Intuitively, the perturbation bound captures the following natural way to obtain query lower bounds: start from some function $f(\cdot)$ with minimizers $\mathcal{M}_f$. There is some non-zero gap δ between the minimizers and the rest, so there exists a sufficiently small ε such that perturbing weights by ε can tie-break among minimizers, but not yield a new minimizer.

▶ **Observation 13.** *If there exists an $f(\cdot)$ witnessing a (Symmetric, Non-Trivial) Perturbation Bound of q, then the query complexity of (Symmetric, Non-Trivial) SFM is at least q.*

Proof. Assume for contradiction that an algorithm correctly outputs the minimum value, x, after $q-1$ queries that are consistent with $f(\cdot)$. If $x \neq \min_S\{f(S)\}$, then all queries are consistent with $f(\cdot)$, so the algorithm could be wrong because the function is $f(\cdot)$. if $x = \min_S\{f(S)\}$, then because $f(\cdot)$ witnesses a Perturbation Bound of q, there exists a $g(\cdot)$ consistent with all $q-1$ queries with $\min_S\{g(S)\} \neq x$, so the algorithm could be wrong because the function is $g(\cdot)$.

The same proof holds verbatim if $f(\cdot)$ is assumed to be symmetric, or if we replace absolute minimizers with non-trivial minimizers. ◀

We now establish that the perturbation bound approach yields exactly the same lower bound as the generalized cut dimension. Our proof will make use of the following observation.

▶ **Observation 14.** *For any $g \in \mathcal{G}(f)$, $g(S) = \vec{v}^S \cdot \vec{w}'$ (where $\vec{w}'$ is the weight vector defining $g(\cdot)$).*

Proof. First, recall that $g(S) := \sum_{i \in h(S)} w'_i$. Recall further that $v_i^S = 1$ whenever $w_i \neq 0$ and $i \in h(S)$. Importantly, note that $w_i = 0 \Leftrightarrow w'_i = 0$ for all $g(\cdot) \in \mathcal{G}(f)$, so in fact $v_i^S = 1$ whenever $w'_i \neq 0$ and $i \in h(S)$ (and 0 otherwise). This immediately implies that $\vec{v}^S \cdot \vec{w}' = \sum_{i \in h(S)} w'_i = g(S)$. ◀

▶ **Theorem 15.** *Let $f(\cdot)$ be (symmetric) weight-based. Then the (Symmetric, Non-Trivial) Perturbation Bound of $f(\cdot)$ is exactly equal to the Generalized (Non-Trivial) Cut Dimension of $f(\cdot)$.*

Proof. We break the proof down into two lemmas, one establishing that the Perturbation Bound is at most the Generalized Cut Dimension, and one establishing that the Perturbation Bound is at least the Generalized Cut Dimension. We first establish the easy direction, that if $f(\cdot)$ has Generalized (Non-Trivial) Cut Dimension d, it witnesses a (Symmetric, Non-Trivial) Perturbation Bound of at most d. For simplicity of notation throughout the proof, we explicitly prove the standard case, but the claims for Symmetric and Non-Trivial follow verbatim.

▶ **Lemma 16.** *For all (Symmetric) weight-based $f(\cdot)$, the (Symmetric, Non-Trivial) Perturbation Bound is at most the Generalized (Non-Trivial) Cut Dimension.*

Proof. Say that $f(\cdot)$ has Generalized Cut Dimension d, and let $S_1, \ldots, S_d$ be such that $v^{S_1}, \ldots, v^{S_d}$ form a basis for the span of $\{\vec{v}^S\}_{S \in \mathcal{M}_f}$. We claim that queries to $S_1, \ldots, S_d$ completely determine $g(S) = f(S)$ for all $S \in \mathcal{M}_f$ and all $g(\cdot) \in \mathcal{G}(f)$. If true, this establishes a set of q queries for which there does not exist a $g(\cdot) \in \mathcal{G}(f)$ consistent with these queries for which $\min_S\{g(S)\} \neq \min_S\{f(S)\}$ (and therefore the Perturbation Bound for $f(\cdot)$ is at most d).

Consider any $S \in \mathcal{M}_f$. Then we know by definition of the Generalized Cut Dimension that $\vec{v}^S = \sum_i c_i \vec{v}^{S_i}$ for some $c_1, \ldots, c_d \in \mathbb{R}$. We claim that this implies that $g(S) = \sum_i c_i g(S_i)$ *for any* $g(\cdot) \in \mathcal{G}(f)$. This follows from the following equalities, which make use of Observation 14.

$$\begin{aligned} g(S) &= \vec{v}^S \cdot \vec{w}' \\ &= \sum_i c_i \vec{v}^{S_i} \cdot \vec{w}' \\ &= \sum_i c_i \cdot g(S_i). \end{aligned}$$

Therefore, if we query $S_1, \ldots, S_d$ and learn that $g(S_i) = f(S_i)$, this fully determines $g(S) = f(S)$ for all $S \in \mathcal{M}_f$, and therefore establishes that the Perturbation Bound for $f(\cdot)$ is at most d. ◀

We now show the hard direction: Perturbation Bound is at least the Generalized Cut Dimension.

▶ **Lemma 17.** *Any (Symmetric) weight-based $f(\cdot)$ witnesses a (Symmetric, Non-Trivial) Perturbation Bound of d, the (Non-Trivial) Generalized Cut Dimension.*

Proof. Let $T_1, \ldots, T_{d-1}$ be any $d-1$ sets queried. Let X denote the subspace of vectors $\vec{y}$ which satisfy the linear equations $\vec{v}^{T_i} \cdot \vec{y} = 0$ for all $1 \leq i \leq d-1$. Observe that X has dimension at least $m - d + 1$. Let Y denote the subspace of vectors spanned by $\{\vec{v}^S\}_{S \in \mathcal{M}_f}$. Observe that Y has dimension d.

The dimension of X ($\geq m - d + 1$) and the dimension of Y (d) sum to $> m$. This means that there exists a non-zero vector, $\vec{z} \in X \cap Y$.[5] Because $\vec{z} \in X$, we can add $\varepsilon\vec{z}$ to $\vec{w}$ for any ε and arrive at a $\vec{w}'$ which is consistent with the queries so far. Because $\vec{z} \in Y$, we must have $z_i = 0$ whenever $w_i = 0$ (because all $\vec{v}^S$ have $v_i = 0$ when $w_i = 0$). Therefore, there exists a sufficiently small ε such that $\vec{w} + \varepsilon\vec{z}$ results in a $g(\cdot)$ which is consistent with all $d-1$ queries so far, and is in $\mathcal{G}(f)$, and also $\vec{w} - \varepsilon\vec{z}$ results in such a $g(\cdot)$ as well.

Consider now $\vec{z} \cdot \vec{v}^S$ for any $S \in \mathcal{M}_f$. If $\vec{z} \cdot \vec{v}^S > 0$, then when $\vec{w}' := \vec{w} - \varepsilon\vec{z}$, we have $g(S) < f(S)$, and therefore $\min_S\{g(S)\} < \min_S\{f(S)\}$, meaning that we have found the desired Perturbation Bound $g(\cdot)$ for these $d-1$ queries. If $\vec{z} \cdot \vec{v}^S < 0$ we can instead use $\vec{w}' := \vec{w} + \varepsilon\vec{z}$. So if these $d-1$ queries have no witness, it must be that $\vec{z} \cdot \vec{v}^S = 0$ for all $S \in \mathcal{M}_f$. In particular that this holds for the basis $\vec{v}^{S_1}, \ldots, \vec{v}^{S_d}$ of Y. To summarize this paragraph: unless $\vec{v}^{S_i} \cdot \vec{z} = 0$ for all i (note that these S_i were not necessarily queried), then these $d-1$ queries have a witness for the Perturbation Bound.

We will now establish that we can't have $\vec{z} \cdot \vec{v}^{S_i} = 0$ for all i, which will establish that in fact there is a witness for these $d-1$ queries (and all $d-1$ queries, since they were arbitrary). Consider that because $\vec{z} \in Y$, we can write $\vec{z} = \sum_i \beta_i \vec{v}^{S_i}$ for some $\vec{\beta}$ which is not $\vec{0}$. If $\vec{z} \cdot \vec{v}^{S_i} = 0$ for all i we have

$$\sum_i \beta_i \vec{v}^{S_i} \cdot \vec{v}^{S_j} = 0, \quad \forall j.$$

[5] To see why this is the case, write a basis $\mathcal{B}_X = \{v_1, v_2, \ldots, v_{m-q}\}$ of X and a basis $\mathcal{B}_Y = \{w_1, w_2, \ldots, w_d\}$ of Y. If $\mathcal{B}_X \cap \mathcal{B}_Y$ is non-empty then we are of course done, otherwise $\mathcal{B}_X \cup \mathcal{B}_Y$ is a set of strictly more than m vectors in $\mathbb{R}^m$. Hence they must be linearly dependent, implying we can write $\alpha_1 v_1 + \ldots \alpha_{m-q} v_{m-q} + \beta_1 w_1 + \ldots + \beta_d w_d = 0$ for some coefficients $\{\alpha_i\}$, $\{\beta_j\}$ that are not all zero. Then note that $\beta_1 w_1 + \ldots \beta_d w_d$ is clearly in both X and Y, and cannot be zero as otherwise all coefficients would be zero (because both $\mathcal{B}_X$ and $\mathcal{B}_Y$ are linearly independent).

Therefore, if we let A denote the $d \times m$ matrix whose rows are the vectors $\vec{v}^{S_i}$, we get that:

$$(A \cdot A^T) \begin{bmatrix} \beta_1 \\ \vdots \\ \beta_d \end{bmatrix} = 0$$

Because $\vec{v}^{S_1}, \ldots, \vec{v}^{S_d}$ form a basis for Y we know A, A^T, and $A \cdot A^T$ have rank d.[6] But $\vec{\beta}$ is a non-zero vector in the kernel of the $d \times d$ matrix $A \cdot A^T$, which is a contradiction. Therefore, we must have $\vec{z} \cdot \vec{v}^{S_i} \neq 0$ for some i, implying that there exists the desired $g(\cdot)$ for any set of $d-1$ queries, and the Perturbation Bound is hence at least d. ◀

The proof of the theorem now follows directly from Lemmas 16 and 17. ◀

Theorem 15 lets us now restrict attention to the study of generalized cut dimension if we aim to prove lower bounds through the canonical perturbation approach. The subsequent sections establish that this is fruitful for symmetric, non-trivial SFM, but not for standard SFM.

3.3 An Undirected Graph with Global Cut Dimension $3n/2 - 2$

In this section, we provide an explicit undirected graph G on n vertices which has global cut dimension $3n/2 - 2$. This establishes the following theorem:

▶ **Theorem 18.** *The query complexity of Symmetric Non-Trivial SFM is at least* $3n/2 - 2$.

Proof. First, let n be odd and $n \geq 3$. Then $n = 2a + 1$ for some $a \geq 1$, so label the vertices of G as $\{v, w_1, w_1', w_2, w_2', \ldots, w_a, w_a'\}$. For edges (all undirected), put an edge between v and all other nodes, and an edge between w_i and w_i' for all i (and no other edges). It is easy to see that every cut in G has value at least 2, and that the mincuts indeed have value 2. The mincuts either separate w_i from the rest of the graph, w_i' from the rest of the graph, or $\{w_i, w_i'\}$ from the rest of the graph.

For any $i \in [a]$, let i_1, i_2, i_3 denote the three positions in indicator vectors corresponding to the three edges (v, w_i), (v, w_i'), (w_i, w_i'). Restricted to these positions, the indicator vectors for the three minimum cuts $\{w_i\}$, $\{w_i'\}$, $\{w_i, w_i'\}$ are $(1, 0, 1)$, $(0, 1, 1)$, and $(1, 1, 0)$, which span a subspace of dimension three. As these three cuts have zeroes for all other entries, the full vectors also span a subspace of dimension three. For each $i \in [a]$, the set of three indices referenced above are distinct, which means that taking all these indicator vectors together has rank $3a$.

As $n = 2a + 1$, $3a = 3(n-1)/2$. So the claim holds when n is odd. If n is even, use exactly the same construction on $n - 1$ nodes, and connect the remaining node to v with an edge of weight two. Now there is one additional mincut (separating the extra node from the rest), so the dimension is $3a + 1 = 3(n-2)/2 + 1 = 3n/2 - 2$. ◀

[6] A short proof of this is through the singular value decomposition (SVD) of A. Write $A = U\Sigma V$ where $U \in \mathbb{R}^{d \times d}$, $\Sigma \in \mathbb{R}^{d \times m}$, and $V \in \mathbb{R}^{m \times m}$ (where U and V satisfy $UU^T = I$ and $VV^T = I$, and Σ is diagonal with d non-zero entries). Note then that $A \cdot A^T = U\Sigma VV^T\Sigma^T U^T = U(\Sigma\Sigma^T)U^T$. As $\Sigma\Sigma^T$ is diagonal of rank d and $UU^T = I$, this is a singular value decomposition of $A \cdot A^T$, and directly implies that its rank is d.

3.4 Generalized Cut Dimension is at most $n + 1$

The previous section establishes that the Non-Trivial Symmetric Cut Dimension can be much larger than n, which leads to novel lower bounds. In this section, we establish that this approach will not yield novel lower bounds for standard SFM (and by Theorem 15, neither will the canonical perturbation argument for weight-based functions).

▶ **Theorem 19.** *The Generalized Cut Dimension of any weight-based function is at most* $n + 1$.

Proof. First, recall that for any submodular $f(\cdot)$, the set of minimizes $\mathcal{M}_f$ is closed under union and intersection.[7] For each $i \in [n]$, define $S_i := \cap_{S \in \mathcal{M}_f, i \in S} S$ (if there exists a minimizer containing i, otherwise let S_i be null). If S_i is not null, then $S_i \in \mathcal{M}_f$, because $\mathcal{M}_f$ is closed under intersection. Our goal will be to show that these S_i (and $\emptyset$, if $\emptyset \in \mathcal{M}_f$) span $\mathcal{M}_f$ through a sequence of lemmas.

Define the *base sets* $\mathcal{B}$ of $\mathcal{M}_f$ to be the set of all non-null S_i, together with $\emptyset$ (if $\emptyset \in \mathcal{M}_f$). It is clear that $\mathcal{B}$ has size at most $n + 1$. It is also the case that every minimizer $S \in \mathcal{M}_f$ can be written as the union of elements in $\mathcal{B}$:

▶ **Lemma 20.** *For all* $S \in \mathcal{M}_f$, $S = \cup_{i \in S} S_i$.

Proof. For any $i \in S$, we know that $i \in S_i$ which means that $S \subseteq \cup_{i \in S} S_i$. We need only show that for any $i \in S$, $S_i \subseteq S$. This is true by definition of S_i because S is a minimizer containing i. ◀

We next show that the base sets "cover" $\mathcal{M}_f$ in the following sense. Say that a set S is covered by $\mathcal{B}$ if either: (a) $S \in \mathcal{B}$, or (b) S can be written as the union of two sets which are covered by $\mathcal{B}$.

▶ **Lemma 21.** *Every set in* $\mathcal{M}_f$ *is covered by* $\mathcal{B}$.

Proof. Assume for contradiction that there is some $S \in \mathcal{M}_f$ which is not covered by $\mathcal{B}$. Take the S which minimizes $|S|$. Then clearly $S \notin \mathcal{B}$. So pick an arbitrary $i \in S$ and we can write $S = \cup_{j \in S} S_j = S_i \cup (\cup_{j \in S \setminus S_i} S_j)$. S_i is clearly non-empty, and also because $S \notin \mathcal{B}$, it is not equal to S. Similarly, $\cup_{j \notin S_i} S_j$ is non-empty (or else S_i would equal S), and is also not equal to S (because it does not contain i). Because $|\cup_{j \in S \setminus S_i} S_j| < |S|$, it is covered. We have just written S as the union of two covered sets, so therefore S is also covered, a contradiction. ◀

Now, we are ready for the last step. We will argue that for all $g \in \mathcal{G}(f)$, knowledge of $g(S), g(T)$, and $g(S \cap T)$ suffices to deduce $g(S \cup T)$. We will then deduce that knowledge of $g(S)$ for all $S \in \mathcal{B}$ suffices to deduce $g(S)$ for all $S \in \mathcal{M}_f$.

▶ **Lemma 22.** *Let* $S, T \in \mathcal{M}_f$. *Then* $\vec{v}^{S \cup T} = \vec{v}^S + \vec{v}^T - \vec{v}^{S \cap T}$.

Proof. Recall from the definition of weight-based that $h(S \cap T) \overline{\cup} h(S \cup T) \subseteq h(S) \overline{\cup} h(T)$. But recall also that $\sum_{i \in h(S \cap T) \overline{\cup} h(S \cup T)} w_i = \sum_{i \in h(S) \overline{\cup} h(T)} w_i$ because all of $S, T, S \cap T, S \cup T$ are minimizers. As all w_i are non-negative, this means that the only possible i which are counted fewer times on the LHS than the RHS must have $w_i = 0$. This immediately means that $\vec{v}^{S \cap T} + \vec{v}^{S \cup T} = \vec{v}^S + \vec{v}^T$. ◀

[7] To see this, recall that $f(S \cup T) + f(S \cap T) \leq f(S) + f(T)$. If both of the sets on the RHS are minimizers, both sets on the LHS must be as well.

▶ **Corollary 23.** *Every $S \in \mathcal{M}_f$ has $\vec{v}^S \in span(\{\vec{v}^T\}_{T\in\mathcal{B}})$.*

Proof. Lemma 22 establishes that if S, T, and $S \cap T$ are in span$(\{\vec{v}^T\}_{T\in\mathcal{B}})$, then so is $S \cup T$. Assume for contradiction that some $S \in \mathcal{M}_f$, $\vec{v}^S$ is not in span$(\{\vec{v}^T\}_{T\in\mathcal{B}})$, and take the one of minimal $|S|$. Then S is covered by $\mathcal{B}$ by Lemma 21, so we can write $S = A \cup B$, where $|A|, |B| < |S|$. $\vec{v}^A, \vec{v}^B$, and $\vec{v}^{A\cap B}$ are therefore in span$(\{\vec{v}^T\}_{T\in\mathcal{B}})$. By Lemma 22, so then is $\vec{v}^S$, a contradiction. ◀

The proof is now concluded: we have argued that $|\mathcal{B}| \leq n+1$, and Corollary 23 establishes that all of $\mathcal{M}_f$ is in the span of $\mathcal{B}$, so the Generalized Cut Dimension is at most $n+1$.

Importantly, observe that this proof fails to hold for the Generalized Non-Trivial Cut Dimension (it must, as we previously demonstrated an example with Generalized Non-Trivial Cut Dimension $3n/2-2$). The point of failure is that the set of Non-Trivial minimizers is not closed under intersection or union (if either the intersection is empty or the union is $[n]$). ◀

4 A $\binom{n}{2}$ Query Lower Bound for Non-Trivial SFM

In this section, we establish our lower bound for Non-Trivial SFM. The class of functions we consider will be the following:

▶ **Definition 24.** *A function $f(\cdot)$ is* cost-based *if there exists a cost function $c : 2^{[n]} \to \mathbb{R}_+$ with $c(T) = 0$ whenever $|T| \leq 1$ such that $f(S) = \sum_{i\in S} f(\{i\}) - \sum_{T\subseteq S} c(T)$.*

▶ **Proposition 25.** *Every cost-based function is submodular.*

Proof. We will establish that $f(S \cup \{i\}) - f(S) \leq f(T \cup \{i\}) - f(T)$ whenever $T \subseteq S$ and $i \notin S$. Observe that for any $X \subseteq [n]$ with $i \notin X$ we have $f(X \cup \{i\}) - f(X) = f(\{i\}) - \sum_{U\subseteq X} c(U \cup \{i\})$. $f(\{i\})$ is independent of X, and the second term is clearly at least as large for $X = S$ than $X = T$ (as $c(U) \geq 0$ for every U). Therefore, $f(\cdot)$ has diminishing marginal returns and is submodular. ◀

▶ **Theorem 26.** *The query complexity of Non-Trivial SFM is at least $\binom{n}{2}$.*

Proof. Consider the following $\binom{n}{2}+1$ cost functions. Define $c(\cdot)$ so that $c(S) = 0$ if $|S| \leq n-2$, $c([n] \setminus \{i\}) = n-1$ for all i, and $c([n]) = 2n$. Call the associated function $f(\cdot)$ where we set $f(\{i\}) = 1$ for all i. Then $f(S) = |S|$ when $|S| \leq n-2$, $f([n] \setminus \{i\}) = 0$, and $f([n]) = -n^2$.

For every $1 \leq i < j \leq n$ define $c_{ij}(\cdot)$ so that $c_{ij}(S) = 0$ if $|S| \leq n-3$. For sets of size $n-2$, set $c_{ij}([n] \setminus \{i, j\}) = n-1$, and $c_{ij}([n] \setminus \{k, \ell\}) = 0$ for all other $\{k, \ell\} \neq \{i, j\}$. For sets of size $n-1$, set $c_{ij}([n] \setminus \{i\}) = c_{ij}([n] \setminus \{j\}) = 0$, and $c_{ij}([n] \setminus \{k\}) = n-1$ for all $k \notin \{i, j\}$. Finally, set $c_{ij}([n]) = 3n-1$. Call the associated function $f_{ij}(\cdot)$ where we set $f_{ij}(\{\ell\}) = 1$ for all ℓ. Observe that $f_{ij}(S) = |S|$ when $|S| \leq n-3$, $f_{ij}(S) = n-2$ if $|S| = n-2$ and $S \neq [n] \setminus \{i, j\}$, $f_{ij}([n] \setminus \{i, j\}) = -1$, $f_{ij}([n] \setminus \{\ell\}) = 0$ for all ℓ, and $f_{ij}([n]) = -n^2$.

Observe, importantly, that the non-trivial minimum of $f(\cdot)$ is 0, while the non-trivial minimum of $f_{ij}(\cdot)$ is -1 for all i, j. Observe also that $f(\cdot)$ and $f_{ij}(\cdot)$ *differ only on their evaluation for* $[n] \setminus \{i, j\}$. Therefore, an adversary could answer any query S with $f(S)$. If the algorithm terminates with fewer than $\binom{n}{2}$ queries, then there is some $[n] \setminus \{i, j\}$ that has not been queried. Therefore, the adversary is free to decide that the function is either $f(\cdot)$ or $f_{ij}(\cdot)$. As the value of the minima for these two functions are distinct, the algorithm cannot be correct. Therefore, any correct algorithm for Non-Trivial SFM must make at least $\binom{n}{2}$ queries. ◀

5 Conclusions and Open Questions

We establish the first query lower bounds exceeding n for SFM ($2n$), Non-Trivial Symmetric SFM ($3n/2 - 2$), and Non-Trivial SFM ($\binom{n}{2}$). Our asymmetric lower bounds are from direct constructions. Our symmetric lower bound arises from the novel *cut dimension*.

Our work leaves open a clear direction for future work: what is the maximum possible Global Cut Dimension for an undirected graph? Or more generally, what is the maximum possible Non-Trivial Symmetric Generalized Cut Dimension of a weight-based function?

It is also of course generally important to further improve query complexity lower bounds for SFM variants (and also develop better algorithms).

A Omitted Proofs from Section 2

We will make use of the following technical lemma:

▶ **Lemma 27.** *If $R_i \subseteq S$, then $f^{\vec{c}}_{\sigma}(S) \leq (|S| - i) \cdot (n + 2 - i)$.*

Proof. If $S = R_{j(S)}$, then $f^{\vec{c}}_{\sigma}(S) = -c_j \leq 0 \leq (|S| - i) \cdot (n + 2 - i)$, as desired. Otherwise because $j(S) \geq i$ (by definition of $j(S)$), we know $|S| - j(S) \leq |S| - i$ and $n + 2 - j(S) \leq n + 2 - i$, which implies that $f^{\vec{c}}_{\sigma}(S) \leq (|S| - i) \cdot (n + 2 - i)$ as desired. ◀

Proof of Lemma 6. Let X, Y be any two subsets of $[n]$; we will show that

$$f^{\vec{c}}_{\sigma}(X) + f^{\vec{c}}_{\sigma}(Y) \geq f^{\vec{c}}_{\sigma}(X \cup Y) + f^{\vec{c}}_{\sigma}(X \cap Y).$$

Note that if $X \subseteq Y$, the inequality is trivially satisfied, as $X \cap Y = X$ and $X \cup Y = Y$; the inequality is also trivially satisfied if $Y \subseteq X$. Hence, we will assume that neither set is contained in the other; note that this means neither set could equal $\emptyset$ or $[n]$. From here we consider two separate cases.

In the first case, assume neither X nor Y is an important set. Let R_i be the largest important set that is a subset of X and R_j be the largest important set that is a subset of Y. Without loss of generality, let's assume that $i \geq j$. Let $A := (X \setminus R_i) \setminus (Y \setminus R_i)$, $B := (Y \setminus R_i) \setminus (X \setminus R_i)$, $C := (X \setminus R_i) \cap (Y \setminus R_i)$, and $D := Y \cap (R_i \setminus R_j)$ and for convenience define $a := |A|$, $b := |B|$, $c := |C|$, and $d := |D|$. From the definition of f we have that

$$f^{\vec{c}}_{\sigma}(X) = (a + c) \cdot (n + 2 - i)$$

and

$$f^{\vec{c}}_{\sigma}(Y) = (b + c + d) \cdot (n + 2 - j).$$

First, we prove the inequality when $i = j$. In this case, $D = \emptyset$, but A and B are both non-empty (as otherwise either $X \subseteq Y$ or $Y \subseteq X$). As $X \cap Y$ contains R_i we have

$$f^{\vec{c}}_{\sigma}(X \cap Y) \leq c(n + 2 - i)$$

from Lemma A.1. As $X \cup Y$ contains R_i we similarly have

$$f^{\vec{c}}_{\sigma}(X \cup Y) \leq (a + b + c) \cdot (n + 2 - i).$$

Hence,

$$\begin{aligned} f^{\vec{c}}_{\sigma}(X \cup Y) + f^{\vec{c}}_{\sigma}(X \cap Y) &\leq (a+b+2c)(n+2-i) \\ &= (a+c)(n+2-i) + (b+c)(n+2-i) \\ &= f^{\vec{c}}_{\sigma}(X) + f^{\vec{c}}_{\sigma}(Y) \end{aligned}$$

which proves the inequality as $d = 0$. We'll next prove the inequality assuming $i > j$. In that case, we again have that R_j is a subset of $X \cap Y$ so

$$f^{\vec{c}}_{\sigma}(X \cap Y) \leq (c+d)(n+2-j)$$

by Lemma A.1. Similarly, R_i is a subset of $X \cup Y$ so

$$f^{\vec{c}}_{\sigma}(X \cup Y) \leq (a+b+c)(n+2-i).$$

Hence it is sufficient to prove

$$(a+c) \cdot (n+2-i) + (b+c+d) \cdot (n+2-j) \geq (c+d)(n+2-j) + (a+b+c)(n+2-i)$$

which reduces to $b(n+2-j) \geq b(n+2-i)$, which is true as $b \geq 0$ and $i > j$. Hence we have completed our analysis for the first case.

Our second case is when X is an important set and Y is not. Say $X = R_i$ for some $i \geq 1$ and let R_j be the largest important set contained in Y. Clearly, $i > j$ (as otherwise we would have $X \subseteq Y$). Let $A := Y \setminus R_i$, $B := (Y \setminus R_j) \cap R_i$, and for convenience define $a := |A|$ and $b := |B|$. Note that $a > 0$ (as otherwise $Y \subseteq X$) and that there are exactly $a + b$ elements of Y not in R_j. Because $X \cap Y$ contains R_j but not R_{j+1} we know

$$f^{\vec{c}}_{\sigma}(X \cap Y) = b \cdot (n+2-j).$$

Also, as $X \cup Y$ contains R_i we know that

$$f^{\vec{c}}_{\sigma}(X \cup Y) \leq a \cdot (n+2-i).$$

Hence it is sufficient to prove

$$-c_i + (a+b) \cdot (n+2-j) \geq b \cdot (n+2-j) + a \cdot (n+2-i).$$

This inequality is equivalent to $-c_i + a(i-j) \geq 0$, which is true since $a \geq 1, i - j \geq 1$ and $c_i \leq 1$, hence concluding the second case.

By symmetry, we now also have the same conclusion if Y is an important set and X is not. Moreover, we need not consider the case where both are important sets as then one must be a subset of the other. Hence we have the result. ◀

B On Cut Queries in Directed Graphs

In this section, we examine the limits of cut queries when learning the edges of a graph. This appendix is not directly relevant to our main results, but may be of interest for future work.

▷ Claim 28. A directed weighted graph can be learned via cut queries up to directed cycles. That is, with cut queries one can learn a graph G' that is equivalent to the true graph G up to adding/deleting directed cycles. Moreover, no set of queries can determine the weight of a directed cycle.

Proof. We first work over unweighted graphs and show that a graph can be learned up to the direction of directed cycles. Let $G(V, E)$ be a directed, unweighted graph. First, we note that for any two vertices u and v in V, we can learn if

- both edges (u, v) and (v, u) exist,
- exactly one of the edges (u, v) and (v, u) exist (but not which one),
- or neither of these edges exist.

To see this, consider creating a new function $f'(\cdot)$ which outputs $f(S) + f(V \setminus S)$. Then $f'(\cdot)$ corresponds to an undirected *weighted* graph G' where the weight between two nodes is zero, one, or two (and equal to the number of edges between them in G). As G' is undirected, we can learn G' exactly using cut queries [17].[8]

Moreover, for every vertex u, by querying $\{u\}$ and $V \setminus \{u\}$, we know the in degree and the out degree of u.

Now, suppose two graphs G and G' both satisfy all the queries made so far. We claim that G can be converted to G' by flipping the direction of certain cycles. Let $e = (u, v)$ be an edge in G that does not exist in G'. We know that (v, u) must be an edge in G'. Suppose we flip edge (v, u) in G'. Now, the in degree of u in G' is one less than the in degree of u in G', while the out degree of u in G' is one more than that of G. Hence, there is an edge (u, v') in G', and an edge (v', u) in G. We flip this edge in G'. Continuing this way, we flip all edges in a path, until we reach v. If G' is the same as G, we are done, else, we pick another edge and repeat this procedure. Hence, G' and G are the same, up to the directions of directed cycles.

Moreover, for any cut queried, every directed cycle either does not contribute anything to the cut or adds exactly 1 to the cut (irrespective of the direction). Hence, the direction of cycles in a directed graph cannot be learned by cut queries.

This argument can be extended to weighted graphs as well. For weighted graphs, we can learn the sum of the weights of edges (u, v) and (v, u) for all edges, as well as the in degree and out degree of every vertex.

Suppose we have two graphs G and G' which satisfy all the queries made to learn the above. Similar to the unweighted case, we claim that G' can be converted to G by changing the weights of certain directed cycles. Let (u, v) be an edge which has weight w in G and w' in G'. We change the weight of (u, v) in G' to w, and add $w' - w$ to the weight of (v, u) in G'. Now, the in degree of u has increased by $w' - w$. Since the in degree of u is the same in both G and G' initially, this implies that there are edges incident on u in G whose weights differ from those in G' by exactly $w' - w$. We change the weights of each of those edges to match the ones in G, continuing till we complete each of these cycles. Hence, G and G' are identical up to the weights of certain directed cycles.

Note that each time we decrease the weight of a cycle in one direction by α, we increase the weight of the cycle in the other direction by exactly α. That is, the sum of the weights of the cycle in both directions remains constant. Let's assume that a cut query cuts k edges of this cycle. This implies that the cut query also cuts k edges of the cycle in the opposite direction. Hence, we can only determine the sum of the weights of these two cycles, irrespective of the number of queries made. ◁

▷ Claim 29. For a weighted undirected graph, when making s-t cut queries, the weight of edge (s, u) cannot be learned for any vertex u. Similarly, the weight of edge (u, t) cannot be learned for any vertex u.

[8] To see this, observe that $f'(\{u\}) + f'(\{v\}) - f'(\{u, v\})$ is exactly twice the weight of the edge between u and v in G'.

Proof. We first note that we can always learn the weight of edges of the form (u, v), with $u, v \neq s \neq t$. This can be done by querying $\{s\}$, $\{s, u\}$, $\{s, v\}$ and $\{s, u, v\}$. Hence, we can learn all edges except for those of the form (s, u) and (u, t) (because these queries are redundant or invalid in that case). After learning these weights, every query $S \cup \{s\}$ can be viewed as the sum of n weights (the weights of edges from S to t, and the weights of edges from $V \setminus S$ to s). Let us denote the weight of edge (s, u) as w_u, and the weight of edge (u, t) as w'_u. Every query $S \cup \{s\}$ can be written as a linear equation

$$\sum_{u \in S} w'_u + \sum_{u \in V \setminus S} w_u = c_S$$

Let α_S denote a $2n$ dimensional vector with the coefficients of the above equation. Let $\mathbf{w}$ be a $2n$ dimensional vector with w_u and the w'_u, for all u. The above equation can be written as

$$\langle \alpha_S, \mathbf{w} \rangle = c_S$$

Let us consider the subspace Π spanned by $\{\alpha_S \colon S \subseteq V \setminus \{s, t\}\}$. Let e_u denote the vector with a 1 in the position of edge (s, u) and zeros elsewhere. If $e_u \in \Pi$, we can compute the value of w_u. We show that $e_u \notin \Pi$, for all u.

To show this, it is enough to describe a vector in the kernel of Π, whose dot product with e_u is non-zero. Consider the vector β with 1 in the position of edges (s, u) and (u, t), and $-\frac{1}{n}$ elsewhere.

$$\langle e_u, \beta \rangle = 1$$

However, for any S,

$$\langle \alpha_S, \beta \rangle = 0$$

Hence, we cannot compute the weight of edge (s, u) for any vertex u. The same argument can also be made for the edge (u, t). ◁

Computation-Aware Data Aggregation

Abstract

Data aggregation is a fundamental primitive in distributed computing wherein a network computes a function of every nodes' input. However, while compute time is non-negligible in modern systems, standard models of distributed computing do not take compute time into account. Rather, most distributed models of computation only explicitly consider communication time.

In this paper, we introduce a model of distributed computation that considers *both* computation and communication so as to give a theoretical treatment of data aggregation. We study both the structure of and how to compute the fastest data aggregation schedule in this model. As our first result, we give a polynomial-time algorithm that computes the optimal schedule when the input network is a complete graph. Moreover, since one may want to aggregate data over a pre-existing network, we also study data aggregation scheduling on arbitrary graphs. We demonstrate that this problem on arbitrary graphs is hard to approximate within a multiplicative 1.5 factor. Finally, we give an $O(\log n \cdot \log \frac{\mathrm{OPT}}{t_m})$-approximation algorithm for this problem on arbitrary graphs, where n is the number of nodes and OPT is the length of the optimal schedule.

1 Introduction

Distributed systems drive much of the modern computing revolution. However, these systems are only as powerful as the abstractions which enable programmers to make use of them. A key such abstraction is data aggregation, wherein a network computes a function of every node's input. For example, if every node stored an integer value, a programmer could run data aggregation to compute the sum or the largest value of every node in the network. Indeed, the well-studied and widely-used AllReduce abstraction [29, 16] consists of a data aggregation step followed by a broadcast step.

The utility of modern systems is their ability to perform massive computations and so, applications of data aggregation often consist of a function which is computationally-intensive to compute. A rigorous theoretical study of data aggregation, then, must take the cost of computation into account. At the same time, one cannot omit the cost of communication, as many applications of data aggregation operate on large datasets which take time to transmit over a network.

However, to our knowledge, all existing models of distributed computation – e.g., the CONGEST [28], SINR [4], (noisy) radio network [21, 9, 7, 8], congested clique [12], dual graph [6], store-and-forward [22, 31], LOCAL [23], and telephone broadcast models [30, 20, 17] – all only consider the cost of communication. Relatedly, while there has been significant applied research on communication-efficient data aggregation algorithms, there has been relatively little work that explicitly considers the cost of computation, and even less work that considers how to design a network to efficiently perform data aggregation [25, 19, 26, 27, 18]. In this way, there do not seem to exist theoretical results for efficient data aggregation scheduling algorithms that consider both the cost of communication and computation.

Thus, we aim to provide answers to two theoretical questions in settings where both computation and communication are non-negligible:

1. *How should one structure a network to efficiently perform data aggregation?*
2. *How can one coordinate a fixed network to efficiently perform data aggregation?*

1.1 Our Model and Problem

The Token Network Model

So as to give formal answers to these questions we introduce the following simple distributed model, the Token Network Model. A Token Network is given by an undirected graph $G = (V, E)$, $|V| = n$, with parameters $t_c, t_m \in \mathbb{N}$ which describe the time it takes nodes to do computation and communication, respectively.[1]

Time proceeds in synchronous rounds during which nodes can compute on or communicate atomic tokens. Specifically, in any given round a node is busy or not busy. If a node is not busy and has at least one token it can *communicate*: any node that does so is busy for the next t_m rounds, at the end of which it passes one of its tokens to a neighbor in G. If a node is not busy and has two or more tokens, it can *compute*: any node that does so is busy for the next t_c rounds, at the end of which it combines (a.k.a. aggregates) two of its tokens into a single new token.[2] At a high level, this means that communication takes t_m rounds and computation takes t_c rounds.

[1] We assume $t_c, t_m = \text{poly}(n)$ throughout this paper.

[2] Throughout this paper, we assume for ease of exposition that the smaller of t_c and t_m evenly divides the larger of t_c and t_m, or equivalently that either t_c or t_m is 1.

The Token Computation Problem

We use our Token Network model to give a formal treatment of data aggregation scheduling. In particular, we study the Token Computation problem. Given an input Token Network, an algorithm for the Token Computation problem must output a schedule S which directs each node when to compute and when and with whom to communicate. A schedule is valid if after the schedule is run on the input Token Network where every node begins with a single token, there is one remaining token in the entire network; i.e., there is one node that has aggregated all the information in the network. We use $|S|$ to notate the length of S – i.e., the number of rounds S takes – and measure the quality of an algorithm by the length of the schedule that it outputs. For completeness, we give a more technical and formal definition in Appendix A.

Discussion of Modeling Choices

Our Token Network model and the Token Computation problem are designed to formally capture the challenges of scheduling distributed computations where both computation and communication are at play. In particular, combining tokens can be understood as applying some commutative, associative function to the private input of all nodes in a network. For instance, summing up private inputs, taking a minimum of private inputs, or computing the intersection of input sets can all be cast as instances of the Token Computation problem. We assume that the computation time is the same for every operation and that the output of a computation is the same size as each of the inputs as a simplifying assumption. We allow nodes to receive information from multiple neighbors as this sort of communication is possible in practice.

Lastly, our model should be seen as a so-called "broadcast" model [21] of communication. In particular, it is easy to see that our assumption that a node can send its token to only a single neighbor rather than multiple copies of its token to multiple neighbors is without loss of generality: One can easily modify a schedule in which nodes send multiple copies to one of equal length in which a node only ever sends one token per round. An interesting followup question could be to consider our problem in a non-broadcast setting.

1.2 Our Results

We now give a high-level description of our technical results.

Optimal Algorithm on Complete Graphs (Section 3)

We begin by considering how to construct the optimal data aggregation schedule in the Token Network model for complete graphs for given values of t_c and t_m. The principal challenge in constructing such a schedule is formalizing how to optimally pipeline computation and communication and showing that any valid schedule needs at least as many rounds as one's constructed schedule. We overcome this challenge by showing how to modify a given optimal schedule into an efficiently computable one in a way that preserves its pipelining structure. Specifically, we show that one can always modify a valid optimal schedule into another valid optimal schedule with a well-behaved recursive form. We show that this well-behaved schedule can be computed in polynomial time. Stronger yet, we show that the edges over which communication takes place in this schedule induce a tree. It is important to emphasize that this result has implications beyond producing the optimal schedule for a complete graph; it shows one optimal way to *construct* a network for data aggregation (if one had the freedom to include any edge), thereby suggesting an answer to the first of our two research questions.

Hardness and Approximation on Arbitrary Graphs (Section 4)

We next consider the hardness of producing good schedules efficiently for arbitrary graphs and given values of t_c and t_m. We first show that no polynomial-time algorithm can produce a schedule of length within a multiplicative 1.5 factor of the optimal schedule unless P = NP. This result implies that one can only *coordinate* data aggregation over a pre-existing network so well.

Given that an approximation algorithm is the best one can hope for, we next give an algorithm which in polynomial time produces an approximately-optimal Token Computation schedule. Our algorithm is based on the simple observation that after $O(\log n)$ repetitions of pairing off nodes with tokens, having one node in each pair route a token to the other node in the pair, and then having every node compute, there will be a single token in the network. The difficulty in this approach lies in showing that one can route pairs of tokens in a way that is competitive with the length of the optimal schedule. We show that by considering the paths in G traced out by tokens sent by the optimal schedule, we can get a concrete hold on the optimal schedule. Specifically, we show that a polynomial-time algorithm based on our observation produces a valid schedule of length $O(\mathrm{OPT} \cdot \log n \cdot \log \frac{\mathrm{OPT}}{t_m})$ with high probability,[3] where OPT is the length of the optimal schedule. Using an easy bound on OPT, this can be roughly interpreted as an $O(\log^2 n)$-approximation algorithm. This result shows that data aggregation over a pre-existing network can be *coordinated* fairly well.

Furthermore, it is not hard to see that when $t_c = 0$ and $t_m > 0$, or when $t_c > 0$ and $t_m = 0$, our problem is trivially solvable in polynomial time. However, we show hardness for the case where $t_c, t_m > 0$, which gives a formal sense in which computation and communication cannot be considered in isolation, as assumed in previous models of distributed computation.

1.3 Terminology

For the remainder of this paper we use the following terminology. A token a *contains* token a' if $a = a'$ or a was created by combining two tokens, one of which contains a'. For shorthand we write $a' \in a$ to mean that a contains a'. A *singleton* token is a token that only contains itself; i.e., it is a token with which a node started. We let a_v be the singleton token with which vertex v starts and refer to a_v as v's singleton token. The *size* of a token is the number of singleton tokens it contains. Finally, let a_f be the last token of a valid schedule S; the *terminus* of S is the node at which a_f is formed by a computation.

2 Related Work

Cornejo et al. [10] study a form of data aggregation in networks that change over time, where the goal is to collect tokens at as few nodes as possible after a certain time. However, they do not consider computation time and they measure the quality of their solutions with respect to the optimal offline algorithm. Awerbuch et al. [5] consider computation and communication in a setting where jobs arrive online at nodes, and nodes can decide whether or not to complete the job or pass the job to a neighbor. However, they study the problem of job scheduling, not data aggregation, and, again, they approach the problem from the perspective of competitive analysis with respect to the optimal offline algorithm.

[3] Meaning at least $1 - 1/\mathrm{poly}(n)$ henceforth.

Another line of theoretical work related to our own is a line of work in centralized algorithms for scheduling information dissemination [30, 20, 17]. In this problem, an algorithm is given a graph and a model of distributed communication, and must output a schedule that instructs nodes how to communicate in order to spread some information. For instance, in one setting an algorithm must produce a schedule which, when run, broadcasts a message from one node to all other nodes in the graph. The fact that these problems consider spreading information is complementary to the way in which we consider consolidating it. However, we note that computation plays no role in these problems, in contrast to our Token Computation problem.

Of these prior models of communication, the model which is most similar to our own is the telephone broadcast model. In this model in each round a node can "call" another node to transmit information or receive a call from a single neighbor. Previous results have given a hardness of approximation of 3 [13] for broadcasting in this model and logarithmic as well as sublogarithmic approximation algorithms for broadcasting [14]. The two notable differences between this model and our own are (1) in our model nodes can receive information from multiple neighbors in a single round[4] and (2) again, in our model computation takes a non-negligible amount of time. Note, then, that even in the special case when $t_c = 0$, our model does not generalize the telephone broadcast model; as such we do not immediately inherit prior hardness results from the telephone broadcast problem. Furthermore, (1) and especially (2) preclude the possibility of an easy reduction from our problem to the telephone broadcast problem.

There is also a great deal of related applied work; additional details are in Appendix B.

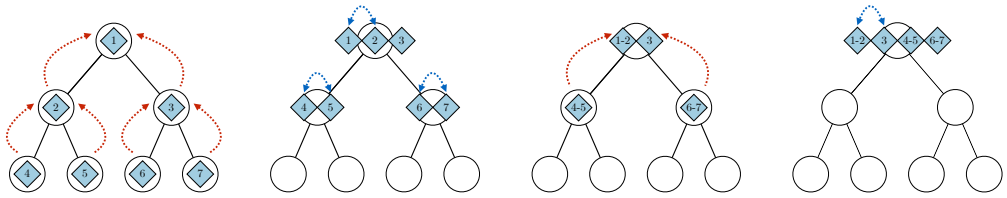
3 Optimal Algorithm for Complete Graphs

In this section we provide an optimal polynomial-time algorithm for the Token Computation problem on a complete graph. The schedule output by our algorithm ultimately only uses the edges of a particular tree, and so, although we reason about our algorithm in a fully connected graph, in reality our algorithm works equally well on said tree. This result, then, informs the design of an optimal network.

3.1 Binary Trees (Warmup)

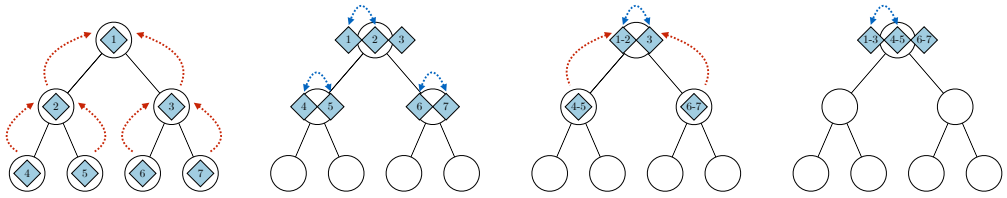
We build intuition by considering a natural solution to Token Computation on the complete graph: naïve aggregation on a rooted binary tree. In this schedule, nodes do computations and communications in lock-step. In particular, consider the schedule S which alternates the following two operations until only a single node with tokens remains on a fixed binary tree: (1) every non-root node that has a token sends its token to its parent in the binary tree; (2) every v with at least two tokens performs one computation. Once only one node has any tokens, that node performs computation until only a single token remains. After $\log n$ iterations of this schedule, the root of the binary tree is the only node with any tokens, and thereafter only performs computation for the remainder of S. However, S does not efficiently pipeline communication and computation: after each iteration of (1) and (2), the root of the tree gains an extra token. Therefore, after $\log n$ repetitions of this schedule, the root has $\log n$ tokens. In total, then, this schedule aggregates all tokens after essentially $\log n(t_c + t_m) + \log n \cdot t_c$ rounds. See Figure 1.

[4] See above for the justification of this assumption.



(a) Round 1. **(b)** Round 2. **(c)** Round 3. **(d)** Round 4.

Figure 1 The naïve aggregation schedule on a binary tree for $t_c = t_m = 1$ and $n = 7$ after 4 rounds. tokens are represented by blue diamonds; a red arrow from node u to node v means that u sends to v; and a double-ended blue arrow between two tokens a and b means that a and b are combined at the node. Notice that the root gains an extra token every 2 rounds.



(a) Round 1. **(b)** Round 2. **(c)** Round 3. **(d)** Round 4.

Figure 2 The aggregation schedule on a binary tree for $t_c = t_m = 1$ and $n = 7$ after 4 rounds where the root pipelines its computations. Again, tokens are represented by blue diamonds; a red arrow from node u to node v means that u sends to v; and a double-ended blue arrow between two tokens a and b means that a and b are combined at the node. Notice that the root will never have more than 3 tokens when this schedule is run.

For certain values of t_c and t_m, we can speed up naïve aggregation on the binary tree by pipelining the computations of the root with the communications of other nodes in the network. In particular, consider the schedule S' for a fixed binary tree for the case when $t_c = t_m$ in which every non-root node behaves exactly as it does in S but the root always computes. Since the root always computes in S', even as other nodes are sending, it does not build up a surplus of tokens as in S. Thus, this schedule aggregates all tokens after essentially $\log n(t_c + t_m)$ rounds when $t_c = t_m$, as shown in Figure 2.

However, as we will prove, binary trees are not optimal even when they pipeline computation at the root and $t_c = t_m$. In the remainder of this section, we generalize this pipelining intuition to arbitrary values of t_c and t_m and formalize how to show a schedule is optimal.

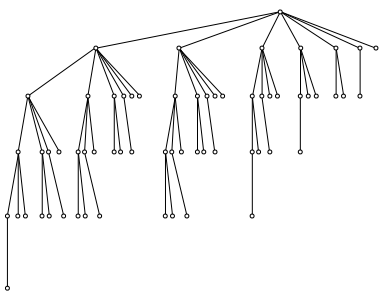


Figure 3 $T(16)$ for $t_c = 2$, $t_m = 1$.

3.2 Complete Graphs

We now describe our optimal polynomial-time algorithm for complete graphs. This algorithm produces a schedule which greedily aggregates on a particular tree, T_n^*. In order to describe this tree, we first introduce the tree $T(R, t_c, t_m)$. This tree can be thought of as the largest tree for which greedy aggregation aggregates all tokens in R rounds given computation cost t_c and communication cost t_m. We will overload notation and let $T(R)$ denote $T(R, t_c, t_m)$ for some fixed values of t_c and t_m. Let the root of a tree be the node in that tree with no parents. Also, given a tree T_1 with root r we define T_1 JOIN T_2 as T_1 but where r also has T_2 as an additional subtree. We define $T(R)$ as follows (see Figure 3 for an example):

$$T(R) \coloneqq \begin{cases} \text{A single leaf} & \text{if } R < t_m + t_c \\ T(R - t_c) \text{ JOIN } T(R - t_c - t_m) & \text{otherwise} \end{cases}$$

Since an input to the TOKEN COMPUTATION problem consists of n nodes, and not a desired number of rounds, we define $R^*(n, t_c, t_m)$ to be the minimum value such that $|T(R^*(n, t_c, t_m))| \geq n$. We again overload notation and let $R^*(n)$ denote $R^*(n, t_c, t_m)$. Formally,

$$R^*(n) \coloneqq \min\{R : |T(R)| \geq n\}.$$

We let T_n^* denote $T(R^*(n))$. For ease of presentation we assume that $|T_n^*| = n$.[5]

The schedule produced by our algorithm will simply perform greedy aggregation on T_n^*. We now formally define greedy aggregation and establish its runtime on the tree $T(R)$.

▶ **Definition 1** (Greedy Aggregation). Given an r-rooted tree, let the *greedy aggregation* schedule be defined as follows. In the first round, every node except for r sends its token to its parent. In subsequent rounds we do the following. If a node is not busy and has at least two tokens, it performs a computation. If a non-root node is not busy, has exactly one token, and has received a token from every child in previous rounds, it forwards its token to its parent.

▶ **Lemma 2.** *Greedy aggregation on $T(R)$ terminates in R rounds.*

Proof. We will show by induction on $k \geq 0$ that greedy aggregation results in the root of $T(k)$ having a token of size $|T(k)|$ after k rounds. The base cases of $k \in [0, t_m + t_c)$ are trivial, as nothing needs to be combined. For the inductive step, applying the inductive hypothesis and using the recursive structure of our graph tells us that the root of $T(k + t_c)$ has a token of size $|T(k)|$ at its root in k rounds, and the root of the child $T(k - t_m)$ has a token of size $|T(k - t_m)|$ at its root in $k - t_m$ rounds. Therefore, by the definition of greedy aggregation, the root of $T(k - t_m)$ sends its token of size $|T(k - t_m)|$ to the root of $T(k + t_c)$ at time $k - t_m$, which means the root of $T(k + t_c)$ can compute a token of size $|T(k - t_m)| + |T(k)| = |T(k + t_c)|$ by round $k + t_c$. ◀

To build intuition about how quickly T_n^* grows, see Figure 6 for an illustration of $|T_n^*|$ as a function of n for specific values of t_c and t_m. Furthermore, notice that $T(R)$ and T_n^* are constructed in such a way that greedy aggregation pipelines computation and communication. We can now formalize our optimal algorithm, which simply outputs the greedy aggregation schedule on T_n^*, as Algorithm 1. The following theorem is our main result for this section.

[5] If $|T_n^*| > n$, then we could always "hallucinate" extra nodes where appropriate.

Algorithm 1 OptComplete(t_c, t_m, n).

Input: t_c, t_m, n
Output: A schedule for Token Computation on K_n with parameters t_c and t_m
Arbitrarily embed T_n^* into K_n
return Greedy aggregation schedule on T_n^* embedded in K_n

▶ **Theorem 3.** *Given a complete graph K_n on n vertices and any $t_m, t_c \in \mathbb{Z}^+$,* OptComplete *optimally solves* Token Computation *on the* Token Network *(K_n, t_c, t_m) in polynomial time.*

To show that Theorem 3 holds, we first note that OptComplete trivially runs in polynomial time. Therefore, we focus on showing that greedy aggregation on T_n^* optimally solves the Token Computation problem on K_n. We demonstrate this claim by showing that, given R rounds, $|T(R)|$ is the size of the largest solvable graph. Specifically, we will let $N^*(R)$ be the size of the largest complete graph on which one can solve Token Computation in R rounds, and we will argue that $N^*(R)$ obeys the same recurrence as $|T(R)|$.

First notice that the base case of $N^*(R)$ is trivially 1.

▶ **Lemma 4.** *For $R \in \mathbb{Z}_0^+$ we have that $N^*(R) = 1$ for $R < t_c + t_m$.*

Proof. If $R < t_c + t_m$, there are not enough rounds to send and combine a token, and so the Token Computation problem can only be solved on a graph with one node. ◀

We now show that for the recursive case $N^*(R)$ is always at least as large as $N^*(R - t_c) + N^*(R - t_c - t_m)$, which is the recurrence that defines $|T(R)|$.

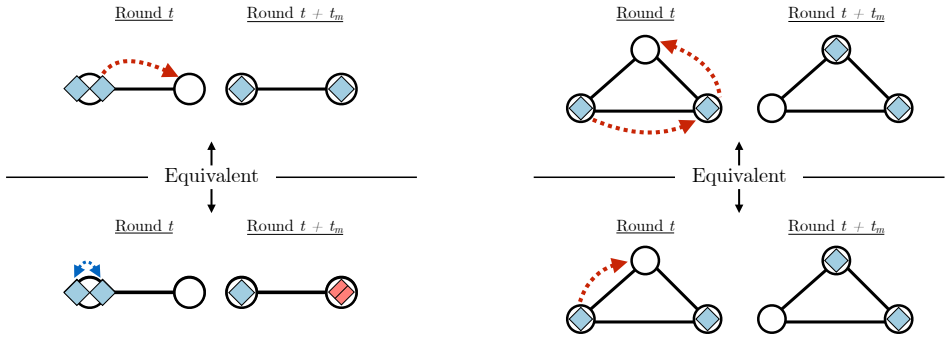
▶ **Lemma 5.** *For $R \in \mathbb{Z}_0^+$ we have that $N^*(R) \geq N^*(R-t_c)+N^*(R-t_c-t_m)$ for $R \geq t_c+t_m$.*

Proof. Suppose $R \geq t_c + t_m$. Let S_1 be the optimal schedule on the complete graph of $N^*(R-t_c)$ nodes with terminus v_{t1} and let S_2 be the optimal schedule on the complete graph of size $N^*(R-t_c-t_m)$ with corresponding terminus v_{t2}. Now consider the following solution on the complete graph of $N^*(R-t_c)+N^*(R-t_c-t_m)$ nodes. Run S_1 and S_2 in parallel on $N^*(R-t_c)$ and $N^*(R-t_c-t_m)$ nodes respectively, and once S_2 has completed, forward the token at v_{t2} to v_{t1} and, once it arrives, have v_{t1} perform one computation. This is a valid schedule which takes R rounds to solve Token Computation on $N^*(R-t_c)+N^*(R-t_c-t_m)$ nodes. Thus, we have that $N^*(R) \geq N^*(R-t_c)+N^*(R-t_c-t_m)$ for $R \geq t_c+t_m$. ◀

It remains to show that this bound on the recursion is tight. To do so, we case on whether $t_c \geq t_m$ or $t_c < t_m$. When $t_c \geq t_m$, we perform a straightforward case analysis to show that N^* follows the same recurrence as T_n^*. Specifically, we case on when the last token in the optimal schedule was created to show the following.

▶ **Lemma 6.** *When $t_c \geq t_m$ for $R \in \mathbb{Z}_0^+$ it holds that $N^*(R) = N^*(R-t_c)+N^*(R-t_c-t_m)$.*

Proof. Suppose that $R \geq t_c + t_m$. By Lemma 5, it is sufficient to show that $N^*(R) \leq N^*(R-t_c)+N^*(R-t_c-t_m)$. Consider the optimal solution given R rounds. The last action performed by any node must have been a computation that combines two tokens, a and b, at the terminus v_t because, in an optimal schedule, any further communication of the last token increases the length of the schedule. We now consider three cases.



(a) Combining insight. **(b)** Shortcutting insight.

Figure 4 An illustration of the shortcutting and combining insights. Here, tokens are denoted by blue diamonds, and hallucinated tokens are denoted by striped red diamonds. As before, a red arrow from node u to node v means that u sends to v, and a double-ended blue arrow between two tokens a and b means that a and b are combined at the node. Notice that which nodes have tokens and when nodes have tokens are the same under both modifications (though in the combining insight, a node is only hallucinating that it has a token).

- In the first case, a and b were both created at v_t. Because both of a or b could not have been created at time $R - t_c$, one of them must have been created at time $R - 2t_c$ at the latest. This means that $N^*(R) \leq N^*(R-t_c)+N^*(R-2t_c) \leq N^*(R-t_c)+N^*(R-t_c-t_m)$.
- In the second case, exactly one of a or b (without loss of generality, a) was created at v_t. This means that b must have been sent to v_t at latest at time $R - t_c - t_m$. It follows that $N^*(R) \leq N^*(R - t_c) + N^*(R - t_c - t_m)$.
- In the last case, neither a nor b was created at v_t. This means that both must have been sent to v_t at the latest at time $R - t_c - t_m$. We conclude that $N^*(R) \leq N^*(R - t_c - t_m) + N^*(R - t_c - t_m) \leq N^*(R - t_c) + N^*(R - t_c - t_m)$.

Thus, in all cases we have $N^*(R) \leq N^*(R - t_c) + N^*(R - t_c - t_m)$. ◀

We now consider the case in which communication is more expensive than computation, $t_c < t_m$. One might hope that the same case analysis used when $t_c \geq t_m$ would prove the desired result for when $t_c < t_m$. However, we must do significantly more work to show that $N^*(R) = N^*(R - t_c) + N^*(R - t_c - t_m)$ when $t_c < t_m$. We do this by establishing structure on the schedule which solves Token Computation on $K_{N^*(R)}$ in R rounds: we successively modify an optimal schedule in a way that does not affect its validity or length but which adds structure to the schedule.

Specifically, we leverage the following insights – illustrated in Figure 4 – to modify schedules. *Combining insight*: Suppose node v has two tokens in round t, a and b, and v sends a to node u in round t. Node v can just aggregate a and b, treat this aggregation as it treats b in the original schedule and u can just pretend that it receives a in round $t + t_m$. That is, u can "hallucinate" that it has token a. Note that this insight crucially leverages the fact that $t_c < t_m$, since otherwise the performed computation would not finish before round $t + t_m$. *Shortcutting insight*: Suppose node v sends a token to node u in round t and node u sends a token to node w in a round in $[t, t + t_m]$. Node v can "shortcut" node u and send to w directly and u can just not send.

Through modifications based on these insights we show that there exists an optimal schedule where the last node to perform a computation never communicates, and every computation performed by this node computes on the token with which this node started. This structure, in turn, allows us to establish the following lemma, which asserts that when $t_c < t_m$ we have that $N^*(R)$ and $|T(R)|$ follow the same recurrence.

▶ **Lemma 7.** *When $t_c < t_m$, for $R \in \mathbb{Z}_0^+$ it holds that $N^*(R) = N^*(R-t_c)+N^*(R-t_c-t_m)$.*

The proof of the lemma is relegated to Appendix D. We are now ready to prove the theorem.

Proof of Theorem 3. On a high level, we argue that the greedy aggregation schedule on $T(R)$ combines $N^*(R)$ nodes in R rounds and is therefore optimal. Combining Lemma 4, Lemma 6, and Lemma 7 we have the following recurrence on $N^*(R)$ for $R \in \mathbb{Z}_0^+$.

$$N^*(R) = \begin{cases} 1 & \text{if } R < t_c + t_m \\ N^*(R - t_c) + N^*(R - t_c - t_m) & \text{if } R \geq t_c + t_m \end{cases}$$

Notice that this is the recurrence which defines $|T(R)|$ so for $R \in \mathbb{Z}_0^+$ we have that $N^*(R) = |T(R)|$, and by Lemma 2, the greedy aggregation schedule on $T(R)$ terminates in R rounds.

Thus, the greedy aggregation schedule on $T(R)$ solves Token Computation on $K_{|T(R)|} = K_{N^*(R)}$ in R rounds, and therefore is an optimal solution for $K_{N^*(R)}$. Since T_n^* is the smallest $T(R)$ with at most n nodes, greedy aggregation on T_n^* is optimal for K_n and so OptComplete optimally solves Token Computation on K_n. Finally, the polynomial runtime is trivial. ◀

4 Hardness and Approximation for Arbitrary Graphs

We now consider the Token Computation problem on arbitrary graphs. Unlike in the case of complete graphs, the problem turns out to be computationally hard on arbitrary graphs. The challenge in demonstrating the hardness of Token Computation is that the optimal schedule for an arbitrary graph does not have a well-behaved structure. Our insight here is that by forcing a single node to do a great deal of computation we can impose structure on the optimal schedule in a way that makes it reflect the minimum dominating set of the graph. The following theorem formalizes this; its full proof is relegated to Appendix E.

▶ **Theorem 8.** Token Computation *cannot be approximated by a polynomial-time algorithm within $(1.5-\epsilon)$ for $\epsilon \geq \frac{1}{o(\log n)}$ unless $P = NP$.*

Therefore, our focus in this section is on designing an approximation algorithm. Specifically, we construct a polynomial-time algorithm, SolveTC, which produces a schedule that solves Token Computation on arbitrary graphs using at most $O(\log n \cdot \log \frac{\mathrm{OPT}}{t_m})$ multiplicatively more rounds than the optimal schedule, where OPT is the length of the optimal schedule. Define the diameter D of graph G as $\max_{v,u} d(u,v)$. Notice that OPT/t_m is at most $(n-1)t_c/t_m + D$ since $\mathrm{OPT} \leq (n-1)(t_c + D \cdot t_m)$: the schedule that picks a pair of nodes, routes one to the other then aggregates and repeats $n-1$ times is valid and takes $(n-1)(t_c + D \cdot t_m)$ rounds. Thus, our algorithm can roughly be understood as an $O(\log^2 n)$ approximation algorithm. Formally, our main result for this section is the following theorem whose lengthy proof we summarize in the rest of this section.

▶ **Theorem 9.** SolveTC *is a polynomial-time algorithm that gives an $O(\log n \cdot \log \frac{\mathrm{OPT}}{t_m})$-approximation for* Token Computation *with high probability.*

The rest of this section provides an overview of this theorem's lengthy proof. Our approximation algorithm, SolveTC, is given as Algorithm 2. SolveTC performs $O(\log n)$ repetitions of: designate some subset of nodes with tokens sinks and the rest of the nodes with tokens sources; route tokens at sources to sinks. If $t_c > t_m$, we will delay computations until tokens from sources arrive at sinks, and if $t_m \geq t_c$, we will immediately aggregate tokens that arrive at the same node.

4.1 Token Computation Extremes (Warmup)

Before moving on to a more technical overview of our algorithm, we build intuition by considering two extremes of Token Computation.

$t_m \ll t_c$

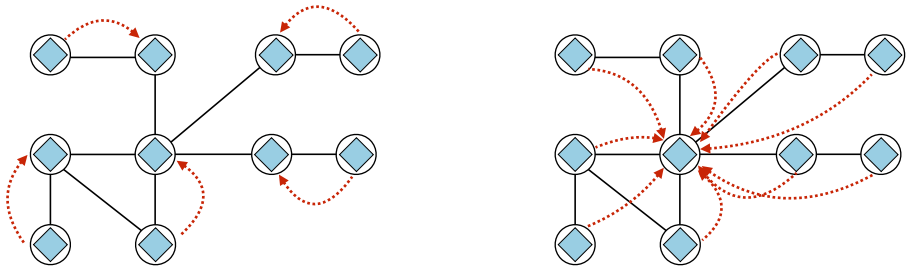
First, consider the case where $t_m \ll t_c$; that is, communication is very cheap compared to computation. As computation is the bottleneck here, we can achieve an essentially optimal schedule by parallelizing computation as much as possible. That is, consider a schedule consisting of $O(\log n)$ repetitions of: (1) each node with a token uniquely pairs off with another node with a token; (2) one node in each pair routes its token to the other node in its pair; (3) nodes that received a token perform one computation. This takes $O(t_c \cdot \log n)$ rounds to perform computations along with some amount of time to perform communications. But, any schedule takes at least $\Omega(t_c \cdot \log n)$ rounds, even if communication were free and computation were perfectly parallelized. Because the time to perform communications is negligible, this schedule is essentially optimal.

$t_c \ll t_m$

Now consider the case where $t_c \ll t_m$; that is, computation is very cheap compared to communication. In this setting, we can provide an essentially optimal schedule by minimizing the amount of communication that occurs. In particular, we pick a center c of the graph[6] and have all nodes send their tokens along the shortest path towards c. At any point during this schedule, it is always more time efficient for a node with multiple tokens to combine its tokens together before forwarding them since $t_c \ll t_m$. Thus, if at any point a node has multiple tokens, it combines these into one token and forwards the result towards c. Lastly, c aggregates all tokens it receives. This schedule takes $t_m \cdot r$ time to perform its communications, where r is the radius of the graph,[7] and some amount of time to perform its computations. However, because for every schedule there exists a token that must travel at least r hops, any schedule takes at least $\Omega(r \cdot t_m)$ rounds. Computations take a negligible amount of time since $t_c \ll t_m$, which means that this schedule is essentially optimal.

See Figure 5 for an illustration of these two schedules. Thus, in the case when $t_m \ll t_c$, we have that routing between pairs of nodes and delaying computations is essentially optimal, and in the case when $t_c \ll t_m$, we have that it is essentially optimal for nodes to greedily aggregate tokens before sending. These two observations will form the foundation of our approximation algorithm.

[6] The center of graph G is $\arg\min_v \max_u d(v,u)$ where $d(v,u)$ is the length of the shortest $u-v$ path.
[7] The radius of graph G is $\min_v \max_u d(v,u)$.



(a) $t_m \ll t_c$. **(b)** $t_c \ll t_m$.

Figure 5 An illustration of essentially optimal schedules for the extremes of the Token Computation problem. Dotted red arrows give the node towards which each node routes. In the case where $t_m \ll t_c$ one would repeat this sort of routing $O(\log n)$ times.

4.2 Approximation Algorithm

Recall that our approximation algorithm routes tokens from designated sources to designated sinks $O(\log n)$ times. Formally, the problem which our algorithm solves $O(\log n)$ times is as follows.

▶ **Definition 10** (Route and Compute Problem)**.** The input to the Route and Compute Problem consists of a set $U \subseteq V$ and a set of directed paths $\vec{\mathcal{P}_U} = \{\vec{P_u} : u \in U\}$ where: (1) $u \in U$ has a token and is the source of $\vec{P_u}$; (2) every sink of every path $\vec{P_u}$ has a token; (3) if u and t_u are the sources and sinks of $\vec{P_u} \in \vec{\mathcal{P}_U}$, respectively, then neither u nor t_u are endpoints of any $\vec{P_{u'}} \in \vec{\mathcal{P}_U}$ for $u' \neq u$. A solution of cost C is a schedule of length C which, when run, performs computations on a constant fraction of tokens belonging to nodes in U.

SolveTC repeatedly calls a subroutine, GetDirectedPaths, to get a set of paths for which it would like to solve the Route and Compute Problem. It then solves the Route and Compute Problem for these paths, using RoutePaths$_m$ if $t_c \leq t_m$ or RoutePaths$_c$ if $t_c > t_m$. Below we give an overview of these procedures. The proofs of the lemmas in this section, as well as further details regarding SolveTC, are relegated to Appendix F.

Algorithm 2 SolveTC.

Input: Token Computation instance given by graph $G = (V, E), t_c, t_m$
Output: A schedule for the input Token Computation problem
$W \leftarrow V$
for iteration $i \in O(\log n)$ **do**
  $\vec{\mathcal{P}_U} \leftarrow$ GetDirectedPaths(W, G)
  if $t_c > t_m$ **then** RoutePaths$_m(\vec{\mathcal{P}_U})$
  if $t_c \leq t_m$ **then** RoutePaths$_c(\vec{\mathcal{P}_U})$
  $W \leftarrow \{v : v$ has 1 token$\}$

4.2.1 Producing Paths on Which to Route

We now describe GetDirectedPaths. First, for a set of paths $\mathcal{P}$, we define the *vertex congestion* of $\mathcal{P}$ as $\text{con}(\mathcal{P}) = \max_v \sum_{P \in \mathcal{P}}(\#$ occurences of $v \in P)$, and the *dilation* of $\mathcal{P}$ as $\max_{P \in \mathcal{P}} |P|$.

Given that nodes in $W \subseteq V$ have tokens, GetDirectedPaths solves a flow LP which has a flow for each $w \in W$ whose sinks are $w' \in W$ such that $w' \neq w$. The objective of this flow LP is the vertex congestion. The flow for each $w \in W$ defines a probability

distribution over (undirected) paths with endpoints w and w' where $w' \neq w$ and $w' \in W$. Given these probability distributions, we repeatedly sample paths by taking random walks proportional to LP values of edges until we produce a set of paths – one for each $w \in W$ – with low vertex congestion. Lastly, given our undirected paths, we apply another subroutine to direct our paths and fix some subset of nodes $U \subset W$ as sources such that $|U|$ is within a constant fraction of $|W|$. The key property of the LP we use is that it has an optimal vertex congestion comparable to OPT, the length of the optimal Token Computation schedule. Using this fact and several additional lemmas we can prove the following properties of GetDirectedPaths.

▶ **Lemma 11.** *Given $W \subseteq V$,* GetDirectedPaths *is a randomized polynomial-time algorithm that returns a set of directed paths, $\vec{\mathcal{P}}_U = \{P_u : u \in U\}$ for $U \subseteq W$, such that with high probability at least $1/12$ of nodes in W are sources of paths in $\vec{\mathcal{P}}_U$ each with a unique sink in W. Moreover,*

$$con(\vec{\mathcal{P}}_U) \leq O\left(\frac{\mathrm{OPT}}{\min(t_c, t_m)} \log \frac{\mathrm{OPT}}{t_m}\right) \text{ and } dil(\vec{\mathcal{P}}_U) \leq \frac{8\mathrm{OPT}}{t_m}.$$

4.2.2 Routing Along Produced Paths

We now specify how we route along the paths produced by GetDirectedPaths. If $t_c > t_m$, we run RoutePaths$_m$ to delay computations until tokens from sources arrive at sinks, and if $t_m \geq t_c$, we run RoutePaths$_c$ to immediately aggregate tokens that arrive at the same node.

Case of $t_c > t_m$

RoutePaths$_m$ adapts the routing algorithm of Leighton et al. [22] – which was simplified by Rothvoß [31] – to efficiently route from sources to sinks.[8] We let OPTRoute be this adaptation of the algorithm of Leighton et al. [22].

▶ **Lemma 12.** *Given a set of directed paths $\vec{\mathcal{P}}_U$ with some subset of endpoints of paths in $\vec{\mathcal{P}}_U$ designated sources and the rest of the endpoints designated sinks,* OPTRoute *is a randomized polynomial-time algorithm that w.h.p. produces a* Token Network *schedule that sends from all sources to sinks in $O(con(\vec{\mathcal{P}}_U) + dil(\vec{\mathcal{P}}_U))$.*

Given $\vec{\mathcal{P}}_U$, RoutePaths$_m$ is as follows. Run OPTRoute and then perform a single computation. As mentioned earlier, this algorithm delays computation until all tokens have been routed.

▶ **Lemma 13.** RoutePaths$_m$ *is a polynomial-time algorithm that, given $\vec{\mathcal{P}}_U$, solves the* Route and Compute *Problem w.h.p. using $O(t_m(con(\vec{\mathcal{P}}_U) + dil(\vec{\mathcal{P}}_U)) + t_c)$ rounds.*

Case of $t_c \leq t_m$

Given directed paths $\vec{\mathcal{P}}_U$, RoutePaths$_c$ is as follows. Initially, every sink is *asleep* and every other node is *awake*. For $O(\mathrm{dil}(\vec{\mathcal{P}}_U) \cdot t_m)$ rounds we repeat the following: if a node is not currently sending and has exactly one token then it forwards this token along its path; if

[8] Our approach for the case when $t_c > t_m$ can be simplified using techniques from Srinivasan and Teo [32]. In fact, using their techniques we can even shave the $\frac{\log \mathrm{OPT}}{t_c}$ factor in our approximation. However, because these techniques do not take computation into account, they do not readily extend to the case when $t_c \leq t_m$. Thus, for the sake of a unified exposition, we omit the adaptation of their results.

a node is not currently sending and has two or more tokens then it sleeps for the remainder of the $O(\mathrm{dil}(\vec{\mathcal{P}_U}) \cdot t_m)$ rounds. Lastly, every node combines any tokens it has for $t_c \cdot \mathrm{con}(\vec{\mathcal{P}_U})$ rounds.

▶ **Lemma 14.** RoutePaths$_c$ *is a polynomial-time algorithm that, given* $\vec{\mathcal{P}_U}$*, solves the* Route and Compute *Problem w.h.p. using* $O(t_c \cdot con(\vec{\mathcal{P}_U}) + t_m \cdot dil(\vec{\mathcal{P}_U}))$ *rounds.*

By leveraging the foregoing results, we can prove Theorem 9; see Appendix F.3 for details.

5 Future Work

There are many promising directions for future work. First, as Section 4.1 illustrates, the extremes of our problem – when $t_c \ll t_m$ and when $t_m \ll t_c$ – are trivial to solve. However, our hardness reduction demonstrates that for $t_c = 1$ and t_m in a specific range, our problem is hard to approximate. Determining precisely what values of t_m and t_c make our problem hard to approximate is open.

Next, it is not always the case that there exists a centralized coordinator to produce a schedule. We hope to give an analysis of our problem in a distributed setting as no past work in this setting takes computation into account. Even more broadly, we hope to analyze formal models of distributed computation in which nodes are not assumed to have unbounded computational resources and computation takes a non-trivial amount of time.

We also note that there is a gap between our hardness of approximation and the approximation guarantee of our algorithm. The best possible approximation, then, is to be decided by future work.

Furthermore, we are interested in studying technical challenges similar to those studied in approximation algorithms for network design. For instance, we are interested in the problem in which each edge has a cost and one must build a network subject to budget constraints which has as efficient a Token Computation schedule as possible.

Lastly, there are many natural generalizations of our problem. For instance, consider the problem in which nodes can aggregate an arbitrary number of tokens together, but the time to aggregate multiple tokens is, e.g., a concave function of the number of tokens aggregated. These new directions offer not only compelling theoretical challenges but may be of practical interest.

A Formal Model, Problem, and Definitions

Let us formally define the Token Computation problem. The input to the problem is a Token Network specified by graph $G = (V, E)$ and parameters $t_c, t_m \in \mathbb{N}$. Each node starts with a single token.

An algorithm for this problem must provide a schedule, $S : V \times [l] \to V \cup \{\mathsf{idle}, \mathsf{busy}\}$ where we refer to $|S| \coloneqq l$ as the length of the schedule. Intuitively, a schedule S directs each node when to compute and when to communicate as follows:

- $S(v, r) = v' \neq v$ indicates that v begins passing a token to v' in round r of S;
- $S(v, r) = v$ indicates that v begins combining two token in round r of S;
- $S(v, r) = \mathsf{idle}$ indicates that v does nothing in round r;
- $S(v, r) = \mathsf{busy}$ indicates that v is currently communicating or computing.

Moreover, we define the number of computations that v has performed up to round r as $C_S(v, r) \coloneqq \sum_{r' \in [r-t_c]} \mathbb{1}(S(v, r') == v)$, the number of messages that v has received up to round r as $R_S(v, r) \coloneqq \sum_{r' \in [r-t_m]} \sum_{v' \neq v} \mathbb{1}(S(v', r') == v)$, and the number of messages that v has sent up to round r as $M_S(v, r) \coloneqq \sum_{r' \in [r-t_m]} \sum_{v' \neq v} \mathbb{1}(S(v, r') == v')$. Finally, define the number of tokens a node has in round r of S as follows.

$$\mathsf{tokens}_S(v, r) \coloneqq I(v) + R_S(v, r) - M_S(v, r) - C_S(v, r).$$

A schedule, S, is *valid* for Token Network (G, t_c, t_m) if:

1. Valid communication: If $S(v, r) = v' \neq v$ then $(v, v') \in E$, $S(v, r') = \mathsf{busy}$ for $r' \in [r + 1, r + t_m]$ and $\mathsf{tokens}_S(v, r) \geq 1$;
2. Valid computation: If $S(v, r) = v$ then $S(v, r') = \mathsf{busy}$ for $r' \in [r + 1, r + t_c]$ and $\mathsf{tokens}_S(v, r) \geq 2$;
3. Full aggregation: $\sum_{v \in V} \mathsf{tokens}_S(v, |S|) = 1$.

An algorithm solves Token Computation if it outputs a valid schedule.

B Deferred Related Work

There is a significant body of applied work in resource-aware scheduling, sensor networks, and high-performance computing that considers both the relative costs of communication and computation, often bundled together in an energy cost. However, these studies have been largely empirical rather than theoretical, and much of the work considers distributed algorithms (as opposed to our centralized setting).

AllReduce in HPC

There is much related applied work in the high-performance computing space on AllReduce [29, 16]. However, while there has been significant research on communication-efficient AllReduce algorithms, there has been relatively little work that explicitly considers the cost of computation, and even less work that considers the construction of optimal topologies for efficient distributed computation. Researchers have empirically evaluated the performance of different models of communication [25, 19] and have proven (trivial) lower bounds for communication without considering computation [26, 27]. Indeed, to the best of our knowledge, the extent to which they consider computation is through an additive penalty that consists of a multiplicative factor times the size of all inputs at all nodes, as in the work of Jain et al. [18]; crucially, this penalty is the same for any schedule and cannot be reduced via intelligent scheduling. Therefore, there do not seem to exist theoretical results for efficient algorithms that consider both the cost of communication and computation.

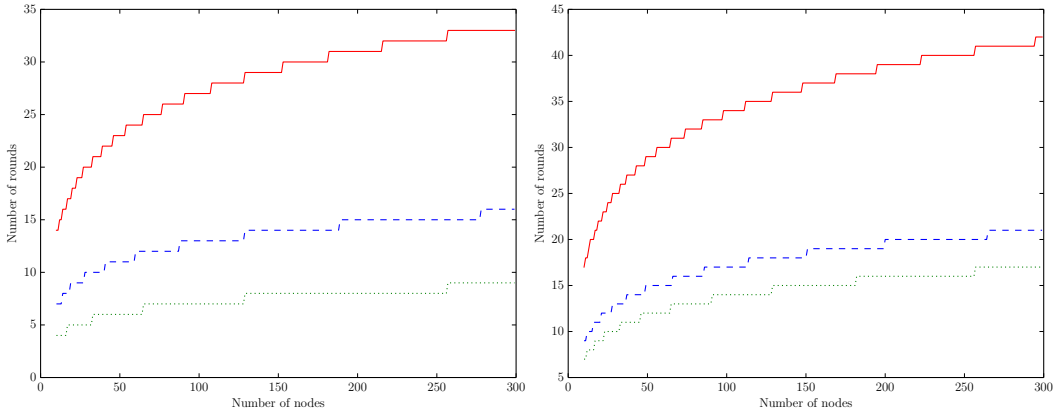
Resource-Aware Scheduling

In the distributed computation space, people have considered resource-aware scheduling on a completely connected topology with different nodes having different loads. Although this problem considers computation-aware communication, these studies are much more empirical than theoretical, and only consider distributed solutions as opposed to centralized algorithms [33, 24].

Sensor Networks

Members of the sensor networks community have studied the problem of minimizing an energy cost, which succinctly combines the costs of communication and computation. However, sensor networks involve rapidly-changing, non-static topologies [1, 2], which means that their objective is not to construct a fixed, optimal topology, but rather to develop adaptive algorithms for minimizing total energy cost with respect to an objective function [3].

C Deferred Figures



(a) $t_c = 1$, $t_m = 2$. **(b)** $t_c = 2$, $t_m = 1$.

Figure 6 An illustration of the optimal schedule length for different sized trees. The solid red line is the number of rounds taken by greedy aggregation with pipelining on a binary tree (i.e., $\lceil 2 \cdot t_c \cdot \log n + t_m \cdot \log n \rceil$); the dashed blue line is the number of rounds taken by greedy aggregation on T_n^*; and the dotted green line is the trivial lower bound of $\lceil t_c \cdot \log n \rceil$ rounds. Note that though we illustrate the trivial lower bound of $\lceil t_c \cdot \log n \rceil$ rounds, the true lower bound is given by the number of rounds taken by greedy aggregation on T_n^*.

D Proof of Lemma 7

Using our combining and shortcutting insights, we establish the following structure on a schedule which solves Token Computation on $K_{N^*(R)}$ in R rounds when $t_c < t_m$.

▶ **Lemma 15.** *When $t_c < t_m$, for all $R \in \mathbb{Z}_0^+$, there exists a schedule, $\tilde{S}^*$, of length R that solves* Token Computation *on $K_{N^*(R)}$ such that the terminus of $\tilde{S}^*$, v_t, never communicates and every computation performed by v_t involves a token that contains v_t's singleton token, a_{v_t}.*

Proof. Let S^* be some arbitrary schedule of length R which solves Token Computation on $K_{N^*(R)}$; we know that such a schedule exists by definition of $N^*(R)$. We first show how to modify S^* into another schedule, S^*_{1-4}, which not only also solves Token Computation on $K_{N^*(R)}$ in R rounds, but which also satisfies the following four properties.

(1) v only sends at time t if v at time t has exactly one token for $t \in [R]$;
(2) if v sends in round t then v does not receive any tokens in rounds $[t, t + t_m]$ for $t \in [R]$;
(3) if v sends in round t then v is idle during rounds $t' > t$ for $t \in [R]$;
(4) the terminus never communicates.

Achieving property (1)

Consider an optimal schedule S^*. We first show how to modify S^* to an R-round schedule S_1^* that solves Token Computation on $K_{N^*(R)}$ and satisfies property (1). We use our combining insight here. Suppose that (1) does not hold for S^*; i.e., a node v sends a token a_1 to node u at time t and v has at least one other token, say a_2, at time t. We modify S^* as follows. At time t, node v combines a_1 and a_2 into a token which it then performs operations on (i.e., computes and sends) as it does to a_2 in the original schedule. Moreover, node u

pretends that it receives token a_1 at time $t + t_m$: any round in which S^* has u compute on or communicate a_1, u now simply does nothing; nodes that were meant to receive a_1 do the same. It is easy to see that by repeatedly applying the above procedure to every node when it sends when it has more than one token, we can reduce the number of tokens every node has whenever it sends to at most one. The total runtime of this schedule is no greater than that of S^*, namely R, because $t_c < t_m$. Moreover, it clearly still solves Token Computation on $K_{N^*(R)}$. Call the schedule S_1^*.

Achieving properties (1) and (2)

Now, we show how to modify S_1^* into S_{1-2}^* such that properties (1) and (2) both hold. Again, S_{1-2}^* is of length R and solves Token Computation on $K_{N^*(R)}$. We use our shortcutting insight here. Suppose that (2) does not hold for S_1^*; i.e., there exists a v that receives a token a_1 from node u while sending another token a_2 to node u'. We say that node u is *bothering* node v in round t if node u communicates a token a_1 to v in round t, and node v communicates a token a_2 to node $u' \in V \setminus \{v, u\}$ in round $[t, t + t_m]$. Say any such pair is a *bothersome* pair. Furthermore, given a pair of nodes (u, v) and round t such that node u is bothering node v in round t, let the *resolution* of (u, v) in round t be the modification in which u sends its token directly to the node u' to which v sends its token. Note that each resolution does not increase the length of the optimal schedule because, by the definition of bothering, this will only serve as a shortcut; u' will receive a token from u at the latest in the same round it would have received a token from v in the original schedule, and nodes u' and v can pretend that they received tokens from v and u, respectively. However, it may now be the case that node u ends up bothering node u'. We now show how to repeatedly apply resolutions to modify S_1^* into a schedule S_{1-2}^* in which no node bothers another in any round t.

Consider the graph $B_t(S_1^*)$ where the vertices are the nodes in G and there exists a directed edge (u, v) if node u is bothering node v in round t in schedule S_1^*. First, consider cycles in $B_t(S_1^*)$. Note that, for any time t in which $B_t(S_1^*)$ has a cycle, we can create a schedule $\tilde{S}_1^*$ in which no nodes in any cycle in $B_t(S_1^*)$ send their tokens in round t; rather, they remain idle this round and pretend they received the token they would have received under S_1^*. Clearly, this does not increase the length of the optimal schedule and removes all cycles in round t. Furthermore, this does not violate property (1) because fewer nodes send tokens in round t, and no new nodes send tokens in round t.

Therefore, it suffices to consider an acyclic, directed graph $B_t(\tilde{S}_1)$. Now, for each round t, we repeatedly apply resolutions until no node bothers any other node during that round. Note that for every t, each node can only be bothering at most one other node because nodes can only send one message at a time. This fact, coupled with the fact that $B_t(\tilde{S}_1)$ is acyclic, means that $B_t(\tilde{S}_1)$ is a DAG where nodes have out-degree 1. It is not hard to see that repeatedly applying resolutions to a node v which bothers another node will decrease the number of edges in $B_t(\tilde{S}_1)$ by 1. Furthermore, because there are n total nodes in the network, the number of resolutions needed for any node v at time t is at most n.

Furthermore, repeatedly applying resolutions to $B_t(\tilde{S}_1)$ for times $t = 1, \ldots, R$ in order results in a schedule S_{1-2}^* with no bothersome pairs at any time t and that still satisfies property (1), and so schedule S_{1-2}^* satisfies properties (1) and (2). Since each resolution did not increase the length of the schedule we also have that S_{1-2}^* is of length R. Lastly, S_{1-2}^* clearly still solves Token Computation on $K_{N^*(R)}$.

Achieving properties (1) - (3)

Now, we show how to modify S^*_{1-2} into S^*_{1-3} which satisfies properties (1), (2), and (3). We use our shortcutting insight here as well as some new ideas. Given S^*_{1-2}, we show by induction over k from 0 to $R - t_m$, where R is the length of an optimal schedule, that we can modify S^*_{1-2} such that if a node finishes communicating in round $R-k$ (i.e., begins communicating in round $R-k-t_m$), it remains idle in rounds $t' \in (R-k, R]$ in the modified optimal schedule. The base case of $k = 0$ is trivial: If a node communicates in round $R - t_m$, it must remain idle in round R because the entire schedule is of length R.

Suppose there exists a node v that finishes communicating in round $t = R - k$ but is not idle in some round $t' > R - k$ in S^*_{1-2}; furthermore, let round t' be the first round after t in which node v is not idle. By property (1), node v must have sent its only token away in round t, and therefore node v must have received at least one other token after round t but before round t'. We now case on the type of action node v performs in round t'.

- If node v communicates in round t', it must send a token it received after time t but before round t'. Furthermore, as this is the first round after t in which v is not idle, v cannot have performed any computation on this token, and by the inductive hypothesis, v must remain idle from round $t' + t_m$ on. Therefore, v receives a token a_u from some node u and then forwards this token to node u' at time t'. One can modify this schedule such that u sends a_u directly to u' instead of sending to v.
- If node v computes in round t', consider the actions of node v after round $t' + t_c$. Either v eventually performs a communication after some number of computations, after which point it is idle by the inductive hypothesis, or v only ever performs computations from time t' on.

  In round t', v must combine two tokens it received after time $t + t_m$ by property (1). Note that two distinct nodes must have sent the two tokens to v because, by the inductive hypothesis, each node that sends after round t remains idle for the remainder of the schedule. Therefore, the nodes u_1 and u_2 that sent the two tokens to v must have been active at times $t'_1, t'_2 > t$, where $t_1 \leq t_2$, after which they remain idle for the rest of the schedule. Call the tuple (v, u_1, u_2) a *switchable* triple. We can modify the schedule to make v idle at round t' by picking the node that first sent to v and treating it as v while the original v stays idle for the remainder of the schedule. In particular, we can modify S^*_{1-2} such that, without loss of generality, u_2 sends its token to u_1 and u_1 performs the computation that v originally performed in S^*_{1-2}. Note that this now ensures that v will be idle in round t' and does not increase the length of the schedule, as u_1 takes on the role of v. Furthermore, node u_1's new actions do not violate the inductive hypothesis: Either u_1 only ever performs computations after time t', or it eventually communicates and thereafter remains idle.

  We can repeat this process for all nodes that are not idle after performing a communication in order to produce a schedule S^*_{1-3} in which property (3) is satisfied.

First, notice that these modifications do not change the length of S^*_{1-2}: in the first case u' can still pretend that it receives a_u at time $t' + t_m$ even though it now receives it in an earlier round and in the second case u_2 takes on the role of v at the expense of no additional round overhead. Also, it is easy to see that S^*_{1-3} still solves Token Computation on $K_{N^*(R)}$.

We now argue that the above modifications preserve (1) and (2). First, notice that the modifications we do for the first case do not change when any nodes send and so (1) is satisfied. In the second case, because we switch the roles of nodes, we may potentially add a send for a node. However, note that we only require a node u_1 to perform an additional send

when it is part of a switchable triple (v, u_1, u_2), and u_1 takes on the role of v in the original schedule from time t' on. However, because S^*_{1-2} satisfies (1), u was about to send its only token away and therefore only had one token upon receipt of the token from u_2. Therefore, because u_1 performs the actions that v performs in S^*_{1-2} from time t' on, and because at time t', both u_1 and v have exactly two tokens, (1) is still satisfied by S^*_{1-3}. Next, we argue that (3) is a strictly stronger condition than (2). In particular, we show that since S^*_{1-3} satisfies (3) it also satisfies (2). Suppose for the sake of contradiction that S^*_{1-3} satisfies (3) but not (2). Since (2) is not satisfied there must exist some node v that sends in some round t to, say node u, but receives a token in some round in $[t, t + t_m]$. By (3) it then follows that v is idle in all rounds after t. However, u also receives a token in round $t + t_m$. Therefore, in round $t + t_m$, two distinct nodes have tokens, one of which is idle in all rounds after $t + t_m$; this contradicts the fact that S^*_{1-3} solves Token Computation. Thus, S^*_{1-3} must also satisfy (2)

Achieving properties (1) - (4)

It is straightforward to see that S^*_{1-3} also satisfies property (4). Indeed, by property (3), if the terminus ever sends in round $t < R - t_c$, then the terminus must remain idle during rounds $t' > t$, meaning it must be idle in round $R - t_c$ which contradicts the fact that in this round the terminus performs a computation. Therefore, $S^*_{1-4} = S^*_{1-3}$ satisfies properties (1) - (4), and we know that there exists an optimal schedule in which v_t is always either computing or idle.

Achieving the final property

We now argue that we can modify S^*_{1-4} into another optimal schedule $\tilde{S}^*$ such that every computation done at the terminus v_t involves a token that contains the original singleton token that started at the terminus. Suppose that in S^*_{1-4}, v_t performs computation that does not involve a_{v_t}. Take the first instance in which v_t combines tokens a_1 and a_2, neither of which contains a_{v_t}, in round t. Because this is the first computation that does not involve a token containing a_{v_t}, both a_1 and a_2 must have been communicated to the terminus in round $t - t_m$ at the latest.

Consider the earliest time $t' > t$ in which v_t computes a token a_{comb} that contains all of a_1, a_2, and a_{v_t}. We now show how to modify S^*_{1-4} into $\tilde{S}'$ such that v_t computes a token a'_{comb} at time t' that contains all of a_1, a_2, and a_{v_t} and is at least the size of a_{comb} by having nodes swap roles in the schedule between times t and t'. Furthermore, because the rest of the schedule remains the same after time t', this implies that $\tilde{S}'$ uses at most as many rounds as S^*_{1-4}, and therefore that $\tilde{S}'$ uses at most R rounds.

The modification is as follows. At time t, instead of having v_t combine tokens a_1 and a_2, have v_t combine one of them (without loss of generality, a_1) with the token containing a_{v_t}. Now, continue executing S^*_{1-4} but substitute a_2 for the token containing a_{v_t} from round t on; this is a valid substitution because v_t possesses a_2 at time t. In round t', v_t computes a token $a'_{comb} = a_{comb}$; the difference from the previous schedule is that the new schedule has one fewer violation of property (4), i.e., one fewer round in which it computes on two tokens, neither of which contains a_{v_t}.

We repeat this process for every step in which the terminus does not compute on the token containing a_{v_t}, resulting in a schedule $\tilde{S}^*$ in which the terminus is always combining a communicated token with a token containing its own singleton token. Note that these modifications do not affect properties (1) - (4) because this does not affect the sending

actions of any node, and therefore $\tilde{S}^*$ still satisfies properties (1) - (4). It easily follows, then, that $\tilde{S}^*$ solves Token Computation on $K_{N^*(R)}$ in R rounds. Thus, $\tilde{S}^*$ is a schedule of length R that solves Token Computation on $K_{N^*(R)}$ in which every computation the terminus v_t does is on two tokens, one of which contains a_{v_t}, and, by (4), the terminus v_t never communicates. ◀

Having shown that the schedule corresponding to $N^*(R)$ can be modified to satisfy a nice structure when $t_c < t_m$, we can conclude our recursive bound on $N^*(R)$.

▶ **Lemma 7.** *When $t_c < t_m$, for $R \in \mathbb{Z}_0^+$ it holds that $N^*(R) = N^*(R-t_c)+N^*(R-t_c-t_m)$.*

Proof. Suppose $R \geq t_c + t_m$. We begin by applying Lemma 15 to show that $N^*(R) \leq N^*(R-t_c) + N^*(R-t_c-t_m)$. Let v_t be the terminus of the schedule $\tilde{S}^*$ using R rounds as given in Lemma 15. By Lemma 15, in all rounds after round t_m of $\tilde{S}^*$ it holds that v_t is either computing on a token that contains a_{v_t} or busy because it did such a computation. Notice that it follows that every token produced by a computation at v_t contains a_{v_t}.

Now consider the last token produced by our schedule. Call this token a. By definition of the terminus, a must be produced by a computation performed by v_t, combining two tokens, say a_1 and a_2, in round $R-t_c$ at the latest. Since every computation that v_t does combines two tokens, one of which contains a_{v_t}, without loss of generality let a_1 contain a_{v_t}.

We now bound the size of a_1 and a_2. Since a_1 exists in round $R-t_c$ we know that it is of size at most $N^*(R-t_c)$. Now consider a_2. Since every token produced by a computation at v_t contains a_{v_t} and a_2 does not contain a_{v_t} it follows that a_2 must either be a singleton token that originates at a node other than v, or a_2 was produced by a computation at another node. Either way, a_2 must have been sent to v, who then performed a computation on a_2 in round $R-t_c$ at the latest. It follows that a_2 exists in round $R-t_c-t_m$, and so a_2 is of size no more than $N^*(R-t_c-t_m)$.

Since the size of a just is the size of a_1 plus the size of a_2, we conclude that a is of size no more than $N^*(R-t_c) + N^*(R-t_c-t_m)$. Since, $\tilde{S}^*$ solves Token Computation on a complete graph of size $N^*(R)$, we have that a is of size $N^*(R)$ and so we conclude that $N^*(R) \leq N^*(R-t_c) + N^*(R-t_c-t_m)$ for $R \geq t_c + t_m$ when $t_c < t_m$.

Lastly, since $N^*(R) \geq N^*(R-t_c) + N^*(R-t_c-t_m)$ for $R \geq t_c + t_m$ by Lemma 5, we conclude that $N^*(R) = N^*(R-t_c) + N^*(R-t_c-t_m)$ for $R \geq t_c + t_m$ when $t_c < t_m$. ◀

E Proof of Theorem 8

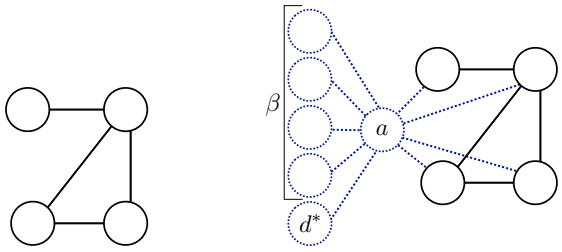
As a warmup for our hardness of approximation result, and to introduce some of the techniques, we begin with a proof that the decision version of Token Computation is NP-complete in Appendix E.1. We then prove the hardness of approximation result in Appendix E.2.

E.1 NP-Completeness (Warmup)

An instance of the decision version of Token Computation is given by an instance of Token Computation and a candidate ℓ. An algorithm must decide if there exists a schedule that solves Token Computation in at most ℓ rounds.

We reduce from k-dominating set.

▶ **Definition 16** (k-dominating set)**.** *An instance of k-dominating set consists of a graph $G = (V, E)$; the decision problem is to decide whether there exists $\kappa \subseteq V$ where $|\kappa| = k$ such that for all $v \in V \setminus \kappa$ there exists $\nu \in \kappa$ such that $(v, \nu) \in E$.*



(a) G. **(b)** $\Psi(G, 1)$.

Figure 7 An example of Ψ for a given graph G and $t_m = 1$. Nodes and edges added by Ψ are dashed and in blue. Notice that $|\beta| = \Delta + t_m = 3 + 1 = 4$.

Recall that k-dominating set is NP-complete.

▶ **Lemma 17** (Garey and Johnson [15]). *k-dominating set is NP-complete.*

Given an instance of k-dominating set, we would like to transform G into another graph G' in polynomial time such that G has a k-dominating set iff there exists a Token Computation schedule of some particular length for G' for some values of t_c and t_m.

We begin by describing the intuition behind the transformation we use, which we call Ψ. Any schedule on graph G in which every node only performs a single communication and which aggregates all tokens down to at most k tokens corresponds to a k-dominating set of G; in particular, those nodes that do computation form a k-dominating set of G. If we had a schedule of length $< 2t_m$ which aggregated all tokens down to k tokens, then we could recover a k-dominating set from our schedule. However, our problem aggregates down to only a single token, not k tokens. Our crucial insight, here, is that by structuring our graph such that a single node, a, must perform a great deal of computation, a must be the terminus of any short schedule. The fact that a must be the terminus and do a great deal of computation, in turn, forces any short schedule to aggregate all tokens in G down to at most k tokens at some point, giving us a k-dominating set.

Formally, Ψ is as follows. Ψ takes as input a graph G and a value for t_m and outputs $G' = (V', E')$. G' has G as a sub-graph and in addition has auxiliary node a where a is connected to all $v \in V$; a is also connected to dangling nodes $d \in \beta$, where $|\beta| = \Delta + t_m$, along with a special dangling node d^*.[9] Thus, $G' = (V \cup \{a, d^*\} \cup \beta, E \cup \{(a, v') : v' \in V' \setminus \{a\}\})$. See Figure 7.

We now prove that the optimal Token Computation schedule on $G' = \Psi(G, t_m)$ can be upper bounded as a function of the size of the minimum dominating set of G.

▶ **Lemma 18.** *The optimal* Token Computation *schedule on $G' = \Psi(G, t_m)$ is of length at most $2t_m + \Delta + k^*$ for $t_c = 1$, where k^* is the minimum dominating set of G.*

Proof. We know by definition of k^* that there is a dominating set of size k^* on G. Call this set κ and let $\sigma : V \to \kappa$ map any given $v \in V$ to a unique node in κ that dominates it. We argue that it must be the case that Token Computation requires at most $2t_m + t_c(\Delta + k^*)$ rounds on G' for $t_c = 1$. Roughly, we solve Token Computation by first aggregating at κ and then aggregating at a.

In more detail, in stage 1 of the schedule, every $d \in \beta$ sends to a, every node $v \in V$ sends to $\sigma(v)$ and a sends to d^*. This takes t_m rounds. In stage 2, each node does the following in parallel. Node d^* computes and sends its single token to a. Each $\nu \in \kappa$ computes until

[9] Δ is the max degree of G.

it has a single token and sends the result to a. Node a combines all tokens from $\beta \cup \{d^*\}$. Node d^* takes $1 + t_m$ rounds to do this. Each $\nu \in \kappa$ takes at most $\Delta + t_m$ rounds to do this. Node a takes $\Delta + t_m$ rounds to do this since a will receive d^*'s token after $t_m + 1$ rounds (and $\Delta \geq 1$ without loss of generality). Thus, stage 2, when done in parallel, takes $\Delta + t_m$ rounds. At this point a has $k^* + 1$ tokens and no other node in G' has a token. In stage 3, a computes until it has only a single token, which takes k^* rounds.

In total the number of rounds used by this schedule is $t_m + \Delta + t_m + k^* = 2t_m + \Delta + k^*$. Thus, the total number of rounds used by the optimal Token Computation schedule on G' is at most $2t_m + \Delta + k^*$. ◀

Next, we show that any valid Token Computation schedule on $G' = \Psi(G, t_m)$ that has at most two serialized sends corresponds to a dominating set of size bounded by the length of the schedule.

▶ **Lemma 19.** *Given $G' = \Psi(G, t_m)$ and a* Token Computation *schedule S for G' where $|S| < 3t_m$, $t_c = 1$, $\kappa = \{v : v \in G,\ v \text{ sends to } a \text{ in } S\}$ is a dominating set of G of size $|S| - 2t_m - \Delta$.*

Proof. Roughly, we argue that a must be the terminus of S and must perform at most $|S| - 2t_m - \Delta$ computations on tokens from G, each of which is the aggregation of a node's token and some of its neighbors' tokens. We begin by arguing that a must be the terminus.

First, we prove that no $d \in \beta \cup \{d^*\}$ is the terminus of S. Suppose for the sake of contradiction that some $\bar{d} \in \beta \cup \{d^*\}$ is the terminus. Since our schedule takes fewer than $3t_m$ rounds, we know that every node sends a token that is not just the singleton token with which it starts at most once. Thus, a sends tokens that are not just the singleton token that it starts with at most once. Since $|\beta \cup \{d^*\} \setminus \{\bar{d}\}| = \Delta + t_m$ and a is the only node connected to these nodes, we know that every singleton token that originates in $\beta \cup \{d^*\} \setminus \{\bar{d}\}$ must travel through a. Moreover, since a sends tokens that are not just the singleton token that it starts with at most once, a must send all such tokens as a single token. It follows that a must perform at least $\Delta + t_m$ computations, but then our entire schedule takes at least $t_m + \Delta + t_m + t_m = 3t_m + \Delta > 3t_m$ rounds – a contradiction to our assumption that our schedule takes less than $3t_m$ rounds.

