Corollary 1.2.** *For any constant c, any graph family $\mathcal{F}$ where each $G \in \mathcal{F}$ has a public-coin 2-way communication protocol computing adjacency with cost c has an implicit representation.*

Distributive & Modular Lattices. Distributive and modular lattices are generalizations of the Boolean hypercube and hypergrids (see Section 3 for definitions). We define a *weakly-universal* SMP protocol as one where the referee shares the randomness of Alice and Bob. For distributive lattices we get the following:

▶ **Theorem 1.3.** *The k-distance problem on the family of distributive lattices has: a weakly-universal SMP protocol with cost $O(k \log k)$; a universal SMP protocol with cost $O(k^2)$; and a size $O(k^2 \log n)$ labeling scheme.*

Modular lattices are a superset of distributive lattices, but they do not admit k-distance protocols with a cost independent of n; we show that any universal SMP protocol (and any labeling scheme) deciding 2-distance must have cost $\Omega(n^{1/4})$ (Theorem 3.14). To our knowledge, there are no known labeling schemes for distributive or modular lattices. Our adjacency labeling scheme (i.e. for $k = 1$) requires $O(n \log n)$ space to store the whole lattice; this can be compared to Munro and Sinnamon [26], who present a data structures of size $O(n \log n)$ for distributive lattices that supports *meet* and *join* operations (and therefore distance queries, due to our Lemma 3.5). However, these are not labelings, so the result is not directly comparable.

Planar graphs and other efficiently-labelable families. When they introduced graph labeling, Kannan, Naor, and Rudich [23] studied trees, low-arboricity graphs (whose edges can be partitioned into a small number of trees), and planar graphs, and interval graphs (whose vertices are intervals in $\mathbb{R}$, with an edge if the intervals intersect), among others. These families have $O(\log n)$ adjacency labeling schemes. Trees, low-arboricity graphs, and planar graphs have constant-cost universal SMP protocols for adjacency. Trees admit an efficient k-distance protocol:

▶ **Theorem 1.4.** *The family of trees has a universal SMP protocol deciding k-distance with cost $O(k)$ and a $O(k \log n)$ labeling scheme deciding k-distance.*

Planar graphs admit an efficient 2-distance protocol, which implies a new 2-distance labeling scheme:

▶ **Theorem 1.5.** *The 2-distance problem on the family of planar graphs has a universal SMP protocol with cost $O(1)$ and a labeling scheme of size $O(\log n)$.*

On the other hand, a universal SMP protocol deciding 2-distance on the family of graphs with arboricity 2 has cost at least $\Omega(\sqrt{n})$ (Proposition 4.4), and a universal SMP protocol deciding adjacency in interval graphs has cost $\Theta(\log n)$ (Proposition 4.5).

Gavoille et al. [15] showed that trees have an $O(\log^2 n)$ labeling allowing $\mathsf{dist}(x, y)$ to be computed exactly from labels of x, y, and gave a matching lower bound; Kaplan and Milo [24] and Alstrup *et al* [2] studied k-distance for trees, with the latter achieveing a $\log n + O(k^2(\log \log n + \log k))$ labeling scheme. For planar graphs, [15] gives a lower bound of $\Omega(n^{1/3})$ for computing distances exactly, and an upper bound of $O(\sqrt{n} \log n)$, which was later improved to $O(\sqrt{n})$ in [16].

Communication Complexity. Our lower bounds are achieved by reduction from the family of all graphs, which has complexity $\Theta(n)$, in contrast to the upper bound of $\lceil \log n \rceil$ for the standard SMP cost of computing adjacency in any graph (since Alice and Bob can send $\lceil \log n \rceil$ bits to identify their vertices).

▶ **Theorem 1.6.** *For the family $\mathcal{G}$ of all graphs, the universal SMP cost of computing adjacency in $\mathcal{G}$ is $\Theta(n)$.*

The basic relationships between universal SMP, standard SMP, and universal graphs are as follows. Below, we use $D^{\|}(\textsc{Adj}(G))$ and $R^{\|}(\textsc{Adj}(G))$ for the deterministic and randomized (standard) SMP cost of computing adjacency on G, and $D^{\mathsf{univ}}(\mathcal{F}), R^{\mathsf{univ}}(\mathcal{F})$ for the deterministic and randomized universal SMP cost for computing adjacency in the family $\mathcal{F}$. We use the term "$\sqsubset$-universal graph" as opposed to "induced-universal" to denote a slightly different object that allows non-injective embeddings (see Section 2 for definitions).

▶ **Theorem 1.7.** *For a set $\mathcal{F}$, the following relationships hold. Let U range over the set of all $\sqsubset$-universal graphs:*

$$\max_{G\in\mathcal{F}} D^{\|}(\textsc{Adj}(G)) \leq D^{\mathsf{univ}}(\mathcal{F}_i) = \min_{U} D^{\|}(\textsc{Adj}(U)) = \min_{U} \lceil \log |U| \rceil \,,$$

with equality on the left iff $\exists H \in \mathcal{F}$ such that $\forall G \in \mathcal{F}$, G can be embedded *in H. For $\widetilde{U}$ ranging over the set of all* probabilistic universal graphs*:*

$$\max_{G\in\mathcal{F}} R^{\|}(\textsc{Adj}(G)) \leq R^{\mathsf{univ}}(\mathcal{F}) \leq \min_{\widetilde{U}} D^{\|}(\textsc{Adj}(\widetilde{U})) \leq O\left(R^{\mathsf{univ}}(\mathcal{F})\right) \,.$$

Randomized and deterministic universal SMP satisfy

$$\Omega\left(\frac{D^{\mathsf{univ}}(\mathcal{F})}{\log n}\right) \leq R^{\mathsf{univ}}(\mathcal{F}) \leq D^{\mathsf{univ}}(\mathcal{F}) \,.$$

The above results on graph labeling are proved through the relationship between randomized and deterministic universal SMP. We obtain this relationship by adapting Newman's Theorem [28], a standard derandomization result in communication complexity. Finally, we note the interesting fact that universal SMP characterizes the gap between standard SMP models where the referee does or does not share the randomness with Alice and Bob:

▶ **Proposition 1.8** (Informal). *Let $\mathcal{F}$ be a family of graphs and let Π be a weakly-universal SMP protocol for $\mathcal{F}$, which defines a distribution over the referee's decision functions F, which we interpret as the adjacency matrices of graphs. Let $\mathcal{U}_\Pi$ be the family on which this distribution is supported. Then, taking the minimum over all such protocols Π,*

$$R^{\mathsf{univ}}_{\epsilon}(\mathcal{F}) = \min_{\Pi} D^{\mathsf{univ}}(\mathcal{U}_\Pi) \,.$$

1.2 Other Related Work

Graph labeling. Randomized labeling schemes for trees have been studied by Fraigniaud and Korman [12], who give a randomized adjacency labeling scheme of $O(1)$ bits per label that has one-sided error (i.e. it can erroneously report that x, y are adjacent when they are not), and they show that achieving one-sided error in the opposite direction requires a randomized labeling with $\Omega(\log n)$ bits. They also give randomized schemes for determining if x is an ancestor of y, but they do not address distance problems. Spinrad's book [33] has a chapter on implicit graphs and Alstrup et al. [6] for a recent survey on adjacency labeling

schemes and induced-universal graphs. We know of no labeling schemes for lattices, but Fraigniaud and Korman [13] recently studied adjacency labeling schemes for posets of low "tree-dimension".

Distance-preserving labeling studies an opposite problem to k-distance labeling, where distances must be accurately reported when they are *above* some threshold D. Recent work includes Alstrup et al. [4].

To our knowledge, k-distance or even 2-distance has not been studied for planar graphs, but there are many results on other types of planar graph labelings with restrictions at distance 2. An example is the *frequency assignment problem* or $L(p,q)$*-labeling* problem, which asks how to construct a labeling ℓ assigning integers $[k]$ to vertices of a planar graph so that $\mathsf{dist}(x,y) \le 1 \implies |\ell(x) - \ell(y)| \ge p$ and $\mathsf{dist}(x,y) \le 2 \implies |\ell(x) - \ell(y)| \ge q$, with various optimization goals. See [7] for a survey.

Uncertain communication. There are several works studying communication problems where the parties do not agree on the function to be computed, starting with Goldreich, Juba, and Sudan [19] who studied communication where parties have different "goals". Canonne et al. [8] study communication in the shared randomness setting where the randomness is shared imperfectly. Haramarty and Sudan [20] study compression (á la Shannon) in situations where the parties do not agree on a common distribution. As mentioned earlier, Ghazi et al. [17] and Ghazi and Sudan [18] study 2-way communication where the parties do not agree on the function to be computed.

1.3 Notation

$[k]$ means $\{1,\dots,k\}$. The letter n always denotes the number of vertices in a graph. We use the notation $\mathbb{1}[E] = 1$ iff the statement E holds, and $\mathbb{1}[E] = 0$ otherwise. For a graph G, $V(G)$ is the set of vertices and $E(G)$ is the set of edges. For vertices x, y, we write $G(x,y) = \mathbb{1}[x, y \text{ are adjacent in } G]$ for the entry in the adjacency matrix of G. For an undirected, unweighted graph G and vertices u, v, $\mathsf{dist}(u,v)$ is the length of the shortest path from u to v.

For any graph G and integer k, we denote by G^k the k*-closure* of G, where two vertices u, v are adjacent iff $\mathsf{dist}(u,v) \le k$ in G; it is convenient to require that each vertex is adjacent to itself in G^k. For a set of graphs $\mathcal{F}$, $\mathcal{F}^k = \{G^k : G \in \mathcal{F}\}$.

$D^{\|}(f)$ is the deterministic SMP cost of the function f and $R^{\|}(f)$ is the randomized SMP cost of the function f, in the model where Alice and Bob share randomness but the deterministic referee does not.

2 Universal Communication and Universal Graphs

In this paper we focus on deciding adjacency. Every Boolean communication problem $f : \mathcal{X} \times \mathcal{Y} \to \{0,1\}$ on finite domains $\mathcal{X}, \mathcal{Y}$ is equivalent to the adjacency problem on the graph G with vertex set $\mathcal{X} \cup \mathcal{Y}$ and $G(u,v) = f(u,v)$. We may either allow self-loops in G if $\mathcal{X} = \mathcal{Y}$ or take G to be bipartite. We will generally permit graphs to have self-loops.

▶ **Definition 2.1.** *A* family of graphs $\mathcal{F} = (\mathcal{F}_i)$ *is a sequence of sets* $\mathcal{F}_i$ *indexed by integers* i*, along with a strictly increasing size function* $n(i)$*, so that* $\mathcal{F}_i$ *is a set of graphs with vertex set* $[n(i)]$*. If* $\mathcal{F}_i$ *has size* $n(i) = i$ *then we write* $\mathcal{F}_n$*.*

▶ **Definition 2.2** (Universal SMP and Variations). *Let $\mathcal{F}$ be a family of graphs with size function n and let Φ be an operation taking size $n(i)$ graphs to size $n(i)$ graphs. Let $c : \mathbb{N} \to \mathbb{N}$ and let $\epsilon > 0$ be a constant. An ϵ-error, cost c sequence of* universal SMP *communication protocols for $\mathcal{F}$ is as follows. For any $i \in \mathbb{N}$, a protocol Π_i for $\mathcal{F}_i$ is a triple (a_i, b_i, F_i) where:*

- *Alice and Bob receive $(G, x), (G, y)$ respectively, where $G \in \mathcal{F}_i$ and $x, y \in V(G) = [n(i)]$;*
- *Alice and Bob share a random string r and compute messages $a_i(r, G, x), b_i(r, G, y) \in \{0,1\}^{c(i)}$, respectively;*
- *For each i, the (deterministic) referee has a function $F_i : \{0,1\}^{c(i)} \times \{0,1\}^{c(i)} \to \{0,1\}$, called the* decision function. *$F_i(a_i(r, G, x), b_i(r, G, y))$ must satisfy:*
  1. *If x, y are adjacent in $\Phi(G)$ then $\mathbb{P}_r[F_i(a_i(r, G, x), b_i(r, G, y)) = 1] > 1 - \epsilon$; and*
  2. *If x, y are not adjacent in $\Phi(G)$ then $\mathbb{P}_r[F_i(a_i(r, G, x), b_i(r, G, y))] < \epsilon$.*

A universal SMP protocol is symmetric *when the functions a_i, b_i computed by Alice and Bob are identical and the function F_i satisfies $F_i(a, b) = F_i(b, a)$ for all messages $a, b \in \{0,1\}^c$. We write $R^{\mathsf{univ}}_\epsilon(\Phi(\mathcal{F}))$ for the communication complexity in the universal SMP model of computing adjacency in graphs $\Phi(\mathcal{F}) = \{\Phi(G) : G \in \mathcal{F}\}$, where ϵ is the allowed probability of error. We write $R^{\mathsf{univ}}(\Phi(\mathcal{F}))$ for $R^{\mathsf{univ}}_{1/3}(\Phi(\mathcal{F}))$. If no operation Φ is specified, it is assumed to be the identity.*

It is also convenient to define a weakly-universal SMP *protocol as a universal SMP protocol where the referee can see the shared randomness, so the choice function is of the form $F_i(r, a(r, G, x), b(r, G, y))$ for random seed r, graph $G \in \mathcal{F}$, and $x, y \in V(G)$. We denote the ϵ-error complexity in this model with $R^{\mathsf{weak}}_\epsilon(\Phi(\mathcal{F}))$.*

Finally, we write $D^{\mathsf{univ}}(\Phi(\mathcal{F}))$ for the deterministic *universal SMP complexity.*

▶ Remark 2.3. We include the operator Φ in the definition to emphasize that the players are given the original graph G, not the graph $\Phi(G)$; for example, the players are not given G^k (from which it may be difficult to compute G), but are instead given G.

2.1 Deterministic Universal Communication and Universal Graphs

We will show that a deterministic universal SMP protocol is equivalent to an *embedding* into a $\sqsubset$-universal graph, which we we define using the following notion of embedding (following the terminology of Rado [30]):

▶ **Definition 2.4.** *For graphs G, H, a mapping $\phi : V(G) \to V(H)$ is an* embedding *iff $\forall u, v \in V(G)$, $G(u, v) = H(\phi(u), \phi(v))$. If such a mapping exists we write $G \sqsubset H$.*

For a set of graphs $\mathcal{F}_i$, a graph U is $\sqsubset$-universal *if $\forall G \in \mathcal{F}_i, G \sqsubset U$; i.e. $\forall G \in \mathcal{F}_i$ there exists an embedding $\phi_G : V(G) \to V(U)$. For a family of graphs $\mathcal{F} = (\mathcal{F}_i)$, a sequence $U = (U_i)$ is a* $\sqsubset$-universal graph sequence *if for each i, U_i is $\sqsubset$-universal for $\mathcal{F}_i$.*

Define an equivalence relation on $V(G)$ by $u \equiv v$ iff $\forall w \in V(G), G(u, w) = G(v, w)$, i.e. u, v have identical rows in the adjacency matrix. For a graph G, define the $\equiv$-reduction $G^{\equiv}$ as a graph on the equivalence classes $\mathcal{C}$ of $V(G)$ with $U, W \in \mathcal{C}$ adjacent iff $\exists u \in U, w \in W$ such that u, w are adjacent.

An embedding is not the same as a homomorphism since we must map non-edges to non-edges, and $G \sqsubset H$ is not the same as G being an induced subgraph of H since the mapping is not necessarily injective. Therefore a universal graph by our definition is not the same as an induced-universal graph, where G must exist as an induced subgraph. We could for example map the path $a - b - c \mapsto a' - b' - a'$. This difference between definitions is captured by the $\equiv$ relation between vertices. It is necessary to allow self-loops, otherwise the $\sqsubset$ relation is not transitive. The important properties of $\sqsubset, \equiv$, and $\equiv$-reductions are stated in the next proposition; the proofs are routine and for completeness are included in the appendix. The relation $\simeq$ is the isomorphism relation on graphs.

▶ **Proposition 2.5.** *The following properties are satisfied by the $\sqsubset$ relation, the $\equiv$ relation, and $\equiv$-reductions:*

1. *$\sqsubset$ is transitive.*
2. *For any graph G and $u, v \in V(G)$, $u \equiv v$ iff there exists H and an embedding $\phi : G \to H$ such that $\phi(u) = \phi(v)$.*
3. *For any graph G, $(G^{\equiv})^{\equiv} \simeq G^{\equiv}$.*
4. *For any graph G, $G \sqsubset G^{\equiv}$ and $G^{\equiv} \sqsubset G$.*
5. *For any graphs G, H, $G \sqsubset H$ iff $G^{\equiv} \sqsubset H^{\equiv}$.*
6. *For any graphs G, H, $G^{\equiv} \sqsubset H^{\equiv}$ iff $G^{\equiv}$ is an induced subgraph of $H^{\equiv}$.*

These properties allows us to prove relationships between the standard SMP model, deterministic universal SMP, and $\sqsubset$-universal graphs. First we show that deterministic universal SMP protocols can always be made symmetric[1].

▶ **Proposition 2.6.** *If Π is a deterministic universal SMP protocol for the set $\mathcal{F}$, then there exists a deterministic universal SMP protocol Π' that is symmetric and has the same cost as Π.*

Proof. Let $G \in \mathcal{F}$ and let $a, b : V(G) \to \{0,1\}^m$ be the encoding functions for G and F the decision function for graphs of size $|G|$. The restriction of b to the domain $V(G^{\equiv}) \to \{0,1\}^m$ is injective so it has an inverse $b^{-1} : \text{image}(b) \to V(G^{\equiv})$ that satisfies $b^{-1}b(x) \equiv x$; the same holds for a, a^{-1}. Define the encoding function $b' : V(G) \to \{0,1\}^m$ as $b' = ab^{-1}b$ and define the decision function $F'(p,q) = F(p, ba^{-1}(q))$. Then for any $x, y \in V(G), F'(a(x), b'(y)) = F(a(x), ba^{-1}ab^{-1}b(y)) = F(a(x), b(y)) = G(x,y)$ so this is a valid protocol. Since $\text{image}(b') \subseteq \text{image}(a)$ we can write $b'(x) = aa^{-1}b'(x) = aa^{-1}ab^{-1}b(x) = a(x)$ for every x so $b' = a$, thus $F'(a(x), a(y)) = G(x,y) = G(y,x) = F'(a(y), a(x))$ so the protocol is symmetric. ◀

The standard deterministic SMP complexity measure can be expressed in terms of $\equiv$-reductions:

▶ **Proposition 2.7.** *For all graphs G, $D^{\|}(\textsc{Adj}(G)) = \lceil \log |G^{\equiv}| \rceil$.*

Proof. It is well-known that for any function $f : \mathcal{X} \times \mathcal{Y} \to \{0,1\}$, $D^{\|}(f) = \lceil \log \min(r, c) \rceil$ where r is the number of distinct columns in the communication matrix of f, and c is the number of distinct rows [34]. The communication matrix of the function $\textsc{Adj}(G)$ is the adjacency matrix of G, which is symmetric, and two rows (or columns) indexed by u, v are distinct iff $u \not\equiv v$; so the number of distinct rows is the size of $G^{\equiv}$. ◀

The analogous fact for universal SMP is that the deterministic universal SMP cost is determined by the size of the smallest universal graph.

▶ **Proposition 2.8.** *For any graph family $\mathcal{F} = (\mathcal{F}_i)$,*

$$D^{\mathsf{univ}}(\mathcal{F}_i) = \min_U \{ \lceil \log |U^{\equiv}| \rceil : \forall G \in \mathcal{F}_i, G \sqsubset U^{\equiv} \}.$$

Proof. Let U be any graph such that $G \sqsubset U^{\equiv}$ for all $G \in \mathcal{F}_i$ and for each $G \in \mathcal{F}_i$ let g be the embedding $G \to U^{\equiv}$. Consider the protocol where on inputs $(G, x), (G, y)$, Alice and Bob send $g(x), g(y)$ using $\lceil \log |U^{\equiv}| \rceil$ bits and the referee outputs $U^{\equiv}(g(x), g(y))$. This is correct by definition so $D^{\mathsf{univ}}(\mathcal{F}_i) \leq \lceil \log |U^{\equiv}| \rceil$.

[1] Note that this does not imply that every deterministic SMP protocol is symmetric, since in this paper we are only concerned with adjacency on an undirected graph, for which the communication matrix is symmetric. This proposition shows that for symmetric communication matrices, the deterministic SMP protocol is symmetric.

Now suppose there is a protocol Π for $\mathcal{F}_i$ with cost c and decision function F_i, and let $G \in \mathcal{F}_i$. By Proposition 2.6 we may assume that on inputs $(G, x), (G, y)$ Alice and Bob share the encoding function $g : V(G) \to \{0,1\}^c$. Let U be the graph with vertices $\{0,1\}^c$ and $U(u, v) = F(u, v)$. Then $U(g(x), g(y)) = F(g(x), g(y)) = G(x, y)$ so $G \sqsubset U \sqsubset U^{\equiv}$ (by transitivity). Now $|U^{\equiv}| \leq 2^c$ so $c \geq \log |U^{\equiv}|$. ◀

It is easy to see that $D^{\|}$ can be used as a lower bound on D^{univ} but such lower bounds are tight only when the family $\mathcal{F}$ is essentially a "trivial" family of equivalent graphs.

▶ **Lemma 2.9.** *For any family $\mathcal{F} = (\mathcal{F}_i)$, let $U = (U_i)$ be the smallest $\sqsubset$-universal graph sequence for $\mathcal{F}$. Then*

$$\max_{G \in \mathcal{F}_i} D^{\|}(\textsc{Adj}(G)) \leq D^{\mathsf{univ}}(\mathcal{F}_i) = D^{\|}(\textsc{Adj}(U_i)),$$

with equality holding on the left iff $\exists H \in \mathcal{F}_i$ such that $\forall G \in \mathcal{F}_i, G^{\equiv} \sqsubset H^{\equiv}$.

Proof. The equality on the right holds by the two prior propositions. The lower bound follows from the fact that any protocol Π_i for $\mathcal{F}_i$ in the universal model can be used as a protocol in the SMP model. Now we must show the equality condition. Let $U \in \mathcal{F}_i$ be a graph maximizing $|U^{\equiv}|$ over all graphs in $\mathcal{F}_i$, and suppose $D^{\mathsf{univ}}(\mathcal{F}_i) = \max_{G \in \mathcal{F}_i} D^{\|}(\textsc{Adj}(G)) = \max_{G \in \mathcal{F}_i} \lceil \log |G^{\equiv}| \rceil = \lceil \log |U^{\equiv}| \rceil$, so $\lceil \log |U^{\equiv}| \rceil = \min\{\lceil \log |H^{\equiv}| \rceil : \forall G \in \mathcal{F}_i, G \sqsubset H^{\equiv}\}$. Then there exists H such that $U^{\equiv} \sqsubset H^{\equiv}$ and $|U^{\equiv}| = |H^{\equiv}|$. Since $U^{\equiv}$ is an induced subgraph of $H^{\equiv}$ and $|U^{\equiv}| = |H^{\equiv}|$ we must have $U^{\equiv} \simeq H^{\equiv}$ so $\forall G \in \mathcal{F}_i, G^{\equiv} \sqsubset U^{\equiv}$. ◀

2.2 Randomized Universal Communication

Just as deterministic universal communication is equivalent to embedding a family into a universal graph, we will define probabilistic universal graphs and show that they are tightly related to universal communication with shared randomness.

▶ **Definition 2.10.** *For graphs G, H, a random mapping $\phi : V(G) \to V(H)$ (i.e. a distribution over such mappings) is an* ϵ-error embedding *iff $\forall u, v \in V(G)$,*

$$\mathop{\mathbb{P}}_{\phi}[G(u, v) = H(\phi(u), \phi(v))] > 1 - \epsilon.$$

We will write $G \sqsubset_\epsilon H$ if there exists an ϵ-error embedding $G \to H$. A graph U is ϵ-error universal *for a set of graphs S if $\forall G \in S, G \sqsubset_\epsilon U$. $U = (U_i)$ is an ϵ-error universal graph sequence for the family $\mathcal{F} = (\mathcal{F}_i)$ if for each i, U_i is ϵ-error universal for $\mathcal{F}_i$.*

In the randomized setting we obtain equivalence (up to a constant factor) between universal SMP protocols and probabilistic universal graphs.

▶ **Lemma 2.11.** *For any graph family $\mathcal{F} = (\mathcal{F}_i)$ and any $\epsilon > 0$, if there exists a ϵ-error universal SMP protocols for $\mathcal{F}$ with cost $c(i)$, then there exists a 2ϵ-error symmetric universal SMP protocols for $\mathcal{F}$ with cost at most $2c(i)$.*

Proof. On input $G \in \mathcal{F}_i, x, y \in V(G)$, and random string r, Alice and Bob send the concatentations $g_r(x) := a_i(r, G, x)b_i(r, G, x)$ and $g_r(y) := a_i(r, G, y)b_i(r, G, y)$. Then the referee computes

$$F'_i(g_r(x), g_r(y)) = \max\{F_i(a_i(r, G, x), b_i(r, G, y)), F_i(a_i(r, G, y), b_i(r, G, x))\}.$$

It is clear that F'_i is symmetric. If x, y are adjacent then

$$\mathop{\mathbb{P}}_{r}[F'_i(g_r(x), g_r(y)) = 0] \le \mathop{\mathbb{P}}_{r}[F_i(a_i(r, G, x), b_i(r, G, y)) = 0] < \epsilon\,,$$

and if x, y are not adjacent then, by the union bound,

$$\begin{aligned}&\mathop{\mathbb{P}}_{r}[F'_i(g_r(x), g_r(y)) = 1]\\ &\qquad \le \mathop{\mathbb{P}}_{r}[F_i(a_i(r, G, x), b_i(r, G, y)) = 1] + \mathop{\mathbb{P}}_{r}[F_i(a_i(r, G, y), b_i(r, G, x)) = 1] < 2\epsilon\,.\end{aligned}$$ ◀

Applying this symmetrization, we get a relationship between universal SMP protocols and probabilistic universal graphs.

▶ **Lemma 2.12.** *Let $\mathcal{F} = (\mathcal{F}_i)$ be a graph family and $\epsilon > 0$. Then*

1. *There is an ϵ-error universal graph sequence of size at most $2^{2R^{\mathsf{univ}}_{\epsilon/2}(\mathcal{F})}$; and*
2. *If there is an ϵ-error universal graph sequence of size $c(i)$ then $R^{\mathsf{univ}}_{\epsilon}(\mathcal{F}) \le \lceil \log c \rceil$.*

Proof. If Π_i is an ϵ-error symmetric universal protocol for $\mathcal{F}_i$ then there exists a function F_i such that for every $G \in \mathcal{F}_i$ there is a random g such that $\mathop{\mathbb{P}}_{g}[F_i(g(x), g(y)) \ne G(x, y)] < \epsilon$. Using F_i as an adjacency matrix, we get a graph U_i of size at most 2^c, where c is the cost of Π_i, such that for all $G \in \mathcal{F}_i, G \sqsubset_\epsilon U_i$. Then $U = (U_i)$ is an ϵ-error probabilistic universal graph sequence. By Lemma 2.11 we obtain an ϵ-error symmetric protocol with cost $2R^{\mathsf{univ}}_{\epsilon/2}(\mathcal{F})$, so we have proved the first conclusion. The second conclusion follows by definition. ◀

The basic relationships to standard SMP models follow essentially by definition and from the above lemma.

▶ **Lemma 2.13.** *Let $\mathcal{F}$ be any graph family and let $\epsilon > 0$. Let $U = (U_i)$ be an $\sqsubset$-universal graph sequence for $\mathcal{F}$, and $\widetilde{U} = (\widetilde{U}_i)$ an ϵ-error universal graph sequence. Then*

$$\begin{aligned}\max_{G \in \mathcal{F}_i} R^{\|}_{\epsilon}(\textsc{Adj}(G)) &\le R^{\mathsf{univ}}_{\epsilon}(\mathcal{F}_i) \le D^{\|}(\textsc{Adj}(\widetilde{U}_i))\\ &\le 2R^{\mathsf{univ}}_{\epsilon/2}(\mathcal{F}_i) \;\; \textit{and} \;\; R^{\mathsf{univ}}_{\epsilon}(\mathcal{F}_i) \le R^{\|}_{\epsilon}(\textsc{Adj}(U_i))\,.\end{aligned}$$

Proof. The inequalities on the left follow the definitions and from the above lemma. On the right, we can obtain a universal SMP protocol by choosing for each $G \in \mathcal{F}_i$ a (deterministic) embedding $g : G \to U_i$ and then using the randomized SMP protocol for $\textsc{Adj}(U_i)$. ◀

Universal graphs describe an interesting relationship between weakly-universal and universal SMP protocols (and therefore between standard SMP protocols where the referee does and does not share the randomness); namely, the optimal universal protocol is obtained by finding the smallest universal graph for the family of protocol graphs (decision functions) defined by a weakly-universal protocol.

▶ **Proposition 1.8** (Restated). *Let $\mathcal{F}$ be a family of graphs, let $\epsilon > 0$, and let W_ϵ be the set of all ϵ-error weakly-universal SMP protocols for $\mathcal{F}$. For each $\Pi \in W_\epsilon$ let $\mathcal{U}_\Pi = (\mathcal{U}_{\Pi,i})$ be the family of graphs $\mathcal{U}_{\Pi,i} = \{F_i(r, \cdot, \cdot) : r \text{ is a random seed for } \Pi\}$ where F_i is the decision function of Π. Then*

$$R^{\mathsf{univ}}_{\epsilon}(\mathcal{F}) = \min_{\Pi \in W_\epsilon} D^{\mathsf{univ}}(\mathcal{U}_\Pi)\,.$$

Proof. Let $\Pi \in W_\epsilon$; we will construct a universal SMP protocol as follows. On input $(G,x),(G,y)$, Alice and Bob use shared randomness r to simulate Π and obtain vertices $a(r,G,x), b(r,G,y)$ in some graph $U_r \in \mathcal{U}_\Pi$ with $\mathbb{P}_r[U_r(a(r,G,x),b(r,G,y)) \neq G(x,y)] < \epsilon$. They now simulate the deterministic universal SMP protocol, i.e. an embedding $\phi : V(U_r) \to U'$ for some graph U' that is $\sqsubset$-universal for $\{U_r\}$, and send $\phi(a(r,G,x)), \phi(b(r,G,y))$ to the referee who computes $U'(\phi(a(r,G,x)),\phi(b(r,G,x))) = U_r(a(r,G,x),b(r,G,y))$.

Now let Π be an ϵ-error universal SMP protocol. Then $\Pi \in W_\epsilon$ and for each i, $\mathcal{U}_{\Pi,i} = \{U_i\}$, where U_i is the graph of the decision function. $D^{\mathsf{univ}}(\mathcal{U}_\Pi) \leq \lceil \log |U_i| \rceil$, which is the cost of Π, so $\min_{\Pi \in W_\epsilon} D^{\mathsf{univ}}(\mathcal{U}_\Pi) \leq R^{\mathsf{univ}}_\epsilon(\mathcal{F})$. ◀

Newman's Theorem for public-coin randomized (2-way) protocols is a classic result that gives a bound on the number of uniform random bits required to compute a function $f : \mathcal{X} \times \mathcal{Y} \to \{0,1\}$ in terms of the size of the input domain [28]. In the universal model, the input size can be very large since the graph (function) itself is part of the input. However, the shared part of the input does not contribute to the number of random bits required in the universal SMP model.

▶ **Lemma 2.14** (Newman's Theorem for universal SMP). *Let $\epsilon, \delta > 0$ and suppose there is an ϵ-error universal SMP protocol Π for the family $\mathcal{F} = (\mathcal{F}_i)$. Then there is an $(\epsilon+\delta)$-error universal SMP protocol for the family $\mathcal{F}$ that uses at most $\log\log\left(n(i)^{O(\epsilon/\delta^2)}\right)$ bits of randomness and has the same communication cost.*

Proof. Fix i, let F be the deterministic decision function for $\mathcal{F}_i$, and let $a(r,\cdot,\cdot), b(r,\cdot,\cdot)$ be Alice and Bob's encoding functions for the random seed r. For $G \in \mathcal{F}_i$ and $x,y \in V(G)$ we will say a seed r is *bad* for G,x,y if $F(a(r,G,x),b(r,G,y)) \neq G(x,y)$, and we will call this event $\mathsf{bad}(G,x,y,r)$.

Let $r_1,\dots,r_m$ be independent random seeds, and let $i \sim [m]$ be uniformly random, where $m > \frac{3\epsilon}{\delta^2}\ln(n^2)$. Then for every G, the expected number of vertex pairs x,y for which the strings $r_1,\dots,r_m$ fail is

$$\begin{aligned}
&\mathop{\mathbb{E}}_{r_1,\dots,r_m}\left[\sum_{x,y} \mathbb{1}\left[\mathop{\mathbb{P}}_{i\sim[m]}[\mathsf{bad}(G,x,y,r_i)] > \epsilon+\delta\right]\right] \\
&\quad\leq n^2 \max_{x,y} \mathop{\mathbb{E}}_{r_1,\dots,r_m}\left[\mathbb{1}\left[\mathop{\mathbb{P}}_{i}[\mathsf{bad}(G,x,y,r_i)] > \epsilon+\delta\right]\right] \\
&\quad= n^2 \max_{x,y} \mathop{\mathbb{P}}_{r_1,\dots,r_m}\left[\mathop{\mathbb{P}}_{i}[\mathsf{bad}(G,x,y,r_i)] > \epsilon+\delta\right] \\
&\quad= n^2 \max_{x,y} \mathop{\mathbb{P}}_{r_1,\dots,r_m}\left[\sum_{i=1}^{m} \mathbb{1}\left[\mathsf{bad}(G,x,y,r_i)\right] > m(\epsilon+\delta)\right].
\end{aligned}$$

The sum has mean $\mu = \sum_{i=1}^m \mathop{\mathbb{E}}_{r_i}[\mathbb{1}[\mathsf{bad}(G,x,y,r_i)]] < m\epsilon$, so by the Chernoff bound, the probability is at most

$$\begin{aligned}
&n^2 \mathop{\mathbb{P}}_{r_1,\dots,r_m}\left[\sum_{i=1}^{m} \mathbb{1}\left[\mathsf{bad}(G,x,y,r_i)\right] > (1+m\delta/\mu)\mu\right] \\
&\quad\leq n^2 \exp\left(-\frac{m^2\delta^2}{3\mu}\right) \leq n^2\exp\left(-\frac{m\delta^2}{3\epsilon}\right) < 1\,.
\end{aligned}$$

Since the expected number of pairs x,y where choosing $i \sim [m]$ fails with probability more than $\epsilon+\delta$ is less than 1, there must be some values of $r_1,\dots,r_m$ with no bad pairs for G. So

for every $G \in \mathcal{F}_i$ we may choose $r_1, \dots, r_m$ so that choosing i uniformly at random is the only random step; since $m = \frac{6\epsilon}{\delta^2} \ln n = \log n^{O(\epsilon/\delta^2)}$ this requires at most $\log m = \log\log\left(n^{O(\epsilon/\delta^2)}\right)$ random bits. ◀

With this result, we can conclude the proof of Theorem 1.7 in the next lemma.

▶ **Lemma 2.15.** *For any family $\mathcal{F} = (\mathcal{F}_i)$ with size function $n(i)$,*

$$\Omega\left(\frac{D^{\mathsf{univ}}(\mathcal{F}_i)}{\log n(i)}\right) \le R^{\mathsf{univ}}(\mathcal{F}_i) \le D^{\mathsf{univ}}(\mathcal{F}_i)\,.$$

Proof. The upper bound is clear, so we prove lower bound. Let $\Pi = (\Pi_i)$ be a sequence of randomized universal SMP protocols for $\mathcal{F}$. By Newman's theorem, we may assume that Π_i uses at most $\log\log n(i)^c$ random bits for some constant c and has error probability $3/8$. Let F_i be the decision function of Π_i, let $m(i)$ be the cost of Π_i, and let $k = \lceil c \log n(i) \rceil$. To obtain a deterministic protocol, we can define the decision function F_i' on messages of $k \cdot m(i)$ bits as $F_i'(a_1, b_1, a_2, b_2, \dots, a_k, b_k) = \text{majority}(F_i(a_j, b_j))_j$. Alice and Bob iterate over all $k = 2^{\log\log n(i)^c}$ random strings r and send $a(r, G, x), b(r, G, y)$ for each. Since the probability of error is at most $3/8$ when r is uniform, at least $5k/8 > k/2$ of the functions $F_i(a_j, b_j)$ will give the correct answer. This proves that $D^{\mathsf{univ}}(\mathcal{F}_i) = O(R^{\mathsf{univ}}(\mathcal{F}_i) \log n(i))$. ◀

In this paper we show lower bounds for a family $\mathcal{F}$ by giving embeddings of an arbitrary graph G into $\mathcal{F}$, so we need to know the complexity of the family $\mathcal{G} = (\mathcal{G}_n)$ of all graphs with n vertices. For our purposes, it is convenient to require that each graph $G \in \mathcal{G}_n$ has $G(u, u) = 1$ for all u (i.e. all self-loops are present). However, since equality can be checked with cost $O(1)$, the presence or absence of self-loops does not affect the complexity.

▶ **Theorem 1.6** (Restated). $R^{\mathsf{univ}}(\mathcal{G}) = \Theta(n)$.

Proof. For the upper bound, consider the (deterministic) protocol where on input G, x, y, Alice and Bob send x and y and the respective rows of the adjacency matrix of G. This has cost $n + \lceil \log n \rceil = O(n)$ and the referee can determine $G(x, y)$ by finding y in the row sent by Alice.

Let Π be any protocol for $\mathcal{G}_n$ with cost c. By Lemma 2.11, we may assume that Π is symmetric. Let F be the decision function for graphs on n vertices and let $G \in \mathcal{G}_n$ with vertex set $[n]$. Π defines a distribution over functions $g : [n] \to \{0,1\}^c$ so that for all x, y, $\mathbb{P}_g[F(g(x), g(y)) \neq G(x, y)] < \epsilon$. Therefore, for x, y drawn uniformly from $[n]$, $\mathbb{E}_{f,x,y}[\mathbb{1}[F(f(x), f(y)) \neq G(x, y)]] < \epsilon$. Therefore, for every graph $G \in \mathcal{G}_n$ there is a function f_G such that for $x, y \sim [n]$ uniformly at random, $\mathbb{P}_{x,y}[F(f_G(x), f_G(y)) \neq G(x, y)] < \epsilon$. Write $N = \binom{n}{2}$. There are at most 2^{cn} functions $[n] \to \{0,1\}^c$ and there are 2^N simple graphs on $[n]$ so there is some function $f : [n] \to \{0,1\}^c$ where the number of graphs G such that $f_G = f$ is at least $\frac{2^N}{2^{cn}} = 2^{N-cn}$. Let G, G' be any two such graphs. Then

$$\begin{aligned}&\mathbb{P}_{x,y\sim[n]}[G(x, y) \neq G'(x, y)]\\ &\quad\le \mathbb{P}_{x,y\sim[n]}[G(x, y) \neq F(f(x), f(y)) \text{ or } G'(x, y) \neq F(f(x), f(y))] < 2\epsilon\,.\end{aligned}$$

So G, G' differ on at most $2\epsilon N$ pairs. However, the largest number of graphs that differ from any graph G on at most $2\epsilon N$ pairs of vertices is at most

$$\sum_{k=0}^{2\epsilon N} \binom{N}{k} \le 2\epsilon N \binom{N}{2\epsilon N} \le \epsilon N \left(\frac{eN}{2\epsilon N}\right)^{2\epsilon N} = 2^{2\epsilon N \log(e/2\epsilon) + \log(2\epsilon N)}\,.$$

Therefore we must have

$$N - cn \leq 2\epsilon N \log(e/2\epsilon) + \log(2\epsilon N)$$

so $c = \Omega(n)$. ◀

Recall the example in the first paragraph of the introduction, for which we observed that a single decision function would work for many problems. We now make a note about this phenomenon. A communication protocol for a graph family $\mathcal{F} = (\mathcal{F}_i)$ is really a sequence of protocols, one for each set $\mathcal{F}_i$ of graphs with $n(i)$ vertices. Our next proposition addresses the uniformity of the sequence of protocols, that is, the question of how the protocols are related to one another as the size of the input grows. In general, we ask the question: If the family $\mathcal{F}$ has some relationship between $\mathcal{F}_i$ and $\mathcal{F}_{i+1}$, what does this imply about the relationship between the protocols for i and $i+1$? The families of graphs we study in this paper have constant-cost protocols and they are also *upwards families*, which we define next. These families have enough structure so that there exists a single, one-size-fits-all probabilistic universal graph, into which all graphs can be embedded regardless of their size; in other words, the referee can be ignorant not only of the graph G and vertices x, y, but also of the *size* of the graph, without increasing the cost of the protocol.[2]

▶ **Definition 2.16.** *We call a graph family $\mathcal{F} = (\mathcal{F}_i)$ an* upwards family *if for every i and every $G \in \mathcal{F}_i$ there exists $G' \in \mathcal{F}_{i+1}$ such that G is an induced subgraph of G'.*

Many graph families are upwards families, for example: bounded-degree graphs, bounded-arboricity graphs, planar graphs, and transitive reductions of distributive lattices.

▶ **Proposition 2.17.** *If $\mathcal{F}$ is an upwards graph family with an ϵ-error randomized universal graph sequence $U = (U_i)$ satisfying $|V(U_i)| \leq c$ for some constant c (which may depend on ϵ), then there exists a graph U^* of size c such that $\forall G \in \mathcal{F}, G \sqsubset_\epsilon U^*$. Furthermore, for any $i < j$ and any $G \in \mathcal{F}_i$, there exists $G' \in \mathcal{F}_j$ with ϵ-error embedding $g' : V(G') \to V(U^*)$ such that G is an induced subgraph of G' and the restriction of g' to the domain $V(G)$ is an ϵ-error embedding $V(G) \to V(U^*)$.*

Proof. Let $G \in \mathcal{F}_i$ and let $G' \in \mathcal{F}_{i+1}$ be such that G is an induced subgraph of G'. Let $g' : V(G') \to V(U_{i+1})$ the random function determined by the randomized universal graph sequence. Then g' restricted to the domain $V(G) \subset V(G')$ satisfies

$$\mathop{\mathbb{P}}_{g'}[U_{i+1}(g'(x), g'(y)) = G(x,y)] = \mathop{\mathbb{P}}_{g'}[U_{i+1}(g'(x), g'(y)) = G'(x,y)] > 1 - \epsilon\,.$$

Therefore we may replace U_i with U_{i+1} in the sequence, for any i.

Since each U_i has size at most c, there are at most 2^{c^2} graphs U_i appearing in the sequence U. Thus there is some graph U^* that occurs an infinite number of times in the sequence. For every i there exists $j > i$ such that $U_j = U^*$. By applying the above argument, we may replace U_i with $U_j = U^*$ in the sequence. We arrive at the sequence $U' = (U'_i)$ with $U'_i = U^*$ for every i. ◀

[2] Any family $\mathcal{F}$ with a constant-cost protocol can be turned into a protocol ignorant of the size by requiring that Alice and Bob tell the referee which of the 2^{c^2} possible decision functions to use, where $c = 2^{R^{\text{univ}}(\mathcal{F})}$.

2.3 Implicit Graph Representations and Induced-Universal Graphs

Kannan, Naor, and Rudich [23] call a family of graphs an *implicit* graph family if each of the n vertices can be given a label of $O(\log n)$ bits so that adjacency can be determined from the labels of two vertices. They observe that an implicit encoding gives an upper bound on the size of an *induced-universal graph*. We define these terms below in slightly more generality (and omit the requirement that encoding and decoding be done in polynomial time):

▶ **Definition 2.18.** *Let $\mathcal{F} = (\mathcal{F}_i)$ be a graph family and $m(i)$ a function of the graph size. The family $\mathcal{F}$ has an* m-implicit *encoding if $\forall i, \exists F_i : \{0,1\}^{m(i)} \times \{0,1\}^{m(i)} \to \{0,1\}$ such that F_i is symmetric and $\forall G \in \mathcal{F}_i, \exists g : V(G) \to \{0,1\}^{m(i)}$ satisfying $\forall x, y \in V(G), F_i(g_i(x), g_i(y)) = G(x, y)$.*

For a graph family $\mathcal{F} = (\mathcal{F}_i)$, an induced-universal graph sequence *is a sequence $U = (U_i)$ such that for each i and all $G \in \mathcal{F}_i$, G is an induced sugraph of U_i.*

Our notion of $\sqsubset$-universal graphs differs from induced-universal graphs, since the embedding relation $G \sqsubset U_i$ allows non-injective mappings (two vertices of G may be mapped to the same vertex in U_i). This difference accounts for the extra factor $n(i)$ in the next theorem.

▶ **Theorem 2.19** ([33])**.** *Let $\mathcal{F} = (\mathcal{F}_i)$ be a graph family with size $n(i)$. If there exists an m-implicit encoding of $\mathcal{F}$ there is an induced-universal graph sequence $U = (U_i)$ such that $|U_i| \leq n(i)2^{m(i)} = 2^{m(i)+\log n(i)}$.*

Due to the fact that a deterministic universal SMP protocol may always be assumed to be symmetric (Proposition 2.6), it follows by definition and from Lemma 2.15 that:

▶ **Theorem 1.1** (Restated)**.** *A graph family $\mathcal{F} = (\mathcal{F}_i)$ is m-implicit iff $D^{\mathsf{univ}}(\mathcal{F}_i) \leq m(i)$ for every i. Therefore, $\mathcal{F}$ is $O(R^{\mathsf{univ}}(\mathcal{F}) \cdot \log n)$-implicit.*

If one's goal is merely to obtain an $O(1)$-cost universal SMP protocol for a family $\mathcal{F}$, the next observation shows that it suffices to find an $O(1)$-cost, public-coin, 2-way protocol for each member of $\mathcal{F}$. Therefore the family of all graphs with an $O(1)$-cost 2-way protocol is an implicit graph family with a polynomial-size induced-universal graph.

▶ **Corollary 1.2** (Restated)**.** *Let $\mathcal{F} = (\mathcal{F}_i)$ be a family of graphs with size $n(i)$ and suppose that for every graph $G \in \mathcal{F}_i$ there is an ϵ-error 2-way randomized communication protocol with cost at most $c(i)$. Then $R^{\mathsf{univ}}_{\epsilon}(\mathcal{F}) \leq 2^{c(i)}$. Furthermore, for any fixed constant c, the family $\mathcal{F}$ of graphs with $R^{\leftrightarrow}(\textsc{Adj}(G)) \leq c$ is $O(\log n)$-implicit.*

Proof. Every 2-way, deterministic cost c protocol can be represented as a binary tree with at most 2^c nodes, where each node is owned by either Alice or Bob and the message sent at each step is a 0 or 1 informing the other player of which branch to take in the tree. A randomized 2-way protocol is a distribution over such trees. To obtain a universal SMP protocol for the family $\mathcal{F}$, Alice and Bob do the following. On input $G \in \mathcal{F}$ and $x, y \in V(G)$, Alice and Bob use shared randomness to draw the deterministic cost c protocol for G from the distribution defined by the randomized 2-way protocol. Alice sends the size 2^c protocol tree and for each node she owns she identifies the branch to be taken. Bob does the same. The referee may then simulate the protocol. The conclusion follows from Theorem 1.1. ◀

3 Distance Labeling of Distributive Lattices

Distributive lattices and distances on these lattices will be defined in the next subsection, where we also give a necessary lemma characterizing the distances in terms of the *meet* and *join*. We will then present an $O(k \log k)$ weakly-universal protocol and an $O(k^2)$ universal

communication protocol for the family $\mathcal{D}^k$, where $\mathcal{D}$ are the distributive lattices. This implies a $O(k^2 \log n)$-implicit encoding $\mathcal{D}^k$ of the family $\mathcal{D}$ of distributive lattices. The $O(k \log k)$ weakly-universal protocol is optimal for sufficiently small values of k, since it applies to the k-Hamming Distance problem as a special case, for which Sağlam [31] recently gave a matching lower bound (even for 2-way communication). We obtain this result by adapting the optimal $O(k \log k)$ communication protocol for k-Hamming Distance originally presented by Huang et al. [21].

We also consider *modular* lattices, a generalization of distributive lattices, and show that deciding $\mathsf{dist}(x, y) \leq 2$ requires a protocol with cost $\Omega(n^{1/4})$.

3.1 Preliminaries on Distributive Lattices

A lattice is a type of partial order. We briefly review distributive lattices (see e.g. [9] for a good introduction) and then give a characterization of distances in modular and distributive lattices. The undirected graphs we study are the *cover graphs* of partial orders. For x, y in a partial order P, we say that y *covers* x and write $x \prec y$ if $\forall z \in P$: if $x \leq z < y$ then $x = z$. The *cover graph* (which is the undirected version of the *transitive reduction*) is the graph $\mathrm{cov}(P)$ on vertex set P with an edge $\{x, y\}$ iff $x \prec y$ or $y \prec x$.

We will define a few types of lattices.

▶ **Definition 3.1.** *Let $(P, <)$ be a partial order. For a pair $x, y \in P$:*

- *If the set $\{z \in P : x, y \geq z\}$ has a unique maximum, we call that maximum the* join *of x, y and write it as $x \wedge y$;*
- *If the set $\{z \in P : x, y \leq z\}$ has a unique minimum, we call that minimum the* meet *of x, y and write it as $x \vee y$.*

If $\forall x, y \in P$ the elements $x \wedge y, x \vee y$ exist, then P is a lattice. *A lattice L is* ranked *if there exists a rank function such that $x \prec y \implies \mathrm{rank}(x) + 1 = \mathrm{rank}(y)$ and the minimum element 0_L satisfies $\mathrm{rank}(0_L) = 0$. A finite lattice L is* upper-semimodular *if for every $x, y \in L$, $x \wedge y \prec x, y \implies x, y \prec x \vee y$. L is* lower-semimodular *if for every $x, y \in L$, $x, y \prec x \vee y \implies x \wedge y \prec x, y$. L is* modular *if it is both upper- and lower-semimodular. A lattice L is* distributive *if for all $x, y, z \in L$, $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$. Every distributive lattice is modular and every modular lattice is ranked [9].*

A point x in a lattice L is join-irreducible *if there is no set $S \subseteq L$ such that $x = \bigvee S$ and* meet-irreducible *if there is no set $S \subseteq L$ such that $x = \bigwedge S$. Write $J(L)$ for the set of join-irreducible elements.*

A subset D of a partial order P is a downset *or* ideal *if: for all $x, y \in L$, if $x \in D$ and $y \leq x$ then $y \in D$. We will write $D(P)$ for the set of ideals of P.*

▶ **Theorem 3.2** (Birkhoff (see e.g. [9])). *Every distributive lattice L is isomorphic to the lattice of downsets of the partial order on its join-irreducible elements, ordered by inclusion; i.e. $L \simeq D(J(L))$, with the meet and join operations given by set union and intersection respectively.*

We need to prove some facts about distances in modular lattices.

▶ **Proposition 3.3.** *Let L be a graded lattice and let $x, y \in L$. Then $\mathsf{dist}(x, y) \geq |\mathrm{rank}(x) - \mathrm{rank}(y)|$, with equality if $x < y$ or $y < x$.*

Proof. This follows from the fact that for every edge $u \prec v$ in the path from x to y has $\mathrm{rank}(u) + 1 = \mathrm{rank}(v)$. ◀

To prove our characterization of distance, we define *inversions* in the path.

▶ **Definition 3.4.** *Let L be a lattice and let $c_1, \dots, c_m$ be a path in $\mathrm{cov}(L)$, so that $c_i \prec c_{i+1}$ or $c_{i+1} \prec c_i$ for each i. If $c_{i-1}, c_{i+1} \prec c_i$ or $c_i \prec c_{i-1}, c_{i+1}$ we call c_i an* inversion *on the path.*

▶ **Lemma 3.5.** *The following holds for any x, y in a lattice $\mathcal{M}$:*
1. *If $\mathcal{M}$ is lower-semimodular then $\mathsf{dist}(x, y) = \mathsf{dist}(x, x \wedge y) + \mathsf{dist}(y, x \wedge y)$;*
2. *If $\mathcal{M}$ is upper-semimodular then $\mathsf{dist}(x, y) = \mathsf{dist}(x, x \vee y) + \mathsf{dist}(y, x \vee y)$;*
3. *If $\mathcal{M}$ is distributive then $\mathsf{dist}(x, y) = |X \Delta Y|$ where $X, Y \in D(J(\mathcal{M}))$ are isomorphic images of x, y in Birkhoff's representation.*

Proof. It suffices to prove the first statement: the second follows by the analogous argument and the third follows from the modulartiy of distributive lattices and Birkhoff's representation.

Let $\mathcal{M}$ be lower-semimodular, let $x, y \in \mathcal{M}$, and let $x = c_0, c_1, \dots, c_m = y$ be a shortest path between x and y, so that $\mathsf{dist}(x, y) = \mathsf{dist}(x, c_i) + \mathsf{dist}(y, c_i)$ for any i. The statement holds trivially when $x < y$ or $y < x$ (since $x \wedge y = x$ or $x \wedge y = y$), so we assume x, y are incomparable. We prove the statement by induction on the largest rank of an inversion of the form $c_{i-1}, c_{i+1} \prec c_i$ in the path.

First suppose that c_i is any element of the path and assume for contradiciton that $\mathrm{rank}(c_i) < \mathrm{rank}(x \wedge y)$. Then

$$\mathsf{dist}(x, x \wedge y) = \mathrm{rank}(x) - \mathrm{rank}(x \wedge y) < \mathrm{rank}(x) - \mathrm{rank}(c_i) \leq \mathsf{dist}(x, c_i),$$

a contradiction. Thus $\mathrm{rank}(c_i) \geq \mathrm{rank}(x \wedge y)$ for each element of the path.

Suppose there are no inversions of the form $c_{i-1}, c_{i+1} \prec c_i$. Then $c_i < x, y$ and therefore $c_i \leq x \wedge y$ so $\mathrm{rank}(c_i) \leq \mathrm{rank}(x \wedge y)$, and by the above inequality we have $\mathrm{rank}(c_i) \geq \mathrm{rank}(x \wedge y)$, so $\mathrm{rank}(c_i) = \mathrm{rank}(x \wedge y)$. Therefore, as desired,

$$\begin{aligned}\mathsf{dist}(x, y) &= \mathsf{dist}(x, c_i) + \mathsf{dist}(y, c_i) = \mathrm{rank}(x) - \mathrm{rank}(c_i) + \mathrm{rank}(y) - \mathrm{rank}(c_i) \\ &= \mathrm{rank}(x) - \mathrm{rank}(x \wedge y) + \mathrm{rank}(y) - \mathrm{rank}(x \wedge y) \\ &= \mathsf{dist}(x, x \wedge y) + \mathsf{dist}(y, x \wedge y)\,.\end{aligned}$$

Now let c_i be an inversion of the form $c_{i-1}, c_{i+1} \prec c_i$ with $\mathrm{rank}(c_i) > \mathrm{rank}(x \wedge y)$. Then by lower-semimodulariity there is an element $c_i' = c_{i-1} \wedge c_{i+1} \prec c_{i-1}, c_{i+1}$. Then replacing c_i with c_i' maintains the length of the path. Performing the same operation on all such inversions of maximum rank reduces the maximum rank by 1 and the result holds by induction. ◀

3.2 A Universal Protocol for Distributive Lattices

Write $\mathcal{D} = (\mathcal{D}_n)$ for the family of cover graphs of distributive lattices on n vertices. We first give an optimal protocol for distances in distributive lattices in the *weak* universal model (recall that in this model, the referee sees the shared randomness). This protocol is adapted from a simplified presentation of Huang et al.'s k-Hamming Distance protocol ([21]) communicated to us by E. Blais.

▶ **Theorem 3.6.** *For any $\epsilon > 0$ and integer k, $R_\epsilon^{\mathsf{weak}}(\mathcal{D}^k) = O\left(k \log(k/\epsilon)\right)$.*

Proof. For any distributive lattice $L \simeq D(J(L))$, identify each vertex $x \in L$ with its ideal $X \subseteq J(L)$ of join-irreducibles. Write $e_1, \dots, e_m$ for the basis vectors of $\mathbb{F}_2^m$. Consider the following protocol. On the distributive lattice L and vertices x, y, Alice and Bob perform the following:

1. Define $m = \lceil \frac{(k+2)^2}{\epsilon} \rceil, q = \lceil \log \frac{1}{\epsilon} + \log \sum_{i=0} \binom{m}{i} \rceil$.
2. Let $S = (s_1, \ldots, s_m)$ be a multiset of uniformly random elements of $\mathbb{F}_2^q$.
3. For each join-irreducible element $j \in J(L)$ assign a uniformly random index $i_j \sim [m]$.
4. For each vertex $v \subseteq J(L)$ there is an indicator vector $a(v) \in \mathbb{F}_2^m$ defined by $a(v) = \sum_{j \in v} e_{i_j}$. Label v with $\ell(v) = \sum_{i=1}^m a(v)_i s_i$.
5. Alice sends $\ell(x)$ and Bob sends $\ell(y)$ to the referee.
6. The referee accepts iff $\ell(x) + \ell(y)$ is a sum of at most k elements of S.

By Lemma 3.5 and Birkhoff's theorem, $\mathsf{dist}(x,y) = \mathsf{dist}(x, x\wedge y) + \mathsf{dist}(x\wedge y, y) = |X \setminus Y| + |Y \setminus X| = |X \Delta Y|$, where Δ denotes the symmetric difference. Suppose $\mathsf{dist}(x,y) = |X\Delta Y| \le k$. Then $\ell(x) + \ell(y) = \sum_{j \in X\Delta Y} c(j)$ is a sum of at most k elements of S, so the protocol accepts with probability 1 (so this protocol has 1-sided error).

Now suppose $\mathsf{dist}(x,y) = |X\Delta Y| \ge k+1$. The correctness of the protocol follows from the next two claims along with the observations that $a(x)+a(y) = a(x\wedge y)$ and $\ell(x)+\ell(y) = \ell(x\wedge y)$ (with arithmetic in $\mathbb{F}_2$) and that $\mathsf{dist}(x,y) \ge k+1$ implies $\mathrm{rank}(x \wedge y) \ge k+1$. We will write $|a(v)|$ for the number of 1's in the vector $a(v)$.

▷ Claim 3.7. Any vertex $v \subseteq J(L)$ with $\mathrm{rank}(v) \ge k+1$ has $|a(v)| \ge k+1$ with probability at least $1 - \epsilon/2$.

Proof of claim. If $\mathrm{rank}(v) = k+1$, so v is a set of $k+1$ join-irreducibles, then the probability that any two indices $i_j, i_{j'}$ collide, for $j, j' \in v$, is by the union bound at most

$$\binom{k+1}{2} \mathbb{P}[i_j = i_{j'}] = \frac{k(k+1)}{2}\frac{1}{m} \le \frac{(k+1)^2}{2}\frac{\epsilon}{(k+2)^2} = \epsilon/2\,.$$

For $\mathrm{rank}(v) > k+1$ choose $v' \prec v$ so $k+1 \le \mathrm{rank}(v') < \mathrm{rank}(v)$, so using induction and the assumption $\epsilon < 1/2$,

$$\begin{aligned}\mathbb{P}[|a(v)| \le k] &= \frac{k+1}{m}\mathbb{P}[|a(v')| = k+1] + \frac{k}{m}\mathbb{P}[|a(v')| \le k] < \frac{\epsilon}{k+2} + \frac{\epsilon}{k+2}\cdot\frac{\epsilon}{2} \\ &= \epsilon\left(\frac{1}{k+2} + \frac{\epsilon}{2(k+2)}\right) \le \epsilon\left(\frac{1}{3} + \frac{1}{12}\right) < \epsilon/2\,.\end{aligned}$$

◁

▷ Claim 3.8. For any vertex $v \subseteq J(L)$, if the indicator vector $a(v)$ has weight $\ge k+1$ then, with probability at least $1 - \epsilon/2$, $\ell(v)$ is not a sum of at most k vectors in S.

Proof of claim. Write kS for the set of all sums of at most k vectors of S. Fix any $a(v)$ with weight $\ge k+1$ and let $A = \{i : a(v)_i = 1\}$ so $|A| \ge k+1$. Let $b \in kS$ be any sum of k vectors in S, and let $B \subset [m]$ be a set of indices of size $|B| \le k$ such that $b = \sum_{i\in B} s_i$.

Since $|B| \le k < |A|$ we must always have $A \setminus B \ne \emptyset$ and $\ell(v) + b = \sum_{i \in A\setminus B} s_i$, so $\mathbb{P}[\ell(v) + b = 0] = 2^{-q}$. Therefore, by the union bound over all such vectors b,

$$\mathbb{P}[\ell(v) \in kS] \le \sum_{i=0}^{k} \binom{m}{i} 2^{-q} < \epsilon/2\,.$$

◁

We can put a bound on q by using

$$\sum_{i=0}^{k}\binom{m}{i} \le k\binom{m}{k} \le k\left(\frac{em}{k}\right)^k$$

so

$$q \le 1 + \log\frac{1}{\epsilon} + \log k + k\log\frac{em}{k} \le \log\frac{2k}{\epsilon} + k\log\lceil\frac{ek}{\epsilon}\rceil = O\left(k\log\frac{k}{\epsilon}\right)\,.$$

◀

Observe that the referee must see the set S for the above protocol to work. We can easily modify the above protocol to get $O(k^2)$.

▶ **Theorem 3.9.** *For any $\epsilon > 0$ and any integer k, $R_\epsilon^{\mathsf{univ}}(\mathcal{D}^k) = O\left(k^2 \log(1/\epsilon)\right)$.*

Proof. The protocol is the same as above, with the following modification: Alice and Bob each send the indicator vectors $a(x), a(y) \in \mathbb{F}_2^m$.

The correctness of this protocol for error $1/3$ follows from Claim 3.7. Observe that Alice and Bob use the same strategy to send their messages and that the decision function is symmetric. The communication cost is now at most $m = \lceil 3(k+2)^2/2 \rceil$.

This protocol is one-sided, so to achieve error ϵ we can run the protocol $r = \lceil \log_3(1/\epsilon) \rceil$ times and take the AND of the results. The probability of failure is $(1/3)^r = 3^{-r} < \epsilon$. ◀

Now we apply Theorem 1.1 to obtain Theorem 1.3.

Since the family of distributive lattices is an upwards family (simply append a new least element to obtain a larger distributive lattice), we see from Proposition 2.17 that lattices in $\mathcal{D}^k$ can be randomly embedded into a constant-size graph, for any constant k. In fact, by inspection of the protocol, we see that the family $\mathcal{D}$ can be randomly embedded into a small-dimensional hypercube, while $\mathcal{D}^k$ can be embedded into the k-closure of the $O(k^2)$-dimensional hypercube.

▶ **Corollary 3.10.** *For any $\epsilon > 0$ and any k, there exists a graph U of size $2^{O(k^2 \log(1/\epsilon))}$ such that for all $L \in \mathcal{D}^k$, $L \sqsubset_\epsilon U$.*

3.3 Lower Bound for Modular Lattices

Since Lemma 3.5 works for any modular lattices, it is natural to ask whether we can achieve a similar constant-cost protocol for computing distance thresholds in modular lattices. However, we show that this is impossible.

▶ **Lemma 3.11.** *There is a function $m(n) = O(n^4)$ such that if G is any graph with n vertices (where $G(u,u) = 1$ for all u), there exists a modular lattice M with size $m(n)$ such that G is an induced subgraph of $\mathrm{cov}(M)^2$.*

Proof. Construct the lattice M as follows:

1. Start with vertices V, which are all incomparable.
2. For each edge $e = \{u, v\} \in E$, add vertices a_e, b_e such that $a_e < u, v < b_e$.
3. $\forall e = \{u, v\}, e' = \{u', v'\} \in E$ such that $e \cap e' = \emptyset$ add a vertex $c_{e,e'}$ with $a_e, a_{e'} < c_{e,e'} < b_e, b_{e'}$.
4. Add vertices 0_M and 1_M such that $0_M < a_e$ and $b_e < 1_M$ for all $e \in E$.

First we prove that M is a modular lattice and then we prove the bound on the size.

▷ Claim 3.12. M is a modular lattice.

Proof of claim. Observe that all orderings $<$ directly imposed by this process are covering orders $\prec$. Let $A = \{a_e\}_{e \in E}, B = \{b_e\}_{e \in E}, C = \{c_e\}_{e \in E}$ and V the original set of vertices. By construction, M is graded with $\mathrm{rank}(0_M) = 0, \mathrm{rank}(A) = 1, \mathrm{rank}(V) = \mathrm{rank}(C) = 2, \mathrm{rank}(B) = 3, \mathrm{rank}(1_M) = 4$. Note that for every pair of vertices $x, y \in M, 0_M \leq x, y \leq 1_M$ so upper- and lower-bounds exist.

Assume for contradiction that M is not a modular lattice, so there exist incomparable $x, y \in M$ such that either $x \wedge y$ or $x \vee y$ does not exist, or such that $x \wedge y \prec x, y \not\prec x \vee y$ or $x \wedge y \not\prec x, y \prec x \vee y$.

Case 1: Suppose $\text{rank}(x) \neq \text{rank}(y)$. Then $x \wedge y = 0_M$ and $x \vee y = 1_M$ so $x \wedge y \not\prec x, y \not\prec x \vee y$.
Case 2: Suppose $x, y \in A$ so $x = a_e, y = a_{e'}$. Then $0_M = a_e \wedge a_{e'} \prec a_e, a_{e'}$. If $a_e, a_{e'} < u, v$ for $u, v \in V$ then $u, v \in e \cap e'$ so $u = v$. If $a_e, a_{e'} < v, c_{d,d'}$ for $v \in V$ and $c_{d,d} \in C$ then $v \in e \cap e'$ and $c_{d,d'} = c_{e,e'}$ so $e \cap e' = \emptyset$, a contradiction. Finally, if $a_e, a_{e'} < c_{d,d'}, c_{d',d''}$ then $c_{d,d'} = c_{d',d''} = c_{e,e'}$. So $a_e \vee a_{e'}$ exists and $a_e \wedge a_{e'} \prec a_e, a_{e'} \prec a_e \vee a_{e'}$. The same argument holds for $x, y \in B$.
Case 3: Suppose $x, y \in V$ and assume $a_e, a_{e'} < x, y$. Then $x, y \in e \cap e'$ so $a_e = a_{e'}$. A similar argument holds for $x, y < b_e, b_{e'}$. So $x \wedge y \prec x, y \prec x \vee y$.
Case 4: Suppose $x, y \in C$ so $x = c_{e,e'}, y = c_{d,d'}$. Suppose $a_s, a_t < c_{e,e'}, c_{d,d'}$. Then $s, t \in \{e, e'\} \cap \{d, d'\}$ so either $\{e, e'\} = \{d, d'\}$ or $s = t$. The same argument holds for $c_{e,e'}, c_{d,d'} < b_s, b_t$ so $x \wedge y \prec x, y \prec x \vee y$.
Case 5: Suppose $x \in V, y \in C$ so $y = c_{e,e'}$ which implies $e \cap e' = \emptyset$. If $x \notin e \cup e'$ then $x \wedge c_{e,e'} = 0_M$ and $x \vee c_{e,e'} = 1_M$ so $x \wedge c_{e,e'} \not\prec x, c_{e,e'} \not\prec x \vee c_{e,e'}$; so suppose $x \in e \cup e'$. If $a_e, a_{e'} < x, c_{e,e'}$ then $x \in e \cap e'$ which is a contradiction. Then $x \in e$ or $x \in e'$; say $x \in e$. Then $a_e = x \wedge c_{e,e'}$. The same argument holds for B so $a_e = x \wedge c_{e,e'} \prec x, c_{e,e'} \prec x \vee c_{e,e'} = b_e$. ◁

▷ Claim 3.13. G is an induced subgraph of $\text{cov}(M)^2$.

Proof of claim. Suppose $\{u, v\} \in E$. Then there is $a_e \prec u, v$ so $\mathsf{dist}(u, v) \leq 2$ in $\text{cov}(M)$. Now let $u, v \in V(G)$ and suppose $\mathsf{dist}(u, v) \leq 2$ in $\text{cov}(M)$ so that, by Lemma 3.5, $u \wedge v \prec u, v \prec u \vee w$. By construction, either $u = v$ so $G(u, v) = G(u, u) = 1$, or $u \wedge v = a_e$ for some $e \in E(G)$ so $u, v \in e$ and therefore $G(u, v) = 1$. ◁

The size of M is at most $2 + |E(G)| + |E(G)|^2 = O(n^4)$. Let $m(n)$ be the maximum size of a modular lattice obtained in this way from a graph of size n. We want all constructions to be of the same size, so repeatedly append new least elements until the size reaches $m(n)$; this maintains the modular lattice property. ◀

▶ **Theorem 3.14.** *Let $\mathcal{M} = (\mathcal{M}_n)$ be the family of cover graphs of modular lattices. $R^{\text{univ}}(\mathcal{M}^2) \geq \Omega(n^{1/4})$.*

Proof. Suppose there is a protocol for $\mathcal{M}^2$ with cost $o(n^{1/4})$. Given a graph G of size n, Alice and Bob construct the modular lattice of size $m(n) = O(n^4)$ with G an induced subgraph of $\text{cov}(M)^2$ and run the protocol for $\mathcal{M}^2$ with size $m(n)$ (observe that all possible constructions must be of the same size, since the referee does not know which lattice Alice and Bob construct). This has cost $o(m(n)^{1/4}) = o(n)$, which contradicts Theorem 1.6. ◀

4 Communication on Efficiently Labelable Graphs

In this section we take inspiration from the field of implicit graphs and graph labeling and show that one may often, but not always, obtain constant-cost adjacency and k-distance protocols for families that are commonly studied in the graph labeling literature.

4.1 Trees, Forests, and Interval Graphs

In this section we pick the low-hanging fruit from trees and forests (and interval graphs). Applying Theorem 1.1 with the next lemma, we get Theorem 1.4.

▶ **Lemma 4.1.** *Let $\mathcal{T} = (\mathcal{T}_n)$ be the family of trees of size n. $R^{\text{univ}}_{\epsilon}(\mathcal{T}^k) = O\left(k \log \frac{1}{\epsilon}\right)$, and this protocol will correctly compute the distance in the case $\mathsf{dist}(x, y) \leq k$.*

Proof. Consider the following protocol. On input $(T, x), (T, y)$ for a tree T, Alice and Bob perform the following.

1. Partition the vertices of T into sets $T_1, \ldots, T_m$ such that $T_i = \{v \in V(T) : (i-1)k \leq \text{depth}(v) < ik\}$. For each $v \in V(T)$ let $t(v)$ be the index of the unique set satisfying $v \in T_{t(v)}$.
2. For each vertex $v \in V(T)$ assign a uniformly random color $\ell(v)$ in $[m]$ for $m = \lceil 6/\epsilon \rceil$. Let x' be root of the subtree of $T_{t(x)}$ that contains x, and let x'' be the root of the subtree of $T_{t(x)-1}$ that contains x. Let $x_0, x_1, \ldots, x_k, \ldots, x_{k_1} = x$ be the path from x'' to x (with $x_k = x'$) and let $y_0, \ldots, y_k, \ldots, y_{k_2}$ be the path from y'' to y. Alice and Bob send $\ell(x_0), \ldots, \ell(x_{k_1})$ and $\ell(y_0), \ldots, \ell(y_{k_2})$ respectively.
3. If $\ell(x') = \ell(y')$, let p be the maximum index such that $\ell(x_i) = \ell(y_i)$ for each $k < i \leq p$. Let $d = (k_1 - p) + (k_2 - p)$. If $\ell(x'') = \ell(y'')$, let p be the maximum index such that $\ell(x_i) = \ell(y_i)$ for each $i \leq p$ and let $d = (k_1 - p) + (k_2 - p)$. If $\ell(x'') = \ell(y')$ let p be the maximum index such that $\ell(x_i) = \ell(y_{k+i})$ for each $i \leq p$ and let $d = (k_1 - p) + (k_2 - k - p)$. If $\ell(x') = \ell(y'')$ do the same with x, y reversed. In each case, if $d \leq k$, the referee outputs d, otherwise they output "$> k$". If none of the above cases hold, output "$> k$".

The cost of this protocol is $2k\lceil \log m \rceil = O(k \log(1/\epsilon))$. With probability at least $1 - 4/m > 1 - \epsilon/2$, each of the possible equalities $x'' = y'', x' = y', x'' = y', x' = y''$ will be correctly observed by the referee. If $\{x', x''\} \cap \{y', y''\} = \emptyset$ then x, y are not in the same subtree rooted at depth $\text{depth}(x'')$, so the distance from x to any common ancestor of x, y is at least $\mathsf{dist}(x, x'') > k$. Therefore if $\mathsf{dist}(x, y) \leq k$, one of these equalities will hold. If $x'' = y''$ and q is the maximum integer such that $x_i = y_i$ for all $i \leq q$ then $\mathsf{dist}(x, y) = (k_1 - q) + (k_2 - q)$, because the deepest common ancestor of x, y is at depth $\text{depth}(x_0) + q$. Conditional on the 4 equalities being correctly observed, we will have $d = (k_1 - p) + (k_2 - p) \leq k$ since $p \geq q$. If $p > q$ then $\ell(x_{q+1}) = \ell(y_{q+1})$ even though $x_{q+1} \neq y_{q+1}$, which occurs with probability $1/m < \epsilon/2$. Therefore the probability that $d \neq \mathsf{dist}(x, y)$ is at most $2(\epsilon/2) = \epsilon$ when $\mathsf{dist}(x, y) \leq k$. A similar argument holds in the other 3 cases.

If $\mathsf{dist}(x, y) > k$ then still with probability at least $1 - \epsilon/2$ all 4 possible equalities are correctly observed. Following the same argument as in the equality case, we see that if any of the equalities hold we will have $d = \mathsf{dist}(x, y)$ with probability greater than $1 - \epsilon/2$, for total error probability less that ϵ. If none of the 4 equalities hold then the probability of error is at most $\epsilon/2$. ◀

Since trees have efficient protocols, one might wonder about generalizations of trees. The *arboricity* of a graph is one such generalization, which measures the minimum number of forests required to partition all the edges.

▶ **Definition 4.2.** *A graph $G = (V, E)$ has* arboricity α *iff there exists an edge partition of G into forests $T_1, \ldots, T_\alpha$. Equivalently, for S ranging over the set of subgraphs of G, G has*

$$\max_S \left\lceil \frac{E(S)}{V(S) - 1} \right\rceil \leq \alpha \,.$$

Low-arboricity graphs easily admit an efficient universal SMP protocol for adjacency.

▶ **Proposition 4.3.** *Let $\mathcal{F}$ be any family of graphs with arboricity at most α. For all $\epsilon > 0, R_\epsilon^{\mathsf{univ}}(\mathcal{F}) = O\left(\alpha \log \frac{\alpha}{\epsilon}\right)$.*

Proof. On the graph G and vertices x, y, Alice and Bob perform the following:

1. Compute a partition of G into α forests $T_1, \ldots, T_\alpha$.
2. Assign to each vertex v a uniformly random number $\ell(v) \sim [m]$ for $m = \lceil 2\alpha/\epsilon \rceil$.

3. Let x_i be the parent of x in tree i and let y_i be the parent of y. Alice sends $\ell(x)$ and $\ell(x_i)$ for each i, and Bob does this same with y.
4. The referee accepts iff $\ell(x) = \ell(y_i)$ or $\ell(y) = \ell(x_i)$ for any i.

This protocol has one-sided error since if x, y are adjacent then either $x_i = y$ or $y_i = x$ for some i, so the referee will accept with probability 1. If x, y are not adjacent then the referee will accept with probability at most $2\alpha \cdot \frac{1}{m} < \epsilon$. ◀

However, even graphs of arboricity 2 do not admit efficient protocols or labeling schemes for distance 2, which we can show by embedding an arbitrary graph of size $\Omega(\sqrt{n})$ into the 2-closure of an arboricity 2 graph of size n:

▶ **Proposition 4.4.** *Let $\mathcal{F}$ be the family of arboricity-2 graphs. Then $R^{\mathsf{univ}}(\mathcal{F}^2) \geq \Omega(\sqrt{n})$.*

Proof. The lower bound is obtained via Theorem 1.6 in the same way as in Theorem 3.14, using the following construction. For all simple graphs $G = (V, E)$ with n vertices, there exists a graph A of size $n + \binom{n}{2}$ and arboricity 2 such that G is an induced subgraph of A^2. Let A be the graph defined as follows:

1. Add each vertex $v \in V$ to A;
2. For each pair of vertices $\{u, v\}$ add a vertex $e_{\{u,v\}}$ and add edges $\{u, e_{\{u,v\}}\}, \{v, e_{\{u,v\}}\}$ iff $\{u, v\} \in E$.

This graph has arboricity 2 since for each $e_{\{u,v\}}$ we may assign each of its 2 incident edges a color in $\{1, 2\}$ (if the edges exist). Then the edges with color $i \in \{1, 2\}$ form a forest with roots in V. ◀

Now we give an example of a family, the interval graphs, with size $O(\log n)$ adjacency labels but with no constant-cost universal SMP protocol; in fact, randomization does not give more than a constant-factor improvement for this family. An *interval graph* of size n is a graph G where for each vertex x there is an interval $X \subset [2n]$ such that any two vertices x, y are adjacent in G iff $X \cap Y \neq \emptyset$. These have an $O(\log n)$ adjacency labeling scheme [23] (one can simply label a vertex with its two endpoints in $[2n]$).

There is a simple reduction from the Greater-Than communication problem, in which Alice and Bob receive integers $x, y \in [n]$ and must decide if $x < y$. It is known that the one-way public-coin communication cost of Greater-Than is $\Omega(\log n)$ [25], so $R^{\parallel}(\text{Greater-Than}) = \Omega(\log n)$.

▶ **Proposition 4.5.** *For the family $\mathcal{F}$ of interval graphs, $R^{\mathsf{univ}}(\mathcal{F}) = \Omega(\log n)$.*

Proof. We can use a universal SMP protocol for $\mathcal{F}$ to get a protocol for Greater-Than as follows. Alice and Bob construct the interval graph with intervals $[1, i], [i, n]$ for each $i \in [n]$, so there are $2n$ vertices in G. On input $x, y \in [n]$, Alice and Bob compute adjacency on the intervals $[1, x], [1, y]$ and then again on $[1, x], [y, n]$. Assume both runs of the protcol succeed. Then when the output is 1 for both runs we must have $y \in [1, x]$ so $y \leq x$ and otherwise we have $y \notin [1, x]$ so $x < y$. ◀

4.2 Planar Graphs

Write $\mathcal{P}_n$ for the set of planar graphs of size n and write $\mathcal{P} = (\mathcal{P}_n)$ for the family of planar graphs. Gavoille et al. [15] gave an $O(\sqrt{n} \log n)$ labeling scheme where $\mathsf{dist}(x, y)$ can be computed from the labels of x, y, and Gawrychowski and Uznański [16] improved this to $O(\sqrt{n})$. These labeling schemes recursively identify size-$O(\sqrt{n})$ sets S and record the distance of each vertex v to each $u \in S$, so the $\sqrt{n}$ factor is unavoidable using this technique. We want to solve k-distance with a cost independent of n, so we need a new method. Our main tool is Schnyder's elegant decomposition of planar graphs into trees:

▶ **Theorem 4.6** (Schnyder [32], see [11]). *Define the dimension* $\dim(G)$ *of a graph* G *as is the minimum* d *such that there exist total orders* $<_1, \ldots, <_d$ *on* $V(G)$ *satisfying:*

(*) For every edge $\{u, v\} \in E$ *and* $w \notin \{u, v\}$ *there exists* $<_i$ *such that* $u, v <_i w$.

G *is planar iff* $\dim(G) \leq 3$. *If* G *is planar then there exists a partition* T_1, T_2, T_3 *of the edges into directed trees satisfying the following. Let* T_i^{-1} *be edge-induced directed graph on* $V(G)$ *obtained by reversing the direction of each edge in* T_i. *The graphs with edges* $T_i \cup T_{i-1}^{-1} \cup T_{i+1}^{-1}$ *have linear extensions* $<_i$ *such that* $<_1, <_2, <_3$ *satisfy (*).*

Schnyder's Theorem implies that the arboricity of planar graphs is at most 3, so we may use the protocol for low-arboricity graphs (Proposition 4.3) to determine adjacency in $\mathcal{P}$, so we move on to $\mathcal{P}^2$, which may have large arboricity (arboricity is within a constant factor of *degeneracy*):

▶ **Theorem 4.7** ([1]). *There are planar graphs* P *for which the degeneracy of* P^2 *is* $\Theta(\deg P)$, *where* $\deg P$ *is the maximum degree of any vertex in* P.

We avoid this blowup in arboricity by treating edges of the form $a \leftarrow b \rightarrow c$ separately (with directions taken from the Schnyder wood). The proof uses the following split operation:

▶ **Definition 4.8.** *Let* $G \in \mathcal{P}$ *and fix a planar map and a Schnyder wood* T_1, T_2, T_3. *Define the graph* $\mathsf{split}(G)$ *by the following procedure (see Figure 1):*

1. *For each vertex* $s \in V(G)$ *add vertices* s, s_1, s_2, s_3 *to* $\mathsf{split}(G)$ *(excluding* s_i *if* s *has no incoming edge in* T_i*). Add edges* (s_i, s) *to* T_i';
2. *For each (directed) edge* $(u, v) \in T_i$ *add the edges* $(u_{i-1}, v_i), (u_{i+1}, v_i)$ *(arithmetic mod 3) to* T_i';
3. *For the unique (directed) edge* $(v, u) \in T_i$ *add the edges* $(v_{i-1}, u), (v_{i+1}, u)$ *to* T_i'.

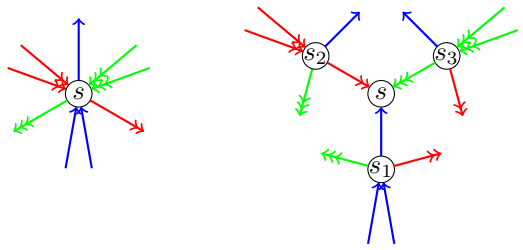

Figure 1 Splitting vertex s, with T_1, T_2, T_3 in blue, red, and green respectively (1,2, and 3 arrowheads).

▶ **Proposition 4.9.** $\mathsf{split}(G)$ *is planar.*

Proof. We prove that splitting any vertex s results in a planar graph. By induction we may then split each vertex in sequence and obtain a planar graph. Let $<_i$ be any total order on $V(G)$ extending $T_i \cup T_{i-1}^{-1} \cup T_{i+1}^{-1}$, which satisfies condition (*) by Schnyder's theorem. Let $<_1', <_2', <_3'$ be the same total orders, extending T_1', T_2', T_3', and augmented to include s_1, s_2, s_3 as follows:

1. For each $u \in V(G)$, $s_i <_j' u$ iff $s <_j u$ and $u <_j' s_i$ iff $u <_j s$;
2. For each i, set $s_i <_i' s <_i' s_{i+1} <_i' s_{i-1}$. This is possible since $\{s_i\}$ do not have a defined ordering in $<_i$ and remain incomparable after the previous step.

Note that for any edge $(u, v) \in T_i'$ we have $u <_i' v$ and $v <_j' u$ for $j \neq i$. It suffices to prove that condition (*) is satisfied by the new orders. Let $\{u, v\} \in E(\mathsf{split}(G))$ and let $w \notin \{u, v\}$. We will show that there exists i such that $u, v <_i' w$.

If $u, v, w \in V(G)$ then we are done since the orders $<'_i$ are the same as $<_i$ on these vertices.

If $u = s_i$ then either $v \in V(G) \setminus s$, in which case $v <_i s$ so $v <'_i u$ and therefore $u <'_j v$ for $j \neq i$, or $v = s$ so $u <'_i v$ and therefore $v <'_j u$ for $j \neq i$. Let $v \neq s$. For any $w \in V(G) \setminus \{v\}$ we have, by (*), either $v, s <_i w$ so $v <'_i u <'_i s <'_i w$, or $v, s <_j w$ so $u <'_j v <'_j w$. If $v = s$ then by construction there exists $(u', u) \in T_i$. By (*), either $u', v <_i w$ so $u <'_i v <'_i w$, or $u', v <_j w$ so $v <'_j u <'_j u' <'_j w$.

The only case remaining is if $w = s_i$ and $u, v \in V(G)$. By construction there exists $(w', w) \in T_i$. Either $u, v <_i w' <'_i w <'_i s$ or by (*) there exists j such that $u, v <_j s$ and since (w, s) is an edge in T'_i, $s <'_j w$ for $j \neq i$. ◀

▶ **Definition 4.10.** *Let $G = (V, E)$ be a planar graph. Fix a planar map and a Schnyder wood T_1, T_2, T_3. For each i, define the graph $G_i = (V, E \setminus T_i)$ as the graph obtained by removing each edge in T_i. Define the* head-to-head closure *of G_i, written $G_i^{\leftarrow\rightarrow}$, as the graph with an edge $\{u, v\}$ iff there exists $w \in V$ such that $u \leftarrow w \rightarrow v$ in G_i. (Observe that the two outgoing edges of w must be in T_{i-1}, T_{i+1}.) Let $G^{\leftarrow\rightarrow}$ be the subgraph of G^2 containing all edges occuring in $G_i^{\leftarrow\rightarrow}$ for each i.*

▶ **Lemma 4.11.** *Let G be a planar graph. For any graph M, if M is a minor of $G_i^{\leftarrow\rightarrow}$ then M is a minor of* $\mathsf{split}(G)$.

Proof. We will prove the following claim.

▷ Claim 4.12. For any set $P = \{P_j\}$ of simple paths $P_j \subseteq V(G_i^{\leftarrow\rightarrow})$, with endpoints $\{(s_j, t_j)\}$ such that no two paths P_j, P_k have the same endpoints and $P_j \cap P_k \subseteq \{s_j, s_k, t_j, t_k\}$, there exists a set of paths $Q = \{Q_j\}$ of paths in $\mathsf{split}(G)$ with the same endpoints such that

$$Q_j \cap Q_k \subseteq \{s_j, s_k, t_j, t_k\} \cup \{(s_j)_{i-1}, (s_k)_{i-1}, (t_j)_{i-1}, (t_k)_{i-1}\} \cup \{(s_j)_{i+1}, (s_k)_{i+1}, (t_j)_{i+1}, (t_k)_{i+1}\},$$

where the vertices s_i, s_{i+1}, s_{i-1} are defined as in the split operation.

Proof of claim. For each path P_j, perform the following. For each edge $\{u, w\}$ in the path P_j, there is some (not necessarily unique) vertex v such that either $(v, u) \in T_{i-1}$ and $(v, w) \in T_{i+1}$, or the same holds with u, w reversed. Add the edges $\{u, u_{i-1}\}, \{u_{i-1}, v_i\}, \{v_i, w_{i+1}\}, \{w_{i+1}, w\}$ to Q_j. If P_j is a singleton $P_j = \{u\}$ so $s_j = t_j$ then add u to Q_j.

Consider two paths Q_j, Q_k constructed this way. $G_i^{\leftarrow\rightarrow}$ has vertex set V and $\mathsf{split}(G)$ has vertex set $V' \supset V$. By construction, $P_j \subseteq Q_j$ and $P_k \subseteq Q_k$ and $(Q_j \cap V) = P_j$. Suppose there exists $z \in Q_j \cap Q_k$ that is not an endpoint, so $z \notin \{s_j, s_k, t_j, t_k\}$. If $z \in V$ then $z \in P_j \cap P_k \subseteq \{s_j, s_k, t_j, t_k\}$, so we only need to worry about $z \in V' \setminus V$.

If $z = v_i$ for some vertex v then there are unique distinct vertices $u_{i-1}, w_{i+1} \in V'$ adjacent to v_i such that $u_{i-1}, w_{i+1} \in Q_j \cap Q_k$. Then $u, w \in Q_j \cap Q_k$ also, so $u, w \in P_j \cap P_k$; but then $u \neq w$ are the start and end points of P_j, P_k, so $P_j = P_k$, a contradiction.

If $z = v_{i-1}$ for some vertex $v \in V$ then $v \in Q_j \cap Q_k$, so by the case above, $v \in \{s_j, s_k, t_j, t_k\}$ and $z \in \{(s_j)_{i-1}, (s_k)_{i-1}, (t_j)_{i-1}, (t_k)_{i-1}\}$. Likewise for $z = v_{i+1}$. ◁

Let M be a minor of $G_i^{\leftarrow\rightarrow}$, so a subdivision of M occurs as a subgraph of $G_i^{\leftarrow\rightarrow}$. Therefore there is a set of paths P in $G_i^{\leftarrow\rightarrow}$ satisfying the conditions of the claim, so that by contracting each path into a single edge, and deleting the rest of the graph, we obtain M. Let $Q = \{Q_j\}$ be the set of paths given by the claim. For endpoints $s_j, t_j \in Q_j$, contract the edges $\{s_j, (s_j)_{i\pm1}\}$ and $\{t_j, (t_j)_{i\pm1}\}$. The result is a contraction of $\mathsf{split}(G)$ and a set of paths Q' that is a subdivision of M, so M is a minor of $\mathsf{split}(G)$, which proves the lemma. ◀

▶ **Corollary 4.13.** *$G_i^{\leftarrow\rightarrow}$ is planar and $G^{\leftarrow\rightarrow}$ has arboricity at most 9.*

Proof. A graph is planar iff it does not contain K_5 or $K_{3,3}$ as a minor (Kuratowski's Theorem). If $G_i^{\leftarrow\rightarrow}$ is not planar then it contains K_5 or $K_{3,3}$ as a minor, so by the above lemma, $\mathsf{split}(G)$ contains K_5 or $K_{3,3}$ as a minor, so $\mathsf{split}(G)$ is not planar, a contradiction. Since planar graphs have arboricity at most 3, the edge union $G^{\leftarrow\rightarrow}$ of 3 planar graphs has arboricity at most 9. ◀

By separating the $\leftarrow\rightarrow$ edges from the remaining edges of $\mathcal{P}^2$, we obtain a constant-cost universal SMP protocol for $\mathcal{P}^2$, and then by applying Theorem 1.1 we obtain Theorem 1.5.

▶ **Lemma 4.14.** *For all $\epsilon > 0$, $R_\epsilon^{\mathsf{univ}}(\mathcal{P}^2) = O\left(\log \frac{1}{\epsilon}\right)$.*

Proof. For a planar graph $G = (V, E)$ with a fixed planar map and a Schnyder wood T_1, T_2, T_3, define the graph $G_i = (V, E \setminus T_i)$ as the graph obtained by removing the edges in tree T_i.

On planar graph $G \in \mathcal{P}_n$ and vertices x, y, Alice and Bob perform the following:

1. For each i define x_i, y_i to be the parents of x, y in T_i. Run the protocol for adjacency with error $\epsilon/7$ on (x, y_i) and (x_i, y) for each i.
2. Run the protocol for low-arboricity graphs on $G^{\leftarrow\rightarrow}$ with error $\epsilon/7$.
3. Accept iff one of the above sub-protocols accepts.

By Corollary 4.13, $G^{\leftarrow\rightarrow}$ has arboricity at most 9, we may apply the protocol for low-arboricity graphs in step 2. If $\mathsf{dist}(x, y) > 2$ then the protocol will correctly reject with probability at least $1 - \epsilon$ since there are 7 applications of $\epsilon/7$-error protocols. It remains to show that if $\mathsf{dist}(x, y) = 2$ then the algorithm will accept.

Suppose x, y are of distance 2. Then the paths between them are of the following forms (with edge directions taken from the Schnyder wood).

1. $x \to v \to y$ or $x \to v \leftarrow y$. This is covered by step 1.
2. $x \leftarrow v \to y$. This is covered by step 2. ◀

Since planar graphs are an upwards family (just insert a new vertex), we obtain a constant-size probabilistic universal graph for $\mathcal{P}^2$.

▶ **Corollary 4.15.** *For any $\epsilon > 0$, there is a graph U of size $O(\log(1/\epsilon))$ such that for every $G \in \mathcal{P}^2$, $G \sqsubset_\epsilon U$.*

5 Discussion and Open Problems

Error-tolerance. In the introduction we mentioned that the universal SMP model allows us to study error-tolerance in the SMP model. This could be done as follows: suppose the referee knows a reference graph G and the players are guaranteed to see a graph that is "close" to G by some metric. How much does this change the complexity of the problem, compared to computing G? One common distance metric in, say, the property testing literature, is to count the number of edges that one must add or delete. That is, for two graphs G, H on vertex set $[n]$, write $\mathsf{dist}(G, H) = \frac{1}{n^2} \sum_{i,j \in [n]} \mathbb{1}\left[G(i, j) \neq H(i, j)\right]$. The distance is usually thought of as a constant. We can easily give a strong negative result for this situation:

▶ **Proposition 5.1.** *Let $\mathcal{F}$ be any family of graphs and $\mathcal{F}_\delta$ the family of graphs G such that $\min_{F \in \mathcal{F}} \mathsf{dist}(G, F) \leq \delta$. Then*

$$R^{\mathsf{univ}}(\mathcal{F}_\delta) = \Omega(\sqrt{\delta} n)\,.$$

Proof. Let G be any graph on $\sqrt{\delta}n$ vertices and let $F \in \mathcal{F}$. Choose any set $S \subseteq V(F)$ with $|S| = |G|$. Construct F' by replacing the subgraph induced by S with the graph G. Then $\mathsf{dist}(F, F') \leq \frac{|G|^2}{n^2} = \delta$ so $F' \in \mathcal{F}_\delta$. Then the conclusion follows from Theorem 1.6. ◀

This suggests that this is not the correct way to model contextual uncertainty in the SMP model, but universal SMP gives a framework for studying many other error tolerance settings. For example, we could suppose that the referee knows a reference planar graph G, and the players are guaranteed to see a graph G' that is close to G and also planar; this would not increase the cost of the protocol due to our results on planar graphs.

Implicit graph conjecture. A major open problem in graph labeling is the *implicit graph conjecture* of Kannan, Naor, and Rudich [23], which asks if every *hereditary* graph family $\mathcal{F}$ (where for each $G \in \mathcal{F}$, every induced subgraph of G is also in $\mathcal{F}$) containing at most $2^{O(n \log n)}$ graphs of size n has an $O(\log n)$ adjacency labeling scheme. Not much progress has been made on this conjecture (see e.g. [33, 10]). We ask a weakened version of this conjecture:

▶ **Question 5.2.** *For every hereditary family $\mathcal{F} = (\mathcal{F}_n)$ such that $|\mathcal{F}_n| \leq 2^{O(n \log n)}$, is $R^{\mathsf{univ}}(\mathcal{F}) = O(\log n)$?*

Good candidates for disproving the implicit graph conjecture are geometric intersection graphs, like disk graphs (intersections of disks in $\mathbb{R}^2$) or k-dot product graphs (graphs whose vertices are vectors in $\mathbb{R}^k$, with an edge if the inner product is at least 1) [33]. These are good candidates because encoding the coordinates of the vertices as integers will fail [22]. Randomized communication techniques may be able to make progress.

Modular lattices. We have shown that there is no constant-cost universal protocol for distance 2 in modular lattices but, like low-arboricity graphs, adjacency (and therefore $O(\log n)$-implicit encodings) may still be possible.

Planar graphs. Our protocol for computing distance 2 on planar graphs did not generalize in a straightforward fashion to distance 3. Nevertheless, we expect that there is a method for computing k-distance on planar graphs with complexity dependent only on k; given that a Schnyder wood partitions each edge into 3 groups, we expect that $\widetilde{O}(3^k)$ should be possible, and maybe only $\mathrm{poly}(k)$, considering that there is a $O(\sqrt{n})$ distance-labeling scheme.

Sharing randomness with the referee. Finally, it seems to be unknown what the relationship is between SMP protocols where the referee shares the randomness, and protocols where the referee is deterministic, even though both models are used extensively in the literature. Our Proposition 1.8 relates these two models via universal SMP but does not yet give a general upper bound on the universal cost in terms of the weakly-universal cost.

▶ **Question 5.3.** *What general upper bounds can we get on universal SMP in terms of weakly-universal SMP?*

A Appendix

Proof of Proposition 2.5.

1. If $A \sqsubset B$ and $B \sqsubset C$ with ϕ, ψ being the respective embeddings then for all $u, v \in V(A)$ we have

$$C(\psi\phi(u), \psi\phi(v)) = B(\phi(u), \phi(v)) = A(u, v)\,.$$

2. In the "only if" direction, it suffices to choose $G^{\equiv}$. In the other direction, if $\phi : V(G) \to V(H)$ is an embedding and $\phi(u) = \phi(v)$ then for all $w \in V(G), G(u, w) = H(\phi(u), \phi(w)) = H(\phi(v), \phi(w)) = G(v, w)$ so $u \equiv v$.
3. Let g map a vertex of G to its equivalence class and let $u, v \in V(G)$. If $G(u, v) = 1$ then $G^{\equiv}(g(u), g(v)) = 1$ by definition. If $G^{\equiv}(g(u), g(v)) = 1$ then there exists $u' \in g(u), v' \in g(v)$ such that $G(u', v') = 1$, so $G(u, v) = G(u', v) = G(u', v') = 1$.
4. Let g map vertices in $V(G)$ to their equivalence class and let $g(u), g(v) \in V(G^{\equiv})$. If $g(u) \equiv g(v)$ then for any $w, G(u, w) = G^{\equiv}(g(u), g(w)) = G^{\equiv}(g(v), g(w)) = G(v, w)$ so $u \equiv v$ and therefore $g(u) = g(v)$. Therefore the map $g(u) \mapsto \{g(u)\}$ is an isomorphism $G^{\equiv} \to (G^{\equiv})^{\equiv}$.
5. If $G \sqsubset H$ then by transitivity, $G^{\equiv} \sqsubset G \sqsubset H \sqsubset H^{\equiv}$. Likewise, if $G^{\equiv} \sqsubset H^{\equiv}$ then $G \sqsubset G^{\equiv} \sqsubset H^{\equiv} \sqsubset H$.
6. If $G^{\equiv}$ is an induced subgraph of $H^{\equiv}$ then clearly there is an embedding. On the other hand, let $g(u), g(v) \in V(G^{\equiv})$ be the equivalence classes of $u, v \in V(G)$ and suppose there is an embedding $\phi : G^{\equiv} \to H^{\equiv}$. If $\phi(g(u)) = \phi(g(v))$ then $g(u) \equiv g(v)$ so $g(u) = g(v)$ since $(G^{\equiv})^{\equiv} \simeq G^{\equiv}$. Therefore $G^{\equiv}$ is an induced subgraph of $H^{\equiv}$. ◀

Approaching MCSP from Above and Below: Hardness for a Conditional Variant and $\mathsf{AC}^0[p]$

Rahul Ilango
Massachusetts Institute of Technology, Cambridge, MA, USA
rilango@mit.edu

Abstract

The Minimum Circuit Size Problem (MCSP) asks whether a given Boolean function has a circuit of at most a given size. MCSP has been studied for over a half-century and has deep connections throughout theoretical computer science including to cryptography, computational learning theory, and proof complexity. For example, we know (informally) that if MCSP is easy to compute, then most cryptography can be broken. Despite this cryptographic hardness connection and extensive research, we still know relatively little about the hardness of MCSP unconditionally. Indeed, until very recently it was unknown whether MCSP can be computed in $\mathsf{AC}^0[2]$ (Golovnev et al., ICALP 2019).