We now argue that no $v \in G$ is the terminus. Suppose for the sake of contradiction that some $\bar{v} \in V$ is the terminus. Again, we know that a sends tokens that are not just the singleton token that it starts with at most once. Thus, every token in $\beta \cup \{d^*\}$ must travel through a, meaning that a must perform $\Delta + t_m + 1$ computations. It follows that the schedule takes $t_m + \Delta + t_m + t_m + 1 > 3t_m$ rounds, a contradiction to our assumption that the schedule takes $< 3t_m$ rounds.

Thus, since no $d \in \beta \cup \{d^*\}$ and no $v \in G$ is the terminus, we know that a must be the terminus.

We now argue that a sends a token in the first round and this is the only time that a sends (i.e., the only thing that a sends is the singleton token that it starts with, which it sends immediately). Assume for the sake of contradiction that a sends a token that it did not start with. It must have taken at least t_m rounds for this token to arrive at a and at least an additional t_m rounds for a to send a token containing it. Moreover, since a is the terminus, a token containing this token must eventually return to a and so an additional t_m rounds are required. Thus, at least $3t_m$ rounds are required if a sends a token other than that with which it starts, a contradiction to the fact that our schedule takes $< 3t_m$ rounds.

Thus, since a is the terminus, our schedule solves Token Computation in fewer than $3t_m$ rounds, and no computations occur in the first t_m rounds, a does at most $|S| - t_m$ computations. Since a never sends any token aside from its singleton token, and a is the only node to which $\beta \cup \{d^*\}$ are connected, we know that a must combine all tokens of nodes in $\beta \cup \{d^*\}$, where a must take $\Delta + t_m$ rounds to do so. Thus, since a takes $\Delta + t_m$ rounds to aggregate tokens from $\beta \cup \{d^*\}$ and it performs at most $|S| - t_m$ computations in total, a must receive at most $|S| - 2t_m - \Delta$ tokens from G. It follows that $|\kappa| \leq |S| - 2t_m - \Delta$.

Since each token sent by a node in κ to a must be sent at the latest in round $|S| - t_m$ and since $|S| < 3t_m$, we have that every token sent by a node in κ is formed in fewer than $2t_m$ rounds. It follows that each such token is formed by tokens that travel at most 1 hop in G. Since every node in G must eventually aggregate its tokens at a, it follows that every node in G is adjacent to a node in κ. Thus κ is a dominating set of G, and as shown before $|\kappa| \leq |S| - 2t_m - \Delta$. ◀

Having shown that the optimal Token Computation schedule of $G' = \Psi(G, t_m)$ is closely related to the size of the minimum dominating set, we prove that Token Computation is NP-complete.

▶ **Theorem 20.** *The decision version of* Token Computation *is NP-complete.*

Proof. The problem is clearly in NP. To show hardness, we reduce from k-dominating set. Specifically, we give a polynomial-time Karp reduction from k-dominating set to the decision version of Token Computation.

Our reduction is as follows. First, run $\Psi(G, t_m)$ for $t_m = \Delta + k + 1$ to get back G'. Next, return a decision version instance of Token Computation given by graph G' with $t_m = \Delta + k + 1$, $t_c = 1$ and $\ell = 2t_m + \Delta + k$. We now argue that G' has a schedule of length ℓ iff G has a k-dominating set.

- Suppose that G has a k-dominating set. We know that $k \geq k^*$, where k^* is the minimum dominating of G, and so by Lemma 18 we know that G' has a schedule of length at most $2t_m + \Delta + k^* \leq 2t_m + \Delta + k$.
- Suppose that G' has a Token Computation schedule S of length at most $2t_m + \Delta + k$. Notice that by our choice of t_m, we have that $|S| = 2t_m + \Delta + k < 3t_m$ and so by Lemma 19 we know that $\kappa = \{v : v \in G,\ v \text{ sends to } a \text{ in } S\}$ is a dominating set of G of size $|S| - 2t_m - \Delta$. Since $|S| \leq 2t_m + \Delta + k$ we conclude that $|\kappa| = |S| - 2t_m - \Delta \leq k$.

Lastly, notice that our reduction, Ψ, runs in polynomial time since it adds at most a polynomial number of vertices and edges to G. Thus, we conclude that k-dominating is polynomial-time reducible to the decision version of Token Computation, and therefore the decision version of Token Computation is NP-complete. ◀

E.2 Hardness of Approximation

We now show that unless P = NP there exists no polynomial-time algorithm that approximates Token Computation multiplicatively better than 1.5.

Recall that k-dominating set is $\Omega(\log n)$ hard to approximate.

▶ **Lemma 21** (Dinur and Steurer [11]). *Unless $P = NP$ every polynomial-time algorithm approximates minimum dominating set at best within a $(1 - o(1))(\log n)$ multiplicative factor.*

We prove hardness of approximation by using a $(1.5 - \epsilon)$ algorithm for Token Computation to approximate minimum dominating set with a polynomial-time algorithm better than $O(\log n)$. Similar to our proof of NP-completeness, given input graph G whose minimum

dominating set we would like to approximate, we would like to transform G into another graph G' such that a $(1.5-\epsilon)$-approximate Token Computation schedule for G' allows us to recover an approximately minimum dominating set.

One may hope to simply apply the transformation Ψ from the preceding section to do so. However, it is not hard to see that the approximation factor on the minimum dominating set recovered in this way has dependence on Δ, the maximum degree of G. If Δ is significantly larger than the minimum dominating set of G, we cannot hope that this will yield a good approximation to minimum dominating set. For this reason, before applying Ψ to G, we duplicate G a total of Δ/ϵ times to create graph G_α; this keeps Δ unchanged but increases the size of the minimum dominating set.[10] By applying Ψ to G_α instead of G to get back G'_α we are able to free our approximation factor from a dependence on Δ. Lastly, we show that we can efficiently recover an approximate minimum dominating set for G from an approximate Token Computation schedule for G'_α using our polynomial-time algorithm DSFromSchedule. Our full algorithm is given by MDSApx.

We first describe the algorithm – DSFromSchedule – we use to recover a minimum dominating set for G given a Token Computation schedule for $G'_\alpha = \Psi(G_\alpha, t_m)$. We denote copy i of G as G_i.

Algorithm 3 DSFromSchedule.

Input: $G'_\alpha = \Psi(G_\alpha, t_m)$; a valid Token Computation schedule for G'_α, S, of length $< 3t_m$; ϵ
Output: A dominating set for G of size $|S| - 2t_m - \Delta$
$\mathcal{K} \leftarrow \emptyset$
for $i \in \left[\frac{\Delta}{\epsilon}\right]$ **do**
  $\kappa_i \leftarrow \{v \in V_i : v \in G_\alpha \text{ sends to } a \text{ in } S\}$
  $\mathcal{K} \leftarrow \mathcal{K} \cup \{\kappa_i\}$
return $\arg\min_{\kappa_i \in \mathcal{K}} |\kappa_i|$

▶ **Lemma 22.** *Given $G'_\alpha = \Psi(G_\alpha, t_m)$ and a valid* Token Computation *schedule S for G'_α where $|S| < 3t_m$, $t_c = 1$ and $\epsilon \in (0, 1]$,* DSFromSchedule *outputs in polynomial time a dominating set of G of size $\frac{\epsilon}{\Delta}(|S| - 2t_m - \Delta)$.*[11]

Proof. Polynomial runtime is trivial, so we focus on the size guarantee. By Lemma 19 we know that $\kappa = \{v : v \in G_\alpha,\ v \text{ sends to } a \text{ in } S\}$ is a dominating set of G_α of size $|S| - 2t_m - \Delta$. Moreover, notice that $\kappa_i = \kappa \cap G_i$, and so it follows that κ_i is a dominating set of G_i, or equivalently G because G_i is just a copy of G. Thus we have that $\arg\min_{\kappa_i \in \mathcal{K}} |\kappa_i|$ will return a dominating set of G.

We now prove that $\arg\min_{\kappa_i \in \mathcal{K}} |\kappa_i|$ is small. Since each κ_i is disjoint we have $\sum_{i=1}^{\Delta/\epsilon} |\kappa_i| = |\kappa| \leq |S| - 2t_m - \Delta$. Thus, by an averaging argument we have that there must be some κ_i such that $|\kappa_i| \leq \frac{\epsilon}{\Delta}(|S| - 2t_m - \Delta)$. It follows that $\min_{\kappa_i \in \mathcal{K}} |\kappa_i| \leq \frac{\epsilon}{\Delta}(|S| - 2t_m - \Delta)$, meaning the κ_i that our algorithm returns is not only a dominating set of G but of size at most $\frac{\epsilon}{\Delta}(|S| - 2t_m - \Delta)$. ◀

[10] Since the max degree of G and G_α are the same, throughout this section Δ will be used to refer to both the max degree of G and the max degree of G_α.

[11] Since this lemma allows for $\epsilon \in (0, 1]$, it may appear that we will be able to achieve an arbitrarily good approximation for minimum dominating set. In fact, it might even seems as though we can produce a dominating set of size smaller than the minimum dominating set by simply letting ϵ be arbitrarily small. However, this is not the case. Intuitively, the smaller ϵ is, the larger G_α is and so the longer any feasible schedule S must be. Thus, decreases in ϵ are balanced out by increases in $|S|$ with respect to the size of our dominating set, $\frac{\epsilon}{\Delta}(|S| - 2t_m - \Delta)$.

Lastly, we combine Ψ with DSFromSchedule to get MDSApx, our algorithm for approximating minimum dominating set. Roughly, MDSApx constructs G'_α by applying Ψ to G_α, uses a $(1.5-\epsilon)$ approximation to Token Computation to get a schedule to G'_α and then uses DSFromSchedule to extract a minimum dominating set for G from this schedule. MDSApx will carefully choose a t_m that is large enough so that the schedule produced by the $(1.5-\epsilon)$ approximation for Token Computation is of length $< 3t_m$ but also small enough so that the produced schedule can be used to recover a small dominating set.

Algorithm 4 MDSApx.

Input: Graph G; $(1.5-\epsilon)$ Token Computation approximation algorithm $\mathcal{A}$
Output: An $O(1/\epsilon)$-approximation for the minimum dominating set of G
$\mathcal{D} \leftarrow \emptyset$
for $\hat{k} \in [n]$ **do**
  $G_\alpha \leftarrow \bigcup_{i=1}^{\Delta/\epsilon} G_i$
  $t_m \leftarrow \frac{1}{\epsilon}\left(\Delta + \frac{\hat{k}\Delta}{\epsilon}\right) + 1$; $t_c \leftarrow 1$
  $G'_\alpha \leftarrow \Psi(G_\alpha, t_m)$
  $S_{\hat{k}} \leftarrow \mathcal{A}\left(G'_\alpha, \frac{\hat{k}}{\epsilon}, t_m, t_c\right)$
  if $|S_{\hat{k}}| < 3t_m$ **then**
    $\kappa_{\hat{k}} \leftarrow$ DSFromSchedule(G_α, S, ϵ)
    $\mathcal{D} \leftarrow \mathcal{D} \cup \{\kappa_{\hat{k}}\}$
return $\arg\min_{\kappa \in \mathcal{D}} |\kappa|$.

▶ **Lemma 23.** *Given graph G and a $(1.5-\epsilon)$-approximation algorithm for* Token Computation, *$\mathcal{A}$,* MDSApx *outputs in* poly$\left(n, \frac{1}{\epsilon}\right)$ *time a dominating set of G of size $O\left(\frac{k^*}{\epsilon}\right)$, where k^* is the size of the minimum dominating set of G.*

Proof. By Lemma 22 we know that any set $\kappa_{\hat{k}} \in \mathcal{D}$ is a dominating set of G of size at most $\frac{\Delta}{\epsilon}\left(|S_{\hat{k}}| - 2t_m - \Delta\right)$. Thus, it suffices to show that $\mathcal{D}$ contains at least one dominating set of G, $\kappa_{\hat{k}}$ such that $S_{\kappa_{\hat{k}}}$ is small. We do so now.

Let k^* be the size of the minimum dominating set of G. We know that $k^* \leq n$ and so in some iteration of MDSApx we will have $\hat{k} = k^*$. Moreover, the minimum dominating set of G_α in this iteration just is $\frac{\Delta k^*}{\epsilon}$ since G_α is just $\frac{\Delta}{\epsilon}$ copies of G. Consider this iteration. Let S^* be the optimal schedule for G'_α when $\hat{k} = k^*$. By Lemma 18 we know that $|S^*| \leq 2t_m + \Delta + \frac{k^*\Delta}{\epsilon}$. We now leverage the fact that that we chose t_m to be *large enough* so that $|S^*| < 3t_m$. In particular, combining the fact that $|S^*| \leq 2t_m + \Delta + \frac{k^*\Delta}{\epsilon}$ with the fact that $\mathcal{A}$ is a $(1.5-\epsilon)$ approximation we have that

$$
\begin{aligned}
|S_{k^*}| &\leq (1.5-\epsilon)|S^*| \\
&\leq (1.5-\epsilon)\left(2t_m + \Delta + \frac{k^*\Delta}{\epsilon}\right) \\
&= 3t_m - 2\,\epsilon\, t_m + (1.5-\epsilon)\left(\Delta + \frac{k^*\Delta}{\epsilon}\right) \\
&= 3t_m - 2\,\epsilon\, t_m + (1.5-\epsilon)\,\epsilon\,(t_m - 1) && \text{(By } t_m \text{ dfn.)} \\
&= 3t_m - \epsilon(0.5+\epsilon)t_m - \epsilon(1.5-\epsilon) \\
&< 3t_m. && (1)
\end{aligned}
$$

Thus, since $|S_{k^*}| < 3t_m$ we know that $\kappa_{k^*} \in \mathcal{D}$. Lastly, we argue that $|\kappa_{k^*}| = O\left(\frac{k^*}{\epsilon}\right)$, thereby showing that $\arg\min_{\kappa \in \mathcal{D}} |\kappa|$, the returned dominating set of our algorithm, is $O\left(\frac{k^*}{\epsilon}\right)$.

We now leverage the fact that we chose t_m to be *small enough* to give us a small dominating set. Applying Lemma 22 we have that

$$\begin{aligned}
|\kappa_{k^*}| &\leq \frac{\epsilon}{\Delta}\left(|S_{k^*}| - 2t_m - \Delta\right) && \text{(By Lemma 22)} \\
&< \frac{\epsilon}{\Delta}(t_m - \Delta) && \text{(By Equation (1))} \\
&= \frac{\epsilon}{\Delta}\left(\frac{1}{\epsilon}\left(\Delta + \frac{k^*\Delta}{\epsilon}\right) + 1 - \Delta\right) && \text{(By } t_m \text{ dfn.)} \\
&= \left(1 + \frac{k^*}{\epsilon}\right) + \frac{\epsilon}{\Delta} - \epsilon \\
&= O\left(\frac{k^*}{\epsilon}\right)
\end{aligned}$$

Thus, we conclude that MDSApx produces an $O\left(\frac{k^*}{\epsilon}\right)$ minimum dominating set of G.

Lastly, we argue a polynomial in n and $1/\epsilon$ runtime of MDSApx. First we argue that each iteration requires polynomial time. Constructing G_α takes polynomial time since the algorithm need only create $\frac{\Delta}{\epsilon} = \text{poly}\left(n, \frac{1}{\epsilon}\right)$ copies of G. Running Ψ also requires polynomial time since it simply adds polynomially many nodes to G_α. $\mathcal{A}$ is polynomial by assumption and DSFromSchedule is polynomial by Lemma 22. Thus, each iteration takes polynomial time and since MDSApx has n iterations, MDSApx takes polynomial time in n and $1/\epsilon$. ◀

Given that MDSApx demonstrates an efficient approximation for minimum dominating set given a polynomial-time $(1.5 - \epsilon)$ approximation for Token Computation, we conclude our hardness of approximation.

▶ **Theorem 8.** Token Computation *cannot be approximated by a polynomial-time algorithm within* $(1.5 - \epsilon)$ *for* $\epsilon \geq \frac{1}{o(\log n)}$ *unless* $P = NP$.

Proof. Assume for the sake of contradiction that P ≠ NP and there existed a polynomial-time algorithm $\mathcal{A}$ that approximated Token Computation within $(1.5 - \epsilon)$ for $\epsilon = \frac{1}{o(\log n)}$. It follows by Lemma 23 that MDSApx when run with $\mathcal{A}$ is a $o(\log n)$-approximation for minimum dominating set. However, this contradicts Lemma 21, and so we conclude that Token Computation cannot be approximated within $(1.5 - \epsilon)$ for $\epsilon \geq \frac{1}{o(\log n)}$. ◀

F Omitted Lemmas of the Proof of Theorem 9

F.1 Proof of Lemma 11

The goal of this section is to prove Lemma 11, which states the properties of GetDirectedPaths. To this end we will begin by rigorously defining the LP we use for GetDirectedPaths and establishing its relevant properties. We then formally define GetDirectedPaths, establish the properties of its subroutines and then prove Lemma 11.

F.1.1 Our Flow LP

The flow LP we use for GetDirectedPaths can be thought of as flow on a graph G "time-expanded" by the maximum length that a token in the optimal schedule travels. Given any schedule we define the *distance* that singleton token a travels as the number of times

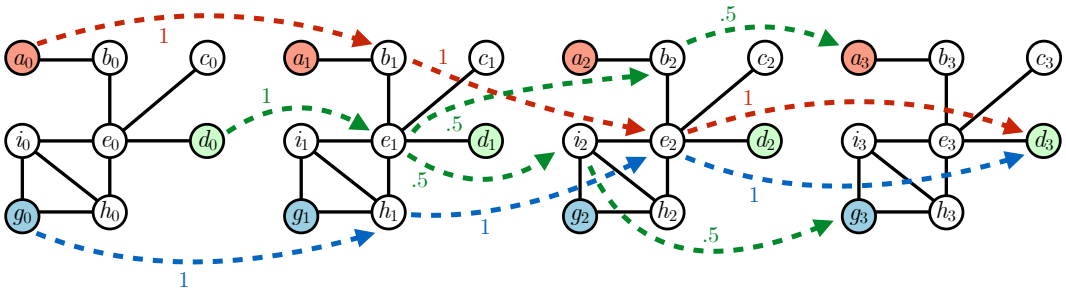


Figure 8 An illustration of non-zero flows for a feasible solution for PathsFlowLP(3) for graph G. Nodes a, d, and g are in W, and f_w is colored by w. For this feasible solution, $z = 2$.

any token containing a is sent in said schedule. Let L^* be the furthest distance a singleton token travels in the optimal schedule. Given a guess for L^*, namely $\hat{L}$, we define a graph $G_{\hat{L}}$ with vertices $\{v_r : v \in V, r \in [\hat{L}]\}$ and edges $\{e = (u_r, v_{r+1}) : (u, v) \in E, r \in [\hat{L} - 1]\}$. We have a flow type for each $w \in W$, where $W = \{v : v \text{ has at least 1 token}\}$, which uses $\{w' : w' \in W \wedge w' \neq w\}$ as sinks. Correspondingly, we have a flow variable, $f_w(x_r, y_{r+1})$ for every $r \in [\hat{L} - 1]$, $w \in W$ and $(x, y) \in E$. The objective function of the LP is to minimize the maximum vertex congestion, given by variable z. Let $z(\hat{L})$ be the objective value of our LP given our guess $\hat{L}$. Formally, our LP is given in PathsFlowLP($\hat{L}$), where $\Gamma(v)$ gives the neighbors of v in G. See Figure 8 for an illustration of a feasible solution to this LP.

$$\min z \text{ s.t.} \qquad \text{(PathsFlowLP}(\hat{L})\text{)}$$

"Conserve flow across rounds"

$$\sum_{x' \in \Gamma(x)} f_w(x'_{r-1}, x_r) = \sum_{x'' \in \Gamma(x)} f_w(x_r, x''_{r+1}) \qquad \forall w \in W, x \notin W, r \in [\hat{L} - 1] \quad (2)$$

"Every $w \in W$ is a source for f_w and not a sink for f_w"

$$\sum_{r \in [\hat{L}-1]} \left[\sum_{x' \in \Gamma(w)} f_w(w_r, x'_{r+1}) - \sum_{x' \in \Gamma(w)} f_w(x'_r, w_{r+1}) \right] \geq 1 \qquad \forall w \in W \quad (3)$$

"w-flow ends at $w' \in W$ s.t. $w' \neq w$"

$$\sum_{w' \in W : w' \neq w} \sum_{u \in \Gamma(w')} f_w(u_{\hat{L}}, w'_{\hat{L}}) = 1 \qquad \forall w \quad (4)$$

"z is the vertex congestion"

$$z \geq \sum_{w} \sum_{v \in \Gamma(v)} \sum_{r \in [D-1]} f_w(v'_r, v_{r+1}) \qquad \forall v \quad (5)$$

"Non-negative flow"

$$f_w(x_r, y_{r+1}) \geq 0 \qquad \forall, x, y, r, w \in W \quad (6)$$

F.1.2 Proof of the Key Property of our LP

The key property of our LP is that it has an optimal vertex congestion comparable to OPT. In particular, we can produce a feasible solution for our LP of cost 2OPT by routing tokens along the paths taken in the optimal schedule.

▶ **Lemma 24.** $\min(t_c, t_m) \cdot z(2L^*) \leq 2\text{OPT}$.

The remainder of this section is a proof of Lemma 24. Consider a W as in Section 4.2.1 where $W \leftarrow \{v : v \text{ has at least 1 token}\}$ and the optimal schedule that solves Token Computation in time OPT.

We will prove Lemma 24 by showing that, by sending flow along paths taken by certain tokens in the optimal schedule, we can provide a feasible solution to PathsFlowLP($\hat{L}$) with value commensurate with OPT. For this reason we now formally define these paths, OptPaths(W). Roughly, these are the paths taken by tokens containing singleton tokens that originate in W. Formally, these paths are as follows. Recall that a_w is the singleton token with which node w starts in the optimal schedule. Notice that in any given round of the optimal schedule exactly one token contains a_w. As such, order every round in which a token containing a_w is received by a node in ascending order as $r_0(w), r_1(w) \ldots$ where we think of w as receiving a_w in the first round. Correspondingly, let $v_i(w)$ be the vertex that receives a token containing a_w in round $r_i(w)$; that is $(v_1(w), v_2(w), \ldots)$ is the path "traced out" by a_w in the optimal schedule. For token a, let $C(a) \coloneqq \{a_{w'} : w' \in W \wedge a'_w \in a\}$ stand for all singleton tokens contained by token a that originated at a $w' \in W$. Say that token a is *active* if $|C(a)|$ is odd. Let $v_{L_w}(w)$ be the first vertex in $(v_1(w), v_2(w), \ldots)$ where an active token containing a_w is combined with another active token. Correspondingly, let $c(w)$ be the first round in which an active token containing a_w is combined with another active token. Say that a singleton token a_w is *pending* in round r if $r < c(w)$. We note the following behavior of pending singleton tokens.

▶ **Lemma 25.** *In every round of the optimal schedule, if a token is active then it contains exactly one pending singleton token and if a token is inactive then it contains no pending singleton tokens.*

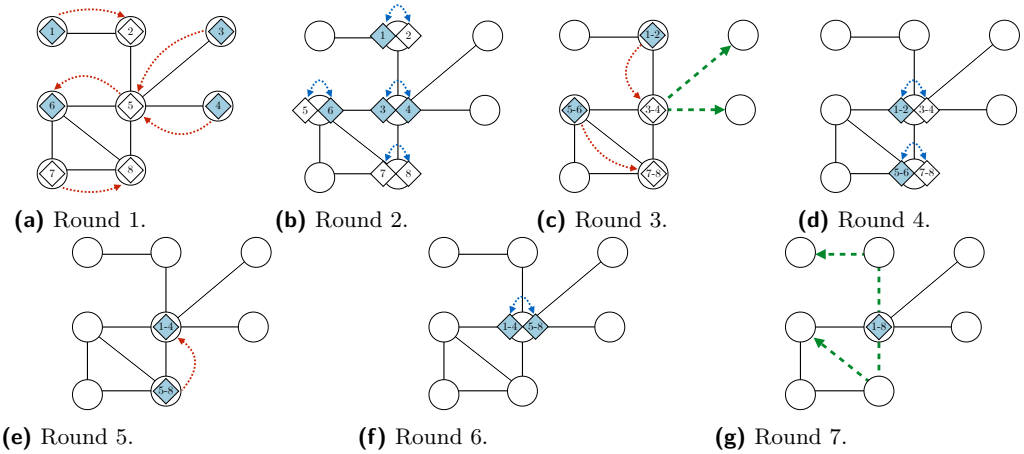
Proof. We prove this by induction over the rounds of the optimal schedule. As a base case, we note that in the first round of the optimal schedule a token is active iff it is a singleton node and every singleton node is pending. Now consider an arbitrary round i and assume that our claim holds in previous rounds. Consider an arbitrary token a. If a is not computed on by a node in this round then by our inductive hypothesis we have that it contains exactly one pending singleton token if it is active and no pending singleton tokens if it is not active. If a is active and combined with an inactive token, by our inductive hypothesis, the resulting token contains exactly one pending singleton token. Lastly, if a is active and combined with another active token by our inductive hypothesis these contain pending singletons a_w and a_u respectively such that $c(w) = c(u) = i$; it follows that the resulting token is inactive and contains no pending singleton tokens. This completes our induction. ◀

This behavior allows us to pair off vertices in W based on how their singleton tokens are combined.[12]

▶ **Lemma 26.** *For each $w \in W$ there exists a unique $u \in W$ such that $u \neq w$ and $v_{L_w}(w) = v_{L_u}(u)$ and $c(w) = c(u)$.*

Proof. Consider the round in which a token containing a_w, say a, is combined with an active token, say b, at vertex $v_{L_w}(w)$. Recall that this round is notated $c(w)$. By Lemma 25 we know that a and b contain exactly one pending singleton token, say a_w and a_u respectively.

[12] Without loss of generality we assume that $|W|$ is even here; if not, we can simply drop one element from W each time we construct OptPaths(W).



(a) Round 1. **(b)** Round 2. **(c)** Round 3. **(d)** Round 4.

(e) Round 5. **(f)** Round 6. **(g)** Round 7.

Figure 9 An illustration of the optimal schedule and how OptPaths(W) is constructed from it for a particular G. Active tokens are denoted by blue diamonds; inactive tokens are denoted by white diamonds; a dotted red arrow from node u to node v means that u sends to v; a double-ended blue arrow between two tokens a and b means that a and b are combined at the node; thick, dashed green lines give a path and its reversal in OptPaths(W) (for a total of 4 paths across all rounds) where $(v_1(w), v_2(w), \ldots v_{L_w}(w) = v_{L_u}(u), v_{L_u-1}(u), \ldots, v_1(u)) = P \in \text{OptPaths(W)}$ drawn only in round $c(w)$. Furthermore, token a labeled with $\{v : a \text{ contains } a_v\}$ and $W = \{1, 3, 4, 6\}$.

Since both a and b are active in this round and b contains a_u we have $c(u) = c(w)$. Moreover, since both a and b are combined at the same vertex we have $v_{L_u}(u) = v_{L_w}(w)$. Lastly, notice that this u is unique since by Lemma 25 there is exactly one singleton token, a_u, contained by b such that $c(u) \leq c(w)$. ◀

Having paired off vertices in W, we can now define OptPaths(W). Fix a w and let u be the vertex it is paired off with as in Lemma 26. We define $\text{OptPath}(w) := (v_1(w), v_2(w), \ldots v_{L_w}(w) = v_{L_u}(u), v_{L_u-1}(u), \ldots, v_1(u))$. Lastly, define $\text{OptPaths}(W) = \bigcup_{w \in W} \text{OptPath}(w)$. See Figure 9 for an illustration of how OptPaths(W) is constructed from the optimal schedule.

The critical property of OptPaths(W) is that it has vertex congestion commensurate with OPT as follows.

▶ **Lemma 27.** $con(\text{OptPaths}(W)) \leq \frac{2 \cdot \text{OPT}}{\min(t_c, t_m)}$.

Proof. Call a pair of directed paths in OptPaths(W) *complementary* if one path is OptPath(w) and the other OptPath(u) where u is to w as in Lemma 26. We argue that each pair of complementary paths passing through a given vertex v uniquely account for either t_c or t_m rounds of v's OPT rounds in the optimal schedule. Consider a pair of complementary paths, $P = (\text{OptPath}(w), \text{OptPath}(u))$, passing through a given vertex v. This pair of paths pass through v because in some round, say r_P, v sends a token containing a_u or a_w or v combines together tokens a and a' containing a_u and a_w respectively. Say that whichever of these operations accounts for P is *responsible* for P. Now suppose for the sake of contradiction that this operation of v in round r_P is responsible for another distinct pair P' of complementary paths, OptPath(w') and OptPath(u'). Notice that a_w, $a_{w'}$, a_u and $a_{u'}$ are all pending in round r_P. We case on whether v's action is a communication or a computation and show that v's operation cannot be responsible for P' in either case.

- Suppose that v is responsible for P and P' because it performs a computation in r_P. It follows that v combines an active token a and another active token a' where without loss of generality $a_w, a_{w'} \in a$ and $a_{w'}, a_u \in a'$. However, it then follows that a is active and contains two pending singleton tokens, which contradicts Lemma 25.
- Suppose that v is responsible for P and P' because it performs a communication in r_P by sending token a. It follows that without loss of generality $a_w, a_{w'} \in a$. However, either a is active or it is not. But by Lemma 25 if a is active it contains 1 pending singleton token and if a is not active then it contains 0 pending singleton tokens. Thus, the fact that v sends a token containing two pending singleton tokens contradicts Lemma 25.

Thus, it must be the case that v's action in r_P is uniquely responsible for P.

It follows that each computation and communication performed by v uniquely corresponds to a pair of complementary paths (consisting of a pair of paths in $\textsc{OptPaths}(W)$) that passes through v. Since v performs at most $\mathrm{OPT}/\min(t_c, t_m)$ operations in the optimal schedule, it follows that there are at most $\mathrm{OPT}/\min(t_c, t_m)$ pairs of complementary paths in $\textsc{OptPaths}(W)$ incident to v. Since each pair consists of two paths, there are at most $2 \cdot \mathrm{OPT}/\min(t_c, t_m)$ paths in $\textsc{OptPaths}(W)$ incident to v and so v has vertex congestion at most $2 \cdot \mathrm{OPT}/\min(t_c, t_m)$ in $\textsc{OptPaths}(W)$. Since v was arbitrary, this bound on congestion holds for every vertex. ◀

We now use $\textsc{OptPaths}(W)$ to construct a feasible solution for $\textsc{PathsFlowLP}(2L^*)$. We let $\tilde{f}$ be this feasible solution. Intuitively, $\tilde{f}$ simply sends flow along the paths of $\textsc{OptPaths}(W)$. More formally define $\tilde{f}$ as follows. For $w \in W$ and its corresponding path $\textsc{OptPath}(w) = (v_1(w), v_2(w), \ldots)$ we set $\tilde{f}_w(v_i, v_{i+1}) = 1$. We set all other variables of $\tilde{f}$ to 0 and let $\tilde{z}$ be the vertex congestion of $\textsc{OptPaths}(W)$.

▶ **Lemma 28.** *$(\tilde{f}, \tilde{z})$ is a feasible solution for $\textsc{PathsFlowLP}(2L^*)$ where $\tilde{z} \leq 2\mathrm{OPT}/\min(t_c, t_m)$.*

Proof. We begin by noting that every path in $\textsc{OptPaths}(W)$ is of length at most $2L^*$: for each $w \in W$, $\textsc{OptPath}(w)$ is the concatenation of two paths, each of which is of length no more than L^*. Moreover, notice that for each $w \in W$, the sink of $\textsc{OptPath}(w)$ is a $w' \in W$ such that $w' \neq w$.

We now argue that $(\tilde{f}, \tilde{z})$ is a feasible solution for $\textsc{PathsFlowLP}(2L^*)$: each vertex v with incoming w-flow that is not in $W \setminus w$ sends out this unit of flow and so Equation (2) is satisfied; since each $\textsc{OptPath}(w)$ is of length at most $2L^*$ and ends at a $w' \in W$ we have that every $w \in W$ is a source for f_w and not a sink for f_w, satisfying Equation (3); for the same reason, Equation (4) is satisfied; letting $\tilde{z}$ be the vertex congestion of $\textsc{OptPaths}(W)$ clearly satisfies Equation (5); and flow is trivially non-zero.

Lastly, since $\tilde{f}$ simply sends one unit of flow along each path in $\textsc{OptPaths}(W)$, our bound of $\tilde{z} \leq 2\mathrm{OPT}/\min(t_c, t_m)$ follows immediately from Lemma 27. ◀

We conclude that $\tilde{f}$ demonstrates that our LP has value commensurate with OPT.

▶ **Lemma 24.** $\min(t_c, t_m) \cdot z(2L^*) \leq 2\mathrm{OPT}$.

Proof. Since *Lemma* 28 shows that $(\tilde{f}, \tilde{z})$ is a feasible solution for $\textsc{PathsFlowLP}(2L^*)$ with cost at most $2\mathrm{OPT}/\min(t_c, t_m)$, our claim immediately follows. ◀

F.1.3 GetDirectedPaths Formally Defined

GetDirectedPaths solves our LP for different guesses of the longest path used by the optimal, samples paths based on the LP solution for our best guess, and then directs these paths. Formally, GetDirectedPaths is given in Algorithm 5, where $\xi := \lceil 2(n-1) \cdot (t_c + D \cdot t_m)/t_m \rceil$ is the range over which we search for L^*.

Algorithm 5 GetDirectedPaths(G, W).

Input: $W \subseteq V$ where $w \in W$ has a token
Output: Directed paths between nodes in W
$L \leftarrow \arg\min_{\hat{L} \in [\xi]} \left[t_m \cdot \hat{L} + \min(t_c, t_m) \cdot t(\hat{L}) \right]$
$f_w^* \leftarrow$ PathsFlowLP(L)
$\mathcal{P}_W \leftarrow$ SampleLPPaths(f_w^*, L, W)
$\vec{\mathcal{P}_U} \leftarrow$ AssignPaths($\mathcal{P}_W, W$)
return $\vec{\mathcal{P}_U}$

F.1.4 Sampling Paths from LP

Having shown that our LP has value commensurate with OPT and defined our algorithm based on this LP, we now provide the algorithm which we use to sample paths from our LP solution, SampleLPPaths. This algorithm produces a single sample by taking a random walk from each $w \in W$ where edges are taken with probability corresponding to their LP value. It repeats this $O(\log n)$ times to produce $O(\log n)$ samples. It then takes the sample with the most low congestion paths, discarding any high congestion paths in said sample. In particular, SampleLPPaths takes the sample $\mathcal{P}_W^i$ that maximizes $|Q(\mathcal{P}_W^i)|$ where $Q(\mathcal{P}_W^i) = \{P_w : P_w \in \mathcal{P}_W^i, \text{con}(P_w) \leq 10 \cdot z(\hat{L}) \log \hat{L}\}$ for an input $\hat{L}$.

Algorithm 6 SampleLPPaths(f_w^*).

Input: f_w^*, solution to PathsFlowLP($\hat{L}$); $\hat{L}$, guess of L^*; $W \subseteq V$
Output: Undirected paths between nodes in W
$\mathcal{C} \leftarrow \emptyset$
for sample $i \in O(\log n)$ **do**
  $\mathcal{P}_W^i \leftarrow \emptyset$
  for $w \in W$ **do**
    $v \sim f_w^*(w_1, v_2)$
    $P_w \leftarrow (w, v)$
    while $v \notin W$ **do**
      $v' \sim f_w^*(v_{|P_w|}, v'_{|P_w|+1})$
      $v \leftarrow v'$
      $P_w += v$
    $\mathcal{P}_W^i \leftarrow \mathcal{P}_W^i \cup \{P_w\}$
  $\mathcal{C} \leftarrow \mathcal{C} \cup \mathcal{P}_W^i$
$\mathcal{P}_S \leftarrow Q(\arg\max_{\mathcal{P}_W^i \in \mathcal{C}} |Q(\mathcal{P}_W^i)|)$
return $\mathcal{P}_W$

The properties of SampleLPPaths are as follows.

▶ **Lemma 29.** *For any fixed $W \subseteq V$, $\hat{L}$ and an optimal solution f^*_w to PathsFlowLP($\hat{L}$),* SampleLPPaths *is a polynomial-time randomized algorithm that outputs a set of undirected paths $\mathcal{P}_W$ such that $P_w \in \mathcal{P}_W$ is an undirected path with endpoints $w, w' \in S$ where $w \neq w'$. Also $|\mathcal{P}_W| \geq \frac{1}{3}|W|$ w.h.p., $con(\mathcal{P}_W) \leq z(\hat{L}) \cdot O(\log \hat{L})$, and $dil(\mathcal{P}_W) \leq \hat{L}$.*

Proof. Our proof consists of a series of union and Chernoff bounds over our samples. Consider an arbitrary $W \subseteq V$. Define T_w for $w \in W$ as the (directed) subgraph of $G_{\hat{L}}$ containing arc $(v, u) \in E_{\hat{L}}$ if for some r we have $f^*_w(x, y) > 0$. Notice that T_w is a weakly connected DAG where w has no edges into it: T_w does not contain any cycles since flow only moves from x_r to y_{r+1} for $x, y \in V$; by our flow constraints T_w must be weakly connected and w_r must have no edges into it for any r. Moreover, notice that P_w is generated by a random walk on T_w starting at w_1, where if the last vertex added to P_w was v, then we add u to P_w in step r of the random walk with probability $f^*_w(v_r, u_{r+1})$.

We first argue that every $P_w \in \mathcal{P}_W$ has endpoints $w, w' \in W$ for $w \neq w'$ and $\text{dil}(\mathcal{P}_W) \leq \hat{L}$. By construction, one endpoint of P_w is w. Moreover, the other endpoint of P_w will necessarily be a $w' \in W$ such that $w' \neq w$: by Equation (2) flow is conserved and by Equation (4) all flow from w must end at a point $w' \in W$ such that $w' \neq w$; thus our random walk will always eventually find such an w'. Moreover, notice that our random walk is of length at most $\hat{L}$ since T_w is of depth at most $\hat{L}$. Thus, every P_w is of length at most $\hat{L}$, meaning $\text{dil}(\mathcal{P}_W) \leq \hat{L}$.

Next, notice that, by the definition of Q, $\text{con}(\mathcal{P}_W) \leq z(\hat{L}) \cdot O(\log \hat{L})$ by construction since every element in $Q(\arg\max_{\mathcal{P}^i_W \in \mathcal{C}} |Q(\mathcal{P}^i_W)|)$ has $O(z(\hat{L}) \cdot O(\log \hat{L}))$ congestion.

Thus, it remains only to prove that $|\mathcal{P}_W| \geq \frac{1}{3}|W|$. We begin by arguing that for a fixed path P_w in a fixed set of sampled paths, $\mathcal{P}^i_W$ we have $\text{con}(P_w) \geq z(\hat{L}) \cdot O(\log \hat{L})$ with probability at most $\frac{1}{3}$. Consider a fixed path $P_w \in \mathcal{P}^i_W$ and fix an arbitrary $v \in P_w$. Now let X_{wv} stand for the random variable indicating the number of times that path P_w visits vertex w. without loss of generality we know that P_w contains no cycles (since if it did we could just remove said cycles) and so X_{sv} is either 1 or 0. By a union bound over rounds, then, we have $\mathbb{E}[X_{wv}] \leq \sum_r \sum_{u \in \Gamma(v)} f^*_W(u_r, v_{r+1}) \cdot \Pr(u \text{ taken in } (r-1)\text{th step}) \leq \sum_{u \in \Gamma(v)} \sum_r f^*_W(u_r, v_{r+1})$.

Now note that the congestion of a single vertex under our solution is just $\text{con}(v) = \sum_{w \in W} X_{wv}$. It follows that

$$\mathbb{E}[\text{con}(v)] = \sum_{w \in W} \mathbb{E}[X_{wv}] \leq \max_v \sum_w \sum_{u \in \Gamma(v)} \sum_r f^*_W(u_r, v_{r+1}) \leq z(\hat{L}).$$

Also notice that for a fixed v every X_{wv} is independent. Thus, we have by a Chernoff bound that that

$$\begin{aligned} \Pr(\text{con}(v) \geq z(\hat{L}) \cdot O(\log \hat{L})) &\leq \Pr\left(\sum_{w \in W} X_{wv} \geq \mathbb{E}\left[\sum_{w \in W} X_{wv}\right] \cdot O(\log \hat{L})\right) \\ &\leq \frac{1}{(\hat{L})^c} \end{aligned} \tag{7}$$

for c given by constants of our choosing. P_w is of length at most $\hat{L}$ by construction. Thus, by a union over $v \in P_w$ and Equation (7) we have that

$$\Pr\left(\text{con}(P_w) \geq z(\hat{L}) \cdot O(\log \hat{L})\right) \leq \frac{1}{\hat{L}^{c-1}} \leq \frac{1}{3}.$$

Thus, for a fixed path $P_w \in \mathcal{P}_W^i$ we know that this path has congestion at least $z(\hat{L}) \cdot O(\log \hat{L}))$ with probability at most $\frac{1}{3}$.

We now argue at least one of our $O(\log n)$ samples is such that at least $\frac{1}{3}$ of the paths in the sample have congestion at most $z(\hat{L}) \cdot O(\log \hat{L}))$. Let Y_{iw} be the random variable that is 1 if $P_w \in \mathcal{P}_W^i$ is such that $\text{con}(P_w) \geq z(\hat{L}) \cdot O(\log \hat{L}))$ and 0 otherwise. Notice that $\mathbb{E}[Y_{iw}] \leq \frac{1}{3}$ by the fact that a path has congestion at least $z(\hat{L}) \cdot O(\log \hat{L})$ with probability at most $\frac{1}{3}$. Now let $Z_i = \sum_{w \in W} Y_{iw}$ stand for the number of paths in sample i with high congestion. By linearity of expectation we have $\mathbb{E}[Z_i] \leq |W|\frac{1}{3}$. By Markov's inequality we have for a fixed i that $\Pr(Z_i \geq \frac{2}{3}|W|) \leq \Pr(Z_i \geq 2\,\mathbb{E}[Z_i]|W|) \leq \frac{1}{2}$. Now consider the probability that every sample i is such that more than $\frac{2}{3}$ of the paths have congestion more than $z(\hat{L}) \cdot O(\log \hat{L})$, i.e. consider the probability that for all i we have $Z_i \geq |W|\frac{2}{3}$. We have

$$\Pr\left(Z_i \geq |W|\frac{2}{3}, \forall i\right) \leq \left(\frac{1}{2}\right)^{O(\log n)} = \frac{1}{\text{poly}(n)}.$$

Thus, with high probability there will be some sample, i, such that $Z_i \leq |W|\frac{2}{3}$. It follows that with high probability $\max_{\mathcal{P}_W^i \in \mathcal{C}} |Q(\mathcal{P}_W^i)| \geq \frac{1}{3}|W|$ and since $\mathcal{P}_W = Q(\arg\max_{\mathcal{P}_W^i \in \mathcal{C}} |Q(\mathcal{P}_W^i)|)$, we conclude that with high probability $\mathcal{P}_W \geq \frac{1}{3}|W|$.

◀

F.1.5 Directing Paths

Given the undirected paths that we sample from our LP, $\mathcal{P}_W$, we produce a set of directed paths $\vec{\mathcal{P}}_U$ using AssignPaths, which works as follows. Define G' as the directed supergraph consisting of nodes W and directed edges $E' = \{(w, w') : w' \text{ is an endpoint of } P_w \in \mathcal{P}_W)\}$. Let $\Gamma_{G'}(v) = \{v' : (v', v) \in E' \vee (v, v') \in E'\}$ give the neighbors of v in G'. For each node $w \in G'$ with in-degree of at least two we do the following: if v has odd degree delete an arbitrary neighbor of w from G'; arbitrarily pair off the neighbors of w; for each such pair (w_1, w_2) add the directed path $P_{w_1} \circ rev(P_{w_2})$ to $\vec{\mathcal{P}}_U$ where $rev(P_{w_2})$ gives the result of removing the last element of P_{w_2} (namely, w) and reversing the direction of the path; remove $\{w, w_1, w_2\}$ from G'. Since we remove all vertices with in-degree of two or more and every vertex has out-degree 1, the remaining graph trivially consists only of nodes with in-degree at most 1 and out-degree at most 1. The remaining graph, therefore, is all cycles and paths. For each cycle or path $w_1, w_2, w_3, \ldots$ add the path corresponding to the edge from w_i to w_{i+1} for odd i to $\vec{\mathcal{P}}_U$. We let U be all sources of paths in $\vec{\mathcal{P}}_U$ and we let P_u be the path in $\vec{\mathcal{P}}_U$ with source u.

The properties of AssignPaths are as follows.

▶ **Lemma 30.** *Given $W \subseteq V$ and $\mathcal{P}_W = \{P_w : w \in W\}$ where the endpoints of P_w are $w, w' \in W$ for $w \neq w'$,* AssignPaths *in polynomial-time returns directed paths $\vec{\mathcal{P}}_U$ where at least $1/4$ of the nodes in W are the source of a directed path in $\vec{\mathcal{P}}_U$, each path in $\vec{\mathcal{P}}_U$ is of length at most $2 \cdot dil(\mathcal{P}_W)$ with congestion at most $con(\mathcal{P}_W)$ and each path in $\vec{\mathcal{P}}_U$ ends in a unique sink in W.*

Proof. When we add paths to $\vec{\mathcal{P}}_U$ that go through vertices of in-degree at least two, for every 4 vertices we remove we add at least one directed path to $\vec{\mathcal{P}}_U$ that is at most double the length of the longest a path in $\mathcal{P}_U$: in the worst case v has odd in-degree of 3 and we add only a single path. When we do the same for our cycles and paths for every 3 vertices we remove we add at least one directed path to $\vec{\mathcal{P}}_U$. Notice that by construction we clearly never reuse sinks in our directed paths. The bound on congestion and a polynomial runtime are trivial. ◀

F.1.6 Proof of Lemma 11

Finally, we conclude with the proof of Lemma 11.

▶ **Lemma 11.** *Given $W \subseteq V$,* GetDirectedPaths *is a randomized polynomial-time algorithm that returns a set of directed paths, $\vec{\mathcal{P}}_U = \{P_u : u \in U\}$ for $U \subseteq W$, such that with high probability at least $1/12$ of nodes in W are sources of paths in $\vec{\mathcal{P}}_U$ each with a unique sink in W. Moreover,*

$$con(\vec{\mathcal{P}}_U) \leq O\left(\frac{\mathrm{OPT}}{\min(t_c, t_m)} \log \frac{\mathrm{OPT}}{t_m}\right) \text{ and } dil(\vec{\mathcal{P}}_U) \leq \frac{8\mathrm{OPT}}{t_m}.$$

Proof. The fact that GetDirectedPaths returns a set of directed paths, $\vec{\mathcal{P}}_U$, such that at least $1/12$ of nodes in W are sources in a path with a sink in W follows directly from Lemma 29 and Lemma 30.

We now give the stated bounds on congestion and dilation. First notice that $2L^* \in [\xi]$. Moreover, $2\mathrm{OPT} \leq 2(n-1)(t_c + D \cdot t_m)$: the schedule that picks a pair of nodes, routes one to the other then aggregates and repeats $n-1$ times is always feasible and takes $(n-1)(t_c + D \cdot t_m)$ rounds. Thus, $2L^* \leq 2\frac{\mathrm{OPT}}{t_m} \leq \xi$.

Thus, by definition of L we know that

$$\begin{aligned} t_m \cdot L + \min(t_c, t_m) \cdot t(L) &\leq 2t_m \cdot L^* + \min(t_c, t_m) \cdot z(2L^*) \\ &\leq 2L^* + 2\mathrm{OPT} && \text{(By Lemma 24)} \\ &\leq 4\mathrm{OPT} && \text{(By dfn. of } L^*) \end{aligned}$$

It follows, then, that $t_m \cdot L \leq 4\mathrm{OPT}$ and so $L \leq \frac{4\mathrm{OPT}}{t_m}$. Similarly, we know that $\min(t_c, t_m) \cdot z(L) \leq 4\mathrm{OPT}$ and so $z(L) \leq \frac{4\mathrm{OPT}}{\min(t_c, t_m)}$.

Lastly, by Lemma 29 we know that $\mathrm{dil}(\mathcal{P}_W) \leq L \leq \frac{4\mathrm{OPT}}{t_m}$ and $\mathrm{con}(\mathcal{P}_W) \leq t(L) \cdot O(\log L) \leq O\left(\frac{\mathrm{OPT}}{\min(t_c, t_m)} \cdot \log \frac{\mathrm{OPT}}{t_m}\right)$. By Lemma 30 we get that the same congestion bound holds for $\vec{\mathcal{P}}_U$ and $\mathrm{dil}(\vec{\mathcal{P}}_U) \leq \frac{8\mathrm{OPT}}{\min(t_c, t_m)}$.

A polynomial runtime comes from the fact that we solve at most $(n-1)(t_c + D \cdot t_m) = \mathrm{poly}(n)$ LPs and then sample at most $(n-1)(t_c + D \cdot t_m)$ edges $O(\log n)$ times to round the chosen LP. ◀

F.2 Deferred Proofs of Section 4.2.2

▶ **Lemma 12.** *Given a set of directed paths $\vec{\mathcal{P}}_U$ with some subset of endpoints of paths in $\vec{\mathcal{P}}_U$ designated sources and the rest of the endpoints designated sinks,* OptRoute *is a randomized polynomial-time algorithm that w.h.p. produces a* Token Network *schedule that sends from all sources to sinks in $O(con(\vec{\mathcal{P}}_U) + dil(\vec{\mathcal{P}}_U))$.*

Proof. Given a set of paths $\vec{\mathcal{P}_U}$, Rothvoß [31] provides a polynomial-time algorithm that produces a schedule that routes along all paths in $O(\text{con}_E(\vec{\mathcal{P}_U}) + \text{dil}(\vec{\mathcal{P}_U})$ where $\text{con}_E(\mathcal{P}) = \max_e \sum_{P \in \mathcal{P}} \mathbb{1}(e \in P)$ is the edge congestion. However, the algorithm of Rothvoß [31] assumes that in each round a vertex can send a token along each of its incident edges whereas we assume that in each round a vertex can only forward a single token.

However, it is easy to use the algorithm of Rothvoß [31] to produce an algorithm that produces a Token Network routing schedule using $O(\text{con}(\vec{\mathcal{P}_U}) + \text{dil}(\vec{\mathcal{P}_U}))$ rounds which assumes that vertices only send one token per round as we assume in the Token Network model as follows. Let G be our input network with paths $\vec{\mathcal{P}_U}$ along which we would like to route where we assume that vertices can only send one token per round. We will produce another graph G' on which to run the algorithm of Rothvoß [31]. For each node $v \in G$ add nodes v_i and v_o to G'. Project each path $P \in \vec{\mathcal{P}_U}$ into G' to get $P' \in \vec{\mathcal{P}_U}'$ as follows: if edge (u, v) is in path $P \in \vec{\mathcal{P}_S}$ then add edge (u_o, v_i) and edge (v_i, v_o) to path P' in G'. Notice that $\text{con}(\vec{\mathcal{P}_U}) = \text{con}_E(\vec{\mathcal{P}_U}')$ and $\text{dil}(\vec{\mathcal{P}_U}) = 2\text{dil}(\vec{\mathcal{P}_U}')$. Now run the algorithm of Rothvoß [31] on G' with paths $\mathcal{P}'_U$ to get back some routing schedule S'.

Without loss of generality we can assume that S' only has nodes in G' send along a single edge in each round: every v_i is incident to a single outbound edge across all paths (namely (v_i, v_o)) and so cannot send more than one token per round; every v_o has a single incoming edge and so receives at most one token per round which, without loss of generality, we can assume v_o sends as soon as it receives (it might be the case that v_o collects some number of tokens over several rounds and then sends them all out at once but we can always just have v_o forward these tokens as soon as they are received and have the recipients "pretend" that they do not receive them until v_o would have sent out many tokens at once).

Now generate a routing schedule for G as follows: if v_o sends token a in round r of S' then v will send token a in round r of S. Since S only ever has vertices send one token per round, it is easy to see by induction over rounds that S will successfully route along all paths. Moreover, S takes as many rounds as S' which by [31] we know takes $O(\text{con}(\vec{\mathcal{P}'_U}) + \text{dil}(\vec{\mathcal{P}'_U})) = O(\text{con}(\vec{\mathcal{P}_U}) + 2\text{dil}(\vec{\mathcal{P}_U})) = O(\text{con}(\vec{\mathcal{P}_U}) + \text{dil}(\vec{\mathcal{P}_U}))$. Thus, we let OPTRoute be the algorithm that returns S. ◀

▶ **Lemma 13.** RoutePaths$_m$ *is a polynomial-time algorithm that, given* $\vec{\mathcal{P}_U}$*, solves the* Route and Compute *Problem w.h.p. using* $O(t_m(con(\vec{\mathcal{P}_U}) + dil(\vec{\mathcal{P}_U})) + t_c)$ *rounds.*

Proof. By Lemma 12, OPTRoute takes $t_m(\text{con}(\vec{\mathcal{P}_U}) + \text{dil}(\vec{\mathcal{P}_U}))$ rounds to route all sources to sinks. All sources are combined with sinks in the following computation and so RoutePaths$_m$ successfully solves the Route and Compute Problem since every source has its token combined with another token. The polynomial runtime of the algorithm is trivial. ◀

▶ **Lemma 14.** RoutePaths$_c$ *is a polynomial-time algorithm that, given* $\vec{\mathcal{P}_U}$*, solves the* Route and Compute *Problem w.h.p. using* $O(t_c \cdot con(\vec{\mathcal{P}_U}) + t_m \cdot dil(\vec{\mathcal{P}_U}))$ *rounds.*

Proof. We argue that every source's token ends at an asleep node with at least two tokens and no more than $\text{con}(\vec{\mathcal{P}_U})$ tokens. It follows that our computation at the end at least halves the number of tokens.

First notice that if a vertex falls asleep then it will receive at most $\text{con}(\vec{\mathcal{P}_S})$ tokens by the end of our algorithm since it is incident to at most this many paths. Moreover, notice that every token will either end at a sink or a sleeping vertex and every sleeping vertex is asleep because it has two or more tokens. It follows that every token is combined with at least one other token and so our schedule at least halves the total number of tokens.

The length of our schedule simply comes from noting that we have $O(\mathrm{dil}(\vec{\mathcal{P}_U}) \cdot t_m)$ forwarding rounds followed by $\mathrm{con}(\vec{\mathcal{P}_U}) \cdot t_c$ rounds of computation. Thus, we get a schedule of total length $O(t_c \cdot \mathrm{con}(\vec{\mathcal{P}_S}) + t_m \cdot \mathrm{dil}(\vec{\mathcal{P}_S}))$. A polynomial runtime is trivial. ◀

F.3 Proof of Theorem 9

▶ **Theorem 9.** SolveTC *is a polynomial-time algorithm that gives an* $O(\log n \cdot \log \frac{\mathrm{OPT}}{t_m})$*-approximation for* Token Computation *with high probability.*

Proof. By Lemma 11 we know that the paths returned by GetDirectedPaths, $\vec{\mathcal{P}_U}$ are such that $\mathrm{con}(\vec{\mathcal{P}_U}) \leq O\left(\frac{\mathrm{OPT}}{\min(t_c,t_m)} \log \frac{\mathrm{OPT}}{t_m}\right)$ and $\mathrm{dil}(\vec{\mathcal{P}_U}) \leq \frac{8\mathrm{OPT}}{t_m}$ and the paths returned have unique sinks and sources in W and there are at least $|W|/12$ paths w.h.p.

If $t_c > t_m$ then $\textsc{RoutePaths}_m$ is run which by Lemma 13 solves the Route and Compute Problem in $O(t_m \cdot \mathrm{con}(\vec{\mathcal{P}_U}) + t_m \cdot \mathrm{dil}(\vec{\mathcal{P}_U}) + t_c)$ rounds which is

$$\leq O\left(t_m \cdot \frac{\mathrm{OPT}}{\min(t_c,t_m)} \cdot \log \frac{\mathrm{OPT}}{t_m} + t_m \cdot \frac{8\mathrm{OPT}}{t_m} + t_c\right)$$
$$= O\left(\mathrm{OPT} \cdot \log \frac{\mathrm{OPT}}{t_m} + t_c\right)$$

If $t_c \leq t_m$ then $\textsc{RoutePaths}_c$ is run to solve the Route and Compute Problem which by Lemma 14 takes $O(t_c \cdot \mathrm{con}(\vec{\mathcal{P}_U}) + t_m \cdot \mathrm{dil}(\vec{\mathcal{P}_U}))$ rounds which is

$$\leq O\left(t_c \cdot \frac{4\mathrm{OPT}}{\min(t_c,t_m)} \cdot \log \frac{\mathrm{OPT}}{t_m} + t_m \cdot \frac{8\mathrm{OPT}}{t_m}\right)$$
$$= O\left(\mathrm{OPT} \cdot \log \frac{\mathrm{OPT}}{t_m}\right)$$

Thus, in either case, the produced schedule takes at most $O\left(\mathrm{OPT} \cdot \log \frac{\mathrm{OPT}}{t_m} + t_c\right)$ rounds to solve the Route and Compute Problem on at least $|W|/12$ paths in each iteration. Since solving the Route and Compute Problem reduces the total number of tokens by a constant fraction on the paths over which it is solved, and we have at least $|W|/12$ paths in each iteration w.h.p., by a union bound, every iteration reduces the total number of tokens by a constant fraction w.h.p. Thus, the concatenation of the $O(\log n)$ schedules produced, each of length $O(\mathrm{OPT} \cdot \log \frac{\mathrm{OPT}}{t_m} + t_c)$, is sufficient to reduce the total number of tokens to 1.

Thus, SolveTC produces a schedule that solves the problem of Token Computation in $O(\mathrm{OPT} \cdot \log n \log \frac{\mathrm{OPT}}{t_m} + t_c \cdot \log n)$ rounds. However, notice that $t_c \cdot \log n \leq \mathrm{OPT}$ (since the optimal schedule must perform at least $\log n$ serialized computations) and so the produced schedule is of length $O(\mathrm{OPT} \cdot \log n \log \frac{\mathrm{OPT}}{t_m} + t_c \log n) \leq O(\mathrm{OPT} \cdot \log n \log \frac{\mathrm{OPT}}{t_m})$. Lastly, a polynomial runtime is trivial given the polynomial runtime of our subroutines. ◀

Convertible Codes: New Class of Codes for Efficient Conversion of Coded Data in Distributed Storage

Abstract

Erasure codes are typically used in large-scale distributed storage systems to provide durability of data in the face of failures. In this setting, a set of k blocks to be stored is encoded using an $[n, k]$ code to generate n blocks that are then stored on different storage nodes. A recent work by Kadekodi et al. [32] shows that the failure rate of storage devices vary significantly over time, and that changing the rate of the code (via a change in the parameters n and k) in response to such variations provides significant reduction in storage space requirement. However, the resource overhead of realizing such a change in the code rate on already encoded data in traditional codes is prohibitively high.

Motivated by this application, in this work we first present a new framework to formalize the notion of *code conversion* – the process of converting data encoded with an $[n^I, k^I]$ code into data encoded with an $[n^F, k^F]$ code while maintaining desired decodability properties, such as the maximum-distance-separable (MDS) property. We then introduce *convertible codes*, a new class of code pairs that allow for code conversions in a resource-efficient manner. For an important parameter regime (which we call the merge regime) along with the widely used linearity and MDS decodability constraint, we prove tight bounds on the number of nodes accessed during code conversion. In particular, our achievability result is an explicit construction of MDS convertible codes that are optimal for all parameter values in the merge regime albeit with a high field size. We then present explicit low-field-size constructions of optimal MDS convertible codes for a broad range of parameters in the merge regime. Our results thus show that it is indeed possible to achieve code conversions with significantly lesser resources as compared to the default approach of re-encoding.

1 Introduction

Erasure codes have become an essential tool for protecting against failures in distributed storage systems [18, 9, 30, 4]. Under erasure coding, a set of k data symbols to be stored is encoded using an $[n, k]$ code to generate n coded symbols, called a *codeword* (or *stripe*).

Each of the n symbols in a codeword is stored on a different storage node, and the system as a whole will contain several independent codewords distributed across different sets of storage nodes in the cluster.

A key factor that determines the choice of parameters n and k is the failure rate of the storage devices. It has been shown that failure rates of storage devices in large-scale storage systems can vary significantly over time and that changing the code rate, by changing n and k, in response to these variations yields substantial savings in storage space and hence the operating costs [32]. For example, in [32], the authors show that an 11% to 44% reduction in storage space can be achieved by tailoring n and k to changes in observed device failure rates. Such a reduction in storage space requirement translates to significant savings in the cost of resources and energy consumed in large-scale storage systems. It is natural to think of potentially achieving such a change in code rate by changing only n while keeping k fixed. However, due to several practical system constraints, changing code rate in storage systems often necessitates change in both the parameters n and k [32]. We refer the reader to [32] for a more detailed discussion on the practical benefits and constraints of adapting the erasure-code parameters with the variations in failure rates in a storage system.

Changing n and k for stripes in a storage system would involve converting already encoded data from one code to another. Such conversions, however, can generate a large amount of load (as explained below) which adversely affects the operation of the cluster. Furthermore, in some cases these conversions might need to be performed in an expedited manner, for example, to avoid the risk of data loss when facing an unexpected rise in failure rate. Hence it is critical to minimize the resource consumption of code conversion operations. Clearly, it is always possible to re-encode the data in a codeword (or a stripe) according to a new code by accessing (or decoding if needed) all the (original) message symbols. However, such an approach, which we call the *default approach*, requires accessing a large number of nodes (for example, for MDS codes, the initial value of k number of nodes need to be accessed) reading out all the data, transferring over the network, and re-encoding, which consumes large amounts of resources.

To the best of our knowledge, the existing literature [44, 59, 29] on formally studying the problem of changing parameters n and k for already encoded data model the code conversion problem within the framework of *repair-efficient* codes. Repair-efficient codes (e.g., [16, 47, 71, 49, 21]), which are a class of codes that can reconstruct a small subset of codeword symbols more efficiently than reconstructing the entire (original) message, has been an active area of research in the recent past. While the existing approach of exploiting repair efficiency for conversion efficiency provides reduction in the network bandwidth consumed as compared to the default approach for several parameter regimes, it has several drawbacks. For example, under this approach conversion requires accessing every symbol in the codeword and redistributing ("subsymbols") around. A more detailed discussion on repair-efficient codes and existing works which exploit repair efficiency for conversion efficiency is provided in Section 6.

In this paper, we propose a fundamentally new framework to model the code conversion problem, which is independent of repair efficiency. Our approach is based on the observation that the problem of changing code parameters in a storage system can be viewed as converting *multiple codewords* of an $[n^I, k^I]$ code (denoted by $\mathcal{C}^I$) into (potentially multiple) codewords of an $[n^F, k^F]$ code (denoted by $\mathcal{C}^F$)[1], with desired constraints on decodability such as both

[1] The superscripts I and F stand for initial and final respectively, representing the initial and final state of the conversion.

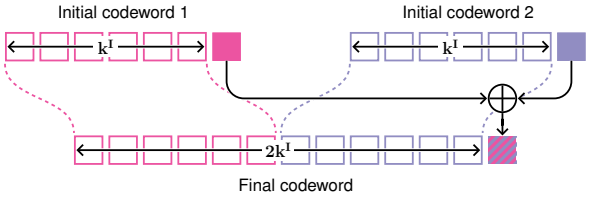

Figure 1 Example of code conversion: two codewords of a $[k^I + 1, k^I]$ single-parity-check code become one codeword of a $[2k^I + 1, 2k^I]$ single-parity-check code. The parity symbols are shown shaded. The data symbols from each codeword are preserved, and the parity symbol from the final codeword is the sum of the parities from each initial codeword.

codes satisfying the maximum-distance-separability (MDS) property. The code constructions that we present in this paper, under this new framework, require accessing significantly fewer symbols during conversion than existing works. Furthermore, even though the constructions presented in this paper optimize for reducing the number of symbols accessed for conversion, the bandwidth consumed for conversion is also lower in several parameter regimes of practical interest, compared to existing works (based on repair efficiency) that optimize for network bandwidth.

We now present a toy example to elucidate the concept of code conversion in our framework.

▶ **Example 1.** Consider conversion from an $[n^I = k^I + 1, k^I]$ code $\mathcal{C}^I$ to an $[n^F = k^F + 1, k^F]$ code $\mathcal{C}^F$. In our framework, this conversion is achieved by "merging" two codewords of the initial code for each codeword of the final code. Let us focus on the number of symbols accessed during conversion. The default approach requires accessing k^I symbols from each codeword belonging to $\mathcal{C}^I$ (initial codewords), and accessing at least one symbol for each codeword belonging to $\mathcal{C}^F$ (final codewords) to write out the result, totalling $2k^I + 1$ symbols accessed per final codeword. Alternatively, as depicted in Figure 1, one can choose $\mathcal{C}^I$ and $\mathcal{C}^F$ to be single-parity-check codes with the parity symbol holding the sum of the data symbols in each codeword (shown with a shaded box in the figure). To convert from $\mathcal{C}^I$ to $\mathcal{C}^F$, one sums the parity symbol from each initial codeword and stores the result as the parity symbol of the final codeword $\mathcal{C}^F$. This alternative approach requires accessing only three symbols for each final codeword, which is significantly more efficient.

Next, we give an overview of the main results and key ideas presented in this paper.

1.1 Overview of results

In this paper, we propose a *new framework to model the problem of code conversion*, that is, the process of converting data encoded with an $[n^I, k^I]$ code into data encoded with an $[n^F, k^F]$ code while maintaining desired decodability properties, such as maximum-distance-separable (MDS) property (Section 2). We then introduce a new class of code pairs, which we call *convertible codes*, that allow for resource-efficient conversions. We begin the study of this new class of code pairs, by focusing on an important regime where $k^F = \lambda k^I$ for any integer $\lambda \geq 2$ with arbitrary values of n^I and n^F, which we call the *merge regime*. Furthermore, we focus on the *access cost* of code conversion, which corresponds to *the total number of symbols accessed during conversion*. Keeping the number of symbols accessed small makes conversion less disruptive, allows the unaffected nodes to remain available for normal operations, and also reduces the amount of computation and communication needed.

Using our framework, we prove a tight lower bound on the access cost of conversions for linear MDS codes in the merge regime (Section 3). Let $r^I = n^I - k^I$ and $r^F = n^F - k^F$. This lower bound identifies two regions: (1) $r^F \leq r^I$, where significant savings in access cost can be achieved when $r^F < k^I$, and (2) the complement $r^F > r^I$, where linear MDS codes cannot achieve lower access cost than the default approach. Specifically, we prove:

▶ **Theorem 15.** *For all linear MDS $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible codes, the access cost of conversion is at least $r^F + \lambda \min\{k^I, r^F\}$. Furthermore, if $r^I < r^F$, the access cost of conversion is at least $r^F + \lambda k^I$.*

We prove this lower bound first on a class of linear MDS convertible codes that we call *stable* convertible codes. We then extend this lower bound to all linear MDS convertible codes by showing that non-stable convertible codes cannot achieve this lower bound, and thus all optimal linear MDS convertible codes in the merge regime are stable.

Then, we describe a construction of linear MDS Convertible Codes in the merge regime that meet the bound of Theorem 15, thereby providing convertible codes that are access-optimal (Section 4). Specifically:

▶ **Theorem 22.** *The explicit construction provided in Section 4.1 yields access-optimal linear MDS convertible codes for all parameter values in the merge regime.*

The construction is deterministic and yields codes over a finite extension field. To prove that those codes are access-optimal, we show that the resulting generator matrices have a particular structure, and that none of their minors are zero when the degree of the field extension is large enough. This implies that the field size required is very large (exponential in n^F for fixed constant final code rate and typical parameters). Field size is an important aspect of code design that has been widely studied in the context of other code families [12, 62, 2, 24]. To address this issue, we introduce a sequence of constructions of convertible codes that have significantly lower field size requirements (Section 5). This sequence of constructions, which we denote Hankel$_s$ ($s \in \{\lambda, \ldots, r^I\}$), presents a tradeoff between field size and the parameter range that they support. Specifically, we show:

▶ **Theorem 25.** *Given parameters k^I, r^I, λ, and a field $\mathbb{F}_q$, Hankel$_s$ ($s \in \{\lambda, \ldots, r^I\}$) constructs an access-optimal $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code if:*

$$r^F \leq (s - \lambda + 1)\left\lfloor \frac{r^I}{s} \right\rfloor + \max\{(r^I \bmod s) - \lambda + 1, 0\} \quad \text{and} \quad q \geq sk^I + \left\lfloor \frac{r^I}{s} \right\rfloor - 1.$$

Of particular interest are the two extreme points of this tradeoff which we call Hankel-I and Hankel-II respectively: Hankel-I supports $r^F \leq \lfloor r^I/\lambda \rfloor$ requiring field size $q \geq \max\{n^I - 1, n^F - 1\}$; and Hankel-II supports a wider range $r^F \leq r^I - \lambda + 1$ requiring field size $q \geq k^I r^I$.

The key idea behind our construction is to construct the parity generator matrices of the initial and final codes as cleverly-chosen submatrices of a specially constructed upper-left triangular array. This array has two important properties: (1) every square submatrix of this array is non-singular, and (2) it has *Hankel form*, that is, each ascending diagonal from left to right is constant. By exploiting the repetitive structure of the array, our constructions yield convertible codes that achieve optimal access cost during conversion. Given the way in which these codes are constructed, they also have the additional property of being (punctured) generalized doubly-extended Reed-Solomon codes.

Our results thus show that there is a broad regime where code conversions can be achieved with significantly less access cost than the default approach, and another regime where achieving less access cost than the default approach is not possible. We provide a

general explicit construction of access-optimal convertible codes in the former regime, and low-field-size constructions for a wide parameter range within this regime. The framework of convertible codes presented in this work opens several new opportunities which pose interesting theoretical questions that have a potential for impact on real-world systems.

1.2 Background

In this subsection we introduce some notation and basic definitions related to linear codes. Let $\mathbb{F}_q$ be a finite field of size q. An $[n, k]$ linear code $\mathcal{C}$ over $\mathbb{F}_q$ is a k-dimensional subspace $\mathcal{C} \subseteq \mathbb{F}_q^n$. Here, n is called the length of the code, and k is called the dimension of the code. A *generator matrix* of an $[n, k]$ linear code $\mathcal{C}$ over $\mathbb{F}_q$ is a $k \times n$ matrix $\mathbf{G}$ over $\mathbb{F}_q$ such that the rows of $\mathbf{G}$ form a basis of the subspace $\mathcal{C}$. A $k \times n$ generator matrix $\mathbf{G}$ is said to be *systematic* if it has the form $\mathbf{G} = [\mathbf{I} \mid \mathbf{P}]$, where $\mathbf{I}$ is the $k \times k$ identity matrix and $\mathbf{P}$ is a $k \times (n - k)$ matrix. Even though the generator matrix of a code $\mathcal{C}$ is not unique, we will sometimes associate code $\mathcal{C}$ to a specific generator matrix $\mathbf{G}$, which will be clear from the context. The encoding of a message $\mathbf{m} \in \mathbb{F}_q^k$ under an $[n, k]$ code $\mathcal{C}$ with generator matrix $\mathbf{G}$ is denoted $\mathcal{C}(\mathbf{m}) = \mathbf{m}^T\mathbf{G}$.

Let $[i]$ denote the set $\{1, 2, \ldots, i\}$. A linear code $\mathcal{C}$ is *maximum distance separable* (MDS) if the minimum distance of the code is the maximum possible:

$$\text{min-dist}(\mathcal{C}) = \min_{c \neq c' \in \mathcal{C}} |\{i \in [n] : c_i \neq c'_i\}| = n - k + 1$$

where $c_i \in \mathbb{F}_q$ denotes the i-th coordinate of c. Equivalently, a linear code $\mathcal{C}$ is MDS if and only if every $k \times k$ submatrix of its generator matrix $\mathbf{G}$ is non-singular [34].

2 A framework for studying code conversions

In this section, we formally define our new framework for studying *code conversions* and introduce *convertible codes*. While we use the notation of linear codes introduced in Section 1.2, the framework introduced in this section can be applied to arbitrary (not necessarily linear) codes. Suppose one wants to convert data that is already encoded using an $[n^I, k^I]$ initial code $\mathcal{C}^I$ into data encoded using an $[n^F, k^F]$ final code $\mathcal{C}^F$ where both codes are over the same field $\mathbb{F}_q$. In the initial and final configurations, the system must store the same information, but encoded differently. In order to capture the changes in the dimension of the code during conversion, we consider $M = \text{lcm}(k^I, k^F)$ number of "message" symbols (i.e., the data to be stored) over a finite field $\mathbb{F}_q$, denoted by $\mathbf{m} \in \mathbb{F}_q^M$. This corresponds to multiple codewords in the initial and final configurations. We note that this *need for considering multiple codewords in order to capture the smallest instance of the problem* deviates from existing literature on the code repair problem (e.g., [16, 26, 47, 49]) and code locality (e.g., [21, 41, 27]), where a single codeword is sufficient to capture the problem.

Since there are multiple codewords, we first specify an *initial partition* $\mathcal{P}_I$ and a *final partition* $\mathcal{P}_F$ of the set $[M]$, which map the message symbols of $\mathbf{m}$ to their corresponding initial and final codewords. The initial partition $\mathcal{P}_I \subseteq 2^{[M]}$ is composed of M/k^I disjoint subsets of size k^I, and the final partition $\mathcal{P}_F \subseteq 2^{[M]}$ is composed of M/k^F disjoint subsets of size k^F. In the initial (respectively, final) configuration, the data indexed by each subset $S \in \mathcal{P}_I$ (respectively, $\mathcal{P}_F$) is encoded using the code $\mathcal{C}^I$ (respectively, $\mathcal{C}^F$). The codewords $\{\mathcal{C}^I(\mathbf{m}_S),\ S \in \mathcal{P}_I\}$ are referred to as *initial codewords*, and the codewords $\{\mathcal{C}^F(\mathbf{m}_S),\ S \in \mathcal{P}_F\}$ are referred to as *final codewords*, where $\mathbf{m}_S$ corresponds to the projection of $\mathbf{m}$ onto the coordinates in S. The descriptions of the initial and final partitions and codes, along with the conversion procedure, define a convertible code. We now proceed to define conversions and convertible codes formally.

▶ **Definition 2** (Code conversion). *A* conversion *from an initial code $\mathcal{C}^I$ to a final code $\mathcal{C}^F$ with initial partition $\mathcal{P}_I$ and final partition $\mathcal{P}_F$ is a procedure, denoted by $T_{\mathcal{C}^I \to \mathcal{C}^F}$, that for any $\mathbf{m}$, takes the set of initial codewords $\{\mathcal{C}^I(\mathbf{m}_S) \mid S \in \mathcal{P}_I\}$ as input, and outputs the corresponding set of final codewords $\{\mathcal{C}^F(\mathbf{m}_S) \mid S \in \mathcal{P}_F\}$.*

▶ **Definition 3** (Convertible code). *A $(n^I, k^I; n^F, k^F)$ convertible code over $\mathbb{F}_q$ is defined by: (1) a pair of codes $(\mathcal{C}^I, \mathcal{C}^F)$ where $\mathcal{C}^I$ is an $[n^I, k^I]$ code over $\mathbb{F}_q$ and $\mathcal{C}^F$ is an $[n^F, k^F]$ code over $\mathbb{F}_q$; (2) a pair of partitions $\mathcal{P}_I, \mathcal{P}_F$ of $[M = \text{lcm}(k^I, k^F)]$ such that each subset in $\mathcal{P}_I$ is of size k^I and each subset in $\mathcal{P}_F$ is of size k^F; and (3) a conversion procedure $T_{\mathcal{C}^I \to \mathcal{C}^F}$ that on input $\{\mathcal{C}^I(\mathbf{m}_S) \mid S \in \mathcal{P}_I\}$ outputs $\{\mathcal{C}^F(\mathbf{m}_S) \mid S \in \mathcal{P}_F\}$ for all $\mathbf{m} \in \mathbb{F}_q^M$.*

Typically, additional constraints would be imposed on $\mathcal{C}^I$ and $\mathcal{C}^F$, such as requiring both codes to be MDS.

▶ Remark 4. Note that the definition of convertible codes (Definition 3) assumes that $(n^I, k^I; n^F, k^F)$ are known at the time of code construction. This will be helpful in understanding the fundamental limits of the conversion process. In practice, this assumption might not hold. For example, n^F, k^F might depend on the node failure rates that are yet to be observed. *Interestingly, it is possible for a $(n^I, k^I; n^F, k^F)$ convertible code to facilitate conversion to multiple values of n^F, k^F simultaneously, as is the case for the code constructions presented in this paper.*

The cost of conversion is determined by the cost of the conversion procedure $T_{\mathcal{C}^I \to \mathcal{C}^F}$, as a function of the parameters $(n^I, k^I; n^F, k^F)$. Towards minimizing the overhead of the conversion, our general objective is to design codes $(\mathcal{C}^I, \mathcal{C}^F)$, partitions $(\mathcal{P}_I, \mathcal{P}_F)$ and conversion procedure $T_{\mathcal{C}^I \to \mathcal{C}^F}$ that satisfy Definition 3 and minimize the conversion cost for given parameters $(n^I, k^I; n^F, k^F)$, subject to desired decodability constraints on $\mathcal{C}^I$ and $\mathcal{C}^F$.

Depending on the relative importance of various resources in the cluster, one might be interested in optimizing the conversion with respect to various types of costs such as symbol access, computation (CPU), communication (network bandwidth), read/writes (disk IO), etc., or a combination of these costs. The general formulation of code conversions above provides a powerful framework to theoretically reason about convertible codes. In what follows, we will focus on a specific regime and a specific cost model.

3 Lower bounds on access cost of code conversion

The focus of this section is on deriving lower bounds on the access cost of code conversion in the merge regime (as defined below). We focus on a fundamental regime given by $k^F = \lambda k^I$, where integer $\lambda \geq 2$ is the number of initial codewords merged, with arbitrary values of n^I and n^F. We call this regime as *merge regime*. We additionally require that both the initial and final code are linear and MDS. Since linear MDS codes are widely used in storage systems and are well understood in the Coding Theory literature, they constitute a good starting point. In terms of cost of conversion, we focus on the *access cost* of code conversion, that is, the number of symbols that are affected by the conversion. Each symbol read from the initial codewords requires one symbol access and each symbol written to the final codeword requires one symbol access. Therefore, minimizing access cost amounts to *minimizing the sum of the number of symbols written to the final codeword and the number of symbols read from the initial codewords.*[2] Keeping this number small makes code conversion less disruptive

[2] Readers who are familiar with the literature on regenerating codes might observe that convertible codes optimizing for the access cost are "scalar" codes as opposed to being "vector" codes.

and allows the unaffected symbols to remain available for normal operation. Furthermore, reducing the number of accesses also reduces the amount of computation and communication required in contrast to the default approach.

▶ Remark 5. Note that, when defining the access cost above, we implicitly assume that conversion is performed by downloading all the required data to a central location, where the new symbols are computed and then distributed to their final locations. This assumption does not affect the access cost, but it could affect other forms of cost, such as network bandwidth, which could be reduced by transferring data in a different way.

We now introduce some notation. We use the term *unchanged symbols* to refer to symbols from the initial codewords that remain *as is* in the final codeword, and we use the term *new symbols* to refer to symbols from the final codeword that are not present in the initial codewords (i.e. they are not unchanged). For example, in Figure 1, all the data symbols are unchanged symbols (unshaded boxes), and the parity symbol of the final codeword is a new symbol (striped box). We define the *read access set* of an $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code as a set of tuples $\mathcal{D} \in [\lambda] \times [n^I]$, where $(i, j) \in \mathcal{D}$ corresponds to the j-th symbol of initial codeword i. The set $\mathcal{D}$ must be such that all new symbols are linear combinations of symbols indexed by the tuples in $\mathcal{D}$. Furthermore, we use $\mathcal{D}_i = \{j \mid (i, j) \in \mathcal{D}\}$, $\forall i \in [\lambda]$ to denote the symbols read from a particular initial codeword.

In Section 4, we show that the lower bounds on the access cost derived in this section are in fact achievable. Therefore, we refer to MDS convertible codes in the merge regime achieving these lower bounds as *access-optimal*.

▶ **Definition 6** (Access-optimal). *A linear MDS $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code is said to be* access-optimal *if and only if it attains the minimum access cost over all linear MDS $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible codes.*

Now we present the access cost lower bounds of convertible codes in the merge regime.

3.1 Lower bounds on the access cost of code conversion

In this subsection, we present lower bounds on the access cost of linear MDS convertible codes in the merge regime. This is done in four steps:

1. We show that in the merge regime, all possible pairs of partitions $\mathbf{P}^I$ and $\mathbf{P}^F$ partitions are equivalent up to relabeling, and hence do not need to be specified.
2. An upper bound on the maximum number of unchanged symbols is proved. We call convertible codes that meet this bound as "*stable*".
3. Lower bounds on the access cost of linear MDS convertible codes are proved, under the added restriction that the convertible codes are stable.
4. The stability restriction is removed, by showing that non-stable linear MDS convertible codes necessarily incur higher access cost, and hence it suffices to consider only stable MDS convertible codes.

In the general regime, partitions need to be specified since they indicate how message symbols from the initial codewords are mapped into the final codewords. In the merge regime, however, the choice of the partitions does not matter.

▶ **Proposition 7.** *For every $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code, all possible pairs of initial and final partitions $(\mathcal{P}_I, \mathcal{P}_F)$ are equivalent up to relabeling.*

Proof. It holds that $M = \lambda k^I$, and there is only one possible final partition $\mathcal{P}_F = \{[\lambda k^I]\}$. Thus, all data is mapped to the same final codeword, regardless of $\mathcal{P}_I$. ◀

Since one of the terms in access cost is the number of new symbols, a natural way to reduce access cost is to maximize the number of unchanged symbols. However, there is a limit on the number of symbols that can remain unchanged.

▶ **Proposition 8.** *In an MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible code, there can be at most* k^I *unchanged symbols from each initial codeword.*

Proof. By the MDS property of $\mathcal{C}^I$ every subset of $k^I + 1$ symbols is linearly dependent. Hence, there can be at most k^I unchanged symbols from each initial codeword for $\mathcal{C}^F$ to be MDS. ◀

This implies that there are at most λk^I unchanged symbols and at least r^F new symbols in total.

Intuitively, having more new symbols means that more symbols have to be read in order to construct them, resulting in higher access cost. With this intuition in mind, we first focus on convertible codes that minimize the number of new symbols, which we call *stable*.

▶ **Definition 9** (Stability)**.** *An MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible code is* stable *if and only if it has exactly* λk^I *unchanged symbols, or in other words, exactly* r^F *new blocks.*

We first prove lower bounds on the access cost of stable linear MDS convertible codes, and then show that the minimum access cost of conversion in MDS codes without this stability property can only be higher. Minimizing the access cost of a stable convertible code reduces to minimizing the size of its read access set $\mathcal{D}$. The first lower bound on the size of $\mathcal{D}_i$ is given by the interaction between new symbols and the MDS property.

▶ **Lemma 10.** *For all linear stable MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible codes, the read access set* $\mathcal{D}_i$ *from each initial codeword* $i \in [\lambda]$ *satisfies* $|\mathcal{D}_i| \geq \min\{k^I, r^F\}$.

Proof sketch. For the MDS property to hold in the final code, the encoding vectors of the new symbols must fulfill certain independence requirements. This requires reading at least as many symbol from each initial codeword as there are new symbols, up to k^I symbols. Please refer to Appendix A.2 for full proof. ◀

We next show that when the number of new symbols r^F is greater than r^I in a MDS stable convertible code in the merge regime, then the default approach is optimal in terms of access cost.

▶ **Lemma 11.** *For all linear stable MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible codes, if* $r^I < r^F$ *then the read access set* $\mathcal{D}_i$ *from each initial codeword* $i \in [\lambda]$ *satisfies* $|\mathcal{D}_i| \geq k^I$.

Proof sketch. By Lemma 10, one is forced to read at least $r^I + 1$ symbols. Hence there exist symbols that are both unchanged and are read during conversion. Since unchanged blocks are also part of the final codeword, the information read from these symbols is not useful in creating a new symbol that retains the MDS property of the final code, unless k^I symbols (that is, full data) are read. Please refer to Appendix A.3 for full proof. ◀

Combining the above results leads to the following theorem on the lower bound of read access set size of linear stable MDS convertible codes.

▶ **Theorem 12.** *Let* $d^*(n^I, k^I; n^F, k^F)$ *denote the minimum integer* d *such that there exists a linear stable MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible code with read access set* $\mathcal{D}$ *of size* $|\mathcal{D}| = d$*. For all valid parameters,* $d^*(n^I, k^I; n^F, k^F) \geq \lambda \min\{k^I, r^F\}$*. Furthermore, if* $r^I < r^F$*, then* $d^*(n^I, k^I; n^F, k^F) \geq \lambda k^I$.

Proof. Follows directly from Lemma 10 and Lemma 11. ◀

We next show that this lower bound generally applies even for non-stable convertible codes by proving that increasing the number of new symbols from the minimum possible does not decrease the lower bound on the size of the read access set $\mathcal{D}$.

▶ **Lemma 13.** *The lower bounds on the size of the read access set from Theorem 12 hold for* ***all*** *linear MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible codes.*

Proof. In Appendix A.4. ◀

The above result, along with the fact that the lower bound in Theorem 12 is achievable (as will be shown in Section 4), implies that all access-optimal linear MDS convertible codes in the merge regime are stable.

▶ **Lemma 14.** *All access-optimal linear MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible codes are stable.*

Proof. In Appendix A.5. ◀

Thus, for MDS convertible codes in the merge regime, it suffices to focus only on stable codes. Combining all the results above, leads to the following key result.

▶ **Theorem 15.** *For all linear MDS* $(n^I, k^I; n^F, k^F = \lambda k^I)$ *convertible codes, the access cost of conversion is at least* $r^F + \lambda \min\{k^I, r^F\}$. *Furthermore, if* $r^I < r^F$, *the access cost of conversion is at least* $r^F + \lambda k^I$.

Proof. Follows from Theorem 12, Lemma 13, Lemma 14, and the definition of access cost. ◀

Next, in Section 4 we show that the lower bound of Theorem 15 is achievable for all parameters. Thus, Theorem 15 implies that it is possible to perform conversion of MDS convertible codes in the merge regime with significantly less access cost than the default approach if and only if $r^F \leq r^I$ and $r^F < k^I$.

▶ Remark 16. As discussed in Section 1, existing works [44, 59, 29] on code conversion model the problem within the framework of repair-efficient codes and optimize for network bandwidth consumed during conversion. These works require accessing every symbol, i.e. n^F symbols in total, during conversion. Our approach, thus, provides a significant reduction in terms of access cost in comparison to existing solutions for code conversion. To compare in terms of network bandwidth, consider each symbol to be a vector of size α as in these existing works. Then, our constructions (Section 4) can be easily implemented in a way that only requires a network bandwidth of $(\lambda - 1)r^F\alpha$ in the merge regime, by independently constructing each new symbol at the same location as one of the retired symbols it depends on. On the other hand, existing solutions [44, 59, 29] require network bandwidth of at least $[(\lambda - 1)k^I + r^F - r^I]\alpha$. Thus, although our constructions are optimized for access cost and not network bandwidth, they outperform existing solutions for several parameter regimes of practical interest, such as the merge regime with $r^I = r^F < k^I$ which corresponds to increasing the code rate for a code with rate greater than 0.5 (most storage systems use codes with rate greater than 0.5 and a conversion that increases the rate has been shown to be beneficial when a reduction in failure rate of storage devices is observed [32]).

4 Achievability: Explicit access-optimal convertible codes in the merge regime

In this section, we present an explicit construction of access-optimal MDS convertible codes for all parameters in the merge regime. In Section 4.1, we describe the construction of the generator matrices for the initial and final code. Then, in Section 4.2, we describe sufficient conditions for optimality and show that this construction yields access-optimal convertible codes.

4.1 Explicit construction

Recall that, in the merge regime, $k^F = \lambda k^I$, for an integer $\lambda \geq 2$ and arbitrary n^I and n^F. Also, recall that $r^I = n^I - k^I$ and $r^F = n^F - k^F$. Notice that when $r^I < r^F$, or $k^I \leq r^F$, constructing an access-optimal convertible code is trivial, since one can simply use the default approach. Thus, assume $r^F \leq \min\{r^I, k^I\}$.

Let $\mathbb{F}_q$ be a finite field of size $q = p^D$, where p is any prime and the degree D is a function of the convertible code parameters, which grows as $\Theta((n^F)^3)$ when $n^F > n^I$ and the rate of the final code is constant. Let θ be a primitive element of $\mathbb{F}_q$. Let $\mathbf{G}^I = [\mathbf{I}|\mathbf{P}^I]$ and $\mathbf{G}^F = [\mathbf{I}|\mathbf{P}^F]$ be systematic generator matrices of $\mathcal{C}^I$ and $\mathcal{C}^F$ over $\mathbb{F}_q$, where $\mathbf{P}^I$ is a $k^I \times r^I$ matrix and $\mathbf{P}^F$ is a $k^F \times r^F$ matrix. Define entry (i, j) of $\mathbf{P}^I \in \mathbb{F}_q^{k^I \times r^I}$ as $\theta^{(i-1)(j-1)}$, where (i, j) ranges over $[k^I] \times [r^I]$. Entry (i, j) of $\mathbf{P}^F \in \mathbb{F}_q^{k^F \times r^F}$ is defined identically as $\theta^{(i-1)(j-1)}$, where (i, j) ranges over $[k^F] \times [r^F]$. Notice that this construction is stable, because it is access-optimal (recall Lemma 14). The unchanged symbols of the initial code are exactly the systematic symbols.

4.2 Proof of optimality

Throughout this section, we use the following notation for submatrices: let M be a $n \times m$ matrix, the submatrix of M defined by row indices $\{i_1, \ldots, i_a\}$ and column indices $\{j_1, \ldots, j_b\}$ is denoted by $M[i_1, \ldots, i_a; j_1, \ldots, j_b]$. For conciseness, we use $*$ to denote all row or column indices, e.g., $M[*; j_1, \ldots, j_b]$ denotes the submatrix composed by columns $\{j_1, \ldots, j_b\}$, and $M[i_1, \ldots, i_a; *]$ denotes the submatrix composed by rows $\{i_1, \ldots, i_a\}$.

We first recall an important fact about systematic generator matrices of MDS codes.

▶ **Proposition 17** ([34]). *Let $\mathcal{C}$ be an $[n, k]$ code with generator matrix $G = [I|P]$. Then $\mathcal{C}$ is MDS if and only if P is superregular, that is, every square submatrix of P is nonsingular*[3].

Thus, to be MDS, both $\mathbf{P}^I$ and $\mathbf{P}^F$ need to be superregular.

To be access-optimal during conversion in the non-trivial case, the new symbols (corresponding to the columns of $\mathbf{P}^F$) have to be such that they can be generated by accessing r^F symbols from the initial codewords (corresponding to columns of $\mathbf{G}^I$).

During conversion, the encoding vectors of symbols from the initial codewords are represented as λk^I-dimensional vectors, where each initial codeword occupies a disjoint subset of k^I coordinates. To capture this property, we introduce the following definition.

[3] This definition of superregularity is stronger than the definition introduced in [19] in the context of convolutional codes.

▶ **Definition 18** (t-column block-constructible)**.** *We will say that an $n \times m_1$ matrix M_1 is* t-column constructible *from an $n \times m_2$ matrix M_2 if and only if there exists a subset $S \subseteq \text{cols}(M_2)$ of size t, such that the m_1 columns of M_1 are in the span of S. We say that a $\lambda n \times m_1$ matrix M_1 is* t-column block-constructible *from an $n \times m_2$ matrix M_2 if and only if for every $i \in [\lambda]$, the submatrix $M_1[(i-1)n+1, \ldots, in; *]$ is t-column constructible from M_2.*

▶ **Theorem 19.** *A systematic $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code with $k^I \times r^I$ initial parity generator matrix $\mathbf{P}^I$ and $k^F \times r^F$ final parity generator matrix $\mathbf{P}^F$ is MDS and access-optimal, if the following two conditions hold: (1) if $r^I \geq r^F$ then $\mathbf{P}^F$ is r^F-column block-constructible from $\mathbf{P}^I$, and (2) $\mathbf{P}^I, \mathbf{P}^F$ are superregular.*

Proof. Follows from Proposition 17 and the fact that $\mathbf{P}^F$ must be generated by accessing just r^F symbols from each initial codeword (Lemma 10). ◀

Thus, we can reduce the problem of proving the optimality of a systematic MDS convertible code in the merge regime to that of showing that matrices $\mathbf{P}^I$ and $\mathbf{P}^F$ satisfy the two properties mentioned in Theorem 19.

We first show that the construction specified in Section 4.1 satisfies condition (1) of Theorem 19.

▶ **Lemma 20.** *Let $\mathbf{P}^I, \mathbf{P}^F$ be as defined in Section 4.1. Then $\mathbf{P}^F$ is r^F-column block-constructible from $\mathbf{P}^I$.*

Proof sketch. Given the structure of $\mathbf{P}^I$ and $\mathbf{P}^F$, it is easy to see that $\mathbf{P}^F$ can be obtained by "vertically stacking" copies of $\mathbf{P}^I$, with their columns appropriately scaled by powers of θ. Please refer to Appendix B.1 for full proof. ◀

It only remains to show that the construction in Section 4.1 satisfies condition (2) of Theorem 19, that is, that $\mathbf{P}^I$ and $\mathbf{P}^F$ are superregular.

▶ **Lemma 21.** *Let $\mathbf{P}^I, \mathbf{P}^F$ be as defined in Section 4.1. Then $\mathbf{P}^I$ and $\mathbf{P}^F$ are superregular, for sufficiently large field size.*

Proof sketch. Consider the minors of $\mathbf{P}^I$ and $\mathbf{P}^F$ as polynomials on θ. Due to the structure of the the matrices $\mathbf{P}^I$ and $\mathbf{P}^F$ as specified in Section 4.1, all of these are non-zero polynomials which cannot have θ as a root as long as the degree of the extension field is large enough. Therefore none of the minors can be zero. Please refer to Appendix B.2 for the full proof. ◀

Combining the above results leads to the following key result on the achievability of the lower bounds on access cost derived in Section 3.

▶ **Theorem 22.** *The explicit construction provided in Section 4.1 yields access-optimal linear MDS convertible codes for all parameter values in the merge regime.*

Proof. Follows from Theorem 19, Lemma 20, and Lemma 21. ◀

The construction presented in this section is practical only for very small values of these parameters since the required field size grows exponentially with the lengths of the initial and final codes. In Section 5 we present practical low-field-size constructions.

5 Low field-size convertible codes based on superregular Hankel arrays

In this section we present alternative constructions for $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible codes that require a significantly lower (polynomial) field size than the construction presented in Section 4. The key idea behind our constructions is to take the matrices $\mathbf{P}^I$ and $\mathbf{P}^F$ as cleverly-chosen submatrices from a specially constructed triangular array of the following form:

$$T_m: \quad \begin{matrix} b_1 & b_2 & b_3 & \cdots & b_{m-1} & b_m \\ b_2 & b_3 & \cdots & \cdots & b_m & \\ b_3 & \vdots & \iddots & \iddots & & \\ \vdots & \vdots & \iddots & & & \\ b_{m-1} & b_m & & & & \\ b_m & & & & & \end{matrix} \tag{1}$$

with the property that every submatrix of T_m is superregular (the submatrix must lie completely within the triangular array). Here, (1) $b_1, \ldots, b_m$ are (not necessarily distinct) elements from $\mathbb{F}_q$, and (2) m is at most the field size q. The array T_m has Hankel form, that is, $T_m[i, j] = T_m[i-1, j+1]$, for all $i \in [2, m]$, $j \in [m-1]$. We denote T_m a *superregular Hankel array*. Such an array can be constructed by employing the algorithm proposed in [52] (where the algorithm was employed to generate generalized Cauchy matrices to construct generalized Reed-Solomon codes). This algorithm is described in Appendix D for reference, although it is not necessary for understanding the constructions in this section.

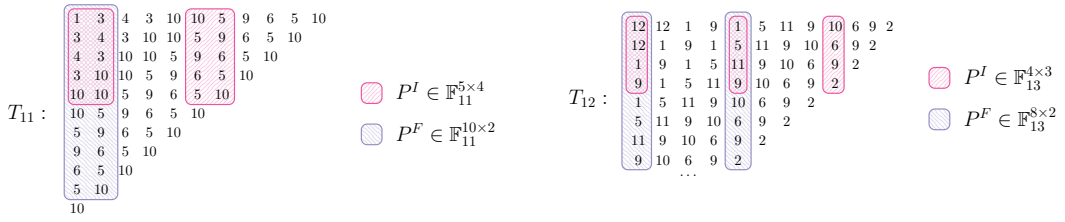
We construct the initial and final codes by taking submatrices $\mathbf{P}^I$ and $\mathbf{P}^F$ in a specific manner from superregular Hankel arrays (the submatrices have to be contained in the triangle where the array is defined). This guarantees that $\mathbf{P}^I$ and $\mathbf{P}^F$ are superregular. In addition, we exploit the Hankel form of the array by carefully choosing the submatrices that form $\mathbf{P}^I$ and $\mathbf{P}^F$ to ensure that $\mathbf{P}^F$ is r^F-column block-constructible from $\mathbf{P}^I$. Given the way we construct these matrices and the properties of T_m, all the initial and final codes presented in this subsection are (punctured) *generalized doubly-extended Reed-Solomon* codes [52].

The above idea yields a sequence of constructions with a tradeoff between the field size and the range of r^F supported. We first present two examples that correspond to the extreme ends of this tradeoff, which we call *Hankel-I* and *Hankel-II*. Construction Hankel-I, shown in Example 23, can be applied whenever $r^F \leq \lfloor r^I/\lambda \rfloor$, and requires a field size of $q \geq \max\{n^I, n^F\} - 1$. Construction Hankel-II, shown in Example 24, can be applied whenever $r^F \leq r^I - \lambda + 1$, and requires a field size of $q \geq k^I r^I$.

We then describe in detail the sequence of constructions that define a tradeoff between field size and coverage of r^F values in Section 5.1. In Section 5.2, we finalize with a discussion on the ability of these constructions to be optimal even when parameters of the final code are a priori unknown. Throughout this section we will assume that $\lambda \leq r^I \leq k^I$. The ideas presented here are still applicable when $r^I > k^I$, but the constructions and analysis change in minor ways.

▶ **Example 23** (Hankel-I)**.** Consider the parameters $(n^I = 9, k^I = 5; n^F = 12, k^F = 10)$ and the field $\mathbb{F}_{11}$. Notice that these parameters satisfy:

$$r^F = 2 \leq \left\lfloor \frac{r^I}{\lambda} \right\rfloor = 2 \quad \text{and} \quad q = 11 \geq \max\{n^I, n^F\} - 1 = 11.$$



(a) Hankel-I **(b)** Hankel-II

Figure 2 Examples of constructions based on Hankel arrays: (a) Hankel-I construction parity generator matrices for systematic $(n^I = 9, k^I = 5; n^F = 12, k^F = 10)$ convertible code. Notice how matrix $\mathbf{P}^F$ corresponds to the vertical concatenation of the first two columns and the last two columns of matrix $\mathbf{P}^I$. (b) Hankel-II construction parity generator matrices for systematic $(n^I = 7, k^I = 4; n^F = 10, k^F = 8)$ convertible code. Notice how matrix $\mathbf{P}^F$ corresponds to the vertical concatenation of the first and second column of $\mathbf{P}^I$, and the second and third column of $\mathbf{P}^I$.

First, construct a superregular Hankel array of size $n^F - 1 = 11$, T_{11}, employing the algorithm in [52]. Then, divide the $r^I = 4$ initial parities into $\lambda = 2$ groups: encoding vectors of parities in the same group will correspond to contiguous columns of T_{11}. The submatrix $\mathbf{P}^I \in \mathbb{F}_{11}^{5\times 4}$ is formed from the top $k^I = 5$ rows and columns $1, 2, k^I + 1 = 6$ and $k^I + 2 = 7$ of T_{11}, as shown in Figure 2a. The submatrix $\mathbf{P}^F \in \mathbb{F}_{11}^{10\times 2}$ is formed from the top $k^I = 10$ rows and columns $1, 2$ of T_{11}, as shown in Figure 2a. Checking that these matrices are superregular follows from the superregularity of T_{11}. It is to check that both these matrices are superregular, which follows from the the superregularity of T_{11}. Furthermore, notice that the chosen parity matrices have the following structure:

$$\mathbf{P}^I = \begin{bmatrix} | & | & | & | \\ \mathbf{p}_1 & \mathbf{p}_2 & \mathbf{p}_3 & \mathbf{p}_4 \\ | & | & | & | \end{bmatrix}, \qquad \mathbf{P}^F = \begin{bmatrix} \mathbf{p}_1 & \mathbf{p}_2 \\ \mathbf{p}_3 & \mathbf{p}_4 \end{bmatrix}.$$

From this structure, it is clear that $\mathbf{P}^F$ is 2-column block-constructible from $\mathbf{P}^I$. Therefore, $\mathbf{P}^I$ and $\mathbf{P}^F$ satisfy the sufficient conditions of Theorem 19, and define an access-optimal convertible code.

▶ **Example 24** (Hankel-II). Consider parameters $(n^I = 7, k^I = 4; n^F = 10, k^F = 8)$ and field $\mathbb{F}_{13}$. Notice that these parameters satisfy:

$$r^F = 2 \leq r^I - \lambda + 1 = 2 \quad \text{and} \quad q = 13 \geq k^I r^I = 12$$

First, construct a superregular Hankel array of size $k^I r^I = 12$, T_{12}, by choosing $q = 13$ as the field size, and employing the algorithm in [52]. The submatrix $\mathbf{P}^I \in \mathbb{F}_{13}^{4\times 3}$ is formed by the top $k^I = 4$ rows and columns $1, k^I + 1 = 5$ and $2k^I + 1 = 9$ of T_{12}, as shown in Figure 2b. The submatrix $\mathbf{P}^F \in \mathbb{F}_{13}^{8\times 2}$ is formed by the top $k^F = 8$ rows and columns 1 and $k^I + 1 = 5$ of T_{12}, as shown in Figure 2b. It is easy to check that $\mathbf{P}^I$ and $\mathbf{P}^F$ are superregular, which follows from the superregularity of T_{12}. Furthermore, notice that the chosen parity matrices have the following structure:

$$\mathbf{P}^I = \begin{bmatrix} | & | & | \\ \mathbf{p}_1 & \mathbf{p}_2 & \mathbf{p}_3 \\ | & | & | \end{bmatrix}, \qquad \mathbf{P}^F = \begin{bmatrix} \mathbf{p}_1 & \mathbf{p}_2 \\ \mathbf{p}_2 & \mathbf{p}_3 \end{bmatrix}$$

It is easy to see that $\mathbf{P}^F$ is 2-column block-constructible from $\mathbf{P}^I$. Therefore, $\mathbf{P}^I$ and $\mathbf{P}^F$ satisfy the sufficient conditions of Theorem 19, and define an access-optimal convertible code.

5.1 General Hankel-array-based construction of convertible codes

In this subsection, we present a sequence of Hankel-array-based constructions of access-optimal MDS convertible codes. This sequence of constructions presents a tradeoff between field size and the range of r^F supported. To index the sequence we use a $s \in \{\lambda, \lambda+1, \ldots, r^I\}$ which corresponds to the number of groups into which the initial parity encoding vectors are divided. Given parameters k^I, r^I, λ and a field $\mathbb{F}_q$, construction Hankel_s ($s \in \{\lambda, \lambda+1, \ldots, r^I\}$) supports:

$$r^F \leq (s-\lambda+1)\left\lfloor \frac{r^I}{s} \right\rfloor + \max\{(r^I \bmod s) - \lambda + 1, 0\}, \text{ requiring } q \geq \max\{sk^I + \left\lfloor \frac{r^I}{s} \right\rfloor - 1, n^I - 1\}.$$

Therefore, Hankel-I, from Example 23 corresponds to Hankel_λ and Hankel-II from Example 24 corresponds to Hankel_{r^I}.

Construction of Hankel_s. Assume, for the sake of simplicity, that $s \mid r^I$ and let $t = r^I/s$. Now we describe how to construct $\mathbf{P}^I$ and $\mathbf{P}^F$ over a field $\mathbb{F}_q$ whenever:

$$r^F \leq (s-\lambda+1)t \quad \text{and} \quad q \geq sk^I + t - 1.$$

Without loss of generality, we consider $r^F = (s-\lambda+1)t$ (lesser values of r^F can be obtained by puncturing the final code, i.e., eliminating some of the final parities). Let T_m be as in Equation (1), with $m = sk^I + t - 1$. Divide the r^I initial parity encoding vectors into s disjoint sets $S_1, S_2, \ldots, S_s$ of size t each. We associate each set S_i ($i \in [s]$) with a set of column indices $\text{col}(S_i) = \{(i-1)k^I+1, (i-1)k^I+2, \ldots, (i-1)k^I+t\}$ of T_m. Matrix $\mathbf{P}^I$ is the submatrix formed by the top k^I rows and the columns indexed by the set $\text{col}(S_1) \cup \cdots \cup \text{col}(S_s)$ of T_m. Matrix $\mathbf{P}^F$ is the submatrix formed by the top λk^I rows and the columns indexed by the set $\text{col}(S_1) \cup \cdots \cup \text{col}(S_{s-\lambda+1})$ of T_m. This results in the following matrices $\mathbf{P}^I$ and $\mathbf{P}^F$:

$$\mathbf{P}^I = \left[\begin{array}{ccc|c|ccc|c|ccc} b_1 & \cdots & b_t & \cdots & b_{(i-1)k^I+1} & \cdots & b_{(i-1)k^I+t} & \cdots & b_{(s-1)k^I+1} & \cdots & b_{(s-1)k^I+t} \\ b_2 & \cdots & b_{t+1} & \cdots & b_{(i-1)k^I+2} & \cdots & b_{(i-1)k^I+t+1} & \cdots & b_{(s-1)k^I+2} & \cdots & b_{(s-1)k^I+t+1} \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ b_{k^I} & \cdots & b_{k^I+t-1} & \cdots & b_{ik^I} & \cdots & b_{ik^I+t-1} & \cdots & b_{sk^I} & \cdots & b_{sk^I+t-1} \end{array}\right],$$

$$\mathbf{P}^F = \left[\begin{array}{ccc|c|ccc|c|ccc} b_1 & \cdots & b_t & \cdots & b_{(i-\lambda)k^I+1} & \cdots & b_{(i-\lambda)k^I+t} & \cdots & b_{(s-\lambda)k^I+1} & \cdots & b_{(s-\lambda)k^I+t} \\ b_2 & \cdots & b_{t+1} & \cdots & b_{(i-\lambda)k^I+2} & \cdots & b_{(i-\lambda)k^I+t+1} & \cdots & b_{(s-\lambda)k^I+2} & \cdots & b_{(s-\lambda)k^I+t+1} \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ b_{\lambda k^I} & \cdots & b_{\lambda k^I+1} & \cdots & b_{ik^I} & \cdots & b_{ik^I+t-1} & \cdots & b_{sk^I} & \cdots & b_{sk^I+t-1} \end{array}\right].$$

▶ **Theorem 25.** *Given parameters k^I, r^I, λ, and a field $\mathbb{F}_q$ Hankel_s ($s \in \{\lambda, \ldots, r^I\}$) constructs an access-optimal $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code if:*

$$r^F \leq (s-\lambda+1)\left\lfloor \frac{r^I}{s} \right\rfloor + \max\{(r^I \bmod s) - \lambda + 1, 0\} \quad \textit{and} \quad q \geq sk^I + \left\lfloor \frac{r^I}{s} \right\rfloor - 1.$$

Proof. In Appendix C.1. ◀

(Access-optimal) conversion process. During conversion, the k^I data symbols from each of the λ initial codewords remain unchanged, and become the $k^F = \lambda k^I$ data symbols from the final codeword. The r^F new (parity) blocks from the final codeword are constructed by accessing symbols from the initial codewords as detailed below. To construct the l-th new

symbol (corresponding to the l-th column of $\mathbf{P}^F$, $l \in [r^F]$), read parity symbol $l + (i-1)t$ from each initial codeword $i \in [\lambda]$, and then sum the λ symbols read. The encoding vector of the new symbol will be equal to the sum of the encoding vectors of the symbols read. This is done for every new encoding vector $l \in [r^F]$.

5.2 Handling a priori unknown parameters

So far, we had assumed that the parameters of the final code, n^F, k^F, are known a priori and are fixed. As discussed in Section 2, this is useful in developing an understanding of the fundamental limits of code conversion. When realizing code conversion in practice, however, the parameters n^F, k^F might not be known at code construction time (as it depends on the empirically observed failure rates). Thus, it is of interest to be able to *convert a code optimally to multiple different parameters*. The Hankel-array based constructions presented above indeed provide such a flexibility. Our constructions continue to enable access-optimal conversion for any $k^{F'} = \lambda' k^I$ and $n^{F'} = r^{F'} + k^{F'}$ with $0 \leq r^{F'} \leq r^F$ and $2 \leq \lambda' \leq \lambda$.

6 Related work

MDS erasure codes, such as Reed-Solomon codes, are widely used in storage systems because they achieve the optimal tradeoff between failure tolerance and storage overhead [43, 42]. However, the use of erasure codes in storage systems raises a host of other challenges. Several works in the literature have studied these aspects.

The encoding and decoding of data, and the finite field arithmetic that they require, can be compute intensive. Motivated by this, *array codes* [7, 70, 31, 28] are designed to use XOR operations exclusively, which are typically faster to execute, and aim to decrease the complexity of encoding and decoding.

The repair of failed nodes can require a large amount of network bandwidth. Several approaches have been proposed to alleviate this problem. Dimakis et al. [16] proposed a new class of codes called *regenerating codes* that minimize the amount of network bandwidth consumed during repair operations. Under the regenerating codes model [16], each symbol (i.e., node) is represented as an α-dimensional vector over a finite field. During repair of a failed node, download of elements of the finite field (i.e., "sub-symbols") is allowed as opposed to the whole vector (i.e., one "entire" symbol). This line of research has led to several constructions [10, 47, 55, 60, 68, 69, 64, 11, 40, 53, 71, 73, 50, 54, 22, 13, 35, 36], generalizations [56, 58, 1], and more efficient repair algorithms for Reed-Solomon codes [57, 26, 72, 15, 66, 37, 14, 67]. It has been shown that meeting the lower bound on the repair bandwidth requirement when MDS property and high rate are desired necessitates large sub-packetization [65, 23, 5, 3], which negatively affects certain key performance metrics in storage systems [45]. To overcome this issue, several works [49, 25] have proposed code constructions that relax the requirement of meeting lower bounds on IO and bandwidth requirements for repair operations. For example, the Piggybacking framework [49] provides a general framework to construct repair-efficient codes by transforming any existing codes, while allowing a small sub-packetization (even as small as 2).

Several works [46, 39] study the problem of two stage encoding: first generating a certain number of parities during the encoding process and then adding additional parities. As discussed in [46], adding additional parities can be conceptually viewed as a repair process by considering the new parity nodes to be generated as failed nodes. Furthermore, as shown in [55], for MDS codes, the bandwidth requirement for *repair of even a single node* is lower bounded by the same amount as in regenerating codes that require repair of *all* nodes. Thus one can always employ a regenerating code to add additional parities with minimum

bandwidth overhead. However, when MDS property and high rate are desired, as discussed above, using regenerating codes requires a large sub-packetization. The paper [39] employs the Piggybacking framework [48, 49] to construct codes that reduce the sub-packetization factor for two-stage encoding. The scenario of adding a fixed number of additional parities, when viewed under the setting of conversions, corresponds to having $k^I = k^F$ and $n^I < n^F$.

Existing works that consider changing the parameters n and k of already encoded data [44, 59, 29] consider a model similar to the regenerating codes model, wherein symbols are represented as vectors and communication is modeled via an information flow graph. In order to accommodate the changes in parameter k, the dimension α of each vector is changed, and constructions exploit repair efficiency to achieve conversion efficiency. However, this approach has the disadvantage that during conversion every symbol must be accessed. Our approach circumvents this problem by considering multiple codewords at a time, which allows convertible codes to achieve significantly smaller access cost during conversion. For a more detailed comparison between convertible codes and existing works on code conversion, see Remark 16 in Section 3.

Another class of codes, called *locally repairable codes* (LRCs) [21, 51, 8, 20, 41, 61, 33, 12, 63, 62, 6, 17, 2, 38, 27], focuses on the locality of codeword symbols during repair, that is, the number of nodes that need to be accessed when repairing a single failure. LRCs improve repair and degraded read performance, since missing information can be recovered by accessing a small subset of symbols. The objective of LRCs and convertible codes optimized for access cost is similar, as both aim to minimize the number of symbols that need to be accessed for different operations in storage systems.

7 Conclusions and future directions

In this paper, we propose a new framework to model the code conversion problem, that of converting data encoded with an $[n^I, k^I]$ code into data encoded with an $[n^F, k^F]$ code in a resource-efficient manner. The code conversion problem is motivated by the practical necessity of reducing the overhead of redundancy adaptation in erasure-coded storage systems [32]. We present the framework of convertible codes for studying code conversions, and fully characterize the fundamental limits on the access cost of conversions for an important regime of convertible codes. Furthermore, we present practical low-field-size constructions for access-optimal convertible codes for a wide range of parameters.

This work leads to a number of challenging and potentially impactful open problems. An important future direction is to go beyond the merge regime considered in this paper. While the construction techniques presented in this paper can be easily extended to upper bound the access cost of some parameter values outside the merge regime, identifying the fundamental limits on the access cost in general and constructing access-optimal convertible codes for all parameters remains open. Another important future direction is to analyze the fundamental limits of convertible codes on the overhead of other resources, such as disk IO (i.e., device bandwidth), communication (network bandwidth), computation (CPU), and construct convertible codes optimizing these resources. Note that while the access-optimal convertible codes considered in this paper also reduce the total disk IO, communication and computation during conversion as compared to the default approach, the overhead on these other resources may not be optimal. A final important direction is to explore additional applications of convertible codes beyond our initial motivation, to other problems within theoretical computer science where codes are used.

A Proofs of Section 3

A.1 Notation used in proofs

Let $\mathcal{C}^I$ be an $[n^I, k^I]$ MDS code over field $\mathbb{F}_q$, specified by generator matrix $\mathbf{G}^I$, with columns (that is, encoding vectors) $\{\mathbf{g}^I_1, \ldots, \mathbf{g}^I_{n^I}\} \subseteq \mathbb{F}_q^{k^I}$. Let $\lambda \geq 2$ be an integer, and let $\mathcal{C}^F$ be an $[n^F, k^F = \lambda k^I]$ MDS code over field $\mathbb{F}_q$, specified by generator matrix $\mathbf{G}^F$, with columns (that is, encoding vectors) $\{\mathbf{g}^F_1, \ldots, \mathbf{g}^F_{n^F}\} \subseteq \mathbb{F}_q^{k^F}$. Let $r^I = n^I - k^I$ and $r^F = n^F - k^F$. When $\mathcal{C}^I$ and $\mathcal{C}^F$ are systematic, r^I and r^F correspond to the initial number of parities and final number of parities, respectively. All vectors are assumed to be column vectors. We will use the notation $\mathbf{v}[l]$ to denote the l-th coordinate of a vector $\mathbf{v}$.

We will represent *all* the code symbols in the initial codewords as being generated by a single $\lambda k^I \times \lambda n^I$ matrix $\tilde{\mathbf{G}}^I$, with encoding vectors $\{\tilde{\mathbf{g}}^I_{i,j} \mid i \in [\lambda], j \in [n^I]\} \subseteq \mathbb{F}_q^{k^F}$. This representation can be viewed as embedding the column vectors of the generator matrix $\mathbf{G}^I$ in an λk^I-dimensional space, where the index set $\mathcal{K}_i = \{(i-1)k^I+1, \ldots, ik^I\}, i \in [\lambda]$ corresponds to the encoding vectors for initial codeword i. Let $\tilde{\mathbf{g}}^I_{i,j}$ denote the j-th encoding vector in the initial codeword i in this (embedded) representation. Thus, $\tilde{\mathbf{g}}^I_{i,j}[l] = \mathbf{g}^I_j[l - (i-1)k^I]$ for $l \in \mathcal{K}_i$, and $\tilde{\mathbf{g}}^I_{i,j}[l] = 0$ otherwise. As an example, Figure 3 shows the values of the defined terms for the single parity-check code from Figure 1 with $n^I = 3, k^I = 2, n^F = 5, k^F = 4$.

At times, focus will be only on the coordinates of an encoding vector of a certain initial codeword i. For this purpose, define $\text{proj}_{\mathcal{K}_i}(\mathbf{v}) \in \mathbb{F}_q^{k^I}$ to be the projection of $\mathbf{v} \in \mathbb{F}_q^{k^F}$ to the coordinates in an index set $\mathcal{K}_i$, and for a set $\mathcal{V}$ of vectors, $\text{proj}_{\mathcal{K}_i}(\mathcal{V}) = \{\text{proj}_{\mathcal{K}_i}(\mathbf{v}) \mid \mathbf{v} \in \mathcal{V}\}$. For example, $\text{proj}_{\mathcal{K}_i}(\tilde{\mathbf{g}}^I_{i,j}) = \mathbf{g}^I_j$ for all $i \in [\lambda]$ and $j \in [n^I]$.

The following sets of vectors are defined: the encoding vectors from initial codeword i, $\mathcal{S}^I_i = \{\tilde{\mathbf{g}}^I_{i,j} \mid j \in [n^I]\}$, all the encoding vectors from all the initial codewords, $\mathcal{S}^I = \cup_{i \in [\lambda]} \mathcal{S}^I_i$, and all the encoding vectors from the final codeword $\mathcal{S}^F = \{\mathbf{g}^F_j \mid j \in [n^F]\}$.

We use the term *unchanged symbols* to refer to symbols from the initial codewords that remain as is (that is, unchanged) in the final codeword. The symbols in the final codeword that were not present in the initial codewords are called *new*, and the symbols from the initial codewords that do not carry over to the final codeword are called *retired*. For example, in Figure 1, all the data symbols are unchanged symbols (unshaded boxes), the single parity symbol of the final codeword is a new symbol, and the two parity blocks from the initial codewords are retired symbols. Each unchanged symbol corresponds to a pair of identical initial and final encoding vectors, that is, a tuple of indices (i, j, l) such that $\tilde{\mathbf{g}}^I_{i,j} = \mathbf{g}^F_l$. For instance, the example in Figure 1 has four unchanged symbols, corresponding to the identical encoding vectors $\tilde{\mathbf{g}}^I_{i,j} = \mathbf{g}^F_{2(i-1)+j}$ for $i, j \in [2]$. The final encoding vectors $\mathcal{S}^F$ can thus be partitioned into the following sets: *unchanged encoding vectors* from initial codeword i, $\mathcal{U}_i = \mathcal{S}^F \cap \mathcal{S}^I_i$ for all $i \in [\lambda]$, and *new encoding vectors* $\mathcal{N} = \mathcal{S}^F \setminus \mathcal{S}^I$.

From the point of view of conversion cost, unchanged symbols are ideal, because they require no extra work. On the other hand, constructing new symbols require accessing symbols from the initial codewords. When a symbol from the initial codewords is accessed, all of its contents are downloaded to a central location, where they are available for the construction of all new symbols. For example, in Figure 1, one symbol from each initial codeword is accessed during conversion.

During conversion, new symbols are constructed by reading symbols from the initial codewords. That is, every new encoding vector is simply a linear combination of a specific subset of $\mathcal{S}^I$. Define the *read access set* for an MDS $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code as the set of tuples $\mathcal{D} \in [\lambda] \times [n^I]$ such that the set of new encoding vectors $\mathcal{N}$ is contained in the span of the set $\{\tilde{\mathbf{g}}^I_{i,j} \mid (i,j) \in \mathcal{D}\}$. Furthermore, define the index sets $\mathcal{D}_i = \{j \mid (i,j) \in \mathcal{D}\}$, $\forall i \in [\lambda]$ which denote the encoding vectors accessed from each initial codeword.

$$\mathbf{G}^I = \begin{matrix} \mathbf{g}_1^I & \mathbf{g}_2^I & \mathbf{g}_3^I \end{matrix} \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} \quad \tilde{\mathbf{G}}^I = \begin{matrix} \tilde{\mathbf{g}}_{1,1}^I & \tilde{\mathbf{g}}_{1,2}^I & \tilde{\mathbf{g}}_{1,3}^I & \tilde{\mathbf{g}}_{2,1}^I & \tilde{\mathbf{g}}_{2,2}^I & \tilde{\mathbf{g}}_{2,3}^I \end{matrix} \begin{bmatrix} 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 \end{bmatrix} \quad \mathbf{G}^F = \begin{matrix} \mathbf{g}_1^F & \mathbf{g}_2^F & \mathbf{g}_3^F & \mathbf{g}_4^F & \mathbf{g}_5^F \end{matrix} \begin{bmatrix} 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 \end{bmatrix}$$

Figure 3 Generator matrices for a specific $(n^I = 3, k^I = 2; n^F = 5, k^F = 4)$ convertible code: $\mathbf{G}^I$ is the generator matrix of the initial code; $\tilde{\mathbf{G}}^I$ is the generator matrix of all initial codewords; $\mathbf{G}^F$ is the generator matrix of the final code.

A.2 Proof of Lemma 10

The notation used in this proof is introduced in Appendix A.1. By the MDS property, every subset $\mathcal{V} \in \mathcal{S}^F$ of size at most $k^F = \lambda k^I$ is linearly independent. For any initial codeword $i \in [\lambda]$, consider the set of all unchanged encoding vectors from other codewords, $\cup_{\ell \neq i} \mathcal{U}_\ell$, and pick any subset of new encoding vectors $\mathcal{W} \subseteq \mathcal{N}$ of size $|\mathcal{W}| = \min\{k^I, r^F\}$. Consider the subset $\mathcal{V} = (\cup_{\ell \neq i} \mathcal{U}_\ell \cup \mathcal{W})$: it is true that $\mathcal{V} \subseteq \mathcal{S}^F$ and $|\mathcal{V}| = (\lambda - 1)k^I + \min\{k^I, r^F\} \leq k^F$. Therefore, all the encoding vectors in $\mathcal{V}$ are linearly independent.

Notice that the encoding vectors in $\mathcal{V} \setminus \mathcal{W}$ contain no information about initial codeword i and complete information about every other initial codeword $\ell \neq i$. Therefore, the information about initial codeword i in each encoding vector in $\mathcal{W}$ has to be linearly independent since, otherwise, $\mathcal{V}$ could not be linearly independent. Formally, it must be the case that $\mathcal{W}_i = \text{proj}_{\mathcal{K}_i}(\mathcal{W})$ has rank equal to $\min\{k^I, r^F\}$ (recall from Appendix A.1 that $\mathcal{K}_i$ is the set of coordinates belonging to initial codeword i). However, by definition, the subset $\mathcal{W}_i$ must be contained in the span of $\{\mathbf{g}_j^I \mid j \in \mathcal{D}_i\}$. Therefore, the rank of $\{\mathbf{g}_j^I \mid j \in \mathcal{D}_i\}$ is at least that of $\mathcal{W}_i$, which implies that $|\mathcal{D}_i| \geq \min\{k^I, r^F\}$. ◀

A.3 Proof of Lemma 11

The notation used in this proof is introduced in Appendix A.1. When $r^F \geq k^I$, this lemma is equivalent to Lemma 10, so assume $r^I < r^F < k^I$. From the proof of Lemma 10, for every initial codeword $i \in [\lambda]$ it holds that $|\mathcal{D}_i| \geq r^F$. Since $r^F > r^I$, this implies that $\mathcal{D}_i$ must contain at least one index of an unchanged encoding vector.

Choose a subset of at most $k^F = \lambda k^I$ encoding vectors from $\mathcal{S}^F$, which must be linearly independent by the MDS property. In this subset, include all the unchanged encoding vectors from the other initial codewords, $\cup_{l \neq i} \mathcal{U}_l$. Then, choose all the unchanged encoding vectors from initial codeword i that are accessed during conversion, $\mathcal{W}_1 = (\{\tilde{\mathbf{g}}_{i,j}^I \mid j \in \mathcal{D}_i\} \cap \mathcal{U}_i)$. For the remaining vectors (if any), choose an arbitrary subset of new encoding vectors, $\mathcal{W}_2 \subseteq \mathcal{N}$, such that:

$$|\mathcal{W}_2| = \min\{k^I - |\mathcal{W}_1|, r^F\}. \tag{2}$$

It is easy to check that the subset $\mathcal{V} = \cup_{l \neq i} \mathcal{U}_l \cup \mathcal{W}_1 \cup \mathcal{W}_2$ is of size at most $k^F = \lambda k^I$, and therefore it is linearly independent. This choice of $\mathcal{V}$ follows from the idea that the information contributed by $\mathcal{W}_1$ to the new encoding vectors is already present in the unchanged encoding vectors, which will be at odds with the linear independence of $\mathcal{V}$.

Since the elements of $\mathcal{W}_1$ and $\mathcal{W}_2$ are the only encoding vectors in $\mathcal{V}$ that contain information from initial codeword i, it must be the case that $\widetilde{\mathcal{W}} = \text{proj}_{\mathcal{K}_i}(\mathcal{W}_1) \cup \text{proj}_{\mathcal{K}_i}(\mathcal{W}_2)$ has rank $|\mathcal{W}_1| + |\mathcal{W}_2|$. Moreover, $\widetilde{\mathcal{W}}$ is contained in the span of $\{\mathbf{g}_j^I \mid j \in \mathcal{D}_i\}$ by definition, so it holds that:

$$|\mathcal{D}_i| \geq |\mathcal{W}_1| + |\mathcal{W}_2|. \tag{3}$$

From Equation (2), there are two cases:

Case 1: $k^I - |\mathcal{W}_1| \leq r^F$. Then $|\mathcal{W}_2| = k^I - |\mathcal{W}_1|$ and by Equation (3) it holds that $|\mathcal{D}_i| \geq |\mathcal{W}_1| + |\mathcal{W}_2| = k^I$.

Case 2: $k^I - |\mathcal{W}_1| > r^F$. Then $|\mathcal{W}_2| = r^F$ and by Equation (3) it holds that:

$$|\mathcal{D}_i| \geq |\mathcal{W}_1| + r^F. \tag{4}$$

Notice that there are only r^I retired (i.e. not unchanged) encoding vectors in codeword i. Since every accessed encoding vector is either in $\mathcal{W}_1$ or is a retired encoding vector, it holds that:

$$|\mathcal{D}_i| \leq |\mathcal{W}_1| + r^I. \tag{5}$$

By combining Equation (4) and Equation (5), we arrive at the contradiction $r^F \leq r^I$, which occurs because there are not enough retired symbols in the initial codeword i to ensure that the final code has the MDS property. Therefore, case 1 always holds, and $|\mathcal{D}_i| \geq k$. ◀

A.4 Proof of Lemma 13

The notation used in this proof is introduced in Appendix A.1. We show that, even for non-stable convertible codes, that is, when there are more than r^F new symbols, the bounds on the read access set $\mathcal{D}$ from Theorem 12 still hold.

Case 1: $r^I \geq r^F$. Let $i \in [\lambda]$ be an arbitrary initial codeword. We lower bound the size of $\mathcal{D}_i$ by invoking the MDS property on a subset $\mathcal{V} \subseteq \mathcal{S}^F$ of size $|\mathcal{V}| = \lambda k^I$ that minimizes the size of the intersection $|\mathcal{V} \cap \mathcal{U}_i|$. There are exactly r^F encoding vectors in $\mathcal{S}^F \setminus \mathcal{V}$, so the minimum size of the intersection $|\mathcal{V} \cap \mathcal{U}_i|$ is $\max\{|\mathcal{U}_i| - r^F, 0\}$. Clearly, the subset $\text{proj}_{\mathcal{K}_i}(\mathcal{V})$ has rank k^I due to the MDS property. Therefore, it holds that $|\mathcal{D}_i| + \max\{|\mathcal{U}_i| - r^F, 0\} \geq k^I$. By reordering, the following is obtained:

$$|\mathcal{D}_i| \geq k^I - \max\{|\mathcal{U}_i| - r^F, 0\} \geq \min\{r^F, k^I\},$$

which means that the bound on $\mathcal{D}_i$ established in Lemma 10 continues to hold for non-stable codes.

Case 2: $r^I < r^F$. Let $i \in [\lambda]$ be an arbitrary initial codeword, let $\mathcal{W}_1 = (\{\tilde{\mathbf{g}}^I_{i,j} \mid j \in \mathcal{D}_i\} \cap \mathcal{U}_i)$ be the unchanged encoding vectors that are accessed during conversion, and let $\mathcal{W}_2 = \mathcal{U}_i \setminus \mathcal{W}_1$ be the unchanged encoding vectors that are *not* accessed during conversion. Consider the subset $\mathcal{V} \subseteq \mathcal{S}^F$ of $k^F = \lambda k^I$ encoding vectors from the final codeword such that $\mathcal{W}_1 \subseteq \mathcal{V}$ and the size of the intersection $\mathcal{W}_3 = (S \cap \mathcal{W}_2)$ is minimized. Since $\mathcal{V}$ may exclude at most r^F encoding vectors from the final codeword, it holds that:

$$|\mathcal{W}_3| = \max\{0, |\mathcal{W}_2| - r^F\}. \tag{6}$$

By the MDS property, $\mathcal{V}$ is a linearly independent set of encoding vectors of size k^F, and thus, must contain all the information to recover the contents of every initial codeword, and in particular, initial codeword i. Since all the information in $\mathcal{V}$ about codeword i is in either $\mathcal{W}_3$ or the accessed encoding vectors, it must hold that:

$$|\mathcal{D}_i| + |\mathcal{W}_3| \geq k^I. \tag{7}$$

From Equation (6), there are two cases:

Subcase 2.1: $|\mathcal{W}_2| - r^F \leq 0$. Then $|\mathcal{W}_3| = 0$, and by Equation (7) it holds that $|\mathcal{D}_i| \geq k^I$, which matches the bound of Lemma 11.

Subcase 2.2: $|\mathcal{W}_2| - r^F > 0$. Then $|\mathcal{W}_3| = |\mathcal{W}_2| - r^F$, and by Equation (7) it holds that:

$$|\mathcal{D}_i| + |\mathcal{W}_2| - r^F \geq k^I. \tag{8}$$

The initial codeword i has $k^I + r^I$ symbols. By the principle of inclusion-exclusion we have that:

$$|\mathcal{D}_i| + |\mathcal{U}_i| - |\mathcal{W}_1| \leq k^I + r^I. \tag{9}$$

By using Equation (8), Equation (9) and the fact that $|\mathcal{W}_2| = |\mathcal{U}_i| - |\mathcal{W}_1|$, we conclude that $r^I \geq r^F$, which is a contradiction and means that subcase 2.1 always holds in this case. ◀

A.5 Proof of Lemma 14

Lemma 13 shows that the lower bound on the read access set $\mathcal{D}$ for stable linear MDS convertible codes continues to hold in the non-stable case. Furthermore, this bound is achievable by stable linear MDS convertible codes in the merge regime (as will be shown in Section 4). The number of new blocks written during conversion under stable MDS convertible codes is r^F. On the other hand, the number of new symbols under a non-stable convertible code is strictly greater than r^F. Thus, the overall access cost of a non-stable MDS $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code is strictly greater than the access cost of an access-optimal $(n^I, k^I; n^F, k^F = \lambda k^I)$ convertible code. ◀

B Proofs of Section 4

B.1 Proof of Lemma 20

Consider the first r^F columns of $\mathbf{P}^I$, which we denote as $\mathbf{P}^I_{r^F} = \mathbf{P}^I[*; 1, \ldots, r^F]$. Notice that $\mathbf{P}^F$ can be written as the following block matrix:

$$\mathbf{P}^F = \begin{bmatrix} \mathbf{P}^I_{r^F} \\ \mathbf{P}^I_{r^F} \operatorname{diag}(1, \theta^{k^I}, \theta^{2k^I}, \ldots, \theta^{k^I(r^F-1)}) \\ \mathbf{P}^I_{r^F} \operatorname{diag}(1, \theta^{2k^I}, \theta^{2\cdot 2k^I}, \ldots, \theta^{2k^I(r^F-1)}) \\ \vdots \\ \mathbf{P}^I_{r^F} \operatorname{diag}(1, \theta^{(\lambda-1)k^I}, \theta^{2(\lambda-1)k^I}, \ldots, \theta^{(\lambda-1)k^I(r^F-1)}) \end{bmatrix},$$

where $\operatorname{diag}(a_1, a_2, \ldots, a_n)$ is the $n \times n$ diagonal matrix with $a_1, \ldots, a_n$ as the diagonal elements. From this representation, it is clear that $\mathbf{P}^F$ can be constructed from the the first r^F columns of $\mathbf{P}^I$. ◀

B.2 Proof of Lemma 21

Let $\mathbf{R}$ be a $t \times t$ submatrix of $\mathbf{P}^I$ or $\mathbf{P}^F$, determined by the row indices $i_1 < i_2 < \cdots < i_t$ and the column indices $j_1 < j_2 < \cdots < j_t$, and denote entry (i, j) of $\mathbf{R}$ as $\mathbf{R}[i, j]$. The determinant of $\mathbf{R}$ is defined by the Leibniz formula:

$$\det(\mathbf{R}) = \sum_{\sigma \in \operatorname{Perm}(t)} \operatorname{sgn}(\sigma) \prod_{l=1}^{t} \mathbf{R}[l, \sigma(l)] = \sum_{\sigma \in \operatorname{Perm}(t)} \operatorname{sgn}(\sigma) \theta^{E_\sigma} \tag{10}$$

$$\text{where} \qquad E_\sigma = \sum_{l=1}^{t} (i_l - 1)(j_{\sigma(l)} - 1), \tag{11}$$

Perm(t) is the set of all permutations on t elements, and $\text{sgn}(\sigma) \in \{-1, 1\}$ is the sign of permutation σ. Clearly, $\det(\mathbf{R})$ defines a univariate polynomial $f_{\mathbf{R}} \in \mathbb{F}_p[\theta]$. We will now show that $\deg(f_{\mathbf{R}}) = \sum_{l=1}^{t}(i_l - 1)(j_l - 1)$ by showing that there is a unique permutation $\sigma^* \in \text{Perm}(t)$ for which E_{σ^*} achieves this value, and that this is the maximum over all permutations in Perm(t). This means that $f_{\mathbf{R}}$ has a leading term of degree E_{σ^*}.

To prove this, we show that any permutation $\sigma \in \text{Perm}(t)\backslash\{\sigma^*\}$ can be modified into a permutation σ' such that $E_{\sigma'} > E_{\sigma}$. Specifically, we show that $\sigma^* = \sigma_{\text{id}}$, the identity permutation. Consider $\sigma \in \text{Perm}(t)\backslash\{\sigma_{\text{id}}\}$: let a be the smallest index such that $\sigma(a) \neq a$, let $b = \sigma^{-1}(a)$, and let $c = \sigma(a)$. Let σ' be such that $\sigma'(a) = a$, $\sigma'(b) = c$, and $\sigma'(d) = \sigma(d)$ for $d \in [t]\backslash\{a, b\}$. In other words, σ' is the result of "swapping" the images of a and b in σ. Notice that $a < b$ and $a < c$. Then, we have that:

$$E_{\sigma'} - E_{\sigma} = (i_a - 1)(j_a - 1) + (i_b - 1)(j_c - 1) - (i_a - 1)(j_c - 1) - (i_b - 1)(j_a - 1) \quad (12)$$

$$= (i_b - i_a)(j_c - j_a) > 0 \quad (13)$$

The last inequality comes from the fact that $a < b$ implies $i_a < i_b$ and $a < c$ implies $j_a < j_c$. Therefore, $\deg(f_{\mathbf{R}}) = \max_{\sigma \in \text{Perm}(t)} E_{\sigma} = E_{\sigma_{\text{id}}}$.

Let $E^*(\lambda, k^I, r^I, r^F)$ be the maximum degree of $f_{\mathbf{R}}$ over all submatrices $\mathbf{R}$ of $\mathbf{P}^I$ or $\mathbf{P}^F$. Then, $E^*(\lambda, k^I, r^I, r^F)$ corresponds to the diagonal with the largest elements in $\mathbf{P}^I$ or $\mathbf{P}^F$. In $\mathbf{P}^F$ this is the diagonal of the square submatrix formed by the bottom r^F rows. In $\mathbf{P}^I$ it can be either the diagonal of the square submatrix formed by the bottom r^I rows, or by the right k^I columns. Thus, we have that:

$$E^*(\lambda, k^I, r^I, r^F) = \max\left\{\sum_{i=0}^{r^F-1} i(\lambda k^I - r^F + i), \sum_{i=0}^{r^I-1} i(k^I - r^I + i), \sum_{i=0}^{k^I-1} i(r^I - k^I + i)\right\}$$

$$= (1/6) \cdot \max\left\{\begin{matrix} r^F(r^F - 1)(3\lambda k^I - r^F - 1), \\ r^I(r^I - 1)(3k^I - r^I - 1), \\ k^I(k^I - 1)(3r^I - k^I - 1) \end{matrix}\right\}.$$

Let $D = E^*(\lambda, k^I, r^I, r^F) + 1$. Then, if $\det(\mathbf{R}) = 0$ for some submatrix $\mathbf{R}$, θ is a root of $f_{\mathbf{R}}$, which is a contradiction since θ is a primitive element and the minimal polynomial of θ over $\mathbb{F}_p$ has degree $D > \deg(f_{\mathbf{R}})$ [34]. ◀

C Proofs of Section 5

C.1 Proof of Theorem 25

Consider the construction Hankel$_s$ described in this section, for some $s \in \{\lambda, \ldots, r^I\}$. The Hankel form of T_m and the manner in which $\mathbf{P}^I$ and $\mathbf{P}^F$ are constructed guarantees that the l-th column of $\mathbf{P}^F$ corresponds to the vertical concatenation of columns $l, l+t, \ldots, l+(\lambda-1)t$ of $\mathbf{P}^I$. Thus, $\mathbf{P}^F$ is r^F-column block-constructible from $\mathbf{P}^I$. Furthermore, since $\mathbf{P}^I$ and $\mathbf{P}^F$ are submatrices of T_m, they are superregular. Thus $\mathbf{P}^I$ and $\mathbf{P}^F$ satisfy both of the properties laid out in Theorem 19 and hence the convertible code constructed by Hankel$_s$ is access-optimal. ◀

D Algorithm for constructing superregular Hankel triangular arrays

In this appendix we describe the algorithm from [52] for constructing a superregular Hankel triangular array over any finite field. This is supplied as reference and is not necessary for understanding the constructions described in this paper. We note that the algorithm outlined in [52] takes the field size q as input, and generates T_q as the output. It is easy to see that T_q thus generated can be truncated to generate the triangular array T_m for any $m \leq q$.

Let $\mathbb{F}_q$ be a given base field, and let $m \leq q$ be the size of the output triangular array T_m. The triangular array T_m has Hankel form, as shown in Equation (1). Therefore, it suffices to specify the entries $b_1, b_2, \ldots, b_m$ in the first column of T_m. On input $m \leq q$, the algorithm proceeds as follows:

1. Consider the extension field $\mathbb{F}_{q^2}$ and choose an element $\beta \in \mathbb{F}_{q^2}$ such that $\beta^i \notin \mathbb{F}_q$ for $i \in [q]$ and $\beta^{q+1} \in \mathbb{F}_q$. Let $p(x) = x^2 + \mu\, x + \eta$ be the minimal polynomial of β over $\mathbb{F}_{q^2}$.
2. Let $\sigma_{-1}, \sigma_0, \ldots, \sigma_m \in \mathbb{F}_q$ be such that $\sigma_{-1} = -\eta^{-1}, \sigma_0 = 0$, and $\sigma_i = -\mu\, \sigma_{i-1} - \eta\, \sigma_{i-2}$, for $i \in [m]$.
3. Set $b_i = \sigma_i^{-1}$, for all $i \in [m]$.

The resulting triangular array is superregular, that is, every square submatrix taken from T_m is superregular. Please refer to [52] for a proof of this fact.

Incentive Compatible Active Learning

Abstract

We consider active learning under incentive compatibility constraints. The main application of our results is to economic experiments, in which a learner seeks to infer the parameters of a subject's preferences: for example their attitudes towards risk, or their beliefs over uncertain events. By cleverly adapting the experimental design, one can save on the time spent by subjects in the laboratory, or maximize the information obtained from each subject in a given laboratory session; but the resulting adaptive design raises complications due to incentive compatibility. A subject in the lab may answer questions strategically, and not truthfully, so as to steer subsequent questions in a profitable direction.

We analyze two standard economic problems: inference of preferences over risk from multiple price lists, and belief elicitation in experiments on choice over uncertainty. In the first setting, we tune a simple and fast learning algorithm to retain certain incentive compatibility properties. In the second setting, we provide an incentive compatible learning algorithm based on scoring rules with query complexity that differs from obvious methods of achieving fast learning rates only by subpolynomial factors. Thus, for these areas of application, incentive compatibility may be achieved without paying a large sample complexity price.

1 Introduction

We study active learning under incentive compatibility constraints. Consider a learner: Alice, who seeks to elicit the parameters governing the behavior of a human subject: Bob. The chief application of our paper is to the design of laboratory experiments in economics. In such applications, Alice is an experimenter observing choices made by Bob in her laboratory. The active learning paradigm seeks to save on the number of questions posed by Alice by making the formulation of each question dependent on Bob's answers to previous questions [8, 21]. Now, Bob may misrepresent his answers to some of Alice's questions so as to guide Alice's line of questioning in a direction that he can benefit from.

Our setting differs from standard applications of active learning in computer science, in that data are labeled by a self-interested human agent (in our story, Bob). Computer scientists have thought of active learning as applied to, for example, combinatorial chemistry, or image detection. A learner then makes queries that are always truthfully answered. In economic settings, in contrast, one must recognize the role of incentives.

The existing literature on applications of passive learning to preference elicitation (see for example [12, 30, 11, 17]) does not have to deal with agents' incentives to manipulate the learning mechanism, but active learning does, because an agent who understands the learner's algorithm may answer strategically early on in the experiment so as to influence the questions he faces later in the experiment.

We should emphasize that experimental orthodoxy in economics requires that subjects (such as Bob) know as much as possible about the experimental design. No deception is allowed in economic experiments. In addition, subjects' participation is almost universally incentivized: Bob gets a payoff that depends on his answers to Alice's questions. Our model relates to a long-standing interest among economists for adaptive experimental design, see [23, 32, 16, 29].

Consider a concrete example. Bob has a utility function x^σ over money, so that if he faces a random amount of money X, his expected utility is $\mathbf{E}[X^\sigma]$. In other words, Bob has a utility of the "constant relative risk aversion" (CRRA) form, and Alice wants to learn the value of the parameter σ –Bob's relative risk aversion coefficient.[1] A standard procedure for estimating σ is a *multiple price list*.[2]

In a multiple-price list (MPL), Alice successively asks Bob to choose between a sure payoff of x dollars and a fixed lottery L, for example a lottery that flips a fair coin and pays 0 dollars if the coin turns up Heads, and 1 dollar if it turns up Tails. Alice would first ask Bob to choose between a very small amount x (almost zero) and L. Then Alice would raise x a little and ask Bob to choose again. The procedure is repeated, each time increasing the amount x, until reaching a number equal to, or close to 1. At some value x, Bob would switch from preferring the lottery to preferring the fixed amount of money. Then Alice would solve the equation

$$x^\sigma = (1/2)0^\sigma + (1/2)1^\sigma = (1/2) \tag{1}$$

to find the value of σ. Now, it is important to explain how the experiment is incentivized: When the experiment is over, Alice will actually implement one of the choices made by Bob. Conventional experimental methodology dictates [7] that she chooses one of the questions at random and implements it.

A proponent of active learning will immediately remark that the MPL design asks too many questions. Alice only needs to know the value of x at which Bob is indifferent between x and the lottery L. We can thus imagine an adaptive design, where Alice raises x until Bob switches from L to x, and stops the experiment when that happens. This design will result in strictly fewer questions than the passive (supervised) learning design.

Bob, however, understands that Alice stops raising x when he declares indifference to L. So he will manipulate Alice into offering him values of x *beyond* what he truly views as indifferent to L. Specifically, suppose that Alice raises x continuously (this is a simplifying assumption; see Section 3 for a realistic version of this design), and that if Bob declares indifference at x then the last question is implemented with probability $p(x) \in (0, 1)$. The function p is strictly decreasing since reporting a larger value of x increases the probability that a question for which Bob preferred L will be implemented.

---

[1] The coefficient σ captures Bob's willingness to assume risk. It is a parameter that economic experiments very often seek to measure, even when the experiment is ostensibly about a totally different question. Economic experimentalists want to understand the relation between risk and their general experimental findings, so they include risk elicitation as part of the design.

[2] Multiple price lists are a very common experimental design, first used by [13], and popularized by [28] as a method to estimate σ, as described here.

Bob's payoff from stopping at x is $\pi(x;\sigma) = p(x)x^\sigma + (1-p(x))(1/2)$ because with probability $p(x)$ the last question gets implemented, so he gets the sure amount x, and with the complementary probability one of the other questions is implemented and Bob gets his preference for those questions, namely the lottery L. The expected utility of L is $1/2$.

Then it is clear that Bob would like to stop at an x that is strictly greater than the value at which he would truly be indifferent to L, the value that solves (1). If he stops at the true value of x, he gets for sure something that he values as much as L (either L or the amount x that he values exactly as L). By stopping at a strictly greater x, he has a shot at getting a value of x that he prefers over L.

The situation is, however, far from hopeless. Bob's optimal value of x is strictly increasing in σ.[3] Alice can then undo Bob's strategic choice of x and back out the true value of σ. (Alice's approach is common in applied econometrics, often called the "structural" method.)

In this paper, we prove general possibility results, to illustrate that there are many situations where active learning is consistent with incentive compatibility. In Section 3 we shall present a formal model of multiple price lists, and show that it is possible to learn while satisfying incentive compatibility. In Section 4 we discuss incentive issues in active learning in a more general sense. We present a formal notion of incentive compatible active learning in a general preference elicitation environment, and provide characterizations of the complexity of incentive compatible learning in certain "nice" environments.

A recent and growing body of work studies the problem of inferring models of economic choice from a learning theoretic perspective [30, 12, 35, 9, 11, 17, 10]. The learnability of preference relations has also received very recent attention [11, 17]. Our investigation takes a different angle: in attempting to model an experimental situation where subjects are asked to make choices in an interactive manner, via, e.g., a computer program, or in person, we allow the analyst complete control over the learning data. In the active learning literature, this framework is known as the *membership queries* model. There is also an ongoing line of work that considers learning problems when the data provider is strategic [22, 1, 31, 18]. Finally, the recent work of [27] studies a model where an agent may (at a cost) manipulate the input to a classification algorithm.

The membership query model closely captures an adaptive economic experiment, while in this context the more traditional learning/active learning models (e.g. PAC learning, stream-based active learning) seem to place unnecessary restrictions on how the analyst learns. This notion is briefly discussed in [17], where classical learning theoretic approaches appear to give much weaker complexity guarantees than the membership queries model in learning time-dependent discounted utility preferences. *For the remainder of this paper, whenever we use the phrase "active learning", we refer to the membership query setting – all other forms of learning can be viewed as a special case of membership queries.*

The other important component in modelling an economic experiment is a payment to the agent after the experiment has concluded. Experiments in economics are always *incentivized*, meaning that there are actual material consequences to subjects' decisions in the lab. Subjects are paid for their decisions in the experiment. We incorporate this incentive payment into the execution of the algorithm by which the analyst chooses questions – the analyst implements the outcome chosen by the agent in the final round of the interaction. Thus, rather than treating the payment scheme as a separate problem, we use it to demand a certain level of

[3] If $\pi(x;\sigma) = p(x)x^\sigma + (1-p(x))(1/2)$ and we assume that p is smooth, then $\partial^2\pi(x;\sigma)/\partial\sigma\partial x = p'(x)x^\sigma \ln(x) + (\sigma+1)p(x)x^{\sigma-1} > 0$ as $x \in (0,1]$ and p is decreasing. So π is strictly supermodular. Hence the optimal x is increasing in σ.

robustness from our learning algorithms. As we demonstrate, this precludes the analyst from running naive learning algorithms that, despite achieving good query complexities, allow the agent to strategically and dishonestly answer questions to get offered higher payoff outcomes.

Finally, the framework we introduce engenders the following natural question: is there a combinatorial measure of complexity, akin to VC dimension for PAC learning concept classes, that precisely captures the complexity of incentive compatible learning in preference environments? Our results examine certain sufficient conditions for incentive compatible learning, a potential first step towards better understanding this new and interesting learning model.

Summary of results

We begin by discussing incentive issues in a very common experimental paradigm, that of convex budgets. We present an example to the effect that incentive problem are present and can be critical. Then we turn to the *Multiple Price Lists* (MPL), another very common experimental design used to infer agents' attitudes towards risk. In MPL experiments, an agent is asked to choose between receiving various deterministic monetary amounts and participating in a lottery. The goal of the analyst is to elicit the agent's *certainty equivalent*, i.e. the deterministic quantity at which the agent values the lottery (in our previous discussion, the certainty equivalent is the quantity that solves Equation (1)). We analyze a simple sequential search mechanism that is used in practice – start from the lowest possible deterministic amount and keep increasing the offer until the agent prefers it to the lottery. The analyst pays the agent by implementing the agent's decision on a randomly selected question that was asked. We show that while this mechanism is not incentive compatible, under relatively benign assumptions it satisfies a one-to-one condition where the analyst can accurately infer the agent's true certainty equivalent after learning the agent's reported certainty equivalent. We then show how a modified payment scheme that only depends on the final decision of the agent allows the analyst to do a binary search and retain incentive compatibility, giving a mechanism for learning the certainty equivalent of a strategic agent to within an error of ε using $O(\log 1/\varepsilon)$ questions.

We then turn to an abstract model of learning preference parameters/types. The idea is, as in the MPL, to induce incentive compatibility by incentivizing the payment from the last question asked of the agent. To this end, we coin a formal notion of incentive compatible (IC) learnability. A learning algorithm is simply an adaptive procedure that at each step asks the agent to choose between two outcomes. Informally, the *IC learning complexity* of an algorithm is the number of rounds required to both

1. Accurately learn (with high probability) the agent's type with respect to some specified metric on the type space.
2. Ensure that (with high probability) the payment mechanism of implementing the agent's choice on the final question cannot be strategically manipulated to yield a significant payoff gain over answering questions truthfully.

A simple structural condition allows a strong notion of incentive compatibility to be achieved via a deterministic exhaustive search (truthful reporting is the agent's unique best response), and we give examples of commonly studied economic preference models that fit our condition. We demonstrate that a large class of preference relations over Euclidean space – those exhibiting strict convexity under a condition which we call *hyperplane uniqueness* (detailed in Section 4) – can be learned in an incentive compatible manner.

▶ **Theorem 1** (informal). *Let Θ be a type space such that the preferences induced by each $\theta \in \Theta$ are continuous, strictly convex, and satisfy hyperplane uniqueness. Then, Θ is IC learnable, under a suitably chosen metric.*

However, this strong notion of incentive compatibility comes at a cost – the associated IC learning complexity can be massive (exponential in the preference parameters). In the abstract setting of preferences over outcomes, it is unclear how to obtain a tangible improvement in this complexity (even with randomization), and specifically it would appear that the problem parameters (e.g. the outcome space, the set of possible agent types) require much more structure for any sort of improvement.

We then analyze the specific setting of learning the beliefs of an expected utility agent, where we have the required structure. Here, an agent holds a belief represented by a distribution $\alpha \in \Delta_n$ (there are n uncertain states of the world, and α_i is the probability with which the agent believes state i will occur), and is asked to make choices between vectors of rewards $x \in \mathbb{R}^n$, where the utility an agent of type α enjoys from x is simply $\alpha.x$. We first observe that naive learning algorithms can vastly beat the learning complexity of the general preference framework, but fail to be incentive compatible. Our main result is an incentive compatible learning algorithm for eliciting an agent's beliefs that significantly improves upon the complexity in the general framework, and only differs from the fast naive learning algorithms by subpolynomial factors.

▶ **Theorem 2.** *There is an algorithm for learning the belief of an expected utility agent that when run for*

$$O\left(n^{3/2}\log n \max\left(\log\frac{n}{\varepsilon}, \log\frac{1}{\tau}\right)\right)$$

rounds (with high probability) cannot be manipulated to yield more than a τ increase in payoff, and learns a truthful agent's belief to within total variation distance of ε. [4]

Our algorithm is built upon disagreement based active learning methods that provide learning guarantees, and employs the spherical scoring rule to ensure incentive compatibility properties.

2 Example: Convex budgets

We present a simple example to illustrate how incentive issues can prevent a very popular experimental design from being implementable in an active learning setting.

Consider an experiment on choice under uncertainty, with an adaptive "convex budgets" design. Such designs are ubiquitous in experimental economics: see [5, 19, 2, 25, 4, 6] among (many) others. Convex budgets is very popular as a design because it parallels the most basic model in economic theory, the model of consumer choice.[5]

Bob, a subject in the lab, has expected utility preferences. Specifically, suppose that the experiment involves two possible states of the world, and that Bob chooses among vectors $x = (x_1, x_2) \in \mathbb{R}^2_+$. If Bob chooses the vector (x_1, x_2) and the state of the world turns out to

[4] Typical supervised learning bounds have a logarithmic dependence on the confidence parameter $\frac{1}{\delta}$, and so for the sake of brevity we omit terms depending on δ in our complexity bounds.

[5] Consumer choice is probably the first model a student of economics is ever exposed to. It captures optimal choice from an economic budget sets, defined from linear prices and a maximum expenditure level.

be i, then he is paid x_i. Bob believes that the state of the world i occurs with probability α_i, so his expected utility from choosing x is $\alpha_1 x_1 + \alpha_2 x_2$ (we assume for simplicity that Bob is risk-neutral).

The experiment seeks to learn the subjects' beliefs α with a design that has Bob choosing

$$x \in B(p, I) = \{y \in \mathbb{R}^2_+ : p \cdot y \leq I\},$$

at prices $p \in \mathbb{R}^2_+$ and income $I > 0$. The problem is equivalent to learning the ratio α_1/α_2. It is obviously optimal for Bob to choose $x = (1/p_1, 0)$ if $\alpha_1/p_1 > \alpha/p_2$ and $x = (0, 1/p_2)$ if $\alpha_1/p_1 < \alpha/p_2$.

The experimental design presents the subject with a sequence of prices p and incomes I, and asks him to choose from $B(p, I)$. Usually only one of the choice problems in the sequence will actually be paid off. It is standard practice in experimental economics to pay out only one of the questions posed to a subject. For the purpose of this example, imagine that the sequence has a length of 2: (p^1, I^1) and (p^2, I^2). Moreover, suppose (again for simplicity) that incomes and prices are such that $I^t = p^t \cdot (1/2, 1/2) = 1$, for $t = 1, 2$.

Fix the first price at $p^1 = (1, 1)$. If Alice, the experimenter, observes a choice of $(1/p_1, 0)$ she should conclude that $\alpha_1/\alpha_2 > p^1_1/p^1_2$. And given such an inference, it would not make sense to set the second set of prices so that $p^2_1/p^2_2 < p^1_1/p^1_2$. Alice, following an active learning paradigm of adaptive experimental design, should adjust p_1/p_2 upwards. So let us assume that she decides to adjust the ratio p^1_1/p^1_2 by a factor of 2 *in the direction in which there is something to learn:* If the choice from $B(p^1, I^1)$ is $(1/p^1_1, 0)$, Alice will set $p^2_1/p^2_2 = 2(p^1_1/p^1_2)$. If the choice is $(0, 1/p^1_2)$, she will set $p^2_1/p^2_2 = (1/2)(p^1_1/p^1_2)$.

Now consider the problem facing our subject, Bob. Suppose that Bob's beliefs are such that $\alpha_1 < \alpha_2$, and, to make our calculations simpler, that $\alpha_1/\alpha_2 \leq 1/2$. If he chooses "truthfully" according to his beliefs, he would choose $x = (0, 1/p^1_1) = (0, 1)$ from $B(p^1, I^1)$ and thus face prices $p^2 = (2/3, 4/3)$. This means that the relative price of payoffs in state 2 increase, the state that Bob values the most because he thinks it is the most likely to occur. If instead Bob "manipulates" the experiment by choosing $x = (1/p_1, 0)$, he will face prices $p^2 = (4/3, 2/3)$. It is obvious that Bob is better off in the second choice problem from facing the second budget because he will be able to afford a much larger payoff in state 2. If Alice only incentivizes (pays out) the choice from $B(p_2, I_2)$, then Bob is always better off by misrepresenting his choice from the first budget.

If, instead, Alice incentivizes the experiment by implementing one of the choices made by Bob at random (a common practice in economic experiments, see [7] for a formal justification), then the utility from truthtelling is $(1/2)\alpha_2(1+3/4) = \alpha_2(7/8)$. The utility from manipulation is $(1/2)(\alpha_1 + \alpha_2(3/2))$. As long as $\alpha_1/\alpha_2 \in (1/4, 1/2)$, the manipulation yields a higher utility than truth telling.

The convex budgets example illustrates the perils of active learning as a guide to adaptive experimental design, when human subjects understand how the experiment unfolds conditional on how they make choices. The main result of our paper (see Section 4.2) considers belief elicitation, but proposes an active learning algorithm that is based on pairwise comparisons, not choices from convex budgets.

3 Multiple Price Lists

We begin by formally considering the application in the introduction: the use of *Multiple Price Lists* (MPL) to elicit an agent's preferences over risk. MPL was first proposed by [13], and popularized by [28], who used it to estimate risk attitudes along the lines of the discussion in the sequel.

We shall consider a version of MPL where a lottery with monetary outcomes is fixed, and an agent chooses between a sure (deterministic) monetary payment x or the lottery. More specifically, consider a lottery where a coin is flipped and if the outcome is heads, the payoff is $\overline{x}$ dollars, while if the outcome is tails, the payoff is $\underline{x}$ dollars. An analyst wants to assess an agent's willingness to participate in the lottery when presented with various deterministic alternatives. Denote this lottery by L.

At every round of the experiment, the analyst asks the agent to choose between a deterministic payoff of x or participation in the lottery, and aims to learn the agent's *certainty equivalent*: the deterministic amount that yields indifference. Conventionally (for example, see [28, 3]), the experiment is run by presenting the agent with a list of n pairs (x_i, L). The agent makes a choice from each pair, either the sure amount x_i or the lottery L. Then the experimenter draws one of the n questions at random an pays the agent according to the decision he made for that question. (i.e. if he preferred the deterministic amount x, he is paid x, and otherwise gets to participate in the lottery). We now present a formal model of the MPL experimental design and analyze issues of incentive compatibility.

3.1 The model

We consider a lottery L with a low outcome $\underline{x}$ and a high outcome $\overline{x}$, $\underline{x} < \overline{x}$. The lottery can operate in any number of ways, for example, by a coin flip. The analyst chooses a discretization $\underline{x} = x_0 < x_1, \ldots < x_{n-1} < x_n = \overline{x}$ of the interval $I = [\underline{x}, \overline{x}]$ such that the intervals $I_k = (x_k, x_{k+1}]$ all have equal length $\ell = \frac{\overline{x}-\underline{x}}{n}$. This discretization of I represents the deterministic amounts that the analyst will offer to the agent.

An agent's certainty equivalent is the point $x \in (\underline{x}, \overline{x})$ such that he is indifferent between receiving x versus participating in the lottery. Certainty equivalents will be uniquely determined by an agent's utility over money, as long as his utility function is strictly increasing.

For example, if an agent values money according to $u : \mathbb{R} \to \mathbb{R}$, his certainty equivalent (assuming that L is a coin-flip) would be the point $x \in (\underline{x}, \overline{x})$ such that $u(x) = \frac{1}{2}u(\underline{x}) + \frac{1}{2}u(\overline{x})$. In our model, we consider agents whose utility functions belong to a given family $\mathcal{U}$ of functions such that a given certainty equivalent uniquely determines the utility function of the agent, and vice-versa. For example, if $\mathcal{U} = \{x \mapsto x^\sigma : 0 < \sigma < 1\}$, so utilities take the CRRA form we discussed in the introduction, then σ uniquely determines the point x such that $x^\sigma = \frac{1}{2}\underline{x}^\sigma + \frac{1}{2}\overline{x}^\sigma$.

3.2 Sequential Search

We first consider a simple mechanism that aims to find the agent's certainty equivalent by performing a sequential search on $x_1, \ldots, x_n$. On round t of the experiment, the agent chooses between the lottery and a deterministic payoff of x_t. If he chooses the lottery, the experiment continues, and if he chooses x_t or claims indifference, the experiment terminates. If the experiment terminates at round T, the analyst can conclude that the agent reported a certainty equivalent lying in the interval $(x_{T-1}, x_T]$.

The goal of the analyst is to make a payment to the agent at the end of the experiment such that the agent is incentivized to answer questions according to his true certainty equivalent. We analyze a common scheme used in experiments: if the experiment terminates after T rounds, choose t randomly from $\{1, \ldots, T\}$, and pay the agent based on his preference on the tth question: so if $t = T$, the agent receives x_T, otherwise the agent receives a payment that is the outcome of the lottery. However, as discussed in the introduction, this scheme

is not incentive compatible. Indeed, if x_T is the agent's true certainty equivalent, he has a profitable deviation to push the experiment to terminate at x_{T+1}. The agent is indifferent between receiving x_T and participating in the lottery, so by declaring a certainty equivalent that is higher than x_T he may possibly win an amount larger than x_T, and which he values strictly more than the lottery.

We now show that under some simplifying assumptions, this kind of payment scheme can at least be implemented in a manner such that the agent's true certainty equivalent can be accurately inferred based on his report. Let $\mathcal{U}$ be a family of utility functions such that each $u \in \mathcal{U}$ satisfies an inverse Lipschitz condition with constant K_u: for all x, x^*, $|u(x) - u(x^*)| > K_u|x - x^*|$. Let $K = \sup_{u\in\mathcal{U}} K_u$. Finally, let $M = \sup_{u\in\mathcal{U}}(u(\overline{x}) - u(\underline{x}))$.

For $t \in \{1, \dots, n\}$ let p_t denote the probability that the agent is paid the deterministic amount x_t if the experiment stops on round t (so the agent participates in the lottery with probability $1 - p_t$). An agent with true certainty equivalent x and corresponding utility function u has an expected payoff of

$$\text{Payoff}(x, x_t) = p_t u(x_t) + (1 - p_t)u(x)$$

for reporting a certainty equivalent in $(x_{t-1}, x_t]$.

Let $r : (\underline{x}, \overline{x}) \to \{x_1, \dots, x_n\}$ be the best response of an agent with certainty equivalent x:

$$r(x) = \text{argmax}_{x_t} \text{Payoff}(x, x_t).$$

We refer to r as the report function.

We now show that when $p_1, \dots, p_n$ satisfy $p_{t+1} < p_t$[6] and $p_{t+1} < \frac{K\ell}{2M} p_t$, the analyst can recover the agent's true certainty equivalent up to some low error via the sequential search mechanism.

We should emphasize that the agent will not be truthful, in the sense of reporting their true certainty equivalent. However, we are still able to back out the true certainty equivalent from understanding the agents strategic incentives.

We proceed in steps. First, we characterize the best responses for agents with certainty equivalents belonging to $\{x_1, \dots, x_{n-1}\}$. We show that the report function is one to one. This implies that $r(x_t) = x_{t+1}$, since $r(x_t) > x_t$, for each $t = 1, \dots, n-1$.

▶ **Proposition 3.** *For $x_t \in \{x_1, \dots, x_{n-1}\}$, $r(x_t) = x_{t+1}$.*

Proof. Note that since $r(x_{n-1}) = x_n$, it suffices to show that r is injective on $\{x_1, \dots, x_{n-1}\}$.

Suppose $r(x_{t_1}) = r(x_{t_2})$, and without loss of generality let $t_1 \geq t_2$. Let $r(x_{t_1}) = r(x_{t_2}) = x_t$. Since any agent is incentivized to report higher than their true certainty equivalent, $t > t_1, t_2$, so in particular $t \geq t_1 + 1$. Let u_1 denote the utility function of the agent with true type x_{t_1}, u_2 that of the agent with true type x_{t_2}.

For any $s \neq t$ we have (since r gives the best response):

$$p_t u_1(x_t) - p_t u_1(x_{t_1}) > p_s u_1(x_s) - p_s u_1(x_{t_1}),$$
$$p_t u_2(x_t) - p_t u_2(x_{t_2}) > p_s u_2(x_s) - p_s u_2(x_{t_2}).$$

Adding the two inequalities and rearranging gives

$$\frac{p_t}{p_s} > \frac{u_1(x_s) - u_1(x_{t_1}) + u_2(x_s) - u_2(x_{t_2})}{u_1(x_t) - u_1(x_{t_1}) + u_2(x_t) - u_2(x_{t_2})}. \tag{2}$$

[6] This is true for the standard uniform randomization scheme, as $p_t = 1/t$. More generally, without this condition the agent will have incentives to report high certainty equivalents as this is not penalized by lower probabilities of winning the certain amount.

At $s = t_1$ (we know $t_1 \neq t$, since $r(x_{t_1}) > x_{t_1}$), Equation 2 simplifies to

$$\frac{p_t}{p_{t_1}} > \frac{u_2(x_{t_1}) - u_2(x_{t_2})}{u_1(x_t) - u_1(x_{t_1}) + u_2(x_t) - u_2(x_{t_2})} > \frac{u_2(x_{t_1}) - u_2(x_{t_2})}{2M},$$

so

$$u_2(x_{t_1}) - u_2(x_{t_2}) < 2M\frac{p_t}{p_{t_1}} \leq 2M\frac{p_{t_1+1}}{p_{t_1}} < K\ell.$$

The inverse Lipschitz condition on u_2 then implies that $|x_{t_1} - x_{t_2}| < \ell$, which cannot happen unless $t_1 = t_2$. ◀

Thus, if an agent's true certainty equivalent happens to coincide with one of the points of the discretization, the agent will answer questions as if his certainty equivalent is the next point in the discretization.

For the next step, we need an additional Lipschitz type condition on utility functions. Suppose there are constants C_1 and C_2 such that for any $x, x^* \in (\underline{x}, \overline{x})$, with u, u^* the corresponding utility functions, and for any $x, x'' \in (\underline{x}, \overline{x})$,

$$|u(x') - u^*(x'')| \leq C_1|x - x^*| + C_2|x' - x''|.$$

Moreover, let

$$\lambda = \inf_{x \in (\underline{x}, \overline{x})} \min_{s,t} |\text{Payoff}(x, x_s) - \text{Payoff}(x, x_t)|,$$

be the smallest possible deviation in payoff obtained by changing one's report.

We also require the assumption that if $x^* \geq x$, then $u^*(x') \geq u(x')$ for any x', where u^* and u are the utility functions corresponding to certainty equivalents x^* and x, respectively. This is an intuitive condition stating that agents with a higher certainty equivalent value money more than agents with a lower certainty equivalent (note that the CRRA utilities discussed previously satisfy this property). This in particular implies that $u^*(x^*) \geq u^*(x) \geq u(x)$, so $\text{Payoff}(x^*, x_k) \geq \text{Payoff}(x, x_k)$ for any x_k in the discretization. We will use this in the proof of the following proposition, which establishes that r satisfies a certain weak monotonicity property.

▶ **Proposition 4.** *Let $x_{t-1} < x < x^* \leq x_t$ with $x^* - x < \frac{\lambda}{2(2C_1+C_2)}$, and suppose $r(x^*) \leq x_{t+1}$. Then, $r(x) \leq x_{t+1}$.*

Proof. Let u, u^* be the utility functions corresponding to certainty equivalents x and x^*, respectively. We first bound the increase in payoff an agent of type x^* experiences over an agent of type x for making the same report. For any x_k, we have

$$\begin{aligned}
\text{Payoff}(x^*, x_k) - \text{Payoff}(x, x_k) &= p_k(u^*(x_k) - u(x_k)) - p_k(u^*(x^*) - u(x)) + (u^*(x^*) - u(x)) \\
&< p_k(u^*(x_k) - u(x_k)) + (u^*(x^*) - u(x)) \\
&< (u^*(x_k) - u(x_k)) + (u^*(x^*) - u(x)) \\
&\leq C_1\ell + (C_1 + C_2)\ell \\
&\leq \frac{\lambda}{2}
\end{aligned}$$

As $r(x^*) \leq x_{t+1}$, either $r(x^*) = x_{t+1}$ or $r(x^*) = x_t$. Suppose $r(x^*) = x_{t+1}$. We show that an agent of type x cannot increase his payoff by reporting above x_{t+1}. Let $s > t + 1$.

Plugging x_{t+1} into the above bound gives

$$\text{Payoff}(x^*, x_{t+1}) \leq \frac{\lambda}{2} + \text{Payoff}(x, x_{t+1}),$$

and the definition of λ gives that

$$\text{Payoff}(x^*, x_{t+1}) \geq \text{Payoff}(x^*, x_s) + \lambda.$$

Combining the two inequalities yields

$$\begin{aligned}\text{Payoff}(x, x_{t+1}) \geq \text{Payoff}(x^*, x_{t+1}) - \frac{\lambda}{2} &> \text{Payoff}(x^*, x_s) + \frac{\lambda}{2} \\ &> \text{Payoff}(x^*, x_s) \\ &> \text{Payoff}(x, x_s),\end{aligned}$$

so $r(x) \leq x_{t+1}$.

In the case that $r(x^*) = x_t$, we similarly get $r(x) \leq x_t$. ◀

We can then repeatedly apply this proposition starting with $r(x_t) = x_{t+1}$ to conclude that for any $x_{t-1} < x \leq x_t$, we have $r(x) \leq x_{t+1}$.

Putting things together, we get:

▶ **Theorem 5.** *If $r(x) = x_{t+1}$, then $x_{t-1} < x < x_{t+1}$.*

Thus, to learn the agent's true certainty equivalent to within ε-error, the analyst chooses a discretization with $\frac{\overline{x}-\underline{x}}{n} \leq \frac{\varepsilon}{2}$, and runs a sequential search over the discretization. The number of questions the analyst asks is $O(\frac{1}{\varepsilon})$.

Of course, to lower the number of questions asked, the analyst could instead perform a binary search. It is easy to see that, like in the sequential search mechanism, simply implementing a uniformly random question is not incentive compatible. For example, consider a discretization with deterministic amounts $x_1, \ldots, x_7$, and consider an agent with true certainty equivalent at x_3. For simplicity, we assume that if when presented with (x_i, L) the agent is indifferent between x_i and L, he chooses x_i. If the agent answers truthfully, the pairs offered by a binary search would be (x_4, L), (x_2, L), and (x_3, L), and his choices would have been x_4, L, and x_3, respectively. The agent's expected payoff is $(1/3)u(x_4) + (1/3)u(L) + (1/3)u(x_3) = (1/3)u(x_4) + (2/3)u(L)$. Suppose instead the agent answers as if his true certainty equivalent is x_5. Then, the pairs he gets offered would be (x_4, L), (x_6, L), and (x_5, L), and his choices would have been L, x_6, and x_5, respectively. His expected payoff is then $(1/3)u(L) + (1/3)u(x_6) + (1/3)u(x_5)$, which is clearly a profitable deviation.

It is unclear if this scheme can be directly modified to satisfy incentive compatibility properties, but since the payments in the sequential search mechanism only depended on the last question asked, we can use the same payment scheme here so that Theorem 5 holds. So now the analyst can learn the agent's certainty equivalent to within an error of ε with $O(\log 1/\varepsilon)$ questions.

4 General Preference Elicitation

Our discussion so far has focused on a specific, albeit ubiquitous, preference elicitation environment. In the rest of the paper we introduce a general model of incentive compatible active learning. We introduce the idea of incentive compatible query complexity: the sample size that guarantees some learning objective while maintaining incentive compatibility.

The main application of our tools will be to expected utility theory. We shall introduce a learning algorithm that is incentive compatible for learning the beliefs of an agent that has expected utility preferences.

We focus on learning an agent's preferences. The agent will be modeled as having a utility function parameterized by some type, which generates the agent's choices, that the learner wishes to infer. To this end, Θ is a type space equipped with a metric $d : \Theta \times \Theta \to \mathbb{R}_{\geq 0}$ that is bounded with respect to d. $\mathcal{O}$ is the space of possible outcomes. An agent of type $\theta \in \Theta$ has utility $u(\theta, o)$ if the outcome is $o \in \mathcal{O}$. θ induces a preference relation $\succsim$ over $\mathcal{O}$ defined by $o \succsim o' \iff u(\theta, o) \geq u(\theta, o')$.

An analyst aims to learn the agent's type by asking him to make a sequence of choices between pairs of outcomes.[7] The agent makes choices among the pairs presented to him.

The agent's choices can be thought of as the result of a strategy. Formally, a strategy σ is a mapping

$$\sigma : \bigcup_t \{((o_1, o_1'), \mathbf{1}_{o_1 \succsim o_1'}), \ldots, ((o_t, o_t'), \mathbf{1}_{o_t \succsim o_t'}), (o_{t+1}, o_{t+1'})\} \to \Delta\{0, 1\}$$

that dictates a (potentially randomized) response for every possible history of the interaction up to any given time. Let Σ denote the collection of all possible consistent strategies (a strategy is consistent if its outputs up to any given time are consistent with some preference relation in the type space).

For any strategy σ, let $\hat{\sigma}$ denote an oracle with memory that responds to queries of the form "is o preferred to o'?" according to σ given the history of previous queries made so far. Let $\hat{\Sigma} = \{\hat{\sigma} : \sigma \in \Sigma\}$ denote the collection of oracles corresponding to all possible strategies. For a type $\theta \in \Theta$, let $\hat{\theta} \in \hat{\Sigma}$ denote the oracle that responds truthfully according to θ (i.e. on query (o, o') it returns $\mathbf{1}_{u(\theta,o) \geq u(\theta,o')}$).

We imagine the oracle playing the role of the agent: in an interaction with the analyst, an agent of true type θ chooses to act as an oracle for some strategy σ (departing from standard terminology, we allow the oracle to have randomized responses).

The analyst implements a learning mechanism, which consists of the following steps:

1. Run a (potentially randomized) learning algorithm $\mathcal{A} : \hat{\Sigma} \to \Theta$ that has access to oracle $\hat{\sigma}$ and can make queries to $\hat{\sigma}$ of the form (o, o') for $o, o' \in \mathcal{O}$.
2. Arrive at a hypothesis $\theta^h \sim \mathcal{A}(\hat{\sigma})$ for the agent's type.
3. Implement the agent's response on the last query.[8]

We now establish the notion of learnability that we work with. This definition is not concerned with issues of incentive compatibility: it is simply a refinement of the standard notion of a learning algorithm that stipulates that we learn a truthfully reported hypothesis accurately. Since in our setting the analyst has full control over the data he learns from, our requirements on the error of the algorithm are with respect to the metric d on the space of types Θ.

[7] One can imagine many other protocols for learning. We constrain ourselves to protocols that are based on a sequence of pairwise comparisons. Such protocols are common in practice, and are the obvious empirical counterpart to the decision theory literature in economics and statistics. This stands in contrast with the literature on scoring rules, which allows for richer message spaces.

[8] Within adaptive experimental design, the idea of making a last choice on behalf of the agent is due to Ian Krajbich.

▶ **Definition 6.** *$\mathcal{A} : \hat{\Sigma} \to \Theta$ is an (ε, δ)-learning algorithm if for all $\theta \in \Theta$,*

$$\Pr_{\theta^h \sim \mathcal{A}(\hat{\theta})} [d(\theta, \theta^h) \leq \varepsilon] \geq 1 - \delta.$$

The number of queries made by $\mathcal{A}$ to the oracle $\hat{\theta}$ is the query complexity *of $\mathcal{A}$, denoted by $q(\varepsilon, \delta)$.*

Next, we define what it means for a learning algorithm to be incentive compatible. Intuitively, we require that if the learning algorithm is terminated on round T, and the analyst implements the agent's preferred outcome on the Tth query (o_T, o'_T), then the agent (with high probability) cannot gain a non-negligible advantage over truthfully reporting by attempting to answer questions strategically. Let $\mathcal{A}_T(\hat{\sigma}) = (o_T, o'_T) \in \Delta(\mathcal{O} \times \mathcal{O})$ denote the Tth query to $\hat{\theta}$ made by an execution of $\mathcal{A}(\hat{\sigma})$.

▶ **Definition 7.** *$\mathcal{A} : \hat{\Sigma} \to \Theta$ is (τ, ν)-incentive compatible if there exists a $T(\tau, \nu) \in \mathbb{N}$ such that for all $T \geq T(\tau, \nu)$, the following holds for any type θ and strategy σ:*

$$\Pr_{\substack{(o_T, p_T) \sim \mathcal{A}_T(\hat{\theta}) \\ (o'_T, p'_T) \sim \mathcal{A}_T(\hat{\sigma})}} [u(\theta, q_T) \geq u(\theta, q'_T) - \tau] \geq 1 - \nu,$$

where q_T (q'_T) is the preferred outcome between o_T and p_T (o'_T and p'_T) according to oracle $\hat{\theta}$ ($\hat{\sigma}$). The quantity $T(\tau, \nu)$ is the IC complexity *of $\mathcal{A}$.*[9]

Our goal is to design mechanisms that learn the agent's true type in an incentive compatible manner.

▶ **Definition 8.** *$\mathcal{A} : \hat{\Sigma} \to \Theta$ is an $(\varepsilon, \delta, \tau, \nu)$-IC learning algorithm if it is an (ε, δ)-learning algorithm that is (τ, ν)-IC. We refer to the quantity $\max(q(\varepsilon, \delta), T(\tau, \nu))$ as the* IC learning complexity *of $\mathcal{A}$.*

4.1 An incentive compatible exhaustive search

We first give a very simple method of achieving incentive compatible learning in the general framework introduced in Section 4. The method proceeds by exhaustively searching over the type space, and requires a simple structural assumption. The assumption connects agents' payoffs to the distance metric used by the learner to assess learning accuracy. In a sense, this lines up the agent's incentives with the learner's objective, and makes it easy to obtain a satisfactory algorithm.

Suppose there exists a one-to-one assignment of outcomes to types $s : \Theta \to \mathcal{O}$ such that

$$u(\theta, s(\theta')) > u(\theta, s(\theta'')) \iff d(\theta, \theta') < d(\theta, \theta''),$$

so in particular $\theta = \operatorname{argmax}_{\theta'} u(\theta, s(\theta'))$. In the literature on scoring rules, s is called *effective* with respect to d [24].

The following is an incentive compatible learning algorithm. Recall that an ε-cover of a subset K of a metric space (M, d) is a set of points C such that for every $x \in K$, there is an $x^* \in C$ such that $d(x, x^*) \leq \varepsilon$.

1. Initialize an ε-cover $\{\theta_1, \ldots\}$ of Θ with respect to d.
2. Initialize $\theta^h \leftarrow \theta_1$.

[9] In this definition, (o_T, p_T) and (o'_T, p'_T) are drawn from independent executions of $\mathcal{A}$.

3. For $t = 1$ to T:
   a. Query $(s(\theta_{t+1}), s(\theta^h))$.
   b. If $s(\theta_{t+1})$ is preferred, $\theta^h \leftarrow \theta_{t+1}$.
4. Output θ^h.
5. Pay the agent $s(\theta^h)$.

By definition of the function s, allowing the algorithm to exhaustively search over all points of the cover will yield a θ^h that is the most preferred point in the cover and is also the closest point in the cover to the report. So reporting θ yields $d(\theta, \theta^h) \leq \varepsilon$. Moreover, this (deterministic) algorithm satisfies $(0, 0)$-incentive compatibility for any runtime T, since lying at any round would simply reduce the payoff of stopping at any round. The learning complexity is the covering number $N_\varepsilon(\Theta)$ of the type space (which is finite as Θ is bounded).

We now present some natural preference environments in which such an assignment function can be constructed. In the following discussion, the outcome space is $\mathcal{O} = \mathbb{R}^n$, and Θ is assumed to be bounded so that the search above terminates.

- *Euclidean preferences.* Each agent has an "ideal point" $\theta \in \mathbb{R}^n$, and $u(\theta, x) \geq u(\theta, y)$ iff $||x - \theta|| \leq ||y - \theta||$. Let $s : \mathbb{R}^n \to \mathbb{R}^n$ be the identity.
- *Linear preferences.* The type of an agent is a vector $\theta \in \mathbb{R}^n$ and $u(\theta, x) \geq u(\theta, y)$ iff $\theta.x \geq \theta.y$ (in order for preferences to be distinguishable we assume that no two $\theta, \theta' \in \Theta$ are scalar multiples of one another, and so for simplicity we normalize so that all types have the same length). The indifference sets of an agent of type θ are the hyperplanes $\{x : \theta.x = k\}$, for $k \in \mathbb{R}$. For each θ, there is a unique indifference set that is tangent to the unit $(n-1)$-sphere S^{n-1}. Let $s(\theta)$ be that tangent point.

Euclidean and linear preferences are characterized by natural axioms for preference relations [14].

More generally, suppose the preferences of each agent are continuous and strictly convex, which we define as the upper contour sets $C(x) = \{y : y \succsim x\}$ being closed, convex, and any supporting hyperplane of $C(x)$ being unique, for all x. For a type θ, real number k, and outcome $x \in \mathbb{R}^n$ such that $u(\theta, x) = k$, let $H_k^\theta(x)$ denote the supporting hyperplane of the upper contour set $\{y : u(\theta, y) \geq k\}$ at x.

Suppose that the following uniqueness requirement holds: for every pair of types $\theta \neq \theta'$, real number k, and outcome $x \in \mathbb{R}^n$ such that $u(\theta, x) = k$, if k' is such that $u(\theta', x) = k'$, it holds that $H_k^\theta(x) \neq H_{k'}^{\theta'}(x)$. We call this property *hyperplane uniqueness.*[10] Then, the argument for IC learnability in the case of linear preferences can be adapted to this setting as well. Though the assignment function s we construct may not necessarily be effective, we show that exhaustively searching over a sufficiently fine cover is nevertheless incentive compatible.

▶ **Theorem 1.** *Let Θ be a type space such that the preferences induced by each $\theta \in \Theta$ are continuous, strictly convex, and satisfy hyperplane uniqueness. Then, there exists a metric on Θ with respect to which Θ is $(\varepsilon, 0, 0, 0)$-IC learnable.*

Proof. For each θ, let $s(\theta)$ be the unique maximizer of $u(\theta, x)$ over the unit $(n-1)$-sphere S^{n-1}; uniqueness follows from the strict convexity of preferences. Note that S^{n-1} and $C = \{y : u(\theta, y) \geq k\}$, with $k = u(\theta, s(\theta))$, are on differing sides of the supporting hyperplane of C at $s(\theta)$. Hyperplane uniqueness ensures that s is one-to-one. Let d be the metric where $d(\theta, \theta')$ is the Euclidean distance between $s(\theta)$ and $s(\theta')$.

[10] Hyperplane uniqueness is reminiscent of the single-crossing property in mechanism design.

Let $C^\theta_{k'} = \{y : u(\theta, y) > k'\}$ with $k' < k$ and let $N^\theta_{k'} = C_{k'} \cap S^{n-1}$. Clearly the diameter of $N^\theta_{k'}$ converges to 0 as $k' \uparrow k$. Therefore, for each θ and $\varepsilon > 0$, there is an open neighborhood $N^\theta_\varepsilon \subset B_\varepsilon(s(\theta))$ of $s(\theta)$ such that $u(\theta, x) > u(\theta, y)$ for all $x \in N^\theta_\varepsilon$ and all $y \in S^{n-1} \setminus N^\theta_\varepsilon$ (where N^θ_ε is of the form $N^\theta_{k'}$, for k' sufficiently close to k). [11]

Now, fix the learning parameter ε, and let $\eta > 0$ be sufficiently small such that if K is an η-cover of S^{n-1}, $K \cap N^\theta_\varepsilon \neq \emptyset$ for all θ. Then, any $x \in K \cap N^\theta_\varepsilon$ satisfies $u(\theta, x) > u(\theta, y)$, for all $y \in S^{n-1} \setminus B_\varepsilon(s(\theta))$. Thus, the most preferred point of an agent of type θ is contained in $K \cap N^\theta_\varepsilon \subset B_\varepsilon(s(\theta))$, and so exhaustively searching over this η-cover is an ε-learning algorithm with respect to d that is incentive compatible. ◀

It is an interesting question to see what structural conditions one can impose on the type space, the outcome space, etc. to write down better learning mechanisms. For example, one might hope to achieve a learning complexity that is logarithmic in the size of the cover $N_\varepsilon(\Theta)$. As we will see in the case of expected utility, naive learning algorithms achieve this sample complexity, but fail to be incentive compatible. More generally one can ask if there is a combinatorial complexity measure (such as VC dimension in the case of PAC learning) that characterizes the complexity of incentive compatible learning.

4.2 The expected utility model of choice under uncertainty

We now turn to the case of belief elicitation for an expected utility agent. Belief elicitation has a long history in experimental economics, and in the theoretical literature on scoring rules (e.g. [15]; see [20] for a survey). A major difference with the theory of scoring rules is that we shall take as given a protocol that is based on pairwise comparisons among uncertain prospects.[12] The case of passive learning was studied in [11].

There are n states of the world, indexed by $i = 1, \ldots, n$. An agent has a subjective belief $\alpha \in \Delta_n$, where α_i is the probability the agent assigns to state i occurring. The agent evaluates the payoff of a vector of rewards $x \in \mathbb{R}^n$ by computing expectation according to α. An agent's belief α defines a preference relation $\succsim \subseteq \mathbb{R}^n \times \mathbb{R}^n$, where

$$x \succsim y \iff \alpha.x \geq \alpha.y.$$

An analyst would like to learn α by asking the agent to make several choices between vectors of rewards. The analyst presents the agent with a sequence of pairs (x, y) and if the agent chooses x she infers that $(x - y).\alpha \geq 0$. So the problem is related to that of learning half spaces, but with the added complication of having to respect incentive compatibility. An important assumption is that the analyst is able to simulate the states of the world and observe a state according to the "ground truth" process governing the states (so for example if the states were "rain", "snow", and "shine", the analyst could simply observe the weather on the given day).

Using the notation of the previous section, $\Theta = \Delta_n$, $\mathcal{O} = \mathbb{R}^n$, and $u(\alpha, x) = \mathbf{E}_{i \sim \alpha}[x] = \alpha.x$.

In the context of learning the agent's true belief, the analyst uses total variation distance $||\alpha - \beta||_{TV} = \frac{1}{2} \sum_{i=1}^n |\alpha_i - \beta_i|$ to measure accuracy/error.

[11] The neighborhoods and balls are with respect to the subspace topology on S^{n-1}.

[12] This follows experimental practice, as well as the standard model of choice under uncertainty; starting from von-Neumann and Morgenstern [34] and Savage [33]. In the scoring rule model, subjects are asked to report beliefs rather than carrying out a sequence of binary choices. In any case we shall use scoring rules in our solution, just not by asking subjects to report their beliefs.

4.2.1 Naive algorithms are not incentive compatible

First, to illustrate the restrictions of our definitions, we write down a naive algorithm for eliciting α that achieves a good query complexity, but is not incentive compatible.

Consider a mechanism that tries to elicit each α_i by performing a search (sequential or binary) on each state. That is, for each state i, the algorithm makes queries $(e_i, c_i\vec{1})$, varying c_i over a $\frac{2\varepsilon}{n}$-cover of $[0,1]$ to find the indifference points, which reveal α_i to within an error of $\frac{2\varepsilon}{n}$. So, for example, a binary search uses $O(n \log \frac{n}{\varepsilon})$ questions to arrive at a hypothesis within total variation distance ε from α. Note that a $\frac{2\varepsilon}{n}$-cover of the simplex Δ_n with respect to total variation distance contains $O((n/\varepsilon)^n)$ elements, so performing a state-wise binary search exponentially improves upon a search over the entire cover.

However, incentive compatibility is broken rather easily, since the agent has a great deal of control over what questions the agent asks (in a similar manner to the situation in MPL). Consider the following simple example: suppose the analyst fixes a discretization of $[0,1]$ with sure amounts $x_1, \ldots, x_7$, as in the binary search MPL example from Section 3, and suppose an agent has a true belief α, with $\alpha_n \leq x_6$. If, instead of α, the agent reports an α' with $\alpha'_n \in (x_6, x_7)$, the final question he would get asked would be $(e_n, x_7\vec{1})$. The agent would prefer $x_7\vec{1}$, and thus would get paid off a sure amount of x_7. It is clear that truthfully reporting yields a strictly lower payoff than the misrepresentation. Notice that this situation is even worse than that of MPL, since if the binary search ends on state n, then regardless of the probabilities an agent assigns to states $1, \ldots, n-1$, he will want to answer questions as if he assigns most weight to state n – so there is no hope of backing-out an agent's true belief using this kind of scheme.

A strategic agent can easily outwit minor modifications to this scheme: for example if the analyst does the binary searches in a random order over the states, the agent can adaptively report a belief that assigns most weight to the last state over which the analyst performs a binary search.

4.2.2 A mechanism based on scoring rules.

In this section we present an IC learning algorithm with IC learning complexity

$$O\left(n^{3/2} \log n \max\left(\log \frac{n}{\varepsilon}, \log \frac{1}{\tau}\right)\right).$$

The algorithm is based on ideas from active learning, and specifically leverages convergence bounds on so-called disagreement based methods. Let $||\cdot||$ denote the L^2 norm, let S^{n-1} denote the unit $(n-1)$-sphere, and let $\rho : \mathbb{R}^n \to S^{n-1}$ denote the projection map onto the unit sphere defined by $\rho(\alpha) = \frac{\alpha}{||\alpha||}$.

We now present an incentive compatible learning algorithm that we henceforth refer to as $\mathcal{A}$.

1. Initialize $\mathcal{H}^0 \leftarrow \Delta_n$.
2. For $t = 1$ to T:
   a. Choose v uniformly at random from S^{n-1}. If the hyperplane $\{x : v.x = 0\}$ does not intersect $\mathcal{H}^{t-1}$, resample.
   b. Let β^1, β^2 be any elements of $\mathcal{H}^{t-1}$ such that $\rho(\beta^1) - \rho(\beta^2)$ is a scalar multiple of v.
   c. Query oracle on pair $(x_t = \rho(\beta^1), y_t = \rho(\beta^2))$.
   d. $\mathcal{H}^t \leftarrow \mathcal{H}^{t-1} \cap \{\beta \in \Delta_n : \beta \text{ is consistent with label on } (x_t, y_t)\}$
3. Output any $\beta^h \in \mathcal{H}^T$.
4. Pay the agent off based on preference from (x_T, y_T). If z_T is the preferred vector, simulate states of the world, and pay $(z_T)_i$ if state i occurs.

Before analyzing the algorithm, let us briefly remark that the analyst can always find β^1, β^2 satisfying the required conditions to query the agent. Let normal vector $v \in S^{n-1}$ define a hyperplane $v.x = 0$ that cuts through the projection $\rho(\mathcal{H}) \subset S^{n-1}$ of the current hypothesis set onto the unit sphere. Let w be a point in the interior of $\rho(\mathcal{H})$ such that $v.w = 0$.[13] We can find an open ball $B(w, r)$ (with respect to the subspace topology on S^{n-1} induced by $\mathbb{R}^n$) of radius r centered at w such that $B(w, r) \subset \rho(\mathcal{H})$. Then, take a point $x \in B(w, r)$ in the positive v direction from w and $y \in B(w, r)$ in the negative v direction from w such that $||x - w|| = ||y - w||$. Then, $x - y = v||x - y||$.

Choosing β^1 and β^2 in this manner has no effect on the analysis of the learning rate, but is the main ingredient in achieving incentive compatibility. The learning guarantees we obtain are due to standard bounds on the label complexity of disagreement based active learning.

▶ **Theorem 9.** *$\mathcal{A}$ is a learning algorithm of query complexity $O(n^{3/2} \log n \log \frac{n}{\varepsilon})$ with respect to total variation distance.*

Proof. Suppose $\mathcal{A}$ receives as input an oracle $\hat{\alpha}$. If on a given round we sample a normal vector v and correspondingly query points (x_t, y_t), the truthful agent's/oracle's preference from (x_t, y_t) precisely reveals $\text{sgn}(v.\alpha)$ – this is simply because $x_t - y_t$ and v determine the same hyperplane.

The VC dimension of the expected utility model is linear (Theorem 2 of [11]), and the disagreement coefficient of the class of homogeneous linear separators with respect to the uniform distribution over normal vectors is bounded above by $\pi\sqrt{n}$ (Theorem 1 of [26]). Standard convergence results in active learning (see, e.g., [21]) then imply that with $O(n^{3/2} \log n \log \frac{1}{\eta})$ queries, it holds with high probability that $\text{err}_\alpha(\alpha^h) \leq \eta$ for all α^h in the final hypothesis set, where

$$\text{err}_\alpha(\beta) = \Pr_{v \sim S^{n-1}}[\text{sgn}(v.\alpha) \neq \text{sgn}(v.\beta)] = \frac{\arccos(\rho(\alpha).\rho(\beta))}{\pi}.$$

For $\varepsilon > 0$, let $\eta = \frac{2\varepsilon}{\pi n} < \frac{1}{\pi} \arccos\left(1 - \frac{2\varepsilon^2}{n^2}\right)$, so $\cos(\pi\eta) > 1 - \frac{2\varepsilon^2}{n^2}$.
Running $\mathcal{A}$ for $O(n^{3/2} \log n \log \frac{n}{\varepsilon})$ rounds yields that for any hypothesis $\alpha^h \in \mathcal{H}^T$,

$$\begin{aligned} ||\rho(\alpha) - \rho(\alpha^h)|| &= \sqrt{(\rho(\alpha) - \rho(\alpha^h)).(\rho(\alpha) - \rho(\alpha^h))} \\ &= \sqrt{2 - 2\rho(\alpha).\rho(\alpha^h)} \\ &\leq \sqrt{2 - 2\cos(\pi\eta)}, \end{aligned}$$

which is at most $2\varepsilon/n$ (where the final inequality is with high probability over the execution of $\mathcal{A}$). Thus $||\alpha - \alpha^h|| \leq \frac{2\varepsilon}{n}$, and so $||\alpha - \alpha^h||_{TV} \leq \varepsilon$. [14] ◀

We now analyze incentive compatibility properties of the algorithm. The main ingredient is in using the mapping $(\alpha, i) \mapsto \rho(\alpha)_i = \frac{\alpha_i}{||\alpha||}$ to choose what questions to ask. This mapping is known as the *spherical scoring rule*, and incentivizes truthful forecasts, in the sense that $\alpha = \text{argmax}_\beta \mathbf{E}_{i \sim \alpha}[\rho(\beta)_i]$. The spherical scoring rule satisfies the geometric property that

[13] The interior of $\rho(\mathcal{H})$ can be written as $\rho(\{\beta \in \Delta_n : v_1.\beta > 0, \ldots, v_T.\beta > 0\})$ for some $v_1, \ldots, v_T$, which is a non-empty intersection of open half-spaces as the agent's responses are required to be consistent.

[14] $||\alpha - \alpha^h|| \leq \frac{2\varepsilon}{n} \implies \sum_{i=1}^n (\alpha_i - \alpha_i^h)^2 \leq \frac{4\varepsilon^2}{n^2}$, so $(\alpha_i - \alpha_i^h) \leq \frac{2\varepsilon}{n}$ for each i, which implies that $||\alpha - \alpha^h||_{TV} \leq \varepsilon$.

$\mathbf{E}_{i\sim\alpha}[\rho(\beta)_i] = ||\alpha|| \cos(\alpha, \beta)$, where $\cos(\alpha, \beta)$ is the cosine of the angle formed by vectors α, β. Moreover, the spherical scoring rule is *effective* with respect to the renormalized L^2 metric, i.e. $\mathbf{E}_{i\sim\alpha}[\rho(\beta)_i] > \mathbf{E}_{i\sim\alpha}[\rho(\beta')_i]$ if and only if $||\rho(\alpha) - \rho(\beta)|| < ||\rho(\alpha) - \rho(\beta')||$. Note that the spherical scoring rule plays the role of the assignment function s in the more general preference framework.

We use the following straightforward observation bounding the deviation from the maximum possible payoff in terms of the renormalized L^2 distance from the true type.

▶ **Lemma 10.** *Let* $||\rho(\alpha) - \rho(\alpha')|| \leq \lambda$. *Then*

$$\mathbf{E}_{i\sim\alpha}[\rho(\alpha')_i] \geq \mathbf{E}_{i\sim\alpha}[\rho(\alpha)_i] - \frac{1}{2}\lambda^2.$$

Proof. We can write $||\rho(\alpha) - \rho(\alpha')||^2 = 2(1 - \cos(\alpha, \alpha'))$, so

$$\mathbf{E}_{i\sim\alpha}[\rho(\alpha')_i] = ||\alpha|| \cos(\alpha, \alpha') = ||\alpha|| \left(1 - \frac{1}{2}||\rho(\alpha) - \rho(\alpha')||^2\right) \geq \mathbf{E}_{i\sim\alpha}[\rho(\alpha)_i] - \frac{1}{2}\lambda^2. \quad \blacktriangleleft$$

▶ **Theorem 2.** *The IC learning complexity of* $\mathcal{A}$ *is* $O\left(n^{3/2} \log n \max\left(\log \frac{n}{\varepsilon}, \log \frac{1}{\tau}\right)\right)$.

Proof. Suppose we run $\mathcal{A}$ for T rounds to achieve (ε, δ)-learning. By Theorem 9, it holds with high probability that the hypothesis set obtained will be contained inside a small ball with respect to renormalized L^2 distance. More precisely, if $\mathcal{A}$ is given access to oracle $\hat{\alpha}$, and $\lambda = 2\varepsilon/n$, then

$$\Pr[\mathcal{H}^T(\alpha) \subseteq B(\alpha, \lambda)] \geq 1 - \delta,$$

where $\mathcal{H}^T(\alpha)$ is shorthand to denote a hypothesis set drawn from an execution of $\mathcal{A}_T(\hat{\alpha})$ and $B(\alpha, \lambda) = \{\alpha' : ||\rho(\alpha) - \rho(\alpha')|| \leq \lambda\}$.

By Lemma 10,

$$\Pr\left[\forall \alpha^h \in \mathcal{H}^T(\alpha), \mathbf{E}_{i\sim\alpha}[\rho(\alpha^h)_i] \geq \mathbf{E}_{i\sim\alpha}[\rho(\alpha)_i] - \frac{1}{2}\lambda^2\right] \geq \Pr[\mathcal{H}^T(\alpha) \subseteq B(\alpha, \lambda)] \geq 1 - \delta,$$

so any strategy can yield an advantage of at most $\frac{1}{2}\lambda^2 = \frac{2\varepsilon^2}{n^2}$ over truthful reporting. For $\varepsilon < n\sqrt{\tau}$ and $\delta = \nu$ we get (τ, ν)-incentive compatibility. The IC complexity is the query complexity of $(n\sqrt{\tau}, \nu)$-learning, which is $O(n^{3/2} \log n \log \frac{1}{\tau})$.

Thus, the number of queries required to simultaneously achieve (ε, δ)-learning and (τ, ν)-incentive compatibility is $O\left(n^{3/2} \log n \max\left(\log \frac{n}{\varepsilon}, \log \frac{1}{\tau}\right)\right)$. ◀

Our notion of incentive compatibility is approximate, and allows for small gains to the agent from misrepresenting their beliefs. We now demonstrate that, even though Theorem 2 allows for the possibility of gaining some advantage by playing strategically, we can ensure that with high probability any type learned by the analyst as a result of a strategic interaction will be sufficiently close to the true type that the analyst accurately learns the true type nonetheless.

Suppose the analyst wants to achieve ε learning accuracy, and additionally wants to guarantee that with probability at least $1 - \delta$, any best-responding agent will report a belief, or type, that is within ε total variation distance to the true type (note that this is a slightly different notion of incentive compatibility than the previous one). As usual, let α denote the agent's true type. Let $\varepsilon_0 < \frac{\varepsilon}{3}$, $\lambda = \frac{2\varepsilon_0}{n}$, $\delta_0 < 1 - \sqrt{1 - \delta}$, and run the algorithm to achieve $(\varepsilon_0, \delta_0)$-learning.

We first show that any misreport that is sufficiently far from the true type yields, with high probability, a strictly worse payoff than truthful reporting. Recall that $B(\alpha, \lambda)$ denotes the closed ball of radius λ centered at α with respect to the renormalized L^2 distance.

Suppose that $||\rho(\alpha) - \rho(\beta)|| > 2\lambda$, so that $B(\alpha, \lambda) \cap B(\beta, \lambda) = \emptyset$. Then, as the spherical scoring rule is effective with respect to renormalized L^2-distance,

$$\begin{aligned}
&\Pr\left[\forall \alpha^h \in \mathcal{H}^T(\alpha), \forall \beta^h \in \mathcal{H}^T(\beta), \mathbf{E}_{i\sim\alpha}[\rho(\alpha^h)_i] > \mathbf{E}_{i\sim\alpha}[\rho(\beta^h)_i]\right] \\
&\quad \geq \Pr[\mathcal{H}^T(\alpha) \subseteq B(\alpha, \lambda) \wedge \mathcal{H}^T(\beta) \subseteq B(\beta, \lambda)] \\
&\quad \geq (1 - \delta_0)^2 \\
&\quad \geq 1 - \delta,
\end{aligned}$$

so it holds with high probability that any such misreport yields a strictly worse payoff.

The remaining misreports are sufficiently close to the true type such that the analyst does not care if these allow the agent to increase his payoff. Indeed, if $||\rho(\alpha) - \rho(\beta)|| \leq 2\lambda$, since $\mathcal{H}^T(\alpha) \subseteq B(\alpha, \lambda)$ and $\mathcal{H}^T(\beta) \subseteq B(\beta, \lambda)$ with high probability, the triangle inequality yields

$$||\rho(\alpha) - \rho(\beta^h)|| \leq ||\rho(\alpha) - \rho(\beta)|| + ||\rho(\beta) - \rho(\beta^h)|| \leq 3\lambda,$$

so $||\alpha - \beta^h||_{TV} \leq 3\varepsilon_0 < \varepsilon$. Thus with probability at least $1 - \delta$, the analyst will learn a β^h such that $||\alpha - \beta^h||_{TV} \leq \varepsilon$ for any such misreport.

To summarize, the algorithm can be run for $O(n^{3/2} \log n \log \frac{n}{\varepsilon})$ rounds (the exact number of rounds would just be a small constant factor more than that required by the vanilla learning requirement) such that regardless of what strategy an agent may use to best respond during the interaction, with high probability the analyst will end up accurately learning the agents true type.

5 Concluding remarks

We have analyzed the incentive compatibility of active learning using data labeled by human subjects. Our results are directly applicable to the adaptive design of economic experiments that seek to estimate subjects' preference parameters. Our paper has discussed some of the leading areas of economic experimentation: estimation of risk aversion from multiple price lists, and belief elicitation using convex budgets and scoring rules. We highlight some challenges in making active learning compatible with incentives, but for the most part we offer satisfactory algorithmic solutions to the specific areas of experimentation we have focused on.

There are, of course, many other areas of application of active learning, and incentive issues will be important as long as the required training data is labeled by human subjects under incentivized conditions. To this end, we have introduced a general model of active learning under incentives: we believe that we are the first to do so, and we expect our findings to motivate additional investigations of the problems at the intersection of learning and incentives.

Pseudorandomness and the Minimum Circuit Size Problem

Rahul Santhanam
Department of Computer Science, University of Oxford, United Kingdom
rahul.santhanam@cs.ox.ac.uk

Abstract

We explore the possibility of basing one-way functions on the average-case hardness of the fundamental Minimum Circuit Size Problem ($\mathsf{MCSP}[s]$), which asks whether a Boolean function on n bits specified by its truth table has circuits of size $s(n)$.

1. (Pseudorandomness from Zero-Error Average-Case Hardness) We show that for a given size function s, the following are equivalent: Pseudorandom distributions supported on strings describable by $s(O(n))$-size circuits exist; Hitting sets supported on strings describable by $s(O(n))$-size circuits exist; $\mathsf{MCSP}[s(O(n))]$ is zero-error average-case hard. Using similar techniques, we show that Feige's hypothesis for random k-CNFs implies that there is a pseudorandom distribution (with constant error) supported entirely on satisfiable formulas. Underlying our results is a general notion of *semantic sampling*, which might be of independent interest.
2. (A New Conjecture) In analogy to a known universal construction of succinct hitting sets against arbitrary polynomial-size adversaries, we propose the Universality Conjecture: there is a universal construction of succinct pseudorandom distributions against arbitrary polynomial-size adversaries. We show that under the Universality Conjecture, the following are equivalent: One-way functions exist; Natural proofs useful against sub-exponential size circuits do not exist; Learning polynomial-size circuits with membership queries over the uniform distribution is hard; $\mathsf{MCSP}[2^{\epsilon n}]$ is zero-error hard on average for some $\epsilon > 0$; Cryptographic succinct hitting set generators exist.
3. (Non-Black-Box Results) We show that for weak circuit classes $\mathfrak{C}$ against which there are natural proofs [44], pseudorandom functions secure against poly-size circuits in $\mathfrak{C}$ imply superpolynomial lower bounds in P against poly-size circuits in $\mathfrak{C}$. We also show that for a certain natural variant of MCSP, there is a polynomial-time reduction from approximating the problem well in the worst case to solving it on average. These results are shown using non-black-box techniques, and in the first case we show that there is no black-box proof of the result under standard crypto assumptions.