Our main contribution in this paper is to formulate a new "oracle" variant of circuit complexity and prove that this problem is NP-complete under randomized reductions. In more detail, we define the Minimum Oracle Circuit Size Problem (MOCSP) that takes as input the truth table of a Boolean function f, a size threshold s, and the truth table of an oracle Boolean function $\mathcal{O}$, and determines whether there is a circuit with $\mathcal{O}$-oracle gates and at most s wires that computes f. We prove that MOCSP is NP-complete under randomized polynomial-time reductions.

We also extend the recent $\mathsf{AC}^0[p]$ lower bound against MCSP by Golovnev et al. to a lower bound against the circuit minimization problem for depth-d formulas, (AC^0_d)-MCSP. We view this result as primarily a technical contribution. In particular, our proof takes a radically different approach from prior MCSP-related hardness results.

Acknowledgements I would like to give a special thanks to Eric Allender for innumerable suggestions and perspectives during all stages of this work. To name just a single example, one of his suggestions led me to improve a PARITY-reduction to the presented MAJORITY-reduction for (AC^0_d)-MCSP. I would also like to thank Abhishek Bhrushundi and Aditi Dudeja for their help in results about constant depth formulas that lead to this paper. I am grateful to Ryan Williams for asking interesting questions and helping to improve the exposition of the paper. Finally, I thank Harry Buhrman, Lance Fortnow, Igor Oliveira, Ján Pich, Aditya Potukuchi, Ninad Rajgopal, Michael Saks, and Rahul Santhanam for answering my questions and engaging in many useful discussions about this work.

1 Introduction

The Minimum Circuit Size Problem (MCSP) takes as input a Boolean function f (represented by its truth table) and a size parameter s and asks if there is a circuit of size at most s computing f. Study of this problem began in the 1950s by complexity theorists in the Soviet Union [31], where MCSP was of such great interest that Levin is said to have delayed

publishing his initial NP-completeness results in hope of showing that MCSP is NP-complete.[1] Interest in MCSP was revitalized when Kabanets and Cai [19] connected the problem with the natural proofs framework of Razborov and Rudich [28]. Since then, MCSP has been the subject of intense research. We begin by (non-exhaustively) reviewing this work.[2]

1.1 Known lower bounds, hardness, and non-hardness for MCSP

It is easy to see that MCSP is in NP (the circuit of size at most s can be used as a witness), but, despite work by numerous researchers, the exact complexity of MCSP remains unknown.

Hardness results for MCSP. We believe MCSP is not easy to compute. Kabanets and Cai [19] show that MCSP $\notin$ P conditioned on a widely-believed cryptographic hypothesis.

Thus, the most natural question about MCSP's complexity is whether it is NP-complete. As of yet, we have not managed to uncover even strong supporting evidence for, or against, MCSP being NP-complete. The strongest known hardness result is by Allender and Das [3] who show MCSP is hard for the cryptographically important class SZK under randomized reductions.

Under less powerful types of reductions, we only know hardness for some subclasses of P. For instance, building on the results of Oliveira and Santhanam [26], Golovnev et al. [12] show that the class of functions computable by polynomial-sized formulas (NC^1) reduces to MCSP under AC^0 reductions.

Lower Bounds for MCSP. Unconditionally, we know lower bounds against MCSP for several restricted computational models. Cheraghchi, Kabanets, Lu, and Myrisiotis [10] prove lower bounds for MCSP against DeMorgan formulas, branching programs, and AC^0 circuits that essentially match the best known explicit lower bounds for these models. Golovnev et al. [12] show that MCSP requires exponential-sized $\mathsf{AC}^0[p]$ circuits by proving MAJORITY $\in (\mathsf{AC}^0)^{\mathsf{MCSP}}$. The MAJORITY hardness result of [12] generalizes to the circuit minimization problem for many circuit classes, however, the techniques fail in the case of constant depth formulas.

Non-hardness results for MCSP. Surprisingly, we know MCSP cannot be NP-hard under certain types of reductions. For example, Hirahara and Watanabe [16] show that "oracle-independent polynomial reductions" cannot show that MCSP is hard for a class larger than P. Moreover, while essentially all NP-complete problems are complete under rather weak reductions such as uniform $\mathsf{TIME}[n^{o(1)}]$ reductions (which we do not define here), Murray and Williams [23] prove that MCSP is not even NP-hard under $\mathsf{TIME}[n^{.49}]$ reductions.

Conditioned on a widely-believed cryptographic hypothesis, Allender and Hirahara [4] show that a very weak approximation of MCSP is actually neither in P nor NP-complete.

Approaching MCSP from below. Given the apparent difficulty of resolving the complexity of MCSP, a natural approach is to progress towards MCSP "from below": considering restricted classes of circuits $\mathcal{C}$ that we understand better and determining whether the $\mathcal{C}$-circuit minimization problem, ($\mathcal{C}$)-MCSP, is NP-hard.

---

[1] [6] cites a personal communication from Levin regarding this.

[2] In our review, we are sometimes slightly informal and imprecise in order to be more accessible. We encourage the reader to look at the corresponding references for precise statements.

As it stands, we know that minimizing DNF formulas and minimizing $\mathsf{OR} \circ \mathsf{AND} \circ \mathsf{MOD}_m$ circuits are both NP-hard by Masek [20] and by Hirahara, Oliveira, and Santhanam [15] respectively. It is still open whether the circuit minimization problem for, say, depth-3 formulas is NP-hard.

1.2 Implications of lower bounds and hardness for MCSP

Since the main goal of this paper is to shed light on the complexity of MCSP, it is worth motivating why the complexity of MCSP is important.

Indeed, while researchers have not yet managed to establish the complexity of MCSP, a series of works, beginning with Kabanets and Cai [19], connect the computational complexity of MCSP and its variants to longstanding open questions in the field.

Separations of complexity classes. Several works ([17], [23], [3], [19]) show that MCSP being NP-hard, under various notions of reducibility, implies unknown class separations. For example, Hitchcock and Pavan [17] and Murray and Williams [23] show that if MCSP is NP-hard under polynomial-time reductions, then $\mathsf{ZPP} \neq \mathsf{EXP}$, a major open problem.[3]

Worst-case versus average-case complexity for NP. Using tools developed by Nisan and Wigderson [24] and Carmosino, Impagliazzo, Kabanets, and Kolokova [9], Hirahara [14] gives a "worst-case to average-case" reduction for NP conditioned on a certain approximation to MCSP being NP-hard. Thus, if one could show this approximation to MCSP is NP-hard, the worst-case and average-case complexity of NP would be equivalent.

Circuit Lower Bounds. Recent work ([22], [27], [25]) explores a "hardness magnification" phenomenon whereby even weak circuit lower bounds on certain computational problems imply strong lower bounds on other problems. For example, Mckay, Murray, and Williams [22] show that if MCSP (under a small size parameterization) cannot be solved by circuits of size $n \cdot \mathsf{poly}(\log n)$, then NP does not have polynomial-size circuits.

1.3 Our Contributions

In this work, we focus on hardness results for natural variants of MCSP with the aim of shedding light on the complexity of MCSP itself.

NP-Hardness of oracle MCSP (MOCSP)

As mentioned previously, some research has approached the problem of proving NP-hardness for MCSP "from below," that is, showing that the circuit minimization problem is NP-hard for restricted classes of circuits like DNF circuits and $\mathsf{OR} \circ \mathsf{AND} \circ \mathsf{MOD}_m$ circuits.

In this paper, we attempt to approach MCSP "from above." That is, we study the complexity of a problem that is at least as hard as MCSP. In particular, we define the *Minimum Oracle Circuit Size Problem* (MOCSP) to take as input a truth table T, a size parameter $s \in \mathbb{N}$, and an oracle truth table $\mathcal{O}$. The goal is to determine whether there is an $\mathcal{O}$-oracle circuit with at most s wires that computes T. It is easy to see that $\mathsf{MOCSP} \in \mathsf{NP}$ (the oracle circuit of size s can still act as an NP-witness).

[3] [23] only shows the result under many-one reductions, but their techniques easily generalize to the truth table case. [17] explicitly proves the truth table result using a different approach than [23].

A natural way to think of MOCSP is as a "conditional" version of MCSP where we are now measuring the complexity of computing T when we are given easy access to $\mathcal{O}$.

Although our problem definition is new, this is not the first time someone has considered an "oracle version" of MCSP. Several papers ([2, 5, 16, 18]) study the problem $\mathsf{MCSP}^{\mathsf{A}}$ of minimizing oracle circuits for a *fixed* oracle *language* A. MOCSP differs fundamentally from $\mathsf{MCSP}^{\mathsf{A}}$ in that the oracle circuit gets access to an *arbitrary* Boolean function, not a language, and the function the oracle circuit has access to is an *input* to the problem.

Furthermore, while $\mathsf{MOCSP} \in \mathsf{NP}$, the complexity of $\mathsf{MCSP}^{\mathsf{A}}$ depends on the oracle A. For example, the reference [2] proves $\mathsf{MCSP}^{\mathsf{QBF}}$ is complete for PSPACE under randomized reductions. Moreover, there is a trivial reduction from MCSP to MOCSP: simply provide no oracle truth tables. Therefore, since MOCSP is still in NP and MOCSP and is at least as hard as MCSP, MOCSP is a nice "testing ground" for hardness results we conjecture for MCSP.

Indeed, as is conjectured for MCSP, we *can* prove that MOCSP is NP-hard under randomized reductions.

▶ **Theorem 1.1.** MOCSP *is* NP *hard under:*
- *randomized many-one reductions with one-sided error, and*
- *randomized Turing reductions with zero-sided error.*

These NP-hardness results are both proved by giving a reduction from approximating set cover to MOCSP. It is worth noting that the NP-hardness results of (DNF)-MCSP [20] and $(\mathsf{OR} \circ \mathsf{AND} \circ \mathsf{MOD}_m)$-MCSP [15] are also proved via set cover problems, although both of these reductions are deterministic while our reduction is randomized.

Given that we can show MOCSP is NP-hard under randomized reductions, one might even begin to hope that we can prove hardness under, say, polynomial-time reductions. Unfortunately, this seems difficult. Essentially the same proofs Murray and Williams [23] or Hitchcock and Pavan [17] use to show that MCSP being NP-hard under polynomial-time truth table reductions implies $\mathsf{EXP} \neq \mathsf{ZPP}$ also work for MOCSP.

▶ **Theorem 1.2** (Essentially proven in [17] and [23])**.** *If* NP *reduces to* MOCSP *under polynomial time (truth table) reductions, then* $\mathsf{EXP} \neq \mathsf{ZPP}$*.*

Thus, improving our reduction to a polynomial-time truth table reduction requires separating EXP from ZPP, a longstanding open problem. For completeness, we give the MOCSP version of Murray and Williams' proof in Appendix B.

Even so, we expect that the ground truth is that MOCSP is NP-hard under, at least, deterministic polynomial-time Turing reductions.

▶ **Conjecture 1.3.** MOCSP *is* NP*-hard under polynomial-time Turing reductions.*

A perspective on MOCSP and some questions

In light of the fact that hardness for MCSP beyond SZK under even non-uniform reductions is unknown, we found these MOCSP hardness results to be quite surprising. Moreover, the NP-hardness of MOCSP seems to bolster the conjecture that MCSP is in fact NP-hard. To an optimist, NP-hardness results for MOCSP could even be a first step towards proving NP-hardness for MCSP. Indeed, a PSPACE-hardness result was first proved by Buhrman and Torenvliet [8] for an "oracle" version of space-bounded Kolmogorov complexity before Allender et al. [2] showed PSPACE-hardness for the non-oracle version about four years later.[4]

[4] The conference versions of [8] and [2] are four years apart.

Even if stronger hardness results for MCSP remain out of reach, MOCSP could still yield valuable insights about MCSP. For instance, it would be interesting to see which of the barriers and non-hardness results known for MCSP carry over to MOCSP.

▶ **Open Question 1.4.** *Can one show that other barriers or non-hardness results that hold for* MCSP *also hold for* MOCSP*?*

As an example of the insight given by answers to this question, consider Murray and Williams' [23] result that proving MCSP is NP-hard under polynomial-time reductions implies EXP $\neq$ ZPP. A natural question one might ask is whether we can improve this theorem to show that MCSP being NP-hard under randomized reductions implies unknown class separations. As we note in Theorem 1.2, however, Murray and Williams' proof carries over to MOCSP, and Theorem 1.1 shows MOCSP is indeed NP-hard under randomized reductions. Thus, any improvement of Murray and Williams' result to randomized reductions likely requires a fact about MCSP that we do not know for MOCSP.

In another direction, our results seem to imply that proving hardness for MOCSP is more tractable than proving hardness for MCSP. Since we have already noted that MOCSP can be used as a "testing ground" for questions about MCSP (since any hardness result for MCSP must also hold for MOCSP), one can explore whether other conjectured hardness results for MCSP hold for MOCSP. For example, Hirahara's [14] worst-case to average-case reduction for NP can be based on a certain approximation of MCSP being NP-hard, which would imply that a certain approximation of MOCSP is also NP-hard. Given that we can prove the NP-hardness of MOCSP under randomized reductions, we ask if one can prove something similar for the approximation version of MOCSP.

▶ **Open Question 1.5.** *Can one prove that, for some $\epsilon > 0$, approximating* MOCSP *on n-inputs to a factor of n^ϵ is* NP*-hard under, say,* P/poly *reductions? Conversely, can one prove that there is any barrier to showing such a hardness result?*

Finally, while in this paper we concentrate on approaching MCSP from above via MOCSP, it would be interesting to explore other problems that are harder than MCSP but still in NP. Perhaps this could help clarify what aspects of MCSP make it difficult to prove hardness for.

MAJORITY-hardness for (AC^0_d)-MCSP

As mentioned previously, Golovnev et al. [12] proves that MAJORITY $\in (\mathsf{AC}^0)^{\mathsf{MCSP}}$. Using similar techniques, they also show that, for restricted classes of circuits $\mathcal{C}$ such as formulas and constant depth circuits, the $\mathcal{C}$-circuit minimization problem, denoted $(\mathcal{C})$-MCSP, is hard for MAJORITY under AC^0 reductions. For these MAJORITY reductions to work, [12] requires that the size of the minimum $\mathcal{C}$-circuit on truth tables of length n is roughly $(n^{.49})$-Lipschitz, that is, flipping one bit in any truth table can change the $\mathcal{C}$-circuit complexity by at most an $n^{.49}$ additive term. This Lipschitzness hypothesis is unknown (and in our estimation probably false) in the class of depth-d *formulas*, which we denote AC^0_d.[5] As a result, until this work, it was unknown whether, say, (AC^0_d)-MCSP $\in \mathsf{AC}^0[2]$.

We stress that even though AC^0_d is an extremely restrictive class of formulas, (AC^0_d)-MCSP should be a very hard problem. For example, Allender *et al.* [1] prove that if (AC^0_d)-MCSP had polynomial-size circuits for sufficiently large d, then one could factor Blum integers using circuits of size 2^{n^ϵ} for all $\epsilon > 0$.

[5] We will always use the notation AC^0_d to refer to depth-d *formulas* and never depth-d *circuits*.

In this paper, we prove that (AC^0_d)-MCSP is indeed hard for MAJORITY by giving a win-win argument depending on whether the Lipschitzness hypothesis is true. Applying the lower bounds of Razborov [28] and Smolensky [30] then gives an $\mathsf{AC}^0[p]$ lower bound for (AC^0_d)-MCSP.

▶ **Theorem 1.6.** *Let $d \geq 2$. Then* MAJORITY $\leq^{\mathsf{AC}^0}_{tt}$ (AC^0_d)-MCSP. *Consequently, for any prime p,* (AC^0_d)-MCSP $\notin \mathsf{AC}^0[p]$.

One can view this theorem as (small) progress towards the program of approaching MCSP from below. The natural next step in the program is to prove that (AC^0_3)-MCSP is NP-hard, and, until this work, $\mathsf{AC}^0[p]$ lower bounds were open for this problem (despite knowing such $\mathsf{AC}^0[p]$ lower bounds for less restrictive circuit classes!). Perhaps the techniques introduced here could be useful in proving further hardness results for (AC^0_3)-MCSP.

Indeed, our techniques[6] may be the most interesting part of Theorem 1.6. They are entirely different than the ones used by [12] for general MCSP and, to our knowledge, all known MCSP hardness results. For example, a crucial step in the proof is introducing algebraic machinery and examining the size of a function's smallest circuits modulo a certain prime.

Indeed, all previously known MCSP-related reductions (to our knowledge) continue to work even when the reduction is given access to close approximations of a function's minimum circuit size. Because of this, it was not clear if, for the purpose of reductions, there was any difference between knowing whether a function has circuits of size exactly s or $s+1$. However, the algebraic nature of this MAJORITY reduction actually requires knowing such exact quantities, illustrating the existence of useful techniques that can distinguish between MCSP and approximations of MCSP.

1.4 Proof Overviews

In this section, we give fairly detailed overviews of our proofs. In doing this, we will often state results without filling in lower-level details. To make clear to the reader when we are doing this, we mark such sentences with an italicized *we observe*.

NP-hardness of Oracle MCSP (MOCSP)

Recall, the Minimum Oracle Circuit Size Problem, MOCSP, takes as input a truth table T, a threshold $s \in \mathbb{N}$, and an oracle truth table $\mathcal{O}$ and outputs whether there is an $\mathcal{O}$-oracle circuit with at most s wires that computes T. We denote the output of MOCSP on such an input as $\mathsf{MOCSP}(T, s; \mathcal{O})$. We denote the minimum size (measured by wires) of any $\mathcal{O}$-oracle circuit computing T as $\mathsf{CC}^{\mathcal{O}}(T)$.

We prove that MOCSP is NP-hard by giving a reduction from 6-approximating the Set Cover Problem (6-SetCover) to MOCSP. In our notation, 6-SetCover takes as input sets $S_1, \ldots, S_t \subseteq [n]$ whose union is $[n]$ as well as an integer $c \in [n]$ and requires outputting YES when $c \geq \ell$ and NO when $c < \ell/6$ where ℓ is the optimal cover size, i.e.

$$\ell = \min\{|I| : I \subseteq [t] \text{ and } \bigcup_{i \in I} S_i = [n]\}.$$

Approximating SetCover to an $((1 - o(1)) \ln n)$ factor is known to be NP-hard by Dinur and Steurer [11].

[6] Specifically, our techniques in the case when the Lipschitz hypothesis fails (which we expect to be the ground truth).

Informal idea. We begin by giving a high-level overview of the reduction to orient the reader. (It will be very informal, but we are building to a more detailed description.) Say we are given sets $S_1, \dots, S_t \subseteq [n]$ whose union is $[n]$. One can think of each of these sets S_i as "seeing" a small portion of the ground set $[n]$. Then, for a uniformly random truth table T of length $m \geq (nt)^5$, we let each set $S_1, \dots, S_t$ induce truth tables $T_{S_1}, \dots, T_{S_t}$ respectively where each truth table T_{S_i} has the same length at T and "sees" roughly the same part of T as S_i "sees" of $[n]$. We define our oracle $\mathcal{O}$ to be the concatenation of these truth tables. Finally, we ask how hard it is for a circuit to compute T given oracle access to $\mathcal{O}$.

The idea is that if a circuit looks at a collection of induced truth tables corresponding to a set cover, then it can "see" all of T and thus easily compute T. If not, then a large part of T is still random to the circuit and thus hard to compute. Indeed, we show that with high probability the quantity $\mathsf{CC}^{\mathcal{O}}(T)$ can be used to estimate ℓ up to a constant factor.

We now describe the reduction in more detail. Fix sets $S_1, \dots, S_t \subseteq [n]$ whose union is $[n]$ and, let ℓ be the optimal cover size of $[n]$ by $S_1, \dots, S_t$. Let T be a uniformly random truth table of length $m \geq (nt)^5$.

The truth tables induced by $S_1, \dots, S_t$ and T. We now rigorously define the truth tables $T_{S_1}, \dots, T_{S_t}$ of length m induced by $S_1, \dots, S_t$ and T. To do this, we chose a uniformly random partition of $[m]$ into n parts, that is, let $P : [m] \to [n]$ be a uniformly random function, and let $\mathcal{P} = (P_1, \dots, P_n)$ be the partition of $[m]$ into n parts where for $j \in [n]$

$$P_j = \{x \in [m] : P(x) = j\}.$$

We can then use this partition to "lift" any subset of $[n]$ into a subset of $[m]$ as follows. For a subset $S \subseteq [n]$, let S^m denote the subset of $[m]$ given by $S^m = \bigcup_{j \in S} P_j$.

Next, for a subset $S' \subseteq [m]$, we let $T_{\langle S' \rangle}$ be the truth table of length m that "sees" T on the elements of S' and zeroes everywhere else, that is

$$T_{\langle S' \rangle}(x) = T(x) \wedge \mathbb{1}_{x \in S'}$$

Finally, we define the truth table T_{S_i} induced by S_i to be the truth table $T_{\langle S_i^m \rangle}$ (we are dropping the m superscript and the bracketed subscript for concision).

Building the oracle $\mathcal{O}$. We build our oracle $\mathcal{O}$ by concatenating the induced truth tables $T_{S_1}, \dots, T_{S_t}$. In other words, let $\mathcal{O} : \{0,1\}^{\lceil \log t \rceil} \times \{0,1\}^{\log m} \to \{0,1\}$ be given by

$$\mathcal{O}(i, x) = \begin{cases} T_{S_i}(x) & , \text{ if } i \in [t] \\ 0 & , \text{ otherwise} \end{cases}$$

$\mathsf{CC}^{\mathcal{O}}(T)$ is at most $\ell(3 + \log(tm))$. Suppose, without loss of generality, that $S_1 \cup \dots \cup S_\ell$ is an optimal cover of $[n]$. We claim that $\bigvee_{i \in [\ell]} \mathcal{O}(i, x)$ is a circuit computing T. Unraveling our definitions, we have that

$$\bigvee_{i \in [\ell]} \mathcal{O}(i, x) = \bigvee_{i \in [\ell]} T_{S_i}(x) = \bigvee_{i \in [\ell]} (T(x) \wedge \mathbb{1}_{x \in S_i^m}) = T(x) \wedge (\bigvee_{i \in [\ell]} \mathbb{1}_{x \in S_i^m}) = T(x) \wedge \mathbb{1}_{x \in S_1^m \cup \dots \cup S_\ell^m}.$$

Using the fact that $S_1, \dots, S_\ell$ is a cover of $[n]$, we have that

$$T(x) \wedge \mathbb{1}_{x \in S_1^m \cup \dots \cup S_\ell^m} = T(x) \wedge \mathbb{1}_{x \in [m]} = T(x).$$

Thus, $\bigvee_{i \in [\ell]} \mathcal{O}(i, x)$ computes T and has at most

$$2\ell + \ell(1 + \log t + \log m) \leq \ell(3 + \log t + \log m)$$

wires.

With high probability, $\mathsf{CC}^{\mathcal{O}}(T) > \ell \log(tm)/2$. We do this by a union bound argument. Fix any oracle circuit C with at most $\ell \log(tm)/2$ wires. We show that the probability that $C^{\mathcal{O}}$ computes T is very small.

We begin by showing that on any fixed input x that

$$\Pr[C^{\mathcal{O}}(x) = T(x)] \leq 1 - \frac{1}{2n}.$$

Fix some x. We prove the following claim: that with probability at least $\frac{1}{n}$ over the choice of $P(x)$, the output of $C^{\mathcal{O}}(x)$ does not depend whether the value of $T(x)$ is one or zero. If this claim were true, then we would get the desired bound

$$\Pr[C^{\mathcal{O}}(x) = T(x)] \leq 1 - \frac{1}{2n}$$

since, assuming that $C^{\mathcal{O}}(x)$ does not depend on $T(x)$, the probability $C^{\mathcal{O}}(x) = T(x)$ is exactly $\frac{1}{2}$ (since $T(x)$ is chosen uniformly at random).

To prove the claim, we first note that the only way that the output of $C^{\mathcal{O}}(x)$ can depend on the value of $T(x)$ is if during the computation of $C^{\mathcal{O}}(x)$ C makes an oracle query (i', x') to $\mathcal{O}$ such that the value of $\mathcal{O}(i', x')$ depends on the value of $T(x)$. However, from the definition of $\mathcal{O}$, we know that the output of $\mathcal{O}(i', x')$ depends on $T(x)$ if and only if $x' = x$ and $P(x) \in S_{i'}$. Summarizing, $C^{\mathcal{O}}(x)$ depends on $T(x)$ only if $C^{\mathcal{O}}$ makes a query of the form (i', x) such that $P(x) \in S_{i'}$. But $C^{\mathcal{O}}$ has at most $\ell/2$ oracle gates, so it only has $\ell/2$ "tries" to find a set $S_{i'}$ that contains the uniformly random ground set element $P(x)$, which is less than the number of tries needed to cover the ground set! Hence, it is intuitive that with probability at least $\frac{1}{n}$, $P(x)$ takes on a value that is not in any of the $S_{i'}$ that $C^{\mathcal{O}}$ queries. *We observe* that this intuition can be made rigorous (with some more details), and hence, the claim is true.

At this point, we have completed our sketch of why for any fixed x

$$\Pr[C^{\mathcal{O}}(x) = T(x)] \leq 1 - \frac{1}{2n}.$$

Unfixing x, we would like to say that we can multiply these probabilities together for all $x \in [m]$ to bound the probability that $C^{\mathcal{O}}$ computes T. However, we cannot do this, as these events might have some dependencies between each other. Luckily, since, for any x, $C^{\mathcal{O}}(x)$ makes at most $\ell/2 \leq n$ oracle calls, *we observe* that applying the above probability bound can only "spoil" the bound for at most n other values of x. Hence, we can repeatedly apply the bound to about m/n different values of x yielding

$$\Pr[C^{\mathcal{O}} \text{ computes } T] \leq (1 - \frac{1}{2n})^{m/n} \leq e^{-\frac{m}{2n^2}} \leq e^{-n^3 t^5/2}.$$

Finally, union bounding over the at most

$$2^{O(\ell \log(tm)/2)^2} \leq 2^{O(n^2 t)}$$

oracle circuits with at most $\ell \log(tm)/2$ wires yields the desired result.

RP and ZPP reductions. At this point, we have shown that if $S_1, \ldots, S_t$ admits a c-cover, then $\mathsf{MOCSP}(T, c(3 + \log(tm)); \mathcal{O}) = \mathsf{YES}$ (note that this fact did not depend on our random choice of T or $\mathcal{P}$), and we have shown that if $S_1, \ldots, S_t$ does not admit a c-cover, then $\mathsf{MOCSP}(T, c \log(tm)/2; \mathcal{O}) = \mathsf{NO}$ with high probability. It is easy to see that this yields an RP many-one reduction (a randomized many-one reduction with one-sided error) from 6-SetCover to MOCSP.

Furthermore, since this RP reduction only errs by incorrectly classifying NO instances as YES instances, we can use the search-to-decision reduction for SetCover to check the correctness of purported YES instances, transforming our RP reduction into a ZPP-Turing reduction (a randomized zero-error reduction that can make multiple adaptive queries to MOCSP).

Majority Hardness for (AC^0_d)-MCSP

Recall, AC^0_d is the class of depth-d formulas made up of AND and OR gate with unbounded fan-in. We also define $\mathsf{AND} \circ \mathsf{AC}^0_{d-1}$ and $\mathsf{OR} \circ \mathsf{AC}^0_{d-1}$ be the classes of AC^0_d formulas with a top AND and top OR gate respectively. For $\mathcal{F} \in \{\mathsf{AC}^0_d, \mathsf{AND} \circ \mathsf{AC}^0_{d-1}, \mathsf{OR} \circ \mathsf{AC}^0_{d-1}\}$ and a truth table T, we let $\mathsf{CC}_{\mathcal{F}}(T)$ denote the size of the minimum $\mathcal{F}$-formula computing T where the size of a formula is the number of input leaves.

Our analysis proceeds by considering each $n \in \mathbb{N}$ and splitting into cases depending on whether $\mathsf{CC}_{\mathsf{AC}^0_d}$ is Lipschitz on truth tables of length around n. In more detail, fix some sufficiently large n. Let $q = \Theta(n^2)$ be a power of two. We divide into cases depending on whether there exists an $m \in \{q^{10}, q^{50}\}$ such that $\mathsf{CC}_{\mathsf{AC}^0_d}$ is $(m^{.25})$-Lipschitz on truth tables of length m.

Case 1: Lipschitzness holds for some m

If there does exist an $m \in \{q^{10}, q^{50}\}$ such that $\mathsf{CC}_{\mathsf{AC}^0_d}$ is $(m^{.25})$-Lipschitz on truth tables of length m, then the techniques of Golovnev *et al.* [12] yield an AC^0 truth table reduction from MAJORITY on n-bits to (AC^0_d)-MCSP on m-bits. For completeness, we include a self-contained proof of this case in Appendix A.

Case 2: Lipschitzness fails

Assume that for all $m \in \{q^{10}, q^{50}\}$ $\mathsf{CC}_{\mathsf{AC}^0_d}$ is not $(m^{.25})$-Lipschitz on truth tables of length m. Let $u = q^{10}$ and $v = q^{50}$.

Lipschitzness failing $\implies$ functions easier to compute with a top AND gate. *We observe*, as a straight forward consequence of Lipschitzness failing, that there exists a truth table of length u that has an optimal formula with large top fan-in and a truth table of length v that is easier to compute with a top AND gate:

1. There exists a Boolean function f^u that takes $\log u$ inputs and an AC^0_d formula ϕ^u such that ϕ^u is an optimal AC^0_d formula for f^u and $\phi^u = \phi^u_1 \wedge \cdots \wedge \phi^u_t$ for some $t \geq n$ and some $\phi^u_1, \ldots, \phi^u_t \in \mathsf{AC}^0_{d-1}$.
2. There exists a Boolean function f^v that takes $\log v$ inputs such that $\mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(f^v) > \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^v) + u \log u$.

We will make use of f^u and ϕ^u to reduce MAJORITY to $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}$ and we will use f^v to reduce $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}$ to $\mathsf{CC}_{\mathsf{AC}^0_d}$.

Using $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}$ and optimal subformulas of ϕ^u to compute a dot product. The heart of our MAJORITY reduction is a fairly elementary observation about optimal $(\mathsf{AND} \circ \mathsf{AC}^0_{d-1})$ formulas. Recall, $\phi^u = \phi^u_1 \wedge \cdots \wedge \phi^u_t$ is an optimal (AC^0_d) formula for f^u and, hence, also an optimal $(\mathsf{AND} \circ \mathsf{AC}^0_{d-1})$ formula for f^u. *We observe* that for any $A \subseteq [t]$, the $(\mathsf{AND} \circ \mathsf{AC}^0_{d-1})$-optimality of ϕ^u implies that $\bigwedge_{i \in A} \phi^u_i$ is also an optimal $(\mathsf{AND} \circ \mathsf{AC}^0_{d-1})$ formula for the function it computes.

Introducing some notation, for a string $x \in \{0,1\}^n$, we let f^u_x be the function given by $\bigwedge_{i \in O_x} \phi^u_i$ where $O_x \subseteq [n]$ are the bits in x that are one. Using the above observation about subformulas being optimal, we have that[7] $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^u_x) = \sum_{i \in O_x} |\phi^u_i|$. Thus, one can think of $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^u_x)$ as computing the dot product between x and the vector $\langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$.

Note that that the definition of f^u_x depends on the labeling of $\phi^u_1, \ldots, \phi^u_t$, in particular the choice of which ϕ^u_i have $i \leq n$. We will later choose a labeling of the ϕ^u_i that is convenient.

Computing MAJORITY (non-uniformly) using $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}$. Our goal is to compute MAJORITY on a string $x \in \{0,1\}^n$ using the above "dot product" observation. Before we show how to do this, we give some intuition on how we came up with the idea.

Instead of trying to compute MAJORITY, suppose we relaxed the problem to computing PARITY given access to the integer produced by the dot product $x \cdot \langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$. Well, if it so happened that all the entries in the vector $\langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$ were odd, then it is clear that the integer produced by $x \cdot \langle |\phi^u_1|, \ldots, |\phi^u_n| \rangle$ is odd if and only if x has an odd number of ones. Our approach for MAJORITY is a generalization of this.

Let $p = O(n)$ be prime greater than n. *We observe*, via a pigeon-hole principle argument, that there exist integers $k \geq 0$ and $1 \leq r \leq p-1$ and indices $i_1, \ldots, i_n \in [m]$ such that

$$|\phi^u_{i_1}|/p^k \equiv \cdots \equiv |\phi^u_{i_n}|/p^k \equiv r \mod p.$$

Thus, after an appropriate relabeling of ϕ^u_i, we have that

$$|\phi^u_1|/p^k \equiv \cdots \equiv |\phi^u_n|/p^k \equiv r \mod p.$$

Hence, we can determine the weight w of x (and hence compute MAJORITY of x) by computing the value of

$$\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^u_x)/p^k = \sum_{i \in O_x} |\phi^u_i|/p^k \equiv rw \mod p$$

and multiplying by the inverse of r modulo p. [8]

Reducing computing $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}$ to computing $\mathsf{CC}_{\mathsf{AC}^0_d}$. Ultimately, we want to compute MAJORITY using $\mathsf{CC}_{\mathsf{AC}^0_d}$ not $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}$. By the above procedure, it suffices to show how to compute $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^u_x)$ using $\mathsf{CC}_{\mathsf{AC}^0_d}$.

We can make such a computation as follows. Recall that f^v is a function satisfying

$$\mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(f^v) > \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^v) + u \log u$$

whose existence is guaranteed by the failure of Lipschitzness. Take the direct product of f^u_x with f^v to obtain a function $g_x(y,z) = f^u_x(y) \wedge f^v(z)$. Since the difference between computing f^v with a top AND gate and a top OR gate is larger than $u \log u$ (which is the maximum complexity of f^u_x), *we observe*[9] any optimal AC^0_d formula for g_x must have a top AND gate, so

$$\mathsf{CC}_{\mathsf{AC}^0_d}(g_x) = \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(g_x).$$

---

[7] Recall, our notion of formula size is the number of input leaves.

[8] In case the reader is unsure of whether the last parts of this procedure are implementable in AC^0, realize that the output of $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f^u_x)$ is a binary string of length $O(\log n)$ and that any function on a string of length $O(\log n)$ can be computed by a polynomial-sized DNF. See the proof in Section 4 for more details.

[9] both the "*we observe" statements in this paragraph are consequences of standard direct product theorems for formulas.*

Then, *we observe* that

$$\mathsf{CC}_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(g_x) = \mathsf{CC}_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^u_x) + \mathsf{CC}_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^v).$$

Hence, if we are non-uniformly given the value of $\mathsf{CC}_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^v)$, we can subtract $\mathsf{CC}_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^v)$ from $\mathsf{CC}_{\mathsf{AC}^0_d}(g_x)$ to find $\mathsf{CC}_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^u_x)$.

▶ Remark 1.7. We remark that the only time we use the failure of the Lipschitzness hypothesis is to show the existence of functions like f^u with high top fan-in and functions like f^v with a large difference between top AND gate and top OR gate complexity. Using known PARITY lower bounds and depth-hierarchy theorems for AC^0 circuits, we can unconditionally prove the existence of f^u and f^v respectively but with slightly worse parameters that would yield a quasi-polynomial reduction (at least in the $d \geq 3$ case) rather than the polynomial reduction we present.

1.5 Paper Organization

In Section 2 we fix notation and review precise definitions. In Section 3 we prove our MOCSP results, and in Section 4 we prove that MAJORITY reduces to (AC^0_d)-MCSP.

2 Preliminaries

For an integer n, we let $[n]$ denote the set $\{1, \ldots, n\}$. For a binary string $x \in \{0,1\}^*$, the *weight* of x, denoted $\mathsf{wt}(x)$, is the number ones in x. We identify a Boolean function $f : \{0,1\}^n \to \{0,1\}$ with its truth table $T \in \{0,1\}^{2^n}$ and often use them interchangeably.

We let log denote the base-2 logarithm and ln represent the base-e logarithm. For functions f and g, we say $f = \tilde{O}(g)$ if there exists a c such that $f(x) \leq \log^c(g(x))g(x)$ for all sufficiently large x. We say that $f = \tilde{\Omega}(g)$ if $g = \tilde{O}(f)$.

We say a function $f : \{0,1\}^n \to \mathbb{N}$ is *c-Lipschitz* if for all $x, y \in \{0,1\}^n$ that differ in at most one bit, $|f(x) - f(y)| \leq c$. (In this paper, the function f for which we care about c-Lipschitzness is the function that maps a truth table to its circuit complexity.)

Complexity classes and reductions

We assume the reader is familiar with the standard complexity classes such as $\mathsf{AC}^0, \mathsf{P}, \mathsf{ZPP}, \mathsf{RP}, \mathsf{NP}, \mathsf{E}$ and the notion of Turing machines. For background on these, we refer to Arora and Barak's excellent textbook [7]. For us, AC^0 always refers to *non-uniform* AC^0.

We review the types of reductions we use in case the reader is not familiar with randomized reductions, truth table reductions, or our notation.

Many-one reductions. We will make use of the following notions of many-one reduction.

- $L \leq^{\mathsf{P}}_m L'$ if there is a polynomial-time Turing machine M such that $x \in L \iff M(x) \in L'$.
- $L \leq^{\mathsf{RP}}_m L'$ if there is a polynomial-time probabilistic Turing machine M taking in a "random" auxiliary input r such that

$$x \in L \implies \forall r\, M(x,r) \in L', \text{ and}$$

$$x \notin L \implies \Pr_r[M(x,r) \notin L'] \geq 2/3,$$

and $|r|$ is polynomial in the length of x.

Truth table reductions. We will also make use of the following notions of truth table reductions.

- We say an oracle circuit C is a *truth table oracle circuit* if there is no directed path between oracle gates in C.
- $L \leq_{tt}^{\mathsf{AC}^0} L'$ if there is a non-uniform (polynomial-sized) AC^0 truth table oracle circuit C such that C computes L when given oracle access to L'.

Turing reductions. Finally, we say $L \leq_{\mathsf{T}}^{\mathsf{ZPP}} L'$ if L can be computed with zero-error by a polynomial-time probabilistic oracle Turing machine M with oracle access to L'. On any single input, M is allowed to output "don't know" with probability at most $1/2$.

AC^0_d formulas, (AC^0_d)-MCSP, and $\mathsf{CC}_{\mathsf{AC}^0_d}$

For an integer $d \geq 2$, we let AC^0_d denote the class of depth-d formulas that use AND and OR gates with unbounded fan-in and fan-out 1 and that takes as "input leaves" the bits of a binary string and the negation of each of those bits.

For an AC^0_d formula ϕ, we define the size of ϕ, denoted $|\phi|$, to be the total number of input leaves ϕ uses. For a Boolean function f, we let $\mathsf{CC}_{\mathsf{AC}^0_d}(f)$ be the size of the smallest AC^0_d formula computing f.

▶ **Definition 2.1** (Minimum Circuit Size Problem for constant depth formulas). *(AC^0_d)-MCSP, is the language given by*

$$\{(T, s) \in \{0,1\}^\star \times \mathbb{N} : T \text{ is the truth table of a Boolean function, and } \mathsf{CC}_{\mathsf{AC}^0_d}(T) \leq s\}.$$

We will also make use of the classes of formulas $\mathsf{OR} \circ \mathsf{AC}^0_{d-1}$ and $\mathsf{AND} \circ \mathsf{AC}^0_{d-1}$, defined as the subclasses of AC^0_d formulas with a top OR gate and a top AND gate respectively. For $\mathcal{C} \in \{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}, \mathsf{AND} \circ \mathsf{AC}^0_{d-1}\}$, we define $\mathsf{CC}_{\mathcal{C}}$ and $(\mathcal{C})$-MCSP analogous to $\mathsf{CC}_{\mathsf{AC}^0_d}$ and (AC^0_d)-MCSP.

We also require the following elementary lemmas regarding AC^0_d formulas.

▶ **Lemma 2.2.** *Let f be a Boolean function. Then $\mathsf{CC}_{\mathsf{AC}^0_d}(f) = \mathsf{CC}_{\mathsf{AC}^0_d}(\neg f)$.*

Proof. One can use DeMorgan's laws to turn any AC^0_d formula for f of size s into an AC^0_d formula for $\neg f$ of size s. ◀

We note that our specific notion of AC^0_d formula size is crucial for the next lemma.

▶ **Lemma 2.3** (Direct product theorem for formulas). *Let $f : \{0,1\}^n \to \{0,1\}$ and $g : \{0,1\}^m \to \{0,1\}$ be Boolean functions that are both not the constant zero function. Define $h : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}$ by $h(x,y) = f(x) \wedge g(y)$. Then*

$$\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(h) = \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f) + \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(g), \text{ and}$$

$$\mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(h) \geq \mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(f) + \mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(g).$$

Proof. It is easy to see that

$$\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(h) \leq \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f) + \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(g).$$

On the other hand, since f is not the constant 0 function, it has a 1-valued input x_0. Then, $h(x_0, y)$ computes $g(y)$. Thus, if ϕ is an $\mathsf{OR} \circ \mathsf{AC}^0_{d-1}$ formula for h, then ϕ has at least $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(g)$ y-input leaves. A similar argument shows that ϕ has at least $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f)$ x-input leaves. Hence

$$\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(h) \geq \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f) + \mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(g).$$

A similar argument shows that

$$\mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(h) \geq \mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(f) + \mathsf{CC}_{\mathsf{OR} \circ \mathsf{AC}^0_{d-1}}(g). \quad \blacktriangleleft$$

Oracle Circuits and Oracle MCSP: MOCSP

An oracle circuit C is made up of NOT gates, fan-in two AND and OR gates, and oracle gates $g_1, \ldots, g_t$ for some integer $t \geq 0$. When given an oracle functions $\mathcal{O}$, we let $C^{\mathcal{O}}(x)$ be the value obtained when evaluating C on input x by using the $\mathcal{O}$ function to compute the outputs of the oracle gates $g_1, \ldots, g_t$.

We define the size of an oracle circuit C, denoted $|C|$, to be the number of wires in C. For Boolean functions $f, \mathcal{O}$, we let $\mathsf{CC}^{\mathcal{O}}(f)$ be the size of the smallest $\mathcal{O}$-oracle circuit that computes f. Analogous to MCSP, we define the following.

▶ **Definition 2.4** (The Minimum Oracle Circuit Size Problem). *The Minimum Oracle Circuit Size Problem, denoted* MOCSP*, takes as input a truth table T, a threshold $s \in \mathbb{N}$, and an oracle truth table $\mathcal{O}$ and outputs whether $\mathsf{CC}^{\mathcal{O}}(T) \leq s$. The output of* MOCSP *on such an input is written as* $\mathsf{MOCSP}(T, s; \mathcal{O})$.

Set Cover

We will make use of the following well known NP-complete problem.

▶ **Definition 2.5** (Set Cover). *Set Cover, denoted* SetCover*, is the problem that takes as input a tuple $(n, c, S_1, \ldots, S_t)$, where $n \in \mathbb{N}$ is a universe size, $c \in \mathbb{N}$ is a proposed cover size $1 \leq c \leq n$, and $S_1, \ldots, S_t \subseteq [n]$ are sets whose union is $[n]$, and outputs whether $c \geq \ell$ where ℓ is the optimal cover size given by*

$$\ell = \min\{|I| : I \subseteq [t] \text{ and } \cup_{i \in I} S_i = [n]\}.$$

We will use that SetCover is NP-hard even to approximate to a roughly $\log n$ factor.

▶ **Theorem 2.6** (Dinur and Steurer [11]). *It is* NP*-hard to approximate* SetCover *to within a factor of $(1 - o(1)) \ln n$*

3 On the NP-hardness of MOCSP

First, we introduce some useful notation and definitions. For a truth table T of length m and a set $R \subseteq [m]$, let $T_{\langle R \rangle}$ be the truth table of length m where the jth bit of $T_{\langle R \rangle}$ equals

$$\begin{cases} \text{the } j\text{th bit of } T & \text{, if } j \in R \\ 0 & \text{, otherwise.} \end{cases}.$$

Equivalently,

$$T_{\langle R \rangle}(x) = T(x) \wedge \mathbb{1}_{x \in R}.$$

Next, we define a uniformly random partition $\mathcal{P} = (P_1, \ldots, P_n)$ of $[m]$ into n parts to be such that each element $i \in [m]$ is put into P_j where $j \in [n]$ is chosen uniformly at random. It will be also useful to think of $\mathcal{P}$ as a uniformly random function $P : [m] \to [n]$.

Next, for a partition $\mathcal{P} = (P_1, \ldots, P_n)$ of $[m]$ and any set $S \subseteq [n]$, we define the *$\mathcal{P}$-lift of* S, denoted $S^{\mathcal{P}}$, to be the subset of $[m]$ given by

$$S^{\mathcal{P}} = \bigcup_{i \in S} P_i.$$

Our main theorem shows that MOCSP can approximate set cover.

▶ **Theorem 3.1.** *Let $S_1, \ldots, S_t \subseteq [n]$ be sets that cover $[n]$. Let T be a truth table of length $m \geq (nt)^5$, and let $\mathcal{P} = (P_1, \ldots, P_n)$ be a uniformly random partition of $[m]$ into n parts. Define the oracle function the $\mathcal{O} : \{0,1\}^{\lceil \log t \rceil} \times \{0,1\}^{\log m} \to \{0,1\}$ by*

$$\mathcal{O}(i, y) = \begin{cases} T_{\langle S_i^{\mathcal{P}} \rangle}(y) & \text{, if } i \in [t] \text{ (identifying } i \text{ as an integer in the natural way)} \\ 0 & \text{, otherwise} \end{cases}.$$

Then

- $\mathsf{CC}^{\mathcal{O}}(T) \leq \ell(3 + \log m + \log t)$, *and*
- $\mathsf{CC}^{\mathcal{O}}(T) > \ell(\log m + \log t)/2$ *with high probability*

where ℓ is size of the optimal cover of $[n]$ by $S_1, \ldots, S_t$.

Proof. First, we show the upper bound.

▷ Claim 3.2. $\mathsf{CC}^{\mathcal{O}}(T) \leq \ell(3 + \log m + \log t)$

Proof. Without loss of generality, assume that the optimal cover size ℓ is witnessed by $S_1 \cup \cdots \cup S_\ell = [n]$. Then, by construction, the function computed by oracle circuit C given by

$$C(x) = \mathcal{O}(1, x) \vee \cdots \vee \mathcal{O}(\ell, x)$$

computes T and has at most

$$2\ell + \ell \cdot (\log m + \log t + 1) \leq \ell(3 + \log m + \log t)$$

wires. In more detail,

$$\bigvee_{i \in [\ell]} \mathcal{O}(i, x) = \bigvee_{i \in [\ell]} \bigvee_{j \in S_i} T_{\langle P_j \rangle}(x) = \bigvee_{j \in S_1 \cup \cdots \cup S_\ell} T_{\langle P_j \rangle}(x) = \bigvee_{j \in [n]} T_{P_j}(x) = T(x).$$

Therefore $\mathsf{CC}^{\mathcal{O}}(T) \leq \ell(3 + \log m + \log t)$. ◁

Now, we show the lower bound. We do this by a union bound argument. Fix some $\mathcal{O}$-oracle circuit C such that with at most $\ell(\log m + \log t)/2$ wires. Then C has at most $\ell/2$ oracle gates. We will show that

$$\Pr_{T, \mathcal{P}}[C^{\mathcal{O}} \text{ computes } T]$$

is exponentially small.

We do this by finding a long sequence of inputs $x_1, \ldots, x_d$ on which $C^{\mathcal{O}}$ has a not too large chance of computing T.

We construct this list of inputs recursively as follows. Let $x_1 = 0^{\log m}$, and let

$$Q_1 = \{x : C^{\mathcal{O}}(x_1) \text{ makes a query of the form } (i, x) \text{ to an oracle gate for some } i\}.$$

Now, for $j \geq 1$, if $\{0,1\}^{\log m} \setminus Q_j$ is non-empty, then let x_{j+1} be an element of $\{0,1\}^{\log m} \setminus Q_j$, and let

$$Q_{j+1} = Q_j \cup \{x : C^{\mathcal{O}}(x_{j+1}) \text{ makes a query of the form } (i, x) \text{ to an oracle gate for some } i\}.$$

If $\{0,1\}^{\log m} = Q_j$, then terminate the sequence.

Since C has at most $\ell/2 \leq n$ oracle gates, we know that $|Q_j| \leq j \cdot n$. Thus, since

$$|Q_d| = |\{0,1\}^{\log m}| = m,$$

the length d of this sequence is at least m/n.

It remains to bound

$$\Pr[C^{\mathcal{O}}(x_j) = T(x_j) \forall j] = \prod_{j=1}^{d} \Pr[C^{\mathcal{O}}(x_j) = T(x_j) | \bigwedge_{k \in [j-1]} C^{\mathcal{O}}(x_k) = T(x_k)].$$

Fix some $j \in [d]$. We will bound

$$\Pr[C^{\mathcal{O}}(x_j) = T(x_j) | \bigwedge_{k \in [j-1]} C^{\mathcal{O}}(x_k) = T(x_k)].$$

For convenience, let E denote the event we are conditioning on.

▷ Claim 3.3.

$$\Pr[C^{\mathcal{O}}(x_j) = T(x_j) | E] \leq 1 - \frac{1}{2n}.$$

Proof. By construction of the sequence $x_1, \ldots, x_d$, we know that on all the inputs $x_1, \ldots, x_{j-1}$, $C^{\mathcal{O}}$ does not make an oracle call of the form (i, x_j) for some i. Thus, since the only time the value of $\mathcal{O}$ depends on $T(x_j)$ and $P(x_j)$ is on inputs of the form (i, x_j) for some i, and $T(x_j)$ and $P(x_j)$ are chosen at independently at random, we know that $T(x_j)$ and $P(x_j)$ are still uniform random variables conditioned on E. In other words,

$$\Pr[T(x_j) = 1 | E] = \frac{1}{2}$$

and

$$\Pr[P(x_j) = r | E] = \frac{1}{n}$$

for all $r \in [n]$.

Now, define the alternate oracle $\mathcal{O}'$ that acts the same as $\mathcal{O}$ except that it rejects all queries containing x_j, that is

$$\mathcal{O}'(i, x) = \begin{cases} 0 & , \text{ if } x = x_j \\ \mathcal{O}(i, x) & , \text{otherwise.} \end{cases}$$

Now let $i_1, \ldots, i_v$ with $v \leq \ell/2$ be such that, using the modified oracle $\mathcal{O}'$, the only oracle queries $C^{\mathcal{O}'}(x_j)$ makes that end with x_j are $(i_1, x_j), \ldots, (i_v, x_j)$ (note that queries of this form are the only ones that could reveal information about $T(x_j)$). Since $v < \ell$ (recall ℓ is the size of the optimal cover) there actually exists an element $r^\star \in [n]$ that is not in $S_{i_1} \cup \cdots \cup S_{i_v}$.

Moreover, observe that if $P(x) = r^\star$, then $C^{\mathcal{O}}(x_j)$ will actually make the same oracle queries (and get the same zero responses) as the modified oracle circuit $C^{\mathcal{O}'}(x_j)$. In this case, since $P(x) = r^\star \notin S_{i_1} \cup \cdots \cup S_{i_v}$, it follows from the definition of $\mathcal{O}$ that

$$\mathcal{O}(i_1, x_j) = \cdots = \mathcal{O}(i_v, x_j) = 0$$

regardless of the value of $T(x_j)$. Thus, the output of $C^{\mathcal{O}}$ on input x does not depend at all on the value of $T(x)$. Hence, the probability it correctly guesses $C^{\mathcal{O}}(x) = T(x)$ is at most one half when $P(x_j) = r^\star$.

Since $P(x_j)$ is chosen uniformly at random, we have that $P(x_j) = r^\star$ with probability $1/n$.

Therefore, the probability

$$\Pr[C^{\mathcal{O}}(x_j) = T(x_j) | E] \leq 1 - \frac{1}{2n}$$ ◁

Using this claim, we now have

$$\prod_{j=1}^{d} \Pr[C^{\mathcal{O}}(x_j) = T(x_j) | \bigwedge_{k \in [j-1]} C^{\mathcal{O}}(x_k) = T(x_k)] \leq (1 - \frac{1}{2n})^d \leq e^{-\frac{d}{2n}} \leq e^{-\frac{m}{2n^2}} \leq e^{-\frac{n^3 t^5}{2}}.$$

On the other hand the number of oracle circuits of size $\ell(\log m + \log t)/2 = O(nt \log n)$ is at most $2^{O(n^2 t^2)}$. Thus, by the union bound the probability that there exists an $\mathcal{O}$-oracle circuit of size at most $\ell(\log m + \log t)/2$ computing T is $o(1)$ as desired. ◀

As an immediate consequence of Theorem 3.1, we get that MOCSP is hard for NP under many-one randomized reductions with one-sided error (the reduction is one-sided because the upper bound on the oracle circuit size of T in Theorem 3.1 is independent of the random choices of T and $\mathcal{P}$).

▶ **Corollary 3.4.** $\mathsf{NP} \leq_m^{\mathsf{RP}} \mathsf{MOCSP}$.

Moreover, the RP-reduction in Corollary 3.4 only errs by outputting YES when the answer should be NO. Thus, using the search-to-decision reduction for SetCover, we can check the correctness of purported YES answers, yielding a ZPP Turing reduction.

▶ **Corollary 3.5.** $\mathsf{NP} \leq_{\mathsf{T}}^{\mathsf{ZPP}} \mathsf{MOCSP}$.

4 MAJORITY $\leq_{tt}^{\mathsf{AC}^0}$ (AC^0_d)-MCSP

Let $d \geq 2$. Our goal in this section is to prove the following theorem.

▶ **Theorem 4.1.** $\mathsf{MAJORITY} \leq_{tt}^{\mathsf{AC}^0} (\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}$.

We will do this by showing that for all sufficiently large $n \in \mathbb{N}$, there exists an AC^0 truth table oracle circuit that computes MAJORITY on n-bits when given access to (AC^0_d)-MCSP.

Fix some n, and let q be the least power of two such that $n \leq \sqrt{q}/2$. We will split our analysis into cases depending on whether there exists an $m \in \{q^{10}, q^{50}\}$ such that $\mathsf{CC}^0_{\mathsf{AC}^0_d}$ is $(m^{.25})$-Lipschitz on inputs of length m.

4.1 Case 1: Lipschitzness Holds

If Lipschitzness holds, then the desired (AC^0_d)-MCSP oracle circuit C exists for computing MAJORITY on n-inputs by the work of Golovnev et al. [12]. At a high-level, C works by using the input string to sample a random variable whose circuit complexity spikes (in expectation) depending on the weight of the input and using Lipschitzness to show that this spike happens with such high probability that it can be derandomized using non-uniformity.

For completeness, we give a self-contained proof of this case in Appendix A.

4.2 Case 2: Lipschitzness fails

Assume that for all $m \in \{q^{10}, q^{50}\}$, $\mathsf{CC}_{\mathsf{AC}^0_d}$ is not $(m^{.25})$-Lipschitz on inputs of length m. Thus, for all $m \in \{q^{10}, q^{50}\}$ there exist functions $f^m, h^m : \{0,1\}^{\log m} \to \{0,1\}$ that differ only on a single input $z^m \in \{0,1\}^{\log m}$ such that $\mathsf{CC}_{\mathsf{AC}^0_d}(h^m) - \mathsf{CC}_{\mathsf{AC}^0_d}(f^m) > m^{.25}$.

We assume, without loss of generality, that for all $m \in \{q^{10}, q^{50}\}$, $f^m(z^m) = 0$ and $h^m(z^m) = 1$. (If this is not the case, then replace f^m and h^m by $\neg f^m$ and $\neg h^m$ respectively and apply Lemma 2.2.)

First, we show that the failure of Lipschitzness implies the existence of functions that are much easier to compute by formulas with an AND gate on top. For $m \in \{q^{10}, q^{50}\}$ let $\mathbb{1}_{z^m} : \{0,1\}^{\log m} \to \{0,1\}$ denote the indicator function that accepts just the string z^m.

▶ **Proposition 4.2.** *Let $m \in \{q^{10}, q^{50}\}$. For sufficiently large n, $\mathsf{CC}_{\mathsf{OR}\circ\mathsf{AC}^0_{d-1}}(f^m) \geq \mathsf{CC}_{\mathsf{AC}^0_d}(f^m) + m^{.24}$, and so any optimal AC^0_d formula for f^m has an AND gate on top.*

Proof. Suppose ϕ is an $\mathsf{OR} \circ \mathsf{AC}^0_{d-1}$ formula computing f^m, that is, f^m is computed by $\phi = \phi_1 \vee \cdots \vee \phi_t$ for some AC^0_{d-1} formulas $\phi_1, \ldots, \phi_t$. Then

$$\mathbb{1}_{z^m} \vee \phi_1 \vee \cdots \vee \phi_t$$

computes h^m. Since $\mathbb{1}_{z^m}$ can be computed by a single AND gate of formula size $\log m$, this shows that $\mathsf{CC}_{\mathsf{AC}^0_d}(h^m) \leq |\phi| + \log m$. Combining this with the fact that $\mathsf{CC}_{\mathsf{AC}^0_d}(h^m) - \mathsf{CC}_{\mathsf{AC}^0_d}(f^m) \geq m^{.25}$ gives the desired result. ◀

At this point, we will need to refer to both q^{10} and q^{50} individually, so for convenience let $u = q^{10}$ and $v = q^{50}$.

Let ϕ^u be an optimal AC^0_d formula for f^u. By Proposition 4.2, for sufficiently large n, we know that $\phi^u = \phi^u_1 \wedge \cdots \wedge \phi^u_t$ for some AC^0_{d-1} formulas $\phi^u_1, \ldots, \phi^u_t$. Moreover, we can assume, without loss of generality, that the top gate of ϕ^u_i is OR for all $i \in [t]$. (If some ϕ^u_i has an AND gate on top, then this AND can be carried out by the AND gate on top of ϕ^u without increasing the size of the formula.)

Our next Proposition shows that ϕ^u has high top fan-in.

▶ **Proposition 4.3.** *For sufficiently large n,*

$$t \geq u^{.24}.$$

Proof. We divide into cases depending on d.

Case 1: $d \geq 3$. Realize that

$$(\phi^u_1 \vee \mathbb{1}_{z^u}) \wedge \cdots \wedge (\phi^u_t \vee \mathbb{1}_{z^u})$$

computes h^u. Since $\mathbb{1}_{z^u}$ can be computed by a single AND gate of formula size $\log u$ and the top gate of each ϕ^u_i is an OR gate and $d \geq 3$, this yields a depth-d formula for h^u of size $\mathsf{CC}_{\mathsf{AC}^0_d}(f^u) + t \log u$. Since $\mathsf{CC}_{\mathsf{AC}^0_d}(h^u) - \mathsf{CC}_{\mathsf{AC}^0_d}(f^u) \geq u^{.25}$, the desired bound on t follows.

Case 2: $d = 2$. Let $\mathbb{1}_{z^u,j} : \{0,1\}^{\log u} \to \{0,1\}$ be the function that accepts a string x if and only if the jth bit of x equals the jth bit of z^u. Observe that, since $\bigwedge_{i\in[t]} \phi_i^u$ computes f^u, we have that

$$\bigwedge_{i\in[t]} \bigwedge_{j\in[\log u]} (\phi_i^u \vee \mathbb{1}_{z^u,j})$$

computes h^u. Since $\mathbb{1}_{z^u,j}$ is computed by a single input leaf and ϕ_i^u has an OR gate on top, this yields a depth-2 formula for h^u of size $(|\phi^u|+1)\log u$. Since ϕ^u is an optimal CNF, each clause ϕ_i^u of ϕ^u is the OR of at most $\log u$ input leaves. In other words, $|\phi_i^u| \leq \log u$. Therefore, we have that

$$\mathsf{CC}^0_{\mathsf{AC}^0_d}(h^u) \leq (|\phi^u|+1)\log u \leq (\sum_{i\in[t]} |\phi_i^u|+1)\log u \leq (t\log u+1)\log u = t\log^2 u + \log u.$$

On the other hand, we know by assumption that

$$\mathsf{CC}^0_{\mathsf{AC}^0_d}(h^u) > \mathsf{CC}^0_{\mathsf{AC}^0_d}(f^u) + u^{.25} \geq u^{.25}.$$

Combining these two inequalities gives us the desired bound on t. ◀

Let p be smallest prime greater than n. (Note that $p \leq 2n$ by Betrand's postulate, also known as Chebyshev's theorem. See [13] for a proof.) We say that an integer j is (k,r)-*good* for integers $k \geq 0$ and $1 \leq r \leq p-1$ if p^k divides j and $j/p^k \equiv r \mod p$. In other words, an integer j is (k,r)-good for $k \geq 0$ and $r \in [p-1]$ if the kth largest entry of the base-p representation of the integer j equals r and all previous entries equal zero. From this "base-p" perspective, it is clear that all positive integers j are (k,r)-good for some $k \geq 0$ and $r \in [p-1]$.

We show that, for some k and r, a large subset of the $|\phi_i^u|$ are (k,r)-good.

▶ **Proposition 4.4.** *For all sufficiently large n, there exist integers $k \geq 0$ and $1 \leq r \leq p-1$ and a set $S \subseteq [t]$ of cardinality n such that, for all $i \in S$, the integer $|\phi_i^u|$ is (k,r)-good.*

Proof. We do this by an averaging argument. First, we show that each $|\phi_i^u|$ is (k,r)-good for a k not too large.

▷ Claim 4.5. For all $i \in [t]$, $|\phi_i^u|$ is (k,r)-good for some $0 \leq k \leq \log(u\log u)+1$ and some $r \in [p-1]$.

Proof. Fix some $i \in [t]$. $|\phi_i^u|$ is a positive integer, so $|\phi_i^u|$ is (k,r)-good for some $k \geq 0$ and some $r \in [p-1]$. We still need to upper bound this k. Note that the size of $|\phi_i^u|$ is at most $u\log u$ since ϕ^u is optimal for f^u and f^u can be computed by a DNF of size $u\log u$. Thus, for p^k to divide $|\phi_i^u|$, we must have that $k \leq \log_p(u\log u)+1 \leq \log(u\log u)+1$. ◁

Since for all $i \in [t]$ we have shown that $|\phi_i^u|$ is (k,r) good for some $0 \leq k \leq \log(u\log u)+1$ and some $r \in [p-1]$, a standard averaging argument implies that there exists a set $S \subseteq [t]$ of cardinality at least

$$\frac{t}{(\log(u\log u)+1)(p-1)}$$

such that for all $i \in S$, $|\phi_i^u|$ is (k,r)-good for some fixed $k \geq 0$ and $1 \leq r \leq p-1$. For sufficiently large n, we have that

$$\frac{t}{(\log(u\log u)+1)(p-1)} \geq \frac{u^{.24}}{4n\log u} \geq n$$

using that $u = q^{10} \geq n^{10}$. We then can truncate S so that it has only n elements as desired. ◀

Assume that n is large enough that all the sufficiently large hypotheses in Propositions 4.2, 4.3, and 4.4 apply. For convenience, relabel $\phi_1, \ldots, \phi_t$ so that the set S guaranteed by Proposition 4.4 is just $S = [n]$. Fix $k \geq 0$ and $r \in [p-1]$ to be the values such that for all $i \in S = [n]$, $|\phi_i^u|$ is (k, r)-good.

Introducing notation, for a set $A \subseteq [n]$, let f_A^u be the function computed by $\bigwedge_{i \in A} \phi_i^u$.

▶ **Lemma 4.6.** *Let $A \subseteq [n]$. Then $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f_A^u) = \sum_{i \in A} |\phi_i^u|$.*

Proof. By construction, we have that $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f_A^u) \leq \sum_{i \in A} |\phi_i|$. Suppose for contradiction that $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f_A^u) < \sum_{i \in A} |\phi_i^u|$.

Let $\theta_1 \wedge \cdots \wedge \theta_\ell$ be a minimum-sized $(\mathsf{AND} \circ \mathsf{AC}^0_{d-1})$ formula for f_A^u. By assumption, we have that $\sum_{j=1}^{\ell} |\theta_j| < \sum_{i \in A} |\phi_i^u|$. We can thus replace the $\bigwedge_{i \in A} \phi_i^u$ in the optimal formula for f^u with $\theta_1 \wedge \cdots \wedge \theta_\ell$ and get a smaller formula. In more detail, we have that

$$f^u = f_A^u \wedge \Big(\bigwedge_{i \in [t] \setminus A} \phi_i^u \Big) = (\theta_1 \wedge \cdots \wedge \theta_\ell) \wedge \Big(\bigwedge_{i \in [t] \setminus A} \phi_i^u \Big)$$

which is a formula of size

$$\sum_{j=1}^{\ell} |\theta_j| + \sum_{i \in [t] \setminus A} |\phi_i^u| < \sum_{i \in A} |\phi_i^u| + \sum_{i \in [t] \setminus A} |\phi_i^u| = \sum_{i=1}^{t} |\phi_i^u| = |\phi^u|$$

which contradicts the optimality of ϕ^u for f^u. ◀

For a string $x \in \{0,1\}^n$, let f_x^u be shorthand for $f_{A_x}^u$ where $A_x \subseteq [n]$ is the set of indices where x is one.

▶ **Proposition 4.7.** *Let $x \in \{0,1\}^n$. Then x has weight w if and only if the integer $\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f_x^u)$ is (k, rw)-good.*

Proof. By Lemma 4.6 and the fact that $|\phi_i^u|$ is (k, r)-good for all $i \in [n]$, we have that

$$\frac{\mathsf{CC}_{\mathsf{AND} \circ \mathsf{AC}^0_{d-1}}(f_x^u)}{p^k} = \frac{\sum_{i \in A_x} |\phi_i^u|}{p^k} \equiv w \cdot r \mod p$$

where $A_x \subseteq [n]$ are bits of x that are ones. The "only if" part of the statement is guaranteed by the fact that $1 \leq r \leq p-1$ has a multiplicative inverse modulo p since p is prime. ◀

▶ **Theorem 4.8.** *Assume n is sufficiently large. Then there is a depth-8 AC^0 truth table oracle circuit C with $O(n^{250})$ wires such that $C^{(\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}}$ computes $\mathsf{MAJORITY}$ on n-bits.*

Proof. It suffices to show that for every $w \in [n]$, there exists a depth-7 AC^0 oracle circuit C_w with $O(n^{249})$ wires such that $C_w^{(\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}}(x) = 1 \iff \mathsf{wt}(x) = w$. Then $\mathsf{MAJORITY}(x) = \bigvee_{w \geq n/2} C_w(x)$.

Fix some $w \in [n]$. The circuit C_w works as follows. On input $x \in \{0,1\}^n$, first check if x is the all zeroes string. If so, then reject. Otherwise, compute the truth table of the direct product function $g_x : \{0,1\}^{\log u} \times \{0,1\}^{\log v} \to \{0,1\}$ given by $g_x(y,z) = f_x^u(y) \wedge f^v(z)$. Compute $s = \mathsf{CC}_{\mathsf{AC}^0_d}(g_x)$ in binary using oracle access to (AC^0_d)-MCSP. Finally accept if the integer s has the property that $s - \mathsf{CC}_{\mathsf{AC}^0_d}(f^v)$ is (k, rw)-good. Reject otherwise.

We now verify this yields a (non-uniform) AC^0 truth table oracle circuit. We can check if x is the all zeroes string with a single OR gate. This requires one level of depth and $O(n)$ wires. Next, realize the jth bit in the truth table of g_x is either zero for all x or equal to

$$f_x^u(j) = \bigvee_{i \in [n] : \phi_i^u(j) = 1} x_i$$

where x_i denotes the ith bit of x. Thus, using non-uniformity, we can compute the truth table of g_x with $O(nuv) = O(nq^{60}) = O(n^{121})$ wires and depth-one. Next, we can compute $s = \mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x)$ in binary with $O(uv\log(uv))$ calls to (AC^0_d)-MCSP using the fact that $\mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x) \leq uv\log(uv)$ by the DNF bound and the fact that

$$\mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x) = s \iff (\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}(g_x, s) = 1 \text{ and } (\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}(g_x, s-1) = 0.$$

This takes at most $\tilde{O}((uv)^2) = O(n^{241})$ wires, an additional three layers of depth, and $2uv\log(uv)$ oracle calls that all do not depend on each other. Finally, the DNF upper bound guarantees that $\mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x) \leq uv\log(uv) \leq n^{61}$, so the length of the integer $s = \mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x)$ in binary is at most $61\log n$. Therefore we can check if s has the property that $s - \mathsf{CC}^0_{\mathsf{AC}^0_d}(f^v)$ is (k, rw)-good using a DNF with at most n^{62} wires and at most an additional two layers of depth. Combining all this yields a AC^0 circuit of depth-7 with at most $O(n^{241})$ wires and no directed path between oracle gates.

Next, we argue for correctness. Clearly, C_w rejects the all zero string, so assume $x \neq 0^n$. By Proposition 4.7, it suffices to show that, for $s = \mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x)$,

$$s - \mathsf{CC}^0_{\mathsf{AC}^0_d}(f^v) = \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^u_x).$$

We confirm that neither f^u_x nor f^v is the constant zero function, so that we can use the direct product theorems in Lemma 2.3.

▷ Claim 4.9. Neither f^u_x nor f^v is the constant zero function.

Proof. If f^v were the constant zero function, then $\mathsf{CC}^0_{\mathsf{AC}^0_d}(h^v) \leq \log v$ by DNF computation which contradicts that

$$\mathsf{CC}^0_{\mathsf{AC}^0_d}(h^v) - \mathsf{CC}^0_{\mathsf{AC}^0_d}(f^v) \geq v^{.25}.$$

Next, let $i \in [n]$ be a bit of x that is not zero. (Recall, we assumed that $x \neq 0^n$.) Then f^u_x has accepts every input that that ϕ^u_i accepts. For contradiction, suppose that ϕ^u_i had no ones. Then we can remove ϕ^u_i from the optimal formula $\phi^u = \phi^u_1 \wedge \ldots \phi^u_t$ for f^u and get a smaller formula for f^u which contradicts the optimality of ϕ^u. ◁

Next we show that the optimal AC^0_d formula for g_x has an AND gate on top.

▷ Claim 4.10. $\mathsf{CC}^0_{\mathsf{OR}\circ\mathsf{AC}^0_{d-1}}(g_x) > \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(g_x)$. Consequently,

$$\mathsf{CC}^0_{\mathsf{AC}^0_d}(g_x) = \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(g_x).$$

Proof. Let $\Delta = \mathsf{CC}^0_{\mathsf{OR}\circ\mathsf{AC}^0_{d-1}}(g_x) - \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(g_x)$. We need to show $\Delta > 0$.

$$\begin{aligned}
\Delta &\geq \mathsf{CC}^0_{\mathsf{OR}\circ\mathsf{AC}^0_{d-1}}(f^v) - \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^v) + \mathsf{CC}^0_{\mathsf{OR}\circ\mathsf{AC}^0_{d-1}}(f^u_x) && \text{(by Lemma 2.3)}\\
&\quad - \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^u_x)\\
&\geq (v)^{.24} + \mathsf{CC}^0_{\mathsf{OR}\circ\mathsf{AC}^0_{d-1}}(f^u_x) - \mathsf{CC}^0_{\mathsf{AND}\circ\mathsf{AC}^0_{d-1}}(f^u_x) \geq && \text{(by Proposition 4.2)}\\
&\geq (v)^{.24} - u\log u && \text{(by DNF bound on } f^u_x)\\
&\geq n^{50\cdot.24} - n^{10}\log(n^{10}) && \text{(by definition of } u \text{ and } v)\\
&> 0 && \text{(for sufficiently large } n)
\end{aligned}$$

◁

Using the claim we have that

$$\begin{aligned}
& s - \mathsf{CC}^0_d(f^v) \\
=\ & \mathsf{CC}^0_d(g_x) - \mathsf{CC}^0_d(f^v) && \text{(definition)} \\
=\ & \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(g_x) - \mathsf{CC}^0_d(f^v) && \text{(Claim 4.10)} \\
=\ & \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(f^u_x) + \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(f^v) - \mathsf{CC}^0_d(f^v) && \text{(Lemma 2.3)} \\
=\ & \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(f^u_x) + \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(f^v) - \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(f^v) && \text{(Prop 4.2)} \\
=\ & \mathsf{CC}^0_{d-1}(\mathsf{AND} \circ \mathsf{AC}^0)(f^u_x)
\end{aligned}$$

as desired. ◀

A MAJORITY reduces to (AC^0_d)-MCSP when Lipschitzness holds

Our goal in this section is to find a small (AC^0_d)-MCSP-oracle circuit that computes MAJORITY on n-bits for sufficiently large n. We can do this using the techniques of Golovnev et al. [12]. In order to make our proof relatively self-contained, we differ slightly from the presentation in [12]. In particular, our presentation follows a method for computing MAJORITY that is described in Shaltiel and Viola [29].

At a high-level, this procedure works by using the input string to sample a random variable whose circuit complexity spikes depending on the weight of the input and then using Lipschitzness to prove that this spike occurs with high enough probability that we can derandomize using non-uniformity.

Continuing the notation from Section 4, assume that there is an $m \in \{q^{10}, q^{50}\}$ such that $\mathsf{CC}^0_{\mathsf{AC}^0_d}$ is $(m^{.25})$-Lipschitz on inputs of length m.

We define the random variable $T_{p,m} \in \{0,1\}^m$ where each bit in $T_{p,m}$ is independently chosen to be one with probability p and zero with probability $1-p$.

▶ **Lemma A.1.** $\mathbb{E}[\mathsf{CC}^0_{\mathsf{AC}^0_d}(T_{p,m})] = \tilde{O}(pm)$ *if* $p \geq m^{-1/3}$

Proof. By Hoeffding's inequality we have that the probability that $T_{p,m}$ has greater than k ones is at most $\mathsf{exp}(-2\epsilon^2 m)$. Via computation by DNF, if a truth table $T \in \{0,1\}^m$ has at most k ones, $\mathsf{CC}^0_{\mathsf{AC}^0_d}(T) = k \log m = \tilde{O}(k)$. Similarly, we have that $\max\{C(T) : T \in \{0,1\}^m\} = \tilde{O}(m)$. Hence, we get that

$$\mathbb{E}[\mathsf{CC}^0_{\mathsf{AC}^0_d}(T_{p,m})] = \tilde{O}(k) + \tilde{O}(\mathsf{exp}(-2\epsilon^2 m)m) = \tilde{O}(pm + pm\epsilon + \mathsf{exp}(-2\epsilon^2 m)m).$$

If we set $\epsilon = \sqrt{\frac{\ln m}{2m}}$, then we have

$$\mathbb{E}[\mathsf{CC}^0_{\mathsf{AC}^0_d}(T_{p,m})] \leq \tilde{O}(pm + p\sqrt{m}\ln m + 1) \leq \tilde{O}(pm + \sqrt{m}\ln m)$$

Finally, if $p \geq 1/m^{1/3}$, we have $\mathbb{E}[T_{p,m}] = \tilde{O}(pm)$ as desired ◀

We will make use of the following concentration inequality.

▶ **Theorem A.2** (McDiarmid's "bounded differences inequality" [21])**.** *Let* $f : \{0,1\}^n \to \mathbb{R}$ *be* c*-Lipschitz. Let* $X_1, \ldots, X_n$ *be independent random variables with values in* $\{0,1\}$*. Let* $\mu = \mathbb{E}_{X_1,\ldots,X_n}[f(X_1, \ldots, X_n)]$*. Then*

$$\Pr[|f(X_1, \ldots, X_n) - \mu| \geq \epsilon] \leq 2\mathsf{exp}(-\frac{\epsilon^2}{nc^2}).$$

For $t \in \mathbb{N}$ and $w_1 \neq w_2 \in [t]$, we say a Boolean function $f : \{0,1\}^t \to \{0,1\}$ computes $\mathsf{WTDIS}_t[w_1, w_2]$ if $\mathsf{wt}(x) = w_1$ implies $f(x) = 1$ and $\mathsf{wt}(x) = w_2$ implies $f(x) = 0$. (WTDIS is short for weight distinguishing.)

▶ **Theorem A.3.** *If* n *is sufficiently large, then for all* $1 \leq b \leq \sqrt{q}/2$*, there exists a (non-uniform)* NC^0 *oracle circuit* C *with at most* $O(n^{100})$ *wires such that* $C^{(\mathsf{AC}^0_d)\text{-MCSP}}$ *computes* $\mathsf{WTDIS}_q[w_1, w_1 + b]$ *for some* $w_1 \geq \sqrt{q}/2$*. Moreover,* C *has a single gate.*

Proof. For $w \in [q]$, let $p_w = \frac{w}{2q}$. Let w_0 be the largest integer less than $\sqrt{q}$ such that $q - w_0$ is a multiple of b. (Note that $w_0 \geq \sqrt{q} - b \geq \sqrt{q}/2$).

By Lemma A.1, we have that

$$\mathbb{E}[\mathsf{CC}^0_{\mathsf{AC}^0_d}(T_{p_{w_0},m})] = \tilde{O}(\frac{\sqrt{q}}{q}m) = \tilde{O}(m/\sqrt{q}).$$

On the other hand, since $p_q = 1/2$, $T_{p_q,m}$ is just a binary string of length m picked uniformly at random, so the formula size lower bounds of Shannon and Riordan imply

$$\mathbb{E}[\mathsf{CC}^0_{\mathsf{AC}^0_d}(T_{p_q,m})] = \mathop{\mathbb{E}}_{x\in\{0,1\}^m}[C(x)] = \tilde{\Omega}(m)$$

(note that an AC^0_d formula of size s implies an unrestricted formula of size s). Hence, by an averaging argument there exists a $w_1 \geq w_0 \geq \sqrt{q}/2$ such that

$$\mathbb{E}[\mathsf{CC}^0_d(T_{p_{w_1+b},m})] - \mathbb{E}[\mathsf{CC}(T_{p_{w_1},m})] \geq \frac{\tilde{\Omega}(m) - \tilde{O}(m/\sqrt{q})}{q} = \tilde{\Omega}(m/q).$$

Let $t = \frac{\mathbb{E}[T_{p_{w_1+b},m}]+\mathbb{E}[T_{p_{w_1},m}]}{2}$. Then we have that $\mathbb{E}[T_{p_{w_1+b},m}] - t = \tilde{\Omega}(m/q)$ and $t - \mathbb{E}[T_{p_{w_1},m}] = \tilde{\Omega}(m/q)$.

We now outline a probabilistic oracle circuit D that we will later make into a deterministic NC^0 circuit. D takes as input a string $x \in \{0,1\}^n$ and takes as its random "inputs" strings $u_1, \ldots, u_m \in \{0,1\}^{\log q}$ and $v_1, \ldots, v_m \in \{0,1\}$. The reduction then computes the string $y := y_1 \ldots y_m$ where y_i is zero if v_i is zero and y_i is the u_ith bit of x if v_i is one (recall, q is a power of two). D then outputs (AC^0_d)-$\mathsf{MCSP}(y,t)$.

We now argue for correctness with high probability. Realize each y_i is independent with probability $\frac{\mathsf{wt}(x)}{2n}$ of being 1. Hence, y is just the random variable $T_{p_w,m}$ where $w = \mathsf{wt}(x)$. Hence, if $\mathsf{wt}(x) = w_1$, then

$$\Pr[R(x) \neq 1] = \Pr[\mathcal{C}(T_{p_{w_1},m}) > t]$$

Recall that $t - \mathbb{E}[T_{p_{w_1},m}] = \tilde{\Omega}(m/q)$ and, by assumption, $\mathsf{CC}^0_{\mathsf{AC}^0_d}$ on inputs of length m is $(m^{.25})$-Lipschitz, so by Theorem A.2, we have that this probability is bounded by

$$2\mathsf{exp}(-2\frac{\tilde{\Omega}(m^2)}{\tilde{O}(q^2 m^{1.5})}) \leq \mathsf{exp}(-2\frac{\tilde{\Omega}(q^{.5\cdot 10})}{\tilde{O}(q^2)}) = O(\mathsf{exp}(-q^3))$$

using the fact that $m \geq q^{10}$. A similar analysis shows that the probability D errs if $\mathsf{wt}(x) = w_1 + b$ is at most $O(\mathsf{exp}(-q^3))$. This completes the analysis of D.

We now argue that this reduction can be derandomized using non-uniformity. For each input of weight either w_1 or $w_1 + b$, we have shown the fraction of random strings which err on that input is $O(\mathsf{exp}(-q^3))$. Hence, the fraction of random seeds which err on at least one input of weight w_1 or $w_1 + b$ is at most

$$2^q O(\mathsf{exp}(-q^3)) < 1$$

for large enough n. Thus, there exists some fixed $u_1, \ldots, u_m$ and $v_1, \ldots, v_m$ which work on all inputs of length q. Once we are (non-uniformly) given these $u_1, \ldots, u_m$ and $v_1, \ldots, v_m$ which work on all inputs, we can turn D into an NC^0 oracle circuit C which has just a single gate (an oracle gate) whose inputs are the fixed number t and the string y where each bit of y is either a fixed bit of x or zero. This yields a NC^0 oracle circuit with $O(m) = O(q^{50}) = O(n^{100})$ wires. ◀

▶ **Corollary A.4.** *If n is sufficiently large, then for all distinct $w_1, w_2 \in [n]$ there is an NC^0 oracle circuit C with at most two gates and $O(n^{100})$ wires such that $C^{(\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}}$ computes $\mathsf{WTDIS}_n[w_1, w_2]$.*

Proof. Fix some $w_1 \neq w_2$. Without loss of generality assume $w_1 < w_2$ (if this is not the case, then swap the names of w_1 and w_2 in this proof and add a NOT gate to the top of C). Let $b = w_2 - w_1$. Recall q is the least power of two such that $n \leq \sqrt{q}/2$. Note that $q = \Theta(n^2)$ and $b \leq n \leq \sqrt{q}/2$. Theorem A.3 guarantees there exists an NC^0 oracle circuit D of size $O(n^{20})$ such that D^{MCSP} computes $\mathsf{WTDIS}_q[w_3, w_3 + b]$ for some $w_3 \geq \sqrt{q}/2 \geq n$. Finally, let C be the oracle circuit that on input x outputs $D(y)$ where $y = 1^{w_3 - w_1} 0^{q-n-w_3+w_1} x$. The correctness of this output is guaranteed by the fact that $\mathsf{wt}(y) = w_3$ if and only if $\mathsf{wt}(x) = w_1$ and $\mathsf{wt}(y) = w_3 + b$ if and only if $\mathsf{wt}(x) = w_2$. ◀

▶ **Corollary A.5.** *If n is sufficiently large, then there exists a depth-4* AC^0 *truth table oracle circuit C with $O(n^{102})$ wires such that $C^{(\mathsf{AC}^0_d)\text{-}\mathsf{MCSP}}$ computes* MAJORITY *on strings on length n.*

Proof. It suffices to show that, for all $w \in [n]$, one can check if a string $x \in \{0,1\}^n$ has weight w using a depth-3 AC^0 truth-table oracle circuit C_w of size $O(n^{101})$. If one is able to do this, then MAJORITY is computed by $\bigvee_{w \geq n/2} C_w(x)$.

For $w \in [n]$, let $\mathsf{wt}_w : \{0,1\}^n \to \{0,1\}$ be the Boolean function that outputs one if and only if its input is a string of weight w. Now fix some $w \in [n]$. We claim that

$$\mathsf{wt}_w(x) = \bigwedge_{w' \in [n]: w \neq w'} \mathsf{WTDIS}_n[w, w']$$

If x has weight w, then $\mathsf{WTDIS}_n[w,w'](x) = 1$ for all $w' \neq w$, so

$$\mathsf{wt}_{w'}(x) = 1 = \bigwedge_{w' \in [n]: w \neq w'} \mathsf{WTDIS}_n[w, w'].$$

On the other hand, if x has weight $w' \neq w$,then $\mathsf{WTDIS}_n[w,w'](x) = 0$, so

$$\mathsf{wt}_w(x) = 0 = \bigwedge_{w' \in [n]: w \neq w'} \mathsf{WTDIS}_n[w, w'].$$

Finally, by Corollary A.4 we have that $\bigwedge_{w \in [n]: w \neq w'} \mathsf{WTDIS}_n[w', w]$ is computable by a depth-3 AC^0 truth table oracle circuit with $O(n^{101})$ wires. ◀

B $\mathsf{NP} \leq^{\mathsf{P}}_{tt} \mathsf{MOCSP}$ implies $\mathsf{EXP} \neq \mathsf{ZPP}$

The proof of this result follows essentially exactly from Murray and Williams's [23] proof for MCSP. For completeness, we replicate the proof here (even using their words and structure).

▶ **Proposition B.1.** *If* $\mathsf{NP} \leq^{\mathsf{P}}_{tt} \mathsf{MOCSP}$*, then* $\mathsf{EXP} \subseteq \mathsf{P/poly}$ *implies* $\mathsf{EXP} = \mathsf{NEXP}$.

Proof. Assume $\mathsf{NP} \leq^{\mathsf{P}}_{tt} \mathsf{MOCSP}$ and $\mathsf{EXP} \subseteq \mathsf{P/poly}$. Let $L \in \mathsf{NTIME}(2^{n^c})$ for some $c \geq 1$. It suffices to show that $L \in \mathsf{EXP}$.

We pad L into the $L' = \{x01^{2^{|x|^c}} : x \in L\}$. Note that $L' \in \mathsf{NP}$. Hence there is a polynomial-time truth table reduction from L' to MOCSP. Composing the reduction from L to L' with the reduction from L' to MOCSP, we get a $2^{c'n^c}$-time truth table reduction R from n-bit instances of L to $2^{c'n^c}$-bit instances of MOCSP for some constant c'.

Let $Q(x)$ denote the concatenated string of all MOCSP queries produced by R in order on input x. Define the language

$$BITS_Q := \{(x,i) : \text{ the } i\text{th bit of } Q(x) \text{ is } 1\}$$

$BITS_Q$ is clearly in EXP. Since $\mathsf{EXP} \subseteq \mathsf{P/poly}$, for some $d \geq 1$ there is a circuit family C_n of size at most $n^d + d$ computing $BITS_Q$ on n-bit inputs.

Thus, on a given instance x, we have $\mathsf{CC}(Q(x)) \leq s(|x|)$ where $s(|x|) := (|x| + 2c'|x|^c)^d + d$. Therefore, every MOCSP query $(T, s', \mathcal{O})$ produced by the reduction R on input x satisfies

$$\mathsf{CC}^{\mathcal{O}}(T) \leq \mathsf{CC}(T) \leq e \cdot \mathsf{CC}(Q(x)) \leq e \cdot s(|x|)$$

for some constant e since T is a substring of $Q(x)$ (see Lemma 2.2 in [23] for a proof of this substring fact). This leads to the following exponential time algorithm for L:

> On input x, run the exponential-time reduction $R(x)$ by using the following procedure for answering each MOCSP oracle query $(T, s'; \mathcal{O})$. If $s' > e \cdot s(|x|)$, then respond YES to the query. Otherwise, cycle through every oracle circuit E of size at most s'. If $E^{\mathcal{O}}$ computes T, then respond YES. If no such E is found, then respond NO.

It suffices to show the procedure for answering MOCSP oracle queries runs in exponential time. Let $n = |x|$. First, we need to count the number of oracle circuits E on $(\log |T| \leq c'n^c)$-inputs with size at most $s(n)$. The logarithm of the number of oracle circuit of size at most $s(|x|)$ on $(c'n^c)$-inputs with t oracle functions is at most

$$O(s(n)\log(4+t) + s(|x|)\log(c'n^c)\log(s(|x|) + \log(c'n^c))).$$

Since $t \leq 2^{c'n^c}$ and s is polynomial in n, it is easy to see that the number of such circuits E is at most exponential. Second, one can check if an oracle circuit E satisfies $E^{\mathcal{O}}$ computes T in time polynomial in $(|E| + |T| + |\mathcal{O}|)$ and hence exponential in n. As a result, $L \in \mathsf{EXP}$, completing the proof. ◀

▶ **Theorem B.2.** *If* $\mathsf{NP} \leq_{tt}^{\mathsf{P}} \mathsf{MOCSP}$*, then* $\mathsf{EXP} \neq \mathsf{NP} \cap \mathsf{P/poly}$*. Consequently,* $\mathsf{EXP} \neq \mathsf{ZPP}$*.*

Proof. For contradiction, suppose $\mathsf{NP} \leq_{tt}^{\mathsf{P}} \mathsf{MOCSP}$ and $\mathsf{EXP} = \mathsf{NP} \cap \mathsf{P/poly}$. Then by Proposition B.1 $\mathsf{NEXP} \subseteq \mathsf{EXP} \subseteq \mathsf{NP}$ contradicting the nondeterministic time hierarchy theorem [32]. ◀

Equivalence of Systematic Linear Data Structures and Matrix Rigidity

Abstract

Recently, Dvir, Golovnev, and Weinstein have shown that sufficiently strong lower bounds for linear data structures would imply new bounds for rigid matrices. However, their result utilizes an algorithm that requires an NP oracle, and hence, the rigid matrices are not explicit. In this work, we derive an equivalence between rigidity and the systematic linear model of data structures. For the n-dimensional inner product problem with m queries, we prove that lower bounds on the query time imply rigidity lower bounds for the query set itself. In particular, an explicit lower bound of $\omega\left(\frac{n}{r}\log m\right)$ for r redundant storage bits would yield better rigidity parameters than the best bounds due to Alon, Panigrahy, and Yekhanin. We also prove a converse result, showing that rigid matrices directly correspond to hard query sets for the systematic linear model. As an application, we prove that the set of vectors obtained from rank one binary matrices is rigid with parameters matching the known results for explicit sets. This implies that the vector-matrix-vector problem requires query time $\Omega(n^{3/2}/r)$ for redundancy $r \geq \sqrt{n}$ in the systematic linear model, improving a result of Chakraborty, Kamma, and Larsen. Finally, we prove a cell probe lower bound for the vector-matrix-vector problem in the high error regime, improving a result of Chattopadhyay, Koucký, Loff, and Mukhopadhyay.

1 Introduction

A matrix is *rigid* if it is far in Hamming distance from low rank matrices; it is *explicit* if its entries are computable in polynomial time. A classic result of Valiant proves that explicit rigid matrices imply super-linear lower bounds for linear circuits [35], a major open problem in computational complexity [34, 37]. Implications of new lower bounds for communication complexity and other models are also known [24, 39]. Unfortunately, the current bounds for explicit matrices are very far from the required parameters [16, 33], and natural candidates (e.g., Fourier and Hadamard matrices) have been discovered to

be less rigid than desired [3, 12, 14]. This motivates alternative avenues for constructing rigid matrices. Recently, multiple connections between data structures and circuits have arisen [7, 11, 13, 38]. The premise of these results is that hard problems for these models may shed new light on rigid matrices and circuits. We take a similar angle, studying a generic linear problem for a model that resembles a depth-two circuit with linear gates.

Valiant's result concerns arithmetic circuits computing the linear map $v \mapsto Mv$ for a matrix M. In other words, the circuit computes the inner products between v and the rows of M. We study a related data structure problem, the *inner product problem*. The task is to preprocess an n-bit vector v to compute inner products $\langle q, v\rangle$ over $\mathbb{F}_2$ for queries $q \in Q$, where $Q \subseteq \mathbb{F}_2^n$ is the *query set*. This problem generalizes the prefix-sum problem [17] and vector-matrix-vector problem [8, 23].

We consider solving this problem using a restricted data structure model, the *systematic linear model*. This model may only store v verbatim along with a small number $r \ll n$ of *redundant* bits, which are the evaluations of r linear functions of v. To compute $\langle q, v\rangle$ for $q \in Q$, the query algorithm must output a linear function of these r bits along with any t bits of v, where t is the *query time*. We motivate this model with a simple upper bound. Suppose that the query set Q happens to be close to an r-dimensional subspace U. More precisely, assume that $d_H(q, U) \leq t$ for any $q \in Q$, where $d_H(q, U) := \min_{u \in U} d_H(q, u)$ and $d_H(q, u)$ denotes the Hamming distance. The systematic linear model will store r bits that correspond to inner products between v and some r vectors that form a basis for U. The query algorithm computes $\langle q, v\rangle$ by invoking the identity $\langle q, v\rangle = \langle u, v\rangle + \langle q - u, v\rangle$, using any vector $u \in U$ with $d_H(q, u) \leq t$. Indeed, the r precomputed bits suffice to determine $\langle u, v\rangle$, and at most t bits of v are needed to calculate $\langle q - u, v\rangle$.

We observe that rigidity exactly captures the complexity of the inner product problem in the above model. This connection uses a notion of rigid sets, defined by Alon, Panigrahy and Yekhanin [5]. Our result shows that an efficient algorithm exists in the above model if and only if the query set is not rigid in their sense. Conversely, it is possible to derive new rigidity lower bounds by proving lower bounds for the systematic linear model. A parameter of interest is the size of the rigid set, which corresponds to the number of queries in the inner product problem.

Dvir, Golovnev, and Weinstein also demonstrate a connection between rigidity and a different linear model, which is a restriction of the cell probe model [13]. This model stores $s \geq n$ linear functions, and the query algorithm outputs a linear function of t of these s bits. For the inner product problem with query set Q, they show that a lower bound for linear data structures leads to a semi-explicit rigid set. When $|Q| = m$, their result uses a $\mathsf{poly}(m)$ time algorithm that requires access to an NP oracle. Compared to their work, our connection preserves explicitness and offers a two-way equivalence via the systematic linear model. In particular, when $c'n \leq r \leq cn$ for constants $c', c < 1$, a lower bound of $t = \omega(\log m)$ in the systematic linear model implies that Q is rigid with better parameters than known results. Their work requires a lower bound of $t = \omega(\log m \log n)$ against the linear model, and the resulting set is not explicit. Our results also extend to show that linear data structure lower bounds lead to explicit rigid matrices. However, compared to the work of Dvir, Golovnev, and Weinstein, we require stronger lower bounds to achieve new rigidity parameters.

As an application of our framework, we provide new results for the vector-matrix-vector problem. The task is to preprocess a 0-1 matrix M to compute $u^\intercal Mv$ when given vectors u, v as the query. The boolean semiring version of this problem has received much recent attention due to connections to the online matrix-vector multiplication conjecture [18]. Moreover, this problem has motivated the study of data structures for a super polynomial number of queries,

even when the output is binary [8, 9]. Other prior work has either studied binary output problems with $\mathsf{poly}(n)$ queries (see e.g. [28, 30]) or achieved better lower bounds by looking at multi-output problems (see e.g. [10, 20]). In general, the vector-matrix-vector problem is a good testbed for proving better data structure lower bounds, because linear algebraic tools could provide new insights.

The $\mathbb{F}_2$ variant of this problem specializes the inner product problem because $u^\intercal Mv$ equals the inner product of $uv^\intercal$ and M (viewed as vectors). The query set consists of $\sqrt{n} \times \sqrt{n}$ matrices with rank one; its size m satisfies $\log m = \Theta(\sqrt{n})$. As another contribution, we lower bound the rigidity of this set, and consequently, we obtain a query time lower bound of $\Omega(\frac{n}{r} \log m) = \Omega(n^{3/2}/r)$ for the systematic linear model with redundancy $r \geq \sqrt{n}$. Any asymptotically better lower bounds for this problem (in the systematic linear model) would directly imply that this query set is rigid with better parameters than the currently known results for explicit matrices [4, 5].

As a final result, we prove a new cell probe lower bound for the vector-matrix-vector problem, without restrictions on the data structure. Our result improves the current best lower bound due to Chattopadhyay, Koucký, Loff, and Mukhopadhyay [9]. Our lower bound matches the limit of present techniques and achieves the current best time-space trade-off in terms of query set size.

1.1 Rigid sets, systematic linear model, and the inner product partial function

Throughout, let $m = m(n)$ and $t = t(n)$ and $r = r(n)$ denote positive integers, with $m \geq n \geq t, r$. Alon, Panigrahy and Yekhanin defined the following notion of a rigid set [5].

▶ **Definition** (Rigid Set). *A set $Q \subseteq \mathbb{F}_2^n$ is (r,t)-rigid if for every subspace $U \subseteq \mathbb{F}_2^n$ with dimension at most r, some vector $q \in Q$ has Hamming distance at least t from all vectors in U, that is, $d_H(q, U) \geq t$.*

We define (r', t')-rigid for non-integral r', t' to mean $(\lfloor r' \rfloor, \lceil t' \rceil)$-rigid. It will be convenient to equate a set Q with a matrix M_Q by arranging vectors in Q as rows in M_Q in any order. If Q is (r,t)-rigid and $|Q| = m$, then the corresponding matrix $M_Q \in \mathbb{F}_2^{m \times n}$ is rigid in the usual sense: for any rank r matrix A, some row in $(M_Q - A)$ contains at least t nonzero entries. Hence, we may refer to rigid sets and rigid rectangular matrices interchangeably. A matrix in $\mathbb{F}_2^{m \times n}$ (or a set of n-dimensional vectors) is *explicit* if every entry can be computed in $\mathsf{poly}(n)$ time.

A random $m \times n$ matrix with $m = \mathrm{poly}(n)$ will be $(\epsilon n, \delta n/\log n)$-rigid with high probability for some constants $\epsilon, \delta \in (0,1)$. The key challenge here is to construct explicit rigid matrices, because they provide circuit lower bounds for functions that can be described in polynomial time [35]. Alon, Panigrahy and Yekhanin [5] followed by Alon and Cohen [4] exhibit multiple examples of explicit $m \times n$ matrices that are (r,t)-rigid with

$$t \geq \min\left\{ \frac{cn}{r} \log \frac{m}{r},\ n \right\} \tag{1}$$

where $m \geq n$ and c is a constant. Note that when $r = \epsilon n$, the current best bound is $t = \Omega\left(\log \frac{m}{n}\right)$. For $m = poly(n)$, this amounts to $t = \Omega(\log n)$, exponentially far from the ideal bounds (i.e., matching random constructions). It is an important open problem to improve the dependence on m in Eq. (1) and to find other candidate sets that may be rigid with better parameters.