Acknowledgements Discussions with Shuichi Hirahara and Igor Carboni Oliveira were very helpful at an early stage of this research. Thanks to Igor for his detailed comments on an early draft of this work. Thanks to Shuichi for telling me about his independent work [23] and for alerting me to the relevance of auxiliary-input one-way functions. Thanks also to Andrej Bogdanov and Hoeteck Wee for e-mail correspondence about cryptographic hitting set generators. Conversations with Marco Carmosino, Manuel Sabin and Prashant Nalini Vasudevan were useful. Part of this work was done while participating in the Simons Institute Semester on Lower Bounds in Computational Complexity. I wish to thank the Simons Institute for their hospitality.

1 Introduction

We investigate the relationship between the complexity of the Minimum Circuit Size Problem (MCSP) [2] and the existence of various kinds of pseudorandom objects, such as hitting sets and pseudorandom sets, succinctly describable or not, in the cryptographic regime. There are two broad regimes of pseudorandom constructions: the complexity-theoretic regime, where the generator has more resources than the adversary, and the cryptographic regime, where the adversary can have more resources than the generator. In the complexity-theoretic regime, there is a beautiful theory [40, 31] giving equivalences between the existence of hard problems in E (linear exponential time), and explicit constructions of hitting set generators and pseudorandom generators.

In the cryptographic regime, the celebrated result of [22] gives an equivalence between pseudorandom generators and one-way functions, which are in many ways the fundamental cryptographic primitive. However, as we point out, there are several gaps in our understanding of the relationships between hardness and pseudorandomness in the cryptographic regime. To some extent, these gaps reflect an imperfect knowledge of average-case hardness for NP in general. In this paper, we make the argument that the average-case complexity of MCSP in particular is deeply relevant to pseudorandomness in the cryptographic regime.

We first discuss the questions that motivate us.

1.1 Our Questions

1.1.1 One-way Functions

From a cryptographer's point of view, one-way functions are an extremely robust and useful primitive, forming the basis for a range of important crypo constructions [34]. However, one-way functions do not fit very neatly into the complexity landscape. The hardness assumptions required to do cryptography seem stronger than the assumptions traditionally studied in complexity theory, and bridging this gap is an important open problem.

▶ **Question 1.** *Is there a natural well-studied problem in* NP *whose average-case hardness with respect to some natural distribution is equivalent to the existence of one-way functions?*

An attempt to base one-way functions on a standard complexity assumption was made by Ostrovsky and Wigderson [42], who showed that a weak variant of one-way functions called auxiliary-input one-way functions follow from the assumption that ZK (computational zero-knowledge) is not contained in BPP. It is unknown whether the existence of one-way functions is equivalent to the existence of auxiliary-input one-way functions. An equivalence result would imply that one-way functions could be based on worst-case hardness of ZK, which "would have a major impact on cryptography" [10].

▶ **Question 2.** *Are one-way functions equivalent to auxiliary-input one-way functions?*

One-way functions are also relevant to proof complexity. The main result of [44] is that if one-way functions exist, "natural proofs" of lower bounds against superpolynomial-size circuits do not. Here a "natural proof" is a property of Boolean functions that is satisfied with significant probability by a random Boolean function, and is moreover easy to check. Most standard algebraic and combinatorial lower bound techniques yield properties of this form.

Thus one-way functions rule out natural proofs of lower bounds, but could it be the case that neither one-way functions exist nor natural proofs? Both objects are useful, the first for cryptographic applications and the second for proof theory, so it would be nice to have at least one of them available, even if it is impossible to have both.

▶ **Question 3.** *Can we base one-way functions on the non-existence of natural proofs?*

1.1.2 Pseudorandomness

In many contexts where pseudorandomness is relevant, there is a distinction between a one-sided "hitting" notion where the goal is to find an explicit set of points that hits every "easy" dense set and a two-sided "pseudorandom" notion, where the question is to find an explicit distribution on points that approximates every easy set. The support of a pseudorandom distribution is a hitting set, but it is not clear in general how to get pseudorandom distributions from hitting sets. Sometimes the two notions coincide, and this makes for a cleaner theory. This is the case for example with the complexity-theoretic regime, where the results of [40, 31] imply that hitting set generators (HSGs) and pseudorandom generators (PRGs) are equivalent.

How about the cryptographic regime? What is the power of HSGs in this setting? Surprisingly, this question doesn't seem to have received much attention, though it seems a very natural one.

Part of the reason might be that, in contrast to PRGs, HSGs are not obviously robust. For instance, while we can increase the "stretch" of a PRG simply by iterating it, this does not seem to work with HSGs.

▶ **Question 4.** *Can HSGs be stretched in the cryptographic regime? For example, does a HSG with seed length $N^{0.5}$ (where N is the output length) imply one with seed length $N^{0.25}$?*

Question 4 might seem purely curiosity-driven, but in fact it has relevance to proof complexity and cryptography against non-deterministic adversaries, as suggested by Rudich [45]. The notion of cryptographic pseudorandomness does not make sense against non-deterministic adversaries, as a non-deterministic adversary could break the PRG by simply guessing the seed and checking that it maps to his/her input. However, a crucial observation is that the notion of HSG still does make sense against non-deterministic adversaries. Rudich defined the notion of a "demi-bit" to capture hitting sets in this setting, and asked questions about whether they can be stretched. Indeed, Question 4 is a version of his question for deterministic adversaries.

Cryptographic PRGs are equivalent to the existence of one-way functions, as shown by [22]. Is there a comparable connection for HSGs?

▶ **Question 5.** *In the cryptographic regime, is the existence of HSGs equivalent to some notion of average-case hardness for a decision or search problem?*

Finally, an ideal situation in terms of the cleanness of the resulting theory would be if HSGs are simply equivalent to PRGs.

▶ **Question 6.** *Are HSGs equivalent to PRGs in the cryptographic regime?*

1.1.3 The Minimum Circuit Size Problem and Learning

The Minimum Circuit Size Problem (MCSP), which asks if a given string is the truth table of a function with small circuits, is both fundamental and elusive. It asks a very natural question about the complexity of a string, and the naturalness and importance of the problem have been clear since work by Soviet researchers in the 50s and 60s [46]. However, the problem has also been elusive in terms of classifying its complexity. It is said that Levin delayed publication of his seminal paper on NP-completness because he was hoping to show MCSP is NP-complete [8]. Nearly 50 years later, we still lack even a clear belief about whether MCSP is NP-complete or not.

Natural proofs are essentially zero-error algorithms for MCSP on average over the uniform distribution [44, 24], so it is no surprise that the "natural proofs" paper revived work on MCSP and its place in the complexity of landscape. There has been a long line of recent works on the problem [33, 5, 3, 4, 7, 39, 53, 6, 25, 26, 24, 41]. In fact, the work by Williams [53] implicitly studies connections between MCSP and derandomization, but he is interested in connections to complexity-theoretic derandomization, while we are interested in the cryptographic regime, which raises some very different issues.

Despite recent work, major questions still remain about how the problem relates to other problems. Indeed, a number of the cited works deal with the difficulties of constructing reductions to MCSP.

▶ **Question 7.** *Is* MCSP *or one of its variants equivalent in complexity to some other complexity class or notion of independent interest?*

MCSP comes supplied with a parameter - the size s for which we wish to know whether the input truth table has circuits of that size. Often complexity results about MCSP are fairly robust to this parameter, but there is no formal justification known for this. It was suggested in [24] that the problem might be easier to show robust to its parameter in terms of average-case complexity.

▶ **Question 8.** *Does the average-case easiness of* MCSP *with parameter* $2^{n/4}$ *imply the average-case easiness of* MCSP *with parameter* $2^{n/2}$*?*

The MCSP problem is closely connected to Valiant's PAC learning model [52]. Learning algorithms can be thought of as methods to solve the *search* version of MCSP - they are given access to the truth table of a Boolean function with small circuits, and need to efficiently find a small circuit that approximates the truth table well. Valiant observed in his original paper that polynomial-size circuits are not learnable in his model under cryptographic assumptions, and it was observed in [43] that non-learnability follows from the assumption that one-way functions exist. However the precise complexity of learning in various models is still not known despite more than three decades of work [52, 35, 11, 10, 15, 50]. In particular, one can ask if there is a converse to the hardness result of [52, 43] for some natural learning model.

▶ **Question 9.** *For some natural learning model, does non-learnability of polynomial-size circuits imply the existence of one-way functions?*

MCSP has stubbornly resisted attempts to show that it is NP-complete. It is natural to wonder if it has structural features that distinguish it from other NP-complete problems, such as for example random self-reducibility or a worst-case to average-case reduction. This might give some evidence that MCSP is not NP-complete - it is known under standard complexity assumptions that NP-complete problems do not have black-box worst-case to average-case reductions [17, 12].

▶ **Question 10.** *Is there a worst-case to average-case reduction for* MCSP*? Or to ask a more relaxed question, does average-case easiness of* MCSP *imply non-trivial approximations for the problem?*

1.2 Results

1.2.1 Pseudorandomness from Zero-Error Average-Case Hardness

We begin by showing connections between zero-error average-case hardness of MCSP, and the existence of *succinct* hitting sets and pseudorandom distributions. As mentioned before, we are inspired by the connections between these notions in the complexity-theoretic setting [40, 31], and are looking for analogous results in the cryptographic setting.

Let us first explain what we mean by zero-error average-case hardness of MCSP. Given any size function $s : \mathbb{N} \to \mathbb{N}$, MCSP$[s]$ has a very natural distribution on inputs associated with it, namely the uniform distribution. MCSP$[s]$ is heavily biased over the uniform distribution since the overwhelming majority of truth tables correspond to hard Boolean functions. So it does not make sense to study bounded-error notions of average-case hardness over the uniform distribution - the trivial algorithm that always says "no" will do very well. Instead, we consider zero-error algorithms, i.e., algorithms that always output the correct answer or "?", and output the correct answer with noticeable probability over the uniform distribution.

It turns out that this notion of average-case hardness is fairly robust. It was shown in [24] that average-case hardness is essentially equivalent to the non-existence of Razborov-Rudich natural proofs. Thus the main result of Razborov and Rudich [44] showing that natural proofs don't exist if one-way functions exist can also be interpreted as showing zero-error average-case hardness of MCSP$[s]$ for any $s = 2^{\Omega(n)}$ under the assumption that one-way functions exist. A major motivation for this paper is the question of whether the *converse* holds, i.e., whether one-way functions can be based on zero-error average-case hardness of MCSP$[s]$ for reasonable size functions s. Indeed, by the connection we just mentioned with natural proofs, this is equivalent to Question 3.

It is known in the cryptographic setting that the existence of pseudorandom functions of circuit complexity $2^{\epsilon n}$ for any $\epsilon > 0$ is equivalent to the existence of one-way functions [22, 20]. In order to make progress toward basing one-way functions on zero-error average-case hardness of MCSP, we first show how to derive weaker versions of pseudorandom functions. Succinct hitting sets and succinct pseudorandom distributions are examples of such weaker objects, as we explain below.

A succinct set (resp. distribution) is a set of (resp. distribution over) strings, each of which, when interpreted as the truth table of a Boolean function, has circuits that are not too large. Succinct hitting sets are simply succinct sets that are hitting sets against arbitrary poly-size adversaries. A succinct pseudorandom distribution is a succinct distribution that is pseudorandom against arbitrary poly-size adversaries.

To compare these notions with pseudorandom functions, we note that pseudorandom functions are essentially equivalent to succinct PRGs, i.e., succinct pseudorandom distributions that are efficiently samplable. Similarly, a succinct HSG is an efficiently computable function whose range is a collection of succinct hitting sets.

It is fairly straightforward to show that zero-error average-case hardness of MCSP$[\tilde{O}(s)]$, $\tilde{O}(s(n))$-succinct hitting sets and $\tilde{O}(s(n))$-succinct HSGs are all equivalent. We give this argument in Subsection 3.1 of Section 3. The equivalence between the second and third notions follows from the existence of *universal succinct HSGs*, i.e., a fixed polynomial-time construction that is guaranteed to be a succinct HSG if succinct hitting sets exist. This is essentially folklore - the idea is to use the mapping from circuits to the truth tables of functions they compute. Indeed, this has been a very fruitful technique in complexity theory - the "easy witness" method of [32, 29].

What seems less straightforward is to get a connection between succinct hitting sets and succinct pseudorandom sets. This is what we manage to show.

▶ **Theorem 1** (Informal Statement). *The following are equivalent:*

1. *For all $\epsilon > 0$, there are succinct hitting sets supported on truth tables of circuit complexity $2^{\epsilon n}$.*
2. *For all $\epsilon > 0$,* MCSP *with parameter $2^{\epsilon n}$ is zero-error hard on average.*
3. *For all $\epsilon > 0$, there are succinct pseudorandom distributions supported on truth tables of circuit complexity $2^{\epsilon n}$.*

It is perhaps surprising that based on a *zero-error* average-case notion of hardness for MCSP, we are able to get pseudorandom distributions that are indistinguishable from random with respect to *bounded two-sided error*.

The proof of Theorem 1 proceeds via a certain Sampler-Distinguisher game we define here, inspired by the PRF-Distinguisher game in [41]. The analysis of the game uses the approximate Min-Max theorem of [9, 38] and is fairly general. We note that the approximate Min-Max theorem has been used in many different contexts in complexity theory and pseudorandomness (see [51]), but as far as we are aware, our use of it here to derive pseudorandomness from zero-error average-case hardness is novel.

Indeed our techniques can be used to establish an analogous result for Satisfiability based on Feige's hypothesis [16] that random k-CNFs of linear density are hard to refute. Feige's hypothesis is essentially a hypothesis about zero-error average-case hardness of k-SAT under a natural distribution on k-CNFs, just as the non-existence of natural proofs is a hypothesis about zero-error average-case hardness of MCSP. One way of stating the hypothesis is that errorless polynomial-time algorithms, which always output the correct answer or "?" and output the correct answer with high probability over randomly chosen k-CNFs of linear density, do not exist.

In this case again, we get a consequence for pseudorandom distributions. Just as the pseudorandom distributions obtained in Theorem 1 are succinct, i.e., supported on YES instances of $\mathsf{MCSP}[s]$, here the pseudorandom distributions obtained are supported on satisfiable instances.

▶ **Theorem 2** (Informal Statement). *For any fixed integer k, if random k-CNFs with any linear number of clauses are hard to refute for non-uniform poly-time algorithms, then for each $\epsilon > 0$ there is a pseudorandom distribution over satisfiable formulas with error ϵ.*

We abstract out the main idea behind the proofs of Theorems 1 and 2 to show a more general connection between zero-error average-case hardness for a language $Q \subseteq \{0,1\}^*$ and the existence of pseudorandom distributions supported on a language $Q' \subseteq \{0,1\}^*$. We show that such a connection exists whenever there are samplers satisfying a certain *semantic* condition. Recall that a sampler f from n bits to m bits with seed length ℓ is a polynomial-time computable function such that for any bounded function g on m bits, for *most* inputs x of length n, the expectation of $g(f(x, U_\ell))$ is close to the expectation of $g(U_m)$. Samplers are closely related to randomness extractors [49]. We consider samplers with an additional condition: whenever $x \in Q$, for every y of length ℓ, $f(x, y) \in Q'$. We call such samplers (Q, Q')-semantic samplers, and show that the existence of semantic samplers with good parameters implies a strong connection between zero-error average-case hardness and pseudorandomness.

We note that this connection between samplers and pseudorandomness is *different* to the well-known connection of Trevisan [47] between hardness-based pseudorandom generators and extractors. Indeed, Trevisan's connection does not involve any semantic property of the extractor.

1.2.2 A New Conjecture and Its Consequences

Theorem 1 partly addresses Questions 5 and 6 in Subsection 1.1, but it is not clear what it says about the others. Motivated by a belief that the questions in Subsection 1.1 are all connected and part of a unified picture, we propose a natural conjecture about universal succinct PRGs that results in such a picture.

A universal succinct PRG is a fixed polynomial-time computable function f such that if succinct pseudorandom distributions exist, then f induces such distributions on uniformly chosen seeds.

▶ **Universality Conjecture** (Informal Statement). *There exist universal succinct PRGs.*

We briefly discuss the context for the Conjecture. Universality is a phenomenon that is widely observed in complexity theory and the foundations of cryptography. For example, there are universal one-way functions [36], and via the equivalence between one-way functions and PRGs [22], there are universal PRGs in the cryptographic setting. In the complexity-theoretic setting, universal HSGs and PRGs follow from the equivalence of HSGs, PRGs and circuit lower bounds for $\mathsf{E} \stackrel{\text{def}}{=} \mathsf{DTIME}(2^{O(n)})$, together with the existence of complete problems for $\mathbb{E}$. Given the variety of such universal examples, and the variety of ways for establishing that they exist, it is perhaps not unreasonable to expect them in the context of succinct PRGs.

An even closer analogy is to the case of succinct HSGs, which are the one-sided error version of succinct PRGs. As described in the previous subsection, universal succinct HSGs can be shown to exist by interpreting circuits succinctly describing hitting sets as seeds to a hitting set generator. This is a folklore argument that we formalize in Section 3 as Proposition 9. The Universality Conjecture is simply the analogue of Proposition 9 for pseudorandom distributions.

Next we turn to the consequences of our Conjecture for the questions raised in the introduction. We make a few clarifications about notation in the informal statement of our main result below. N always refer to the output size of some generator and is a power of 2, and $n \stackrel{\text{def}}{=} \log(N)$. By default, we take the succinctness parameter (i.e., the size of circuits representing each element of the range) to be the same as the seed length. To clarify any further notational issues, please refer to Section 2.

▶ **Theorem 3** (Informal Statement). *If the Univerality Conjecture is true, then the following hold:*

1. *One-way functions exist iff there is an $\epsilon < 1$ such that* MCSP *with parameter $2^{\epsilon n}$ is zero-error hard on average.*
2. *One-way functions exist iff auxiliary one-way functions exist.*
3. *One-way functions exist iff natural proofs against* SIZE(poly) *do not exist.*
4. *For any $0 < \epsilon < \delta < 1$, a succinct HSG with seed length N^{δ} implies a succinct HSG with seed length N^{ϵ}.*
5. *For any $\epsilon < 1$, a succinct HSG with seed length N^{ϵ} exists iff* MCSP *with parameter $2^{\epsilon n}$ is zero-error hard on average.*
6. *For any $\epsilon < 1$, a succinct HSG with seed length N^{ϵ} exists iff a PRG with seed length N^{ϵ} exists.*
7. *For any $0 < \epsilon < \delta$,* MCSP *with parameter $2^{\epsilon n}$ is zero-error hard on average iff* MCSP *with parameter $2^{\delta n}$ is zero-error hard on average.*
8. *One-way functions exist iff polynomial-size circuits cannot be learned with membership queries under the uniform distribution in polynomial time.*

Items 1 to 3 of Theorem 3 answer Questions 1 to 3. Items 4 to 6 answer Questions 4 to 6, but for *succinct* HSGs rather than HSGs. Question 7 is also answered by Item 1. Questions 8 and 9 are answered by Items 7 and 8.

Of the items in Theorem 3, it is perhaps Item 1 which is of most interest. Most candidate one-way functions are based on problems in $\mathsf{NP} \cap \mathsf{coNP}$. MCSP, however, is believed by many to be NP-complete, and therefore unlikely to be in coNP. Indeed, a conjecture of Rudich [45] even asserts that MCSP is hard on average for coNP.

Item 1 also has implications for Impagliazzo's "Five Worlds" [28]. In particular, if the Conjecture were true and we could base one-way functions on average-case hardness of MCSP, we would get evidence against the existence of Pessiland: a world where there are problems that are hard on average, but one-way functions do not exist.

We briefly explain how the Conjecture helps to show these results. For every item in Theorem 3, one of the two directions of the equivalence was known before, and it is the Conjecture, together with Theorem 1, that enables us to show the reverse direction. The crucial aspect of the Conjecture is that it allows us to derive succinct PRGs from succinct pseudorandom distributions. Once we have a PRG, we are able to stretch the PRG using standard techniques, and this enables us to close the chain of implications between average-case hardness of MCSP, succinct HSGs and succinct PRGs.

We discuss some reasons why it might be useful to consider the Universality Conjecture.

First note that common beliefs in the crypto and complexity communities support the Conjecture. Indeed, most complexity theorists and cryptographers believe that one-way functions exist. If one-way functions exist, by [22] and [20], pseudorandom function generators exist, and any pseudorandom function generator is trivially a universal succinct PRG.

Of course, the issue is not simply *truth* but also *provability*. Is it likely the Universality Conjecture will be proved in the near future? We do not have a strong belief about this, but there is at least some reason to hope that more sophisticated versions of the proof technique of Theorem 1 might help. More precisely, understanding uniformity and succinctness of approximate strategies for Min-Max games [9, 38] is a possible direction.

Regardless of whether the Conjecture will be settled in the near future, it could function as an organizing principle connecting various fundamental phenomena that we still don't understand well, including the complexity of MCSP, the hardness of learning, the relationship between uniform and non-uniform versions of one-way functions, the structure of zero knowledge, reducibilities between average-case problems over the uniform distribution, and the role of pseudorandomness in proof complexity, among others.

1.2.3 Non-Black-Box Results

Finally, we show a couple of *non-black-box* results about MCSP. As a meta-complexity problem, i.e., a problem whose instances themselves encode computations, MCSP seems particularly amenable to non-black-box techniques. Hopefully this amenability will come in useful in establishing strong unconditional connections between the hardness of MCSP and the existence of one-way functions. Basing one-way functions on NP-hardness in a black-box fashion has unlikely consequences [1], so if MCSP did turn out to be NP-complete and we wished to base one-way functions on its *worst-case* hardness, we would need to use non-black-box techniques.

Our first result is about circuit classes that are weak in the sense that there are natural proofs useful against them. For such circuit classes (which include AC^0, $\mathsf{AC}^0[p]$ for prime p, etc.), we establish a surprising implication from lower bounds for MCSP to lower bounds for P.

▶ **Theorem 4** (Informal Statement). *Let $\mathfrak{D}$ be any circuit class closed under projections for which there are natural proofs against $\mathfrak{D}$. If there is a constant k such that* MCSP *with parameter n^k is zero-error hard on average against $\mathfrak{D}$, then* P *is not contained in $\mathfrak{D}$.*

The proof of Theorem 4 is non black-box, i.e., it does not work when the circuit class $\mathfrak{D}$ against which we are arguing is given access to an oracle. Indeed, we can prove that under standard crypto assumptions, there is no black-box implication of the sort we show.

The reason we find the implication in Theorem 4 somewhat surprising is that the hypothesis is about the hardness of a problem in NP and unlikely to be in P, indeed even believed by many to be NP-complete. Yet the conclusion is about super-polynomial lower bounds within P!

Our next result addresses the relaxed version of Question 10. We observe that a recent search-to-decision reduction of [14] for a slight variant of MCSP called AveMCSP (where the question is whether there is a small circuit that computes the input truth table correctly on a 0.9 fraction of inputs) actually gives an approximation to average-case reduction. We note that Shuichi Hirahara [23] independently observed an analogous approximation to average-case reduction for the standard version of MCSP, based on [13], however the approximation factor there is much larger.

▶ **Theorem 5** (Informal Statement). *There is an approximation to average-case reduction for* AveMCSP.

Theorem 5 has implications for the NP-hardness of problems such as MCSP and AveMCSP. For several NP-hard problems, the theory of probabilistically checkable proofs establishes strong inapproximability results under the NP $\neq$ P assumption. Thus an approximation to average-case reduction can be considered morally similar to a worst-case to average-case reduction. It is known under standard complexity assumptions that NP-complete problems do not have black-box worst-case to average-case reductions [17, 12].

Does this suggest that AveMCSP is unlikely to be NP-complete? Not quite! The proof of Theorem 5 is *also* non black-box, even though the ideas are quite different from the proof of Theorem 4.

1.3 Related Work

The first paper to connect the complexity of MCSP with the existence of one-way functions was the "natural proofs" paper of Razborov and Rudich [44]. Razborov and Rudich do not explicitly consider MCSP - indeed, this problem was only defined in subsequent work of Kabanets and Cai [33]. The main result of [44] states that exponentially-hard one-way functions imply the non-existence of natural proofs with poly-size constructibility that are useful against polynomial-size circuits. This can be re-interpreted [24] as saying that if exponentially-hard one-way functions exist, then MCSP[poly(n)] is zero-error hard on average. Thus an average-case algorithm for MCSP can be used to break *any* one-way function. The main question we consider in this paper is whether the converse holds.

Various works have attempted to connect the existence of one-way functions and their variants with other complexity notions. Ostrovsky and Wigderson [42] showed that if ZK $\neq$ BPP, then auxiliary-input one-way functions exist. They also showed that if ZK is hard for BPP on average (in the bounded-error sense), then one-way functions exist. [30] and [11] (see also [10]) show equivalences between the existence of one-way functions and certain average-case hardness assumptions for learning.

More recently, interest in the complexity of MCSP and its connections with learning and pseudorandomness has been re-awakened by the result of [13] which shows that natural proofs useful against a circuit class $\mathfrak{C}$ imply efficient learning algorithms for $\mathfrak{C}$, under certain reasonable conditions on $\mathfrak{C}$. Building on this, [41] show equivalences between various forms of learning, as well as a dichotomy between learning and pseudorandomness in a certain parameter regime.

A very recent work of Hirahara [23] (who obtained his results independently from ours) builds on [13] to show that solving MCSP on average in the zero-error sense implies efficient non-trivial approximability of the minimum circuit size. Thus, if MCSP were NP-hard even to approximate non-trivially, the existence of hard-on-average problems in NP would follow. This suggests the possibility of excluding Impagliazzo's Heuristica world [28] where NP is hard in the worst case but not hard on average by studying MCSP and showing that it is NP-hard to approximate.

In contrast to [23], our focus in this paper is on finding evidence against the existence of Pessiland: another world of Impagliazzo's [28] where there are hard-on-average problems but one-way functions do not exist.

2 Preliminaries

2.1 Notation

For convenience, we use $f\colon K \to N$ to denote a function mapping K bits to N bits, i.e., $f\colon \{0,1\}^K \to \{0,1\}^N$. We let $\mathcal{F}_{K\to N}$ denote the family of all functions $f\colon K \to N$. We sometimes view a boolean function $f\colon N \to 1$ as a subset of $\{0,1\}^N$.

Throughout this paper, we use capital letters to denote the input length and output length of a function when we are interested in interpreting the output as the truth table of a Boolean function. In such a case, we will use a lowercase letter to denote the logarithm of the number represented by the corresponding uppercase letter.

We let $\mathcal{U}_L$ denote the uniform distribution over $\{0,1\}^L$. We occasionally abuse notation and identify a set S with the uniform distribution over the set. We say that a function $f\colon K \to N$ ε-fools a family of functions $\mathcal{D} \subseteq \mathcal{F}_{N\to 1}$ if $|\Pr[g(f(\mathcal{U}_K)) = 1] - \Pr[g(\mathcal{U}_N) = 1]| \leq \varepsilon$ for every $g \in \mathcal{D}$.

A function $g\colon N \to 1$ is γ-dense if $\Pr[g(\mathcal{U}_N) = 1] \geq \gamma$. We say that $f \in \mathcal{F}_{K\to N}$ *hits* g is $f(\{0,1\}^K) \cap g^{-1}(1) \neq \emptyset$.

Given a Boolean function $f \in \mathcal{F}_{n\to 1}$, $\mathtt{tt}(f)$ is the 2^n-bit string which represents the truth table of f in the standard way, and conversely, given a string $y \in \{0,1\}^{2^n}$, $\mathtt{fn}(y)$ is the Boolean function in $\mathcal{F}_{n\to 1}$ whose truth table is represented by y.

Given a circuit class $\mathfrak{C}$, we use $\mathfrak{C}[s(n)]$ to refer to the class of functions computed by $\mathfrak{C}$-circuits of size $s(n)$. Given a language $L \subseteq \{0,1\}^*$, co-L denotes the complement of L.

We say a circuit class $\mathfrak{C}$ is standard if there is a quasi-linear time Turing machine which, given a representation $\tilde{C}$ of a circuit C from the class and an input x, computes $C(x)$. All commonly studied circuit classes contained in the class of general Boolean circuits are standard.

For a size bound $s\colon \mathbb{N} \to \mathbb{N}$, we use quasi-$s(n)$ to denote a function of growth rate $s(n) \cdot \mathsf{poly}(\log s(n))$.

The density of a set $A \subseteq \{0,1\}^N$ is $|A|/2^N$. Given a language L and an integer n, $L_n = L \cap \{0,1\}^n$ denotes the slice of L at length n.

2.2 Pseudorandomness and Average-Case Hardness

Let $K : \mathbb{N} \to \mathbb{N}$ be a function such that $K(N) < N$ for all N, and $\epsilon : \mathbb{N} \to [0,1]$ be a function. Moreover, let $\mathfrak{C}$ be a complexity class and $\mathfrak{D}$ be a class of functions. A $\mathfrak{C}$-PRG against $\mathfrak{D}$ with seed length K and error ϵ is a sequence $f = \{f_N\}_{N\in\mathbb{N}}$ of functions such that (i) $f \in \mathcal{F}_{K(N)\to N}$; (ii) $f \in \mathfrak{C}$; and (iii) the output of f_N $\epsilon(N)$-fools every function in $\mathcal{F}_{N\to 1} \cap \mathfrak{D}$, whenever N is sufficiently large. If ϵ is left unspecified, it will be taken to be $1/N^{\omega(1)}$ by default. Similarly $\mathfrak{C}$ will be taken to be $\mathsf{DTIME}(\mathrm{poly}(N))$ by default, and $\mathfrak{D}$ will be taken to be $\mathsf{SIZE}(\mathrm{poly}(N))$ by default. Note that in this default situation, the generator is computable in a *fixed* polynomial time in its output length, but must be secure against arbitrary poly-size distinguishers.

We say $f = \{f_N\}_{N\in\mathbb{N}}$ is a $\mathfrak{C}$-HSG against $\mathfrak{D}$ if instead of condition (iii) above the output of f_N hits every set $A_N \subseteq \{0,1\}^N$ of density $\epsilon(N)$ in $\mathfrak{D}$. Again the error parameter is taken to be $1/N^{\omega(1)}$ by default.

It is instructive to consider the following examples: standard cryptographic PRGs are default PRGs with seed length $K(N) = N^{\Omega(1)}$, while complexity-theoretic (Nisan-Wigderson) PRGs are E-PRGs against $\mathsf{SIZE}(N)$ with error $1/N$, where the seed length can be anything between $\log N$ and $N-1$.

We say the seed length K is non-trivial if $K(N) < N$.

We will be interested in *succinct* pseudorandom distributions and hitting sets. Let $\mathfrak{C}$ be a circuit class and $\epsilon : \mathbb{N} \to [0,1]$ be an error bound. We say that there are $\mathfrak{C}$-succinct pseudorandom distributions against $\mathfrak{D}$ with error ϵ if there is a set $S \subseteq \{0,1\}^*$ and a probability distribution μ_S supported on S such that for each N a power of 2, (i) For each $y \in S_N$, $\mathtt{fn}(y) \in \mathfrak{C}$; and (ii) $|\Pr_{y\leftarrow\mu_S}[g(y)=1] - \Pr_{y\leftarrow\mathcal{U}_N}[g(y)=1]| \leq \epsilon(N)$ for every $g \in \mathcal{D}$. By default, we will take $\epsilon(N)$ to be $1/N^{\omega(1)}$ as usual.

Similarly, we say that there are $\mathfrak{C}$-succinct hitting sets against $\mathfrak{D}$ with error ϵ if there is a set $S \subseteq \{0,1\}^*$ such that for each N a power of 2, (i) For each $y \in S_N$, $\mathtt{fn}(y) \in \mathfrak{C}$; and (ii) For each set $A_N \subseteq \{0,1\}^N$ of density $\epsilon(N)$, S_N has non-empty intersection with A_N.

A $\mathfrak{C}$-succinct PRG is simply a PRG that induces a $\mathfrak{C}$-succinct pseudorandom distributions when a seed of any given length is chosen uniformly at random, and a $\mathfrak{C}$-succinct HSG is a HSG whose range is a collection of $\mathfrak{C}$-succinct hitting sets.

▶ **Definition 6** (Universal Succinct Generators). *Let $\mathfrak{C}$ be a circuit class and $K : \mathbb{N} \to \mathbb{N}$ be a function. A universal $\mathfrak{C}$-succinct HSG with seed length K is a poly-time computable sequence $f = \{f_N\}_{N\in\mathbb{N}}$ of functions from $K(N)$ bits to N bits such that if there are $\mathfrak{C}$-succinct hitting sets against $\mathsf{SIZE}(\mathrm{poly})$ with error $\epsilon(N)$, then f is a $\mathfrak{C}$-succinct HSG with error $\epsilon(N)$. A universal $\mathfrak{C}$-succinct PRG with seed length K is a poly-time computable family f of functions from $K(N)$ bits to N bits such that if there are $\mathfrak{C}$-succinct pseudorandom distributions against $\mathsf{SIZE}(\mathrm{poly})$ with error $\epsilon(N)$, then f is a $\mathfrak{C}$-succinct PRG with error $\epsilon(N)$. A non-uniform universal $\mathfrak{C}$-succinct PRG with seed length K is a poly-size computable family f of functions from $K(N)$ bits to N bits such that if there are $\mathfrak{C}$-succinct pseudorandom distributions against $\mathsf{SIZE}(\mathrm{poly})$ with error $\epsilon(N)$, then f is a $\mathfrak{C}$-succinct $\mathsf{SIZE}(\mathrm{poly})$-PRG with error $\epsilon(N)$.*

Given $\epsilon : \mathbb{N} \to \mathbb{R}$, a one-way function with security $\epsilon(N)$ is a polynomial-time computable sequence of functions $f = \{f_N : K(N) \to N\}$ for some $K(N) = N^{\Omega(1)}$, such that for any sequence $\{C_N\}$ of polynomial-size circuits, for large enough N, $\Pr_{x\sim U_N}[f_N(C_N(1^N, f(x))) = f_N(x)] \leq \epsilon(N)$. A one-way function is called *weak* if it has security $1 - 1/\mathrm{poly}(N)$, and *strong* if it has security $1/N^{\omega(1)}$. One-way functions are often defined against uniform adversaries; in this work, we only consider security against non-uniform adversaries.

Informally, an auxiliary-input one-way function is a poly-time computable sequence of functions f with an "auxiliary" input z such that for any poly-size adversary, there is an infinite set of auxiliary inputs z for which f is hard to invert. For a formal definition and a good discussion of the significance of auxiliary-input one-way functions, see [48].

We require a notion of zero-error average-case hardness for languages. Given a parameter $\epsilon : \mathbb{N} \to [0,1]$, a language $Q \subseteq \{0,1\}^*$, and a circuit class $\mathfrak{D}$, we say that Q is zero-error average-case feasible for $\mathfrak{D}$ with success probability ϵ if there is a sequence of circuits $D_N \in \mathfrak{D}$ such that for each N, D_N always outputs 0,1 or "?", never outputs the wrong answer for any input to Q, and outputs "?" with probability at most $1 - \epsilon(N)$. We say Q is zero-error average-case easy if it is average-case feasible for $\mathsf{SIZE}[\text{poly}]$ with success probability $1/N^{O(1)}$.

We say that Q is zero-error average-case infeasible for $\mathfrak{D}$ with success probability ϵ if for every sequence of circuits $D_N \in \mathfrak{D}$ such that D_N always outputs 0,1 or "?", for large enough N, D_N either outputs the wrong answer for some input to Q or outputs "?" with probability greater than $1 - \epsilon(N)$. We say Q is zero-error average-case hard if it is average-case infeasible for $\mathsf{SIZE}[\text{poly}]$ with success probability $1/N^{O(1)}$.

Note that hardness is not just defined as the complement of easiness - hardness and easiness are both required to hold on almost all input lengths.

2.3 MCSP, Natural Proofs and Learning

$\mathsf{MCSP}[s(n)]$ denotes the Minimum Circuit Size Problem for a size parameter $s(n)$, where the truth table given as input to the problem has size 2^n. In other words, an input truth table is a positive instance if and only if it is computed by a circuit of size at most $s(n)$. This notation is adopted for convenience. Thus the most interesting functions $s(n)$ would satisfy $n \leq s(n) \leq 2^n$. Given a class $\mathfrak{C}$, $\mathfrak{C}$-$\mathsf{MCSP}[s(n)]$ denotes MCSP for $\mathfrak{C}$-circuits. In case the input size N is not a power of two, we consider the input truth table to be the first $2^{\lfloor \log(N) \rfloor}$ bits of the input.

We also require some variants of MCSP. Given an approximation parameter $\delta : \mathbb{N} \to [0,1]$, and size functions $c, s : \mathbb{N} \to \mathbb{N}$ with $n \leq c(n) \leq s(n) \leq 2^n$ for all n, δ-$\mathsf{AveMCSP}[c,s]$ is the following promise problem: YES instances are truth tables of Boolean functions that can be $\delta(n)$-approximated by circuits of size at most $c(n)$, and NO instances are truth tables of Boolean functions that cannot be δ-approximated by circuits of size at most $s(n)$. When δ is left unspecified, we take it to be 0.9 for convenience.

We say that $\mathfrak{R} = \{\mathcal{R}_n\}_{n \in \mathbb{N}}$ is a *combinatorial property* (of boolean functions) if $\mathcal{R}_n \subseteq \mathcal{F}_n$ for all n. We use $L_{\mathfrak{R}}$ to denote the language of truth-tables of functions in $\mathfrak{R}$. Formally, $L_{\mathfrak{R}} = \{y \mid y = \mathtt{tt}(f) \text{ for some } f \in \mathcal{R}_n \text{ and } n \in \mathbb{N}\}$.

▶ **Definition 7** (Natural Properties [44]). *Let $\mathfrak{R} = \{\mathcal{R}_n\}$ be a combinatorial property, $\mathfrak{C}$ a circuit class, and $\mathfrak{D}$ a (uniform or non-uniform) complexity class. We say that $\mathfrak{R}$ is a $\mathfrak{D}$-natural property useful against $\mathfrak{C}[s(n)]$ if there is $n_0 \in \mathbb{N}$ such that the following holds*:

- **(i)** Constructivity. $L_{\mathfrak{R}} \in \mathfrak{D}$.
- **(ii)** Density. *For every $n \geq n_0$,* $\Pr_{f \sim \mathcal{F}_n}[f \in \mathcal{R}_n] \geq 1/2$.
- **(iii)** Usefulness. *For every $n \geq n_0$, we have $\mathcal{R}_n \cap \mathcal{C}_n[s(n)] = \emptyset$.*

By default, $\mathfrak{D}$ is taken to be $\mathsf{SIZE}[\text{poly}]$.

It has been observed that the density parameter in the definition above can be amplified using a straightforward reduction (cf. [13]).

▶ **Proposition 8** ([24]). *Let $s : \mathbb{N} \to \mathbb{N}$ be a size function.* $\mathsf{MCSP}[s(n)]$ *is zero-error easy on average iff there are* $\mathsf{SIZE}(\text{poly})$*-natural properties useful against* $\mathsf{SIZE}[s(n)]$.

We give only a brief description of learning in Valiant's PAC model. We will be concerned here only with learning using membership queries under the uniform distribution. A learning algorithm in this context is a probabilistic oracle algorithm making queries to an oracle for some function f. Given a circuit class $\mathfrak{C}$ and a function $T : \mathbb{N} \to \mathbb{N}$, a time T learner for $\mathfrak{C}$ is an oracle algorithm which given input 1^n and oracle access to a function f from $\mathcal{C}$ halts in time $T(n)$ and outputs with high probability a circuit computing f correctly on a 0.9 fraction of inputs of length n.

3 Hitting Sets, Pseudorandom Distributions and the Hardness of MCSP

3.1 Succinct HSGs and MCSP

We first observe that there is a universal succinct HSG.

▶ **Proposition 9.** *Let $\mathfrak{C}$ be any standard circuit class, and $s : \mathbb{N} \to \mathbb{N}$ be any function such that $n \leq s(n) \leq 2^n$ for all n. There is a universal $\mathfrak{C}[s(n)]$-succinct HSG U with seed length* quasi-$s(n)$.

Proof. The idea of the proof is simple. We define a HSG U with seed length quasi-$s(n)$ that interprets its seed as the representation of a $\mathfrak{C}$-circuit of size $s(n)$, and outputs the truth table of the function computed by this circuit. U can be computed in time 2^nquasi-$s(n)$, which is quasi-quadratic in $N = 2^n$.

We need to show that U is a universal $\mathfrak{C}[s(n)]$-succinct HSG. The $\mathfrak{C}[s(n)]$-succinctness is immediate from the definition of the HSG - every output of the HSG is the truth table of a Boolean function in $\mathfrak{C}[s(n)]$. For the universality, suppose that there is some collection H of $\mathfrak{C}[s(n)]$-succinct hitting sets. Every string in this collection is the truth table of a Boolean function in $\mathfrak{C}[s(n)]$. Hence H is contained in the range of U, from which it follows that the range of U is a collection of hitting sits. ◀

Next we observe that the existence of succinct hitting set generators is equivalent to hardness for MCSP. This observation is closely related to similar observations in the theory of Boolean or arithmetic circuit complexity and meta-mathematics of lower bounds [53, 21, 18].

▶ **Proposition 10.** *Let $\mathfrak{C}$ be a standard circuit class and $\mathfrak{D}$ be a family of functions. Moreover, let $s(n) \geq n$. For every large n, the following are equivalent:*

1. *There are* $\mathfrak{C}$[quasi-$s(n)$]-succinct *hitting sets against $\mathfrak{D}$*
2. *There is a* $\mathfrak{C}$[quasi-$s(n)$]-succinct *HSG with seed length* quasi-$s(n)$ *against $\mathfrak{D}$*
3. $\mathfrak{C}$-MCSP[quasi-$s(n)$] *is zero-error average-case hard against $\mathfrak{D}$.*

Proof. The second item follows from the first by Proposition 9.

Next we show that the third item follows from the second. Let H be a $\mathfrak{C}$[quasi-$s(n)$]-succinct HSG against $\mathfrak{D}$. Assume for the sake of contradiction that $\mathfrak{C}$-MCSP[quasi-$s(n)$] is zero-error average-case solvable with success probability $1/N^{O(1)}$ in $\mathfrak{D}$, where $N = 2^n$. This implies that there is a subset A of co-$\mathfrak{C}$-MCSP[quasi-$s(n)$] with density $1/N^{O(1)}$. For each large N, A_N has no strings of $\mathfrak{C}$-circuit complexity $\leq$ quasi-$s(n)$, hence A_N does not intersect the range of H_N for such N. Yet the density of A_n is at least $1/N^{O(1)}$, which contradicts the assumption that H is a HSG against $\mathfrak{D}$.

Finally we show that the first item follows from the third. Suppose $\mathfrak{C}$-MCSP[quasi-$s(n)$] is zero-error average-case hard against $\mathfrak{D}$. Consider the set of truth tables of functions with $\mathfrak{C}$-complexity at most quasi-$s(n)$. We show that this is a collection of $\mathfrak{C}$[quasi-$s(n)$]-succinct

hitting sets against $\mathfrak{D}$. The succinctness condition follows from the definition of the set. To show that this is a collection of hitting sets, suppose to the contrary that there is a set $A \in \mathfrak{D}$ such that A_N has density $1/N^{O(1)}$ for each N a power of 2, and A does not intersect the collection. Then we can define a zero-error average-case algorithm which outputs 0 for $x \in A$ and "?" otherwise. This algorithm only outputs 0 on truth tables that do not have quasi-$s(n)$ size $\mathfrak{C}$-circuits, hence it always outputs the correct answer when it does not output "?". By the density condition on A, the algorithm has success probability $1/N^{O(1)}$. ◀

3.2 From Zero-Error Average-Case Hardness to Succinct Pseudorandomness

In this section, we show that zero-error average-case hardness for MCSP in fact yields succinct *pseudorandom* distributions, where the complexity parameter of the succinctness is slightly worse than that of the MCSP problem we assume to be hard.

In fact, we show something more general for languages $Q, Q' \subseteq \{0,1\}^*$: assuming the existence of certain "semantic" samplers, zero-error average-case hardness over the uniform distribution for a problem Q implies the existence of pseudorandom distributions supported on YES instances of Q'. The main idea for showing the implication to pseudorandomness is to analyze a family of *Sampler-Distinguisher* zero-sum games, which we introduce in this work. This is inspired by, but different from, the PRF-Distinguisher game analyzed in [41]. The strategies of the row player in the Sampler-Distinguisher game are YES instances of a given length for the problem Q we wish to solve. The strategies of the column player are circuits from some circuit class $\mathfrak{D}$, corresponding to the class against which we are analyzing average-case hardness.

The payoff corresponding to a row (instance) x and column (circuit) D is defined as the average of $D(x_j), j = 1 \dots k$ minus the expectation of D on inputs of length $|x_j|$. Here the strings x_j are generated from x to have the following properties. First, when x is a YES instance of Q, the x_j's are YES instances of Q'. Second, when y is random, the set $\{y_i\}$ is a good sampler with high probability, meaning that it can be used to estimate the expectation of any bounded function to within reasonable error.

We are able to argue that when the Row player wins the game, there are succinct pseudorandom distributions against $\mathfrak{D}$, and when the column player wins the game, there is a zero-error average case algorithm for Q. The argument in the second case relies on the approximately optimal succinct strategies for zero-sum games given by [9, 38].

▶ **Lemma 11** ([9, 38]). *Let M be a $r \times c$ matrix with entries in $[-1,1]$ representing the payoffs of a zero-sum game. Let $v(M)$ denote the value of the game. Let $\delta < 1$ be a parameter. Then there is a strategy for the row (Min) player supported uniformly on at most $10\log(c)/\delta^2$ pure strategies that guarantees her a payoff at most $v(M) + \delta$ and a strategy for the column (Max) player supported uniformly on at most $10\log(r)/\delta^2$ pure strategies that guarantees here a payoff at least $v(M) - \delta$.*

We will need a special case of the standard Hoeffding inequalities.

▶ **Proposition 12** ([27]). *Let $X_1 \dots X_n$ be independent random variables taking values in $[-1,1]$. Let $\bar{X} \stackrel{\text{def}}{=} \sum_i X_i/n$ denote the empirical mean of these variables. Then, for any $t > 0$, $\Pr(|\bar{X} - E(\bar{X})| \geq t) \leq 2e^{-t^2 n/2}$.*

We now define the notion of semantic sampler we require.

▶ **Definition 13.** *Let $Q, Q' \subseteq \{0,1\}^*$ be languages, $\ell, m : \mathbb{N} \to \mathbb{N}$ and $\epsilon, \delta : \mathbb{N} \to [0,1]$ be functions. A poly-time computable sequence of functions $f = \{f_N : \{0,1\}^N \times \{0,1\}^{\ell(N)} \to \{0,1\}^{m(N)}\}$ is a (Q, Q')-semantic sampler f with seed length ℓ, output length m, accuracy ϵ and error δ if:*

1. *(Semantic condition) For large enough $N \in \mathbb{N}$, for all $x \in \{0,1\}^N$ and $y \in \{0,1\}^{\ell(N)}$, $x \in Q$ implies $f_N(x,y) \in Q'$.*
2. *(Sampling condition) For large enough $N \in \mathbb{N}$, for every function $g : \{0,1\}^{m(N)} \to [-1,1]$, for all but a $\delta(N)$ fraction of N-bit strings x, $|E_{z \in U_{m(N)}} g(z) - E_{y \in U_{\ell(N)}} g(f_N(x,y))| \leq \epsilon(N)$.*

We are ready to prove our general connection between zero-error average-case hardness and pseudorandomness.

▶ **Theorem 14.** *Let $Q, Q' \subseteq \{0,1\}^*$ be languages, $m : \mathbb{N} \to \mathbb{N}$ be a surjective function such that $m(N) \leq N$ for all $N \in \mathbb{N}$, and $\epsilon, \delta : \mathbb{N} \to [0,1]$ be functions. Suppose there is a (Q, Q')-semantic sampler f with output length m, accuracy ϵ and error δ. If Q is zero-error average-case infeasible for* SIZE[poly] *with success probability $1 - \delta(N)$, then there are pseudorandom distributions with error $30\epsilon(N)$ against* SIZE[poly] *that are supported on Q'.*

Proof. Let $t : \mathbb{N} \to \mathbb{N}$ be a size function, and f be the (Q, Q')-semantic sampler in the statement of the theorem. We define the (f,t) Sampler-Distinguisher family of zero-sum games at level N by their payoff functions as follows. For each positive integer N, the set A_N corresponding to strategies of the Row (Min) player is defined to be the set of N-bit strings x such that $x \in Q$. The set B_N corresponding to strategies of the Column (Max) player is defined to be the set of Boolean circuits with input length $m(N)$ and size at most $t(N)$.

Now we define the Column player's payoff function $P_N : A_N \times B_N \to [-1,1]$ as follows. Given a string $x \in A_N$ and a circuit $D \in B_N$, $P_N(x,D) = E_{y \in U_{\ell(N)}} D(f_N(x,y)) - E_{z \in U_{m(N)}} D(z)$. Since the class of Boolean circuits is closed under complement, we can assume wlog that the value of the game is non-negative for each N.

Let $\gamma : \mathbb{N} \to [0,1]$ be a monotonically decreasing error parameter to be specified later. There are two cases: either for every polynomially bounded t, for almost all N, the value of the (f,t) Sampler-Distinguisher game at level N is at most $\gamma(N)$, or there exists some polynomially bounded t such that for infinitely many N, the value of the game at level N is greater than $\gamma(N)$.

In the first case, using Lemma 11, for each $t(N)$, for N large enough, there is a $\gamma(N)/2$-approximately optimal strategy of the Row player for the game at level N that is a uniform distribution on a multiset R of strings x of length N in Q.

Now the induced distribution on strings $z = f_N(x,y)$ obtained by picking x uniformly from R and y uniformly from strings of length $\ell(N)$ is a pseudorandom distribution with error at most $3\gamma(N)/2$ against circuits with input length $m(N)$ and size at most $t(N)$, just by linearity of expectation. Then we have that there are pseudorandom distributions with error at most $3\gamma(N)/2$ against SIZE(poly) that are supported on Q', using the fact that $R \subseteq Q$ and that $f(x,y) \in Q'$ whenever $x \in Q$ and $y \in \{0,1\}^{\ell(N)}$. We will eventually choose $\gamma(N) = 20\epsilon(N)$, which yields pseudorandom distributions with error at most $30\epsilon(N)$.

In the second case, let t be polynomially bounded in N and I' be an infinite set of input lengths such that the value of the (f,t) Sampler-Distinguisher game is at least $\gamma(N')$ on each $N' \in I'$. Define the set I of input lengths as follows: $N \in I$ iff $m(N) \in I'$. Since I' is infinite and m is surjective, I is also infinite. We show that there is a sequence of circuits $\{C_N\}$ of polynomial size such that for each input length $N \in I$, C_N solves Q well on average, contradicting the assumption that Q is average-case hard against SIZE[poly].

Since the value of the game is at least $\gamma(N')$ on each $N' \in I'$, we have that for each $N' \in I'$, there is an approximately optimal strategy for the Column player supported uniformly on at most $O(N'/\gamma(N')^2)$ pure strategies that guarantees her a payoff at least $\gamma(N')/2$. Note that each pure strategy is simply a circuit of size $O(t)$. For each $N' \in I'$, define the probabilistic circuit $C'_{N'}$ on input z of length N' as follows. $C'_{N'}$ samples uniformly a circuit D from the set of circuits $S_{N'}$ in the support of the approximate strategy for the Column player, and outputs $D(z)$. $C'_{N'}$ can be implemented straightforwardly to have size at most $O(tN'/\gamma(N')^2)$. Let v denote the value $E_{z \leftarrow U_{N'}, D \leftarrow S_{N'}} D(z)$.

Next we define the circuit C_N. We first construct a probabilistic circuit and then show how to fix the randomness. On input x of length N, the circuit samples y uniformly at random from $\{0,1\}^{\ell(N)}$ and computes $f_N(x,y)$. C_N runs the probabilistic circuit C' independently $100N/(\gamma(N))^2$ times on $f_N(x,y)$ for uniformly and independently chosen $y \in \{0,1\}^{\ell(N)}$. It computes the average v' of the outputs obtained by C' over all these runs, and checks if $v' - v \geq \epsilon/4$. In order to implement this check, the value v (which does not depend on x) is hardcoded into C. If the majority of checks succeed, C_N outputs "?", else it outputs 0.

Let $N \in I$ and $N' = m(N)$. We show that if x of length N is a YES instance of Q, C_N always outputs "?" with probability $> 1 - 2^{-N}$, and for a $1 - o(1)$ fraction of inputs of length N, C_N outputs 0 with probability $> 1 - 2^{-N}$. By fixing the randomness of C_N using Adleman's trick, we get deterministic circuits which *always* output "?" on YES inputs, and output 0 on almost all NO instances. Moreover, they output either "0" or "?" on every NO instance. This implies that for each $N \in I$, C_N is a circuit that solves Q well on average.

We first establish our claim for YES instances. Suppose x of length N is in Q. This implies that for all $y \in \{0,1\}^{\ell(N)}$, $f_N(x,y) \in Q'$ by the semantic condition on the (Q,Q')-semantic sampler f. Hence, for each $y \in \{0,1\}^{\ell(N)}$, $f_N(x,y)$ is a pure strategy for the Row player in the (s'',t) Sampler-Distinguisher game at level N'. Since $N' \in I'$, the game at level N' has value greater than $\gamma(N')$. In particular, this means that the Row player's strategy of playing $f(x, U_{\ell N})$ yields payoff at least $\gamma(N')/2$ in expectation to the Column player when the Column player plays the approximately optimal strategy corresponding to the probabilistic circuit C'. Thus, over the randomness of C' and random choice of $y \in \{0,1\}^{\ell(N)}$, $E[C'(f_N(x,y))] > v + \gamma(N')/2$. Since γ is a monotonically decreasing function, and $N' \leq N$, we have that $E[C'(f_N(x,y))] > v + \gamma(N)/2$. Applying Proposition 12, when C' is simulated $100N/(\gamma(N))^2$ times independently on uniformly chosen $y \in \{0,1\}^{\ell(N)}$ to compute the empirical average v', $v' > v + \gamma(N)/4$ with probability $> 1 - 2^{-N}$. Hence C_N outputs "?" with at least this probability, as claimed.

Next we argue that when $\gamma(N)$ is chosen to be $20\epsilon(N)$, for all but approximately $\delta(N)$ fraction of inputs of length N, C_N outputs 0 with probability $> 1 - 2^{-N}$. Intuitively, this follows from the fact that a large enough randomly chosen set of strings is a good sampler for a function with range $[-1,1]$.

More formally, consider the quantity v defined above as the expectation of $C'(z)$ over uniformly chosen N'-bit z and randomness of the circuit C'. We upper bound the probability, for a uniformly chosen x of length N, that the empirical average v' of the outputs obtained by $100N/(\gamma(N))^2$ independent runs of $C'(f_N(x,y))$ for uniformly chosen y, is greater than $v + \gamma(N)/4$.

By the sampling condition for the (Q,Q')-semantic sampler f, with probability at least $1 - \delta(N)$ over uniformly chosen x of length N, $|E_{y \in U_{\ell(N)}} C'(f_N(x,y)) - v| \leq \epsilon(N)$. Call a string x "good" if this inequality is satisfied. Applying Proposition 12 again, for any x, with probability $> 1 - 2^{-N}$ over the internal randomness of C, $|v' - E_{y \in U_{\ell(N)}} C'(f_N(x,y))| \leq \gamma(N)/5$. In particular, for good x, by the triangle inequality, we have that with probability $> 1 - 2^{-N}$, $|v' - v| < \gamma/5 + \epsilon(N) \leq \gamma(N)/5 + \gamma(N)/20 = \gamma(N)/4$. Thus, for all but a $\delta(N)$ fraction of strings x of length N, C_N outputs 0 with probability $> 1 - 2^{-N}$, as claimed. ◀

We now show how to use Theorem 14 to derive pseudorandom distributions from zero-error average-case hardness for MCSP and SAT, by showing the existence of appropriate semantic samplers. Indeed, in both cases, we will use the simple sampler defined below.

▶ **Definition 15.** *Given a function $q : \mathbb{N} \to \mathbb{N}$ such that $q(N) \leq N$ is a power of two for all N, we define the $q(N)$-projection sampler to be the function sequence $Proj = \{Proj_N : \{0,1\}^N \times \{0,1\}^{\log(q(N))} \to \{0,1\}^{\lfloor N/q(N) \rfloor}$, where for any string $x = x_1 x_2 \ldots x_N$ of length N and a string y of length $\log(q(N))$ interpreted in the standard way as an integer in $[q(N)]$, $Proj_N(x,y) = x_{y\lfloor N/q(N) \rfloor} \ldots x_{(y+1)\lfloor N/q(N) \rfloor - 1}$. In other words, $Proj_N(x,y)$ is the contiguous substring of x of length $\lfloor N/q(N) \rfloor$ beginning at index $y\lfloor N/q(N) \rfloor$.*

We first show how to apply Theorem 14 in the case of MCSP.

▶ **Theorem 16.** *Let $\mathfrak{C}$ be any circuit class closed under projections. Let $s : \mathbb{N} \to \mathbb{N}$ be a size function, and $q : \mathbb{N} \to \mathbb{N}$ be any super-constant poly-time computable function such that $q(N) \leq N$ is a power of two for all N. Let $\epsilon : \mathbb{N} \to \mathbb{R}$ be any poly-time computable monotonically decreasing error function such that $\epsilon(N) = \omega(1/\sqrt{q(N)})$. If $\mathfrak{C}$-MCSP$[s(n)]$ is zero-error average-case infeasible for* SIZE[poly] *with success probability $1 - o(1)$, then there are $\mathfrak{C}[s']$-*succinct *pseudorandom distributions with error $O(\epsilon(N))$ against* SIZE[poly]*, where $s' : \mathbb{N} \to \mathbb{N}$ is any size function such that $s'(n - \log(q(2^n))) \geq s(n)$.*

Proof. Let Q be $\mathfrak{C}$-MCSP$[s(n)]$, and Q' be $\mathfrak{C}$-MCSP$[s'(n)]$, where s' is any size function such that $s'(n - 2\log(q(2^n))) \geq s(n)$, as in the statement of the theorem. We show that the $q(N)$-projection sampler $Proj$ is in fact a (Q, Q')-semantic sampler with error $o(1)$ and accuracy $\epsilon(N)$, and then apply Theorem 14.

First we show the semantic condition. Let x of length N be the truth table of a Boolean function with $\mathfrak{C}$-circuits of size at most $s(n)$, where $n = \log(N)$. We show that for any $y \in \{0,1\}^{\log(q(n)}$, $Proj_N(x,y)$ is the truth table of a Boolean function with $\mathfrak{C}$-circuits of size at most $s'(n)$. Indeed, $Proj_N(x,y)$ is the truth table of a function on $n - \log(q(N))$ bits, obtained from x by fixing the first $\log(q(n))$ input bits. Let C_N be a $\mathfrak{C}$-circuit of size $s(n)$ computing $\mathtt{fn}(x)$. By fixing $\log(q(n))$ input bits of C_N to constants, and using the fact that $\mathfrak{C}$ is closed under projections, we obtain a $\mathfrak{C}$-circuit of size at most $s(n)$ computing $\mathtt{fn}(Proj(x,y))$, which is a function with $n - \log(q(N))$ input bits. Since $s'(n - \log(q(N)) \geq s(n)$, we have that $\mathtt{fn}(Proj(x,y))$ is in $\mathfrak{C}$-MCSP$[s'(n)]$.

Next we establish the sampling condition. Note that for x uniformly chosen in $\{0,1\}^N$, the $q(N)$ strings $Proj_N(x,y), y \in [q(N)]$ are uniformly and independently distributed in $\{0,1\}^{\lfloor N/q(N) \rfloor}$. Applying Proposition 12, we have that with for any function $g : \{0,1\}^{\lfloor N/q(N) \rfloor} \to [-1,1]$, for at least a $1 - o(1)$ fraction of x, $|E_{z \in U_{\lfloor N/q(N) \rfloor}} g(z) - E_{y \in U_{\log(q(N))}} g(Proj_N(x,y))| \leq \epsilon(N)$, where $\epsilon(N)$ is as in the statement of the theorem.

Now applying Theorem 14, the statement of the theorem follows immediately. ◀

Theorem 16 gives a connection from zero-error average-case hardness of MCSP to succinct pseudorandom distributions. It is perhaps surprising that zero-error average-case hardness in this context implies the existence of pseudorandom distributions that approximate any poly-size circuit well with respect to *two-sided error*. This is reminiscent of the situation with complexity-theoretic pseudo-random generators, where the generator is allowed to run in time exponential in the seed length. Known equivalences between worst-case hardness of exponential time and existence of complexity-theoretic PRGs [40, 31] also imply an equivalence between complexity-theoretic PRGs and complexity-theoretic hitting set generators. Such an equivalence is unknown in the cryptographic setting, and is a major motivation for our work. Theorem 16 provides partial unconditional evidence for such an equivalence extending to the

cryptographic setting. Indeed, combining Theorem 16 with Proposition 10 for appropriately chosen parameters, we get the following equivalence between succinct hitting sets and succinct pseudorandom distributions in the medium-error regime.

▶ **Corollary 17.** *Let $\mathfrak{C}$ be a standard circuit class closed under projections. Moreover, let $s(n) \geq n$. For every large n, the following are equivalent:*

1. *For every $\delta < 1/2$, there are $\mathfrak{C}[s(O(n))]$-succinct hitting sets with error $N^{-\delta}$ against* SIZE[poly]
2. *For every $\delta < 1/2$, $\mathfrak{C}$-MCSP$[s(O(n))]$ is zero-error average-case infeasible for* SIZE[poly] *with success probability $N^{-\delta}$.*
3. *For every $\delta < 1/2$, there are $\mathfrak{C}[s(O(n))]$-succinct pseudorandom distributions with error $N^{-\delta}$ against* SIZE[poly]

Proof. The second item follows from the first using the proof idea of Proposition 10. By using a direct implication from the first item to the third item of Proposition 10, we avoid the quasi-linear blow-up in the parameter, and preserve the error to within a neglibible additive term.

The third item follows from the second by using Theorem 16 with $\epsilon(N) = N^{\delta}$ and $k(N) = N^{2\delta+\gamma}$ for some γ such that $2\delta + \gamma < 1$. Note that for this parameter choice of k, $s'(N) = s(O(N))$, as desired.

The first item follows trivially from the third, since pseudorandom sets are also hitting sets. ◀

▶ Remark. For MCSP, the equivalence above can be extended to the setting of negligible error by using samplers more sophisticated than the projection sampler used in the proof of Theorem 16, such as samplers corresponding to the Nisan-Wigderson generator. However, this extension comes at the cost of generality - it does not work for $\mathfrak{C}$-MCSP for arbitrary $\mathfrak{C}$ closed under projections.

Corollary 17 implies Theorem 1 by choosing s appropriately.

We next show how to apply Theorem 14 to SAT, by showing an analogous construction of pseudorandom satisfiable formulas based on Feige's hypothesis [16] that random k-CNF formulas with a linear number of clauses are hard to refute. In our terminology, Feige's hypothesis states that random k-SAT is zero-error average-case hard. Here, as elsewhere in this paper, we consider non-uniform algorithms rather than uniform ones.

We would like to construct a pseudorandom distribution supported on satisfiable formulae based on Feige's hypothesis, similar to the construction of succinct pseudorandom distribution in Theorem 16 based on the zero-error average-case hardness of MCSP. However, we need to be careful in how we encode our formulas. With an arbitrary encoding, it might be the case that satisfiable formulas are easily distinguishable from random strings. This would the case, for example, if any valid encoding of any formula began with a 1. To solve this issue, we specify a natural information-theoretically efficient encoding of formulas as follows.

We consider k-CNF formulas on N variables, where k is a constant and N is a power of 2. We encode a formula ϕ with cN clauses by using $(n+1)kcN$ bits of information. Each clause is encoded by $(n+1)k$ bits, n bits to encode each variable, and 1 bit to encode whether the variable is positive or negative. These blocks of bits are simply concatenated together. Thus every string of $(n+1)kcN$ represents a unique k-CNF in a valid way.

Assuming the encoding of inputs to SAT above, we can show the following result.

▶ **Theorem 18.** *Fix a positive integer k. If for every $c > 0$, k-SAT on cN clauses is zero-error infeasible for* SIZE[poly] *with success probability $\Omega(1)$, then for every $\epsilon > 0$ there are pseudorandom distributions with error $O(\epsilon)$ supported entirely on satisfiable formulas.*

Proof. We provide a sketch, since the proof is quite similar to that of Theorem 16.

Let $\epsilon > 0$ be any constant, and q be a power of two to be chosen large enough as a function of ϵ. Let Q be k-SAT with cN clauses for some c a large enough power of two, encoded as described above, and Q' be k-SAT with cN/q clauses. We show that that the q-projection sampler is a (Q, Q')-semantic sampler with error ϵ and accuracy ϵ.

For the semantic condition, we simply note that any sub-formula of a satisfiable formula is itself satisfiable, and therefore the q-projection sampler maps satisfiable formulas to satisfiable formulas in our encoding, whenever q is a power of two. The sampling condition is easy to check by again using Proposition 12.

Now the theorem follows by applying Theorem 14. ◀

Theorem 18 is a formal statement of Theorem 2.

We use the simple projection sampler in the proof of Theorem 18. We might be able to reduce the error for the pseudorandom sets by using more sophisticated samplers, however it is tricky to ensure that satisfiable formulas remain satisfiable when the sampler is applied.

4 On Universal Succinct PRGs

We first state our main conjecture formally.

▶ **Conjecture 19** (Universality Conjecture). *For every $\epsilon < 1$, there is a universal* $\mathsf{SIZE}(2^{\epsilon n})$-succinct *PRG with non-trivial seed length.*

We need the standard fact that a PRG can be stretched by iteration.

▶ **Lemma 20.** *For each $0 < \epsilon < 1$, if there is a PRG with non-trivial seed length, there is a PRG with seed length N^{ϵ}.*

We also need the construction of succinct PRGs from PRGs due to [20].

▶ **Lemma 21** ([20]). *For each $\epsilon > \delta < 1$, if there is a PRG with seed length N^{δ}, there is a* $\mathsf{SIZE}[2^{\epsilon n}]$*-succinct PRG*

▶ **Theorem 22.** *Under Conjecture 19, the following are equivalent:*

1. *There is a one-way function secure against* $\mathsf{SIZE}(\mathrm{poly})$.
2. *There is an non-uniform one-way function secure against* $\mathsf{SIZE}(\mathrm{poly})$.
3. *There is a* $\mathsf{SIZE}[2^{\delta n}]$*-succinct HSGs secure against* $\mathsf{SIZE}[\mathsf{poly}(N)]$*, for some $0 < \delta < 1$.*
4. *There are* $\mathsf{SIZE}[2^{\varepsilon n}]$*-succinct HSGs secure against* $\mathsf{SIZE}[\mathsf{poly}(N)]$*, for any $0 < \varepsilon < 1$.*
5. *There is a PRG secure against* $\mathsf{SIZE}[\mathsf{poly}(N)]$ *with non-trivial seed length.*
6. $\mathsf{MCSP}[2^{\delta n}]$ *is hard on average against* $\mathsf{SIZE}[\mathsf{poly}(N)]$ *for some $0 < \delta < 1$.*
7. $\mathsf{MCSP}[2^{\varepsilon n}]$ *is hard on average against* $\mathsf{SIZE}[\mathsf{poly}(N)]$ *for every $0 < \varepsilon < 1$.*
8. *There are no* $\mathsf{SIZE}(\mathrm{poly})$*-natural proofs against* $\mathsf{SIZE}(2^{\epsilon n})$ *for any $\epsilon > 0$.*
9. *Polynomial-size circuits cannot be PAC-learned with membership queries over the uniform distribution in polynomial time.*

Proof. We establish the equivalence through a series of implications.

(3) implies (6): Follows from Proposition 10.

(6) implies (5): By setting $k(N)$ to be a sufficiently small power of N in Theorem 16, we get that there are $\mathsf{SIZE}[2^{\delta' n}]$-succinct pseudorandom distributions with error $1/N^{\gamma}$ for some $\gamma > 0$. Using Conjecture 19 we get that there is a PRG G with non-trivial seed length and error $1/N^{\gamma}$. The PRG G yields a weak one-way function, and by using the standard conversion from weak to strong one-way functions [54, 19], and then applying the HILL construction [22], we get a PRG with non-trivial seed length and negligible error.

(5) implies (4): By using Lemma 20 and Lemma 21, we get $\mathsf{SIZE}[2^{\varepsilon n}]$-succinct PRGs for any $\varepsilon > 0$. This trivially implies $\mathsf{SIZE}[2^{\varepsilon n}]$-succinct HSGs for any $\varepsilon > 0$.

(4) implies (7): Again follows from Proposition 10.

(7) implies (3): Trivial.

(7) equivalent to (8): Shown in [24].

(1) equivalent to (5): Shown in [22].

(1) implies (2): Trivial.

(2) implies (8): Given any infinite set I of auxiliary inputs, by applying the constructions of [22] and [20] to auxiliary-input one-way functions, for any $\varepsilon > 0$, we get a $\mathsf{SIZE}[2^{\varepsilon n}]$-succinct distribution which can be distinguished from uniform by SIZE(poly)-natural proofs against $\mathsf{SIZE}(2^{\epsilon n})$. This implies that the auxiliary-input one-way function can be inverted on I, in contradiction to the assumption that for each poly-size adversary, there is some infinite set of inputs on which the function is hard to invert.

(6) equivalent to (8): Shown in [13]. ◀

Theorem 22 can easily be seen to imply all the items in Theorem 3.

The equivalences above give a fairly clean picture of connections between various fundamental notions, modulo Conjecture 19. We now discuss some of the more interesting individual connections in more detail.

The connection between auxiliary-input one-way functions and one-way functions has been an important question in cryptography since the former notion was introduced in [42]. The notion of auxiliary-input one-way functions has played an important role in the study of zero-knowledge [42, 48] and learning [10]. In particular, it follows from the main result of [42] that under Conjecture 19, if there is a language with zero-knowledge proofs that is not in polynomial size, then one-way functions exist[1].

The notion of HSGs has not been much studied in cryptography, and this is perhaps because it is not obvious how to use HSGs in crypto applications. One of the issues is that it is not clear how to stretch a HSG, i.e., increase the gap between seed length and output length. As a consequence of the Conjecture, succinct HSGs are stretchable. It remains unclear whether the same is true for standard HSGs under plausible assumptions.

One of the main questions about MCSP is how robust its complexity is with respect to the size parameter s. Known results about the complexity of the problem are not very sensitive to the size parameter, but there are no known equivalences between the complexity of $\mathsf{MCSP}[s]$ and the complexity of $\mathsf{MCSP}[s']$ for s and s' that are different. As a consequence of the Conjecture, we get such an equivalence in the average-case setting. It would be interesting to try to establish this equivalence unconditionally.

The equivalence we get between hardness of learning and one-way functions (modulo the Conjecture) is the first such equivalence of which we are aware for a natural worst-case notion of learning. It is shown in [11] that hardness of PAC-learning *on average* implies the existence of one-way functions. The question of whether the hardness of PAC-learning (over any distribution, and without membership queries) implies the existence of one-way functions is posed in [10]. It would be nice if we could use the Conjecture to resolve this question.

Perhaps the most interesting connection is the equivalence between the average-case hardness of MCSP over the uniform distribution and the existence of one-way functions. This has potential applications for the construction of a natural universal one-way function [37]. One also wonders if under the Conjecture, there are other natural problems and distributions

[1] Note that we are using security against non-uniform adversaries throughout our work.

such that the average-case hardness of the problem under the distibution is equivalent to the existence of one-way functions. One would like a richer theory of reducibility between average-case problems, and equivalences of this sort might help.

5 MCSP and Circuit Lower Bounds against Weak Classes

Pseudorandomness is intimately connected to circuit lower bounds. Complexity-theoretic PRGs are equivalent to circuit lower bounds for E, and cryptographic PRGs are equivalent to one-way functions and hence imply circuit lower bounds for NP. In this section, we consider "weak" circuit classes, i.e., circuit classes $\mathfrak{C}$ for which there are natural proofs useful against $\mathfrak{C}[\text{poly}]$. We show that for weak circuit classes $\mathfrak{C}$, succinct hitting sets imply lower bounds for P against $\mathfrak{C}[\text{poly}]$. Using the connection between succinct hitting sets and average-case hardness for MCSP, we show that zero-error average-case lower bounds for $\mathsf{MCSP}[\text{poly}]$ against $\mathfrak{C}[\text{poly}]$ imply lower bounds for P against $\mathfrak{C}[\text{poly}]$. This is surprising in that we establish a hardness consequence for P based on a hardness assumption about a problem not believed to be in P. Indeed, we show that our result is inherently non-black box if one-way functions exist.

▶ **Lemma 23.** *Let $\mathfrak{C}$ be a weak circuit class closed under projections. If there is a constant k such that there are $\mathsf{SIZE}(n^k)$-succinct hitting sets against $\mathfrak{C}[\text{poly}]$, then $\mathsf{P} \not\subseteq \mathfrak{C}[\text{poly}]$*

Proof. Let $\mathfrak{C}$ be a weak circuit class closed under projections. Suppose there is a constant k such that there are $\mathsf{SIZE}(n^k)$-succinct hitting sets against $\mathfrak{C}[\text{poly}]$. Using Proposition 9, we have that there is a $\mathsf{SIZE}(n^k)$-succinct HSG U with seed length $\mathsf{quasi}\text{-}n^k$ against $\mathfrak{C}[\text{poly}]$. Now consider the following function $f(x,i)$, where i is of length n and x is of length $\mathsf{quasi}\text{-}n^k$. $f(x,i)$ is defined to be 1 iff the i'th bit of $G(x)$=1. Now, since Boolean circuits are a standard class, given seed x to G and index i of $G(x)$, the i'th bit of $G(x)$ is computable in time $\mathsf{quasi}\text{-}s(n)$, which is $\mathsf{quasi}\text{-}n^k$. Thus $f \in \mathsf{P}$.

Now we use a win-win analysis. If $\mathsf{P} \not\subseteq \mathfrak{C}[\text{poly}]$, we are done. Hence we can assume that $\mathsf{P} \subseteq \mathfrak{C}[\text{poly}]$. This implies that $f \in \mathfrak{C}[n^{k'}]$ for some constant k'. Since $\mathfrak{C}$ is closed under projections, it follows that every string in the range of U is the truth table of a function with $\mathfrak{C}$-circuits of size at most $n^{k'}$.

Since $\mathfrak{C}$ is weak, there are natural proofs useful against $\mathfrak{C}[\text{poly}]$. This implies that there is a set $A \subseteq \mathsf{SIZE}(\text{poly})$ of density $1/2$ such that no string y for which $\mathtt{fn}(y)$ is in $\mathfrak{C}[n^{k'}]$ belongs to A .

Now again using the assumption that $\mathsf{P} \subseteq \mathsf{C}[\text{poly}]$, we have that $\mathsf{SIZEpoly} \subseteq \mathfrak{C}[\text{poly}]$, and hence $A \in \mathfrak{C}[\text{poly}]$. But now A is a set in $\mathfrak{C}[\text{poly}]$ of density $1/2$ which does not intersect the range of U non-trivially, contradicting the assumption that U is a hitting set generator against $\mathfrak{C}[\text{poly}]$. ◀

The smallest complexity class within which weakness of $\mathfrak{C}$ is known to imply a super-polynomial lower bound against $\mathfrak{C}$ is ZPEXP [41]. Lemma 23 shows that if additionally there are succinct hitting sets against $\mathfrak{C}[\text{poly}]$, the function for which we get a lower bound is much more explicit - it is in P.

Next we combine Lemma 23 with Proposition 10 to get a surprising implication.

▶ **Theorem 24.** *Let $\mathfrak{C}$ be a weak circuit class closed under projections. If there is a constant k such that $\mathsf{MCSP}[n^k]$ is zero-error average-case hard against $\mathfrak{C}[\text{poly}]$, then P is not contained in $\mathfrak{C}[\text{poly}]$.*

Proof. if there is a constant k such that $\mathsf{MCSP}[n^k]$ is zero-error average-case hard against $\mathfrak{C}[\mathrm{poly}]$, then by Proposition 10, we get that there are $\mathsf{SIZE}(n^k)$-succinct hitting sets against $\mathfrak{C}[\mathrm{poly}]$. Now applying Lemma 23, we get the desired consequence. ◀

Theorem 24 is essentially a restatement of Theorem 4.

Theorem 24 is a partial converse to the following corollary to Theorem 2 from [41].

▶ **Theorem 25.** *Let $\mathfrak{C}[\mathrm{poly}]$ be any circuit class closed under composition with poly-size AC^0. If there is a language in P that cannot be approximated on $1/2 + 1/\mathrm{poly}(n)$ fraction of inputs by $\mathfrak{C}$-circuits of polynomial size, then $\mathsf{MCSP}[2^{n/2}]$ is zero-error average-case hard against $\mathfrak{C}[\mathrm{poly}]$.*

Note that there are examples of weak circuit classes such as AC^0 and $\mathsf{AC}^0[p]$ which satisfy the condition in Theorem 25.

Theorem 24 is a rare example of a non-black-box reduction between two problems - the reduction does not work when the circuit class against which we are arguing is given access to an oracle. Indeed, under standard crypto assumptions, there is no black-box reduction from $\mathsf{MCSP}[n^k]$ to P, for k chosen large enough.

▶ **Theorem 26.** *Let $\mathfrak{C}$ be any Boolean circuit class which contains the projection functions. If there are one-way functions of exponential hardness, there is a constant k for which there is no black-box reduction from zero-error average-case hardness of $\mathsf{MCSP}[n^k]$ against $\mathfrak{C}[\mathrm{poly}]$ to $\mathsf{P} \not\subseteq \mathfrak{C}[\mathrm{poly}]$.*

Proof. If there were such a black-box reduction, then for each oracle A, $\mathsf{P} \subseteq \mathfrak{C}^A[\mathrm{poly}]$ would imply $\mathsf{MCSP}[n^k]$ is zero-error easy on average for $\mathfrak{C}^A[\mathrm{poly}]$. But now consider an oracle A that is complete for P under projections. The antecedent trivially holds for such an oracle, but if the consequent held, we would have $\mathsf{MCSP}[n^k]$ is zero-error easy on average for $\mathsf{SIZE}[\mathrm{poly}]$ for any k, which by the "natural proofs" argument of Razborov and Rudich [44] would invert any one-way function in sub-exponential time. ◀

6 An approximation to average-case reduction for AveMCSP

Finally, we observe that a certain search-to-decision reduction for a variant of MCSP given in recent work [14] actually yields a non black-box approximation to average-case reduction. We will use the following variant of the Nisan-Wigderson generator [14], for which the output of the generator has small average-case circuit complexity for most seeds when the function on which the generator is based has small average-case circuit complexity.

▶ **Theorem 27** ([40, 14])**.** *There is a fixed constant $d > 1$ such that for any constant $c > d$ there is a sequence of functions $\{G_m : \{0,1\}^{m^c} \times \{0,1\}^{O(\log(m))} \to \{0,1\}^m\}$ computable in polynomial time such that*

1. *Given $y \in \{0,1\}^{m^c}$ and for any $t = \log(m)^{\omega(1)}$, if $\mathtt{fn}(y)$ can be computed correctly on 0.9 fraction of inputs by circuits of size t, then with probability $1 - o(1)$ over choice of the seed $z \in \{0,1\}^{O(\log(m))}$, $\mathtt{fn}(G_m(y,z))$ can be computed correctly on 0.9 fraction of inputs by circuits of size t^2.*
2. *Given $y \in \{0,1\}^{m^c}$, if $\mathtt{fn}(y)$ cannot be computed correctly on 0.9 fraction of inputs by circuits of size m^d, then $G_m(y,\cdot)$ is a PRG with error $1/m$ against $\mathsf{SIZE}(m)$.*

▶ **Theorem 28.** *For any $\delta > 0$ and $k > 0$, there is $\epsilon > 0$ such that if $\mathsf{AveMCSP}[2^{n/2}]$ is zero-error easy on average for circuits of size N^k, then $\mathsf{AveMCSP}[2^{\epsilon n}, 2^{\delta n}]$ has polynomial-size circuits.*

Proof. Suppose there is $k > 0$ such that $\mathsf{AveMCSP}[2^{n/2}]$ is zero-error easy on average for circuits of size N^k. Without loss of generality, this means that there exists a set $A \subseteq \{0,1\}^*$ with circuits of size N^k such that A has density at least 0.01 and A does not contain any strings y for which $\mathtt{fn}(y)$ has circuits of size at most $2^{n/2}$.

We show how to solve $\mathsf{AveMCSP}[2^{\epsilon n}, 2^{\delta n}]$ in polynomial size, for some ϵ fixed during the argument which depends on δ and k. Given an input z of length N, our non-uniform polynomial time algorithm runs as follows. First it finds m such that $m^c = N$, where d is the fixed constant given by Theorem 27, and c is chosen to be $2kd/\delta$ in the construction of Theorem 27. It then computes $G_{m^k}(z,x)$ for each $x \in \{0,1\}^{O(\log(m))}$ in polynomial time, truncating each output string to its first m bits. It calculates the fraction η of these strings that belong to A. If $\eta \geq 0.005$, it rejects, else it accepts. This algorithm can clearly be implemented by circuits of polynomial size.

In the following argument, we use "average-case circuit complexity" to mean the size of the smallest circuit computing the function correctly on a 0.9 fraction of inputs.

We argue that when $\mathtt{fn}(z)$ has average-case circuit complexity at least N^δ, the algorithm rejects, and that when $\mathtt{fn}(z)$ has average-case circuit complexity at most N^ϵ for appropriately chosen ϵ, the algorithm accepts. For the first item, note that when $\mathtt{fn}(z)$ has average-case circuit complexity at least N^δ, by the second part of Theorem 27, $G_{m^k}(z,\cdot)$ is a $1/m^k$-error PRG against circuits of size m^k. Since A has circuits of size m^k and also has density at least 0.01, this means that $G_{m^k}(z,\cdot)$ fools A, and hence the fraction η calculated by the algorithm in this case is at least $0.01 - o(1)$, which is at least 0.005 for large enough N.

Now if $\mathtt{fn}(z)$ has average-case circuit complexity at most N^ϵ, where we are yet to fixe ϵ, we have from the first part of Theorem of Theorem 27, for at least a $1 - o(1)$ fraction of seeds x, $G_{m^k}(z,x)$ has average-case circuit complexity at most $N^{2\epsilon}$. Note that we are truncating the output of the PRG to the first m bits, hence the function represented by the output has length $m = N^{\delta/2kd}$. If ϵ is chosen so that $\epsilon < \delta/8kd$, we have that with probability $1 - o(1)$ over choice of seed x, the truncated output of the PRG has average-case circuit complexity at most $2^{n/2}$. Since A does not contain any strings y for which $\mathtt{fn}(y)$ has circuits of size at most $2^{n/2}$, we have that the fraction η is calculated to be $o(1) < 0.005$ for large enough N. ◀

Theorem 28 is a formal version of Theorem 5.

Note that the approximation to average-case reduction in Theorem 28 has a very unusual feature - the gap in the approximation version depends on the *complexity* of the average-case algorithm. In particular, this reduction is not black-box, meaning that the reduction does not extend to the case where the average-case algorithm uses an oracle.

7 Future Work

The Universality Conjecture opens up several directions for future work. The first is to derive further interesting implications from the Conjecture. For example, is the Learning is Hard assumption of [10] equivalent to the non-existence of natural proofs under the Conjecture?

The second is to establish the connections and equivalences we seek unconditionally, or under weaker forms of the Conjecture. Our unconditional results such as Theorem 1 are a step in this direction.

The third is to develop approaches to proving the Conjecture. A useful step here would be to come up with an explicit candidate for universal succinct PRGs.

A fourth direction is to explore consequences of the Conjecture being false. As mentioned before, the Conjecture holds if one-way functions exist, and therefore the failure of the Conjecture would imply the non-existence of one-way functions. But perhaps even stronger consequences follow from the failure of the Conjecture, lending further support to it?

More generally, there are other pathways to connecting average-case hardness of MCSP to the existence of one-way functions. In this work, we have explored average-case hardness in the zero-error sense. But perhaps it would be easier to use average-case hardness of MCSP in the bounded-error sense to construct one-way functions. One question here is to come up with a natural distribution under which MCSP is hard on average in the bounded-error sense – clearly the uniform distribution is not a valid candidate.

Abstract

We propose a new setting for testing properties of distributions while receiving samples from several distributions, but few samples per distribution. Given samples from s distributions, $p_1, p_2, \ldots, p_s$, we design testers for the following problems: (1) Uniformity Testing: Testing whether all the p_i's are uniform or ϵ-far from being uniform in ℓ_1-distance (2) Identity Testing: Testing whether all the p_i's are equal to an explicitly given distribution q or ϵ-far from q in ℓ_1-distance, and (3) Closeness Testing: Testing whether all the p_i's are equal to a distribution q which we have sample access to, or ϵ-far from q in ℓ_1-distance. By assuming an additional natural condition about the source distributions, we provide sample optimal testers for all of these problems.

1 Introduction

Statistical tests are a crucial tool in scientific endeavors to analyze data: We routinely model data to be a set of samples from an unknown distribution, and use statistical tests to infer or verify the properties of the underlying distribution. While these tests typically operate under the assumption that data points are drawn from a *single* underlying distribution, in applications, usually the data is gathered from multiple sources. Furthermore in many situations, it is the case that the dataset contains only a few data points from each source. For example, an online shop may have the purchase history of thousands of customers while each customer may shop at the store a small number of times. Alternatively, a medical dataset might record the lifestyle behaviors of patients of a particular disease while only having few data points from any specific demographic (such as age).

[1] Corresponding author

On the other hand, data that comes from multiple sources may result in a dataset consisting of a collection of unconnected and unrelated data points. For example, it might not be possible to derive any meaningful conclusions from a dataset that contains the blood pressure of patients with heart diseases, Alzheimer patients, and healthy individuals. However, if there is some consensus among the sources, we may be able to make reasonable inferences based on the data. Therefore, an important question to ask is: how can we mathematically model agreement among the sources such that it is possible to design testers with theoretical guarantees?

In this work, we propose a framework for hypothesis testing, one of the most fundamental problems in statistics, while allowing for the underlying data to be drawn from multiple distributions (sources) and only receiving "few" samples from each distribution. More specifically, we study the following problem: suppose we have s source distributions, $p_1, \ldots, p_s$. We have a distribution q (hypothesis), and we aim to distinguish between the case where all the source distributions are equal to q and the case where all the source distributions are far from q. We propose a *structural condition* in order to model the agreement among the sources to enable us to draw meaningful conclusions.

Our *structural condition* requires all the sources to have the same preference for every element, meaning that for each domain element x, either all the sources assign higher probability than the "speculated" probability, $q(x)$, or all of them assign lower probabilities. However, the sources can go arbitrarily higher or lower than $q(x)$ as long as they stay on the same side of the $q(x)$. For example, suppose one has tried several prize wheels (lottery machines) in a casino. The player spins the wheel and expects to receive one of the prizes uniformly. Given the results of each spin, our goal is to test whether all the machines were fair (i.e., selecting the prize uniformly), or they are far from being fair. In this case, we can naturally assume that if the machines are unfair, the house will assign a lower probability to the expensive prizes, and higher probability to cheap ones. Another example is political affiliation at a local vs. national level. Suppose a political party polls its constituents in a district about their opinion on the most crucial policy and compares it with national polls. It is natural to assume that the policies of national interest will receive the same responses in different districts. On the other hand, if a policy affects the district positively (or negatively), members of the district are more (less) likely to pick them. It is worth noting that if no structural condition is assumed, the problem becomes vacuous even in the simplest cases. The main issue is that two completely different sets of distributions may result in identical set of samples. For example, suppose each p_i is a singleton distribution on a random element $x \in [n]$. If we draw one sample from each distribution, the samples we obtain will be indistinguishable from the samples that are i.i.d. from a uniform distribution over $[n]$. See Section 2.2 for more elaboration.

Given our agreement condition, we consider three different cases for our hypothesis q: (*i*) *Uniformity testing:* q is uniform. (*ii*) *Identity testing (goodness of fit):* q is explicitly known. (*iii*) *Closeness testing (equivalence test):* q is accessible through samples. We require each source distribution to provide *exactly one* sample for uniformity and one sample in expectation for identity and closeness testing. We develop sample optimal testers for all these three problems. In fact, the sample complexity of our testers is exactly equal to the standard versions of these problems when samples are drawn from a single source. These results lead to the belief that our agreement condition provides the same power as the standard setting for designing the testers while operating under a weaker assumption.

Our sample complexity upper bounds are achieved by using variants of testers previously used for distribution testing in the case where samples are drawn from a fixed distribution. The challenge however, lies in analyzing these testers in our more general setting with multiple sources. The sample complexity lower bounds follow directly from the single distribution setting. For a full description of our contributions and approaches, see Section 2.3.

1.1 Necessity of modeling multiple sources

We might hypothesize that data points drawn from different distributions can be thought of as coming from some "average" or "aggregated" distribution. Indeed, we know by de Finetti's theorem that an infinite sequence of exchangeable random variables is actually drawn from a mixture of product distributions. In other words, there is some latent variable such that conditioning on this variable, all the samples are independently drawn from one probability distribution. However in the case that we have finitely many samples (or equivalently finitely many sources), de Finetti type theorems only hold up to some approximation error and in the case where the number of samples is sublinear in the domain size, we give a family of distributions where the sequence of random variables with each sample drawn from a different distribution cannot be seen as a mixture of product distributions. This result implies that modeling data as samples from a single distribution is not sufficient when multiple sources are involved. See Section 2.3.4 for more information.

1.2 Comparison with other models

Studying properties of a collection of distributions has been studied prior to our work in [26, 2, 16]. These papers consider two primary models for sampling a collection of distributions. In the first model, which is called the *query model*, the user can query each distribution and receive a sample from it. In the second model, which is called the *sampling model*, the user does not get to choose the source distribution, but the user receives a pair (i, j) which can be interpreted as a sample from the collection: the first element i indicates that distribution i was selected with a probability proportional to some (known or unknown) weight, and then j is a sample drawn from the i-th distribution.

There are few differences between our model and two models listed above. In these models, there is no limit on the number of samples that can come from a distribution. This is in contrast to our setting where every distribution contributes only one sample in expectation. On the other hand, in these two models, there is no agreement condition imposed between the different distributions, and their goal is to distinguish if all the distributions are equal or their *average distance* from a single distribution is at least ϵ. Considering the average distance essentially turns this problem into testing closeness of a distribution over the domain $[n] \times [s]$ which requires more samples.

While our problems are inherently different, none of the results in the papers cited above solve the problems we consider using a sublinear number of queries. In fact in some regime of the parameters, their algorithms draw $\omega(1)$ samples (even in expectation). In some special case, where the number of samples per distribution is $\Theta(1)$ in expectation, the sample complexity of their algorithm is greatly larger than ours. In particular, suppose we have s distributions over a domain of size n and we draw m samples from them in total. In the query model, the provided algorithms pick a few distributions and draw $O(n^{2/3})$ samples from them which is in contrast to our requirement of one sample per distribution. Moreover for the sampling model, the optimal algorithm needs $m = O(\sqrt{ns}/\epsilon^2 + n^{2/3}s^{1/3}/\epsilon^{4/3})$ samples in total. Roughly speaking, if the number of distributions is asymptotically smaller than n,

i.e., $s = o(n)$, then certainly the number of samples, m, has to be $\omega(s)$ meaning that we need more than $\Theta(1)$ samples per distribution. On the other hand, if the number of distributions, s, is $\Omega(n)$, then the number of samples, m, has to be $\Omega(n/\epsilon^2)$ which is drastically larger than our sample complexity, $O(\sqrt{n}/\epsilon^2 + n^{2/3}/\epsilon^{4/3})$.

In [31, 36], the authors consider a similar setting as our paper. In their setting, they have N distributions over the domain of size two. Each distribution is determined by a parameter which indicates the probability of the first domain element, and the algorithm receives t samples from each distribution. However, these papers consider a very different problem compared to ours as their goal is to optimally learn the histogram of the parameters with approximation error as a function of t.

1.3 Other related work

Distribution property testing is a framework for investigating properties of a distribution(s) upon receiving samples. This framework was first introduced in [21, 6], and it is part of the broader topic of hypothesis testing in statistics [27, 25]. In this framework, we wish to determine if one or more unknown distributions satisfy a certain property or are "far" from satisfying the property. The goal is to obtain an algorithm, or tester, for this task that has the optimal sample complexity. Since its introduction, several properties have been considered. See [30, 9, 20] for a survey of results.

The problems of testing uniformity, identity, and closeness of distributions have first been considered in [22, 6, 5]where it is assumed that samples are always drawn from a fixed distribution. Many subsequent work improved on their results, and eventually testers with optimal sample complexities of $\Theta(\sqrt{n}/\epsilon^2)$ for identity and uniformity testing, and $\Theta(n^{2/3}/\epsilon^{4/3} + \sqrt{n}/\epsilon^2)$ for closeness testing were obtained. See [34, 28, 33, 10, 17, 1, 16, 18, 14, 15, 8, 4]. For a survey of techniques used for these problems, see [9].

1.4 Organization

We start with definitions and preliminaries in Section 2. In Section 3, we study uniformity testing with samples from multiple sources.

In Section 4, we study identity testing with non-identically drawn samples. In Section 5 we study closeness testing with non-identically drawn samples. Finally, we prove Theorem 2 in Appendix 6.

2 Preliminaries

2.1 Notation and Definitions

We use $[n]$ to denote the set $\{1, \cdots, n\}$. We consider discrete distributions over $[n]$, which are non-negative functions $p : [n] \to [0, 1]$ such that $\sum_{i\in[n]} p(i) = 1$. We let $p(i)$ denote the probability assigned to element $i \in [n]$ by a distribution p and for a set $A \subseteq [n]$, we define $p(A) = \sum_{i\in A} p(i)$. For $q \geq 1$, the ℓ_q-norm of distribution q is defined as $\|p\|_q = (\sum_{i\in[n]} p(i)^q)^{1/q}$. Given two distributions p and p', the ℓ_q-distance between them is defined as the ℓ_q-norm of the vector of their differences: $\|p - p'\|_q = (\sum_{i\in[n]} |p(i) - q(i)|^q)^{1/q}$. The total variation distance of two distributions p and p' is defined as $\|p - p'\|_{TV} = \sup_A |p(A) - p'(A)|$ which is known to be equal to $\|p - p'\|_1/2$. We say that two distributions p and p' are ϵ-far in ℓ_q-distance if $\|p - p'\|_q \geq \epsilon$. Otherwise, we say that p and p' are ϵ-close in ℓ_q-distance. In this paper, we primarily focus on ℓ_1-distance. We denote the uniform distribution over $[n]$ by $\mathcal{U}_n$. Also, we refer to a Poisson random variable with parameter λ as $\text{Poi}(\lambda)$.

2.2 The Structural Condition

We introduce the structural condition used in our multiple source distribution testing setting. This condition models the assumption that the different sources have an *agreement* of the preferences which we explain earlier.

▶ **Definition 1** (Structural Condition). *Given a sequence of distributions $p_1, p_2, \cdots$ over $[n]$ and another distribution q over $[n]$, we say that $\{p_i\}_{i\geq 1}$ satisfy the structural condition if there exist sets $A \subset [n], B = [n] \setminus A$, such that for all the p_i's,*

$$p_i(j) \geq q(j) \qquad \forall j \in A\,,$$
$$p_i(j) \leq q(j) \qquad \forall j \in B.$$

Note that we ***do not*** *assume knowledge of what the sets A and B are, just that they exist.*

2.2.1 Alternative agreement conditions

To motivate Definition 1, our *structural condition*, we focus on the problem of uniformity testing. In the usual setting of uniformity testing, we are given sample access to a *single* unknown probability distribution p over $[n]$, and we wish to determine if p is equal to $\mathcal{U}_n$ or if $\|p - \mathcal{U}_n\|_1 \geq \epsilon$.

The most general relaxation of the single source assumption is to allow each sample to be drawn from a possibly different distribution. In particular, we wish to distinguish the completeness case, where each sample is i.i.d. from $\mathcal{U}_n$, from the soundness case, where sample i is drawn independently from p_i, and p_i and p_j are not necessarily the same for $i \neq j$, and $\|p_i - \mathcal{U}_n\|_1 \geq \epsilon$ for all i. By using the relation between the ℓ_1-norm and the total variation distance, this general setting can be written in the following way in the soundness case which we require the total variation distance between every p_i and the uniform distribution to be at least $\epsilon/2$:

$$\min_i \max_{A\subseteq[n]} |p_i(A) - \mathcal{U}_n(A)| \geq \epsilon/2. \tag{1}$$

However, we cannot hope to drive meaningful conclusions in this setting. Consider the case where each p_i is a singleton distribution on a random element $x \in [n]$. If we draw one sample from each distribution, the samples we obtain will be indistinguishable from the samples that are i.i.d. from a uniform distribution over $[n]$. A natural strengthening of (1) is to assume that in the soundness case, not only each distribution is different from $\mathcal{U}_n$ on some set A, as we had above, but all the p_i's are far from $\mathcal{U}_n$ on the *same* set A. This can be written as:

$$\max_{A\subseteq[n]} \min_i |p_i(A) - \mathcal{U}_n(A)| \geq \epsilon/2. \tag{2}$$

(Note that the min and max are switched from Equation (1)). In other words, there is some fixed set A such that p_i and $\mathcal{U}_n$ are assigning very different probability mass to the set A. However, this assumption is still too weak to support uniformity testing in sublinear time. The main reason is that we can come up with s distribution satisfying Equation (2), but the samples drawn from them look the same as uniform distribution. In general, for testing a symmetric property (i.e., a property that does not depend on the labeling of the elements), e.g., uniformity, we only consider the number of repetition in the sample set. The main sources of information is how many elements repeated t many times in the sample set. In the single distribution setting, these information is related to the moments of the underlying distribution, and it is known that distributions with the similar moments requires a lot of samples to tell them apart [29, 35, 37].

Consider the following example where we have $s < n$ distributions, and each distribution p_i is supported on $[1, i] \subset [n]$. For $i \in [s]$ The distribution p_i assigns the following probability to the domain element $x \in [n]$.

$$p_i(x) = \begin{cases} \frac{1}{n} & \text{if } x < i \\ 1 - \frac{i-1}{n} & \text{if } x = i \\ 0 & \text{if } x > i \end{cases}.$$

Let A be the set of elements that all the p_i's assign zero probability to them: $\{s+1, s+2, \ldots, n\}$. Clearly in our example Equation (2) holds for a parameter $\epsilon < 1$. As long as $s \leq (1-\epsilon)n$ since $\|p_i - \mathcal{U}_n\|_1/2 \geq |p_i(A) - \mathcal{U}_n(A)| \geq (n-s)/n \geq \epsilon$ for all i. Now, the probability that samples i and j, where $i < j$, are equal is

$$\frac{i-1}{n^2} + \left(1 - \frac{i-1}{n}\right)\frac{1}{n} = \frac{1}{n}$$

which is exactly the probability of a collision between two different samples in the completeness case. Furthermore, for any $k \leq s \leq (1-\epsilon)n$, we can compute the probability that any k samples $i_1 < \cdots < i_k$ match. Due to the support of p_{i_1}, we know that this quantity is precisely

$$\frac{i_1 - 1}{n^k} + \left(1 - \frac{i_1 - 1}{n}\right)\frac{1}{n^{k-1}} = \frac{1}{n^{k-1}}$$

which is exactly the probability that any k samples all match if all samples are drawn from the uniform distribution. Therefore with some generalized notion of the moments, the set of distributions in the above example match the first $O(n)$ moments of the uniform distribution. Due to the matching of these moments, we cannot hope to test uniformity (or any other symmetric property). Hence, a stronger structural condition than (2) is needed to allow testing in our setting. In this work, we proposed a natural strengthening of the assumption (2), given in Definition 1, which is enough to perform uniformity testing, along with other hypothesis testing problems. This is elaborated in Section 2.3.

2.3 Our Contributions

2.3.1 Uniformity testing with multiple sources

In our multiple source distributions setting for uniformity testing, we have s distributions, $p_1, \ldots, p_s$, and each distribution provides *exactly one* sample. Our goal is to distinguish the following cases with probability at least $2/3$[2]:

- **Completeness case:** $p_1, p_2, \cdots$ are all uniform on $[n]$.
- **Soundness case:** $p_1, p_2, \cdots$ are all ϵ-far from uniform on $[n]$ in ℓ_1-distance.

Furthermore, we impose that in the soundness case, the distributions $\{p_i\}_{i=1}^s$ satisfy the *structural condition* given in Definition 1 with q being $\mathcal{U}_n$, the uniform distribution. That is in the soundness case, all the distributions have mass at least $1/n$ on the elements in A and at most $1/n$ on the elements in B for some sets A and B that are **unknown** to us. Note that the structural condition trivially holds in the completeness case when all the p_i's are the same distribution. Therefore, we can think of our setting as a generalization of uniformity testing.

[2] Note that the constant $2/3$ is arbitrary here. One can boost the accuracy to $1 - \delta$ for an arbitrary small δ by increasing the number of samples (distributions) by a $O(\log \delta^{-1})$ factor.

We show that the standard collision-based algorithm used in the single distribution case of uniformity testing ([23, 6, 14]) is able to distinguish the completeness and the soundness case in our multiple sources setting. The statistic that we calculate is the number of pairwise collisions among the samples. We show that in the completeness case, there are "few" collisions among the samples whereas in the soundness case, we see "many" collisions. The main challenge is the analysis of this statistic in the soundness case, since the distributions $p_1, p_2, \cdots$ are not necessarily the same.

In the completeness case that all the p_i's are equal to some distribution p, the collision statistic is equal to a multiple of the ℓ_2-norm of p. We proceed similarly by introducing a more general notion of ℓ_2-norm in our setting. In addition, we argue that our statistic is sufficiently concentrated by calculating its variance. We generalize the tight variance analysis of [14], which shows that the collision based tester is optimal in the single source setting. Again if all the p_i's are equal to some distribution p, as is the case in the single source uniformity testing setting, the variance is related to the ℓ_3-norm of p. In our case where the p_i's are not necessarily the same, we introduce a generalized notion of ℓ_3-norm and relate it to our notion of ℓ_2-norm. This argument relies on Maclaurin's inequality. Altogether, our analysis shows that we can perform uniformity testing in our setting using $O(\sqrt{n}/\epsilon^2)$ samples, which is optimal since the standard single source uniformity testing is a special case of our setting, has a known sample complexity lower bound of $\Omega(\sqrt{n}/\epsilon^2)$ [28]. This result is presented in Section 3.

2.3.2 Identity testing with multiple sources

We now describe identity testing in the multiple source distributions setting. We first assume that we explicitly know some fixed distribution q over $[n]$. We suppose we have s distributions, $p_1, \ldots, p_s$. Our goal then is to distinguish the following cases with probability at least 2/3:

- **Completeness case:** $p_1, p_2, \cdots, p_s$ are identical to q
- **Soundness case:** $p_1, p_2, \cdots, p_s$ are all ϵ-far from q in ℓ_1-distance.

Furthermore, we impose that the distributions $\{p_i\}_{i=1}^s$ and q satisfy the *structural condition* given in Definition 1. For identity testing with multiple sources, we use a generalization of the poissonization method used in many distribution testing problem (see [9]): we assume that we receive Poi(1) samples, as opposed to one sample from each distribution p_i that we had in the uniformity case. Clearly, each distribution provides one sample in expectation, and with high constant probability, no distribution provides more than $O(\log s)$ samples.

In standard single distribution identity testing, a modified version of Pearson's χ^2-test statistic is picked to calculate the expected value of $\|q-p\|_2^2$, where q is the known distribution and all samples are from p [32, 10, 1, 16]. In our case, we generalize this approach and give a new statistic, again a modified version of Pearson's χ^2-test, which calculates a variant of the ℓ_2-distance between our known distribution q and the distributions that our samples come from.

In particular, if we take s samples, we show that the expected value of our statistic is $\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_2^2$, where $\vec{\mathbf{e}}_j$ is a vector in $\mathbb{R}^n$ where the x-th entry is $|p_j(x) - q(x)|$ for $x \in [n]$. Note that one can think of this quantity as a generalization of $\|q - p\|_2^2$. We then show that the sample complexity of distinguishing the soundness and completeness cases for our generalized identity testing depends on $\|q\|_2$, the ℓ_2-norm of the known distribution. The main technical issue is to analyze the variance of our statistic which is challenging since each sample can come from a possibly distinct distribution. Finally, we show how to reduce $\|q\|_2$ using a "flattening" scheme adapted from [16] that only enlarges the domain size by a

constant factor which results in the sample complexity of $O(\sqrt{n}/\epsilon^2)$ which is optimal since the standard single distribution uniformity testing is a special case of our generalized identity testing, and it requires $\Omega(\sqrt{n}/\epsilon^2)$ samples [28].

Remark on Goldreich's reduction from identity to uniformity testing. There is a reduction from identity testing to uniformity testing given in [19] in which Goldreich gives mappings F_1 and F_2 such that if p is ϵ-far from q, then $F_2(F_1(p))$ is a distribution that is $O(\epsilon)$-far from the uniform distribution over a larger domain of size $m = n/\gamma$ where γ is a parameter of the reduction. This reduction works partially in our case. Denote $F = F_2 \circ F_1$. Then we can check that $F(p_i)$ is $O(\epsilon)$-far from q for every p_i in the soundness case. Furthermore, if $x \in [n]$ is also in A, then the domain elements corresponding to x in $[m]$ are all at least $1/m$ and similarly, if $x \in [n]$ is in the set B, the domain elements corresponding to x in $[m]$ are all at most $1/m$. In particular, F maps the set $A \subseteq [n]$ to a set $A' \subseteq [m]$ that has the same properties as A and similarly, F maps the set $B \subseteq [n]$ to another subset $B' \subseteq [m]$.

The issue in applying this reduction to our setting is with F_1. In particular, $F_1(p_i)$ increases the domain size from $[n]$ to possibly $[n+1]$, and there is no guarantee if the domain elements in m corresponding to $n+1$ will be in A' or B'. In particular, it could be that for some p_i's, these domain elements will be in A' and for other p_i's, these domain elements can possibly be in B'. This could create potential "cancellations" that hide collisions when observing samples from $F(p_i)$. To fix this, we would have to make sure these domain elements don't have much probability mass, which leads to letting $\gamma = O(\epsilon)$. This ultimately leads to a sub optimal query complexity in terms of ϵ for identity testing. Therefore, we do not pursue this approach.

2.3.3 Closeness testing with multiple sources

We now describe our generalized version of closeness testing. We assume that we have access to two streams of samples. In the first stream, all samples are i.i.d. from some fixed distribution q over $[n]$ that is unknown to us. In the second stream, samples are drawn independently from distributions $p_1, \ldots, p_s$ where p_i and p_j are not necessarily the same distribution for $i \neq j$. Our goal then is to distinguish the following cases with probability at least $2/3$:

- **Completeness case:** $p_1, p_2, \cdots, p_s$ are identical to q
- **Soundness case:** $p_1, p_2, \cdots, p_s$ are all ϵ-far from q in ℓ_1-distance.

We also impose that the distributions $\{p_i\}_{i=1}^s$ and q satisfy the *structural condition* given in Definition 1. Note that the structural condition trivially holds in the completeness case.

Our approach to closeness testing with multiple sources is very similar to our approach for identity testing above. We make use of the poissonization method. In particular, we draw $\mathrm{Poi}(s)$ samples from distribution q. Also, we take $\mathrm{Poi}(1)$ samples from each of the distributions p_i, so in total we have $\mathrm{Poi}(s)$ samples from the distributions $\{p_i\}_{i=1}^s$. Furthermore, we use a (different) modified version of Pearson's χ^2-test proposed in [10, 16] and show that the expected value of our statistic is $\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_2^2$ where the vector $\vec{\mathbf{e}}_j$ is the same as in the identity testing case above. With a careful analysis of the statistic, in contrast with [16], we show that the sample complexity only depends on the ℓ_2^2-norm of the q. [3] Finally, we use a (randomized) "flattening" scheme from [16] which results in the sample complexity of $O(n^{2/3}/\epsilon^{4/3} + \sqrt{n}/\epsilon^2)$

[3] Similar analysis has appeared in [3] before this work.

which is optimal since there is a known lower bound of $\Omega(\max(n^{2/3}/\epsilon^{4/3}, \sqrt{n}/\epsilon^2))$ for the single distribution setting of closeness testing [16]. Using the same techniques, we also obtain a tester which uses asymptotically different number of samples from q compared to the number of sources (known as testing with unequal-sized samples). See Remark 18 for more details.

2.3.4 Failure of de Finetti's Theorem with sublinear number of samples

An infinite sequence $X_1, X_2, \ldots$ of random variables is called exchangeable if for all $m \geq 1$, the distribution of the sequence $X_1, \ldots, X_m$ is identical to the distribution of $X_{\sigma(1)}, \ldots, X_{\sigma(m)}$ for any permutation σ on m elements. de Finetti's theorem states that any *infinite* exchangeable sequence is a mixture of product distributions. In other words, there exists a probability measure μ such that conditioned on μ, $X_1, X_2, \ldots$ can be seen as i.i.d. samples from a distribution.

Similarly, a finite sequence $X_1, \ldots, X_m$ is called exchangeable if all the permutations of the sequence have the same distribution. If an exact version of de Finetti's theorem were to hold for finite sequences, our new setting where each sample can come from a different distribution reduces to the known setting where all the samples are i.i.d. (since an algorithm can turn the samples it sees into an exchangeable sequence by randomly permuting the samples). However, all the known finite versions of de Finetti's type theorems have an error term which roughly states that finite exchangeable sequences are only *approximately* close to mixtures of product distributions (see [13, 12, 24]).

In Section 6, we give an example of a finite sequence of random variables that falls in the soundness case of our setting of uniformity testing with multiple sources that is $\Omega(1)$-far from any mixture of product distributions. More precisely, our theorem, Theorem 2, tells us that it is not always possible to approximate a finite exchangeable sequence $X_1, \ldots, X_s$ arbitrarily well by a mixture of product distributions. This suggests that it is not possible to use de Finetti's theorem in our setting and therefore, more refined tools are needed rather than a hammer like de Finetti's theorem. More formally, our theorem is the following.

▶ **Theorem 2.** *Let $s = O(\sqrt{n})$ be the number of samples required by Algorithm 1 for $\epsilon = 1/3$. There exists an exchangeable sequence $X_1, \ldots, X_s$ such that X_i is drawn from distribution q_i which are all supported in $[n]$ and satisfy $\|q_i - \mathcal{U}_n\|_1 \geq 1/3$ for all i. Furthermore, $\{q_i\}_{i=1}^s$ all satisfy the structural condition given in Definition 1 with $q = \mathcal{U}_n$. Let P denote the distribution of the sequence $X_1, \ldots, X_s$. Then P is $\Omega(1)$-far in ℓ_1-distance from any mixture of product distributions.*

The proof of Theorem 2 uses ideas from Diaconis and Freedman in [13]. For other variants and finite extension of de Finetti's theorem, see [24].

3 Uniformity Testing with Multiple Sources

We now present our algorithm, Uniformity-Tester, for uniformity testing with multiple sources. We show the standard collision based statistic, introduced in [22, 7], is a sufficient statistic to distinguish whether all sources are uniform or all sources are ϵ-far from uniform in our multiple sources setting. The collision statistic is selected based on a simple observation: if we draw two samples from a distribution, the probability that these two samples are equal (also known as a *collision*) is lowest when the distribution is uniform. Thus, the number of pairwise collisions tends to be "small" if the samples are drawn from a uniform distribution. We show that this observation still holds in our setting. Our algorithm takes s samples (for

Algorithm 1 UNIFORMITY-TESTER.

Input : n, ϵ, one sample from each of $p_1, p_2, \ldots, p_s$
Output : accept or reject

$s \leftarrow \frac{c_1\sqrt{n}}{\epsilon^2}$
Take s samples $X_1, \cdots, X_s$.
For each $1 \le i < j \le s$, let σ_{ij} be the indicator variable for the event $X_i = X_j$.
$\tau \leftarrow \frac{1+\epsilon^2/16}{n}$
$Z \leftarrow \sum_{i<j} \sigma_{ij} / \binom{s}{2}$
if $Z \ge \tau$ **then**
    Output reject and abort.
Output accept.

a parameter s which we determine later) and calculates the number of pairwise collisions in the samples. Then, it compares the number collisions to a threshold, τ, which we specify later. If the number of collisions is less than τ, we infer the sources are uniform and output accept; otherwise, we infer the sources are far from uniform, and output reject. We present our approach in Algorithm 1 along with the main theorem, Theorem 3, which proves the correctness of our algorithm.

▶ **Theorem 3** (Correctness of UNIFORMITY-TESTER)**.** *There exists a constants c_1 independent of n such that the following statements hold with probability $2/3$:*

- ***Completeness case:*** UNIFORMITY-TESTER *outputs* accept *if each of the s distributions $p_1, \ldots, p_s$ are uniform.*
- ***Soundness Case:*** UNIFORMITY-TESTER *outputs* reject *if the p_i's are ϵ-far from the uniform distribution (i.e., $\|p_i - \mathcal{U}_n\|_1 \ge \epsilon$) and $\{p_i\}_{i=1}^s$ satisfy the structural condition of Definition 1 with $q = \mathcal{U}_n$.*

▶ Remark 4. The sample complexity of Algorithm 1 is optimal due to the lower bound of $\Omega(\sqrt{n}/\epsilon^2)$ for testing uniformity in the standard single source setting presented in [28].

Overview of the proof. To prove the correctness of UNIFORMITY-TESTER, we analyze the statistic Z which is the number of collisions in the sample set:

$$Z = \frac{1}{\binom{s}{2}} \sum_{1 \le i < j \le s} \sigma_{ij}$$

where σ_{ij}, for $i < j$, is the indicator that sample i is equal to sample j. The algorithm outputs accept or reject by comparing the statistic Z to a threshold τ. Our goal is to show Z is below the threshold in the completeness case and above the threshold in the soundness case. To do so, we first compute the expectation of Z and then show a sufficiently strong concentration around its expectation by bounding the variance of Z. By a careful selection of the number of samples and the threshold τ, we can prove with high probability that Z is on the desired side of the threshold, and consequently the correctness of the algorithm.

Proof of Theorem 3. We start by setting the parameters: Let the threshold τ be $(1 + \epsilon^2/16)/n$. Define α to be the solution to $\mathbf{E}[Z] = (1+\alpha)/n$. Let the number of samples, s, to be $c_1\sqrt{n}/\epsilon^2$ for a sufficiently large constant c_1.

Note that in the completeness case, all samples are coming from the uniform distribution. In this case, Z is analyzed in [22, 6, 14], so we know the expected value of the statistic is as follows:

$$\mathbf{E}[Z] = \|\mathcal{U}_n\|_2^2 = \frac{1}{n}\,.$$

Furthermore, the variance of Z is bounded from above as below (see Lemma 2.3 in [14]):

$$\mathbf{Var}[Z] \leq \Theta\left(\frac{s^2 \cdot \|\mathcal{U}_n\|_2^2 + m^3\left(\|\mathcal{U}_n\|_3^3 - \|\mathcal{U}_n\|_2^4\right)}{\binom{s}{2}^2}\right) \leq \Theta\left(\frac{1}{ns^2}\right)\,.$$

Now, by Chebyshev's inequality, we can bound the probability that Z become larger than the threshold as follows

$$\Pr\left[Z \geq \tau\right] \leq \Pr\left[|Z - \mathbf{E}[Z]| \geq \frac{\epsilon^2}{16\,n}\right] \leq \Theta\left(\frac{n}{\epsilon^4\, s^2}\right) \leq \frac{1}{3}$$

where the last inequality holds for a sufficiently large constant c_1 and having $s = c_1\sqrt{n}/\epsilon^2$ which proves the correctness of the completeness case.

The main challenge of this proof is to analyze the soundness case when the p_i's are potentially different. We first give a lower bound for the expected value of Z. We begin by providing an intuitive overview of our approach. In the soundness case, we can compute that the expected value of the indicator random variable for a collision between the i-th and the j-th sample is given by

$$\mathbf{E}[\sigma_{ij}] = \sum_{x\in[n]} p_i(x)p_j(x) \tag{3}$$

where p_i and p_j are the distributions that sample i and j are respectively drawn from. One can think of Equation (3) as a generalization of $\|p\|_2^2$ when two distributions are involved. To bound Equation (3) from below, we make use of the *structural condition*. Namely, we can define the error terms

$$\begin{aligned} e_i(x) &= p_i(x) - \frac{1}{n} \qquad \forall x \in A \\ e_i(x) &= \frac{1}{n} - p_i(x) \qquad \forall x \in B\,. \end{aligned} \tag{4}$$

We know that

$$\sum_{x\in A} e_i(x) = \sum_{x\in B} e_i(x)\,.$$

In fact, the above quantities are half the ℓ_1-distance between p_i and the uniform distribution. We define $e_j(x)$ similarly for p_j, and the above identity similarly holds for the e_j's as well. Using these equations, we show in Lemma 5 that

$$\sum_{x\in[n]} p_i(x)p_j(x) = \frac{1}{n} + \sum_{x\in[n]} e_i(x)e_j(x).$$

Recall that our goal is to show that the expected number of collisions in the soundness case is substantially larger than $\binom{s}{2}/n$. Thus, we desired to bound find a lower bound for the second term in the right hand side above. However, since p_i and p_j are not necessarily the same distribution, it could be the case that for a fixed pair i, j we have $\sum_{x\in[n]} e_i(x)e_j(x) = 0$ which is what we would expect if p_i and p_j were both uniform. Thus, instead of bounding $\sum_{x\in[n]} e_i(x)e_j(x)$ for each pair i and j, we show that the sum of these terms over *all the pairs* $i < j$ is $\Theta(\epsilon^2)$. More formally, we have the following lemma.

▶ **Lemma 5.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that are all ϵ-far from $\mathcal{U}_n$ in ℓ_1-distance, and satisfy the structural condition given in Definition 1 with $q = \mathcal{U}_n$. Let X_i be drawn independently from p_i for all $1 \le i \le s$. Let σ_{ij} be the indicator variable for the event $X_i = X_j$ and define $Z = \sum_{i<j} \sigma_{ij} / \binom{s}{2}$. Then the following estimate holds*

$$\mathbf{E}[Z] \ge \frac{1 + \epsilon^2/8}{n}\,.$$

Proof. Recall the error terms which we defined in Equation (4):

$$e_i(x) = p_i(x) - \frac{1}{n} \qquad \forall x \in A\,,$$
$$e_i(x) = \frac{1}{n} - p_i(x) \qquad \forall x \in B\,.$$

We start by giving a convenient representation of $\mathbf{E}[\sigma_{ij}]$ in terms of the error terms:

$$\mathbf{E}[\sigma_{ij}] = \frac{1}{n} + \sum_{x\in[n]} e_i(x)e_j(x)\,. \tag{5}$$

To prove the above equation, observe that since the sum of the probabilities in any discrete distribution is one, we have:

$$\sum_{x\in A} e_i(x) = \sum_{x\in B} e_i(x) \tag{6}$$

and similar for the e_j's. All of the $e_i(x)$'s and the $e_j(x)$'s are non-negative for any domain element x by definition and the *structural condition*. Thus, we can obtain:

$$\begin{aligned}
\mathbf{E}[\sigma_{ij}] &= \sum_{x\in[n]} p_i(x)p_j(x) \\
&= \sum_{x\in A}\left(e_i(x) + \frac{1}{n}\right)\left(e_j(x) + \frac{1}{n}\right) + \sum_{x\in B}\left(\frac{1}{n} - e_i(x)\right)\left(\frac{1}{n} - e_j(x)\right) \\
&= \frac{|A|}{n^2} + \frac{1}{n}\sum_{x\in A} e_i(x) + \frac{1}{n}\sum_{x\in A} e_j(x) + \sum_{x\in A} e_i(x)e_j(x) \\
&+ \frac{|B|}{n^2} - \frac{1}{n}\sum_{x\in B} e_i(x) - \frac{1}{n}\sum_{x\in B} e_j(x) + \sum_{x\in B} e_i(x)e_j(x)\,.
\end{aligned}$$

Using Equation (6), it is clear that the sum of two middle terms above are zero:

$$\frac{1}{n}\sum_{x\in A} e_i(x) - \frac{1}{n}\sum_{x\in B} e_i(x) = 0\,, \quad \text{and} \qquad \frac{1}{n}\sum_{x\in A} e_j(x) - \frac{1}{n}\sum_{x\in B} e_j(x) = 0\,,$$

which implies the desired identity we claimed in Equation (5):

$$\mathbf{E}[\sigma_{ij}] = \frac{|A| + |B|}{n^2} + \sum_{x\in[n]} e_i(x)e_j(x) = \frac{1}{n} + \sum_{x\in[n]} e_i(x)e_j(x)\,.$$

Using this identity for all $\binom{s}{2}$ pair of samples, yields to the following:

$$\mathbf{E}\left[\binom{s}{2} Z\right] = \mathbf{E}\left[\sum_{j<i} \sigma_{ij}\right] = \sum_{j<i}\sum_{x\in[n]} p_i(x)p_j(x) = \binom{s}{2}\frac{1}{n} + \sum_{j<i}\sum_{x\in[n]} e_i(x)e_j(x). \tag{7}$$

Now, we focus on the second term on the right hand side of the equation above. We can compute that

$$\sum_{j<i}\sum_{x\in B} e_i(x)e_j(x) = \frac{1}{2}\left(\underbrace{\sum_{x\in B}\left(\sum_{i=1}^{s} e_i(x)\right)^2}_{\text{first term}} - \underbrace{\sum_{i=1}^{s}\sum_{x\in B} e_i(x)^2}_{\text{second term}}\right). \tag{8}$$

To fine a lower bound $\mathbf{E}[Z]$, we find a lower bound for the first term and an upper bound for the second term in the right hand side above.

Lower bound for the first term. Note that if $x \in B$, by definition, $e_i(x)$ is at most $1/n$. On the other hand, $\sum_{x\in B} e_i(x)$ is half of the ℓ_1-distance between p_i and the uniform distribution. Define ϵ_i' to be $\|p_i - \mathcal{U}_n\|_1 = 2\sum_{x\in B} e_i(x)$. Clearly, ϵ_i' is at least ϵ. Then, we have the following lower bound for the size of B:

$$|B|\cdot\frac{1}{n} \geq \sum_{x\in B} e_i(x) = \frac{\epsilon_i'}{2}, \quad \Rightarrow \quad |B| \geq \frac{\epsilon_i' n}{2} \geq \frac{\epsilon n}{2}.$$

Therefore, it follows that for any i, we have

$$\sum_{x\in B} e_i(x)^2 \leq \frac{1}{n^2}\cdot\frac{\epsilon_i' n}{2} = \frac{\epsilon_i'}{2n}.$$

Now by the Cauchy-Schwarz inequality, and having $|B| \leq n$, we have:

$$\sum_{x\in B}\left(\sum_{i=1}^{s} e_i(x)\right)^2 \geq \frac{1}{|B|}\left(\sum_{i=1}^{s}\sum_{x\in B} e_i(x)\right)^2 \geq \frac{\left(\sum_{i=1}^{s}\epsilon_i'\right)^2}{4\,n}.$$

Upper bound for the second term. On the other hand, for the second term in Equation (8), we obtain:

$$\sum_{i=1}^{s}\sum_{x\in B} e_i(x)^2 \leq \sum_{i=1}^{s}\sum_{x\in B}\frac{e_i(x)}{n} \leq \frac{1}{2n}\sum_{i=1}^{s}\epsilon_i'$$

where the first inequality holds since the $e_i(x)$'s are at most $1/n$.

Putting it all together. Using the two bounds above, we achieve the following lower bound for Equation (8):

$$\sum_{j<i}\sum_{x\in B} e_i(x)e_j(x) \geq \frac{1}{2}\left(\frac{\left(\sum_{i=1}^{s}\epsilon_i'\right)^2}{4n} - \frac{\sum_{i=1}^{s}\epsilon_i'}{2n}\right).$$

Observe that since $s = c_1\sqrt{n}/\epsilon^2$, for a sufficiently large c_1, s is at least $\Theta(1/\epsilon)$. Therefore, we have:

$$\sum_{i=1}^{s}\epsilon_i' \geq s\epsilon \geq 4 \quad \Rightarrow \quad \frac{1}{2}\left(\sum_{i=1}^{s}\epsilon_i'\right)^2 - \sum_{i=1}^{s}\epsilon_i' \geq \frac{\left(\sum_{i=1}^{s}\epsilon_i'\right)^2}{4}.$$

Therefore, we obtain:

$$\sum_{j<i}\sum_{x\in B} e_i(x)e_j(x) \geq \frac{1}{2}\left(\frac{\left(\sum_{i=1}^{s}\epsilon_i'\right)^2}{4n} - \frac{\sum_{i=1}^{s}\epsilon_i'}{2n}\right) \geq \frac{\left(\sum_{i=1}^{s}\epsilon_i'\right)^2}{16n} \geq \frac{s^2\epsilon^2}{16n}.$$

Going back to Equation (7), we achieve:

$$\mathbf{E}\left[\binom{s}{2}Z\right] \geq \binom{s}{2}\frac{1}{n} + \frac{s^2\epsilon^2}{16n} \geq \binom{s}{2}\frac{(1+\epsilon^2/8)}{n},$$

which concludes the proof of the lemma. ◀

We now proceed with the proof of Theorem 3. In the next step, we show a tight bound for the variance of the our statistic Z. We generalize the tight variance analysis given in [14] for the standard collision based tester in the single source setting to our multiple source setting. We start by a useful identity for the variance: $\mathbf{Var}[Z] = \mathbf{E}[Z^2] - \mathbf{E}[Z]^2$. Note that when we expand $Z^2 = (\sum_{i<j}\sigma_{ij})^2$, we get terms of the form $\sigma_{ij}\sigma_{jk}$. In the single distribution case, this term can be related to the ℓ_3-norm of p. In our setting, we introduce a generalization of the ℓ_3-norm which is the following:

$$\mathbf{E}[\sigma_{ij}\sigma_{jk}] = \sum_{x\in[n]} p_i(x)p_j(x)p_k(x). \tag{9}$$

To upper bound Equation (9), we again make use of the *structural condition* and relate it to our version of the ℓ_2-norm, Equation (3), by using Maclaurin's inequality which roughly states that the ℓ_3-norm is at most the ℓ_2-norm. More formally, we have the following lemma and our proof is presented in Section 3.1.

▶ **Lemma 6.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that are all ϵ-far from $\mathcal{U}$ in ℓ_1-distance and satisfy the structural condition given in Definition 1 with $q = \mathcal{U}_n$. Let X_i be drawn independently from p_i for all $1 \leq i \leq s$. Let σ_{ij} be the indicator variable for the event $X_i = X_j$. Then the following estimate holds*

$$\mathbf{Var}\left(\sum_{i<j}\sigma_{ij}\right) \leq \frac{18\alpha s}{n^2}\binom{s}{2} + 3\left(\frac{\alpha}{n}\binom{s}{2}\right)^{3/2} + \sum_{i<j}\mathbf{E}[\sigma_{ij}]$$

where α is defined to be the solution to $\mathbf{E}[Z] = (1+\alpha)/n$, and it is at least $\epsilon^2/8$.

We can now prove the correctness of the algorithm by bounding the probability that Z is below the threshold τ. Recall that $\mathbf{E}[Z] = (1+\alpha)/n \geq (1+\epsilon^2/8)/n$ from Lemma 5. Therefore, $\alpha \geq \epsilon^2/8$. By Chebyshev's inequality, we have

$$\begin{aligned}
\Pr[Z < \tau] &= \Pr[\mathbf{E}[Z] - Z \geq \mathbf{E}[Z] - \tau] \leq \Pr[|\mathbf{E}[Z] - Z| \geq \mathbf{E}[Z] - \tau] \\
&\leq \Pr\left[|\mathbf{E}[Z] - Z| \geq \frac{\alpha - \epsilon^2/16}{n}\right] \leq \mathbf{Var}[Z]\cdot\left(\frac{n}{\alpha-\epsilon^2/16}\right)^2 \\
&\leq \mathbf{Var}\left[\sum_{i<j}\sigma_{ij}\right]\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2.
\end{aligned}$$

Now, Lemma 6 gives us

$$\mathbf{Var}\left(\sum_{i<j}\sigma_{ij}\right) \leq \underbrace{\frac{18\alpha s}{n^2}\binom{s}{2} + 3\left(\frac{\alpha}{n}\binom{s}{2}\right)^{3/2}}_{T_1} + \underbrace{\sum_{i<j}\mathbf{E}[\sigma_{ij}]}_{T_2}.$$

We use T_1 and T_2 to indicate the two terms in the upper bound above. In either of the cases $T_1 \leq T_2$ or $T_1 > T_2$, we show the error probability is bounded by $1/3$.

Case 1: $T_1 \leq T_2$. In this case, we bound the variance of the number of collisions by $2\,T_2$. We have:

$$\Pr[Z < \tau] \leq \mathbf{Var}\left[\sum_{i<j}\sigma_{ij}\right]\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2 \leq 2\,T_2\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2$$
$$\leq 2\sum_{i<j}\mathbf{E}[\sigma_{ij}]\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2 \leq \Theta\left(\frac{s^2(1+\alpha)}{n}\cdot\frac{n^2}{s^4(\alpha-\epsilon^2/16)^2}\right)$$
$$\leq \Theta\left(\frac{n}{s^2}\cdot\underbrace{\frac{1+\alpha}{(\alpha-\epsilon^2/16)^2}}_{f(\alpha)}\right).$$

Define $f(\alpha) := (1+\alpha)/(\alpha-\epsilon^2/16)^2$. We can compute that f is a decreasing function over the range $[\epsilon^2/8, \infty)$, so we can bound $f(\alpha)$ by $f(\epsilon^2/8) = \Theta(1/\epsilon^2)$ from above. Thus, we bound the probability of $Z < \tau$ as

$$\Pr[Z < \tau] \leq \Theta\left(\frac{n}{s^2\epsilon^2}\right) \leq \frac{1}{3},$$

where the last inequality holds for a sufficiently large constant c_1 and having $s = c_1\sqrt{n}/\epsilon^2$.

Case 2: $T_1 > T_2$. In this case, we bound the variance of Z by $2\,A$. Note that we know $\alpha \geq \epsilon^2/8$, so we have:

$$\Pr[Z < \tau] \leq \mathbf{Var}\left[\sum_{i<j}\sigma_{ij}\right]\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2 \leq 2\,T_2\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2$$
$$\leq 2\left(\frac{18\alpha s}{n^2}\binom{s}{2} + 3\left(\frac{\alpha}{n}\binom{s}{2}\right)^{3/2}\right)\cdot\left(\frac{n}{\binom{s}{2}(\alpha-\epsilon^2/16)}\right)^2$$
$$\leq \Theta\left(\left(\frac{\alpha s^3}{n^2} + \frac{\alpha^{3/2}s^3}{n^{3/2}}\right)\cdot\frac{n^2}{s^4\alpha^2}\right) \leq \Theta\left(\frac{1}{s\,\alpha} + \frac{\sqrt{n}}{s\sqrt{\alpha}}\right).$$

The number of samples, s is chosen to be

$$s = c_1\cdot\frac{\sqrt{n}}{\epsilon^2} \geq \Theta\left(\frac{1}{\epsilon^2} + \frac{\sqrt{n}}{\epsilon}\right) \geq \Theta\left(\frac{1}{\alpha} + \frac{\sqrt{n}}{\sqrt{\alpha}}\right),$$

and therefore, by picking a sufficiently large constant c_1, we can bound the probability of outputting the incorrect answer in the soundness case by $1/3$. ◀

3.1 Proof of Lemma 6

▶ **Lemma 6.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that are all ϵ-far from $\mathcal{U}$ in ℓ_1-distance and satisfy the structural condition given in Definition 1 with $q = \mathcal{U}_n$. Let X_i be drawn independently from p_i for all $1 \leq i \leq s$. Let σ_{ij} be the indicator variable for the event $X_i = X_j$. Then the following estimate holds*

$$\mathbf{Var}\left(\sum_{i<j}\sigma_{ij}\right) \leq \frac{18\alpha s}{n^2}\binom{s}{2} + 3\left(\frac{\alpha}{n}\binom{s}{2}\right)^{3/2} + \sum_{i<j}\mathbf{E}[\sigma_{ij}]$$

where α is defined to be the solution to $\mathbf{E}[Z] = (1+\alpha)/n$, and it is at least $\epsilon^2/8$.

Proof. For simplicity, let W denote $\sum_{i<j} \sigma_{ij}$. We bound the variance of W from above in the following steps.

$$\begin{aligned}
&\mathbf{Var}[W] = \mathbf{E}[W^2] - \mathbf{E}[W]^2 = \mathbf{E}\left[\left(\sum_{i<j} \sigma_{ij}\right)^2\right] - \left(\sum_{i<j} \mathbf{E}[\sigma_{ij}]\right)^2 \\
&= \mathbf{E}\left[\sum_{\substack{i<j,k<\ell \\ \text{all distinct}}} \sigma_{ij}\sigma_{k\ell} + 2\sum_{i<j<\ell} (\sigma_{ij}\sigma_{ik} + \sigma_{ij}\sigma_{jk} + \sigma_{ik}\sigma_{jk}) + \sum_{i<j} \sigma_{ij}^2\right] \\
&- \sum_{\substack{i<j,k<\ell \\ \text{all distinct}}} \mathbf{E}[\sigma_{ij}]\,\mathbf{E}[\sigma_{k\ell}] - 2\sum_{i<j<\ell} (\mathbf{E}[\sigma_{ij}]\,\mathbf{E}[\sigma_{ik}] + \mathbf{E}[\sigma_{ij}]\,\mathbf{E}[\sigma_{jk}] + \mathbf{E}[\sigma_{ik}]\,\mathbf{E}[\sigma_{jk}]) \\
&- \sum_{i<j} \mathbf{E}[\sigma_{ij}]^2 .
\end{aligned}$$

Note that if i, j, k, and ℓ are all distinct, then σ_{ij} is independent from $\sigma_{k\ell}$. Thus, we have:

$$\mathbf{E}[\sigma_{ij}\sigma_{k\ell}] = \mathbf{E}[\sigma_{ij}]\,\mathbf{E}[\sigma_{k\ell}] .$$

Moreover, we know that $\mathbf{E}[\sigma_{ij}] \geq 1/n$ for all $i < j$ from Lemma 5. Having $\sigma_{ij}^2 = \sigma_{ij}$, we continue bounding the variance as follows:

$$\begin{aligned}
\mathbf{Var}[W] &= 2\sum_{i<j<\ell} (\mathbf{E}[\sigma_{ij}\sigma_{ik}] + \mathbf{E}[\sigma_{ij}\sigma_{jk}] + \mathbf{E}[\sigma_{ik}\sigma_{jk}]) \\
&\quad + \mathbf{E}\left[\sum_{i<j} \sigma_{ij}\right] - \binom{s}{3}\frac{6}{n^2} - \sum_{i<j} \mathbf{E}[\sigma_{ij}]^2 .
\end{aligned}$$

For now, we focus on the first sum in the right hand side above. We bound this term via the error terms we defined in Equation (4). We note that

$$\begin{aligned}
&\mathbf{E}[\sigma_{ij}\sigma_{ik}] = \mathbf{E}[\sigma_{ij}\sigma_{jk}] = \mathbf{E}[\sigma_{ik}\sigma_{jk}] = \sum_{x\in[n]} p_i(x)p_j(x)p_k(x) \\
&= \sum_{x\in A}\left(\frac{1}{n} + e_i(x)\right)\left(\frac{1}{n} + e_j(x)\right)\left(\frac{1}{n} + e_k(x)\right) \\
&+ \sum_{x\in B}\left(\frac{1}{n} - e_i(x)\right)\left(\frac{1}{n} - e_j(x)\right)\left(\frac{1}{n} - e_k(x)\right) \\
&\leq \frac{1}{n^2}\left(\underbrace{\sum_{x\in A} e_i(x) - \sum_{x\in B} e_i(x)}_{=0} + \underbrace{\sum_{x\in A} e_j(x) - \sum_{x\in B} e_j(x)}_{=0} + \underbrace{\sum_{x\in A} e_k(x) - \sum_{x\in B} e_k(x)}_{=0}\right) \\
&+ \frac{1}{n}\left(\sum_{x\in[n]} e_i(x)e_j(x) + e_i(x)e_k(x) + e_j(x)e_k(x)\right) + \sum_{x\in[n]} e_i(x)e_j(x)e_k(x) + \sum_{x\in[n]} \frac{1}{n^3}
\end{aligned}$$

where the last inequality holds since all the $e_i(x)$'s are non-negative. Therefore, we can

continue bounding the variance as follows:

$$\mathbf{Var}[W] \leq \binom{s}{3}\frac{6}{n^2} + \frac{18\,s}{n}\sum_{i<j}\sum_{x\in[n]} e_i(x)e_j(x) + 6\sum_{i<j<k}\sum_{x\in[n]} e_i(x)e_j(x)e_k(x) + \mathbf{E}[W] - \binom{s}{3}\frac{6}{n^2}.$$

To bound the above terms, we use Maclaurin's inequality proved in [11].

▶ **Lemma 7** (Maclaurin's inequality). *Let $\{a_i\}_{i=1}^s$ be non-negative real numbers. Define*

$$S_k = \frac{1}{\binom{s}{k}}\sum_{1\leq i_1<\cdots<i_k\leq s} a_{i_1}a_{i_2}\cdots a_{i_k}.$$

Then,

$$S_1 \geq \sqrt{S_2} \geq \sqrt[3]{S_3} \geq \cdots \geq \sqrt[s]{S_s}.$$

For our purposes, we prove a strengthening of Maclaurin's inequality which is given in the following lemma:

▶ **Lemma 8** (Strengthened Maclaurin's Inequality).

$$\left(2\sum_{i<j<k}\sum_{x\in[n]} e_i(x)e_j(x)e_k(x)\right)^2 \leq \left(\sum_{i<j}\sum_{x\in[n]} e_i(x)e_j(x)\right)^3.$$

Proof. We prove this by induction on n. Consider the case $n = 1$. By Lemma 7, we have:

$$\left(\sum_{i<j} e_i(1)e_j(1)\right)^3 \geq \frac{\binom{s}{2}^3}{\binom{s}{3}^2}\left(\sum_{i<j<k} e_i(1)e_j(1)e_k(1)\right)^2.$$

Now for $s \geq 3$, we have: $\binom{s}{2}^3/\binom{s}{3}^2 > 4$ which proves our claim. We now proceed by induction. Suppose that the induction hypothesis is true for $n-1$. We know by the induction hypothesis that the following two inequalities hold:

$$\left(\underbrace{2\sum_{i<j<k}\sum_{x\in[n-1]} e_i(x)e_j(x)e_k(x)}_{F}\right)^2 \leq \left(\underbrace{\sum_{i<j}\sum_{x\in[n-1]} e_i(x)e_j(x)}_{F'}\right)^3$$

$$\left(\underbrace{2\sum_{i<j<k} e_i(n)e_j(n)e_k(n)}_{G}\right)^2 \leq \left(\underbrace{\sum_{i<j} e_i(n)e_j(n)}_{G'}\right)^3$$

where the first inequality is the induction hypothesis and the second inequality is just the base case of the induction which was proved earlier. Let F, F', G, and G' denote the terms as indicated above. The above inequalities after substituting new variables become: $F'^3 \geq F^2$ and $G'^3 \geq G^2$. Since all of these terms are positive, we have:

$$(F'^3G'^3)^{1/2} \geq FG$$

Then, by the arithmetic mean-geometric mean inequality, we have

$$3F'^2G' + 3F'G'^2 \geq 6(F'G')^{3/2} \geq 6FG \geq 2FG.$$

Using the fact that $F'^3 \geq F^2$ and $G'^3 \geq G^2$ again, yields

$$(F' + G')^3 \geq (F + G)^2\,,$$

which concludes the lemma. ◀

We now proceed to bound the variance of W. We know

$$\mathbf{Var}[W] \leq \frac{18\,s}{n} \sum_{i<j} \sum_{x\in[n]} e_i(x)e_j(x) + 6 \sum_{i<j<k} \sum_{x\in[n]} e_i(x)e_j(x)e_k(x) + \mathbf{E}[W]\,.$$

In the next step, we bound the two middle term based on n, s, and α. Using Lemma 8, we have

$$\sum_{i<j<k} \sum_{x\in[n]} e_i(x)e_j(x)e_k(x) \leq \frac{1}{2}\left(\sum_{i<j} \sum_{x\in[n]} e_i(x)e_j(x)\right)^{3/2}.$$

Recall that $\mathbf{E}[Z] = (1+\alpha)/n$. Thus, using Equation (5), we know

$$\binom{s}{2}\frac{1+\alpha}{n} = \mathbf{E}[W] = \sum_{i<j} \sum_{x\in[n]} p_i(x)p_j(x) = \sum_{i<j} \sum_{x\in[n]} \left(e_i(x)e_j(x) + \frac{1}{n}\right),$$

which immediately implies that

$$\sum_{i<j} \sum_{x\in[n]} e_i(x)e_j(x) = \binom{s}{2}\frac{\alpha}{n}.$$

Putting all of it together, we obtain

$$\mathbf{Var}[W] \leq \frac{18\,\alpha\,s}{n^2}\binom{s}{2} + 3\left(\binom{s}{2}\frac{\alpha}{n}\right)^{3/2} + \sum_{i<j} \mathbf{E}[\sigma_{ij}]\,,$$

as desired. ◀

4 Identity Testing with Multiple Sources

In this section, we present our algorithm for identity testing with multiple sources and its analysis. Recall that our goal is to distinguish the following two cases with probability at least 2/3 given knowledge of some fixed distribution q over $[n]$:

- **Completeness case:** $p_1, p_2, \cdots, p_s$ are identical to q
- **Soundness case:** $p_1, p_2, \cdots, p_s$ are all ϵ-far from q in ℓ_1-distance

where we receive samples from $\{p_i\}_{i=1}^s$. In the soundness case, we also assume that the p_i's satisfy the *structural condition* given in Definition 1: we assume there are disjoint sets A and B that partition $[n]$ such that all p_i's are larger than q on the indices in A, and all the p_i's are smaller than q on the indices in B. Note that *structural condition* trivially holds in the completeness case.

4.1 Algorithm for Identity Testing

We now present our algorithm, Identity-Tester, for identity testing with multiple sources. Suppose we receive Poi(1) samples from each of the distributions p_i. This is a generalization of the standard technique in distribution testing which significantly simplifies the analysis of our algorithm by making certain random variables independent, as we explain later. Furthermore, as Poi(s) is tightly concentrated around s, we can carry out this poissonization method at the expense of only constant factor increases in the sample complexity. Moreover, while we draw one sample in expectation per source, with probability 0.9, we will not receive more than $O(\log s)$ samples per distribution.

Our algorithm calculates a new χ-square type statistics inspired by the previous χ^2-type statistics [32, 1, 10, 16]). The statistic is designed so that its expected value is related to the "ℓ_2-norm" of the difference of the distributions, as explained in Section 2.3. Similarly to uniformity testing, our algorithm in this section also proceeds by taking samples and calculating our statistic. Then, it compares the value of this statistic to a threshold τ. If the value of the statistic is "large", the algorithm outputs reject and aborts, and outputs accept otherwise. Ultimately, we prove that the sample complexity of our generalized identity tester depends on the ℓ_2-norm of q, the known distribution. We give a flattening procedure in Section 4.2 which allows us to assume that the ℓ_2-norm of the known distribution is $O(1/\sqrt{n})$, resulting in the optimal sample complexity. We present our algorithm below along with the main theorem, Theorem 9, which proves the correctness of our algorithm.

Algorithm 2 Identity-Tester.

Input : n, ϵ, q, Poi(1) samples from each of $p_1, p_2, \cdots, p_s$
Output : accept or reject

$s \leftarrow \frac{c_1 n \|q\|_2}{\epsilon^2}$
Draw Poi(1) samples from each of the s distributions $\{p_j\}_{j=1}^s$.
$T_x \leftarrow$ # times we see element $x \in [n]$ among the samples.
$\tau \leftarrow \frac{5s^2\epsilon^2}{8n}$
$Z \leftarrow \sum_{x\in[n]} (T_x - sq(x))^2 - T_x$
if $Z \geq \tau$ **then**
    Output reject and abort.
Output accept

▶ **Theorem 9** (Correctness of Identity-Tester)**.** *There exist a constant c_1 independent of n such that the following statements hold with probability 2/3:*

- Identity-Tester *outputs accept if each of the s distributions $p_1, \cdots, p_s$ are equal to q.*
- Identity-Tester *outputs reject if the p_i's are ϵ-far from q ($\|p_i - q\|_1 \geq \epsilon$) and $\{p_i\}_{i=1}^s$ satisfy the structural condition given in Definition 1.*

▶ Remark 10. The sample complexity of Algorithm 2 is $\Theta(n\|q\|_2/\epsilon^2)$. Using the flattening procedure of Section 4.2, the sample complexity of Identity-Tester reduces to $\Theta(\sqrt{n}/\epsilon^2)$ which is optimal since the lower bound of $\Omega(\sqrt{n}/\epsilon^2)$ holds for identity testing in the standard single distribution setting [28].

▶ Remark 11. Note that identity testing is a generalization of uniformity testing in Section 3. However, we keep our approach for uniformity testing since we only use *exactly one* sample per distribution, rather than one sample in expectation.

Overview of the proof. To prove the correctness of IDENTITY-TESTER, we analyze the statistic

$$Z = \sum_{x\in[n]} (T_x - s\,q(x))^2 - T_x\,,$$

where T_x denotes the number of times we observe element x among our $s' \sim \mathrm{Poi}(s)$ samples. Note that by employing the poissonization method, T_x is a Poisson random variable with parameter $\lambda_x \coloneqq \sum_{j=1}^{s} p_j(x)$ and T_x and T_y are independent for $x \neq y$. The independence among T_x's greatly simplifies our calculations.

Our goal is to show Z is below the threshold τ in the completeness case, and above the threshold in the soundness case. To do so, we make use of the *structural condition* to first define a convenient representation of $\mathbf{E}[Z]$ in Lemma 12. We then show a strong concentration around its expectation by bounding the variance of Z in Lemma 13. Finally, we show that Z is always on the desired side of the threshold proving the correctness of our algorithm.

Proof of Theorem 9. Note that we set the (expected) number of samples to be $s = c_1 n\|q\|_2/\epsilon^2$ for some sufficiently large constant c_1, and the threshold τ to be equal to $5s^2\epsilon^2/(8n)$. We begin by stating a convenient representation of $\mathbf{E}[Z]$. To motivate our calculations, note that for a fixed x,

$$\begin{aligned}\mathbf{E}[(T_x - s\,q(x))^2 - T_x] &= \mathbf{E}[T_x^2] - \mathbf{E}[T_x] - 2sq(x)\mathbf{E}[T_x] + s^2q(x)^2\\ &= \lambda_x^2 - 2s\,q(x)\lambda_x + s^2q(x)^2 = (\lambda_x - s\,q(x))^2\end{aligned}$$

which follows from the fact that T_x is a Poisson random variable with parameter $\lambda_x = \sum_{j=1}^{s} p_j(x)$. Now using the *structural condition*, we can define error terms similar to our uniformity testing section. For each distribution p_j, we define

$$\begin{aligned} e_j(x) &= p_j(x) - q(x) \qquad \forall x \in A\\ e_j(x) &= q(x) - p_j(x) \qquad \forall x \in B.\end{aligned}$$

After plugging in $e_j(x)$ for all x into our expression for λ_x, we combine these terms into a more useful representation of $\mathbf{E}[Z]$. We precisely show this representation in Lemma 12 where we prove that $\mathbf{E}[Z]$ is given by $\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$ where we interpret the vector $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ as the vector with entries $e_j(x) = |q(x) - p_j(x)|$. Note that this is a natural generalization of the quantity $s^2\|q-p\|_2^2$ which is the quantity calculated by all χ^2-based testers in the single distribution setting of identity testing (where all the samples are i.i.d. from a fixed distribution p). More formally, we have the following lemma which we prove in Section 4.3.

▶ **Lemma 12.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that satisfy the* structural condition *given in Definition 1. Suppose we draw* $\mathrm{Poi}(1)$ *samples from each p_i and let T_x be the number of times we see element $x \in [n]$ among the samples. Let $Z = \sum_{x\in[n]}(T_x - sq(x))^2 - T_x$. Then,*

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$$

where the x-th coordinate of $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ is $|q(x) - p_j(x)|$.

We now give a tight upper bound for the variance of our statistic Z. Let Z_x denote the x-th term in Z, $(T_x - sq(x))^2 - T_x$. As we establish earlier, using the Poissonization method, T_x's are independent from each other. Thus, the Z_x's are independent as well. Therefore, one can expand the variance of Z as bellow:

$$\mathbf{Var}[Z] = \sum_{x\in[n]} \mathbf{Var}[Z_x] = \sum_{x\in[n]} \mathbf{E}[Z_x^2] - \mathbf{E}[Z_x]^2\,.$$

As we expand the term Z_x^2, to bound $\mathbf{E}\left[Z_x^2\right]$, higher norms of T_x, i.e., $\mathbf{E}\left[T_x^k\right]$ for $k \in [4]$, appear in our calculation. We can compute the closed-form of these quantities via the known norms of the Poisson distribution. Combining these terms, we again get an upper bound of $\mathbf{Var}[Z]$ in terms of the vectors $\vec{\mathbf{e}}_j$. Formally, we prove the following lemma in Section 4.4.

▶ **Lemma 13.** *Let $\{p_i\}_{i=1}^s$ be s distributions over $[n]$ that satisfy the structural condition given in Definition 1. Suppose we draw* Poi(1) *samples from each p_i, and let T_x be the number of times we see element $x \in [n]$ among the samples. Let $Z = \sum_{x\in[n]}(T_x - sq(x))^2 - T_x$. Then, we have:*

$$\mathbf{Var}[Z] \le 4s\|q\|_2 \left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_4^2 + 2\left\|\sum_{j=1}^s \vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_3^3,$$

where $|q(x) - p_j(x)|$ is the x-th coordinates of $\vec{\mathbf{e}}_j \in \mathbb{R}^n$, and $\vec{p_j}$ is the vector representation of the distribution p_j.

We can now proceed to the proof of the theorem in the completeness case.

Proof of the completeness case. In this case, Lemma 12 gives us $\mathbf{E}[Z] = 0$, and Lemma 13 gives us $\mathbf{Var}[Z] \le 2s^2\|q\|_2^2$. Therefore by Chebyshev's inequality,

$$\Pr[Z \ge \tau] \le \Pr\left[|Z| = |Z - \mathbf{E}[Z]| \ge \frac{s^2\epsilon^2}{4n}\right] \le \frac{32s^2\|q\|_2^2 n^2}{s^4\epsilon^4} = \frac{32\|q\|_2^2 n^2}{s^2\epsilon^4}.$$

Recall that we let $s = c_1 n\|q\|_2/\epsilon^2$. The right hand side of the above inequality can be made arbitrarily small by picking a sufficiently large constant c_1, which proves the completeness case.

Proof of the soundness case. In this case, Lemma 12 gives us

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2 = \sum_{x\in[n]}\left(\sum_{j=1}^s e_j(x)\right)^2 \ge \frac{1}{n}\left(\sum_{j=1}^s\sum_{x\in[n]} e_j(x)\right)^2 \ge \frac{s^2\epsilon^2}{n}$$

where the first inequality is Cauchy-Schwarz, and the second inequality follows from the fact that

$$\sum_{x\in[n]} e_j(x) = \|q - p_j\|_1 \ge \epsilon$$

for each $j \in [s]$. Then by Chebyshev's inequality and Lemma 13,

$$\begin{aligned}\Pr\left[|Z - \mathbf{E}[Z]| \ge \frac{\mathbf{E}[Z]}{4}\right] &\le \frac{16\mathbf{Var}[Z]}{\mathbf{E}[Z]^2} \\ &\le \frac{4s\|q\|_2\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_4^2}{\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_2^4} + \frac{2\left\|\sum_{j=1}^s \vec{\mathbf{p}}_j\right\|_2^2}{\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_2^4} + \frac{4\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_3^3}{\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_2^4} \qquad (10)\end{aligned}$$

Now, we bound each of the three terms above separately. We start off by introducing a new distribution denoted by $\widetilde{\mathbf{p}}$ to be $\widetilde{\mathbf{p}} := \frac{1}{s}\sum_{j=1}^s \mathbf{p}_j$. In some of our calculation, this new representation simplifies our calculations.

- **First term:** Now, we focus on the first term in Equation (10). We note that all the $e_j(x)$ are positive, so we have:

$$\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2 = \sqrt{\sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^4} \le \sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^2 \le \left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^2. \tag{11}$$

  We again use the same Cauchy-Schwarz calculation as in $\mathbf{E}[Z]$ and get:

$$\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^2 = \sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^2 \ge \frac{1}{n}\left(\sum_{x\in[n]}\sum_{j=1}^{s}e_j(x)\right)^2 \ge \frac{s^2\epsilon^2}{n}. \tag{12}$$

  Therefore, we bound the first term from above:

$$\frac{4s\|q\|_2\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4} \le \frac{4n\|q\|_2}{s\epsilon^2}.$$

- **Second term**: For the second term, we have:

$$\frac{2\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4} = \frac{2s^2\|\widetilde{\mathbf{p}}\|_2^2}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4}$$

  where $\widetilde{\mathbf{p}} = \frac{1}{s}\sum_{j=1}^{s}\mathbf{p}_j$. We now consider two cases. If it is the case that $\|\widetilde{\mathbf{p}}\|_2 \le 3\|q\|_2$, then we have:

$$\frac{2s^2\|\widetilde{\mathbf{p}}\|_2^2}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4} \le \left(\frac{5n\|q\|_2}{s\epsilon^2}\right)^2.$$

  On the other hand, suppose that $\|\widetilde{\mathbf{p}}\|_2 > 3\|q\|_2$. Then, using our *structural condition*, we obtain:

$$\frac{2s^2\|\widetilde{\mathbf{p}}\|_2^2}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4} = \frac{2\|\widetilde{\mathbf{p}}\|_2^2}{s^2\|\widetilde{\mathbf{p}}-q\|_2^4}$$

  and note that

$$\|\widetilde{\mathbf{p}}-q\|_2^2 \ge \|\widetilde{\mathbf{p}}\|_2^2 + \|q\|_2^2 - 2\|q\|_2\|\widetilde{\mathbf{p}}\|_2 \ge \|\widetilde{\mathbf{p}}\|_2^2/3.$$

  Hence,

$$\frac{2\|\widetilde{\mathbf{p}}\|_2^2}{s^2\|\widetilde{\mathbf{p}}-q\|_2^4} \le \frac{18}{s^2\|\widetilde{\mathbf{p}}\|_2^2} \le \left(\frac{5}{s\|q\|_2}\right)^2.$$

- **Third term**: Again, we use the Cauchy-Schwarz inequality to obtain:

$$\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3 = \sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^3 \le \sqrt{\left(\sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^2\right)\cdot\left(\sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^4\right)}$$
$$\le \left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2\cdot\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2$$

Now, we use Equation (11) and Equation (12), which we show earlier, to bound the third term:

$$\frac{4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4} \leq \frac{4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2 \cdot \left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2^4} \leq \frac{4}{\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_2} \leq \frac{4\sqrt{n}}{s\epsilon}.$$

Thus in all cases, we have

$$\Pr\left[|Z - \mathbf{E}[Z]| \geq \frac{\mathbf{E}[Z]}{4}\right] \leq \frac{4n\|q\|_2}{s\epsilon^2} + \left(\frac{5n\|q\|_2}{s\epsilon^2}\right)^2 + \left(\frac{5}{s\|q\|_2}\right)^2 + \frac{4\sqrt{n}}{s\epsilon}.$$

Note that $s = c_1 n\|q\|_2/\epsilon^2$ and $\|q\|_2 \geq 1/\sqrt{n}$. Therefore, by letting c_1 be a sufficiently large constant, we get that the above probability is smaller than $1/3$. Hence with probability at least $2/3$, we know $Z \geq 3s^2\epsilon^2/(4n)$ in the soundness case, so we reject with probability at least $2/3$, as desired. ◀

4.2 Flattening Procedure

In this section, we present the flattening procedure which allows us to assume that $\|q\|_2^2 = O(1/n)$ in Remark 10 without loss of generality where q is our known distribution. While this procedure is similar to the one used in [16], we state it here for the sake of completeness. For each $x \in [n]$, define

$$b_x \coloneqq \lfloor nq(x) \rfloor + 1.$$

We note that $b_x \geq 1$ for each $x \in [n]$. Given a sample x from a distribution p over $[n]$, we can get a sample from the "flattened" distribution p' over a new domain, $\mathcal{D}$, defined as

$$\mathcal{D} \coloneqq \{(x, y) \mid x \in [n], y \in [b_x]\},$$

by drawing an element from $y \in [b_x]$ uniformly at random and creating the tuple (x, y). This is the flattening procedure that we use for our version of identity testing. Note that the probability mass over $[n]$ placed by p gets "flattened" to be a probability distribution over the domain $\mathcal{D}$.

Furthermore, this procedure has a few desired properties which we state here: First, the size of this new domain is $O(n)$:

$$|\mathcal{D}| = \sum_{x\in[n]} b_x \leq 2n.$$

Second, the procedure preserves the ℓ_1-distance between two distributions: let p' and q' denote the flattened versions of p and q. Then, we have:

$$\|q' - p'\|_1 = \sum_{x\in[n]}\sum_{y\in[b_x]} \frac{|q(x) - p(x)|}{|b_x|} = \sum_{x\in[n]} |q(x) - p(x)| = \|q - p\|_1.$$

Third, by definition of the b_x's, we can show that q' has a low ℓ_2-norm:

$$\|q'\|_2^2 = \sum_{x\in[n]}\sum_{y\in[b_x]} \frac{q(x)^2}{b_x^2} = \sum_{x\in[n]} \frac{q(x)^2}{b_x} \leq \sum_{x\in[n]} \frac{q(x)}{n} \leq \frac{1}{n}.$$

The above inequality implies that the ℓ_2-norm of q' is within a constant factor of the smallest possible norm, which is $(|\mathcal{D}|)^{-1/2}$.

Therefore whenever we get a sample over $[n]$ in IDENTITY-TESTER, we can use this flattening procedure to draw a sample over $\mathcal{D}$. By using this flattening procedure to draw samples from a slightly larger domain, we can assume that the ℓ_2-norm of the known distribution q is $O(1/\sqrt{n})$. Note that since the size of the larger domain is still $O(n)$, the flattening procedure only affects the sample complexity up to constant factors. Therefore, by combining with Theorem 9, we can perform our generalized version of identity testing by using $s = O(\sqrt{n}/\epsilon^2)$ samples, which is optimal up to constant factors.

4.3 Proof of Lemma 12

▶ **Lemma 12.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that satisfy the* structural condition *given in Definition 1. Suppose we draw* Poi(1) *samples from each p_i and let T_x be the number of times we see element $x \in [n]$ among the samples. Let $Z = \sum_{x\in[n]}(T_x - sq(x))^2 - T_x$. Then,*

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$$

where the x-th coordinate of $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ is $|q(x) - p_j(x)|$.

Proof. Let

$$Z_x = (T_x - sq(x))^2 - T_x.$$

We have:

$$Z_x^2 = T_x^2 - 2sq(x)T_x + s^2q(x)^2 - T_x.$$

We can compute that:

$$\begin{aligned}\mathbf{E}[Z_x] &= \mathbf{E}[T_x^2] - \mathbf{E}[T_x] - 2sq(x)\mathbf{E}[T_x] + s^2q(x)^2 \\ &= \lambda_x^2 - 2sq(x)\lambda_x + s^2q(x)^2\end{aligned}$$

where we have used the fact that the variance of a Poisson random variable with parameter λ is also λ. We introduce the following notation $(-1)^{x\in B}$ which is defined as

$$(-1)^{x\in B} = \begin{cases} -1 & \text{if } x \in B, \\ 1 & \text{if } x \notin B. \end{cases}$$

Using the fact that $\lambda_x = \sum_{j=1}^s p_j(x)$, we can compute that

$$\sum_{x\in[n]} \lambda_x = \sum_{j=1}^{s}\sum_{x\in[n]} \left(q(x) + (-1)^{x\in B}e_j(x)\right).$$

In Appendix A, we calculate the $\sum_{x\in[n]} \lambda_x^2$. There we show that

$$\begin{aligned}\sum_{x\in[n]} \lambda_x^2 = s^2||q||_2^2 + 2s\sum_{j=1}^{s}\sum_{x\in[n]} (-1)^{x\in B}q(x)e_j(x) \\ + \sum_{j=1}^{s}\sum_{x\in[n]} e_j(x)^2 + \sum_{j\neq k}\sum_{x\in[n]} e_j(x)e_k(x).\end{aligned}$$

Using these two results, we have:

$$\begin{aligned}\sum_{x\in[n]}\mathbf{E}[Z_x] &= \sum_{x\in[n]}\lambda_x^2 - 2s\sum_{x\in[n]}q(x)\lambda_x + s^2\sum_{x\in[n]}q(x)^2\\ &= 2s\sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}q(x)e_j(x) + \sum_{j=1}^{s}\sum_{x\in[n]}e_j(x)^2 + \sum_{j\neq k}\sum_{x\in[n]}e_j(x)e_k(x)\\ &\quad - 2s\sum_{j=1}^{s}\sum_{x\in[n]}(q(x)^2 + (-1)^{x\in B}q(x)e_j(x)) + 2s^2\|q\|_2^2\\ &= \sum_{j=1}^{s}\sum_{x\in[n]}e_j(x)^2 + \sum_{j\neq k}\sum_{x\in[n]}e_j(x)e_k(x)\\ &= \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2.\end{aligned}$$

Therefore, our final result is as follows:

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2,$$

as desired. ◀

▶ Remark 14. Note that the quantity $\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$ is a natural generalization of the quantity $s^2\|q-p\|_2^2$ which is the expectation of the random variable calculated by identity testers in the single distribution case where samples come from a fixed distribution p.

4.4 Proof of Lemma 13

▶ **Lemma 13.** *Let $\{p_i\}_{i=1}^s$ be s distributions over $[n]$ that satisfy the structural condition given in Definition 1. Suppose we draw* Poi(1) *samples from each p_i, and let T_x be the number of times we see element $x \in [n]$ among the samples. Let $Z = \sum_{x\in[n]}(T_x - sq(x))^2 - T_x$. Then, we have:*

$$\mathbf{Var}[Z] \le 4s\|q\|_2\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2 + 2\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3,$$

where $|q(x)-p_j(x)|$ is the x-th coordinates of $\vec{\mathbf{e}}_j \in \mathbb{R}^n$, and $\vec{p_j}$ is the vector representation of the distribution p_j.

Proof. Let

$$Z_x = (T_x - sq(x))^2 - T_x.$$

Due to the independence of T_x, we have

$$\mathbf{Var}[Z] = \sum_{x\in[n]}\mathbf{Var}[Z_x] = \sum_{x\in[n]}\mathbf{E}[Z_x^2] - \mathbf{E}[Z_x]^2$$

where

$$Z_x = (T_x - sq(x))^2 - T_x.$$

Noting that T_x is a Poisson with parameter λ_x, we can compute that

$$\mathbf{E}[Z_x^2] = \lambda_x^4 + 4\lambda_x^3(1-sq(x)) + 2\lambda_x^2(1-4sq(x)+3s^2q(x)^2) + 4s^2q(x)^2\lambda_x(1-sq(x)) + s^4q(x)^4.$$

In Appendix A we calculate the $\sum_{x\in[n]} \lambda_x^k$ for $k \in \{1,2,3,4\}$. Using these results and simplifying, we arrive at the following expression:

$$\begin{aligned}
&\sum_{x\in[n]} \mathbf{E}[Z_x^2] = 4s\sum_{j=1}^{s}\sum_{x\in[n]} q(x)e_j(x)^2 + 4s\sum_{j\neq k}\sum_{x\in[n]} q(x)e_j(x)e_k(x) + 2s^2\|q\|_2^2\\
&+ 4s\sum_{j=1}^{s}\sum_{x\in[n]} (-1)^{x\in B}q(x)e_j(x) + 2\sum_{j=1}^{s}\sum_{x\in[n]} e_j(x)^2 + 2\sum_{j\neq k}\sum_{x\in[n]} e_j(x)e_k(x)\\
&+ 4\sum_{j=1}^{s}\sum_{x\in[n]} (-1)^{x\in B}e_j(x)^3 + 12\sum_{j\neq k}\sum_{x\in[n]} (-1)^{x\in B}e_j(x)^2e_k(x)\\
&+ 4\sum_{j\neq k\neq \ell}\sum_{x\in[n]} (-1)^{x\in B}e_j(x)e_k(x)e_\ell(x) + \left(\sum_{j=1}^{s}\sum_{x\in[n]} e_j(x)^4 + 6\sum_{j\neq k\neq \ell} e_j(x)^2e_k(x)e_\ell(x)\right.\\
&\left.+ 4\sum_{j\neq k} e_j(x)^3e_k(x) + 3\sum_{j\neq k} e_j(x)^2e_k(x)^2 + \sum_{j\neq k\neq \ell\neq t} e_j(x)e_k(x)e_\ell(x)e_t(x)\right).
\end{aligned}$$

We now simplify the above expression. First note that

$$\begin{aligned}
&4s\sum_{j=1}^{s}\sum_{x\in[n]} q(x)e_j(x)^2 + 4s\sum_{j\neq k}\sum_{x\in[n]} q(x)e_j(x)e_k(x)\\
&= 4s\sum_{x\in[n]} q(x)\left(\sum_{j=1}^{s} e_j(x)^2 + \sum_{j\neq k} e_j(x)e_k(x)\right) = 4s\sum_{x\in[n]} q(x)\left(\sum_{j=1}^{s} e_j(x)\right)^2\\
&\leq 4s\|q\|_2\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_4^2.
\end{aligned}$$

Furthermore,

$$\begin{aligned}
&2s^2\|q\|_2^2 + 4s\sum_{j=1}^{s}\sum_{x\in[n]} (-1)^{x\in B}q(x)e_j(x) + 2\sum_{j=1}^{s}\sum_{x\in[n]} e_j(x)^2 + 2\sum_{j\neq k}\sum_{x\in[n]} e_j(x)e_k(x)\\
&= 2\sum_{j\neq k}\sum_{x\in[n]} (q(x) + (-1)^{x\in B}e_j(x))(q(x) + (-1)^{x\in B}e_k(x))\\
&= 2\|\vec{\mathbf{p}}_1 + \cdots \vec{\mathbf{p}}_s\|_2^2
\end{aligned}$$

and

$$\begin{aligned}
&4\sum_{j=1}^{s}\sum_{x\in[n]} (-1)^{x\in B}e_j(x)^3 + 12\sum_{j\neq k}\sum_{x\in[n]} (-1)^{x\in B}e_j(x)^2e_k(x)\\
&+ 4\sum_{j\neq k\neq \ell}\sum_{x\in[n]} (-1)^{x\in B}e_j(x)e_k(x)e_\ell(x)\\
&\leq 4\left(\sum_{j=1}^{s}\sum_{x\in[n]} e_j(x)^3 + 3\sum_{j\neq k}\sum_{x\in[n]} e_j(x)^2e_k(x) + \sum_{j\neq k\neq \ell}\sum_{x\in[n]} e_j(x)e_k(x)e_\ell(x)\right)\\
&= 4\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_3^3.
\end{aligned}$$

Finally, the last expression inside the parenthesis in the expression for $\sum_{x\in[n]} \mathbf{E}[Z_x^2]$ which is:

$$\sum_{j=1}^{s}\sum_{x\in[n]} e_j(x)^4 + 6\sum_{j\neq k\neq \ell} e_j(x)^2 e_k(x) e_\ell(x) + 4\sum_{j\neq k} e_j(x)^3 e_k(x) + 3\sum_{j\neq k} e_j(x)^2 e_k(x)^2 + \sum_{j\neq k\neq \ell\neq t} e_j(x)e_k(x)e_\ell(x)e_t(x)$$

is precisely $\sum_{x\in[n]} \left(\sum_{j=1}^{s} e_j(x)\right)^4$. Therefore, we obtain the following bound:

$$\sum_{x\in[n]} \mathbf{E}[Z_x^2] \leq 4s\|q\|_2 \left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2 + 2\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3 + \sum_{x\in[n]}\left(\sum_{j=1}^{s} e_j(x)\right)^4.$$

Using the calculation for $\mathbf{E}[Z_x]$ that we performed for Lemma 12, we see that:

$$\sum_{x\in[n]} \mathbf{E}[Z_x]^2 = \sum_{x\in[n]}\left(\sum_{j=1}^{s} e_j(x)^2 + \sum_{j\neq k} e_j(x)e_k(x)\right)^2 = \sum_{x\in[n]}\left(\sum_{j=1}^{s} e_j(x)\right)^4$$

so altogether,

$$\mathbf{Var}[Z] \leq 4s\|q\|_2 \left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2 + 2\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3,$$

as desired. ◀

▶ Remark 15. As stated in Section 4.3, the quantity $\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2$ is a natural generalization of $s^2\|q-p\|_2^2$ which appears in the variance calculations of the statistic used by identity testers in the single distribution setting where samples come from a fixed distribution p. Similarly, the quantity $\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2$ is a natural generalization of $s^2\|p\|_2^2$ which also appears in these calculations.

5 Closeness Testing with Multiple Sources

in this section, we present our algorithm for closeness testing with multiple sources and its analysis. Recall that our goal is to distinguish the following two cases with probability at least 2/3:

- **Completeness case:** $p_1, p_2, \cdots$ are identical to q
- **Soundness case:** $p_1, p_2, \cdots$ are all ϵ-far from q in ℓ_1-distance

where we have access to two streams. In the first stream, all samples are i.i.d. from some fixed distribution q over $[n]$ that is unknown to us while in the second stream, we receive samples from $\{p_i\}_{i=1}^{s}$. In the soundness case, we also assume that the p_i's satisfy the *structural condition* given in Definition 1: we assume there are disjoint sets A and B that partition $[n]$ such that all p_i's are larger than q on the indices in A, and all the p_i's are smaller than q on the indices in B. Note that the *structural condition* is trivially satisfied in the completeness case.

5.1 Algorithm for Closeness Testing

We now present our algorithm, Closeness-Tester, for closeness testing with multiple sources. Overall, our approach is very similar to our approach in Section 4. As in the identity testing section, we again make the assumption that we are able to receive Poi(1) samples from each of the distributions p_i. This is a generalization of the standard assumption in the single source closeness testing [10, 16] and it significantly simplifies the analysis of our algorithm by making certain random variables independent, similar to the identity testing section. Furthermore, as Poi(s) is tightly concentrated around s, we can carry out this poissonization method at the expense of only constant factor increases in the sample complexity.

As in the identity testing section, the statistic calculated by our algorithm is introduced in [10, 16]. We show that the expected value of our statistic is related to the "ℓ_2-norm" of the difference of the distributions, as explained in Section 2.3. If the value of the statistic is "large" compared to some threshold τ, the algorithm outputs reject and outputs accept otherwise. As in uniformity testing, the challenge is to show that the value of this statistic concentrates which we do so by analyzing its variance. Ultimately, we prove that the sample complexity of our generalized identity tester depends on the ℓ_2-norm of q, the distribution that we have i.i.d. sample access from. We then present a randomized flattening procedure in Section 5.2 which shows how to reduce the ℓ_2-norm of q to $O(1/\sqrt{k})$ where k is a parameter in our algorithm. This randomized flattening procedure is slightly different than the one used in Section 4.2 since we do not know q in advance. Therefore, we must use some samples from q to towards this procedure. We present our algorithm below along with the main theorem, Theorem 16, which proves the correctness of our algorithm.

Algorithm 3 Closeness-Tester.

Input : n, ϵ, sample access to q, Poi(1) samples from each of $p_1, p_2, \cdots, p_s$
Output : Accept or Reject

$k \leftarrow \frac{n^{2/3}}{\epsilon^{4/3}}$
Draw Poi(k) samples from q to perform the randomized flattening procedure given in Section 5.2.
$s \leftarrow \frac{c_1 n}{\epsilon^2 \sqrt{k}}$
Draw Poi(s) samples from q.
Draw Poi(1) samples from each of the s distributions $\{p_j\}_{j=1}^s$.
$Y_x \leftarrow$ # times we see element $x \in [n]$ among the Poi(s) samples from q
$T_x \leftarrow$ # times we see element $x \in [n]$ among the samples from $\{p_j\}_{j=1}^s$.
$\tau \leftarrow \frac{5s^2\epsilon^2}{8n}$
$Z \leftarrow \sum_{x\in[n]} (T_x - Y_x)^2 - T_x - Y_x$
if $Z \geq \tau$ **then**
    Output reject and abort.
Output accept

▶ **Theorem 16** (Correctness of Closeness-Tester)**.** *There exist a constant c_1 independent of n such that the following statements hold with probability 2/3:*

- Closeness-Tester *outputs accept if each of the s distributions $p_1, \cdots, p_s$ are q.*
- Closeness-Tester *outputs reject if each of the p_i's are ϵ-far from q ($\|p_i - q\|_1 \geq \epsilon$) and $\{p_i\}_{i=1}^s$ satisfy the structural condition given in Definition 1.*

▶ Remark 17. The sample complexity of Closeness-Tester is $\Theta(k + n/(\epsilon^2\sqrt{k}))$ using the flattening procedure of Section 5.2. Optimizing in k, the sample complexity of **Closeness-Tester** reduces to $\Theta(n^{2/3}/\epsilon^{4/3} + \sqrt{n}/\epsilon^2)$ which is optimal since the same lower bound holds for closeness testing in the standard single distribution setting [16].

▶ Remark 18. Note that given the above result, we may need fewer sources as long as we have more samples from the distribution q. In particular, suppose we use $k_1 = \Theta\left(\min\left(n^{2/3}/\epsilon^{4/3} + \sqrt{n}/\epsilon^2, n\right)\right)$ samples from q for flattening, which implies that the ℓ_2-norm of the "flattened" q is $O(1/\sqrt{k_1})$ with high probability. Then, we can use $s = \Theta(n/(\sqrt{k_1}\,\epsilon^2) + \sqrt{n}/\epsilon^2)$ sources, and $\Theta(s)$ samples from the "flattened" q and use **Closeness-Tester** to distinguish between the completeness and the soundness case. This is an sample-optimal trade off up to constant factors since the same lower bound holds in the standard single distribution setting [16].

Overview of the proof. To prove the correctness of Closeness-Tester, we analyze the statistic

$$Z = \sum_{x\in[n]} (T_x - Y_x)^2 - T_x - Y_x$$

where T_x denote the number of times we observe element x among the samples from $\{p_i\}_{i=1}^s$ and Y_x denotes the number of times we see element x among the $\mathrm{Poi}(s)$ samples from q. Note that by the poissonization method, T_x is a Poisson random variable with parameter $\lambda_x = \sum_{j=1}^s p_j(x)$, similar to the identity testing section. Furthermore, T_x and T_y are independent for $x \neq y$ and furthermore, Y_x is a Poisson random variable with parameter $s\,q(x)$. Our goal is to show Z is below the threshold τ in the completeness case, and above the threshold in the soundness case. To do so, we make use of the *structural condition* to first define a convenient representation of $\mathbf{E}[Z]$ in Lemma 19. We then show a strong concentration around its expectation by bounding the variance of Z in Lemma 20. These two lemmas are very similar to the ones proved in Section 4 due to the similarity of the statistic Z used here and in Section 4. Finally, we show that Z is always on the desired side of the threshold proving the correctness of our algorithm.

Proof of Theorem 16. Note that we set the number of samples to be $c_1 n/(\epsilon^2\sqrt{k})$ for a sufficiently large constant c_1, and the threshold τ to be equal to $5s^2\epsilon^2/(8n)$. We begin by stating a convenient representation of $\mathbf{E}[Z]$. To motivate our calculations, note that for a fixed x,

$$\begin{aligned}\mathbf{E}[(T_x - Y_x)^2 - T_x - Y_x] &= \mathbf{E}[T_x^2] - \mathbf{E}[T_x] + \mathbf{E}[Y_x^2] - \mathbf{E}[Y_x] - 2\mathbf{E}[Y_x]\mathbf{E}[T_x] \\ &= \lambda_x^2 - 2sq(x)\lambda_x + s^2q(x)^2\end{aligned}$$

where we have used the fact that T_x and Y_x are Poisson random variables with parameters $\lambda_x = \sum_{j=1}^s p_j(x)$ and $sq(x)$ respectively. Now using the *structural condition*, we can define error terms similar to Sections 3 and 4. For each distribution p_j, we define

$$\begin{aligned} e_j(x) &= p_j(x) - q(x) \qquad \forall x \in A \\ e_j(x) &= q(x) - p_j(x) \qquad \forall x \in B. \end{aligned}$$

After plugging in $e_j(x)$ for for all x into our expression for λ_x, we again get terms of the form $\sum_j e_j(x)^2$ and cross terms $\sum_{j\neq k} e_j(x)e_k(x)$, similar to the proof of Theorem 9. Our goal is to combine these terms into a more useful representation. We precisely show this in

Lemma 19 where we prove that $\mathbf{E}[Z]$ is given by $\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$ where we interpret the vector $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ as the vector with entries $e_j(x) = |q(x) - p_j(x)|$. Note that this is a natural generalization of the quantity $s^2\|q - p\|_2^2$. More formally, we have the following lemma which we prove in Section 5.3.

▶ **Lemma 19.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that satisfy the structural condition given in Definition 1. Suppose we draw* $\mathrm{Poi}(1)$ *samples from each p_i and* $\mathrm{Poi}(s)$ *samples from q and let T_x be the number of times we see element $x \in [n]$ among the samples among the p_i, and let Y_x be the number of times we see element $x \in [n]$ among the samples from q. Let $Z = \sum_{x\in[n]}(T_x - y_x)^2 - T_x - Y_x$. Then*

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$$

where $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ has coordinates $|q(x) - p_j(x)|$.

We now give a tight upper bound for the variance of our statistic Z. Defining $Z_x = (T_x - Y_x)^2 - T_x - Y_x$ and recalling the poissonization method, we see that

$$\mathbf{Var}[Z] = \sum_{x\in[n]} \mathbf{Var}[Z_x] = \sum_{x\in[n]} \mathbf{E}[Z_x^2] - \mathbf{E}[Z_x]^2.$$

Expanding Z_x^2, we get terms involving λ_x^k for $k \in \{1, 2, 3, 4\}$. Combining these terms, we again get an upper bound of $\mathbf{Var}[Z]$ in terms of the vectors $\vec{\mathbf{e}}_j$. Formally, we prove the following lemma in Section 5.4.

▶ **Lemma 20.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that satisfy the structural condition given in Definition 1. Suppose we draw* $\mathrm{Poi}(1)$ *samples from each p_i and* $\mathrm{Poi}(s)$ *samples from q and let T_x be the number of times we see element $x \in [n]$ among the samples among the p_i, and let Y_x be the number of times we see element $x \in [n]$ among the samples from q. Let $Z = \sum_{x\in[n]}(T_x - y_x)^2 - T_x - Y_x$. Then*

$$\mathrm{Var}(Z) \le 8s\|q\|_2 \left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_4^2 + 8\left\|\sum_{j=1}^s \vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_3^3$$

where $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ has coordinates $|q(x) - p_j(x)|$ and $\vec{\mathbf{p}}_j \in \mathbb{R}^n$ has coordinates $p_j(x)$.

We can now proceed to the proof of the theorem in the completeness case.

Proof of the Completeness Case. In this case, Lemma 19 gives us $\mathbf{E}[Z] = 0$ and Lemma 20 gives us $\mathbf{Var}[Z] \le 8s^2\|q\|_2^2$. Therefore by Chebyshev's inequality,

$$\Pr[|Z| \ge \tau] = \Pr\left[|Z| \ge \frac{s^2\epsilon^2}{4n}\right] \le \frac{128s^2\|q\|_2^2 n^2}{s^4\epsilon^4} = \frac{128\|q\|_2^2 n^2}{s^2\epsilon^4}.$$

The right hand side of the above inequality can be made arbitrarily small by letting $s = c_1 n\|q\|_2/\epsilon^2$ for a sufficiently large constant c_1. Due to our randomized flattening procedure of Section 5.2, we can assume that $\|q\| = O(1/\sqrt{k})$. Therefore, we can make the above probability bound arbitrarily small by letting $s = c_1 n/(\epsilon^2\sqrt{k})$ for a sufficiently large constant c_1.

Proof of the Soundness Case. In this case,

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2 = \sum_{x\in[n]} \left(\sum_{j=1}^s e_j(x)\right)^2 \ge \frac{1}{n}\left(\sum_{j=1}^s \sum_{x\in[n]} e_j(x)\right)^2 \ge \frac{s^2\epsilon^2}{n}$$

where the first inequality is Cauchy-Schwarz and the last inequality follows from our assumption about the error terms $e_j(x)$ in the soundness case. Then by Chebyshev's inequality,

$$\Pr\left[|Z - \mathbf{E}[Z]| \geq \frac{\mathbf{E}[Z]}{4}\right] \leq \frac{16\mathbf{Var}[Z]}{\mathbf{E}[Z]^2}$$
$$\leq \frac{8s\|q\|_2 \left\|\sum_{j=1}^{s} \vec{\mathbf{e}}_j\right\|_4^2}{\left\|\sum_{j=1}^{s} \vec{\mathbf{e}}_j\right\|_2^4} + \frac{8\left\|\sum_{j=1}^{s} \vec{\mathbf{p}}_j\right\|_2^2}{\left\|\sum_{j=1}^{s} \vec{\mathbf{e}}_j\right\|_2^4} + \frac{4\left\|\sum_{j=1}^{s} \vec{\mathbf{e}}_j\right\|_3^3}{\left\|\sum_{j=1}^{s} \vec{\mathbf{e}}_j\right\|_2^4}.$$

Note that the right hand side of the above inequality is identical to the right hand side of Inequality (10) that appears in the probability calculation in the proof of Theorem 9. Using the identical bounds given there, we arrive at the following inequality:

$$\Pr\left[|Z - \mathbf{E}[Z]| \geq \frac{\mathbf{E}[Z]}{4}\right] \leq C\left(\frac{n\|q\|_2}{s\epsilon^2} + \left(\frac{n\|q\|}{s\epsilon^2}\right)^2 + \left(\frac{1}{s\|q\|_2}\right)^2 + \frac{\sqrt{n}}{s\,\epsilon}\right)$$

for some constant C. Note that if we let $s = c_1 n\|q\|_2/\epsilon^2$ for a sufficiently large constant c_1 and use the fact that $\|q\|_2 \geq 1/\sqrt{n}$, we have that the above probability is smaller than $1/3$. Again using the randomized flattening procedure of Section 5.2, we see that we can let $s = c_1 n/(\epsilon^2\sqrt{k})$. Hence with probability at least $2/3$, we know $Z \geq 3s^2\epsilon^2/(4n)$ in the soundness case so we reject with probability at least $2/3$, as desired. ◀

5.2 Randomized Flattening Procedure

in this section, we present our randomized flattening procedure. Let k be some fixed parameter (which is an input to **Closeness-Tester**). We show that we can assume that $\|q\|_2^2 = O(1/k)$ for Section 5 without loss of generality where q is the distribution that we have i.i.d. sample access to. This procedure is similar to the one used in [16] for single distribution closeness testing.

First, suppose that we draw $\mathrm{Poi}(k)$ i.i.d. samples from q. Then for each $x \in [n]$, define b_x to be the number of instances of element $x \in [n]$ that we see among these samples plus 1. Note the resemblance between this definition and the one given in the flattening procedure for identity testing in Section 4.2. Now given a sample x from a distribution p over $[n]$, we can get a sample from the "flattened" distribution p' over

$$\mathcal{D} = \{(x, y) \mid x \in [n], y \in [b_x]\}$$

by drawing an element from $y \in [b_x]$ uniformly at random and creating the tuple (x, y). This is the flattening procedure that we use for our generalized version closeness testing. Note that the probability mass over $[n]$ placed by p gets "flattened" to be a probability distribution over $\mathcal{D}$, hence the name. The size of this new domain is $n + k$. We can calculate that this procedure preserves the ℓ_1-distance:

$$\|q' - p'\|_1 = \sum_{x\in[n]} \sum_{y\in[b_x]} \frac{|q(x) - p(x)|}{|b_x|} = \sum_{x\in[n]} |q(x) - p(x)| = \|q - p\|_1.$$

Furthermore,

$$\mathbf{E}[\|q'\|_2^2] = \mathbf{E}\left[\sum_{x\in[n]} \sum_{y\in[b_x]} \frac{q(x)^2}{b_x^2}\right] \leq \sum_{x\in[n]} q(x)^2 \mathbf{E}\left[1/b_x\right].$$

By the poissonization method, we know that b_x is distributed as $1+Z$ where Z is a $\mathrm{Poi}(kq(x))$ random variable. Therefore, similar to [16], we have:

$$\mathbf{E}\left[1/(Z+1)\right] = \mathbf{E}\left[\int_0^1 s^z \, ds\right] = \int_0^1 \mathbf{E}[s^z] \, ds = \int_0^1 e^{kq(x)(s-1)} \, ds \leq \frac{1}{kq(x)}$$

where we have used the probability generating function for a Poisson random variable. This gives us

$$\mathbf{E}[\|q'\|_2^2] \leq \sum_{x\in[n]} \frac{q(x)}{k} \leq \frac{1}{k}.$$

Hence by Markov's inequality, we can say that $\|q'\|_2^2 = O(1/k)$ holds with an arbitrarily large, constant probability. Now whenever we get a sample over $[n]$, we can use this flattening procedure to draw a sample over $\mathcal{D}$. Furthermore, by using this flattening procedure to draw samples from a slightly larger domain, we can assume that $\|q\|_2^2 = O(1/k)$ in Section 5 at the expense of losing a negligible factor in our error probability.

Note that the size of the larger domain is $O(n+k) = O(n)$ if we pick $k \leq n$. Therefore, combining with Theorem 16, we show that we can perform closeness testing with multiple sources by using

$$O\left(k + \frac{n\|q\|_2}{\epsilon^2}\right) = O\left(k + \frac{n}{\epsilon^2\sqrt{k}}\right) = O\left(\frac{n^{2/3}}{\epsilon^{4/3}} + \frac{\sqrt{n}}{\epsilon^2}\right)$$

samples after optimizing the value of k. This sample complexity is optimal since a matching lower bound holds for the single distribution closeness testing setting.

5.3 Proof of Lemma 19

▶ **Lemma 19.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that satisfy the structural condition given in Definition 1. Suppose we draw* $\mathrm{Poi}(1)$ *samples from each p_i and* $\mathrm{Poi}(s)$ *samples from q and let T_x be the number of times we see element $x \in [n]$ among the samples among the p_i, and let Y_x be the number of times we see element $x \in [n]$ among the samples from q. Let $Z = \sum_{x\in[n]}(T_x - y_x)^2 - T_x - Y_x$. Then*

$$\mathbf{E}[Z] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2$$

where $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ has coordinates $|q(x) - p_j(x)|$.

Proof. Note that T_x is a Poisson random variable with parameter $\lambda_x = \sum_{j=1}^s p_j(x)$ and Y_x is a Poisson random variable with parameter $sq(x)$. Let

$$Z_x = (T_x - Y_x)^2 - T_x - Y_x.$$

We can compute that

$$\begin{aligned}\mathbf{E}[Z_x] &= \mathbf{E}[T_x^2] - \mathbf{E}[T_x] + \mathbf{E}[Y_x^2] - \mathbf{E}[Y_x] - 2\mathbf{E}[Y_x]\mathbf{E}[T_x] \\ &= \lambda_x^2 - 2sq(x)\lambda_x + s^2q(x)^2.\end{aligned}$$

This is the same as the expected value of the variable Z_x in Lemma 12. Therefore, the same computations hold and we arrive at

$$\mathbf{E}[Z] = \sum_{x\in[n]} \mathbf{E}[Z_x] = \|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_2^2,$$

as desired. ◀

5.4 Proof of Lemma 20

▶ **Lemma 20.** *Let $\{p_i\}_{i=1}^s$ be distributions over $[n]$ that satisfy the structural condition given in Definition 1. Suppose we draw* $\mathrm{Poi}(1)$ *samples from each p_i and* $\mathrm{Poi}(s)$ *samples from q and let T_x be the number of times we see element $x \in [n]$ among the samples among the p_i, and let Y_x be the number of times we see element $x \in [n]$ among the samples from q. Let $Z = \sum_{x\in[n]}(T_x - y_x)^2 - T_x - Y_x$. Then*

$$\mathrm{Var}(Z) \le 8s\|q\|_2 \left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_4^2 + 8\left\|\sum_{j=1}^s \vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^s \vec{\mathbf{e}}_j\right\|_3^3$$

where $\vec{\mathbf{e}}_j \in \mathbb{R}^n$ has coordinates $|q(x) - p_j(x)|$ and $\vec{\mathbf{p}}_j \in \mathbb{R}^n$ has coordinates $p_j(x)$.

Proof. Define

$$Z_x = (T_x - Y_x)^2 - T_x - Y_x.$$

Due to the independence of T_x and Y_x, we have

$$\mathrm{Var}(Z) = \sum_{x\in[n]} \mathrm{Var}(Z_x) = \sum_{x\in[n]} \mathbf{E}[Z_x^2] - \mathbf{E}[Z_x]^2.$$

Noting that T_x is Poisson with parameter $\lambda_x = \sum_{j=1}^s p_j(x)$ and Y_x is Poisson with parameter $sq(x)$, we can compute that

$$\begin{aligned}\mathbf{E}[Z_x^2] = {} & \lambda_x^4 + 4\lambda_x^3(1 - sq(x)) + 2\lambda_x^2(3s^2q(x)^2 - 2sq(x) + 1) \\ & + 4sq(x)\lambda_x(1 - sq(x) - s^2q(x)^2) + s^4q(x)^4 + 4s^3q(x)^3 + 2s^2q(x)^2.\end{aligned}$$

Using the formula for λ_x^k for $k \in \{1, 2, 3, 4\}$ given in Appendix A and simplifying, we arrive at the following expression:

$$\begin{aligned}\sum_{x\in[n]} \mathbf{E}[Z_x^2] = {} & 8s\sum_{j=1}^s \sum_{x\in[n]} q(x)e_j(x)^2 + 8s\sum_{j\neq k}\sum_{x\in[n]} q(x)e_j(x)e_k(x) + 8s^2\|q\|_2^2 \\ & + 8s\sum_{j=1}^s\sum_{x\in[n]}(-1)^{x\in B}q(x)e_j(x) + 2\sum_{j=1}^s\sum_{x\in[n]} e_j(x)^2 + 2\sum_{j\neq k}\sum_{x\in[n]} e_j(x)e_k(x) \\ & + 4\sum_{j=1}^s\sum_{x\in[n]}(-1)^{x\in B}e_j(x)^3 + 12\sum_{j\neq k}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)^2e_k(x) \\ & + 4\sum_{j\neq k\neq \ell}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)e_k(x)e_\ell(x) + \Bigg(\sum_{j=1}^s\sum_{x\in[n]} e_j(x)^4 + 6\sum_{j\neq k\neq \ell} e_j(x)^2e_k(x)e_\ell(x) \\ & + 4\sum_{j\neq k} e_j(x)^3e_k(x) + 3\sum_{j\neq k} e_j(x)^2e_k(x)^2 + \sum_{j\neq k\neq \ell\neq t} e_j(x)e_k(x)e_\ell(x)e_t(x)\Bigg).\end{aligned}$$

Similar to Lemma 13, we have

$$8s\sum_{j=1}^s\sum_{x\in[n]} q(x)e_j(x)^2 + 8s\sum_{j\neq k}\sum_{x\in[n]} q(x)e_j(x)e_k(x) \le 8s\|q\|_2\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_4^2,$$

and

$$8s^2\|q\|_2^2 + 8s\sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}q(x)e_j(x) + 2\sum_{j=1}^{s}\sum_{x\in[n]}e_j(x)^2 + 2\sum_{j\neq k}\sum_{x\in[n]}e_j(x)e_k(x)$$
$$\leq 8\|\vec{\mathbf{p}}_1 + \cdots \vec{\mathbf{p}}_s\|_2^2,$$

and finally,

$$4\sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)^3 + 12\sum_{j\neq k}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)^2e_k(x)$$
$$+ 4\sum_{j\neq k\neq \ell}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)e_k(x)e_\ell(x) = 4\|\vec{\mathbf{e}}_1 + \cdots + \vec{\mathbf{e}}_s\|_3^3.$$

As in Lemma 13, the last expression inside the parenthesis of $\mathbf{E}[Z_x^2]$ is precisely

$$\sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^4.$$

Therefore,

$$\sum_{x\in[n]}\mathbf{E}[Z_x^2] \leq 8s\|q\|_2\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2 + 8\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3 + \sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^4.$$

The same calculation as in Lemma 13 gives us

$$\sum_{x\in[n]}\mathbf{E}[Z_x]^2 = \sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)^2 + \sum_{j\neq k}e_j(x)e_k(x)\right)^2 = \sum_{x\in[n]}\left(\sum_{j=1}^{s}e_j(x)\right)^4$$

so altogether,

$$\mathrm{Var}(Z) \leq 8s\|q\|_2\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_4^2 + 8\left\|\sum_{j=1}^{s}\vec{\mathbf{p}}_j\right\|_2^2 + 4\left\|\sum_{j=1}^{s}\vec{\mathbf{e}}_j\right\|_3^3. \tag{13}$$

◀

6 Failure of de Finetti's Theorem with Sublinear Number of Samples

in this section, we prove Theorem 2. Recall the statement of Theorem 2.

▶ **Theorem 2.** *Let $s = O(\sqrt{n})$ be the number of samples required by Algorithm 1 for $\epsilon = 1/3$. There exists an exchangeable sequence $X_1, \ldots, X_s$ such that X_i is drawn from distribution q_i which are all supported in $[n]$ and satisfy $\|q_i - \mathcal{U}_n\|_1 \geq 1/3$ for all i. Furthermore, $\{q_i\}_{i=1}^s$ all satisfy the structural condition given in Definition 1 with $q = \mathcal{U}_n$. Let P denote the distribution of the sequence $X_1, \ldots, X_s$. Then P is $\Omega(1)$-far in ℓ_1-distance from any mixture of product distributions.*

Note that an algorithm can turn samples $Y_1, \cdots, Y_s$ into an exchangeable sequence $X_1, \cdots, X_s$ by permuting randomly. In this section, we given an example of samples $Y_1, \cdots, Y_s$ such that after permuting them to turn them into an exchangeable sequence

$X_1, \cdots, X_s$, the exchangeable sequence is "far" from a mixture of product distributions. The main idea behind Theorem 2 is based on Proposition 31 in [13]. Essentially, Diaconis and Freedman show in [13] that a Polya's urn process generates an exchangeable sequence that is far from the mixture of any product distributions. This example does not quite work in our case since we would like the *structural condition* to hold. Therefore, we adapt the Polya's urn idea by partitioning our domain into a "large" set and a "small" set. We then apply a Polya's urn type process on the small set so that no collisions can happen on it. This results in an event $\mathcal{E}_1$ which we use to lower bound the distance from the distribution of our exchangeable sequence to any mixture of product distributions. However, we need an additional event $\mathcal{E}_2$ to deal with the large set. Combining these two events allows us to prove Theorem 2. This overview is formalized below.

Proof of Theorem 2. Let $\epsilon = 1/3$ and let s be the number of samples required by our uniformity tester in Algorithm 1 for this value of ϵ. In particular, $s^2 = Cn$ for some constant $C > 10$ and define δ as $\delta = 1/C$. We now construct distributions $\{q_i\}_{i=1}^s$ as follows:

$$q_i(x) = \begin{cases} 1 - \delta/20 - s/n, & x = 1 \\ 1/n, & x \in \{2, \cdots, s+1\} \setminus \{i+1\} \\ \delta/20, & x = i+1. \end{cases}$$

Note that all distributions are supported only on $\{1, \cdots, s+1\}$. We can check that for large enough n, we have $\|q_i - \mathcal{U}_n\|_1 \geq 1/3$ for all i. We then draw sample Y_i independently from q_i. Note that $A = \{1, \cdots, s+1\}$ and $B = [n] \setminus \{1, \cdots, s+1\}$ for the *structural condition* in Definition 1. In other words, all the distributions are larger than uniform on A and smaller than uniform on B so $\{q_i\}_{i=1}^s$ satisfy the conditions of the theorem.

Now let $\{X_i\}_{i=1}^s$ be an exchangeable sequence derived from $\{Y_i\}_{i=1}^s$ (for example, by permuting them randomly). Let p be the distribution of $(X_1, \cdots, X_s)$. Consider the following two events:

$\mathcal{E}_1 =$ Event that $X_i = X_j \in \{2, \cdots, s+1\}$ for some $i \neq j$

$\mathcal{E}_2 =$ Event that at least $s(1 - \delta^2/2)$ of the X_i's are equal to 1.

We first compute $p(\mathcal{E}_1)$. Note that for any $i \neq j$, we have

$$\mathbb{P}(X_i = X_j \in \{2, \cdots, s+1\}) \leq \frac{\delta}{10n} + \frac{s}{n^2}.$$

Therefore by a union bound, the probability that there exists some $i \neq j$ such that $\mathcal{E}_1$ holds is at most

$$\frac{C\delta}{10} + \frac{s^3}{n^2} \leq \frac{1}{9}$$

for sufficiently large n. We now compute $p(\mathcal{E}_2)$. We know that $\mathbb{P}(X_i = 1) \leq 1 - \delta/20$ for all i. Therefore, the number of 1's among the X_i's is sum of s Bernoulli random variables with parameters at most $1 - \delta/20$ and hence, the expected number of 1's is at most $s(1 - \delta/20)$. Then by a Chernoff bound, we have $\mathbb{P}(\mathcal{E}_2) \leq 1/100$ if we take n (and therefore s) sufficiently large.

Now for a distribution p_k over $[n]$, we let p_k^s be the distribution of s independent picks from p_k. Let $M = \sum_k w_k p_k^s$ be any mixture of product distributions p_k^s. We wish to show that $\|p - M\|_1 = \Omega(1)$ for any M. Note that all of the $\{q_i\}_{i=1}^s$ are only supported on $\{1, \cdots, s+1\}$. Therefore, we can assume without loss of generality that the p_k is also supported only on $\{1, \cdots, s+1\}$ for all k. Now consider a single p_k^s. We consider two cases.

Case 1: $p_k(\{2, \cdots, s+1\}) \geq \delta^2$. In this case, let Z be the number of collisions among elements in $\{2, \cdots, s+1\}$ if we draw s independent samples from p_k. We have

$$\mathbf{E}[Z] = \binom{s}{2} \sum_{i \in \{2,\cdots,s\}} p_k(i)^2.$$

Define $\sum_{i\in\{2,\cdots,s\}} p_k(i)^2 = \|\widetilde{p_k}\|_2^2$. Using standard calculations as in the single distribution uniformity testing case, see [23, 6], we can compute

$$\mathbf{Var}[Z] \leq 4\left(\binom{s}{2}\|\widetilde{p_k}\|_2^2\right)^{3/2}.$$

Hence by Chebyshev's inequality,

$$\mathbb{P}(Z=0) \leq \mathbb{P}(|Z - \mathbf{E}[Z]| \geq \mathbf{E}[Z]) \leq \frac{4\binom{s}{2}^{3/2}\|\widetilde{p_k}\|_2^3}{\binom{s}{2}^2\|\widetilde{p_k}\|_2^4} \leq \frac{C'}{s\|\widetilde{p_k}\|_2}$$

for some absolute constant C'. Now by Cauchy Schwarz,

$$\|\widetilde{p_k}\|_2 \geq \frac{\delta^2}{\sqrt{s}}$$

so we have $\mathbb{P}(Z=0) \leq 1/100$ for sufficiently large n. Therefore, $p_k^s(\mathcal{E}_1) \geq 99/100$.