Our connection between rigidity and data structures arises via the inner product problem. The task is to preprocess a vector $v \in \mathbb{F}_2^n$ to compute inner products. The queries are specified by $Q \subseteq \mathbb{F}_2^n$, which is called the *query set*. The data structure must compute the inner product of v and any $q \in Q$, that is, $\langle q, v \rangle := \sum_{i=1}^{n} q[i] \cdot v[i] \mod 2$, where $q[i]$ denotes the i^{th} coordinate of q.

Consider the following model for solving this problem, known as a systematic linear data structure. During preprocessing, the data structure stores v along with the evaluations of r linear functions $\langle a_1, v \rangle, \ldots, \langle a_r, v \rangle$, where these inner products are single bits, and $a_1, \ldots, a_r$ denote vectors in $\mathbb{F}_2^n$. To compute the answer on query q, the data structure accesses these r bits in addition to any t entries of v. That is, the r linear functions are fixed, and the t bits from v may depend on q and the linear functions. Finally, the query algorithm must output a linear function of these r bits and the t entries of v. In this fashion it must be able to correctly compute $\langle q, v \rangle$ for all queries $q \in Q$. We note that a result of Jukna and Schnitger [19] shows that the $\{a_1, \ldots, a_r\}$ vectors do not depend on v without loss of generality. Letting $T(Q, r)$ denote the minimum value t of the best data structure for this problem (over worst-case v), we formalize the model as follows.

▶ **Definition** (Systematic Linear Model)**.** *Let $Q \subseteq \mathbb{F}_2^n$ be a set. Define $T(Q, r)$ to be the maximum over all $v \in \mathbb{F}_2^n$ of the minimum t sufficient to compute the inner product $\langle q, v \rangle$ for every $q \in Q$ when only allowed to output a linear function of r precomputed linear functions of v along with any t bits of v.*

Note that the model does not charge the query time for accessing the r precomputed bits, even if $t \ll r$. This coincides with the systematic model studied by Chakraborty, Kamma and Larsen [8].

1.2 Equivalence between rigidity and data structures

We prove that the rigidity of a set Q corresponds to the time complexity $T(Q, r)$ in the systematic linear data structure model. Some aspects of this result are implicit in prior work [19, 31], but no previous work seems to show this exact correspondence.

▶ **Theorem 1.** *A set $Q \subseteq \mathbb{F}_2^n$ is (r, t)-rigid if and only if $T(Q, r) \geq t$.*

Proof. We first prove that $T(Q, r) \geq t$ implies that Q is (r, t)-rigid. Assume for contradiction that there is an r-dimensional subspace U such that $d_H(q, U) < t$ for all $q \in Q$. Let $v \in \mathbb{F}_2^n$ be the input data. Store v along with the r bits $\langle b_1, v \rangle, \ldots, \langle b_r, v \rangle$, where $b_1, \ldots, b_r$ form a basis for U. For every $q \in Q$, there exists $u_q \in U$ such that $q - u_q$ has Hamming weight less than t. Using the r redundant bits, the algorithm on query q can compute $\langle u_q, v \rangle$ by writing u_q in terms of the stored basis vectors. Then, it computes $\langle q - u_q, v \rangle$ by accessing fewer than t coordinates of v. Since $\langle q, v \rangle = \langle u_q, v \rangle + \langle q - u_q, v \rangle$, we have that $T(Q, r) < t$, which is a contradiction.

We now prove that if Q is (r, t)-rigid, then $T(Q, r) \geq t$. Let $e_1, \ldots, e_n$ denote the standard basis, and let $k = T(Q, r)$ be the query time. We show that $k \geq t$. Consider a systematic linear data structure whose redundant bits are given by $\langle a_1, v \rangle, \ldots, \langle a_r, v \rangle$. Let U denote the span of $\{a_1, \ldots, a_r\}$. As Q is (r, t)-rigid, there exists $q^* \in Q$ with $d_H(q^*, U) \geq t$. When q^* is the query, assume that the query algorithm accesses the bits $v_{i_1}, \ldots, v_{i_k}$ for indices $i_1, \ldots, i_k$ to compute $\langle q^*, v \rangle$. Now, define U' to be the span of $\{a_1, \ldots, a_r, e_{i_1}, \ldots, e_{i_k}\}$. Observe that all points in U' are at distance at most k from U. Thus, $d_H(q^*, U) \leq d_H(q^*, U') + k$. We will show that $d_H(q^*, U') = 0$, which implies that $k \geq t$. We claim that if $d_H(q^*, U') \geq 1$, then the query algorithm makes an error. Since $d_H(q^*, U') \geq 1$, there exists a vector y with

$\langle y, q^* \rangle = 1$. Moreover, this vector can be taken to be orthogonal to U' so that $\langle y, x \rangle = 0$ for every $x \in U'$. In other words, for every $x \in U'$ we have $\langle y + v, x \rangle = \langle y, x \rangle + \langle v, x \rangle = \langle v, x \rangle$. Hence, the query algorithm sees the same values on input data $y + v$ and v because it only accesses the input via vectors in U', and we have $x \in U'$. Thus, the algorithm on query q^* must err either on input $y + v$ or v because $\langle q^*, y + v \rangle \neq \langle q^*, v \rangle$. ◀

1.3 Relationship to the cell probe model and other models

The systematic linear model specializes the *systematic model* [8, 17]. The latter model still stores the input data $x \in \mathbb{F}_2^n$ verbatim, and it also stores $r < n$ bits that can be precomputed from x, where these need not be linear functions of the input data. The query time is t if the query algorithm reads at most t bits from x to compute a query. The output can also be an arbitrary function of these t bits along with the r precomputed bits. The systematic linear model only makes sense for linear queries, whereas the systematic model applies to arbitrary query functions.

Yao's *cell probe model* is the most general data structure model [40]. On input data $x \in \mathbb{F}_2^n$, the data structure stores s cells, containing w bits that are arbitrary functions of x. Here, w is the *word size* and s is the *space*. The *query time* is t if the algorithm accesses at most t cells to answer any query about x from a set of m possible query functions. There is a rich collection of lower bounds for this model (see e.g. [2, 15, 20, 26, 27, 28, 29]). The best lower bounds known are of the form

$$t \geq \min \left\{ \frac{c \log \frac{m}{n}}{\log \frac{sw}{n}}, \ \frac{cn}{w} \right\}, \tag{2}$$

where $m \geq n$ is the number of queries and c is a constant. It is a long-standing problem to prove that $t = \omega(\log m)$ for any explicit problem, even in the linear space regime $s = O(n)$ and $w = O(1)$.

A special case of the cell probe model is the *linear model* [1, 13]. The latter model stores $s \geq n$ linear functions of x (implicitly $w = 1$ is fixed). The query time is t if the query algorithm reads at most t of these s bits to compute a query. The output is restricted to be a linear function of these t bits. A distinguishing aspect between linear and systematic linear is that in the latter model, the query algorithm is not charged for accessing the r precomputed bits. In Section 2, we compare the linear and systematic linear models in the context of rigidity and previous work [13].

Equivalences all the way down

We note that the systematic data structure model is identical to the common bits model defined by Valiant [36]. Corrigan-Gibbs and Kogan [11] demonstrate a relationship between the common bits model and a variant of the systematic model defined by Gal and Miltersen [17]. The common bits model is nothing but a certain depth two circuit, and the systematic linear model is simply the common bits model with the restriction that the common bits and output gates are linear functions [31]. Hence, in language of data structures, the linearization conjecture of Jukna and Schnitger posits that the systematic linear model is asymptotically as powerful as the systematic model for answering linear queries [19].

1.4 The vector-matrix-vector problem

We now define the vector-matrix-vector problem, which we call "the $\mathsf{u}^\intercal\mathsf{M}\mathsf{v}$ problem" for short. Let n be a perfect square. After preprocessing a matrix $M \in \mathbb{F}_2^{\sqrt{n} \times \sqrt{n}}$, the goal is to output the binary value $u^\intercal M v$ for vectors $u, v \in \mathbb{F}_2^{\sqrt{n}}$. It will be convenient to consider

a $\sqrt{n} \times \sqrt{n}$ matrix as an n-bit vector $\mathsf{vec}(M)$ by concatenating consecutive rows. More formally, let $x = \mathsf{vec}(M)$, and for $i \in \{1, 2, \ldots, n\}$, set $x[i] = M[a, b]$, where a and b satisfy $i = (a-1)\sqrt{n} + b$ and $a, b \in \{1, 2, \ldots, \sqrt{n}\}$. Then, $u^\intercal M v = \langle \mathsf{vec}(uv^\intercal), \mathsf{vec}(M) \rangle$. In this way we consider the $\mathsf{u^\intercal Mv}$ problem a special case of the inner product problem. The query set is the collection of rank one binary matrices. Let $\Upsilon \subseteq \mathbb{F}_2^n$ denote the set of vectors obtained from rank one binary matrices via $M \mapsto \mathsf{vec}(M)$, that is,

$$\Upsilon := \left\{ \mathsf{vec}(uv^\intercal) \;\middle|\; u, v \in \mathbb{F}_2^{\sqrt{n} \times \sqrt{n}} \right\} \subseteq \mathbb{F}_2^n. \tag{3}$$

This set has size $|\Upsilon| = 2^{2\sqrt{n}} - 2^{\sqrt{n}+1} + 1$.

A classic result of Artazarov, Dinic, Kronrod and Faradzev [6] provides a data structure with space $s = \mathsf{poly}(n)$, word size $w = O(\log n)$, and time $t = O(n/\log n)$. In fact, this algorithm operates in the linear cell probe model. It is a central open question to determine whether $t = \Omega(n)$ is necessary in linear space regime, that is, when $s = O(n)$ and $w = O(1)$.

The current best cell probe lower bound for the $\mathsf{u^\intercal Mv}$ problem is due to Chattopadhyay, Koucký, Loff, and Mukhopadhyay [9]. Moreover, their lower bound holds for a randomized model with high error. For constants c and c', they prove that if for every matrix M and every query $uv^\intercal$, the query algorithm correctly computes $u^\intercal M v$ with probability at least $\frac{1}{2} + \frac{1}{2^{c'\sqrt{n}}}$, then

$$t \geq \min\left\{ \frac{c\sqrt{n}}{\log \frac{sw}{\sqrt{n}}},\ \frac{cn}{w} \right\} \tag{4}$$

We know better lower bounds for the $\mathsf{u^\intercal Mv}$ problem in the systematic model. Chakraborty, Kamma, and Larsen [8] prove that t and r must satisfy $t \cdot r = \Omega(n^{3/2}/\log n)$ as long as $r \geq \sqrt{n}$. In the case of $r \leq \sqrt{n}$, they prove that $t = \Omega(n/\log n)$. As the systematic model subsumes the linear version of this model, combining their result with Theorem 1 implies that Υ is (r, t)-rigid with

$$t = \Omega\left(\frac{n^{3/2}}{\max\{\sqrt{n}, r\} \cdot \log n} \right). \tag{5}$$

1.5 New results on the rigidity of Υ and the cell probe complexity of the $\mathsf{u^\intercal Mv}$ problem

We lower bound the rigidity of Υ, defined in Eq. (3). This also implies a lower bound in the systematic linear model. The proof is inspired by a result of Alon, Panigrahy, and Yekahnin [5].

▶ **Theorem 2.** *Let $n \geq 1024$. The set $\Upsilon \subseteq \mathbb{F}_2^n$ of rank one matrices is (r, t)-rigid with $t \geq \frac{n^{3/2}}{128 \cdot \max\{\sqrt{n}, r\}}$.*

We improve the prior bound in Eq. (5) by an $\Omega(\log n)$ factor. For example, when $r \leq \sqrt{n}$, then $t = \Omega(n)$, and when $r = n/2$, then $t = \Omega\left(n^{1/2}\right)$. Theorem 2 matches Eq. (1), the current best bound for explicit rigid sets. We do not know whether there is a subspace U of linear dimension such that all elements of Υ are at distance $o(n)$ from U (unlike for some set rigidity results, where the bounds are tight). As a corollary of Theorem 1, we immediately get that

$$T(\Upsilon, r) \geq \frac{n^{3/2}}{128 \cdot \max\{\sqrt{n}, r\}}.$$

In other words, we prove a lower bound for the $\mathsf{u}^\intercal\mathsf{Mv}$ problem in the systematic linear model that improves the prior bound by an $\Omega(\log n)$ factor. The proof of Theorem 2 appears in Section 3.

We also prove a general cell probe lower bound for the $\mathsf{u}^\intercal\mathsf{Mv}$ problem in the high error regime. Our result improves the previous lower bound in Eq. (4). For example, in the linear space regime, when $s = O(n)$ and $w = O(1)$, we show that $t = \Omega(\sqrt{n})$ while the prior result gives only $t = \Omega(\sqrt{n}/\log n)$.

▶ **Theorem 3.** *Let $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$ be a matrix. If a randomized data structure with space s, word size w, and time t correctly computes queries for the $\mathsf{u}^\intercal\mathsf{Mv}$ problem with probability at least $\frac{1}{2} + \frac{1}{2^{\sqrt{n}/64}}$, then*

$$t \geq \min\left\{\frac{c\sqrt{n}}{\log\frac{s\alpha}{n}}, \frac{cn}{\alpha}\right\}$$

where $0 < c \leq 1/36$ is a universal constant and $\alpha := 2(w + \log\frac{sw}{n})$.

The prior work utilizes a general lifting result for two-way communication complexity from parity decision trees [9]. To obtain the improved bound, we use a variant of the cell sampling technique [21, 27] combined with a reduction to a new lower bound on one-way communication (via discrepancy). The modifications over standard techniques are needed to handle the high error regime for a binary output problem. We note that a recent result of Larsen, Weinstein and Yu also uses one-way communication to prove lower bounds for binary output problems for dynamic data structures [22]. However, their method seems limited to only handling zero error query algorithms. The proof of Theorem 3 appears in Section 4. Specifically, see Lemma 14 in Section 4 for the variant of cell sampling and see Theorem 11 in Section 4.1 for the discrepancy argument.

2 Linear Data Structures and Rigidity

In this section, we relate linear data structures and rigidity. As linear data structures are a special case of the cell probe model, we may obtain rigidity lower bounds from strong enough static data structure lower bounds (when the queries are linear). We also compare with Dvir, Golovnev, and Weinstein, who exhibit a similar connection [13]. We first provide some notation.

▶ **Definition.** *Let $Q \subseteq \mathbb{F}_2^n$ be a set. Define $\mathsf{LT}(Q, s)$ to be the maximum over all $v \in \mathbb{F}_2^n$ of the minimum t sufficient to compute the inner product $\langle q, v\rangle$ for every $q \in Q$ when the query algorithm's output is a linear function of t bits chosen from the s precomputed linear functions of v.*

Table 1 provides a glimpse of our results on linear data structures along with a comparison to [13]. Recall that a set $Q \subseteq \mathbb{F}_2^n$ is explicit if each coordinate of an arbitrary element of the set can be computed in $\mathsf{poly}(n)$ time. The prior work shows that sufficiently strong lower bounds against linear data structures will imply *semi-explicit* rigid sets. A bit more formally, consider a data structure query set $Q \subseteq \mathbb{F}_2^n$ of size m for the inner product problem. They show the following: If $\mathsf{LT}(\mathsf{Q}, \mathsf{c}\cdot\mathsf{n}) \geq t$ for some constant c, then there is a $(n'/2, t/\log n)$-rigid set Q' of size at most m contained in $\mathbb{F}_2^{n'}$, where $n' \geq t$. However, the set Q' is only semi-explicit in that it is in P^{NP} – every element can be computed by a $\mathsf{poly}(m)$ time algorithm with access to an NP oracle.

Table 1 Comparison with [13, Theorem 7.1]: Let $Q \subseteq \mathbb{F}_2^n$ of size m be a query set, $c \geq 1$ and $\delta > 0$ be constants, and let $k = \mathsf{LT}(Q, 3n/2)$. The second column states the lower bound on $\mathsf{LT}(Q, 3n/2)$ that implies existence of rigid sets whose parameters are given in the third column. All rigid sets have size at most $\mathsf{poly}(m)$ and are contained in $\mathbb{F}_2^k$.

m vs n	$k = \mathsf{LT}(Q, 3n/2)$	Rigidity Bounds	Explicitness	Reference
$m = n^c$	$k = \omega\left(\sqrt{n \log n}\right)$	$(k/2, \omega(\log n))$-rigid	$\mathsf{poly}(n)$ time	This work
	$k = \omega\left(\log^2 n\right)$	$(k/2, \omega(\log n))$-rigid	$\mathsf{poly}(n)$ time + NP oracle calls	[13]
$m = n^c$	$k = \Omega\left(n^{(1+\delta)/2}\right)$	$\left(k/2, \Omega\left(n^\delta\right)\right)$-rigid	$\mathsf{poly}(n)$ time	This work
	$k = \Omega\left(n^\delta \log n\right)$	$\left(k/2, \Omega\left(n^\delta\right)\right)$-rigid	$\mathsf{poly}(n)$ time + NP oracle calls	[13]
$m = 2^{c\sqrt{n}}$	$k = \omega\left(n^{3/4}\right)$	$\left(k/2, \omega\left(\sqrt{n}\right)\right)$-rigid	$\mathsf{poly}(n)$ time	This work
	$k = \omega\left(\sqrt{n} \cdot \log n\right)$	$\left(k/2, \omega\left(\sqrt{n}\right)\right)$-rigid	$\mathsf{poly}\left(2^{\sqrt{n}}\right)$ time + NP oracle calls	[13]

We now summarize a few differences between our work and [13]. Our result proves that polynomial lower bounds on the query time imply the existence of an explicit rigid set, which is in contrast to semi-explicit sets obtained by [13]. On the other hand, explicitness comes with a cost; when $m = \mathsf{poly}(n)$, we need much stronger data structure lower bounds to produce explicit rigid sets. When $m \gg \mathsf{poly}(n)$, the algorithm of [13] takes $\mathsf{poly}(m)$ time with access to an NP oracle to compute an element of the semi-explicit rigid set. For problems such as the $\mathsf{u}^\intercal\mathsf{Mv}$ problem, this is super polynomial time. The rest of this section concerns proving the following theorem, which implies all of our results in Table 1.

▶ **Theorem 4.** *Let $k = \mathsf{LT}(Q, 3n/2)$ and let $Q \subseteq \mathbb{F}_2^n$ of size m be an explicit query set. There exists a set $Q' \subseteq \mathbb{F}_2^k$ with size at most $m \cdot \lceil \frac{n}{k} \rceil$, whose elements can be computed in $\mathsf{poly}(n)$ time. Moreover, if $k \geq 2\sqrt{n}$, then Q' is explicit and $\left(\frac{k}{2}, \frac{k^2}{4n}\right)$-rigid.*

Note that for every $s \geq 3n/2$, we have that $\mathsf{LT}(Q, 3n/2) \geq \mathsf{LT}(Q, s)$. Hence, a sufficiently strong lower bound on $\mathsf{LT}(Q, s)$ for any $s \geq 3n/2$ will imply a rigidity lower bound. The following corollary shows the consequence of Theorem 4 for specific values of k.

▶ **Corollary 5.** *Let $k = \mathsf{LT}(Q, 3n/2)$ and let $Q \subseteq \mathbb{F}_2^n$ of size m be an explicit query set. There exists a set $Q' \subseteq \mathbb{F}_2^k$ with size at most $m \cdot \lceil \frac{n}{k} \rceil$, whose elements can be computed in $\mathsf{poly}(n)$ time. Moreover,*

(a) *If $k = \omega\left(\sqrt{n \log m}\right)$, then Q' is explicit and $(k/2, \omega(\log m))$-rigid.*

(b) *If $k = \Omega\left(n^{(1+\delta)/2}\right)$ for some $\delta > 0$, then Q' is explicit and $\left(k/2, \Omega\left(n^\delta\right)\right)$-rigid.*

Corollary 5(a) explains the first and last rows in Table 1, and Corollary 5(b) explains the middle row. Using Corollary 5(a) applied to Υ with $m = 2^{2\sqrt{n}} - 2^{\sqrt{n}+1} + 1$, we obtain that a lower bound of $\mathsf{LT}(\Upsilon, 3n/2) \geq \omega(n^{3/4})$ would imply the existence of an explicit set $Q' \subseteq \mathbb{F}_2^k$ of size $2^{O(\sqrt{n})}$ that is $(k/2, \omega(\sqrt{n}))$-rigid. We note that it is an open question to prove $\mathsf{LT}(\Upsilon, 3n/2) \geq \omega(\sqrt{n})$.

2.1 Proof of Theorem 4

We already know the equivalence between systematic linear data structures and rigidity (from Theorem 1). Therefore, it is sufficient to design a linear data structure from a systematic linear data structure to relate the former with rigidity.

▶ **Proposition 6.** *Let $Q \subseteq \mathbb{F}_2^n$ be a query set. If $T(Q,r) \leq t$, then $\mathsf{LT}(Q, n+r) \leq t+r$.*

Proof. Let $v \in \mathbb{F}_2^n$ be the input data and $\langle a_1, v\rangle, \ldots, \langle a_r, v\rangle$ be the r redundant bits stored by the systematic linear data structure. We now describe a linear data structure for Q with space $n+r$ and query time $t+r$. The data structure stores $\langle a_1, v\rangle, \ldots, \langle a_r, v\rangle, \langle e_1, v\rangle, \ldots, \langle e_n, v\rangle$, where $e_1, \ldots, e_n$ are the standard basis vectors. The query algorithm on $q \in Q$ first accesses $\langle a_1, v\rangle, \ldots, \langle a_r, v\rangle$ and then simulates the query algorithm of the systematic linear data structure on q. Since the systematic linear data structure accesses at most t bits from $\langle e_1, v\rangle, \ldots, \langle e_n, v\rangle$, we can conclude that the query time is at most $t+r$. ◀

We prove that if a set contained in a n-dimensional space is (r,t)-rigid, then there is another $(r, tr/n)$-rigid set which is contained in a $2r$-dimensional space.

▶ **Lemma 7.** *Let r, n be positive integers. If $S \subseteq \mathbb{F}_2^n$ is (r,t)-rigid of size m, then there is a set $S' \subseteq \mathbb{F}_2^{2r}$ of size at most $m \cdot \lceil \frac{n}{2r} \rceil$ that is $(r, tr/n)$-rigid. Moreover, if S is explicit, then each element of S' can be computed in $\mathsf{poly}(n)$ time.*

Proof. Let $k = \lfloor \frac{n}{2r} \rfloor$ and define $S_1, \ldots, S_k \subseteq \mathbb{F}_2^{2r}$ by

$$S_i = \{(s[2r \cdot (i-1)+1], \ldots, s[2r \cdot i]) \mid s \in S\}$$

for each $i \in \{1, 2, \ldots, k\}$. Additionally, if $n/2r$ is not an integer, then define

$$S_{k+1} = \{(s[2r \cdot k + 1], \ldots, s[n], 0, \ldots, 0) \mid s \in S\} \subseteq \mathbb{F}_2^{2r};$$

otherwise set $S_{k+1} = \emptyset$. Define $S' = \bigcup_{i=1}^{k+1} S_i$. We claim that S' is $(r, tr/n)$-rigid. Indeed, for the sake of contradiction assume that there is a subspace V in $\mathbb{F}_2^{2r}$ of dimension r such that all points in S' are at a distance less than tr/n from V. Consider the subspace $\{(v, v, \ldots, v) \mid v \in V\} \subseteq \mathbb{F}_2^{2r \cdot (k+1)}$ and project it to the first n coordinates. Call this subspace V', which has dimension r. Now, the distance of each point in S from V' is less than $\frac{tr}{n} \cdot \lceil \frac{n}{2r} \rceil < t$, which is a contradiction.

Regarding the explicitness of S', it is clear that all coordinates of an element of S' correspond to some coordinate of a specific element of S. Since S is explicit, we can infer that each element of S' can be computed in $\mathsf{poly}(n)$. ◀

Proof of Theorem 4. We know that $\mathsf{LT}(Q, 3n/2) = k$ and $k \leq n$, Proposition 6 implies that $T(Q, k/2) \geq k/2$. Therefore by Theorem 1, we can conclude that Q is $(k/2, k/2)$-rigid. Lemma 7 implies that there exists a set Q' that is $\left(\frac{k}{2}, \frac{k^2}{4n}\right)$-rigid and the size of Q' is at most $m \cdot \lceil \frac{n}{k} \rceil$. Moreover, every element of Q' can be computed in time $\mathsf{poly}(n)$. Since $k/2 \geq \sqrt{n}$, we can conclude that Q' is explicit. ◀

3 Rigidity Lower Bounds for the Set of Rank One Matrices

Before proving Theorem 2, we present preliminaries. Recall two standard binomial estimates:

▶ **Proposition 8.** *For integers $0 \leq k \leq \ell$,*

1. $\log \binom{\ell}{k} \leq k \cdot \log \frac{e\ell}{k}$.
2. *if $k \leq \ell/16$, then $\sum_{i=0}^{k} \binom{\ell}{i} \leq 2^{\ell/4}$.*

We will need a useful property about the distance of a point from a subspace.

▶ **Lemma 9.** *Let $V \subseteq \mathbb{F}_2^\ell$ be a subspace. For $u_1, u_2 \in \mathbb{F}_2^\ell$, $d_H(u_1+u_2, V) \leq d_H(u_1, V) + d_H(u_2, V)$.*

Proof. Let $u_1', u_2' \in V$ be the points in V closest to u_1 and u_2 respectively. Since $u_1' + u_2' \in V$, we have $d_H(u_1 + u_2, V) \leq d_H(u_1 + u_2, u_1' + u_2')$. Note that $d_H(u_1 + u_2, u_1' + u_2')$ is the number of ones in $u_1 + u_2 + u_1' + u_2'$, which is at most the sum of the number of ones in $u_1 + u_1'$ and $u_2 + u_2'$. Therefore,

$$d_H(u_1 + u_2, u_1' + u_2') \leq d_H(u_1, u_1') + d_H(u_2, u_2') = d_H(u_1, V) + d_H(u_2, V). \quad \blacktriangleleft$$

A simple counting argument establishes the existence of a point that is far away in Hamming distance from a collection of large sized sets.

▶ **Lemma 10.** *Let $V_1, \ldots, V_k$ be subsets of $\mathbb{F}_2^\ell$, each of size at most $2^{\ell/2}$. If $k < 2^{\ell/4}$, then there is a vector $v \in \mathbb{F}_2^\ell$ such that the Hamming distance of v from each V_i is at least $\ell/16$.*

Proof. For every $i \in [k]$, define $\mathsf{B}(V_i, \ell/16) = \left|\left\{v \in \mathbb{F}_2^\ell \;\middle|\; d_H(v, V_i) < \ell/16\right\}\right|$. For any $u \in V_i$, the number of vectors in $\mathbb{F}_2^\ell$ at a distance less than $\ell/16$ from u is at most $\sum_{j=0}^{\ell/16} \binom{\ell}{j} \leq 2^{\ell/4}$, where the inequality follows from Proposition 8. Hence $\mathsf{B}(V_i, \ell/16) \leq |V_i| \cdot 2^{\ell/4} = 2^{3\ell/4}$. Since

$$\sum_{i=1}^{k} \mathsf{B}(V_i, \ell/16) \leq k \cdot 2^{3\ell/4} < 2^\ell,$$

there is a $v \in \mathbb{F}_2^\ell$ such that $d_H(v, V_i) \geq \ell/16$ for every $i \in [k]$. $\blacktriangleleft$

3.1 Proof of Theorem 2

Let V be any r'-dimensional subspace of $\mathbb{F}_2^n$, where $r' \geq r$ is the smallest positive integer divisible by $\sqrt{n}$. We first define the inverse of $\mathsf{vec}(\cdot)$. For every $v \in \mathbb{F}_2^n$, define $\mathsf{mat}(v)$ to be the matrix obtained by splitting v into $\sqrt{n}$ length consecutive blocks and stacking each of these blocks to form a $\sqrt{n} \times \sqrt{n}$ matrix. Formally, $\mathsf{mat}(v) \in \mathbb{F}_2^{\sqrt{n} \times \sqrt{n}}$ is such that $\mathsf{mat}(v)[a, b] = v[(a-1)\sqrt{n} + b]$ for every $a, b \in [\sqrt{n}]$. Note that $\mathsf{vec}(\mathsf{mat}(v)) = v$.

We provide a brief outline of the proof of Theorem 2. The first step of the proof is to produce a vector in v that is at a distance of $\Omega(n)$ from V and $\mathsf{mat}(v)$ is low rank. The rank being low is helpful as we can express $\mathsf{mat}(v)$ as the sum of a small number of rank one matrices. Lemma 9 will then imply the existence of a rank one matrix that is far away from V. If we only cared about the existence of a vector that is far away from V, Lemma 10 would suffice. To ensure that simultaneously the rank is small, we first project V on to $n/2r'$ coordinates indexed by consecutive blocks each of length $2r'$. Then we find a vector $v' \in \mathbb{F}_2^{2r'}$ that is far away from all the projections, which is still guaranteed by Lemma 10. Concatenating v' with itself $2r'$ times has the property that its corresponding matrix is low rank.

Let $k = \max\left\{\left\lfloor \frac{n}{2r'} \right\rfloor, 1\right\}$. The goal is to find a $v \in \mathbb{F}_2^n$ such that $d_H(v, V) \geq k \cdot r'/8$ and the rank of $\mathsf{mat}(v)$ is at most $2r'/\sqrt{n}$. If $\left\lfloor \frac{n}{2r'} \right\rfloor \geq 1$, then define $S_1, \ldots, S_k$ such that

$$S_i = \{(i-1) \cdot 2r' + 1, \ldots, i \cdot 2r'\}$$

for $i \in [k]$; otherwise, define $S_1 = [n]$. By definition, the dimension of V_{S_i} is at most $r' = |S_i|/2$, for every $i \in [k]$. Since $r' \geq \sqrt{n}$ and $n \geq 1024$, we can infer that $k \leq 2r'$ and $2r' < 2^{r'/2}$. Lemma 10 implies the existence of a $v' \in \mathbb{F}_2^{2r'}$ with the property that $d_H(v', V_{S_i}) \geq r'/8$ for every $i \in [k]$. Now define $v \in \mathbb{F}_2^n$ by

$$v[i] = \begin{cases} v'[i \bmod 2r'] & \text{if } i \leq k \cdot 2r' \text{ and } i \bmod 2r' \neq 0, \\ v'[2r'] & \text{if } i \leq k \cdot 2r' \text{ and } i \bmod 2r' = 0, \\ 0 & \text{if } i > 2kr', \end{cases}$$

for all $i \in [n]$. In words, v is the length n vector that is the concatenation of k copies of v' along with the vector of zeros of length $n - 2kr'$. By the choice of v, we get that,

$$d_H(v, V) \geq \sum_{i=1}^{k} d_H(v, V_{S_i}) \geq k \cdot r'/8.$$

Moreover, the rank of $\mathsf{mat}(v)$ is at most $\frac{2r'}{\sqrt{n}}$. Therefore we can express

$$\mathsf{mat}(v) = \sum_{i=1}^{2r'/\sqrt{n}} a_i b_i^{\intercal},$$

for some $a_1, b_1, \ldots, a_{\frac{2r'}{\sqrt{n}}}, b_{\frac{2r'}{\sqrt{n}}} \in \mathbb{F}_2^{\sqrt{n}}$. By Lemma 9, we know that

$$d_H(v, V) \leq \sum_{i=1}^{2r'/\sqrt{n}} d_H(\mathsf{vec}(a_i b_i^{\intercal}), V).$$

Hence there exists an $i \in \left[\frac{2r'}{\sqrt{n}}\right]$ such that $d_H(\mathsf{vec}(a_i b_i^{\intercal}), V) \geq \frac{\sqrt{n} \cdot k}{16} \geq \frac{n^{3/2}}{64r'}$. The observation that $r' \leq 2\max\{\sqrt{n}, r\}$ completes the proof of the theorem.

▶ Remark (Extension to strong rigidity). Alon and Cohen [4] defined the notion of *strong* rigidity; a set $Q \subseteq \mathbb{F}_2^n$ is (r,t)-strongly rigid if for every subspace of $\mathbb{F}_2^n$ of dimension at most r, the average distance of all the points to the subspace is at least t. For strong rigidity, the best lower bounds known for explicit sets are also of the form given in Eq. (1). We can show that Υ is (r,t)-strongly rigid with $t \geq \Omega\left(\frac{n^{3/2}}{\max\{\sqrt{n}, r\}}\right)$, matching the best strong rigidity bounds known for explicit sets. We sketch the proof here. We know that

$$u^{\intercal}Mv + (u + e_i)^{\intercal}Mv + u^{\intercal}M(v + e_j) + (u + e_i)^{\intercal}M(v + e_j) = b_i^{\intercal}Mb_j,$$

where $u, v \in \mathbb{F}_2^{\sqrt{n}}$ and $e_1, \ldots, e_{\sqrt{n}}$ are standard basis vectors in $\mathbb{F}_2^{\sqrt{n}}$. This fact can be used to prove that the matrix M_{Υ} corresponding to the set Υ is a generator matrix of a 4-query locally decodable code that tolerates a constant fraction of errors. A result of [13, Theorem 6] shows that Theorem 2 and the locally decodable code property of M_{Υ} imply the strong rigidity of Υ.

4 Cell Probe Lower Bounds for the $u^{\intercal}Mv$ Problem

We know of two techniques for proving cell probe lower bounds matching Eq. (2). One is a technique of Pătraşcu and Thorup [30] who combined the communication complexity simulation of Miltersen [25] with multiple queries on the same input data. The other is the technique we use, which is based on cell sampling. Cell sampling typically requires one to work with large sized fields in order to handle errors. This large field size is needed to encode a large subset of the correctly computed queries using a small subset of cells. Here, we avoid encoding the subset of queries by a reduction to one-way communication complexity.

Proof outline for Theorem 3

By Yao's min-max principle, it suffices to prove a lower bound on deterministic data structures. The hard distribution on the input data M and query $uv^{\intercal}$ we use is given by sampling $M, (u, v)$ uniformly and independently at random. We prove the theorem by contradiction,

and we start by assuming that the query time is small. The proof is carried out in three steps. First, modify the data structure so that for every M, the fraction of queries correctly computed is at least $1/2$. This modification only increases the query time and space by 1, and it can only increase the overall probability of the query algorithm being correct. Second, for a given M, we use a variant of cell sampling (see Lemma 14) to obtain a small subset of cells S and a large subset of queries Q' such that all queries in Q' can be computed by only accessing cells in S. Moreover,

$$\Pr\left[\text{query algorithm correctly computes } u^\intercal Mv \mid uv^\intercal \in Q'\right]$$
$$\approx \Pr\left[\text{query algorithm correctly computes } u^\intercal Mv\right].$$

Third, we show that S can be used to design an efficient protocol for the following communication game: Alice's input is M and Bob's input is $uv^\intercal$, and the goal is for Bob to correctly compute $u^\intercal Mv$ on a sufficiently good fraction of the inputs after receiving a message from Alice.

We now describe the protocol (see Figure 1). Alice sends the locations and contents of S. This ensures that Bob correctly computes $u^\intercal Mv$ on a large fraction of queries in Q'. Alice also communicates the majority value of $u^\intercal Mv$ for $uv^\intercal \notin Q'$ so that Bob is correct on half of his possible inputs that are not in Q'. Overall, Bob's output is correct on a sufficiently good fraction of all $M, (u, v)$. Since we have assumed that the query time is small, we are able to show that Alice's communication is small. This contradicts a lower bound on the communication complexity of this game. More precisely, we prove the following lower bound.

▶ **Theorem 11.** *Suppose that Alice gets a uniformly random matrix $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$ as input and Bob receives a uniform pair $(u, v) \in \mathbb{F}_2^{\sqrt{n}} \times \mathbb{F}_2^{\sqrt{n}}$ as input. If Alice sends a deterministic message to Bob and Bob computes $u^\intercal Mv$ such that*

$$\Pr_{M,u,v}[\textit{Bob computes } u^\intercal Mv \textit{ correctly}] \geq \frac{1}{2} + \frac{1}{2^{\sqrt{n}/8}},$$

then Alice must communicate at least $n/10$ bits.

Previously, in the *randomized* two-way communication setting, Chattopadhyay, Koucký, Loff, and Mukhopadhyay [9] proved a lower bound for the game given in Theorem 11. Their lower bound implies the lower bound in Theorem 11 against randomized protocols. We need a lower bound against *deterministic* protocols under the *uniform distribution* on the inputs, and we cannot use their theorem as a black-box. We provide a straightforward proof of Theorem 11 in Section 4.1 by using the *discrepancy method* on a related communication game (resembling a direct sum, where Bob receives multiple inputs).

Preliminaries

Before presenting the proof of Theorem 3, we define some notation. For a real valued function f with a finite domain $X \times Y$, $\mathbb{E}_{x,y}[f(x,y)] = \frac{1}{|X|\cdot|Y|} \cdot \sum_{x\in X, y\in Y} f(x,y)$. Similarly, for $X' \subseteq X$, $\mathbb{E}_{x,y}[f(x,y) \mid x \in X'] = \frac{1}{|X'|\cdot|Y|} \cdot \sum_{x\in X', y\in Y} f(x,y)$. An argument in the proof of Theorem 3 requires an upper bound on the number of bits to encode the contents and locations of a subset of the cells, which is given by the following proposition.

▶ **Proposition 12.** *Let S be a subset of the cells of a data structure with word length w and size s. Then, the contents and locations of S can be encoded in $|S| \cdot w + |S| \cdot \log \frac{es}{|S|}$ bits.*

Proof. Since each cell stores w bits, the number of bits to encode the contents is $|S| \cdot w$. Since the total number of cells is s, the locations can be encoded in $\log \binom{s}{|S|} \leq |S| \cdot \log \frac{es}{|S|}$ bits, where the inequality followed from Proposition 8. ◀

4.1 Proof of Theorem 11

We start by discussing a slightly related problem, whose solution will lead to the proof strategy used here. Let $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$, $v \in \mathbb{F}_2^{\sqrt{n}}$, and $e_1, \ldots, e_{\sqrt{n}}$ be the standard basis vectors in $\mathbb{F}_2^{\sqrt{n}}$. Consider the communication game in which Alice gets as input a uniform random M and Bob gets as input a uniform random pair (e_i, v). Bob's goal is to compute $e_i^\intercal Mv$ after receiving a message from Alice. To understand how much Alice has to communicate, it is natural to look at the problem where Bob computes $\sum_{i=1}^{\sqrt{n}} e_i^\intercal Mv_i$, where $v_1, \ldots, v_{\sqrt{n}} \in F_2^{\sqrt{n}}$. Now observe that this sum is the same as the trace of $\left(\sum_{i=1}^{\sqrt{n}} e_i v^\intercal\right) M$, which in turn is the inner product between two n-bit vectors. The communication complexity of the inner product between two n-bit vectors is very well understood. Therefore, the lower bound on the amount of communication to compute the inner product between two n-bit vectors translates to a lower bound to the problem of computing $e_i^\intercal Mv$. This strategy applied to our setting gives us the following lower bound, which will be used to prove Theorem 11. Our presentation closely follows [32, Chapter 5].

▶ **Lemma 13.** *Let $0 < \epsilon \leq 1/2$ and let k be an integer. Alice gets a uniformly random $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$ as input and Bob receives k uniform pairs $(u_1, v_1), \ldots, (u_k, v_k) \in \mathbb{F}_2^{\sqrt{n}} \times \mathbb{F}_2^{\sqrt{n}}$ as input. Assume that Alice communicates a deterministic message to Bob, and Bob computes $\sum_{i=1}^k u_i^\intercal Mv_i$ with*

$$\Pr_{M,u_1,v_1,\ldots,u_k,v_k}\left[\textit{Bob computes } \sum_{i=1}^{k} u_i^\intercal Mv_i \textit{ correctly}\right] \geq \frac{1}{2} + \epsilon.$$

If $k \leq \sqrt{n}$, then Alice must communicate at least $9k\sqrt{n}/40 - \log(1/\epsilon)$ bits.

Proof. We use the discrepancy method to prove the communication lower bound. This requires upper bounding the discrepancy of the *communication matrix* under a given distribution. Let R be a rectangle of the communication matrix, which is defined by indicator functions A_R and B_R such that $(M, ((u_1, v_1), \ldots, (u_k, v_k)))$ is in the rectangle R if and only if $A_R(M) = 1$ and $B_R((u_1, v_1), \ldots, (u_k, v_k)) = 1$.

Consider the distribution in which $M, (u_1, v_1), \ldots, (u_k, v_k)$ are chosen at random uniformly and independently. We upper bound the discrepancy under this distribution. In other words, we claim that for every rectangle R,

$$\mathop{\mathbb{E}}_{M,(u_1,v_1),\ldots,(u_k,v_k)}\left[A_R(M)B_R((u_1, v_1), \ldots, (u_k, v_k))(-1)^{\sum_{i=1}^k u_i^\intercal Mv_i}\right] \leq 2 \cdot 2^{-9k\sqrt{n}/40}. \tag{6}$$

By a standard relation in communication complexity between the number of bits communicated and discrepancy of rectangles (see [32, Chapter 5, Theorem 5.2]), Eq. (6) implies that Alice must communicate at least $9k\sqrt{n}/40 - \log(1/\epsilon)$ bits. We are left with the proof of Eq. (6).

$$\begin{aligned}
&\left(\mathop{\mathbb{E}}_{(u_1,v_1),\ldots,(u_k,v_k)}\left[B_R((u_1, v_1), \ldots, (u_k, v_k)) \mathop{\mathbb{E}}_{M}\left[A_R(M)(-1)^{\sum_{i=1}^k u_i^\intercal Mv_i}\right]\right]\right)^2 \\
&\leq \mathop{\mathbb{E}}_{(u_1,v_1),\ldots,(u_k,v_k)}\left[B_R((u_1, v_1), \ldots, (u_k, v_k))^2 \left(\mathop{\mathbb{E}}_{M}\left[A_R(M)(-1)^{\sum_{i=1}^k u_i^\intercal Mv_i}\right]\right)^2\right] \\
&\leq \mathop{\mathbb{E}}_{(u_1,v_1),\ldots,(u_k,v_k)}\left[\left(\mathop{\mathbb{E}}_{M}\left[A_R(M)(-1)^{\sum_{i=1}^k u_i^\intercal Mv_i}\right]\right)^2\right].
\end{aligned}$$

where the first inequality follows from convexity and the second one follows from the fact that $B_R((u_1,v_1),\ldots,(u_k,v_k)) \leq 1$. Now

$$\begin{aligned}
&\mathop{\mathbb{E}}_{(u_1,v_1),\ldots,(u_k,v_k)}\left[\left(\mathop{\mathbb{E}}_{M}\left[A_R(M)(-1)^{\sum_{i=1}^k u_i^\intercal M v_i}\right]\right)^2\right] \\
&\leq \mathop{\mathbb{E}}_{(u_1,v_1),\ldots,(u_k,v_k),M,M'}\left[A_R(M)A_R(M')(-1)^{\sum_{i=1}^k u_i^\intercal M v_i+\sum_{i=1}^k u_i^\intercal M' v_i}\right] \\
&\leq \mathop{\mathbb{E}}_{M,M'}\left[\left|\mathop{\mathbb{E}}_{(u_1,v_1),\ldots,(u_k,v_k)}\left[(-1)^{\sum_{i=1}^k u_i^\intercal (M+M') v_i}\right]\right|\right] \\
&= \mathop{\mathbb{E}}_{M}\left[\left|\mathop{\mathbb{E}}_{(u,v)}\left[(-1)^{u^\intercal M v}\right]\right|^k\right],
\end{aligned}$$

where the last equality follows from the fact that $(u_1,v_1),\ldots,(u_k,v_k)$ are chosen independent of each other and $M+M'$ is uniformly distributed as M and M' are chosen uniformly and independently at random. We are left with upper bounding $\mathbb{E}_M\left[\left|\mathbb{E}_{(u,v)}\left[(-1)^{u^\intercal M v}\right]\right|^k\right]$. First note that if M has rank r, then $\mathbb{E}_{u,v}\left[(-1)^{u^\intercal M v}\right] = 2^{-r}$. This is because,

$$\begin{aligned}
\mathop{\mathbb{E}}_{u,v}\left[(-1)^{u^\intercal M v}\right] &= \frac{1}{2^{\sqrt{n}}}\cdot\left(\sum_{v:Mv=0} 1\right) + \frac{1}{2^{\sqrt{n}}}\cdot\left(\sum_{v:Mv\neq 0}\mathop{\mathbb{E}}_{u}\left[(-1)^{u^\intercal M v}\right]\right) \\
&= \frac{2^{\sqrt{n}-r}}{2^{\sqrt{n}}} + 0 = 2^{-r}.
\end{aligned}$$

In addition, $\Pr_M\left[\text{rank of } M \leq 9\sqrt{n}/20\right] \leq 2^{-9n/10}$. Indeed, the number of matrices in $\mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$ of rank at most k is at most

$$\binom{2^{\sqrt{n}}}{k}\cdot\left(2^k\right)^{\sqrt{n}} \leq 2^{2k\sqrt{n}}.$$

Therefore, using the law of total expectation, we have that

$$\mathop{\mathbb{E}}_{M}\left[\left|\mathop{\mathbb{E}}_{(u,v)}\left[(-1)^{u^\intercal M v}\right]\right|^k\right] \leq \Pr_M\left[\text{rank of } M \leq 9\sqrt{n}/20\right] + 2^{-9k\sqrt{n}/20} \leq 2\cdot 2^{-9k\sqrt{n}/20},$$

where the last inequality followed from the fact that $k \leq \sqrt{n}$. ◀

Proof of Theorem 11. Let c be the number of bits communicated by Alice. We show that $c > n/10$. Define $Z_M(u,v) = 1$ if Bob correctly computes $u^\intercal M v$ and $Z_M(u,v) = -1$ otherwise. By the definition of $Z_M(u,v)$ and the lower bound on the probability of Bob's computation being correct, we have that $\mathbb{E}_{M,u,v}\left[Z_M(u,v)\right] \geq 2\cdot 2^{-\sqrt{n}/8}$.

We note that it is without loss of generality that $\mathbb{E}_{u,v}\left[Z_M(u,v)\right] \geq 0$ for every $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$. This is because Alice on input M can send an extra bit indicating whether $\mathbb{E}_{u,v}\left[Z_M(u,v)\right] < 0$ and Bob will flip his output accordingly.

We now use the given protocol to design a protocol for a new communication game: Suppose that Alice gets a uniformly random $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$ as input and Bob receives $\sqrt{n}$ uniform pairs $(u_1,v_1),\ldots,(u_{\sqrt{n}},v_{\sqrt{n}}) \in \mathbb{F}_2^{\sqrt{n}}\times\mathbb{F}_2^{\sqrt{n}}$ as input. We will use Lemma 13 with $k = \sqrt{n}$ to obtain the desired lower bound on c.

We claim that there is a communication protocol in which Alice communicates c bits and Bob computes $\sum_{i=1}^{\sqrt{n}} u_i^\intercal M v_i$ such that

$$\Pr_{M,u_1,v_1,\ldots,u_{\sqrt{n}},v_{\sqrt{n}}}\left[\text{Bob computes } \sum_{i=1}^{\sqrt{n}} u_i^\intercal M v_i \text{ correctly}\right] \geq \frac{1}{2} + \frac{2^{\sqrt{n}-1}}{2^{n/8}}. \tag{7}$$

Alice's message is same as before, and Bob computes each of $u_i^\intercal M v_i$ separately and outputs the sum modulo 2. We now prove Eq. (7). For a fixed M, the probability that Bob correctly computes $\sum_{i=1}^{\sqrt{n}} u_i^\intercal M v_i$ is $\frac{1}{2}\left(1 + \left(\mathbb{E}_{u,v}\left[Z_M(u,v)\right]\right)^{\sqrt{n}}\right)$. Therefore the overall probability that Bob correctly computes $\sum_{i=1}^{\sqrt{n}} u_i^\intercal M v_i$ is at least

$$\frac{1}{2}\left(1 + \frac{\sum_M \left(\mathbb{E}_{u,v}\left[Z_M(u,v)\right]\right)^{\sqrt{n}}}{2^n}\right) \geq \frac{1}{2}\left(1 + \left(\mathop{\mathbb{E}}_{M,u,v}\left[Z_M(u,v)\right]\right)^{\sqrt{n}}\right) \geq \frac{1}{2} + \frac{2^{\sqrt{n}-1}}{2^{n/8}},$$

where the first inequality follows from convexity of the function $f(x) = x^k$ with $k = \sqrt{n}$. Applying Lemma 13 with $k = \sqrt{n}$ implies that $c > n/10$, which completes the proof of the theorem. ◀

4.2 Proof of Theorem 3

If $n < 36$, the theorem is vacuously true as $c \leq 1/36$. For the rest of the argument we will assume that $n \geq 36$. We prove a lower bound on the query time t against deterministic data structures with space s and word size w. Suppose that the input data M and query $uv^\intercal$ is given by choosing M, u, v uniformly and independently at random, and the query algorithm is guaranteed to satisfy

$$\Pr_{M,u,v}\left[\text{query algorithm computes } u^\intercal M v \text{ correctly}\right] \geq \frac{1}{2} + 2^{-\sqrt{n}/16}.$$

By Yao's minmax principle, this will imply a lower bound on randomized data structures.

We first modify the given data structure to ensure that for every $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$, the probability that $u^\intercal M v$ is correctly computed is at least $1/2$. Assume that we have a data structure with query time t', space s' and word size w. The modified data structure stores an extra bit indicating whether the $\Pr_{u,v}\left[\text{query algorithm computes } u^\intercal M v \text{ correctly}\right]$ is less than $1/2$ or not for a given M. The query algorithm is the same as before, but accesses this extra bit to flip the output if it is set to 1. Clearly, the new data structure has query time $t = t' + 1$, space $s = s' + 1$ and word size w. Moreover, under this modification, we have

- $\Pr_{M,u,v}\left[\text{query algorithm computes } u^\intercal M v \text{ correctly}\right] \geq 1/2 + 2^{-\sqrt{n}/16}$.
- $\Pr_{u,v}\left[\text{query algorithm computes } u^\intercal M v \text{ correctly}\right] \geq 1/2$ for every M.

In the rest of the proof, we work with this modification and show that $t \geq \Omega\left(\min\left\{\frac{n}{\beta}, \frac{\sqrt{n}}{\log\frac{s\beta}{n}}\right\}\right)$, where $\beta = 2(w + \log sw/n)$. Observe that $\beta \leq n/256$; otherwise the lower bound is vacuous.

Assume by contradiction that $t \leq \min\left\{\frac{n}{256\beta}, \frac{\sqrt{n}}{256\log\frac{s\beta}{n}}\right\}$. Define $Z_M(u,v) = 1$ if the query algorithm correctly computes $u^\intercal M v$, and -1 otherwise. We have

$$\begin{aligned}\mathop{\mathbb{E}}_{M,u,v}\left[Z_M(u,v)\right] &= 2\Pr_{M,u,v}\left[\text{query algorithm computes } u^\intercal M v \text{ correctly}\right] - 1 \\ &\geq 2\cdot 2^{-\sqrt{n}/16}. \end{aligned} \tag{8}$$

Note that $\mathbb{E}_{M,u,v}\left[Z_M(u,v)\right]$ captures the *advantage* or *bias* of the data structure - it is much more convenient to work with the advantage than the probability of the query algorithm being correct.

Input: Alice's input is M and Bob's input is (u, v)
Output: Alice communicates a deterministic message and Bob computes $u^\intercal Mv$.

1 Let $Q_1 = \{uv^\intercal \mid Z_M(u,v) = 1\}$ and $Q_2 = \{uv^\intercal \mid Z_M(u,v) = -1\}$;
2 Apply Lemma 14 with Q_1, Q_2 to obtain a subset of cells S and subsets $Q_1' \subseteq Q_1$ and $Q_2' \subseteq Q_2$;
3 Let $b \in \{0,1\}$ be such that $\Pr_{u,v}[u^\intercal Mv = b \mid uv^\intercal \notin Q'] \geq \Pr_{u,v}[u^\intercal Mv = 1-b \mid uv^\intercal \notin Q']$, where $Q' = Q_1' \cup Q_2'$;
4 Alice communicates b followed by locations and contents of S;
5 **if** $uv^\intercal \in Q'$ **then** Bob uses the query algorithm to compute $u^\intercal Mv$;
6 **else** Bob outputs b;

Figure 1 One-way protocol on inputs $M, (u, v)$ computing $u^\intercal Mv$.

The following lemma, a variant of cell sampling, guarantees the existence of a small subset S of cells such that a large number of queries Q' can be computed by only accessing S, and $\mathbb{E}_{u,v}[Z_M(u,v) \mid uv^\intercal \in Q'] \approx \mathbb{E}_{u,v}[Z_M(u,v)]$.

▶ **Lemma 14.** *Let $M \in \mathbb{F}_2^{\sqrt{n}\times\sqrt{n}}$, and define the sets $Q_1 = \{uv^\intercal \mid Z_M(u,v) = 1\}$ and $Q_2 = \{uv^\intercal \mid Z_M(u,v) = -1\}$. If $t \leq \min\left\{\frac{n}{256\beta}, \frac{\sqrt{n}}{256\log\frac{s\beta}{n}}\right\}$, then there exits a subset of cells S, and subsets $Q_1' \subseteq Q_1$ and $Q_2' \subseteq Q_2$ such that*

1. $|S| = \left\lceil \frac{n}{128\beta} \right\rceil$,
2. $\Pr_{u,v}[uv^\intercal \in Q_1'] - \Pr_{u,v}[uv^\intercal \in Q_2'] \geq \mathbb{E}_{u,v}[Z_M(u,v)] \cdot 2^{-\sqrt{n}/16}$,
3. *$Q_1' \cup Q_2'$ is the set of all queries computed by accessing cells only in S.*

We move on to the final step of the proof of Theorem 3. What is left is to design a one-way protocol using the sets guaranteed by Lemma 14. The protocol is described in Figure 1. We will show the validity of this protocol by showing that both Alice and Bob know the subset Q' of queries. Since Alice's input is M, she knows the contents of all the cells, which gives S. With regard to knowing Q', the locations and contents of cells in S suffice. This is because the query algorithm can be simulated on all queries to check if any cell outside of S is being accessed. We are proving Theorem 3 by contradicting Theorem 11, which is achieved by the following.

▶ **Lemma 15.** *The protocol in Figure 1 has the following guarantees (a) Alice communicates fewer than $n/10$ bits, and (b) $\Pr_{M,u,v}[$Bob computes $u^\intercal Mv$ correctly$] \geq 1/2 + 1/2^{\sqrt{n}/8}$.*

Now, we need to prove Lemmas 14 and 15 to complete the proof of Theorem 3.

Proof of Lemma 14. Let S be a uniformly random subset of the cells of size $|S| = \left\lceil \frac{n}{128\beta} \right\rceil$. Define $D(u,v,S) = Z_M(u,v)$ if the query algorithm only accesses cells in S to compute $u^\intercal Mv$; otherwise $D(u,v,S) = 0$. By linearity of expectation,

$$\mathop{\mathbb{E}}_{u,v,S}[D(u,v,S)] = \mathop{\mathbb{E}}_{u,v}[Z_M(u,v)] \cdot \frac{\binom{s-t}{|S|-t}}{\binom{s}{|S|}} = \mathop{\mathbb{E}}_{u,v}[Z_M(u,v)] \cdot \frac{|S| \cdot (|S|-1) \cdots (|S|-t+1)}{s \cdot (s-1) \cdots (s-t+1)}$$
$$\geq \mathop{\mathbb{E}}_{u,v}[Z_M(u,v)] \cdot \left(\frac{|S|-t}{s}\right)^t.$$

Recall that $|S| \geq \frac{n}{128\beta}$ and $t \leq \frac{n}{256\beta}$. Moreover, $\beta = 2(w + \log sw/n) \geq 2$. This implies that

$$\left(\frac{|S|-t}{s}\right)^t \geq 2^{-t\cdot\log\frac{256s\beta}{n}} \geq 2^{-16t\cdot\log\frac{s\beta}{n}}.$$

So we get $\mathbb{E}_{u,v,S}\left[D(u,v,S)\right] \geq \mathbb{E}_{u,v}\left[Z_M(u,v)\right]\cdot 2^{-16\cdot t\cdot\log\frac{s\beta}{n}}$. Therefore, there exists an S such that

$$\mathop{\mathbb{E}}_{u,v}\left[D(u,v,S)\right] \geq \mathop{\mathbb{E}}_{u,v}\left[Z_M(u,v)\right]\cdot 2^{-16\cdot t\cdot\log\frac{s\beta}{n}} \geq \mathop{\mathbb{E}}_{u,v}\left[Z_M(u,v)\right]\cdot 2^{-\sqrt{n}/16},$$

where the last inequality follows from the fact that $16\cdot t\cdot\log\frac{s\beta}{n} \leq \sqrt{n}/16$. Setting

$$Q_1' = \{uv^\intercal \in Q_1 \mid D(u,v,S) = 1\} \text{ and } Q_2' = \{uv^\intercal \in Q_2 \mid D(u,v,S) = -1\}$$

completes the proof of the lemma. ◀

Proof of Lemma 15. We first prove part (a). Recall that $\beta = 2\left(w + \log\frac{sw}{n}\right)$. Let c be the number of bits communicated by Alice. By Proposition 12 and the definition of β,

$$\begin{aligned} c &\leq 1 + \left\lceil\frac{n}{128\beta}\right\rceil\cdot w + \left\lceil\frac{n}{128\beta}\right\rceil\cdot\log\frac{128e\cdot s\beta}{n} \\ &= 1 + \left\lceil\frac{n}{128\beta}\right\rceil\cdot\left(w + \log\frac{s\beta}{n}\right) + \left\lceil\frac{n}{128\beta}\right\rceil\cdot\log 128e. \end{aligned}$$

Since $\beta \geq 2w$, $\beta \geq 2\log\frac{s}{n}$ and $\beta \geq \log\beta$, we get that $w + \log\frac{s\beta}{n} \leq 2\beta$. Moreover, using the fact that $\left\lceil\frac{n}{128\beta}\right\rceil \leq \frac{n}{128\beta} + 1$, $\beta \geq 2$ and $\beta \leq n/256$, we can say that

$$\begin{aligned} c &\leq 1 + \frac{2n}{128} + 2\beta + \frac{n\log 128e}{128\beta} + \log 128e \\ &\leq 1 + \frac{2n}{128} + \frac{4.5n}{128(\beta/2)} + \frac{n}{128} + \log 128e \leq 10 + \frac{7.5n}{128} < \frac{n}{10}, \end{aligned}$$

where the last inequality follows from $n \geq 36$.

We now prove part (b) of the claim. Define $Z_M'(u,v) = 1$ if the Bob correctly computes $u^\intercal Mv$ and $Z_M'(u,v) = -1$ otherwise. The probability with which Bob correctly computes $u^\intercal Mv$ is given by $\left(1 + \mathbb{E}_{M,u,v}\left[Z_M'(u,v)\right]\right)/2$. We will show that $\mathbb{E}_{M,u,v}\left[Z_M'(u,v)\right] \geq 2\cdot 2^{-\sqrt{n}/8}$, which will imply that the probability of being correct is at least $1/2 + 2^{-\sqrt{n}/8}$.

Let Q_1, Q_2, Q_1', Q_2', and Q' be as defined in the protocol in Figure 1. We first establish some properties about these sets. We know that $\Pr_{u,v}[uv^\intercal \in Q_1] - \Pr_{u,v}[uv^\intercal \in Q_2] = \mathbb{E}_{u,v}\left[Z_M(u,v)\right]$. Moreover, the application of Lemma 14 in the protocol is valid since $t \leq \frac{n}{256\alpha}$, and hence

$$\Pr_{u,v}\left[uv^\intercal \in Q_1'\right] - \Pr_{u,v}\left[uv^\intercal \in Q_2'\right] \geq \mathop{\mathbb{E}}_{u,v}\left[Z_M(u,v)\right]\cdot 2^{-\sqrt{n}/16}. \tag{9}$$

Since Bob can simulate the query algorithm on Q' by accessing only S, which is guaranteed by Lemma 14, we have

$$\begin{aligned} \mathop{\mathbb{E}}_{u,v}\left[Z_M'(u,v)\right] &= \Pr_{u,v}\left[uv^\intercal \in Q'\right]\left(\Pr_{u,v}\left[uv^\intercal \in Q_1' \mid uv^\intercal \in Q'\right] - \Pr_{u,v}\left[uv^\intercal \in Q_2' \mid uv^\intercal \in Q'\right]\right) + \\ &\quad \Pr_{u,v}\left[uv^\intercal \notin Q'\right]\left(\Pr_{u,v}\left[u^\intercal Mv = b \mid uv^\intercal \notin Q'\right] - \Pr_{u,v}\left[u^\intercal Mv = 1-b \mid uv^\intercal \notin Q'\right]\right) \\ &\geq \left(\Pr_{u,v}\left[uv^\intercal \in Q_1'\right] - \Pr_{u,v}\left[uv^\intercal \in Q_2'\right]\right) \geq \mathop{\mathbb{E}}_{u,v}\left[Z_M(u,v)\right]\cdot 2^{-\sqrt{n}/16}, \end{aligned}$$

where the first inequality follows from the choice of b and the second inequality used Eq. (9).

To conclude,

$$\begin{aligned}\mathop{\mathbb{E}}_{M,u,v}[Z'_M(u,v)] = \mathop{\mathbb{E}}_{M}\left[\mathop{\mathbb{E}}_{u,v}[Z'_M(u,v)]\right] &\geq \mathop{\mathbb{E}}_{M}\left[\mathop{\mathbb{E}}_{u,v}[Z_M(u,v)]\cdot 2^{-\sqrt{n}/16}\right] \\ &= \mathop{\mathbb{E}}_{M}\left[\mathop{\mathbb{E}}_{u,v}[Z_M(u,v)]\right]\cdot 2^{-\sqrt{n}/16} \\ &= \mathop{\mathbb{E}}_{M,u,v}[Z_M(u,v)]\cdot 2^{-\sqrt{n}/16} \geq 2\cdot 2^{-\sqrt{n}/8},\end{aligned}$$

where the last inequality follows from Eq. (8). ◀

Abstract

Memory hard functions (MHFs) are an important cryptographic primitive that are used to design egalitarian proofs of work and in the construction of moderately expensive key-derivation functions resistant to brute-force attacks. Broadly speaking, MHFs can be divided into two categories: data-dependent memory hard functions (dMHFs) and data-independent memory hard functions (iMHFs). iMHFs are resistant to certain side-channel attacks as the memory access pattern induced by the honest evaluation algorithm is independent of the potentially sensitive input e.g., password. While dMHFs are potentially vulnerable to side-channel attacks (the induced memory access pattern might leak useful information to a brute-force attacker), they can achieve higher cumulative memory complexity (CMC) in comparison than an iMHF. In particular, any iMHF that can be evaluated in N steps on a sequential machine has CMC *at most* $\mathcal{O}\left(\frac{N^2 \log\log N}{\log N}\right)$. By contrast, the dMHF scrypt achieves maximal CMC $\Omega(N^2)$ – though the CMC of scrypt would be reduced to just $\mathcal{O}(N)$ after a side-channel attack.

In this paper, we introduce the notion of computationally data-independent memory hard functions (ciMHFs). Intuitively, we require that memory access pattern induced by the (randomized) ciMHF evaluation algorithm appears to be independent from the standpoint of a computationally bounded eavesdropping attacker – even if the attacker selects the initial input. We then ask whether it is possible to circumvent known upper bound for iMHFs and build a ciMHF with CMC $\Omega(N^2)$. Surprisingly, we answer the question in the affirmative when the ciMHF evaluation algorithm is executed on a two-tiered memory architecture (RAM/Cache).

We introduce the notion of a k-restricted dynamic graph to quantify the continuum between unrestricted dMHFs ($k = n$) and iMHFs ($k = 1$). For any $\epsilon > 0$ we show how to construct a k-restricted dynamic graph with $k = \Omega(N^{1-\epsilon})$ that provably achieves maximum cumulative pebbling cost $\Omega(N^2)$. We can use k-restricted dynamic graphs to build a ciMHF provided that cache is large enough to hold k hash outputs and the dynamic graph satisfies a certain property that we call "amenable to shuffling". In particular, we prove that the induced memory access pattern is indistinguishable to a polynomial time attacker who can monitor the locations of read/write requests to RAM, but not cache. We also show that when $k = o\left(N^{1/\log\log N}\right)$, then any k-restricted graph with constant indegree has cumulative pebbling cost $o(N^2)$. Our results almost completely characterize the spectrum of k-restricted dynamic graphs.

1 Introduction

Memory hard functions (MHFs) [1, 27] are a central component in the design of password hashing functions [9], egalitarian proofs of work [21], and moderately hard key-derivation functions [27]. In the setting of password hashing, the objective is to design a function that can be computed relatively quickly on standard hardware for honest users, but is prohibitively expensive for an offline attacker to compute millions or billions of times while checking each password in a large cracking dictionary. The first property allows legitimate users to authenticate in a reasonable amount of time, while the latter goal discourages brute-force offline guessing attacks, even on low-entropy secrets such as passwords, PINs, and biometrics. The objective is complicated by attackers that use specialized hardware such as Field Programmable Gate Arrays (FPGAs) or Application Specific Integrated Circuits (ASICs) to significantly decrease computation costs by several orders of magnitude, compared to an honest user using standard hardware. For example, the Antminer S17, an ASIC Bitcoin miner exclusively configured for SHA256 hashes, can compute up to 56 trillion hashes per second, while the rate of many standard CPUs and GPUs are limited to 200 million hashes per second and 1 billion hashes per second, respectively.

Memory hard functions were developed on the observation that memory costs such as chip area tend to be equitable across different architectures. Therefore, the cost of evaluating an ideal "egalitarian" function would be dominated by memory costs. Blocki et al. [12] argued that key derivation functions without some form of memory hardness provide insufficient defense against a economically motivated offline attacker under the constraint of reasonable authentication times for honest users. In fact, most finalists in the 2015 Password Hashing Competition claimed some form of memory hardness [22, 9, 24]. To quantify these memory costs, memory hardness [27] considers the cost to build, obtain, and empower the necessary hardware to compute the function. One particular metric heavily considered by recent cryptanalysis [2, 5, 4, 3, 15] is cumulative memory complexity (CMC) [7], which measures the amortized cost of any parallel algorithm evaluating the function on several distinct inputs. Despite known hardness results for quantifying [16] or even approximating [13] a function's CMC, even acquiring asymptotic bounds provide automatic bounds for other attractive metrics such as space-time complexity [26] or energy complexity [29, 14].

Data-Dependent vs. Data-Independent Memory Hard Functions

At a high level, memory hard functions can be categorized into two design paradigms: data-dependent memory hard functions (dMHFs) and data-independent memory hard functions (iMHFs). dMHFs induce memory access patterns that depend on the input, but can achieve

high memory hardness with potentially relatively easy constructions [6]. However, dMHFs are also vulnerable to side-channel attacks due to their inherent data dependent memory access patterns [8]. Examples of dMHFs include scrypt [27], Argon2d [10] and Boyen's halting puzzles [19]. On the other hand, iMHFs have memory access patterns that are independent of the input, and therefore resist certain side-channel attacks such as cache timing [8]. Examples of iMHFs include 2015 Password Hashing Competition (PHC) winner Argon2i [9], Balloon Hashing [17] and DRSample [4]. iMHFs with high memory hardness can be more technically challenging to design, but even more concerning is the inability of iMHFs to be maximally memory hard.

Alwen and Blocki [2] proved that the CMC of any iMHF running in time N is at most $\mathcal{O}\left(\frac{N^2 \log\log N}{\log N}\right)$, while the dMHF scrypt has cumulative memory complexity $\Omega(N^2)$ [6], which matches the maximal amount and cannot be obtained by any iMHF. However, the cumulative memory complexity of a dMHF can be greatly decreased through a side-channel attack, if an attacker has learned the memory access pattern induced by the true input. Namely, a brute-force attacker can preemptively quit evaluation on a guess y once it is clear that the induced memory access pattern on input y differs from that on the true input x. For example, the cumulative memory complexity of scrypt after a side-channel attack is just $\mathcal{O}(N)$.

Ideally, we would like to obtain a family of memory hard functions with cumulative memory complexity $\Omega(N^2)$ without any vulnerability to side-channel attacks. A natural approach would be some sort of hybrid between data-dependent and data-independent modes, such as Argon2id, which runs the MHF in data-independent mode for $\frac{N}{2}$ steps before switching to data-dependent mode for the final $\frac{N}{2}$ steps. Although the cumulative memory complexity is the maximal $\Omega(N^2)$ if there is no side-channel attack, the security still reduces to that of the underlying iMHF (e.g., Argon2i) if there is a side-channel attack. Hence even for a hybrid mode, the cumulative memory complexity is just $\mathcal{O}\left(\frac{N^2 \log\log N}{\log N}\right)$ (or lower) in the face of a side-channel attack. Thus in this paper we ask:

> In the presence of side-channel attacks, does there exist a family of functions with $\Omega(N^2)$ cumulative memory complexity?

1.1 Our Contributions

Surprisingly, we answer the above question in the affirmative for a natural class of side-channel attacks that observe the read/write memory locations. We introduce the concept of computationally data-independent memory hard functions to overcome the inability of data-independent memory hard functions to be maximally memory hard [2] without the common side-channel vulnerabilities of data-dependent memory hard functions [8]. Our constructions work by randomly "shuffling" memory blocks in cache before they are stored in RAM (where the attacker can observe the locations of read/write requests). Intuitively, each time $\mathsf{MHF.Eval}(x)$ is executed the induced memory access pattern will appear different due to this scrambling step. The goal is to ensure that an attacker can not even distinguish between the observed memory access pattern on two known inputs $x \neq y$.

Towards this goal we define k-restricted dynamic graphs as a tool to quantify the continuum between dMHFs and iMHFs. Intuitively, in a k-restricted dynamic graph $G = (V = [N], E)$ we have $\mathsf{parents}(v) = \{v-1, r(v)\}$ where the second (data-dependent) parent $r(v) \in R_v$ must be selected from a fixed (data-independent) restricted set $R_v \subseteq V$ of size $|R_v| \leq k$. When $k = 1$ the function is an iMHF (the parent $r(v) \in R_v$ of each node v is fixed in a data-independent manner) and when $k = N$ the function is an unrestricted dMHF – scrypt

and Argon2d are both examples of unrestricted dMHFs. Intuitively, when k is small it becomes easier to scramble the labels R_v in memory so that the observed memory access patterns on two known inputs $x \neq y$ are computationally indistinguishable.

We then develop a graph gadget that generates a family of ciMHFs using k-restricted graphs. Using this family of ciMHFs, we characterize the tradeoffs between the value of k and the overall cumulative memory cost of k-restricted graphs.

Impossibility Results for Small k

Since k-restricted graphs correspond to iMHFs for $k = 1$, and it is known that $\mathsf{cc}(\mathbb{G}) = \mathcal{O}\left(\frac{N^2 \log\log N}{\log N}\right)$ for any family $\mathbb{G}$ of iMHFs [2], then one might expect that it is impossible to obtain maximally memory hard ciMHFs for small k. Indeed, our first result shows that this intuition is correct; we show that for any $k = o\left(N^{1/\log\log N}\right)$, then any family of k-restricted graphs $\mathbb{G}$ with constant indegree has $\mathsf{cc}(\mathbb{G}) = o(N^2)$.

▶ **Theorem 1.** *Let $\mathbb{G}$ be any family of k-restricted dynamic graphs with constant $\mathsf{indeg}(\mathbb{G})$. Then*

$$\mathsf{cc}(\mathbb{G}) = \mathcal{O}\left(\frac{N^2}{\log\log N} + N^{2-1/2\log\log N}\sqrt{k^{1-1/\log\log N}}\right).$$

Thus for $k = o\left(N^{1/\log\log N}\right)$, we have $\mathsf{cc}(\mathbb{G}) = o(N^2)$.

We prove this result in Theorem 10 and Corollary 11 in Section 3 by generalizing ideas from the pebbling attack of Alwen and Blocki [2] against any iMHF to k-restricted dynamic graphs graphs. The pebbling attack of Alwen and Blocki [2] exploited the fact that any constant indegree DAG G is somewhat depth-reducible e.g., we can always find a set $S \subseteq V(G)$ of size $e = \mathcal{O}\left(\frac{N \log\log N}{\log N}\right)$ such that any path in $G - S$ has length at most $d = \frac{N}{\log^2 N}$. The attack then proceeds in a number of *light phases* and *balloon phases*, where the goal of light phase i is to place pebbles on the interval $[ig + 1, (i + 1)g]$, for some parameter g to be optimized. At the same time, the attacker discards pebbles on all nodes v unless $v \in S$ or unless v is a parent of one of the next g nodes $[ig + 1, (i + 1)g]$ that we want to pebble. Once light phase i is completed, balloon phase i uses the pebbles on S to recover all previously discarded pebbles. Note that balloon phase i thus promises that pebbles are placed on the parents of the nodes $[(i + 1)g + 1, (i + 2)g]$, so that light phase $i + 1$ can then be initiated and so forth.

One key difference is that we must maintain pebbles on all gk nodes $u \in \bigcup_{v\in[ig+1,(i+1)g]} R_v$ that are "potential parents" of the next g nodes $[ig+1, (i+1)g]$. The total cost of the pebbling attack is $\mathcal{O}\left(eN + gkN + \frac{N^2 d}{g}\right)$, which is identical to [2] when $k = 1$ for (e, d)-reducible DAGs. In general for small values of k, the dynamic pebbling strategy can still achieve cumulative memory cost $o(N^2)$ after optimizing for g.

Maximally Hard k-restricted dMHF

In Section 4, we show how to construct a k-restricted dynamic graph for $k = \mathcal{O}\left(N^{1-\epsilon}\right)$, which has cumulative pebbling cost $\Omega(N^2)$ for any constant $\epsilon > 0$. Intuitively, our goal is to force the pebbling strategy to maintain $\Omega(N)$ pebbles on the graph for $\Omega(N)$ steps or pay a steep penalty. In particular, we want to ensure that if there are $o(N)$ pebbles on the graph at time i then the cumulative pebbling cost to advance a pebble just $2k = \mathcal{O}\left(N^{\epsilon}\right)$ steps is at least $\Omega(N^{2-\epsilon})$ with high probability. This would imply that the pebbling strategy either keeps $\Omega(N)$ pebbles on the graph for $\Omega(N)$ steps or that the pebbling strategy pays a penalty of $\Omega(N^{2-\epsilon})$ at least $\Omega\left(\frac{N}{k}\right) = \Omega(N^{\epsilon})$ times. In either case the cumulative pebbling cost will be $\Omega(N^2)$.

One of our building blocks is the "grates" construction of Schnitger [30] who, for any $\epsilon > 0$, showed how to construct a constant indegree DAG G_ϵ that is (e, d)-depth robust graph with $e = \Omega(N)$ and $d = \Omega(N^{1-\epsilon})$. Our second building block is the superconcentrator [28, 26] graph. By overlaying the DAG G_ϵ with a superconcentrator, we can spread out the data-dependent edges on the top layer of our graph to ensure that (with high probability) advancing a pebble $2k = \mathcal{O}(N^\epsilon)$ steps on the top layer starting from a pebbling configuration with $o(N)$ pebbles on the graph requires us to repebble an (e, d)-depth robust graph with $e = \Omega(N)$ and $d = \Omega(N^{1-\epsilon})$. This is sufficient since Alwen et al. [5] showed that the cumulative pebbling cost of any (e, d)-depth robust graph is at least ed.

Open Question

We emphasize that we only show that any dynamic pebbling strategy for our k-restricted dynamic graph has cumulative cost $\Omega(N^2)$. This is not quite the same as showing that our dMHF has CMC $\Omega(N^2)$ in the parallel random oracle model. For static graphs, we know that the CMC of an iMHF is captured by the cumulative pebbling cost of the underlying DAG [7]. We take the dynamic pebbling lower bound as compelling evidence that the corresponding MHF has maximum cumulative memory cost. Nevertheless, proving (or disproving) that the CMC of a dMHF is captured by the cumulative cost of the optimal dynamic pebbling strategy for the underlying dynamic graph is still an open question that is outside the scope of the current work.

ciMHF Implementation Through Shuffling

The only problem is that the above k-restricted dynamic graph is actually a data-dependent construction; once the input x is fixed, the memory access patterns of the above construction is completely deterministic! Thus a side-channel attacker that obtains a memory access pattern will possibly be able to distinguish between future inputs. Our solution is to have a hidden random key K for each separate evaluation of the password hash. The hidden random key K does not alter the hash value of x in any manner, so we emphasize that there is no need to know the value of the hidden key K to perform computation. However, each computation using a separate value of K induces a different memory access pattern, so that no information is revealed to side-channel attackers looking at locations of read/write instructions.

Let L be a set of the last N consecutive nodes from our previous graph construction, which we suppose is called G_0. We form G by appending a path of length N to the end of G_0. We introduce a gadget that partitions the nodes in L into blocks $B_1, B_2, \ldots, B_{N/k}$ of size k each. We then enforce that for $i \in [N]$ and $j = i \mod k$, the i^{th} node in the final N nodes of G has a parent selected uniformly at random from B_{j+1}, depending on the input x. Thus to compute the label of i, the evaluation algorithm should know the labels of all nodes in B_{j+1}.

We allow the evaluation algorithm to manipulate the locations of these labels so that the output of the algorithm remains the same, but each computation induces a different memory access pattern. Specifically, the random key K induces a shuffling of the locations of the information within each block of the block partition gadget. Thus if the size of each block is sufficiently large, then with high probability, two separate computations of the hash for the same password will yield distinct memory access patterns, effectively computationally data-independent. Then informally, a side-channel attacker will not be able to use the memory access patterns to distinguish between future inputs.

In fact, this approach works for a general class of graphs satisfying a property that we call "amenable to shuffling". We characterize the properties of the dynamic graphs that are amenable to shuffling in Section 5 and show that k-restricted dynamic graphs that are ameanble to shuffling can be used in the design of MHFs to yield computationally data-independent sequential evaluation algorithms.

▶ **Theorem 2.** *For each DAG G that is amenable to shuffling, there exists a computationally data-independent sequential evaluation algorithm computing a MHF based on the graph G that runs in time $\mathcal{O}(N)$. (Informal, see Theorem 24.)*

We believe that our techniques for converting graphs that are amenable to shuffling to ciMHFs may be of independent interest.

Finally, we provide a version of our dMHF with $\Omega(N^2)$ cumulative memory complexity that is amenable to shuffling. Combining this maximally hard k-restricted dMHF using a DAG that is amenable to shuffling with Theorem 2, we obtain a maximally hard ciMHF.

▶ **Theorem 3.** *Let $0 < \epsilon < 1$ be a constant and $k = \Omega(N^\epsilon)$. Then there exists a family $\mathbb{G}$ of k-restricted graphs with $\mathsf{cc}(\mathbb{G}) = \Omega(N^2)$ that is amenable to shuffling.*

We prove Theorem 3 in Section 6, introducing the necessary formalities for computationally data-independent memory hard functions and the underlying systems model. Our results in Theorem 1 and Theorem 3 almost completely characterize the spectrum of k-restricted graphs. In fact, for a graph G drawn uniformly at random from our distribution $\mathbb{G}$ in Theorem 3 and any pebbling strategy S, not only do we have $\mathop{\mathbb{E}}_{G \sim \mathbb{G}}[\mathsf{cc}(S, G)] = \Omega(N^2)$, but we also have $\mathsf{cc}(S, G) = \Omega(N^2)$ with high probability.

2 Preliminaries

We use the notation $[N]$ to denote the set $\{0, 1, \ldots, N-1\}$. For two numbers x and y, we use $x \circ y$ to denote their concatenation.

Given a directed acyclic graph (DAG) $G = (V, E)$ and a node $v \in V$, we use $\mathsf{parents}_G(v) = \{u \ : \ (u, v) \in E\}$ to denote the parents of node v. We use $\mathsf{ancestors}_G(v) = \bigcup_{i \geq 1} \mathsf{parents}^i_G(v)$ to denote the set of all ancestors of v – here, $\mathsf{parents}^2_G(v) = \mathsf{parents}_G(\mathsf{parents}_G(v))$ and $\mathsf{parents}^{i+1}_G(v) = \mathsf{parents}_G\left(\mathsf{parents}^i_G(v)\right)$. We use $\mathsf{indeg}(v) = |\mathsf{parents}(v)|$ to denote the number of incoming edges into v and define $\mathsf{indeg}(G) = \max_{v \in V} \mathsf{indeg}(v)$. Given a set $S \subseteq V$, we use $G - S$ to refer to the graph obtained by deleting all nodes in S and all edges incident to S. We use $\mathsf{depth}(G)$ to denote the number of nodes in the longest directed path in G.

▶ **Definition 4.** *A DAG $G = (V, E)$ is* (e, d)-reducible *if there exists a subset $S \subseteq V$ of size $|S| \leq e$ such that any directed path P in G of length d contains at least one node in S. We call such a set S a* depth-reducing set*. If G is not (e, d)-reducible, then we say that G is* (e, d)-depth robust*.*

For a DAG $G = (V = [N], E)$, we use $G_{\leq i}$ to denote the subgraph of G induced by $[i]$. In other words, $G_{\leq i} = (V', E')$ for $V' = [i]$ and $E' = \{(a, b) \in E \,|\, a, b \leq i\}$.

The Parallel Random Oracle Model

We review the parallel random oracle model (pROM), as introduced by Alwen and Serbinenko [7]. There exists a probabilistic algorithm $\mathcal{A}^{\mathcal{H}}$ that serves as the main computational unit, where $\mathcal{A}^{\mathcal{H}}$ has access to an arbitrary number of parallel copies of an oracle $\mathcal{H}$ sampled uniformly at random from an oracle set $\mathbb{H}$ and proceeds to do computation in a number of

rounds. In each round i, $\mathcal{A}^{\mathcal{H}}$ maintains a state σ_i along with initial input x. $\mathcal{A}^{\mathcal{H}}$ determines a batch of queries $\mathbf{q}_i$ to send to $\mathcal{H}$, receives and processes the responses to determine an updated state σ_{i+1}. At some point, $\mathcal{A}^{\mathcal{H}}$ completes its computation and outputs the value $\mathcal{A}^{\mathcal{H}}(x)$.

We say that $\mathcal{A}^{\mathcal{H}}$ computes a function $f_{\mathcal{H}}$ on input x with probability ϵ if $\mathbf{Pr}\left[\mathcal{A}^{\mathcal{H}}(x) = f_{\mathcal{H}}\right] \geq \epsilon$, where the probability is taken over the internal randomness of $\mathcal{A}$. We say that $\mathcal{A}^{\mathcal{H}}$ uses t running time if it outputs $\mathcal{A}^{\mathcal{H}}(x)$ after round t. In that case, we also say $\mathcal{A}^{\mathcal{H}}$ uses space $\sum_{i=1}^{t} |\sigma_i|$ and that $\mathcal{A}^{\mathcal{H}}$ makes q queries if $\sum_{i=1}^{t} \leq q$.

The Ideal Cipher Model

In the ideal cipher model (ICM), there is a publicly available random block cipher, which has a κ-bit key K and an N bit input and output. Equivalently, all parties, including any honest parties and adversaries, have access to a family of 2^{κ} independent random permutations of $[N]$. Moreover for any given key K and $x \in [N]$, both encryption $\mathsf{Enc}(K, x)$ and decryption $\mathsf{Dec}(K, x)$ queries can be made to the random block cipher.

Graph Pebbling

The goal of the (black) pebbling game is to place pebbles on all sink nodes of some input directed acyclic graph (DAG) $G = (V, E)$. The game proceeds in rounds, and each round i consists of a number of pebbles $P_i \subseteq V$ placed on a subset of the vertices. Initially, the graph is unpebbled, $P_0 = \emptyset$, and in each round $i \geq 1$, we may place a pebble on $v \in P_i$ if either all parents of v contained pebbles in the previous round ($\mathsf{parents}(v) \subseteq P_{i-1}$) or if v already contained a pebble in the previous round ($v \in P_{i-1}$). In the sequential pebbling game, at most one new pebble can be placed on the graph in any round (i.e., $|P_i \backslash P_{i-1}| \leq 1$), but this restriction does not apply in the parallel pebbling game.

We use $\mathcal{P}_G^{\parallel}$ to denote the set of all valid parallel pebblings of a fixed graph G. The *cumulative cost* of a pebbling $P = (P_1, \ldots, P_t) \in \mathcal{P}_G^{\parallel}$ is the quantity $\mathsf{cc}(P) := |P_1| + \ldots + |P_t|$ that represents the sum of the number of pebbles on the graph during every round. The (parallel) *cumulative pebbling cost* of the fixed graph G, denoted $\mathsf{cc}(G) := \min_{P \in \mathcal{P}_G^{\parallel}} \mathsf{cc}(P)$, is the cumulative cost of the best legal pebbling of G.

▶ **Definition 5** (Dynamic/Static Pebbling Graph)**.** *We define a* dynamic pebbling graph *as a distribution $\mathbb{G}$ over directed acyclic graphs $G = (V = [N], E)$ with edges $E = \{(i-1, i) : i \leq N\} \cup \{(r(i), i) : i \leq N\}$, where $r(i) < i - 1$ is a randomly chosen directed edge. We say that an edge $(r(i), i)$ is* dynamic *if $r(i)$ is not chosen until a black pebbled is place on node $i - 1$. We say that the graph is* static *if none of the edges are dynamic.*

We now define a labeling of a graph G.

▶ **Definition 6.** *Given a DAG $G = (V = [N], E)$ and a random oracle function $H : \Sigma^* \to \Sigma^w$ over an alphabet Σ, we define the labeling of graph G as $L_{G,H} : \Sigma^* \to \Sigma^*$. In particular, given an input x the (H, x) labeling of G is defined recursively by*

$$L_{G,H,x}(v) = \begin{cases} H(v \circ x), & \mathsf{indeg}(v) = 0 \\ H\left(v \circ L_{G,H,x}(v_1) \circ \cdots \circ L_{G,H,x}(v_d)\right), & \mathsf{indeg}(v) > 0, \end{cases}$$

where $v_1, \ldots, v_d$ are the parents of v in G, according to some predetermined lexicographical order. We define $f_{G,H}(x) = L_{G,H,x}(s_1) \circ \ldots \circ L_{G,H,x}(s_k)$, where $s_1, \ldots, s_k$ are the sinks of G sorted lexicographically by node index. If there is a single sink node s_G then $f_{G,H}(x) = L_{G,H,x}(s_G)$. We omit the subscripts G, H, x when the dependency on the graph G and hash function H is clear. For a distribution of dynamic graphs $\mathbb{G}$, we say $f_{\mathbb{G},H}(x) = f_{G,H}(x)$ once a dynamic graph G has been determined from the choice of H and x.

For a node i, we define $\mathsf{PotentialParents}(i)$ to be set Y_i of minimal size such that $\mathbf{Pr}[r(i) \in Y_i] = 1$. We now define k-restricted dynamic graphs, which can characterize both dMHFs and iMHFs.

▶ **Definition 7** (k-Restricted Dynamic Graph). *We say that a dynamic pebbling graph $\mathbb{G}$ is k-restricted if for all i, $\mathsf{PotentialParents}(i) \leq k$.*

Observe that $k = 1$ corresponds to an iMHF while $k = N$ corresponds to a dMHF. Hence, k-restricted dynamic graphs can be viewed as spectrum between dMHFs and iMHFs.

We define the cumulative cost of pebbling a dynamic graph similar to the definition of cumulative cost of pebblings on static graphs. We first require the following definition of a dynamic pebbling strategy:

▶ **Definition 8** (Dynamic Pebbling Strategy). *A dynamic pebbling strategy S is a function that takes as input*
(1) *an integer $i \leq N$*
(2) *an initial pebbling configuration $P_0^i \subseteq [i]$ with $i \in P_0^i$*
(3) *a partial graph $G_{\leq i+1}$*
The output of $S(i, P_0^i, G_{\leq i+1})$ is a legal sequence of pebbling moves $P_1^i, \ldots, P_{r_i}^i$ that will be used in the next phase, to place a pebble on node $i+1$, so that $i+1 \in P_{r_i}^i \subseteq [i+1]$. Given $G \sim \mathbb{G}$ we can abuse notation and write $S(G)$ for the valid pebbling produced by S on the graph G i.e., $P_1^0, \ldots, P_{r_0}^0, P_1^1, \ldots, P_{r_1}^1, \ldots, P_{r_1}^{N-1}, \ldots, P_{r_{N-1}}^{N-1}$. Here, $P_1^i, \ldots, P_{r_i}^i = S(i, P_0^i, G_{\leq i+1})$ where $P_0^i = P_{r_{i-1}}^{i-1}$ and for $i = 1$ we set $P_0^0 = \emptyset$.

We thus define $\mathsf{cc}(S, G)$ to the pebbling cost of strategy S when we sample a dynamic graph G and $\mathsf{cc}(S, \mathbb{G}) = \mathop{\mathbb{E}}_{G \sim \mathbb{G}}[\mathsf{cc}(S, G)]$. Finally, we define $\mathsf{cc}(\mathbb{G}) = \min_S \mathsf{cc}(S, \mathbb{G})$, where the minimum is taken over all dynamic pebbling strategies S. More generally, we define $\mathsf{cc}(S, \mathbb{G}, \delta) = \max\{k : \mathop{\mathbf{Pr}}_{G \in \mathbb{G}}[\mathsf{cc}(S, G) \geq k] \geq 1 - \delta\}$. Fixing δ to be some negligible function of N, we can define $\mathsf{cc}_\delta(\mathbb{G}) = \min_S \mathsf{cc}(S, \mathbb{G}, \delta)$.

3 General Attack Against k-Restricted Graphs

In this section, we describe a general attack against k-restricted graphs. We show that the attack incurs cost $o(N^2)$ for $k = o\left(N^{1/\log\log N}\right)$, proving that there is no maximally memory hard k-restricted graph for small k.

We first require the following formulation of Valiant's Lemma, which shows the existence of a subroutine $\mathsf{Valiant}(G, e, d)$ to find a depth-reducing set S of size at most e within a graph G, for $e = \frac{\eta\delta N}{\log(N) - \eta}$ and $d = \frac{N}{2^\eta}$, where $\eta > 0$.

▶ **Lemma 9** (Valiant's Lemma). *[32] For any DAG $G = (V, E)$ with N nodes, indegree δ, and $\eta > 0$, there exists an efficient algorithm $\mathsf{Valiant}(G, e, d)$ to compute a set S of size $|S| \leq e := \frac{\eta\delta N}{\log(N) - \eta}$ such that $\mathsf{depth}(G - S) \leq d := \frac{N}{2^\eta}$.*

The high level intuition of the generic attack is as follows. By Valiant's Lemma (Lemma 9), $G \sim \mathbb{G}$ is (e, d)-reducible for $e = \frac{\eta\delta N}{\log(N) - \eta}$ and $d = \frac{N}{2^\eta}$. We will construct a dynamic pebbling strategy $\mathcal{A}$ that for all times t, maintains a depth-reducing set S_t such that $\mathsf{depth}(G_t - S_t) \leq d$, where G_t is the portion of G revealed after running $\mathcal{A}$ for time t, $G_t = G_{\leq i}$ for $i = 1 + \max \bigcup_{j=1}^t P_j$, where each $P_j \subseteq [N]$ represents the set of pebbled nodes during round j. Observe that for any i, $G_{\leq i}$ is (e, d)-reducible and hence G_t is also (e, d)-reducible for all times t. Thus, the depth reducing set S_t has size at most e for all times t and can be computed by a subroutine $\mathsf{Valiant}$, by Lemma 9. We now describe how $\mathcal{A}$ maintains this depth-reducing set through a series of *light phases* and *balloon phases*.

We first set a parameter g that we will eventually optimize. The goal of each light phase i is to pebble the next g nodes that have yet to be revealed. That is, if x_i is the largest node for which $\mathcal{A}$ has placed a pebble at some point prior to light phase i, then the goal of light phase i is to pebble the interval $[x_i + 1, x_i + g]$. To begin light phase i at some time t_i, we require that $(\mathsf{PotentialParents}([x_i + 1, x_i + g]) \cup S_{t_i}) \subseteq P_{t_i}$ for some depth-reducing set S_{t_i} of size at most e, such that $\mathsf{depth}(G_{t_i} - S_{t_i}) \leq d$. Once this pre-condition is met, then light phase i simply takes g steps to pebble $[x_i + 1, x_i + g]$, since pebbles are already placed on $\mathsf{PotentialParents}([x_i + 1, x_i + g])$. Hence, the post-condition of light phase i at some time u_i is pebbles on the node $x_i + g$ and some depth-reducing set S_{u_i} of size at most e, such that $\mathsf{depth}(G_{u_i} - S_{u_i}) \leq d$.

The goal of each balloon phase i is to place pebbles on all revealed nodes of the graph, to meet the pre-condition of light phase $i + 1$. To begin balloon phase i at some time r_i, we first have a necessary pre-condition that pebbles are placed on some depth-reducing set S_{r_i} of size at most e such that $\mathsf{depth}(G_{r_i} - S_{r_i}) \leq d$. Once this pre-condition is met, then balloon phase i simply takes d steps to pebble the entire graph G_{r_i}, meeting the post-condition of balloon phase i.

We now formally prove the cumulative memory complexity of the attack in Algorithm 1.

▶ **Theorem 10.** *Let $\mathbb{G}$ be any family of k-restricted dynamic graphs with constant* $\mathsf{indeg}(\mathbb{G})$. *Then*

$$\mathsf{cc}(\mathbb{G}) = \mathcal{O}\left(\frac{N^2}{\log\log N} + N^{2-1/2\log\log N}\sqrt{k^{1-1/\log\log N}}\right).$$

Proof. We analyze the cost of the pebbling strategy of Algorithm 1. Since G is drawn from a distribution of k-restricted dynamic graphs, then for any node x_i, $r(x_i)$ must be one of at most k labels. Thus for any consecutive g nodes, $|\mathsf{PotentialParents}([x_i + 1, x_i + g])| \leq gk$. Hence it suffices to keep gk pebbles on the set of potential parents $\mathsf{PotentialParents}([x_i + 1, x_i + g])$ to pebble the interval $[x_i + 1, x_i + g]$, as well as a depth-reducing set of size at most e, for each of the g steps during light phase i. On the other hand, balloon phase i takes d steps, each of which trivially contains at most N pebbles.

$\mathcal{A}$ proceeds using $\frac{N}{g}$ total rounds of light and balloon phases, by pebbling g consecutive nodes at a time. Therefore, the total cost of the attack is $\mathcal{O}\left(Ngk + Ne + \frac{N}{g} \cdot dN\right)$, where the first and second terms originate from the cost of the light phases and the third term results from the cost of the balloon phases. Since we set $e = \frac{\eta\delta N}{\log(N)-\eta}$ and $d = \frac{N}{2^\eta}$ from Valiant's Lemma (Lemma 9) so that the total cost is $\mathcal{O}\left(\frac{\eta\delta N^2}{\log(N)-\eta} + Ngk + \frac{N^3}{2^\eta g}\right)$. By setting $g = \frac{N}{\sqrt{k2^\eta}}$, the total cost is $\mathcal{O}\left(\frac{N^2\eta\delta}{\log N-\eta} + N^2\sqrt{\frac{k}{2^\eta}}\right)$. Finally, by setting $\eta = \frac{\log k+\log N-\log\delta}{\log\log N}$, the total cost is $\mathcal{O}\left(\frac{N^2}{\log\log N} + N^{2-1/2\log\log N}\sqrt{k^{1-1/\log\log N}}\right)$. ◀

Note that if $k = o(N^{1/\log\log N})$, then $\mathsf{cc}(\mathbb{G}) = o(N^2)$.

▶ **Corollary 11.** *Let $\mathbb{G}$ be any k-restricted dynamic graph with $k = o(N^{1/\log\log N})$ and constant indegree. Then* $\mathsf{cc}(\mathbb{G}) = o(N^2)$.

Algorithm 1 Generic pebbling strategy against dynamic DAG G.

Input: An integer i, an initial pebbling configuration $P_0^i \subseteq [i]$ with $i \in P_0^i$, a partial graph $G_{\leq i+1}$, and parameters d, e, g.
Output: A legal pebbling of $G_{\leq i+1}$.

invariant $\leftarrow$ True
if $i \pmod g \equiv 0$ and $\mathsf{depth}(G_{\leq i+1} - P_0^i) > d$ **then**
    invariant $\leftarrow$ False
else if $\mathsf{depth}(G_{\leq i+1} - P_0^i) > d$ or $\{i\} \cup \mathsf{PotentialParents}([i+1, i+g]) \not\subseteq P_0^i$ **then**
    invariant $\leftarrow$ False
if invariant **then** ▷ If pre-conditions met.
    if $i \pmod g \equiv 0$ **then** ▷ Balloon phase
        for $j = 1$ to $j = d$ **do**
            $P_j^i = P_{j-1}^i \cup D_j$, where D_j are the nodes at depth d from P_0^i.
        $P_{d+1}^i = \mathsf{Valiant}(G_{\leq i}, e, d) \cup \mathsf{PotentialParents}([i+1, i+g])$. ▷ See Lemma 9
    else ▷ Light phase
        $P_1^i = P_0^i \cup \{i+1\}$.
else ▷ If pre-conditions not met.
    for $j = 1$ to $j = i+1$ **do**
        $P_j^i = P_{j-1}^i \cup \{j\}$.

4 k-Restricted Graphs with high CMC

In this section, we describe a construction of k-restricted graphs with high cumulatively memory complexity that builds into our ultimate ciMHF implementation. We first describe the block partition extension gadget, which requires an input graph G and outputs a family of k-restricted dynamic graphs. However, naïvely choosing the input graph G does not yield a construction with high CMC.

Intuitively, the block partition extension gadget takes the last N nodes of G and partitions them into $\frac{N}{k}$ blocks of k nodes each. The gadget then creates N more nodes in a path, such that a parent $r(j)$ of node j in this path is drawn uniformly at random from block i, where $i = j \pmod{\frac{N}{k}}$. The intuition is that by drawing parents uniformly at random from each block in round robin fashion, we encourage an algorithm to keep $\Omega(N)$ nodes on the graph for $\Omega(N)$ steps. Of course, the graph could always maintain $o(n)$ pebbles on the graph and repebble when necessary, but we can discourage this strategy by making the repebbling procedure as expensive as possible.