Case 2: $p_k(\{2, \cdots, s+1\}) < \delta^2$. In this case, we have $p_k(1) \geq 1 - \delta^2$. Therefore, if we draw s samples from p_k, the number of 1's that we will see is at least $s(1-\delta^2)$ in expectation. By Chernoff, the probability that we see less than $s(1-\delta^2/2)$ number of 1's is at at most $1/100$ for sufficiently large n. Hence, $p_k^s(\mathcal{E}_2) \geq 99/100$.
Now note that

$$\|p - M\|_1 = 2\|p - M\|_{TV} \geq |P(\mathcal{E}_1) - M(\mathcal{E}_1)| + |p(\mathcal{E}_2) - M(\mathcal{E}_2)|.$$

We have

$$|p(\mathcal{E}_1) - M(\mathcal{E}_1)| \geq \sum_{k|p_k \in \text{Case 1}} w_k p_k^s(\mathcal{E}_1) - \frac{1}{9} \geq \frac{99}{100} \sum_{k|p_k\in\text{Case 1}} w_k - \frac{1}{9}.$$

Similarly,

$$|p(\mathcal{E}_2) - M(\mathcal{E}_2)| \geq \sum_{k|p_k \in \text{Case 2}} w_k p_k^s(\mathcal{E}_2) - \frac{1}{100} \geq \frac{99}{100} \sum_{k|p_k\in\text{Case 2}} w_k - \frac{1}{100}.$$

Hence we have that

$$\|p - M\|_1 \geq \frac{99}{100}\left(\sum_k w_k\right) - \left(\frac{1}{9} + \frac{1}{100}\right) \geq \Omega(1).$$

Since M was arbitrary, we are done. Hence, p is $\Omega(1)$-far from any mixture of product distributions. ◀

A Moment Calculations of Sections 4 and 5

In this section, we calculate the moments of random variables that appear in Section 4 and Section 5. Suppose we have distributions q and $p_1, \cdots, p_s$ such that there exist subsets A and $B = [n] \setminus A$ with the property that $p_j(x) \geq q(x)$ for all $x \in A$ and all j and $p_j(x) \leq q(x)$ for all $x \in B$ and all j. Now, let T_x be a Poisson random variable with parameter

$$\lambda_x = \sum_{j=1}^{s} p_j(x).$$

We compute $\sum_{x\in[n]} \lambda_x^k$ for $k \in \{1,2,3,4\}$. We note that

$$\sum_{x\in[n]} \lambda_x = \sum_{j=1}^{s} \sum_{x\in[n]} (q(x) + (-1)^{x\in B} e_j(x)) \tag{14}$$

We now compute $\sum_{x\in[n]} \lambda_x^2$. We use the notation $(-1)^{x\in B}$ as follows:

$$(-1)^{x\in B} = \begin{cases} -1 & \text{if } x \in B \\ 1 & \text{if } x \notin B \end{cases}.$$

Note that:

$$\sum_{x\in[n]} \lambda_x^2 = \sum_{x\in[n]} \left(\sum_{j=1}^{s} p_j(x)\right)^2 = \sum_{x\in[n]} \left(\sum_{j=1}^{s} p_j(x)^2 + \sum_{j\neq k} p_j(x)p_k(x)\right).$$

For fixed j and k, we can compute that:

$$p_j(x)^2 = q(x)^2 + 2(-1)^{x\in B} q(x)e_j(x) + e_j(x)^2\,,$$

and we have:

$$p_j(x)p_k(x) = q(x)^2 + (-1)^{x\in B}(q(x)e_k(x) + q(x)e_j(x)) + e_j(x)e_k(x)\,.$$

Putting everything together, we obtain:

$$\begin{aligned}\sum_{x\in[n]} \lambda_x^2 = s^2||q||_2^2 + 2s \sum_{j=1}^{s} \sum_{x\in[n]} (-1)^{x\in B} q(x)e_j(x) \\ + \sum_{j=1}^{s} \sum_{x\in[n]} e_j(x)^2 + \sum_{j\neq k} \sum_{x\in[n]} e_j(x)e_k(x).\end{aligned} \tag{15}$$

We now compute $\sum_{x\in[n]} \lambda_x^3$. For a fixed x, we have:

$$\lambda_x^3 = \left(\sum_{j=1}^{s} p_j(x)\right)^3 = \sum_{j=1}^{s} p_j(x)^3 + 3\sum_{j\neq k} p_j(x)^2 p_k(x) + \sum_{j\neq k\neq \ell} p_j(x)p_k(x)p_\ell(x).$$

Now for a fixed j,

$$\begin{aligned}&p_j(x)^3 = (q(x) + (-1)^{x\in B} e_j(x))^3 \\ &= q(x)^3 + 3(-1)^{x\in B} q(x)^2 e_j(x) + 3q(x)e_j(x)^2 + (-1)^{x\in B} e_j(x)^3,\end{aligned}$$

while for fixed $j \neq k$,

$$\begin{aligned}p_j(x)^2 p_k(x) &= (q(x) + (-1)^{x\in B} e_j(x))^2 (q(x) + (-1)^{x\in B} e_k(x)) \\ &= q(x)^3 + (-1)^{x\in B} q(x)^2 (2e_j(x) + e_k(x)) + (-1)^{x\in B} e_j(x)^2 e_k(x) \\ &\quad + q(x)(e_j(x)^2 + 2e_j(x)e_k(x) + e_k^2(x)),\end{aligned}$$

and finally for $j \neq k \neq \ell$, we have:

$$\begin{aligned}&p_j(x)p_k(x)p_\ell(x) = (q(x) + (-1)^{x\in B} e_j(x))(q(x) + (-1)^{x\in B} e_k(x))(q(x) + (-1)^{x\in B} e_\ell(x)) \\ &= q(x)^3 + (-1)^{x\in B} q(x)^2 (e_j(x) + e_k(x) + e_\ell(x)) + (-1)^{x\in B} e_j(x)e_k(x)e_\ell(x) \\ &+ q(x)(e_j(x)e_k(x) + e_k(x)e_\ell(x) + e_j(x)e_\ell(x)).\end{aligned}$$

Putting everything together, we have

$$\begin{aligned}\sum_{x\in[n]}\lambda_x^3 = s^3\|q\|_3^3 + 3s^2\sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}q(x)^2e_j(x) + 3\sum_{j=1}^{s}\sum_{x\in[n]}q(x)e_j(x)^2 \\ + 3s\sum_{j\neq k}\sum_{x\in[n]}q(x)e_j(x)e_k(x) + 3\sum_{j\neq k}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)^2e_k(x) \\ + \sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)^3 + \sum_{j\neq k\neq \ell}\sum_{x\in[n]}(-1)^{x\in B}e_j(x)e_k(x)e_\ell(x). \qquad (16)\end{aligned}$$

We now compute $\sum_{x\in[n]}\lambda_x^4$. We have

$$\begin{aligned}\lambda_x = \left(\sum_{j=1}^{s}p_j(x)\right)^4 = \sum_{j=1}^{s}p_j(x)^4 + 3\sum_{j\neq k}p_j(x)^2p_k(x)^2 + 4\sum_{j\neq k}p_j(x)^3p_k(x) \\ + 6\sum_{j\neq k\neq \ell}p_j(x)^2p_k(x)p_\ell(x) + \sum_{j\neq k\neq \ell\neq t}p_j(x)p_k(x)p_\ell(x)p_t(x).\end{aligned}$$

We first analyze $p_j(x)^4$ for a fixed j. We have:

$$\begin{aligned}p_j(x)^4 = (q(x)+(-1)^{x\in B}e_j(x))^4 = q(x)^4 + 4(-1)^{x\in B}q(x)^3e_j(x) + 6q(x)^2e_j(x)^2 \\ + 4(-1)^{x\in B}q(x)e_j(x)^3 + e_j(x)^4.\end{aligned}$$

Then for fixed $j\neq k$, we have:

$$\begin{aligned}p_j(x)^2p_k(x)^2 &= (q(x)+(-1)^{x\in B}e_j(x))^2(q(x)+(-1)^{x\in B}e_k(x))^2 \\ &= q(x)^4 + (-1)^{x\in B}q(x)^3(2e_j(x)+2e_k(x)) \\ &+ q(x^2(e_j(x)^2 + 4e_j(x)e_k(x) + e_k(x)^2) \\ &+ (-1)^{x\in B}q(x)(2e_j(x)^2e_k(x) + 2e_j(x)e_k(x)^2) + e_j(x)^2e_k(x)^2\,,\end{aligned}$$

and, we can get:

$$\begin{aligned}p_j(x)^3p_k(x) &= (q(x)+(-1)^{x\in B}e_j(x))^3(q(x)+(-1)^{x\in B}e_k(x)) \\ &= q(x)^4 + (-1)^{x\in B}q(x)^3(e_j(x)+e_k(x)) + q(x)^2(3e_j(x)^2 + 3e_j(x)e_k(x)) \\ &+ (-1)^{x\in B}q(x)(e_j(x)^3 + 3e_j(x)^2e_k(x)) + e_j(x)^3e_k(x).\end{aligned}$$

Furthermore, for fixed $j\neq k\neq \ell$, we have:

$$\begin{aligned}&p_j(x)^2p_k(x)p_\ell(x) \\ &= (q(x)+(-1)^{x\in B}e_j(x))^2(q(x)+(-1)^{x\in B}e_k(x))(q(x)+(-1)^{x\in B}e_\ell(x)) \\ &= q(x)^4 + (-1)^{x\in B}q(x)^3(2e_j(x)+e_\ell(x)+e_k(x)) \\ &+ q(x)^2(e_j(x)^2 + 2e_j(x)e_k(x) + 2e_j(x)e_\ell(x) + e_k(x)e_\ell(x)) \\ &+ (-1)^{x\in B}q(x)(e_j(x)^2e_\ell(x) + e_j(x)^2e_k(x) + 2e_j(x)e_k(x)e_\ell(x)) \\ &+ e_j(x)^2e_k(x)e_\ell(x).\end{aligned}$$

Finally, for fixed $j \neq k \neq \ell \neq t$, we have:

$$
\begin{aligned}
&p_j(x)p_k(x)p_\ell(x)p_t(x)\\
&= (q(x) + (-1)^{x\in B}e_j(x))(q(x) + (-1)^{x\in B}e_k(x))\\
&\cdot (q(x) + (-1)^{x\in B}e_\ell(x))(q(x) + (-1)^{x\in B}e_t(x))\\
&= q(x)^4 + (-1)^{x\in B}q(x)(e_j(x) + e_k(x) + e_\ell(x) + e_t(x))\\
&+ q(x)^2(e_j(x)e_k(x) + e_j(x)e_\ell(x) + e_j(x)e_t(x) + e_k(x)e_\ell(x) + e_k(x)e_t(x) + e_\ell(x)e_t(x))\\
&+ (-1)^{x\in B}q(x)(e_j(x)e_k(x)e_\ell(x) + e_j(x)e_k(x)e_t(x) + e_j(x)e_t(x)e_\ell(x) + e_k(x)e_\ell(x)e_t(x))\\
&+ e_j(x)e_k(x)e_\ell(x)e_t(x).
\end{aligned}
$$

Altogether, we have:

$$
\begin{aligned}
&\sum_{x\in[n]} \lambda_x^4\\
&= s^4\|q\|_4^4 + \sum_{x\in[n]}\sum_{j=1}^{s} e_j(x)^4 + 6s^2\sum_{j=1}^{s}\sum_{x\in[n]} q(x)^2e_j(x)^2 + 4s\sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}q(x)e_j(x)^3\\
&+ 4s^3\sum_{j=1}^{s}\sum_{x\in[n]}(-1)^{x\in B}q(x)^3e_j(x) + 6s^2\sum_{j\neq k}\sum_{x\in[n]} q(x)^2e_j(x)e_k(x)\\
&+ 12s\sum_{j\neq k}\sum_{x\in[n]}(-1)^{x\in B}q(x)e_j(x)^2e_k(x) + 4s\sum_{j\neq k\neq \ell}\sum_{x\in[n]}(-1)^{x\in B}q(x)e_j(x)e_k(x)e_\ell(x)\\
&+ 6\sum_{j\neq k\neq \ell} e_j(x)^2e_k(x)e_\ell(x) + 4\sum_{j\neq k}\sum_{x\in[n]} e_j(x)^3e_k(x) + 3\sum_{j\neq k}\sum_{x\in[n]} e_j(x)^2e_k(x)^2\\
&+ \sum_{j\neq k\neq \ell\neq t} e_j(x)e_k(x)e_\ell(x)e_t(x). \qquad (17)
\end{aligned}
$$

Beyond Natural Proofs: Hardness Magnification and Locality

Abstract

Hardness magnification reduces major complexity separations (such as $\mathsf{EXP} \not\subseteq \mathsf{NC}^1$) to proving lower bounds for some natural problem Q against weak circuit models. Several recent works [42, 36, 13, 39, 12, 38, 10] have established results of this form. In the most intriguing cases, the required lower bound is known for problems that appear to be significantly easier than Q, while Q itself is susceptible to lower bounds but these are not yet sufficient for magnification.

In this work, we provide more examples of this phenomenon, and investigate the prospects of proving new lower bounds using this approach. In particular, we consider the following essential questions associated with the hardness magnification program:

- *Does hardness magnification avoid the natural proofs barrier of Razborov and Rudich* [46]*?*
- *Can we adapt known lower bound techniques to establish the desired lower bound for* Q*?*

We establish that some instantiations of hardness magnification overcome the natural proofs barrier in the following sense: slightly superlinear-size circuit lower bounds for certain versions of the minimum circuit size problem MCSP imply the non-existence of natural proofs. As a corollary of our result, we show that certain magnification theorems not only imply strong worst-case circuit lower bounds but also rule out the existence of efficient learning algorithms.

Hardness magnification might sidestep natural proofs, but we identify a source of difficulty when trying to adapt existing lower bound techniques to prove strong lower bounds via magnification. This is captured by a *locality barrier*: existing magnification theorems *unconditionally* show that the problems Q considered above admit highly efficient circuits extended with small fan-in oracle gates, while lower bound techniques against weak circuit models quite often easily extend to circuits containing such oracles. This explains why direct adaptations of certain lower bounds are unlikely to yield strong complexity separations via hardness magnification.

1 Introduction

Proving circuit size lower bounds for explicit Boolean functions is a central problem in Complexity Theory. Unfortunately, it is also notoriously hard, and arguments ruling out a wide range of approaches have been discovered. The most prominent of them is the *natural proofs barrier* of Razborov and Rudich [46].

A candidate approach for overcoming this barrier was investigated recently by Oliveira and Santhanam [42]. *Hardness Magnification* identifies situations where strong circuit lower bounds for explicit Boolean functions (e.g. $\mathsf{NP} \not\subseteq \mathsf{P/poly}$) follow from much weaker (e.g. slightly superlinear) lower bounds for specific natural problems. As discussed in [42], in some cases the lower bounds required for magnification are already known for explicit problems, but not yet for the problem for which the magnification theorem holds. This approach to lower bounds has attracted the interest of several researchers, and a number of recent works have proved magnification results [36, 13, 39, 12, 38, 10] (see also [50, 3, 35, 37] for related previous work). We provide a concise review of existing results in Appendix A.1.

In this work, we are interested in understanding the prospects of proving new lower bounds using hardness magnification, including potential barriers.

1.1 Hardness Magnification Frontiers

While hardness magnification is a broad phenomenon, its most promising instantiations seem to occur in the setting of circuit classes such as NC^1. The potential of hardness magnification stems from establishing the following scenario.

> **HM Frontier:** There is a natural problem Q and a computational model $\mathcal{C}$ such that:
>
> 1. (*Magnification*) $Q \notin \mathcal{C}$ implies $\mathsf{NP} \not\subseteq \mathsf{NC}^1$ or a similar breakthrough.
> 2. (*Evidence of Hardness*) $Q \notin \mathcal{C}$ under a standard conjecture.
> 3. (*Lower Bound against* $\mathcal{C}$) $L \notin \mathcal{C}$, where L is a simple function like PARITY.
> 4. (*Lower Bound for* Q) $Q \notin \mathcal{C}^-$, where $\mathcal{C}^-$ is slightly weaker than $\mathcal{C}$.

A frontier of this form provides hope that the required lower bound in Item 1 is true (thanks to Item 2), and that it might be within the reach of known techniques (thanks to Items 3 and 4, which provide evidence that we can analyse the circuit model and the problem). HM frontiers have been already achieved in earlier works with a striking example appearing in [39] (see also [10]). Despite the number of works in this area, we note that the HM frontier is achieved only by some magnification theorems (Item 3 is often unknown; e.g. in the case of results in [3, 13]).

[1] Most of this work was completed while Igor C. Oliveira was affiliated with the University of Oxford.

In order to make our subsequent discussion more concrete, we provide five examples of HM frontiers. Some of these results are new or require an extension of previous work, and the relevant statements will be explained in more detail in Section 3. The list of frontiers is not meant to be exhaustive, but we have tried to cover different computational models.

(A) HM Frontier for $\mathsf{MKtP}[n^c, 2n^c]$ and AC^0-XOR:

- **A1.** If $\mathsf{MKtP}[n^c, 2n^c] \notin \mathsf{AC}^0\text{-XOR}[N^{1.01}]$ for large $c > 1$ then $\mathsf{EXP} \not\subseteq \mathsf{NC}^1$ (Section 3.1).
- **A2.** $\mathsf{MKtP}[n^c, 2n^c] \notin \mathsf{P/poly}$ for large enough c under exponentially secure PRFs [46].
- **A3.** $\mathsf{Majority} \notin \mathsf{AC}^0\text{-XOR}[2^{N^{o(1)}}]$ (immediate from [44, 49]).
- **A4.** $\mathsf{MKtP}[n^c, 2n^c] \notin \mathsf{AC}^0$ for any sufficiently large constant c (Section 3.1).

A. $\mathsf{MKtP}[s, t]$ refers to the promise problem of determining if an N-bit input has Levin Kolmogorov complexity at most s versus at least t (cf. [39]). Here $N = 2^n$. The AC^0-XOR model is the extension of AC^0 where gates at the bottom layer of the circuit can compute arbitrary parity functions. $\mathsf{AC}^0\text{-XOR}[s]$ denotes AC^0-XOR circuits of size s where the size is measured as the number of gates. This circuit class has received some attention in recent years (cf. [15]), and a few basic questions about AC^0 circuits with parity gates (such as constructing PRGs of seed length $o(n)$ and learnability using random examples) remain open for AC^0-XOR as well.

(B) HM Frontier for $\mathbf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ and Formula-XOR:

- **B1.** $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \notin \mathsf{Formula\text{-}XOR}[N^{1.01}]$ implies $\mathsf{NQP} \not\subseteq \mathsf{NC}^1$ (Section 3.2).
- **B2.** $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \notin \mathsf{P/poly}$ under standard cryptographic assumptions [46].
- **B3.** $\mathsf{InnerProduct} \notin \mathsf{Formula\text{-}XOR}[N^{1.99}]$ (immediate consequence of [52]).
- **B4.** $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \notin \mathsf{Formula}[N^{1.99}]$ ([23]; see also [39]).

B. Here, NQP is nondeterministic quasi-polynomial time, InnerProduct is the Boolean function defined as $\mathsf{InnerProduct}(x, y) = \sum_i x_i \cdot y_i \pmod 2$, where $x, y \in \{0,1\}^N$, Formula-XOR$[s]$ refers to the class of Boolean formulas over the De Morgan basis with at most s leaves, where each leaf is an XOR of arbitrary arity over the inputs[2], and $\mathsf{MCSP}[s, t]$ denotes a promise problem over $N = 2^n$ input bits with YES inputs being truth-tables of Boolean functions on n inputs which are computable by circuits of size s, and NO instances being truth-tables of Boolean functions which are hard for circuits of size t.

(C) HM Frontier for $\mathbf{MCSP}[2^{n^{1/2}}/10n, 2^{n^{1/2}}]$ and Almost-Formulas:

- **C1.** $\mathsf{MCSP}[\frac{2^{n^{1/2}}}{10n}, 2^{n^{1/2}}] \notin N^{0.01}\text{-}\mathsf{Almost\text{-}Formula}[N^{1.01}]$ implies $\mathsf{NP} \not\subseteq \mathsf{NC}^1$ (Section 3.3).
- **C2.** $\mathsf{MCSP}[\frac{2^{n^{1/2}}}{10n}, 2^{n^{1/2}}] \notin \mathsf{P/poly}$ under standard cryptographic assumptions [46].
- **C3.** $\mathsf{PARITY} \notin N^{0.01}\text{-}\mathsf{Almost\text{-}Formula}[N^{1.01}]$ (Section 3.3).
- **C4.** $\mathsf{MCSP}[2^{n^{1/2}}/10n, 2^{n^{1/2}}] \notin \mathsf{Formula}[N^{1.99}]$ ([23]; see also [39]).

[2] Note that $\mathsf{Formula\text{-}XOR}[N^{1.01}] \subseteq \mathsf{Formula}[N^{3.01}]$. A better understanding of the former class is therefore necessary before we can understand the power and limitations of super-cubic formulas, which is a major open question in circuit complexity.

C. An almost-formula is a circuit with a bounded number of gates of fan-out larger than 1. More precisely, a γ-Almost-Formula$[s]$ is a circuit containing at most s AND, OR, NOT gates of fan-in at most 2, and among such gates, at most γ of them have fan-out larger than 1. Consequently, this class naturally interpolates between formulas and circuits. This magnification frontier can be seen as progress towards establishing magnification theorems for worst-case variants of MCSP in the regime of sub-quadratic formulas (see the discussion in [39]).

(D) HM Frontier for MCSP$[2^{\sqrt{n}}]$ and one-sided error randomized formulas:

D1. MCSP$[2^{\sqrt{n}}] \notin$ GapAND$_{O(N)}$-Formula$[N^{2.01}] \Rightarrow$ NQP $\notin$ NC^1 (Section 3.2).
D2. MCSP$[2^{\sqrt{n}}] \notin$ P/poly under standard cryptographic assumptions [46].
D3.1. Andreev$_N \notin$ GapAND$_{O(N)}$-Formula$[N^{2.99}]$ (implicit in [21]).
D3.2. MCSP$[2^n/n^4] \notin$ GapAND$_{O(N)}$-Formula$[N^{2.99}]$ (implicit in [16]).
D4. MCSP$[2^{\sqrt{n}}] \notin$ GapAND$_{O(N)}$-Formula$[N^{1.99}]$ ([11], building on [23, 39]).

D. GapAND$_N$ is the promise function on N bits such that it outputs 1 when all input bits are 1, and outputs 0 when at most 1/10 of the input bits are 1. GapAND$_{O(N)}$-Formula$[s]$ denotes circuits with GapAND$_{O(N)}$ gate at the top with formulas of size s being inputs of the top gate. Therefore, GapAND$_{O(N)}$-Formula can be seen as *randomized formulas with one-sided error*.[3] The most interesting aspect of this magnification frontier is that the gap between the known hardness result and the magnification threshold is *nearly-tight* ($N^{2-\varepsilon}$ versus $N^{2+\varepsilon}$).[4]

(E) HM Frontier for $(n-k)$-Clique and AC^0:

E1. If $(n-k)$-Clique $\notin$ AC$^0[m^{1.01}]$ for some $k = (\log n)^C$, then NP $\not\subseteq$ NC^1 (Section 3.4).
E2. (Non-uniform) ETH $\Rightarrow$ $(n-k)$-Clique $\notin$ P/poly for some $k = (\log n)^C$ (Section 3.4).
E3. Parity $\notin$ AC^0 [1, 19].
E4. $(n-k)$-Clique $\notin$ mP/poly for some $k = (\log n)^C$ ([4]; see Section 3.4).

E. The ℓ-Clique problem is defined on graphs on n vertices in the adjacency matrix representation of size $m = \Theta(n^2)$. (The statements above refers to the regime of very large clique detection.) The class mP/poly refers to monotone circuits of polynomial size. In this frontier we are modifying Item 4 from HM frontier so that instead of slightly weaker $\mathcal{C}^-$ we consider an incomparable $\mathcal{C}^-$. This frontier is however particularly interesting, as items E1 and E4 connect hardness magnification to a basic question about the power of *non-monotone*

[3] Suppose there is a GapAND$_{O(N)}$-Formula circuit computing a function $f\colon \{0,1\}^N \to \{0,1\}$. Consider a uniform distribution of all sub-formulas below the top GapAND$_{O(N)}$ gate. Then for any input x, if $f(x) = 1$ then a sample formula from that distribution always outputs 1 on x, otherwise it outputs 0 with probability at least 0.9 on x. On the other hand, it is possible to derandomize a distribution of formulas computing f with one-sided error using a top GapAND$_{O(N)}$ gate.

[4] This tight threshold is first observed in [11], we include it here to show that the barrier discussed in this paper also applies to this particular setting.

circuits when computing *monotone* functions (see [14, 20] and references therein): Is every monotone function in AC^0 computable by a monotone (unbounded depth) boolean circuit of polynomial size? If this is the case, $\mathsf{NP} \not\subseteq \mathsf{NC}^1$ would follow.

Note that these hardness magnification frontiers offer different approaches to proving lower bounds against NC^1.

Essential Questions. Do magnification theorems bring us closer to strong circuit lower bounds? In order to understand the limits and prospects of hardness magnification, the following questions are relevant.

Q1. *Naturalization.* Is hardness magnification a *non-naturalizing* approach to circuit lower bounds? If we accept standard cryptographic assumptions, non-naturalizability is a necessary property of any successful approach to strong circuit lower bounds.[5]

Q2. *Extending known lower bounds.* Can we adapt an existing lower bound proof from Items 3 and 4 in some HM frontier to show the lower bound required from Item 1 in that HM frontier? Is it possible to establish the required lower bounds via a reduction from L to Q?

Q3. *Improving existing magnification theorems.* Can we close the gap between Items 1 and 4 in HM frontier by establishing a magnification theorem that meets *known* lower bounds, such as the ones appearing in Item 4?

In the next sections, we present results that shed light into all these questions.

1.2 Hardness Magnification and Natural Proofs

The very existence of the natural proofs barrier provides a direction for proving strong circuit lower bounds: one can proceed by *refuting the existence of natural properties*.[6] In other words, a way to avoid natural proofs is to prove that there are no natural proofs. It is also easy to see that $\mathsf{P/poly}$-natural properties useful against $\mathsf{P/poly}$ can be turned into natural properties with much higher constructivity, e.g. into linear-size natural properties useful against circuits of polynomial-size. If read contrapositively, this gives a form of hardness magnification.

The initial hardness magnification theorem of Oliveira and Santhanam [42] proceeds in a similar fashion. It proposes to approach $\mathsf{NP} \not\subseteq \mathsf{P/poly}$ by deriving slightly superlinear circuit lower bounds for specific problems such as an *approximate version* of MCSP, which asks to distinguish truth-tables of Boolean functions computable by small circuits from truth-tables of Boolean functions which are hard to approximate by small circuits. Interestingly, this approach does not seem to naturalize, as it appears to yield strong lower bounds only for certain problems, and not for most of them. (The same heuristic argument appears in [3].) However, this is only an informal argument, and we would like to get stronger evidence that the natural proofs barrier does not apply here.

We show that hardness magnification for approximate MCSP can be used to conclude the *non-existence* of natural proofs against polynomial-size circuits. More precisely, we prove that if approximate MCSP requires slightly superlinear-size circuits, then there are no $\mathsf{P/poly}$-natural properties against $\mathsf{P/poly}$. This strongly suggests that the natural proofs

[5] We assume familiarity of the reader with the natural proofs framework of [46].

[6] A similar perspective has been employed in proof complexity in attempts to approach strong proof complexity lower bounds by extending the natural proofs barrier (see [34, 45]).

barrier isn't relevant to the magnification approach. Indeed, there remains the possibility that the weak circuit lower bound for MCSP in the hypothesis of the result can be shown using naturalizing techniques (as there aren't any strong enough plausible cryptographic conjectures known that rule this out), and yet by using magnification to "break" naturalness, we could get strong circuit lower bounds and even conclude the non-existence of natural proofs!

The core of our proof is the following new hardness magnification theorem: if approximate MCSP requires slightly superlinear-size circuits, then not only $\mathsf{NP} \not\subseteq \mathsf{P/poly}$ but *it is impossible even to learn efficiently*. We can then refute the existence of natural proofs by applying the known translation of natural properties to learning algorithms [8]. Similar implications hold with a *worst-case gap version* of MCSP (in the sense of HM Frontiers B and C but with different parameters) instead of approximate MCSP, following an idea from [22].

Interestingly, all the implications above are actually *equivalences*. In particular, the existence of natural properties is equivalent to the existence of highly efficient circuits for computing approximate MCSP and worst-case gap MCSP with certain parameters (cf. Theorem 1). This extends a known characterization of natural properties: Carmosino et al. [8] showed that P/poly natural proofs against P/poly are equivalent to learning P/poly by subexponential-size circuits, which was in turn shown to be equivalent by Oliveira and Santhanam [41] to the non-existence of non-uniform pseudorandom function families of sub-exponential security. The connection of hardness magnification to learning and pseudorandom function generators might be of independent interest, since it extends the consequences of magnification into two central areas in Complexity Theory.

▶ **Theorem 1** (Equivalences for Hardness Magnification). *The following statements are equivalent:*[7]

(a) ***Hardness of approximate* MCSP *against almost-linear size circuits.*** *There exist $c \geq 1$, $0 < \gamma < 1$, and $\varepsilon > 0$ such that $\mathit{MCSP}[(n^c, 0), (2^{n^\gamma}, n^{-c})] \notin \mathit{Circuit}[N^{1+\varepsilon}]$.*

(b) ***Hardness of worst-case* MCSP *against almost-linear size circuits.*** *There exists $c \geq 1$ and $\varepsilon > 0$ such that $\mathit{MCSP}[n^c, 2^n/n^c] \notin \mathit{Circuit}[N^{1+\varepsilon}]$.*

(c) ***Hardness of sub-exponential size learning using non-adaptive queries.*** *There exist $\ell \geq 1$ and $0 < \gamma < 1$ such that $\mathit{Circuit}[n^\ell]$ cannot be learned up to error $O(1/n^\ell)$ under the uniform distribution by circuits of size $2^{O(n^\gamma)}$ using non-adaptive membership queries.*

(d) ***Non-existence of natural properties against polynomial size circuits.*** *For some $d \geq 1$ there is no $\mathit{Circuit}[\mathsf{poly}(N)]$-natural property useful against $\mathit{Circuit}[n^d]$.*

(e) ***Existence of non-uniform* PRFs *secure against sub-exponential size circuits.*** *For every constant $a \geq 0$, there exists $d \geq 1$, a sequence $\mathfrak{F} = \{\mathcal{F}_n\}_{n\geq 1}$ of families $\mathcal{F}_n$ of n-bit boolean functions $f_n \in \mathit{Circuit}[n^d]$, and a sequence of probability distributions $\mathfrak{D} = \{\mathcal{D}_n\}_{n\geq 1}$ supported over $\mathcal{F}_n$ such that, for infinitely many values of n, $(\mathcal{F}_n, \mathcal{D}_n)$ is pseudo-random function family that $(1/N^{\omega(1)})$-fools (oracle) circuits of size $2^{a\cdot n}$.*

The proof of this result appears in Section 4.1. We highlight below the most interesting implications of Theorem 1. (Note that some of them have appeared in other works in similar or related forms.)

- $(a) \to (d)$: The initial hardness magnification result from [42, Theorem 1] (stated for circuits) implies the *non-existence* of natural proofs useful against polynomial-size circuits, indicating that the natural proofs barrier might not be relevant to the magnification approach.

[7] See Preliminaries (Section 2) for definitions.

- (a), $(b) \leftrightarrow (d)$: *Any* P/poly natural property useful against P/poly can be transformed into an almost-linear size natural property that is simply the approximate $\mathsf{MCSP}[(n^c, 0), (2^{n^\gamma}, n^{-c})]$ or worst-case gap $\mathsf{MCSP}[n^c, 2^n/n^c]$. (Note the different regime of circuit size parameters for these problems.)
- (a), $(b) \leftrightarrow (c)$: A weak-seeming hardness assumption for worst-case gap and approximate versions of MCSP implies a strong non-learnability result: polynomial-size circuits cannot be learned over the uniform distribution even non-uniformly in sub-exponential time.
- (a), $(b) \leftrightarrow (e)$: Hardness magnification for MCSP also yields cryptographic hardness in a certain regime.

We note that the use of non-adaptive membership queries in Theorem 4.1 Item (c) is not essential. It follows from [8] that, in the context of learnability of polynomial size circuits under the uniform distribution in sub-exponential time, adaptive queries are not significantly more powerful than non-adaptive queries.[8]

Towards a more robust theory. While Theorem 1 formally connects hardness magnification and natural properties, it would be very interesting to understand to which extent different hardness magnification theorems are provably non-naturalizable. This would provide a more complete answer to Question Q1 asked above. For instance, Theorem 1 leaves open whether hardness magnification for worst-case versions of MCSP such as $\mathsf{MCSP}[n^c, 2^{n^\varepsilon}]$ refutes natural proofs as well. Note that one way of approaching this question would be to study reductions from $\mathsf{MCSP}[n^c, 2^{n^\gamma}]$ to its approximate version $\mathsf{MCSP}[(n^{c'}, 0), (2^{n^{\gamma'}}, n^{-c'})]$.[9] In Section 4.2, we observe that this question is related to the problem of basing *hardness of learning* on *worst-case assumptions* such as $\mathsf{P} \neq \mathsf{NP}$ (cf. [5]). We refer to the discussion in Section 4.2 for more details.

1.3 The Locality Barrier

The results from the preceding section show that hardness magnification can go beyond natural proofs. Is there another barrier that makes it difficult to establish lower bounds via magnification? In this section, we present a general argument to explain why the lower bound techniques behind A3-E3, A4-D4 in the magnification frontiers from Section 1.1 cannot be adapted (without significantly new ideas) to establish the required lower bounds in Items A1-E1, respectively. We refer to it as the *locality barrier*. While we will focus on these particular examples to make the discussion concrete, we believe that this barrier applies more broadly.

In order to explain the locality barrier, let's consider the argument behind the proof of B1 presented in Section 3.2. Recall that this result shows that if $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \notin \mathsf{Formula\text{-}XOR}[N^{1.01}]$ then $\mathsf{NQP} \not\subseteq \mathsf{NC}^1$. This and other known hardness magnification theorems are established in the contrapositive. The core of the argument is to prove that there are highly efficient Formula-XOR circuits that reduce an input to $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ of length $N = 2^n$ to deciding whether certain strings of length N' (much smaller than N) belong to

[8] In a bit more detail, one can easily extract a natural property from a learner that uses adaptive queries. In turn, closer inspection of the technique of [8] shows that a non-adaptive learner can be obtained from a natural property.

[9] More precisely, the existence of a reduction from $\mathsf{MCSP}[n^c, 2^{n^\gamma}]$ to $\mathsf{MCSP}[(n^{c'}, 0), (2^{n^{\gamma'}}, n^{-c'})]$ shows that lower bounds for the former problem yield lower bounds for the latter. Since any such lower bound must be non-naturalizable by Theorem 1, we obtain the same consequence for $\mathsf{MCSP}[n^c, 2^{n^\gamma}]$. (Note that in the context of hardness magnification it is also important to have highly efficient reductions.)

a certain language L'. Then, under the assumption that $\mathsf{NQP} \subseteq \mathsf{NC}^1$, one argues that L' has polynomial size formulas. Finally, since $N' \ll N$, we can employ such formulas and still conclude that $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ is in $\mathsf{Formula\text{-}XOR}[N^{1.01}]$, which completes the proof.

Note that the argument above provides a *conditional* construction of highly efficient formulas for the original problem. Crucially, however, we can derive an *unconditional* circuit upper bound from this argument: If we stop right before we replace the calls to L' by an algorithm for L' (this is what makes the reduction conditional), it unconditionally follows that $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ can be computed by highly efficient $\mathsf{Formula\text{-}XOR}$ circuits containing oracle gates of small fan-in, for some oracle. Similarly, one can argue that the problems in Items A1-E1 can be computed in the respective models by highly efficient Boolean devices containing oracles of small fan-in.

We stress that, as opposed to a magnification theorem, where one cares about the complexity of the oracle gates, in our discussion of the locality barrier we only need the fact that there is *some way* of setting these oracles gates so that the resulting circuit or formula solves the original problem. (A definition of this model appears in Section 2.5.) A more exhaustive interpretation of magnification theorems as construction of circuits with small fan-in oracles can be found in Appendix A.2.

On the other hand, we argue that the lower bound arguments from Items A3-E3 of the hardness magnification frontiers quite easily handle (in the respective models) the presence of oracles of small fan-in, *regardless of the function* computed by these oracles. Using a more involved argument we can localize also lower bounds from items A4-D4. Consequently, these methods do not seem to be refined enough to prove the lower bounds required by A1-D1 without excluding oracle circuits that are unconditionally known to exist for the corresponding problems.

Following the example above, we state our results for the Magnification Frontier B.

▶ **Theorem 2** (Locality Barrier for HM Frontier B). *The following results hold.*

- (B1$^{\mathcal{O}}$) (Oracle Circuits from Magnification) : *For any $\varepsilon > 0$, $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \in \mathsf{Formula\text{-}}\mathcal{O}\mathsf{\text{-}XOR}[N^{1.01}]$ for some oracle $\mathcal{O}$, where every oracle gate has fan-in at most N^{ε} and appears in the layer right above the* XOR *leaves.*
- (B3$^{\mathcal{O}}$) (Extension of Lower Bound Techniques Above Magnification Threshold) : *For any $\delta > 0$,* InnerProduct *over N input bits cannot be computed by $N^{2-3\delta}$-size $\mathsf{Formula\text{-}}\mathcal{O}\mathsf{\text{-}XOR}$ circuits with at most $N^{2-3\delta}$ oracle gates of fan-in N^{δ} in the layer right above the* XOR *leaves, for any oracle $\mathcal{O}$.*
- (B4$^{\mathcal{O}}$) (Extension of Lower Bound Techniques Below Magnification Threshold) : *There is a universal constant c such that for all constants $\varepsilon > 0$ and $\alpha > 2$, $\mathsf{MCSP}[n^c, 2^{\varepsilon/\alpha \cdot n}]$ cannot be computed by oracle formulas F with $\mathsf{SIZE}_3(F) \leq N^{2-\varepsilon}$ and adaptivity $o(\log N / \log\log N)$.*[10]

Here, $\mathsf{Size}_t(F)$ denotes the size of the formula, if we replace every oracle $\mathcal{O}$ with fan-in β in F by a formula of size β^t which reads all its inputs exactly β^{t-1} times (see Section 5.2.2 for the motivation of this definition).

The first two items of Theorem 2 are proved in Section 5.1.2. The third item is proved in Section 5.2.2. While Theorem 2 does not specify that, we actually localize all proofs of the lower bounds from B3 and B4 we are aware of. Interestingly, the localization of B4 allows us to refute the Anti-Checker Hypothesis from [39] (and a family of potential hardness magnification theorems), cf. Section 5.2.2. We refer to Section 5 for analogous statements describing the locality barrier in frontiers A, C, D, and E.

[10] That is, on any path from root to a leaf, there are at most $o(\log N / \log\log N)$ oracles.

Locality of Computations and Lower Bound Techniques. The fact that many lower bound techniques extend to computational devices with oracles of small fan-in was observed already by Yao in 1989 on a paper on local computations [56]. According to Yao, a local function is one that can be efficiently computed using only localized processing elements. In our terminology, this corresponds to circuits with oracles of small fan-in. Among other results, [56] argues that Razborov's monotone circuit size lower bound for k-Clique [43] and Karchmer and Wigderson's monotone formula size lower bound for ST-CONN [31] extend to boolean devices with monotone oracles of bounded fan-in. Compared to Yao's work, our motivation and perspective are different. While Yao is particularly interested in lower bounds that can be extended in this sense (see e.g. Sections 2 and 6 in [56]), here we view such extensions as a *limitation* of the corresponding arguments, meaning that they are not refined enough to address the locality barrier.[11]

We note, however, that not every lower bound technique extends to circuits with small fan-in oracles.[12] For instance, by the work of Allender and Koucký [3] (also a more recent work by Chen and Tell [13]), the parity function Parity_n over n input bits can be computed by a TC^0 circuit of size $O(n)$ (number of wires) containing $\leq n^{1-\varepsilon}$ oracle gates of fan-in $\leq n^{\varepsilon}$, provided that its depth $d = O(1/\varepsilon)$. On the other hand, it is known that $\mathsf{Parity}_n \notin \mathsf{TC}^0_d[n^{1+c^{-d}}]$ for a constant $c > 0$ [25] (again, the complexity measure is the number of wires). Since the latter lower bound is super-linear for every choice of d, it follows by the result of [3, 13] that it cannot be extended to circuits containing a certain number of oracles of fan-in n^{ε}, for a large enough depth d that depends on ε. Incidentally, the hardness magnification theorems of [3, 13] do not achieve a magnification frontier.

In Section 3.2 we identify one specific lower bound related to HM frontier D which is both above the magnification threshold and provably non-localizable, cf. Theorem 49. In principle, there might be ways to overcome the locality barrier and match the lower bound with the magnification threshold. We refer to Section 1.4 below for additional discussion.

On Lower Bounds Through Reductions. The discussion above has focused on the possibility of *directly* adapting existing lower bounds from Item 3 in HM frontier to establish the desired lower bound in Item 1. There is however an *indirect* approach that one might hope to use: *reductions*. For instance, in the context of the HM Frontier B discussed above, can we have a reduction from InnerProduct to $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ that would allow us to show that $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \notin \mathsf{Formula\text{-}XOR}[N^{1.01}]$? The first thing to notice is that, for this approach to make sense, the reduction needs to have a specific form so that composing the reduction with a candidate Formula-XOR circuit for $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ violates the hardness of InnerProduct. Is there any hope to design a reduction of this form?

The locality barrier presents a *definitive answer* in this case. Indeed, it is immediate from the first two items of Theorem 2 that such a reduction *does not exist*. For the same reason, it is not possible to use reductions to establish the required lower bounds in some other magnification frontiers, cf. Section 5.1.6.

[11] On a more technical level, we are interested in the regime of barely super-linear size circuits and formulas, and our results do not impose a monotonicity constraint on the oracle.

[12] Of course any such discussion depends on parameters such as number of oracles and their fan-ins, so whether a technique avoids or not the locality barrier is relative to a particular magnification theorem.

1.4 Concluding Remarks and Open Problems

Hardness magnification shows that obtaining a refined understanding of weak computational models is an approach to major complexity lower bounds, such as separating EXP from NC^1. As discussed in Sections 1.1 and 1.2 above, its different instantiations are connected to a few basic questions in Complexity Theory, including the power of non-monotone operations, learnability of circuit classes, and pseudorandomness.

One of our main conceptual contributions in this work is to identify a challenge when implementing this strategy for lower bounds. Quoting the influential article [46] that introduced the natural proofs barrier,

> *"We do not conclude that researchers should give up on proving serious lower bounds. Quite the contrary, by classifying a large number of techniques that are unable to do the job we hope to focus research in a more fruitful direction."*
>
> Razborov and Rudich [46, Section 6]

We share a similar opinion with respect to hardness magnification and the obstruction identified in Section 1.3. While locality provides a unified explanation for the difficulty of adapting combinatorial lower bound techniques to exploit most (if not all) known magnification frontiers, it might be possible to discover new HM frontiers whose associated lower bound techniques in Item 3 are sensitive to the presence of small fan-in oracles. For instance, in the case of *uniform* complexity lower bounds, this has been achieved in [38] via an indirect diagonalization that explores the theory of pseudorandomness.[13] Alternatively, it might be possible to establish magnification theorems using a technique that does not produce circuits with small fan-in oracles. Even if one is pessimistic about these possibilities, we believe that an important contribution of the theory of hardness magnification is to break the divide between "weak" and "strong" circuit classes advocated by the natural proofs barrier, and that it deserves further investigation.

We finish with a couple of technical questions related to our contributions. First, we would like to understand if it is possible to strengthen items (a) and (b) in Theorem 1 to a wider range of parameters. For example, is hardness magnification for worst-case $\mathsf{MCSP}[n^c, 2^{n^\gamma}]$ with $\gamma < 1$ non-naturalizable? The core of this question seems to be the problem of reducing worst-case MCSP from item (a) to approximate MCSP from item (b).

Another important direction is to show that hardness magnification avoids natural proofs also in the context of *non*-meta-computational problems. Interestingly, many magnification theorems from [39] established for MCSP and variants were subsequently shown to hold for any sparse language in NP [10]. Could it be the case that hardness magnification overcomes natural proofs in a much broader sense?

Finally, it would be useful to investigate the locality of additional lower bound techniques. Can we, for example, come up with non-localizable lower bounds similar to Theorem 49 which would be above the magnification threshold and work for a problem more closely related to the one from the corresponding HM frontier?

[13] In other words, the magnification theorem discussed in [38] admits a formulation for uniform randomized algorithms, and its proof provides an algorithm with oracle gates of small fan-in in the spirit of the oracle circuits discussed here. Nevertheless, the unconditional lower bound established in the same paper does not extend to algorithms with such oracle gates.

2 Preliminaries

2.1 Notation

Given a Boolean function $f : \{0,1\}^n \to \{0,1\}$, $\mathsf{tt}(f)$ denotes the 2^n-bit string representing the truth table of f. On the other hand, for any string $y \in \{0,1\}^{2^n}$, define f_y as the function on n inputs such that $\mathsf{tt}(f_y) = y$.

$\mathsf{Circuit}[s]$ denotes fan-in two Boolean circuits of size at most s where we count the number of gates. $\mathsf{Formula}[s]$ denotes formulas over the basis U_2 (fan-in two ANDs and ORs) of size at most s (counting the number of leaves) with input leaves labelled by literals or constants.

For a circuit class $\mathcal{C}$, $\mathcal{C}[s]$ denotes circuits from $\mathcal{C}$ of size at most s.

A function $f : \{0,1\}^n \to \{0,1\}$ is γ-approximated by a circuit C, if $\Pr_x[C(x) = f(x)] \geq \gamma$.

2.2 Complexity of Learning

▶ **Definition 3** (Learning). *A circuit class $\mathcal{C}$ is learnable over the uniform disribution by circuits in $\mathcal{D}$ up to error ε with confidence δ if there are randomized oracle $\mathcal{D}$-circuits L^f such that for every boolean function $f : \{0,1\}^n \mapsto \{0,1\}$ computable by a circuit from $\mathcal{C}$, when given oracle access to f, input 1^n and the internal randomness $w \in \{0,1\}^*$, L^f outputs the description of a circuit satisfying*

$$\Pr_w\{L^f(1^n, w) \ (1-\varepsilon)\text{-approximates } f\} \geq \delta.$$

L^f uses non-adaptive membership queries if the set of queries which L^f makes to the oracle does not depend on the answers to previous queries. If $\delta = 1$, we omit mentioning the confidence parameter.

2.3 Natural Properties, MCSP, and its Variants

Let $\mathcal{F}_n$ be the set of all functions on n variables. $\mathfrak{R} = \{\mathcal{R}_n \subseteq \mathcal{F}_n\}_{n\in\mathbb{N}}$ is a combinatorial property of Boolean functions.

▶ **Definition 4** (Natural property [46]). *Let $\mathfrak{R} = \{\mathcal{R}_n\}$ be a combinatorial property, $\mathcal{C}$ be a circuit class and Γ be a complexity class. Then, $\mathfrak{R}$ is a Γ-natural property useful against $\mathcal{C}[s(n)]$, if there exists an $n_0 \in \mathbb{N}$ such that the following hold:*

- ***Constructivity** : For any function $f_n \in \mathcal{F}_n$, the predicate $f_n \overset{?}{\in} \mathcal{R}_n$ is computable in Γ in the size of the truth table of f_n.*
- ***Largeness** : For every $n \geq n_0$, $\Pr_{f_n\sim\mathcal{F}_n}\{f_n \in \mathcal{R}_n\} \geq \frac{1}{2^{O(n)}}$.*
- ***Usefulness** : For every $n \geq n_0$, $\mathcal{R}_n \cap \mathcal{C}[s(n)] = \emptyset$.*

The following result which follows from [8] connects the existence of natural properties useful against a class $\mathcal{C}$ to designing learning algorithms for $\mathcal{C}$.

▶ **Theorem 5** (From Theorem 5.1 of [8] and Lemma 14 of [27]). *Let R be a P/poly-natural property useful against $\mathsf{Circuit}[n^d]$ for some $d \geq 1$. Then, for each $\gamma \in (0,1)$, there are randomized, oracle circuits $\{D_n\}_{n\geq 1} \in \mathsf{Circuit}[2^{O(n^\gamma)}]$ that learn $\mathsf{Circuit}[n^k]$ up to error $\frac{1}{n^k}$ using non-adaptive oracle queries to f_n, where $k = \frac{d\gamma}{a}$ and a is a universal constant that does not depend on d and γ.*

▶ **Definition 6** (Gap MCSP). *Let $s, t : \mathbb{N} \to \mathbb{N}$, where $s(n) \leq t(n)$ and $0 \leq \varepsilon, \sigma < 1/2$. Define MCSP$[(s, \sigma), (t, \varepsilon)]$ on inputs of length $N = 2^n$, as the following promise problem :*

- *YES instances: $y \in \{0,1\}^N$ such that there exists a circuit of size $s(n)$ that $(1-\sigma)$-approximates f_y.*
- *NO instances: $y \in \{0,1\}^N$ such that no circuit of size $t(n)$ $(1-\varepsilon)$-approximates f_y.*

We refer to MCSP$[(s,0),(t,0)]$ as MCSP$[s,t]$. Informally speaking, if $\varepsilon > 0$, we say that MCSP$[(s,0),(t,\varepsilon)]$ is an *approximate* version of MCSP. Otherwise, it is a *worst-case* version of MCSP.

▶ Remark 7. In Definition 6, if $s(n) = t(n)$, we also require that $\sigma < \varepsilon$ for the yes and no instances to be disjoint.

▶ **Definition 8** (Succinct MCSP). *For functions $s, t : \mathbb{N} \mapsto \mathbb{N}$, Succinct-MCSP$[s(n), t(n)]$ is the following problem. Given an input $\langle 1^n, 1^s, (x_1, b_1), \ldots, (x_t, b_t)\rangle$ where $x_i \in \{0,1\}^n, b_i \in \{0,1\}$, decide if there is a circuit C of size s such that $\bigwedge_{i=1,\ldots,t} C(x_i) = b_i$.*

2.4 Pseudorandom Generators

▶ **Definition 9** (Pseudorandom function families). *For any circuit class $\mathcal{C}$, size functions $s(n), t(n) \geq n$, family $\mathcal{G}_n$ of n-bit Boolean functions and distribution $\mathcal{D}_n$ over $\mathcal{G}_n$, we say that a pair $(\mathcal{G}_n, \mathcal{D}_n)$ is a $(t(n), \varepsilon(n))$-pseudorandom function family (PRF) in $\mathcal{C}[s(n)]$, if each function in $\mathcal{G}_n$ is in $\mathcal{C}[s(n)]$ and for every randomized circuit $A^O \in$ Circuit$^O[t(n)]$, where O denotes oracle access to a fixed Boolean function over n inputs, we have*

$$\left| \Pr_{g \sim \mathcal{D}_n, w} \{A^g(w) = 1\} - \Pr_{f \sim \mathcal{F}_n, w} \{A^f(w) = 1\} \right| \leq \varepsilon(n)$$

[41] state an equivalence between the non-existence of PRFs in a circuit class $\mathcal{C}$ and learning algorithms for $\mathcal{C}$. In particular, we care about the following direction which they prove using a small-support version of Von-Neumann's Min-max Theorem.

▶ **Theorem 10** (No PRFs in $\mathcal{C}$ implies Learning Algorithm for $\mathcal{C}$ [41]). *Let $t(n) \leq 2^{O(n)}$. Suppose that for every $k \geq 1$ and large enough n, there exists no $(\mathsf{poly}(t(n)), 1/10)$-pseudorandom function families in $\mathcal{C}[n^k]$. Then, for every $\varepsilon > 0, k \geq 1$ and large enough n, there is a randomized oracle circuit in Circuit$^O[2^{n^\varepsilon}]$ that learns every function $f_n \in \mathcal{C}[n^k]$ up to error $1/n^k$ with confidence $1 - 1/n$, where O denotes membership query access to f_n.*

2.5 Local Circuit Classes

Our definition of local computation is somewhat similar to some definitions appearing in [56].

▶ **Definition 11** (Local circuit classes). *Let $\mathcal{C}$ be a circuit class (such as $\mathsf{AC}^0[s]$, $\mathsf{TC}^0_d[s]$, Circuit$[s]$, etc). For functions $q, \ell, a \colon \mathbb{N} \to \mathbb{N}$, we say that a language L is in $[q, \ell, a]$–$\mathcal{C}$ if there exists a sequence $\{E_n\}$ of oracle circuits for which the following holds:*

- **(i)** *Each oracle circuit E_n is a circuit from $\mathcal{C}$.*
- **(ii)** *There are at most $q(n)$ oracle gates in E_n, each of fan-in at most $\ell(n)$, and any path from an input gate to an output gate encounters at most $a(n)$ oracle gates.*
- **(iii)** *There exists a language $\mathcal{O} \subseteq \{0,1\}^*$ such that the sequence $\{E_n^{\mathcal{O}}\}$ (E_n with its oracle gates set to $\mathcal{O}$) computes L.*

In the definition above, q stands for *quantity*, ℓ for *locality*, and a for *adaptivity* of the corresponding oracle gates.

2.6 Random Restrictions

Let $\rho : [N] \to \{0, 1, *\}$ be a *restriction*, and $\boldsymbol{\rho}$ be a *random restriction*, i.e., a distribution of restrictions. We say that $\boldsymbol{\rho}$ is p-regular if $\Pr[\boldsymbol{\rho}(i) = *] = p$ and $\Pr[\boldsymbol{\rho}(i) = 0] = \Pr[\boldsymbol{\rho}(i) = 1] = (1 - p)/2$ for every $i \in [N]$. We also say $\boldsymbol{\rho}$ is k-wise independent if any k coordinates of $\boldsymbol{\rho}$ are independent. For a function $f : \{0,1\}^N \to \{0,1\}$, we use $f\restriction_\rho$ to denote the function $\{0,1\}^{|\rho^{-1}(*)|} \to \{0,1\}$ obtained by restricting f according to ρ in the natural way.

We need the following lemma stating that one can sample from a k-wise independent random restriction with a short seed, and moreover all restrictions have a small circuit description.

▶ **Lemma 12** ([24, 55]). *There exists a q-regular k-wise independent random restriction $\boldsymbol{\rho}$ distributed over $\rho : [N] \to \{0, 1, *\}$ samplable with $O(k \cdot \log(N) \log(1/q))$ bits. Furthermore, each output coordinate of the random restriction can be computed in time polynomial in the number of random bits.*

2.7 Technical Results

▶ **Lemma 13** (Hoeffding's inequality). *Let $X_1, \ldots, X_n$ be independent random variables such that $0 \le X_i \le 1$ for every $i \in [n]$. Let $X = \sum_{i=1}^n X_i$. Then, for any $\varepsilon > 0$, we have*

$$\Pr\{|X - \boldsymbol{E}X| \ge \varepsilon n\} \le 2\exp(-2\varepsilon^2 n)$$

3 Magnification Frontiers

3.1 EXP $\not\subseteq$ NC^1 and AC^0-XOR Lower Bounds for MKtP

In this Section, we present the proofs of the new results stated in HM Frontier A. Recall that $\mathsf{Kt}(x)$ is defined as the minimum over $|M| + \log t$ such that a program M outputs x in t steps. For thresholds $\theta, \theta' \colon \mathbb{N} \to \mathbb{N}$, we denote by $\mathsf{MKtP}[\theta(N), \theta'(N)]$ the promise problem whose YES instances consist of the strings $x \in \{0,1\}^N$ such that $\mathsf{Kt}(x) \le \theta(N)$ and NO instances consist of the strings such that $\mathsf{Kt}(x) > \theta'(N)$.

We start with the hardness magnification theorem of HM Frontier A1.

▶ **Theorem 14.** *There exists a constant c such that, for every large enough constant $d > 1$,*

$$\mathit{MKtP}[(\log N)^d, (\log N)^d + c \log N] \notin \mathit{AC}^0\text{-}\mathsf{XOR}[N^{1.01}] \quad \textit{implies} \quad \mathsf{EXP} \not\subseteq \mathit{NC}^1.$$

Proof. We prove the contrapositive. Assume that $\mathsf{EXP} \subseteq \mathsf{NC}^1$. First, recall that any N-bit-input polynomial-size NC^1 circuit can be converted into a depth-d' AC^0 circuit of size $2^{N^{O(1/d')}}$ for every positive integer constant d' (see, e.g., [2, Lemma 8.1]).

Oliveira, Pich, and Santhanam [39] showed that there exists a problem $L \in \mathsf{EXP}$ such that $\mathsf{MKtP}[\theta(N), \theta(N) + c \log N] \in \mathsf{AND}_{O(N)}\text{-}L_{O(\theta(N))}\text{-}\mathsf{XOR}$ for $\theta(N) \ge \log N$. (Here the subscript denotes the fan-in of a gate.) That is, the promise problem $\mathsf{MKtP}[\theta(N), \theta(N) + c \log N]$ can be computed by the following form of an L-oracle circuit: The output gate is an AND gate of fan-in $O(N)$, at the middle layer are L-oracle gates of fan-in $O(\theta(N))$, and at the bottom layer are XOR gates. Under the assumption that $\mathsf{EXP} \subseteq \mathsf{NC}^1$, we can replace L-oracle circuits with depth-d' AC^0 circuits of size $2^{(\log N)^{O(d/d')}}$, which is smaller than $N^{0.01}$ by choosing a constant d' large enough. In particular, we obtain a depth-$(d' + O(1))$ almost linear size AC^0 circuit with bottom XOR gates that computes $\mathsf{MKtP}[\theta(N), \theta(N) + c \log N]$. ◀

The rest of this section is devoted to proving the following AC^0 lower bound for MKtP, which establishes HM Frontier A4.

▶ **Theorem 15.** *For any $d = d(N)$, for some $\theta(N) = d \cdot \widetilde{O}(\log N)^3$ and any $\theta'(N) = N/\omega(\log N)^d$, it holds that $\mathsf{MKtP}[\theta(N), \theta'(N)] \notin \mathsf{AC}^0_d$.*

Note that Theorem 15 is only meaningful if $d = o(\log N / \log\log N)$, because otherwise the promise problem is not well-defined.

The idea of the proof is as follows: Trevisan and Xue [54] showed that there exists a pseudorandom restriction ρ of seed length $\mathsf{polylog}(N)$ that shrinks every polynomial-size depth-2 circuit into shallow decision trees. Moreover, the expected fraction of unrestricted variables $\rho^{-1}(*)$ is at least $p = \Omega(1/\log N)$. In particular, by composing d independent pseudorandom restrictions $\rho_1, \cdots, \rho_d$, every depth-d circuit can be turned into a constant function, while still leaving at least p^d-fraction of inputs unrestricted. The seed length required to sample d independent pseudorandom restrictions is at most $d \times \mathsf{polylog}(N)$, and thus $\mathsf{Kt}(0^N \circ \rho) \leq \mathsf{polylog}(N)$. We stress that the exponent of the seed length does not depend on d. Since the circuit hit with the pseudorandom restriction becomes a constant function, it cannot distinguish $0^N \circ \rho$ with $U_N \circ \rho$, i.e., the distribution where the unrestricted variables of ρ are replaced with the uniform distribution U_N. Assuming that there remain sufficiently many unrestricted inputs (e.g., $N/O(\log N)^d \gg \mathsf{polylog}(N)$), the latter distribution has a large Kt complexity, which is a contradiction to the fact that the circuit computes a gap version of MKtP.

We note that Cheraghchi, Kabanets, Lu, and Myrisiotis [16] used the pseudorandom restriction method in order to obtain an exponential-size AC^0 lower bound. A crucial difference in this work is that instead of optimizing the size of AC^0 circuits, we aim at minimizing the threshold θ of $\mathsf{MKtP}[\theta]$.

Following [54], in order to generate a random restriction $\rho \in \{0,1,*\}^N$ that leaves a variable unrestricted with probability 2^{-q}, we regard a binary string $w \in \{0,1\}^{(q+1)N}$ as a random restriction ρ_w. Specifically:

▶ **Definition 16.** *For a string $w \in \{0,1\}^{(q+1)N}$, we define a restriction $\rho_w \in \{0,1,*\}^N$ as follows: Write w as $(w_1, b_1) \cdots (w_N, b_N)$, where $w_i \in \{0,1\}^q$ and $b_i \in \{0,1\}$. For each $i \in [N]$, if $w_i = 1^q$ then set $\rho_w(i) := *$; otherwise, set $\rho_w(i) := b_i$.*

Note that this is defined so that $\Pr_w[\rho_w(i) = *] = 2^{-q}$ for every $i \in [N]$, when w is distributed uniformly at random.

Trevisan and Xue [54] showed that Håstad's switching lemma can be derandomized by using a distribution that fools CNFs. To state this formally, we need the following definitions. Define a t-width CNF as one which has at most t literals in each clause. We say that a distribution $\mathcal{D}$ over $\{0,1\}^n$ ε-fools a set of functions $\mathcal{S}_n$ over n variables if for every $f \in \mathcal{S}_n$, $|\Pr_{x \sim D}\{f(x) = 1\} - \Pr_{x \sim U_n}\{f(x) = 1\}| \leq \varepsilon$. Finally, define $\mathsf{DT}(f)$ as the depth of the smallest decision tree computing f.

▶ **Lemma 17** (Derandomized Switching Lemma [54, Lemma 7])**.** *Let φ be a t-width M-clause CNF formula over N inputs. Let $p = 2^{-q}$ for some $q \in \mathbb{N}$. Assume that a distribution $\mathcal{D}$ over $\{0,1\}^{(q+1)N}$ ε_0-fools $M \cdot 2^{t(q+1)}$-clause CNFs. Then,*

$$\Pr_{w \sim \mathcal{D}}[\mathsf{DT}(\varphi|_{\rho_w}) > s] \leq 2^{s+t+1}(5pt)^s + \varepsilon_0 \cdot 2^{(s+1)(2t+\log M)}.$$

▶ **Theorem 18** (Based on [54] and [53, Theorem 56])**.** *Let $s, M, d, N \in \mathbb{N}$ be positive integers. Let $p = 2^{-q}$ for some $q \in \mathbb{N}$ so that $1/128s \leq p < 1/64s$. Assume that there is a pseudorandom generator $G\colon \{0,1\}^r \to \{0,1\}^{(q+1)N}$ that ε_0-fools CNFs of size $M \cdot 2^s \cdot 2^{s(q+1)}$. Then, there exists a distribution $\mathcal{R}$ of random restrictions that satisfies the following:*

1. *For every circuit C of size M and depth d over N inputs,*

$$\Pr_{\rho\sim\mathcal{R}}[\mathsf{DT}(C\restriction_\rho) > s] \leq M \cdot \left(2^{-s+1} + \varepsilon_0 \cdot 2^{(s+1)(3s+\log M)}\right).$$

2. *For any parameter $\delta < 1$, with probability at least $1-N(\delta+d\varepsilon_0)$, the number of unrestricted variables in $[N]$ is at least $\lfloor N \cdot p^{d-1}/64\log(1/\delta)\rfloor$.*
3. *$\mathcal{R}$ can be generated by a seed of length dr in polynomial time.*

Proof. We apply the derandomized switching lemma (Lemma 17) d times. In the first iteration, we set $p := 1/64$ (and $q := 6$) and generate $\rho_{G(z)[1,\cdots,(6+1)N]}$. (Here we use the first $(6+1)N$ bits of $G(z)$ to generate $\rho_{G(z)}$.) This turns a circuit C of size M into a circuit whose bottom fan-in is at most s. For every other iteration i (where $i = 2, \cdots, d$), we set $p := 2^{-q}$ and turn a circuit C of depth $d-i+2$ into a circuit of depth $d-i+1$. Our final pseudorandom restriction $\rho \sim \mathcal{R}$ is defined by the composition of the d independent pseudorandom restrictions $\rho_{G(z_1)[1,\cdots,(6+1)N]}, \rho_{G(z_2)}, \cdots, \rho_{G(z_d)}$.

Our proof is essentially the same with [53], except that (1) we apply the switching lemma d times (instead of $d-1$) in order to turn depth-d circuits into shallow decision trees, and (2) in [54, 53], for the application of constructing a pseudorandom generator for AC^0, fixed bits of pseudorandom restrictions must be generated by using truly random bits, whereas in our case we generate all the bits by using G.

In more detail, for each $i \in [d]$, let M_i be the number of the gates at level i in C (i.e., the gates whose distance from the input gates is i). At the first iteration, we set $p := 1/64 = 2^{-6}$ and $q := 6$. We then generate $\rho^1 := \rho_{G(z_1)[1,\cdots,(6+1)N]}$ by choosing a seed $z_1 \sim \{0,1\}^r$ uniformly at random. We regard C as a depth-$(d+1)$ circuit of bottom fan-in 1, and apply Lemma 17 to each gate at level 1 (in the original circuit C). The probability that there exists a gate at level 1 in $C\restriction_{\rho^1}$ that cannot be computed by a decision tree of depth s is bounded above by

$$M_1 \cdot \left(2^{s+1+1}(5/64)^s + \varepsilon_0 \cdot 2^{(s+1)(2+\log M)}\right).$$

In the complement event, each gate at level 1 can be written as DNFs and CNFs of width s, and hence can be merged into some gate at level 2. Thus a circuit $C\restriction_{\rho^1}$ can be turned into a circuit of depth d and bottom fan-in s. Moreover, the number of gates at level 1 is bounded by $M \cdot 2^s$, which is an invariant preserved during the iterations.

For every other iteration i ($i = 2, \cdots, d$), we generate $\rho^i := \rho_{G(z_i)}$ by choosing a seed $z_i \sim \{0,1\}^r$ uniformly at random. Using the invariant that the number of gates at level $i-1$ is at most $M \cdot 2^s$, the probability that some gate at level i in $C\restriction_{\rho^1\cdots\rho^i}$ cannot be computed by a decision tree of depth s is bounded above by

$$M_i \cdot \left(2^{s+s+1}(5ps)^s + \varepsilon_0 \cdot 2^{(s+1)(2s+\log(M2^s))}\right).$$

In the complement event, every gate at level i can be written as width-s CNFs or DNFs of size 2^s, and hence can be merged into some gate at level $i+1$ (for $i < d$). At the last iteration (i.e., $i = d$), the circuit $C\restriction_{\rho^1\cdots\rho^d}$ can be written as a decision tree of depth s. We define the pseudorandom restriction ρ as $\rho^d \circ \cdots \circ \rho^1$. Item 3 is obvious from this construction.

Overall, the probability that $\mathsf{DT}(C\restriction_\rho) > s$ is at most $M \cdot (2^{-s+1} + \varepsilon_0 \cdot 2^{(s+1)(3s+\log M)})$. This completes the proof of Item 1.

To see Item 2, we divide N input bits into k disjoint blocks $T_1, \cdots, T_k$ of size at least t (and hence $k = \lfloor N/t \rfloor$), where t is a parameter chosen later. We claim that each block must contain at least one unrestricted variable in $\rho \sim \mathcal{R}$ with high probability (and hence $|\rho^{-1}(*)| \geq \lfloor N/t \rfloor$).

Fix any block $T = T_i$ for some $i \in [k]$. As in [53], one can easily observe that the condition that every variable in T is restricted can be checked by a CNF of size at most $|T|$ ($\leq N$). By a simple hybrid argument, the concatenation of d independent pseudorandom distributions $G(z_1), \cdots, G(z_d)$ $d\varepsilon_0$-fools CNFs (cf. [53, Corollary 55]). Therefore, the probability that every variable in T is restricted by $\rho \sim \mathcal{R}$ is bounded by $(1 - p^{d-1}/64)^t + d\varepsilon_0$, where the first term is an upper bound for the probability that every variable in T is restricted by a truly random restriction. Choosing $t = 64 \log(1/\delta)/p^{d-1}$ and using a union bound, the probability that some block T_i is completely fixed can be bounded above by $\lfloor N/t \rfloor \cdot (\delta + d\varepsilon_0)$, which completes the proof of Item 2. ◀

▶ **Corollary 19.** *For every circuit C of size M ($\geq N$) and depth d over N inputs, there exists a restriction ρ such that*

1. *$C\restriction_\rho$ is a decision tree of depth at most $s := 2 \log 8M$,*
2. *$|\rho^{-1}(*)| \geq N/O(\log M)^d$, and*
3. *$\mathsf{Kt}(\rho) \leq d \cdot \widetilde{O}((\log M)^3)$.*

Proof. Tal [53, Theorem 52] showed that there exists a polynomial-time pseudorandom generator G of seed length $r := \widetilde{O}(\log M_0 \cdot \log(M_0/\varepsilon_0))$ that ε_0-fools CNFs of size M_0. We set $M_0 := M \cdot 2^s \cdot 2^{s(q+1)}$, $s := 2 \log 8M$, and $\varepsilon_0 := 2^{-9s^2}$. Then the seed length r of G is at most $r = \widetilde{O}(\log M_0 \cdot \log(M_0/\varepsilon_0)) = \widetilde{O}(\log M \cdot (\log M)^2)$. Applying Theorem 18, the probability that $\mathsf{DT}(C\restriction_\rho) > s$ is bounded by $\frac{1}{2}$. Choosing $\delta = 1/8N$, we also have that the probability that $|\rho^{-1}(*)| < \lfloor N \cdot p^{d-1}/64 \log(1/\delta) \rfloor$ is at most $\frac{1}{4}$. Thus there exists some restriction ρ in the support of $\mathcal{R}$ such that $\mathsf{DT}(C\restriction_\rho) \leq s$ and $|\rho^{-1}(*)| \geq \Omega(N \cdot p^{d-1}/\log N) \geq N/O(\log M)^d$. ◀

Using the assumption that a circuit computes MKtP, we show that shallow decision trees must be a constant function.

▶ **Lemma 20.** *Let C be a circuit and ρ be a restriction such that $C\restriction_\rho$ is a decision tree of depth s. If $\mathsf{MKtP}[O(s \log N) + \mathsf{Kt}(\rho)] \subseteq C^{-1}(1)$, then $C\restriction_\rho \equiv 1$.*

Proof. We prove the contrapositive. Assume that $C\restriction_\rho \not\equiv 1$, which means that there is a path $\pi \colon [N] \to \{0, 1, *\}$ of a decision tree $C\restriction_\rho$ that assigns at most s variables so that $C\restriction_{\rho\pi} \equiv 0$. Note that $\mathsf{Kt}(\pi) \leq O(s \log N)$, because one can specify each restricted variable of π by using $O(\log N)$ bits. Thus we have $\mathsf{Kt}(0^N \circ \pi \circ \rho) \leq O(s \log N) + \mathsf{Kt}(\rho)$. On the other hand, $C(0^N \circ \pi \circ \rho) = C\restriction_{\rho\pi}(0^N) = 0$. Therefore, we obtain $\mathsf{MKtP}[O(s \log N) + \mathsf{Kt}(\rho)] \not\subseteq C^{-1}(1)$. ◀

Now we are ready to prove the main result of this section.

Proof of Theorem 15. Assume, by way of contradiction, that there is a circuit C of size $M := N^{O(1)}$ and depth d that computes $\mathsf{MKtP}[d \cdot \widetilde{O}(\log N)^3, N/\omega(\log N)^d]$. Using Corollary 19, we take a restriction ρ such that $C\restriction_\rho$ is a decision tree of depth $s = O(\log N)$. By Lemma 20, we have $C\restriction_\rho \equiv 1$, under the assumption that $O(s \log N) + \mathsf{Kt}(\rho) \leq \theta(N)$, which is satisfied by choosing $\theta(N)$ large enough. Now, by counting the number of inputs accepted by $C\restriction_\rho$, we obtain

$$2^{N/O(\log N)^d} \leq 2^{|\rho^{-1}(*)|} = |(C\restriction_\rho)^{-1}(1)| \leq 2^{\theta'(N)+1},$$

where, in the last inequality, we used the fact that the number of strings whose Kt complexity is at most $\theta'(N)$ is at most $2^{\theta'(N)+1}$. However, the inequality contradicts the choice of $\theta'(N)$. ◀

3.2 NQP $\not\subseteq$ NC^1 and Formula-XOR or GapAND-Formula for MCSP

This section is devoted to proving HM Frontier B1 and HM Frontier D1. In fact, we provide two different proofs of HM Frontier B1, one based on [42], another one based on [10].

In both proofs, the hardness magnification is achieved by constructing an oracle circuit for MCSP. The most interesting part of the first proof is that it gives a *conditional* construction assuming QP $\subseteq$ P/poly. While the oracle circuit construction can be made *unconditional* (as in the second proof), it illustrates a potentially more applicable approach: proving the hardness magnification theorem while assuming the target circuit lower bound is false (i.e., NQP $\subseteq$ NC^1).

3.2.1 Reduction Based Approach from [42]

In the initial magnification theorem [42, Theorem 1], approximate MCSP was shown to admit hardness magnification phenomena. Here we present a similar hardness magnification theorem for a worst-case version of MCSP.

A natural way of reducing worst-case MCSP to approximate MCSP is to apply error-correcting codes. Error-correcting codes map a hard Boolean function to a Boolean function which is hard on average. A problem with this approach is that error-correcting codes do not guarantee that an easy Boolean function will be mapped to an easy Boolean function. Our main idea is to enforce the latter property with an extra assumption QP $\subseteq$ P/poly. Here, QP denotes TIME$[n^{\log^{O(1)} n}]$. Similarly, NQP will stand for NTIME$[n^{\log^{O(1)} n}]$.

We will use the following explicit error-correcting code.

▶ **Theorem 21** (Explicit linear error-correcting codes [30, 48]). *There exists a sequence $\{E_N\}_{N\in\mathbb{N}}$ of error-correcting codes $E_N\colon \{0,1\}^N \to \{0,1\}^{M(N)}$ with the following properties:*

- *$E_N(x)$ can be computed by a uniform deterministic algorithm running in time* poly(N).
- *$M(N) = b \cdot N$ for a fixed $b \geq 1$.*
- *There exists a constant $\delta > 0$ such that any codeword $E_N(x) \in \{0,1\}^{M(N)}$ that is corrupted on at most a δ-fraction of coordinates can be uniquely decoded to x by a uniform deterministic algorithm D running in time* poly$(M(N))$.
- *Each output bit is computed by a parity function: for each input length $N \geq 1$ and for each coordinate $i \in [M(N)]$, there exists a set $S_{N,i} \subseteq [N]$ such that for every $x \in \{0,1\}^N$,*

$$E_N(x)_i = \bigoplus_{j\in S_{N,i}} x_j.$$

Under the assumption that QP $\subseteq$ P/poly, we present an efficient reduction from worst-case MCSP to approximate MCSP: Given the truth table of a function f, we simply map it to $E_N(\mathsf{tt}(f))$. The following lemma establishes the correctness of this reduction.

▶ **Lemma 22** (Reducing worst-case MCSP to approximate MCSP). *Assume QP $\subseteq$ P/poly. Then the error-correcting code E_N from Theorem 21 satisfies the following:*

1. *$f_n \in$ Circuit$[2^{n^{1/3}}] \Rightarrow E_N(tt(f_n)) \in$ Circuit$[2^{\sqrt{m}}]$,*[14]
2. *$f_n \notin$ Circuit$[2^{n^{2/3}}] \Rightarrow E_N(tt(f_n))$ is hard to $(1-\delta)$-approximate by $2^{\sqrt{m}}$-size circuits,*

where $m = \Theta(n)$.

[14] Here we identify $E_N(\mathsf{tt}(f_n))$ with the function whose truth table is $E_N(\mathsf{tt}(f_n))$.

Proof. For the first implication we consider the map

$$C, i \mapsto E_N(\mathsf{tt}(C))_i$$

where C is a circuit with n inputs and size $2^{n^{1/3}}$, $i \in \{0,1\}^m$, and $m = \log |E_N|$. The map takes an input of length $2^{O(n^{1/3})}$, and is computable in time $2^{O(n)}$; hence the map is in $\mathsf{QP} \subseteq \mathsf{P/poly}$. Thus, there exists a circuit F of size $2^{O(n^{1/3})}$ that, taking the description of a circuit C of size $2^{n^{1/3}}$ and $i \in \{0,1\}^m$ as input, outputs the ith bit of $E_N(\mathsf{tt}(C))$. Therefore if f_n is computed by a circuit C of size $2^{n^{1/3}}$, the function $i \mapsto E_N(\mathsf{tt}(f_n))_i$ is computable by a circuit $F(C,\text{-})$ of size $2^{O(n^{1/3})} < 2^{\sqrt{m}}$.

The second implication is obtained in a similar way by considering the map

$$C, i \mapsto D_N(\mathsf{tt}(C))_i$$

where C is a circuit with $m = \log |E_N|$ inputs and size $2^{\sqrt{m}}$, $i \in \{0,1\}^n$ and D_N is an efficient decoder of E_N. The new map is computable in time $2^{O(m)}$ and again is in $\mathsf{QP} \subseteq \mathsf{P/poly}$. Therefore if $E_N(\mathsf{tt}(f_n))$ is $(1-\delta)$-approximated by a circuit C of size $2^{\sqrt{m}}$, f_n is computable by a circuit of size $2^{O(\sqrt{m})} < 2^{n^{2/3}}$. ◀

Since the error-correcting code of Theorem 21 can be computed by using one layer of XOR gates, we obtain the following corollary.

▶ **Corollary 23.** *If $\mathsf{QP} \subseteq \mathsf{P/poly}$, then $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ is reducible to $\mathsf{MCSP}[(2^{\sqrt{n}}, 0), (2^{\sqrt{n}}, \delta)]$ by using a many-one reduction computed by a linear-size circuit of* XOR *gates.*

We are ready to prove the main result of this section:

▶ **Theorem 24** (Magnification for worst-case MCSP via error-correcting codes)**.** *Assume that $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \notin \mathsf{Formula}\text{-}\mathsf{XOR}[N^{1+\varepsilon}]$ for some constant $\varepsilon > 0$. Then either $\mathsf{QP} \not\subseteq \mathsf{P/poly}$ or $\mathsf{NP} \not\subseteq \mathsf{NC}^1$. In particular, $\mathsf{NQP} \not\subseteq \mathsf{NC}^1$.*

Proof. We prove the contrapositive. Assume that $\mathsf{QP} \subseteq \mathsf{P/poly}$ and $\mathsf{NP} \subseteq \mathsf{NC}^1$. [42, Lemma 16] shows that $\mathsf{NP} \subseteq \mathsf{NC}^1$ implies $\mathsf{MCSP}[(2^{\sqrt{n}}, 0), (2^{\sqrt{n}}, \delta)] \in \mathsf{Formula}[N^{1+\varepsilon}]$ for any constant $\varepsilon > 0$. By combining this with Corollary 23, we obtain that $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \in \mathsf{Formula}\text{-}\mathsf{XOR}[O(N^{1+\varepsilon})]$. ◀

3.2.2 Kernelization Based Approach from [10]

Now we give another proof of HM Frontier B1 by adapting techniques from [10]. In fact, the following proof implies (under a straightforward adjustment of parameters) both HM Frontier B1 and HM Frontier D1.

▶ **Theorem 25** (Magnification for worst-case MCSP via kernelization for GapAND-Formula-XOR)**.** *Assume that $\mathsf{MCSP}[2^{n^{1/3}}] \notin \mathsf{GapAND}_{O(N)}\text{-}\mathsf{Formula}\text{-}\mathsf{XOR}[N^{\varepsilon}]$ for some constant $\varepsilon > 0$. Then $\mathsf{NQP} \not\subseteq \mathsf{NC}^1$.*

Proof Sketch. The following proof is just an adaption of Theorem 3.4 of [10].

Let $N = 2^n$ and $s = 2^{n^{1/3}} = 2^{(\log N)^{1/3}}$. Let $S = \mathsf{MCSP}[2^{n^{1/3}}]^{-1}(1)$ (that is, all yes instances of $\mathsf{MCSP}[2^{n^{1/3}}]$ on inputs of length N), and $m = |S|$. We have that $m \leq s^{O(s)}$. Let E_N be the error correcting code from Theorem 21. Recall that E_N maps from $\{0,1\}^N$ to $\{0,1\}^{b \cdot N}$ for a constant b.

Let $T = c_1 \cdot \log m$ for a large enough constant c_1. Suppose we pick T random indexes $I = (i_1, i_2, \ldots, i_T)$ from $[b \cdot N]$ independently and uniformly at random. Given $x \in \{0,1\}^N$, let $H_I(x) := (E_N(x)_{i_1}, E_N(x)_{i_2}, \ldots, E_N(x)_{i_T})$.

By a Chernoff bound and a union bound, we can see that with high probability over random choices of I, all inputs from S are mapped into distinct strings in $\{0,1\}^T$ by H_I. We fix such a good collection of indexes I_{good}.

Now, consider the following language

$$L_{\mathsf{check}} : [b \cdot N]^T \times \{0,1\}^T \times [b \cdot N] \times \{0,1\} \to \{0,1\},$$

which takes as inputs I (hash function coordinates), w (hash value), i (index), and z (check-bit). $L_{\mathsf{check}}(I, w, i, z)$ guesses an input $y \in \{0,1\}^N$, and accepts if $H_I(y) = w$, $\mathsf{MCSP}[2^{n^{1/3}}](y) = 1$, and $E_N(y)_i = z$. It is easy to see that L_{check} is in NQP.

Given $x \in \{0,1\}^N$, we claim that $\mathsf{MCSP}[2^{n^{1/3}}](x) = 1$ iff $L_{\mathsf{check}}(I_{\mathsf{good}}, H_{I_{\mathsf{good}}}(x), i, E_N(x)_i) = 1$ for all $i \in [b \cdot N]$.

1. When $\mathsf{MCSP}[2^{n^{1/3}}](x) = 1$, on the particular guess $y = x$, $L_{\mathsf{check}}(I_{\mathsf{good}}, H_{I_{\mathsf{good}}}(x), i, E_N(x)_i)$ accepts for all $i \in [b \cdot N]$.
2. When $\mathsf{MCSP}[2^{n^{1/3}}](x) = 0$, we set $z = H_{I_{\mathsf{good}}}(x)$. By our choice of I_{good}, there is at most one x' satisfying both $\mathsf{MCSP}[2^{n^{1/3}}](x') = 1$ and $H_{I_{\mathsf{good}}}(x') = z$. If there is no such x', then all $L_{\mathsf{check}}(I_{\mathsf{good}}, H_{I_{\mathsf{good}}}(x), i, x_i)$ reject. Otherwise, we have $x \neq x'$. Let i be an index such that $E_N(x)_i \neq E_N(x')_i$. Then $L_{\mathsf{check}}(I_{\mathsf{good}}, H_{I_{\mathsf{good}}}(x), i, E_N(x)_i)$ rejects.

Moreover, in the second case, $L_{\mathsf{check}}(I_{\mathsf{good}}, H_{I_{\mathsf{good}}}(x), i, E_N(x)_i)$ indeed rejects at least for a constant fraction of $i \in [b \cdot N]$, since $E_N(x)$ is an error correcting code,

Now suppose $\mathsf{NQP} \subseteq \mathsf{NC}^1$ for the sake of contradiction. Since $H_{I_{\mathsf{good}}}(x)$ can be computed by $T = N^{o(1)}$ many XOR gates (I_{good} is hardwired into the circuit), we can construct $b \cdot N$ $\mathsf{Formula\text{-}XOR}[N^{o(1)}]$ circuits $C_1, C_2, \ldots, C_{b \cdot N}$, such that if $\mathsf{MCSP}[2^{n^{1/3}}](x) = 1$ then $C_i(x) = 1$ for all x, and otherwise $C_i(x) = 0$ for a constant fraction of i's.

By a simple error reduction via random sampling, we construct $m = O(N)$ $\mathsf{Formula\text{-}XOR}[N^{o(1)}]$ circuits $D_1, D_2, \ldots, D_m$, such that if $\mathsf{MCSP}[2^{n^{1/3}}](x) = 1$ then $D_i(x) = 1$ for all x, and otherwise $D_i(x) = 0$ for at least a 0.9 fraction of inputs. Hence, we have $\mathsf{MCSP}[2^{n^{1/3}}] \in \mathsf{GapAND}_{O(N)}\text{-}\mathsf{Formula\text{-}XOR}[N^{o(1)}]$, a contradiction to the assumption. ◀

▶ Remark 26. We note that $\mathsf{GapAND}_{O(N)}\text{-}\mathsf{Formula\text{-}XOR}[N^{\varepsilon}]$ circuits are a special case of both $\mathsf{Formula\text{-}XOR}[N^{1+\varepsilon}]$ circuits and $\mathsf{GapAND}_{O(N)}\text{-}\mathsf{Formula}[N^{2+\varepsilon}]$ circuits. Therefore, the above proof implies both HM Frontier B1 and HM Frontier D1.

3.3 NP $\not\subseteq$ NC^1 and Almost-Formula Lower Bounds for MCSP

Recall that near-quadratic *formula* lower bounds are known for $\mathsf{MCSP}[2^{n^{o(1)}}, 2^{n^{o(1)}}]$. On the other hand, a hardness magnification obtained by a super efficient construction of anticheckers established in [39] states that $\mathsf{NP} \subseteq \mathsf{P/poly}$ implies almost linear-size circuits for a worst-case version of parameterized $\mathsf{MCSP}[2^{n^{o(1)}}, 2^{n^{o(1)}}]$. Consequently, if we could make the hardness magnification work for formulas, $\mathsf{NP} \not\subseteq \mathsf{NC}^1$ would follow. We make a step in this direction by showing that $\mathsf{NP} \subseteq \mathsf{NC}^1$ implies the existence of almost-formulas of almost linear size solving the worst-case $\mathsf{MCSP}[2^{n^{o(1)}}, 2^{n^{o(1)}}]$, cf. Theorem 29. This is established by a more detailed analysis of the proof from [39] extended with an application of the Valiant-Vazirani Isolation Lemma (cf. [6, Lemma 17.19]) in the process of selecting anticheckers. We also observe that almost-formulas of sub-quadratic size cannot solve PARITY, cf. Theorem 30. These results yield HM Frontier C1 and HM Frontier C3.

We start the presentation with a lemma needed to derive HM Frontier C1.

▶ **Lemma 27** (Anticheckers). *Assume* $NP \subseteq NC^1$. *Then for any* $\lambda \in (0,1)$ *there are circuits* $\{C_{2^n}\}_{n=1}^{\infty}$ *of size* $2^{n+O(n^\lambda)}$ *which given* $\mathsf{tt}(f) \in \{0,1\}^N$, *outputs* $2^{O(n^\lambda)}$ n*-bit strings* $y_1, \ldots, y_{2^{O(n^\lambda)}}$ *together with bits* $f(y_1), \ldots, f(y_{2^{O(n^\lambda)}})$ *forming a set of anticheckers for* f, *i.e. if* f *is hard for circuits of size* 2^{n^λ} *then every circuit of size* $2^{n^\lambda}/2n$ *fails to compute* f *on one of the inputs* $y_1, \ldots, y_{2^{O(n^\lambda)}}$. *Moreover, each* $y_i, f(y_i)$ *is generated by a subcircuit of* C_{2^n} *with inputs* $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1}), \mathsf{tt}(f)$ *whose only gates with fanout* > 1 *are* $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1})$.

Proof. This proof follows [39]. Our contribution here is the "moreover" part, but we also give a more succinct self-contained proof. For each Boolean function f the desired set of anticheckers is known to exist, the only problem is to find it with a circuit of the desired size and formula-like form. In order to do so, we will simulate the proof of the existence of anticheckers, but make the involved counting constructive by using linear hash functions and the assumption $\mathsf{NP} \subseteq \mathsf{NC}^1$. Additionally, for the "moreover" part of the lemma, we will employ the Valiant-Vazirani Isolation Lemma (cf. [6, Lemma 17.19]) in the process of selecting good anticheckers.

Let $\lambda \in (0,1)$ and f be a Boolean function with n inputs hard for circuits of size 2^{n^λ}. For j n-bit strings $y_1, \ldots, y_j$ and $s \in [0,1]$, define a predicate

$$P_f(y_1, \ldots, y_j)[s] \text{ iff } \leq s \text{ fraction of all circuits of size } 2^{n^\lambda}/2n \text{ compute } f \text{ on } y_1, \ldots, y_j.$$

Further, let $R_f(y_1, \ldots, y_j)$ be the number of circuits of size $2^{n^\lambda}/2n$ which do not make any error on $y_1, \ldots, y_j$ when computing f. Note that P_f and R_f depend on j values of f, not on the whole $\mathsf{tt}(f)$, but for simplicity we do not display them.

Suppose that given $\mathsf{tt}(f)$ we already generated $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1})$ such that $P_f(y_1, \ldots, y_{i-1})[(1-1/4n)^{i-1}]$ holds. For $i = 1$ the generated set is empty. We want to find $y_i, f(y_i)$ such that $P_f(y_1, \ldots, y_i)[(1-1/4n)^i]$. In order to do so, we will construct a formula $F(y_1, \ldots, y_i, f(y_1), \ldots, f(y_i))$ of size $2^{O(n^\lambda)}$ (if $i \leq 2^{O(n^\lambda)}$) such that under the assumption $R_f(y_1, \ldots, y_{i-1}) \geq 2n^2$,

$$F(y_1, \ldots, y_i, f(y_1), \ldots, f(y_i)) = 1 \quad \Rightarrow \quad P_f(y_1, \ldots, y_i)[(1-1/4n)^i]$$

$$P_f(y_1, \ldots, y_{i-1})[(1-1/4n)^{i-1}] \quad \Rightarrow \quad \exists y_i, F(y_1, \ldots, y_i, f(y_1), \ldots, f(y_i)) = 1.$$

Assume for now that we already have such a formula F. We firstly show how to find $y_i, f(y_i)$ given F by an exhaustive search through all n-bit strings in combination with Valiant-Vazirani Lemma.

Consider a $2^{O(n^\lambda)}$-size formula $F^{r,h}(y_1, \ldots, y_{i-1}, z, f(y_1), \ldots, f(y_{i-1}), f(z))$ computing the following predicate

$$F(y_1, \ldots, y_{i-1}, z, f(y_1), \ldots, f(y_{i-1}), f(z)) \wedge h(z) = 0^r \tag{1}$$

where $z \in \{0,1\}^n$, $r \leq n+2$ and $h \in \mathcal{H}_{n,r}$ for a pairwise independent efficiently computable hash function collection $\mathcal{H}_{n,r}$ from $\{0,1\}^n$ to $\{0,1\}^r$. Formula $F^{r,h}$ exists since $\mathsf{NP} \subseteq \mathsf{NC}^1$. By Valiant-Vazirani Lemma, for fixed $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1})$, if h is chosen randomly from $\mathcal{H}_{n,r}$ and r randomly from $\{2, \ldots, n+1\}$, then with probability $\geq 1/8n$, there is a unique z satisfying (1). Therefore, the probability that none of $2^{O(n^\lambda)}$ many randomly chosen tuples r, h guarantees a unique solution is $< (1-1/8n)^{2^{O(n^\lambda)}} \leq 1/2^{2^{O(n^\lambda)}/8n}$. That

is, there exist a set $\mathcal{R}$ of $2^{O(n^\lambda)}$ tuples r, h such that for each $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1})$, at least one tuple r, h from $\mathcal{R}$ will guarantee a unique solution. Consequently, for each $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1})$ for at least one $r, h \in \mathcal{R}$ the following $2^{n+O(n^\lambda)}$-size formula

$$\bigvee_{k=1,\ldots,2^n} (b^k_j \wedge F^{r,h}(y_1, \ldots, y_{i-1}, b^k, f(y_1), \ldots, f(y_{i-1}), f(b^k)),$$

where b^k_j is the jth bit of the kth n-bit string b^k (in the lexicographic order), outputs the jth bit of a good antichecker y_i. Since $\mathsf{NP} \subseteq \mathsf{NC}^1$, we can select the right y_i from the $2^{O(n^\lambda)}$ candidate strings corresponding to tuples r, h from $\mathcal{R}$ by applying a formula of size $2^{O(n^\lambda)}$ on top of them. Having y_i, a formula of size $poly(n)2^n$ with access to $\mathsf{tt}(f)$ can generate $f(y_i)$.

Iteratively, a circuit of size $2^{n+O(n^\lambda)}$ will generate $y_1, \ldots, y_{2^{O(n^\lambda)}}, f(y_1), \ldots, f(y_{2^{O(n^\lambda)}})$ such that $P_f(y_1, \ldots, y_{2^{O(n^\lambda)}})[(1-1/4n)^{2^{O(n^\lambda)}}]$ as long as $R_f(y_1, \ldots, y_{2^{O(n^\lambda)}}) \geq 2n^2$. Deciding whether $R_f(y_1, \ldots, y_i) \geq 2n^2$ is in $\mathsf{NP} \subseteq \mathsf{NC}^1$ (on input $y_1, \ldots, y_i, f(y_1), \ldots, f(y_i), 1^{2^{n^\lambda}}$), so there are formulas of size $2^{O(n^\lambda)}$ for it. Since $(1-1/4n)^{2^{O(n^\lambda)}} \leq 1/2^{2^{O(n^\lambda)}/4n}$, we reach $R_f(y_1, \ldots, y_i) < 2n^2$ with $i \leq 2^{O(n^\lambda)}$. When this happens, the remaining $< 2n^2$ circuits of size $2^{n^\lambda}/2n$ can be generated by an $\mathsf{NP}^{\mathsf{coNP}}$ algorithm, and since $\mathsf{NP} \subseteq \mathsf{NC}^1$, by a formula of size $2^{O(n^\lambda)}$. Finally, for each of the remaining circuits we can find an n bit string witnessing its error exhaustively by a formula of size $2^{n+O(n^\lambda)}$. Altogether, the desired antichecker $y_1, \ldots, y_{2^{O(n^\lambda)}}$ with bits $f(y_1), \ldots, f(y_{2^{O(n^\lambda)}})$ will be generated by a circuit of size $2^{n+O(n^\lambda)}$. Note that this circuit will have the desired formula-like structure because its only gates with fanout bigger than 1 are those computing tuples $y_i, f(y_i)$.

▷ Claim 28. If $P_f(y_1, \ldots, y_{i-1})[(1-1/4n)^{i-1}]$ and $R_f(y_1, \ldots, y_{i-1}) \geq 2n^2$, then for some y_i, $P_f(y_1, \ldots, y_i)[(1-1/4n)^{i-1}(1-1/2n)]$.

Claim 28 is proved by a standard counting argument, cf. [39, Claim 22]. Observe that with Claim 28 we can construct the desired formula F. Here we employ approximate counting with linear hash functions: if $X \subseteq \{0,1\}^m$ is a set of size s, there are matrices $A_1, \ldots, A_{\log(4s^c)}$ such that each A_j defines a linear function mapping a Cartesian power X^c to $(s(1+\varepsilon))^c/\log(4s^c)$, for $c = 2(\varepsilon^{-1}(\log\log s + \log\varepsilon^{-1}))$. Moreover, for each A_j there is $X^c_j \subseteq X^c$ satisfying $\forall x \in X^c_j \forall x' \in X^c$ $(x \neq x' \to A_j(x) \neq A_j(x'))$, and $\bigcup_j X^c_j = X^c$. Mapping $x \in X^c$ to $A_j(x)$ in the jth block of size $(s(1+\varepsilon))^c/\log(4s^c)$, for the first A_j with $x \in X^c_j$, thus defines an injection from X^c to $(s(1+\varepsilon))^c$ which witnesses that the size of X is $\leq s(1+\varepsilon)$. See e.g. [28, Section 3, 2nd paragraph] for details.

Therefore, once we have $P_f(y_1, \ldots, y_i)[(1-1/4n)^{i-1}(1-1/2n)]$ we can conclude that there are matrices $A_1, \ldots, A_{2^{O(n^\lambda)}}$ defining an injective mapping of a Cartesian power (with exponent of rate $poly(n)$) of the set of all circuits of size $2^{n^\lambda}/2n$ that compute f on $y_1, \ldots, y_i$ to the same Cartesian power of $(1-1/4n)^{i-1}(1-1/2n)(1+1/4n) \leq (1-1/4n)^i$ fraction of the set of all circuits of size $2^{n^\lambda}/2n$. The existence of such matrices, not only witnesses $P_f(y_1, \ldots, y_i)[(1-1/4n)^i]$ but is also an $\mathsf{NP}^{\mathsf{coNP}}$ property, and since $\mathsf{NP} \subseteq \mathsf{NC}^1$, decidable by a formula F of size $2^{O(n^\lambda)}$. ◀

▶ **Theorem 29** (Improved magnification via anticheckers). *Assume that MCSP$[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$ is hard for circuits C (with 2^n inputs) of size $2^{n+O(n^{1/2})}$ with the following form. Given $\mathsf{tt}(f)$, subcircuits of C generate $y_1, \ldots, y_{2^{O(n^{1/2})}}, f(y_1), \ldots, f(y_{2^{O(n^{1/2})}})$ so that each $y_i, f(y_i)$ is generated by a subcircuit of C with inputs $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1}), \mathsf{tt}(f)$ whose only gates with fanout $>$ 1 are $y_1, \ldots, y_{i-1}, f(y_1), \ldots, f(y_{i-1})$. Having $y_1, \ldots, y_{2^{O(n^{1/2})}}, f(y_1), \ldots, f(y_{2^{O(n^{1/2})}})$, C applies a formula of size $2^{O(n^{1/2})}$ on top of these gates.*

Then $\mathsf{NP} \not\subseteq \mathsf{NC}^1$.

Proof. If $\mathsf{NP} \subseteq \mathsf{NC}^1$, then $\mathsf{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$ can be solved by circuits of size $2^{n+O(n^{1/2})}$ of the required form: given a Boolean function f, apply Lemma 27 to generate a set of its anticheckers $y_1, \ldots, y_{2^{O(n^{1/2})}}$ together with bits $f(y_1), \ldots, f(y_{2^{O(n^{1/2})}})$ and using $\mathsf{NP} \subseteq \mathsf{NC}^1$ decide whether f is hard for circuits of size $2^{n^{1/2}}/2n$ on $y_1, \ldots, y_{2^{O(n^{1/2})}}$. ◀

Note that circuits from the assumption of hardness magnification via anticheckers, Theorem 29, are $2^{O(n^{1/2})}$-almost formulas of almost linear size which gives us HM Frontier C1. We can now complement it with HM Frontier C3.

Consider an s-almost formula. Each gate G of F with fanout larger than 1 is computed by a formula with inputs being either the original inputs of F or gates of F with fanout larger than 1. We call any maximal formula of this form a *principal* formula of G.

▶ **Theorem 30.** *PARITY* $\notin n^{\varepsilon}$-almost-*Formula*$[n^{2-9\varepsilon}]$, *if* $\varepsilon < 1$.

Proof Sketch. For the sake of contradiction, assume PARITY has n^{ε}-almost formulas of size $n^{2-9\varepsilon}$. Since there are only n^{ε} gates of fanout > 1, we can replace these gates by appropriate constants and obtain formulas F_n of size $n^{2-8\varepsilon}$ computing PARITY with probability $\geq 1/2 + 1/2^{n^{\varepsilon}}$. In more detail, each formula F_n checks if the principal formulas compute the fixed constants. If this is the case, then F_n outputs the output of the original almost-formula (since gates with fan-out larger than 1 are fixed, the output can be computed by a formula). Otherwise, F_n outputs a fixed constant, whichever is better on the majority of the remaining inputs. This does not increase the size of the resulting formula F_n by more than a constant factor. As pointed out by Komargodski-Raz [32], each boolean function f on n input bits can be approximated by a real polynomial of degree $O(t\sqrt{L(f)}\frac{\log n}{\log\log n})$ up to a point-wise additive error of 2^{-t}, and this can be shown to imply that each formula of size $o((n/t)^2(\log\log n/\log n)^2)$ computes PARITY over n input bits with probability at most $1/2 + 1/2^{t+O(1)}$ (for large enough t). Taking $t = n^{2\varepsilon}$ we get a contradiction. ◀

3.4 NP $\not\subseteq$ NC^1 and AC^0 Lower Bounds for $(n-k)$-Clique

In this Section, we discuss the proofs of some statements claimed in HM Frontier E from Section 1.1. Recall that we consider graphs on n vertices that are described in the adjacency matrix representation. The input graph is therefore represented using $m = \Theta(n^2)$ bits. We begin with the proof of the magnification result in HM Frontier E1.

▶ **Proposition 31.** *Let* $k(n) = (\log n)^C$ *for some constant* C. *If there exists* $\varepsilon > 0$ *such that for every depth* $d \geq 1$, $(n-k)$-Clique $\notin \mathsf{AC}^0_d[m^{1+\varepsilon}]$, *then* NP $\not\subseteq$ NC^1.

Proof. We use a straightforward reduction to the magnification theorem for k-Vertex-Cover established in [42, Theorem 7]. (We state Proposition 31 in a slightly weaker form just for simplicity.) Indeed, a graph G on n vertices has a vertex cover of size $\leq k$ if and only if G has an independent set of size $\geq n-k$. In turn, the latter is true if and only if the complement graph $\overline{G}$ has a clique of size $\geq n-k$. Therefore, by negating input literals, the complexities of $(n-k)$-Clique and k-Vertex-Cover are equivalent with respect to AC^0 circuits. For this reason, the hardness magnification theorem of [42] immediately implies Proposition 31. ◀

We state below conditional and unconditional lower bounds on the complexity of detecting very large cliques. The next proposition implies the lower bound claimed in HM Frontier E4.

▶ **Proposition 32** ([4]; see also [29, Section 9.2])**.** *For* $k(n) \leq n/2$, *every monotone circuit for* $(n-k)$-Clique *requires* $2^{\Omega(k^{1/3})}$ *gates.*

Interestingly, the problem can be solved by (bounded depth) polynomial size monotone circuits if $k \leq \sqrt{\log n}$ [4].

Finally, by the observation employed in the proof of Proposition 31, for non-monotone computations the complexities of detecting large cliques and small vertex covers are equivalent. A consequence of this is that one can show the following result, which implies the statement in HM Frontier E2.

▶ **Proposition 33.** *If* ETH *for non-uniform circuits holds, then* $(n-k)$-Clique $\notin$ P/poly *as long as* $\omega(\log n) \leq k \leq n/2$.

Indeed, under ETH the k-Vertex-Cover problem cannot be solved in time $2^{o(k)} \cdot \mathsf{poly}(m)$ (see [26] and [17, Theorem 29.5.9]). Further discussion on the conditional hardness of k-Vertex-Cover that also applies to $(n-k)$-Clique appears in [42].

4 Hardness Magnification and Natural Proofs

4.1 Equivalences

The main contribution of this section is new hardness magnification results showing non-learnability of circuit classes from slightly super-linear lower bounds for the approximate version of MCSP and the gap version of MCSP. We then use these magnification results to establish a series of equivalences.

▶ **Lemma 34** (Hardness Magnification for Learnability from Lower Bounds for Approximate MCSP)**.** *Let* $s, t : \mathbb{N} \to \mathbb{N}$ *be size functions such that* $n \leq s(n) \leq t(n)$ *and* ε, δ *be parameters such that* $\varepsilon < 1/2$, $0 \leq \delta \leq 1/9$. *If for infinitely many input lengths* $N = 2^n$, $\mathit{MCSP}[(s,0),(t,\varepsilon)] \notin \mathit{Circuit}[N \cdot \mathsf{poly}(t(n)/\varepsilon)]$, *then for infinitely many inputs* n, $\mathit{Circuit}[s(n)]$ *cannot be learnt up to error* $\varepsilon/2$ *with confidence* $1-\delta$ *by* $t(n)$*-size circuits using non-adaptive membership queries over the uniform distribution.*

We also show a related result which gives lower bounds for learnability of a circuit class $\mathcal{C}$ using $\mathcal{C}$-circuits by starting with a lower bound against worst-case MCSP instead of the average-case.

▶ **Lemma 35** (Hardness Magnification for Learnability from Lower Bounds for Gap MCSP)**.** *Let* $c \geq 1$ *be an arbitrary constant. If there is* $\varepsilon < 1/2$, *such that infinitely many input lengths* $N = 2^n$, $\mathit{MCSP}[n^c, 2^n/n^c] \notin \mathit{Circuit}[N^{1+\varepsilon}]$, *then for every* $\gamma \in (0,1)$, *for infinitely many inputs* n, $\mathit{Circuit}[n^c]$ *cannot be learnt up to error* $1/O(n^{2c})$ *with confidence* $1-1/n$ *by* $\mathit{Circuit}[2^{O(n^\gamma)}]$*-circuits using non-adaptive membership queries over the uniform distribution.*

Proof of Theorem 1. The following implications establish the desired equivalences.

$(a) \Longrightarrow (c)$: For the parameters c, γ, ε given by (a), we apply Lemma 34 for $s(n) = n^c$ and $t(n) = 2^{n^\gamma}$, to see that for some $\gamma' > 0$, Circuit$[n^c]$ cannot be learned by circuits of size $2^{O(n^{\gamma'})}$ via non-adaptive queries up to an error $O(1/n^c)$.

$(c) \Longrightarrow (d)$: We show the contrapositive of this implication. Suppose that for every $d \geq 1$, there exists a Circuit$[\mathsf{poly}(n)]$-natural property that is useful against Circuit$[n^d]$ for all large enough n. By Theorem 5, for every $c \geq 1$, we can learn Circuit$[n^c]$ by a sequence of oracle Circuit$[2^{O(n^{1/2})}]$-circuits up to an error of n^{-c}, by choosing $d = 2ac$ for the constant a from Theorem 5.

$(d) \Longrightarrow (a)$, $(d) \Longrightarrow (b)$: Trivial, using the fact that random functions are hard.

$(c) \Longrightarrow (e)$: Follows from the contrapositive of Theorem 10.

$(e) \implies (c)$: Follows from the non-uniform version of Proposition 29 in [41], using essentially the same proof.

$(b) \implies (c)$: For the parameter c given by (b), we apply Lemma 35 to see that $\mathsf{Circuit}[n^c]$ cannot be learned by circuits of size $2^{O(n^\gamma)}$ via non-adaptive queries up to an error $O(1/n^c)$, for any $\gamma \in (0,1)$. ◀

We now complete the proof of Theorem 1 by proving Lemmas 34 and 35.

Proof of Lemma 34. For the promise problem $\mathsf{MCSP}[(s,0),(t,\varepsilon)]$ over N inputs, define

$$\Pi_{yes} = \{y \in \{0,1\}^N \mid \exists \text{ circuit of size} \leq s(n) \text{ that computes } f_y\}$$
$$\Pi_{no} = \{y \in \{0,1\}^N \mid \text{no circuit of size} \leq t(n) \ (1-\varepsilon)\text{-approximates } f_y\}$$

We prove the contrapositive of the statement, by showing a reduction from $\mathsf{MCSP}[(s,0),(t,\varepsilon)]$ to a learning algorithm for $\mathsf{Circuit}[s(n)]$ using non-adaptive membership queries over the uniform distribution. For a fixed $\varepsilon < 1/2$ and $0 \leq \delta \leq 1/9$, let $\{D_n\}_{n\geq 1} \in \mathsf{Circuit}[t(n)]$ be the corresponding sequence of oracle circuits which learns $\mathsf{Circuit}[s(n)]$ up to error $\varepsilon/2$, where D_n makes non-adaptive queries to some function $f \in \mathsf{Circuit}[s(n)]$ over n inputs.

Let $q = q(n) = \frac{200}{\varepsilon^2}$. Define $F_N : \{0,1\}^N \times \{0,1\}^{nq(n)} \times \{0,1\}^{t(n)} \to \{0,1\}$ as the sequence of randomized circuits such that :

$$z \in \Pi_{yes} \implies \Pr_{y_1,w}\{F_N(z,y_1,w)=1\} > 2/3$$
$$z \in \Pi_{no} \implies \Pr_{y_1,w}\{F_N(z,y_1,w)=1\} < 1/3$$

The reduction F_N does the following. Let $Y = (x_1,\ldots,x_{t(n)})$ be the set of queries made by D_n. F_N runs the learner D_n with input w as its source of internal randomness and answers its oracle queries to f_z by using the other input $z \in \{0,1\}^N$. If the output string of the learner cannot be interpreted as a $t(n)$-sized circuit, then F_N outputs 0. Otherwise, let h be the $t(n)$-sized circuit on n inputs, which can interpret the hypothesis output by the learner as a $t(n)$-sized circuit. F_N then interprets the random input y_1 as a sequence of q random examples $v_1,\ldots,v_q \in \{0,1\}^n$ and computes h on each of these. It then forms a string $u \in \{0,1\}^q$, where for every $i \in [q], u_i = 1$ if and only if $h(v_i) = f_z(v_i)$. Finally, it uses a threshold gate on T on $q(n)$ inputs to check if the Hamming weight of u is at least $((1-3\varepsilon/4)q)$.

We now show the correctness of the reduction. If $z \in \Pi_{yes}$, then f_z is computed by some circuit of size at most $s(n)$. Thus, for every random choice of y_1 and w, D_n can learn the function f_z and with probability at least $(1-\delta)$, output a hypothesis h which has an error of at most $\varepsilon/2$ with respect to f_z. Now, for the q samples given by y_1, by an application of Hoeffding's inequality (Lemma 13), the probability that the Hamming weight of $u \in \{0,1\}^q$ is lesser than $(1-0.6\varepsilon)\,q$ is at most $2\exp(-2q\varepsilon^2/100)$ which is at most $1/4$ for our choice of q. When $\delta \leq 1/9$, we see that $T(u) = 1$ with probability at least $(1-\delta)3/4 \geq 2/3$.

On the other hand, if $z \in \Pi_{no}$, then no circuit of size at most $t(n)$ can even $(1-\varepsilon)$-approximate f_z. Thus, for any random choice of y_1 and w, any hypothesis h which D_n outputs is a circuit of size at most $t(n)$ and thus is at least ε-far from f_z. By a similar application of Hoeffding's inequality, we see that the probability that the Hamming weight of $u \in \{0,1\}^q$ is greater than $(1-0.9\varepsilon)\,q$ is at most $2\exp(-2q\varepsilon^2/100) \leq 1/4$. Therefore, $T(u) = 0$ with probability $2/3$.

For the next step, we need to derandomize the circuits F_N. Define E_N as

$$E_N : \{0,1\}^N \times \left(\{0,1\}^{n\cdot q+t(n)}\right)^R \to \{0,1\}$$
$$E_N(z, y^{(1)}, \ldots, y^{(R)}) = \mathsf{MAJ}_R(F_N(z, y^{(1)}), \ldots, F_N(z, y^{(R)}))$$

where $R = CN$ and each $y^{(j)} \in \{0,1\}^{n\cdot q+t(n)}$, for each $j \in [R]$.

When, $z \in \Pi_{yes}$, then using Hoeffding's inequality, we see that with probability at most 2^{-2N} (for suitably chosen C), the string $(F_N(z, y^{(1)}), \ldots, F_N(z, y^{(R)}))$ has Hamming weight $\leq 3R/5$. Similarly, when $z \in \Pi_{no}$, with probability at most 2^{-2N}, the string $(F_N(z, y^{(1)}), \ldots, F_N(z, y^{(R)}))$ has Hamming weight $\geq 2R/5$. Thus, the majority gate differentiates between the two cases except with probability at most 2^{-2N}. We use Adleman's trick [6] to fix a string $\alpha \in \{0,1\}^{R\cdot(n\cdot q+t(n))}$ which correctly derandomizes F_N on all inputs in Π_{yes} and Π_{no} and call the resulting circuit as E_N^* which computes the function $E_N^* : \{0,1\}^N \to \{0,1\}$.

We next compute the size of E_N^*. Each $F_N(z, y^{(i)})$ is fixed to $F_N(z, \alpha^{(i)})$, where $\alpha^{(i)} \in \{0,1\}^{(n\cdot q+t(n))}$ is the i^{th} section of the hardwired random string α. Observe that for the set of oracle queries Y made by D_n, it is enough to use appropriate literals from the input z whenever we need to access the truth table of f_z. Indeed, whenever D_n uses a random example, the randomness comes from $\alpha^{(i)}$ which is fixed non-uniformly and whenever it makes a membership query, the set of queries Y is fixed for D_n because of its non-adaptivity. Recall that the size of the circuit D_n is $t(n)$ and the hypothesis h output by the learner can be interpreted as a circuit and efficiently computed by another circuit of size $\mathsf{poly}(t(n))$. Thus, the circuit size to compute $F_N(z, \alpha)$ is at most $\mathsf{poly}(t(n) \cdot q)$ and the total circuit size to construct E_N^* is $O(N \cdot \mathsf{poly}(t(n)/\varepsilon))$. ◀

Proof sketch of Lemma 35. We show a two-sided error randomized reduction from $\mathsf{MCSP}[n^c, 2^n/n^c]$ to $\{D_n\}_{n\geq 1}$. Let $q = q(n) = O\left(n^{3c}\right)$. The reduction is almost the same as that of Lemma 34. Here we use a threshold gate on $q(n)$ inputs which answers 1 whenever the Hamming weight of its input is greater than $(1 - 1/n^{1.5c})q(n)$.

When the input to $\mathsf{MCSP}[n^c, 2^n/n^c]$ is a yes instance, with probability at least $(1 - 1/n)$, D_n outputs a hypothesis $h_n \in \mathsf{Circuit}[2^{n^\gamma}]$ which has error at most $1/O(n^{2c})$. Now for the $q(n)$ samples drawn uniformly at random, the probability that h agrees with the input instance on at least a $(1 - 1/n^{1.5c})q(n)$ samples is at least $(1 - 1/n)2/3$.

When the input to $\mathsf{MCSP}[n^c, 2^n/n^c]$ is a no instance, any hypothesis h which D_n outputs must have error greater than $1/O(n^{c+2})$. Indeed, if the error is less than $O(1/n^{c+2})$, then by hardwiring all the error inputs by using circuits of size at most $O\left(\frac{2^n}{n^{c+2}} \cdot n\right)$ we get a circuit of size at most $2^n/n^c$, which is a contradiction to the promise of the no instance. By Hoeffding's inequality, the probability that h agrees with the input instance on at most a $(1 - 1/n^{1.5c})q(n)$ samples is at least $2/3$.

The derandomization is the same as that of Lemma 34, obtained by repeating the above reduction $R = O(N)$ times and computing the majority over the R outputs of the reduction. The circuit size to compute $\mathsf{MCSP}[n^c, 2^n/n^c]$ is thus $O(N \cdot 2^{O(n^\gamma)} n^{3c}) = O(N^{1+\varepsilon})$, for $\varepsilon = o(1)$. ◀

4.2 Towards a More Robust Theory

The question of non-naturalizability of hardness magnification for $\mathsf{MCSP}[n^c/2n, n^c]$ is connected to the question of basing hardness of learning on the assumption $\mathsf{NP} \not\subseteq \mathsf{Circuit}[2^{O(n^\gamma)}]$.

▶ **Proposition 36.** *Assume that for every $\gamma \in (0,1)$ there is $d \geq 2$ such that $\mathsf{NP} \not\subseteq \mathsf{Circuit}[2^{O(n^\gamma)}]$ implies hardness of learning $\mathsf{Circuit}[n^d]$ by 2^{n^γ}-size circuits with error $1/n^d$. Then, there is a constant e such that for every $\gamma \in (0,1)$ and $c \geq 1$, $\mathsf{MCSP}[n^c/2n, n^c] \notin \mathsf{Circuit}[N^{1+e\gamma c}]$ implies that there is no $\mathsf{P/poly}$-natural property against $\mathsf{P/poly}$.*

Proof. By Theorem 5, $\mathsf{P/poly}$-natural property against $\mathsf{P/poly}$ implies that for every d there is $\gamma < 1/d$ and 2^{n^γ}-size circuits learning $\mathsf{Circuit}[n^d]$ with error $1/n^d$. By our assumption, this implies $\mathsf{NP} \subseteq \mathsf{Circuit}[2^{O(n^\gamma)}]$. We can now use $\mathsf{NP} \subseteq \mathsf{Circuit}[2^{O(n^\gamma)}]$ as the assumption in the proof of Theorem 29 to conclude that there is a constant e independent of γ such that for $c \geq 1$, $\mathsf{MCSP}[n^c/2n, n^c] \in \mathsf{Circuit}[N^{1+e\gamma c}]$. ◀

A form of the opposite implication holds as well if we assume NP-completeness of MCSP. Moreover, instead of the non-naturalizability of hardness magnification, we need to assume a reduction from worst-case MCSP to approximate MCSP.

▶ **Definition 37.** *A p-time algorithm A k-reduces $\mathsf{MCSP}[s,t]$ to $\mathsf{MCSP}[(s,0),(t,\varepsilon)]$ if it maps instances of $\mathsf{MCSP}[s,t]$ to instances of $\mathsf{MCSP}[(s,0),(t,\varepsilon)]$ and*

1. *For $f \in \mathsf{Circuit}[s]$, $A(\mathsf{tt}(f))$ is the truth-table of a Boolean function in $\mathsf{Circuit}[s^k]$.*
2. *For $f \notin \mathsf{Circuit}[t]$, $A(\mathsf{tt}(f))$ is not $(1-\varepsilon)$-approximable by circuits of size $t^{1/k}$.*

▶ **Proposition 38.** *Assume there is a p-time algorithm k-reducing $\mathsf{MCSP}[s,t]$ to $\mathsf{MCSP}[(s,0),(t,\varepsilon)]$ and that for all $0 < \alpha < \beta < 1$, $\mathsf{MCSP}[2^{\alpha n}, 2^{\beta n}]$ is NP-complete. If for every sufficiently small $\alpha > 0$ there is $\beta < 1/k$ and a $2^{\beta n}$-time algorithm learning $\mathsf{Circuit}[2^{\alpha n}]$ with error ε, then $\mathsf{P} = \mathsf{NP}$.*

Proof. Let A bet the p-time k-reduction from the statement and $\alpha > 0$ be sufficiently small. Assume we can learn in $2^{\beta n}$-time $\mathsf{Circuit}[2^{k\alpha n}]$ with error ε and $k\alpha < \beta < 1/k$. This implies that $\mathsf{MCSP}[(2^{k\alpha n}, 0), (2^{\beta n}, \varepsilon)]$ can be solved in p-time. Since A reduces an NP-complete problem $\mathsf{MCSP}[2^{\alpha n}, 2^{k\beta n}]$ to $\mathsf{MCSP}[(2^{k\alpha n}, 0), (2^{\beta n}, \varepsilon)]$, this shows that $\mathsf{P} = \mathsf{NP}$. ◀

5 The Locality Barrier

5.1 Lower Bounds Above Magnification Threshold

5.1.1 The Razborov-Smolensky Polynomial Approximation Method

In this section, we observe that the lower bound techniques of Razborov and Smolensky [44, 49] can be "localized." The following proposition instantiates the locality barrier for HM Frontier A.

▶ **Proposition 39** (Locality Barrier for HM Frontier A)**.** *The following results hold.*

- (A1$^{\mathcal{O}}$) (Oracle Circuits from Magnification) : $\mathsf{MKtP}[n^c, 2n^c] \in \mathsf{AND}\text{-}\mathcal{O}\text{-}\mathsf{XOR}[N^{1.01}]$. *More precisely, $\mathsf{MKtP}[n^c, 2n^c]$ is computed by circuits with $N^{1.01}$ gates and of the following form: the output gate is an AND gate of fan-in $O(N)$, at the middle layer are oracle gates of fan-in $\mathrm{poly}(n)$, and at the bottom layer are XOR gates.*
- (A3$^{\mathcal{O}}$) (Extension of Lower Bound Techniques) : *For a constant d, assume that $O_1, \cdots, O_d \in \mathbb{N}$ satisfy $\prod_{i=1}^{d} O_i \leq \sqrt{N}/\omega(\log N)^d$. Then* Majority *cannot be computed by a depth-d polynomial-size oracle $(\mathsf{AC}^0[\oplus])^{\mathcal{O}}$ circuit whose oracle gates on the i-th level have fan-in at most O_i.*

The first item is immediate from the proof of Theorem 14 in Section 3.1. In what follows, we prove the second item of Proposition 39.

Recall that the proof techniques of Razborov and Smolensky [44, 49] consist of two parts: The first lemma shows that any low degree polynomial cannot approximate Majority. (A simple proof sketch can be found in, e.g., [33].)

▶ **Lemma 40.** *For any polynomial $p \in \mathbb{F}_2[x_1, \cdots, x_N]$ of degree $\leq \sqrt{N}/4$,*

$$\Pr_{x \sim \{0,1\}^N}[p(x) \neq \mathsf{Majority}(x)] \geq \frac{1}{4}.$$

The second lemma shows that $\mathsf{AC}^0[\oplus]$ circuits can be approximated by low degree polynomials. We show that this argument can be localized.

▶ **Lemma 41.** *Let C be a depth-d polynomial-size oracle $\mathsf{AC}^0[\oplus]$ circuit whose oracle gates on the i-th level have fan-in at most O_i. Then there exists a polynomial $p \in \mathbb{F}_2[x_1, \cdots, x_N]$ of degree $\leq O(\log N)^d \cdot \prod_{i=1}^d O_i$ such that $\Pr_{x \sim \{0,1\}^N}[p(x) \neq C(x)] < \frac{1}{4}$.*

Proof Sketch. We convert each layer of the circuit C into a low degree probabilistic polynomial p that approximates C.

Consider the i-th level of a circuit C. NOT, OR, AND, and XOR gates can be converted into a probabilistic polynomial of degree $O(\log N)$ and error $1/\mathsf{poly}(N)$ in the standard way [44]. In order to represent an oracle gate $\mathcal{O}$ as a low-degree polynomial, we simply take the multilinear extension of the oracle gate $\mathcal{O}$. Note that, at the i-th level, the fan-in of the oracle gate $\mathcal{O}$ is bounded by O_i; thus the oracle gate at the i-th level can be represented as a polynomial of degree $\leq O_i$. Thus, in either cases, any gate at i-th level can be represented as a probabilistic polynomial of degree $\max\{O(\log N), O_i\}$. Continuing this for $i = 1, \cdots, d$ and composing resulting polynomials, we obtain a probabilistic polynomial of degree $\prod_{i=1}^d \max\{O(\log N), O_i\}$ that approximates C. This implies via standard techniques the existence of a (deterministic) polynomial of the same degree that correctly computes the circuit on most inputs. ◀

These two lemmas immediately imply the Majority lower bound for $(\mathsf{AC}^0[\oplus])^{\mathcal{O}}$:

Proof of *(A3$^{\mathcal{O}}$)* of Proposition 39. Suppose that there exists a depth-d polynomial-size oracle $\mathsf{AC}^0[\oplus]$ circuit that computes Majority and satisfies the condition of Proposition 39. By Lemma 41, there exists a polynomial p of degree at most $O(\log N)^d \cdot \prod_{i=1}^d O_i \leq o(\sqrt{N})$ that approximates Majority. However, this contradicts Lemma 40. ◀

Finally, we mention that an incomparable bound can be obtained by using a lower bound for $\mathsf{AC}^0[\oplus]$ interactive compression games.

▶ **Proposition 42** ([40, Corollary 5.3])**.** (A3$^{\mathcal{O}}$) Majority $\notin (\mathsf{AC}^0[\oplus])^{\mathcal{O}}[\mathsf{poly}(n)]$ *if the total number of input wires in the circuit feeding the $\mathcal{O}$-gates is $N/(\log N)^{\omega(1)}$.*

5.1.2 The Formula-XOR Lower Bound of [52]

This section captures an instantiation of the locality barrier for HM Frontier B. Throughout this section we use the $\{-1, 1\}$ realization of the Boolean domain (that is, -1 represents True and 1 represents False). Let Formula-XOR on variables $x_1, \ldots, x_n$ be the class of formulas where the input leaves are labeled by parity functions of arbitrary arity over $x_1, \ldots, x_n$.

▶ **Proposition 43** (Locality Barrier for HM Frontier B). *The following results hold.*

- (B1$^{\mathcal{O}}$) (Oracle Circuits from Magnification) : *For any $\varepsilon > 0$,* $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}] \in$ Formula-$\mathcal{O}$-XOR$[N^{1.01}]$*, where every oracle $\mathcal{O}$ has fan-in at most N^{ε} and appears in the layer right above the* XOR *leaves.*
- (B3$^{\mathcal{O}}$) (Extension of Lower Bound Techniques) : *For any $\delta > 0$,* InnerProduct *over N input bits cannot be computed by $N^{2-3\delta}$-size* Formula-$\mathcal{O}$-XOR *circuits with at most $N^{2-3\delta}$ oracle gates of fan-in N^{δ} in the layer right above the* XOR *leaves, for any oracle $\mathcal{O}$.*

To prove item 2 of Proposition 43, we adapt Tal's [52] lower bound for bipartite formulas[15], for which we need the following results.

▶ **Lemma 44** ([47, 52]). *Let F be a De Morgan formula of size s which computes $f : \{-1,1\}^n \to \{1,1\}$. Then, there exists a multilinear polynomial p over $\mathbb{R}$ of degree $O(\sqrt{s})$, such that for every $x \in \{-1,1\}^n$, $p(x) \in [F(x) - 1/3, F(x) + 1/3]$.*

For any function $f : \{-1,1\}^n \to \{-1,1\}$, f is ε-correlated with a parity $p_S(x) = \prod_{i \in S} x_i$, if $|\mathbb{E}_{x \in \{-1,1\}^n}[f(x) \cdot p_S(x)]| \geq \varepsilon$. We have

▶ **Lemma 45.** *For any $\delta > 0$, let $F(x_1, \ldots, x_n)$ be a* Formula-$\mathcal{O}$-XOR *formula of size s, where every oracle $\mathcal{O}$ has fan-in at most n^{δ} and appears in the layer right above the* XOR *leaves. Then the following hold true:*

1. *There exists a multi-linear polynomial $p(x_1, \ldots, x_n)$ over $\mathbb{R}$ with at most $s^{O(\sqrt{s})} \cdot 2^{n^{\delta} \cdot O(\sqrt{s})}$ monomials such that for every $x \in \{-1,1\}^n$, sign$(p(x)) = F(x)$.*
2. *There exists a parity function $f_T(x_1, \ldots, x_n)$ which is at least $\left(\frac{1}{s^{O(\sqrt{s})} \cdot 2^{n^{\delta} O(\sqrt{s})}}\right)$-correlated with F.*

Proof. We assume that the oracle function is a Boolean function on n^{δ} inputs. Let $t \leq s/n^{\delta}$ be the number of oracle gates in F. Let $p_1, \ldots, p_s$ be the leaves of F, where each p_i is an XOR gate over $x_1, \ldots, x_n$ and every oracle gate $g_1, \ldots, g_t$ is such that $g_i(x) = \mathcal{O}(p_{i1}(x), \ldots, p_{i\ell}(x))$, where $\ell = n^{\delta}$ and $p_{ij} \in \{p_1, \ldots, p_t\}$ for every $i \in [t], j \in [\ell]$.

Let F' be a De morgan formula obtained by replacing oracle gates in F with new variables z_i (for notational simplicity we assume that every leaf is an input to some oracle gate), for $i \in [t]$. We now use Lemma 44 on F' to get a degree $d = O(\sqrt{t})$ polynomial $q(z)$ such that for every $z \in \{-1,1\}^t$, sign$(q(z)) = F'(z)$. Expanding $q(z)$ as a multilinear polynomial :

$$q(z) = \sum_{S \subseteq [t], |S| \leq d} \hat{q}(S) \prod_{i \in S} z_i$$

To prove the first item, we replace each z_i by the original leaf and we get that for every $x \in \{-1,1\}^n$,

[15] A bipartite formula on variables $x_1, \ldots, x_n, y_1, \ldots, y_n$ is a formula such that each leaf computes an arbitrary function in either $(x_1, \ldots, x_n)$ or $(y_1, \ldots, y_n)$. Formula-XOR circuits are a subset of bipartite formulas as one can always write $\oplus(x_1, \ldots, x_{2n})$ as the parity of $\oplus(x_1, \ldots, x_n)$ and $\oplus(x_{n+1}, \ldots, x_{2n})$.

$$
\begin{aligned}
F(x) &= \operatorname{sign}\left(\sum_{S\subseteq[t],|S|\leq d} \hat{q}(S)\prod_{i\in S} g_i(x)\right)\\
&= \operatorname{sign}\left(\sum_{S\subseteq[t],|S|\leq d} \hat{q}(S)\prod_{i\in S}\left(\sum_{U\subseteq[\ell]} \hat{\mathcal{O}}(U)\prod_{j\in U} p_{ij}(x)\right)\right)\\
&= \operatorname{sign}\left(\sum_{\substack{S\subseteq[t]\\ S=\{i_1,\ldots,i_{|S|}\}\\ |S|\leq d}}\ \sum_{U_{i_1},\ldots,U_{i_{|S|}}\subseteq[\ell]} \hat{q}(S)\cdot\left(\prod_{1\leq k\leq|S|}\hat{\mathcal{O}}(U_{i_k})\prod_{j\in U_{i_k}} p_{i_kj}(x)\right)\right)
\end{aligned}
$$

where the second equality uses the fact that any Boolean function on ℓ inputs can be represented by a multilinear polynomial of degree at most ℓ where each coefficient is between $[-1,1]$. Clearly the number of monomials is at most $s^{O(\sqrt{s})}\cdot 2^{n^\delta\cdot O(\sqrt{s})}$.

To prove the second item, firstly observe that for every $z\in\{-1,1\}^t$, $q(z)\cdot F'(z)\in[2/3,4/3]$, because $|q(z)-F'(z)|\leq 1/3$ for every z. This also means that for the polynomial $r(x)=q(g_1(x),\ldots,g_t(x))$, $\mathbb{E}_{x\in\{-1,1\}^n}[r(x)\cdot F(x)]\geq 2/3$.

Given that $\hat{q}(S)=\mathbb{E}_{z\in\{-1,1\}^s}\left[q(z)\prod_{i\in S} z_i\right]$, we see that $|\hat{q}(S)|\leq 4/3$. We have

$$
\begin{aligned}
2/3 &\leq \mathop{\mathbb{E}}_{x\in\{-1,1\}^n}[F(x)\cdot r(x)]\\
&= \mathop{\mathbb{E}}_{x\in\{-1,1\}^n}\left[F(x)\cdot\sum_{S\subseteq[t],|S|\leq d}\hat{q}(S)\prod_{i\in S} g_i(x)\right]\\
&\leq \sum_{\substack{S\subseteq[t]\\ S=\{i_1,\ldots,i_{|S|}\}\\ |S|\leq d}}\ \sum_{U_{i_1},\ldots,U_{i_{|S|}}\subseteq[\ell]}\hat{q}(S)\prod_{1\leq k\leq|S|}\hat{\mathcal{O}}(U_{i_k})\mathop{\mathbb{E}}_{x\in\{-1,1\}^n}\left[F(x)\prod_{1\leq k\leq|S|}\prod_{j\in U_{i_k}} p_{i_kj}(x)\right]
\end{aligned}
$$

Since, $|\hat{q}(S)|\leq 4/3$ for every $S\subseteq[t]$ and $|\hat{\mathcal{O}}(U)|\leq 1$ for every $U\subseteq[\ell]$, we see that there exists a set S of size at most d and sets $U_{i_1},\ldots,U_{i_{|S|}}$ such that $\left|\mathbb{E}_{x\in\{-1,1\}^n}\left[F(x)\cdot\prod_{1\leq k\leq|S|}\prod_{j\in U_{i_k}} p_{i_kj}(x)\right]\right|\geq\frac{1}{t^{O(\sqrt{t})}\cdot 2^{n^\delta O(\sqrt{t})}}\geq\frac{1}{s^{O(\sqrt{s})}\cdot 2^{n^\delta O(\sqrt{s})}}$. Taking p_T be the parity of the parities given by $p_T=\prod_{1\leq k\leq|S|}\prod_{j\in U_{i_k}} p_{i_kj}(x)$, we see that p_T is $\frac{1}{s^{O(\sqrt{s})}\cdot 2^{n^\delta O(\sqrt{s})}}$-correlated with F. ◀

Define the Inner Product modulo 2 function, $\mathsf{InnerProduct}_n:\{-1,1\}^n\times\{-1,1\}^n\to\{-1,1\}$ as $IP_n(x,y)=(-1)^{\sum_{i=1}^n(1-x_i)(1-y_i)/4}$.

Proof Sketch of Proposition 43. The first item follows from an inspection of the proof of Theorem 25 in Section 3.2. Theorem 24 gives the same oracle circuit construction (with different oracles) under the assumption $\mathsf{QP}\subseteq\mathsf{P/poly}$.

The second item follows from Lemma 45. We observe that three different techniques used to show Formula-XOR lower bounds localize. Firstly, Tal's lower bound based on sign rank shows that the sign rank of any Formula-XOR circuit F is at most the number of monomials in the polynomial p given by the first item of lemma 45. Since this is at most $s^{O(\sqrt{s})}\cdot 2^{n^\delta\cdot O(\sqrt{s})}$ and InnerProduct has a sign rank which is at least $2^{n/2}$ [18], the lower

bound follows. Secondly, Tal's lower bound based on the discrepancy of a function also localizes, as he shows that the discrepancy of F is at least a constant times the correlation of F with the parity f_T given by item 2 of Lemma 45, which is at least $\Omega\Big(\frac{1}{s^{O(\sqrt{s})}\cdot 2^{n^{\delta}O(\sqrt{s})}}\Big)$, whereas the discrepancy of the inner product is at most $1/2^{n/2}$ (cf. [29, Lemma 14.5]), thus proving the given lower bound for inner product. Finally, we also observe that the lower bound technique of showing high correlation of F with some parity f_T and the fact that inner product has exactly $2^{-n/2}$-correlation with any parity also localizes to give the same lower bound. ◀

5.1.3 Almost-Formula Lower Bounds

This section captures an instantiation of the locality barrier for HM Frontier C. We recall the following definition. Consider an s-almost formula. Each gate G of F with fanout larger than 1 is computed by a formula with inputs being either the original inputs of F or gates of F with fanout larger than 1. We call any maximal formula of this form a *principal* formula of G.

▶ **Theorem 46** (Locality Barrier for HM Frontier C). *The following results hold.*

- (C1$^{\mathcal{O}}$) (Oracle Circuits from Magnification) : $\mathit{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$ *is computable by* $2^{O(n^{1/2})}$*-almost formulas of size* $2^{n+O(n^{1/2})}$ *with oracles of fanin* $2^{O(n^{1/2})}$ *at the bottom layer of principal formulas computing gates with fanout larger than 1.*
- (C3$^{\mathcal{O}}$) (Extension of Lower Bound Techniques) : *For every* $\varepsilon < 1$, PARITY *is not in* n^{ε}-almost-$\mathit{Formula}[n^{2-9\varepsilon}]$ *even if the almost-formulas are allowed to use arbitrary oracles of fanin* $< n^{\varepsilon}$ *at the bottom layer of principal formulas computing gates with fanout larger than* 1.

Proof. The first item follows by inspecting the proof of Theorem 29. It is not hard to see that $\mathsf{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$ is computable by $2^{O(n^{1/2})}$-almost formulas F_N of size $2^{n+O(n^{1/2})}$ with local oracles of fanin $2^{O(n^{1/2})}$. Moreover, the only gates of fanout larger than 1 are the gates computing anticheckers $y_1, \ldots, y_{2^{O(n^{1/2})}}$ with bits $f(y_1), \ldots, f(y_{2^{O(n^{1/2})}})$. We want to show that the local oracles are at the bottom of principal formulas generating gates with fanout larger than 1. In order to achieve this we need to modify formulas F_N a bit.

First, note that F_N contains an oracle which is applied on top of anticheckers $y_1, \ldots, y_{2^{O(n^{1/2})}}$ with bits $f(y_1), \ldots, f(y_{2^{O(n^{1/2})}})$. In order to ensure that this oracle is at the bottom of a principal formula computing a gate with fanout bigger than 1 we simply add dummy negation gates to the output gate and the gates computing anticheckers $y_1, \ldots, y_{2^{O(n^{1/2})}}$ with bits $f(y_1), \ldots, f(y_{2^{O(n^{1/2})}})$, if necessary.

Second, note that each y_{i+1}, $f(y_{i+1})$ is generated as follows: 1. if $R_f(y_1, \ldots, y_i) \geq 2n^2$ then a subformula F' generates anticheckers y_{i+1}, $f(y_{i+1})$, and 2. if $R_f(y_1, \ldots, y_i) < 2n^2$ then a subformula F'' generates anticheckers y_{i+1}, $f(y_{i+1})$. In both cases we replace predicates $R_f(y_1, \ldots, y_i) < 2n^2$ by oracles. In case 1, subformulas of F' with oracles at the bottom compute predicates $F^{r,h}$ from the proof of Lemma 27. This process generates a set of $2^{O(n^{1/2})}$ potential anticheckers. F' chooses the right antichecker by applying another oracle. In order to ensure that this top oracle is at the bottom of a principal formula, we add dummy negation gates to the gates generating the potential anticheckers. This increases the number of gates with fanout larger than 1 only by $2^{O(n^{1/2})}$. In case 2, y_{i+1}, $f(y_{i+1})$ is generated by oracles outputting circuits which have not been killed yet and evaluating them on all possible inputs. Here we ensure that the oracles are at the bottom by asking them to perform both tasks: choose the next alive circuit and evaluate it on a given input. The oracle selecting the right antichecker from the set of potential anticheckers is treated in the same way as in case 1. All in all, we obtain the desired oracle almost formulas.

The second item is proved analogously to Theorem 30. For the sake of contradiction assume PARITY has n^ε-almost formulas of size $n^{2-9\varepsilon}$ with local oracles at the bottom of principal formulas. Since there are only n^ε gates of fanout > 1, we can replace these gates by constants and obtain formulas F_n of size $n^{2-8\varepsilon}$ with local oracles at the bottom computing PARITY with probability $\geq 1/2 + 1/2^{n^\varepsilon}$. Let $L'(f)$ be the size (i.e. the number of leafs) of the smallest formula with local oracles at the bottom computing f. Since oracles have fanin $< n^\varepsilon$ and are located at the bottom, each function $f : \{-1,1\}^n \mapsto \{-1,1\}$ can be approximated by a polynomial of degree $O(t\sqrt{L'(f)}\frac{\log n}{\log\log n}n^\varepsilon)$ up to point-wise error of 2^{-t}. This implies that each formula of size $o((n/t)^2(\log\log n/\log n)^2(1/n^\varepsilon)^2)$ with local oracles at the bottom computes PARITY with probability at most $1/2 + 1/2^{t+O(1)}$ (for large enough t). Taking $t = n^{2\varepsilon}$ we get a contradiction. ◀

5.1.4 GapAND-Formula Lower Bounds

This section captures an instantiation of the locality barrier for HM Frontier D.

▶ **Theorem 47** (Locality Barrier for HM Frontier D). *The following results hold.*

1. (D1$^{\mathcal{O}}$) (Oracle Circuits from Magnification) : $\mathit{MCSP}[2^{\sqrt{n}}] \in \mathsf{GapAND}_{O(N)}\text{-}O_{N^{o(1)}}\text{-}\mathsf{Formula}[N^2]$.
2. (D3$^{\mathcal{O}}$) (Extension of Lower Bound Techniques) : *For* $0 < \beta < \varepsilon < 1$, $\mathsf{Andreev}_N \notin \mathsf{GapAND}_{O(N)}\text{-}O_{N^\beta}\text{-}\mathsf{Formula}[N^{3-\varepsilon}]$.
3. (D3$^{\mathcal{O}}$) : *Furthermore,* $\mathit{MCSP}[2^n/n^4] \notin \mathsf{GapAND}_{O(N)}\text{-}O_{N^\beta}\text{-}\mathsf{Formula}[N^{3-\varepsilon}]$, *for* $0 < \beta < \varepsilon < 1$.

Item 1 of the theorem above follows directly from Theorem 25.

Next we show that the classical $N^{3-o(1)}$ formula size lower bound for the Andreev's function [21, 51] localizes, even in the presence of a GapAND gate of bounded fan-in at the top of the formula.

Proof of Item 2. Let $m = N/2$, recall that $\mathsf{Andreev}_N$ is defined on a $2m$-bit string $z = x \circ y$, where $x, y \in \{0,1\}^m$. For simplicity, we assume m is a power of 2 in the following.

$\mathsf{Andreev}_N(x,y)$ first partitions x into $\log m$ blocks $x_1, x_2, \ldots, x_{\log m}$, each of length $m/\log m$. After that, it computes $i \in \{0,1\}^{\log m}$ as $i = \mathsf{PARITY}(x_1) \circ \mathsf{PARITY}(x_2) \circ \ldots \mathsf{PARITY}(x_{\log m})$. It then treats i as an integer from $[m]$, and outputs y_i.

Now, suppose there is a $\mathsf{GapAND}_{O(N)}\text{-}O_{N^\beta}\text{-}\mathsf{Formula}[N^{3-\varepsilon}]$ formula for $\mathsf{Andreev}_N$. Suppose we fix the y variables to a string $w \in \{0,1\}^m$, and apply a random restriction keeping exactly one variable from each block alive to x variables, then w.p. 0.9, we obtain a $\mathsf{GapAND}_{O(N)}\text{-}O_{N^\beta}\text{-}\mathsf{Formula}[N^{1-\varepsilon}\cdot\mathrm{polylog}(N)]$ formula computing $f_w : \{0,1\}^{\log m} \to \{0,1\}$ [51].

That is, for all $w \in \{0,1\}^m$, there exists an $O_{N^\beta}\text{-}\mathsf{Formula}[N^{1-\varepsilon}\cdot\mathrm{polylog}(N)]$ formula 0.8-approximating f_w. Note that there are at most $2^{N^{1-\varepsilon+\beta}\cdot\mathrm{polylog}(N)}$ such $O_{N^\beta}\text{-}\mathsf{Formula}[N^{1-\varepsilon}\cdot\mathrm{polylog}(N)]$ formulas, and there are 2^N possible w's (Note that O is a fixed oracle which does not depend on w). Since each $O_{N^\beta}\text{-}\mathsf{Formula}[N^{1-\varepsilon}\cdot\mathrm{polylog}(N)]$ formula can only 0.8-approximate $2^{\alpha\cdot N}$ many functions from $\{0,1\}^{\log m} \to \{0,1\}$ for a constant $\alpha < 1$, there must exist a w such that f_w cannot be 0.8-approximated by such formulas, contradiction. ◀

Next, we observe that the $N^{3-o(1)}$ formula lower bound for MCSP [16] also localizes.

Proof of Item 3. We first observe that the PRG construction of [16] also works for oracle formulas. (We omit the details of this proof.)

▷ Claim 48 ([16]). For $0 < \beta < \varepsilon < 1$, there is $M = N^{1-\Omega_{\beta,\varepsilon}(1)}$ and a PRG $G : \{0,1\}^M \to \{0,1\}^N$ such that the following hold.

1. For each fixed $z \in \{0,1\}^M$, $G(z)$, when interpreted as a function from $\{0,1\}^{\log N} \to \{0,1\}$, can be computed by a circuit of size $N^{1-\Omega(1)}$.
2. For all O_{N^β}-Formula$[N^{3-\varepsilon}]$ formulas C, we have

$$\left| \Pr_{z\in\{0,1\}^N}[C(z)=1] - \Pr_{z\in\{0,1\}^M}[C(G(z))=1] \right| \le 0.01.$$

Now, suppose MCSP$[2^n/n^4]$ on $N = 2^n$ bits can be computed by a GapAND$_{O(N)}$-O_{N^β}-Formula$[N^{3-\varepsilon}]$ formula C. Let $C_1, C_2, \ldots, C_{b\cdot N}$ be the O_{N^β}-Formula$[N^{3-\varepsilon}]$ sub-formulas of C under the top GapAND gate, where b is a constant.

We know that

$$\Pr_{z\in\{0,1\}^N}[\mathsf{MCSP}[2^n/n^4](z)=1] = o(1).$$

Since C computes MCSP$[2^n/n^4]$, and $C(x) = 0$ implies $C_i(x) = 0$ for at least a 0.9 fraction of $i \in [b \cdot N]$. We have that

$$\Pr_{i\in[b\cdot N],\, z\in\{0,1\}^N}[C_i(z)=1] \le 0.2.$$

On the other side, by the definition of MCSP$[2^n/n^4]$, and the Item (1) of Claim 48, it follows that

$$\Pr_{z\in\{0,1\}^M}[\mathsf{MCSP}[2^n/n^4](G(z))=1] = 1.$$

Again, since C computes MCSP$[2^n/n^4]$, and $C(x) = 1$ implies $C_i(x) = 1$ for all $i \in [b \cdot N]$. We have that

$$\Pr_{i\in[b\cdot N],\, z\in\{0,1\}^M}[C_i(G(z))=1] = 1.$$

Therefore, there must exist an i such that

$$\left| \Pr_{z\in\{0,1\}^N}[C_i(z)=1] - \Pr_{z\in\{0,1\}^M}[C_i(G(z))=1] \right| \ge 0.5,$$

which is a contradiction to Item (2) of Claim 48. ◀

Finally, we show that there is a language in E which cannot be computed by GapAND$_{O(N)}$-Formula$[N^{3-\varepsilon}]$ formulas, but it *can* be computed by an $O_{N^{o(1)}}$-Formula$[N^2]$ formula. Therefore, this lower bound does not localize in the sense of Theorem 47.

▶ **Theorem 49.** *There is a language $L \in$ E, such that $L \notin$ GapAND$_{O(N)}$-Formula$[N^{3-\varepsilon}]$ for all constants $\varepsilon > 0$, but $L \in O_{N^{o(1)}}$-Formula$[N^2]$.*

Proof. The function L is very similar to the Andreev's function. On an input x of length N, let $m = \log N$ (we assume N is a power of 2 for simplicity). To avoid the second input to Andreev$_N$, we want to find a function $f_{\mathsf{hard}} : \{0,1\}^m \to \{0,1\}$ which cannot be 0.8-computed by $N^{1-\varepsilon/2}$ formulas in $2^{O(N)}$ time (such a function exists by a simple counting argument). To find f_{hard}, we simply enumerate all possible functions $f : \{0,1\}^m \to \{0,1\}$, and check whether it can be 0.8-approximated by an $N^{1-\varepsilon/2}$-size formula.

There are $2^{2^m} = 2^N$ possible functions on m bits, and $(N^{1-\varepsilon/2})^{O(N^{1-\varepsilon/2})} = 2^{N^{1-\varepsilon/2}\cdot \mathrm{polylog}(N)}$ many formulas of $N^{1-\varepsilon/2}$ size. Hence, a straightforward implementation of the algorithm runs in $2^{O(N)}$ time.

Next, L partitions x into m blocks $x_1, x_2, \ldots, x_m$, each of length N/m. After that, it computes $i \in \{0,1\}^m$ as $i = \mathsf{PARITY}(x_1) \circ \mathsf{PARITY}(x_2) \circ \ldots \mathsf{PARITY}(x_m)$. It then outputs $f_{\mathsf{hard}}(i)$.

Now, suppose there is a $\mathsf{GapAND}_{O(N)}$-$\mathsf{Formula}[N^{3-\varepsilon}]$ for L. We apply a random restriction keeping exactly one variable from each block alive, then w.p. 0.9, we obtain a $\mathsf{GapAND}_{O(N)}$-$\mathsf{Formula}[N^{1-\varepsilon} \cdot \mathrm{polylog}(N)]$ formula for f_{hard} [51], which implies that there is an $N^{1-\varepsilon} \cdot \mathrm{polylog}(N)$-size formula 0.8-approximating f_{hard}, contradiction.

Finally, it is easy to verify that $L \in \mathsf{E}$ and $L \in O_{N^{o(1)}}$-$\mathsf{Formula}[N^2]$. ◀

5.1.5 AC^0 Lower Bounds via Random Restrictions

This section states and proves a result capturing an instantiation of the locality barrier for HM Frontier E.

▶ **Proposition 50** (Locality Barrier for HM Frontier E). *The following results hold.*

- ($\mathrm{E1}^{\mathcal{O}}$) (Oracle Circuits from Magnification) : *For each $k = (\log n)^C$ and every large enough depth d, $(n-k)$-$\mathsf{Clique} \in (\mathsf{AC}^0_d)^{\mathcal{O}}[m^{1+\varepsilon_d}]$, where $\varepsilon_d \to 0$ as $d \to \infty$, and the corresponding circuit employs a single oracle gate $\mathcal{O}$ of fan-in at most $O((\log n)^{4C})$.*
- ($\mathrm{E3}^{\mathcal{O}}$) (Extension of Lower Bound Techniques) : $\mathsf{Parity} \notin (\mathsf{AC}^0)^{\mathcal{O}}[\mathsf{poly}(n)]$ *if the total number of input wires in the circuit feeding the $\mathcal{O}$-gates is $n/(\log n)^{\omega(1)}$.*

Proof. The first item is established by inspection of the proof of Proposition 31, which relies on the circuit construction from [42] and a straightforward translation between vertex cover and clique detection. Recall that the circuit in [42] simulates a well-known kernelization algorithm for k-Vertex-Cover. This algorithm produces a graph H containing $O(k^2)$ vertices and a new parameter $k_H \leq k$. This graph can be described by a string of length $O(k^4)$, and the pair (H, k_H) becomes the input string to the single oracle $\mathcal{O}$ that is necessary in the oracle circuit construction. (If $\mathcal{O}$ solves vertex cover, the resulting oracle circuit correctly solves $(n-k)$-Clique.)

The second item easily follows by simulating oracle circuits via interactive compression games (see e.g. [40, Section 5]). In other words, one can view a circuit with oracles as an interactive protocol between two parties, where one of them has unbounded computational power, and the other is restricted to computations in a fixed circuit class. The total number of wires feeding the oracle gates corresponds to the number of bits sent to the unbounded party. The desired lower bound for oracle circuits then follows immediately from the main result from [9], which shows that the random restriction method can be extended to establish limitations on circuits with oracle gates of large fan-in. ◀

Informally, the main difficulty with the use of random restrictions in connection to HM Frontier E is that as soon as one simplifies a boolean circuit so that the oracle gate $\mathcal{O}$ is directly fed by input literals, one can fix just $(\log n)^{O(C)}$ input variables and eliminate this gate. Sacrificing such a small number of coordinates won't affect a typical worst-case lower bound based on the random restriction method.

5.1.6 Lower Bounds Through Reductions

Consider a reduction of PARITY to $\mathsf{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$ by subquadratic-size n^{ε}-almost formulas with $n^{\varepsilon'}$ MCSP (possibly non-local) oracles at the bottom of each principal formula computing a gate with fanout > 1. By Theorem 46, such a reduction would imply $\mathsf{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}] \notin n^{\varepsilon}$-almost-$\mathsf{Formula}[N^{1.1}]$ assuming that after replacing all oracles by

n^ε-almost formulas of size $N^{1.1}$ the total size of the resulting circuit remains $< N^{2-9(\varepsilon+\varepsilon')}$. In combination with hardness magnification, this would give us $\mathsf{NP} \not\subseteq \mathsf{NC}^1$. Unfortunately, Theorem 46 rules this possibility out.

▶ **Corollary 51.** *PARITY is not computable by subquadratic-size n^ε-almost formulas with $n^{\varepsilon'}$ oracle gates computing $\mathsf{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$, assuming that after replacing all oracles by n^ε-almost formulas of size $N^{1.1}$ the total size of the resulting circuit remains $< N^{2-9(\varepsilon+\varepsilon')}$ for $\varepsilon + \varepsilon' < 1$.*

Proof. Assume the reduction in question exists. By Theorem 29, for every $\varepsilon > 0$ and all sufficiently big n, $\mathsf{MCSP}[2^{n^{1/2}}/2n, 2^{n^{1/2}}]$ is computable by $N^{1.1}$-size n^ε-almost formulas with local oracles at the bottom of principal formulas computing gates with fanout > 1. By the assumption, if we replace the MCSP oracles in the reduction by almost-formulas with local oracles, the resulting circuit is an $n^{\varepsilon+\varepsilon'}$-almost formula of size $N^{2-9(\varepsilon+\varepsilon')}$ with oracles of bounded fan-in. This contradicts the second item of Theorem 46. ◀

Analogous arguments rule out the possibility of establishing strong lower bounds via reductions also in other HM frontiers.

5.2 Lower Bounds Below Magnification Threshold

The localizations presented in this section show that one cannot obtain strong circuit lower bounds by "lowering the threshold" in certain hardness magnification proofs. As a consequence of one of our results (Theorem 59 in Section 5.2.2), we also refute the Anti-Checker Hypothesis from [39].

5.2.1 AC^0 Lower Bounds via Pseudorandom Restrictions

In this section we show that the AC^0 lower bounds proved for MCSP (MKtP) via pseudorandom restrictions [16] (see also Section 3.1) localize in a very strong sense.

We use $\mathsf{AC}^0_d[O_1, O_2, \ldots, O_d]$ to denote AC^0_d circuits extended with arbitrary oracles, such that oracle gates on the i-th level (the gates whose distance from the inputs is i) have fan-in at most O_i.

▶ **Theorem 52.** *There is a constant c such that for all $\varepsilon > 0$, constants d, and $O_1, O_2, \ldots, O_d$ such that $\prod_{i=1}^{d} O_i \leq N/(\log N)^{\omega(1)}$, $\mathsf{MCSP}[n^c, n^{2c}] \notin \mathsf{AC}^0_d[O_1, O_2, \ldots, O_d][\mathsf{poly}(N)]$.*

▶ Remark 53. We remark that the constraint on oracles in the above theorem is incomparable to the second item of Proposition 50. Here we focus on the maximum oracle fan-in at each level, while there the focus is on the total fan-in of all oracles. A lower bound result for an explicit problem with parameters similar to Theorem 52 is not known for AC^0 oracle circuits extended with parity gates *(see [40] for results in this direction)*.

We are going to apply Lemma 17, together with the following well-known results on k-wise independence fooling CNFs.

▶ **Lemma 54** ([7, 53])**.** *$k = O(\log(M/\varepsilon) \cdot \log(M))$-wise independent distribution ε-fools M-clauses CNFs.*

Combining Lemma 17 and Lemma 54, we have the following lemma.

▶ **Lemma 55.** *Let φ be a t-width M-clause CNF formula over N inputs, $p = 2^{-q}$ for some $q \in \mathbb{N}$, and $\varepsilon_0 > 0$ be a real. There is a p-regular,*

$$k = \Theta(\log(M \cdot 2^{t(q+1)}/\varepsilon_0) \cdot \log(M \cdot 2^{t(q+1)}) \cdot q^{-1})\text{-wise}$$

independent random restriction $\boldsymbol{\rho}$ such that

$$\Pr_{\rho \sim \boldsymbol{\rho}}[\mathsf{DT}(\varphi\restriction_\rho) > s] \leq 2^{s+t+1}(5pt)^s + \varepsilon_0 \cdot 2^{(s+1)(2t+\log M)}.$$

Moreover, $\boldsymbol{\rho}$ is samplable with $O(t \cdot q \cdot \mathrm{polylog}(M, N) \cdot \log(1/\varepsilon_0))$ bits, and each output coordinate of the random restriction can be computed in time polynomial in the number of random bits.

The moreover part follows from standard construction of k-wise independent distributions (see e.g. [55]).

We also need the following lemma which states that an arbitrary oracle with inputs being small-size decision trees shrinks to a small-size decision tree with high probability, under suitable pseudorandom restrictions.

▶ **Lemma 56.** *Let $O : \{0,1\}^T \to \{0,1\}$ be an arbitrary function, and $D_1, D_2, \ldots, D_T$ be T k-query decision trees on variables $x_1, x_2, \ldots, x_N$. Let $F := O \circ (D_1, D_2, \ldots, D_T)$ be their compositions. For $s \in \mathbb{N}$, and all $k(s+1)$-wise independent $1/(T \cdot k^2)$-regular random restriction $\boldsymbol{\rho}$, we have*

$$\Pr_{\rho \sim \boldsymbol{\rho}}[\mathsf{DT}(F\restriction_\rho) > s] \leq \left(\frac{k(s+1)}{2e^2}\right)^{-(s+1)}.$$

Proof. We focus on the following particular decision tree for evaluating $\{D_1, D_2, \ldots, D_T\}$ with respect to a restriction $\rho : [N] \to \{0, 1, *\}$:

Algorithm 1 $\mathsf{Eval}(\rho, D_1, D_2, \ldots, D_T)$.

- For i from 1 to T:
  - Simulate decision tree D_i with restriction ρ. That is, when D_i queries an index j, we feed ρ_j to D_i if $\rho_j \in \{0,1\}$, and query the j-th bit otherwise.
- Let α_i be the output of the i-th decision tree, we output $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_T)$.

To obtain a decision tree for $F\restriction_\rho$, we can run $\mathsf{Eval}(\rho, D_1, D_2, \ldots, D_T)$ to obtain α first and output $F(\alpha)$ at the end.

Let $\widetilde{\mathsf{DT}}(F\restriction_\rho)$ be the query complexity of the above decision tree. Since $\mathsf{DT}(F\restriction_\rho) \leq \widetilde{\mathsf{DT}}(F\restriction_\rho)$ ($\mathsf{DT}(F\restriction_\rho)$ is the minimum complexity among all decision trees computing $F\restriction_\rho$), it suffices to bound

$$\Pr_{\rho \sim \boldsymbol{\rho}}[\widetilde{\mathsf{DT}}(F\restriction_\rho) > s].$$

Consider the event that $\widetilde{\mathsf{DT}}(F\restriction_\rho) > s$, it is equivalent to that there exists a string $w \in \{0,1\}^s$, such that if we fix the first s queried unrestricted bits in ρ according to w, Eval ends up querying $> s$ bits. (Note that since we only care about whether $\widetilde{\mathsf{DT}}(F\restriction_\rho) > s$, we can force the algorithm to abort if it tries to make the $(s+1)$-th query.)

Now, suppose we fix the string w, then the number of queries made by Eval only depends on ρ. Suppose the algorithm has queried at least $s+1$ bits, we let $D'_1, D'_2, \ldots, D'_t$ ($t \leq s+1$) be the decision trees in which the algorithm made queries during the first $s+1$ queries. This implies that if we run $\mathsf{Eval}(\rho, D'_1, D'_2, \ldots, D'_t)$ with respect to the same string w, the algorithm also makes at least $s+1$ queries.

Now, since $\boldsymbol{\rho}$ is $k(s+1)$-wise independent. The probability that $\mathsf{Eval}(\rho, D'_1, D'_2, \ldots, D'_t)$ makes at least $s+1$ queries with respect to the fixed string w is bounded by

$$\begin{aligned}
&(T \cdot k^2)^{-(s+1)} \cdot \binom{t \cdot k}{s+1} \\
\leq &(T \cdot k^2)^{-(s+1)} \cdot \left(\frac{t \cdot k \cdot e}{s+1}\right)^{s+1} \\
\leq &\left(\frac{T \cdot k \cdot (s+1)}{t \cdot e}\right)^{-(s+1)} \leq \left(\frac{T \cdot k}{e}\right)^{-(s+1)}.
\end{aligned}$$

Putting everything together, we have

$$\begin{aligned}
&\Pr_{\rho \sim \boldsymbol{\rho}}[\widetilde{\mathsf{DT}}(F\restriction_\rho) > s] \\
\leq &2^s \cdot \left(\frac{T \cdot k}{e}\right)^{-(s+1)} \cdot \sum_{t=0}^{s+1} \binom{T}{t} \\
\leq &2^s \cdot \left(\frac{T \cdot k}{e}\right)^{-(s+1)} \cdot \left(\frac{T \cdot e}{s+1}\right)^{s+1} \\
\leq &\left(\frac{k \cdot (s+1)}{2e^2}\right)^{-(s+1)}.
\end{aligned}$$

◀

▶ Remark 57. Clearly, Lemma 56 also holds when $\boldsymbol{\rho}$ is $k(s+1)$-wise independent and p-regular, for $p \leq \frac{1}{T \cdot k^2}$.

Now we are ready to prove Theorem 52.

Proof of Theorem 52. We assume N and $\log N$ are both powers of 2 for simplicity. Let $p = 1/\log^5 N$, $\varepsilon_0 = 2^{-\log^6 N}$, $s = t = 10\log^2 N$, $M = 2^s \cdot N^{\log N}$, and $\boldsymbol{\rho}$ be the k-wise independent p-regular random restriction guaranteed by Lemma 55. Note that we have $k = \omega(\log^6 N)$ and $k = \log^{O(1)} N$.

Let $C \in \mathsf{AC}^0_d[O_1, O_2, \ldots, O_d]$ be a circuit with S gates computing $\mathsf{MCSP}[n^c, n^{2c}]$. For each $i \in [d]$, let S_i be the number of gates at level i (i.e., the gates whose distance from the input gates is i). Recall that O_i is the maximum oracle fan-in at level i. We are going to prove the stronger claim that $S = \Omega(N^{\log N})$. Now, suppose for the sake of contradiction that $S \leq N^{\log N}/8$.

Now we proceed in d iterations. We will ensure that at the end of the i-th iteration, all gates at level i become s-query decision trees with high probability. At the i-th iteration, we apply ρ

$$\tau_i = \lceil \log_{1/p} O_i \rceil + 1$$

times. It is straightforward to see that the composition of τ_i independent restrictions from $\boldsymbol{\rho}$ is a k-wise independent p_i-regular random restriction for $p_i = p^{\tau_i} \leq \frac{1}{O_i \cdot \log^5 N}$.

Note that each oracle gate at original level i has inputs computed by s-query decision trees (at the first step, one can treat the input variables as 1-query decision trees). By Lemma 56 and noting that $k \geq s(s+1)$ and $O_i \cdot \log^5 N \geq O_i \cdot s^2$, with probability at least

$$1 - S_i \cdot \left(\frac{s(s+1)}{2e^2}\right)^{-(s+1)} \geq 1 - S_i \cdot N^{-\log N},$$

all oracle gates at level i become s-query decision trees after these τ_i restrictions.

Similarly, note that each AND / OR gate at level i are equivalent to a CNF or DNF with width-s and size at most $2^s \cdot S$. By Lemma 55, again with probability at least

$$\begin{aligned}
&1 - S_i \cdot \left(2^{s+t+1}(5pt)^s + \varepsilon_0 \cdot 2^{(s+1)(2t+\log M)}\right) \\
&\geq 1 - S_i \cdot \Big(2^{20\log^2 N+1}(5 \cdot (1/\log^5 N) \cdot 10\log^2 N)^{10\log^2 N} \\
&\qquad + 2^{-\log^6 N} \cdot 2^{(10\log^2 N+1)(20\log^2 N+\log(N^{\log N} \cdot 2^{10\log^2 N}))}\Big) \\
&\geq 1 - S_i \cdot N^{-\log N},
\end{aligned}$$

all AND / OR gates at level i become s-query decision tree after these τ_i restrictions.

Finally, note that in total we have applied $\boldsymbol{\rho}$ at most

$$\tau_{\mathsf{total}} = 2d + \log_{1/p}\left(\prod_{i=1}^{d} O_i\right) = \log_{1/p} N - \omega(1)$$

times, and the final output gate shrinks to an s-query decision tree with probability at least

$$1 - 2 \cdot S \cdot N^{-\log N}.$$

Since $S \leq N^{\log N}/8$, with probability at least $3/4$, after all these restrictions, C is equivalent to an s-query decision tree.

Now let $p_{\mathsf{end}} = p^{\tau_{\mathsf{total}}} = N^{-1} \cdot p^{-\omega(1)}$. By Chebyshev's inequality, the number of unrestricted variables at the end of the restriction is at least $N_{\mathsf{remain}} = \frac{1}{2} \cdot p_{\mathsf{end}} \cdot N = (\log N)^{\omega(1)}$ with probability at least $1/2$. Therefore, with probability at least $1/4$, at the end of the restrictions, it holds that the remaining circuit C is equivalent to an s-query decision tree D, and the number of unrestricted variables is at least N_{remain}.

Suppose we fix all these remaining unrestricted variables to be 0 to get an input x^*, since each restriction from $\boldsymbol{\rho}$ can be computed by a $\mathsf{poly}(n)$-size circuit, x^* has a circuit of $\mathsf{poly}(n) \cdot \log N = \mathsf{poly}(n) \leq n^c$ size (now we set c). Let S be the set of input variables that D queries on the input x^*. Note that there are at least $2^{N_{\mathsf{remain}}-|S|}$ ways of assigning values to unrestricted variables while keeping variables in S all 0. And we can see that F's output on x^* is the same as its output on all of these assignments. But there must exist at least one assignment such the MCSP value is at least $(\log N)^{2c} = n^{2c}$ ($2^{N_{\mathsf{remain}}-|S|} = 2^{n^{\omega(1)}}$), contradiction to the assumption that C computes $\mathsf{MCSP}[n^c, n^{2c}]$. ◀

5.2.2 The Nearly Quadratic Formula Lower Bound of [23]

In this section, we prove that the nearly quadratic formula lower bound of [23] localizes, and thereby proving the third item of Theorem 2. This localization indeed refutes a family of possible approaches to establish circuit lower bounds through hardness magnification via "lowering the threshold".

More concretely, consider the following hypothesized approach. Suppose we can compute $\mathsf{MCSP}[2^{\sqrt{n}}]$ by a formula F with NP oracles, such that when we replace every oracle O with fan-in β in F by a formula of size β^k which reads all its inputs exactly β^{k-1} times, the size of the new formula is less than $N^{1.99}$. Then we know that NP cannot be computed by formulas of size n^k which reads all its inputs exactly n^{k-1} times, as otherwise we get an $N^{1.99}$-size formula for $\mathsf{MCSP}[2^{\sqrt{n}}]$, which is a contradiction to the lower bound in [23]. If this holds for all $k > 0$, then we would have $\mathsf{NP} \not\subset \mathsf{Formula}[n^k]$ for all k.

In the following, by localizing [23], we show that there is no such oracle formula construction for MCSP even if the oracles can be arbitrary. This excludes magnification theorems obtained by approaches that unconditionally produce circuits with oracles, and essentially addresses a question from [39]. It also suggests that the consideration of almost-formulas in HM Frontier C is unavoidable.

A Size Measure on Oracle Formulas and A Potential Approach to Formula Size Lower Bound

We first introduce a size measure Size_t on oracle formulas to formalize the previous discussion.

For a parameter t and an oracle formula F, we define $\mathsf{Size}_t(F)$ as the size of the formula, if we replace every oracle O with fan-in β in F by a formula of size β^t which reads all its inputs exactly β^{t-1} times.

More formally,

$$\mathsf{SIZE}_t(F) := \begin{cases} \mathsf{SIZE}_t(F_1) + \mathsf{SIZE}_t(F_2) & F = F_1 \wedge F_2 \text{ or } F = F_1 \vee F_2, \\ \beta^{t-1} \cdot \left(\sum_{i=1}^{\beta} \mathsf{SIZE}_t(F_i)\right) & F = O(F_1, F_2, \ldots, F_\beta). \end{cases}$$

▶ **Proposition 58.** *For a constant $k > 0$, if there is an NP oracle formula F (all oracles are languages in NP) for $\mathsf{MCSP}[2^{\sqrt{n}}]$ such that $\mathsf{SIZE}_{k+1}(F) \le N^{2-\varepsilon}$ for a constant $\varepsilon > 0$, then $\mathsf{NP} \not\subseteq \mathsf{Formula}[n^k]$.*

Proof. Suppose $\mathsf{NP} \subseteq \mathsf{Formula}[n^k]$ for the sake of contradiction. Then in particular each NP language can be computed by a size-n^{k+1} formula which reads all its inputs exactly n^k times by adding some dummy nodes in the formula. Therefore, by replacing all NP oracles in F by such formulas, we have an $N^{2-\varepsilon}$-size formula for $\mathsf{MCSP}[2^{\sqrt{n}}]$, in contradiction to the lower bound in [23]. ◀

Localization of [23]

Our following theorem shows that the above approach is not viable even with $k = 3$ by localizing [23], with a moderate constraint on the adaptivity of the oracle circuits.

▶ **Theorem 59.** *There is a universal constant c such that for all constants $\varepsilon > 0$ and $\alpha > 2$, $\mathsf{MCSP}[n^c, 2^{(\varepsilon/\alpha)\cdot n}]$ cannot be computed by oracle formulas F with $\mathsf{SIZE}_3(F) \le N^{2-\varepsilon}$ and adaptivity $o(\log N/\log\log N)$ (that is, on any path from root to a leaf, there are at most $o(\log N/\log\log N)$ oracles).*

▶ Remark 60. It is not hard to see that the adaptivity can be at most $O(\log N)$ given the condition $\mathsf{SIZE}_3(F) \le N^{2-\varepsilon}$.

Before proving Theorem 59, we first show it refutes the Anti-Checker Hypothesis (restated below) from [39].

The Anti-Checker Hypothesis. *For every $\lambda \in (0,1)$, there are $\varepsilon > 0$ and a collection $\mathcal{Y} = \{Y_1, \ldots, Y_\ell\}$ of sets $Y_i \subseteq \{0,1\}^n$, where $\ell = 2^{(2-\varepsilon)n}$ and each $|Y_i| = 2^{n^{1-\varepsilon}}$, for which the following holds.*

If $f : \{0,1\}^n \mapsto \{0,1\}$ and $f \notin \mathsf{Circuit}[2^{n^\lambda}]$, then some set $Y \in \mathcal{Y}$ forms an anti-checker for f: For each circuit C of size $2^{n^\lambda}/10n$, there is an input $y \in Y$ such that $C(y) \neq f(y)$.

▶ **Corollary 61.** *The Anti-Checker Hypothesis is false.*

Proof. It is easy to see that, assuming the Anti-Checker Hypothesis, we can solve $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ with a formula F of $N^{2-\varepsilon}$ size which uses $N^{2-\varepsilon}$ oracles of fan-in $\mathsf{poly}(n)2^{n^{1-\varepsilon}} = \mathrm{polylog}(N) \cdot 2^{(\log N)^{1-\varepsilon}} = N^{o(1)}$ only at the layer above the inputs, for some $\varepsilon > 0$. However, since $\mathsf{SIZE}_3(F) \leq N^{2-\varepsilon+o(1)}$, F cannot compute $\mathsf{MCSP}[2^{n^{1/3}}, 2^{n^{2/3}}]$ by Theorem 59, contradiction. ◀

Now we are ready to prove Theorem 59.

Proof of Theorem 59. Let $k = \log^3 N$, and $\boldsymbol{\rho}$ be the k-wise independent $(1/\sqrt{k})$-regular random restriction guaranteed by Lemma 12.

For an oracle formula F and a sub-formula G of it, we say G is a maximal sub-formula if G is an entire subtree rooted at either the root, an oracle gate, or a gate whose father is an oracle.

We are going to apply $t = \Theta(\log_k N)$ independent pseudorandom restrictions $\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \ldots, \boldsymbol{\rho}_t$, each distributed identically to $\boldsymbol{\rho}$, where t will be set precisely later.

The Overall Proof Structure

To analyze the size of the oracle formula under the random restriction sequence $\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \ldots, \boldsymbol{\rho}_t$, we define a potential function Φ inductively for all maximal sub-formulas of the given formula F. As it will be clear from the definition, Φ is not only a function of the structure of the oracle formula, but also depends on the history of the pseudorandom restrictions.

Formally, for each maximal sub-formula G of the given formula F, and for each integer $0 \leq i \leq t$, we define a random variable $\Phi_{G,i}$, which denotes the potential function of G after the first i pseudorandom restrictions and only depends on $\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \ldots, \boldsymbol{\rho}_i$.

Definition of Tiny formulas and Blow up

For an oracle formula, if the top gate is an oracle, we say it is tiny if it depends on at most $\log N$ variables. Otherwise, we say it is tiny if it depends on at most $c_{\mathsf{tiny}} \cdot k$ variables, for a constant c_{tiny} to be specified later.

After each pseudorandom restriction, for a formula with an oracle gate at the top, when it depends on at most $b = 20$ variables, we blow it up to a formula of size $B = 2^b$ (note that if there are two oracle gates u, v such that u and v both depend on at most b variables and u is an ancestor of v, then it suffices to only blow up u).

The above two definitions (tiny formulas and the process of blowing up) may not seem easy to understand at first. Let us explain the motivation behind them. The key difficulty of the proof is to handle the oracle gates properly. The process of blowing up ensures that whenever an oracle becomes too small, we just replace it with a constant size normal formula, so it becomes easier to deal with.

The definition of tiny formulas is more subtle. As it will be clearly in Case II and Case III of the inductive definition of Φ, setting the threshold of being tiny to $\log N$ for oracle formulas with top oracle gates ensures that the corresponding event of becoming tiny happens with high probability, which is indeed crucial in our proof.

The properties of Φ

We require the following properties on Φ.

1. For an oracle formula F, Φ is multiplied by a factor of $\frac{c_F}{k}$ under $\boldsymbol{\rho}$ in expectation, where c_F depends on F but it is upper bounded by a universal constant.
2. With probability $1 - p_F$, for all stages, and all maximal sub-formulas G of F, $\Phi = 0$ for G implies that G is tiny, where p_F depends on F but it is upper bounded by N^{-2}.
3. It holds that either $\Phi = 0$ or $\Phi \geq 1$. Together with the second item, it implies that if the oracle formula is not tiny then $\Phi \geq 1$.

With these carefully designed properties of Φ, the overall proof is straightforward. We first show that Φ of F is closely related to $\mathsf{SIZE}_3(F)$, and our conditions on the oracle formula imply that Φ of the whole oracle formula is bounded by $N^{2-\varepsilon+o(1)}$ at the beginning. Then after roughly $t \approx \log_k(N^{2-\varepsilon+o(1)})$ rounds of restrictions from $\boldsymbol{\rho}$, Φ becomes 0 with a good probability, which also implies the whole oracle formula becomes tiny (only depend on $\mathrm{polylog}(N)$ bits).

But then we argue that after t rounds of restrictions from $\boldsymbol{\rho}$, with high probability the number of unrestricted variables is still at least $N^{\Omega(1)}$. Using a similar argument as from [23, 42, 39], we show that the tiny oracle formula left behind cannot compute $\mathsf{MCSP}[n^c, 2^{\varepsilon/\alpha \cdot n}]$ on the remaining variables, which concludes the proof.

The Inductive Definition of the Potential Function Φ

In the following, we gradually develop the definition of the potential function Φ. We remark that Case I and Case II below are actually special cases of Case III and Case IV respectively. We discuss them first in the hope that they provide some intuitions and make it easier to understand the more complicated Case III and Case IV.

Case I: Φ for a Pure Formula

We begin with the simplest case of pure formulas F (formulas with no oracles) of size S. We define

$$\Phi = \begin{cases} S & S \geq 100 \cdot k, \\ 0 & \text{otherwise.} \end{cases}$$

It follows from the shrinkage lemma [21], formula decomposition [51, Claim 6.2], and the k-wise independence of $\boldsymbol{\rho}$ that, when $S \geq 100 \cdot k$, the *expected size* of S drops by a factor of at least k/c_{Tal}, for a universal constant c_{Tal} (we can set $c_F = c_{\mathsf{Tal}}$). Otherwise, the formula is tiny. It is straightforward to verify that all three properties of Φ are satisfied (we can set $p_F = 0$ in this case).

Case II: Φ for a Pure Oracle

Next we consider the case that F is a pure oracle O with fan-in T (pure oracle means each input to O is just a variable). We set

$$\Phi = T^2 \cdot k^3$$

at the beginning. And set $\Phi \leftarrow \Phi/k$ after each $\boldsymbol{\rho}$. Whenever it happens $\Phi < 1$, we set $\Phi = 0$ afterwards. Here, we can simply set $c_F = 1$.

Now we argue that with probability at least $1 - N^{-5}$ (that is, we set $p_F = N^{-5}$), when $\Phi = 0$, O only depends on at most $\log N$ variables and therefore becomes tiny.

Note that $\Phi = 0$ means at least $\log_k T^2$ rounds of random restrictions have been applied.[16] Their composition is a k-wise independent restriction which keeps a variable unrestricted with probability at most T^{-1}. Therefore, the probability that the number of alive variable is larger than $\log N$ is smaller than

$$\binom{T}{\log N} \cdot T^{-\log N} \leq \left(\frac{e \cdot T}{\log N}\right)^{\log N} \cdot T^{-\log N} \leq \left(\frac{e}{\log N}\right)^{\log N} \leq N^{-5}.$$

Note that in the above inequalities we can safely assume $T > \log N$.

Case III: Φ for an Oracle Formula with an Oracle Top Gate

Then we move to the case of a maximal sub-formula F with an oracle top gate O with fan-in T. Let Φ_i be the corresponding potential function of the maximal sub-formula with root being the i-th input to O. We set

$$\Phi = \max\left(\sum_{i=1}^{T} \Phi_i, 1/k\right) \cdot T^2 \cdot k^4,$$

at the beginning.

When $\sum_{i=1}^{T} \Phi_i > 0$, we still let $\Phi = \left(\sum_{i=1}^{T} \Phi_i\right) \cdot T^2 \cdot k^4$. When $\sum_{i=1}^{T} \Phi_i$ first becomes 0 (this could happen before the first restriction, if $\sum_{i=1}^{T} \Phi_i = 0$ at the beginning), we set $\Phi = T^2 \cdot k^3$ and decrease it by a factor of k during each later restriction, and set it to 0 if it becomes < 1.

Here, we set c_F to be the maximum of $c_{F'}$ for all maximal sub-formulas F' whose root is an input to the top oracle gate O in F.

First let us argue that Φ is multiplied by a factor of $\frac{c_F}{k}$ after each $\boldsymbol{\rho}$ in expectation. When $\sum_{i=1}^{T} \Phi_i = 0$, it is evident from the way we set Φ (note that $c_F \geq 1$). When $\sum_{i=1}^{T} \Phi_i > 0$, it follows from the induction as each Φ_i is multiplied by a factor of $\frac{c_F}{k}$ after each $\boldsymbol{\rho}$ in expectation. In the borderline case when $\sum_{i=1}^{T} \Phi_i > 0$ before $\boldsymbol{\rho}$ and becomes 0 afterwards. One can see Φ drops from at least $T^2 \cdot k^4$ to at most $T^2 \cdot k^3$.

Moreover, when $\sum_{i=1}^{T} \Phi_i = 0$, with probability at least $1 - \sum_{i=1}^{T} p_{F_i}$ (F_i is the i-th sub-formula whose root is an input to the top oracle gate O in F) all the sub-formulas are tiny, so at this time the oracle depends on at most $O(T \cdot k)$ variables.

Therefore, when Φ drops to 0, with probability at least $1 - \sum_{i=1}^{T} p_{F_i} - N^{-5}$ the whole oracle formula becomes tiny, by a calculation similar to the pure oracle case. Therefore, we can set $p_F = \sum_{i=1}^{T} p_{F_i} + N^{-5}$.

Case IV: Φ for a Formula with Oracle Leaves

Finally, we deal with the most complicated case when the maximal sub-formula F is a formula with oracle leaves. Suppose F is a formula of size S with m oracle leaves. Let Φ_i be the potential function of the sub-formula corresponding to the i-th oracle leaf. Also, let c_{drop} be the maximum of the c_F's of all the sub-formulas corresponding to the oracle leaves.

[16] Note that for this argument, a potential function of $T \cdot k$ already suffices. We use $T^2 \cdot k^3$ here to make it consistent with Case III.

The difficulty in analyzing this case is that there could be many oracles which are tiny but have not blown up yet, and we have to keep track of the number of such oracles. Let N_{active} be the number of remaining active tiny oracles (oracles which are tiny but have not blown up). Clearly, $N_{\mathsf{active}} \leq S$ at the beginning.

We set

$$\Phi = S + N_{\mathsf{active}} \cdot k^2 + \sum_{i=1}^{m} \Phi_i \cdot k^4,$$

at the beginning. When $S \leq 100 \cdot k$ happens, we change Φ to be

$$N_{\mathsf{active}} \cdot k^2 + \sum_{i=1}^{m} \Phi_i \cdot k^4$$

afterwards.

After each $\boldsymbol{\rho}$, if $S \geq 100 \cdot k$, the expected size of S becomes at most

$$c_1 \cdot S/k + c_2 \cdot k \cdot \left(\sum_{i=1}^{m} \Phi_i + N_{\mathsf{active}} \right),$$

for two universal constants c_1 and c_2. This bound holds because, by Claim 4.4 of [24], a formula of size S can be decomposed into $6S/k$ sub-formulas, each of size at most k, and each formula has at most 2 sub-formula children.

The number of active oracle leaves (which are not blown up) is at most $\sum_{i=1}^{m} \Phi_i + N_{\mathsf{active}}$. Hence, at least $6 \cdot S/k - \sum_{i=1}^{m} \Phi_i - N_{\mathsf{active}}$ sub-formulas do not contain an active oracle leaf, and their total expected size is $O(S/k)$ after $\boldsymbol{\rho}$ (by Lemma 4.1 and Lemma 4.3 of [24], and [51]). For those sub-formulas containing active oracle leaves, their total size is at most $(\sum_{i=1}^{m} \Phi_i + N_{\mathsf{active}}) \cdot O(k)$ after $\boldsymbol{\rho}$ (this takes account of the worst case situation that all these active oracle leaves blow up).

Also, we can see that after $\boldsymbol{\rho}$, N_{active} becomes at most

$$N_{\mathsf{active}}/k^2 + \sum_{i=1}^{m} \Phi_i$$

in expectation. This is because for a tiny active oracle depending on at most $\log N$ variables, the probability that it does not blow up after $\boldsymbol{\rho}$ is at most

$$\binom{\log N}{b} \cdot k^{-b/2} \leq (\log N)^{b - 1.5 \cdot b} = (\log N)^{-10} \leq 1/k^2.$$

By induction, we also have that $\sum_{i=1}^{m} \Phi_i$ is multiplied by a factor of $\frac{c_{\mathsf{drop}}}{k}$ in expectation as well after each $\boldsymbol{\rho}$. Therefore, after $\boldsymbol{\rho}$, the expectation of Φ can be bounded by

$$\begin{aligned} & c_1 \cdot S/k + c_2 k \left(\sum_{i=1}^{m} \Phi_i + N_{\mathsf{active}} \right) + \left(N_{\mathsf{active}}/k^2 + \sum_{i=1}^{m} \Phi_i \right) \cdot k^2 + \left(\sum_{i=1}^{m} \Phi_i \right) \cdot \frac{c_{\mathsf{drop}}}{k} \cdot k^4 \\ \leq \; & S \cdot \frac{c_1}{k} + N_{\mathsf{active}} \cdot k^2 \cdot \frac{c_2 + 1/k}{k} + \sum_{i=1}^{m} \Phi_i \cdot k^4 \cdot \left(\frac{c_{\mathsf{drop}} + c_2/k^2 + 1/k}{k} \right). \end{aligned}$$

We can set

$$c_F = \max(c_1, c_2 + 1/k, c_{\mathsf{drop}} + c_2/k^2 + 1/k).$$

Recall that when $S \leq 100 \cdot k$ happens, we change Φ to be

$$N_{\mathsf{active}} \cdot k^2 + \sum_{i=1}^{m} \Phi_i \cdot k^4$$

afterwards.

By the previous discussion, after this Φ still drops by a factor of k/c_F in expectation after each $\boldsymbol{\rho}$. Note that when $\Phi = 0$, we can see the size of the whole formula is smaller than $B \cdot 100 \cdot k = O(k)$, therefore it is tiny (here we set $c_{\mathsf{tiny}} = B \cdot 100$). This is because $\Phi = 0$ implies $S \leq 100 \cdot k$ happened at some point, and also $N_{\mathsf{active}} = \sum_{i=1}^{m} \Phi_i = 0$. They together imply that all oracles have blown up, and the size bound follows since each oracle adds at most B leaves.

Let F_i be the sub-formula with root being the i-th oracle leaf. In this case, we can set $p_F = \sum_{i=1}^{m} p_{F_i}$.

The MCSP Lower Bound

Let F be an oracle formula with $\mathsf{SIZE}_3(F) \leq N^{2-\varepsilon}$ and adaptivity $\tau = o(\log N / \log\log N)$. We first need to verify that c_F is upper bounded by a universal constant. One can upper bound

$$c_F \leq \max(c_1, c_2 + 1/k, c_{\mathsf{Tal}}) + \tau \cdot (c_2/k^2 + 1/k) \leq \max(c_1, c_2 + 1/k, c_{\mathsf{Tal}}) + o(1) = O(1).$$

We can also upper bound p_F by $p_F \leq N^{-5} \cdot N^2 = N^{-3}$.

By the inductive definition of the potential function Ψ on maximal sub-formulas, it is not hard to show that

$$\Phi \leq \mathsf{SIZE}_3(F) \cdot k^{O(\tau)} \leq N^{2-\varepsilon+o(1)}.$$

Note that this inequality crucially employs the definition of $\mathsf{SIZE}_3(\cdot)$.

After each $\boldsymbol{\rho}$, Φ is reduced by a factor of k/c_F. After

$$t = \lceil \log_{k/c_F} \Phi \rceil + 2$$

rounds of $\boldsymbol{\rho}$, the expected Φ of the overall formula becomes $< 1/10$, which means with probability $0.9 - p_F \geq 0.8$ it is tiny and only depends on at most $O(k) = O(\log^3 N)$ variables.

Note that by definition

$$(k/c_F)^t \leq \Phi \cdot k^3,$$

and therefore

$$k^t \leq \Phi \cdot k^3 \cdot (c_F)^t \leq N^{2-\varepsilon+o(1)},$$

as $(c_F)^t = (c_F)^{O(\log N / \log\log N)} = N^{o(1)}$.

The composition of t independent $\boldsymbol{\rho}$ keeps a variable unrestricted with probability $k^{-t/2} \geq N^{-1+\varepsilon/2-o(1)}$, and is clearly pairwise independent. By Chebyshev's inequality, after t restrictions from $\boldsymbol{\rho}$, with probability 0.5, at least

$$1/2 \cdot N \cdot N^{-1+\varepsilon/2-o(1)} \geq N^{\varepsilon/2-o(1)}$$

variables remain active. So with probability at least 0.3, after t restrictions from $\boldsymbol{\rho}$, the remaining formula F only depends on $O(\log^3 N)$ variables, and the number of remaining unrestricted variables is at least $N^{\varepsilon/2-o(1)}$.

Suppose we fix all these remaining unrestricted variables to be 0 to get an input x^*. Since each restriction from $\boldsymbol{\rho}$ can be computed by a $\mathsf{poly}(n)$-size circuit, x^* has a circuit of $\mathsf{poly}(n) \cdot t = \mathsf{poly}(n) \leq n^c$ size (here we set c). Let S be the set of input variables that F depends on. Note that there are at least $2^{N^{\varepsilon/2-o(1)}-|S|}$ ways of assigning values to unrestricted variables while keeping variables in S all 0. Since F only depends on S, F's output on x^* is the same as its output on all of these assignments. But there must exist at least one assignment such the MCSP value is at least $N^{\varepsilon/\alpha} = 2^{(\varepsilon/\alpha)\cdot n}$ as $\alpha > 2$. Therefore, F cannot compute $\mathsf{MCSP}[n^c, 2^{(\varepsilon/\alpha)\cdot n}]$. ◀

A Review of Hardness Magnification in Circuit Complexity

A.1 Previous Work

We focus on some representative examples. For definitions and more details, check Section 2 or consult the original papers.

Srinivasan [50] (Informal). If there exists $\varepsilon > 0$ such that $n^{1-o(1)}$-approximating MAX-CLIQUE requires boolean circuits of size at least $m^{1+\varepsilon}$ (where $m = \Theta(n^2)$), then $\mathsf{NP} \not\subseteq \mathsf{Circuit}[\mathsf{poly}]$.

Allender-Koucký [3] and Chen-Tell [13]. The following results hold.

- Let $\Pi \in \{\mathsf{BFE}, \mathsf{W}_{\mathsf{S}_5}, \text{W5-STCONN}\}$. Suppose that for each $c > 1$ there exist infinitely many $d \in \mathbb{N}$ such that TC^0 circuits of depth d require more than $n^{1+c^{-d}}$ wires to solve Π. Then, $\mathsf{NC}^1 \not\subseteq \mathsf{TC}^0$.
- Suppose that for each $c > 1$ there exist infinitely many $d \in \mathbb{N}$ such that MAJ cannot be computed by ACC^0 circuits of depth d with $n^{1+c^{-d}}$ wires. Then $\mathsf{MAJ} \notin \mathsf{ACC}^0$, and consequently $\mathsf{TC}^0 \not\subseteq \mathsf{ACC}^0$.

Lipton-Williams [35]. If there is $\varepsilon > 0$ such that for every $\delta > 0$ we have $\mathsf{CircEval} \notin \mathsf{Size\text{-}Depth}[n^{1+\varepsilon}, n^{1-\delta}]$, then for every $k \geq 1$ and $\gamma > 0$ we have $\mathsf{CircEval} \notin \mathsf{Size\text{-}Depth}[n^k, n^{1-\gamma}]$ (in particular $\mathsf{P} \not\subseteq \mathsf{NC}$).

Oliveira-Santhanam [42]. The following results hold.

- Let $s(n) = n^k$ and $\delta(n) = n^{-k}$, where $k \in \mathbb{N}$. If $\mathsf{MCSP}[(s,0),(s,\delta)] \notin \mathsf{Formula}[N^{1+\varepsilon}]$ for some $\varepsilon > 0$, then there is $L \in \mathsf{NP}$ over m-bit inputs and $\delta > 0$ such that $L \notin \mathsf{Formula}[2^{m^\delta}]$.
- Suppose there exists $k \geq 1$ such that for every $d \geq 1$ there is $\varepsilon_d > 0$ such that $\mathsf{MCSP}[(s,0),(s,\delta)] \notin \mathsf{AC}^0_d[N^{1+\varepsilon_d}]$, where $s(n) = n^k$ and $\delta(n) = n^{-k}$. Then $\mathsf{NP} \not\subseteq \mathsf{NC}^1$.
- Let $k(n) = n^{o(1)}$. If there exists $\varepsilon > 0$ such that k-Vertex-Cover $\notin \mathsf{DTISP}[m^{1+\varepsilon}, m^{o(1)}]$, where the input is an n-vertex graph represented by an adjacency matrix of bit length $m = \Theta(n^2)$, then $\mathsf{P} \neq \mathsf{NP}$.
- Let $k(n) = (\log n)^C$, where $C \in \mathbb{N}$ is arbitrary. If for every $d \geq 1$ there exists $\varepsilon > 0$ such that k-Vertex-Cover $\notin \mathsf{AC}^0_d[m^{1+\varepsilon}]$, then $\mathsf{NP} \not\subseteq \mathsf{NC}^1$.

Oliveira-Pich-Santhanam [39] and McKay-Murray-Williams [36] (Informal). If there exists $\varepsilon > 0$ such that for every small enough $\beta > 0$,

- $\mathsf{MCSP}[2^{\beta n}] \notin \mathsf{Circuit}[N^{1+\varepsilon}]$, then $\mathsf{NP} \not\subseteq \mathsf{Circuit}[\mathrm{poly}]$.
- $\mathsf{MKtP}[2^{\beta n}] \notin \mathsf{TC}^0[N^{1+\varepsilon}]$, then $\mathsf{EXP} \not\subseteq \mathsf{TC}^0[\mathrm{poly}]$.
- $\mathsf{MKtP}[2^{\beta n}] \notin U_2\text{-}\mathsf{Formula}[N^{3+\varepsilon}]$, then $\mathsf{EXP} \not\subseteq \mathsf{Formula}[\mathrm{poly}]$.
- $\mathsf{MKtP}[2^{\beta n}] \notin B_2\text{-}\mathsf{Formula}[N^{2+\varepsilon}]$, then $\mathsf{EXP} \not\subseteq \mathsf{Formula}[\mathrm{poly}]$.
- $\mathsf{MKtP}[2^{\beta n}] \notin \mathsf{Formula\text{-}XOR}[N^{1+\varepsilon}]$, then $\mathsf{EXP} \not\subseteq \mathsf{Formula}[\mathrm{poly}]$.
- $\mathsf{MKtP}[2^{\beta n}] \notin \mathsf{BP}[N^{2+\varepsilon}]$, then $\mathsf{EXP} \not\subseteq \mathsf{BP}[\mathrm{poly}]$.
- $\mathsf{MKtP}[2^{\beta n}] \notin (\mathsf{AC}^0[6])[N^{1+\varepsilon}]$, then $\mathsf{EXP} \not\subseteq \mathsf{AC}^0[6]$.

Many results for MKtP admit analogues for MrKtP, which considers a randomized version of Kt complexity introduced by [38]. An advantage of MrKtP is that strong unconditional lower bounds against uniform computations are known, while the hardness of problems such as MCSP and MKtP currently relies on cryptographic assumptions.

Chen-McKay-Murray-Williams [12]. The following results hold.

- If there is $\varepsilon > 0$, $c \geq 1$, and an n^c-sparse language $L \in \mathsf{NP}$ such that $L \notin \mathsf{Circuit}[n^{1+\varepsilon}]$, then $\mathsf{NE} \not\subseteq \mathsf{Circuit}[2^{\delta \cdot n}]$ for some $\delta > 0$.
- If there is $\varepsilon > 0$ such that for every $\beta > 0$ there is a 2^{n^β}-sparse language $L \in \mathsf{NTIME}[2^{n^\beta}]$ such that $L \notin \mathsf{Circuit}[n^{1+\varepsilon}]$, then $\mathsf{NEXP} \not\subseteq \mathsf{Circuit}[\mathrm{poly}]$.

More recently, [10] established that many hardness magnification theorems for problems such as MCSP and MKtP hold in fact under the assumption that a *sufficiently sparse and explicit language* admits weak lower bounds. We refer to their work for more details.

A.2 Hardness Magnification Through the Lens of Oracle Circuits

We can view the results from Appendix A.1 as *unconditional* upper bounds on the size of small fan-in oracle circuits solving the corresponding problems, for a certain choice of oracle gates. In a magnification theorem, it is important to upper bound the uniform complexity of the oracle gates. For our discussion, this is not going to be relevant.

We repeat here a definition from Section 2, for convenience of the reader.

▶ **Definition 62** (Local circuit classes). *Let $\mathcal{C}$ be a circuit class (such as $\mathsf{AC}^0[s]$, $\mathsf{TC}^0_d[s]$, $\mathsf{Circuit}[s]$, etc). For functions $q, \ell, a \colon \mathbb{N} \to \mathbb{N}$, we say that a language L is in $[q, \ell, a]$–$\mathcal{C}$ if there exists a sequence $\{E_n\}$ of oracle circuits for which the following holds:*

- **(i)** *Each oracle circuit E_n is a circuit from $\mathcal{C}$.*
- **(ii)** *There are at most $q(n)$ oracle gates in E_n, each of fan-in at most $\ell(n)$, and any path from an input gate to an output gate encounters at most $a(n)$ oracle gates.*
- **(iii)** *There exists a language $\mathcal{O} \subseteq \{0,1\}^*$ such that the sequence $\{E^{\mathcal{O}}_n\}$ (E_n with its oracle gates set to $\mathcal{O}$) computes L.*

In the definition above, q stands for *quantity*, ℓ for *locality*, and a for *adaptivity* of the corresponding oracle gates.

The fact that existing magnification theorems produce such circuits is a consequence of the algorithmic nature of the underlying proofs, which show how to reduce an instance of a problem to shorter instances of another related problem. By inspection of each proof, it is possible to establish a variety of upper bounds. We explicitly state some of them below.

▶ **Proposition 63.** *The following results hold.*

- [3] *For every $\Pi \in \{\mathsf{BFE}, \mathsf{W}_{\mathsf{S}_5}, \text{W5-STCONN}\}$ and every $\beta > 0$, $\Pi_n \in \left[O\left(n^{1-\beta}\right), n^{\beta}, O\left(\frac{1}{\beta}\right)\right]$–$\mathsf{TC}^0[O(n)]$.*
- [35] *For every $\delta > 0$, $\mathsf{CircEval}_n \in \left[n \cdot \mathsf{poly}(\log n), n^{\delta}, n^{1-\delta}\right]$–$\mathsf{Circuit}[n \cdot \mathsf{poly}(\log n)]$.*
- [42] *For every constructive function $n \leq s(n) \leq 2^n/\mathsf{poly}(n)$ and parameter $0 < \delta(n) < 1/2$, $\mathsf{MCSP}[(s,0),(s,\delta)] \in [N, \mathsf{poly}(s/\delta), 1]$–$\mathsf{Formula}[N \cdot \mathsf{poly}(s/\delta)]$.*
- [42] *Let $k = (\log n)^C$, where $C \in \mathbb{N}$. Then k-Vertex-Cover $\in [1, (\log n)^{4C}, 1]$–$\mathsf{AC}^0_d[m^{1+\varepsilon}]$, where $\varepsilon_d \to 0$ as $d \to \infty$.*
- [39] *For every $\beta > 0$ and for every constructive function $s(n) \leq 2^{\beta n}$, Gap-MKtP $\in [N, \mathsf{poly}(s), 1]$–$\mathsf{Formula\text{-}XOR}[N \cdot \mathsf{poly}(s)]$.*
- [39] *For every constructive function $s(n) \leq 2^n/\mathsf{poly}(n)$, it follows that Gap-MCSP $\in [N \cdot \mathsf{poly}(s), \mathsf{poly}(s), \mathsf{poly}(s)]$–$\mathsf{Circuit}[N \cdot \mathsf{poly}(s)]$.*
- [36] *For every constructive function $s(n) \leq 2^n/\mathsf{poly}(n)$, we have $\mathit{MCSP}[s(n)] \in [O(N/\mathsf{poly}(s)), \mathsf{poly}(s), O(n/\log(s))]$–$\mathsf{Circuit}[N/\mathsf{poly}(s)]$.*

We stress however that not every hardness magnification theorem needs to lead to an unconditional construction of efficient oracle circuits. (All the proofs that we know of produce such circuits though.)

Separating Two-Round Secure Computation from Oblivious Transfer

Abstract

We consider the question of minimizing the round complexity of protocols for secure multiparty computation (MPC) with security against an arbitrary number of semi-honest parties. Very recently, Garg and Srinivasan (Eurocrypt 2018) and Benhamouda and Lin (Eurocrypt 2018) constructed such 2-round MPC protocols from minimal assumptions. This was done by showing *a round preserving reduction* to the task of secure *2-party* computation of the oblivious transfer functionality (OT). These constructions made a novel non-black-box use of the underlying OT protocol. The question remained whether this can be done by only making black-box use of 2-round OT. This is of theoretical and potentially also practical value as black-box use of primitives tends to lead to more efficient constructions.

Our main result proves that such a black-box construction is impossible, namely that non-black-box use of OT is necessary. As a corollary, a similar separation holds when starting with any 2-party functionality other than OT.

As a secondary contribution, we prove several additional results that further clarify the landscape of black-box MPC with minimal interaction. In particular, we complement the separation from 2-party functionalities by presenting a complete 4-party functionality, give evidence for the difficulty of ruling out a complete 3-party functionality and for the difficulty of ruling out black-box constructions of 3-round MPC from 2-round OT, and separate a relaxed "non-compact" variant of 2-party *homomorphic secret sharing* from 2-round OT.

1 Introduction

Secure multiparty computation (MPC) allows mutually distrusting parties to compute a joint function f of their private inputs without revealing anything more than the output to each other.

In this paper we consider the simplest setting for MPC with *no honest majority*, namely MPC with an arbitrary number of corrupted parties. We focus on the *semi-honest* (aka passive) security model, where corrupted parties follow the protocol but try to (jointly) learn additional information on inputs of uncorrupted parties from the messages they observe. We also assume that the parties can communicate over *secure point-to-point channels* and that corruptions are *non-adaptive* (i.e., the set of corrupted parties is fixed before the protocol's execution). All of the above assumptions make negative results stronger.

The design and analysis of MPC protocols crucially rely on the notion of *secure reductions*. In particular, classical completeness results [54, 34] have shown that the problem of securely computing a general n-party functionality f efficiently reduces to the problem of securely computing the elementary finite 2-party *Oblivious Transfer* (OT) functionality [51, 26]. (Similar results have been proven for active adversaries as well [44, 43].) Perhaps surprisingly, for 2-party secure computation (2PC), Yao's reduction is *round preserving*. That is, it incurs no overhead in the round complexity. It additionally requires the parties to make a black-box use of any pseudorandom generator (PRG).

▶ **Theorem 1** (Round-optimal 2PC [54]). *Every 2-party functionality g admits an MPC protocol that only makes parallel calls to an OT oracle and a black-box use of a PRG.*

In more detail, the OT functionality F_{OT} involves two parties referred to as *Receiver* and *Sender*. The functionality takes a bit x from the Receiver and a pair of bits (more generally, strings) (m_0, m_1) from the Sender, and delivers to the Receiver the message m_x. This is done while hiding m_{1-x} from the Receiver and hiding x from the Sender.

Yao's reduction makes a single round of parallel calls to F_{OT}.[1] Using a suitable composition theorem for MPC in the semi-honest model (see, e.g., [20, 33]), this can be securely replaced by parallel invocations of any *OT protocol*, namely a secure 2-party protocol for F_{OT}. The

[1] If both parties should receive an output, the reduction uses parallel OTs in both directions, where each party acts both as a Sender and as a Receiver.

resulting construction of 2-party MPC from a 2-party OT protocol is *black-box*.[2] This means that the MPC protocol does not depend on the code of the underlying OT protocol, and moreover the security proof is black-box in the sense that any adversary "breaking" the MPC protocol can be used as a black-box to break the OT protocol. Instantiating with one of several natural known 2-round OT protocols (whose existence follows from standard intractability assumptions), we get a 2-round 2-party MPC protocol, which is clearly optimal.

Round Complexity in the Multiparty Setting. In contrast to the 2-party setting, progress on the round complexity of general MPC has been slow and some of the questions still remain unanswered. As already mentioned, the completeness of OT in the multiparty setting was first established by Goldreich, Micali, and Wigderson (GMW) [34]. However, their reduction suffered from large round complexity (proportional to the circuit depth of the target function). The question of achieving a constant-round protocol has been considered by Beaver, Micali, and Rogaway [12], who extended Yao's garbled circuit technique to the multiparty setting. Combined with the GMW result, this yields a reduction to OT with constant overhead in the round complexity.

▶ **Theorem 2** (Constant-round MPC [34, 12]). *Every n-party functionality admits a constant-round protocol, making black-box use of a PRG, given an oracle access to F_{OT}.*

In more concrete terms, the most round-efficient current MPC protocol that makes a black-box use of a 2-round OT protocol requires 4 rounds of interaction [1]. The above results left a gap between the round complexity of 2PC and MPC protocols. In a recent breakthrough, this gap was partially closed.

▶ **Theorem 3** (2-round MPC from minimal assumption [31, 13]). *Suppose a 2-round OT protocol exists. Then every n-party functionality admits a 2-round MPC protocol.*

The theorem settles the high-order bit about the minimal assumptions needed for 2-round MPC by showing that 2-round OT is sufficient. (Being a special case of 2-round MPC, it is clearly necessary.) However, quite surprisingly, the MPC protocol in these works inherently makes use of the code of the underlying OT protocol. This situation is quite rare in the context of MPC protocols and in cryptography in general (see Section 1.2), and it is not clear whether this non-black-box use of OT is inherent. This calls for the following natural question:

> Is it possible to reduce general n-party MPC to a 2-party OT protocol in a round-preserving black-box way? In particular, is there a black-box construction of 2-round MPC from 2-round OT?

The above question is not only of a theoretical interest, but is also potentially relevant to practice. Indeed, black-box use of cryptographic primitives tends to lead to more efficient constructions. The goal of obtaining efficient 2-round MPC protocols is very well motivated, since such protocols have *qualitative* advantages over similar protocols with a bigger number of rounds. Indeed, in a 2-round MPC protocol, each party can send its first-round messages and then go offline until all second-round messages are received and the output can be computed. Moreover, the first-round messages can be potentially reused for several computations in which a party's input remains unchanged. This is analogous to the qualitative advantage of public-key encryption over interactive key agreement.

[2] The notion of a black-box construction used in this paper (also referred to as a black-box reduction) corresponds to the notion of a *fully black-box reduction* in the taxonomy of [52].

In this paper, we will provide a negative answer to the above question, showing that there is a real gap between the power of round-preserving black-box (RPBB) reductions and round-preserving non-black-box reductions. Our findings also reveal a rich and somewhat unexplored world of cryptographic protocols that use a minimal amount of interaction. We will exhibit some of the black-box and non-black-box connections among these primitives and relate them to standard ones.

1.1 Our Results

We now give a more detailed account of our results.

1.1.1 Separating 3-Party Functionalities from 2-Party Functionalities

Our first result shows that 2-round MPC protocols cannot be based on 2-round OT in a black-box way. In fact, we show that even 3-party computation of fairly simple functionalities is unachievable via black-box use of 2-round OT.

▶ **Theorem 4** (Main Result). *There exists a 3-party functionality f that cannot be securely computed by a 2-round protocol with black-box use of 2-round OT.*

We note that we do not just rule out round-preserving reductions to the ideal-OT functionality, but rather rule out all such black-box constructions from an *OT protocol*. (Indeed, much of the technical work is devoted to coping with the latter model; see Section 2.) Moreover, the theorem holds even for constructions in the private-channel setting (where each pair of parties is connected via a private channel), and even when the parties have an access to a public common reference string (CRS), and to a random oracle.

1.1.2 A Complete 4-Party Functionality

OT turns out to be incomplete for MPC under RPBB reductions. Given this state of affairs, one may try to prove a completeness result for some other finite functionality. We show that this is indeed possible. Specifically, let $(3,4)-\mathsf{MULTPlus}$ denote the 4-party functionality that takes a pair of bits (x_i, z_i) from each of the first three parties (and no input from the fourth party) and delivers the value $x_1x_2x_3+z_1+z_2+z_3$ to all four parties where addition and multiplication are over the binary field. We prove that $(3,4)-\mathsf{MULTPlus}$ is MPC-complete under RPBB reductions. (Related results have been proved in other settings [18, 28].) In fact, we prove an "ideal-oracle" completeness result just like in Yao's theorem.

▶ **Theorem 5** (Round Optimal MPC from Finite Ideal Functionality). *Every n-party functionality f can be realized using parallel calls to a $(3,4)-\mathsf{MULTPlus}$ oracle and a black-box use of a PRG.*

It's worth noting that $(3,4)-\mathsf{MULTPlus}$ is related to the standard 2-party OT functionality. In general, for $d \le p$, let $(d,p)-\mathsf{MULTPlus}$ denote the p-party functionality in which each of the first d parties holds an input (x_i, z_i) and the product-sum $\prod_i x_i + \sum_i z_i$ is delivered to all p parties. Then, standard 2-party OT is equivalent (under RPBB reductions) to $(2,2)-\mathsf{MULTPlus}$.[3]

[3] First observe that the receiver's output in OT can be written as $m_0 + x(m_1 - m_0)$ where addition and multiplication are over the binary field. Therefore, we can implement OT based on $(2,2)-\mathsf{MULTPlus}$ by letting the receiver (resp., sender) play the role of the first party (resp., second party) with inputs $x_1 = x$

1.1.3 The Land of Three-Party Functionalities

The finite $(3,4)-\mathsf{MULTPlus}$ therefore stands at the entry point to the general MPC mainland. Across the ocean, lies the island of two party functionalities (including the complete OT) and one cannot cross it in a black-box round-preserving vessel. We move on and explore the mysterious land of three party functionalities.

Given the incompleteness of 2-party functionalities and the completeness of four party functionalities (under round-preserving BB reductions), it is natural to ask whether 3-party functionalities are complete. We show that the answer to this question is related to a well-known open problem in information-theoretic cryptography.

▶ **Question 6** ([41]). *Does every finite function admit a degree-2 statistical randomized encoding?*

A randomized encoding (RE) of a function [41, 6] $f(x)$ is a randomized function $\hat{f}(x;r)$ that, in addition to the input x, takes an additional random input r. For any input x, the random variable $\hat{f}(x)$, induced by a random choice of r, should reveal the value of $f(x)$ and hide everything else. The power of REs stems from the fact that even complicated functions can be encoded by simple encoding. In the context of MPC, it is known that every finite function can be encoded by a function $\hat{f}(x;r)$ that each of its outputs can be written as a degree-3 polynomial over the indeterminates (x,r). While some negative results are known for perfectly-private degree-2 encodings [41], the feasibility of statistically-private degree-2 encodings (that are allowed to have a small non-zero privacy error) has remained open for almost 20 years. (See also the surveys [40, 3].) We relate this longstanding open problem to the completeness of 3-party functionalities under RPBB reductions.

▶ **Proposition 7.** *A positive answer to Question 6 implies that every n-party finite functionality g can be realized using parallel calls to an oracle that implements the 3-party functionality* $(2,3)-\mathsf{MULTPlus}$.

The proposition implies that we cannot rule out the completeness of 3-party functionalities without ruling out the existence of general degree-2 (statistical) randomized encoding. Similar barriers have been established in the context of degree-2 cryptographic hash functions [5]. We note that the completeness of $(2,3)-\mathsf{MULTPlus}$ follows even from the existence of general degree-2 fully-secure *multiparty randomized encoding* [4] – a seemingly weaker variant of RE whose existence is also open. (See the discussion in [4].)

External output functionalities. The $(2,3)-\mathsf{MULTPlus}$ is a special case of an *external-output* 3-party functionality. Formally, let $g(x,y)$ be a 2-party functionality. The *external version* of g, is the 3-party functionality f_g that takes x from Alice, y from Bob and delivers $g(x,y)$ to Alice and Bob, and to Carol who holds no input.[4] Two-round protocols for

and a random bit z_1 (resp., $x_2 = m_1 - m_0$ and $z_2 = m_0$). The receiver gets the required output (by subtracting z_1 from the output of the $(2,2)-\mathsf{MULTPlus}$), and the sender learns noting (since it receives a random bit). In the other direction, first observe that the one-sided variant of $(2,2)-\mathsf{MULTPlus}$, where only the first party has to learn the value $x_1x_2 + z_1 + z_2$, is RPBB-reducible to OT. Indeed, let player 1 (resp., player 2) play the role of the receiver (resp., sender) with inputs $x = x_1$ (resp., $m_0 = z_2$ and $m_1 = z_2 + x_2$), and set the output of player 1 to be the output of the OT plus z_1. Next, observe that standard $(2,2)-\mathsf{MULTPlus}$ can be constructed by making two parallel calls to the one-sided variant.

[4] In fact, for all of our purposes, an even weaker version suffices. In this relaxed version, all parties are allowed to learn the output (for purposes of privacy), but only Carol is *required* to learn it (for purposes of correctness). Since this leads to a cumbersome definition, we stick to the simpler version described above.

such functionalities turn out to have interesting properties. Specifically, at the core of our main impossibility result (Theorem 4), lies the following constructive theorem for external functionalities.

▶ **Theorem 8** (Conversion Theorem). *Let $g(x, y)$ be a 2-party functionality. The external version of g is the 3-party functionality f_g that takes x from Alice, y from Bob and delivers $g(x, y)$ to Alice and Bob, and to Carol who holds no input.*

Suppose that the functionality f_g can be securely computed in 2 rounds by making a black-box use of 2-round OT over private channels. Then, f_g can be securely implemented over random inputs given only an access to a Random Oracle over private channels. Moreover, in the resulting protocol Carol sends no message and so it yields a two-party protocol for computing g over random inputs given only an access to a Random Oracle.

Haitner et al. [36] showed that any 2-party functionality that can be securely realized in the Random Oracle (RO) model is *trivial* in the sense that it admits an unconditional 2-party protocol over random inputs with security against computationally-unbounded adversaries. As a corollary, we derive the following stronger version of Theorem 4.

▶ **Corollary 9.** *Every external functionality f_g that is based on a non-trivial 2-party functionality f cannot be computed by a 2-round protocol that makes a black-box use of 2-round OT even in the private-channel setting.*

A notable example for such a non-trivial 2-party functionality is the AND functionality [21, 46].

Corollary 9 is tight in terms of round complexity. With one additional round, f_g can be black-box reduced to 2-round OT. (Specifically, one can use Yao's theorem to pass the value of $f(x, y)$ to Alice and Bob in two rounds, and then exploit the additional round to send this value to Carol.) The 2-party completeness of OT (Theorem 1) also implies that Corollary 9 holds when the OT functionality is replaced by an arbitrary 2-party functionality $h(x, y)$. Overall, we get a separation between all 2-party functionalities and all external functionalities f_g whose underlying g is non-trivial.