A first attempt would be to choose a highly depth-robust graph G, such as a grates graph, which informally has long paths of length $\Omega(N^{1-\epsilon})$ for any constant $0 < \epsilon < 1$, even when $\Omega(N)$ nodes are removed from G. Thus if an algorithm does not maintain $\Omega(N)$ pebbles on the graph, the repebbling strategy costs at least $\Omega(N^{2-\epsilon})$. Although this is a good start, this does not quite match the $\Omega(N^2)$ CMC of various dMHFs. We defer full discussion of how to increase the CMC to $\Omega(N^2)$ to later in this section.

Instead, we first define a specific way to obtain a k-restricted dynamic graph given a graph G with N nodes and a parameter k.

▶ **Definition 12** (Block Partition Extension). *Given a DAG $G = (V = [\alpha N], E)$ with αN nodes containing a set of $O = [(\alpha-1)N + 1, \alpha N]$ output nodes of size N and a parameter k, let $O_i = [(\alpha-1)N + 1 + ik, (\alpha-1)N + (i+1)k]$ for $i \in \left[\frac{N}{k}\right]$ so that $\{O_i\}$ forms a partition of O. We define the* block partition extension *of G, denoted $\mathsf{BlockPartition}_k(G)$, as*

a distribution of graphs $\mathbb{G}_{G,k}$*. Each graph* G' *sampled from* $\mathbb{G}$ *has vertices* $V' = [(\alpha+1)N]$ *and edges* $E' = E \cup F$*, where* F *is defined as the edges* $(i-1, i)$ *and* $(r(i), i)$ *for each* $i \in [\alpha N + 1, (\alpha+1)N]$*, where* $r(i)$ *is drawn uniformly at random from* $O_{i \mod \frac{N}{k}}$*.*

An example of the block partition extension is given in Figure 1.

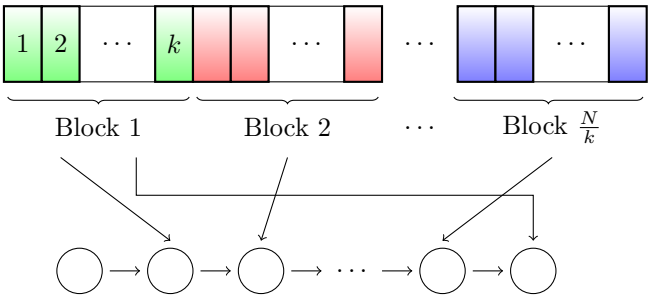

Figure 1 Parent $r(i)$ is drawn uniformly at random from the nodes partitioned to each block.

Our ultimate construction also requires the use of superconcentrator graphs, defined as follows:

▶ **Definition 13.** *A graph* G *with* $\mathcal{O}(N)$ *vertices is a* superconcentrator *if there exists an input set* I *and an output set* O *with* $|I| = |O| = N$ *such that for all* $S_1 \subseteq I, S_2 \subseteq O$ *with* $|S_1| = |S_2| = k$*, there are* k *node disjoint paths from* S_1 *to* S_2*.*

It is known that there exists superconcentrators with $|I| = |O| = N$, constant indegree and $\mathcal{O}(N)$ total nodes [28, 26]. We now show that a set Y, which contains more nodes than a set S of removed nodes, has at least $N - |S|$ ancestors in $G - S$.

▶ **Lemma 14.** *Given a superconcentrator* G *with* N *input nodes* I *and* N *output nodes* O*, let* S *and* $Y \subseteq O$ *be sets of nodes with* $|S| < |Y|$*. Then* $|I \cap \mathsf{ancestors}_{G-S}(Y)| \geq N - |S|$*.*

Proof. Let $X \subseteq I$ be the last $|Y|$ nodes of I. Since G is a superconcentrator, then G contains at least $|Y|$ node disjoint paths between X and Y. Since $|S| < |Y|$, then one of these paths from X to Y that does not intersect S. Thus, X contains some ancestor of Y in $G - S$ and in fact by considering the paths associated with decreasing order of nodes in X, it follows that $|I \cap \mathsf{ancestors}_{G-S}(Y)| \geq N - |S|$. ◀

We require the use of grates graphs $\{\mathsf{grates}_{N,\epsilon}\}_{N=1}^{\infty}$ [30]. For each constant $\epsilon > 0$ and each $N \geq 1$ the graph $\mathsf{grates}_{N,\epsilon} = (V_N, E_{N,\epsilon})$ has $\mathcal{O}(N)$ nodes and constant indegree $\mathsf{indeg}(\mathsf{grates}_{N,\epsilon}) = \mathcal{O}(1)$. Moreover, the graph $\mathsf{grates}_{N,\epsilon}$ contains source nodes $I_N \subset V_N$ and N sinks $O_N \subset V_N$. Given a set $S \subseteq V_N$ of deleted nodes we say that an output node $y \in O_N$ is c-good with respect to S if $\left|I_N \cap \mathsf{ancestors}_{\mathsf{grates}_{N,\epsilon}-S}(y)\right| \geq cN$ i.e., for at least cN input nodes $x \in I_N$ the graph $\mathsf{grates}_{N,\epsilon} - S$ still contains a path from x to y. The grates graph contains several properties summarized below.

▶ **Theorem 15.** *[30] For each* $\epsilon > 0$ *there exist constants* $\gamma, c > 0$ *such that for all* $N \geq 1$ *the graph* $\mathsf{grates}_{N,\epsilon}$ *is* $(\gamma N, cN^{1-\epsilon})$*-depth robust. Furthermore, for each set* $S \subseteq V_N$ *of size* $|S| \leq \gamma N$ *at least* cN *output nodes are still* c*-good with respect to* S*. Formally,*

$$|\{x \in O \ : \ |I_N \cap \mathsf{ancestors}_{G-S}(x)| \geq cN\}| \geq cN \ .$$

We require the use of graph overlays, defined as follows:

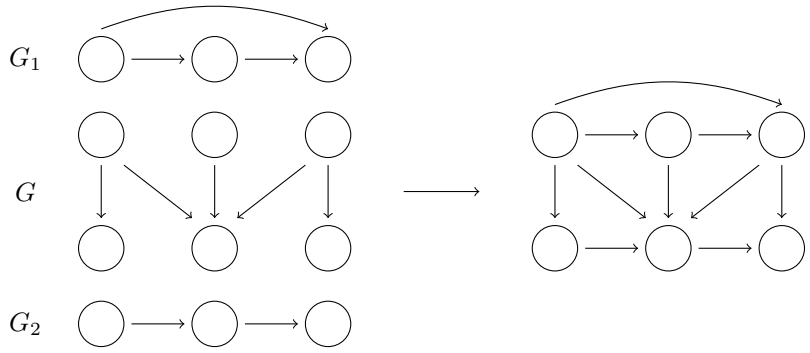

Figure 2 An example of a graph overlay $\mathsf{overlay}(G_1, G, G_2)$.

▶ **Definition 16** (Graph overlays). *Given a DAG $H = (V = [N], E)$ with sources $I = \{1, \ldots, n_1\}$ and sinks $O = \{N - n_2 + 1, \ldots, N\}$, a DAG $G_1 = (V_1 = [n_1], E_1)$, and a DAG $G_2 = (V_2 = [n_2], E_2)$, we define:*

(1) *the* graph overlay $G' = \mathsf{overlay}(G_1, H, G_2)$ *by* $G' = ([N], E')$, *where* $(i, j) \in E'$ *if and only if* $(i, j) \in E$ *or* $(i, j) \in E_1$ *or* $(i + N - n_2, j + N - n_2) \in E_2$

(2) *the* superconcentrator overlay *of an N node DAG G by* $\mathsf{superconc}(G) = \mathsf{overlay}(G, \mathsf{SC}_N, L_N)$, *where SC_N is a superconcentrator with N input (sources) and output (sinks) nodes and L_N is the line graph of N nodes*

(3) *the* grates overlay *of an N node DAG G by* $\mathsf{grates}_\epsilon(G) = \mathsf{overlay}(G, \mathsf{grates}_{N,\epsilon}, L_N)$.

An example of a graph overlay is displayed in Figure 2.

We describe a preliminary attempt at a ciMHF construction in Figure 3. At a high level, the construction consists of four components. The first component is a grates graph G_1 with N nodes. The second component is a superconcentrator overlay with $\mathcal{O}(N)$ nodes, including N input nodes and N output nodes, so that $G_2 = \mathsf{superconc}(G_1)$. The third component consists of a grates overlay with $\mathcal{O}(N)$ nodes including N output nodes, so that $G_3 = \mathsf{grates}_\epsilon(G_2)$. The N output nodes of G_3 are partitioned into $\frac{N}{k}$ blocks, each with k nodes, in preparation for a block partition extension in the final component. Namely, the fourth component consists of a k-restricted graph with N nodes, so that $G_4 = \mathsf{BlockPartition}_k(G_3)$.

Sampling Algorithm, for $k = \Omega(N^\epsilon)$:
(1) $G_1 = \mathsf{grates}_{N,\epsilon}$
(2) $G_2 = \mathsf{superconc}(G_1)$
(3) $G_3 = \mathsf{grates}_\epsilon(G_2)$
(4) $G_4 \sim \mathsf{BlockPartition}_k(G_3)$

Figure 3 First attempt at ciMHF. Each parent $r(i)$ is randomly chosen from the labels in specific block corresponding to i.

The intuition for the $\Omega(N^2)$ cumulative pebbling complexity is as follows. Suppose there exists a time t_{bad} with a "small" number of pebbles on the graph. Then with high probability, walking a pebble $s = \frac{N}{4k}$ steps on the final layer of the graph will require some number of output nodes of the grates graph to be repebbled. Again with high probability, repebbling one of these output nodes requires a large number of input nodes of the grates graph to be repebbled. These input nodes are the output nodes of the superconcentrator at the second layer. The superconcentrator property then implies that $\Omega(N)$ nodes of the grates graph

on the first layer will need to be repebbled. For a grates graph that is $(\Omega(N), \Omega(N^{1-\epsilon}))$-depth robust, this cost is at least $\Omega(N^{2-\epsilon})$ every s steps. Thus, the total cost is at least $\min\left(\Omega(N^2), k\Omega(N^{2-\epsilon})\right)$, which is just $\Omega(N^2)$ for $k = \Omega(N^\epsilon)$.

We now show that our construction in Figure 3 has cumulative memory complexity $\Omega(N^2)$.

▶ **Theorem 17.** *Let G be drawn from the distribution of k-restricted graphs in Figure 3, for $k = \Omega(N^\epsilon)$. There exist constants $c_1 > 0$ and $c_2 \in (0,1)$ such that for any dynamic pebbling strategy S,*

$$\Pr_{\mathbb{G}}\left[\mathsf{cc}(S,G) > c_1 N^2\right] \geq 1 - c_2^{N/k}.$$

Proof. Let αN be the total number of nodes in G_3 so that the total number of nodes in G is $(\alpha+1)N$. Let $x, y \in (0,1)$ be constants such that the grates graph G_1 is $(xN, yN^{1-\epsilon})$-depth robust. By Theorem 15, there exist constants $0 < c < \frac{x}{2}$ and $0 < \gamma < c$ such that for any set S with $|S| \leq \gamma N$, at least cN nodes in the output nodes of G_3 are c-good with respect to S. For each node i, let t_i be the first time that node i is pebbled. Suppose there exists a time t_{bad} with $t_i \leq t_{\mathsf{bad}} < t_{i+1}$ such that there are $|P_{t_{\mathsf{bad}}}| < \frac{\gamma N}{4}$ pebbles on the graph.

For a node j in the output set $[(\alpha-1)N, \alpha N]$ of G_3, we call an index j a *costly index* if j is c-good with respect to $P_{t_{\mathsf{bad}}}$ and let COSTLY be the set of costly indices. Note that if a node $i \in \mathsf{COSTLY}$, then by definition $i \notin P_{t_{\mathsf{bad}}}$. By Theorem 15 and the observation that $|P_{t_{\mathsf{bad}}}| < \frac{\gamma N}{4}$, there are at least cN nodes in the output set of G_3 are c-good with respect to $P_{t_{\mathsf{bad}}}$, i.e., $|\mathsf{COSTLY}| > cN$. Then for $s := \frac{N}{k}$, we call $j \in [i, i+s]$ a *missed costly index* if $r(j) \notin P_{t_{\mathsf{bad}}}$ and let $r(j) \in \mathsf{COSTLY}$.

For each $j \in \left[\frac{N}{k}\right]$, let c_j be the number of costly indices in block j of the output set of G_3, i.e., $c_j := |\mathsf{COSTLY} \cap [(\alpha-1)N + (j-1)k + 1, (\alpha-1)N + jk]|$. Since the parents of $[i, i+s]$ are exactly one random node from each of the $\frac{N}{k}$ blocks, then the probability p that no parent of $[i, i+s]$ is a missed costly index is

$$p := \prod_{j=1}^{N/k}\left(1 - \frac{c_j}{k}\right) \leq \left(\frac{k}{N}\sum_{j=1}^{N/k}\left(1 - \frac{c_j}{k}\right)\right)^{N/k},$$

where the inequality holds by the Arithmetic Mean-Geometric Mean Inequality. Since $\sum c_j = cN$, then

$$p \leq \left(1 - \frac{k}{N}\sum_{j=1}^{N/k}\frac{c_j}{k}\right)^{N/k} \leq (1-c)^{N/k}.$$

Thus with high probability, there will be some missed costly index.

By Lemma 14 and the definition of c-good, any missed costly index requires cN nodes in the input set of G_3 to be repebbled. Since the input set of G_3 is connected by a superconcentrator to the output set of G_1, the cN nodes in the input set of G_3 that need to be repebbled have at least $N - cN$ ancestors in the output set of G_1. Thus, at least $N - cN - |P_{t_{\mathsf{bad}}}|$ nodes in G_1 must be repebbled.

Because G_1 is $(xN, yN^{1-\epsilon})$-depth robust, then $G_1 - S$ is $(xN - |S|, yN^{1-\epsilon})$-depth robust for any set S. Moreover, the cost to pebble $G_1 - S$ is at least $(xN - |S|)(yN^{1-\epsilon})$. In particular, if $G_1 - S$ is the set of nodes in G_1 must be repebbled, then it costs at least $(xN - cN - |P_{t_{\mathsf{bad}}}|)(yN^{1-\epsilon})$ to repebble $G_1 - S$. Since $c < \frac{x}{2}$ and $|P_{t_{\mathsf{bad}}}| < \frac{\gamma N}{4} < \frac{cN}{4} < \frac{xN}{8}$, then the cost is at least $\frac{3xy}{8}N^{2-\epsilon}$.

Hence to pebble an interval $[i, i+s]$ with $s = \frac{N}{k}$, either $\frac{\gamma N}{4}$ pebbles are kept on the graph for all $s = \frac{N}{k}$ steps or if we at any point in time $j \in [i, i+s]$ we have $|P_j| \leq \gamma N/4$ then (whp) an the pebbling algorithm incurs cost $\frac{3xy}{8}N^{2-\epsilon}$ to repebble the graph during the next s steps $[j, j+s]$. By partitioning the last N nodes of the graph G into k disjoint intervals of length $\frac{N}{k}$, it follows that the total cost is at least $\min\left(\frac{\gamma N^2}{4}, \frac{3}{16}xykN^{2-\epsilon}\right)$. Thus for $k = \Omega(N^{\epsilon})$, the total cost is $\Omega(N^2)$ with high probability. ◀

▶ **Corollary 18.** *Let G be drawn from the distribution of k-restricted graphs in Figure 3, for $k = \Omega(N^{\epsilon})$. Then $\mathsf{cc}(G) = \Omega(N^2)$.*

5 k-Restricted Graphs: Amenable to Shuffling

In this section, we introduce a useful property for certain dynamic graphs: amenable to shuffling. In Section 6, we will describe computationally data-independent evaluation algorithms for evaluating memory hard function based on dynamic graphs that are amenable to shuffling.

5.1 Characterization of Dynamic Graphs Amenable to Shuffling

We first describe the properties of dynamic graphs that are amenable to shuffling. Recall that for a node i, we define $\mathsf{PotentialParents}(i)$ to be set Y_i of minimal size such that $\mathbf{Pr}[r(i) \in Y_i] = 1$, where $r(i) < i - 1$ is randomly chosen so that the directed edge $(r(i), i)$ is in the dynamic graph.

▶ **Definition 19** (Amenable to Shuffling)**.** *Let G be a DAG with αN nodes for some constant $\alpha > 1$ and let L be the last N nodes of G. Suppose that L can be partitioned into $\frac{N}{k}$ groups $G_1, \ldots, G_{\frac{N}{k}}$ such that*

(1) *Uniform Size of Groups: $|G_i| = k$ for all $i \in \left[\frac{N}{k}\right]$.*
(2) *Large Number of Potential Parents: For each $v \in L$, $|\mathsf{PotentialParents}(u)| = k$.*
(3) *Potential Parents not in L: For each $v \in L$, $\mathsf{PotentialParents}(u) \subseteq [(\alpha - 1)N]$*
(4) *Same Potential Parents for Each Group: For all $i \in \left[\frac{N}{k}\right]$ and $u, v \in G_i$, $\mathsf{PotentialParents}(u) = \mathsf{PotentialParents}(v)$.*
(5) *Different Potential Parents for Different Groups: For all $i, j \in \left[\frac{N}{k}\right]$ with $i \neq j$, let $u \in G_i$ and $v \in G_j$. Then $\mathsf{PotentialParents}(u) \cap \mathsf{PotentialParents}(v) = \emptyset$.*
(6) *No Collision for Parents: For each $i \in \left[\frac{N}{k}\right]$, define the event UNIQUE_i to be the event that $r(u) \neq r(v)$ for all $u, v \in G_i$. Then $\mathbf{Pr}[\mathsf{UNIQUE}_i] = 1$ for all $i \in \left[\frac{N}{k}\right]$.*
(7) *Data-Independency: The subgraph induced by the first $(\alpha - 1)N$ nodes is a static graph.*

Then we call G amenable to shuffling.

We shall show in Theorem 24 in Section 6 that dynamic graphs that are amenable to shuffling can be used for memory hard functions with computationally data-independent evaluation algorithms. We now describe a version of Figure 3 that is amenable to shuffling.

5.2 Version of Construction Amenable to Shuffling

To ensure that there does not exist $i \neq j$ such that $r(i) = r(j)$, we slightly modify the construction of block partition extensions to the concept of a collision-resistant block partition extension. For the sake of presentation, note that we use $2N$ output nodes in G in the following definition.

▶ **Definition 20** (Collision-Resistant Block Partition Extension). *Given a DAG $G = (V = [\alpha N], E)$ with αN nodes containing a set of $O = [(\alpha-2)N+1, \alpha N]$ output nodes of size $2N$ and a parameter k, let $O_i = [(\alpha-2)N+1+2ik, (\alpha-2)N+2(i+1)k]$ for $i \in \left[\frac{N}{k}\right]$ so that $\{O_i\}$ forms a partition of O. We define the* collision-resistant block partition extension *of G, denoted $\mathsf{CR}-\mathsf{BlockPartition}_k(G)$, as a distribution of graphs $\mathbb{G}_{G,k}$. Each graph G' sampled from $\mathbb{G}$ has vertices $V' = [(\alpha+1)N]$ and edges $E' = E \cup F$, where F is defined as the edges $(i-1, i)$ and $(r(i), i)$ for each $i \in [\alpha N+1, (\alpha+1)N]$, where $r(i)$ is defined as follows:*

(1) *Let* Enc *be the family of all permutations of $[2k]$, so that for each fixed j,*

$$\{\mathsf{Enc}(j,\ell)\}_{\ell\in[2k]} = [2k]\,.$$

(2) *For each $i \in [\alpha N+1, (\alpha+1)N]$, let $j = i \mod \frac{N}{k}$ and define $1 \le p \le k$ to be the unique integer such that $i = \frac{N}{k}(p-1) + \alpha N i + j$. Then we define $r(i) = (\alpha-2)N + 1 + 2jk + \mathsf{Enc}(x \circ j, p)$, so that $r(i) \in O_j$.*

Observe that the collision-resistant block partition extension is a gadget that yields a dMHF, since the parent function $r(i)$ has the key $x \circ j$ to its permutation function Enc. Hence, the underlying dynamic graph differs across different input values x.

Then our construction of the ciMHF appears in Figure 4 and Figure 5. As before, the construction consists of four layers. The first layer consists of a grates graph with $2N$ nodes, $G_1 = \mathsf{grates}_{2N,\epsilon}$. The second layer consists of a superconcentrator overlay with $\mathcal{O}(N)$ nodes with $2N$ input nodes and $2N$ output nodes, so that $G_2 = \mathsf{superconc}(G_1)$. The third layer consists of a grates overlay with $\mathcal{O}(N)$ nodes including $2N$ output nodes, so that $G_3 = \mathsf{grates}_{\epsilon}(G_2)$. The $2N$ output nodes of G_3 are partitioned into $\frac{N}{k}$ blocks, each with $2k$ nodes, which allows the final layer to be a $2k$-restricted grpah. In particular, the fourth layer uses a collision-free block partition extension rather than the block partition extension of Figure 3.

Sampling algorithm, for $k = \Omega(N^{\epsilon})$:
(1) $G_1 = \mathsf{grates}_{2N,\epsilon}$
(2) $G_2 = \mathsf{superconc}(G_1)$
(3) $G_3 = \mathsf{grates}_{\epsilon}(G_2)$
(4) $G_4 \sim \mathsf{CR}-\mathsf{BlockPartition}_k(G_3)$

Figure 4 Second attempt at ciMHF. Each parent $r(i)$ is chosen by a permtuation of the labels in specific block corresponding to i. The underlying graph is visualized in Figure 5.

We now show that the construction of Figure 4 has cumulative cost $\Omega(N^2)$ with high probability. The proof is almost verbatim to Theorem 17 except that the graph overlays now have $2N$ input and output nodes.

▶ **Theorem 21.** *Let $0 < \epsilon < 1$ be a constant and $k = \Omega(N^{\epsilon})$. Let $\mathbb{G}$ be drawn from the distribution of $2k$-restricted graphs in Figure 4. There exist constants $c_1 > 0$ and $c_2 \in (0,1)$ such that for any dynamic pebbling strategy S,*

$$\Pr_{G\in\mathbb{G}}\left[\mathsf{cc}(S,G) > c_1 N^2\right] \ge 1 - c_2^{N/k}.$$

▶ **Corollary 22.** *Let $\mathbb{G}$ be drawn from the distribution of $2k$-restricted graphs in Figure 4, for $k = \Omega(N^{\epsilon})$. Then $\mathsf{cc}(\mathbb{G}) = \Omega(N^2)$.*

Finally, we observe that the construction of Figure 4 is amenable to shuffling since it satisfies the properties of Definition 19.

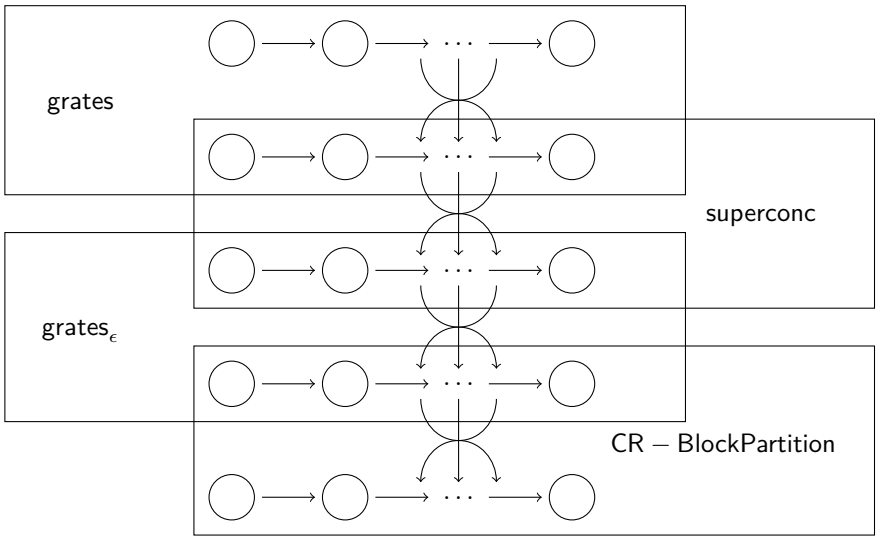

Figure 5 Final construction of Figure 4.

6 Implementation of ciMHF

In this section, we describe how to implement our construction in a way that is computationally data-independent. We first formalize the notion of computationally data-independent and then describe the system model we utilize.

6.1 Computationally Data-Independent MHF (ciMHF) and Systems Model

We define the security of a computationally data-independent memory hard function in terms of the following game: a side-channel attacker $\mathcal{A}$ selects two inputs x_0, x_1 and sends these inputs to an honest party $\mathcal{H}$. We first require the following definition of leakage patterns.

Leakage Pattern

We define the leakage pattern of an evaluation algorithm MHF.Eval by the sequence of request and store instructions made in each round. Specifically, in each round r, an attacker can observe from the leakage pattern the blocks of memory to be loaded into cache, as requested by MHF.Eval. Let $i = (i_1, \ldots, i_m)$ be the sequence of locations of all blocks requested by MHF.Eval in a particular round r through some command load(i). If i is completely contained in cache, then no events will be observed by the attacker. Otherwise, if i is not completely contained in cache, we use request$_r$ to denote the locations of the blocks in memory, as well as their sizes, requested by MHF.Eval in round r. Similarly, we use store$_r$ to denote the locations of the blocks, as well as their sizes, stored into memory by MHF.Eval in round r. We do not allow the attacker to observe the contents of the requested or stored blocks. Formally, the leakage pattern LP is the information $\{(\text{request}_r, \text{store}_r)\}_{r=1}^{t}$ and is dependent on the algorithm MHF.Eval, random oracle H, internal randomness R, and input value x.

Computationally Data-Independency Game

$\mathcal{H}$ runs a (randomized) evaluation algorithm MHF.Eval on both inputs x_0 and x_1, yielding two leakage patterns LP_0 and LP_1, where LP_i for $i \in \{0,1\}$ depends on both the input x_i and the random coins selected during the execution of MHF.Eval. $\mathcal{H}$ then picks a random challenge bit $b \in \{0,1\}$ and sends $\mathsf{LP}_b, \mathsf{LP}_{1-b}$ to $\mathcal{A}$ to simulate a side-channel. The goal of $\mathcal{A}$ is to predict b i.e., match each input with the corresponding leakage pattern. For a secure ciMHF we guarantee that *any* PPT side-channel attacker $\mathcal{A}$ wins the game with only negligible advantage over random guessing.

Formally, the game consists of three phases **setup**, **challenge**, and **guess**, which are described as follows.

Data independency game for ciMHF:

setup In this phase, $\mathcal{A}$ selects the security parameter λ and two challenge messages x_0 and x_1 and sends them to $\mathcal{H}$. Here we assume without loss of generality that the runtime of the evaluation algorithm MHF.Eval on x_0 and x_1 are the same.

challenge In this phase, $\mathcal{H}$ selects a random bit $b \in \{0,1\}$ and random coins $R_0, R_1 \in \{0,1\}^\lambda$ uniformly at random and then samples $\mathsf{lp}_0 \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_0; R_0))$ and $\mathsf{lp}_1 \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_1; R_1))$. $\mathcal{H}$ sends the ordered pair $(\mathsf{lp}_b, \mathsf{lp}_{1-b})$ to $\mathcal{A}$.

guess After receiving $(\mathsf{lp}_b, \mathsf{lp}_{1-b})$, the adversary $\mathcal{A}$ outputs b' as a guess for b. The adversary wins the game if $b = b'$.

The advantage of the adversary to win the game of computationally data independency of the given MHF is defined as

$$Adv^{\mathsf{ind-lp-iMHF}}_{\mathcal{A},\mathsf{MHF}} = \left| \frac{1}{2} - \Pr[\mathcal{A}(x_0, x_1, \mathsf{lp}_b, \mathsf{lp}_{1-b}) = b' : b = b')] \right|,$$

where $\mathsf{lp}_i = \mathsf{LP}(x_i; \mathsf{MHF.Eval}(x_i; R_i))$.

▶ **Definition 23** (Computational data independency)**.** *An evaluation algorithm* MHF.Eval *is computationally data independent if for all non-uniform circuits $\mathcal{A} = \{\mathcal{A}_\lambda\}_{\lambda \in \mathbb{N}}$, there is a negligible function* $\mathsf{negl}(\cdot)$ *such that* $Adv^{\mathsf{ind-lp-iMHF}}_{\mathcal{A},\mathsf{MHF}} < \mathsf{negl}(\lambda)$.

With the proper random coins, a memory-hard function with an evaluation algorithm that satisfies the above definition reveals only a negligible amount of information through its leakage patterns, and we thus call such a function a computationally data-independent memory hard function.

On the Definition of Computational Data Independency

In section Section 6.2.2 we show that the definition is equivalent to a multi round version of the game in which the attacker can adaptively select the challenge $x_{i,0}, x_{i,1}$ in each round $i \leq r$ after observing $\mathsf{lp}_{i-1,b}, \mathsf{lp}_{i-1,1-b}$ – the memory access patterns from the last round. We also prove that the two security notions are asymptotically equivalent when the attacker runs in polynomial time – in terms of concrete security parameters we lose a factor of r (number of challenge rounds) in the reduction.

We are primarily motivated by the password hashing application where the inputs x_0 and x_1 come from a small domain, as user selected passwords tend to have low entropy [18]. In practice it is reasonable to assume that r is polynomial i.e., if the user only authenticates

poly(λ) times then there are at most $r = \text{poly}(\lambda)$ memory access patterns for the attacker to observe. Assuming that the input domain has size poly(λ) a brute-force attacker cannot use the leaked memory access pattern on input x to eliminate any candidate password x' with high probability, otherwise the attacker could have used the pair x and x' to win the data independency game.

However, in settings where the input domain is very large and r is super-polynomial it will be better to adopt a concrete security definition (see Section 6.2.2). The asymptotic definition in Definition 23 does not definitively rule out the possibility that an attacker can substantially narrow the search space after many (super-polynomial) side channel attacks. For example, suppose that the attacker gets to observe $\mathsf{lp}_i \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x; R_i))$ for $i = 1, \ldots, 2^\lambda$, i.e., 2^λ independent evaluations of MHF on secret input x. Supposing that $Adv^{\mathsf{ind-lp-iMHF}}_{\mathcal{A},\mathsf{MHF}} = 2^{-\lambda}$ and that the input domain for MHF has size $2^{2\lambda}$, it is possible that each lp_i allows the attacker to eliminate a random subset of $Adv^{\mathsf{ind-lp-iMHF}}_{\mathcal{A},\mathsf{MHF}} \times 2^{2\lambda} = 2^\lambda$ candidate inputs, allowing the attacker to find x after just $\mathcal{O}\left(\lambda 2^\lambda\right)$ examples. However, in practice it will usually be reasonable to assume that the attacker gets to observe lp_i a polynomial number of times i.e., the honest party will execute $\mathsf{LP}(\mathsf{MHF.Eval}(x; R_i))$ at most poly(λ) times.

Memory Architecture Assumptions

We consider a tiered random access memory architecture with main memory (RAM) and working memory (cache). We assume that main memory (RAM) is a shared resource with other untrusted processes, each of which have their own cache. Although the operating system kernel will enforce memory separation, i.e., only our program has some region of memory and that other processes cannot read/write to this block, it is also possible that an untrusted process will be able to infer the memory address of read/write operations in RAM (due to side-channel effects).

Formally, the system allows programs access to two operations $\mathsf{Write}(i, x)$, which takes an address i within the memory allocated to the program and writes the value x at address i, and $\mathsf{Read}(i)$ which loads the data at location i. When an operation requests memory at location i, there are two possible outcomes. Either the data item is already in cache or the data item is not in cache. In the second case, the location of the item in memory is revealed through the leakage pattern. Hence, the leakage pattern is either $\perp$, if the data item is already in cache, or i, if the data item is not in cache.

Cache Replacement Policy

We now show that our implementation of the dynamic pebbling construction with cumulative memory cost $\Omega(N^2)$ is computationally data-independent. In particular, we provide an evaluation algorithm whose leakage pattern is computationally indistinguishable under each of the following cache replacement policies:

Least recently used (LRU) This policy tracks the most recent time each item in cache was used and discards the least recently used items first when cache is full and items need to be replaced.

First in first out (FIFO) This policy evicts the first item that was loaded into cache, ignoring how recent or how often it has been accessed.

6.2 ciMHF Implementation

Recall from the definition of a graph labeling in Definition 6 that given a function H and a distribution of dynamic graphs $\mathbb{G}$, the goal is to compute $f_{\mathbb{G},H}(x)$ for some input x, which is equivalent to $f_{G,H}(x)$ once the graph G has been determined by the choice of H and x. In this section, we describe a computationally data-independent implementation of the construction of Section 5.2.

We implement the first three layers as data-independent components. Namely, the grates graph G_1, its superconcentrator overlay G_2 and the subsequent grates overlay G_3 can be implemented deterministically. Observe that G_3 has αN nodes, including $2N$ output nodes O that are partitioned into $\frac{N}{k}$ blocks of size $2k$ each. Specifically $O = O_1 \cup \ldots \cup O_{\frac{N}{k}}$, where $O_j = [(\alpha-2)N + 1 + 2jk, (\alpha-2)N + 2(j+1)k]$ for $j \in \left[\frac{N}{k}\right]$.

As stated in Figure 4, the collision-resistant block partition extension G_4 is actually data-independent, since for each $i \in [(\alpha-1)N, \alpha N]$, each parent $r(i)$ of i is chosen uniformly at random from k possible nodes, but the random procedure is independent of the input x. Hence, the challenge is to implement a computationally data-independent version of the collision-resistant block partition extension. We demand the input of a key K for each computation of $f_{G,H}(x)$. The value of $f_{G,H}(x)$ remains the same across all keys K but the leakage pattern is different for each K.

Data-Dependent Dynamic Graph

For each $i \in [\alpha N + 1, (\alpha+1)N]$, let $j = i \mod \frac{N}{k}$. To implement a computationally data-independent version of G_4 from Figure 4, we use the value of $L_{G,H,x}(i-1)$ to select a previously "unused" node of O_j as the parent $r(i)$ for i that is not $i-1$. Here, we say a node $v \in O_j$ is unused if it is not the parent of any node besides $v+1$ and i.

Since $L_{G,H,x}(i-1)$ can be viewed as a random integer modulo $2k$, we can use $L_{G,H,x}(i-1) \pmod{2k}$ as an input to a permutation with key K to randomly choose the parent of i from O_j. Observe that $i = \alpha N + j$ is the first time a parent will be selected from O_j. Moreover, observe that $m = L_{G,H,x}(i-1) \pmod{2k} + 1$ can be viewed as a random number from $[2k]$ so we set $r(i) = m + (\alpha-2)N + 1 + 2jk$ as the m^{th} entry of O_j.

Now if $L_{G,H,x}(i-1) \pmod{2k}$ were all unique across the values of $\{i | i \mod \frac{N}{k} \equiv j\}$, then there would be no collisions among selections of parents in O_j and we would be done. However, since these values are not unique, we must do a little more work to avoid collisions, which would reveal information through leakage patterns about the parents of two nodes being the same. To ensure there are no collisions in O_j among parents, we store an array U_j of size $2k$ for each block O_j. For each $1 \le \ell \le 2k$, we initialize $U_j[\ell] = \ell$. The purpose of the U_j array is to ensure that the nodes of O_j that have already appeared as parents are at the end of U_j. In the above example when $r(i) = m + (\alpha-2)N + 1 + 2jk$, we then set $U_j[m] = 2k$ and $U_j[2k] = m$. Then in the next round of selecting a parent from O_j, we choose uniformly at random from the first $2k-1$ entries of U_j and in general, for the s^{th} round of selecting a parent from O_j, we choose uniformly at random from the first $2k-s+1$ entries of U_j.

Specifically for some $2 \le s \le k$, consider the s^{th} iteration in which a parent is selected from O_j. That is, for $i = \alpha N + j + (s-1)\frac{N}{k}$, the parent $r(i)$ is the s^{th} parent among the nodes of O_j. Observe that $m = L_{G,H,x}(i-1) \pmod{2k-s+1}$ can be viewed as a random number from $[2k-s+1]$ and so $U_j[m]$ is a random entry among the unselected $2k-s+1$ nodes of O_j. We then swap the values of $U_j[m]$ and $U_j[2k-s+1]$ so that if $U_j[m] = a$ and $U_j[2k-s+1] = b$ previously then we set $U_j[m] = b$ and $U_j[2k-s+1] = a$. Hence, the invariant remains that the first $2k-s$ locations of U_j have been unused.

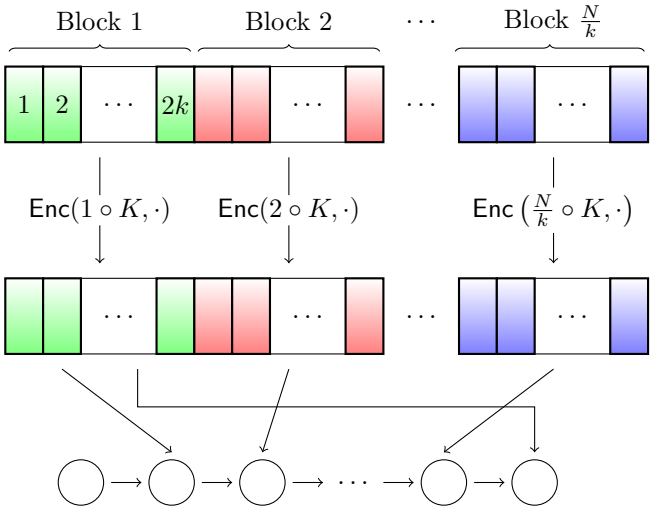

Figure 6 Parent $r(i)$ is drawn uniformly at random from the nodes partitioned to each block.

Shuffling Leakage Patterns

Finally, we point out that the leakage pattern across all computations of $f_{G,H}(x)$ is still the same, since we have not actually incorporated the key K in any of the above details. In summary, the above the description ensures a collision-resistant block partition extension that is data-dependent, but is still vulnerable to side-channel attacks. Hence, we add a final element to our implementation that shuffles the locations of each node $p \in O_j$ inside O_j. That is, for each $1 \leq j \leq \frac{N}{k}$, we use the keyed permutation Enc to store the label of $p \in O_j$ in the location that corresponds to $\mathsf{Enc}(j \circ K, p)$ instead. Thus if $r(i) = p \in O_j$ for some node i, the algorithm must look at the location associated with $\mathsf{Enc}(j \circ K, p)$ to learn the value of $L_{G,H,x}(p)$. Therefore, the underlying graph G is a dynamic graph that is data-dependent but the leakage pattern across each computation of $f_{G,H}(x)$ is different due to the choice of K that shuffles the locations of all labels in each block O_j. A high level example of this shuffling is shown in Figure 6.

Observe that this shuffling must be done completely in the cache to avoid leaking locations of labels during the shuffling. Hence, we require cache eviction policies such as the least recently used (LRU) or first in first out (FIFO) cache eviction policies to ensure that the entire block O_j will remain in cache as the shuffling is performed. We describe the implementation in full in Figure 7.

A Note on Oblivious RAM

The complications with the cache eviction policies and shuffling leakage patterns originate from the necessity of not divulging information in the data-independency game. One reasonable question is whether these complications can be avoided with other implementations that conceal the leakage patterns. For example, an algorithm using oblivious RAM (ORAM), introduced by Goldreich and Ostrovsky [23], reveals no information through the memory access patterns about the underlying operations performed. Thus, an algorithm using an ORAM data structure to evaluate a memory hard function would induce a computationally independent memory hard function, regardless of whether the underlying function is data-

Computationally data-independent sequential evaluation algorithm $\mathsf{MHF.Eval}(x; R)$ to compute $f_{G,H}(x)$ for any k-restricted dynamic graph G that is amenable to shuffling.

(1) Data-independent phase:
- **a.** Let G be a k-restricted dynamic graph with αN nodes for some constant $\alpha > 1$ that is amenable to shuffling, L be the last N nodes of G, and H be an arbitrary hash function.
- **b.** Let $K = \mathsf{Setup}(1^\lambda; R)$ be a hidden random permutation key for each computation of $f_{G,H}(x)$, given the security parameter λ and random bits R.
- **c.** Recall that the subgraph induced by the first $(\alpha - 1)N$ nodes is a static graph. Compute the label $L_{G,H,x}(v)$ for each node $v \in (G - L)$.

(2) Shuffling phase:
- **a.** Since G is amenable to shuffling, L can be partitioned into groups $G_1, \ldots, G_{\frac{N}{k}}$ that satisfy the definition of Definition 19. For each $j \in \left[\frac{N}{k}\right]$, let $O_j = \mathsf{PotentialParents}(G_j)$.
- **b.** For each $j \in \left[\frac{N}{k}\right]$, shuffle the contents of O_j:
  - **i.** Let $v_1, \ldots, v_k$ be the vertices in O_j.
  - **ii.** Load the labels $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k)$ into cache.
  - **iii.** Shuffle the positions of $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k)$ so that for each $p \in [k]$, $L_{G,H,x}(v_p)$ is in the location that previously corresponded to $L_{G,H,x}(v_q)$, where $q = \mathsf{Enc}(j \circ K, p)$, where Enc is a keyed pseudorandom permutation of k.

(3) Data-dependent phase:
- **a.** For each $j \in \left[\frac{N}{k}\right]$, initialize an array U_j such that for all $1 \le \ell \le k$, $U_j[\ell] = \ell$.
- **b.** For each $i = \alpha N + 1$ to $(\alpha + 1)N$:
  - **i.** Let j and s be defined so that $1 \le s \le k$ and $1 \le j \le \frac{N}{k}$ given $i = \alpha N + j + (s-1)\frac{N}{k}$ and let $m = L_{G,H,x}(i-1) \pmod{k - s + 1} + 1$.
  - **ii.** Set $r(i) = U_j[m] + (\alpha - 1)N + 1 + jk$ so that $r(i) \in O_j$ and load $L_{G,H,x}(r(i))$. (Recall that the label of $r(i)$ is actually located at the position where the label of node $\mathsf{Enc}(j \circ K, U[m])$ was previously located prior to the shuffling.)
  - **iii.** Load $L_{G,H,x}(r(i))$ and $L_{G,H,x}(i-1)$ and compute $L_{G,H,x}(i) = H(i \circ L_{G,H,x}(r(i)) \circ L_{G,H,x}(i-1))$.
  - **iv.** Let $U_j[U_j[m]] = a$ and $U_j[k - s + 1] = b$. Then swap the values of U_j at $U_j[m]$ and $k - s + 1$ so that $U_j[U_j[m]] = b$ and $U_j[k - s + 1] = a$.

Figure 7 Description of evaluation algorithm for k-restricted graphs that are amenable to shuffling. Note that each computation of $f_{G,H}(x)$ requires as input random bits R to generate the leakage patterns.

dependent or data-independent. [23] describe an oblivious RAM simulator that transforms any program in the standard RAM model into a program in the oblivious RAM model, where the leakage pattern is information theoretically hidden, which is ideal for the data-independency game.

Existing constructions of ORAM protocols such as Path ORAM [31] require amortized $\Omega(\log N)$ bandwidth overhead. Hence given any dMHF and evaluation algorithm running in sequential time M, we can use ORAM to develop a new evaluation algorithm with a concealed leakage pattern, running in sequential time $N = M \log M$. However, this is not ideal because the cumulative memory complexity of the dMHF is $\mathcal{O}\left(M^2\right) = \mathcal{O}\left(\frac{N^2}{\log^2 N}\right)$. Viewed in this way, the ciMHF construction is worse than known iMHF constructions that achieve CMC $\Omega\left(\frac{N^2}{\log N}\right)$ such as DRSample [4, 11]. In fact, even for k-restricted graphs,

we still obtain a blow-up of $\Omega(\log^2 K)$, which is $\Omega\left(\frac{\log^2 N}{\log^2 \log N}\right)$ when $k = \Omega(N^{1/\log\log N})$. Otherwise for $k = o(N^{1/\log\log N})$, our dynamic pebbling attack in Corollary 11 shows that the CMC is at most $o(N^2)$.

Although Boyle and Naor [20] proposed the notion of *online* ORAM, where the operations to be performed arrive in an online manner, and observe that the lower bounds of [23] do not hold for online ORAM, Larsen and Nielsen [25] answer this open question by proving an amortized $\Omega(\log N)$ bandwidth overhead lower bound on the bandwidth of any online ORAM. Therefore, it does not seem obvious how to use ORAM in the implementations of maximally hard ciMHFs.

6.2.1 Implementation and Analysis

Hybrid:

(1) Data-independent phase:
- **a.** Let G be a k-restricted dynamic graph with αN nodes for some constant $\alpha > 1$ that is amenable to shuffling, L be the last N nodes of G, and H be an arbitrary hash function.
- **b.** Let $K = \mathsf{Setup}(1^\lambda; R)$ be a hidden random permutation key for each computation of $f_{G,H}(x)$, given the security parameter λ and random bits R.
- **c.** Recall that the subgraph induced by the first $(\alpha - 1)N$ nodes is a static graph. Compute the label $L_{G,H,x}(v)$ for each node $v \in (G - L)$.

(2) Shuffling phase:
- **a.** Since G is amenable to shuffling, L can be partitioned into groups $G_1, \ldots, G_{\frac{N}{k}}$ that satisfy the definition of Definition 19. For each $j \in \left[\frac{N}{k}\right]$, let $O_j = \mathsf{PotentialParents}(G_j)$.
- **b.** For each $j \in \left[\frac{N}{k}\right]$, shuffle the contents of O_j:
  - **i.** Let $v_1, \ldots, v_k$ be the vertices in O_j.
  - **ii.** Load the labels $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k)$ into cache.
  - **iii.** Shuffle the positions of $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_k)$ so that for each $p \in [k]$, $L_{G,H,x}(v_p)$ is in the location that previously corresponded to $L_{G,H,x}(v_q)$, where $q = \mathsf{Enc}(j \circ K, p)$, where Enc is a keyed truly random permutation of k.

(3) Data-dependent phase:
- **a.** For each $j \in \left[\frac{N}{k}\right]$, initialize an array U_j such that for all $1 \leq \ell \leq k$, $U_j[\ell] = \ell$.
- **b.** For each $i = \alpha N + 1$ to $(\alpha + 1)N$:
  - **i.** Let j and s be defined so that $1 \leq s \leq k$ and $1 \leq j \leq \frac{N}{k}$ given $i = \alpha N + j + (s-1)\frac{N}{k}$ and let $m = L_{G,H,x}(i-1) \pmod{k - s + 1} + 1$.
  - **ii.** Set $r(i) = U_j[m] + (\alpha - 1)N + 1 + jk$ so that $r(i) \in O_j$ and load $L_{G,H,x}(r(i))$. (Recall that the label of $r(i)$ is actually located at the position where the label of node $\mathsf{Enc}(j \circ K, U[m])$ was previously located prior to the shuffling.)
  - **iii.** Load $L_{G,H,x}(r(i))$ and $L_{G,H,x}(i-1)$ and compute $L_{G,H,x}(i) = H(i \circ L_{G,H,x}(r(i)) \circ L_{G,H,x}(i-1))$.
  - **iv.** Let $U_j[U_j[m]] = a$ and $U_j[k - s + 1] = b$. Then swap the values of U_j at $U_j[m]$ and $k - s + 1$ so that $U_j[U_j[m]] = b$ and $U_j[k - s + 1] = a$.

Figure 8 Description of hybrid. Differs from Figure 7 in that the hidden input key is used to index into the entire family of random permutations, rather than a pseudorandom permutation.

We require the hybrid in Figure 8 to argue that our implementation of Figure 4 is a ciMHF. The hybrid in Figure 8 differs from the implementation of Figure 4 in Figure 7 in that the hidden input key is used to index from the entire family of random permutations, rather than a pseudorandom permutation. Thus the only way an adversary can distinguish between the hybrid and the real world sampler is by distinguishing between a random permutation and a pseudorandom permutation. On the other hand, if an adversary fails to distinguish between the hybrid and the real world sampler, then the cumulative memory complexity of the implementation requires $\Omega(N^2)$ since the leakage pattern of the hybrid is statistically equivalent to the dMHF construction in Figure 4, where each parent is chosen a priori using a permutation drawn uniformly at random.

▶ **Theorem 24.** *For each DAG G that is amenable to shuffling, there exists a computationally data-independent sequential evaluation algorithm* $\mathsf{MHF.Eval}(x; R)$ *computing the function $f_{\mathbb{G},H}$ in time $\mathcal{O}(N)$.*

Proof. Consider the evaluation function in Figure 7. Observe that the hybrid in Figure 8 has the same distribution of leakage patterns as the dMHF of Figure 4. Moreover, under the least recently used (LRU) or first in first out (FIFO) cache eviction policies, if k is less than the size of the cache, then all the shuffling can be performed so an attacker observing the leakage patterns of the hybrid has no advantage in the data-independency game. Furthermore, the ciMHF implementation in Figure 7 only differs from the hybrid in Figure 8 in the implementation of Enc as a pseudorandom permutation compared to a truly random permutation. Therefore, an attacker observing leakage patterns from the implementation in Figure 7 only obtains a negligible advantage $\mathsf{negl}(\lambda)$ in the security parameter λ, in the data-independency game. Hence, the implementation of Figure 7 is a ciMHF. ◀

We now show that the evaluation function in Figure 7 of the dMHF in Figure 4 is a maximally hard ciMHF.

▶ **Theorem 25.** *Let $0 < \epsilon < 1$ be a constant and $k = \Omega(N^\epsilon)$. Then there exists a family $\mathbb{G}$ of k-restricted graphs with $\mathsf{cc}(\mathbb{G}) = \Omega(N^2)$ that is amenable to shuffling. Moreover, there exists a negligible value $\delta = \mathsf{negl}(N)$ such that $\mathsf{cc}_\delta(\mathbb{G}) = \Omega(N^2)$.*

Proof. Consider the evaluation function in Figure 7 of the dMHF in Figure 4. For the sake of completeness, the full implementation is also shown in Figure 9. Since the construction of Figure 4 is amenable to shuffling, then the evaluation algorithm is a ciMHF by Theorem 24. Finally by Theorem 21, $\mathsf{cc}(\mathbb{G}) = \Omega(N^2)$.

In fact, Theorem 21 implies that for $G \in \mathbb{G}$ drawn uniformly at random and any pebbling strategy S, not only is $\mathop{\mathbb{E}}_{G\sim\mathbb{G}}[\mathsf{cc}(S, G)] = \Omega(N^2)$, but also $\mathsf{cc}(S, G) = \Omega(N^2)$ with probability at least $1-c^{N/k}$ for some constant $0 < c < 1$. Thus for $\delta = 1-c^{N/k}$, we have $\mathsf{cc}(S, \mathbb{G}, \delta) = \Omega(N^2)$ for any pebbling strategy S and so $\mathsf{cc}_\delta(\mathbb{G}) = \Omega(N^2)$. ◀

For the sake of completeness, we give the evaluation algorithm for the maximally hard ciMHF in Figure 9.

Computationally data-independent sequential evaluation algorithm $\mathsf{MHF.Eval}(x; R)$

(1) Let H be an arbitrary hash function and $K = \mathsf{Setup}(1^\lambda; R)$ be a hidden random permutation key for each computation of $f_{\mathbb{G},H}(x)$, given the security parameter λ and random bits R. Let $k = \Omega(N^\epsilon)$.

(2) Data-independent phase:

- **a.** $G_1 = \mathsf{grates}_{2N,\epsilon}$
- **b.** $G_2 = \mathsf{superconc}(G_1)$
- **c.** $G_3 = \mathsf{grates}_\epsilon(G_2)$, which has αN total nodes, including $2N$ output nodes $O = O_1 \cup \ldots \cup O_{\frac{N}{k}}$, where $O_j = [(\alpha-2)N+1+2ik, (\alpha-2)N+2(j+1)k]$ for $j \in \left[\frac{N}{k}\right]$.
- **d.** Compute the label $L_{G_3,H,x}(v)$ for each node $v \in G_3$.

(3) Shuffling phase:

- **a.** Let G be the graph G_3 appended with N additional nodes, so that $V = [(\alpha+1)N]$, and edges $(i-1, i)$ for each $\alpha N + 1 \leq i \leq (\alpha+1)N$.
- **b.** For each $j \in \left[\frac{N}{k}\right]$, shuffle the contents of O_j:
  - **i.** Let $v_1, \ldots, v_{2k}$ be the vertices in O_j.
  - **ii.** Load the labels $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_{2k})$ into cache.
  - **iii.** Shuffle the positions of $L_{G,H,x}(v_1), \ldots, L_{G,H,x}(v_{2k})$ so that for each $p \in [2k]$, $L_{G,H,x}(v_p)$ is in the location that previously corresponded to $L_{G,H,x}(v_q)$, where $q = \mathsf{Enc}(j \circ K, p)$, where Enc is a keyed pseudorandom permutation of $2k$.

(4) Data-dependent phase:

- **a.** For each $j \in \left[\frac{N}{k}\right]$, initialize an array U_j such that for all $1 \leq \ell \leq 2k$, $U_j[\ell] = \ell$.
- **b.** For each $i = \alpha N + 1$ to $(\alpha+1)N$:
  - **i.** Let j and s be defined so that $1 \leq s \leq k$ and $1 \leq j \leq \frac{N}{k}$ given $i = \alpha N + j + (s-1)\frac{N}{k}$ and let $m = L_{G,H,x}(i-1) \pmod{2k-s+1} + 1$.
  - **ii.** Set $r(i) = U_j[m] + (\alpha-2)N + 1 + 2jk$ so that $r(i) \in O_j$ and load $L_{G,H,x}(r(i))$. (Recall that the label of $r(i)$ is actually located at the position where the label of node $\mathsf{Enc}(j \circ K, U[m])$ was previously located prior to the shuffling.)
  - **iii.** Load $L_{G,H,x}(r(i))$ and $L_{G,H,x}(i-1)$ and compute $L_{G,H,x}(i) = H(i \circ L_{G,H,x}(r(i)) \circ L_{G,H,x}(i-1))$.
  - **iv.** Let $U_j[U_j[m]] = a$ and $U_j[2k-s+1] = b$. Then swap the values of U_j at $U_j[m]$ and $2k-s+1$ so that $U_j[U_j[m]] = b$ and $U_j[2k-s+1] = a$.

Figure 9 Description of implementation of *maximally hard* ciMHF. Again note that each computation of $f_{G,H}(x)$ requires as input random bits R to generate the leakage pattern.

6.2.2 Extension to Multiple Rounds

Finally, we show that our ciMHF implementation is robust to multiple rounds of leakage by considering a data independency game where an adversary is allowed to submit and observe multiple adaptive queries before outputting a guess for the hidden challenge bit b. The game again consists of the phases **setup**, **challenge**, and **guess**, which are described as follows.

Adaptive data independency game for ciMHF:

setup In this phase, $\mathcal{A}$ selects the security parameter λ and sends it to $\mathcal{H}$. $\mathcal{H}$ then selects a random bit $b \in \{0,1\}$.

challenge For each round $i = 1, 2, \ldots$, $\mathcal{A}$ chooses two adaptive query messages $x_{i,0}$ and $x_{i,1}$ and sends the query messages to $\mathcal{H}$. $\mathcal{H}$ selects random coins $R_{i,0}, R_{i,1} \in \{0,1\}^\lambda$ uniformly at random, samples $\mathsf{lp}_{i,0} \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_{i,0}; R_{i,0}))$ and $\mathsf{lp}_{i,1} \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_{i,1}; R_{i,1}))$, and sends the ordered pair $(\mathsf{lp}_{i,b}, \mathsf{lp}_{i,1-b})$ to $\mathcal{A}$. Note: $\mathcal{A}$ can pick $x_{i+1,0}$ and $x_{i+1,1}$ adaptively after observing the response $(\mathsf{lp}_{i,b}, \mathsf{lp}_{i,1-b})$.

guess The game ends when the adversary $\mathcal{A}$ outputs b' as a guess for b. $\mathcal{A}$ wins the game if $b = b'$.

As before, the advantage of the adversary to win the adaptive data independency game for ciMHF is:

$$Adv^{\mathsf{ind-mult-lp-iMHF}}_{\mathcal{A},\mathsf{MHF}} = \left| \frac{1}{2} - \mathbf{Pr}\left[\mathcal{A}(\mathcal{T}) = b' : b = b')\right] \right|,$$

where $\mathcal{T}$ is the transcript $\{x_{i,0}, x_{i,1}, \mathsf{lp}_{i,b}, \mathsf{lp}_{i,1-b}\}$ and $\mathsf{lp}_{i,j} = \mathsf{LP}(x_{i,j}; \mathsf{MHF.Eval}(x_{i,j}; R_{i,j}))$.

▶ **Definition 26.** *We say an evaluation algorithm* MHF.Eval *has (t,ϵ)-single security if any attacker running in time t has at most advantage ϵ in the data independency game. Similarly, we say an evaluation algorithm* MHF.Eval *has (t,r,ϵ)-adaptive security if any attacker running in time t and making r queries has at most advantage ϵ in the adaptive data independency game.*

We conclude by noting the following relationship between single security and adaptive security, thus implying the security of our evaluation function in Figure 7 of the dMHF in Figure 4 with respect to the adaptive data independency game.

▶ **Theorem 27.** *(t,ϵ)-single security implies $(t - \mathcal{O}(r \cdot \mathsf{time}(\mathsf{MHF.Eval})), r, r\epsilon)$-adaptive security.*

Proof. Suppose that $\mathsf{A}_{adaptive}$ violates $(t - \mathcal{O}(r \cdot \mathsf{time}(\mathsf{MHF.Eval})), r, r\epsilon)$-adaptive security for the sake of contradiction. Without loss of generality we will assume that $\mathsf{A}_{adaptive}$ outputs $b' = b$ with probability greater than $\frac{1}{2} + r\epsilon$. We will use $\mathsf{A}_{adaptive}$ to construct an attacker A_{single} that violates (t,ϵ)-single security.

We first define a sequence of r hybrids in the adaptive data-independency game. In Hybrid i, the challenger $\mathcal{H}$ picks bits $b, b_1, \ldots, b_{i-1}$ uniformly at random and sets $b_i = b, b_{i+1} = b, \ldots, b_r = b$. In round j when the attacker $\mathsf{A}_{adaptive}$ submits two strings $x_{j,0}$ and $x_{j,1}$, the challenger $\mathcal{H}$ samples $\mathsf{lp}_{j,0} \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_{j,0}; R_{j,0}))$ and $\mathsf{lp}_{j,1} \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_{j,1}; R_{j,1}))$ and then responds with $\mathsf{lp}_{j,b_i}, \mathsf{lp}_{j,1-b_i}$ instead of $\mathsf{lp}_{j,b}$ and $\mathsf{lp}_{j,1-b}$ i.e., the bit b_i is used to permute the order of the responses in round i instead of b.

Observe that in Hybrid 1, $b_1 = \ldots = b_r = b$, so that Hybrid 1 is equivalent to the actual adaptive independency game. Similarly, in Hybrid r, the bits $b_1, \ldots, b_r$ are all picked independently so that $\mathsf{A}_{adaptive}$ working in Hybrid r has no advantage i.e., the attacker guesses $b' = b$ correctly with probability at most $\mathbf{Pr}[b' = b \mid \text{Hybrid } r] = \frac{1}{2}$. We observe that the advantage of the attacker is

$$\mathbf{Pr}[b' = b \mid \text{Hybrid } 1] - \frac{1}{2} = \mathbf{Pr}[b' = b \mid \text{Hybrid } 1] - \mathbf{Pr}[b' = b \mid \text{Hybrid } r] = \Delta_2 + \ldots + \Delta_r\,,$$

where $\Delta_i = \mathbf{Pr}[b' = b \mid \text{Hybrid } i-1] - \mathbf{Pr}[b' = b \mid \text{Hybrid } i]$. By an averaging argument, we must have $\Delta_{i+1} > \epsilon$ for some $i < r$. The following observation will also be useful:

$$\Delta_{i+1} = \frac{1}{2}\mathbf{Pr}[b' = b \mid \text{Hybrid } i] - \frac{1}{2}\mathbf{Pr}[b = b' \mid \text{Hybrid } i+1, b_i \neq b]\,.$$

Reduction

We now define A_{single} as follows: (1) A_{single} simulates $\mathsf{A}_{adaptive}$ along with the adaptive challenger $\mathcal{H}_{adaptive}$. A_{single} generates random bits $b_1, \ldots, b_{i-1}$ and sets $b_{i+1} = \ldots = b_r = b''$ for another random bit b''. In each round $j \neq i$, when $\mathsf{A}_{adaptive}$ outputs a query $x_{j,0}, x_{j,1}$, our attacker A_{single} simply computes $\mathsf{lp}_{i,0} \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_{i,0}; R_{i,0}))$ and $\mathsf{lp}_{i,1} \leftarrow \mathsf{LP}(\mathsf{MHF.Eval}(x_{i,1}; R_{i,1}))$ and responds with $\mathsf{lp}_{i,b_i}, \mathsf{lp}_{i,1-b_i}$. When $\mathsf{A}_{adaptive}$ outputs the query $x_{i,0}, x_{i,1}$ in round i, A_{single} forwards this query to the challenger for the single stage challenger $\mathcal{H}_{single}$ and receives back $\mathsf{lp}_{i,b}, \mathsf{lp}_{i,1-b}$ for an unknown bit b selected by $\mathcal{H}_{single}$. Finally, when $\mathsf{A}_{adaptive}$ outputs a guess b' (for b'') A_{single} outputs the same guess b' (for b).

Analysis

Notice that since b'' is just a bit selected uniformly at random and independent from b, then $\mathbf{Pr}[b' = b'' \,|b'' = b] = \mathbf{Pr}[b' = b'' \mid \text{Hybrid } i]$. Then from the above observation, we have $\mathbf{Pr}[b' = b'' \,|b'' \neq b] = \mathbf{Pr}[b' = b'' \mid \text{Hybrid } i+1, b_i \neq b''] = \mathbf{Pr}[b' = b''| \text{ Hybrid } i] - 2\Delta_{i+1}$. It follows that $\mathbf{Pr}[b' = b'' \mid b'' = b] - \mathbf{Pr}[b' = b'' \,|b'' \neq b] = 2\Delta_{i+1}$. Thus, the probability that A_{single} wins is

$$\begin{aligned}\mathbf{Pr}[b' = b] &= \mathbf{Pr}[b'' = b]\,\mathbf{Pr}[b' = b'' \mid b'' = b] + \mathbf{Pr}[b'' \neq b]\,(1 - \mathbf{Pr}[b' = b'' \,|b'' \neq b]) \\ &= \frac{1}{2} + \Delta_{i+1} > \epsilon.\end{aligned}$$

Furthermore, the running time of A_{single} is at most t. This contradicts the assumption that the evaluation algorithm $\mathsf{MHF.Eval}$ has (t, ϵ)-single security. Therefore, (t, ϵ)-single security implies $(t - \mathcal{O}(r \cdot \mathsf{time}(\mathsf{MHF.Eval})), r, r\epsilon)$-adaptive security. ◀

Abstract

Let F be a multivariate function from a product set Σ^n to an Abelian group G. A k-partition of F with cost δ is a partition of the set of variables $\boldsymbol{V}$ into k non-empty subsets $(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ such that $F(\boldsymbol{V})$ is δ-close to $F_1(\boldsymbol{X}_1) + \cdots + F_k(\boldsymbol{X}_k)$ for some $F_1, \ldots, F_k$ with respect to a given error metric. We study algorithms for agnostically learning k partitions and testing k-partitionability over various groups and error metrics given query access to F. In particular we show that

1. Given a function that has a k-partition of cost δ, a partition of cost $O(kn^2)(\delta + \varepsilon)$ can be learned in time $\tilde{O}(n^2 \operatorname{poly} 1/\varepsilon)$ for any $\varepsilon > 0$. In contrast, for $k = 2$ and $n = 3$ learning a partition of cost $\delta + \varepsilon$ is NP-hard.
2. When F is real-valued and the error metric is the 2-norm, a 2-partition of cost $\sqrt{\delta^2 + \varepsilon}$ can be learned in time $\tilde{O}(n^5/\varepsilon^2)$.
3. When F is $\mathbb{Z}_q$-valued and the error metric is Hamming weight, k-partitionability is testable with one-sided error and $O(kn^3/\varepsilon)$ non-adaptive queries. We also show that even two-sided testers require $\Omega(n)$ queries when $k = 2$.

This work was motivated by reinforcement learning control tasks in which the set of control variables can be partitioned. The partitioning reduces the task into multiple lower-dimensional ones that are relatively easier to learn. Our second algorithm empirically increases the scores attained over previous heuristic partitioning methods applied in this context.

1 Introduction

Divide-and-conquer methods rely on the ability to identify independent sub-instances of a given instance, such as connected components of graphs and hypergraphs. When these are not available one looks for partitions into loosely related parts like small or sparse cuts. These classic problems and their variants remain at the forefront of algorithmic research [6, 7, 16, 20, 24, 29].

We study the related problem of function decomposition: Given a multivariate function $F(\boldsymbol{V})$ over n variables $\boldsymbol{V} = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$, we seek to partition the variables into k groups $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k$ so that F decomposes into a sum $F_1(\boldsymbol{X}_1) + \cdots + F_k(\boldsymbol{X}_k)$. In case an exact decomposition of this type is unavailable, we seek an approximate one under a suitable error metric. This algebraic partitioning question can be sensibly asked for any Abelian group. While some of our results are quite general, two particular cases of interest are addition over $\mathbb{Z}_2$ with respect to the Hamming metric and addition over reals with respect to the 2-norm.

As a multivariate function is an exponentially large object, it is sensible to model the input F to the partitioning problem as an oracle and allow query access to it. This departs from the common setup in (hyper)graph partitioning problems, where an explicit representation of the input is assumed to be available. While variable partitioning of real-valued functions under the 2-norm turns out to be closely related to hypergraph partitioning, the difference in input access models renders certain techniques developed for the latter (e.g., random contractions) inapplicable to our setting.

Our work is motivated by learning control variables in high-dimensional reinforcement learning control [25, 33, 34]. If the *advantage function* of the control variables can be partitioned into multiple lower-dimensional subsets, then these subsets of variables can be learned independently with a relatively easier Monte-Carlo sampling. This advantage function involves the estimates of a dynamic system, which is complex enough to not have an explicit representation available. The function is thus treated as an oracle as is in our access model. Sometimes it is natural to assume that the function should be almost decomposable; for example, if we seek to control two robots jointly performing a task, the variables controlling the respective robots are almost independent. (The robots may be collaborating so the decomposition might not be perfect.) In general, the dependencies are not known in advance but need to be learned from observed behavior. Some heuristic methods have been applied to control variable partitioning [23, 36] but not rigorously analyzed.

Our contributions

Our main results are algorithmic: We show that variable partitions can be learned agnostically.

Let $F(\boldsymbol{V})$ be a function from some product set to an Abelian group G. A direct sum decomposition of F is a partition $(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ of the set of variables $\boldsymbol{V}$ such that $F(\boldsymbol{V})$ is $F_1(\boldsymbol{X}_1) + \cdots + F_k(\boldsymbol{X}_k)$ for some functions $F_1, \ldots, F_k$. When the decomposition is imperfect, the decomposition error is measured by

$$\delta(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k) = \min_{F_1,\ldots,F_k} \|F(X_1, \ldots, X_k) - F_1(X_1) - \cdots - F_k(X_k)\|, \tag{1}$$

where $\|\cdot\| \colon G \to \mathbb{R}^+$ is a partial norm. The definition is given in Section 2; the main examples of interest are $G = \mathbb{Z}_q$ under the Hamming metric $\|F\| = \Pr[F(V) = 0]$ and $G = \mathbb{R}$ under the p-norm $\|F\|_p = \mathbb{E}\big[|F(V)|^p\big]^{1/p}$ for any $p \geq 1$ under some product measure. We seek an approximation of the best-possible partition, which minimizes the objective

$$\delta_2(F) = \min_{\boldsymbol{X}} \delta(\boldsymbol{X}, \overline{\boldsymbol{X}}), \tag{2}$$

Notation	Meaning	Notation	Meaning
$\boldsymbol{x}, \boldsymbol{y} \in \boldsymbol{V}$	variables	$\delta_k(F)$	optimal k-partition error
$\boldsymbol{X}, \boldsymbol{Y}, \overline{\boldsymbol{X}} \subseteq \boldsymbol{V}$	sets of variables	$D_F(\boldsymbol{X}, \boldsymbol{Y})$	dependence score
x, y, X, Y	(random) assignment	$\|\cdot\|, \|\cdot\|_{\mathbb{R},p}$	partial norm and p-norm

for bipartition and

$$\delta_k(F) = \min_{\boldsymbol{X}_1,\ldots,\boldsymbol{X}_k} \delta(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k). \tag{3}$$

for k-partition. (For p-norms over $\mathbb{R}$ we use the notations $\|\cdot\|_{\mathbb{R},p}$, $\delta_{\mathbb{R},2}(F)$, and $\delta_{\mathbb{R},k}(F)$.)

▶ **Theorem 1.** *Let $\|\cdot\|$ be either 1) $\|\cdot\|_{\mathbb{R},p}$ assuming $\|F\|_{\mathbb{R},2p} = O(1)$, or 2) the Hamming metric over $\mathbb{Z}_q$. There is an algorithm that given parameters n, k, ε, γ, and oracle access to $F\colon \Sigma^n \to \mathbb{R}$ outputs a k-partition $\mathcal{P}$ such that $\delta(\mathcal{P}) \le O(kn^2)(\delta_k(F) + \varepsilon)$ with probability at least $1 - \gamma$. The algorithm makes $O(K^p n^2 \log(n/\gamma)/\varepsilon^{2p})$ queries to F and runs in time linear in the number of queries, for an absolute constant K.*

This algorithm is closely related to the heuristic ones used in the aforementioned empirical studies. However, it only guarantees optimality up to an $O(kn^2)$ approximation factor. While we do not know if an approximation factor of this magnitude is inevitable, in Proposition 17 we show that obtaining a solution with additive error is NP-hard. The proofs are given in Section 4.

In contrast, our second algorithm obtains an additive error for bipartitions of real-valued functions under the 2-norm:

▶ **Theorem 2.** *Let $F\colon \Sigma^n \to \mathbb{R}$ be a function with $\|F\|_{\mathbb{R},4} \le 1$. There is an algorithm that given inputs n, ε, γ, and oracle access to F, runs in time $O(n^5 \log(n/\gamma)/\varepsilon^2)$ and outputs a bipartition $(\boldsymbol{X}, \overline{\boldsymbol{X}})$ such that $\delta_{\mathbb{R},2}(\boldsymbol{X}, \overline{\boldsymbol{X}})^2 \le \delta_{\mathbb{R},2}(F)^2 + \varepsilon$ with probability at least $1 - \gamma$.*

More generally, we give evidence that it may be possible to output a $\sqrt{2 - 2/k}$-approximate k-partition in time $\mathrm{poly}(n^k, k, 1/\varepsilon)$ (Corollary 21). For unbounded k finding a good approximation is ETH hard (Corollary 19).

Theorem 2 and Corollary 19 are based on an equivalence between variable partitioning under the 2-norm and hypergraph partitioning given in Proposition 18. The results are described and proved in Section 5.

As a consequence of Theorem 1, the property of being close to a k-partition is testable with $\tilde{O}(k^{2p} n^{4p+2}/\varepsilon^{2p})$ queries. The query complexity of the tester can be somewhat improved:

▶ **Theorem 3.** *k-partitionability is testable with one-sided error and $O(kn^3/\varepsilon)$ non-adaptive queries with respect to Hamming weight over $\mathbb{Z}_q$, and with $O(k^{2p} n^3/\varepsilon^{2p})$ non-adaptive queries with respect to the p-norm over $\mathbb{R}$ assuming $\|F\|_{2p} \le 1$.*

In Section 6 we prove Theorem 3 and show that $\Omega(n - k)$ queries are necessary even for two-sided error testers.

Ideas and techniques

Our Theorem 1 is inspired by algebraic property testing techniques. The starting point is the dual characterization of partitionability into sets $(\boldsymbol{X}, \overline{\boldsymbol{X}})$ by the constraints $D_F(\boldsymbol{X}, \boldsymbol{Y}) = 0$, where $D_F = F(X, Y) - F(X', Y) - F(X, Y') + F(X', Y')$, for all assignments X, X' to $\boldsymbol{X}$ and

Y, Y' to $\boldsymbol{Y}$. David et al. [10] apply this relation to random inputs towards testing whether a $\mathbb{Z}_2$-valued function F tensors decomposes into a direct sum. The acceptance probability of this test approximates the best decomposition to within a factor of 4 (Proposition 4).

Our partitioning algorithm estimates the *dependence score* $\|D_F(\boldsymbol{x}, \boldsymbol{y})\|$ on every pair of variables $\boldsymbol{x}, \boldsymbol{y}$ (keeping the rest fixed) to decide whether they should be partitioned or not. Here, $\|D_F\|$ is the probability that the test $D_F = 0$ fails for discrete groups like $\mathbb{Z}_2$. In general, it can represent any error metric satisfying the axioms in Section 2. The proof of Theorem 1 amounts to showing that a collection of single variable partitions $(\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{P}$ for which the local scores $\|D_F(\boldsymbol{x}, \boldsymbol{y})\|$ are small can be glued together into a single k-partition $\mathcal{P}$ with a small global score.

When F is real-valued and error is measured under the 2-norm, variable partitioning has a natural geometric interpretation. Functions that depend on different coordinates are orthogonal modulo their constant term, so the optimal decomposition with respect to a fixed partition $(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ is given by the projection of F onto the respective subspaces of functions. This yields an equality between the distance and the dependence score (6) for bipartitions and a generalization to k-partitions (Proposition 8). Variable partitioning for functions is then equivalent to hypergraph partitioning of their orthogonal decompositions (Proposition 18), with the cost of cut $(\boldsymbol{X}, \overline{\boldsymbol{X}})$ given by $\frac{1}{4}\|D_F(\boldsymbol{x}, \boldsymbol{y})\|^2$.

This connection suggests the application of hypergraph partitioning algorithms that can be implemented with access to an *approximate* cut oracle[2], leading to Theorem 2. On the negative side it reveals that approximately optimal partitions into a large number of components are hard to find (Corollary 19).

Application to reinforcement learning control

We plug our partitioning algorithm back to reinforcement learning control. In this setting, the oracle is real-valued and as we adapt the 2-norm we use the submodularity cut algorithm described in Theorem 2.

We compare empirically with three previous approaches: The baseline that does not involve partitioning [25,35]; the baseline that trivially partitions n variables into n subsets [22,36]; the work that partitions the variables heuristically [23]. The way [23] partitions the variables is to calculate the discrete estimate of the Hessian of the oracle. Then they remove from Hessian the elements with lowest absolute values, until it forms at least k connected components if the Hessian matrix is treated as the adjacency matrix.

The scores we attained on the tasks in the physics simulator are improved over these approaches, which is demonstrated in Section 7.

Relation to other learning and testing problems

A j-junta is a function that depends on at most j of its n variables. The problems of learning and testing juntas have been extensively studied [2,4,8,9,13,26,30]. While a j-junta is always $(n - j + 1)$-partitionable, the two problems are technically incomparable. Moreover, juntas are usually studied in the regime where the junta size j is significantly smaller than the number of variables n and are therefore partitionable into many (mostly trivial) components.

[2]Several state-of-the-art algorithms for cuts in graphs and hypergraphs rely on random contractions [6, 17, 18]. In particular, Rubinstein et al. [29] showed that $\tilde{O}(n)$ queries to an *exact* cut oracle and similar running time are sufficient to find the minimum cut. We do not know if comparable efficiency can be obtained with an approximate oracle.

In this work we are mostly interested in partitions into two or a small number of components. Nevertheless, this connection between juntas and partitionable functions is used to prove the testing lower bound in Section 6.

Dinur and Golubev [12] showed that the existence of decomposition with respect to a fixed k-partition (given as input) is testable with four queries and soundness error $\Omega(\delta)$. The case $k = 2$ was already analyzed by David et al. [10] (see Section 3).

2 Some additional definitions

Let $F(\boldsymbol{V})$ be a function from some product set to an Abelian group G. In general we will assume that the variables $\boldsymbol{V}$ take values in some set Σ endowed with a product measure which is efficiently sampleable. The quality of the partition $(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ of $\boldsymbol{V}$ is measured by $\delta(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ given in (1), where $\|\cdot\| \colon G \to \mathbb{R}^+$ can be any functional satisfying the following three axioms:

1. $\|0\| = 0$;
2. $\|F_1 + F_2\| \leq \|F_1\| + \|F_2\|$;
3. $\mathbb{E}[\|F(X, \cdot)\| \mid X] \leq \|F\|$ for any set of variables X of F.

Our goal is to approximately optimize $\delta_2(F)$ in (2) and $\delta_k(F)$ in (3).

Our algorithms are based on the following dependence estimator inspired by the rank-1 test of [10]. Let $\boldsymbol{X}$ and $\boldsymbol{Y}$ be two disjoint sets of variables. The dependence estimator $D_F(\boldsymbol{X}, \boldsymbol{Y})$ is the random variable

$$D_F = F(X, Y, Z) + F(X', Y', Z) - F(X', Y, Z) - F(X, Y', Z)$$

where X, X' are independent samples of the $\boldsymbol{X}$ variable, Y, Y' are independent samples of the $\boldsymbol{Y}$ variable, and Z is a random sample of the remaining variables. If F decomposes into a direct sum that partitions the $\boldsymbol{X}$ and $\boldsymbol{Y}$ variables then D_F equals zero. Conversely, $\|D_F\|$ measures the quality of the approximation.

In the analysis it will be convenient to use the notation $F \approx_\delta G$ for $\|F - G\|_p \leq \delta$. The following two facts are immediate consequences of axioms 2 and 3:

Triangle inequality: If $F \approx_\delta G$ and $G \approx_{\delta'} H$ then $F \approx_{\delta+\delta'} H$.

Fixing: If $F(X, Z) \approx_\delta G(X, Z)$ then $F(\underline{X}, Z) \approx_\delta G(\underline{X}, Z)$ for some fixed value $\underline{X}$.

3 Estimating the quality of a partition

In this section we show that $\|D_F(\boldsymbol{X}, \boldsymbol{Y})\|$ is an approximate estimator for the quality $\delta(\boldsymbol{X}, \boldsymbol{Y})$ of a decomposition, namely

$$\delta(\boldsymbol{X}, \boldsymbol{Y}) \leq \|D_F(\boldsymbol{X}, \boldsymbol{Y})\| \leq 4 \cdot \delta(\boldsymbol{X}, \boldsymbol{Y}). \tag{4}$$

The proof is given in Claims 5 and 6 below. As $\|D_F(\boldsymbol{X}, \boldsymbol{Y})\|$ can be estimated efficiently from oracle access to F (Claim 7), we obtain an algorithm for estimating the quality of a partition to within a factor of 4 in general, and exactly for the 2-norm over $\mathbb{R}$.

▶ **Proposition 4.** *Let $\|\cdot\|$ be either 1) $\|\cdot\|_{\mathbb{R},p}$ assuming $\|F\|_{\mathbb{R},2p} = O(1)$, or 2) the Hamming metric over $\mathbb{Z}_q$. There is an algorithm that given a bipartition $\boldsymbol{X}, \boldsymbol{Y}$ of the variables and parameters $\varepsilon, \gamma > 0$, outputs a value $\hat{\delta}$ such that*

$$\delta(\boldsymbol{X}, \boldsymbol{Y}) \leq \hat{\delta} \leq 4 \cdot \delta(\boldsymbol{X}, \boldsymbol{Y}) + \varepsilon,$$

with probability at least $1 - \gamma$ from $K^p \log(1/\gamma)/\epsilon^{2p}$ queries to F in time linear in the number of queries, for an absolute constant K.

The value of $\delta(\boldsymbol{X}, \boldsymbol{Y})$ is known to be NP-hard to calculate exactly over $\mathbb{Z}_2$ under the Hamming metric given explicit access to the truth-table of f [28]. Therefore some approximation factor is unavoidable for algorithms running in time polynomial in n and $1/\varepsilon$ unless BPP is in NP. On the positive side Karpinski and Schudy [19] give a fully polynomial-time randomized approximation scheme for this special case. Their algorithm requires at least linear time but it is plausible that a sublinear-time variant can be obtained. However, it appears unrelated to the dependence score D_F which plays an essential role in the results to follow.

The analysis of D_F applies to any pair of disjoint subsets $\boldsymbol{X}$, $\boldsymbol{Y}$ that do not necessarily partition all the variables. In this more general setting distance is measured by the formula

$$\delta(\boldsymbol{X}, \boldsymbol{Y}) = \min_{A,B} \|F(X, Y, Z) - A(X, Z) - B(Y, Z)\|. \tag{5}$$

▷ Claim 5 (Completeness of D_F). For all disjoint $\boldsymbol{X}$, $\boldsymbol{Y}$, $\|D_F(\boldsymbol{X}, \boldsymbol{Y})\| \leq 4 \cdot \delta(\boldsymbol{X}, \boldsymbol{Y})$.

Proof. By definition of $\delta(\boldsymbol{X}, \boldsymbol{Y})$ there exists a decomposition of the form

$$F(X, Y, Z) = A(X, Z) + B(Y, Z) + D(X, Y, Z),$$

where $\|D(X, Y, Z)\| = \delta(\boldsymbol{X}, \boldsymbol{Y})$. In the expansion of D_F all the A and B terms cancel out, leaving

$$\begin{aligned} \|D_F(\boldsymbol{X}, \boldsymbol{Y})\| &= \|D(X, Y, Z) + D(X', Y', Z) - D(X, Y', Z) - D(X', Y, Z)\| \\ &\leq \|D(X, Y, Z)\| + \|D(X', Y', Z)\| + \|D(X, Y', Z)\| + \|D(X', Y, Z)\| \\ &= 4\delta(\boldsymbol{X}, \boldsymbol{Y}). \end{aligned}$$

◁

Soundness for Boolean functions under the uniform measure was proved by David et al. [10]. We reproduce their proof under a more general setting.

▷ Claim 6 (Soundness of D_F). For all disjoint $\boldsymbol{X}$, $\boldsymbol{Y}$, $\delta(\boldsymbol{X}, \boldsymbol{Y}) \leq \|D_F(\boldsymbol{X}, \boldsymbol{Y})\|$.

Proof. Let $\varepsilon = \|D_F(\boldsymbol{X}, \boldsymbol{Y})\|$. Then

$$F(X, Y, Z) \approx_\varepsilon F(X, Y', Z) - F(X', Y, Z) - F(X', Y', Z).$$

We can fix values $\underline{X}'$ and $\underline{Y}'$ for which

$$F(X, Y, Z) \approx_\varepsilon F(\underline{X}', \underline{Y}', Z) - F(X, \underline{Y}', Z) - F(\underline{X}', Y, Z) = A(X, Z) + B(Y, Z),$$

where $A(X, Z) = F(\underline{X}', \underline{Y}', Z) - F(X, \underline{Y}', Z)$ and $B(Y, Z) = F(\underline{X}', Y, Z)$. ◁

Proposition 4 now follows from inequality (4) and the following claim, which states that $\|D_F\|$ can be estimated by sampling in the cases of interest. See Appendix A for the proof.

▷ Claim 7. Assuming $\|F\|_{\mathbb{R},2p} \leq 1$, the value $\|F\|_{\mathbb{R},p}$ can be estimated within ε from $K^p \log(1/\gamma)/\epsilon^{2p}$ (random) queries to F in linear time with probability $1-\gamma$ for some absolute constant K.

3.1 Exact partitioning under the 2-norm

Since computing the optimal partition is in general NP-complete, we do not expect to replace the inequalities in (4) with an equality. However, in the special case of real-valued functions with ℓ^2-norm, the estimate becomes exact:

$$\|D_F(\boldsymbol{X}, \boldsymbol{Y})\|_{\mathbb{R},2} = 2 \cdot \delta_{\mathbb{R},2}(\boldsymbol{X}, \boldsymbol{Y}). \tag{6}$$

This equality is a consequence of the following characterization of $\delta_{\mathbb{R},2}$, which applies more generally to k-partitions:

▶ **Proposition 8.** *Assuming* $\mathbb{E}[F] = 0$*, the* k*-partition* $F_i(X_i) = \mathbb{E}[F|X_i]$ *achieves the minimum for* $\delta_{\mathbb{R},2}(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$*.*

In particular it follows that $\delta_{\mathbb{R},2}$ takes the value

$$\delta_{\mathbb{R},2}(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k) = \mathbb{E}[(\overline{F} - \mathbb{E}[\overline{F}|X_1] - \cdots - \mathbb{E}[\overline{F}|X_k])^2], \tag{7}$$

where $\overline{F} = F - \mathbb{E}[F]$. To derive identity (6) it remains to verify that when $k = 2$, the right-hand side of (7) is a quarter of $\|D_F\|^2$:

▶ **Fact 9.** $\|D_F(\boldsymbol{X}, \boldsymbol{Y})\|^2_{\mathbb{R},2} = 4 \cdot \mathbb{E}[(\overline{F} - \mathbb{E}[\overline{F}|X] - \mathbb{E}[\overline{F}|Y])^2]$.

Armed with this fact we prove the proposition.

Proof of Proposition 8. First assume $F(\boldsymbol{X}, \boldsymbol{Y})$ is bivariate. Let $A(\boldsymbol{X})$ be any function. The inequality $\mathbb{E}[(\mathbb{E}[F|X] - A(X))^2] \geq 0$ can be rewritten as

$$\mathbb{E}[(F - \mathbb{E}[F|X])^2] \leq \mathbb{E}[(F - A(X))^2], \tag{8}$$

stating that the orthogonal projection of F onto the subspace of functions that depend only on $\boldsymbol{X}$ in 2-norm is $\mathbb{E}[F|X]$.

Now let $F(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ be k-variate. Assume $\mathbb{E}[F] = 0$ and $\mathbb{E}[F_i(X_i)] = 0$ for all i. Then $\mathbb{E}[F_i(X_i)|X_j] = 0$ for all $i \neq j$. Applying inequality (8) for k times in succession together with this fact, we obtain

$$\begin{aligned}
&\mathbb{E}[(F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1}) - F_k(X_k))^2] \\
&\quad \geq \mathbb{E}[(F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1}) - \mathbb{E}[F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1})|X_k])^2] \\
&\quad = \mathbb{E}[(F - F_1(X_1) - \cdots - F_{k-1}(X_{k-1}) - \mathbb{E}[F|X_k])^2] \\
&\quad \vdots \\
&\quad \geq \mathbb{E}[(F - \mathbb{E}[F|X_1] - \cdots - \mathbb{E}[F|X_k])^2]
\end{aligned}$$

as desired. Finally, by orthogonality the optimal decomposition must satisfy $\sum \mathbb{E}[F_i(X_i)] = 0$ so the assumption $\mathbb{E}[F_i(X_i)] = 0$ can be made without loss of generality. ◀

By orthogonality, equation (7) can also be written in the following forms:

$$\begin{aligned}
\delta_{\mathbb{R},2}(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k) &= \mathbb{E}\left[\overline{F}^2\right] - \sum\nolimits_{i=1}^{k} \mathbb{E}\left[\mathbb{E}[\overline{F}|X_i]^2\right] \\
&= \mathbb{E}_X\left[\overline{F}(X)^2\right] - \sum_{i=1}^{k} \mathbb{E}_{X,X'}\left[\overline{F}(X_{-i}, X_i)\overline{F}(X'_{-i}, X_i)\right],
\end{aligned} \tag{9}$$

where (X_{-i}, X_i) is the input whose i-th variable takes value X_i and j-th variable takes value X'_j for $j \neq i$. As all these terms can be efficiently estimated, we obtain the following algorithm for estimating the quality of a given k-partition:

▶ **Proposition 10.** *There is an algorithm that given a* k*-partition* $\boldsymbol{X}_1, \cdots, \boldsymbol{X}_k$ *of the variables and parameters* $\varepsilon, \gamma > 0$*, outputs a value* $\hat{\delta}$ *such that*

$$|\hat{\delta}^2 - \delta_{\mathbb{R},2}(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)^2| \leq \varepsilon,$$

with probability at least $1 - \gamma$ *from* $O(k \log(k/\gamma)/\epsilon^4)$ *queries to* F *in time linear in the number of queries.*

4 Variable partitioning over general groups

In this section we present our first partitioning algorithm, which is general enough to work on any normed group G assuming it is possible to efficiently estimate the quantity $\|D_F(\{\boldsymbol{x}\},\{\boldsymbol{y}\})\|$.

The algorithm is based on the pairwise estimates of dependency over sets of single variables. The intuition behind the algorithm is that if the dependency between $\boldsymbol{x}$ and $\boldsymbol{y}$ is low, then these two variables should be assigned to different partitions. Therefore the algorithm keeps asserting such "in different partitions" for the pairs with lowest dependency estimates, until the k-partitioning can be clearly observed from the assertions.

This idea of the algorithm has been used in previous works in reinforcement learning control [23, 36] in a heuristic way. Theorem 1 below shows that the algorithm outputs an $O(kn^2)$ approximation to the optimal partition in time polynomial in n, k, and $1/\varepsilon$.

Algorithm 1 Approximate partitioning via pairwise estimates.

Input: number of partitions k
Output: partition $\mathcal{P}$
For every pair of variables $\boldsymbol{x},\boldsymbol{y} \in \boldsymbol{V}$, find estimate $\hat{e}(\boldsymbol{x},\boldsymbol{y})$ for $e(\boldsymbol{x},\boldsymbol{y}) = \|D_F(\{\boldsymbol{x}\},\{\boldsymbol{y}\})\|$;
Create a weighted graph with vertices $\boldsymbol{V}$ and weights $\hat{e}(\boldsymbol{x},\boldsymbol{y})$;
Order the edges in increasing weight;
repeat
    Remove the edge with the smallest weight;
until The graph has exactly k connected components

▶ **Proposition 11.** *Assuming $e(\boldsymbol{x},\boldsymbol{y}) \le \hat{e}(\boldsymbol{x},\boldsymbol{y}) \le e(\boldsymbol{x},\boldsymbol{y}) + \varepsilon$ for all $\boldsymbol{x}$ and $\boldsymbol{y}$,*

$$\delta(\mathcal{P}) \le (8k-10)n^2(4\delta_k(F)+\varepsilon). \tag{10}$$

If the estimates $\hat{e}(\boldsymbol{x},\boldsymbol{y})$ are obtained by empirical averaging, we obtain Theorem 1.

4.1 Proof of Proposition 11

For a partition $\mathcal{P}$ of the variables, let $\Delta(\mathcal{P}) = \sum \delta(\{\boldsymbol{x}\},\{\boldsymbol{y}\})$, where the sum is taken over all pairs that cross the partition. We will deduce Theorem 1 from the following bound on $\delta(\mathcal{P})$.

▷ Claim 12. For every k-partition $\mathcal{P}$, $\delta(\mathcal{P}) \le (16k-20)\Delta(\mathcal{P})$.

The following fact is immediate from the definitions of δ. The proof of this claim is delayed to the end of this section.

▶ **Fact 13.** *For any partition $(\boldsymbol{U},\overline{\boldsymbol{U}})$ such that $\boldsymbol{X} \subseteq \boldsymbol{U}$ and $\boldsymbol{Y} \subseteq \overline{\boldsymbol{U}}$, $\delta(\boldsymbol{X},\boldsymbol{Y}) \le \delta(\boldsymbol{U},\overline{\boldsymbol{U}})$.*

Now we prove the theorem, assuming the correctness of Claim 12.

▶ **Theorem 1.** *Let $\|\cdot\|$ be either 1) $\|\cdot\|_{\mathbb{R},p}$ assuming $\|F\|_{\mathbb{R},2p} = O(1)$, or 2) the Hamming metric over $\mathbb{Z}_q$. There is an algorithm that given parameters n, k, ε, γ, and oracle access to $F\colon \Sigma^n \to \mathbb{R}$ outputs a k-partition $\mathcal{P}$ such that $\delta(\mathcal{P}) \le O(kn^2)(\delta_k(F)+\varepsilon)$ with probability at least $1-\gamma$. The algorithm makes $O(K^p n^2 \log(n/\gamma)/\varepsilon^{2p})$ queries to F and runs in time linear in the number of queries, for an absolute constant K.*

Proof of Theorem 1. By Claim 5 and Fact 13, all edges $(\boldsymbol{x}, \boldsymbol{y})$ in the optimal partition must satisfy $e(\boldsymbol{x}, \boldsymbol{y}) \leq 4\delta_2(F)$. By our assumption on the quality of the approximations,

$$\hat{e}(\boldsymbol{x}, \boldsymbol{y}) \leq 4\delta_2(F) + \varepsilon. \tag{11}$$

Since the algorithm removes edges in increasing order of weight, all the edges that cross the output partition $\mathcal{P}$ must also satisfy this inequality. Then

$$\begin{aligned}
\delta(\mathcal{P}) &\leq (16k-20)\Delta(\mathcal{P}) && \text{by Claim 12,}\\
&\leq (16k-20)\sum\nolimits_{\boldsymbol{x},\,\boldsymbol{y} \text{ cross } \mathcal{P}} e(\boldsymbol{x}, \boldsymbol{y}) && \text{by Claim 6,}\\
&\leq (16k-20)\sum\nolimits_{\boldsymbol{x},\,\boldsymbol{y} \text{ cross } \mathcal{P}} \hat{e}(\boldsymbol{x}, \boldsymbol{y})\\
&\leq (16k-20)\sum\nolimits_{\boldsymbol{x},\,\boldsymbol{y} \text{ cross } \mathcal{P}} 4\delta_2(F) + \varepsilon && \text{by (11),}\\
&\leq (8k-10)n^2 \cdot (4\delta_2(F) + \varepsilon).
\end{aligned}$$

The last inequality holds because there are at most $\binom{n}{2} \leq n^2/2$ pairs of variables crossing the partition. ◀

We first prove Claim 12 in the case $k = 2$ of bipartitions. This is Claim 15 below. We use $\boldsymbol{X}\boldsymbol{X}'$ to denote the union of the variable sets $\boldsymbol{X}$ and $\boldsymbol{X}'$.

▷ Claim 14. For disjoint sets of variables $\boldsymbol{X}, \boldsymbol{X'}, \boldsymbol{Y}$, $\delta(\boldsymbol{X}\boldsymbol{X'}, \boldsymbol{Y}) \leq \delta(\boldsymbol{X}, \boldsymbol{Y}) + 2\delta(\boldsymbol{X'}, \boldsymbol{Y})$.

Proof. Assume that

$$\begin{aligned}
&F(X, X', Y) \approx_\delta A(X, X') + B(X', Y) \qquad \text{and}\\
&F(X, X', Y) \approx_{\delta'} A'(X, X') + B'(X, Y).
\end{aligned}$$

By the triangle inequality,

$$A(X, X') + B(X', Y) \approx_{\delta+\delta'} A'(X, X') + B'(X, Y).$$

Fix $X'(Z) = \underline{X}'(Z)$. Writing $C(X) = A(X, \underline{X}') - A'(X, \underline{X}')$ and $D(Y') = B(\underline{X}', Y')$ we get that

$$B'(X, Y) \approx_{\delta+\delta'} C(X) + D(Y).$$

By the triangle inequality (with the second equation), we get that

$$F(X, X', Y) \approx_{\delta+2\delta'} A'(X, X') + C(X) + D(Y).$$ ◁

▷ Claim 15. For every bipartition $\boldsymbol{X}, \overline{\boldsymbol{X}}$ of the variables, $\delta(\boldsymbol{X}, \overline{\boldsymbol{X}}) \leq 4 \cdot \Delta(\boldsymbol{X}, \overline{\boldsymbol{X}})$.

Proof. By Claim 14,

$$\delta(\boldsymbol{X}'\{\boldsymbol{x}\}, \{\boldsymbol{y}\}) \leq \delta(\boldsymbol{X}', \{\boldsymbol{y}\}) + 2\delta(\{\boldsymbol{x}\}, \{\boldsymbol{y}\})$$

for all $\boldsymbol{X}' \subseteq \boldsymbol{X} \setminus \{x\}$ and $\boldsymbol{y}$. Applying this inequality iteratively we conclude that $\delta(\boldsymbol{X}, \{\boldsymbol{y}\}) \leq 2\sum_{\boldsymbol{x}\in\boldsymbol{X}} \delta(\{\boldsymbol{x}\}, \{\boldsymbol{y}\})$. Also by Claim 14

$$\delta(\boldsymbol{X}, \boldsymbol{Y}'\{\boldsymbol{y}\}) \leq \delta(\boldsymbol{X}, \boldsymbol{Y}') + 2\delta(\boldsymbol{X}, \boldsymbol{Y}'\{\boldsymbol{y}\}),$$

so $\delta(\boldsymbol{X}, \boldsymbol{Y}) \leq 2\sum_{\boldsymbol{y}\in\boldsymbol{Y}} \delta(\boldsymbol{X}, \{\boldsymbol{y}\})$. Combining the two inequalities we obtain the desired conclusion. ◁

To extend the proof to larger k and obtain Claim 12, we generalize the first inequality in this sequence to k-partitions.

▷ Claim 16. For every $2k$-partition $(\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_k, \boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_k)$,

$$\delta(\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_k, \boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_k) \leq 2\delta(\boldsymbol{Y}_1\boldsymbol{Z}_1, \ldots, \boldsymbol{Y}_k\boldsymbol{Z}_k) + 3\delta(\boldsymbol{Y}_1 \ldots \boldsymbol{Y}_k, \boldsymbol{Z}_1 \ldots \boldsymbol{Z}_k).$$

Proof. Assume that

$$F(V) \approx_\delta F_1(Y_1, Z_1) + \cdots + F_t(Y_t, Z_t)$$
$$F(V) \approx_{\delta'} A(Y_1, \ldots, Y_t) + B(Z_1, \ldots, Z_t).$$

By the triangle inequality

$$A(Y_1, \ldots, Y_t) + B(Z_1, \ldots, Z_t) \approx_{\delta+\delta'} F_1(Y_1, Z_1) + \cdots + F_t(Y_t, Z_t).$$

Fixing $Z_1, \ldots, Z_t$ to values $\underline{Z}_1, \ldots, \underline{Z}_t$ we get the decomposition

$$A(Y_1, \ldots, Y_t) \approx_{\delta+\delta'} F_1(Y_1, \underline{Z}_1) + \cdots + F_t(Y_t, \underline{Z}_t) - B(\underline{Z}_1, \ldots, \underline{Z}_t).$$

and similarly

$$B(Z_1, \ldots, Z_t) \approx_{\delta+\delta'} F_1(\underline{Y}_1, Z_1) + \cdots + F_t(\underline{Y}_t, Z_t) - A(\underline{Y}_1, \ldots, \underline{Y}_t).$$

Plugging these into the second equation gives the desired decomposition. ◁

Proof of Claim 12. We assume that k is a power of two and prove by induction that $\delta(\mathcal{P}) \leq c_k\Delta(\mathcal{P})$, where c_k is the sequence $c_{2k} = 2c_k + 12$, $c_2 = 4$. The base case $k = 2$ follows from Claim 15. Assume the claim holds for k and apply Claim 16 to $\mathcal{P}$. By inductive assumption and Claim 15,

$$\delta(\mathcal{P}) \leq 2 \cdot c_k\Delta(\boldsymbol{Y}_1\boldsymbol{Z}_1, \ldots, \boldsymbol{Y}_k\boldsymbol{Z}_k) + 3 \cdot 4\Delta(\boldsymbol{Y}_1 \ldots \boldsymbol{Y}_k, \boldsymbol{Z}_1 \ldots \boldsymbol{Z}_k).$$

Since $\mathcal{P}$ is a refinement of both these partitions, it follows that $\delta(\mathcal{P}) \leq (2c_k + 12)\Delta(\mathcal{P}) = c_{2k}\Delta(\mathcal{P})$, concluding the induction.

The recurrence solves to $c_k = 8k - 12$, proving the claim when k is a power of two. When it is not, the same reasoning applies to the closest power of two exceeding k (by taking some of the sets in the partition to be empty), which is at most $2k - 1$, proving the desired bound. ◁

4.2 Hardness of exact variable bipartitioning

In contrast to Theorem 1, finding the exact bipartition is NP-hard even when there are only three variables.

▶ **Proposition 17.** *For any $n \geq 3$ there is no algorithm that outputs a bipartition of cost $\delta_2(F) + \varepsilon$ over $\mathbb{Z}_2$ under Hamming distance in time polynomial in $|\Sigma|/\varepsilon$ with constant probability unless BPP is in NP.*

Proof. Assume such an algorithm $BIPARTITION$ exists. We show it can be used to solve the following problem: Given explicit functions $F_1, \ldots, F_{n-1} \colon \Sigma^2 \to G$, find i^* that minimizes $\delta_2(F_{i^*})$ assuming this i^* is unique, i.e. a function that has the smallest bipartition cost among the candidates.

Let $F(x_1, \ldots, x_{n-1}, y) = F_1(x_1, y) + \cdots + F_{n-1}(x_{n-1}, y)$. The cost of the bipartition that splits x_i from all other variables in F is at most the cost of F_i, so F has a bipartition of cost at least $\delta_2(F_{i^*})$. We now argue that the cost of all other bipartitions is greater. In fact, any other bipartition must split y from x_i for some $i \neq i^*$. Assuming the cost of this partition is δ, we must have

$$F(X, Y) \approx_\delta A(X) + B(Y),$$

where $x_i \in X$ and $y \in Y$. After fixing all variables except for x_i and y we obtain

$$F_i(x_i, y) \approx_\delta A(x_i, \underline{X_{-i}}) + B(y, \underline{Y_{-i}}) - \sum_{j \neq i} F_j(\underline{x_j}, y).$$

This is a bipartition for F_i so its cost is strictly greater than $\delta_2(F_{i^*})$. Therefore the output of $BIPARTITION$ with oracle access to F and $\varepsilon = 1/|\Sigma|^2$ has the desired property.

Roth and Viswanathan [28] give an efficient reduction R that maps a graph G into a function F such that if G has a larger max-cut than G' then $\delta_2(R(G)) < \delta_2(R(G'))$. By composing the two reductions we obtain an efficient algorithm for deciding which of two graphs has a larger maximum cut, which is an NP-hard problem. ◀

5 Partitioning real-valued functions under the 2-norm

The problem of partitioning real-valued functions under the 2-norm is closely related to the well-studied problem of hypergraph partitioning. To explain this connection we recall the Efron-Stein decomposition of real-valued functions over product sets. The Efron-Stein decomposition of a function $F\colon \Sigma^n \to \mathbb{R}$ (under some product measure) is the unique decomposition of the form

$$F(x) = \sum\nolimits_{S \subseteq [n]} \hat{F}_S \cdot F_S(x),$$

where $\hat{F}_S$ are real coefficients and F_S are functions satisfying the following properties:

1. F_S depends on the variables in S only;
2. $\mathbb{E}[F_S | x_{-i}] = 0$, where x_{-i} is a fixing of all variables except the i-th one;
3. $\mathbb{E}[F_S^2] = 1$.

In particular, properties 1 and 2 imply that $\mathbb{E}[F_S F_T] = 0$ when $S \neq T$, and so $\mathbb{E}[F^2] = \sum_S \hat{F}_S^2$ by property 3.

▶ **Proposition 18.** *Given $F\colon \Sigma^n \to \mathbb{R}$, let H be the hypergraph whose vertices are the variables of F and whose hyperedges S have weight $\hat{F}_S^2$ for every subset S. The cost of the k-cut $(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ in H equals $\delta_{\mathbb{R},2}(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)^2$.*

Proof. We may assume $\mathbb{E}[F] = 0$ and use expression (9) to evaluate $\delta_{\mathbb{R},2}$. The first term equals $\mathbb{E}[F^2] = \sum_S \hat{F}_S^2$. The rest of the terms have the form $\mathbb{E}[\mathbb{E}[F|X_I]^2] = \mathbb{E}[F(X_{-I}, X_I)F(X'_{-I}, X_I)]$ for subsets I of variables. Plugging in the Efron-Stein decomposition of F we have

$$\mathbb{E}[\mathbb{E}[F|X_I]^2] = \sum_{S,T} \hat{F}_S \hat{F}_T \mathbb{E}[F_S(X_{-I}, X_I) F_T(X'_{-I}, X_I)].$$

By property 2, the terms in the summation in which $S \neq T$ evaluate to zero. Among the rest, if the set S contains any variable i outside I then

$$\mathbb{E}[F_S(X_{-I}, X_I) F_T(X'_{-I}, X_I)] = \mathbb{E}\big[F_S(X_{-I}, X_I)\mathbb{E}[F_T(X'_{-I}, X_I)|X, X'_{-i}]\big]$$

and the inside expectation evaluates to zero by property 2. Therefore the only surviving terms are those where $S = T$ and $S \subseteq I$, from where

$$\mathbb{E}[\mathbb{E}[F|X_I]^2] = \sum\nolimits_{S \subseteq I} \hat{F}_S^2.$$

By (9),

$$\delta_{\mathbb{R},2}(\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k) = \sum\nolimits_S \hat{F}_S^2 - \sum\nolimits_{i=1}^k \sum\nolimits_{S \subseteq \boldsymbol{X}_i} \hat{F}_S^2 = \sum\nolimits_{S \not\subseteq \boldsymbol{X}_i \text{ for any } i} \hat{F}_S^2.$$

The last quantity is the desired value of the cost of k-cut in H. ◀

When $\Sigma = \{-1, 1\}$ under uniform measure, the functions F_S do not depend on F and equal the Fourier characters $\chi_S(x) = \prod_{i \in S} x_i$, allowing us to embed instances of hypergraph partitioning into variable partitioning.

▶ **Corollary 19.** *Assume there is an algorithm A that given oracle access to $F\colon \{-1,1\}^n \to \mathbb{R}$ under uniform measure outputs a k-variable partition of cost at most $C \cdot \delta_2(F) + \varepsilon$ in time $t(n, k, \varepsilon)$. Then given a hypergraph with n vertices and m hyperedges with a k-cut of value opt, it is possible to output a k-cut of value $C \cdot opt$ in time $mnt(n, k, 1/m)$.*

Chekuri and Li [7] give a reduction from hypergraph k-cut to densest-k-subgraph. Manurangsi [24] shows that the latter is hard to approximate to within $O(n^{1/(\log\log n)^c})$ assuming the exponential-time hypothesis, implying inapproximability of the same order for $\delta_{\mathbb{R},2}(F)$.

On the positive side, Proposition 18 can be used to obtain variable partitioning algorithms from hypergraph partitioning ones. The conversion is not direct as hypergraph partitioning assumes explicit access to the hypergraph. Klimmek and Wagner [21] observed that submodularity of the hypergraph cut function $f(\boldsymbol{X}) = \delta_{\mathbb{R},2}(\boldsymbol{X}, \overline{\boldsymbol{X}})^2$ allows for efficient minimization from *exact* oracle access. To derive Theorem 2 we extend the analysis to approximate oracle access.

The following proposition is an analysis of Queyranne's symmetric submodular minimization algorithm [27] for an approximate input oracle. We say g is ε-submodular if $g(\boldsymbol{XYZ}) - g(\boldsymbol{XZ}) - g(\boldsymbol{YZ}) + g(\boldsymbol{Z}) \leq \varepsilon$ for all disjoint subsets $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}$.

▶ **Proposition 20** (Queyranne's algorithm with an approximate oracle)**.** *There is an algorithm that given oracle access to a symmetric ε-submodular g, makes $O(n^3)$ oracle queries and outputs a nontrivial subset $\boldsymbol{X}$ such that $g(\boldsymbol{X})$ is within $n\varepsilon/2$ of the minimum of g.*

▶ **Theorem 2.** *Let $F\colon \Sigma^n \to \mathbb{R}$ be a function with $\|F\|_{\mathbb{R},4} \leq 1$. There is an algorithm that given inputs n, ε, γ, and oracle access to F, runs in time $O(n^5 \log(n/\gamma)/\varepsilon^2)$ and outputs a bipartition $(\boldsymbol{X}, \overline{\boldsymbol{X}})$ such that $\delta_{\mathbb{R},2}(\boldsymbol{X}, \overline{\boldsymbol{X}})^2 \leq \delta_{\mathbb{R},2}(F)^2 + \varepsilon$ with probability at least $1 - \gamma$.*

Proof of Theorem 2. By Proposition 10, $\delta_{\mathbb{R},2}(\boldsymbol{X}, \overline{\boldsymbol{X}})^2$ can be estimated to within error ε/Kn with $O(\log(n/\gamma)n^2/\varepsilon^2)$ queries to F with probability $1 - K\gamma/n^3$ for any constant K. This estimator implements an $\varepsilon/2n$-approximate oracle to $\delta_{\mathbb{R},2}(\boldsymbol{X}, \overline{\boldsymbol{X}})^2$ with probability $1-\gamma$ with respect to an algorithm that makes at most Kn^3 queries. In particular, with probability $1 - \gamma$, the output of the oracle is $\varepsilon/4n$-close to the value of the submodular function $\delta_{\mathbb{R},2}^2$ at all points queried by Queyranne's algorithm and also at the minimum of $\delta_{\mathbb{R},2}^2$. Since from the algorithm's perspective it is interacting with a symmetric ε/n-submodular function g, it outputs a partition such that $g(\boldsymbol{X}, \overline{\boldsymbol{X}})$ is within $\varepsilon/2$ of the minimum of g. By the triangle inequality, $\delta_{\mathbb{R},2}(\boldsymbol{X}, \overline{\boldsymbol{X}})^2$ is within $\varepsilon/2 + 2\varepsilon/4n \leq \varepsilon$ close to the minimum of $\delta_{\mathbb{R},2}^2$. ◀

Saran and Vazirani's approximation algorithm for multiway k-cut (with fixed terminals) can be viewed as a reduction from multiway k-cut to multiway 2-cut. The reduction works given access to approximate s-t-cut oracles, where s and t are designated terminals that must be split by the cut. The corresponding cut function $\delta_{\mathbb{R},2}(\boldsymbol{s}\boldsymbol{X}, \boldsymbol{t}\overline{\boldsymbol{X}})$, where $(\boldsymbol{X}, \overline{\boldsymbol{X}})$ is now a partition of $\boldsymbol{V} - \boldsymbol{s}, \boldsymbol{t}$, is still submodular but no longer symmetric. We believe that an analogue of Proposition 20 for general (non-symmetric) submodular minimization [14, 15] should hold, but were unable to verify the claim. We state the extension of Theorem 2 to k-partitions as a conditional result.

▶ **Corollary 21.** *Assume that a ε-approximate minimum of an n-variate function f that is $\mathrm{poly}(\varepsilon/n)$-close to submodular on every input can be found in time $\mathrm{poly}(n/\varepsilon)$ given oracle access to it. Then there is an algorithm that given inputs k, ε and oracle access to a function F such that $\|F\|_{\mathbb{R},4} \le 1$ runs in time $k^2 n^k \,\mathrm{poly}(n/\varepsilon)\log(1/\gamma)$ and outputs a k-partition $\mathcal{P}$ such that $\delta_{\mathbb{R},2}(\mathcal{P})^2 \le (2 - 2/k)\delta_{\mathbb{R},2}(F)^2 + \varepsilon$ with probability $1 - \gamma$.*

It remains to prove Proposition 20.

▷ Claim 22. Let g be ε-submodular. Assume there exists $\boldsymbol{x} \in \boldsymbol{W}$ such that for all $\boldsymbol{Y} \subseteq \boldsymbol{W} \setminus \boldsymbol{x}$ and $\boldsymbol{u} \notin \boldsymbol{W}$,

$$g(\boldsymbol{W}) + g(\boldsymbol{u}) \le g(\boldsymbol{W} \setminus \boldsymbol{Y}) + g(\boldsymbol{Y}\boldsymbol{u}) + \delta.$$

If $\boldsymbol{x}'$ maximizes $g(\boldsymbol{W}\boldsymbol{u}) - g(\boldsymbol{u})$ among all $\boldsymbol{u} \notin \boldsymbol{W}$ then

$$g(\boldsymbol{W}\boldsymbol{x}') + g(\boldsymbol{u}) \le g(\boldsymbol{W}\boldsymbol{x}' \setminus \boldsymbol{Y}) + g(\boldsymbol{Y}\boldsymbol{u}) + (\delta + \varepsilon).$$

Proof. If $\boldsymbol{x} \notin \boldsymbol{Y}$ then

$$\begin{aligned} g(\boldsymbol{W}\boldsymbol{x}') + g(\boldsymbol{u}) &\le \big(g(\boldsymbol{W}) - g(\boldsymbol{W} \setminus \boldsymbol{Y}) + g(\boldsymbol{W}\boldsymbol{x}' \setminus \boldsymbol{Y})\big) + g(\boldsymbol{u}) + \varepsilon && \text{by } \varepsilon\text{-submodularity} \\ &= g(\boldsymbol{W}\boldsymbol{x}' \setminus \boldsymbol{Y}) + \big(g(\boldsymbol{W}) - g(\boldsymbol{W} \setminus \boldsymbol{Y}) + f(\boldsymbol{u})\big) + \varepsilon \\ &\le g(\boldsymbol{W}\boldsymbol{x}' \setminus \boldsymbol{Y}) + g(\boldsymbol{Y}\boldsymbol{u}) + (\delta + \varepsilon) && \text{by inductive hypothesis.} \end{aligned}$$

Otherwise, $\boldsymbol{x} \notin \boldsymbol{W} \setminus \boldsymbol{Y}$ and

$$\begin{aligned} g(\boldsymbol{W}\boldsymbol{x}') + g(\boldsymbol{u}) &\le g(\boldsymbol{W}\boldsymbol{u}) + g(\boldsymbol{x}') && \text{by optimality of } \boldsymbol{x}' \\ &\le \big(g(\boldsymbol{W}) - g(\boldsymbol{Y}) + g(\boldsymbol{Y}\boldsymbol{u})\big) + g(\boldsymbol{x}') + \varepsilon && \text{by } \varepsilon\text{-submodularity} \\ &= \big(g(\boldsymbol{W}) + g(\boldsymbol{x}') - g(\boldsymbol{Y})\big) + g(\boldsymbol{Y}\boldsymbol{u}) + \varepsilon \\ &\le g(\boldsymbol{W}\boldsymbol{x}' \setminus \boldsymbol{Y}) + g(\boldsymbol{Y}\boldsymbol{u}) + (\delta + \varepsilon) && \text{by inductive hypothesis.} \end{aligned}$$

◁

Proof of Proposition 20. Queyranne's algorithm Q^g is recursive. If $n = 2$ the unique partition is output. Otherwise, starting from an arbitrary singleton set $\boldsymbol{W}_1$, the algorithm sets $\boldsymbol{W}_{i+1} = \boldsymbol{W}_i\boldsymbol{x}_i$, where $\boldsymbol{x}_i$ maximizes $g(\boldsymbol{W}_i\boldsymbol{u}) - g(\boldsymbol{u})$ among all $\boldsymbol{u} \notin \boldsymbol{W}_i$. The algorithm then contracts the elements $\boldsymbol{x}_{n-1}$ and $\boldsymbol{x}_n$ into $\boldsymbol{x}_{n-1}\boldsymbol{x}_n$ and outputs the smaller value of $Q^g(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{n-2}, \boldsymbol{x}_{n-1}\boldsymbol{x}_n)$ and $g(\boldsymbol{x}_n)$.

We prove by induction on n that the output of Q^g is $(n-1)\varepsilon/2$-close to the minimum of g. The base case $n = 2$ is clear. Now assume this is true for inputs of size $n - 1$. If the minimum partition of g doesn't split $\boldsymbol{x}_{n-1}$ and $\boldsymbol{x}_n$ then the claim follows by inductive assumption.

Otherwise, we show that $g(\boldsymbol{x}_n)$ is within $(n-1)\varepsilon/2$-close to the minimum of g. Applying Claim 22 iteratively to the sets $\boldsymbol{W}_1, \ldots, \boldsymbol{W}_{n-1}$, we conclude that

$$g(\boldsymbol{W}_{n-1}) + g(\boldsymbol{x}_n) \le g(\boldsymbol{W}_{n-1} \setminus \boldsymbol{Y}) + g(\boldsymbol{Y}\boldsymbol{x}_n) + (n-1)\varepsilon$$

for all $\boldsymbol{Y}$ that do not contain $\boldsymbol{x}_n$ and $\boldsymbol{x}_{n-1}$. Applying symmetry this inequality can be rewritten as $g(\boldsymbol{x}_n) \leq g(\boldsymbol{x}_n Y) + (n-1)\varepsilon/2$. As $\boldsymbol{x}_{n-1}$ and $\boldsymbol{x}_n$ are split in the optimal solution it must be of type $\boldsymbol{x}_n Y$ for some Y excluding $\boldsymbol{x}_{n-1}$, so $g(\boldsymbol{x}_n)$ is $(n-1)/2\varepsilon$ close to the minimum as desired. ◀

6 Testing partitionability

As a consequence of Theorem 1, k-partitionability is testable with $\tilde{O}(k^{2p}n^{4p+2}/\varepsilon^{2p})$ queries. The yes instances are inputs with $\delta_k(F) = 0$; the no instances are inputs with $\delta_k(F) > \varepsilon$. The query complexity of Theorem 3 can be obtained by the improved analysis that follows.

To simplify notation we only prove the theorem for the Hamming weight over $\mathbb{Z}_q$ and describe the change necessary for p-norms over $\mathbb{R}$.

Algorithm 2 Tester for k-partitionability.

1: Create an empty undirected graph G with vertex set $\boldsymbol{V}$.
2: **for** $O(kn/\varepsilon)$ times **do**
3: **for** For every pair of distinct variables $\boldsymbol{x}, \boldsymbol{y} \in \boldsymbol{V}$ **do**
4: Choose random x, y, x', y', Z
5: If $F(x,y,Z) + F(x',y',Z) \neq F(x,y',Z) + F(x',y,Z)$ create the edge $\{\boldsymbol{x}, \boldsymbol{y}\}$ in G.
6: **end for**
7: **end for**
8: Accept if the graph has at least k connected components.

We will need the following fact:

▶ **Fact 23.** *If $p_1, \ldots, p_n$ are probabilities such that $\sum p_i \geq \varepsilon$ then $1 - \prod(1-p_i) \geq \varepsilon - O(\varepsilon^2)$.*

Proof. Using the inequality $1 - p \leq e^{-p}$ and the second-order estimate $e^{-x} = 1 - x + O(x^2)$, we have

$$\prod(1-p_i) \leq \prod e^{-p_i} = e^{-\sum p_i} \geq e^{-\varepsilon} = \varepsilon - O(\varepsilon^2).$$ ◀

▶ **Theorem 3.** *k-partitionability is testable with one-sided error and $O(kn^3/\varepsilon)$ non-adaptive queries with respect to Hamming weight over $\mathbb{Z}_q$, and with $O(k^{2p}n^3/\varepsilon^{2p})$ non-adaptive queries with respect to the p-norm over $\mathbb{R}$ assuming $\|F\|_{2p} \leq 1$.*

While in this work we are mainly interested in small values of k, in the extreme case when $k = n$ the partition is unique and the property is testable with $O(1/\varepsilon)$ queries by the result of Dinur and Golubev [12].

Proof of Theorem 3. The connected components of G are always contained in the partition components of F, so if F is k partitionable the tester always accepts. We argue that with constant probability, all bipartition of F satisfying $\delta(\boldsymbol{X}, \overline{\boldsymbol{X}}) \geq \varepsilon$ cross an edge in G.

If F is ε-far from k-partitionable, by Claim 12 $\Delta(\mathcal{P}) = \Omega(\varepsilon/k)$ for all k-partitions $\mathcal{P}$. As every k-cut can be coarsened into a 2-cut of at least half the weight, every k-partition can be coarsened into a bipartition such that $\Delta(\boldsymbol{X}, \overline{\boldsymbol{X}}) = \Omega(\varepsilon/k)$. We now argue that with constant probability, all such heavy bipartitions $(\boldsymbol{X}, \overline{\boldsymbol{X}})$ are crossed by an edge in G, so no k-partition is likely to survive in G.

Assume $\Delta(\boldsymbol{X}, \overline{\boldsymbol{X}}) = \sum_{\boldsymbol{x}\in\boldsymbol{X}, \boldsymbol{y}\in\boldsymbol{X}} \|D_F(\boldsymbol{x}, \boldsymbol{y})\| = \Omega(\varepsilon/k)$. As $\|D_F(\boldsymbol{x}, \boldsymbol{y})\|$ is the acceptance probability of the test in line 5, by Fact 23 in any given iteration of the outer loop 3 at least one of these edges will appear in G with probability $\Omega(\varepsilon/k)$. (For p-norms over $\mathbb{R}$,

$\|D_F(\boldsymbol{x}, \boldsymbol{y})\|$ is an expectation that takes $O((\varepsilon/k)^{2p})$ queries to estimate.) After $O(kn/\varepsilon)$ iterations the probability that the cut survives is less than 2^{-n}. By a union bound the probability that any heavy cut survives is at most half. ◀

It is not difficult to see that n queries are required for one-sided error testers when k equals 2 as the relevant constraints span an n-dimensional space. We show that a linear dependence on n is necessary for two-sided error testers as well. Proposition 24 shows a general $\Omega(n)$ lower bound for functions over finite domains (with uniform measure) valued over finite groups under the Hamming metric. Proposition 25 shows that $\Omega(n)$ *non-adaptive* queries are necessary for functions from $\mathbb{R}^n$ to $\mathbb{R}$ under the 2-norm.

▶ **Proposition 24.** *Testing 2-partitionability for functions $F\colon \mathbb{Z}_q^n \to G$ for a finite group G under uniform measure and Hamming metric requires $\Omega(n-k)$ queries even for constant ε.*

For simplicity of notation we present the proof in the case $q = 2$ and $G = \mathbb{Z}_2$. The proof is closely related to Chockler and Gutfreund's lower bound for testing juntas [9].

Proof. Let $R\colon \mathbb{Z}_2^n \to \mathbb{Z}_2$ be a random function and $P\colon \mathbb{Z}_2^{n-1} \to \mathbb{Z}_2$ be a function that depends on all but a random hidden input coordinate I. First we argue that $\delta_2(R) = \Omega(1)$ with high probability. For this it is sufficient to argue that $\|D_R(\boldsymbol{X}, \boldsymbol{Y})\| = \Omega(1)$ for every partition $(\boldsymbol{X}, \boldsymbol{Y})$. By definition $\|D_R(\boldsymbol{X}, \boldsymbol{Y})\|$ is the average value of $\Omega(2^{2n})$ indicator values for events of the type $R(x, y) + R(x', y') - R(x', y) - R(x, y') = 0$. These events have probability half each and are pairwise independent, so by Chebyshev's inequality the probability that the $\|D_R(\boldsymbol{X}, \boldsymbol{Y})\|$ is sub-constant is $\Omega(2^{-2n})$. Taking a union bound over all 2^n bipartitions it follows that $\|D_R(\boldsymbol{X}, \boldsymbol{Y})\| = \Omega(1)$ with probability at least $1 - \Omega(2^{-n})$.

To complete the proof, it is sufficient to argue that with high probability any Q queries to P reveal independent random bits. Consider the subspace of $\mathbb{Z}_2^n$ spanned by the Q queries (or the submodule of $\mathbb{Z}_q^n$ if q is not a prime). This vector space has dimension at most Q, so it can contain at most Q of the elementary basis vectors $e_1, \ldots, e_n$. However, unless it contains e_I for the hidden coordinate I, no two queries differ in a single coordinate and all answers are independent random bits. Since I is uniformly random the probability that P and R can be distinguished is at most Q/n. By a union bound the distinguishing advantage of the tester is at most $\Omega(2^{-n}) + Q/n$, which is subconstant unless $Q = \Omega(n)$. ◀

It was pointed out to us by Guy Kindler that the proof of Proposition 24 to functions from $\mathbb{R}^n$ to $\mathbb{R}$ say under Gaussian measure by considering the functions $R_{\mathbb{R}}$ and $P_{\mathbb{R}}$ given by $F_{\mathbb{R}}(x_1, \ldots, x_n) = F(\operatorname{sign} x_1, \ldots, \operatorname{sign} x_n)$ where the sign is interpreted as a Boolean value. This example is somewhat unnatural because the functions are discontinuous. The following proposition shows that testing still requires $\Omega(n)$ non-adaptive queries even for highly smooth functions.

▶ **Proposition 25.** *Testing 2-partitionability non-adaptively for quadratic functions from $\mathbb{R}^n$ to $\mathbb{R}$ under the 2-norm requires $\Omega(n)$ queries under any measure with zero mean and unit variance and bounded third and fourth moments.*

We need the following claim about distinguishing linear functions of normal random variables.

▷ Claim 26. Let $Z_1, \ldots, Z_n$ be independent standard normal random variables, $F(x) = \sum_{i=1}^n Z_i x_i$, and $F'(x) = \sum_{i \in S} Z_i x_i$ where $S \subseteq [n]$ is a random subset of size s. For any q queries $x^1, \ldots, x^q \in \mathbb{R}^n$, $(F(x^1), \ldots, F(x^q))$ and $(F'(x^1), \ldots, F'(x^q))$ are $O(qs/(n-s+1))$-statistically close.

Proof. It is sufficient to prove the claim for $|S| = n - 1$ and apply the triangle inequality. By convexity it is sufficient to upper bound the expected statistical distance averaged over the choice of the index i that is omitted from S. For fixed i, since the queried functions are linear, without loss of generality we may assume that the queries $x^1, \ldots, x^q$ are orthonormal. Let X be the $q \times n$ matrix whose rows are the queries $x^1, \ldots, x^n$, and X_{-i} be the submatrix obtained by removing the i-th column. The desired statistical distance is then within a constant factor of $\|(X^T X)^{-1}(X_{-i}^T X_{-i}) - I\|_F$, where $\|\cdot\|_F$ is the Frobenius norm [1]. By orthonormality we obtain that $\|(X^T X)^{-1}(X_{-i}^T X_{-i}) - I\|_F = \|x^i\|_2^2$. Averaging over i, the desired statistical distance is at most $O(\mathbb{E}_i[\|x^i\|_2^2]) = O(q/n)$. ◁

Proof of Proposition 25. Let $F(x) = n^{-1} \sum_{j \neq k} Z_{jk} x_j x_k$, where Z_{jk} are independent standard normal random variables. Let $F'(x) = n^{-1} \sum_{j,\, k,\, i \text{ distinct}} Z_{jk} x_j x_k$ where i is chosen at random from $[n]$. By standard concentration inequalities both $\|F\|_4$ and $\|F'\|_4$ are constant with high probability. By Claim 26, the answers to any q non-adaptive queries to F and F' are $O(q/n)$-statistically close.

It remains to argue that F is $\Omega(1)$-far from 2-partitionable. For a fixed bipartition (S, T) of $[n]$, by Claim 26 the cost of F is $n^{-1} \sum_{j \in S, k \in T} Z_{jk}^2$. Therefore the average cost (over the randomness of F) is $|S||T|/n$. By Chernoff bound the cost is at least $\Omega(|S||T|/n) = \Omega(1)$ with probability $1 - \exp(-\Omega(|S||T|))$. Taking a union bound over all 2^{n-1} possible bipartitions we conclude that F is $\Omega(1)$-far from 2-partitionable with probability $1 - \exp(-\Omega(n))$. ◀

If Claim 26 extends to adaptive queries, so would Proposition 25.

7 Applications to reinforcement learning control

In this section we discuss the application of variable partitioning algorithms given real-valued oracle and the 2-norm measure. The set $\boldsymbol{X}$ of variables to be partitioned corresponds to the set a of control variables (the action), while the oracle F corresponds to the advantage function A. While the control task is achieved by a series of actions, the advantage function describes how much one single action in the series can affect the final objective. In general, this function is complex enough so explicit representation is not available. Instead, it is usually estimated by Monte-Carlo sampling of the action series or by function approximation, where in either case it is sensible to treat the function as an oracle.

In a reinforcement learning control task, the objective is to control the action a so as to maximize the expected cumulative reward over time t. The advantage function $A(\cdot, a)$ describes the marginal gain of such an objective of an action $a = a_t$ at time t. This function can be estimated by Monte-Carlo sampling of the actions $a_t, a_{t+1}, \ldots$, or by function approximation. In either of the cases it is sensible to treat the function as an oracle when using it to partition the variables.

We compare empirically with three previous approaches. The first approach is a standard approach proposed by Williams [33, 35] and later improved by Mnih et al. [25] and Schulman et al. [32]. These approaches learn reinforcement learning control without considering the possible partitioning of the advantage function. The second approach is to trivially partition n variables into n subsets [22, 36]. This causes a large partition error which induces bias in the learning update. The third baseline partitions the variables heuristically [23]. In their method the Hessian matrix of the advantage function is first calculated using a discrete gradient method. Then this Hessian matrix is treated as an adjacency matrix of a graph, by the heuristic that two independent variables have a zero element in Hessian. Then elements are removed from Hessian, from those with the lowest absolute values, until the graph has at least k connected components. This algorithm shares some similar intuition with our first algorithm.

The rest of this section will introduce the preliminaries of how this partition may be used in reinforcement learning, and then demonstrate the comparison of scores attained in the experiments.

7.1 Reinforcement learning control and policy gradient

We consider a reinforcement learning task described by a discrete-time Markov decision process (MDP), denoted as the tuple $(\mathcal{S}, \mathcal{A}, \mathcal{T}, r, \rho_0, \beta)$. That includes $\mathcal{S} \in \mathbb{R}^m$ the m dimensional state space, $\mathcal{A} \in \mathbb{R}^n$ the n dimensional action space, $\mathcal{T} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \to \mathbb{R}^+$ the environment transition probability function, $r : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$ the reward function, ρ_0 the initial state distribution and $\beta \in [0, 1)$ the unnormalized discount factor. Here n is the number of the control variables, which is consistent with the dimension of the input oracle. A (stochastic) policy is a function $\pi : \mathcal{S} \times \mathcal{A} \to \mathbb{R}_+$ that outputs a distribution over $\mathcal{A}$ on any given state $s \in \mathcal{S}$. The objective of reinforcement learning is to learn a policy π such that the expected cumulative reward $J(\theta) = \mathbb{E}_{s\sim\rho_\pi, a\sim\pi}[\sum_{t=0}^{\infty} \beta^t r(s_t, a_t)]$, is maximized, where $\rho_\pi(s) = \sum_{t=1}^{\infty} \beta^{t-1}\mathbb{P}(s_t = s)$. Since π is in a functional space, the problem is commonly relaxed to find over the space of parameterized functions the policy, such as the space of neural networks. When the policy is parameterized we denote it as π_θ.

Advantage actor-critic (A2C), a standard approach in policy optimization [25, 32], estimates the gradient of the policy $\nabla_\theta J(\theta)$. According to the policy gradient theorem [35], this gradient can be estimated by $\nabla_\theta J(\theta) = \mathbb{E}_{\pi(a|s)}[\nabla_\theta \log \pi(a|s) A^\pi(s, a)]$, where $A^\pi(s, a)$ is the advantage function of s,a, and policy π. Here $A^\pi(s, a)$ is defined as $A^\pi(s, a) = Q^\pi(s, a) - V^\pi(s)$, where $Q^\pi(s, a) = \mathbb{E}_\pi[\sum_{t'\geq t}^{\infty} \beta^{t'-t} r(s_{t'}, a_{t'})|s = s_t, a = a_t, \pi]$ is the action-state value function and $V^\pi(s) = \mathbb{E}_{a\sim\pi(a|s)}[Q^\pi(s, a)]$ the state-value function.

It is shown later in [36] and [23], that an alternative estimator

$$\nabla_\theta J(\theta) = \sum_{j=1}^{k} \mathbb{E}_{\pi(a_{(j)}|s)}[\nabla_\theta \log \pi(a_{(j)}|s)(A^\pi(s, a_{(j)})], \tag{12}$$

may induces a lower variance. The condition that this estimator holds is that the advantage function can be approximately partitioned into k parts correspondingly:

$$A^\pi(s, a) = A^\pi_1(s, a_{(1)}) + \cdots + A^\pi_k(s, a_{(k)}) + U(s, a)$$

for some state s the estimation takes place, where $U(s, a)$ the partition error is expected to be small for the estimator to be accurate.

The learning is an iterative process that takes N updates by the gradient $\nabla_\theta J(\theta)$ while the k-partition is computed every N/N_1 iterations. Every run of the partitioning algorithm outputs the disjoint subsets $a_{(1)}, \ldots, a_{(k)}$, which is then used by (12) for N_1 iterations. It is worth note that our algorithm has a complexity of $\mathcal{O}(N_1 n^5)$, which is negligible in reinforcement learning. As the Monte-Carlo estimation of $\nabla_\theta J(\theta)$ requires a complete trial of the task (for example, play a game for an entire episode), which involves the interaction of a complex system.

7.2 Experiments

We compare our first algorithm (called pairwise estimates - PE) and our second algorithm (called submodular minimization - SM) with the aforementioned existing approaches. A2C [25] is the baseline approach in reinforcement learning who does not leverage variable partition. It uses control variates (CV) as the primary variance reduction technique. Other methods [23,36]

partition the control variable so as to reduce the variance in the Monte-Carlo estimation by Rao-Blackwellization (RB) [5]. For the discussion on variance reduction we refer the readers to the paper cited above. The comparisons are summarized below

Table 1 Comparisons of our algorithms with previous ones.

PG estimator	Variance reduction	Heuristics	Partitioning	Guarantees	Limits
A2C [25]	CV	-	-	-	-
Wu et al. [36]	CV & RB	yes	fully	no	$k = n$
Li and Wang [23]	CV & RB	yes	greedy	no	**no**
PE (our first)	CV & RB	**no**	greedy	factor-$\mathcal{O}(kn^2)$	**no**
SM (our second)	CV & RB	**no**	**optimal**	**almost opt**	**no**

Now we study the performance in terms of both the correctness and the optimality on graph cuts on weighted graphs. Correctness notes the number of times the algorithm outputs exactly the optimal partition, while optimality describes the average of the ratio of the partition error and the optimal partition error, over all the independent runs. This will illustrate the difference between greedy-based algorithms like [23] and our first algorithm, and submodular minimization based algorithms like our second algorithm. Note that submodular minimization always finds the optimal partition.

Table 2 Performance of the greedy algorithm on variable partition.

#Nodes n	$n = 5$	$n = 10$	$n = 20$	$n = 40$	$n = 100$
Submodular	-	-	-	-	-
Greedy (correctness)	7753	6271	4226	2380	1101
Greedy (optimality)	1.060	1.203	1.408	1.352	1.250

Then Table 3 compares the partitioning algorithms when the oracle is a quadratic function $a^T H_0 a$ for some random H_0. In this case our second algorithm SM also incurs an error per Theorem 2, but the error in practice is shown to be small enough. It has constantly the best empirical performance in both correctness and optimality.

Since we only replaced heuristic partitioning with our partitioning algorithm in reinforcement learning, it is reasonable that our more accurate partitions will improve reinforcement learning.

Table 3 Comparisons of the algorithms on variable partition.

#Nodes n	$n = 5$	$n = 10$	$n = 20$	$n = 40$	$n = 100$
Li and Wang [23] (correctness)	7553	5651	2929	1251	400
PE (correctness)	7709	6108	4001	2020	918
SM (correctness)	**9896**	**9630**	**9243**	**8193**	**6802**
Li and Wang [23] (optimality)	1.150	1.281	1.508	1.501	1.290
Wu et al. [36] (optimality)	9.049	13.54	20.96	34.42	72.55
PE (optimality)	1.075	1.277	1.452	1.400	1.281
SM (optimality)	**1.020**	**1.028**	**1.101**	**1.110**	**1.025**

Finally we plug our algorithms into reinforcement learning control, replacing the partitioning steps in [23]. The tasks we are testing on are standard tasks in reinforcement learning by the MuJoCo physics simulator. This includes training a simplified model of ant, cheetah, or human to run as fast as possible. The score is the cumulative reward over time, where the reward is the speed less the energy cost (which is $0.001\|a\|_2^2$). The control variables a are the forces applied to the joints. We refer to [3] for the exact simulator settings.

We have conducted experiments on all eight environments from MuJoCo that has the action dimensional higher than one, shown in Figure 1 below. In the figure the x-axis is the number of Monte-Carlo sample updates, which can be regarded as the time elapsed on the training, while the y-axis is the score attained by the model. Our second algorithm (SM) has achieved the highest score among most of these tasks, which agrees with our theoretical finding.

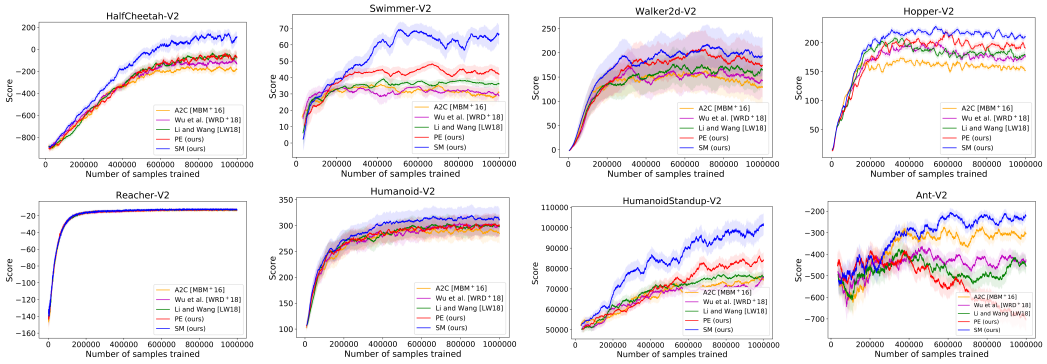

Figure 1 Empirical comparisons on MuJoCo high-dimensional control tasks. Each curve is averaged over 10 independent experiments.

A Statistical claims

▷ Claim 27. Assume $t, \hat{t} \geq 0$. If $t^p \leq \hat{t}^p \leq t^p + (\varepsilon/2)^p$ then $t \leq \hat{t} \leq t + \varepsilon$.

Proof. The left-hand inequalities are immediate. For the right-hand ones we start we consider two cases. If $t \leq \varepsilon/2$, then $\hat{t}^p \leq 2(\varepsilon/2)^p \leq \varepsilon \leq t + \varepsilon$. If $t > \varepsilon/2$ then

$$\hat{t} - t \leq \frac{\hat{t}^p - t^p}{t^{p-1}} \leq \frac{(\varepsilon/2)^p}{(\varepsilon/2)^{p-1}} \leq \varepsilon. \qquad \triangleleft$$

▷ Claim 7. Assuming $\|F\|_{\mathbb{R},2p} \leq 1$, the value $\|F\|^p_{\mathbb{R},p}$ can be estimated within ε^p, and $\|F\|_{\mathbb{R},p}$ can be estimated within ε, from $K^p \log(1/\gamma)/\epsilon^{2p}$ queries to F in linear time with probability $1 - \gamma$ for some absolute constant K.

Proof. By Chebyshev's inequality, $\mathbb{E}[|F|^p]$ can be estimated within an additive error of $(\varepsilon/2)^p$ by averaging $(2/\varepsilon)^{2p}$ samples with probability $3/4$. The error can be improved to $1 - \gamma$ by taking the median value of $O(\log 1/\gamma)$ runs. The second bound follows from Claim 27. $\triangleleft$

B Details in the experiments

The exact reinforcement learning control algorithm we used is described below. The algorithm is based on proximal policy optimization [32] and generalized advantage estimator [11, 31] in reinforcement learning.

Algorithm 3 Policy optimization with variable partitions.

1: **Input:** Total number of samples T, batch size B, partition frequency M_p, number of value iterations M_w, initial policy parameter θ, initial value and advantage parameters w and μ;
2: **Output:** Optimized policy π_θ;
3: **for** each iteration j in $[T/B]$ **do**
4: Collect a batch of trajectory data $\{s_t^{(i)}, a_t^{(i)}, r_t^{(i)}\}_{i=1}^B$;
5: **for** M_θ iterations **do**
6: Update θ by one gradient descent step using proximal policy gradient with the gradient estimator (12);
7: **end for**
8: **for** M_w iterations **do**
9: Update w and μ by minimizing $\|V^w(s_t) - R_t\|_2^2$ and $\|\hat{A} - A^\mu(s_t, a_t)\|_2^2$ in one step;
10: **end for**
11: Estimate $\hat{A}(s_t, a_t)$ using $V^w(s_t)$ by generalized advantage estimator;
12: **if** $j \equiv 0 \pmod{M_p}$ **then**
13: Define estimation $f(\boldsymbol{X}) = \mathbb{E}[D_F(\boldsymbol{X}, \overline{\boldsymbol{X}})^2]$;
14: Run submodular minimization on $f(\boldsymbol{X})$;
15: Assign $\boldsymbol{X}$ and $\bar{\boldsymbol{X}}$ to $a_{(1)}$ and $a_{(-1)}$ in (12), respectively;
16: **end if**
17: **end for**

Variable Partitioning

The differences between our algorithm and proximal policy gradient [32] have been highlighted: Line 6 uses the estimator with partitions on the control variables. Line 12-16 find the near-optimal variable partition using submodular minimization, by Theorem 2.

We use three neural networks as function approximations: a policy network π_θ and a value network V^w as is in the baseline methods, and an advantage network A^μ solely used in the partition algorithm. The networks have the same architecture as is in the previous line of works [25, 32].

In our MuJoCo experiments, the tasks have been slightly modified (the physics simulator keeps intact). As the number of control variables of the original tasks is relatively low, we augment such dimensions by letting the agent controls two independent instances of the tasks at the same time. The scores and the reinforcement signals are then the additions of the scores of the two sub-tasks. Correspondingly, we use $k = 2$ in [23] and our algorithms.

Linear Time Subgraph Counting, Graph Degeneracy, and the Chasm at Size Six

Abstract

We consider the problem of counting all k-vertex subgraphs in an input graph, for any constant k. This problem (denoted SUB-CNT$_k$) has been studied extensively in both theory and practice. In a classic result, Chiba and Nishizeki (SICOMP 85) gave linear time algorithms for clique and 4-cycle counting for *bounded degeneracy graphs*. This is a rich class of sparse graphs that contains, for example, all minor-free families and preferential attachment graphs. The techniques from this result have inspired a number of recent practical algorithms for SUB-CNT$_k$. Towards a better understanding of the limits of these techniques, we ask: for what values of k can SUB-CNT$_k$ be solved in linear time?

We discover a chasm at $k = 6$. Specifically, we prove that for $k < 6$, SUB-CNT$_k$ can be solved in linear time. Assuming a standard conjecture in fine-grained complexity, we prove that for all $k \geqslant 6$, SUB-CNT$_k$ cannot be solved even in near-linear time.

1 Introduction

The subgraph counting problem asks for the number of occurrences of a (typically connected) "pattern" subgraph H in a connected input graph G. It is a fundamental algorithmic problem with a rich theory [34, 51, 16, 53, 5, 24, 69, 19], and widely used in practice [32, 18, 58, 15, 60, 33, 59, 40, 68, 62, 67, 8]. With the explosion of network science, subgraph counting is now a fundamental tool used for analyzing real-world graphs. Thus, the search for fast algorithms for subgraph counting is not just a theoretical problem, but one that has many applications in bioinformatics, social sciences, and computer science.

Especially for the many of the practical applications, a common version of subgraph counting is to count the frequency of *all connected subgraphs* with k vertices [57, 54, 2, 25, 26, 31, 47, 61, 37, 71, 71]. We will denote this problem as SUB-CNT$_k$. Even in the theory literature, it is common to parametrize running time by n (vertices in G) and k, so it is natural to study SUB-CNT$_k$. There is a rich line of theoretical work on getting $n^{\mu k}$ time

algorithms, for $\mu < 1$, using matrix multiplication and tree decomposition methods [34, 53, 5, 13, 44, 70, 45, 20, 14, 19]. Unfortunately, SUB-CNT$_k$ is (a generalization of) the canonical #W[1]-hard problem, and it is not believed that there exist $f(k) \cdot n^{o(k)}$ algorithms for SUB-CNT$_k$. From an application standpoint, these algorithms are typically not practical, and do not provide algorithmic guidance. Real-world graphs are massive, and one typically desires linear-time algorithms.

An alternate perspective is to look for faster algorithms for restricted graph classes, and hope that these classes correspond to real-world graphs. A seminal result of Chiba-Nishizeki gave $O(m\kappa^{k-2})$ algorithms for k-clique counting and an $O(m\kappa)$ algorithm for 4-cycle counting, where m is the number of edges in G and κ is the *graph degeneracy* [16]. We leave the technical definitions for later; but κ can be thought of as the maximum average degree of any subgraph of G. Chiba-Nishizeki implicitly prove linear-time algorithms for SUB-CNT$_k$ for $k = 3, 4$ (explicitly shown in [57, 54]). The class of bounded (constant) degeneracy graphs is immensely rich: it contains all minor-closed families, preferential attachment graphs, and bounded expansion graphs. The graph degeneracy appears heavily in network science, and real-world graphs have typically low degeneracy (though maybe not constant).

But most importantly for subgraph counting, the techniques from Chiba-Nishizeki have inspired a number of recent practical subgraph counting algorithms [57, 54, 37, 35].

The problems of SUB-CNT$_k$ for $k \leqslant 5$ have been successfully tackled in practice using these approaches. These algorithms are often tailored for k (using, for example, specific tricks to count individual 4-vertex subgraphs) and it is not clear how far they will extend for larger k.

Towards a better theoretical understanding, we pose the following question.

For what values k, does the SUB-CNT$_k$ *problem admit a linear time algorithm in bounded degeneracy graphs?*

1.1 Our Results

The question above has a surprisingly clean resolution, assuming conjectures from fine-grained complexity. For simplicity, we assume that the input graph G is connected. We assume Las Vegas randomized algorithms, so we talk of expected running times.

Our main theorem asserts linear time algorithms for counting (up to) 5-vertex subgraphs in bounded degeneracy graphs. For counting 6-vertex subgraphs and beyond, it is unlikely that even near-linear time algorithms exists.

▶ **Theorem 1** (The chasm at size 6)**.** *For $k \leqslant 5$, there is an expected $O(m\kappa^{k-2})$ time algorithm for* SUB-CNT$_k$.

Assume the Triangle Detection Conjecture *(Conj. 2). There exists an absolute constant $\gamma > 0$ such that the following holds. For any $k \geqslant 6$ and any function $f : \mathbb{N} \to \mathbb{N}$, there is no (expected) $o(m^{1+\gamma} f(\kappa))$ algorithm for* SUB-CNT$_k$.

The Triangle Detection Conjecture was first stated by Abboud and Williams [1]. They proved many lower bounds for the dynamic version of many well known graph problems such as bipartite perfect matching, single source reachability etc. It is actually believed that the constant γ could be as large as 1/3.

▶ **Conjecture 2** (Triangle Detection Conjecture [1])**.** There exists a constant $\gamma > 0$ such that in the word RAM model of $O(\log n)$ bits, any algorithm to detect whether an input graph on m edges has a triangle requires $\Omega(m^{1+\gamma})$ time in expectation.

1.2 Main Ideas

Conditional Lower Bounds

It is instructive to look at the conditional lower bounds. The reduction of triangle detection to subgraph counting in bounded degeneracy graphs is actually quite simple. Suppose we want to detect (or even count) triangles in an input graph G. Get graph G' by subdividing each edge into two, so a triangle in G becomes a $\mathcal{C}_6$ (6-cycle) in G'. But the degeneracy of G' is just 2! (In any induced subgraph of G', the minimum degree is at most 2, proving the bound.) Thus, if there exists $o(f(\kappa)m^{1+\gamma})$ time algorithms for counting 6-cycles, that would violate the Triangle Detection Conjecture.

It is fairly straightforward to generalize this idea for larger cycles, by replacing edges in G by short paths. Assuming Triangle Detection Conjecture, for all $k \geqslant 6$ and $k \neq 8$, we can rule out linear time algorithms for counting $\mathcal{C}_k$ in bounded degeneracy graphs. Our reduction does not work for $\mathcal{C}_8$; instead we consider a different subgraph for the case of $k = 8$ ($\mathcal{C}_7$ with a tail). We give the details in Section 5.

This reduction fails for counting 5-cycles and in general, it does not work for counting any 5-vertex subgraph. For good reason, as we discovered an efficient algorithm for this problem. This is the more technical part of our paper.

Algorithmic Framework

We present an algorithmic framework for solving the SUB-CNT$_k$ problem, that generalizes the core idea of Chiba and Nishizeki [16]. It is known from past work that their ideas basically provide an $O(m\kappa^{k-2})$ algorithm for SUB-CNT$_k$, for $k = 3, 4$. The main challenge is to get such an algorithm for $k = 5$, thereby nailing down the chasm of Theorem 1. This leads to new results for counting various 5-vertex subgraphs. Perhaps more than these individual results, our main contribution lies in identifying structural decompositions of the pattern subgraphs that allows for efficient algorithms. This decomposition also sheds light on why certain k-vertex subgraphs, for $k \geqslant 6$, does not seem to have any efficient algorithms in bounded arboricity graphs. We give an outline of our framework next, and present it formally in Section 4.

The key idea that comes from Chiba-Nishizeki is to perform subgraph counting on $G^{\rightarrow}$, an acyclic orientation of G where the out degree of each vertex is bounded by $O(\kappa)$[1]. The classic clique and 4-cycle counting algorithms enumerate directed stars and directed paths of length 2 to count subgraphs. We note that the algorithm does *not* enumerate 4-cycles, since there can be $\Omega(n^2)$ 4-cycles. It requires clever indexing to solve this problem, which we generalize in our algorithm.

The crucial generalization of this idea is to enumerate directed rooted trees. Specifically, we count occurrences of a connected pattern H by counting occurrences of all possible acyclic orientations (up to isomorphism) $H^{\rightarrow}$ of H in $G^{\rightarrow}$. The main idea is to find the largest directed rooted tree in $H^{\rightarrow}$, with edges directed away from the root. Call this tree T. Since outdegrees in $G^{\rightarrow}$ are bounded, we can efficiently enumerate all copies of T. Any copy of $H^{\rightarrow}$ in $G^{\rightarrow}$ is formed by extending a copy of T, but $H^{\rightarrow}$ may contain vertices that are not in T. Thus, the extensions could be expensive to compute. But when H has at most 5 vertices, we can prove that $H^{\rightarrow} \setminus T$ is itself either a collection of rooted stars or paths. We can create hash tables that store information about the occurrences of the latter. The final count of $H^{\rightarrow}$ is obtained by enumerating T and carefully combining counts from the hash tables.

[1] Technically, this is *not* the idea of Chiba-Nishizeki, who use the degree orientation. But it was somewhat of a folklore result that it is easy to get the same result using the degeneracy orientation. Arguably the first such reference is Schank-Wagener [63].

2 Related Work

Subgraph counting problems has a long and rich history. More than three decades ago, Itai and Rodeh [34] gave the first non-trivial algorithm for the triangle detection and counting problems with $O(m^{3/2})$ runtime. Subsequently, Chiba and Nishizeki [16] gave an elegant algorithm based on the degree based vertex ordering that solves triangle counting, 4-cycle counting and ℓ-clique counting with running times of $O(m\kappa)$, $O(m\kappa)$, and $O(m\kappa^{\ell-2})$ respectively (κ denotes the degeneracy). In comparison, our algorithm exploits the *degeneracy ordering* of the vertices (see Section 3 for a formal definition); this enables us to create a uniform framework for any k-vertex subgraph for $k \in \{4, 5\}$. In dense graphs, the best bounds for the clique counting problem are achieved by fast matrix multiplications based algorithms [53, 24]; Vassilevska [69] gave combinatorial algorithm with significantly reduced space requirement. For general subgraphs, there is a rich line of research based on matrix multiplication, tree decomposition and vertex cover methods [34, 53, 5, 13, 44, 70, 45, 20, 14, 19] – these works focus on getting $n^{\mu k}$ time algorithmis, for $\mu < 1$.

Subgraph counting problems, specifically triangle counting, clique counting and cycle counting problems, has also been studied extensively in various Big Data models such as property testing model [22, 23, 6], MapReduce settings [17, 66, 42], and streaming model [7, 38, 46, 39, 3, 36, 56, 49, 9]. Most of these work focuses on an approximate count, rather than an exact count. In the applied world, there are many efficient algorithms that are based on clever sampling techniques [11, 10, 33, 75, 61, 73, 72, 37, 71]. Exact counting has also been studied extensively in the applied world [2, 57, 54, 12, 28, 50, 65, 47, 29, 31, 30, 25, 26]. In particular, Ahmed et al. [2] presented an algorithmic framework for solving the SUB-CNT$_4$ problem, called PGD (Parametrized Graphlet Decomposition), which scales to graphs with tens of millions of edges. Pinar et al. [57] studied the SUB-CNT$_5$ problem, and gave the current state of the art ESCAPE library based on degree ordering techniques. However, the provable runtime of their algorithm for certain 5-vertex subgraphs is quadratic, $O(n^2)$. For a deeper exploration of related applied work, refer to the tutorial on subgraph counting by Seshadhri and Tirthapura [64].

The subgraph detection problem, which asks whether an input graph has a copy of the subgraph, is a well-studied problem [34, 51, 4, 5, 41, 45, 74]. For the triangle detection problem, the best known algorithm is based on fast matrix multiplication and it runs in time $O(\min\{n^\omega, m^{2\omega/(\omega+1)}\})$ [5]. If $\omega = 2$, this would give us $O(\min\{n^2, m^{4/3}\})$ algorithm for the triangle detection problem. Hence, to falsify the Triangle Detection Conjecture, it would require a major breakthrough result in the algorithmic graph theory world. For a more detailed discussion on the Triangle Detection Conjecture and its implications, refer to the paper by Abboud and Williams [1].

In the subgraph enumeration problem, the goal is to output each occurrences of the target subgraph. Chiba and Nishizeki [16] showed that it is possible to enumerate all the triangles in a graph along with counting the total number of triangles in $O(m\kappa)$ time. For enumerating all the triangles, $O(m\kappa)$ time is effectively optimal assuming the 3SUM Conjecture [55, 43]. Eppstein [27] studied the bipartite subgraph enumaration problem in bounded arboricity graphs.

3 Preliminaries

In this paper, we study the SUB-CNT$_k$ problem which asks for the number of occurrences of each k-vertex subgraph H, in an input graph G with n vertices and m edges. We consider k to be a constant. For a fixed subgraph H, we use SUB-CNT$_H$ to denote the problem of

counting all occurrences of H in the input graph G. When H is the triangle subgraph, we denote the corresponding counting problem as TRI-CNT. In the context of the SUB-CNT$_k$ problem, we always use G to denote the input graph and H to denote the subgraph to be counted. Both G and H are simple, connected, undirected and unweighted.

In our algorithmic framework, directed graphs play a crucial role. We use $N^+_G(u)$ and $N^-_G(u)$ to denote the out-neighborhood and in-neighborhood of a vertex u in a directed graph G, respectively. We define $d^+_G(u) = |N^+_G(u)|$ and $d^-_G(u) = |N^-_G(u)|$. If the graph is clear from the context, we drop the subscript G.

A graph G is k-degenerate if every subgraph of G has a vertex of degree at most k. The *degeneracy* of a graph G (also called coloring number, refer to Sec. 5.2 of [21]), denoted as $\kappa(G)$, is the smallest integer k such that G is k-degenerate. The *arboricity* of a graph G, denoted as $\alpha(G)$, is the smallest integer k such that the edge set $E(G)$ can be partitioned into k forests. When the graph G is clear from the context, we simply write κ, and α, instead of $\kappa(G)$ and $\alpha(G)$. A classic theorem of Nash-Williams shows that the degeneracy and arboricity are closely related. All our results can be stated in terms of either of the parameters.

▶ **Theorem 3** (Nash-Williams [52]). *In every graph G, $\alpha(G) \leqslant \kappa(G) \leqslant 2\alpha(G) - 1$.*

Vertex ordering is central to many subgraph counting algorithms. In this paper, we work with the *degeneracy ordering* of G, which is defined as follows.

▶ **Definition 4.** Degeneracy ordering *of a graph G, denoted by $\lhd$, is obtained by repeatedly removing the vertex with minimum degree. The ordering is defined by the removal time.*

For example, if $u \lhd v$, then u is removed before v according to the above process. *Degeneracy ordering* can be found in linear time [48].

Using any vertex ordering $\prec$ of an undirected graph G, we construct a directed graph $G^{\rightarrow}_{\prec}$ as follows: for each edge $\{u, v\} \in E(G)$, direct the edge from u to v iff $u \prec v$. We denote this directed edge as (u, v). Observe that $G^{\rightarrow}_{\prec}$ is necessarily acyclic. We denote the directed graph obtained from *degeneracy ordering* $\lhd$ as $G^{\rightarrow}_{\lhd}$. The following two are folklore results about vertex ordering and degeneracy, and can be derived from Prop. 5.2.2 of [21].

▶ **Lemma 5.** *For each vertex $v \in G^{\rightarrow}_{\lhd}$, $d^+(v) \leqslant \kappa$.*

▶ **Lemma 6.** *If there exists a vertex ordering $\prec$ of G such that in the corresponding directed graph $G^{\rightarrow}_{\prec}$, $d^+(v) \leqslant k$ for each vertex v, then $\kappa(G) \leqslant k$.*

Next, we formally define a match (occurrence) of the target subgraph H in the input graph G. We also define a match in the context of directed graphs H' and G'.

▶ **Definition 7.** *A match of H in G is a bijection $\pi : S \to V(H)$ where $S \subseteq V(G)$ and for any two vertices u and v in S, $\{u, v\} \in E(G)$ if $\{\pi(u), \pi(v)\} \in E(H)$.*

▶ **Definition 8.** *A match of H' in G' is a bijection $\pi : S \to V(H')$ where $S \subseteq V(G')$ and for any ordered pair of vertices (u, v) where u and v are in S, $(u, v) \in E(G')$ if $(\pi(u), \pi(v)) \in E(H')$.*

Our algorithm counts matches of H in G by counting matches of all possible acyclic orientations $H^{\rightarrow}$ of H in $G^{\rightarrow}_{\lhd}$. In general, whenever we use '$\rightarrow$' to denote a directed graph, such as in $G^{\rightarrow}_{\lhd}$ and $H^{\rightarrow}$, the directed graph is a DAG.

We denote the number of matches of H in G by $\mathrm{M}(G, H)$. An incomplete match of H in G is an injection $\pi : S \to V(H)$ (so $|S| < |V(H)|$), that has the same properties of a match except being surjective. Consider two incomplete matches (injections) of H, $\pi_1 : S_1 \to V(H)$, and $\pi_2 : S_2 \to V(H)$. Let $V_{\pi_1} = \{\pi_1(u) \mid u \in S_1\}$ and $V_{\pi_2} = \{\pi_2(u) \mid u \in S_2\}$. We say that π_2 completes π_1 to be a match of H, when $V(H) = V_{\pi_1} \cup V_{\pi_2}$ (surjective), $V_{\pi_1} \cap V_{\pi_2} = \emptyset$ (injective), and for any two vertices $u \in S_1$ and $v \in S_2$, $\{u, v\} \in E(G)$ if $\{\pi_1(u), \pi_2(v)\} \in E(H)$. In case of directed graphs, it should hold that $(u, v) \in E(G')$ if $(\pi_1(u), \pi_2(v)) \in E(H')$ and $(v, u) \in E(G')$ if $(\pi_2(v), \pi_1(u)) \in E(H')$.

Two matches are distinct if they are not authomorphims of a match. In other words, two matches π_1 and π_2 of H are equivalent, if they map two automorphisms of the exact same subgraph of G to H. We denote the number of distinct matches of H in G by $\mathrm{DM}(G, H)$. In the SUB-CNT$_k$ problem, we are interested in $\mathrm{DM}(G, H)$ for all k-vertex subgraphs H.

4 Subgraph Counting Through Orientation and Directed Trees

In this section, we discuss our algorithmic framework for solving the SUB-CNT$_k$ problem. Instead of directly counting the number of occurrences of a k-vertex subgraph H in the input graph G, we count the occurrences of all possible DAG $H^{\rightarrow}$ (up to isomorphism) of H in the graph $G^{\rightarrow}_{\triangleleft}$. To achieve this, our main idea is to find the largest directed tree of $H^{\rightarrow}$, enumerate all matches of this tree, and then count matches of the remaining vertices using structures we save in a hash table. In Section 4.1, we show that our framework solves the SUB-CNT$_5$ problem in expected $O(m\kappa^3)$ time. In Section 4.2, we demonstrate the limitation of our framework as it fails to solve the SUB-CNT$_{\mathcal{C}_6}$ problem *efficiently*.

Algorithm 1 Counting distinct matches of all 5-vertex subgraphs in G (SUB-CNT$_5$).

procedure COUNT-ALL-5(G)
  Derive $G^{\rightarrow}_{\triangleleft}$ by orienting $E(G)$ with respect to degeneracy ordering.
  for all connected 5-vertex subgraphs H except 4-star **do**
    Run COUNT-MATCH($G^{\rightarrow}_{\triangleleft}, H$) and save the result for H.
  Save $\sum_{u \in V(G)} \binom{d(u)}{4}$ for 4-star.

Algorithm 2 Counting distinct matches of H in G (SUB-CNT$_H$).

procedure COUNT-MATCH($G^{\rightarrow}_{\triangleleft}, H$)
  $\mathrm{DM}(G, H) \leftarrow 0$
  for all possible DAGs (up to isomorphism) $H^{\rightarrow}$ of H **do**
    $\mathrm{M}(G^{\rightarrow}_{\triangleleft}, H^{\rightarrow}) \leftarrow 0$
    Find one of the largest DRTSs in $H^{\rightarrow}$, and call it $T_{\max}$.
    for all match π of $T_{\max}$ in $G^{\rightarrow}_{\triangleleft}$ **do**
      if π is a match of $H^{\rightarrow}$ **then** ▷ $V(T_{\max}) = V(H^{\rightarrow})$. Lemma 14
        $\mathrm{M}(G^{\rightarrow}_{\triangleleft}, H^{\rightarrow}) \leftarrow \mathrm{M}(G^{\rightarrow}_{\triangleleft}, H^{\rightarrow}) + 1$
      else if π is an incomplete match of $H^{\rightarrow}$ **then** ▷ Lemma 14
        $k \leftarrow$ number of ways to complete π to a match of $H^{\rightarrow}$. ▷ Lemma 16
        $\mathrm{M}(G^{\rightarrow}_{\triangleleft}, H^{\rightarrow}) \leftarrow \mathrm{M}(G^{\rightarrow}_{\triangleleft}, H^{\rightarrow}) + k$
    $\mathrm{DM}(G, H) \leftarrow \mathrm{M}(G^{\rightarrow}_{\triangleleft}, H^{\rightarrow}) / |Aut(H^{\rightarrow})|$
  return $\mathrm{DM}(G, H)$

4.1 5-vertex Subgraph Counting

Our main algorithmic result is given in the following theorem.

▶ **Theorem 9.** *There is an algorithm that solves the* SUB-CNT$_5$ *problem in* $O(m\kappa^3)$ *time.*

Our strategy is to count matches of all possible DAGs (up to isomorphism) $H^{\rightarrow}$ of H in $G^{\rightarrow}_{\triangleleft}$, to obtain the number of distinct matches of H in G. Alg. 2 demonstrates this subroutine of our algorithm for SUB-CNT$_5$, which is shown in Alg. 1. First, we find one of the largest directed rooted tree subgraphs (*DRTS*), which we define as follows, in $H^{\rightarrow}$.

▶ **Definition 10.** *Given any directed graph D, a directed rooted tree subgraph (DRTS) of D, is a subgraph T of D, where the underlying undirected graph of T is a rooted tree, and edges are oriented away from the root in T.*

The following lemma shows that we can find all matches of any DRTS in $H^{\rightarrow}$ in the desired time.

▶ **Lemma 11.** *Let T be a directed tree with k vertices. All matches of T in $G^{\rightarrow}_{\triangleleft}$ can be enumerated in $O(m\kappa^{k-2})$.*

Proof. Let $t_1, \ldots, t_k$ be a BFS ordering of T starting at the root t_1. Fix an edge $(u, v) \in E(G^{\rightarrow}_{\triangleleft})$ and map u to t_1 and v to t_2. There are m possible matches for (t_1, t_2), which we can find by enumerating the edges of $G^{\rightarrow}_{\triangleleft}$. Now, we will choose vertices to map to $t_3, \ldots, t_k$, one by one, in this order. Since the out-degree of each vertex in $G^{\rightarrow}_{\triangleleft}$ is at most κ, if we have already mapped vertices to $t_1, \ldots, t_i$, there are at most κ vertices that could be mapped to t_{i+1}. Therefor $\mathrm{M}(G^{\rightarrow}_{\triangleleft}, T) = O(m\kappa^{k-2})$, and we can enumerate all of them by first choosing (u, v) to map to (t_1, t_2) and then choosing vertices to map to $t_3, \ldots, t_k$, in this order and one by one. ◀

▶ **Observation 12.** *Call a vertex v of a directed graph a* source *vertex, if $d^-(v) = 0$. Consider T to be one of the largest DRTSs of a DAG D. T has to have a source vertex of D as the root, otherwise the root has an in-neighbor v, which is not in T as it would create a cycle. Adding v to T creates a new DRTS which has one more vertex than T. This contradicts the fact that T is one of the largest DRTSs of D. Hence, the root of T has to be a source vertex of D.*

Given a 5-vertex DAG $H^{\rightarrow}$, we can find a DRTS that has the most number of vertices among all DRTSs of $H^{\rightarrow}$ in constant time. First, find all source vertices, and then apply a Breath First Search (BFS) starting from each of these vertices and pick a BFS tree with the most number of vertices among all. The following lemma shows that the largest DRTS has at least 3 vertices for a 5-vertex connected subgraphs, except 4-star. Notice that, the largest DRTS of a 4-star with all the edges oriented towards the center has two vertices.

▶ **Lemma 13.** *Let H be a connected undirected 5-vertex graph that is not a 4-star. Each largest DRTS of any DAG $H^{\rightarrow}$, which is an acyclic orientation of H, has at least three vertices.*

Proof. We prove this lemma by contradiction. Assume that any DRTS of $H^{\rightarrow}$ has at most two vertices. A directed 2-path, or any vertex with at least two outgoing edges result in a DRTS with three vertices. Therefore,

(a) $H^{\rightarrow}$ does not have a 2-path,

(b) each vertex in $H^{\rightarrow}$ has at most one outgoing edges.

Notice that, since $H^{\rightarrow}$ is a DAG, it has at least one source vertex. Consider a source vertex u. Since H is connected, u has at least one neighbor, and by (b) it should have exactly one neighbor. Let $N^+(u) = \{v\}$, then $N^+(v) = \emptyset$, by (a). So, v should have at least one incoming neighbor w. By (a), w has no incoming edges, and it has no outgoing edges by (b). Call the other two vertices x and y. As H is connected, there should be a connection between $\{u, v, w\}$ and $\{x, y\}$. u and w cannot have any neighbor other than v, so x and y could only be connected to v. Since H is not a star, there should be an edge between x and y. Without loss of generality, let (x, y) be that edge. By (a), $(y, v) \notin E(H^{\rightarrow})$ and by (b) $(x, v) \notin E(H^{\rightarrow})$. So, $\{u, v, w\}$ is not connected to $\{x, y\}$, and H is disconnected, which is a contradiction. Thus, the assumption that any DRTS of $H^{\rightarrow}$ has at most two vertices is wrong, and each largest DRTS of $H^{\rightarrow}$ has at least three vertices. ◀

So far, we know that we can find one of the largest DRTSs of H, which has at least 3 vertices. We use $T_{\max}$ to denote this DRTS. By Lemma 11, we can enumerate all matches of $T_{\max}$ in $G^{\rightarrow}_{\triangleleft}$ in $O(m\kappa^3)$ time. For each such match, we need to validate whether it is a (incomplete) match of $H^{\rightarrow}$ or not. If it is not, then it could not be completed to a match of $H^{\rightarrow}$. The following lemma shows that we can perform this validation efficiently. In the remaining part of this section, "constanct expected time", refers to constant amortized time access to hash maps that we use.

▶ **Lemma 14.** *Let T be a DRTS of a DAG $H^{\rightarrow}$ of a connected k-vertex graph H. Assume edges of $G^{\rightarrow}_{\triangleleft}$ are saved in a hash table. For each match π of T in $G^{\rightarrow}_{\triangleleft}$, it takes $O(|E(H^{\rightarrow})|)$ expected time to validate whether π is a (incomplete) match of $H^{\rightarrow}$ or not.*

Proof. Since π is a bijection, it has an inverse which we denote by π^{-1}. Let $H^{\rightarrow}[V(T)]$ denote the subgraph of $H^{\rightarrow}$ induced on $V(T)$. Observe that, there could be edges in $H^{\rightarrow}[V(T)]$ not present in T. For π to be a match (if $V(T) = V(H^{\rightarrow})$) or incomplete match of $H^{\rightarrow}$, these edges have to be present between corresponding vertices in $G^{\rightarrow}_{\triangleleft}$ mapped to T by π. Formally, consider all ordered pairs of vertices $(a, b) \in V(T) \times V(T)$ such that $(a, b) \in E(H^{\rightarrow})$ and $(a, b) \notin E(T)$, π is a match or incomplete match of $H^{\rightarrow}$ iff $(\pi^{-1}(a), \pi^{-1}(b)) \in E(G^{\rightarrow}_{\triangleleft})$ for all such pairs of vertices. To validate this, we enumerate all edges (a, b) of $H^{\rightarrow}[V(T)]$ which are not present in T, and search for $(\pi^{-1}(a), \pi^{-1}(b))$ in hashed edges of $G^{\rightarrow}_{\triangleleft}$ in expected constant time. So this only requires $O(|E(H^{\rightarrow})|)$ expected time. ◀

If $V(T_{\max}) = V(H^{\rightarrow})$, then a match of $T_{\max}$ could be a match of $H^{\rightarrow}$ too, which could be verified as explained. If there is a vertex in $H^{\rightarrow}$ which is not present in $T_{\max}$, then after validating that a match of $T_{\max}$ is an incomplete match of $H^{\rightarrow}$, we need to find the number of ways to complete it to a match of $H^{\rightarrow}$. For this we need to count matches of each possible structures that $T_{\max}$ does not cover in $H^{\rightarrow}$. We save the count of these structures in $G^{\rightarrow}_{\triangleleft}$, in hash tables. The following lemma shows that this can be done efficiently.

▶ **Lemma 15.** *In $O(m\kappa^3)$ time and space, we can save all the following key and value pairs in hash maps $\mathcal{HM}_1$, $\mathcal{HM}_2$, and $\mathcal{HM}_3$.*

1. $\mathcal{HM}_1 : ((u, v), 1)$ *where* $(u, v) \in E(G^{\rightarrow}_{\triangleleft})$
2. $\mathcal{HM}_2 : (S, k)$ $\forall S \subseteq V(G^{\rightarrow}_{\triangleleft})$ *where* $1 \leqslant |S| \leqslant 4$*, and k is the number of vertices u such that* $S \subseteq N^+(u)$
3. $\mathcal{HM}_3 : ((S_1, S_2), \ell)$ $\forall S_1, S_2 \subseteq V(G^{\rightarrow}_{\triangleleft})$*, where* $1 \leqslant |S_1 \cup S_2| \leqslant 3$*, and ℓ is the number of edges $e = (u, v) \in E(G^{\rightarrow}_{\triangleleft})$ such that $S_1 \subseteq N^+(u)$ and $S_2 \subseteq N^+(v)$.*

Proof. We show how to enumerate and save all these structures in $\mathcal{HM}_1$, $\mathcal{HM}_2$, and $\mathcal{HM}_3$.

1. $\mathcal{HM}_1$: We can easily do this in $O(m)$ by enumerating the out-neighbors of each vertex
2. $\mathcal{HM}_2$: For each edge $e = (u, v)$, we can enumerate all subsets T of the set $\{w \in N^+(u) \mid v \lhd w\}$, where $|T| \leqslant 3$, in $O(\kappa^3)$ time, and increment the value for the key $T \cup \{v\}$ in the hash map by one.
3. $\mathcal{HM}_3$: For each edge $e = (u, v)$ $(v \in N^+(u))$, we enumerate all possible subset $S_1 \subseteq N^+(u) \setminus \{v\}$ where $|S_1| \leqslant 3$. And, for each S_1 we enumerate all possible $S_2 \setminus S_1$ in subsets of $N^+(v)$, such that $1 \leqslant |S_1 \cup S_2| \leqslant 3$. This takes $O(\kappa^3)$ as the out-degree of each vertex is at most κ, and we choose up to three vertices. All possible $S_1 \cap S_2$ can be determined by checking the connection between v and each vertex in S_1 using the hashed edges of $G^{\rightarrow}$ in $\mathcal{HM}_1$. ◀

The following lemma shows that we can count the number of ways to complete a match of $T_{\max}$, which is also an incomplete match of $H^{\rightarrow}$, to a match of $H^{\rightarrow}$ efficiently.

▶ **Lemma 16.** *Let H be a 5-vertex connected graph, $H^{\rightarrow}$ be a DAG of H, and $T_{\max}$ be one of the largest DRTSs in $H^{\rightarrow}$. Assume $\mathcal{HM}_1$, $\mathcal{HM}_2$, and $\mathcal{HM}_3$ are given. For each match π of $T_{\max}$ in $G^{\rightarrow}_{\lhd}$ which is an incomplete match of $H^{\rightarrow}$, we can count the number of ways to complete π to a match of $H^{\rightarrow}$ in expected constant time.*

Proof. By Lemma 13, $T_{\max}$ has at least 3 vertices, and since π is an incomplete match (not a match) of $H^{\rightarrow}$, we can assume that $|V(T_{\max})| < 5$. Observe that, $T_{\max}$ is a maximal DRTS. Any vertex in $H^{\rightarrow}$ which is not in $T_{\max}$ can only be connected to vertices of $T_{\max}$ by outgoing edges, otherwise they could be added to $T_{\max}$ to create a larger DRTS of $H^{\rightarrow}$, which contradicts the maximality of $T_{\max}$. We consider two cases where $T_{\max}$ has three or four vertices.

Let $|V(T_{\max})| = 4$, and i be the only vertex in $H^{\rightarrow}$ that is not in $T_{\max}$. To complete π to a match of $H^{\rightarrow}$, we need to choose a vertex in $G^{\rightarrow}_{\lhd}$, that is connected by outgoing edges to vertices mapped to the out-neighborhood of i in $H^{\rightarrow}$. Let $S_i = \{\pi^{-1}(t) \mid t \in N^+_{H^{\rightarrow}}(i)\}$. $\mathcal{HM}_2(S_i)$ is the number of vertices that could be mapped to i, but some of them may be already mapped to a vertex in $T_{\max}$, by π. Let r_i denote the number of vertices $v \in \{\pi^{-1}(t) \mid t \in V(T_{\max})\}$, where $S_i \subseteq N^+_{G^{\rightarrow}_{\lhd}}(v)$. We can obtain r_i in expected constant time, by enumerating vertices mapped to $V(T_{\max})$, and counting vertices that are connected to all vertices in S_i. For any vertex, we can check the connection to each vertex of S_i using $\mathcal{HM}_1$ in expected constant time. The number of ways to complete π to a match of $H^{\rightarrow}$ in this case is $\mathcal{HM}_2(S_i) - r_i$.

Now we consider the case where $|V(T_{\max})| = 3$. Let $V(H^{\rightarrow}) \setminus V(T_{\max}) = \{i, j\}$. To complete π to a match of $H^{\rightarrow}$, we only need to choose two vertices of $G^{\rightarrow}_{\lhd}$ to map to i and j. Let $S_i = \{\pi^{-1}(t) \mid t \in V(T_{\max}) \cap N^+_{H^{\rightarrow}}(i)\}$ and $S_j = \{\pi^{-1}(t) \mid t \in V(T_{\max}) \cap N^+_{H^{\rightarrow}}(j)\}$. We consider two cases, where i and j are connected or not. If they are connected, without loss of generality, assume $(i, j) \in E(H^{\rightarrow})$. If $(i, j) \in E(H^{\rightarrow})$, then we can use $\mathcal{HM}_3$ in Lemma 15, to find the number of edges (u, v) where u and v could be mapped to i and j, respectively. Let $r_{(i,j)}$ be the number of edges $e = (w, x) \in E(G^{\rightarrow}_{\lhd})$, where w and x are mapped to vertices in $T_{\max}$ by π, such that, $S_i \subseteq N^+_{G^{\rightarrow}_{\lhd}}(w)$, and $S_j \subseteq N^+_{G^{\rightarrow}_{\lhd}}(x)$. We can obtain $r_{(i,j)}$ in expected constant time using $\mathcal{HM}_1$. Then the number of edges (u, v) that could be mapped to (i, j) is $\mathcal{HM}_3((S_i, S_j)) - r_{(i,j)}$. Next case is when $(i, j) \notin E(H^{\rightarrow})$. In this case, we use $\mathcal{HM}_2$ to find the number of pair of vertices of $G^{\rightarrow}_{\lhd}$ which could be mapped to i and j. Let r_i (r_j resp.) denote the number of vertices $v \in V(G^{\rightarrow}_{\lhd})$ where v is mapped to a vertex in $T_{\max}$ and $S_i \subseteq N^+_{G^{\rightarrow}_{\lhd}}(v)$ ($S_j \subseteq N^+_{G^{\rightarrow}_{\lhd}}(v)$ resp.). Also, we use $r_{i,j}$ to denote the number of vertices $v \in V(G^{\rightarrow}_{\lhd})$ that are counted in both r_i and r_j, meaning

$S_i \cup S_j \subseteq N^+_{G^{\rightarrow}_{\lhd}}(v)$. We can obtain r_i, r_j, and $r_{i,j}$ easily in expected constant time using $\mathcal{HM}_1$. The number of pairs of vertices which could be mapped to i and j is equal to $(\mathcal{HM}_2(S_i) - r_i) \cdot (\mathcal{HM}_2(S_j) - r_j) - (\mathcal{HM}_2(S_i \cup S_j) - r_{i,j})$. ◀

Now, we have all the tools to efficiently count distinct matches of a DAG of $H^{\rightarrow}$ in $G^{\rightarrow}_{\lhd}$. The following lemma shows that we can do this in $O(m\kappa^3)$ expected time.

▶ **Lemma 17.** *There is an algorithm which counts distinct matches for each possible DAG (up to isomorphism) $H^{\rightarrow}$ of a 5-vertex connected subgraphs H, in $O(m\kappa^3)$ expected time.*

Proof. Fix a DAG $H^{\rightarrow}$ of H. If H is a 4-star and $H^{\rightarrow}$ has ℓ incoming neighbors, then the number of distinct matches of $H^{\rightarrow}$ is $\sum_{u \in V(G^{\rightarrow}_{\lhd})} \binom{d^-(u)}{\ell}\binom{d^+(u)}{4-\ell}$. Assume that H is not a 4-star. Find a DRTS of $H^{\rightarrow}$ with the most number of vertices among all its DRTSs, and call it $T_{\max}$. This can be done in constant time for $H^{\rightarrow}$. By Lemma 13, $T_{\max}$ has at least three vertices. We will now enumerate all matches of $T_{\max}$ in $G^{\rightarrow}_{\lhd}$. By Lemma 11, this step requires $O(m\kappa^3)$ expected time. For each match π of $T_{\max}$ in $G^{\rightarrow}_{\lhd}$, we can verify whether π is a match (if ($|V(T_{\max})| = 5$) or incomplete match of $H^{\rightarrow}$ in expected constant time, by Lemma 14. If $|V(T_{\max})| = 5$, while enumerating all matches of $T_{\max}$, we only count them if they are a match of $H^{\rightarrow}$. So in this case we can count $\mathrm{M}(G^{\rightarrow}_{\lhd}, H^{\rightarrow})$ in $O(m\kappa^3)$ expected time.

Otherwise, $T_{\max}$ has 3 or 4 vertices. In this case, for each match π of $T_{\max}$, we first verify that it is also an incomplete match of $H^{\rightarrow}$. Then, we count the number of ways to complete π to a match of $H^{\rightarrow}$, which we can do in expected constant time, by Lemma 16. To obtain $\mathrm{M}(G^{\rightarrow}_{\lhd}, H^{\rightarrow})$, we simply sum the ways to complete each incomplete match we have found, to a match of $H^{\rightarrow}$.

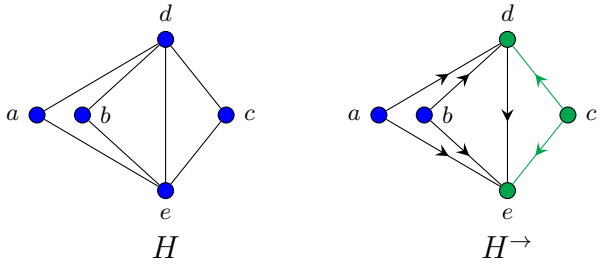
This approach gives us the number of all (not necessarily distinct) matches of $H^{\rightarrow}$ in $G^{\rightarrow}_{\lhd}$. Let $H^{\rightarrow}_{\pi}$ be a subgraph of $G^{\rightarrow}_{\lhd}$ that π maps to $H^{\rightarrow}$. Each automorphism of $H^{\rightarrow}$, gives a new match π' which is not distinct from π, as it is still mapping H_π (the same copy of H) to $H^{\rightarrow}$ (example in Fig. 1b). As each match of $H^{\rightarrow}$, also maps vertices to $T_{\max}$, resulting in a match of $T_{\max}$ and an (incomplete) match of $H^{\rightarrow}$, we will find all distinct matches of $H^{\rightarrow}$ and count each one exactly $|Aut(H^{\rightarrow})|$ times. We want the number of distinct matches, which we can obtain by dividing the count of all matches by $|Aut(H^{\rightarrow})|$.

Thus, it requires $O(m\kappa^3)$ expected time to create $\mathcal{HM}_1$, $\mathcal{HM}_2$, and $\mathcal{HM}_3$ by Lemma 15, $O(m\kappa^3)$ time for enumerating matches of $T_{\max}$, expected constant time to validate these matches, and expected constant time for counting ways to complete each such match, that is verified to be an incomplete match of $H^{\rightarrow}$, to a match of $H^{\rightarrow}$. So overall, we can find $\mathrm{DM}(G^{\rightarrow}_{\lhd}, H^{\rightarrow})$ in $O(m\kappa^3)$ expected time.

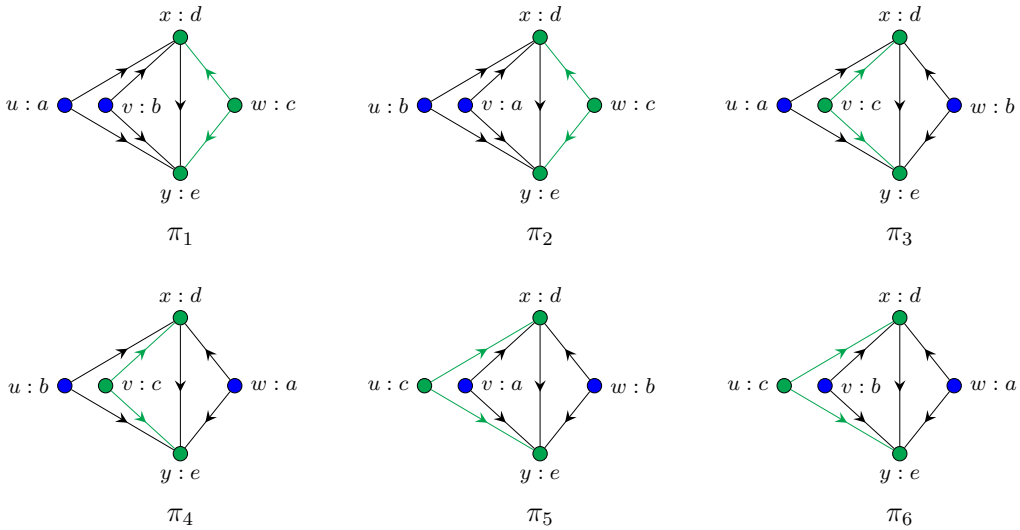
This completes the proof of this lemma. ◀

Lastly, we can prove Theorem 9 as follows.

Proof of Theorem 9. Given a 5-vertex connected subgraph H, we can count all distinct matches of each possible DAG $H^{\rightarrow}$ of H, in $G^{\rightarrow}_{\lhd}$ in $O(m\kappa^3)$ expected time, by Lemma 17. To count all distinct matches of H in G, we just need to sum the number of distinct matches of all possible DAGs (up to isomorphism) of H. The number of such DAGs is constant for H. There are 21 different connected 5-vertex subgraphs (illustrated in [57]), and we perform this process on all of them. This completes the proof of the theorem. ◀



(a) H is 5-vertex connected subgraph and $H^{\rightarrow}$ is one possible acyclic orientation of it. $T_{\max}$ (largest DRTS of $H^{\rightarrow}$) is shown in green and contains three vertices.



(b) All six figures show exactly the same subgraph in $G^{\rightarrow}_{\triangleleft}$. $\pi_1, \ldots, \pi_6$ are six equivalent matches of $H^{\rightarrow}$ in $G^{\rightarrow}_{\triangleleft}$, one for each automorphism of $H^{\rightarrow}$. Notice (u, v, w) being mapped to all permutations of (a, b, c).

Figure 1 Application of Alg. 2 on a DAG $H^{\rightarrow}$ of an example 5-vertex connected subgraph H.

4.2 Limitations of Our Framework for a Six Vertex Subgraph

Consider $\mathcal{C}_6$, shown as H in Fig. 2. Then $H^{\rightarrow}$, shown in the right side of Fig. 2, is a possible DAG of H. In $H^{\rightarrow}$, s_1, s_2, and s_3 are the source vertices, and t_1, t_2, and t_3 are the sink vertices. Any DRTS of $H^{\rightarrow}$ has at most three vertices, and there are three such DRTS, T_1, T_2, and T_3 rooted at s_1, s_2 and s_3, respectively. T_1 is shown by red in Fig. 2. For each of T_1, T_2, and T_3, the remaining vertices include a vertex, with two incoming edges, which we call an in-in wedge. For example, t_2 is such a vertex for T_1. Even graphs with bounded degeneracy can have $\Omega(n^2)$ in-in wedges. We cannot hash the count of such structures in expected time bounded by m and κ. So, Alg. 2 fails to count occurrences of $\mathcal{C}_6$ in the desired time. In the next section, we discuss why such limitations are natural to any framework for the SUB-CNT$_k$ problem at and beyond $k = 6$.

5 A Chasm at Six

At the end of the previous section, we showed the limitations of our framework in counting certain 6-vertex subgraphs. In this section, we show that perhaps such limitations are fundamental to any subgraph counting algorithms. In particular, the landscape of SUB-CNT$_k$ problem in the bounded degeneracy graphs changes dramatically as we move beyond $k = 5$.

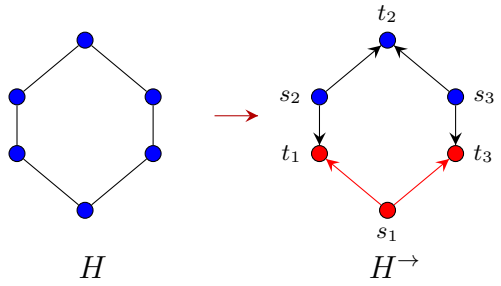


Figure 2 Let $H^{\rightarrow}$ be a DAG of H ($\mathcal{C}_6$). Considering any largest DRTS of $H^{\rightarrow}$, the remaining vertices include a vertex with two incoming edges (in-in wedge). Even graphs with bounded degeneracy can have $\Omega(n^2)$ in-in wedges. So hashing in Alg. 2 will not be bounded by m and κ for H.

We prove that for every integer $k \geqslant 6$, there exists a k-vertex subgraph H such that, the running time of any algorithm for the SUB-CNT$_H$ problem does not depend on the degeneracy of the input graph, assuming the Triangle Detection Conjecture. In contrast, for $k \leqslant 5$, $O(m\kappa^{k-2})$ algorithms exists for SUB-CNT$_k$ (see Section 4). The following theorem captures the main result of this section.

▶ **Theorem 18.** *Assume the* Triangle Detection Conjecture *(Conj. 2). There exists an absolute constant $\gamma > 0$ such that the following holds. For any $k \geqslant 6$ and any function $f : \mathbb{N} \to \mathbb{N}$, there exists a k-vertex subgraph H such that there is no (expected) $o(m^{1+\gamma} f(\kappa))$ algorithm for* SUB-CNT$_H$.

Outline of the Proof. For each $k \geqslant 6$ and $k \neq 8$, the subgraph of interest will be the k-cycle graph, $\mathcal{C}_k$. For $k = 8$, the subgraph of interest will be the $\mathcal{C}_7$ with a tail (see Figure 3). We first give a proof outline. Fix some $k \geqslant 6$ and let H_k denote the target subgraph of size k. Recall the TRI-CNT problem — count the number of triangles in a graph with m edges. Conjecture 2 asserts that for any algorithm $\mathcal{A}$ for the TRI-CNT problem, $T(\mathcal{A}) = \omega(m)$ where $T(\mathcal{A})$ denotes the worst case time complexity of the algorithm $\mathcal{A}$. Our strategy is to reduce from the TRI-CNT problem to the SUB-CNT$_{H_k}$ problem. To this end, we construct a new graph G_k from the input instance G of the TRI-CNT problem such that G_k has $O(m)$ edges, and has degeneracy at most 2. More importantly, the number of triangles in G is a simple linear function of the number of H_k in G_k. Hence, we can derive the number of triangles in G by counting the number of H_k in G_k. As $\kappa(G_k) \leqslant 2$, any $O(mf(\kappa))$ algorithm for the SUB-CNT$_{H_k}$ problem translates to a $O(m)$ algorithm for the TRI-CNT problem, contradicting the Triangle Detection Conjecture. We remark that, for $k = 8$, our proof strategy will be slightly different — instead of reducing from the TRI-CNT problem, we shall reduce from the triangle detection problem itself. However, the gadget construction will follow the same basic principle.

The construction of G_k from G is rather simple. The details of the construction depends on whether k is a multiple of 3 or not. We take two examples to describe the construction.

First, we take $k = 6$, and the target subgraph $H_6 = \mathcal{C}_6$. For each edge e in $E(G)$, we replace e with a length two path $\{e_1, e_2\}$ in $E(G_6)$. To accomplish this, we add a new vertex v_e for each edge: $V(G_6) = V(G) \cup \{v_e\}_{e \in E(G)}$. This is shown in Figure 4a. Each triangle in G creates a $\mathcal{C}_6$ in G_6. We formally prove in Lemma 20 that the number of triangles in G is same as the number of $\mathcal{C}_6$ in G_6. In Lemma 19, we bound the degeneracy of G_6 by 2. This construction can be generalized for any $k = 3\ell$ where $\ell \geqslant 2$, by replacing each edge in $E(G)$ with ℓ-length path.

Next consider the case $k = 7$. For each edge $e \in E(G)$, we first create two parallel copies of e, and then replace the first one with a length two path $\{e_{1,1}, e_{1,2}\}$, and the second one with a length three path $\{e_{2,1}, e_{2,2}, e_{2,3}\}$. So in $E(G_7)$, we have 5 edges for each edge in $E(G)$. We create 3 new vertices per edge to accomplish this, and denote them as v_e, u_{e_1}, u_{e_2}. See Figure 4b for a pictorial demonstration. In Lemma 20, we argue that the number of $\mathcal{C}_7$ is exactly 3 times the number of triangles in G. In Lemma 19, we bound the degeneracy of G_7 by 2. This construction generalizes to any $k = 3\ell + i$ where $\ell \geqslant 2$ and $i \in \{1, 2\}$ (except for the case when $k = 8$, that is $\ell = 2$ and $i = 2$) by splitting each edge into ℓ and $\ell + 1$ many parts respectively.

Finally, we consider the case of $k = 8$. Note that the target subgraph H_8 is the 7-cycle with a tail in this case (see Figure 3). It is natural to wonder why do we not simply take $H_8 = \mathcal{C}_8$? After all, for all other values of k, taking $H_k = \mathcal{C}_k$ suffices. At a first glance, it seems like if we consider the same graph G_7 as described above (and in Figure 4b) the number of $\mathcal{C}_8$ would be a simple linear function of the number of triangles in G — for each triangle in G, there will be exactly three $\mathcal{C}_8$ in G_7. However, each $\mathcal{C}_4$ in G would also lead to a $\mathcal{C}_8$ in G_8. Observe that for $k > 8$, we do not run into this problem. A more formal treatment of this issue appear in Section 5.

So instead, we take H_8 to be the subgraph $\mathcal{C}_7$ with a tail to prove our conditional lower bound for SUB-CNT$_8$. The construction of the graph G_8 remains exactly the same as that of G_7. We show in Lemma 21 that, there exists a $\mathcal{C}_7$ with a tail in G_8 if and only if there exist a triangle in G.

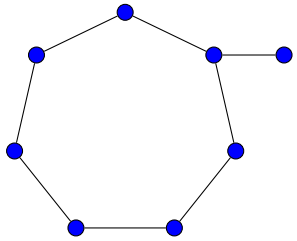

Figure 3 Target subgraph for proving conditional lower bounds for SUB-CNT$_8$: the $\mathcal{C}_7$ with a tail

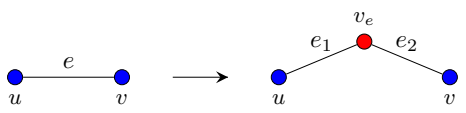
We now present the proof of Theorem 18 in full details.

Proof of Theorem 18. Fix some $k \geqslant 6$. Let the subgraph H_k denote the target subgraph of size k. For $k \neq 8$, H_k is $\mathcal{C}_k$, and for $k = 8$, H_k is $\mathcal{C}_7$ with a tail (see Figure 3). We reduce from the TRI-CNT problem to the SUB-CNT$_{H_k}$. Let $G = (V, E)$ be the input instance for the TRI-CNT problem with $|V| = n$ and $|E| = m$. We construct an input instance $G_k = (V_k, E_k)$ for the SUB-CNT$_{H_k}$ problem from G. The construction of G_k differs based on whether k is divisible by 3 or not. We next consider these two cases separately.

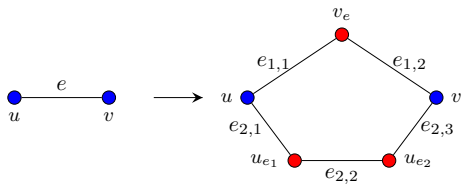
Details of the Reduction. First assume $k = 3\ell$ for some integer $\ell \geqslant 2$. We first define the vertex set V_k. For each vertex in V, we add a vertex in V_k. For each edge $e \in E$, we add a set of $\ell - 1$ many vertices, denoted as $V_e = \{v_{e,1}, v_{e,2}, \ldots, v_{e,\ell-1}\}$. We collect all these second type of vertices into the set V_E. Formally, we have

$$V_k = V \cup V_E\,,$$
$$\text{where } V_E = \bigcup_{e \in E} V_e\,,$$
$$\text{for } V_e = \{v_{e,1}, v_{e,2}, \ldots, v_{e,\ell-1}\}\,.$$



$e \in E(G)$ $\quad e_1, e_2 \in E(G_6)$

(a) Construction of the edge set $E(G_6)$ from the edge set $E(G)$. The red colored nodes are only present in $V(G_6)$, and not in $V(G)$.



$e \in E(G)$ $\quad e_{i,j} \in E(G_7)$

(b) Construction of the edge set $E(G_7)$ from the edge set $E(G)$. The red colored nodes are only present in $V(G_7)$, and not in $V(G)$.

Figure 4 Reduction from the TRI-CNT problem to the SUB-CNT$_{\mathcal{C}_k}$ problem for $k = 6$ (left) and $k = 7$ (right).

We now describe the edge set E_k. We treat each edge $e = \{u, v\} \in E$ as an ordered pair (u, v) where the ordering can be arbitrary of the vertices (for example, assume lexicographical ordering). Now for each edge $e = (u, v)$ construct an ℓ-length path between u and v in V_k by connecting the vertices in $\{u\} \cup V_e \cup \{v\}$ sequentially. More precisely, we define E_k as follows.

$$E_k = \bigcup_{e \in E} E_e \,,$$
$$\text{where } E_e = \{\{u, v_{e,1}\}, \{v_{e,1}, v_{e,2}\}, \ldots, \{v_{e,\ell-2}, v_{e,\ell-1}\}, \{v_{e,\ell-1}, v\}\} \text{ for } e = (u, v)\,.$$

This completes the construction of the graph $G_k = (V_k, E_k)$. We give an example in Figure 4a for $k = 6$.

Now assume $k = 3\ell + i$ for some some integer $\ell \geqslant 2$ and $i \in \{1, 2\}$. In the previous case, we added a set of $\ell - 1$ many vertices for each edge in E. But now, for each edge $e \in E$, we add two sets of vertices, one with $\ell - 1$ many vertices and the other with ℓ many vertices. We denote the first set as $V_e = \{v_{e,1}, v_{e,2}, \ldots, v_{e,\ell-1}\}$, and the second set as $U_e = \{u_{e,1}, u_{e,2}, \ldots, u_{e,\ell}\}$. We also add the set of vertices in V to V_k. Formally, we have

$$V_k = V \cup V_E \,,$$
$$\text{where } V_E = \bigcup_{e \in E} V_e \cup U_e \,,$$
$$\text{for } V_e = \{v_{e,1}, v_{e,2}, \ldots, v_{e,\ell-1}\} \,,$$
$$\text{and } U_e = \{u_{e,1}, u_{e,2}, \ldots, u_{e,\ell}\}\,.$$

To construct the edge set E_k, as before we treat each edge in $e = \{u, v\} \in E$ as an ordered pair (u, v) according to some arbitrary ordering of the vertices. Now, for each edge $e = (u, v)$, construct an $2\ell + 1$-length cycle between u and v in V_k by creating a ℓ-length path via the vertices in V_e and another $\ell + 1$-length path via the vertices in U_e. We denote the corresponding edge sets as $E_{V,e}$ and $E_{U,e}$ respectively. Formally, we define E_k as follows.

$$E_k = \bigcup_{e \in E} (E_{V,e} \cup E_{U,e}) \,,$$
$$\text{where } E_{V,e} = \{\{u, v_{e,1}\}, \{v_{e,1}, v_{e,2}\}, \ldots, \{v_{e,\ell-2}, v_{e,\ell-1}\}, \{v_{e,\ell-1}, v\}\} \,,$$
$$\text{and } E_{U,e} = \{\{u, u_{e,1}\}, \{u_{e,1}, u_{e,2}\}, \ldots, \{u_{e,\ell-1}, u_{e,\ell}\}, \{u_{e,\ell}, v\}\} \text{ for } e = (u, v)\,.$$

This completes the construction of the graph $G_k = (V_k, E_k)$. Note that the construction is independent of the value of i. Hence, we produce the same graph G_k for $k = 3\ell + 1$ and $k = 3\ell + 2$. We give an example in Figure 4b for $k = 7$.

Note that although our target subgraph for the case $k = 8$ is a 7-cycle with a tail instead of 8-cycle, our construction is still the same.

Correctness of the Reduction. In Lemma 19, we prove that G_k has degeneracy at most 2. In Lemma 20, we show that, for $k \neq 8$, the number of $\mathcal{C}_k$ in the graph G_k is a linear function of the number of triangles in G. In Lemma 21, we show that G_8 is H_8 free if and only if G is triangle free.

▶ **Lemma 19.** $\kappa(G_k) \leqslant 2$.

Proof. To prove the lemma it is sufficient to exhibit a vertex ordering $\prec$ such that in the corresponding directed graph $G^{\rightarrow}_{\prec}$, $d^+(v) \leqslant 2$ for all $v \in V_k$ (application of Lemma 6). We use an ordering $\prec$ where $V_E \prec V$ and the ordering within each set is arbitrary. Observe that each vertex $v \in V_E$ has degree exactly 2 and no two vertices in V are connected to each other. Hence, $d^+(v) \leqslant 2$ for all $v \in V_k$. ◀

▶ **Lemma 20.** *Let $\ell \geqslant 2$ be some integer. For $k = 3\ell$, $\mathrm{DM}(G_k, \mathcal{C}_k) = \mathrm{DM}(G, \mathcal{C}_3)$. For $k = 3\ell + i$ with $i \in \{1, 2\}$ and $k \neq 8$, $\mathrm{DM}(G_k, \mathcal{C}_k) = 3 \cdot \mathrm{DM}(G, \mathcal{C}_3)$.*

Proof. Let $\mathcal{T}$ be the set of triangles in G and $\mathcal{C}$ be the set of $\mathcal{C}_k$ in G_k. Note that a triangle in $\mathcal{T}$ and a k-cycle in $\mathcal{C}$ can be uniquely identified by a set of three and k edges, respectively.

We first take up case of $k = 3\ell$ for some $\ell \geqslant 2$. Let g be the mapping between the sets $\mathcal{T}$ and $\mathcal{C}$, $g : \mathcal{T} \to \mathcal{C}$, defined as follows: $g(\{e_1, e_2, e_3\}) = E_{e_1} \cup E_{e_2} \cup E_{e_3}$. To prove the lemma, it is sufficient to exhibit that g is a bijection. To this end, note that if $g(\tau_1) = g(\tau_2)$, then $\tau_1 = \tau_2$. This follows immediately from the definition of g, since $E_{e_1} \cap E_{e_2} = \emptyset$ for all $e_1 \neq e_2$. We now show that every k-cycle in $\mathcal{C}$ has an inverse mapping in g. Let ξ be a k-cycle in $\mathcal{C}$. Fix some edge $e \in E$. By construction, either all the edges from the set E_e are present in ξ, or none of them are. Hence, ξ must be of the form $E_{e_1} \cup E_{e_2} \cup E_{e_3}$ for some three distinct edges e_1, e_2, and e_3. Clearly, $\{e_1, e_2, e_3\}$ forms a triangle in G.

Now assume $k = 3\ell + i$ for some $\ell \geqslant 2$ and $i \in \{1, 2\}$, and $k \neq 8$. It is not difficult to see that each triangle in $\mathcal{T}$ leads to exactly three k-cycles in $\mathcal{C}$. The non-trivial direction is to show that for each k-cycles in $\mathcal{C}$ there is an unique triangle in $\mathcal{T}$. Let ξ be a k-cycle in $\mathcal{C}$. Fix some edge $e \in E$. By construction, exactly one of the following must be true: (i) all the ℓ edges from the set $E_{V,e}$ are present in ξ, (ii) all the $\ell + 1$ edges from the set $E_{U,e}$ are present in ξ, (iii) none of the edges from the set $E_{V,e} \cup E_{U,e}$ are present in ξ. First assume $i = 1$. Since ξ has $3\ell + 1$ many edges, and $\ell \geqslant 2$, it must consist of one $E_{U,e}$ set of size $\ell + 1$, and two $E_{V,e}$ sets of size ℓ. When $i = 2$ and $\ell > 2$, ξ must consist of two $E_{U,e}$ set of size $\ell + 1$, and one $E_{V,e}$ sets of size ℓ. Clearly, the three edges corresponding to these sets form a unique triangle in G. (When $k = 8$, that is $\ell = 2$ and $i = 2$, taking four distinct sets $E_{V,e}$ creates a copy of $\mathcal{C}_8$, and hence the argument does not work.) ◀

▶ **Lemma 21.** *The input graph G is triangle free if and only if G_8 does not have any $\mathcal{C}_7$ with a tail.*

Proof. Observe that, if there exists a triangle τ in G, then in G_8, there would be at least one $\mathcal{C}_7$ with a tail (in fact, the exact number would depend on the degree of the involved vertices). In the proof of Lemma 20, we argued that each 7-cycle in G_7 (which is isomorphic to G_8) corresponds to a triangle in G. Also, by our construction, if G_8 has a $\mathcal{C}_7$, then that 7-cycle necessarily has a tail. Therefore, existence of $\mathcal{C}_7$ with a tail in G_8 implies existence of a triangle in G. This completes the proof of the lemma. ◀

Lemmas 19 to 21 together prove the theorem: if there exists an algorithm $\mathcal{A}$ for the SUB-CNT$_{\mathcal{C}_k}$ problem with $T(\mathcal{A}) = O(mf(\kappa))$, then $\mathcal{A}$ is an algorithm for the TRI-CNT problem (or the triangle detection problem in the case of $k = 8$) with $T(\mathcal{A}) = O(m)$, where $T(\mathcal{A})$ denotes the worst case time complexity of the algorithm $\mathcal{A}$. ◀

6 Future Directions

Although our algorithmic framework fails to produce a linear time algorithm for SUB-CNT$_{\mathcal{C}_6}$ in bounded degeneracy graphs, there are certain other 6-vertex subgraphs where it indeed succeeds. An easy example is SUB-CNT$_{\mathcal{K}_6}$. In fact, our framework gives a linear time algorithm for counting any constant size clique in bounded degeneracy graphs – for each acyclic orientation of a clique, the source vertex construct a DRTS covering all the remaining vertices. There exists other non-clique 6-vertex subgraphs as well, where Alg. 2 succeeds. Consider the subgraph H shown in Fig. 5. It is easy to see that, any acyclic orientation of H such as $H^{\rightarrow}$ has at least one source vertex s that is a root of a DRTS with four vertices. Thus, we can solve SUB-CNT$_H$ in $O(m\kappa^3)$ expected time.

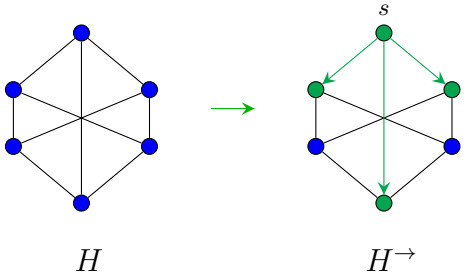


Figure 5 Alg. 2 succeeds to count the number of distinct matches of H in linear time for bounded (constant) degeneracy graphs. Each acyclic orientation of H has a source vertex s, which is connected to exactly three vertices, as in $H^{\rightarrow}$. So, the largest DRTS has at least four vertices (shown in green). Number of matches of the remaining vertices (shown in blue) could be counted using $\mathcal{HM}_2$.

Despite the chasm at six, there exist subgraphs H with 6-vertices (or more) such that SUB-CNT$_H$ admits a linear time algorithm in bounded degeneracy graph. We end this exposition with the following natural problem:

Characterize all subgraphs H such that SUB-CNT$_H$ *has a linear time algorithm in bounded degeneracy graphs.*

Abstract

Parameterization above a guarantee is a successful paradigm in Parameterized Complexity. To the best of our knowledge, all fixed-parameter tractable problems in this paradigm share an *additive form* defined as follows. Given an instance (I, k) of some (parameterized) problem Π with a *guarantee* $g(I)$, decide whether I admits a solution of size at least (at most) $k + g(I)$. Here, $g(I)$ is usually a lower bound (resp. upper bound) on the maximum (resp. minimum) size of a solution. Since its introduction in 1999 for Max SAT and Max Cut (with $g(I)$ being half the number of clauses and half the number of edges, respectively, in the input), analysis of parameterization above a guarantee has become a very active and fruitful topic of research.

We highlight a *multiplicative* form of parameterization above a guarantee: Given an instance (I, k) of some (parameterized) problem Π with a guarantee $g(I)$, decide whether I admits a solution of size at least (resp. at most) $k \cdot g(I)$. In particular, we study the Long Cycle problem with a multiplicative parameterization above the girth $g(I)$ of the input graph, and provide a parameterized algorithm for this problem. Apart from being of independent interest, this exemplifies how parameterization above a multiplicative guarantee can arise naturally. We also show that, for any fixed constant $\epsilon > 0$, multiplicative parameterization above $g(I)^{1+\epsilon}$ of Long Cycle yields para-NP-hardness, thus our parameterization is tight in this sense. We complement our main result with the design (or refutation of the existence) of algorithms for other problems parameterized multiplicatively above girth.

1 Introduction

The goal of parameterized complexity is to find ways of solving NP-hard problems more efficiently than brute force: our aim is to restrict the combinatorial explosion to a parameter that is hopefully much smaller than the input size. Formally, a *parameterization* of a problem is the assignment of an integer k to each input instance, and we say that a parameterized problem is *fixed-parameter tractable (FPT)* if there is an algorithm that solves the problem in time $f(k) \cdot n^{O(1)}$, where n is the size of the input and f is an arbitrary computable function depending on the parameter k only. There is a long list of NP-hard problems that are FPT under various parameterizations: finding a vertex cover of size k, finding a cycle of length k, finding a maximum independent set in a graph of treewidth at most k, etc. For more background, the reader is referred to the monographs [12, 14, 21].

Choosing a suitable parameter plays an important role in the field of parameterized complexity. Traditionally, the *solution size* has been the most sought after parameter. However, in various circumstances this is not a good parameter. To illustrate this, consider the following problems: Max Sat and Max Cut. Observe that there always exists a truth assignment that satisfies half of the clauses, and there is always a max-cut containing at least half the edges. Thus, if we choose solution size as the parameter, then we get the following trivial algorithm: if $k \leq m/2$, then return yes; else $m \leq 2k$, so now any brute-force algorithm is an FPT algorithm. Thus if we want to design a nontrivial parameterized algorithm, then solution size is *not a suitable parameter*. In particular, a general message here is as follows.

> The natural parameterization of, say, a maximization/minimization problem by the solution size is not satisfactory if there is a lower bound for the solution size that is sufficiently large.

Thus, for such cases, it is more natural to parameterize the problem by *the difference between the solution size and the bound*. This perspective is known as "above guarantee" parameterization. This approach was introduced by Mahajan and Raman [33] for the Max Sat and Max Cut problem. This approach was successfully applied to many various problems (see, e.g., [1, 11, 24, 25, 26, 34, 10] for a few illustrative examples).

In some of the above examples there is an explicit lower bound on the solution size, given in terms of the input size. However, in many cases, we do not have explicit lower bounds. We substantiate this with the example of classic Vertex Cover problem. In this problem, we are given a graph G and a positive integer k, and the goal is to test whether there exists a set of vertices C of size at most k that is a vertex cover (i.e., every edge has at least one endpoint in C). Clearly, the size of a *maximum matching* of G or the value of the linear programming relaxation of an integer linear program for Vertex Cover is a lower bound on the size of a vertex cover of G. Observe that these lower bounds are graph dependent

and not the size dependent. This is what we mean by implicit lower bounds. Coming back to Vertex Cover, in polynomial time it is possible to reduce the size of the graph, without changing the answer, such that we are guaranteed that any vertex cover must contain half of the remaining vertices. Thus, again we can employ any brute-force algorithm and design an FPT algorithm for Vertex Cover. This has led to the study of the problem Vertex Cover Above LP (or Vertex Cover Above Matching), which has played a central role in the development of the field of parameterized complexity [12].

In this paper, we take the philosophy of above guarantee parameterization a significant conceptual step forwards. In particular,

> The goal of this paper is to study another classical problem – namely, Long Cycle – from the viewpoint of a new implicit parameterization, that is neither standard nor an additive above guarantee parameterization.

The Long Path problem is to decide, given a directed or undirected n-vertex graph G and an integer k, whether G contains a path on at least k vertices, that is, a self-avoiding walk with at least k vertices. Similarly, the Long Cycle problem is to decide whether G contains a cycle of length at least k, that is, a closed self-avoiding walk with at least k vertices. These problems are natural generalization of the classical Hamiltonian Path and Hamiltonian Cycle problems and have been actively studied. In particular, there is a plethora of results about parameterized complexity of Long Path and Long Cycle (see, e.g., [4, 5, 9, 8, 18, 22, 29, 30, 31, 38]) since the early work of Monien [35]. Let us just mention here that the fastest known randomized algorithm for Long Path is due to Björklund et al. [4] and runs in time $1.657^k \cdot n^{\mathcal{O}(1)}$, whereas the fastest known deterministic algorithm is due to Tsur [37] and runs in time $2.554^k \cdot n^{\mathcal{O}(1)}$. Respectively for Long Cycle, the randomized algorithm with the currently best running time of $4^k \cdot n^{\mathcal{O}(1)}$ was given by Zehavi in [40], and the best deterministic algorithm was given by Fomin et al. in [20] and runs in time $4.884^k \cdot n^{\mathcal{O}(1)}$.

For Long Path, the investigation of above guarantee parameterizations was initiated by Bezáková et al. in [2]. Let s and t be two vertices of a graph G. Clearly, the length of any (s,t)-path in G is lower bounded by the shortest distance, $d(s,t)$, between these vertices. Based on this straightforward observation, Bezáková et al. in [2] introduced the Longest Detour problem that asks, given a graph G, two vertices s,t, and a positive integer k, whether G has an (s,t)-path with at least $d(s,t)+k$ vertices. They proved that for undirected graphs, this problem can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$. That is, it is FPT. For the variant of the problem where the question is whether G has an (s,t)-path with *exactly* $d(s,t)+k$ vertices, a randomized algorithm with running time $2.746^k \cdot n^{\mathcal{O}(1)}$ and a deterministic algorithm with running time $6.745^k \cdot n^{\mathcal{O}(1)}$ were obtained. In a recent work, Fomin et al. [17] studied the parameterization of Long Path and Long Cycle above the degeneracy d of the input graph G. Formally, a graph G has degeneracy at most d if every subgraph of G has a vertex of degree at most d. A classic result by Erdős and Gallai [15] from 1959 states that any graph of degeneracy $d > 1$ has a cycle (and hence also path) on at least d vertices. If the graph G is not guaranteed to be 2-connected, then deciding whether G contains a cycle of length $d+2$ is already NP-hard, and therefore parameterization above degeneracy does not make sense. However, when we add the requirement that G is 2-connected, then then deciding whether G contains a cycle of length $d+k$ parameterized by k can be done in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ and hence FPT. A similar situation holds for Long Path where connectivity replaces 2-connectivity.

1.1 Multiplicative Above Guarantee Parameterization

To the best of our knowledge, all successful above guarantee parameterizations are additive. Roughly speaking, this means that if we have a lower bound τ on the optimal solution size, then we ask whether we can find a solution of size (at least or at most) $\tau + p$ in time $f(p) \cdot n^{\mathcal{O}(1)}$. Our main message of this paper is the following.

> The goal of this paper is to introduce the notion of multiplicative above guarantee parameterization (which is neither standard nor an additive above guarantee parameterization). In multiplicative above guarantee parameterization, we ask whether we can find a solution of size (at least or at most) $\tau \cdot p$ in time $g(p) \cdot n^{\mathcal{O}(1)}$. We will illustrate our new definition by designing several FPT algorithms parameterized above a multiplicative guarantee.

We remark that a few problems in [36] were stated in a way fitting parameterization above a multiplicative guarantee. However, these were shown to be para-NP-hard [27, 28].

Recall that the *girth* of a graph G, denoted by $\gamma(G)$, is the length of the shortest cycle in G. First, consider the problem where we are given a graph G and an integer k and the objective is to test whether there is a cycle of length at least $\gamma(G)+k$ in G. If $\gamma(G) \leq 2k+6$, then clearly we can solve the problem in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ by using the algorithm in [39]. We now show that when $2k + 6 < \gamma(G)$, the problem is solvable in polynomial time. To this end, let (G, k) be a yes-instance, and let C be a hypothetical solution. That is, C is a cycle of length at least $\gamma(G) + k$. Let $g = \gamma(G)$. Let $u, v, w, x \in V(C)$ such that when we traverse C in some order from u, we encounter v at distance $\lfloor \frac{g}{2} \rfloor - 1$ from u, next we encounter w at additional distance $\lfloor \frac{g}{2} \rfloor - 1$ from v, and lastly we encounter x at additional distance $k' = (g + k) - (2\lfloor \frac{g}{2} \rfloor - 2)$ from w. Notice that $k' \in \{k + 2, k + 3\}$. Since the girth of G is g and $k + 3 < \frac{g}{2}$, we have that shortest paths between u and v, v and w, and w and x are unique and they are part of the cycle C. Therefore, we may compute the shortest paths between the pairs above, and later check whether u is reachable from x after deleting these shortest paths. Going over every possible choice of $u, v, w, x \in V(C)$, this leads to a polynomial time algorithm when $2k + 6 < \gamma(G)$. This implies that it can be decided in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ whether a graph has a cycle with at least $\gamma(G) + k$ vertices.

The informal argument above shows that Long Cycle parameterized additively above girth is not more "interesting" than just normal Long Cycle, where the input lower bound on solution size is the parameter. In a sense, it hints that the guarantee may be strengthened. In light of this, we introduce a new above guarantee version of Long Cycle (resp. Long Path), termed Long Cycle (resp. Long Path) parameterized multiplicatively above girth, as follows. The input consists of a graph G and an integer k, and the objective is to decide whether there is a cycle (resp. path) on at least $k \cdot \gamma(G)$ vertices.

1.2 Our Contribution

We first prove our main result, which states that Long Cycle (and Long Path) parameterized multiplicatively above girth is FPT. Specifically, we prove the following theorem.

▶ **Theorem 1.** Long Cycle *(and* Long Path*) parameterized multiplicatively above girth is solvable in time* $2^{\mathcal{O}(k^2)}n$.

As a complementary result to the above theorem, we assert that our parameterization is tight in the following sense.

▶ **Theorem 2.** *For any fixed constant $\epsilon > 0$,* Long Cycle *(and* Long Path*) parameterized multiplicatively above $g^{1+\epsilon}$ is para-NP-hard, where g is the girth of the input graph.*

Next, we further extend the scope of our problem domain by showing that also Vertex Cover, Connected Vertex Cover and Max Internal Spanning Tree parameterized multiplicatively above girth are FPT. Given a graph G and an integer k, the objectives of these problems are to decide whether G has a vertex cover of size at most $k \cdot \gamma(G)$, a connected vertex cover (that is, a vertex cover that induces a connected subgraph) of size at most $k \cdot \gamma(G)$, and a spanning tree with at least $k \cdot \gamma(G)$ internal vertices, respectively. Here, $\gamma(G)/2$ is a lower bound on the size of an optimal solution.

▶ **Theorem 3.** Vertex Cover*,* Connected Vertex Cover *and* Max Internal Spanning Tree *parameterized multiplicatively above girth are solvable in time $2^{\mathcal{O}(k \log k)}n$.*

Lastly, we observe that parameterization above girth (even additively) can often yield NP-hardness when k is a fixed constant. Specifically, we give Feedback Vertex Set and Cycle Packing as illustrative simple examples.

▶ **Theorem 4.** Feedback Vertex Set *and* Cycle Packing *parameterized additively above girth are para-NP-hard.*

2 Preliminaries

For terminology not explicitly defined here, we refer to the book of Diestel [13]. Throughout the paper, we consider finite undirected graphs. For a graph G, let $V(G)$ and $E(G)$ denote its vertex set and edge set, respectively. When G is clear from context, let $n = |V(G)|$ and $m = |E(G)|$. Given a subset $U \subseteq V(G)$, let $G[U]$ be the subgraph of G induced by U. The *girth* of G is the length of the shortest cycle in G,[1] and is denoted by $\gamma(G)$. A *vertex cover* of G is a set of vertices in G whose removal from G yields an edgeless graph. The *vertex cover number* of G is the smallest size of a vertex cover of G. A *feedback vertex set* of G is a set of vertices in G whose removal from G yields a forest. The *feedback vertex set number* of G is the smallest size of a feedback vertex set of G. For any $t \in \mathbb{N}$, let C_t denote the cycle on t vertices and K_t denote the complete graph on t vertices.

A *subdivision* of an edge $e = \{u, v\} \in E(G)$ is its replacement by a new degree-2 vertex whose neighbors are u and v. A *subdivision* of G is any graph that can be obtained by subdividing some of the edges of G (where a single edge can be subdivided multiple times). Let $\mathsf{Paths}(G)$ be the set of all (simple) paths in G. Given two (simple) paths P_1 and P_2 that share one or two endpoints and are internally vertex-disjoint, let $P_1 + P_2$ denote the (simple) path or cycle (if both endpoints are shared) obtained by concatenating P_1 and P_2. The *size* of a cycle or path is its number of vertices, and its *length* is its number of edges. A graph H is a *topological minor* of G if G contains a subgraph that is isomorphic to some subdivision of H. More explicitly, this notion is defined as follows.

▶ **Definition 5** (Topological Minor)**.** *A graph H is a* topological minor *of a graph G if there exist injective functions $\phi : V(H) \to V(G)$ and $\varphi : E(H) \to \mathsf{Paths}(G)$ such that for all $e = \{h, h'\} \in E(H)$, the endpoints of $\varphi(e)$ are $\phi(h)$ and $\phi(h')$, for all distinct $e, e' \in E(H)$, the paths $\varphi(e)$ and $\varphi(e')$ are internally vertex-disjoint, and there do not exist a vertex v in the image of ϕ and an edge $e \in E(H)$ such that v is an internal vertex on $\varphi(e)$.*

[1] If G does not contain any cycle, then its girth is defined as ∞.

The Catersian product of two graphs is defined as follows.

▶ **Definition 6** (Cartesian Product of Graphs). *The* Cartesian product $G \times H$ *of two graphs* G *and* H *is the graph whose vertex set is the Cartesian product* $V(G) \times V(H)$*, where any two vertices* (u, u') *and* (v, v') *are adjacent if and only if one of the following holds: (i)* $u = v$ *and* $\{u', v'\} \in E(H)$*; (ii)* $u' = v'$ *and* $\{u, v\} \in E(G)$*.*

Treewidth is a measure of how "treelike" is a graph, formally defined as follows.

▶ **Definition 7** (Treewidth). *A* tree decomposition *of a graph* G *is a pair* (T, β) *of a tree* T *and* $\beta : V(T) \to 2^{V(G)}$*, such that*

1. *for any edge* $\{x, y\} \in E(G)$ *there exists a node* $v \in V(T)$ *such that* $x, y \in \beta(v)$*, and*
2. *for any vertex* $x \in V(G)$*, the subgraph of* T *induced by the set* $T_x = \{v \in V(T) : x \in \beta(v)\}$ *is a non-empty tree.*

The width *of* (T, β) *is* $\max_{v \in V(T)}\{|\beta(v)|\} - 1$*. The* treewidth *of* G*, denoted by* $\mathtt{tw}(G)$*, is the minimum width over all tree decompositions of* G*.*

The treewidth of a graph can be efficiently approximated up to a constant factor as follows.

▶ **Proposition 8** ([7]). *There exists an algorithm that, given a graph* G *and an integer* t*, in time* $2^{\mathcal{O}(t)}n$ *either determines that the treewidth of* G *is larger than* t*, or outputs a tree decomposition of* G *of width at most* $5t + 4$*.*

The following relation between treewidth and feedback vertex set number is folklore.

▶ **Proposition 9** ([12]). *There exists an algorithm that, given a graph* G *with a feedback vertex set* U*, in time* $\mathcal{O}(|U|n)$ *outputs a tree decomposition of* G *of width* $|U|$*.*

3 FPT Algorithm for Long Cycle

In this section, we consider the parameterized complexity of Long Cycle parameterized multiplicatively above girth, and prove Theorems 1 and 2. For our positive result, we required the following definition and propositions. First, we give the definition of a graph called a t-prism, which has $2t$ vertices and $3t$ edges (see Fig. 1).

▶ **Definition 10** (Prism). *For any* $t \in \mathbb{N}$*, the* t-prism *is the Cartesian product* $C_t \times K_2$*.*

The following proposition asserts that a graph of sufficiently high treewidth necessarily contains a large prism as a topological minor.

▶ **Proposition 11** ([3]). *For any* $k \in \mathbb{N}$*, any graph* G *of treewidth at least* $60k^2$ *contains a* k*-prism as a topological minor.*[2]

In case the treewidth of the graph is low, we will be able to solve the problem by making use of the following proposition.

▶ **Proposition 12** ([6]). *There exists an algorithm that, given a graph* G *and a tree decomposition of* G *of width* t*, in time* $2^{\mathcal{O}(t)}n$ *outputs a cycle (if one exists) and a path in* G *of maximum sizes.*

[2] Although the result is mentioned in terms of minors, the proof given in [3] yields the result stated here.

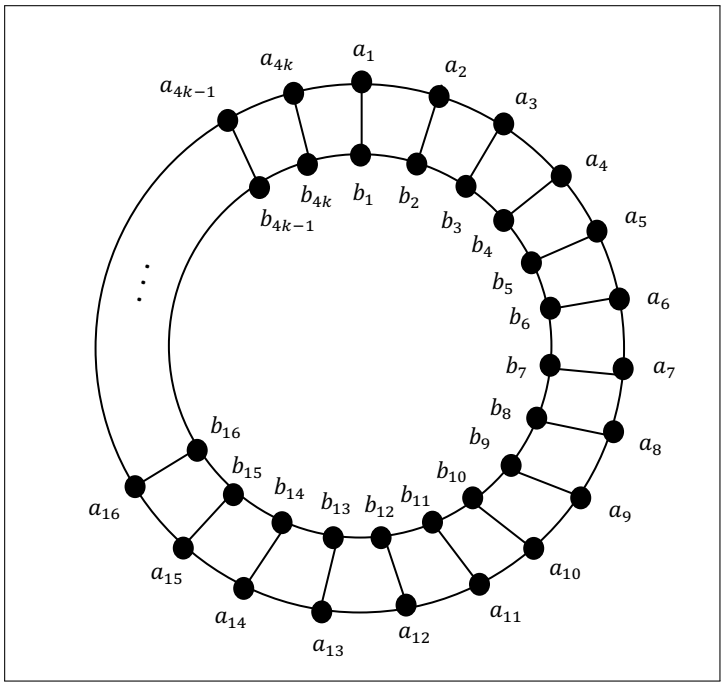

Figure 1 A $4k$-prism.

The main combinatorial lemma we need for our positive result is as follows. This lemma handles the case where the treewidth of the graph is large.

▶ **Lemma 13.** *For any $k \in \mathbb{N}$, any graph G that contains the $4k$-prism as a topological minor also has a cycle on at least $\gamma(G) \cdot k$ vertices.*

Proof. Let H be the $4k$-prism. Notice that the vertex set of H can be denoted by $V(H) = \{a_1, a_2, \ldots, a_{4k}, b_1, b_2, \ldots, b_{4k}\}$ so that $H[\{a_1, a_2, \ldots, a_{4k}\}]$ and $H[\{b_1, b_2, \ldots, b_{4k}\}]$ are cycles and $\{\{a_i, b_i\} : i \in \{1, 2, \ldots, 4k\}\} \subseteq E(H)$ (see Fig. 1). Let $\phi\colon V(H) \to V(G)$ and $\varphi\colon E(H) \to \mathsf{Paths}(G)$ be some two functions that witness that H is a topological minor of G. Let $S_1, \ldots, S_{2k}$ be a set of $2k$ vertex-disjoint cycles of length 4 in H defined as follows: For each $i \in \{0, 1, \ldots, 2k-1\}$, $S_i = H[\{a_{2i+1}, a_{2i+2}, b_{2i+2}, b_{2i+1}\}]$ (see Fig. 1). Additionally, we define two (not vertex-disjoint) cycles C and C' in H as follows: $C = H[\{a_1, a_2, b_2, b_3, a_3, a_4, \ldots, a_{4k-1}, a_{4k}, b_{4k}\}]$ and $C' = H[\{a_1, b_1, b_2, a_2, a_3, b_3, \ldots, b_{4k}, a_{4k}, a_1\}]$ (see Fig. 1).

Now, for each $i \in \{0, 1, \ldots, 2k-1\}$, let $A_i = \varphi(\{a_{2i+1}, a_{2i+2}\}) + \varphi(\{a_{2i+2}, b_{2i+2}\}) + \varphi(\{b_{2i+2}, b_{2i+1}\}) + \varphi(\{b_{2i+1}, a_{2i+1}\})$. This notation is well defined as required to concatenate paths – specifically, here we concatenated internally vertex-disjoint paths sharing exactly one endpoint except for the last concatenation where both endpoints are shared (by the paths $\varphi(\{a_{2i+1}, a_{2i+2}\}) + \varphi(\{a_{2i+2}, b_{2i+2}\}) + \varphi(\{b_{2i+2}, b_{2i+1}\})$ and $\varphi(\{b_{2i+1}, a_{2i+1}\})$). Roughly speaking, A_i is the cycle to which φ maps S_i. Notice that $\{A_i\}_{i=0}^{2k-1}$ is a collection of $2k$ vertex-disjoint cycles in G. Therefore, together they contain at least $2\gamma(G) \cdot k$ edges.

Additionally, let $B = \varphi(\{a_1, a_2\}) + \varphi(\{a_2, b_2\}) + \varphi(\{b_2, b_3\}) + \varphi(\{b_3, a_3\} + \cdots + \varphi(\{a_{4k}, b_{4k}\} + \varphi(\{b_{4k}, a_1\})$. Again, this notation is well defined as required to concatenate paths. Similarly, let $B' = \varphi(\{a_1, b_1\}) + \varphi(\{b_1, b_2\}) + \varphi(\{b_2, a_2\}) + \varphi(\{a_2, a_3\} + \cdots + \varphi(\{b_{4k}, a_{4k}\} + \varphi(\{a_{4k}, a_1\})$. Roughly speaking, B and B' are the cycles to which φ maps C and C', respectively. Notice that $E(H) = E(C) \cup E(C')$. Thus, we deduce that $\bigcup_{i=0}^{2k-1} E(A_i) \subseteq E(C) \cup E(C')$. From this,

we further deduce least one among the cycles B and B' must contain at least half the edges in $\bigcup_{i=0}^{2k-1} E(A_i)$. Because we already showed that $|\bigcup_{i=0}^{2k-1} E(A_i)| \geq 2\gamma(G) \cdot k$, this means that at least one among the cycles B and B' has length (and therefore also size) at least $\gamma(G) \cdot k$. This completes the proof. ◀

By Proposition 11, any graph G of treewidth at least $60 \cdot (4k)^2 = 960k^2$ contains a $4k$-prism as a topological minor. Thus, we derive the following corollary to Lemma 13.

▶ **Corollary 14.** *For any $k \in \mathbb{N}$, any graph G of treewidth at least $960k^2$ has a cycle on at least $\gamma(G) \cdot k$ vertices.*

We are now ready to prove our main theorem.

▶ **Theorem 1.** Long Cycle *(and* Long Path*) parameterized multiplicatively above girth is solvable in time $2^{\mathcal{O}(k^2)}n$.*

Proof. Given an instance (G, k) of Long Cycle (Long Path), the algorithm is executed as follows. First, it calls the algorithm in Proposition 8 with $t = 960k^2$ in time $2^{\mathcal{O}(t)}n = 2^{\mathcal{O}(k^2)}n$ to either determine that the treewidth of G is larger than t, or output a tree decomposition of G of width at most $5t + 4$. In the first case, it concludes that (G, k) is a Yes-instance of Long Cycle (resp. Long Path), which is correct by Corollary 14. In the second case, it calls the algorithm in Proposition 12 to obtain a cycle (resp. path) of maximum size in G in time $2^{\mathcal{O}(5t+4)}n = 2^{\mathcal{O}(k^2)}n$, and concludes that (G, k) is a Yes-instance of Long Cycle (resp. Long Path) if and only if the size of this cycle (resp. path) is at least $\gamma(G) \cdot k$. ◀

▶ **Theorem 2.** *For any fixed constant $\epsilon > 0$,* Long Cycle *(and* Long Path*) parameterized multiplicatively above $g^{1+\epsilon}$ is para-NP-hard, where g is the girth of the input graph.*

Proof. Consider some fixed constant $\epsilon > 0$. Our proof is based on a reduction from the Hamiltonian Cycle (resp. Hamiltonian Path) problem, which is known to be NP-hard [23], to Long Cycle (resp. Long Path) parameterized multiplicatively above $g^{1+\epsilon}$. In the Hamiltonian Cycle (resp. Hamiltonian Path) problem, we are given a graph G and the objective is to decide whether G contains a (simple) cycle (resp. path) on n vertices. In what follows, we only describe the proof for Long Cycle (since the proof for Long Path is similar).

We now describe the reduction. To this end, let G be an instance of Hamiltonian Cycle. Let b be the smallest positive integer such that $b(1 + \epsilon) \in \mathbb{N}$. (Note that b depends only on ϵ.) Let $a = b(1 + \epsilon) - 1$. Notice that $b \leq a$ (since $b \cdot \epsilon$ is a positive integer). Now, subdivide each edge in G $n^a - 1$ times, and let G' be the resulting graph. Let H be the disjoint union of G' and C, where C is a cycle of length n^b. Finally, set $k = 1$, and let (H, k) be the output instance of Long Cycle parameterized multiplicatively above $g^{1+\epsilon}$. Notice that here, g is the girth of H, i.e. $g = \gamma(H)$.

Notice that for any $\ell \in \mathbb{N}$, for any cycle of size ℓ in G, there is a corresponding cycle of size $\ell \cdot n^a$ in G', and vice versa. This implies that any cycle in G' has size at least $3n^a$. Thus, as $b \leq a$, there is a unique shortest cycle in H, which is C. Therefore, $\gamma(H) = n^b$. Then, any cycle (resp. path) C' on at least $(\gamma(H))^{1+\epsilon}k = n^{b(1+\epsilon)} = n^{1+a}$ vertices in H is fully contained in G'. From this, we conclude that for any cycle of size n in G, there is a corresponding cycle of size $(\gamma(H))^{1+\epsilon}k$ in H, and vice versa. This yields the correctness of the reduction. In particular, a parameterized algorithm for Long Cycle parameterized multiplicatively above $g^{1+\epsilon}$ would solve (H, k) is polynomial time (because $k = 1$), and thereby yield a polynomial-time for Hamiltonian Cycle. This completes the proof. ◀

4 FPT Algorithms for (Connected) Vertex Cover and Max Internal Spanning Tree

In this section, we consider the parameterized complexity of (Connected) Vertex Cover and Max Internal Spanning Tree parameterized multiplicatively above girth, and prove Theorem 3. The following proposition asserts that every graph contains either a small feedback vertex set or a large number of vertex-disjoint cycles (with a logarithmic gap), which can also be computed efficiently.

▶ **Proposition 15** ([16, 32]). *For some fixed constant $c \in \mathbb{N}$, there exists an algorithm that, given any $r \in \mathbb{N}$ and a graph G, in time $r^{\mathcal{O}(1)}n$ outputs either a feedback vertex set of G of size at most $cr \log r$ or r vertex-disjoint cycles in G.*

In what follows, we use c to refer to the constant in this proposition. In case the treewidth of the graph is low, we will be able to solve the problem by making use of the following proposition.

▶ **Proposition 16** ([12, 19]). *There exist algorithms for* Vertex Cover, Connected Vertex Cover *and* Max Internal Spanning Tree *that run in time $2^{\mathcal{O}(t)}n$, where t is the treewidth of the input graph.*[3]

The main combinatorial lemmas required for our algorithms are as follows. They handle the case where the feedback vertex set number (and hence also treewidth) of the graph is low. First, for (Connected) Vertex Cover, we need the following lemma.

▶ **Lemma 17.** *For any $r \in \mathbb{N}$, any graph G that contains r vertex-disjoint cycles has vertex cover number at least $\frac{\gamma(G)}{2} \cdot r$.*

Proof. Let $\mathcal{C}$ be a collection of r vertex-disjoint cycles of G. Consider any vertex cover U of G. Then, U must contain at least half the vertices of each cycle in $\mathcal{C}$ in order to contain an endpoint of every edge of that cycle. Since each cycle in $\mathcal{C}$ contains at least $\gamma(G)$ vertices, the lemma follows. ◀

Second, for Max Internal Spanning Tree, we need the following lemma.

▶ **Lemma 18.** *For any $r \in \mathbb{N}$, any* connected *graph G that contains r vertex-disjoint cycles has a spanning tree with at least $(\gamma(G) - 1) \cdot r - 1$ internal vertices.*[4]

Proof. Let $\mathcal{C}$ be a collection of r vertex-disjoint cycles of G. Let H be the graph obtained from G by replacing each cycle $C \in \mathcal{C}$ by a single new vertex v_C (that is made adjacent to all vertices previously adjacent to at least one vertex in C). Let T be some spanning tree of H (whose existence follows from the supposition that G, and hence also H, is connected).

Now, we traverse T in preorder, and when we encounter a new vertex of the form v_C, we perform the following operations. Let p be the parent of v_C in T (if it is not the root), and let u be some vertex in C that is adjacent to p (if v_C is the root, let u be any vertex in C). Then, replace v_C in T by a path P from u to one of its neighbors in C so that this path P contains exactly all the edges of C except one (between u and the chosen neighbor).

[3] Such an algorithm for Max Internal Spanning Tree is not given explicitly, but it is easily seen to follow from the approach of dynamic programming over tree decompositions using representative sets as in [19].

[4] Notice that the supposition that r is positive also implies that G is not a forest and hence $\gamma(G)$ is finite.

Here, make u be the child of p in T, and every child w of v_C is handled as follows: the subtree of w is "hanged" from a vertex of the path P such that w (or some vertex in the cycle represented by w, if w is a new vertex) is adjacent to it in G. Notice that at the end of this process, we obtain a spanning tree of G with the following property. For each cycle $C \in \mathcal{C}$, all vertices except possibly one are internal vertices, with the exception of possibly one cycle (if there was a cycle represented by the root of T) where all vertices except possibly two are internal vertices. Thus, this spanning tree has at least $(\gamma(G) - 1) \cdot r - 1$ internal vertices. This completes the proof. ◀

We are now ready to prove our main theorem.

▶ **Theorem 3.** Vertex Cover, Connected Vertex Cover *and* Max Internal Spanning Tree *parameterized multiplicatively above girth are solvable in time* $2^{\mathcal{O}(k \log k)}n$.

Proof. Given an instance (G, k) of (Connected) Vertex Cover (resp. Max Internal Spanning Tree), the algorithm is executed as follows. Without loss of generality, we suppose that G is connected in the case of Max Internal Spanning Tree, else we clearly have a No-instance of this problem. First, the algorithm calls the algorithm in Proposition 15 with $r = 2k + 1$ in time $r^{\mathcal{O}(1)}n = k^{\mathcal{O}(1)}n$ to obtain either a feedback vertex set of G of size at most $cr \log r$ or $r > 2k$ vertex-disjoint cycles in G. In the second case, by Lemma 17 G has vertex cover number strictly larger than $\frac{\gamma(G)}{2} \cdot 2k = \gamma(G) \cdot k$, and by Lemma 18, it also has a spanning tree with at least $(\gamma(G) - 1) \cdot 2k - 1 \geq \gamma(G) \cdot k$ internal vertices (where the last inequality follows from the facts that $\gamma(G) \geq 3$ and $k \in \mathbb{N}$). Thus, for Vertex Cover and Connected Vertex Cover the algorithm correctly determines that the answer is No, and for Max Internal Spanning Tree the algorithm correctly determines that the answer is Yes. In the first case, the algorithm calls the algorithm in Proposition 9 in time $\mathcal{O}(k \log k \cdot n)$ to obtain a tree decomposition of G of width at most $cr \log r = \mathcal{O}(k \log k)$. Then, it calls the algorithm in Proposition 12 in time $2^{\mathcal{O}(k \log k)}n$ to obtain a (connected) vertex cover of G of minimum size (resp. a spanning tree of G of maximum number of internal vertices), and concludes that (G, k) is a Yes-instance of (Connected) Vertex Cover (resp. Max Internal Spanning Tree) if and only if the output (connected) vertex cover has size at most $\gamma(G) \cdot k$ (resp. the output spanning tree has at least $\gamma(G) \cdot k$ internal vertices). ◀

5 Hardness for Feedback Vertex Set and Cycle Packing

Lastly, we prove the correctness of Theorem 4.

▶ **Theorem 4.** Feedback Vertex Set *and* Cycle Packing *parameterized additively above girth are para-NP-hard.*

Proof. We only prove the lemma for Feedback Vertex Set since the proof for Cycle Packing follows from symmetric arguments. For this purpose, we give a reduction from Feedback Vertex Set itself, which is an NP-hard problem [23]. Towards this, let (G, k) be an instance of Feedback Vertex Set. Then, obtain H from G by subdividing each edge of G k times, and adding a new cycle of size k. Clearly, G has a feedback vertex set of size at most k if and only if H has a feedback vertex set of size at most $k + 1$ (the extra 1 is required to hit the new cycle). Moreover, the girth of H is exactly k. Thus, an algorithm for Feedback Vertex Set parameterized additively above girth should solve $(H, 1)$ in polynomial time (since the parameter is 1), thereby determining whether the feedback vertex set number of H is at most k, and consequently solving (G, k). ◀

Abstract

Consider *sources* that supply sensitive data to an *aggregator*. Standard encryption only hides the data from eavesdroppers, but using specialized encryption one can hope to hide the data (to the extent possible) from the aggregator itself. For flexibility and security, we envision schemes that allow sources to supply encrypted data, such that at any point a dynamically-chosen subset of sources can allow an agreed-upon joint function of their data to be computed by the aggregator. A primitive called multi-input functional encryption (MIFE), due to Goldwasser et al. (EUROCRYPT 2014), comes close, but has two main limitations:

- it requires trust in a third party, who is able to decrypt all the data, and
- it requires function arity to be fixed at setup time and to be equal to the number of parties.

To drop these limitations, we introduce a new notion of *ad hoc* MIFE. In our setting, each source generates its own public key and issues individual, function-specific secret keys to an aggregator. For successful decryption, an aggregator must obtain a separate key from each source whose ciphertext is being computed upon. The aggregator could obtain multiple such secret-keys from a user corresponding to functions of varying arity. For this primitive, we obtain the following results:

- We show that standard MIFE for general functions can be bootstrapped to ad hoc MIFE for *free*, i.e. without making any additional assumption.
- We provide a direct construction of ad hoc MIFE for the inner product functionality based on the Learning with Errors (LWE) assumption. This yields the first construction of this natural primitive based on a standard assumption.

At a technical level, our results are obtained by combining standard MIFE schemes and *two-round* secure multiparty computation (MPC) protocols in novel ways highlighting an interesting interplay between MIFE and two-round MPC.

Acknowledgements We thank Romain Gay for pointing out a subtlety in the security definition of (standard) MIFE for inner products, which necessitated a minor adjustment in our ad hoc MIFE construction.

1 Introduction

In modern society, there is an inherent need for external entities to aggregate and analyze sensitive data from a variety of sources. A few prominent examples are:

- To track diseases, disease control centers would like hospital patients' medical information.
- To determine medication efficacy for a given subpopulation, pharmaceutical companies would like patients' genomic information.
- To provide targeted advertising to consumers, corporations would like buyers' demographic information.

However, this release of sensitive data to external entities is unsettling, as these entities must now be trusted to preserve the confidentiality of the released data. We would like to avoid the need for this trust and believe that specialized encryption schemes will be an important tool for doing so. At a high level, we would like schemes that allow users to encrypt their data before transferring them to an external entity, such that only certain user-specified joint functions of the data are revealed to the entity holding it. We would like this security guarantee to be supported in a flexible way, allowing joint functions of the data to be revealed by any dynamically-chosen subset of users that permit it.

A primitive that comes close, due to Goldwasser et al. [45], is *multi-input functional encryption* (MIFE). To understand MIFE, we first recall the simpler notion of functional encryption (FE) [20]. Just as in traditional encryption, in functional encryption ciphertexts can be generated with an encryption key. However, each *decryption* key is associated with a function f, and decryption of an encryption of m using this key results in not m but $f(m)$. Intuitively, security requires that nothing more than $f(m)$ can be learned from the encryption of m and the decryption key for f. In MIFE, decryption keys allow computing *joint* functions of (possibly) different plaintexts underlying multiple ciphertexts. That is, decryption takes a key for a function f and ciphertexts $c_1, \ldots c_n$ encrypting $m_1, \ldots, m_n$, and outputs $f(m_1, \ldots, m_n)$.

However, MIFE has an important drawback: encryption and decryption keys are generated via a global setup procedure run by an external entity usually called the *key authority*. This begs the question of whether putting trust in the key authority is really better than putting trust in the external entities that aggregate and analyze the data in the first place. A similar point was made by Rogaway about identity-based encryption (IBE) [60]. Indeed, removing this in the case of IBE (and other settings) has been an active area of investigation, *e.g.* see [18, 49, 35]. We contend that for MIFE (and indeed FE) the concern is heightened, as the authority can not only decrypt all the data but is also the one in charge of which functions of the data other external entities can compute. Hence, MIFE does not allow users to enforce their own privacy policies.

Additionally, from a flexibility standpoint, MIFE is limited in that it fixes the number of senders and function arity at setup time. This does not support a dynamic setting in which users can join or leave. Progress on removing this limitation was made by Badrinarayanan et al. [10], who introduced a notion of MIFE for unbounded arity functions. However, their notion does not allow any subset of users to reveal a joint function of their data to an external entity without coordination from all other users, and moreover relies on strong "knowledge type" assumptions. Another closely related notion to ours is that of *decentralized multi-client FE*, recently introduced by Chotard et al. [27]. While this work shares some of the high level motivation of the present work, the two primitives are very different. Please see Section 1.3.3 for a comparison.

1.1 Our Notion: *Ad Hoc* MIFE

To address the above limitations, we introduce a new notion of *ad hoc* MIFE. In ad hoc MIFE, each source (aka. sender or user) will run a *local* setup procedure to generate some public parameters as well as a private encryption key. (One can also consider a public-key setting, but this puts limits on achievable security and we do not do so in this work.[1]) Each source publishes their public parameters and encrypts using their private key. These ciphertexts can be sent to an aggregator (aka. decryptor). Furthermore, using their private keys, sources can issue "partial decryption keys" to an aggregator. Each partial decryption key is associated with an ℓ-ary function f for some ℓ and is generated using the public keys of $\ell - 1$ other (dynamically chosen) sources. If these other $\ell - 1$ sources also issue "matching" partial decryption keys for f to this aggregator, it can decrypt any ℓ ciphertexts $c_1, \ldots, c_\ell$, each produced by the corresponding source, to $f(m_1, \ldots, m_\ell)$ where $m_1, \ldots, m_\ell$ are the plaintexts. One can also consider restricted versions of the above notion, that bound the number of users or fix ℓ (or both). In particular, taking the number of users equal to ℓ gives a version of MIFE that still drops the global setup procedure but lacks the dynamic aspect. Finally, we also consider the restricted notion of *bounded* ad hoc MIFE, where we place a bound on the number of "partial decryption keys" a user is allowed to issue. Intuitively, for security, we require that an aggregator learns only the functions of the data for which it has been given all of the matching partial decryption keys.

Note that while we assume each source can obtain the authentic public parameters of other sources with whom it wants to allow joint functions of the data to be computed, there is no other prior coordination between users (this is one of the main advantages of our notion over [27]). In particular, there is no external entity that generates public parameters or keys. In some of our constructions, we work in the common reference string (CRS) model, but note that this is still much weaker than having an authority who can decrypt all the data.

1.2 Our Results

Our results may be summarized as follows:

- *Feasibility result for general functions*: First, we show that standard MIFE for general functions can be bootstrapped to ad hoc MIFE for general functions for *free*. More specifically, we show that ad hoc MIFE for any functionality is implied by standard MIFE for that functionality combined in a novel way with general FE and a special type of *two-round* secure multiparty computation (MPC) protocol. The latter two are implied by standard MIFE for general functions.

[1] In more detail, in the public-key setting a decryptor could launch an attack where it replaces one user's input with various values to determine information about the input of another user.

Table 1 Our new constructions of ad hoc MIFE.

Functionality	Assumptions	Security	CRS?	Section
General	std. MIFE	Semi-honest	No	4
General	std. MIFE	Malicious	Yes	4
Inner Product	LWE	Semi-honest	Yes	5
Inner Product	LWE	Malicious	Yes	5
Inner Product (Bounded)	DDH, LWE, DCR	Semi-honest	No	5
Inner Product (Bounded)	DDH, LWE, DCR	Malicious	Yes	5

While very general, the result leaves open the goal of obtaining ad hoc MIFE under standard assumptions. In general, this is challenging as standard MIFE is already known to be equivalent to indistinguishability obfuscation [33, 8, 17], which is a central open problem in cryptography. In fact, some negative evidence about the hardness of obtaining such constructions has also been provided [37, 38]. Thus, with the goal of moving towards using standard assumptions, we consider the task of ad hoc MIFE for special but natural functionalities.

- *Constructions for Inner Products from Standard Assumptions*: We provide a construction of ad hoc MIFE for the *inner product* functionality from standard assumptions, namely LWE.[2] Introduced by Abdalla et al. [1] in the single-input setting, this functionality has applications in data mining and information retrieval. Our result is obtained via a general paradigm for constructing ad-hoc MIFE schemes from standard MIFE schemes satisfying certain natural properties; or, what we call "ad hoc friendly" standard MIFE schemes. We show that certain constructions of standard MIFE scheme for inner products from the literature [3, 2] based on standard assumptions (DDH, LWE, or DCR) already satisfy these properties. Additionally, we use a specific two-round MPC protocol [57] that can also be obtained via LWE. We note that by using a two-round MPC protocol from any two-round OT protocol [41, 42, 15] here, we also obtain results for the case of *bounded* ad hoc MIFE for inner products – namely, we get bounded ad hoc MIFE for inner products from DDH, LWE and DCR as well.[3] We remark that since our general construction (first result) already relies on general MIFE for circuits, there is no advantage to mitigating assumptions for the two-round MPC protocol in that setting.

  We emphasize that our transformation is general. Thus, our transformation can be used to upgrade the security of any "ad hoc friendly" standard MIFE for a given functionality to ad hoc MIFE for the same functionality. This result might also be useful in obtaining future constructions of ad hoc MIFE. Furthermore, the modularity of this approach allows for simplifications in our constructions.

We tabulate our results in Table 1 and provide explanation of which MPC protocol is needed for each of the results in Section 1.3.

[2] We stress that this functionality outputs inner products in the clear and is therefore a different type of functionality than that of Katz et al. in [54], which tests if an inner product is zero or not.
[3] Note that semi-honest constructions of two-round OT are known under each of these assumptions.

1.3 Technical Overview

In this section, we describe at a high level the challenges involved in constructing ad hoc MIFE and our techniques for overcoming them.

1.3.1 Ad Hoc MIFE for Arbitrary Functions.

Standard MIFE and ad hoc MIFE can be seen as secure multiparty computation (MPC) protocols with a particular allowable interaction pattern and certain additional reuse capabilities.[4] To begin, let us consider the interaction pattern followed by standard MIFE. In standard MIFE, there is a *trusted* global setup which receives as input the number of parties ℓ, and outputs a public key and a set of ℓ encryption keys. Additionally, global setup on input a function f generates the decryption key DK_f. Of these, the public parameters are broadcast to all users and encryption key EK_i is provided to encryptor i, for $i \in [\ell]$. The encryptors then compute their ciphertexts $\mathsf{CT}(m_i)$ and send these to the aggregator who may now compute the function output $f(m_1 \ldots, m_\ell)$ using the decryption/function key DK_f. Finally, the system supports arbitrary number of decryption keys and ciphertexts. As explained in Section 1.1, in ad hoc MIFE, we seek to eliminate the trusted global procedure as well as support dynamic choice of parties involved in any function computation.

1.3.1.1 Challenges Involved

An approach to eliminating the trusted setup from standard MIFE is to use MPC to replace the global setup. However, naively computing the setup procedure using MPC would introduce interaction between the parties, which the syntax of MIFE does not allow. Moreover, this (interactive) procedure would need to be rerun each time a function key is required to be generated. Using two round MPC, one may hope to overcome the barrier of interaction using the following natural idea: let parties perform a two-round MPC to perform the setup and key generation for a standard MIFE. In more detail, parties in the first round could publish as their public parameters the first round MPC messages with their secret randomness as input. Given the first round messages, parties could send the second round MPC message to the aggregator, who could use it to compute the function key. However, this approach does not suffice since:

1. MIFE requires that the public parameters be published only once whereas the above template requires publishing fresh public parameters for each function key.
2. Even more fundamentally, the above approach precludes users from being able to encrypt, as their encryption keys are not available given just the first round MPC message.

In particular, the above approach does not decouple ciphertexts and functions as in traditional MIFE, which leads to the limitation that an evaluator cannot evaluate the same function on multiple inputs chosen by the parties, nor evaluate other functions on the same set of inputs. Additionally, the problem is made challenging by the fact that in MIFE an aggregator might obtain arbitrary number of secret keys and an encryptor might generate arbitrary number of ciphertexts.

[4] Recall that MPC allows a set of parties to compute a joint function of their inputs without revealing anything else but in general allows these parties to freely interact (although restrictions may apply in special cases).

1.3.1.2 Overcoming the first barrier: Function re-runnable two-round MPC

In order to mitigate the first problem above, we require that the first round MPC message be sent only once, and reused for all subsequent second round messages thus providing re-usability/re-runnability for secret key generation. Towards achieving this re-usability, an idea is to use function rerunnable two-round MPC protocols, where the same first round message can be reused for multiple functions in the second round. As we will see, certain existing two-round MPC protocols satisfy this requirement (see later), but this still does not solve the problem. This is because in adhoc MIFE, we additionally need that for the MPC protocol, the function or even its arity are not known at the time the first round message is sent. We overcome this hurdle by using "function delayed" protocols, which permit the choice of function to be delayed to the second round of the protocol. Together, these special protocols may be used to overcome the first barrier outlined above.

1.3.1.3 Overcoming the second barrier: Delaying Encryption

In order to overcome the second barrier, we allow the encryptor to delay the encryption process until the encryption keys are known (in similar spirit as [13, 30]). In more detail, we will have each source independently run the setup algorithm of a single input FE scheme, denoted as FE and compute the first round message of an MPC protocol using the FE master key as input. This message is published as part of the public key and made available to all other sources. Additionally, each source provides an encryption of its input m_i using the algorithm $\mathsf{FE.Encrypt}$.

The sources may choose the function f to be computed and the group that will participate in the computation dynamically. At this point, each source independently executes the partial key generation algorithm as follows: it generates the second round message of an MPC protocol for a suitable f dependent functionality $\mathsf{GenKeys}_f$ and sends this to the aggregator. Intuitively, the functionality $\mathsf{GenKeys}_f$ has the circuit f hard-coded in it, and enables the aggregator to compute the output.

However, recall that the inputs to the $\mathsf{GenKeys}$ functionality are not the messages on which the computation must be performed, but rather the FE master keys generated independently by each player. To proceed, the functionality instead uses the FE master keys to compute FE *function* keys for a re-encryption procedure, which *translates* FE ciphertexts to MIFE ciphertexts for a freshly generated (standard) MIFE scheme. During this time, the arity of the function f is known, so a suitable standard MIFE scheme may be instantiated. It further outputs an MIFE function key for the function f.

We are almost done: $\mathsf{GenKeys}_f$ runs the setup procedure for a suitable fixed arity standard MIFE scheme, computes FE function keys for each party for the re-encryption functionality, computes the MIFE function key for f and outputs these. The aggregator uses the FE keys together with the FE ciphertexts provided by each encryptor to translate $\mathsf{FE.Enc}(m_i)$ to $c_i = \mathsf{MIFE.Enc}(m_i)$ and then runs the MIFE decryption procedure to obtain $f(m_1, \ldots, m_\ell)$.

Put together, we resolved all difficulties by carefully nesting a a multi-input FE scheme MIFE, within the single input FE scheme FE, which in turn is nested within a re-runnable two-round MPC protocol MPC.

One final problem remains: the adversary could get some partial information from an "incomplete" set of partial decryption keys for some function. This is because standard MPC makes no guarantee when an honest party does not send their final message. We solve this problem by masking the output of MPC by pseudorandom values generated for each party. The partial decryption keys contains the respective user's pseudorandom masks so that only a complete set of user keys can be used to unmask the output.

While security appears to follow intuitively from the security of MPC, FE and MIFE, the proof must contend with several technical hurdles as we are forced to deal with indistinguishability style security of FE, MIFE (simulation security for these primitives is known to be impossible [20, 6]). We argue security via a careful sequence of hybrids, please see Section 4 for details.

1.3.1.4 Instantiating MPC

We now discuss possible instantiations of MPC to fit the above template. Depending on the properties of the underlying two-round MPC protocol, we obtain different properties of the resulting ad hoc MIFE scheme. In both the semi-honest (passive decryptor) and the malicious (active decryptor) settings, the most general function-rerunnable, two-round MPC protocols without CRS can be constructed [32, 48] from indistinguishability obfuscation [33], which itself can be constructed from multi-input functional encryption [8]. Furthermore, as already noted in [40], we remark that in the semi-honest setting the construction of [32] can actually be instantiated in the plain model. This is based on the observation that the CRS in the protocol of [32] was only needed for the computation in the second round. Thus semi-honest parties could obtain a CRS by just performing a one-round coin flipping in the first round. This yields our first result: we get ad hoc MIFE for general functions from standard MIFE for general functions. In the semi-honest setting, the ad hoc MIFE construction is in the plain model. On the other hand, in the malicious setting, these protocols work in the common reference string (CRS) model.

Alternatively, function-rerunnable two-round MPC in the common reference string (CRS) model can be constructed [28, 57, 24, 59] from learning-with-errors (LWE). This yields ad hoc MIFE from LWE and standard MIFE in the CRS model (either semi-honest or malicious). While bounded two-round MPC in the CRS model can be constructed from bilinear maps [41] and even two-round oblivious transfer [15, 42, 39] or information theoretically [9, 36], these constructions are *not* function-rerunnable so do not suffice for our general construction. We note that these constructions would suffice for obtaining bounded ad hoc MIFE, where a user issues only a bounded number of partial decryption keys and maintains *state* across key issues. However, since in our general result we anyway require the minimum assumption of FE/MIFE, instantiating MPC from weaker assumptions does not yield any benefits, and we do not discuss this further. Our results are highlighted in Table 1.

1.3.2 Ad Hoc MIFE for Inner Products.

While our construction of ad hoc MIFE above applies to arbitrary functionalities, it requires use of standard MIFE for general functions. Unfortunately, as noted above, standard MIFE implies indistinguishability obfuscation. Hence, there is limited hope of basing it on standard assumptions. Additionally, our general transformation uses an FE scheme for a potentially complicated re-encryption functionality and also requires general-purpose, function-rerunnable two-round MPC for computing a complex functionality. These aspects limit the practical applicability of our general result.

Next, we describe a paradigm for constructing ad-hoc MIFE schemes from standard MIFE schemes that are "ad hoc friendly" and a (hopefully simple) two-round MPC protocol. This paradigm significantly simplifies our general construction and provides a way for basing it on standard assumptions. We then show that the standard MIFE scheme for inner products [3, 2], which may be based on DDH, LWE or DCR, is ad hoc friendly and the corresponding two-round MPC protocol is only required to compute inner-products, thus obtaining an efficient ad hoc MIFE scheme for inner products.

More formally, in the inner product functionality a decryption key corresponds to a concatenated vector $\mathbf{y} = (\mathbf{y_1} \parallel \cdots \parallel \mathbf{y_n})$ where $\mathbf{y_i} \in \mathbb{Z}_q^m$, and a ciphertext encrypts a vector $\mathbf{x_i} \in \mathbb{Z}_q^m$. The desired result of decryption is $\sum_{i=1}^{n} \langle \mathbf{x_i}, \mathbf{y_i} \rangle$. Importantly, the decryptor should not learn the partial sums $\langle \mathbf{x_i}, \mathbf{y_i} \rangle$. The inner product functionality has applications in data mining and information retrieval [1, 3]. We use constructions of standard MIFE for inner product by [3, 2].

Below, we start by summarizing our notion of "ad hoc freindliness," which (as we see later) is indeed satisfied by the above mentioned standard MIFE for inner product by [3, 2]. Our notion of ad hoc friendliness may be summarized as follows:

1. *Decentralized Setup.* The $\mathsf{MIFE.Setup}$ algorithm of the MIFE is decentralized in the sense that:
   a. The encryption keys EK_i for $i \in [n]$ corresponding to party i may be generated *independently* of the encryption keys of the remaining parties $[n] \setminus i$.
   b. The master secret key MSK can be decomposed into n components $\{\mathsf{MSK}_i\}_{i \in [n]}$. The partial MSK_i corresponding to party i may be generated locally by party i, without any interaction or shared state with the remaining parties.
2. *Local Encryption.* The encryption algorithm only takes its encryption key and message as input and does not depend on the number of parties or their public parameters.
3. *Piecewise Master Secret Key.* The master secret in standard MIFE $\mathsf{MSK} = \{\mathsf{MSK}_1, \ldots, \mathsf{MSK}_n\}$, if restricted to some subset $S \subseteq [n]$ with $|S| = \ell$, has the same distribution as a master secret generated for functions of arity ℓ.

We show that a standard MIFE with the above properties can be upgraded to ad hoc MIFE described above in a more direct manner than our generic transformation from standard MIFE to ad hoc MIFE. To see this, recall that one of the key challenges in ad hoc MIFE is that the encryptor must encrypt her messages without knowing the encryption key for the underlying standard MIFE. This is because the members or size of the group that will participate in the computation are chosen dynamically later.

To handle this, we used single input FE to encrypt messages and the MPC protocol for functionality $\mathsf{GenKeys}$ to sample an MIFE scheme and then translate the FE ciphertexts to MIFE ciphertexts. In the current setting however, due to properties (1) and (2) above, the encryption key of each party can be generated locally and each party can directly perform MIFE encryption locally. Since the re-encryption functionality involves computing a PRF and computing an MIFE encryption, the savings accrued by skipping this step are significant.

We will still require MPC to compute the MIFE function key, but no longer need the MPC functionality to sample the master secret key, so for simple functionalities this protocol may be much leaner than our general MPC protocol. For instance, in the case of inner products, we show that the required MPC protocol only needs to support inner product computations.

While the structural requirements described above may seem very strong, as mentioned earlier, we show that these requirements are enjoyed by the MIFE for inner products recently constructed by Abdalla et al. [2] and can be used to instantiate our compiler providing a very simple and efficient ad hoc MIFE for inner products. Please see Section 5 for details.

1.3.2.1 Instantiating MPC

As discussed for the case of our generic construction, we use two-round MPC protocols to obtain ad hoc MIFE for inner products. Specifically, since function-rerunnable two-round MPC in the common reference string (CRS) model can be constructed [28, 57, 24, 59] from learning-with-errors (LWE), we immediately get ad hoc MIFE from LWE. This result can

be upgraded to the malicious setting at the additional cost of NIZKs. On the other hand, construction of two-round MPC from two-round oblivious transfer [15, 42, 39], yields *bounded* ad hoc MIFE for inner products under DDH, LWE or DCR, albeit with the requirement that the sources maintain state across key issues. One nice feature of these schemes is that they work without the need for a CRS in the semi-honest setting and upgrade to the malicious setting can be made just using CRS. Please see Section 5 for details.

Our results are highlighted in Table 1.

1.3.3 Related Work

In this section, we discuss the prior work in this area. Here, we focus on two related primitives, decentralized multi-client FE and and non-interactive MPC. Further related work on FE, MIFE, MPC and multi-authority FE can be found in Appendix A.

1.3.3.1 Decentralized Multi-Client Functional Encryption

Very recently, Chotard et al [27] proposed the notion of decentralized multi-client functional encryption (D-MCFE). While the motivation for the two works is similar in removing the common key authority, our notion of adhoc MIFE is significantly more general in that:

1. MCFE itself is more restricted than MIFE, since only CTs with the *same labels* can be combined. In MIFE there is no such restriction. MIFE for circuits captures MCFE for circuits (by checking for equal labels within the MIFE functionality) but not vice versa.
2. Crucially, the setup algorithm in D-MCFE is a protocol that is run between multiple senders, requiring interaction, whereas our setup algorithm is run independently by each source and is thus *non-interactive*. Note that developing a non-interactive solution is one of the main motivations of this work.
3. The work of Chotard et al [27] only provides a construction for inner products. We provide a general construction as well as one for inner products. Since our model is stronger, our inner product construction is significantly more involved than theirs.
4. Decentralized MCFE lacks the dynamic aspect, which is one of the main contributions of our work. We permit the function arity and participating parties to be chosen dynamically – a feature no other construction supports (to the best of our knowledge).

Non-Interactive MPC

Another related notion is that of *non-interactive MPC* (NI-MPC), where a group of asynchronous parties may evaluate a function over their inputs by sending a single message to an evaluator who computes the output [51]. While they appear superficially similar, we note that the model of ad hoc MIFE is fundamentally different from NI-MPC since, unlike NI-MPC, it separates inputs and functions, i.e. provides ciphertexts and function keys which allows *reusing* an input/ciphertext with many different functions, and a function with many different inputs. On the other hand, NI-MPC does not support function reusability at all, and only a very restricted version of input re-usability, namely where only ciphertexts in the same "session" may be combined. The function arity in NI-MPC is also fixed, unlike ad hoc MIFE.

2 Preliminaries

Due to space constraints, the preliminaries can be found in Appendix B.

3 *Ad hoc* Multi-Input Functional Encryption

We are now ready to define our new notion of *ad hoc* multi-input functional encryption (MIFE). For simplicity, we define ad hoc MIFE in the private-key setting only. We leave the study of ad hoc MIFE in the public-key setting for future work.

3.1 Syntax and Correctness

An *ad hoc multi-input functional encryption scheme* aMIFE for a message space $\{\mathcal{M}_\kappa\}_{\kappa\in\mathbb{N}}$ and a functionality $\{\mathcal{F}_\kappa\}_{\kappa\in\mathbb{N}}$, where for each $\kappa \in \mathbb{N}$, each $f \in \mathcal{F}_\kappa$ is a (description of a) function on $(\mathcal{M}_\kappa)^\ell$ for some ℓ (which may depend on f), is given by a set of algorithms with the following syntax:

- $\mathsf{aMIFE.Setup}(1^\kappa)$: A PPT algorithm taking the security parameter κ, and outputting the master secret key MSK and the public parameters PP.
- $\mathsf{aMIFE.KeyGen}(i, \mathsf{MSK}_i, (\mathsf{PP}_1, \cdots, \mathsf{PP}_\ell), f)$: A PT algorithm taking an index $i \in [\ell]$, a master secret key MSK_i corresponding to PP_i, a set of public parameters $\mathsf{PP}_1, \cdots, \mathsf{PP}_\ell$, a function $f \in \mathcal{F}_\kappa$ of arity ℓ, and outputting a corresponding partial decryption key $\mathsf{PDK}_{i,f}$.
- $\mathsf{aMIFE.Enc}(\mathsf{MSK}, \mathbf{x})$: A PPT algorithm taking a master secret key MSK and a message $\mathbf{x} \in \mathcal{M}_\kappa$, and outputting a ciphertext c.
- $\mathsf{aMIFE.Dec}((\mathsf{PDK}_{1,f}, \ldots, \mathsf{PDK}_{\ell,f}), (c_1, \ldots, c_\ell))$: A PT algorithm taking partial decryption keys $(\mathsf{PDK}_{1,f}, \ldots, \mathsf{PDK}_{\ell,f})$ and ciphertexts $(c_1, \ldots, c_\ell)$, and outputting a string y.

▶ **Definition 1** (Correctness). *We say that* aMIFE *is* correct *if for all* $\kappa \in \mathbb{N}$ *and* $\ell = \mathit{poly}(\kappa)$, *all* $\mathbf{x}_1 \ldots \mathbf{x}_\ell \in \mathcal{M}_\kappa$ *and all* $f \in \mathcal{F}_\kappa$ *of arity* ℓ

$$\Pr\left[y = f(\mathbf{x}_1, \cdots, \mathbf{x}_\ell) \middle| \begin{array}{l} (\mathsf{PP}_i, \mathsf{MSK}_i) \leftarrow\!\!\$\ \mathsf{aMIFE.Setup}(1^\kappa) \quad (\forall i \in [\ell]) \\ c_i \leftarrow\!\!\$\ \mathsf{aMIFE.Enc}(\mathsf{MSK}_i, \mathbf{x}_i) \\ \mathsf{PDK}_{i,f} \leftarrow\!\!\$\ \mathsf{aMIFE.KeyGen}(i, \mathsf{MSK}_i, (\mathsf{PP}_i)_{i\in[\ell]}, f) \\ y \leftarrow \mathsf{aMIFE.Dec}((\mathsf{PDK}_{i,f})_{i\in[\ell]}, (c_i)_{i\in[\ell]}) \end{array} \right] = 1 \ .$$

▶ Remark 2. We highlight two ways that ad hoc MIFE differs from standard MIFE [45]. First, the $\mathsf{aMIFE.Setup}$ algorithm is run per user and does not output all of the $\mathsf{MSK}_1, \ldots \mathsf{MSK}_n$ at once. Second, the total number of users n and the function arity ℓ are not fixed and input to the $\mathsf{aMIFE.Setup}$ algorithm. We also note that for simplicity in our formulation of ad hoc MIFE the public parameters of the parties input to the key generation algorithm are ordered.

▶ Remark 3. We also consider two relaxations of ad hoc MIFE:

- We can allow an additional algorithm CRSGen taking 1^κ and outputting a common reference string CRS that is input to the remaining algorithms. We refer to this as ad hoc MIFE *in the CRS model*. The CRS model is weaker than having a key generation authority who can decrypt all the data.
- We can allow the total number of users 1^n to be input to the setup algorithm. We refer to this as *bounded* ad hoc MIFE. We can additionally require $n = \ell$, which we refer to as *static* (vs. dynamic) ad hoc MIFE. In particular, static ad hoc MIFE recovers a variant of MIFE that is similar to the standard one but still eliminates the trusted key generation authority.

3.2 Indistinguishability-Based Security

We first present an indistinguishability-based security notion. We note that the fact that the public parameters of the parties input to the key generation algorithm are ordered allows us to work with a somewhat simpler definition than the corresponding one in [45] for the standard MIFE case.

For an ad hoc MIFE scheme aMIFE as above and adversary $\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2)$, consider the experiment in Figure 1.

For an ad hoc MIFE scheme aMIFE as above and adversary $\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2)$, consider the experiment in Figure 1.

Experiment $\mathbf{IND}^{\mathsf{aMIFE}}_{\mathcal{A}}(1^\kappa)$
$(1^n, I, (\mathsf{PP}_i)_{i\in I}, st) \leftarrow\$ \mathcal{A}_0(1^\kappa)$
$b \leftarrow\$ \{0,1\}$
For all $i \notin I$ do:
$(\mathsf{MSK}_i, \mathsf{PP}_i) \leftarrow\$ \mathsf{aMIFE.Setup}(1^\kappa)$
$st \leftarrow\$ \mathcal{A}_1^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}(st)$
$b' \leftarrow\$ \mathcal{A}_2^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}((\mathsf{PP}_i)_{i\notin I}, st)$
Return $(b = b')$

Oracle $\mathcal{O}_{\mathsf{enc}}(i, \mathbf{x}_0, \mathbf{x}_1)$
If $\mathbf{x}_0, \mathbf{x}_1 \in \mathcal{M}_\kappa$ and $|\mathbf{x}_0| = |\mathbf{x}_1|$
$c_b \leftarrow\$ \mathsf{aMIFE.Enc}(\mathsf{MSK}_i, \mathbf{x}_b)$
Return c_b
Else Return $\perp$

Oracle $\mathcal{O}_{\mathsf{kg}}(i, (i_1, \ldots, i_\ell), f)$
If $i \in \{i_1, \cdots, i_\ell\}$
and $f \in \mathcal{F}_\kappa$ of arity ℓ
$\mathsf{PDK}_{i,f} \leftarrow$
$\mathsf{aMIFE.KeyGen}(i, \mathsf{MSK}_i, (\mathsf{PP}_{i_j}), f)$
Return $\mathsf{PDK}_{i,f}$
Else return $\perp$

Figure 1 Experiment for IND-security of ad hoc MIFE.

We say that $f \in \mathcal{F}_\kappa$ is *queried* if for every user associated with its input wires, either the user is corrupt, or has submitted it's partial decryption key to the adversary. Formally, for every $k \in \ell$ where ℓ is the arity of f either $i_k \in I$, *i.e.* i_k is corrupted or there is a key-generation query $(i_k, (\mathsf{PP}_{i_1}, \cdots, \mathsf{PP}_{i_\ell}), f)$.

We call $\mathcal{A}$ *legitimate* if for all $\kappa \in \mathbb{N}$, in all transcripts $\mathbf{IND}^{\mathsf{aMIFE}}_{\mathcal{A}}(1^\kappa)$ it holds that for every queried $f \in \mathcal{F}_\kappa$, there does not exist two sequences $(y_{i_1,0}, \cdots, y_{i_\ell,0})$ and $(y_{i_1,1}, \cdots, y_{i_\ell,1})$ such that

$$f(y_{i_1,0}, \cdots, y_{i_\ell,0}) \neq f(y_{i_1,1}, \cdots, y_{i_\ell,1})$$

and for every $j \in \{i_1, \cdots, i_\ell\}$

- $j \in I$, *i.e.* j is corrupted (so there is no restriction on $y_{j,0}, y_{j,1}$ above), or
- There is an encryption query $(j, \mathbf{x}_0, \mathbf{x}_1)$ such that $y_{j,0} = \mathbf{x}_0$ and $y_{j,1} = \mathbf{x}_1$.

We assume adversaries are legitimate unless otherwise stated. We call $\mathcal{A}$ *passive* if $I = \emptyset$. We call $\mathcal{A}$ *selective* if $\mathcal{A}_2$ makes no queries. We say that aMIFE is xxx-IND-secure if for any adversary $\mathcal{A}$ of type xxx

$$|\Pr\left[\mathbf{IND}^{\mathsf{aMIFE}}_{\mathcal{A}}(\cdot) \text{ outputs } 1\right] - 1/2| = \mathsf{negl}(\cdot)\ .$$

We provide the definition of simulation based security in Appendix C.

4 Ad Hoc MIFE from MIFE + Two-Round MPC

We show how to construct of ad hoc MIFE for any polynomial sized circuit from standard MIFE for the same functionality and a two-round MPC protocol.

Building Blocks

Our scheme will be using the following building blocks:

- A MIFE scheme

  $$\mathsf{MIFE} = (\mathsf{MIFE.Setup}, \mathsf{MIFE.KeyGen}, \mathsf{MIFE.Enc}, \mathsf{MIFE.Dec})$$

  for some message-space $\{\mathcal{M}_\kappa\}_{\kappa\in\mathbb{N}}$ and functionality $\{\mathcal{F}_\kappa\}_{\kappa\in\mathbb{N}}$. For simplicity, we assume $\mathsf{MIFE.KeyGen}$ is deterministic; note that this is without loss of generality since it can be made so by using a PRF.
- A two-round two-round MPC protocol

  $$\mathsf{MPC} = (\mathsf{MPC.RunRoundOne}, \mathsf{MPC.RoundRoundTwo}, \mathsf{MPC.ComputeResult})$$

  for programs of the form $\mathsf{GenKeys}_f$ in Figure 2 for $f \in \mathcal{F}_\kappa$. We assume MPC is function-rerunnable, unbounded and without setup (we discuss the other cases below).
- A PRF F with keyspace $\{\mathcal{K}_\kappa\}_{\kappa\in\mathbb{N}}$, and a punctured PRF puncF with keyspace $\{\mathcal{K}^{\mathsf{punc}}_\kappa\}_{\kappa\in\mathbb{N}}$, both with domain $\{0,1\}^*$. (We leave the ranges implicit for readability, taking the output to be sufficiently long.)
- A private-key single input functional encryption scheme

  $$\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.KeyGen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$$

4.1 Construction

Below we provide our construction for adhoc MIFE for general circuits. Note that setup, encryption and key generation are done independently and in parallel by all the parties in the system.

$\mathsf{aMIFE.Setup}(1^\kappa)$: Upon input the security parameter, do the following:

1. Sample the seed of PRF $K \leftarrow\!\!\$\ \mathcal{K}_\kappa$ and the seed of a puncturable PRF $K^{\mathsf{punc}} \leftarrow\!\!\$\ \mathcal{K}^{\mathsf{punc}}_\kappa$. Puncturing will only be required in the proof.
2. Invoke the single input FE scheme, $(\mathsf{PP_{FE}}, \mathsf{MSK_{FE}}) \leftarrow\!\!\$\ \mathsf{FE.Setup}(1^\kappa)$.
3. Invoke the first round of the MPC protocol

   $$(\rho^{(1)}, \mathfrak{s}) \leftarrow\!\!\$\ \mathsf{MPC.RunRoundOne}(1^\kappa, (K, \mathsf{MSK_{FE}}))$$

   Note that the function is specified later.
4. Return $(\mathsf{PP} = \rho^{(1)}, \mathsf{MSK} = (K, K^{\mathsf{punc}}, \mathsf{MSK_{FE}}, \mathfrak{s}))$.

$\mathsf{aMIFE.KeyGen}((\mathsf{PP}_i)_{i\in[\ell]}, f, \mathsf{MSK})$: Upon input the public parameters of the ℓ parties that are chosen to participate in the computation, and the master secret key, do the following:

1. Parse the public parameters of each party as the first message in an MPC protocol, i.e. $\rho_i^{(1)} \leftarrow \mathsf{PP}_i \quad \forall i \in [\ell]$.
2. Parse the master secret key as $(K, K^{\mathsf{punc}}, \mathsf{MSK}_{\mathsf{FE}}, \mathfrak{s}) \leftarrow \mathsf{MSK}$
3. Run round two of the MPC protocol using round 1 messages as input, for the functionality $\mathsf{GenKeys}$ described in Figure 2:

$$\rho^{(2)} \leftarrow\!\!\$\ \mathsf{MPC.RunRoundTwo}(\mathfrak{s}, \mathsf{GenKeys}_{(\mathsf{PP}_i)_{i\in[\ell]},f}, (\rho_i^{(1)})_{i\in[\ell]})$$

4. Compute the mask $s \leftarrow \mathsf{PRF.Eval}(K, 0 \,\|\, (\mathsf{PP}_i)_{i\in[\ell]} \,\|\, f)$
5. Return $(\rho^{(2)}, s)$.

aMIFE.Enc($\mathsf{MSK}, \mathbf{x}$): Upon input the master secret key and the message $\mathbf{x}$, do the following:

1. Parse the master secret key as $(K, K^{\mathsf{punc}}, \mathsf{MSK}_{\mathsf{FE}}, \mathfrak{s}) \leftarrow \mathsf{MSK}$.
2. Sample the tag $T \leftarrow\!\!\$\ \{0,1\}^\kappa$.
3. Initialize the data structure Trap defined in Figure 10 by setting $\mathsf{mode\text{-}real} = 1$ and all other fields as $\perp$. This indicates that we are in the real system. The remaining fields are only relevant in the proof.
4. Compute the ciphertext $c \leftarrow\!\!\$\ \mathsf{FE.Enc}(\mathsf{MSK}_{\mathsf{FE}}, (\mathbf{x}, T, K^{\mathsf{punc}}, \mathsf{Trap}))$.
5. Return c.

aMIFE.Dec($(\mathsf{PDK}_{i,f})_{i\in[\ell]}, (c_i)_{i\in[\ell]}$): Upon input the partial decryption keys from all relevant parties, as well as ciphertexts from all relevant parties, do the following:

1. Parse $(\rho_i^{(2)}, s_i) \leftarrow \mathsf{PDK}_{i,f} \quad \forall i \in [\ell]$
2. Compute the output of the MPC protocol as $Z \leftarrow \mathsf{MPC.ComputeResult}((\rho_i^{(2)})_{i\in[\ell]})$
3. Unmask the output using partial shares provided by all parties. In more detail, compute $S \leftarrow \bigoplus_{i\in[\ell]} s_i$; $Z \leftarrow Z \oplus S$.
4. Parse the output of the MPC computation as $(\mathsf{SK}_f, \mathsf{SK}_{\mathsf{FE}_1}, \ldots, \mathsf{SK}_{\mathsf{FE}_\ell}) \leftarrow Z$.
5. Perform decryption of the single input FE scheme to obtain MIFE ciphertexts $\psi_i \leftarrow \mathsf{FE.Dec}(\mathsf{SK}_{\mathsf{FE}_i}, c_i) \quad \forall i \in [\ell]$.
6. Perform decryption of the MIFE scheme to obtain the output $y \leftarrow \mathsf{MIFE.Dec}(\mathsf{SK}_f, \psi_1, \ldots, \psi_\ell)$.
7. Return y.

▶ Remark 4. If we use a bounded 2-round MPC protocol then we will obtain a bounded ad hoc MIFE scheme where the setup algorithm also takes 1^n which is passed to $\mathsf{MPC.RunRoundOne}$. If MPC has a setup algorithm (outputting a CRS) then so does the resulting ad hoc MIFE scheme.

Correctness

Correctness follows from the correctness of MPC, MIFE and FE. In more detail, we have:

Step 1: MPC. By correctness of MPC, we have that the decryptor recovers the output $S \oplus (\mathsf{SK}_f, \mathsf{SK}_{\mathsf{FE}_1}, \ldots, \mathsf{SK}_{\mathsf{FE}_\ell})$. Next, if each party $i \in [\ell]$ provides a partial decryption key for f, then this contains partial mask s_i as part of the output of $\mathsf{aMIFE.KeyGen}$. Using these, the decryptor can compute $S \leftarrow \bigoplus_{i\in[\ell]} s_i$ and recover $(\mathsf{SK}_f, \mathsf{SK}_{\mathsf{FE}_1}, \ldots, \mathsf{SK}_{\mathsf{FE}_\ell})$.

Function $\mathsf{GenKeys}_{(\mathsf{PP}_i)_{i\in[\ell]},f}((K_1,\mathsf{MSK}_{\mathsf{FE}_1}),\ldots,(K_\ell,\mathsf{MSK}_{\mathsf{FE}_\ell}))$

1. For $i \in [\ell]$, compute randomness to be used for algorithms below:

$$r_i \leftarrow \mathsf{PRF.Eval}(K_i, 1 \parallel (\mathsf{PP}_i)_{i\in[\ell]} \parallel f), \qquad r_i' \leftarrow \mathsf{PRF.Eval}(K_i, 2 \parallel (\mathsf{PP}_i)_{i\in[\ell]} \parallel f)$$

2. Run the MIFE setup algorithm for the desired arity as:

$$((\mathsf{EK}_1,\ldots,\mathsf{EK}_\ell),\mathsf{MSK}) \leftarrow \mathsf{MIFE.Setup}(1^\kappa; r_1 \oplus \cdots \oplus r_\ell)$$

3. For $i \in [\ell]$, generate the single input FE function key:

$$\mathsf{SK}_{\mathsf{FE}_i} \leftarrow \mathsf{FE.KeyGen}(\mathsf{MSK}_{\mathsf{FE}_i}, \mathsf{ReEnc}_{\mathsf{EK}_i,\perp}; r_i')$$

4. Compute the MIFE secret key as $\mathsf{SK}_f \leftarrow \mathsf{MIFE.KeyGen}(\mathsf{MSK}, f)$
5. Sample the mask s_i for each partial key and compute the mask S as:

$$\forall i \in [\ell], \quad s_i \leftarrow \mathsf{PRF.Eval}(K_i, 0 \parallel (\mathsf{PP}_i)_{i\in[\ell]} \parallel f), \qquad S \leftarrow \bigoplus_{i\in[\ell]} s_i$$

6. Return the masked output $S \oplus (\mathsf{SK}_f, \mathsf{SK}_{\mathsf{FE}_1}, \ldots, \mathsf{SK}_{\mathsf{FE}_\ell})$

Figure 2 Functionality computed by the MPC protocol to generate single and multi input FE keys.

Function $\mathsf{ReEnc}_{\mathsf{EK},\mathsf{ctr}}(\mathbf{x}, T, K, \mathsf{Trap})$

1. Let $r \leftarrow \mathsf{PRF.Eval}(K, 0 \parallel \mathsf{EK} \parallel T)$.
2. If $\mathsf{mode} = R$ then compute $\mathsf{MIFE.Enc}(\mathsf{EK}, \mathbf{x}; r)$ and return it.
3. If $\mathsf{mode} = T$ and $\mathsf{ctr} < \mathsf{Trap.index}$ then compute $\mathsf{MIFE.Enc}(\mathsf{EK}, \mathsf{Trap.val}_1; r)$ and return it.
4. If $\mathsf{mode} = T$ and $\mathsf{ctr} > \mathsf{Trap.index}$ then compute $\mathsf{MIFE.Enc}(\mathsf{EK}, \mathsf{Trap.val}_0; r)$ and return it.
5. If $\mathsf{mode} = T$ and $\mathsf{ctr} = \mathsf{Trap.index}$ then output $\mathsf{Trap.CT}$.

Figure 3 Functionality for translating the ciphertext from FE to MIFE using dynamically generated encryption keys.

Step 2: FE. Next, by correctness of FE, we have that if

$$\psi_i = \mathsf{FE.Dec}(\mathsf{SK}_{\mathsf{FE}_i}, c_i) \quad \forall i \in [\ell]$$

Then, ψ_i are the MIFE ciphertexts computed as $\mathsf{MIFE.Enc}(\mathsf{EK}_i, \mathbf{x}_i; r_i)$.

Step 3: MIFE. Finally, by correctness of MIFE, we have that

$$f(\mathbf{x}_1,\ldots,\mathbf{x}_\ell) = \mathsf{MIFE.Dec}(\mathsf{SK}_f, \psi_1, \ldots, \psi_\ell)$$

4.2 Security Proof

In this section, we argue that the scheme described above is secure. In more detail:

▶ **Theorem 5.** *If* MIFE *is a IND-secure MIFE scheme and* MPC *is a SIM-secure 2-round MPC protocol, then our construction is* sel*-IND-secure.*

Due to space constraints, the proof can be found in Appendix D.

5 Ad Hoc Friendly MIFE and its Application to Inner Products

In this section, we describe a paradigm for constructing ad-hoc MIFE schemes from MIFE schemes that are "ad hoc friendly" and a (hopefully simple) two-round MPC protocol. This paradigm significantly simplifies our general construction. We then show that the standard MIFE scheme for inner products [3, 2], which may be based on DDH, LWE or DCR, is ad hoc friendly and the corresponding two-round MPC protocol is only required to compute inner-products, thus obtaining an efficient ad hoc MIFE scheme for inner products.

Ad Hoc Friendliness

In more detail, we define a notion of "ad hoc friendly" standard MIFE which satisfies the following properties:

- **Decentralized Setup.** The $\mathsf{MIFE.Setup}$ algorithm of the MIFE is decentralized in the sense that:
  1. The encryption keys EK_i for $i \in [n]$ corresponding to party i may be generated *independently* of the encryption keys of the remaining parties $[n] \setminus i$. In more detail, the algorithm $(\mathsf{EK}_1, \ldots, \mathsf{EK}_n) \leftarrow \mathsf{MIFE.Setup}(1^\kappa)$ may be decomposed into n invocations $\mathsf{EK}_i \leftarrow \mathsf{MIFE.SetupLocal}(1^\kappa)$ for $i \in [n]$, which can be run locally by each party.
  2. The master secret key MSK can be decomposed into n components $\{\mathsf{MSK}_i\}_{i\in[n]}$. The partial MSK_i corresponding to party i may be generated locally by party i, without any interaction or shared state with the remaining parties.

- **Local Encryption.** The $\mathsf{MIFE.Enc}$ algorithm of the MIFE is "local" in that it does not take as input the total number of parties or the public parameters of other parties. In more detail, $\mathsf{MIFE.Enc}$ algorithm only takes as input its encryption key EK_i and its input $\mathbf{x}_i$, and nothing else.

- **Piecewise Master Secret Key.** In standard MIFE schemes, the function is assumed to have fixed arity n. However, in ad hoc MIFE, we allow the function to have arity $\ell < n$. To support this, we require that the master secret in standard MIFE $\mathsf{MSK} = \{\mathsf{MSK}_1, \ldots, \mathsf{MSK}_n\}$, if restricted to some subset $S \subseteq [n]$ with $|S| = \ell$, has the same distribution as a master secret generated for functions of arity ℓ.
  Formally, let $\mathsf{MSK} = \{\mathsf{MSK}_1, \ldots, \mathsf{MSK}_n\} \leftarrow \mathsf{FE.Setup}(1^\kappa, 1^n)$ and $\mathsf{MSK}' = \{\mathsf{MSK}'_1, \ldots, \mathsf{MSK}'_\ell\} \leftarrow \mathsf{FE.Setup}(1^\kappa, 1^\ell)$. Then, we require that MSK restricted to subset S, namely $(\mathsf{MSK}_{S[1]}, \ldots, \mathsf{MSK}_{S[\ell]})$ has the same distribution as MSK'.

Since the intuition was discussed in Section 1, we proceed to our construction of ad hoc MIFE for inner products.

5.1 Ad Hoc MIFE for Inner Products

Inner-product functionality

We recall the *multi-input inner-product functionality* over $\mathbb{Z}_p$ for a prime p, adapted from Abdalla et al. [2, Section 2.3]. For $m, n \in \mathbb{N}$, this is the functionality

$$\mathcal{IP}^m_{p,n} = \{\mathsf{ip}_{\mathbf{y}_1,\ldots,\mathbf{y}_n} \colon (\mathbb{Z}_p^m)^n \to \mathbb{Z}_p\}$$

defined by

$$\mathsf{ip}_{\mathbf{y}_1,\ldots,\mathbf{y}_n}(\mathbf{x}_1,\ldots,\mathbf{x}_n) \;=\; \sum_{i=1}^{n}\langle \mathbf{x}_i, \mathbf{y}_i\rangle \bmod p\ .$$

We omit parameters p, m, n when they are arbitrary or clear from context.

5.2 Building Blocks

In the context of ad hoc MIFE for inner products, we want to evaluate a functionality given by a sequence of vectors $\mathbf{y} = (\mathbf{y_1}, \ldots, \mathbf{y_n})$ where $\mathbf{y_i} \in \mathbb{Z}_q^m$. Evaluating the function on inputs $\{\mathbf{x_i}\}_{i\in[n]}$ where $\mathbf{x_i} \in \mathbb{Z}_q^m$ reveals $\sum_{i\in[n]}\langle \mathbf{x_i}, \mathbf{y_i}\rangle$ and nothing more. In particular the evaluator should not be able to learn the partial sums $\langle \mathbf{x_i}, \mathbf{y_i}\rangle$.

Our scheme will be using the following building blocks:

- A 2-round *function-rerunnable MPC for a functionality* GenKey-ip*, which must be support inner product computation.*
- *A standard MIFE with for the inner product functionality, denoted by* $\mathsf{MIFE}_{\mathsf{ip}}$*, satisfying the aforementioned ad hoc friendly properties.*

The MIFE scheme(s) of Abdalla et al. [2]:

Abdalla et al. [2] provide two multi-input encryption schemes for inner products, one for computing inner products over some finite ring $\mathbb{Z}_L$, and the second for computing bounded-norm inner products over the integers. Both schemes rely on:

1. An information theoretic scheme for inner products where only one ciphertext query is supported.
2. A single input functional encryption scheme FE for inner products which is applied on top of the above one time scheme.

Unrolling the above two components, the final MIFE scheme(s) of [2] have algorithms of the form described below.

Below, we unroll the above two components to establish that the schemes of [2] satisfy ad hoc friendliness.

1. **Decentralized Setup.** The encryption keys EK_i corresponding to party i may be generated *independently* of the encryption keys of the remaining parties $[n] \setminus i$. In more detail, the setup algorithm is defined as:

   $\mathsf{MIFE.Setup}(1^\kappa, n)$: Do the following:
   - For $i \in [n]$, sample $\mathbf{u}_i \leftarrow \mathbb{Z}_L^m$.
   - For $i \in [n]$, sample $(\mathsf{FE.PK}_i, \mathsf{FE.MSK}_i) \leftarrow \mathsf{FE.Setup}(1^\kappa, 1^m)$.
   - Output $\mathsf{PP}_i = \mathsf{FE.PK}_i$ and $\mathsf{EK}_i = (\mathsf{FE.MSK}_i,\ \mathbf{u}_i)$ for $i \in [n]$.

   Then, we may define:

   a. $\mathsf{MIFE.SetupLocal}(1^\kappa, n)$: Do the following:
      - Sample $\mathbf{u} \leftarrow \mathbb{Z}_L^m$.
      - Sample $(\mathsf{FE.PK}, \mathsf{FE.MSK}) \leftarrow \mathsf{FE.Setup}(1^\kappa, 1^m)$.
      - Output $\mathsf{PP} = \mathsf{FE.PP}$ and $\mathsf{EK} = (\mathsf{FE.MSK},\ \mathbf{u})$.

To compute the set of n encryption keys, the algorithm $\mathsf{MIFE.SetupLocal}(1^\kappa, n)$ is invoked n times. Additionally, in [2], the master secret key can be decomposed into n components by setting:

$$\mathsf{MSK}_i = \mathsf{EK}_i = (\mathsf{FE.MSK}_i, \mathbf{u}_i) \; \forall \;\; i \in [n]$$

2. **Local Encryption.** The encryption algorithm only takes its encryption key and message as input and does not depend on the number of parties or their public parameters. In more detail, the encryption algorithm is defined as:

   $\mathsf{MIFE.Enc}(\mathsf{EK}_i, \mathbf{x}_i)$: Do the following:
   - Parse $\mathsf{EK}_i = (\mathsf{FE.MSK}_i, \; \mathbf{u}_i)$.
   - Compute $\mathbf{y}_i = \mathbf{x}_i + \mathbf{u}_i \mod L$.
   - Compute $\mathbf{c}_i = \mathsf{FE.Enc}(\mathsf{FE.MSK}_i, \mathbf{y}_i)$.
   - Output $(\mathbf{y}_i, \mathbf{c}_i)$.

   Thus, the ciphertext encoding party i's input may be computed independently by party i.

3. **Piecewise Master Secret Key.** For the inner product functionality, if $\mathsf{MSK} = (\mathsf{MSK}_1, \ldots, \mathsf{MSK}_n)$ is the master secret key for function vector $\mathbf{y} = (\mathbf{y}_1 \| ... \| \mathbf{y}_n)$ then for any $S \subseteq [n]$, we have the corresponding master key $\mathsf{MSK}' = (\mathsf{MSK}_{S[1]}, \ldots, \mathsf{MSK}_{S[\ell]})$ is a well formed master secret key for the vector $\mathbf{y}' = (\mathbf{y}_{S[1]} \| \ldots \| \mathbf{y}_{S[\ell]})$. In more detail, the key generation algorithm is defined as:

   $\mathsf{MIFE.KeyGen}(\mathsf{MSK}, \mathbf{y})$: Do the following:
   - Output $\mathsf{DK}_\mathbf{y} \leftarrow \big(\{\mathsf{FE.KeyGen}(\mathsf{MSK}_i, \mathbf{y}_i)\}_{i \in [n]}, \; \sum_{i \in [n]} \langle \mathbf{u}_i, \; \mathbf{y}_i \rangle \big)$.

   It is easy to see that the function key for $\mathbf{y}'$ can be obtained from the above by simply setting $\mathbf{y}_i = 0$ for $i \notin S$.

5.3 Our Construction

We are now ready to present the construction. Note that for ease of presentation, we describe the scheme for all n users but we remark that it works for any subset of $\ell \leq n$ users.

aMIFE.Setup$(1^\kappa, 1^m)$: Upon input the security parameter and the dimension of the input vector for each party, do the following:

1. Run the partial MIFE setup algorithm to obtain the public parameters and encryption key: $(\mathsf{MIFE.PP}, \mathsf{MIFE.EK}) \leftarrow\!\!\$ \; \mathsf{MIFE.SetupLocal}(1^\kappa, 1^m)$
2. Invoke the first round of the MPC protocol with the encryption key as input:

   $$(\rho^{(1)}, \mathfrak{s}) \leftarrow\!\!\$ \; \mathsf{MPC.RunRoundOne}(1^\kappa, \mathsf{EK})$$

3. Return $\mathsf{PP} := (\mathsf{MIFE.PP}, \rho^{(1)}), \mathsf{MSK} := (\mathsf{MIFE.EK}, \mathfrak{s})$

aMIFE.Enc$(\mathsf{EK}, \mathrm{x})$: Upon input the encryption key and the input, compute $\mathsf{MIFE.enc}(\mathsf{EK}, \mathbf{x})$ and output it.

aMIFE.KeyGen$((\mathsf{PP}_i)_{i \in [\ell]}, \mathrm{y}, \mathsf{MSK}_i)$: Upon input the public parameters of the ℓ parties, the function vector $\mathbf{y}$ and the master secret key MSK_i, do the following:

1. Parse $(\mathsf{MIFE.EK}, \mathfrak{s}) \leftarrow \mathsf{MSK}_i$ and $(\mathsf{MIFE.PP}_j, \rho_j^{(1)}) \leftarrow \mathsf{PP}_j \quad \forall j \in [\ell]$
2. Parse $(\mathbf{y_1}, \ldots, \mathbf{y}_\ell) \leftarrow \mathbf{y}$ where $\mathbf{y_j} \in \mathbb{Z}_q^m$ for $j \in [\ell]$.

3. Invoke round 2 of the MPC protocol $\mathsf{GenKey\text{-}ip}_{\mathbf{y}}$ as defined in Figure 4

$$\rho^{(2)} \leftarrow\!\!\$\ \mathsf{MPC.RunRoundTwo}(\mathfrak{s}, \rho_1^{(1)}, \ldots, \rho_\ell^{(1)},)$$

4. Return $\mathsf{PDK} := \rho^{(2)}$.

aMIFE.Dec$((\mathsf{PDK}_{i,f})_{i\in[\ell]}, (\mathbf{c}_i)_{i\in[\ell]})$**:** Upon input the partial decryption keys from all relevant parties, as well as ciphertexts from all relevant parties, do the following:

1. Compute the output of the MPC protocol as

$$\mathsf{MIFE.DK}_{\mathbf{y}} \leftarrow \mathsf{MPC.ComputeResult}((\rho_i^{(2)})_{i\in[\ell]})$$

2. Compute $\mathsf{MIFE.Dec}(\mathsf{MIFE.DK}_{\mathbf{y}}, \mathbf{y}, \mathbf{c}_1, \ldots, \mathbf{c}_\ell)$ and output it.

Function $\mathsf{GenKey\text{-}ip}_{\mathbf{y}}(\mathsf{EK}_1, \ldots, \mathsf{EK}_\ell)$

1. Let $\mathsf{MIFE.MSK} = (\mathsf{EK}_1, \ldots, \mathsf{EK}_\ell)$.
2. Compute $\mathsf{MIFE.KeyGen}(\mathsf{MIFE.MSK}, \mathbf{y})$ and output it.

Figure 4 Functionality for computing the MIFE function key.

Note that for the inner product functionality, the MIFE key generation algorithm is very simple and in some cases only involves computing inner products, please see [2] for details.

Correctness

Correctness follows from correctness of the MPC protocol and of the standard MIFE scheme. We have by correctness of the MPC protocol, that the output $\mathsf{MIFE.DK}_{\mathbf{y}} = \mathsf{MIFE.KeyGen}(\mathsf{MSK}, \mathbf{y})$ is produced correctly. Since the encryptors encrypted $\mathbf{c}_i = \mathsf{MIFE.Enc}(\mathsf{EK}_i, \mathbf{x}_i)$, it follows from the correctness of MIFE that $\mathsf{MIFE.Dec}(\mathsf{MIFE.DK}_{\mathbf{y}}, \mathbf{y}, \mathbf{c}_1, \ldots, \mathbf{c}_\ell)$ outputs $\sum_{i\in[\ell]} \langle \mathbf{y}_i,\ \mathbf{x}_i \rangle$ as desired.

Security

Given the proof of security in Section 4, the proof of security of the present construction is straightforward, since the present construction is a (much) simplified instance of the general construction. Intuitively, the security of MPC ensures that the output $\mathsf{MIFE.DK}_{\mathbf{y}}$, which is computed using inputs $(\mathsf{MSK}_i, \mathbf{y}_i)_{i\in[\ell]}$ of ℓ disjoint parties, is indistinguishable from the output of a "global" MIFE key generation algorithm which takes the entire $(\mathsf{MSK}, \mathbf{y})$ as input. The encryption algorithm is exactly the same as that of the standard MIFE scheme, with the result that the decryptor sees exactly the same view as in the standard MIFE scheme. Please see Appendix E for details.

An issue with the MIFE scheme of Abdalla et al. [2] which we use above is that an adversary may exploit partial ciphertexts to learn unauthorized information [43]. Specifically, say there are two parties, and the first one provides ciphertexts, for vectors $\mathbf{x}_0$ and $\mathbf{x}_1$ (say). The second encryptor does not give any ciphertexts. Suppose the key generation algorithm in the standard MIFE scheme gives a key for $(\mathbf{y} \parallel \mathbf{0})$. Now, it could be that $\langle \mathbf{x}_0, \mathbf{y} \rangle \neq \langle \mathbf{x}_1, \mathbf{y} \rangle$ but this does not violate admissibility, because admissibility only checks for decryption with respect to complete ciphertexts whereas decryption with respect to partial ciphertexts is not defined. Ideally, the key for $(\mathbf{y} \parallel \mathbf{0})$ should not work to decrypt the partial ciphertexts of encryptor 1, but in the construction of Abdalla et al., it does so (if the corresponding sub-vector in the key is zero).

Note that in a MIFE scheme, the above situation only occurs if one party (party 2 say) *never* gives any ciphertext[5]. In our setting however, a party issues a partial decryption key only if it wishes its data to participate in some computation. Hence, we resolve the issue by requiring that a party only issue a partial decryption key if it has also issued at least one ciphertext.

Instantiating MPC

Since function-rerunnable two-round MPC in the common reference string (CRS) model can be constructed [28, 57, 24, 59] from learning-with-errors (LWE), we get ad hoc MIFE for inner products from LWE. This result can be upgraded to the malicious setting as the additional cost of NIZKs.

While function rerunnable two-round MPC in the CRS model can be constructed from bilinear maps [41] and even two-round oblivious transfer [15, 42, 39] or information theoretically [9, 36], these constructions are *not* function-rerunnable so do not suffice for multi-key ad hoc MIFE. However, if we restrict ourselves to the setting of bounded ad hoc MIFE, where a user issues only a bounded number of partial decryption keys and additionally maintains state across key issues, we may use the above MPC protocols (just via repetition). This yields such a bounded ad hoc MIFE under DDH, LWE or DCR for the both the semi-honest and malicious cases. One nice feature of the semi-honest construction is that it does not use a common random string and is in the plain model.

[5] If party 2 gives even a single ciphertext (say for vector $\mathbf{z}_0$) then admissibility will force $\langle \mathbf{x}_0 \parallel \mathbf{z}_0, \mathbf{y} \parallel \mathbf{0} \rangle = \langle \mathbf{x}_1 \parallel \mathbf{z}_0, \mathbf{y} \parallel \mathbf{0} \rangle$ which implies that $\langle \mathbf{x}_0, \mathbf{y} \rangle = \langle \mathbf{x}_1, \mathbf{y} \rangle$.

A Additional Related Work

Functional Encryption

FE started with the notion of "attribute-based encryption" [61, 50] and evolved over time to a more general primitive that encompasses several primitives such as (hierarchical) identity based encryption [19, 29, 22, 44, 25, 4], attribute based encryption [61, 50, 16, 34], predicate encryption [21, 47, 54, 55, 5, 62, 47] and reusable garbled circuits [46]. Formal definitions of the general primitive were first given in [20, 58]. While there has been substantial progress in constructing FE from standard assumptions [1, 7, 56], the general notion of FE for arbitrary polynomial sized circuits was constructed in the breakthrough work of [33] from indistinguishability obfuscation (iO) [12, 33, 56]. Functional encryption for restricted functionalities such as inner products [1, 7], and quadratic functions [56, 11] from more standard assumptions has also been developed.

Multi-Input Functional Encryption

Extending the more basic concept of functional encryption (FE) [61, 20, 58], the notion of multi-input function encryption (MIFE) was first introduced by Goldwasser et al. [45] and there have since been a number of follow-up works. Ananth and Jain [8] show that private key MIFE for general polynomial-arity functions *implies* iO. On the other hand, Brakerski, Komargodski and Segev [23] construct private-key MIFE for constant-arity functions, based on a private-key single-input FE scheme. They achieve adaptive security but also do not consider sender corruption. Badrinarayanan et al. [10] construct MIFE schemes for "unbounded arity" functions. More recent work [3, 2] constructs *inner-product* MIFE.

Multi-Party Computation

Traditional MPC is *interactive*. Ad hoc MIFE can be seen as a special form of *non-interactive* MPC [31, 14, 53]. In particular, ad hoc MIFE separates inputs and functions, which affords greater flexibility – one can use the same encrypted inputs with different functions, or different encrypted inputs with the same function. Moreover, previous non-interactive MPC protocols require a global setup procedure. In a recent work, [52] constructs non-interactive MPC from indistinguishability obfuscation and DDH, assuming a PKI setup and a CRS, without this requirement. In contrast, our schemes are based on standard MIFE for a given functionality and do not require a CRS in general, as we do not necessarily consider sender corruption.

Multi-Authority Functional Encryption

Our work should also be compared to that of Chandran et al. [26], who proposed a notion of "multi-authority" FE (MAFE). In MAFE, key authorities independently generate their own keys. Roughly speaking, to derive a decryption key for a function f, a user must obtain a partial decryption key for f from each authority. In our context, we could think of the authorities as sources. However, a fundamental difference between multi-authority FE and ad hoc MIFE is that in the former, to encrypt, one needs to know the master public keys of all authorities (users). This is a severe limitation, as a user may not be aware of which other parties are to be involved in a computation at the time of encryption. Furthermore, in multi-authority FE, a given ciphertext can only be used in a computation associated with one fixed group, unlike ad hoc MIFE, where a ciphertext can be used in an unbounded number of dynamically-chosen groups. Finally, in MAFE, decryption only operates on a *single* ciphertext, unlike our notion which is intrinsically multi-user.

B Preliminaries

In this section we define the notation and preliminaries used in our work.

B.1 Notation and Conventions

PPT stands for "probabilistic polynomial time" and PT stands for "polynomial time." Algorithms are PPT unless otherwise noted. Throughout, κ denotes the security parameter and 1^κ its unary encoding. For a probabilistic algorithm $\mathcal{A}$, we denote by $\mathcal{A}(x;r)$ the output of $\mathcal{A}$ on input x with random tape r. We denote $y \leftarrow\!\!\$\, A(x)$ as the process of sampling r at random and letting $y \leftarrow A(x;r)$. For a finite set S, we denote $x \leftarrow\!\!\$\, S$ as the process of sampling x uniformly from S. For a distribution $\mathcal{D}$ we denote $x \leftarrow\!\!\$\, \mathcal{D}$ as the process of sampling x according to $\mathcal{D}$. For $k \in \mathbb{N}$ we let $[k]$ denote the set $\{1, \cdots, k\}$. If s is string

then $|s|$ denotes its length and $s[i]$ denotes its i-th bit. If $\mathbf{x}$ is a vector then $|\mathbf{x}|$ denotes its number of components and $\mathbf{x}[i]$ denotes its i-th component. We will use $\mathsf{negl}(\cdot)$ to denote an unspecified negligible function and $\mathsf{poly}(\cdot)$ to denote an unspecified polynomial. We say that (families of) distributions $\{\mathcal{D}_{0,\kappa}\}_{\kappa\in\mathbb{N}}, \{\mathcal{D}_{1,\kappa}\}_{\kappa\in\mathbb{N}}$ are computationally indistinguishable if for all PPT adversaries A, $\Pr[A(\mathcal{D}_{0,\kappa})=1] - \Pr[A(\mathcal{D}_{1,\kappa})=1] = \mathsf{negl}(\kappa)$. We write this $\mathcal{D}_{0,\kappa} \underset{C}{\approx} \mathcal{D}_{1,\kappa}$.

B.2 Two-Round MPC

A *2-round MPC protocol* MPC for message-space $\{\mathcal{M}_\kappa\}_{\kappa\mathbb{N}}$ and functionality $\{\mathcal{F}_\kappa\}_{\kappa\in\mathbb{N}}$ where for each $\kappa\in\mathbb{N}$ each $f\in\mathcal{F}_\kappa$ is a function on $(\mathcal{M}_\kappa)^n$ for some n, consists of three algorithms with the following syntax:

- $\mathsf{RunRoundOne}(1^\kappa, 1^n, f, i, x)$: A PPT algorithm taking the security parameter κ, number of users n, a (description of a) function $f\in\mathcal{F}_\kappa$ of arity n, an index $i\in[n]$, an input $x\in\mathcal{M}_\kappa$, and outputting a first protocol message $\rho^{(1)}$ and secret $\mathfrak{s}$.
- $\mathsf{RunRoundTwo}(\mathfrak{s}, (\rho_1^{(1)},\ldots,\rho_n^{(1)}))$: A PPT algorithm taking a secret $\mathfrak{s}$ and the first protocol message for all n parties $\rho_1^{(1)},\ldots,\rho_n^{(1)}$, and outputting a second protocol message $\rho^{(2)}$.
- $\mathsf{ComputeResult}$: A PT algorithm taking as input the n second-round protocol messages $\rho_1^{(2)},\ldots,\rho_n^{(2)}$ for each party and outputting a value y.

Correctness

We say that MPC is *correct* if for all $\kappa, n, \in\mathbb{N}$, $\mathbf{x}_1\ldots\mathbf{x}_n\in\mathcal{M}_\kappa$ and $f\in\mathcal{F}_\kappa$

$$\Pr\left[y = f(\mathbf{x}) \;\middle|\; \begin{array}{ll} (\rho_i^{(1)}, \mathfrak{s}_i) \leftarrow\!\!\$\ \mathsf{RunRoundOne}(1^\kappa, 1^n, f, i, \mathbf{x}_i) & \forall i\in[n] \\ \rho_i^{(2)} \leftarrow\!\!\$\ \mathsf{RunRoundTwo}(\mathfrak{s}_i, (\rho_1^{(1)},\ldots,\rho_n^{(1)})) & \forall i\in[n] \\ y \leftarrow \mathsf{ComputeResult}(\rho_1^{(2)},\ldots,\rho_n^{(2)}) & \end{array} \right] = 1\ .$$

▶ Remark 6. The above definition of two-round MPC is without setup (*i.e.*, a CRS). We also consider the case that there is an additional algorithm CRSGen taking 1^κ and outputting a common reference string CRS that is input to the remaining algorithms. We call this two-round MPC *in the CRS model*.

We say that MPC is *unbounded* if the output of $\mathsf{RunRoundOne}$ does not depend on n. In this case, we input n to $\mathsf{RunRoundTwo}$ instead of $\mathsf{RunRoundOne}$. We call MPC *input-delayed* (resp. *function-delayed*) if the output of $\mathsf{RunRoundOne}$ does not depend on x (resp. f) but just on $1^{|x|}$ (resp. $1^{|f|}$). In this case, we input x (resp. f) to $\mathsf{RunRoundTwo}$ instead of $\mathsf{RunRoundOne}$. We call MPC *input-rerunnable* (resp. *function-rerunnable*) if it is *input-delayed* (resp. *function-delayed*) and if $\mathsf{RunRoundTwo}$ can be executed multiple times with different input choices (resp. function choices) while still preserving the security properties of the MPC protocol (see below).

Security

Let MPC be a 2-round MPC protocol as above. Let Coins be the coin-space for the protocol. For an adversary $\mathcal{A}=(\mathcal{A}_0,\mathcal{A}_1)$ and simulator $\mathcal{S}$, consider the experiments in Figure 5. We say that $\mathcal{A}$ is *passive* (aka. semi-honest) of $I=\emptyset$. We say that MPC is $\widetilde{\mathsf{SIM}}$-secure if for any PPT adversary $\mathcal{A}$ there is a stateful PPT simulator $\mathcal{S}=(\widetilde{\mathsf{CRSGen}}, \widetilde{\mathsf{Extract}}, \widetilde{\mathsf{Sim}})$ such that $\mathbf{REAL}_{\mathcal{A}}^{\mathsf{MPC}}(\cdot)$ and $\mathbf{IDEAL}_{\mathcal{A},\mathcal{S}}^{\mathsf{MPC}}(\cdot)$ are computationally indistinguishable. Note that

Experiment $\mathbf{REAL}^{\mathsf{MPC}}_{\mathcal{A}}(1^\kappa)$

(**Optional**) $\mathsf{crs} \leftarrow\!\!\$\ \mathsf{CRSGen}(1^\kappa)$
$(1^n, I, f, (x_i)_{i\notin I}) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$
// $f \in \mathcal{F}_\kappa$ of arity n, $x_i \in \mathcal{M}_\kappa$
$((\rho_i^{(1)})_{i\in I}, \mathsf{st}) \leftarrow\!\!\$\ \mathcal{A}_1(n, I, f)$
For $i \notin I$ do:
$r_i \leftarrow\!\!\$\ \mathsf{Coins}(1^\kappa)$
$(\rho_i^{(1)}, \mathfrak{s}_i)$
$\leftarrow\!\!\$\ \mathsf{RunRoundOne}(1^\kappa, 1^n, f, i, x_i; r_i)$
For $i \notin I$ do:
$\rho_i^{(2)}$
$\leftarrow\!\!\$\ \mathsf{RunRoundTwo}(\mathfrak{s}_i, (\rho_1^{(1)}, \ldots, \rho_n^{(1)}); r_i)$
$\alpha \leftarrow\!\!\$\ \mathcal{A}_2(\mathsf{st}, (\rho_i^{(1)}, \rho_i^{(2)})_{i\notin I})$
Return α

Experiment $\mathbf{IDEAL}^{\mathsf{MPC}}_{\mathcal{A},\mathcal{S}}(1^\kappa)$

(**Optional**) $\mathsf{crs} \leftarrow\!\!\$\ \widetilde{\mathsf{CRSGen}}(1^\kappa)$
$(1^n, I, f, (x_i)_{i\notin I}) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$
// $f \in \mathcal{F}_\kappa$ of arity n, $x_i \in \mathcal{M}_\kappa$
$((\rho_i^{(1)})_{i\in I}, \mathsf{st}) \leftarrow\!\!\$\ \mathcal{A}_1(n, I, f)$
$x_i \leftarrow \widetilde{\mathsf{Extract}}(\rho_i^{(1)}) \quad \forall i \in I$
$(\rho_i^{(1)}, \rho_i^{(2)})_{i\notin I}$
$\leftarrow\!\!\$\ \widetilde{\mathsf{Sim}}((x_i)_{i\in I}, f(x_1, \ldots, x_n))$
$\alpha \leftarrow\!\!\$\ \mathcal{A}_2(\mathsf{st}, (\rho_i^{(1)}, \rho_i^{(2)})_{i\notin I})$
Return α

Figure 5 Experiments for SIM-security of two-round MPC.

simulation of the first-round protocol messages for the honest parties are independent of the inputs, so for convenience and ease of presentation we will partition the algorithm $\widetilde{\mathsf{Sim}}$ into two algorithms: $\widetilde{\mathsf{Sim}_1}$ and $\widetilde{\mathsf{Sim}_2}$, defined as follows:

- $\widetilde{\mathsf{Sim}_1}() \mapsto (\rho_i^{(1)})_{i\notin I}$: Outputs the first-round protocol messages for the honest parties.
- $\widetilde{\mathsf{Sim}_2}((x_i)_{i\in I}, y) \mapsto (\rho_i^{(2)})_{i\notin I}$: On input the inputs of the corrupted parties along with the target output value of the protocol, $\widetilde{\mathsf{Sim}_2}$ outputs the second-round protocol messages for the honest parties.

Input/Function-Rerunnability

For simplicity, the definition in Figure 5 does not capture input/function-rerunnability. It is straightforward to see how the definition can be extended. For example in the case of function-rerunnability (the situation is analogous for input-rerunnability where inputs and functions are swapped), the changes to the definition are (1) $\mathcal{A}_0$ outputs a set of functions $\{f_i\}$ instead of a single function, (2) in the real experiment $\mathsf{RunRoundTwo}$ is executed for each function, (3) in the ideal experiement $\widetilde{\mathsf{Sim}_2}$ is called for each function, and (4) the complete set of second-round protocol messages for all functions is given to $\mathcal{A}_2$.

Input Extractability

Our results in this work rely on the simulator's ability to extract the inputs of the corrupted parties, hence the need for the $\widetilde{\mathsf{Extract}}$ algorithm. In the semi-honest setting, extraction is not necessary. In the malicious case, both known constructions of two-round MPC [33, 57] for general functions satisfy the above extractability property, albeit in the CRS model.

B.3 Punctured Pseudorandom Functions

A PRF F is specified by two algorithms:

- $\mathsf{PRF.Setup}(1^\kappa)$: The setup algorithm takes as input the security parameter and outputs a description of the key space $\mathcal{K}_\kappa$, domain $\mathcal{X}$, range $\mathcal{Y}$ as well as the PRF key K.
- $\mathsf{PRF.Eval}(K, x)$: The eval algorithm takes a key $K \in \mathcal{K}_\kappa$ and domain point $x \in \mathcal{X}_\kappa$ and outputs a range point $y \in \mathcal{Y}_\kappa$.

We require that for all adversaries $\mathcal{A}$

$$\Pr\left[\mathcal{A}^{\mathsf{PRF.Eval}(K,\cdot)} \text{ outputs } 1\right] - \Pr\left[\mathcal{A}^{\$(\cdot)} \text{ outputs } 1\right]$$

is negligible in κ, where $K \leftarrow \mathsf{PRF.Setup}(1^\kappa)$ and $\$(\cdot)$ denotes a random function from $\mathcal{X}_\kappa$ to $\mathcal{Y}_\kappa$.

A punctureable PRF additionally includes an algorithm $\mathsf{PRF.Punc}$ which takes as input a PRF key K and a point $x^* \in \mathcal{X}$ and outputs a punctured key K_{x^*}. For correctness, we require that $\mathsf{PRF.Eval}(K_{x^*}, x) = \mathsf{PRF.Eval}(K, x)$ for all $x \neq x^*$ and $\perp$ when $x = x^*$.

Security of punctured PRF

The security game between the challenger and the adversary A consists of the following four phases.

Setup Phase: The challenger samples a PRF key K and a random bit b.

Evaluation Query Phase: The adversary $\mathcal{A}$ queries for polynomially many evaluations. For each evaluation query x, the challenger sends $\mathsf{F}(K, x)$ to $\mathcal{A}$.

Challenge Phase: $\mathcal{A}$ chooses a challenge x^* and the challenger computes $K_{x^*} \leftarrow \mathsf{PRF.Punc}(K, x^*)$. If $b = 0$, the challenger outputs K_{x^*} and $\mathsf{F}(K, x^*)$. Else, the challenger outputs K_{x^*} and $y \leftarrow\!\!\$\ \mathcal{Y}$ chosen uniformly at random.

Guess: The adversary $\mathcal{A}$ outputs a guess b' of b.

The adversary $\mathcal{A}$ wins if $b' = b$ and the adversary did not query for evaluation on x^*. The advantage of $\mathcal{A}$ is defined to be

$$\mathsf{Adv}^{\mathsf{F}}_{\mathcal{A}}(1^\kappa) = |\Pr[\mathcal{A} \text{ wins}] - 1/2|$$

The PRF F is a secure puncturable PRF if for all probabilistic polynomial time adversaries $\mathcal{A}$, we have that $\mathsf{Adv}^{\mathsf{F}}_{\mathcal{A}}(1^\kappa)$ is negligible in κ.

B.4 Multi-Input Functional Encryption

An *n-input FE scheme* [45] MIFE for a message space $\{\mathcal{M}_\kappa\}_{\kappa\in\mathbb{N}}$ and a functionality $\{\mathcal{F}_\kappa\}_{\kappa\in\mathbb{N}}$, where for each $\kappa \in \mathbb{N}$, each $f \in \mathcal{F}_\kappa$ is a (description of a) function on $(\mathcal{M}_\kappa)^n$, is given by a set of algorithms with the following syntax:

- $\mathsf{MIFE.Setup}(1^\kappa, 1^n)$: A PPT algorithm taking the security parameter κ and number of users n, and outputting the master secret key MSK and encryption keys $(\mathsf{EK}_1, \ldots, \mathsf{EK}_n)$.
- $\mathsf{MIFE.KeyGen}(\mathsf{MSK}, f)$: A PT algorithm taking a master secret key MSK, a function $f \in \mathcal{F}_\kappa$ and outputting a corresponding decryption key DK_f.
- $\mathsf{MIFE.Enc}(\mathsf{EK}, \mathbf{x})$: A PPT algorithm taking an encryption key EK and a message $\mathbf{x} \in \mathcal{M}_\kappa$, and outputting a ciphertext c.
- $\mathsf{MIFE.Dec}(\mathsf{DK}_f, (c_1, \ldots, c_n))$: A PT algorithm taking decryption key DK_f and vector of ciphertexts $(c_1, \ldots, c_n)$, and outputting a string y.

Correctness

We say that MIFE is *correct* if for all $\kappa, \in \mathbb{N}$, $\mathbf{x}_1 \dots \mathbf{x}_n \in \mathcal{M}_\kappa$ and $f \in \mathcal{F}_\kappa$

$$\Pr\left[y = f(\mathbf{x}_1, \cdots, \mathbf{x}_n) \middle| \begin{array}{l} ((\mathsf{EK}_1, \dots, \mathsf{EK}_n), \mathsf{MSK}) \leftarrow\!\!\$\ \mathsf{MIFE.Setup}(1^\kappa) \\ c_i \leftarrow\!\!\$\ \mathsf{MIFE.Enc}(\mathsf{EK}_i, \mathbf{x}_i) \quad \forall i \in [n] \\ \mathsf{DK}_f \leftarrow\!\!\$\ \mathsf{MIFE.KeyGen}(\mathsf{MSK}, f) \\ y \leftarrow \mathsf{MIFE.Dec}(\mathsf{DK}_f, (c_1, \dots, c_n)) \end{array} \right] = 1 \ .$$

▶ Remark 7. We remark that our formulation of MIFE assumes that the senders (as in our application an encryptor is referred to as a sender or source) are ordered. This allows for consistency with our formulation of ad hoc MIFE and allows us to simplify exposition versus [45].

Indistinguishability-Based Security

For an n-input FE scheme MIFE as above and adversary $\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2)$, consider the experiment in Figure 6.

Experiment $\mathbf{IND}^{\mathsf{MIFE}}_{\mathcal{A}}(1^\kappa)$
$(I, st) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$
$b \leftarrow\!\!\$\ \{0,1\}$
$((\mathsf{EK}_1, \dots, \mathsf{EK}_n), \mathsf{MSK})$
$\leftarrow\!\!\$\ \mathsf{MIFE.Setup}(1^\kappa)$
$st \leftarrow\!\!\$\ \mathcal{A}_1^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot), \mathcal{O}_{\mathsf{kg}}(\cdot)}(st)$
$b' \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot), \mathcal{O}_{\mathsf{kg}}(\cdot)}((\mathsf{EK}_i)_{i \in I}, st)$
Return $(b = b')$

Oracle $\mathcal{O}_{\mathsf{enc}}(i, \mathbf{x}_0, \mathbf{x}_1)$
If $\mathbf{x}_0, \mathbf{x}_1 \in \mathcal{M}_\kappa$ and $|\mathbf{x}_0| = |\mathbf{x}_1|$

Return DK_f
Else return $\perp$

Figure 6 Experiment for IND-security of standard MIFE.

We call $\mathcal{A}$ *legitimate* if for all $\kappa \in \mathbb{N}$, in all transcripts $\mathbf{IND}^{\mathsf{MIFE}}_{\mathcal{A}}(1^\kappa)$ it holds that for every key generation query f there does not exist two sequences $(y_{1,0}, \cdots, y_{n,0})$ and $(y_{1,1}, \cdots, y_{n,1})$ such that

$$f(y_{1,0}, \cdots, y_{n,0}) \neq f(y_{1,1}, \cdots, y_{n,1})$$

and for every $j \in [n]$

- $j \in I$, *i.e.* j is corrupted (so there is no restriction on $y_{j,0}, y_{j,1}$ above), or
- there is an encryption query $(j, \mathbf{x}_0, \mathbf{x}_1)$ such that $y_{j,0} = \mathbf{x}_0$ and $y_{j,1} = \mathbf{x}_1$.

We assume adversaries are legitimate unless otherwise stated. We call $\mathcal{A}$ *passive* if $I = \emptyset$. We call $\mathcal{A}$ *selective* if $\mathcal{A}_2$ makes no queries. We say that MIFE is IND-secure if for any adversary $\mathcal{A}$

$$|\Pr\left[\mathbf{IND}^{\mathsf{MIFE}}_{\mathcal{A}}(\cdot) \text{ outputs } 1\right] - 1/2| = \mathsf{negl}(\cdot) \ .$$

Simulation-Based Security

For an MIFE scheme MIFE as above, adversary $\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2)$, and simulator $\mathcal{S} = (\widetilde{\mathsf{Setup}}, \widetilde{\mathsf{Enc}}, \widetilde{\mathsf{KeyGen}})$, consider the experiments in Figure 7. Here $q_{\mathsf{enc},i}$ is the number of encryption queries for user $i \in [n]$. We say that $\mathcal{A}$ is *q-bounded* if $q_{\mathsf{enc},i} \leq q$ for all $i \in [n]$. We say that MIFE is SEL-SIM-secure if for any adversary $\mathcal{A}$ there is a simulator $\mathcal{S}$ such that $\mathbf{REAL}^{\mathsf{MIFE}}_{\mathcal{A}}(\cdot)$ and $\mathbf{IDEAL}^{\mathsf{MIFE}}_{\mathcal{A},\mathcal{S}}(\cdot)$ are computationally indistinguishable.

▶ Remark 8. For consistency with our formulation of simulation-based security for ad hoc MIFE, we restrict the above definition to the selective-security and passive (no sender corruption) setting.

Experiment $\mathbf{REAL}^{\mathsf{MIFE}}_{\mathcal{A}}(1^\kappa)$
$((\mathsf{EK}_1, \ldots, \mathsf{EK}_n), \mathsf{MSK}) \leftarrow\!\!\$\ \mathsf{MIFE.Setup}(1^\kappa)$

For all $i \in [n], j \in [q_{\mathsf{enc},i}]$ do:
  $c_{i,j} \leftarrow\!\!\$\ \mathsf{MIFE.Enc}(\mathsf{MSK}_i, m_{i,j})$
$\alpha \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{kg}}(\cdot)}((\mathsf{EK}_i)_{i\in[n]}, (c_{i,j})_{i\in[n],j\in[q_{\mathsf{enc},i}]})$
Return $((m_{i,j})_{i\in[n],j\in[q_{\mathsf{enc},i}]}, \alpha)$

Oracle $\mathcal{O}_{\mathsf{kg}}(f)$ // $f \in \mathcal{F}_\kappa$
$\mathsf{DK}_f \leftarrow\!\!\$\ \mathsf{MIFE.KeyGen}(\mathsf{MSK}, f)$
Return DK_f

Experiment $\mathbf{IDEAL}^{\mathsf{MIFE}}_{\mathcal{A},\mathcal{S}}(1^\kappa)$
$((\widetilde{\mathsf{EK}_1}, \ldots, \widetilde{\mathsf{EK}_n}), \widetilde{\mathsf{MSK}}) \leftarrow\!\!\$\ \widetilde{\mathsf{Setup}}(1^\kappa)$
$(m_{i,j})_{i\in[n], j\in[q_{\mathsf{enc},i}]} \leftarrow\!\!\$\ \mathcal{A}_1(st)$
For all $i \in [n], j \in [q_{\mathsf{enc},i}]$ do:
  $\widetilde{c_{i,j}} \leftarrow\!\!\$\ \widetilde{\mathsf{Enc}}(\widetilde{\mathsf{MSK}}, |m_{i,j}|)$
$\alpha \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}((\widetilde{\mathsf{EK}_i})_{i\in[n]}, (\widetilde{c_{i,j}}))$
Return $((m_{i,j})_{i\in[n],j\in[q_{\mathsf{enc},i}]}, \alpha)$

Oracle $\widetilde{\mathcal{O}_{\mathsf{kg}}}(f)$ // $f \in \mathcal{F}_\kappa$
$\widetilde{\mathsf{DK}_f} \leftarrow \widetilde{\mathsf{KeyGen}}(f, (f(m_{i,j_i}))_{j_i\in[q_{\mathsf{enc},i}]}, \widetilde{\mathsf{MSK}})$
Return $\widetilde{\mathsf{DK}_f}$

Figure 7 Experiments for SIM-security of standard MIFE.

B.5 Function-Private Functional Encryption

A functional encryption scheme, denoted as FE [20], is a tuple of algorithms $\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.KeyGen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$ for a message space $\{\mathcal{M}_\kappa\}_{\kappa\in\mathbb{N}}$ and a functionality $\{\mathcal{F}_\kappa\}_{\kappa\in\mathbb{N}}$, where for each $\kappa \in \mathbb{N}$, each $f \in \mathcal{F}_\kappa$ is a (description of a) function on $\mathcal{M}_\kappa$. The syntax is the same as for a 1-input MIFE scheme where $\mathsf{EK}_1 = \mathsf{MSK}$ and $I = \emptyset$. The correctness requirement remains the same, as well the notion of indistinguishability based security (which we refer to as "message privacy").

Function Privacy

We additionally define the notion of function privacy as follows. For an FE scheme FE as above and adversary $\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2)$, consider the experiment in Figure 8.

We call $\mathcal{A}$ *legitimate* if for all $\kappa \in \mathbb{N}$, in all transcripts $\mathbf{FP}^{\mathsf{FE}}_{\mathcal{A}}(1^\kappa)$ it holds that for every key generation query f_0, f_1 there does not exist an encryption query $\mathbf{x} \in \mathcal{M}_\kappa$ such that

$$f_0(\mathbf{x}) \neq f_1(\mathbf{x}) .$$

We assume adversaries are legitimate unless otherwise stated. We say that FE is FP-secure if for any adversary $\mathcal{A}$

$$|\Pr\left[\mathbf{FP}^{\mathsf{FE}}_{\mathcal{A}}(\cdot) \text{ outputs } 1\right] - 1/2| = \mathsf{negl}(\cdot) .$$

Experiment $\mathbf{FP}^{\mathsf{FE}}_{\mathcal{A}}(1^\kappa)$
$b \leftarrow\!\!\$\ \{0,1\}$
$\mathsf{MSK} \leftarrow\!\!\$\ \mathsf{FE.Setup}(1^\kappa)$
$b' \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{enc}}(\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot)}(1^\kappa)$
Return $(b = b')$

Oracle $\mathcal{O}_{\mathsf{enc}}(\mathbf{x})$
If $\mathbf{x} \in \mathcal{M}_\kappa$
$c \leftarrow\!\!\$\ \mathsf{MIFE.Enc}(\mathsf{MSK}, \mathbf{x})$
Return c
Else Return $\perp$

Oracle $\mathcal{O}_{\mathsf{kg}}(f_0, f_1)$
If $f_0, f_1 \in \mathcal{F}_\kappa$
$\mathsf{DK}_{f_b} \leftarrow\!\!\$\ \mathsf{MIFE.KeyGen}(\mathsf{MSK}, f_b)$
Return DK_{f_b}
Else return $\perp$

Figure 8 Experiment for FP-security of FE.

C Simulation Based Security for Ad Hoc MIFE

We now present a simulation-based definition of security. The definition has a number of restrictions that we justify below.

For an ad hoc MIFE scheme aMIFE as above, adversary $\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2)$, and simulator $\mathcal{S} = (\widetilde{\mathsf{Setup}}, \widetilde{\mathsf{Enc}}, \widetilde{\mathsf{KeyGen}})$, consider the experiments in Figure 9. Here $q_{E,i}$ is the number of encryption queries for user $i \in [n]$. We say that $\mathcal{A}$ is q-*bounded* if $q_{E,i} \le q$ for all $i \in [n]$.

Experiment $\mathbf{REAL}^{\mathsf{aMIFE}}_{\mathcal{A}}(1^\kappa)$
$(1^n, st) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$
For all $i \in [n]$ do:
$(\mathsf{MSK}_i, \mathsf{PP}_i) \leftarrow\!\!\$\ \mathsf{aMIFE.Setup}(1^\kappa)$
$(m_{i,j})_{i\in[n],j\in[q_{E,i}]} \leftarrow\!\!\$\ \mathcal{A}_1(st)$
For all $i \in [n], j \in [q_{E,i}]$ do:
$c_{i,j} \leftarrow\!\!\$\ \mathsf{aMIFE.Enc}(\mathsf{MSK}_i, m_{i,j})$
$\alpha \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}((\mathsf{PP}_i)_{i\in[n]}, (c_{i,j}))$
Return $(1^n, (m_{i,j})_{i\in[n],j\in[q_{E,i}]}, \alpha)$

Experiment $\mathbf{IDEAL}^{\mathsf{aMIFE}}_{\mathcal{A},\mathcal{S}}(1^\kappa)$
$(1^n, st) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$ // $I \subset [n]$
For all $i \in [n]$ do:
$(\widetilde{\mathsf{MSK}}_i, \widetilde{\mathsf{PP}}_i) \leftarrow\!\!\$\ \widetilde{\mathsf{Setup}}(1^\kappa)$
$(m_{i,j})_{i\in[n],j\in[q_{E,i}]} \leftarrow\!\!\$\ \mathcal{A}_1(st)$
For all $i \in [n], j \in [q_{E,i}]$ do:
$\widetilde{c_{i,j}} \leftarrow\!\!\$\ \widetilde{\mathsf{Enc}}(\widetilde{\mathsf{MSK}}_i, |m_{i,j}|)$
$\alpha \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}((\widetilde{\mathsf{PP}}_i)_{i\in[n]}, (\widetilde{c_{i,j}}))$
Return $(1^n, (m_{i,j})_{i\in[n],j\in[q_{E,i}]}, \alpha)$

Oracle $\mathcal{O}_{\mathsf{kg}}(i, (i_1, \ldots, i_\ell), f)$
If $i \in \{i_1, \cdots, i_\ell\}$, and $f \in \mathcal{F}_\kappa$ of arity ℓ
$\mathsf{PDK}_{i,f} \leftarrow$
$\mathsf{aMIFE.KeyGen}(i, \mathsf{MSK}_i, (\mathsf{PP}_{i_j})_{j\in[\ell]}, f)$
Return $\mathsf{PDK}_{i,f}$
Else return $\perp$

Oracle $\widetilde{\mathcal{O}_{\mathsf{kg}}}(i, (i_1, \ldots, i_\ell), f)$
If $i \in \{i_1, \cdots, i_\ell\}$, and $f \in \mathcal{F}_\kappa$ of arity ℓ
$\widetilde{q} \leftarrow (i, (i_1, \ldots, i_\ell), f)$
$\widetilde{\mathsf{PDK}_{i,f}} \leftarrow$
$\widetilde{\mathsf{KeyGen}}(\widetilde{q}, (f(m_{i_k,j_{i_k}}))_{j_{i_k}\in[q_{E,i_k}]}, (\widetilde{\mathsf{MSK}_{i_j}}))$
Return $\widetilde{\mathsf{PDK}_{i,f}}$
Else return $\perp$

Figure 9 Experiments for SIM-security of ad hoc MIFE.

We say that aMIFE is xxx-SEL-SIM-secure if for any adversary $\mathcal{A}$ of type xxx there is a simulator $\mathcal{S}$ such that $\mathbf{REAL}^{\mathsf{aMIFE}}_{\mathcal{A}}(\cdot)$ and $\mathbf{IDEAL}^{\mathsf{aMIFE}}_{\mathcal{A},\mathcal{S}}(\cdot)$ are computationally indistinguishable.

▶ Remark 9. The above definition has a number of restrictions that we now justify:

- The adversary is passive and does not corrupt any sender. This is justified because otherwise such a scheme implies virtual black-box obfuscation as in the case of standard MIFE [45], which is impossible [12].

- The adversary is selective and chooses its challenge messages before seeing the public parameters of the users. We focus on this formulation for simplicity and leave the study of adaptive security for ad hoc MIFE in the case of simulation-based security for future work.
- The simulator is black-box. This is for simplicity as it is stronger than allowing non-black-box simulation and our constructions achieve it.

D Proof of Theorem 5

▶ **Theorem 5.** *If* MIFE *is a IND-secure MIFE scheme and* MPC *is a SIM-secure 2-round MPC protocol, then our construction is* sel*-IND-secure.*

Proof. The proof of security makes use of a trapdoor data structure which is defined in Figure 10.

The trapdoor data structure

Here, mode is used to indicate whether we are in the real mode Real or trapdoor mode Trap. CT indicates the hardwired MIFE CT which must be output if the field index equals the counter ctr set in the FE key. The fields val_0 and val_1 are used to indicate the values corresponding to bit 0 and bit 1 respectively, where the latter is used when index $>$ ctr and the former when index $<$ ctr.

mode	CT	index	val_0	val_1

Figure 10 Data Structure Trap used for Proof.

The Hybrids

We prove the theorem via a hybrid argument. We describe our hybrids below.

Hybrid 0: This is the real game in which on every encryption query $(i, \mathbf{x}_0, \mathbf{x}_1)$, $\mathbf{x}_0$ is encrypted.

Suppose there are Q_c encryption queries (made selectively). For each $k \in [Q_c]$, let i be the party index queried, $\mathbf{x}_0$ and $\mathbf{x}_1$ the challenge plaintexts, let T be the tag used during encryption and I be the set of users corrupted by the adversary. We use these definitions in the remainder of the proof.

Hybrid 1: The change in this hybrid is twofold.

1. **Simulate the Public Parameters.** We set the first-round protocol message $\rho_i^{(1)}$ for MPC in the public parameters to the output of the simulator $\widetilde{\mathsf{Sim}}_1$ for each uncorrupted user $i \notin I$.
2. **Simulate the Function Key.** For each key generation query $(i, (i_1, \ldots, i_\ell), f)$, we do the following.
   a. Let $J \triangleq I \cap \{i_1, \ldots, i_\ell\}$ be the subset of corrupted users and $\bar{J} = \{i_1, \ldots, i_\ell\} \setminus J$ be the subset of honest users.
   b. We use the simulator's $\widetilde{\mathsf{Extract}}$ algorithm to compute $\mathbf{x}_j \leftarrow \widetilde{\mathsf{Extract}}(\rho_j^{(1)})$ for each corrupted party $j \in J$ where $\mathsf{PP}_j = \rho_j^{(1)}$, then compute $y = \mathsf{GenKeys}_f(\mathbf{x}_{i_1}, \ldots, \mathbf{x}_{i_\ell})$ where $\mathbf{x}_j$ for $j \in \bar{J}$ is (honest) party j's input to the MPC protocol.

c. Compute $(\rho_j^{(2)})_{j\in\bar{I}} \leftarrow \widetilde{\mathsf{Sim}_2}((x_j)_{j\in J}, y)$ and $s \leftarrow \mathsf{PRF.Eval}(K_i, 0 \,\|\, (\mathsf{PP}_{i_j})_{j\in[\ell]} \| f)$. Return $(\rho_i^{(2)}, s)$.

See Figure 11 for a formal description.

Indistinguishability of the hybrids follows from the SIM-security of the MPC protocol. As we see in Figure 11, the only difference from Hybrid 0 is that the inputs of the corrupt parties are extracted using the $\widetilde{\mathsf{Extract}}$ algorithm and the protocol transcript is generated using the MPC simulator. Hence, an adversary who distinguishes between Hybrids 0 and 1 implies an adversary against the MPC protocol by a standard reduction.

Hybrid 1:
$(1^n, I, (\mathsf{PP}_i)_{i\in I}, st) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$
$b \leftarrow\!\!\$\ \{0,1\}$
$\forall i \notin I$:
$(\mathsf{PP}_{\mathsf{FE}_i}, \mathsf{MSK}_{\mathsf{FE}_i}) \leftarrow\!\!\$\ \mathsf{FE.Setup}(1^\kappa)$
$K_i \leftarrow\!\!\$\ \mathcal{K}_\kappa$
$K_i^{\mathsf{punc}} \leftarrow\!\!\$\ \mathcal{K}_\kappa$
$(\rho_i^{(1)})_{i\notin I} \leftarrow\!\!\$\ \widetilde{\mathsf{Sim}_1}()$
$\mathsf{PP}_i \leftarrow \rho_i^{(1)}$

$st \leftarrow\!\!\$\ \mathcal{A}_1^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}(st)$
$b' \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}((\mathsf{PP}_i)_{i\notin I}, st)$
Return $(b = b')$

Oracle $\mathcal{O}_{\mathsf{enc}}(i, \mathbf{x}_0, \mathbf{x}_1)$
$T \leftarrow\!\!\$\ \{0,1\}^\kappa$
Return $\mathsf{FE.Enc}(\mathsf{MSK}_{\mathsf{FE}_i}, (\mathbf{x}_0, T, K_i^{\mathsf{punc}}, \mathsf{Trap}))$

Oracle $\mathcal{O}_{\mathsf{kg}}(i, (i_1, \ldots, i_\ell), f)$
$J \leftarrow I \cap \{i_1, \ldots, i_\ell\}$; $\bar{J} \leftarrow \{i_1, \ldots, i_\ell\} \setminus J$
$(K_j, \mathsf{MSK}_{\mathsf{FE}_j}) \leftarrow \widetilde{\mathsf{Extract}}(\rho_j^{(1)}) \quad \forall j \in J$
$y \leftarrow \mathsf{GenKeys}_f((K_{i_1}, \mathsf{MSK}_{\mathsf{FE}_{i_1}}), \ldots, (K_{i_\ell}, \mathsf{MSK}_{\mathsf{FE}_{i_\ell}}))$
$(\rho_j^{(2)})_{j\in\bar{J}} \leftarrow\!\!\$\ \widetilde{\mathsf{Sim}_2}(K_j, \mathsf{MSK}_{\mathsf{FE}_j})_{j\in J}, y)$
$s \leftarrow \mathsf{PRF.Eval}(K_i, 0 \,\|\, (\mathsf{PP}_{i_j})_{j\in[\ell]} \,\|\, f)$
Return $(\rho_i^{(2)}, s)$.

Figure 11 Hybrid 1.

Hybrid 2: In this hybrid, we replace the outputs of the PRF on key K_i for the honest users i with uniformly random strings in the function $\mathsf{GenKeys}$ described in Figure 2. For every key query pertaining to parties $(i_1, \ldots, i_\ell)$ and function f and every honest party i, we replace $\mathsf{PRF.Eval}(K_i, k \,\|\, (\mathsf{PP}_{i_j})_{j\in[\ell]} \,\|\, f)$ for $k \in \{0,1,2\}$ as in Hybrid 1 with a fresh uniformly random string. The changes are formally described in Figure 12 wherein the algorithm R is used to generate random strings and keep track of those previously generated.

Indistinguishability of Hybrid 1 and Hybrid 2 follows from the security of the PRF. More precisely, a standard argument iterates through sub-hybrids for each honest party, replacing the PRF outputs with uniformly random strings.

Hybrid 3: In this hybrid, we change how y (the target output passed to $\widetilde{\mathsf{Sim2}}$) is generated in each query $((i_1, \ldots, i_\ell), f)$. In this hybrid, y is randomly sampled. Furthermore for a pair $((i_1, \ldots, i_\ell), f)$ that is *fully queried* i.e. a partial decryption query $(i, (i_1, \ldots, i_\ell), f)$ is made for each $i \in \{i_1, \ldots, i_\ell\} \setminus I$, the final partial decryption key that is issued has its masking value, i.e. the second component of the partial decryption key, generated differently. It is generated as

$$s \leftarrow y \oplus S_1 \oplus S_2 \oplus \mathsf{GenKeys}''((r'_1, \mathsf{MSK}_{\mathsf{FE}_1}), \ldots, (r'_\ell, \mathsf{MSK}_{\mathsf{FE}_\ell}))$$

Here S_1 and S_2 are computed so as to satisfy requisite dependencies. Figure 13 captures these changes formally.

Hybrid 2:

$(1^n, I, (\mathsf{PP}_i)_{i\in I}, st) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$
$b \leftarrow\!\!\$\ \{0,1\}$
$\forall i \notin I$:
$(\mathsf{PP}_{\mathsf{FE}_i}, \mathsf{MSK}_{\mathsf{FE}_i}) \leftarrow\!\!\$\ \mathsf{FE.Setup}(1^\kappa)$
~~$K_i \leftarrow\!\!\$\ \mathcal{K}_\kappa$~~
$K_i^{\mathsf{punc}} \leftarrow\!\!\$\ \mathcal{K}_\kappa$
$\Gamma \leftarrow \emptyset$
$(\rho_i^{(1)})_{i\notin I} \leftarrow\!\!\$\ \widetilde{\mathsf{Sim}_1}()$
$\mathsf{PP}_i \leftarrow \rho_i^{(1)}$

$st \leftarrow\!\!\$\ \mathcal{A}_1^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}(st)$
$b' \leftarrow\!\!\$\ \mathcal{A}_2^{\mathcal{O}_{\mathsf{enc}}(\cdot,\cdot,\cdot),\mathcal{O}_{\mathsf{kg}}(\cdot,\cdot,\cdot)}((\mathsf{PP}_i)_{i\notin I}, st)$
Return $(b = b')$

Oracle $\mathcal{O}_{\mathsf{enc}}(i, \mathbf{x}_0, \mathbf{x}_1)$
$T \leftarrow\!\!\$\ \{0,1\}^\kappa$
Return $\mathsf{FE.Enc}(\mathsf{MSK}_{\mathsf{FE}_i}, (\mathbf{x}_0, T, K_i^{\mathsf{punc}}, \mathsf{Trap}))$

Oracle $\mathcal{O}_{\mathsf{kg}}(i, (i_1, \ldots, i_\ell), f)$
$J \leftarrow I \cap \{i_1, \ldots, i_\ell\}$; $\bar{J} \leftarrow \{i_1, \ldots, i_\ell\} \setminus J$
$(K_j, \mathsf{MSK}_{\mathsf{FE}_j}) \leftarrow \widetilde{\mathsf{Extract}}(\rho_j^{(1)}) \quad \forall j \in J$
$(\gamma_j^{(0)}, \gamma_j^{(1)}, \gamma_j^{(2)}) \leftarrow\!\!\$\ R_\Gamma(j, (i_1, \ldots, i_\ell), f) \quad \forall j \in \bar{J}$
$\forall m \in \{0,1,2\}, j \in J$:
$\gamma_j^{(m)} \leftarrow \mathsf{PRF.Eval}(K_j, m \,\|\, (\mathsf{PP}_{i_k})_{k\in[\ell]} \,\|\, f)$
$S \leftarrow \bigoplus_{j\in J\cup\bar{J}} \gamma_j^{(0)}$
$y \leftarrow S \oplus \mathsf{GenKeys}'(\{(r_k, r'_l, \mathsf{MSK}_{\mathsf{FE}_k})\}_{k\in[\ell]})$
$(\rho_j^{(2)})_{j\in\bar{J}} \leftarrow\!\!\$\ \widetilde{\mathsf{Sim}_2}(K_j, \mathsf{MSK}_{\mathsf{FE}_j})_{j\in J}, y)$
Return $(\rho_i^{(2)}, s := \gamma_i^{(0)})$

Algorithm $\mathsf{GenKeys}'(\{(r_k, r'_l, \mathsf{MSK}_{\mathsf{FE}_k})\}_{k\in[\ell]})$
$(\{\mathsf{EK}_k\}_{k\in[\ell]}, \mathsf{MSK}) \leftarrow \mathsf{MIFE.Setup}(1^\kappa; \bigoplus_{k\in[\ell]} r_k)$
$\mathsf{SK}_f \leftarrow \mathsf{MIFE.KeyGen}(\mathsf{MSK}, f)$
$\forall i \in [\ell]$:
$\mathsf{SK}_{\mathsf{FE}_i} \leftarrow \mathsf{FE.KeyGen}(\mathsf{MSK}_{\mathsf{FE}_i}, \mathsf{ReEnc}_{\mathsf{EK}_i,\perp}; r'_i)$
Return $(\mathsf{SK}_f, \mathsf{SK}_{\mathsf{FE}_1}, \ldots, \mathsf{SK}_{\mathsf{FE}_\ell})$

Algorithm $R_\Gamma(i, (i_1, \ldots, i_\ell, f)$
If $(i, (i_1, \ldots, i_\ell), f, \gamma^{(0)}, \gamma^{(1)}, \gamma^{(2)}) \in \Gamma$
Return $(\gamma^{(0)}, \gamma^{(1)}, \gamma^{(2)})$
Else
$\gamma^{(j)} \leftarrow\!\!\$\ \{0,1\}^{\mathsf{rp}} \quad \forall j \in \{0,1,2\}$
// where rp is the range of the PRF
$\Gamma \leftarrow \Gamma \cup \{(i, (i_1, \ldots, i_\ell), f, \gamma^{(0)}, \gamma^{(1)}, \gamma^{(2)})\}$
Return $(\gamma^{(0)}, \gamma^{(1)}, \gamma^{(2)})$

Figure 12 Hybrid 2.

Hybrid 2 and Hybrid 3 are distributed identically. First, y is distributed uniformly in both hybrids for all group-function pairs $((i_1, \ldots, i_\ell), f)$ that are not *fully queried*. In the case of a group-function pair $((i_1, \ldots, i_\ell), f)$ that is fully queried, each partial decryption key $(\rho_i^{(2)}, s_i)$ for $i \in \{i_1, \ldots, i_\ell\}$ is such that

$$y \oplus \bigoplus_{i\in[\ell]} s_i = \mathsf{GenKeys}''((r'_1, \mathsf{MSK}_{\mathsf{FE}_1}), \ldots, (r'_\ell, \mathsf{MSK}_{\mathsf{FE}_\ell}))$$

This is distributed the same as the output of $\mathsf{GenKeys}'$ in the previous hybrid. Hence the y values are distributed identically in both hybrids.

Hybrid 4: Let Q_k be the number of subset-function pairs that are *fully queried*. In this hybrid, the key generation algorithm keeps track of the query number $\mathsf{ctr} \in [\mathsf{Q_k}]$ in the ad hoc MIFE function keys. In more detail, the algorithm $\mathsf{GenKeys}''$ invoked for query index j for all $j \in [Q_k]$ is modified to invoke ReEnc with parameter $\mathsf{ctr} = \mathsf{j}$ (please refer to Figure 3) instead of $\perp$.

We claim that by function hiding of FE, the two hybrids are indistinguishable. To see this, note that since $\mathsf{mode} = R$ in all the FE ciphertexts, changing the ctr value in the FE key has no effect on the decryption value obtained, since this field is only relevant in the trapdoor mode, i.e. when $\mathsf{mode} = T$. Hence, the decryption values for both keys remain exactly the same. Then, by security of FE, we have that Hybrids 3 and 4 are indistinguishable. The formal reduction is standard, and constructs everything except the FE ciphertexts and FE function keys as in the previous hybrid, which are obtained using the FE challenger.

Hybrid 3:
$(1^n, I, (\mathsf{PP}_i)_{i\in I}, st) \leftarrow\!\!\$\ \mathcal{A}_0(1^\kappa)$

Figure 14 Hybrid 4.

key $\mathsf{SK}_{\mathsf{FE}_i}$ is obtained by making a call to the FE key generation oracle with functions $(\mathsf{ReEnc}_{i,\perp}, \mathsf{ReEnc}_{i,\mathsf{ctr}})$. If the FE challenger's bit is 0, then $\mathcal{B}$ perfectly simulates Hybrid $4, i-1$ and if the FE challenger's bit is 1, then $\mathcal{B}$ perfectly simulates Hybrid $4, i$.

For $j \in [Q_k]$, we define:

Hybrid $5_{\mathsf{j},1}$: In this hybrid, we hardwire all the Q_c MIFE CTs that are output by the j^{th} function query in the corresponding single input FE ciphertexts in the field Trap.CT and set mode $= T$.

In more detail, for key query j, we generate the encryption keys exactly as in Figure 2. Now, encryptor $i \in [n]$ computes Q_c ciphertexts as follows:

1. For $k \in [Q_c]$, let $r_{i,j,k} \leftarrow \mathsf{PRF.Eval}(K_i^{\mathsf{punc}}, j \,\|\, \mathsf{EK}_{i,j} \,\|\, T_{i,k})$
2. For $k \in [Q_c]$, let $\psi_{i,j,k} = \mathsf{MIFE.Enc}(\mathsf{EK}_{i,j}, \mathbf{x}_{i,k}; r_{i,j,k})$

For $k \in [Q_c]$, encryptor $i \in [n]$ sets Trap so as to program it for the j^{th} function query as follows:

$$\mathsf{Trap.mode} = T, \quad \mathsf{Trap.CT} = \psi_{i,j,k}, \quad \mathsf{Trap.index} = j, \quad \mathsf{val}_0 = \mathbf{x}_{0,i,k}, \quad \mathsf{val}_1 = \mathbf{x}_{1,i,k}$$

Please see Figure 15 for the complete description.

Figure 15 Hybrid $5_{j,1}$.

Note that the hardwired ciphertext is only output for query j, the outputs for the other queries are exactly equal to those in the previous hybrid. Now, for query j, the ciphertext is hardwired and output is set to be equal to what was output in the previous hybrid. It follows that the output of FE decryption remains exactly the same as in the previous hybrid. Thus, by security of FE, we have that the two hybrids are indistinguishable.

In more detail, we have a series of subhybrids, one for each $i \notin I$, where in Hybrid $5_{j,1}, i$, the change above is made to the ciphertext associated with the FE instance for party i. Let Hybrid $5_{j,1}, 0$ denote Hybrid 4 and let Hybrid $5_{j,1}, |n \setminus I|$ denote Hybrid $5_{j,1}$. We now give the formal reduction to FE semantic security for distinguishing Hybrid $5_{j,1}, i-1$ and Hybrid $5_{j,1}, i$ (for ease of notation, we assume that the indices i are consecutive). The simulator $\mathcal{B}$ is defined as follows. First $\mathcal{B}$ receives the public parameters PP from the FE challenger. Then it receives $(1^\kappa, I, (\mathsf{PP}_j)_{j\in I})$ from the hybrid distinguisher $\mathcal{A}$. Next it runs

Step 2 to Step 11 on the left hand side of Figure 15 and passes $(\mathsf{PP}_j)_{j\notin I}$ (see Step 11) to $\mathcal{A}$. It handles encryption and key generation queries as follows. On an encryption query $(i', \mathbf{x}_0, \mathbf{x}_1)$ with $i' \neq i$, the query is handled the same as $\mathcal{O}_{\mathsf{enc}}$ in Figure 15. On an encryption query $(i, \mathbf{x}_0, \mathbf{x}_1)$, a tag $T \leftarrow\!\!\$\ \{0,1\}^\kappa$ is sampled, then $r \leftarrow \mathsf{PRF.Eval}(K_i^{\mathsf{punc}}, j \parallel \mathsf{EK}_{i,j} \parallel T)$, $\psi \leftarrow \mathsf{MIFE.Enc}(\mathsf{EK}_{i,j}, \mathbf{x}_0; r)$, $\mathsf{Trap}_0 \leftarrow (\mathsf{mode} := R, \perp, \perp, \perp, \perp)$ and $\mathsf{Trap}_1 \leftarrow (\mathsf{mode} := \mathsf{Trap}, \psi, j, \mathbf{x}_0, \mathbf{x}_1)$ are computed and $\mathcal{B}$ makes a call to the FE encryption oracle with messages $(\mathbf{x}_0, T, K_i^{\mathsf{punc}}, \mathsf{Trap}_0)$ and $(\mathbf{x}_0, T, K_i^{\mathsf{punc}}, \mathsf{Trap}_1)$, and returns the returned ciphertext. Key generation queries are handled as in $\mathcal{O}_{\mathsf{kg}}$ in Figure 15 with one exception, namely the secret keys $\mathsf{SK}_{\mathsf{FE}_{i'}}$ are computed as in $\mathsf{GenKeys}''''$ except for the case $i' = i$; the secret key $\mathsf{SK}_{\mathsf{FE}_i}$ is obtained by making a call to the FE key generation oracle for function $\mathsf{ReEnc}_{i,\mathsf{ctr}}$. If the FE challenger's bit is 0, then $\mathcal{B}$ perfectly simulates Hybrid $5_{j,1}, i-1$ and if the FE challenger's bit is 1, then $\mathcal{B}$ perfectly simulates Hybrid $5_{j,1}, i$.

Hybrid $5_{\mathbf{j},\mathbf{2}}$: In this hybrid, we use a punctured PRF to generate the MIFE CTs in the ReEnc functionality encoded in the FE function keys. The PRF for party i is punctured at prefix j so that the randomness $r_{i,j,k}$ defined above, for $i \in [n]$, $k \in [Q_c]$ cannot be generated. All MIFE ciphertexts corresponding to other function queries can be generated as before.

In more detail:

1. For $i \in [n]$, party i samples $K_{i,j}^{\mathsf{punc}} \leftarrow \mathsf{puncF}(K_i^{\mathsf{punc}}, j)$.
2. The i^{th} encryptor computes $\mathsf{FE.enc}\big(\mathsf{MSK}_{\mathsf{FE}}, (\mathbf{x}_{0,i,k}, T_{i,k}, K_{i,j}^{\mathsf{punc}}, \mathsf{Trap})\big)$ where all other fields are set as in the previous hybrid.

During FE decryption, for any query $j' \neq j$, we now obtain:

$$r_{i,j',k} \leftarrow \mathsf{puncF}(K_{i,j}^{\mathsf{punc}}, j' \parallel \mathsf{EK}_{i,j'} \parallel T_{i,k})$$

for $k \in [Q_c]$. Everything else is as in the previous hybrid. For query j, the hardwired CT is output, and the punctured PRF key is not used to generate randomness. Please see Figure 16 for the complete description.

We have by correctness of the punctured PRF that for any $j' \neq j$, all the computed $r_{i,j',k}$ are exactly equal to those computed in the previous hybrid, where the normal PRF key was used. For query j, the PRF is not used and the hardwired value is output in both hybrids. Hence, the outputs of FE decryption are equal in both hybrids. Thus, indistinguishability follows from security of FE.

In more detail, we have a series of subhybrids, one for each $i \notin I$, where in Hybrid $5_{j,2}, i$, the change above is made to the ciphertext associated with the FE instance for party i. Let Hybrid $5_{j,2}, 0$ denote Hybrid $5_{j,1}$ and let Hybrid $5_{j,2}, |n \setminus I|$ denote Hybrid $5_{j,2}$. We now give the formal reduction to FE semantic security for distinguishing Hybrid $5_{j,2}, i-1$ and Hybrid $5_{j,2}, i$ (for ease of notation, we assume that the indices i are consecutive). The simulator $\mathcal{B}$ is defined as follows. First $\mathcal{B}$ receives the public parameters PP from the FE challenger. Then it receives $(1^\kappa, I, (\mathsf{PP}_j)_{j\in I})$ from the hybrid distinguisher $\mathcal{A}$. Next it runs Step 2 to Step 12 on the left hand side of Figure 16 and passes $(\mathsf{PP}_j)_{j\notin I}$ (see Step 12) to $\mathcal{A}$. It handles encryption and key generation queries as follows. On an encryption query $(i', \mathbf{x}_0, \mathbf{x}_1)$ with $i' \neq i$, the query is handled the same as $\mathcal{O}_{\mathsf{enc}}$ in Figure 16. On an encryption query $(i, \mathbf{x}_0, \mathbf{x}_1)$, a tag $T \leftarrow\!\!\$\ \{0,1\}^\kappa$ is sampled, then $r \leftarrow \mathsf{PRF.Eval}(K_i^{\mathsf{punc}}, j \parallel \mathsf{EK}_{i,j} \parallel T)$, $\psi \leftarrow \mathsf{MIFE.Enc}(\mathsf{EK}_{i,j}, \mathbf{x}_0; r)$ and $\mathsf{Trap} \leftarrow (\mathsf{mode} := \mathsf{Trap}, \psi, j, \mathbf{x}_0, \mathbf{x}_1)$ are computed and $\mathcal{B}$ makes a call to the FE encryption oracle with messages $(\mathbf{x}_0, T, K_i^{\mathsf{punc}}, \mathsf{Trap})$ and $(\mathbf{x}_0, T, K_{i,j}^{\mathsf{punc}}, \mathsf{Trap})$, and returns the returned ciphertext. Note that the punctured key $K_{i,j}^{\mathsf{punc}}$ is derived in Step 4 on the left hand side of Figure 16. Key generation queries are handled as in $\mathcal{O}_{\mathsf{kg}}$ in Figure 15 with one exception, namely the secret keys $\mathsf{SK}_{\mathsf{FE}_{i'}}$ are computed as in $\mathsf{GenKeys}''''$ except for the case $i' = i$; the

Figure 16 Hybrid $5_{j,2}$.

secret key $\mathsf{SK}_{\mathsf{FE}_i}$ is obtained by making a call to the FE key generation oracle for function $\mathsf{ReEnc}_{i,\mathsf{ctr}}$. If the FE challenger's bit is 0, then $\mathcal{B}$ perfectly simulates Hybrid $5_{j,2}, i-1$ and if the FE challenger's bit is 1, then $\mathcal{B}$ perfectly simulates Hybrid $5_{j,2}, i$.

Hybrid $5_{\mathsf{j},3}$: In this hybrid, we switch the randomness used in the hardwired MIFE CT to be true randomness. That is, $r_{i,j,k}$ is sampled uniformly at random for $i \in [n]$, $k \in [Q_c]$. We have by the security of the punctured PRF that given the punctured key, the PRF evaluations at the punctured points are indistinguishable from random. Hence, indistinguishability follows from security of punctured PRF.

Please see Figure 17 for the detailed description.

Figure 17 Hybrid $5_{j,3}$.

In more detail, we have a series of subhybrids, one for each $i \notin I$, where in Hybrid $5_{j,3}, i$, the change above is made to the function key associated with the FE instance for party i. Let Hybrid $5_{j,3}, 0$ denote Hybrid $5_{j,2}$ and let Hybrid $5_{j,3}, |n \setminus I|$ denote Hybrid $5_{j,3}$. We now give the formal reduction to PRF security for distinguishing Hybrid $5_{j,3}, i-1$ and Hybrid $5_{j,3}, i$ (for ease of notation, we assume that the indices i are consecutive). The simulator $\mathcal{B}$ is defined as follows. First $\mathcal{B}$ receives $(1^\kappa, I, (\mathsf{PP}_j)_{j\in I})$ from the hybrid distinguisher $\mathcal{A}$. Next it runs

- For all $i' \notin I$, $i' \neq i$:
  - $K_{i'}^{\mathsf{punc}} \leftarrow\!\!\$\ \mathcal{K}_\kappa$
  - $K_{i',j}^{\mathsf{punc}} \leftarrow \mathsf{PRF.Punc}(K_{i'}^{\mathsf{punc}}, j)$

Then it sends a challenge prefix j to the PRF challenger and receives a punctured key; call this $K^{\mathsf{punc}}_{i,j}$. Next $\mathcal{B}$ runs Step 5 to Step 12 on the left hand side of Figure 17 and passes $(\mathsf{PP}_j)_{j\notin I}$ (see Step 12) to $\mathcal{A}$. It handles encryption and key generation queries as follows. Key generation queries are handled as in $\mathcal{O}_{\mathsf{kg}}$ in Figure 17. On an encryption query $(i', \mathbf{x}_0, \mathbf{x}_1)$ with $i' \neq i$, the query is handled the same as $\mathcal{O}_{\mathsf{enc}}$ in Figure 17. On an encryption query $(i, \mathbf{x}_0, \mathbf{x}_1)$, the query is handled the same as $\mathcal{O}_{\mathsf{enc}}$ in Figure 17 except Step 2 of $\mathcal{O}_{\mathsf{enc}}$ where r is computed. To obtain r, the PRF evaluation oracle is queried at the point $j \parallel \mathsf{EK}_{i,j} \parallel T$ where T is derived in Step 1 of $\mathcal{O}_{\mathsf{enc}}$. Now if the PRF challenger's bit is 0, the string r will be computed using the PRF and $\mathcal{B}$ perfectly simulates $5_{j,3}, i-1$. On the other hand, if the PRF challenger's bit is 1, the string r will be uniformly random because the queried evaluation point begins with the challenge prefix j (i.e. the PRF is punctured at that point) and so $\mathcal{B}$ perfectly simulates Hybrid $5_{j,3}, i$.

Hybrid $\mathbf{5_{j,4}}$: In this Hybrid, the protocol $\mathsf{GenKeys}''''$ is modified further so that for key j, $\mathsf{MIFE.Setup}$ or $\mathsf{MIFE.KeyGen}$ are not invoked. Rather, the output of the $\mathsf{MIFE.KeyGen}$ algorithm is hardwired and output for key j. The hardwired value is exactly the same as in the previous hybrid, hence indistinguishability holds by security of MPC. In more detail, the MPC simulator receives identical inputs in both hybrids and hence produces indistinguishable outputs in the two hybrids.

Hybrid $\mathbf{5_{j,5}}$: In this hybrid, we switch the hardwired MIFE CTs within the FE CTs to use bit $b = 1$. Indistinguishability follows from MIFE security. In more detail, we fix query j. For party $i \in [n]$ and ciphertext query $k \in [Q_c]$, we construct a reduction which plays against the MIFE challenger as below. The reduction computes everything as in the previous hybrid except that the hardwired ciphertexts for the j^{th} copy of MIFE, which it receives from the MIFE challenger as below:

1. The reduction requests for MIFE key corresponding to function f_j which it receives. It hardwires this into functionality $\mathsf{GenKeys}$.
2. For $i \in [n]$, $k \in [Q_c]$, the challenge ciphertexts for party i are set as $(\mathbf{x}_{0,i,k}, T_{i,k}, K^{\mathsf{punc}}_{i,j})$ and $(\mathbf{x}_{1,i,k}, T_{i,k}, K^{\mathsf{punc}}_{i,j})$.
3. The reduction receives $\psi_{i,j,k}$ for $i \in [n]$ and $k \in [Q_c]$. It hardwires these into the FE ciphertexts as discussed above.

It is evident that if $b = 0$ then we are in Hybrid $\mathbf{5_{j,4}}$ and if $b = 1$ we are in Hybrid $\mathbf{5_{j,5}}$. Thus, an adversary that distinguishes between these two hybrids can be used to break the security of the j^{th} MIFE scheme.

Now that the bit b has been switched for query j, we roll back our changes. Arguments of indistinguishability are analogous to the above and are skipped.

Hybrid $\mathbf{5_{j,6}}$: Change $\mathsf{GenKeys}''$ to invoke $\mathsf{MIFE.Setup}$ and $\mathsf{MIFE.KeyGen}$ as before.

Hybrid $\mathbf{5_{j,7}}$: Switch randomness in the hardwired CT back to PRF randomness.

Hybrid $\mathbf{5_{j,8}}$: Switch punctured PRF key back to normal PRF key.

Hybrid $\mathbf{5_{j,9}}$: Increment $\mathsf{Trap.index}$ by 1. At this point, for key j, we have $\mathsf{ctr_j} < \mathsf{Trap_{index}}$, hence by the design of the ReEnc algorithm, we have that the bit $b = 1$ is used for MIFE encryption. This is indistinguishable from the previous hybrid by security of FE because decryption values are exactly the same in both the hybrids.

Hybrid $\mathbf{5_{j+1,1}}$: This Hybrid is analogous to Hybrid $\mathbf{5_{j,1}}$. Indistinguishability follows by security of FE as discussed above. Finally, in Hybrid $\mathbf{5_{Q_k,9}}$, all the keys are outputting MIFE CTs corresponding to $b = 1$.

Hybrid 6: In this hybrid, use message corresponding to $b = 1$ and $\mathsf{mode} = R$. Again, indistinguishability follows by security of FE since the outputs are the same.

Hybrid 7: Undo the changes made in Hybrid 4, namely the algorithm $\mathsf{GenKeys}''$ invoked for query index j for all $j \in [Q_k]$ is modified to invoke ReEnc with parameter $\mathsf{ctr} = \bot$. Indistinguishability follows analogously to the transition between Hybrid 3 and Hybrid 4.

Hybrid 8: Undo the changes made in Hybrid 3. Specifically, we generate y (the target output passed to $\widetilde{\mathsf{Sim2}}$) and s (the masking value component of the partial decryption key) the same as in Hybrid 2 for each query $((i_1, \ldots, i_\ell), f)$. Indistinguishability follows analogously to the transition between Hybrid 2 and Hybrid 3.

Hybrid 9: Undo the changes made in Hybrid 2. More precisely, we replace the uniformly random strings used in the function GenKeys for the honest users i with the outputs of the PRF. Indistinguishability follows analogously to the transition between Hybrid 1 and Hybrid 2.

Hybrid 10: Undo the changes made in Hybrid 1, that is, we generate the first-round protocol messages $\rho_i^{(1)}$ (in the public parameters) and second-round protocol messages $\rho_i^{(2)}$ (in the partial decryption keys) for MPC as in the real system for each uncorrupted user $i \notin I$. Indistinguishability follows analogously to the transition between Hybrid 0 and Hybrid 1.

Hybrid 10 is the real world with bit $b = 1$. ◀

E Proof of Security for Ad Hoc MIFE for Inner Products

In this section, we provide the proof of security for our ad hoc MIFE for inner products.

▶ **Theorem 10.** *If the* MIFE *constructed by [2] is a* xxx*-IND-secure MIFE scheme and* MPC *is an* xxx*-SIM-secure 2-round MPC protocol, then our construction is* sel*-IND-secure.*

Proof. The proof follows easily from the proof of theorem 5. For simplicity, we describe the proof for the case of a single key query. The case of multiple queries is handled exactly as in the proof of theorem 5. In more detail, we define:

Hybrid 0: This is the real game in which on every encryption query $(i, \mathbf{x}_0, \mathbf{x}_1)$, $\mathbf{x}_0$ is encrypted.

Hybrid 1: Exactly as in the proof of theorem 5, the MPC transcript in this hybrid is simulated. Indistinguishability follows as in the proof of theorem 5.

Hybrid 2: In this hybrid, we switch the bit in the MIFE ciphertexts to 1. Indistinguishability follows via a reduction, in which the MIFE function key and ciphertexts are obtained from the MIFE challenger. The MIFE function key is input to the MPC simulator and the MPC transcript and MIFE ciphertexts are returned to the adversary.

To support multiple keys, we proceed as in the proof of theorem 5 and change the bit used in the MIFE encryption from 0 to 1 key by key. ◀

Unexpected Power of Random Strings

Abstract

There has been a line of work trying to characterize BPP (the class of languages that are solvable by efficient *randomized* algorithms) by efficient nonadaptive reductions to the set of Kolmogorov-*random* strings: Buhrman, Fortnow, Koucký, and Loff (CCC 2010 [10]) showed that every language in BPP is reducible to the set of random strings via a polynomial-time nonadaptive reduction (irrespective of the choice of a universal Turing machine used to define Kolmogorov-random strings). It was conjectured by Allender (CiE 2012 [1]) and others that their lower bound is tight when a reduction works for every universal Turing machine; i.e., "the only way to make use of *random* strings by a nonadaptive polynomial-time algorithm is to *derandomize* BPP."

In this paper, we *refute* this conjecture under the plausible assumption that the exponential-time hierarchy does not collapse, by showing that the exponential-time hierarchy EXPH can be solved in exponential time by nonadaptively asking the oracle whether a string is Kolmogorov-random or not. In addition, we provide an exact characterization of $\mathsf{S}_2^{\mathrm{exp}}$ in terms of exponential-time-computable nonadaptive reductions to arbitrary dense subsets of random strings.

1 Introduction

Randomness arises everywhere in the theory of computation, and there are at least three different notions of randomness: (1) BPP, one of the most important complexity classes, is the class of languages solvable by a two-sided-error randomized polynomial-time algorithm with high probability. (2) Pseudorandom generators enable us to derandomize BPP. Its one-sided-error version is called a *hitting set generator*. (3) The notion of *Kolmogorov complexity* enables us to quantify the amount of randomness in a finite string from the perspective of compressibility. In this study, we explore the relationship existing among these different notions of "randomness" – efficient randomized algorithms, pseudorandomness, and Kolmogorov-randomness. We present the interplay among these notions of randomness, while reviewing the literature in the subsequent section.

1.1 Pseudorandomness and Kolmogorov-Randomness

The Kolmogorov complexity of a string x can informally expressed as the length of the shortest program that prints x. More formally, the Kolmogorov complexity of $x \in \{0,1\}^*$ with respect to a Turing machine U is defined as

$$\mathrm{K}_U(x) := \min\{\, |d| \mid U \text{ outputs } x \text{ on input } d \,\}.$$

We choose a "universal" Turing machine U so that the Kolmogorov complexity is smallest up to an additive constant. A Turing machine U is said to be *universal* if, for every Turing machine M, there exists a constant c such that $\mathrm{K}_U(x) \leq \mathrm{K}_M(x)+c$ for every string $x \in \{0,1\}^*$. Note that there exists a universal Turing machine because one can take a Turing machine U that, given an input (M,x), simulates a Turing machine M on input x.

Kolmogorov complexity enables us to define the notion of Kolmogorov-randomness. A string x is said to be *(Kolmogorov-)random* if there exists no shorter program that prints x. More generally, given a threshold $s\colon \mathbb{N} \to \mathbb{N}$, we say that $x \in \{0,1\}^\ell$ is s-random if $\mathrm{K}_U(x) \geq s(\ell)$. Throughout this paper, we fix any reasonable threshold s (e.g., $s(\ell) := \ell/2$) and denote by R_{K_U} the set of s-random strings, i.e., $R_{\mathrm{K}_U} := \{\, x \mid \mathrm{K}_U(x) \geq s(|x|) \,\}$.

An important property of the set R_{K_U} of random strings is that R_{K_U} is an extremely powerful distinguisher for any computable hitting set generator. More specifically, there is a simple but powerful connection between pseudorandomness and Kolmogorov-randomness: Consider any "pseudorandom" string x that is generated by a computable process from a short seed. By definition, the string x is not Kolmogorov-random; hence R_{K_U} distinguishes any pseudorandom distribution from the uniform distribution.

A function $G\colon \{0,1\}^{s(\ell)} \to \{0,1\}^\ell$ $(\, s(\ell) < \ell \,)$ is called a *hitting set generator* secure against a class $\mathcal{C}$ if there exists no $\mathcal{C}$-algorithm R that avoids G; here we say that R *avoids* G if R rejects every string in the range of G, and R accepts at least a half of inputs of length ℓ. The notion of hitting set generator naturally arises when one tries to derandomize one-sided-error randomized algorithms: For instance, if there is an efficient hitting set generator of seed length $s(\ell) = O(\log \ell)$ and secure against linear-size circuits, then by exhaustively trying all the seeds of G, one can completely derandomize one-sided-error randomized algorithms, i.e., $\mathsf{RP} = \mathsf{P}$.

What can be efficiently solved by asking the oracle R_{K_U} whether a string is random or not? As mentioned earlier, it is easy to observe that R_{K_U} avoids any computable family of functions $G = \{G_\ell\colon \{0,1\}^{s(\ell)-O(\log \ell)} \to \{0,1\}^\ell\}_{\ell \in \mathbb{N}}$.[1] More generally, any "dense" subset R of random strings R_{K_U} avoids any computable hitting set generator. (Here we say that $R \subseteq \{0,1\}^*$ is *dense* if R contains at least a half of inputs for each input length.) By exploiting this property, a line of work exhibited the power of R_{K_U} as an oracle. Allender, Buhrman, Koucký, van Melkebeek, and Ronneburger [5] proved that $\mathsf{PSPACE} \subseteq \mathsf{P}^{R_{\mathrm{K}_U}}$. Allender, Buhrman, Koucký [4] showed that $\mathsf{NEXP} \subseteq \mathsf{NP}^{R_{\mathrm{K}_U}}$. In the case of nonadaptive reductions, Buhrman, Fortnow, Koucký, and Loff [10] showed that $\mathsf{BPP} \subseteq \mathsf{P}_{\parallel}^{R_{\mathrm{K}_U}}$, where $\mathsf{P}_{\parallel}^{R_{\mathrm{K}_U}}$ denotes the class of languages solvable in polynomial time with nonadaptive oracle access to R_{K_U}.[2] Here, a reduction is said to be *nonadaptive* (also known as a truth-table or parallel-query reduction) if the queries of the reduction do not depend on previous answers from the oracle.

---

[1] Specifically, for every $\ell \in \mathbb{N}$ and seed $z \in \{0,1\}^{s(\ell)-O(\log \ell)}$, the Kolmogorov complexity of $G_\ell(z)$ is less than $s(\ell)$; thus $G_\ell(z) \notin R_{\mathrm{K}_U}$. On the other hand, a simple counting argument shows that $|R_{\mathrm{K}_U} \cap \{0,1\}^\ell| \geq 2^{\ell-1}$ for every ℓ.

[2] The subscript $\parallel$ stands for parallel queries.

1.2 BPP and Kolmogorov-Randomness

Kolmogorov-randomness and BPP originated from different disciplines. The notion of Kolmogorov-randomness usually sits within the realm of *computability theory* as R_{K_U} is not computable, whereas *complexity theory* deals with efficient computations, such as BPP. In particular, it is obvious that there is no computable upper bound on the class $\mathsf{P}_{\|}^{R_{\mathrm{K}_U}}$, since R_{K_U} itself is not computable.

Nevertheless, a surprising interdisciplinary connection between complexity classes and Kolmogorov-random strings has been uncovered in the line of work (e.g., [4, 7, 13]). When a reduction works no matter which universal Turing machine U is used in the definition of R_{K_U}, a computable upper bound can be obtained. Cai, Downey, Epstein, Lempp, and Miller [13] showed that a language reducible to R_{K_U} for every prefix-free universal Turing machine U is computable; Allender, Friedman, and Gasarch [7] showed that any computable language L that reduces to R_{K_U} for every prefix-free universal Turing machine U via a polynomial-time nonadaptive reduction is in PSPACE. Therefore:

▶ **Theorem 1** ([10, 7, 13]).

$$\mathsf{BPP} \subseteq \bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}} \subseteq \mathsf{PSPACE},$$

where the intersection is taken over all prefix-free universal Turing machines U.

For some technical reasons, the upper bounds of [7, 13] are known to hold only for "prefix-free" universal Turing machines. A similar upper bound can be obtained for plain universal Turing machines by imposing a super-constant minimum query length restriction on reductions (cf. Hirahara and Kawamura [16]). Thus, we herein focus on (plain) universal Turing machines for the sake of simplicity.

At this point, a natural question arises: What is the exact computational power of R_{K_U} under polynomial-time nonadaptive reductions? Intuitively, any polynomial-time nonadaptive reduction cannot make any use of the set of Kolmogorov-random strings of length larger than $O(\log n)$ because the Kolmogorov complexity of any query that the reduction can make on input 1^n is at most $O(\log n)$. It was argued in [3] that, intuitively, short queries to Kolmogorov-random strings would only be used as a source of pseudorandomness. Allender [1] thus conjectured that the lower bound of Theorem 1 is exactly tight, and then a fair amount of effort has been made to verify the conjecture.

▶ **Conjecture 2** ([10, 1, 6, 3, 16]). $\mathsf{BPP} = \bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}}$, *where the intersection is taken over all universal Turing machines.*

Beyond its curiosity, such a characterization of BPP might make it possible to study BPP by using the techniques from computability theory, and could be a completely new approach for resolving the $\mathsf{P} = \mathsf{BPP}$ conjecture (as speculated in [1, 6]). Moreover, Conjecture 2 is interesting from the viewpoint of the study of the Minimum Circuit Size Problem (MCSP [20]). In some technical sense, Kolmogorov complexity can be seen as the minimum size of a circuit with oracle access to the halting problem (cf. [5]); thus R_{K_U} can be regarded as a computability-theoretic analogue of MCSP. In the light of this, Conjecture 2 states non-NP-hardness of R_{K_U} under nonadaptive polynomial-time reductions (unless $\mathsf{NP} \subseteq \mathsf{BPP}$), and thus would make it possible to obtain some new insights about NP-hardness of MCSP, which has been the focus of many recent studies on MCSP (e.g. [22, 17, 18, 9, 8]).

The "evidence" in favor of Conjecture 2 seemed to be pilling up, by considering various restrictions on the reductions. For example, Allender, Buhrman, Koucký [4] showed that conjunctive nonadaptive reductions from computable languages to R_{K_U} can be simulated

in P; Hirahara and Kawamura [16] showed that some restricted variant of $\bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}}$ lies between BPP and $\Sigma_2^{\mathrm{p}} \cap \Pi_2^{\mathrm{p}} \cap \mathsf{P/poly}$. We refer interested readers to the survey of Allender [2] for detailed background on MCSP and R_{K_U}.[3]

1.3 Our Results: Unexpected Power of Random Strings

In this work, we disprove Conjecture 2 under the plausible assumption that the exponential-time hierarchy does not collapse to BPEXP, by presenting unexpected power of R_{K_U}. Not only do we disprove Conjecture 2 itself, but also argue that the intuition of [3] is not correct.

Our main new insight is to consider a tally language in $\bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}}$. Recall that the intuition behind Conjecture 2 is that

1. On input 1^n, any long query q to R_{K_U} is answered as "No," since a nonadaptive polynomial-time machine cannot make any query whose Kolmogorov complexity is larger than $O(\log n)$, and that
2. Any query of length $O(\log n)$ *should be* useful only as a source of "pseudorandomness" [3]. We interpret this as follows: Short queries to R_{K_U} should be replaceable with queries to any oracle R that avoids any computable hitting set generator (i.e., R is a dense subset of random strings).

In order to closely examine these intuitions, let us focus on tally languages $L \subseteq \{1^n\}$. By a standard padding argument, this is essentially equivalent to considering an exponential-time analogue of Conjecture 2. More specifically, if Conjecture 2 is true, then a padding argument shows that

$$\mathsf{BPEXP} = \bigcap_U \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$$

is also true.[4] In order to examine the latter intuition, we also focus on an arbitrary oracle R that avoids U. Specifically, Conjecture 2 implies that the subclass $\bigcap_R \mathsf{EXP}_{\|}^{R}$ of $\bigcap_U \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$ is also contained in BPEXP, i.e.,

$$\bigcap_R \mathsf{EXP}_{\|}^{R} \subseteq \mathsf{BPEXP},$$

where the intersection is taken over all dense subsets R of random strings; thus, we first study the subclass $\bigcap_R \mathsf{EXP}_{\|}^{R}$.

We completely settle what can be solved by a nonadaptive exponential-time reduction to dense subsets R of random strings.

▶ **Theorem 3** (Characterizing $\mathsf{S}_2^{\mathrm{exp}}$ Using Efficient Reductions to Dense Subsets of Random Strings)**.** *For any universal Turing machine U, it holds that*

$$\mathsf{S}_2^{\mathrm{exp}} = \bigcap_R \mathsf{EXP}_{\|}^{R},$$

where the intersection is taken over all the dense subsets R of R_{K_U}. (The condition of R can be equivalently stated as follows: R avoids a universal Turing machine U regarded as a family of functions $U = \{U_\ell \colon \{0,1\}^{s(\ell)} \to \{0,1\}^{\ell}\}_{\ell \in \mathbb{N}}$.)

[3] Some unpublished results mentioned there are included in this paper.

[4] In fact, this padding argument together with [4] already shows that Conjecture 2 is false unless NEXP $\subseteq$ BPEXP, which was completely overlooked before this work. Our results significantly weaken the hypothesis.

Here $\mathsf{S}_2^{\mathrm{exp}}$ represents an exponential-time analogue of $\mathsf{S}_2^{\mathrm{p}}$ (the second level of the symmetric hierarchy [23, 14]), and is the class of languages which admit a "competing-two-prover" system: an exponential-time verifier must compute the correct answer when one of the provers presents a correct certificate.

Theorem 3 improves the result of [10] (conjectured to be tight) in two ways: First, it is known that $\mathsf{BPEXP} \subseteq \mathsf{S}_2^{\mathrm{exp}}$, and the inclusion is likely to be proper (e.g., note that $\mathsf{NEXP} \subseteq \mathsf{EXP}^{\mathsf{NP}} \subseteq \mathsf{S}_2^{\mathrm{exp}}$ [23]); thus, Theorem 3 refutes Conjecture 2 unless $\mathsf{S}_2^{\mathrm{exp}} \subseteq \mathsf{BPEXP}$. Second, unlike the proof of [10], our proof does not exploit any specific property of R_{K_U}; we only rely on the pseudorandomness property of R_{K_U} (i.e., the property that R_{K_U} is a distinguisher for any computable hitting set generator).

It is also worthy of note that our $\mathsf{S}_2^{\mathrm{exp}}$ upper bound of Theorem 3 significantly improves the previous $\mathsf{EXPSPACE}$ upper bound of Allender, Friedman, and Gasarch [7]: They proved $\bigcap_R \mathsf{EXP}_{\|}^R \subseteq \mathsf{EXPSPACE}$ as a corollary of their PSPACE upper bound of Theorem 1.

Let us take a look at the original conjecture again. In Conjecture 2, we are allowed to exploit a property of R_{K_U}, instead of just a property that an oracle avoids a computable hitting set generator. In this case, it is possible to reduce the entire exponential-time hierarchy to R_{K_U} via a nonadaptive exponential-time reduction, or even more efficiently, via a PH-Turing reduction.

▶ **Theorem 4.** *For every universal Turing machine U,*

$$\mathsf{EXPH} \subseteq \mathsf{PH}^{R_{\mathrm{K}_U}} \subseteq \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}.$$

Theorem 4 shows that the class $\bigcap_U \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$ is much closer to the $\mathsf{EXPSPACE}$ upper bound of [7] than previously conjectured. To be specific, it implies that Conjecture 2 is false unless $\mathsf{EXPH} \subseteq \mathsf{BPEXP}$.

1.4 Proof Ideas

We briefly mention our proof techniques for proving the lower bounds of Theorem 3 and Theorem 4. It is known that the halting problem is reducible to dense subsets R of random strings via a *nonuniform* polynomial-time reduction [5]. Therefore, by exhaustively searching polynomial-size R-oracle circuits (in exponential time), we can find a "succinct witness" for $\mathsf{S}_2^{\mathrm{exp}}$, whose correctness can be verified in exponential time. In order to extend this argument to EXPH, recall that EXPH can be regarded as a constant-round two-player game whose winner can be computed in exponential time. A winning strategy of round $k+1$ must depend on previous strategies (R_{K_U}-oracle circuits) of rounds $1, \cdots, k$. Using the fact that an R_{K_U}-oracle circuit can be evaluated with oracle access to the halting problem, it can be argued that there exists a polynomial-size R-oracle circuit which encodes a winning strategy for round $k+1$.

In order to prove the $\mathsf{S}_2^{\mathrm{exp}}$ upper bound of Theorem 3, we simulate an exponential-time reduction M by an $\mathsf{S}_2^{\mathrm{exp}}$ algorithm as follows: The ith competing prover sends a set $\bar{R}_i$ for each $i \in \{1,2\}$; the honest prover sends the set $\{0,1\}^* \setminus R_{\mathrm{K}_U}$ of nonrandom strings. While we cannot know which of $\bar{R}_1$ or $\bar{R}_2$ is correct, $\{0,1\}^* \setminus (\bar{R}_1 \cup \bar{R}_2)$ is guaranteed to be a dense subset of R_{K_U}, to which the reduction M works correctly.

The rest of this paper is organized as follows. After reviewing some background in Section 2, Theorem 3 is proved in Section 3. Theorem 4 is proved in Section 4. In Appendix A, the $\mathsf{EXP}_{\|}$ reduction of Theorem 3 is improved.

2 Preliminaries

We identify a language $L \subseteq \{0,1\}^*$ with its characteristic function $L\colon \{0,1\}^* \to \{0,1\}$. Let $[n] := \{1,\dots,n\}$ for $n \in \mathbb{N}$. We say that $R \subseteq \{0,1\}^*$ is *dense* if $|R \cap \{0,1\}^n| \geq 2^{n-1}$ for every $n \in \mathbb{N}$. For a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$, we denote by $\mathtt{tt}(f)$ the truth table of f, i.e., the concatenation of $f(x)$ for all $x \in \{0,1\}^n$ in the lexicographical order. We often identify a Boolean circuit C with the function computed by C.

2.1 On the Threshold of Kolmogorov-Random Strings

Recall that a string $x \in \{0,1\}^*$ is said to be $s(\text{-})$-*random* if $\mathrm{K}_U(x) \geq s(|x|)$. Throughout this paper, we fix any reasonable threshold $s(\text{-})$ of randomness so that there exists a universal constant $\epsilon > 0$ satisfying $n^\epsilon \leq s(n) \leq n-2$ for any $n \in \mathbb{N}$, and denote by R_{K_U} the set of $s(\text{-})$-random strings, i.e., $R_{\mathrm{K}_U} := \{\, x \in \{0,1\}^* \mid \mathrm{K}_U(x) \geq s(|x|) \,\}$. The upper bound of the threshold is for assuming that the set of random strings is sufficiently dense:

▶ **Fact 5.** *$|\{0,1\}^n \setminus R_{\mathrm{K}_U}| \leq 2^{n-2}$ for any $n \in \mathbb{N}$.*

Proof. The number of nonrandom strings is bounded by the number of programs of length less than $s(n)$, which is at most $\sum_{i=0}^{s(n)-1} 2^i \leq 2^{s(n)} \leq 2^{n-2}$. ◀

2.2 Symmetric Alternation

$\mathsf{S}_2^{\mathrm{p}}$ denotes the class of languages that admit a competing-two-prover system. More formally:[5]

▶ **Definition 6** ([14, 23])**.** *$\mathsf{S}_2^{\mathrm{p}}$ is the class of languages L such that there exist a polynomial $p(n) = n^{O(1)}$ and a polynomial-time algorithm V such that, for every input $x \in \{0,1\}^*$,*

1. *$\exists y \in \{0,1\}^{p(|x|)}, \forall z \in \{0,1\}^{p(|x|)},\ V(x,y,z) = L(x)$, and*
2. *$\exists z \in \{0,1\}^{p(|x|)}, \forall y \in \{0,1\}^{p(|x|)},\ V(x,y,z) = L(x)$.*

$\mathsf{S}_2^{\mathrm{exp}}$ is an exponential-time analogue of $\mathsf{S}_2^{\mathrm{p}}$: the definition of $\mathsf{S}_2^{\mathrm{exp}}$ is obtained by allowing $p(n)$ to be exponential in the definition above (i.e., $p(n) = 2^{n^{O(1)}}$). For an oracle A, the relativized version of $\mathsf{S}_2^{\mathrm{p}}$ is denoted by S_2^A; that is, S_2^A is the class of languages that admit a competing-two-prover system with a polynomial-time A-oracle verifier.

2.3 Exponential-Time Hierarchy

EXPH denotes the exponential-time analogue of the polynomial-time hierarchy (PH). That is, a language L is in EXPH if and only if there exist a constant k, an exponential bound $e(n) = 2^{n^{O(1)}}$ and a polynomial-time algorithm M such that, for every input $x \in \{0,1\}^*$,

$$x \in L \iff \exists y_1, \forall y_2, \exists y_3, \forall y_4, \cdots, \exists y_k,\ M(x, y_1, \cdots, y_k) = 1,$$

where $y_i \in \{0,1\}^{e(n)}$ for any $i \in [k]$.

[5] We follow the definition of Canetti [14], which is equivalent to the definition of [23] (cf. [11]).

3 Reductions to Dense Subsets of Random Strings

In this section, we give the characterization of $\mathsf{S}_2^{\mathrm{exp}}$ by exponential-time nonadaptive reductions to arbitrary dense subsets of random strings.

▶ **Reminder of Theorem 3.** Fix any universal Turing machine U.

- *Lower bound:* $\mathsf{S}_2^{\mathrm{exp}} \subseteq \mathsf{EXP}_{\|}^{R}$ for any dense subset R of R_{K_U}.
- *Upper bound:* $\{ L \subseteq \{0,1\}^* \mid L \in \mathsf{EXP}_{\|}^{R}$ for every dense $R \subseteq R_{\mathrm{K}_U} \} \subseteq \mathsf{S}_2^{\mathrm{exp}}$.

3.1 Lower Bound

In order to prove the lower bound on the complexity class $\bigcap_R \mathsf{EXP}_{\|}^{R}$, we use the fact that the halting problem HALT is reducible to any dense subset of random strings via a polynomial-size oracle circuit. The halting problem HALT is the problem of taking as input a description of a Turing machine M and deciding whether M halts.

▶ **Theorem 7** ([5]). $\mathsf{HALT} \in \mathsf{P}^{R}/\mathsf{poly}$ *for any dense subset R of random strings.*

Proof Sketch. It was shown in [5, Corollary 32] that HALT is reducible to R_{K_U} via a nonadaptive P/poly reduction. The proof only uses the fact that R_{K_U} is a distinguisher for some hitting set generator; thus HALT is also reducible to any dense subset R of random strings. ◀

Proof of the Lower Bound of Theorem 3. Let $L \in \mathsf{S}_2^{\mathrm{exp}}$ and V be a polynomial-time verifier associated with L that takes certificates of length $e(n) = 2^{n^{O(1)}}$ on inputs of length n. We claim that $L \in \mathsf{EXP}_{\|}^{R}$ for every dense subset R of random strings. Our $\mathsf{EXP}_{\|}^{R}$ algorithm M exhaustively searches "succinct witnesses", i.e., circuits that encode a correct certificate.

Specifically, for some polynomial $q(n)$ that is chosen later, let $\mathcal{C}_n$ be the set of all the $q(n)$-size $\log e(n)$-input oracle circuit. On input $x \in \{0,1\}^*$, the algorithm M exhaustively searches all the circuits $Y, Z \in \mathcal{C}_{|x|}$ and accepts if and only if there exists an oracle circuit $Y \in \mathcal{C}_{|x|}$ such that, for every oracle circuit $Z \in \mathcal{C}_{|x|}$, $V(x, \mathtt{tt}(Y^R), \mathtt{tt}(Z^R))$ accepts. Since the number $|\mathcal{C}_n|$ of polynomial-size oracle circuits is at most exponential in n, M halts in exponential time. Moreover, M is a nonadaptive reduction to R because the length of any query is bounded by some polynomial $q(n)$ (thus, in exponential time, one can ask every possible query beforehand).

We claim the correctness of M. By the definition of $\mathsf{S}_2^{\mathrm{exp}}$, for any input $x \in \{0,1\}^*$,

1. if $x \in L$, there exists a certificate $y \in \{0,1\}^{e(n)}$ such that $V(x,y,z) = 1$ for every $z \in \{0,1\}^{e(n)}$, and
2. if $x \notin L$, there exists a certificate $z \in \{0,1\}^{e(n)}$ such that $V(x,y,z) = 0$ for every $y \in \{0,1\}^{e(n)}$.

Consider the function η that maps (x,i) to the ith bit of the lexicographically first certificate $y \in \{0,1\}^{e(|x|)}$ such that $V(x,y,z) = 1$ for every $z \in \{0,1\}^{e(|x|)}$ (if exists), where $i \in \{0,1\}^{\log e(|x|)}$. Since η is computable, by Theorem 7, there exists a polynomial-size oracle circuit Y' such that $Y'^R(x,i) = \eta(x,i)$ for any (x,i). Therefore, for every input $x \in L$, by fixing x we obtain a polynomial-size circuit $Y_x := Y'(x,\text{-})$ such that $V(x, \mathtt{tt}(Y_x^R), z) = 1$ for every z. By choosing the bound $q(n)$ large enough, we obtain $Y_x \in \mathcal{C}$, and thus the algorithm M accepts. Similarly, one can prove that, for every input $x \notin L$, there exists a circuit $Z_x \in \mathcal{C}$ such that $V(x, y, \mathtt{tt}(Z_x^R)) = 0$ for every y. ◀

3.2 Upper Bound

Next, we prove the $\mathsf{S}_2^{\mathrm{exp}}$ upper bound on $\bigcap_R \mathsf{EXP}_{\|}^R$. Take an arbitrary language $L \in \bigcap_R \mathsf{EXP}_{\|}^R$. This means that, for every dense subset R of random strings, there exists an exponential-time oracle machine M_R such that M_R solves L given oracle access to R. That is, the reduction M_R is allowed to depend on the oracle R, which makes it hard to simulate the reduction. We first show, by using a diagonalization argument, that there exists a *single* machine that works for every oracle R.

▶ **Lemma 8.** *For any language L, the following are equivalent:*

1. *$L \in \bigcap_R \mathsf{EXP}_{\|}^R$, where the intersection is taken over all dense subsets R of R_{K_U}.*
2. *There exists an exponential-time nonadaptive oracle machine M such that, for every dense subset R of R_{K_U}, for every input $x \in \{0,1\}^*$, $M^R(x) = L(x)$.*

Proof. The direction from the second item to the first item is obvious. We prove below the contrapositive of the other direction.

Suppose that, for any exponential-time nonadaptive oracle machine M, there exists a dense subset R of R_{K_U} such that $M^R(x) \neq L(x)$ for some $x \in \{0,1\}^*$. We claim that there exists a *single* dense subset $R \subseteq R_{\mathrm{K}_U}$ such that $L \notin \mathsf{EXP}_{\|}^R$.

To this end, let $\{M_e\}_{e\in\mathbb{N}}$ be the enumeration of all exponential-time nonadaptive oracle machines. We will construct some dense subset $R_e \subseteq R_{\mathrm{K}_U}$ and input x_e (and $\ell_e \in \mathbb{N}$) by induction on $e \in \mathbb{N}$, so that M_e fails to compute L on input x_e, given oracle access to R_{e+1}; then we will define $R := \bigcup_{e\in\mathbb{N}} R_e$. Let us start with $R_0 := \varnothing$ and $\ell_0 := 0$.

At stage $e \in \mathbb{N}$, we claim that there exists some dense subset $R'_{e+1} \subseteq R_{\mathrm{K}_U}$ and some input $x_e \in \{0,1\}^*$ such that

- $M_e^{R'_{e+1}}(x_e) \neq L(x_e)$, and
- $q \in R_e$ if and only if $q \in R'_{e+1}$ for any string q of length $< \ell_e$.

Indeed, for any oracle Q, let $Q' := \{\, q \in Q \mid |q| \geq \ell_e \,\} \cup \{\, q \in R_e \mid |q| < \ell_e \,\}$. Consider an exponential-time nonadaptive oracle machine M'_e such that $M_e'^Q$ simulates $M_e^{Q'}$; that is, M'_e is hardwired with the set $\{\, q \in R_e \mid |q| < \ell_e \,\}$, and simulates M_e and answer any query q of length $< \ell_e$ by using the hardwired information. By our assumption, there exists some dense subset $\hat{R}_{e+1} \subseteq R_{\mathrm{K}_U}$ such that $M_e'^{\hat{R}_{e+1}}(x_e) \neq L(x_e)$ for some $x_e \in \{0,1\}^*$; by the definition of M'_e, we obtain $M_e^{R'_{e+1}}(x_e) \neq L(x_e)$ for $R'_{e+1} := \{\, q \in \hat{R}_{e+1} \mid |q| \geq \ell_e \,\} \cup \{\, q \in R_e \mid |q| < \ell_e \,\}$, which is again a dense subset of R_{K_U}. This completes the proof of the claim above. Now define $\ell_{e+1} \in \mathbb{N}$ as a large enough integer so that $\ell_{e+1} \geq \ell_e$ and the machine M_e on input x_e does not query any string of length $\geq \ell_{e+1}$, and define an oracle $R_{e+1} := \{\, q \in R'_{e+1} \mid |q| < \ell_{e+1} \,\}$, which completes the construction of stage $e \in \mathbb{N}$.

Define $R := \bigcup_{e\in\mathbb{N}} R_e$, which is a dense subset of R_{K_U} by the construction above. By the choice of $(\ell_e)_{e\in\mathbb{N}}$, we have

$$M_e^R(x_e) = M_e^{R_{e+1}}(x_e) \neq L(x_e),$$

for every exponential-time nonadaptive oracle machine M_e. Thus $L \notin \mathsf{EXP}_{\|}^R$. ◀

We are ready to present the $\mathsf{S}_2^{\mathrm{exp}}$ algorithm that simulates an exponential-time nonadaptive reduction to dense subsets of random strings, which completes the proof of Theorem 3.

Proof of the Upper Bound of Theorem 3. Take any language $L \in \bigcap_R \mathsf{EXP}_{\|}^R$. By Lemma 8, there exists an exponential-time nonadaptive oracle machine M such that, for every dense subset R of R_{K_U}, for every input $x \in \{0,1\}^*$, $M^R(x) = L(x)$. Our goal is to simulate M in $\mathsf{S}_2^{\mathrm{exp}}$.

First, we can assume, without loss of generality, that the length of any query that M makes on input x is bounded by some polynomial $|x|^{O(1)}$. Indeed, since M is a nonadaptive reduction, the set of all the queries $Q(x)$ that M makes on input x can be computed in exponential time; thus, for each query $q \in Q(x)$, its Kolmogorov complexity $\mathrm{K}_U(q)$ is at most $|x| + \log |Q(x)| + O(1) \leq |x|^{O(1)}$, since q is described by x and the index of q in $Q(x)$. Therefore, for any query q whose length is larger than $|x|^{O(1)}$, the answer from the oracle R is "No" because $q \notin R_{\mathrm{K}_U}$ $(\supseteq R)$.

Now we present an $\mathsf{S}_2^{\mathrm{exp}}$ algorithm that simulate M. The idea is that two competing provers send the set of nonrandom strings. Given two possible sets of nonrandom strings $\bar{R}_1, \bar{R}_2 \subseteq \{0,1\}^*$ (one of which is guaranteed to be correct), $R := \{0,1\}^* \setminus (\bar{R}_0 \cup \bar{R}_1)$ is a subset of R_{K_U}. Moreover, since the number of nonrandom strings is small, the set R is dense enough. Details follow.

Let $p(n)$ be a polynomial that upper-bounds the length of any query that M makes on inputs of length n. Our $\mathsf{S}_2^{\mathrm{exp}}$ algorithm operates as follows: Fix any input x of length n. The ith prover ($i \in \{1,2\}$) sends, for each $\ell \leq p(n)$, a subset $\bar{R}_{i,\ell} \subseteq \{0,1\}^\ell$ of size at most $2^{\ell-2}$; an honest prover sets $\bar{R}_{i,\ell} := \{0,1\}^\ell \setminus R_{\mathrm{K}_U}$. Define $\bar{R}_i := \bigcup_{\ell \leq p(n)} \bar{R}_{i,\ell}$. Note that such subsets can be encoded as a string of exponential length. The verifier sets $R := \{0,1\}^* \setminus (\bar{R}_1 \cup \bar{R}_2)$, and accept if and only if $M^R(x)$ accepts.

We claim the correctness of the $\mathsf{S}_2^{\mathrm{exp}}$ algorithm. Assume that the i^*th prover is honest. For each length $\ell \leq p(n)$ and $i \in \{1,2\}$, we assumed that $|\bar{R}_{i,\ell}| \leq 2^{\ell-2}$; thus $|\bar{R}_{1,\ell} \cup \bar{R}_{2,\ell}| \leq 2^{\ell-1}$, from which it follows that R is dense. Moreover, since the number of nonrandom strings of length ℓ is at most $2^{\ell-2}$ (Fact 5)[6], the i^*th prover can set $\bar{R}_{i^*,\ell} := \{0,1\}^\ell \setminus R_{\mathrm{K}_U}$. Define $R' := \{\, q \in R \mid |q| \leq p(n) \,\} \cup \{\, q \in R_{\mathrm{K}_U} \mid |q| > p(n) \,\}$. Then, from the argument above, R' is a dense subset of R_{K_U}, and hence $M^{R'}(x) = L(x)$. Since M does not make any query of length $> p(n)$, it follows that $M^R(x) = M^{R'}(x) = L(x)$. ◀

In Appendix A, we will mention that the reducibility notion of Theorem 3 can be significantly improved from $\mathsf{EXP}_{\|}$ to $\mathsf{S}_2^{\mathrm{p}}$ (at the cost of a slight loss in the lower bound).

4 The Unexpected Power of Kolmogorov-Random Strings

In this section, we show that every language in the exponential-time hierarchy is reducible to the set of Kolmogorov-random strings under PH reductions.

▶ **Reminder of Theorem 4.** For every universal Turing machine U,

$$\mathsf{EXPH} \subseteq \mathsf{PH}^{R_{\mathrm{K}_U}}.$$

For the purpose of refuting Allender's conjecture (Conjecture 2), it is enough to show the weaker statement that $\mathsf{EXPH} \subseteq \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$. Indeed, we observe that a simple padding argument essentially refutes Conjecture 2:

▶ **Corollary 9.** $\mathsf{BPP} \neq \bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}}$ *unless* $\mathsf{EXPH} \subseteq \mathsf{BPEXP}$*, where the intersection is taken over all universal Turing machines.*

Proof. Assume that $\bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}} \subseteq \mathsf{BPP}$. Then by the standard padding argument, we also obtain $\bigcap_U \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}} \subseteq \mathsf{BPEXP}$. (Specifically, take any language $L \in \bigcap_U \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$, and define a padded version $L' := \{\, x 10^{2^{p(|x|)}} \mid x \in L \,\}$ for some large enough polynomial p so that $L' \in \bigcap_U \mathsf{P}_{\|}^{R_{\mathrm{K}_U}}$. By the assumption, we have $L' \in \mathsf{BPP}$, which implies that $L \in \mathsf{BPEXP}$.) It follows from Theorem 4 that $\mathsf{EXPH} \subseteq \bigcap_U \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}} \subseteq \mathsf{BPEXP}$. ◀

[6] This is because of our choice of the threshold for Kolmogorov-randomness.

Now we proceed to a proof of Theorem 4. We first observe that any language computable with oracle access to HALT is in $\mathsf{P}^{\mathsf{HALT}}$.

▶ **Lemma 10.** *Let M be any oracle machine that, on inputs of length n, halts in finite steps and makes a query of length at most $n^{O(1)}$. Then the language decided by M^{HALT} is in $\mathsf{P}^{\mathsf{HALT}}$.*

Proof Sketch. The proof is essentially the same with [5, Theorem 27], and thus we just give a proof sketch. The idea is to decide M^{HALT} in the following two steps: First, by using a binary search and oracle access to HALT, one can decide the number of all the strings in HALT of length at most $n^{O(1)}$ in polynomial time. Then, given as advice the number of strings in HALT of length at most $n^{O(1)}$, the computation of M^{HALT} becomes now computable, and hence it reduces to HALT. ◀

While the ingredients above are enough to obtain EXP reductions, in order to obtain PH reductions, we make use of the efficient proof system of PH given by Kiwi, Lund, Spielman, Russell, and Sundaram [21]. For simplicity, we state their results in the case of the number of alternation is 2, but their results hold for every constant number of alternation. We also state their results in terms of Σ_2^{EXP} instead of Σ_2^{P}.

▶ **Theorem 11** (Kiwi, Lund, Spielman, Russell, and Sundaram [21])**.** *For every language L in Σ_2^{EXP}, there exists a randomized polynomial-time verifier such that,*

1. *for every input $x \in L$, there exists an oracle A such that for any oracle B, $V^{A,B}(x)$ accepts with probability 1, and*
2. *for every input $x \notin L$, for all oracles A, there exists an oracle B, $V^{A,B}(x)$ accepts with probability at most $\frac{1}{2}$.*

We are now ready to present a proof of Theorem 4.

Proof of Theorem 4. The main idea is that, given oracle access to the set of random strings, Theorem 7 tells us that there is a "succinct witness" for any exponential-time computation. However, unlike the proof of Theorem 3, here we need to claim that there exists a succinct witness that encodes some winning strategy of two player games, which may depend on a R_{K_U}-oracle circuit that encodes the opponent's strategy. For simplicity, we will only give a detailed proof for $\Sigma_2^{\mathsf{EXP}} \subseteq \mathsf{PH}^{R_{\mathrm{K}_U}}$, since it is straightforward to extend the proof.

First, we present a proof of $\Sigma_2^{\mathsf{EXP}} \subseteq \mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$. Let V be a polynomial-time verifier for $L \in \Sigma_2^{\mathsf{EXP}}$, and $e(n) = 2^{n^{O(1)}}$ be an exponential bound such that for every input x of length n, it holds that $x \in L$ if and only if there exists a certificate y of length $e(n)$ such that $V(x, y, z)$ accepts for all z of length $e(n)$; Note that V runs in time $2^{n^{O(1)}}$. We regard the computation as a game between the first player y and the second player z.

Our $\mathsf{EXP}_{\|}^{R_{\mathrm{K}_U}}$ algorithm operates as follows: Let $s_Y(n)$ and $s_Z(n)$ be some polynomials specified later. Given input x of length n, the algorithm accepts if and only if there exists an oracle circuit Y of size $s_Y(n)$ such that $V(x, \mathtt{tt}(Y^{R_{\mathrm{K}_U}}), \mathtt{tt}(Z^{R_{\mathrm{K}_U}}))$ accepts for all oracle circuits Z of size $s_Z(n)$, where $\mathtt{tt}(Y^{R_{\mathrm{K}_U}})$ denotes the truth table of the function computed by $Y^{R_{\mathrm{K}_U}}$; the algorithm checks this condition by an exhaustive search. Since there are at most exponentially many circuits of polynomial size, this algorithm runs in exponential time.

We claim the correctness of the algorithm. Fix any input $x \in L$ of length n. In this case, the correctness readily follows from the fact that there exists a succinct witness under the oracle R_{K_U}: Indeed, let y_x be the lexicographically first certificate for $x \in L$. Since each bit of y_x is decidable (in the sense that the language $\{\, (x, i) \mid \text{the } i\text{th bit of } y_x \text{ is } 1 \,\}$ is decidable), by Theorem 7, there exists an oracle circuit Y of size $s_Y(n) := \mathsf{poly}(n, \log |y_x|) = \mathsf{poly}(n)$ such that $\mathtt{tt}(Y^{R_{\mathrm{K}_U}}) = y_x$. Thus $V(x, y_x, \mathtt{tt}(Z^{R_{\mathrm{K}_U}}))$ accepts no matter how the adversarial circuit Z is chosen.

Now fix any input $x \notin L$ of length n. This case requires a more delicate argument. Here we need to claim that, for every circuit Y of size $s_Y(n)$, there exists a circuit Z that encodes a strategy that beats the strategy of $\mathtt{tt}(Y^{R_{\mathrm{K}^U}})$. The point is that, given any circuit Y, the lexicographically first winning strategy of the second player is computable with oracle access to HALT. Indeed, let $z_{x,Y}$ denote the lexicographically first string such that $V(x, \mathtt{tt}(Y^{R_{\mathrm{K}^U}}), z)$ rejects. Consider the language $L' := \{ (x, Y, i) \mid \text{the } i\text{th bit of } z_{x,Y} \text{ is } 1 \}$. Since R_{K^U} is reducible to HALT, the language L' is computable with oracle access to HALT. By Lemma 10, $L' \in \mathsf{P}^{\mathsf{HALT}}$; thus by Theorem 7, we obtain $L' \in \mathsf{P}^{R_{\mathrm{K}^U}}/\mathsf{poly}$. This means that for every circuit Y there exists a circuit Z_Y of size $s_Z(n) := \mathsf{poly}(n, |Y|, \log |z_{x,Y}|) = \mathsf{poly}(n, s_Y(n))$ such that $\mathtt{tt}(Z_Y^{R_{\mathrm{K}^U}}) = z_{x,Y}$. Thus, our algorithm rejects. This completes the proof of $\Sigma_2^{\mathsf{EXP}} \subseteq \mathsf{EXP}_{\|}^{R_{\mathrm{K}^U}}$.

In order to extend the proof above to $\Sigma_{2k}^{\mathsf{EXP}}$ for every constant k, we modify the $\mathsf{EXP}^{R_{\mathrm{K}^U}}$ algorithm so that it checks, given input x of length n, whether $\exists$ a circuit C_1 of size $s_1(n)$, $\forall$ a circuit C_2 of size $s_2(n)$, $\cdots$, $\forall$ a circuit C_{2k} of size $s_{2k}(n)$ such that a verifier $V(x, \mathtt{tt}(C_1^{R_{\mathrm{K}^U}}), \cdots, \mathtt{tt}(C_{2k}^{R_{\mathrm{K}^U}}))$ accepts, where $s_1(n), \cdots, s_{2k}(n)$ are some appropriately chosen polynomials.

We now explain how to reduce the complexity of the EXP reduction to PH. For simplicity, we again focus on a proof of $\Sigma_2^{\mathsf{EXP}} \subseteq \mathsf{PH}^{R_{\mathrm{K}^U}}$. Note that, in the proof above, the bottleneck of the computation is the evaluation of $V(x, \mathtt{tt}(Y^{R_{\mathrm{K}^U}}), \mathtt{tt}(Z^{R_{\mathrm{K}^U}}))$, where V runs in time $2^{|x|^{O(1)}}$. We replace V with the randomized polynomial-time verifier of Theorem 11; then we obtain the following $\Sigma_2^{R_{\mathrm{K}^U}}$ algorithm: Existentially guess a circuit Y of size at most $s_Y(n)$, and universally guess a circuit Z of size at most $s_Z(n)$ as well as a coin flip for V, Then accept if and only if $V^{Y,Z}(x)$ accepts on the guessed coin flip sequence. ◀

A Improving the Complexity of the Reductions

In this appendix, we mention that the reducibility notion of Theorem 3 can be significantly improved by using the efficient proof system of [15]:

▶ **Theorem 12.** *For any universal Turing machine U,*

$$\mathsf{EXP}^{\mathsf{NP}} \subseteq \bigcap_R \mathsf{S}_2^R \subseteq \mathsf{S}_2^{\exp},$$

where the intersection is taken over all the dense subsets R of R_{K_U}.

Hirahara [15] introduced the notion of a selector, and showed that $\mathsf{EXP}^{\mathsf{NP}}$ admits a selector.

▶ **Lemma 13** ([15]). *For any $\mathsf{EXP}^{\mathsf{NP}}$-complete language L, there exists a* selector *for L. That is, there exists a randomized polynomial-time oracle machine S such that, for any input $x \in \{0,1\}^*$ and oracles $A_0, A_1 \subseteq \{0,1\}^*$, if $L \in \{A_0, A_1\}$ then $\Pr_S\left[S^{A_0,A_1}(x) = L(x)\right] \geq \frac{2}{3}$.*

We show that any language L with a selector is low for $\mathsf{S}_2^{\mathrm{p}}$ if $L \in \mathsf{P/poly}$.

▶ **Theorem 14.** *Let L be a language with a selector S and R be any oracle. Then,*

$$L \in \mathsf{P}^R/\mathsf{poly} \quad \Longrightarrow \quad \mathsf{S}_2^L \subseteq \mathsf{S}_2^R.$$

This generalizes a lowness result of [12] from any downward self-reducible language L to any language L with a selector.

Proof. The idea is as follows: We request two competing provers of S_2^R to send R-oracle circuits C_0, C_1 that compute L. Then, for every query q of L, one can decide whether $q \stackrel{?}{\in} L$ by running S and using C_0^R and C_1^R as oracles. Details follow.

Take any $A \in \mathsf{S}_2^L$, and let V be an S_2^L-machine that witnesses $A \in \mathsf{S}_2^L$. Take some constants c, d such that V runs in time n^c and S runs in time n^d on inputs of length n.

Now we describe an $\mathsf{S}_2 \cdot \mathsf{BP} \cdot \mathsf{P}^R$ algorithm that computes A: Given an input $x \in \{0,1\}^*$ of length n, for each $i \in \{0,1\}$, the ith competing prover sends an S_2-type certificate y_i for M. Moreover, each prover sends a polynomial-size R-oracle circuit C_i; an honest prover sends a circuit C_i such that C_i^R computes L on every input of length at most n^{cd}. Then simulate V using the two certificates (i.e., run V on input (x, y_0, y_1)), where each query q that V makes is answered with $S^{C_0^R, C_1^R}(q)$. It is easy to see the correctness of this algorithm.

Therefore, we have $A \in \mathsf{S}_2 \cdot \mathsf{BP} \cdot \mathsf{P}^R$, and by [23], we can derandomize the randomized computation by using the power of S_2 and obtain $L \in \mathsf{S}_2 \cdot \mathsf{BP} \cdot \mathsf{P}^R = \mathsf{S}_2^R$. ◀

Proof of Theorem 12. Under any dense subset R of Kolmogorov-random strings, we have $\mathsf{EXP}^{\mathsf{NP}} \subseteq \mathsf{P}^R/\mathsf{poly}$ (by Theorem 7). Thus by taking any $\mathsf{EXP}^{\mathsf{NP}}$-complete problem L, we obtain $\mathsf{EXP}^{\mathsf{NP}} \subseteq \mathsf{S}_2^L \subseteq \mathsf{S}_2^R$ by combining Lemma 13 and Theorem 14. ◀

Finally, we mention that in the case of reductions to the set of random strings, the $\mathsf{S}_2^{\mathrm{p}}$ reductions of Theorem 12 can be derandomized to obtain P^{NP} reductions.

▶ **Theorem 15.** $\mathsf{EXP}^{\mathsf{NP}} \subseteq \mathsf{P}^{\mathsf{NP}^{R_{\mathrm{K}_U}}}$ *for any universal Turing machine U.*

Proof. By Theorem 12, we immediately obtain $\mathsf{EXP}^{\mathsf{NP}} \subseteq \mathsf{S}_2^{R_{\mathrm{K}_U}}$. By the relativized version of Cai's result [11], we have $\mathsf{P}^{\mathsf{NP}^{R_{\mathrm{K}_U}}} \subseteq \mathsf{S}_2^{R_{\mathrm{K}_U}} \subseteq \mathsf{ZPP}^{\mathsf{NP}^{R_{\mathrm{K}_U}}}$; thus it remains to derandomize the computation of ZPP under an $\mathsf{NP}^{R_{\mathrm{K}_U}}$ oracle. One can find the lexicographically first Kolmogorov-random string by a $\mathsf{P}^{\mathsf{NP}^{R_{\mathrm{K}_U}}}$ algorithm. By Lemma 10 and Theorem 7, the circuit complexity relative to an $\mathsf{NP}^{R_{\mathrm{K}_U}}$ oracle of any Kolmogorov-random string of length n is at least $n^{\Omega(1)}$. Thus by using a Kolmogorov-random string as a hard function of the Impagliazzo-Wigderson pseudorandom generator [19], one can derandomize the computation of ZPP under an $\mathsf{NP}^{R_{\mathrm{K}_U}}$ oracle. ◀

Consensus vs Broadcast, with and Without Noise

Abstract

Consensus and Broadcast are two fundamental problems in distributed computing, whose solutions have several applications. Intuitively, Consensus should be no harder than Broadcast, and this can be rigorously established in several models. Can Consensus be *easier* than Broadcast?

In models that allow noiseless communication, we prove a reduction of (a suitable variant of) Broadcast to binary Consensus, that preserves the communication model and all complexity parameters such as randomness, number of rounds, communication per round, etc., while there is a loss in the success probability of the protocol. Using this reduction, we get, among other applications, the first logarithmic lower bound on the number of rounds needed to achieve Consensus in the uniform Gossip model on the complete graph. The lower bound is tight and, in this model, Consensus and Broadcast are equivalent.

We then turn to distributed models with noisy communication channels that have been studied in the context of some bio-inspired systems. In such models, only one noisy bit is exchanged when a communication channel is established between two nodes, and so one cannot easily simulate a noiseless protocol by using error-correcting codes. An $\Omega(\varepsilon^{-2}n)$ lower bound is proved by Boczkowski et al. [PLOS Comp. Bio. 2018] on the convergence time of binary Broadcast in one such model (noisy uniform Pull), where ε is a parameter that measures the amount of noise).

We prove an $O(\varepsilon^{-2}\log n)$ upper bound on the convergence time of binary Consensus in such model, thus establishing an exponential complexity gap between Consensus versus Broadcast. We also prove our upper bound above is tight and this implies, for binary Consensus, a further strong complexity gap between noisy uniform Pull and noisy uniform Push. Finally, we show a $\Theta(\varepsilon^{-2}n\log n)$ bound for Broadcast in the noisy uniform Pull.

1 Introduction

In this paper we investigate the relation between Consensus and Broadcast, which are two of the most fundamental algorithmic problems in distributed computing [21, 23, 39, 41], and we study how the presence or absence of communication noise affects their complexity.

In the (Single-Source) *Broadcast* problem, one node in a network has an initial message `msg` and the goal is for all the nodes in the network to receive a copy of `msg`.

In the *Consensus* problem, each of the n nodes of a network starts with an input value (which we will also call an *opinion*), and the goal is for all the nodes to converge to a configuration in which they all have the same opinion (this is the *agreement* requirement) and this shared opinion is one held by at least one node at the beginning (this is the *validity* requirement). In the *Binary* Consensus problem, there are only two possible opinions, which we denote by 0 and 1.

In the (binary) *Majority Consensus* problem [5, 22, 40] we are given the promise that one of the two possible opinions is initially held by at least $n/2 + b(n)$ nodes, where $b(n)$ is a parameter of the problem, and the goal is for the nodes to converge to a configuration in which they all have the opinion that, at the beginning, was held by the majority of nodes. Note that Consensus and Majority Consensus are incomparable problems: a protocol may solve one problem without solving the other.[1] Both the notions of Consensus and Majority Consensus above can be further relaxed to those of δ-*Almost Consensus* and δ-*Almost Majority Consensus*, respectively. According to such weaker notions, we allow the system to converge to an almost-consensus regime where δn *outliers* may have a different opinion from the rest of the nodes.

Motivations for studying the Broadcast problem are self-evident. Consensus and Majority Consensus are simplified models for the way inconsistencies and disagreements are resolved in social networks, biological models and peer-to-peer systems [24, 27, 37].[2]

In distributed model that severely restrict the way in which nodes communicate (to model constraints that arise in peer-to-peer systems or in social or biological networks), upper and lower bounds for the Broadcast problem give insights on the effect of the communication constraints on the way in which information can spread in the network. The analysis of algorithms for Consensus often give insights on how to break symmetry in distributed networks, when looking at how the protocol handles an initial opinion vector in which exactly

[1] A Consensus protocol is allowed to converge to an agreement to an opinion that was initially in the minority (provided that it was held by at least one node), while a Majority Consensus protocol must converge to the initial majority whenever the minority opinion is held by fewer than $n/2 - b$ nodes. On the other hand, a Majority Consensus problem is allowed to converge to a configuration with no agreement if the initial opinion vector does not satisfy the promise, while a Consensus protocol must converge to an agreement regardless of the initial opinion vector.

[2] The Consensus problem is often studied in models in which nodes are subject to malicious faults, and, in that case, one has motivations from network security. In this paper we concentrate on models in which all nodes honestly follow the prescribed protocol and the only possibly faulty devices are the communication channels.

half the nodes have one opinion and half have the other. The analysis of algorithms for Majority Consensus usually hinge on studying the rate at which the number of nodes holding the minority opinion shrinks.

If the nodes are labeled by $\{1, \ldots, n\}$, and each node knows its label, then there is an easy reduction of binary Consensus to Broadcast: node 1 broadcasts its initial opinion to all other nodes, and then all nodes agree on that opinion as the consensus opinion. Even if the nodes do not have known identities, they can first run a *leader election* protocol, and then proceed as above with the leader broadcasting its initial opinion. Even in models where leader election is not trivial, the best known Consensus protocol has, in all the cases that we are aware of, at most the "complexity" (whether it's measured in memory per node, communication per round, number of rounds, etc.) of the best known broadcast protocol.

A first major question that we address in this paper is whether the converse hold, that is, are there ways of obtaining a Broadcast protocol from a Consensus problem or are there gaps, in certain models, between the complexity of the two problems?

We will show that, in the presence of noiseless communication channels, every Consensus protocol can be used to realize a weak form of Broadcast. Since, in many cases, known lower bounds for Broadcast apply also to such weak form, we get new lower bounds for Consensus. In a previously studied, and well motivated, distributed model with noisy communication, namely the noisy Gossip, however, we establish an exponential gap between Consensus and Broadcast.

As a second major question, we investigate the impact of the communication noise on the Consensus problem. More in detail, does this impact strongly depend on the particular noisy Gossip model we adopt? We will give a positive answer to this question by establishing a strong complexity separation between the two most popular versions of the Gossip model, namely, the Pull model and the Push one.

Roadmap of the paper and a remark

In order to formally state and discuss our results, in the next section, we introduce the distributed models and their associated complexity measures our results deal with. In Section 3, we describe our results and their consequences for noiseless communication models and compare them with the related previous work. Section 4 is devoted to our results for the noisy communication models and to their comparison with the related previous work. Finally, in Section 5 we provide a short summary of the obtained results and discuss some related open questions. We remark that, in this version, we only sketch the main ideas of the technical proofs: detailed proofs are given in the full version of the paper [17].

2 Communication and computational models

We study protocols defined on a communication network, described by an undirected graph $G = (V, E)$ where V is the set of nodes, each one running an instance of the distributed algorithm, and E is the set of pairs of nodes between which there is a communication link that allows them to exchange data. When not specified, G is assumed to be the complete graph.

In *synchronous parallel* models, there is a global clock and, at each time step, nodes are allowed to communicate using their links.

In the Local model, there is no restriction on how many neighbors a node can talk to at each step, and no restriction on the number of bits transmitted at each step. There is also no restriction on the amount of memory and computational ability of each node. The only complexity measures is the number of rounds of communication. For example, it is easy to

see that the complexity of Broadcast is the diameter of the graph G. The Congest model is like the Local model but the amount of data that each node can send at each time step is limited, usually to $O(\log n)$ bits.

In the (general) Gossip model [20, 30], at each time step, each node v chooses one of its neighbors c_v and *activates* the communication link (v, c_v), over which communication becomes possible during that time step, allowing v to send a message to c_v and, simultaneously, c_v to send a message to v. We will call v the *caller of* c_v. In the Push variant, each node v sends a message to its chosen neighbor c_v; in the Pull variant, each node sends a message to its callers (if any). Note that, although each node chooses only one neighbor, some nodes may be chosen by several others, and so they may receive several messages in the Push setting, or send a message to several recipients in the Pull setting. In our algorithmic results for the Gossip model, we will assume that each message exchanged in each time step is only one bit, while our negative results for the noiseless setting will apply to the case of messages of unbounded length. In the *uniform* Gossip (respectively Push or Pull) model, the choice of c_v is done uniformly at random among the neighbors of v. This means that uniform models make sense even in anonymous networks, in which nodes are not aware of their identities nor of the identities of their neighbors.[3]

In this work, we are mainly interested in models like Gossip that severely restrict communication [5, 2, 22, 24, 37, 40], both for efficiency consideration and because such models capture aspects of the way consensus is reached in biological population systems, and other domains of interest in network science [4, 6, 23, 12, 24, 25, 27]. Communication capabilities in such scenarios are typically constrained and non-deterministic: both features are well-captured by uniform models.

Asynchronous variants of the Gossip model (such as *Population Protocols* [5, 4]) have also been extensively studied [11, 28, 40]. In this variant, no global clock is available to nodes. Instead, nodes are idle until a single node is activated by a (possibly random) scheduler, either in discrete time or in continuous time. When a node wakes up, it activates one of its incident edges and wakes up the corresponding neighbor. Communication happens only between those two vertices, which subsequently go idle again until the next time they wake up.

Previous studies show that, in both Push and Pull variants of uniform Gossip, (binary) Consensus, Majority Consensus and Broadcast can be solved within logarithmic time (and work per node) in the complete graph, via elementary protocols[4], with high probability (for short *w.h.p.*[5]) [5, 9, 11, 22, 28, 31]. Moreover, efficient protocols have been proposed for Broadcast and Majority Consensus for some restricted families of graphs such as regular expanders and random graphs [1, 15, 14, 19, 29, 36].

However, while for Broadcast $\Omega(\log n)$ time and work are necessary in the complete graph [11, 28, 31], prior to this work, it was still unknown whether a more efficient protocol existed for Consensus and Majority Consensus.

3 Our contribution I: Noiseless communication

Our main result is a reduction of a weak form of Broadcast to Consensus which establishes, among other lower bounds, tight logarithmic lower bounds for Consensus and Majority Consensus both in the uniform Gossip (and hence uniform Pull and Push as well) model and in the general Push model.

[3] In the general Gossip model in which a node can choose which incident edge to activate, a node must, at least, know its degree and have a way to distinguish between its incident edges.
[4] In the case of Majority Consensus, the initial additive bias must have size $\Omega(\sqrt{n \log n})$.
[5] In this paper, we say that an event $\mathcal{E}_n$ holds *w.h.p.* if $\mathbf{P}(\mathcal{E}_n) \geqslant 1 - n^{-\alpha}$, for some $\alpha > 1$.

In order to formally state the reduction, we need to introduce a slightly-different variant of Broadcast where, essentially, it is (only) required that *some* information from the source is spread on the network.

▶ **Definition 1.** *A protocol $\mathcal{P}$ solves the* γ-Infection *problem w.r.t. a source node s if it* infects *at least γn nodes, where we define a node* infected *recursively as follows: initially only s is infected; a node v becomes infected whenever it receives* any *message from an infected node.*

Notice that a protocol $\mathcal{P}$ solving the γ-Infection problem w.r.t. a source node s can be easily turned into a protocol for broadcasting a message `msg` from s to at least γn nodes. Indeed, we give the message `msg` to the source node s, and we simulate $\mathcal{P}$. Every time an infected node sends a message, it appends `msg` to it. Clearly, the size of each message in $\mathcal{P}'$ is increased by the size of `msg`.

This notion is helpful in thinking about upper and lower bounds for Broadcast: any successful broadcast protocol from s needs to infect all nodes from source s, and any protocol that is able to infect all nodes from source s can be used to broadcast from s by appending `msg` to each message originating from an infected node. Thus any lower bound for Infection is also a lower bound for Broadcast, and any protocol for Infection can be converted, perhaps with a small overhead in communication, to a protocol for Broadcast. For example, in the Push model, the number of infected nodes can at most double at each step, because each infected node can send a message to only one other node, and this is the standard argument that proves an $\Omega(\log n)$ lower bound for Broadcast.

In the next theorem, we show that lower bounds for Infection *also give lower bounds for* Consensus. More precisely we prove that if we have a Consensus protocol that, for every initial opinion vector, succeeds in achieving almost consensus with probability $1 - o(1/n)$, then there is an initial opinion vector and a source such that the protocol infects many nodes from that source with probability at least $(1 - o(1))/n$.

▶ **Theorem 2.** *Let $\mathcal{P}$ be a protocol reaching δ-Almost Consensus with probability at least $1 - o(1/n)$. Then, a source node s and an initial opinion vector $\mathbf{x}$ exist such that $\mathcal{P}$, starting from $\mathbf{x}$, solves the $(1 - 2\delta)$-Infection problem w.r.t. s with probability at least $(1 - o(1))/n$.*

Notice that the above result implies that any protocol for Consensus actually solves the Infection problem (when initialized with a certain opinion vector) in a weak sense: the infection is w.r.t. a source that depends on the consensus protocol in a (possibly) uncontrolled manner; and (ii) the success probability of the infection is quite low. However, if we are in a model in which there is no source for which we can have probability, say, $\geqslant 1/(2n)$ of infecting all nodes with certain resources (such as time, memory, communication per node, etc.), then, in the same model, and with the same resources, the above theorem implies that every Consensus protocol has probability $\Omega(1/n)$ of failing. For example, by the above argument, we have an $\Omega(\log n)$ lower bound for Consensus in the Push model (because, in fewer than $\log_2 n$ rounds, the probability of infecting all nodes is zero).

In case of Consensus problem (i.e. $\delta = 0$), our proof for Theorem 2 makes use of a hybrid argument to show that there are two initial opinion vectors $\mathbf{x}$ and $\mathbf{y}$, which are identical except for the initial opinion of a node s, such that there is at least a $(1 - o(1))/n$ difference between the probability of converging to the all-zero configuration starting from $\mathbf{x}$ or from $\mathbf{y}$. Then, we prove that this difference must come entirely from runs of the protocol that fail to achieve consensus (which happens only with $o(1/n)$ probability) or from runs of the protocol in which s infects all other nodes. Thus the probability that s infects all nodes from the initial vector $\mathbf{x}$ has to be $\geqslant (1 - o(1))/n$. Then, to extend the above approach for the Almost Consensus problem (i.e. $\delta > 0$), some additional care and a suitable counting argument are required to manage the unknown set of outliers.

As for Majority Consensus, we have a similar reduction, but from a variant of the infection problem in which there is an initial set of b infected nodes.[6] Formally:

▶ **Theorem 3.** *Let $\mathcal{T}$ be any fixed resource defined on a distributed system $\mathcal{S}$ and suppose there is no Infection protocol that, starting from any subset of n^α nodes with $\alpha < 1$, can inform at least $(1-\delta)n$ nodes by using at most τ^{B} units of $\mathcal{T}$, w.h.p. Then, any protocol $\mathcal{P}$ on this model, reaching δ-*Almost Majority Consensus *w.h.p., must use more than τ^{B} units of $\mathcal{T}$.*

3.1 Some applications

Lower bounds for infection are known in several models in which there are no previous negative results for Consensus. We have not attempted to survey all possible applications of our reductions, but here we enumerate some of them (see the full version for the formal statements of such results):

- In the uniform Gossip model (also known as uniform Push-Pull model), and in the general Push model, tight analysis (see [30, 31]) show that any protocol $\mathcal{P}$ for the complete graph w.h.p. does not complete Broadcast within less than $\beta \log n$ rounds, where β is a sufficiently small constant. Combining this lower bound with our reduction result above, we get an $\Omega(\log n)$ lower bound for Consensus. This is the first known lower bound for Consensus showing a full equivalence between the complexity of Broadcast and Consensus in such models. Regarding Majority Consensus, we also obtain an $\Omega(\log n)$ lower bound for any initial bias $b = O(n^\alpha)$, with $\alpha < 1$.
- In a similar way, we are able to prove a lower bound of $\Omega(n \log n)$ number of steps (and hence $\Omega(\log n)$ parallel time) or $\Omega(\log n)$ number of messages per node for Consensus on an asynchronous variant of the Gossip model, the *Population Protocols* with uniform/probabilistic scheduler, as defined in [5].
- The last application we mention here concerns the synchronous *Radio Network* model [3, 7, 16, 42]. Several optimal bounds have been obtained on the Broadcast time [7, 18, 32, 33, 34] while only few results are known for Consensus time [16, 42]. In particular, we are not aware of better lower bounds other than the trivial $\Omega(D)$ (where D denotes the diameter of the network). Then, by combining a previous lower bound in [3] on Broadcast with our reduction result, we get a new lower bound for Consensus in this model.

We remark that our reduction allows us to prove that some of the above lower bounds hold even if the nodes have unbounded memory and can send/receive messages of unbounded size.

4 Our contribution II: Noisy communication

We now turn to the study of distributed systems in which the communication links between nodes are noisy. We will consider a basic model of high-noise communication: the binary symmetric channel [35] in which each exchanged bit is flipped independently at random with probability $1/2 - \varepsilon$, where $0 \leqslant \varepsilon < 1/2$, and we refer to ε as the *noise* parameter of the model. Then, in the sequel, the version of each model $\mathcal{M}$, in which the presence of communication noise above is introduced, will be shortly denoted as *noisy* $\mathcal{M}$.

[6] Recall that b is the value such that we are promised that the majority opinion is held, initially, by at least $n/2 + b$ nodes.

In models such as Local and Congest, the ability to send messages of logarithmic length (or longer) implies that, with a small overhead, one can encode the messages using error-correcting codes and simulate protocols that assume errorless communication.

In the uniform Gossip model with one-bit messages, however, error-correcting codes cannot be used and, indeed, whenever the number of rounds is sublinear in n, most of the pairs of nodes that ever communicate only exchange a single bit.

The study of fundamental distributed tasks, such as Broadcast and Majority Consensus, has been undertaken in the uniform Gossip model with one-bit messages and noisy links [10, 25] as a way of modeling the restricted and faulty communication that takes place in biological systems, and as a way to understand how information can travel in such systems, and how they can repair inconsistencies. Such investigation falls under the agenda of *natural algorithms*, that is, the investigation of biological phenomena from an algorithmic perspective [13, 38].

As for the uniform Push model with one-bit messages, we first notice that there is a simple local strategy that solves both (binary) Broadcast and Consensus in the noisy Push (this strategy holds even assuming that agents share only a *binary* synchronous clock). For instance, consider binary Consensus: let every node with initial opinion 0 start a broadcast process at even rounds, while the same task is started in odd rounds by nodes with initial opinion 1. When a node receives a bit in any even (odd) round, this bit is always interpreted as 0 (1). Then, at every round, each node updates its output with, for instance, the minimum value it has seen so far (any round).

In [25], the authors consider a restricted, natural class of *symmetric* algorithms where the action of the nodes cannot depend on the value of the exchanged bits. In this setting, they prove that (binary) Broadcast and (binary) Majority Consensus can be solved in time $O(\varepsilon^{-2} \log n)$, where ε is the noise parameter. They also prove a matching lower bound for this class of algorithms. This has been later generalized to non-binary opinions in [26].

In the noisy uniform Pull model however, [10] proves an $\Omega(\varepsilon^{-2}n)$ time lower bound[7]. This lower bound is proved even under assumptions that strengthen the negative result, such as unique node IDs, full synchronization, and shared randomness (see Section 2.4 of [10] for more details on this point).

Such a gap between noisy uniform Push and Pull comes from the fact that, in the Push model, a node is allowed to decline to send a message, and so one can arrange a protocol in which nodes do not start communicating until they have some confidence of the value of the broadcast value. In the Pull model, instead, a called node must send a message, and so the communication becomes polluted with noise from the messages of the non-informed nodes.

What about Consensus and Majority Consensus in the noisy Pull model? Our reduction in Theorem 2 suggests that there could be $\Omega(\varepsilon^{-2}n)$ lower bounds for Consensus and Majority Consensus, but recall that the reduction is to the infection problem, and infection is equivalent to Broadcast only when we have errorless channels.

4.1 Upper bounds in noisy uniform Pull

4.1.1 A protocol for Consensus and its analysis

We devise a simple and natural protocol for Consensus for the noisy uniform Pull model having convergence time $O(\varepsilon^{-2} \log n)$, w.h.p., thus exhibiting an exponential gap between Consensus and Broadcast in the noisy uniform Pull model.

[7] They actually proved a more general result including non-binary noisy channels.

▶ **Theorem 4.** *In the noisy uniform* PULL *model, with noisy parameter ε, a protocol exists that achieves Consensus within $O(\varepsilon^{-2}\log n)$ rounds and communication, w.h.p. The protocol requires $\Theta(\log\log n + \log\varepsilon^{-2})$ local memory.*
Moreover, if the protocol starts from any initial opinion vector with bias $b = \Omega(\sqrt{n\log n})$, then it guarantees Majority Consensus, w.h.p.

The protocol we refer to in the above theorem works in two consecutive phases. Each phase is a simple application of the well-known *k-Majority Dynamics* [8, 9]:

> k-MAJORITY. *At every round, each node samples k neighbours*[8] *independently and u.a.r. (with replacement). Then, the node updates its opinion according to the majority opinion in the sample.*

The protocol is thus the following:

> MAJORITY PROTOCOL. Let α be a sufficiently large positive constant[9]. Every node performs $\alpha\log n$ rounds of k-Majority with $k = \Theta(1/\varepsilon^2)$, followed by one round of the k-Majority with $k = \Theta(\varepsilon^{-2}\log n)$.

Our analysis shows that, w.h.p., at the end of the first phase there is an opinion that is held by at least $n/2+\Omega(n)$ nodes, and that if the initial opinions where unanimous then the initial opinion is the majority opinion after the first phase (notice that the latter fact guarantees the validity property, w.h.p.). Then, in the second phase, despite the communication errors, we show every node has a high probability of seeing the true phase-one majority as the empirical majority in the batch and so all nodes converge to the same valid opinion. To analyze the first phase, we break it out into two sub-phases (this breakdown is only in the analysis, not in the protocol): in a first sub-phase of length $O(\varepsilon^{-2}\log n)$, we prove the protocol "breaks symmetry" w.h.p. and, no matter the initial vector and the presence of communication noise, reaches a configuration in which one opinion is held by $n/2+\Omega(\sqrt{n\log n})$ nodes. In the second sub-phase, also of length $O(\varepsilon^{-2}\log n)$, a configuration of bias $\Omega(\sqrt{n\log n})$ w.h.p. becomes a configuration of bias $\Omega(n)$. The analysis of the first sub-phase is our main technical novelty while the analysis of the second sub-phase for achieving Majority Consensus is similar to that in [25, 26]. If the initial opinion vector is unanimous, then it is not necessary to break up the first phase into sub-phases, and one can directly see that a unanimous configuration maintains a bias $\Omega(n)$, w.h.p., for the duration of the first phase.

A consequence of our analysis is that, if the initial opinion vector has a bias $\Omega(\sqrt{n\log n})$, then the protocol converges to the majority, w.h.p. So, we get a Majority-Consensus protocol for this model under the above condition on the bias.

4.1.2 A protocol for Broadcast

We provide a simple two-phases Broadcast protocol that runs in the noisy uniform PULL model.

Protocol NOISYBROADCAST.

- In the first phase, each non-source node displays 0 (obviously, the source displays its input value), and performs a pull operation for $\Theta(\varepsilon^{-2}n\log n)$ rounds; it then chooses to support value 1 iff the fraction of received messages equal to 1 is at least $\frac{1}{2} - \varepsilon(1-\frac{1}{2n})$, zero otherwise.

[8] In the binary case when k is odd, the k-Majority is stochastically equivalent to the $k+1$-Majority where ties are broken u.a.r. (see Lemma 17 in [26]). For this reason, in this section we assume that k is odd.
[9] The value of α will be fixed later in the analysis.

- In the second phase, nodes run the Majority Consensus protocol of Theorem 4, starting with the value obtained at the end of the first phase.

We prove the following performance of the protocol, nearly matching the $\Omega(\varepsilon^{-2}n)$ lower bound mentioned before [10]:

▶ **Theorem 5.** *Protocol* NoisyBroadcast *solves the Broadcast problem in the noisy uniform* Pull *model in* $\mathcal{O}(\varepsilon^{-2}n\log n)$ *rounds, w.h.p.*

Our proof shows that at the end of the first phase, the fraction of nodes which have obtained a value equal to the source's input is greater than those that failed by at least $\sqrt{n\log n}$ nodes. The latter fact satisfies the hypothesis of Theorem 4 for solving Majority Consensus in $\mathcal{O}(\varepsilon^{-2}\log n)$, which constitutes the second phase.

4.2 Lower bounds in noisy Pull models

We prove that any Almost Consensus protocol with at most δn outliers and with error probability at most δ requires $\Omega\left(\varepsilon^{-2}\log\delta^{-1}\right)$ rounds. Formally:

▶ **Theorem 6.** *Let* δ *be any real such that* $0 < \delta < 1/8$ *and consider any protocol* $\mathcal{P}$ *for the noisy general* Pull *model with noise parameter* ε*. If* $\mathcal{P}$ *solves* δ*-Almost Consensus with probability at least* $1-\delta$*, then it requires at least* $t = \Omega(\varepsilon^{-2}\log\delta^{-1})$ *rounds*[10].

This shows that the complexity $O(\varepsilon^{-2}\log n)$ of our protocol described in Subsection 4.1.1 is tight for protocols that succeed w.h.p. We remark that our result holds for any version (general and uniform) of the noisy Pull model with noise parameter ε, unbounded local memory, even assuming unique node IDs. Recalling the $\Theta(\log n)$ bound that holds for (general) Consensus protocols in the noisy uniform Push (for any value of ε), our lower bound above thus implies a strong separation result between noisy uniform Pull and noisy uniform Push.

The proof of Theorem 6 is one of the main technical contributions of this work and below we provide a short discussion.

In [25], an $\Omega\left(\varepsilon^{-2}\log\delta^{-1}\right)$ round lower bound is proved for Majority Consensus in the uniform Push model, for a restricted class of protocols. Their argument, roughly speaking, is that each node needs to receive a bit of information from the rest of the graph (namely, the majority value in the rest of the graph), and this bit needs to be correctly received with probability $1-\delta$, while using a binary symmetric channel with error parameter ε. It is then a standard fact from information theory that the channel needs to be used $\Omega(\varepsilon^{-2}\log\delta^{-1})$ times. It is not clear how to adapt this argument to the Consensus problem. Indeed, it is not true that every node receives a bit of information with high confidence from the rest of the graph (consider the protocol in which one node broadcasts its opinion), and it is not clear if there is a distribution of initial opinions such that there is a node v whose final opinion has mutual information close to 1 to the global initial opinion vector given the initial opinion of v (the natural generalization of the argument of [25]). Instead, we prove that there are two initial opinion vectors $\mathbf{x}$ and $\mathbf{y}$, a node v, and a bit b, such that the initial opinion of v is the same in $\mathbf{x}$ and $\mathbf{y}$, but the probability that v outputs b is $\leqslant\delta$ when the initial opinion vector is $\mathbf{x}$ and $\geqslant\Omega(1)$ when the initial opinion vector is $\mathbf{y}$. Thus, the rest of the graph is sending v a bit of information (whether the initial opinion vector is $\mathbf{x}$ or $\mathbf{y}$) and the communication

[10] We notice the double role parameter δ has in this statement.

succeeds with probability $\geqslant 1-\delta$ when the bit has one value and with probability $\geqslant 1/3$ if the bit has the other value. Despite this asymmetry, if the communication takes place over a binary symmetric channel with error parameter ε, we use KL divergence to show that the channel has to be used $\Omega(\varepsilon^{-2}\log\delta^{-1})$ times.

4.2.1 An improved lower bound for Broadcast

The $\Omega(\varepsilon^{-2}n)$ lower bound of [10] for Broadcast in the uniform PULL model applies to protocols that have constant probability of correctly performing the broadcast operation. With the following theorem we show a way of modifying their proof (in particular, to derive an $\Omega(\varepsilon^{-2}n\log n)$ for uniform PULL protocols for Broadcast that have high probability of success, matching the $O(\varepsilon^{-2}n\log n)$ round complexity of Theorem 5.

▶ **Theorem 7.** *The Broadcast Problem cannot be solved in the noisy uniform* Pull *model w.h.p. in less than* $\Omega(\varepsilon^{-2}n\log n)$ *rounds.*

5 Conclusions

Table 1 shows the two main separation results that follow from a comparison between some previous bounds and the bounds we obtain in this paper: The complexity gap between Consensus and Broadcast in the presence or absence of noise and the different complexity behaviour of Consensus between noisy uniform Pull and noisy uniform Push. The figure also shows our new lower bounds for Consensus in the noiseless Gossip models.

A further consequence regards a separation between general Pull and Push models as far as Consensus is concerned in the noiseless world. Indeed, if we assume unique IDs, in the general Pull model, Consensus can be easily solved in constant time: every node can copy the opinion of a prescribed node by means of a single pull operation. On the other hand, in the general Push model, our Broadcast-Consensus reduction shows that $\Omega(\log n)$ rounds are actually necessary for solving Consensus.

We considered noisy communication models that assume the presence of a global clock: nodes work in parallel sharing the value of the current round. Our protocols definitely exploit this important property of the model. Then, an interesting open issue is to analyse fundamental tasks, such as Consensus and Broadcast, in asynchronous versions of the Push and Pull models where, as in our setting, communication is noisy and takes place via binary messages only. A further interesting future work we plan to consider is to introduce a (strong) bound on the local memory of the nodes.

Table 1 The updated state-of-art for Broadcast and Consensus in Gossip models with and w/o noise. The results of this paper are highlighted bold, while "folklore" results are marked with * (see also the preliminary discussion in Section 4).

	ε-noisy models		Noiseless models	
	Uniform Pull	**Uniform Push**	**Uniform Pull**	**Uniform Push**
Broadcast	$\Omega\left(n/\varepsilon^2\right)$ [10] $\mathbf{\Theta\left(\frac{n\log n}{\varepsilon^2}\right)}$	$\Theta\left(\log n\right)^*$	$\Theta(\log n)$ [30, 31]	$\Theta(\log n)$ [30, 31]
Consensus	$\mathbf{\Theta\left(\frac{\log n}{\varepsilon^2}\right)}$	$\mathbf{\Omega\left(\log n\right)}$ $\mathcal{O}(\log n)^*$	$\mathbf{\Omega\left(\log n\right)}$ $\mathcal{O}(\log n)$ [30, 31]	$\mathbf{\Omega\left(\log n\right)}$ $\mathcal{O}(\log n)$ [30, 31]

Abstract

Property testers are fast randomized algorithms whose task is to distinguish between inputs satisfying some predetermined property $\mathcal{P}$ and those that are far from satisfying it. Since these algorithms operate by inspecting a small randomly selected portion of the input, the most natural property one would like to be able to test is whether the input does not contain certain forbidden small substructures. In the setting of graphs, such a result was obtained by Alon et al., who proved that for any finite family of graphs $\mathcal{F}$, the property of being induced $\mathcal{F}$-free (i.e. not containing an induced copy of any $F \in \mathcal{F}$) is testable.

It is natural to ask if one can go one step further and prove that more elaborate properties involving induced subgraphs are also testable. One such generalization of the result of Alon et al. was formulated by Goldreich and Shinkar who conjectured that for any finite family of graphs $\mathcal{F}$, and any linear inequality involving the densities of the graphs $F \in \mathcal{F}$ in the input graph, the property of satisfying this inequality can be tested in a certain restricted model of graph property testing. Our main result in this paper disproves this conjecture in the following strong form: some properties of this type are not testable even in the classical (i.e. unrestricted) model of graph property testing.

The proof deviates significantly from prior non-testability results in this area. The main idea is to use a linear inequality relating induced subgraph densities in order to encode the property of being a pseudo-random graph.

1 Introduction

Property testers are fast randomized algorithms that distinguish between objects satisfying a certain property and objects that are "far" from the property. The systematic study of such problems originates in the seminal papers of Rubinfeld and Sudan [10] and Goldreich, Goldwasser and Ron [4], and has since become a very active area of research. We refer the reader to the book of Goldreich [3] for more background and references on the subject.

In this paper we study property testing of graph properties in the *dense graph model*. In this model, a graph is given as an $n \times n$ adjacency matrix. An n-vertex graph G is said to be ε-*far* from a graph property Π, if one has to change at least εn^2 entries in the adjacency matrix of G in order to turn it into a graph satisfying Π. A *tester* for Π is a (randomized) algorithm that, given a proximity parameter $\varepsilon \in (0,1)$ and a graph G, accepts if G satisfies Π and rejects if G is ε-far from Π, with success probability at least $\frac{2}{3}$ in both cases. The

tester is given oracle access to the adjacency matrix of the input, to which it makes queries. We say that a tester has query complexity $q(\varepsilon, n)$ if it makes at most $q(\varepsilon, n)$ queries when invoked with proximity parameter ε on inputs with n vertices. A property Π is called *testable* if it has a tester whose query complexity is bounded by a function of ε alone, that is, it is independent of the size of the input. A tester is *canonical* if it works by sampling a random set of vertices of some size $s(\varepsilon, n)$, querying all pairs among these vertices, and making its decision based on (the isomorphism class) of the sample. The integer $s(\varepsilon, n)$ is called the *sample complexity* of the tester. Goldreich and Trevisan [7, Theorem 2] showed that every tester can be transformed to a canonical one, with the cost of possibly squaring the query complexity. A tester is *size-oblivious* if it does not know n; that is, if its function depends only on the proximity parameter ε (and not on the size of the input). The transformation of Goldreich and Trevisan [7] which turns arbitrary testers into canonical testers, preserves the property of being size-oblivious.

In this paper we study a special kind of testers, called *proximity oblivious testers*, which are defined as follows.

▶ **Definition 1.** *A* proximity oblivious tester *(POT) for a graph property* Π *is an algorithm which makes a* constant *(i.e. independent of* n and ε*) number of queries to the input and satisfies the following. There is a constant* $c \in (0, 1]$ *and a function* $f : (0, 1] \to (0, 1]$ *such that:*

1. *If the input graph satisfies* Π *then the tester accepts with probability at least* c*.*
2. *If the input graph is* ε*-far from* Π *then the tester accepts with probability at most* $c - f(\varepsilon)$*.*

Observe that a POT for Π can be used to obtain a standard tester for Π, by invoking the POT $T = \Theta(1/f(\varepsilon)^2)$ times and accepting if and only if the POT accepted in at least $(c - \frac{f(\varepsilon)}{2})T$ of the tests.

POTs were introduced by Goldreich and Ron [5], who studied *one-sided-error POTs*, namely POTs that accept every input which satisfies the property with probability 1 (this corresponds to having $c = 1$ in Definition 1). Later, Goldreich and Shinkar [6] studied general (two-sided-error) POTs in several settings, including those of general boolean functions, dense graphs and bounded degree graphs. For the dense graph model, they designed a POT for the property of being αn-regular (for a given $\alpha \in (0, 1)$), as well as for several related properties. Moreover, they considered properties of the following form: given graphs H, G, the *density* of H in G, denoted by $p(H, G)$, is the fraction of induced subgraphs of G of order $v(H)$ which are isomorphic to H. Given an integer $h \geq 2$, a rational number b and rational numbers $w_H \geq 0$, where H runs over all h-vertex graphs, the property $\Pi_{h,w,b}$ is defined as the property of all graphs G satisfying

$$\sum_H w_H \cdot p(H, G) \leq b.$$

Throughout this paper, a tuple (h, w, b) will always consist of an integer $h \geq 2$, a rational number b, and a function $w \colon \{H : v(H) = h\} \to \mathbb{Q}^+$ from the set of all h-vertex graphs to the positive rationals. The value assigned by w to a graph H is denoted by w_H.

Since property testing algorithms, and POTs in particular, work by inspecting the subgraph induced by a small sample of vertices, it is natural to ask if the property of not containing an induced copy of a fixed graph H is a testable property. Such a result was obtained by Alon, Fischer, Krivelevich and Szegedy [1] who proved that in fact for every finite family of graphs $\mathcal{F}$, the property of being induced $\mathcal{F}$-free (i.e. not containing an induced copy of F for every $F \in \mathcal{F}$) is testable. It is easy to see that the family of properties $\Pi_{h,w,b}$ forms a strict generalization of the family of properties of being induced $\mathcal{F}$-free, since the

former can encode the latter. (Indeed, if all graphs in $\mathcal{F}$ have the same size h then simply set $b = 0$, $w_H = 1$ for each $H \in \mathcal{F}$, and $w_H = 0$ for each h-vertex graph H which is not in $\mathcal{F}$. If graphs in $\mathcal{F}$ have varying sizes, then take advantage of the fact that for every pair of graphs F, G and $h \geq v(F)$, it holds that $p(F,G) = \sum_H p(F,H) \cdot p(H,G)$, where the sum is over all h-vertex graphs H.)

We now arrive at an important definition.

▶ **Definition 2.** *A tuple (h,w,b) has the* removal property *if there is a function $f : (0,1] \to (0,1]$ such that for every $\varepsilon \in (0,1)$ and for every graph G, if G is ε-far from $\Pi_{h,w,b}$ then*

$$\sum_H w_H \cdot p(H,G) \geq b + f(\varepsilon).$$

As an example, the main result of [1] mentioned above is equivalent to the statement that if $b = 0$ then $\Pi_{h,w,b}$ has the removal property. Goldreich and Shinkar [6] observed that if (h,w,b) has the removal property then $\Pi_{h,w,b}$ admits a size-oblivious POT. Indeed, given an input graph G, the POT works by sampling a random induced subgraph of G of order h, and then rejecting with probability w_H if the sampled subgraph is isomorphic to H, for each H on h vertices. If G satisfies $\Pi_{h,w,b}$ then by the definition of this property, G is rejected with probability $\sum_H w_H \cdot p(H,G) \leq b$. On the other hand, if G is ε-far from $\Pi_{h,w,b}$ then by the removal property, G is rejected with probability $\sum_H w_H \cdot p(H,G) \geq b + f(\varepsilon)$. Thus, Definition 1 is satisfied with $c = 1 - b$.

Our first result in this paper is a converse of the above statement, showing that if $\Pi_{h,w,b}$ has a size-oblivious POT, then (h,w,b) has the removal property.

▶ **Theorem 3.** *For each tuple (h,w,b), if $\Pi_{h,w,b}$ has a size-oblivious POT then (h,w,b) has the removal property.*

As a corollary of the above theorem, we infer that if one "representation" of a property as $\Pi_{h,w,b}$ has the removal property, then all such representations have the removal property. This is stated in the following corollary.

▶ **Corollary 4.** *Let (h,w,b) and (h',w',b') be tuples such that $\Pi_{h,w,b} = \Pi_{h',w',b'}$. Then (h,w,b) has the removal property if and only if (h',w',b') has the removal property.*

▶ Remark 5. Theorem 3 contradicts the statement of Proposition 3.14 in [6], which states that there is a tuple (h,w,b) such that $\Pi_{h,w,b}$ has a POT but (h,w,b) does not have the removal property. We believe that the proof of this proposition is wrong. This will be explained in the full version of this paper.

Goldreich and Shinkar conjectured (see [6, Open Problem 3.11]) that every property of the form $\Pi_{h,w,b}$ has a POT . Our next theorem disproves this conjecture by showing that there are properties $\Pi_{h,w,b}$ that are not testable at all (let alone testable using a POT).

▶ **Theorem 6.** *Let K_4 denote the complete graph on 4 vertices, D_4 the diamond graph (i.e. K_4 minus an edge), P_2 the graph on 4 vertices containing a path of length 2 and an isolated vertex, C_4 the 4-cycle, P_4 the path on 4 vertices and $K_{1,3}$ the star on 4 vertices. Let w_H be the following weight function assigning a non-negative weight to each graph on 4 vertices.*

H :	K_4	$\overline{K_4}$	D_4	$\overline{D_4}$	P_2	$\overline{P_2}$	C_4	$\overline{C_4}$	$K_{1,3}$	$\overline{K_{1,3}}$	P_4
w_H :	1	$\frac{1}{2}$	$\frac{5}{12}$	$\frac{5}{12}$	$\frac{1}{6}$	$\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$

Then, the property

$$\Pi_{h,w,b} = \left\{ G : \sum_{H:|V(H)|=4} w_H \cdot p(H,G) \leq \frac{5}{16} \right\} \tag{1}$$

is not *testable.*

Given the above theorem it is natural to ask if every property $\Pi_{h,w,b}$ can at least be tested using $o(n^2)$ edge-queries. We leave this as an open problem.

Paper overview

The rest of the paper is organized as follows. In Section 2 we prove Theorem 3. The proof of Theorem 6 appears in Section 3. The main idea behind its proof is to show that there exists a property $\Pi_{h,w,b}$ (specifically, the one defined in (1)) which encodes the property of being a pseudo-random graph. It is then not hard to show that such a property cannot be tested using a constant number of queries.

2 Proof of Theorem 3

In this section we prove Theorem 3 and Corollary 4. We will need the following auxiliary lemma.

▶ **Lemma 7.** *Let* Π *be a graph property, and suppose that* Π *has a canonical size-oblivious* ε*-tester* $\mathcal{T}$ *with sample complexity* $s = s(\varepsilon)$ *(and success probability* $\frac{2}{3}$*). Then for every* $n \geq s^4$ *and for every* n*-vertex graph* G *which is* ε*-far from* Π*, the following holds. For* U *chosen uniformly at random from* $\binom{V(G)}{s^4}$*, we have* $\mathbb{P}[G[U] \in \Pi] \leq e^{-\Omega(s)}$*.*

Proof. Let $\mathcal{A}$ be the family of all s-vertex graphs A such that $\mathcal{T}$ accepts if it sees a subgraph isomorphic to A. For a graph G, we say that a sequence of subsets $S_1, \ldots, S_s \in \binom{V(G)}{s}$ is *good* if $G[S_i] \in \mathcal{A}$ for at least half of the values of $1 \leq i \leq s$; otherwise $S_1, \ldots, S_s$ is *bad*. For a sequence of vertices $W = (x_1, \ldots, x_{s^2})$, we say that W is good (resp. bad) if $\{x_1, \ldots, x_s\}, \{x_{s+1}, \ldots, x_{2s}\}, \ldots, \{x_{s^2-s+1}, \ldots, x_{s^2}\}$ is good (resp. bad). Note that for a random $S \in \binom{V(G)}{s}$, if $G \in \Pi$ then $\mathbb{P}[G[S] \in \mathcal{A}] \geq \frac{2}{3}$, and if G is ε-far from Π then $\mathbb{P}[G[S] \in \mathcal{A}] \leq \frac{1}{3}$. Using a standard Chernoff-type bound, one can show that the following holds for $S_1, \ldots, S_s \in \binom{V(G)}{s}$ chosen uniformly at random and independently.

1. If $G \in \Pi$ then $S_1, \ldots, S_s$ is good with probability at least $1 - e^{-Cs}$.
2. If G is ε-far from Π then $S_1, \ldots, S_s$ is bad with probability at least $1 - e^{-Cs}$.

In both items above, C is an absolute constant.

The probability that $S_i \cap S_j \neq \emptyset$ for some $1 \leq i < j \leq s$ is at most $\binom{s}{2}\frac{s^2}{n} < \frac{1}{2}$, where the inequality follows from the assumption that $n \geq s^4$. So $|S_1 \cup \cdots \cup S_s| = s^2$ with probability at least $\frac{1}{2}$. Conditioned on the event that $S_1, \ldots, S_s$ are pairwise-disjoint, the set $S := S_1 \cup \cdots \cup S_s$ has the distribution of an element of $\binom{V(G)}{s^2}$ chosen uniformly at random. Thus, a random sequence of vertices $W = (x_1, \ldots, x_{s^2})$ chosen *without repetitions* satisfies the following.

1. If G satisfies Π then W is good with probability at least $1 - 2e^{-Cs}$.
2. If G is ε-far from Π then W is bad with probability at least $1 - 2e^{-Cs}$.

Now let G be a graph on $n \geq s^4$ vertices which is ε-far from Π. Consider a random pair (U, W), where U is chosen uniformly at random from $\binom{V(G)}{s^4}$, and $W = (x_1, \ldots, x_{s^2})$ is a sequence of vertices sampled randomly without repetition from U. Note that W is

distributed as a uniform sequence of s^2 vertices of G, sampled without repetition. Thus, $\mathbb{P}[W \text{ is good}] \leq 2e^{-Cs}$. On the other hand, if $G[U] \in \Pi$, then $\mathbb{P}[W \text{ is good} \mid U] \geq 1 - 2e^{-Cs}$. By combining these two facts, we see that

$$\mathbb{P}[G[U] \in \Pi] \leq \frac{2e^{-Cs}}{1-2e^{-Cs}} \leq 4e^{-Cs} = e^{-\Omega(s)}. \qquad \blacktriangleleft$$

Proof of Theorem 3. As mentioned in the introduction, a POT for $\Pi_{h,w,b}$ can be used to obtain a standard tester for $\Pi_{h,w,b}$ by invoking the POT an appropriate number of times. Moreover, it is clear that if the POT is size-oblivious, then so is the resulting tester. Next, we apply the transformation of Goldreich and Trevisan [7] to get a canonical tester $\mathcal{T}$ for $\Pi_{h,w,b}$. Since this transformation preserves the property of being size-oblivious, $\mathcal{T}$ is size-oblivious, and hence satisfies the condition of Lemma 7. Denote by $s = s(\varepsilon)$ the sample complexity of $\mathcal{T}$. We may and will assume that s is large enough as a function of the parameters h and b.

Let us denote $z(G) = \sum_H w_H \cdot p(H, G)$. By multiplying the inequality $\sum_H w_H \cdot p(H, G) \leq b$ by an appropriate integer, we can assume without loss of generality that b is an integer, and that w_H is an integer for every H.

Let G be a graph which is ε-far from $\Pi_{h,w,b}$. Our goal is to show that $z(G) \geq b + f(\varepsilon)$, for a function $f : (0, 1] \to (0, 1]$ to be chosen later. By Lemma 7, a randomly chosen $U \in \binom{V(G)}{s^4}$ satisfies $G[U] \in \Pi_{h,w,b}$ with probability at most $e^{-\Omega(s)}$. Observe that if a k-vertex graph K does not satisfy $\Pi_{h,w,b}$, then necessarily

$$z(K) = \sum_H w_H \cdot p(H, K) \geq b + \binom{k}{h}^{-1} > b + k^{-h},$$

as b and all weights w_H are integers. Thus, if $G[U] \notin \Pi_{h,w,b}$ then

$$z(G[U]) > b + |U|^{-h} = b + s^{-4h}.$$

Observe that $z(G)$ is the average of $z(G[U])$ over all $U \in \binom{V(G)}{s^4}$. Thus, using the guarantees of Lemma 7, we obtain

$$z(G) \geq (1 - e^{-\Omega(s)})(b + s^{-4h}) > b + \frac{1}{2}s^{-4h},$$

where the last inequality holds provided that s is large enough as a function of h and b. So we may take the function f in Definition 2 to be $f(\varepsilon) = \frac{1}{2}s(\varepsilon)^{-4h}$. This completes the proof. $\blacktriangleleft$

Proof of Corollary 4. We have established that (h, w, b) satisfies the removal property if and only if $\Pi_{h,w,b}$ has a size-oblivious POT. The "only if" part was explained in the introduction (see also [6]), and the "if" part is the statement of Theorem 3. Since the existence of a tester (specifically, a size-oblivious POT) does not depend on the specific representation of a given property as $\Pi_{h,w,b}$, it is now clear that the corollary holds. $\blacktriangleleft$

3 Proof of Theorem 6

Let $\Pi_{h,w,b}$ be as in the statement of Theorem 6. Denote

$$z(G) := \sum_{H:|V(H)|=4} w_H \cdot p(H, G)$$

for every graph G of order at least 4. Under this notation, $\Pi_{h,w,b} = \{G : z(G) \leq b\}$. For a pair of graphs H and G, define

$$t_{\text{inj}}(H,G) = \frac{1}{n^{\underline{h}}}|\{\varphi\colon V(H) \to V(G) \text{ injective s.t. } uv \in E(H) \Rightarrow \varphi(u)\varphi(v) \in E(G)\}|,$$

and

$$t_{\text{ind}}(H,G) = \frac{1}{n^{\underline{h}}}|\{\varphi\colon V(H) \to V(G) \text{ injective s.t. } uv \in E(H) \Leftrightarrow \varphi(u)\varphi(v) \in E(G)\}|,$$

where $n^{\underline{h}} = n \cdot (n-1) \cdot \cdots \cdot (n-h+1)$. Note that $t_{\text{ind}}(H,G) = p(H,G) \cdot \text{aut}(H)/h!$, where $\text{aut}(H)$ is the number of automorphisms of H. The following lemma gives a simpler description of $\Pi_{h,w,b}$.

▶ **Lemma 8.** *$\Pi_{h,w,b} = \{G : \phi(G) \leq 0\}$, where $\phi(G) = 2t_{inj}(C_4,G) - t_{inj}(K_2,G) + \frac{3}{8}$.*

Proof. First, note that $t_{inj}(K_2,G) = p(K_2,G)$. Next, we use the fact that

$$\begin{aligned} t_{\text{inj}}(C_4,G) &= t_{\text{ind}}(C_4,G) + 2t_{\text{ind}}(D_4,G) + t_{\text{ind}}(K_4,G) \\ &= \frac{\text{aut}(C_4)}{4!} \cdot p(C_4,G) + 2\frac{\text{aut}(D_4)}{4!} \cdot p(D_4,G) + \frac{\text{aut}(K_4)}{4!} \cdot p(K_4,G) \\ &= \frac{1}{3}p(C_4,G) + \frac{1}{3}p(D_4,G) + p(K_4,G). \end{aligned}$$

Hence,

$$\begin{aligned} \phi(G) &= \frac{2}{3}p(C_4,G) + \frac{2}{3}p(D_4,G) + 2p(K_4,G) - p(K_2,G) + \frac{3}{8} \\ &= \frac{2}{3}p(C_4,G) + \frac{2}{3}p(D_4,G) + 2p(K_4,G) + p(\overline{K_2},G) - \frac{5}{8} \\ &= \frac{2}{3}p(C_4,G) + \frac{2}{3}p(D_4,G) + 2p(K_4,G) + \sum_{H:|V(H)|=4} p(\overline{K_2},H)p(H,G) - \frac{5}{8} \\ &= \sum_{H:|V(H)|=4} 2w_H \cdot p(H,G) - \frac{5}{8}. \end{aligned}$$

Therefore, $\phi(G) \leq 0$ if and only if $\sum_{H:|V(H)|=4} w_H \cdot p(H,G) \leq 5/16$ ◀

An important ingredient in the proof of Theorem 6 is the following lemma, which shows that graphs in $\Pi_{h,w,b}$ are pseudo-random. In what follows, we write $x = y \pm z$ to mean that $x \in [y-z, y+z]$.

▶ **Lemma 9.** *For every $\delta \in (0,1)$ there is $n_0(\delta)$ such that every graph $G \in \Pi_{h,w,b}$ on $n \geq n_0(\delta)$ vertices satisfies the following. For every $U, V \subseteq V(G)$ with $|U|, |V| \geq \delta n$, it holds that*

$$e(U,V) = \left(\frac{1}{2} \pm \delta\right)|U||V|\,.$$

Proof. We start by showing that for every $\gamma \in (0,1)$ there is $n_0(\gamma)$ such that if $G \in \Pi_{h,w,b}$ is a graph on $n \geq n_0(\gamma)$ vertices, then

$$t_{\text{inj}}(K_2,G) = \frac{1}{2} \pm \gamma \text{ and } t_{\text{inj}}(C_4,G) = \frac{1}{16} \pm \gamma. \tag{2}$$

It is a well-known fact (see for instance [11]) that every n-vertex graph G satisfies[1]

$$t_{\text{inj}}(C_4,G) \geq t_{\text{inj}}(K_2,G)^4 - O\left(\frac{1}{n}\right) \geq t_{\text{inj}}(K_2,G)^4 - \frac{\gamma^2}{2}, \tag{3}$$

where the last inequality holds if n is large enough. Now, observe that every $G \in \Pi_{h,w,b}$ satisfies

$$2t_{\text{inj}}(K_2,G)^4 - t_{\text{inj}}(K_2,G) + \frac{3}{8} \leq 2t_{\text{inj}}(C_4,G) + \gamma^2 - t_{\text{inj}}(K_2,G) + \frac{3}{8} = \phi(G) + \gamma^2 \leq \gamma^2, \tag{4}$$

where the last inequality follows from Lemma 8. Note that the function $x \mapsto 2x^4 - x + \frac{3}{8}$ is convex, and attains its minimum at $x = 1/2$. Therefore, if we had $t_{\text{inj}}(K_2,G) > \frac{1}{2} + \gamma$, then we would have

$$2t_{\text{inj}}(K_2,G)^4 - t_{\text{inj}}(K_2,G) + \frac{3}{8} > 2\left(\frac{1}{2}+\gamma\right)^4 - \left(\frac{1}{2}+\gamma\right) + \frac{3}{8} = 2\gamma^4 + 4\gamma^3 + 3\gamma^2 > \gamma^2.$$

Similarly, if we had $t_{\text{inj}}(K_2,G) < \frac{1}{2} - \gamma$, then we would have

$$2t_{\text{inj}}(K_2,G)^4 - t_{\text{inj}}(K_2,G) + \frac{3}{8} > 2\left(\frac{1}{2}-\gamma\right)^4 - \left(\frac{1}{2}-\gamma\right) + \frac{3}{8} = 2\gamma^4 - 4\gamma^3 + 3\gamma^2 > \gamma^2.$$

In any case, we see that $|t_{\text{inj}}(K_2,G) - \frac{1}{2}| > \gamma$ would stand in contradiction to (4). Hence, $t_{\text{inj}}(K_2,G) = \frac{1}{2} \pm \gamma$. By applying Lemma 8 again we get $t_{\text{inj}}(C_4,G) \leq \frac{1}{16} + \gamma$. By using the intermediate inequality in (3) and $t_{\text{inj}}(K_2,G) \geq \frac{1}{2} - \gamma$, we get

$$t_{\text{inj}}(C_4,G) \geq \left(\frac{1}{2}-\gamma\right)^4 - O\left(\frac{1}{n}\right) \geq \frac{1}{16} - \gamma,$$

where the last inequality can be easily verified, assuming that n is large enough, by expanding the binomial expression. We have thus established (2).

A well-known result of Chung, Graham and Wilson [2] states that for every $\delta \in (0,1)$ there is $\gamma = \gamma(\delta)$ such that if a graph G satisfies (2), then for every $U, V \subseteq V(G)$ with $|U|, |V| \geq \delta n$, it holds that $e(U,V) = \left(\frac{1}{2} \pm \delta\right)|U||V|$. The lemma follows by combining this result with the above. ◀

For a family of graphs $\mathcal{F}$ and a graph G, we define

$$p(\mathcal{F},G) = \sum_{F \in \mathcal{F}} p(F,G)\ .$$

It is well-known (see e.g. [2]) that a pseudo-random graph has approximately the same distribution of small subgraphs as a random graph with the same density. By combining this with Lemma 9, we obtain the following corollary. Note that the expected value of $p(F, G(n, \frac{1}{2}))$ is $2^{-\binom{s}{2}} \frac{s!}{\text{aut}(F)}$.

▶ **Corollary 10.** *For every $s \geq 2$ and $\delta \in (0,1)$ there is $n_1 = n_1(s,\delta)$ such that every $G \in \Pi_{h,w,b}$ on $n \geq n_1$ vertices satisfies the following. For every family $\mathcal{F}$ of s-vertex graphs, it holds that*

$$p(\mathcal{F},G) = \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{s!}{aut(F)} \pm \delta.$$

[1] Usually this inequality is stated in terms of the *homomorphic density*, as $\mathrm{t}(C_4,G) \geq \mathrm{t}(K_2,G)^4$ (see e.g. [9]). The error-term $O(\frac{1}{n})$ accounts for the difference between the homomorphic density and the injective density.

We are now ready to prove Theorem 6.

Proof of Theorem 6. We start by showing that $\Pi_{h,w,b}$ is non-empty. More specifically, we prove that for every integer $n \geq 4$, there exists an n-vertex graph satisfying $\Pi_{h,w,b}$. Let $G \sim G(n, \frac{1}{2})$. It is easy to see that $\mathbb{E}[t_{\text{inj}}(K_2, G)] = \frac{1}{2}$ and $\mathbb{E}[t_{\text{inj}}(C_4, G)] = \frac{1}{16}$. Hence,

$$\mathbb{E}[\phi(G)] = 2\mathbb{E}[t_{\text{inj}}(C_4, G)] - \mathbb{E}[t_{\text{inj}}(K_2, G)] + \frac{3}{8} = 0.$$

It follows that there is an n-vertex graph with $\phi(G) \leq 0$, and hence $G \in \Pi_{h,w,b}$ by Lemma 8.

Now suppose by contradiction that $\Pi_{h,w,b}$ is testable. In particular, there exists a 0.1-tester for $\Pi_{h,w,b}$. This implies – by [7, Theorem 2] (see also [8]) – that there is a canonical 0.1-tester $\mathcal{T}$ for $\Pi_{h,w,b}$. Denote by s the sample complexity of $\mathcal{T}$. Then for every $n > 0$ there is a family $\mathcal{F} = \mathcal{F}(n)$ of (rejection) graphs of order s satisfying the following for every n-vertex graph G.

1. $p(\mathcal{F}, G) \leq \frac{1}{3}$ if $G \in \Pi_{h,w,b}$;
2. $p(\mathcal{F}, G) \geq \frac{2}{3}$ if G is 0.1-far from $\Pi_{h,w,b}$.

Let $n' = \max\{9s^2, n_1(s, \frac{1}{9})\}$ and $n = \max\{n_0(\frac{1}{n'}), n_1(s, \frac{1}{9})\}$, where n_1 is from Corollary 10 and n_0 is from Lemma 9. Let G' be an arbitrary n'-vertex graph which satisfies $\Pi_{h,w,b}$, and let G be the $\frac{n}{n'}$-blow-up of G'. Denote by $V_1 \sqcup \cdots \sqcup V_{n'} = V(G)$ the clusters of this blow-up.

We claim that G is 0.1-far from $\Pi_{h,w,b}$. Indeed, fix any $G^* \in \Pi_{h,w,b}$ with n vertices. By our choice of n via Lemma 9, and as $|V_i| = \frac{n}{n'}$, we must have $e_{G^*}(V_i, V_j) = (\frac{1}{2} \pm \frac{1}{n'})(n/n')^2$. But since $e_G(V_i, V_j) \in \{0, (n/n')^2\}$, we must change at least $(\frac{1}{2} - \frac{1}{n'})(n/n')^2 \geq 0.4(n/n')^2$ edges between V_i and V_j for every $1 \leq i < j \leq n'$, in order to turn G into G^*. Therefore, the edit distance between G and G^* is at least $\binom{n'}{2} \cdot 0.4(n/n')^2 \geq 0.1n^2$, as required.

Now, let $S \in \binom{V(G)}{s}$ be chosen uniformly at random, and let $\mathcal{B}$ be the event that there exists $1 \leq i \leq n'$ for which $|S \cap V_i| > 1$. Note that we have $\mathbb{P}(\mathcal{B}) \leq \binom{s}{2}/n' < \frac{1}{9}$, by the choice of n'. Observe that conditioned on $\mathcal{B}^c$, the probability that S is isomorphic to an s-vertex graph F is exactly $p(F, G')$. Hence, setting $\mathcal{F} = \mathcal{F}(n)$ and $\rho = \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{s!}{\text{aut}(F)}$, we have

$$\begin{aligned} p(\mathcal{F}, G) &= \mathbb{P}[G[S] \in \mathcal{F}] = \mathbb{P}(G[S] \in \mathcal{F} \mid B^c) + \mathbb{P}(B) \\ &< \mathbb{P}(G[S] \in \mathcal{F} \mid B^c) + \frac{1}{9} \\ &= p(\mathcal{F}, G') + \frac{1}{9} \\ &\leq \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{s!}{\text{aut}(F)} + \frac{1}{9} + \frac{1}{9} \\ &= \rho + \frac{2}{9}, \end{aligned} \tag{5}$$

where in the last inequality we used our choice of n' via Corollary 10. On the other hand, our choice of n via Corollary 10 implies that every n-vertex graph $G^* \in \Pi_{h,w,b}$ satisfies

$$p(\mathcal{F}, G^*) \geq \sum_{F \in \mathcal{F}} 2^{-\binom{s}{2}} \frac{s!}{\text{aut}(F)} - \frac{1}{9} = \rho - \frac{1}{9}.$$

By combining this with (5), we get $p(\mathcal{F}, G^*) > p(\mathcal{F}, G) - \frac{1}{3}$. But this stands in contradiction to $p(\mathcal{F}, G^*) \leq \frac{1}{3}$ (as $G^* \in \Pi_{h,w,b}$) and $p(\mathcal{F}, G) \geq \frac{2}{3}$ (as G is 0.1-far from $\Pi_{h,w,b}$). This completes the proof of the theorem. ◀

Abstract

Consider the following heuristic for building a decision tree for a function $f : \{0,1\}^n \to \{\pm 1\}$. Place the *most influential variable* x_i of f at the root, and recurse on the subfunctions $f_{x_i=0}$ and $f_{x_i=1}$ on the left and right subtrees respectively; terminate once the tree is an ε-approximation of f. We analyze the quality of this heuristic, obtaining near-matching upper and lower bounds:

- *Upper bound:* For every f with decision tree size s and every $\varepsilon \in (0, \frac{1}{2})$, this heuristic builds a decision tree of size at most $s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}$.
- *Lower bound:* For every $\varepsilon \in (0, \frac{1}{2})$ and $s \leq 2^{\tilde{O}(\sqrt{n})}$, there is an f with decision tree size s such that this heuristic builds a decision tree of size $s^{\tilde{\Omega}(\log s)}$.

We also obtain upper and lower bounds for monotone functions: $s^{O(\sqrt{\log s}/\varepsilon)}$ and $s^{\tilde{\Omega}(\sqrt[4]{\log s})}$ respectively. The lower bound disproves conjectures of Fiat and Pechyony (2004) and Lee (2009).

Our upper bounds yield new algorithms for properly learning decision trees under the uniform distribution. We show that these algorithms – which are motivated by widely employed and empirically successful top-down decision tree learning heuristics such as ID3, C4.5, and CART – achieve provable guarantees that compare favorably with those of the current fastest algorithm (Ehrenfeucht and Haussler, 1989), and even have certain qualitative advantages. Our lower bounds shed new light on the limitations of these heuristics.

Finally, we revisit the classic work of Ehrenfeucht and Haussler. We extend it to give the first uniform-distribution proper learning algorithm that achieves polynomial sample and memory complexity, while matching its state-of-the-art quasipolynomial runtime.

1 Introduction

Consider the problem of constructing a *decision tree* representation of a function $f : \{0,1\}^n \to \{\pm 1\}$, where the goal is to build a decision tree for f that is as small as possible, ideally of size close to the optimal decision tree size of f. Perhaps the simplest and most natural approach is to proceed in a *top-down*, greedy fashion:

1. Choose a "good" variable x_i to query as the root of the decision tree;
2. Build the left and right subtrees by recursing on the subfunctions $f_{x_i=0}$ and $f_{x_i=1}$ respectively.

This reduces the task of building a decision tree to that of choosing the root variable – i.e. determining the *splitting criterion* of this top-down heuristic. Intuitively, a good root variable should be one that is very "relevant" and "important" in terms of determining the value of f; it is reasonable to expect that querying such a variable first would reduce the number of subsequent queries necessary. Our focus in this paper will be on a specific splitting criterion: *influence*.

▶ **Definition 1** (Influence). *The influence of the variable x_i on a function $f : \{0,1\}^n \to \{\pm 1\}$ is defined to be*

$$\mathrm{Inf}_i(f) \coloneqq \Pr_{\boldsymbol{x} \sim \{0,1\}^n}[f(\boldsymbol{x}) \neq f(\boldsymbol{x}^{\oplus i})],$$

where $\boldsymbol{x}$ is drawn uniformly at random, and $\boldsymbol{x}^{\oplus i}$ denotes $\boldsymbol{x}$ with its i-th coordinate flipped.

Influence is a fundamental and well-studied notion in the analysis of boolean functions [51]. It is the key quantity of interest in many landmark results (e.g. the KKL inequality [35], Friedgut's junta theorem [24], the Invariance Principle [50]) and open problems (e.g. the Gotsman–Linial conjecture [29], the Aaronson–Ambainis conjecture [1], the Fourier Entropy-Influence conjecture [25]) of the field. Beyond the analysis of boolean functions, this notion has been widely employed across both algorithms and complexity theory, where it has indeed proven to be a useful quantitative measure of the relevance and importance of a variable. Most relevant to the algorithmic applications in this paper, influence has been a key enabling ingredient in a large number of results in learning theory [15, 9, 45, 63, 53, 54, 31, 19, 36, 37, 5].

1.1 Influence as a splitting criterion

We now give a formal description of the heuristic for constructing decision trees that we study. We define a *bare tree* to be a decision tree with unlabeled leaves, and write T° to denote such trees. We refer to any decision tree T obtained from T° by a labelling of its leaves as a *completion* of T°. Given a bare tree T° and a function f, there is a canonical completion of T° that minimizes the approximation error with respect to f:

▶ **Definition 2** (f-completion of a bare tree). *Let T° be a bare tree and $f : \{0,1\}^n \to \{\pm 1\}$. Consider the following completion of T°: for every leaf ℓ in T°, label it* $\mathrm{sign}(\mathbb{E}[f_\ell(\boldsymbol{x})])$*, where f_ℓ is the restriction of f by the path leading to ℓ and $\boldsymbol{x} \sim \{0,1\}^n$ is uniform random. This completion minimizes the approximation error* $\Pr[T(\boldsymbol{x}) \neq f(\boldsymbol{x})]$*, and we refer to it as the* f-completion of T°.

In addition to the function f, our heuristic will also take in an error parameter ε, allowing us to construct both *exact* ($\varepsilon = 0$) and *approximate* ($\varepsilon \in (0, \frac{1}{2})$) decision tree representations of f.

BuildTopDownDT(f, ε):

Initialize T° to be the empty tree.

while (f-completion of T° is not an ε-approximation of f) {

1. (Score) For every leaf ℓ in T°, let $x_{i(\ell)}$ denote the most influential variable of the subfunction f_ℓ:

$$\mathrm{Inf}_{i(\ell)}(f_\ell) \geq \mathrm{Inf}_j(f_\ell) \quad \text{for all } j \in [n].$$

   Assign ℓ the score:

$$\mathrm{score}(\ell) \coloneqq \Pr_{\boldsymbol{x} \sim \{0,1\}^n}[\boldsymbol{x} \text{ reaches } \ell] \cdot \mathrm{Inf}_{i(\ell)}(f_\ell) = 2^{-|\ell|} \cdot \mathrm{Inf}_{i(\ell)}(f_\ell),$$

   where $|\ell|$ denotes the depth of ℓ in T°.
2. (Split) Let $\ell^\star$ be the leaf with the highest score. Grow T° by replacing $\ell^\star$ with a query to $x_{i(\ell^\star)}$.

}

Figure 1 Top-down heuristic for building an ε-approximate decision tree representation of f, with influence as the splitting criterion.

In words, BuildTopDownDT builds a bare tree T° in a top-down fashion, starting from the empty tree. In each iteration, we first check if the f-completion of T° is an ε-approximation of f, and if so, we output the completion. Otherwise, we split the leaf $\ell^\star$ with the highest score by querying the most influential variable of $f_{\ell^\star}$, where the score of a leaf ℓ is the influence of the most influential variable of f_ℓ normalized by the depth of ℓ within T°.[1]

1.2 This work

By design, the decision tree returned by BuildTopDownDT(f, ε) is an ε-approximation of f. We write TopDownDTSize(f, ε) to denote the size of this tree, and when $\varepsilon = 0$, we simply write TopDownDTSize(f). The question that motivates our work is:

What guarantees can we make on TopDownDTSize(f, ε) *as a function of the optimal decision tree size of* f *and* ε*?*

That is, we would like to understand the quality of BuildTopDownDT as a heuristic for constructing exact and approximate decision tree representations. In addition to being a natural structural question concerning decision trees, this question also has implications in learning theory. Indeed, BuildTopDownDT is motivated by top-down decision tree learning heuristics such as ID3, C4.5, and CART that are widely employed and empirically successful in machine learning practice. We discuss the learning-theoretic context and applications of our structural results in Section 2.1, and the connection to practical machine learning heuristics in Section 3.1.

[1] There are two possibilities for ties in BuildTopDownDT: two variables may have the same influence within a subfunction f_ℓ, and two leaves may have the same score. Our upper bounds hold regardless of how ties are broken, and our lower bounds hold even if ties are broken in the most favorable way.

To our knowledge, the question above has not been studied in such generality. The most directly relevant prior work is that of Fiat and Pechyony [23], who considered the case when f is either a linear threshold function or a read-once DNF formula, and the setting of exact representation ($\varepsilon = 0$). For such functions, they proved that the heuristic builds an exact decision tree representation of optimal size. We give an overview of other related work in Section 3.2.

2 Our results

As our first contribution, we give near-matching upper and lower bounds that provide a fairly complete answer to the question above. Our upper bound is as follows:

▶ **Theorem 3** (Upper bound for approximate representation). *For every $\varepsilon \in (0, \frac{1}{2})$ and every size-s decision tree f, we have* $\textsc{TopDownDTSize}(f, \varepsilon) \leq s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}$.

We complement Theorem 3 with lower bounds showing that (a) for exact representation ($\varepsilon = 0$), no non-trivial upper bound can be obtained; and (b) for approximate representation ($\varepsilon \in (0, \frac{1}{2})$), the dependence on s in Theorem 3 is essentially optimal:

▶ **Theorem 4** (Lower bounds for exact and approximate representations).

(a) Exact representation: *There is an $f : \{0,1\}^n \to \{\pm 1\}$ with decision tree size $s = \Theta(n)$ such that* $\textsc{TopDownDTSize}(f) \geq 2^{\Omega(s)}$.

(b) Approximate representation: *For every $\varepsilon \in (0, \frac{1}{2})$ and function $s(n) \leq 2^{\tilde{O}(\sqrt{n})}$, there is an $f : \{0,1\}^n \to \{\pm 1\}$ with decision tree size s such that* $\textsc{TopDownDTSize}(f, \varepsilon) \geq s^{\tilde{\Omega}(\log s)}$.

Prior to our work, it was not known whether an upper bound of $\textsc{TopDownDTSize}(f, \varepsilon) \leq \mathrm{poly}(s, 1/\varepsilon)$ holds for all size-s decision trees f and $\varepsilon \in (0, \frac{1}{2})$; Theorem 4(b) provides a strong negative answer. Indeed, such an upper bound had been conjectured to hold for the class of *monotone* functions [44]. We now discuss our results on monotone functions, which disprove this conjecture, along with a stronger variant of it for exact representation [23].

Monotone functions

A monotone boolean function $f : \{0,1\}^n \to \{\pm 1\}$ is one that satisfies $f(x) \leq f(y)$ for all $x \preceq y$ (where $x \preceq y$ iff $x_i \leq y_i$ for all $i \in [n]$). An elementary and useful fact about monotone functions is that the influence of a variable on a monotone function f is equivalent to its *correlation* with f:

▶ **Fact 5** (Influence ≡ correlation for monotone functions). *For all monotone functions $f : \{0,1\}^n \to \{\pm 1\}$ and $i \in [n]$, we have* $\mathrm{Inf}_i[f] = 2\,\mathbb{E}[f(\boldsymbol{x})\boldsymbol{x}_i] - \mathbb{E}[f(\boldsymbol{x})]$.[2]

Therefore, for monotone functions, splitting on the most influential variable of a subfunction is equivalent to splitting on the variable that has the *highest correlation* with the subfunction.[3]

---

[2] The equivalence between influence and correlation for monotone functions is more transparent if one works with $\{\pm 1\}^n$ instead of $\{0,1\}^n$ as the domain: for monotone functions $f : \{\pm 1\}^n \to \{\pm 1\}$, we have $\mathrm{Inf}_i[f] = \mathbb{E}[f(\boldsymbol{x})\boldsymbol{x}_i]$.

[3] We observe that for general *non-monotone* functions, correlation can in general be a very poor splitting criterion, in the sense of building a decision tree that is much larger than the optimal decision tree. Consider $f : \{0,1\}^n \to \{\pm 1\}$ where $f(x) = x_j \oplus x_k$, the parity of two variables. The optimal decision tree size of f is 4, but since $\mathbb{E}[f(\boldsymbol{x})\boldsymbol{x}_i] = 0$ for all $i \in [n]$, the top-down heuristic using correlation as its splitting criterion may build a tree of size $\Omega(2^n)$ before achieving any non-trivial accuracy $\varepsilon < \frac{1}{2}$. (On the other hand, the top-down heuristic using influence as its splitting criterion would build the optimal tree of size 4.) We revisit this observation in Section 3.1.

Our proof of Theorem 3 extends in a straightforward manner to give a different upper bound under the assumption of monotonicity, where the dependence on s is significantly better. We refer to a size-s decision tree computing a monotone function as a size-s monotone decision tree.

▶ **Theorem 6** (Upper bound for approximate representation of monotone functions.). *For every $\varepsilon \in (0, \frac{1}{2})$ and every size-s monotone decision tree f, we have* $\textsc{TopDownDTSize}(f, \varepsilon) \leq s^{O(\sqrt{\log s}/\varepsilon)}$.

In analogy with Theorem 4, we also obtain lower bounds for exact and approximate representations of monotone functions:

▶ **Theorem 7** (Lower bounds for exact and approximate representations of monotone functions).

(a) Exact representation: *There is a monotone $f : \{0,1\}^n \to \{\pm 1\}$ with decision tree size $s = \Theta(n)$ such that* $\textsc{TopDownDTSize}(f) \geq 2^{\Omega(s)}$.

(b) Approximate representation: *For every $\varepsilon \in (0, \frac{1}{2})$ and function $s(n) \leq 2^{\tilde{O}(n^{4/5})}$, there is an $f : \{0,1\}^n \to \{\pm 1\}$ with decision tree size s such that* $\textsc{TopDownDTSize}(f, \varepsilon) \geq s^{\tilde{\Omega}(\sqrt[4]{\log s})}$.

Although we have stated Theorem 7 in terms of the specific heuristic BuildTopDownDT that we study, the actual lower bounds that we establish are significantly stronger: they apply to all "impurity-based top-down heuristics". This is a broad class that captures a wide variety of decision tree learning heuristics used in machine learning practice, including ID3, C4.5, and CART; see Section 3.1 for details.

▶ **Theorem 8** (Stengthening of Theorem 7(b)). *For every $\varepsilon \in (0, \frac{1}{2})$ and function $s(n) \leq 2^{\tilde{O}(n^{4/5})}$, there is a size-$s$ monotone decision tree f such that the ε-approximator built by any impurity-based top-down heuristic must have size $s^{\tilde{\Omega}(\sqrt[4]{\log s})}$.*

Disproving conjectures of Fiat–Pechyony and Lee

Motivated by applications in learning theory (discussed next in Section 2.1), Fiat and Pechyony [23] and Lee [44] also considered the quality of BuildTopDownDT as a heuristic for building decision trees for monotone functions.