Relation with homomorphic secret sharing. Two-round MPC for extended-output functionalities can be seen as closely related to the problem of homomorphic secret sharing (HSS) [16, 18]. HSS is the secret-sharing analogue of fully homomorphic encryption. A (2-party) HSS scheme allows local computation of a function $g(x, y)$ on independently shared inputs x and y, where the output $g(x, y)$ can be decoded from the pair of output shares. The standard notions of HSS require either *additive* decoding over a group or, more generally, that the output shares be *compact* in the sense that they are shorter than the inputs. A natural variant is to replace compactness by the requirement that the pair of output shares give no information except $g(x, y)$, even from the point of view of one of the input holders. This security requirement is easily obtained from additive HSS via a simple additive refreshing of the output shares. This flavor of non-compact HSS easily implies (in a black-box way) a 2-round external output protocol for g (in the private-channel setting), which by Corollary 9 can be separated from 2-round OT. On the other hand, a non-black-box construction of non-compact HSS from 2-round OT follows from [31, 28].

1.2 Discussion

In this section we give some further perspective on our results and some future research directions which they motivate.

1.2.1 Why is the multiparty setting different than the 2-party setting?

It is instructive to reconsider the round complexity of MPC in light of our results. Protocols with low round complexity are based on two types of reductions.

1. A *degree reduction* that takes a general n-party functionality f and reduces it (via RPBB reduction) to a degree-d functionality for a constant d. Specifically, the standard machinery of randomized-encoding leads to degree 3. In the special case of two parties, we can trivially reduce the degree down to 2, and so we get a degree reduction to $d = \min(3, n)$.
2. A *player reduction* that takes an n-party functionality of degree d and reduces it to the (d, p)–MULTPlus functionality. We show that p can be dropped down to $d + 1$ and, in any case, it is no larger than n, leading to an expression of the form $p = \min(d + 1, n)$.

In the special case of two parties $n = 2$ we get an RPBB-reduction to $(2, 2)$–MULTPlus which is equivalent to OT. For large n's, this leads to the completeness of $(3, 4)$–MULTPlus (Theorem 5). In order to prove that OT is complete (under RPBB-reductions) we have to bypass two barriers: A *Degree barrier* (prove completeness of degree 2 functionalities) and a *Player reduction barrier* (reducing the 3-party functionality (2,3)–MULTPlus to (2,2)–MULTPlus). While the first barrier is well-known, the second one appears to be new to this work. Clearly, both barriers are bypassed by non-black-box techniques (Theorem 3). We show that this is inherent for the second "player reduction" barrier, and leave the possibility of breaking the degree-barrier via RPBB-reduction open.

1.2.2 On the Role of Non-Black-Box Constructions in Cryptography

Our main result provides a very natural example of a pair of cryptographic primitives for which a non-black-box construction of one from the other exists but a black-box construction can be ruled out. Thus, our work further demonstrates the essential role of non-black-box techniques in cryptography.

To give some historical perspective, following the seminal result of Impagliazzo and Rudich [39] and subsequent works on black-box separations in cryptography [53, 32, 52], the question of finding a pair of "natural" cryptographic primitives for which a non-black-box reduction is provably necessary has been put forward as a desirable but elusive goal.[5] For some of the conjectured candidate examples, such as constructing "malicious OT" from "semi-honest OT," black-box constructions were subsequently found [35]. However, in recent years several such provable examples emerged. We survey some of the most notable ones below.

- *Non-interactive commitments from OWFs*: Mahmoody and Pass [48] showed that non-interactive commitments cannot be constructed from so-called "hitting-OWFs" in a black-box manner, even though a non-black-box construction was previously shown [10]. One nice feature of this example is that a non-interactive commitment is a very basic primitive. However, in comparison hitting-OWFs have found little other applications in cryptography. Furthermore, the separation here is intuitively weak since knowing the *circuit size* of the OWF enables a black-box construction. This is contrasted with the non-black-box constructions of 2-round MPC from OT [31, 13], which make an essential use of the full code of the OT protocol.

[5] The question is informal due to the subjective nature of the term "natural primitive." It should not be confused with the question of black-box vs. non-black-box *simulation*, for which Barak's breakthrough non-black-box simulation technique [8] gave the first such natural examples.

- *Two-round OT extension*: Beaver gave a construction of two-round OT extension [11] making a non-black-box use of one-way functions. This construction can be cast in the OT-hybrid model. However, very recently, Garg et al. [29] showed that a back-box variant of such a constriction is impossible. They showed that such constructions are not possible even when black-box use of a random oracle (and not just a one-way function) is allowed. One limitation of this example is that the separation is only proved for protocols in the OT-hybrid model.
- *IBE from CDH (or Generic Groups)*: In a recent result, Döttling and Garg [24] show that Identity-Based Encryption (IBE) can be realized under the Computational Diffie-Hellman (CDH) assumption, while black-box constructions of the same had been previously ruled out [15, 50]. However, in this case both the positive and the negative result use strong "structured" primitives.
  In another very related example, Döttling and Garg [23] showed a generic non-black-box construction of hierarchical-IBE from IBE but we can expect a black-box impossibility for the same using techniques from [15].[6]
- *Constructions of IO*: In a very recent work, Garg et al. [30] showed that indistinguishability obfuscation (IO) [27] cannot be constructed from compact functional encryption (FE) in a black-box manner, even though non-black-constructions achieving this were already known [14, 2].
- *Secret-Key FE vs Public-Key FE*: In a recent work, Kitagawa et al. [45] showed that public-key FE can be constructed from secret-key FE in a non-black-box manner, even though black-box positive constructions had been previously ruled out [7].

In comparison with the above works, our main result has the advantage that it considers two very natural and simple primitives. Our separation lives entirely in the "passive adversary" world, and does not depend on the input domain being super-polynomial. For instance, our separation is also meaningful for MPC with a uniform input distribution over a constant-size domain. Thus, it is arguably similar in spirit to the Impagliazzo-Rudich separation of key agreement from one-way functions [39], except that in the latter case no analogous non-black-box construction is known.

1.3 Open Problems

While we settle the main open question concerning black-box round-optimal MPC, our work leaves several interesting directions for future research. We highlight a few below, focusing on our current setting of semi-honest security with no honest majority.

- **3-round MPC from black-box OT.** Our main result rules out 2-round MPC protocols making a black-box use of 2-round OT. On the other hand, a previous result of Ananth et al. [1] shows that such 4-round protocols exist. What about 3-round protocols? In the full version of the paper, we give evidence that extending our negative result to the 3-round case would require settling Question 6 in the negative. This barrier does not seem to apply to 3-round protocols in which the first round messages do not depend on the inputs, or alternatively 2-round protocols with a public-key infrastructure (PKI) setup.
- **Black-box use of stronger primitives.** Can our negative result be bypassed by replacing OT with stronger or more structured primitives? It is known that 2-round MPC can make black-box use of different flavors of multi-key homomorphic encryption [49, 22]

[6] Even though we expect such an impossibility to hold, we are not aware of a work that gives a full proof of this claim.

or homomorphic secret sharing [17, 18]. However, this is almost immediate from the definitions of such primitives. Using simpler structured primitives, such as a "DDH-hard" group or a generic group, we have black-box 2-round protocols that require a PKI setup [28]. Can we get similar group-based constructions in the plain model? Alternatively, can the separation be bypassed by using stronger variants of 2-round OT, such as OT with high information rate [25] or OT with a stronger notion of receiver privacy [42]?

- **Minimal complete primitive for 2-round MPC.** We have shown the existence of a 4-party functionality such that general MPC reduces to *parallel* calls to this functionality without further interaction. We have also ruled out such a 2-party functionality. This leaves open the 3-party case. As in the case of 3-round MPC from 2-round OT, we can show that proving a *negative* result would require settling Question 6 in the negative.
- **Standard MPC vs. client-server MPC.** Our main negative result automatically carries over to the stronger *client-server model* for MPC, where n clients interact with n servers who have no inputs or outputs. It is known that 2-round client-server MPC can be constructed in a non-black-box way from standard 2-round MPC [28]. Whether such a black-box construction exists remains open.

2 Technical Overview

In this section, we give a high-level overview of our techniques in proving the main result (Theorem 4). To keep the exposition simple, we restrict ourselves to proving the impossibility result for securely computing external-AND.

External-AND Functionality. Let us denote the three parties by (P_1, P_2, P_3). The private input of P_1 is a bit x, the private input of P_2 is a bit y and P_3 does not have any private inputs. The functionality $f_\times$ outputs $x \cdot y$ to all the parties. Specifically, $f_\times(x, y, \perp) = x \cdot y$.

Main Idea. To prove the impossibility result, we define a set of oracles such that 2-round oblivious transfer exists with respect to these oracles, but there exists no 2-round, semi-honest protocol for securely computing $f_\times$. This is sufficient to rule out a black-box transformation from 2-round oblivious transfer to 2-round, 3-party semi-honest protocols for general functionalities. Below, we describe these oracles (throughout this overview, sec denotes the security parameter):

- OT_1 is a random length tripling function that takes in the receiver's choice bit $b \in \{0,1\}$ and its random tape $r \in \{0,1\}^{\text{sec}}$ and outputs the receiver's message otm_1.
- OT_2 is a random length tripling function that takes in the receiver's message otm_1, the sender's inputs $m_0, m_1 \in \{0,1\}$, its random tape $s \in \{0,1\}^{\text{sec}}$ and outputs the sender's message otm_2.
- OT_3 is a function that takes the transcript $(\mathsf{otm}_1, \mathsf{otm}_2)$ along with (b, r) as input and outputs m_b if there exists unique (m_0, m_1, s) for which $\mathsf{OT}_1(b, r) = \mathsf{otm}_1$ and $\mathsf{OT}_2(\mathsf{otm}_1, m_0, m_1, s) = \mathsf{otm}_2$. Otherwise, it outputs $\perp$.

As observed by [37], the oracles $(\mathsf{OT}_1, \mathsf{OT}_2, \mathsf{OT}_3)$ naturally give rise to a 2-round oblivious transfer protocol. Specifically, letting b, r denote the input/randomness of the receiver, and letting $(m_0, m_1), s$ denote the input/randomness of the sender, the protocol proceeds as follows: The receiver sends $\mathsf{otm}_1 = \mathsf{OT}_1(b, r)$ to the sender, who responds with $\mathsf{otm}_2 = \mathsf{OT}_2(\mathsf{otm}_1, m_0, m_1, s)$, allowing the receiver to output the value $\mathsf{OT}_3(\mathsf{otm}_1, \mathsf{otm}_2, b, r)$.

In this work, we prove that the existence of a 2-round protocol for external-AND w.r.t. $(\mathsf{OT}_1, \mathsf{OT}_2, \mathsf{OT}_3)$ implies a *two-party* protocol for computing $g(x, y) = x \cdot y$ in the random oracle model. (Note that we start with a three-party protocol for an external functionality,

and show a two-party protocol for a related functionality.) The existence of such two-party protocol is known to be impossible [21, 46, 36, 47] and therefore the original protocol can also not exist. This proves Theorem 8 discussed above, and implies Theorem 4 as a corollary.

Outline. The above result is proven using a sequence of transformations depicted in Figure 1.

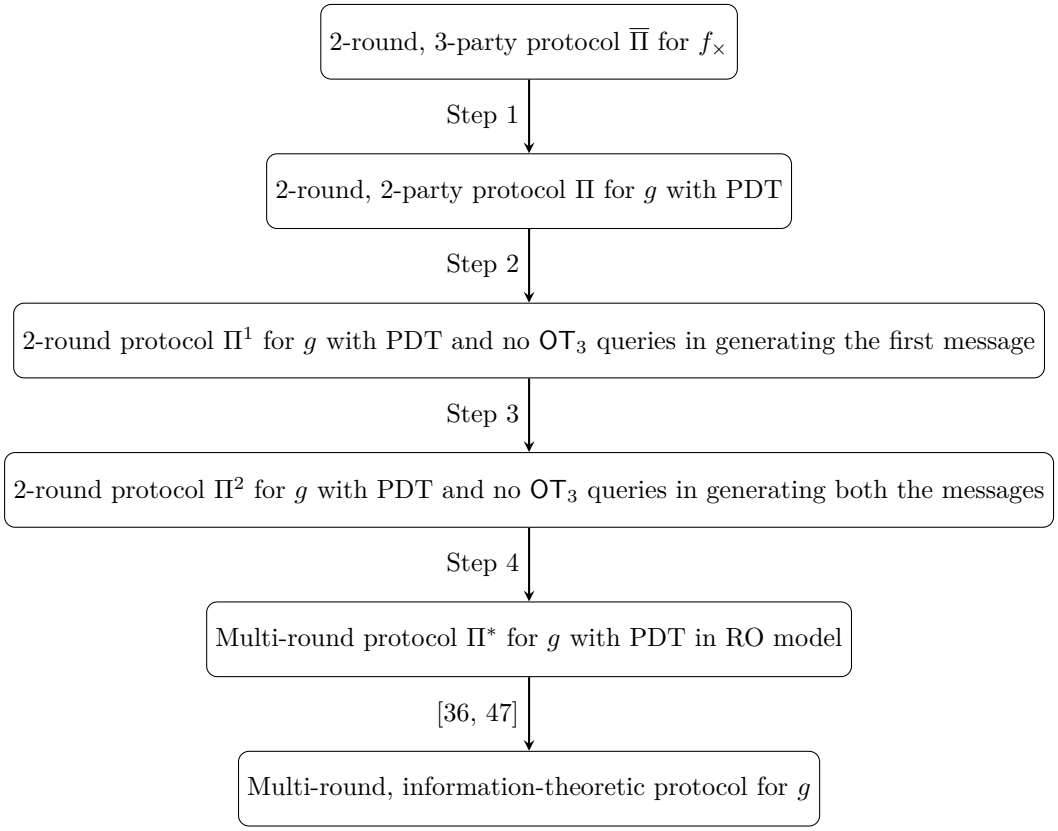

Figure 1 Key Steps in the Proof. Here, PDT denotes publicly decodable transcript, $g(x, y) = x \cdot y$ and $f_\times(x, y, \perp) = g(x, y)$.

Step-1: Publicly Decodable Transcript. Let $\overline{\Pi}$ be a 2-round protocol for securely computing $f_\times$ w.r.t. $(\mathsf{OT}_1, \mathsf{OT}_2, \mathsf{OT}_3)$. We first show that this implies a 2-round, 2-party protocol Π for computing the two-party functionality $g = g(x, y) = x \cdot y$, which has an additional special property – the output is *publicly decodable* from the transcript. More formally, there exists a deterministic algorithm Dec that computes the output of the functionality given the transcript of the two-party protocol. In particular, if there exists a protocol Π that computes g with publicly decodable transcript, then Dec on input $\mathbb{T}$ (which is the transcript of the protocol Π) outputs $g(x, y)$. In terms of security, Π is required to have the standard security properties of a two-party (semi-honest) protocol, i.e., the corrupted party does not learn any information about the other party's input except the output.

To transform a 2-round protocol for $f_\times$ into a 2-round protocol Π for g with publicly decodable transcript, we use a player emulation technique.[7] Concretely, we ask P_1 to choose a uniform random tape for P_3 and send this random tape in the first round. Using this random

[7] The idea of player emulation goes back to [19]; see also [38].

tape, P_1 and P_2 can generate the messages P_3 would have sent in the original protocol. Additionally, P_1 and P_2 forwards all its outgoing messages that are sent to each other as well the messages sent to P_3 in the original protocol.

This protocol satisfies public decodability since given the transcript of the protocol (which includes the entire view of P_3 in the original protocol), one can run the output computing algorithm of P_3 to learn $g(x, y)$. Further, the security follows directly from the security of the original protocol when (P_1, P_3) and (P_2, P_3) are corrupted.[8]

Remaining Steps – Removing OT_3 Queries. In the remainder of the proof, we show that use of the oracle OT_3 can be removed. More specifically, we show how to convert any two-round two-party secure computation protocol Π with access to $(\mathsf{OT}_1, \mathsf{OT}_2, \mathsf{OT}_3)$ and publicly decodable transcript into a two-party protocol that computes the same functionality, but with a few differences. The oracles OT_3 will no longer be used in the new protocol, but this will come at a cost, both in round-complexity and in security:

- The round complexity of the protocol will grow by a polynomial factor (essentially upper bounded by the query complexity of Dec).
- The correctness and security guarantees will only be with respect to random inputs (we call this "weak security"). One instructive way to think about weak security is to think of a protocol between parties that have no input, and at the beginning of the execution they sample a random input using their local random tape (or shared randomness) and proceed to execute the protocol. Note that this makes simulation easier since we no longer need to worry about consistency with an adversarially chosen (or sampled) input.

In other words, the new protocol Π^* only makes queries to $(\mathsf{OT}_1, \mathsf{OT}_2)$ which are essentially random oracles. Therefore, Π^* securely computes g in the random oracle model. However, it follows from [36, 47] that such a protocol can be used to securely compute g in the information-theoretic setting and this is known to be impossible for the AND functionality [21, 46] (even with weak security as described above).

The remainder of the overview describes this transformation. We transform Π to Π^* through a sequence of steps. We first transform Π to Π^1 in which the first message function of the protocol does not make any OT_3 queries (Step 2 below). Then, we transform Π^1 to Π^2 such that the first and second message functions of the protocol do not make any OT_3 queries (Step 3 below). Finally, we transform Π^2 to Π^* such that the decoder Dec does not make any OT_3 queries (Step 4 below). It is the final step that incurs the blow-up in the round complexity. Additional details follow.

Step-2: $\Pi \Rightarrow \Pi^1$. The first message function of Π has access to $(\mathsf{OT}_1, \mathsf{OT}_2, \mathsf{OT}_3)$ oracles and may make multiple queries to all of them. In order to perform this transformation, we devise a mechanism to emulate the OT_3 oracle without making actual queries to it. Recall that any query to the OT_3 oracle contains $((\mathsf{otm}_1, \mathsf{otm}_2), (b, r))$ and it outputs m_b if and only if there exists (m_0, m_1, s) for which $\mathsf{OT}_1(b, r) = \mathsf{otm}_1$ and $\mathsf{OT}_2(\mathsf{otm}_1, m_0, m_1, s) = \mathsf{otm}_2$. The first step of the OT_3 oracle is easy to emulate; we can query OT_1 on (b, r) and check if the output is otm_1. To emulate the second step, we maintain a list of all the queries/responses made by the first message function to OT_2. If we find an entry $(\mathsf{otm}_1, m_0, m_1, s, \mathsf{otm}_2)$ in this list, we output m_b; else, we output $\perp$. Note that since OT_2 is length tripling, it is

[8] It is easy to see that the security of the transformed protocol requires security against collusion of P_1, P_3 since P_1 has the entire view of P_3. We also require security against (P_2, P_3) collusion since P_1 forwards all its messages sent to P_3 in the second-round of the protocol.

injective with overwhelming probability. Thus, if we find such an entry then our emulation is correct. On the other hand, if we don't find such an entry, we output $\perp$ and it can be easily shown that the original oracle also outputs $\perp$ except with negligible probability. Thus, our emulation is statistically close to the real oracle.

Step-3: $\Pi^1 \Rightarrow \Pi^2$. It might be tempting to conclude that a similar strategy as before should work even for OT_3 queries made in the second round. That is, maintain the list of queries to the OT_2 oracle and when the second message function makes an OT_3 query, check if there is entry in this list with the response equal to otm_2. If such an entry is found, output the corresponding m_b; else, output $\perp$. This strategy fails because in the second round it is possible that the relevant OT_2 query was made by the other party and therefore it is not possible for each party to only consider the list of OT_2 queries made locally. Note, however, that only one simultanous round of communication has been made by the parties so far. Therefore, it must be the case that the party that made the OT_2 query also made the respective OT_1 query.

To take care of such queries, that we call "correlated queries", we modify the first round of Π^1 as follows. The parties will prepare an additional list L that contains all correlated queries that are "likely" to be asked by the other party. (No OT_3 calls will be made while preparing this list.)

The parties will now send this list L along with the first round message of Π^1. Now, when the second message function of a party in Π^1 attempts to make an OT_3 query on $(\mathsf{otm}_1, \mathsf{otm}_2, (b, r))$, we first check if otm_1 is valid (by querying OT_1) and then answer this query as follows. If otm_2 is a result of a local query then find the response using the list of local queries/responses. If otm_2 is a correlated query, use the list L sent by the other party to answer. If we don't find any entry in the local list or the correlated list, we output $\perp$. We show that with overwhelming probability, the real oracle also outputs $\perp$ in this case. We also prove that sending this additional list of "likely" correlated queries does not harm the security of Π^2.

To conclude, we describe how the list L is generated, say by P_1. Note that the list needs to be generated at a point where P_1 already decided on its first Π^1 message; now it just needs to come up with L. To this end, P_1 executes many copies of Π^1 executions of P_2, each time with fresh randomness and random input. Then the list L contains the responses to the list of all correlated OT_2 queries, i.e., the valid queries made to OT_3 by "virtual" P_2 such that both OT_1 and OT_2 have been generated by P_1. This will allow to preserve correctness on an average input, and does not violate privacy since given the first Π^1 messages, anyone can sample such executions.

Step-4: $\Pi^2 \Rightarrow \Pi^*$. At the end of step-3, we have a protocol where the first and the second message functions do not make any queries to the OT_3 oracle. However, for the parties to learn the output, they must run the decoder Dec on the transcript, and this decoder might make queries to OT_3. Recall that Dec is a deterministic decoding function whose input is the transcript of the interaction. Further recall that Π^* will be a protocol that does not use OT_3 but will have many communication rounds.

In Π^*, the parties will first execute the two rounds of Π^2 to obtain a transcript. Then they will jointly execute the decoder, where for each OT_3 query that the decoder needs to make, the party that made the relevant OT_2 query will "help out" by sending the decoding value to the other party. This will proceed for as many rounds as the number of queries that Dec needs to make, but eventually it will allow both parties to complete the execution of Dec locally and compute the output of the functionality. We will then need to show that privacy is not harmed in this process. Details follow.

Let us go back to the point where both parties finished executing the two rounds of Π^2 now wish to engage in joint decoding. One of the parties, say P_1, starts running the decoder on the transcript, and along the way maintain the list of $\mathsf{OT}_1, \mathsf{OT}_2$ made in this process. When the decoder attempts to make an OT_3 query on input $((\mathsf{otm}_1, \mathsf{otm}_2), (b, r))$, P_1 checks if otm_1 is valid (by making a query to OT_1). It then checks if there is an entry $(\mathsf{otm}_1, m_0, m_1, s, \mathsf{otm}_2)$ in the list of OT_2 queries made by the decoder and in the case such an entry is found, it answers with m_b. If such an entry is not found, P_1 checks its local list of queries/responses made to OT_2 during the generation of the first two messages. If it finds an entry $(\mathsf{otm}_1, m_0, m_1, s, \mathsf{otm}_2)$ in that list, it answers with m_b. If even this list does not contain an entry, there are 3 possibilities.

1. otm_2 is not in the image of OT_2 oracle in which case P_1 has to output $\perp$.
2. otm_2 is in the image of OT_2 oracle and P_2 has made this query.
3. otm_2 is in the image of OT_2 oracle and P_2 has not made this query.

The probability that case-3 happens can be shown to be negligible for similar reasons to ones discussed above: if neither party made the relevant OT_2 query then the value otm_2 is almost surely invalid. Thus, P_1 must decide whether it is in case-1 or case-2 and if it is in case-2, it must give the corresponding m_b. To accomplish this, P_1 sends a message to P_2 with (b, otm_2) and asks P_2 to see if there is an entry of the form $(\mathsf{otm}_1, m_0, m_1, s, \mathsf{otm}_2)$ in its local list of queries to OT_2 oracle. If yes, P_2 responds with m_b; else, it responds with $\perp$. P_1 just gives P_2's message as the corresponding response to that query. This blows up the number of rounds of the protocol Π^* proportional to the number of queries made by the decoder.

Observe that Π^* does not make any queries to the OT_3 oracle. At the end, P_1 learns the output $g(x, y)$ and it can send this as the last round message to P_2. Thus, Π^* also has publicly decodable transcript. The correctness of this transformation directly follows since we prove that case-3 happens with negligible probability and if OT_2 is injective (which occurs with overwhelming probability), it follows that if an entry is found in either of the lists of the two parties or on the local list of the decoder, the response given by the emulation is correct.

To see why this transformation is secure, notice that the query $((\mathsf{otm}_1, \mathsf{otm}_2), (b, r))$ is made by the Dec by just looking at the transcript. Hence, there is no harm in P_1 sending (b, otm_2) to the other party. Similarly, if P_2 has indeed made a query to OT_2 such that the response obtained is otm_2, it should follow from the security of Π^2 that the P_2's privacy is not affected if it sends m_b to P_1. Indeed, this information is efficiently learnable given the transcript and an access to the OT_3 oracle. However, there is a subtle issue with this argument which we elaborate next.

Problem of Intersecting Queries. A subtle issue arises when we try to formally reduce the security of Π^* to the security of Π^2. To illustrate this, let us assume the case where P_2 is corrupted. To get a reduction to the security of Π^2, we must give an algorithm that takes the view of P_2 in Π^2 and efficiently generates the view of P_2 in Π^*. In particular, it must generate the additional messages in Π^* given only the view of P_2 in Π^2. This algorithm is allowed to make OT_3 queries as we are trying to give a reduction to the security of Π^2. For the sake of illustration, assume that the Dec makes a single OT_3 query. A natural approach for this algorithm is to take the transcript available in the view of P_2 and start running the decoder on the transcript. When the decoder makes an OT_3 query, the algorithm uses the real OT_3 oracle to respond to this query. However, notice that the algorithm must generate the messages that correspond to answering this OT_3 query in Π^*. Recall that in Π^*, P_1 first checks in its local list whether there an entry of the form $(\mathsf{otm}_1, m_0, m_1, s, \mathsf{otm}_2)$, and only if such an entry is not found, P_1 sends the message (b, otm_2) to P_2. Thus, to generate the

transcript of Π^*, the algorithm must somehow decide whether P_1 would find this entry in its local list or not. However, the algorithm is only given the view of P_2 and does not have any information about the queries that P_1 has made to OT_2.

We see that the problem arises when there is an OT_2 query that potentially was made by both parties. To handle this issue, we resort to the notion of *intersection queries* taken from the key-agreement impossibility result [39, 9]. These works show that it is possible, in polynomial time, to recover a superset of all oracle queries made by both parties (with all but small probability). Given this algorithm, we modify the transformation as follows. The parties will first run the two rounds of communication of Π^2. Then they will run the intersection query finder to recover the intersection query superset. We assume for the purpose of this outline this process is deterministic.[9] Now, upon each potential OT_3 query of the decoder, P_1 will look for the preimage query not only in its query history, but also in the superset of intersection queries, and send a message to P_2 only if the preimage is found in either of this. In particular this means that if the preimage is in the intersection query superset, then we are guaranteed that P_1 will not send a message.

The above modified protocol can be efficiently simulated, since the simulator can also run the intersection query finder and recover the same superset as the parties. Now, if OT_3 gives a valid answer, the simulator looks for a preimage in the intersection query superset. If it finds one, then it concludes that P_1 will not send any message to P_2. If not, then it knows that (except with small probability) exactly one of the parties made the preimage query, and it furthermore knows the internal state of one of the parties, so it knows whether this party made the preimage query. This allows the simulator to always deduce which is the party that made the preimage query and simulate appropriately.

Abstract

Building on [Clegg et al. '96], [Impagliazzo et al. '99] established that if an unsatisfiable k-CNF formula over n variables has a refutation of size S in the polynomial calculus resolution proof system, then this formula also has a refutation of degree $k + O(\sqrt{n \log S})$. The proof of this works by converting a small-size refutation into a small-degree one, but at the expense of increasing the proof size exponentially. This raises the question of whether it is possible to achieve both small size and small degree in the same refutation, or whether the exponential blow-up is inherent. Using and extending ideas from [Thapen '16], who studied the analogous question for the resolution proof system, we prove that a strong size-degree trade-off is necessary.

1 Introduction

The main task of proof complexity is to quantify the amount of different resources required to prove that some given formula is unsatisfiable. The particular resources examined depend on the proof system under study, but it is believed that no proof system can have proofs that are both efficiently verifiable and short – that is, polynomial in the size of the given formula. Establishing such an impossibility result in full generality is equivalent to proving

NP $\neq$ coNP, and hence this goal currently seems out of reach. Current research in proof complexity instead focuses on studying more limited, concrete methods of reasoning, and on proving lower bounds for these methods.

In this paper we consider **polynomial calculus resolution (PCR)**. This is a more powerful proof system than what is arguably the most well studied system in all of proof complexity, namely **resolution** [12], but is therefore also less well understood. PCR, introduced by Clegg et al. [15] and Alekhnovich and Razborov [1] can be seen as a dynamic version of Hilbert's Nullstellensatz [6]. In order to refute a CNF formula in PCR, the clauses in the formula are translated into multilinear polynomials, and the proof of unsatisfiability, or **refutation**, consists essentially of certifying that the polynomial 1 is a member of the ideal generated by these polynomials.

Two important masures for PCR refutations are the **size** (the number of monomials in the refutation when all polynomials are expanded out as linear combinations of monomials) and the **degree** (the maximal monomial degree in the refutation). Impagliazzo et al. [24] showed a strong connection between these two measures: if a k-CNF formula over n variables admits a PCR refutation of size S then there is also a refutation of degree $k + O(\sqrt{n \log S})$. This result, which is known by [21] to be tight, plays a crucial role in almost all known size lower bounds for PCR. By proving strong enough degree lower bounds one can also obtain size lower bounds, and techniques for establishing lower bounds on degree have been developed in, e.g., [2, 21, 20, 26]. An interesting aspect of [24], however, is that the small-size refutation is not the same as the small-degree one. Instead, the transformation from small size to small degree increases the proof size exponentially. It is natural to ask whether this exponential blow-up is nescessary.

A similar question arises also in the context of the resolution proof system, where the measures of interest are length and width. Building on [24], Ben-Sasson and Wigderson [10] showed that every small-length resolution refutation can be transformed into a small-width refutation with the same parameters as in [24]. Again, this bound is again known to be tight [13], and the conversion increases the length exponentially. For resolution, Thapen [29] proved that such a blow-up cannot be avoided in the worst case. In this work, we show that this holds true for PCR as well.[1] More precisely we prove the following theorem.

▶ **Theorem 1.** *For any $\epsilon > 0$ and c large enough, there is a CNF formula φ with $\theta(c^{1+\epsilon})$ variables, of size $\theta(c^{1+\epsilon})$ and degree $O(\log c)$ such that*

- *φ has a PCR refutation of size polynomial in c and degree $c + O(\log c)$,*
- *φ has a PCR refutation of degree $O(c^{\epsilon})$,*
- *any PCR refutation of degree strictly less than $c - 1$ has size $\exp\big(c^{\Omega(\epsilon)}\big)$.*

In particular, this implies that any PCR refutation of the formula φ in degree $O(\log c) + O(\sqrt{c^{1+o(1)} \log c}) \ll c$, as obtained by the size-degree bound in [24], must have size $\exp\big(c^{\Omega(\epsilon)}\big)$.

1.1 Related work

The study of connections between different complexity measures has received a fair amount of attention in proof complexity. We give a brief overview below, referring the reader to the book [25] or the upcoming survey chapter [14] for more details.

[1] Note that this is more precise than just saying that there is a trade-off between length and width, or between size and degree, so that minimizing the latter measure must lead to an increase in the former. It is easy to show that there are trade-offs between length/size and width/degree as observed in [27], but such trade-offs are very far from being strong enough to show that the blow-ups in [10, 24] is necessary.

We have already mentioned connections between size and degree in PCR [24] and between length and width in resolution [10]. Let us also mention that in [3] a beautiful relation is exhibited between width and **space** in resolution, showing that width provides a lower bound on space, and that a similar, but weaker, result was recently proved in [19] for PCR.

When studying trade-offs, we are asking whether two different complexity measures can be minimized at the same time, or whether optimizing one measure must lead to an increase in the other in the worst case. This question was first raised in the context of proof complexity by Ben-Sasson [8], who proved trade-offs between space and width in resolution. This result was later extended to size-degree trade-offs in PCR [7], and the result for resolution was extended to a wider regime of parameters in [11].

Trade-offs between length/size and space have been shown for resolution in [5, 9] and for PCR in [7]. There are even some size-space trade-offs for stronger proof systems such as **cutting planes** [16] in [18, 22, 23], but since this proof system will not be relevant for the current paper we will not discuss it further.

For length versus width in resolution, or size versus degree in PCR, it is not too hard to show that there are trade-offs [27], but to prove that the length blow-up in [10] is necessary requires the stronger result in [29]. Recently, Razborov [28] established another length-width trade-off showing that low-width *tree-like* resolution refutations of certain k-CNF formulas must have doubly exponential size,

For Nullstellensatz, which as noted above can be viewed as a weaker version of PCR, strong trade-offs between size and degree were shown in [17]. That paper states as an open problem whether similarly strong results could be established for PCR, and this is the problem that we resolve here.

1.2 Organization of the paper

We start with preliminaries in Section 2 where we define the relevant proof systems and discuss some basic properties of ideals in polynomial rings. In Section 3, we present the family of CNF formulas that we will consider, which we call *safe colored polynomial local search* formulas. Section 4 is devoted to a description of the overall proof strategy. Section 5 develops the machinery used to prove PCR degree lower bounds together with the adaptations needed to obtain our results. Section 6, finally, contains some concluding remarks. We refer to the upcoming full-length version of the paper for the details missing in this extended abstract.

2 Preliminaries

Throughout this paper, we let $\mathbb{F}$ denote a fixed but arbitrary field. For a an integer, we denote by $[a]$ the set $\{0, 1, \ldots, a-1\}$. Given a graph H and a vertex $v \in H$, we write $N(v)$ for the set of neighbours of v in the graph H.

2.1 Resolution and Polynomial calculus

We use x to denote boolean variables ranging over $\{0, 1\}$, and write $\bar{x}$ to denote the negation of x. A **literal** is either a variable x or its negation $\bar{x}$. A **clause** C is a disjunction of literals, such as $x \vee \bar{y}$. The **width** of a clause is the number of literals in it. A **CNF formula** F is a conjunction of clauses, and F is a **k-CNF formulas** if all clauses in it have width at most k. Clauses and formulas are considered as sets, so that there are no repetitions and the ordering is immaterial.

The **resolution** proof system has a single derivation rule $\frac{C \vee x \quad D \vee \bar{x}}{C \vee D}$, called the **resolution rule**, for any clauses C, D and any variable x. In this proof system, a **derivation** of a clause D from a CNF formula $F = C_1 \wedge \cdots \wedge C_m$ is a sequence of clauses such that each clause is either an original clause C_i or the conclusion of the resolution rule applied to previously derived clauses. A **resolution refutation** of F is a derivation of the empty clause containing no literals from F. The **length** of a derivation, or refutation, is the length of the sequence of clauses, and the width is the maximum width of any clause appearing in the sequence.

Moving on to polynomial calculus, we let X denote a set of algebraic variables containing x and $\bar{x}$ for all boolean variables, where x and $\bar{x}$ are considered to be distinct, and consider polynomials in the ring $\mathbb{F}[X]$. We note that in the context of algebraic proof systems it is natural to think of 0 as **True** and 1 as **False**, and so we will use this convention in what follows.

The **PCR** proof system contains the following axioms:

- **boolean axioms:** $x^2 - x$ for all variables x;
- **complementary axioms:** $x + \bar{x} - 1$ for all variables x.

It also contains the following derivation rules:

- **linear combination:** $\frac{p \quad q}{\alpha p + \beta q}$ for any $\alpha, \beta \in \mathbb{F}, p, q \in \mathbb{F}[X]$;
- **multiplication:** $\frac{p}{xp}$ for any $p \in \mathbb{F}[X]$ and $x \in X$.

A polynomial f is **derivable** from a set of polynomials $g_1, \ldots, g_k$ (written $g_1, \ldots, g_k \vdash f$) if there is a sequence of polynomials such that each polynomial is either an axiom, an original polynomial g_i, or the conclusion of a derivation rule applied to previously derived polynomials. We refer to such a sequence of polynomials as a **PCR derivation**. A **PCR refutation** of a set of polynomials $g_1, \ldots, g_k$ is a derivation of the polynomial 1 from $g_1, \ldots, g_k$.

▶ **Example 2.** Over the variables x, y, z, if we are given xz and $y\bar{z}$ we can derive xy. This is a simulation, in PCR, of the resolution rule deriving $x \vee y$ from $x \vee z$ and $y \vee \bar{z}$.

$$\dfrac{\dfrac{\dfrac{y\bar{z}}{xy\bar{z}} \quad \dfrac{z + \bar{z} - 1}{xyz + xy\bar{z} - xy}}{xy - xyz} \quad \dfrac{xz}{xyz}}{xy}$$

A set I of polynomials in $\mathbb{F}[X]$ is an **ideal** if I is closed under linear combination and multiplication by any polynomial in $\mathbb{F}[X]$. Given a set of polynomials $S = \{g_1, \ldots, g_k\}$, the **ideal generated by** S is defined as the smallest ideal I_S that contains the set S.

Observe that, by definition, $g_1, \ldots, g_k \vdash f$ is equivalent to saying that f is in the ideal generated by $g_1, \ldots, g_k$ together with all boolean and complementary axioms. Intuitively, a PCR refutation is a certificate that the system of polynomial equations $\{g_1 = 0, \ldots, g_k = 0\}$ has no boolean solutions. If the polynomials have no common boolean solution then there always exists such a certificate, since it can be shown that 1 lies in the ideal generated by the polynomials arising in the system together with the polynomials from the boolean and complementary axioms. In other words, the PCR proof system is *sound* and *complete*.

The **size** of a PCR refutation is the total number of non-zero monomials (counted with repetition) that appear in the derivation when all polynomials are expanded out as linear combinations of monomials. The **degree** of a PCR refutation is the maximal degree of a non-zero monomial that appears in the derivation.

There is a standard **translation** $tr(\cdot)$ from clauses to monomials defined by induction in the following way:

- $tr(x) = x$;
- $tr(\neg x) = \bar{x}$;
- $tr(C \vee D) = tr(C) \cdot tr(D)$.

Using $tr(\cdot)$, any k-CNF formula F with s clauses can be converted into a set of s polynomials of degree at most k by applying the translation to all clauses in F. Denote this set by $tr(F)$. It is not hard to see that F is satisfiable if and only if the set of polynomials $tr(F)$ have a common boolean root. Therefore F is an unsatisfiable CNF formula if and only if there is a PCR refutation of the set of polynomials $tr(F)$. Furthermore, a straightforward generalization of Example 2 shows that a resolution refutation in length ℓ and width w can be converted into a PCR refutation in size $O(\ell w)$ and degree $w+1$.

A **restriction** is a partial assignment of the variables, that is a function $\rho : X \to X \cup \mathbb{F}$ such that the value $\rho(x)$ is either x or a constant from $\mathbb{F}$. For a polynomial p, we denote by $p \restriction \rho$ the polynomial p in which any variable x is replaced by $\rho(x)$.

2.2 Reduction over ideals

Two polynomials p, q are said to be **equivalent modulo an ideal** I, written $p \sim_I q$, if $p - q \in I$. This is an equivalence relation. For any polynomial p we fix a special representative of the equivalence class $[p]$ that we call the **reduction of** p **modulo** I and write as $R_I(p)$. If an ideal I is generated by a set of polynomials S, we abuse notation slightly and write $R_S(p)$ for $R_I(p)$.

To define the representative, we fix any order $\prec$ on the polynomials that respects inclusion as follows:

1. Firstly, for two monomials m_1 and m_2 we have $m_1 \prec m_2$ whenever m_1 is a submonomial of m_2.
2. Secondly, we extend this in an arbitrary way to a total order on monomials.
3. Finally, we order polynomials in the following way. To any polynomial p we associate a sequence s_p consisting of the non-zero monomials of p, sorted in decreasing order with respect to $\prec$. The polynomials are then compared by comparing lexicographically their associated sequences. For example, if $m_1 \prec m_2 \prec m_3$, then the polynomial m_2 is strictly smaller than the polynomial $m_2 + m_1$, which is itself strictly smaller than the polynomial m_3.

The representative $R_I(p)$ is then defined as $\min(\{q \in [p]\})$. We now observe two easy but useful properties of $\prec$.

▶ **Fact 3.** *For any restriction ρ, we have that $p \restriction \rho \preceq p$.*

Proof. To see this, observe that any monomial in $p \restriction \rho$ is either a monomial or a submononial from p; this can only decrease p. ◀

▶ **Fact 4.** *If I_1, I_2 are two ideals such that $I_1 \subseteq I_2$, then*

$$R_{I_2}(p \times R_{I_1}(q)) = R_{I_2}(p \times q).$$

Proof. By definition, $q = R_{I_1}(q) + h$ for some $h \in I_1$. Therefore

$$\begin{aligned} R_{I_2}(p \times q) &= R_{I_2}(p \times (R_{I_1}(q) + h)) \\ &= R_{I_2}(p \times (R_{I_1}(q)) + R_{I_2}(p \times h) \end{aligned}$$

by linearity. To conclude, observe that $p \times h \in I_1$ so is reduced to zero modulo I_1, and hence is reduced to zero modulo I_2 since $I_1 \subseteq I_2$. ◀

3 The formula

In this section, we describe the construction of the family of formulas for which we establish our size-degree trade-off result. We also argue why they have small-size refutations. Our formulas encode a modified version of the **colored polynomial local search (CPLS)** principle, and are very similar to the ones used in [29] to prove trade-offs between length and width in resolution, but there are two main differences. First, we add an *extra color* that we call the *safe color* that plays a role slightly different from the normal ones. The reason for adding this color is purely technical – we were not able to make the PCR machinery works without it. Second, instead of using a grid graph where any two consecutive layers form a complete bipartite graph, we restrict the edges between two consecutive layers to be a well-chosen expander graph. Since this makes the formula more constrained than that in [29], it makes our lower bound slightly stronger.

3.1 The modified CPLS formula

Let a, b, c be positive integers. We work only with graphs $H = (V, E)$ of the following form:

- The set V of vertices are given by $\{(i, x), i \in [a], x \in [b]\}$. We say a vertex (i, x) is the vertex x on layer i.
- Edge appear only between consecutive layers. I.e., if $((i, x), (i', x'))$ is an edge then $i' = i + 1$.

To any such graph H we associate a formula $CPLS^H(a, b, c)$ (or simply $CPLS(a, b, c)$ if H is clear from the context). Intuitively, the formula will give a set of colors (which is a subset of $[c]$) to each node in H according to the following rules.

1. Node $(0, 0)$ gets no color.
2. From every node u there is some special neighbor v on the next layer. If v gets a color then u gets a color. Specifically, there is a **safe color** (corresponding to the first color from $[c]$) and either u gets the safe color or it gets all of v's colors.
3. Every node on the bottom layer gets some color.

Of course, this means there is a path of special neighbors from $(0, 0)$ to the bottom layer. The last node must get some color, so we can trace backward and see $(0, 0)$ gets some color, a contradiction. Hence $CPLS(a, b, c)$ is unsatisfiable. Now we state this formally. We use $\Theta(abc)$ variables:

- $G(u, y)$ for each $u \in V$ and $y \in [c]$. This says whether y is set at u.
- $f(u, v)$ for each $u \in V$ and $v \in N(u)$. This says whether v is a special neighbor of u.
- $h(u)_j$ for each $u = (a - 1, x)$ and $j \in [\log c]$. The function $h(u)$ identifies a color that must be present at u, but is encoded in binary.

Now we can restate the intuitive rules above as formal axioms:

1. for each color $y \in [c]$,
   $\neg G((0, 0), y)$;
2. for each node $u \in V$
   (a) for each neighbor $v \in N(u)$, and color $y \in [c]$,
   $(f(u, v) \wedge G(v, y)) \to G(u, y) \vee G(u, 0)$;
   (b) if u is not on the bottom layer,
   $\bigvee_{v \in N(u)} f(u, v)$;
3. for each node $u \in V$ on the last layer and color $y \in [c]$,
   $(h(u) = y) \to G(u, y)$.

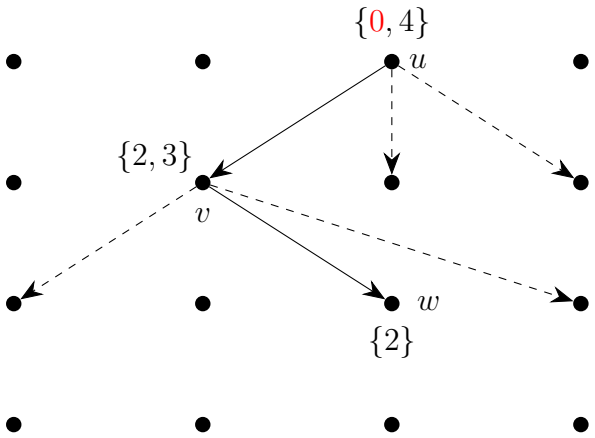

Figure 1 Nodes u and v have three possible neighbors represented by the arrows. The two arrows that are not dotted represent the actual values of f; for these arrows, axioms 2a are respected. Indeed the axioms $P_{v,w,\cdot}$ are satisfied because the colors at v is a superset of the colors at w; the axioms $P_{u,v,\cdot}$ are satisfied because u contains the safe color 0.

See Figure 1 for an illustration of the formula. We refer to instances of axioms 2a, 2b, and 3 as $P_{u,v,y}, Q_u$, and $T_{u,y}$ respectively.

▶ **Definition 5.** *An (s,e)-**expander** is a bipartite graph (V_L, V_R, E) such that for any subset of "left" vertices $S \subseteq V_L$ such that $|S| \leq s$, the following holds: $|N(S)| \geq e|S|$. We recall that $N(S)$ is the neighborhood of S.*

We will use $a = b = c^\epsilon$ in this paper. Let H_i be H restricted to the i^{th} layer. That is $H_i \coloneqq H \cap \{(i,x),(i+1,y) \mid x,y \in [b]\}$. We need H_i to be an $(a^{7/8}, e)$-expander, where any constant $e > 1$ suffices. We also need H_i to have vertex degrees bounded above and below by some constants. For simplicity we assume it has constant degree d.

▶ Remark 6. Note that it is also possible to ask each H_i to be a full bipartite graph. Because the vertex degree then grows with a, we need to change the formula by encoding the neighbors of any vertex in "binary", as in Thapen's paper [29], in order to avoid the width becoming too large (due to type 2b axioms).

3.2 Short and narrow refutations

We give a refutation of $CPLS^H(a,b,c)$ which is of small size. While this refutation can be translated into a refutation of small degree, by a result from [24], we additionally give a much lower degree refutation. The rest of the paper will consist of proving that small size and small degree cannot be obtained simultaneously. The proof of the next two propositions can be found in the appendix of the full version and are very similar to the one from Thapen [29].

▶ **Proposition 7.** *For any graph H, $CPLS^H(a,b,c)$ has a resolution refutation Π of length $O(ab^2c)$ and width $c + \log b + 1$.*

As discussed in Section 2, this gives a PCR refutation of size $O(a^2b^4c^2)$ and degree $c+\log b+2$.

▶ **Proposition 8.** *For any graph H, $CPLS^H(a,b,c)$ has a resolution refutation Π of width $a(\mathrm{d}+1) + \log c$.*

4 Restricting the formula and refutation

The strategy we are going to use is as follows: we suppose for contradiction that we have a refutation Π of the formula $CPLS$ which is both of small size and small degree. Then we will apply a random restriction ρ to both $CPLS$ and Π, which is a partial assignment to the variables. At this point, we have in hand a refutation $\Pi \restriction \rho$ of the restricted formula $CPLS \restriction \rho$. By the assumption that Π is both of small size and small degree, we show that $\Pi \restriction \rho$ enjoys some nice properties; we call such a refutation a **beautiful** refutation. We conclude by showing that $CPLS \restriction \rho$ cannot have any beautiful refutation, yielding the desired contradiction.

We start with the definition of ρ.

4.1 The restriction

Let $p = a^{-3/4}$ and $w = a^{7/8}$. The restriction ρ is randomly set in the following way.

- With probability p, for any vertex u, we set independently for all $y \in [1, c-1]$ the value of $G(u, y)$ to True or False with probability $1/2$; if this happens for a vertex u, we say that **the colors at u are set**. Moreover, if such a vertex is at the bottom layer, then we select one color y that has been set to True during the process and we set $h(u) = y$.
- If we set the colors at u then we also give the safe color to this vertex, i.e., we set $G(u, 0) =$ True. Otherwise we set $G(u, 0) =$ False.
- If we set the colors at u then with probability $\frac{1}{2}$ we also set $f(u, v) =$ True for a uniformly random chosen vertex $v \in N(u)$ and we set all others values $f(u, \cdot)$ to zero.

For the rest of the paper, we write this restriction ρ.

▶ Remark 9. Note that for any u where the colors are set, u gets the safe color. Hence we satisfy all type 2a axioms mentioning $f(u, \cdot)$ and we can treat the vertex u as if it is removed from the graph. For any node v with an edge (v, u) in the graph this reduces the (out-)degree of v by 1. We must maintain a positive degree for vertices outside the last layer. If vertices have degree at least 3 then the chance of reducing any vertex degree to 0 is $o(1)$. Hence our random choice of ρ works with high probability in this case. It is still a $CPLS$ formula (over a smaller graph) and we can now reason over this new graph.

4.2 Beautiful properties after restriction

In this section, we prove that applying the above restriction ρ to a small sized refutation Π gives a refutation $\Pi \restriction \rho$ of $CPLS \restriction \rho$ enjoying useful properties.

▶ **Definition 10.** *A term t **touches** vertex $u \in H$ iff t contains at least one of the following:*

- *$G(u, y)$ for some $y \in [c] \setminus \{0\}$;*
- *$f(u, v)$ for some $v \in N(u)$;*
- *$h(u)_j$ for some $j \in [\log c]$.*

*The **vertex-degree** of a term t is the number of vertices it touches.*

See Figure 2 for an example.

▶ **Definition 11.** *We say that a term t is **almost beautiful** if:*

- *the vertex-degree of t is at most $w + 1$;*
- *it does not contain any $G(\cdot, 0)$ variable;*
- *it touches at most $c - 2$ different colors.*

*If the vertex-degree of t is at most w then we say it is **beautiful**. By extension, a derivation Π is beautiful if every term that appears in Π is beautiful.*

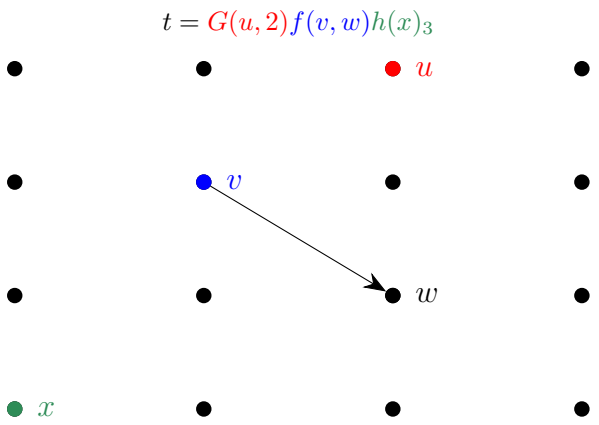

Figure 2 The term t touches three vertices that are the ones colored in the figure.

▶ **Proposition 12.** *There is an ϵ so that if $|\Pi| = s \leq 2^{c^\epsilon}$ then with probability $1 - s \cdot 2^{-c^\epsilon}$ over the choice of ρ, every term in $\Pi \restriction \rho$ is beautiful.*

Proof. Consider a term t and suppose it touches at least w distinct vertices u. We show that except with exponentially small probability ρ sets t to 0.

Suppose we set the colors at u, which happens with probability p. If t contains $G(u,y)$ for $0 < y$ then with probability $\frac{1}{2}$ we set $G(u,y) = 0$. If t contains $h(u)_j$ then because $h(u)$ is uniformly random we set $h(u)_j = 0$ with probability $\frac{1}{2}$.

We also set the arrow at u with probability $p/2$. There are d neighbors of u so we set $f(u,v)$ to True with probability $\frac{1}{d}$ and False with probability $\frac{d-1}{d}$ Hence if t contains $f(u,v)$ then we set t to 0 with probability at least $\frac{p}{2d}$.

Hence, for each u, if t touches u then with probability at least $\frac{p}{2d}$ we set t to 0. For distinct u these events are independent so the probability of not setting t to 0 is at most:

$$(1 - \frac{p}{2d})^w < e^{-\frac{1}{2d}a^{1/8}}.$$

To conclude the proof, observe that $t \restriction \rho$ does not contain any $G(\cdot, 0)$ variable since the restriction sets the value $G(u,0)$ to True of False for any vertex u. ◀

5 PCR machinery

In this section, we ask the order on monomials to have the additional property that it respects the vertex-degree: if a monomial m_1 has a vertex-degree smaller than a monomial m_2, then $m_1 \prec m_2$.

5.1 R operator

We follow a strategy similar in spirit to the technique developed by Alekhnovich and Razborov [2]. The idea is to define a linear map $R : \mathbb{F}[X] \to \mathbb{F}[X]$ that acts as a witness that the polynomial 1 is not reachable from the axioms by any beautiful derivation. Such a linear map was constructed by Alekhnovich and Razborov to separate the polynomial 1 from polynomials reachable by small degree derivations. It has been applied to Tseitin tautologies, among other formulas. Note that Mikša and Nordström [26] gave some sufficient (and quite general) conditions to prove existence of such operators. Unfortunately, we can not use directly these results since they deal with degree and we therefore need to adapt them to handle our notion of beautifulness. More precisely, we aim to prove the following theorem.

▶ **Theorem 13.** *There is a linear map $R : \mathbb{F}[X] \to \mathbb{F}[X]$ such that:*

1. $R(A) = 0$ *for any axiom A;*
2. $R(1) \neq 0$*;*
3. $R(xt) = R(xR(t))$ *whenever xt is a beautiful monomial.*

Theorem 13 is sufficient to prove our main theorem, since any polynomial derived by a beautiful derivation is mapped to zero under the R operator, leaving the polynomial 1 unreachable.

The operator R that we will use is defined on monomials and then extended linearly to general polynomials. To do that, we associate to any monomial t a set of vertices, written $\mathrm{Supp}(t)$, and the value $R(t)$ is defined to be the reduction of t under the ideal generated by axioms associated to $\mathrm{Supp}(t)$. Again, we abuse notation slightly and write this reduced polynomial as $R_{\mathrm{Supp}(t)}(t)$.

More formally, to a given set A of vertices, we identify the following set of axioms:

$$\begin{aligned}
&\{Q_u \mid u \in A\}\\
&\cup \{P_{u,v,y} \mid u \in A, v \in N(u), y \in [c]\}\\
&\cup \{T_{u,y} \mid u \in A, y \in [c]\}\\
&\cup \{\neg G((0,0), y) \mid y \in [c]\}\\
&\cup \text{all boolean axioms}\\
&\cup \text{all complementary axioms.}
\end{aligned}$$

This set contains some axioms that are related to set A as well as the axioms saying that $(0, 0)$ is not colored. $R_A(t)$ is then interpreted as the reduction of t under the ideal generated by the axioms above.

5.2 Closure/support

We first associate to any term t a set of vertices called its *support* and written $\mathrm{Supp}(t)$. The motivation here is that only axioms associated with certain vertices could have been meaningfully used to derive t. Any axiom that mentions a variable of t certainly could be used, but axioms associated with a node u that is in turn associated with a variable in t may be used, and even axioms at some nearby nodes in H may be used.

The support is defined using the following closure operation:

▶ **Definition 14.** *Given a bipartite graph with partition (V_L, V_R), and $S \subseteq V_R$ a subset of "right" vertices. We say that $\mathrm{Cl}(S) \coloneqq \{v \in V_L \mid N(v) \subseteq S\}$ is the* ***closure*** *of S.*

The following property of the closure will be useful.

▶ **Lemma 15.** *Let $G = (V_L, V_R)$ be an (s, e)-expander. If $S, S' \subseteq V_R$ such that $|S|, |S'| < e\frac{s}{2}$ then:*

- $|\mathrm{Cl}(S)| \leq \frac{|S|}{e}$*;*
- $\mathrm{Cl}(S) \cup \mathrm{Cl}(S') \subseteq \mathrm{Cl}(S \cup S')$*;*
- $\forall V \subseteq (V_L \setminus \mathrm{Cl}(S))$ *such that* $|V| \leq \frac{s}{2}$ *we have* $N(V) \not\subseteq S$*.*

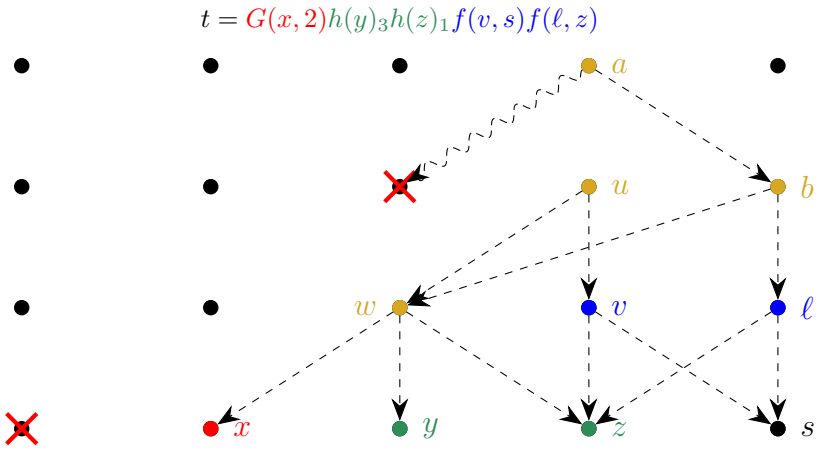

Figure 3 Example of the support of a term t. Color notation:

- nodes for which t contains f variables: $\{v, \ell\}$;
- nodes for which t contains G variables: $\{x\}$;
- nodes for which t contains h variables: $\{y, z\}$;
- nodes that are not touched by t but included in $\mathrm{Supp}(t)$: $\{a, b, u, w\}$;
- nodes that are banished from the graph after application of the restriction from Section 4.

The proof is straightforward and appears in the full version. We can now define the **support** (and **extended support**) associated with a term t. We do this by a downward induction on i over the layers of the graph H as follows:

$$\begin{aligned} b_i &:= \{(i,x) \mid \exists v. f((i,x),v) \text{ or } h((i,x)) \text{ appears in } t\} \\ c_i &:= \{(i,x) \mid \exists y. G((i,x),y) \text{ appears in } t\} \\ d_{i-1} &:= b_{i-1} \cup \mathrm{Cl}(d_i \cup c_i) \\ \mathrm{Supp} &:= \bigcup_{i \in [a]} d_i \\ \mathrm{ExSupp} &:= \bigcup_{i \in [a]} (d_i \cup c_i) \end{aligned}$$

▶ Remark 16. For any terms t, t' it holds that

$$\mathrm{Supp}(t) \cup \mathrm{Supp}(t') \subseteq \mathrm{Supp}(t \cup t').$$

Proof. Follows from Lemma 15, third item. ◀

▶ **Lemma 17.** *If t touches at most ℓ vertices where $\ell \leq 2w$, then $|\mathrm{Supp}(t)| \leq |\mathrm{ExSupp}(t)| = O(\ell)$.*

The proof uses a simple induction and telescoping sum and appears in the full version.

5.3 Proof of Theorem 13

The following propositions are sufficient to prove that the R operator fulfills the desired properties.

▶ **Proposition 18.** *For any variable x, any monomial t such that xt is beautiful, and any $t' \in R(t)$, we have $R_{\mathrm{Supp}(xt')}(xt') = R_{\mathrm{Supp}(xt)}(xt')$.*

▶ **Proposition 19.** *For any almost beautiful monomial t and any $A \subseteq H$ with $|A| \leq O(w)$ we have:*

$$R_{\mathrm{Supp}(t)\cup A}(t) = R_{\mathrm{Supp}(t)}(t).$$

With these propositions in hand, let us now prove Theorem 13

Proof of Theorem 13. We start with the first item, that $R(A) = 0$ for any axiom A. Consider some axiom A and note that it touches a set of vertices $H_A \subseteq H$ of constant size. Let $\sum t_i$ be a polynomial representation of A. By Remark 16, $\bigcup \mathrm{Supp}(t_i) \subseteq \mathrm{Supp}(\bigcup t_i)$ and by Proposition 19, $R(\sum t_i) = \sum R_{\mathrm{Supp}(t_i)}(t_i) = \sum R_{\mathrm{Supp}(\bigcup t_i)\cup H_A}(t_i) = 0$.

For the second item, that $R(1) \neq 0$, observe that since $\mathrm{Supp}(1) = \emptyset$ the set of axioms associated to it is simply:

$$\{\neg G((0,0), y) \mid y \in [c]\}$$
$$\cup \text{ all boolean axioms}$$
$$\cup \text{ all complementary axioms.}$$

This is a satisfiable set of polynomial equations and thus the polynomial 1 is irreducible over the ideal generated by $\mathrm{Supp}(1)$.

Let us now prove the third item, that $R(xt) = R(xR(t))$ whenever xt is beautiful. Consider a beautiful term xt.

$$\begin{aligned}
R(xR(t)) &= \sum_{t' \in R(t)} R(xt') && \text{by linearity} \\
&= \sum_{t' \in R(t)} R_{\mathrm{Supp}(xt')}(xt') && \text{by definition of } R(\cdot) \\
&= \sum_{t' \in R(t)} R_{\mathrm{Supp}(xt)}(xt') && \text{using Proposition 18} \\
&= R_{\mathrm{Supp}(xt)}(xR(t)) && \text{by linearity} \\
&= R_{\mathrm{Supp}(xt)}(xR_{\mathrm{Supp}(t)}(t)) && \text{by definition of } R(\cdot)
\end{aligned}$$

Observe that since $\mathrm{Supp}(t) \subseteq \mathrm{Supp}(xt)$, we can remove the righthand R operator using Fact 4. We then get

$$\begin{aligned}
&= R_{\mathrm{Supp}(xt)}(xt) \\
&= R(xt)
\end{aligned}$$

by definition of $R(\cdot)$. ◀

5.4 Proof of Proposition 19

Proof of Proposition 19. We assume for sake of contradiction that the proposition is false and let A be a minimal witness of this. Without loss of generality $A \cap \mathrm{Supp}(t) = \emptyset$ and A is nonempty. We find A' with $|A'| < |A|$ where the lemma also fails.

Let $r \coloneqq R_{\mathrm{Supp}(t)\cup A}(t)$. We have an equation $t = r + \sum q_i p_i$ where p_i is one of the axiom that correspond to $\mathrm{Supp}(t) \cup A$. By assumption, we also have that $r \prec R_{\mathrm{Supp}(t)}(t)$. We want to construct an assignment α that:

- sets p_i to 0 for at least one $p_i \in A$;
- leaves t unchanged;
- for any p_i either satisfies it or leaves it unchanged.

If such an assignment exists then $t \restriction \alpha = r \restriction \alpha + \sum (q_i \restriction \alpha)(p_i \restriction \alpha)$ and thus $t = r \restriction \alpha + \sum q'_i (p_i \restriction \alpha)$ with $r \restriction \alpha \preceq r$. Since α sets at least one p_i, this shows we can reduce t using only $\mathrm{Supp}(t) \cup (A \setminus \{p_i\})$, as desired.

First observe that if there is a vertex $u \in A$ with neighbor $v \in N(u) \setminus (A \cup \mathrm{ExSupp}(t))$ then we can:

- set the arrow out of u to point to v ($\alpha(f(u,v)) = \mathrm{True}$);
- set all other arrows out of u to False ($\forall v' \in N(u) \setminus v . \alpha(f(u,v')) = \mathrm{False}$);
- set all colors to False at v ($\forall y \in [c] . \alpha(G(v,y)) = \mathrm{False}$).

This satisfies all $P_{u,\cdot,\cdot}$ and Q_u axioms at u and leaves axioms at other vertices in $A \cup \mathrm{Supp}(t)$ untouched. Also $v \notin \mathrm{ExSupp}(t)$ and hence t is also untouched.

The only way we can fail to find such a u and v is if $N(A) \subseteq A \cup \mathrm{ExSupp}(t)$. Note that this implies A contains a vertex in the last layer. Indeed, consider the largest $i \in [a]$ that contains some vertices from A. If $i < a - 1$ then for any vertex $u \in A$ on this layer there is at least one neighbor $v \notin \mathrm{ExSupp}(t)$ because otherwise by definition of closure u should be included in the $\mathrm{Supp}(t)$. Since we picked the largest possible i we also know $v \notin A$.

If A contains a vertex on the last layer then we consider some layer i such that axioms from $\mathrm{ExSupp}(t) \cup A$ do not touch any vertex on layers $i, i+1$ and let

$$B \coloneqq \{(i', j) \mid i' > i, j \in [b]\}.$$

B is the set of all vertices between this layer and the bottom layer. Since $|A| + |\mathrm{Supp}(t)| = O(w)$ we know such a row exists. We pick some color y not mentioned by t, set $G(u,y) = \mathrm{True}$ for all $u \in B$, and set $h((a-1,x)) = y$ for any $(a-1,x) \in B \setminus \mathrm{Supp}(t)$.

Furthermore, for any $u \in B \cap A$ that is not on the last layer we know by the second item of Lemma 15 that u has a neighbor $z \notin \mathrm{ExSupp}(t)$. We set f so it points u to z and set $G(z,y') = \mathrm{False}$ for all other colors. Here we use the fact that $z \notin \mathrm{ExSupp}(t)$ and if we set colors for z the term t remains unchanged. That is, $f(u,v) = \mathrm{False}$ for all $v \in N(u) \setminus \{z\}$ and $f(u,z) = \mathrm{True}$. If there were no such z then u would be included in $\mathrm{Supp}(t)$ and hence would not be in A.

By setting colors in this way we satisfy all axioms for all $u \in B \cap A$. At $u \in B \cap \mathrm{Supp}(t)$ we only set a single color to True and satisfy the corresponding axiom. We can always pick a color y because $|t| < c$ and we touch no variable in t. Finally, we satisfy the Q_u and $T_{u,y}$ axioms anywhere they are touched by setting h and f. ◀

The proof of Proposition 18 uses similar ideas to that of Proposition 19 and appears in the full version.

6 Concluding remarks

In this paper, we have shown that although it is known from [24] that size provides an upper bound on degree in polynomial calculus resolution (PCR) – in the sense that if a set of degree-k polynomials have a PCR refutation in size S, then there is also a refutation in degree $k + O(\sqrt{n \log S})$ – it is not possible in general to construct PCR refutations that get even remotely close to these two upper bounds simultaneously. This extends the analogous trade-off result in [29] for the weaker resolution proof system.

We would like to remark that while our trade-off result is currently stated for formulas of logarithmic width – in order to avoid extra technical complications – it is also possible to obtain the result for constant-width formulas. This involves converting the wide clauses in our formulas to 3-CNF using the standard approach with extension variables. Since the upper bounds for our formulas also work in resolution, this strengthens [29]. We refer to the upcoming full-length version of the paper for the details.

As mentioned in the introduction, in addition to generalizing [29] from resolution to PCR, our main theorem is also a counterpart of the size-degree trade-offs for the weaker algebraic system Nullstellensatz established in [17]. In contrast to our result, however, the Nullstellensatz trade-offs only hold for the version of the proof system without formal variables for negated literals. It would be desirable to obtain more robust trade-off theorems that also applies to Nullstellensatz with separate formal variables for positive and negative literals.

Another, even more interesting, question would be to investigate stronger proof systems. Very recently, Atserias and Hakoniemi [4] showed that if a system of degree-k polynomial constraints over n boolean variables has a **Sums-of-Squares (SOS)** refutation of size S, then it also has a refutation of degree at most $O(k + \sqrt{n \log S})$. They also proved a similar statement for the stronger **Positivstellensatz** proof system, and an analogous result for the weaker system **Sherali-Adams** also follows from the proofs in the paper. However, for these proof systems the question of whether the conversion from small size to small degree can be achieved without blowing up the size remains open, and it is not even known if the upper bound on degree in terms of size in [4] is tight.

Abstract

We study the smoothed complexity of finding pure Nash equilibria in Network Coordination Games, a PLS-complete problem in the worst case, even when each player has two strategies. This is a potential game where the *sequential-better-response* algorithm is known to converge to a pure NE, albeit in exponential time. First, we prove polynomial (respectively, quasi-polynomial) smoothed complexity when the underlying game graph is complete (resp. arbitrary), and every player has constantly many strategies. The complete graph assumption is reminiscent of perturbing *all parameters*, a common assumption in most known polynomial smoothed complexity results. We develop techniques to bound the probability that an (adversarial) better-response sequence makes slow improvements to the potential. Our approach combines and generalizes the local-max-cut approaches of Etscheid and Röglin (SODA '14; ACM TALG, '17) and Angel, Bubeck, Peres, and Wei (STOC '17), to handle the multi-strategy case. We believe that the approach and notions developed herein could be of interest in addressing the smoothed complexity of other potential games.

Further, we define a notion of a *smoothness-preserving reduction* among search problems, and obtain reductions from 2-strategy network coordination games to local-max-cut, and from k-strategy games (k arbitrary) to local-max-bisection. The former, with the recent result of Bibak, Chandrasekaran, and Carlson (SODA '18) gives an alternate $O(n^8)$-time smoothed algorithm when $k = 2$. These reductions extend smoothed efficient algorithms from one problem to another.

1 Introduction

Coordination games are a widely studied class of games, where players receive equal payoffs, and so are incentivized to coordinate. Network coordination games are a succinctly represented, natural multi-player extension of coordination games. The players simultaneously play multiple two-player coordination games, and receive the sum of their payoffs from these individual games. As a caveat, the players must choose the same strategy to play in all games.

These games naturally arise in various settings like social and biological networks [3, 32, 29], and have been extensively studied in various areas like Game theory and economics, Learning, Networks etc [25, 11, 20, 14, 2].

The natural dynamics in such a game imply that agents will change their strategy choices if this increases their payoff. Because these are coordination games, this also increases the total sum of payoffs. This sum is then a proxy for the progression towards an equilibrium, where no player can improve, hence is a *potential function* for the game, and the game becomes a *potential game*. When no player can benefit by deviating, or equivalently the potential function reaches a *local maximum*, this is a *pure Nash equilibrium*, and the standard search problem for most potential games is to find such an equilibrium.

Finding a pure Nash equilibrium in a network coordination game is complete for the class PLS (Polynomial Local Search) [12]. Although it is widely conjectured that PLS is unlikely to lie in P [6, 9, 38], problems in this class admit local-search algorithms [27], which have been observed to be empirically fast [27, 15, 18], but requiring exponential time in the worst case [40, 39]. To understand this discrepancy, we naturally turn to a beyond worst-case analysis technique called *smoothed analysis*, which "continuously interpolates between the worst-case and average-case analyses of algorithms," [41] (see Section 1.2 for a detailed discussion). Informally, we wish to show that adversarial instances are "scattered" in a probabilistic sense. We say that an algorithm is smoothed-efficient if it is efficient with high probability when all input parameters are perturbed by small random noise. This is one of the strongest performance metrics beyond worst-case performance. We ask the following:

▶ **Question.** *Can we design smoothed efficient algorithms for finding pure Nash equilibria for network coordination games?*

In this paper we answer the question in the affirmative. In particular, we obtain smoothed (quasi-)polynomial time algorithms to find pure Nash equilibria (PNE) in network-coordination games (NetCoordNash) with a constant number of strategies. We also introduce a notion for a *smoothness-preserving reduction*, and show that a special case of NetCoordNash admits such a reduction to local-max-cut, and the general case admits a reduction to local-max-bisection (see Section 2.2 for the problem definitions).

To the best of our knowledge, no smoothed efficient algorithm for a worst-case hard Nash equilibrium problem was known prior to this work, apart from the party affiliation games, the smoothed complexity of which directly follows from local-max-cut [23]. Similarly, to the authors' knowledge, no notion of smoothness-preserving reduction has been shown in the past, and we believe that such reductions are of independent interest.

Local-max-cut is a PLS-complete problem, where the goal is to find a cut in a graph that is maximal up to switching one vertex. In a recent series of results, the smoothed complexity of local-max-cut was shown to be first quasi-polynomial for arbitrary graphs [22], and then polynomial for complete graphs [1]. Both results and a recent (simultaneous) work [8] follow a common high-level framework: using anti-concentration bounds for linear combinations of random variables to argue that bad events are unlikely. Our analysis extends this high-level approach to NetCoordNash. However, local-max-cut is a special case of NetCoordNash where every player has two strategies and the matrix on every edge is off-diagonal (see Figure 1). To handle the extra complexity of NetCoordNash in general, we need to define novel bounds.

1.1 Our Results

A network coordination game is represented by an undirected *game graph* $G = (V, E)$, where the nodes are the players, and each player $v \in V$ simultaneously plays a two-player coordination game with each of its neighbors. If players have k strategies to choose from,

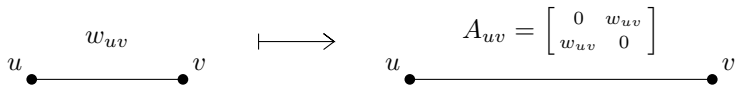

Figure 1 Local-max-cut to 2-strategy network coordination games: mapping of edge (u, v).

the game on each edge uv can be represented by a $k \times k$ payoff matrix. Once every player chooses a strategy, the payoff value for each edge is fixed, and players receive the sum of the payoffs from incident edges. The goal is to find a PNE of this game. We show the natural *better-response algorithm* converges quickly with high probability on perturbed instances.

Smoothed Analysis of NetCoordNash. A strategy profile is at equilibrium if no single player can gain by deviating while others' unilaterally. Better-response dynamics/algorithms are an iterative procedure where any player who benefits by deviating, does so, one at a time, until an equilibrium is reached. This need not converge in general, *e.g.* for a game of rock-paper-scissors, where the players would infinitely cycle through the three strategies. In our setting, however, the sum of payoffs of all players acts as a *potential function*, which increases with every better-response move (Section 2.1). Thus, starting from any initial choice of strategies, *better-response algorithm (BRA)* will converge to a PNE in network coordination games, since it can be shown that the potential function is bounded.

We show that the BRA is an efficient algorithm with probability $1 - 1/poly(n)$ for perturbed instances: when the payoff values are independently sampled from distributions with density bounded by ϕ, the runtime will be polynomial in ϕ and the input size with high probability. One may interpret ϕ as the inverse of the minimum allowed perturbation. The exact relation between perturbation size and running time are as follows:

▶ **Theorem 1.** *Let $G = (V, E)$ be a game graph for an instance of NetCoordNash, with $k \times k$ payoff matrices, whose entries are independently distributed, continuous, random variables, with densities $f_{u,v,i,j} : [-1, 1] \to [0, \phi]$. Let $n := |V|$. If G is a complete graph, then with probability $1 - (nk)^{-3}$, all valid executions of the BRA (even adversarial) will converge to a PNE in at most $(nk\phi)^{O(k)}$ steps, and the expected running time $(nk\phi)^{O(k)}$ as well.*

If G is arbitrary, all valid executions of the BRA, from all starting points, will converge to a PNE in at most $\phi \cdot (nk)^{O(k \log(nk))}$ steps with probability $1 - (nk)^{-2}$ over the payoff entries. Furthermore, the expected running time is also at most $\phi \cdot (nk)^{O(k \log(nk))}$.

The proof of this is discussed in Section 3. The polynomial running time requires the graph to be complete so that *all* parameters can be perturbed. This seems to be unavoidable as all known results on *polynomial* smoothed complexity so far, *e.g.,* linear-programming [41], local-max-cut [1], etc., require this.

The above performance guarantees are only (quasi-)polynomial in the input size for k constant. It is an open problem to improve this to general k. This can be achieved either by showing that local-max-bisection has polynomial smoothed complexity (see below), or by directly tightening the bounds in the proof presented in this paper (Section 3).

Smoothness-Preserving Reductions. Note that standard Karp reductions do not suffice to extend a smoothed efficient algorithm across problems. This is because, among other things, such a reduction needs to ensure that independently perturbed parameters of the original problem produce independent perturbations of all parameters in the reduced problem. In this work, we introduce a notion of a *smoothness-preserving reduction*, which to the knowledge of the authors, has not been studied prior to this work. We obtain two such reductions:

▶ **Theorem 2.** *NetCoordNash with 2×2 payoff matrices admits a weak smoothness-preserving reduction to the local-max-cut problem. Furthermore, NetCoordNash with $k \times k$ matrices for general k admits a weak smoothness-preserving reduction to the local-max-bisection problem. For both results, an instance of NetCoordNash with a general or complete game graph reduces to an instance of local-max-cut/bisection on a general or complete graph, respectively.*

The definition of weak reductions is given in Section 4, and a formal statement of the local-max-cut and -bisection problems is in Section 2.2. In this writeup, we provide an outline of the reductions in Section 4, and a formal description and proofs of correctness are given in the full version of this paper [10]. The first reduction, together with smoothed efficient algorithms for local-max-cut, gives alternate smoothed efficient algorithms for the $k = 2$ instance; namely, the result of [8] implies an $O(n^8)$ algorithm when the game graph is complete. For general network coordination games, the smoothed complexity of local-max-bisection is open, and so any conclusion on the complexity of NetCoordNash is conditional.

1.2 Related Work

The works most closely related to ours are [22] and [1], where the smoothed complexity of local-max-cut was first analyzed, and [8] which refined the analyses. As discussed above, local-max-cut is a special case of NetCoordNash, therefore the techniques do not immediately apply. Independently, [8] also obtained smoothed polynomial algorithms for local-max-3-cut on complete graphs, and quasi-polynomial algorithms in general for local-max-k-cut with constant k. Local-max-k-cut naturally reduces to NetCoordNash with $k \times k$ payoff matrices. However, our result does not subsume theirs as the reduction is not *smoothness preserving*.

Complexity of Equilibrium Computation. There has been extensive work on various potential games, equivalently congestion games (e.g., [35, 31, 36, 23]), capturing routing and traffic situations (e.g., [37, 25]), and resource allocation under strategic agents (e.g., [26, 24]). A potential function ensures that these games always have a pure NE [35]. Finding pure NE is typically PLS-complete in the worst case [23, 12]. Our approach provides tools to prove smoothed analysis results for such games.

For the general games, NE computation is PPAD-complete [17, 13], even (1/poly)-additive approximation. This latter result also implies smoothed complexity does not lie in P unless RP = PPAD [13]. Towards average case analysis, Bárány, Vempala, and Vetta [5] showed that a game picked uniformly at random has a NE with support size 2 for both the players with inverse-logarithmic probability The average case complexity of a random potential game was shown to be polynomial in the number of players and strategies by Durand and Gaujal [19].

Smoothed Analysis. The work of Spielman and Teng [41] introduced the smoothed analysis framework to study the empirical performance of the Simplex method for linear programming. They showed that introducing independent random perturbations to any given (adversarial) LP instance, ensures that Simplex terminates fast with high probability, with polynomial dependence on the inverse of the magnitude of perturbation. Performance on such perturbed instances has since been known as *smoothed complexity* of the problem – one of the strongest guarantees one can hope for *beyond worst-case* analysis. In the past decade and a half, much work has sought to obtain smoothed efficient algorithms when worst-case efficiency seems infeasible [16, 7, 30, 34, 4, 21, 22, 1], including for integer programming, binary search trees, iterative-closest-point (ICP) algorithms, the 2-OPT algorithm for the Traveling Salesman problem (TSP), the knapsack problem, and the local-max-cut problem.

2 Preliminaries: Game Model and Smoothed Analysis

In what follows, the set $\{1, 2, \ldots, k\}$ is denoted as $[k]$, and $\langle \cdot, \cdot \rangle$ denotes inner product.

2.1 Nash Equilibria in Network Coordination Games

A two-player game, where each player has finitely many strategies to choose from is given by two payoff matrices A and B. Assume without loss of generality that both players have k strategies, and thus the matrices are $k \times k$. It is called a *coordination game* if $A = B$.

A *network coordination game* is a multi-player extension of coordination games. The game is specified by an underlying undirected graph $G = (V, E)$, where the nodes are players, and each edge represents a two-player coordination game between its endpoints. It is a *k-network coordination game* if each player has k strategies. For disambiguation, we represent the payoff values as an $|E|k^2$-dimensional vector A, and denote as $A((u, i)(v, j))$ the payoff that players u and v get for the game-edge $uv \in E$, when u chooses strategy i, and v, strategy j. As Nash equilibria are invariant to shifting and scaling of the payoffs, assume without loss of generality that every entry of A is contained in $[-1, 1]$.

Potential Function. Below we show that it suffices to only consider pure strategies, *i.e.* players needn't randomize. Let n be the number of players; a *strategy profile* is a vector $\boldsymbol{\sigma} \in [k]^n$, assigning to each player a strategy in $[k]$. The payoff to player u is given by

$$\text{payoff}_u(\boldsymbol{\sigma}) := \sum_{v:\, uv \in E} A((u, \sigma_u)(v, \sigma_v))$$

Define the *potential function* $\Phi : [k]^n \to \mathbb{R}$ to be the sum of all payoffs. Formally,

$$\Phi(\boldsymbol{\sigma}) := \sum_{(u,v)\in E} A((u, \sigma_u), (v, \sigma_v)) = \tfrac{1}{2} \sum_{u \in V} \text{payoff}_u(\boldsymbol{\sigma}) \tag{1}$$

The potential function is of interest since it captures the possible improvements to all players' payoffs in the following sense [12]: if player u changes their strategy, $\Phi(\boldsymbol{\sigma})$ and $\text{payoff}_u(\boldsymbol{\sigma})$ vary by the same amount. Formally, for all $u \in V$, $\sigma_u, \sigma'_u \in [k]$, and $\boldsymbol{\sigma}_{-u} \in [k]^{n-1}$

$$\Phi(\sigma_u, \boldsymbol{\sigma}_{-u}) - \Phi(\sigma'_u, \boldsymbol{\sigma}_{-u}) \;=\; \text{payoff}_u(\sigma_u, \boldsymbol{\sigma}_{-u}) - \text{payoff}_u(\sigma'_u, \boldsymbol{\sigma}_{-u})$$

where $\boldsymbol{\sigma}_{-u} \in [k]^{n-1}$ denotes the strategy profile on $V \setminus u$. Network coordination games are termed *potential games* because they admit such a potential function. As a consequence, they must admit pure Nash equilibria [35].

Nash Equilibrium and Better-Response Algorithm (BR alg., or BRA). At a Nash equilibrium (NE), no player gains by deviating unilaterally.

$$\textit{NE:} \quad \forall u \in V, \quad \text{payoff}_u(\sigma_u, \boldsymbol{\sigma}_{-u}) \geq \text{payoff}_u(\sigma'_u, \boldsymbol{\sigma}_{-u}), \quad \forall \sigma'_u \in [k]$$

Such a $\boldsymbol{\sigma}$ is called *pure* NE (PNE) as every player is playing a deterministic strategy. By the discussion above, $\boldsymbol{\sigma}$ is a PNE if and only if it is a local maximum for Φ, where $\boldsymbol{\sigma}'$ is in the local neighbourhood of $\boldsymbol{\sigma}$ when they differ in exactly one entry. A deviation for one player is termed a *better-response (BR) move* if their individual payoff strictly increases. Note that if $\boldsymbol{\sigma}'$ is a BR deviation from $\boldsymbol{\sigma}$, differing in a single player, then $\Phi(\boldsymbol{\sigma}') > \Phi(\boldsymbol{\sigma})$. The *better-response algorithm* (BRA) repeatedly makes better-response moves, increasing the Φ value in every step. The terminating point has to be a local maximum of Φ, and thereby a PNE. Since Φ may only take k^n different values, this procedure must terminate at a PNE.

2.2 Smoothed Analysis and Reductions

The notion of smoothed analysis was introduced by Spielman and Teng [41] to bridge the gap between average- and worst-case analysis. The parameters of the problem are perturbed by some small noise, and the performance is measured as a function of the perturbation size. We present first a formal definition of smoothed-efficient algorithms in our setting.

▶ **Definition 3** (Independent distributions with bounded density). *Let X be a random vector in $[-1,1]^d$. We say it is* independently distributed with density bounded by ϕ *if the entries are independently distributed, and the p.d.f. for the i-th entry is a function $f_i : [-1,1] \to [0,\phi]$. Observe that the joint distribution on X has p.d.f. upper-bounded by ϕ^d.*

Intuitively, a bounded-density X is "spread" by at least $1/\phi$. Running-time bounds will be defined as a function of ϕ. We define here polynomial smoothed complexity in our setting:

▶ **Definition 4** (Polynomial Smoothed Complexity). *Let $\mathcal{P}$ be a search problem, whose instances consist of some structural information D – e.g. a graph – and some real-valued information X – e.g. edge weights. We say $\mathcal{A}$ is a* smoothed efficient algorithm *for $\mathcal{P}$ if, $\mathcal{A}(D,X)$ returns a correct solution with probability 1, and there exist constants $c, c' > 0$ such that whenever $X \in \mathbb{R}^d$ is an independently distributed random vector with density bounded by ϕ,*

$$\max_{D} \Pr_{X} \left[\textit{running time of } \mathcal{A} \textit{ on } (D,X) \ \geq (d \cdot |D| \cdot \phi)^c\right] \ \leq (d \cdot |D|)^{-c'} \ .$$

$\mathcal{P}$ is said to have polynomial smoothed complexity *if a smoothed efficient algorithm exists. It has* quasi-poly smoothed complexity *if the above holds for running time $(d \cdot |D| \cdot \phi)^{O(\log(d \cdot |D|))}$.*

An algorithm is smoothed-efficient in expectation if the expected running time over a worst-case choice of ϕ-bounded distributions is (quasi-)polynomial in d, ϕ, and $|D|$; a problem $\mathcal{P}$ is said to have (quasi-)polynomial smoothed complexity in expectation similarly.

Local-max-cut and -bisection. In this paper, we define *smoothness preserving reductions* which allow the extension of smoothed-complexity results, as defined above, from one problem to another. Namely, we obtain reductions to the local-max-cut and -bisection problems. These problems are defined as FLIP and SWAP respectively in [40]. Given a weighted graph $G = (V, E)$, local-max-cut is the problem of finding a cut which is maximal up to flipping one vertex across the cut, and local-max-bisection is the problem of finding a balanced cut of the nodes into two sets of equal size, whose cut value is maximal up to swapping a pair of nodes across the cut. Both problems are shown to be PLS-hard in [40], and the smoothed complexity of local-max-cut has been studied at length, as discussed in the introduction.

3 Smoothed Performance of the BR algorithm

This section is a partial proof of Theorem 1. All missing details may be found in the full version [10]. Recall that Theorem 1 stated that for ϕ-bounded random variables, the BRA converges in $(nk\phi)^{O(k)}$ steps with probability $1 - (nk)^{-3}$ on complete graphs, and $\phi \cdot (nk)^{O(k \log(nk))}$ steps with probability $1 - (nk)^{-2}$ over the payoff entries. Only the payoff values are randomized, the BR moves may be chosen adversarially after sampling.

Recall that a profile $\boldsymbol{\sigma}$ is a PNE if and only if it is a local maximum of the potential Φ. Note that Φ may only take values in the interval $[-n^2, n^2]$, since the payoffs are in $[-1, 1]$. It suffices then to show that with high probability, *every* linear-length sequence of BR moves has significant increase in Φ. We show the following:

▶ **Theorem 5.** *Let $G = (V, E)$ be a game graph, with random payoff vector A, and $\boldsymbol{\sigma}^0 \in [k]^n$ be an arbitrary strategy profile. With probability $1 - (nk)^{-2}$ over the values of A, all BR sequences of length at least $2nk$, initiated at any choice of $\boldsymbol{\sigma}^0$, must have at least one step in which the potential increases by $\epsilon = \phi^{-1}(2n^2k^3)^{-20k\log(nk)}$. If G is a complete graph, then with probability $1 - (nk)^{-3}$, all BR sequences of length at least $2nk$, will have at least one step increasing by $\epsilon' = (20\phi^2n^3k^3)^{-4k-4}$.*

From the above discussion, this implies that the BRA must terminate in $\phi(nk)^{O(k\log(nk))}$ steps with probability $1-(nk)^{-2}$ in general, and $(\phi nk)^{O(k)}$ steps with probability $1-(nk)^{-3}$ on complete game graphs, implying Theorem 1. We proceed with a proof of Theorem 5.

The high level approach of this paper, and also that of [22, 1, 8], is as follows: Express the increase in potential as a linear combination of the payoff values, and conclude Theorem 5 via an anti-concentration inequality and a union bound. Each step of the BRA is some player u, deviating to a new $\sigma \in [k]$, denoted as the (player,strategy) pair (u, σ). Thus, an execution of the BRA is fully specified by a sequence of pairs $S = (u_1, \sigma_1), (u_2, \sigma_2), \ldots$, along with an initial strategy vector $\boldsymbol{\sigma}^0 \in [k]^n$. The strategy profile at time t is given by $\boldsymbol{\sigma}^t := (\sigma_t, \boldsymbol{\sigma}^{t-1}_{-u_t})$.

We wish to control the value of $\Phi(\boldsymbol{\sigma}^t) - \Phi(\boldsymbol{\sigma}^{t-1})$ as a function of the payoff values. To this end, define the *potential-change indicator matrix* for a BR sequence as follows:

▶ **Definition 6.** *For any fixed BR sequence S of length ℓ, let $L(S, \boldsymbol{\sigma}^0) := \{\boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2, \ldots, \boldsymbol{\lambda}_\ell\}$, where $\boldsymbol{\lambda}_t \in \{-1, 0, 1\}^{(|E|\times k^2)}$, for all t. The entries of $\boldsymbol{\lambda}_t$ are indexed by indices of payoff matrix entries, denoted $((v, i)(w, j))$. The values of its entries are chosen as follows:*

$$\boldsymbol{\lambda}_t((v,i)(w,j)) := \begin{cases} 1 & \text{if: } u_t \in \{v,w\} \text{ and } \sigma^t_v = i \text{ and } \sigma^t_w = j. \\ -1 & \text{if: } u_t \in \{v,w\} \text{ and } \sigma^{t-1}_v = i \text{ and } \sigma^{t-1}_w = j. \\ 0 & \text{otherwise.} \end{cases}$$

Each entry denotes whether the payoff values remain in the payoff (0), get added to the total payoff $(+1)$, or removed (-1). This set of vectors – or equivalently the matrix whose rows consist of the $\boldsymbol{\lambda}_t$'s – is termed the potential-change indicator matrix of a sequence.

The arguments $S, \boldsymbol{\sigma}^0$ are omitted if they are clear from context. Observe $\Phi(\boldsymbol{\sigma}^t) - \Phi(\boldsymbol{\sigma}^{t-1}) = \langle \boldsymbol{\lambda}_t, A\rangle$, where A is the vector of payoff values, so the product LA represents the sequence of changes in Φ along an execution of the BRA. Bounding the probability of $LA \notin [0, \epsilon]^\ell$ for all sequences of length $\ell \geq 2nk$ then implies Theorem 5. We use the following.

▶ **Lemma 7** ([33])**.** *Let $X \in \mathbb{R}^d$ be a random vector such that the joint probability on any $a \leq d$ coordinates of X is upper-bounded by ϕ^a at all points. Let M be a rank r matrix in $\eta\mathbb{Z}^{\ell\times d}$, i.e. all entries are multiples of η. Then the joint density of the vector MX is bounded by $(\phi/\eta)^r$, and for any given $b_1, b_2, \ldots, b_\ell \in \mathbb{R}$ and $\epsilon > 0$,*

$$\Pr\Big[MX \in [b_1, b_1+\epsilon] \times \cdots \times [b_\ell, b_\ell + \epsilon]\Big] \leq (\phi\epsilon/\eta)^r \tag{2}$$

Observe that if X is a vector whose entries are independently distributed, and each X_i has probability density bounded by ϕ, then the joint distribution over any ℓ coordinates of X has density bounded by ϕ^ℓ. This statement is a generalization of a lemma from [33], but the proof therein easily extends.

To conclude Theorem 5, we first show that L has large enough rank, then apply the above lemma with $M = L(S, \boldsymbol{\sigma}^0)$ and $X = A$, and finally take a union bound over the choice of S and $\boldsymbol{\sigma}^0$. The following parameters are introduced for clarity of exposition.

▶ **Definition 8** (Active, Inactive, Repeating, and Non-Repeating players.)**.** *Let S be a BR sequence, then player u is said to be* active *if she appears in the sequence, and* inactive *otherwise. An active player u is said to be* repeating *if there exists some strategy i such that (u, i) appears at least twice in S, or if (u, σ_u^0) appears in S at all. An active player who is not repeating is said to be* non-repeating*. We introduce the following notation:*

$p(S)$	*number of active players in S,*	$d(S)$	*number of distinct (u, i) moves in S,*
$p_1(S)$	*num. non-repeating players in S,*	$d_1(S)$	*distinct moves by non-rept. players in S,*
$p_2(S)$	*number of repeating players in S,*	$q_0(S)$	*number of distinct (u, σ_u^0) moves in S.*

Observe that $p = p_1 + p_2$, $k \cdot p \geq d \geq p$, $k \cdot p_1 \geq d_1 \geq p_1$, and $q_0 \leq p_2$. We will often use the quantity $d(S) - q_0(S)$, which is the number of "new" strategies played by the players.

3.1 Inactive Players, Rank Bounds, and Union Bounds

As discussed above, the goal is to show that $L(S)$ has large rank, and apply Lemma 7, taking a union bound over all possible choices of S and $\boldsymbol{\sigma}^0$. Naïvely, there are $k^n(nk)^\ell$ choices for sequences of length ℓ. However, if $p(S) \ll n$, the rank bound cannot exceed $d(S) \leq k \cdot p(S)$ in our model, which does not match the union bound. To circumvent this issue, we modify the matrix L in two different ways, for the cases $p_1(S) \geq p_2(S)$ and $p_2(S) \geq p_1(S)$, respectively. This case analysis is similar to the proofs in [1, 8], however these two papers each use only one of the two constructions, whereas our analyses require both, as the large strategy space allows for more complex interactions between the rows of L, and each construction only allows bounds of one kind.

3.1.1 Control by rounding.

The first modification to L builds on a technique of [1]. While the construction is valid for arbitrary graphs, the rank bounds hold only for complete graphs. Let $V_0 \subset V$ be the set of inactive players, and V_1 the active players. For any $u \in V_1$ and i fixed, all $((u, i)(w, \sigma_w^0))$ rows of L for $w \in V_0$ are identical, up to flipping a row's signs, since w's strategy remains unchanged. Therefore, in the inner product $\langle \boldsymbol{\lambda}_t, A \rangle$, these $((u, i), (w, \sigma_v^0))$ terms are added or subtracted together, and we may simply "guess" this value approximately, and take a union bound on the guesses, rather than guessing strategy choices. This is formalized below.

The quantity of interest is the change in $\Phi(\boldsymbol{\sigma}^t)$ over t, so it is equivalent to instead consider $\Phi(\boldsymbol{\sigma}^t) - \Phi(\boldsymbol{\sigma}^0)$, a constant shift. Let $\widetilde{A}_{uv}^{t-0} = A((u, \boldsymbol{\sigma}_u^t)(v, \boldsymbol{\sigma}_v^t)) - A((u, \boldsymbol{\sigma}_u^0)(v, \boldsymbol{\sigma}_v^0))$.

$$\begin{aligned}\Phi(\boldsymbol{\sigma}^t) - \Phi(\boldsymbol{\sigma}^0) &= \sum_{u,v \in V} A((u, \boldsymbol{\sigma}_u^t)(v, \boldsymbol{\sigma}_v^t)) - A((u, \boldsymbol{\sigma}_u^0)(v, \boldsymbol{\sigma}_v^0)) \\ &= \sum_{u,v \in V_1} \widetilde{A}_{uv}^{t-0} + \sum_{w,w' \in V_0} \widetilde{A}_{ww'}^{t-0} + \sum_{u \in V_1} \sum_{w \in V_0} \widetilde{A}_{uw}^{t-0}\end{aligned}$$

For $w \in V_0$, $\boldsymbol{\sigma}_w^t = \boldsymbol{\sigma}_w^0$, so the "$\widetilde{A}_{ww'}^{t-0}$" terms are 0. Furthermore, the rightmost terms are in fact constants, depending only on σ_u. Let then $C(u, \sigma) := \sum_{w \in V_0} A((u, \sigma)(w, \boldsymbol{\sigma}_w^0)) - A((u, \boldsymbol{\sigma}_u^0)(w, \boldsymbol{\sigma}_w^0))$. Note $C(u, \boldsymbol{\sigma}_u^0) = 0$. The above sum is therefore equivalent to

$$\Phi(\boldsymbol{\sigma}^t) - \Phi(\boldsymbol{\sigma}^0) \;=\; \sum_{u,v \in V_1} \widetilde{A}_{uv}^{t-0} \;+\; 0 \;+\; \sum_{u \in V_1} C(u, \sigma_u^t)$$

For $p(S)$ fixed, we need only take a union bound over the nk^ℓ choices of BR sequence, $k^{p(S)}$ choices of initial strategy, and the $d(S) - q_0(S)$ different C values for each $(u, \sigma \neq \sigma_u^0)$. We will round these to the nearest multiple of ϵ, leaving $2n/\epsilon$ choices for each. With this, we have a union bound of size $k^{p(S)}(nk)^\ell(2n/\epsilon)^{d(S)-q_0(S)}$.

Critical Subsequences and Rank Bounds. It remains to argue that $L(S, \boldsymbol{\sigma}^0)$ has sufficiently large rank bounds. The statements below are presented informally, in the interest of space. See the full version for complete details [10]. To this end, we define *critical subsequences* as follows, based on the definition of critical block from [1]:

▶ **Definition 9** (Critical Subsequence). *Let B be a contiguous subsequence of S. If $\ell(B) \geq 2\big(d(B) - q_0(B)\big)$, but for every $B' \subseteq B$, $\ell(B') < 2\big(d(B') - q_0(B')\big)$, we say that B is* critical. *Note that a return move – i.e. q_0-type move – for a subsequence B which starts at time t_B is a move $(u, \boldsymbol{\sigma}_u^{t_B})$, as opposed to a $(u, \boldsymbol{\sigma}_u^0)$ move.*

Observe that for any BR sequence S of length $2nk$, $\ell(S) \geq 2(d(S) - q_0(S))$, and so a maximal (up-to-inclusion) subsequence satisfying $\ell \leq 2(d - q_0)$ will be critical. Thus, any sequence of length $2nk$ must contain a critical subsequence B, with $\ell(B) = 2(d(B) - q_0(B))$. Critical subsequences are key to the analysis, since their length and number of distinct moves are perfectly correlated. This will be used in conjunction with the notion of *separated blocks*.

▶ **Definition 10** (Separated Blocks). *Fix a BR sequence S. For any active, non-repeating, player u, let T_u be the set of indices where the moving player is u, and $T := \{t_1 < t_2 < \cdots < t_m\}$ be the union of the T_u's. Note that $|T| = d_1(S)$. Let S_i for $0 \leq i \leq m$ be the subsequences of S from time t_i to t_{i+1} excluding boundaries, respectively, where $t_0 = 0$ and $t_{m+1} = |S|$. We say these S_i's are the* separated blocks *of S.*

The separated blocks allow us to isolate large-rank submatrices and combine their ranks. Let w be any inactive player, and (u_i, σ_i) be the non-repeating move which begins separated block i for all i. Then, up to column permutations, the submatrix with rows from T and columns indexed by $((u_i, \sigma_i)(w, \sigma_w))$ is upper-triangular with a non-zero diagonal. The diagonal is necessarily nonzero because the graph is complete. Furthermore, for a separated block S' which begins at move (u_i, σ_i), the submatrix of rows from S' and columns $((v, \sigma_v)(u_i, \sigma_i))$ also form an upper-triangular matrix with non-zero diagonals, where the columns are sorted by the first appearance of v, σ_v in S'. Finally, if we sort the rows of T first, then by chronological order of separated blocks, we can form a block-upper-triangular submatrix with non-zero diagonal terms, of size $d_1(S) + \sum_{S' \text{ separated}}(d(S') - q_0(S'))$. As above, graph completeness is necessary for the diagonal to be nonzero. This submatrix is block-upper-triangular because $((\cdot, \cdot), (u_i, \sigma_i))$ rows are all 0 before u_i first enters σ_i, since u_i is non-repeating. Assuming that the overall sequence S is critical, this gives

$$rank(L) \;\geq\; d_1(S) + \sum_{S' \text{ sep.}} d(S') - q_0(S') \;>\; \tfrac{1}{2}d_1(S) + \tfrac{1}{2}d_1(S) + \sum_{S' \text{ sep.}} \tfrac{1}{2}\ell(S')$$

However, $\ell(S) = d_1(S) + \sum_{S' \text{ sep.}} \ell(S')$, so we have $rank(L) \geq \frac{1}{2}d_1(S) + \frac{1}{2}\ell(S)$. By criticality, $\ell(S) = 2(d(S) - q_0(S))$, which gives a rank bound of $\frac{1}{2}(d_1(S) + \ell(S)) = \frac{1}{2}d_1(S) + d(S) - q_0(S)$.

Combining Rank and Union bounds. Recall that we have shown, for any BR sequence of length $2nk$, it must contain a critical subsequence B. Assuming B has length ℓ, there are $k^{p(B)}(nk)^\ell$ choices for the (modified) matrix $L(B, \boldsymbol{\sigma}^0)$, and $(4n/\epsilon)^{d(B) - q_0(B)}$ choices for the approximate $C(u, \sigma)$ values. The $C(u, \sigma)$'s are rounded to the nearest ϵ, so the true improvements lie in $(0, \epsilon)$ if the approximated improvements lie in $(-\epsilon, 2\epsilon)$, since there can be at most two C terms in each change, and rounding introduces error at most $\epsilon/2$.

We have shown that $L(B, \boldsymbol{\sigma}^0)$ has rank at least $\frac{1}{2}d_1(B) + d(B) - q_0(B)$. Applying Lemma 7, we conclude that the probability that every critical subsequence of a valid BR sequence of length at least $2nk$ has all improvements in $(0, \epsilon)$ is upper-bounded by

$k^{p(B)}(nk)^{\ell}(4n/\epsilon)^{d(B)-q_0(B)}(3\phi\epsilon)^{d_1(B)/2+d(B)-q_0(B)}$. Recall $d_1(B) \geq p_1(B)$, and assume $p_1(B) \geq p_2(B) \implies d_1(B) \geq p_1(B) \geq \frac{1}{2}p(B)$. Also, $d(B) - q_0(B) \leq k \cdot p(B)$, and recall $\ell = 2(d(B) - q_0(B))$. Thus the probability that all improvements are small, for complete graphs, when $p_1(B) \geq p_2(B)$ is at most $\left((20n^3k^3\phi^2)^k\epsilon^{1/4}\right)^{p(B)}$. We later combine this bound with one for the case $p_2(B) \geq p_1(B)$, and take a union bound over the choice of $p(B)$.

3.1.2 Control by cyclic sums

The second rank bound argument is more intricate, and is loosely based on a construction in [22]. The bounds proved here hold for arbitrary graphs. We construct a new matrix Q whose columns lie in the span of L, which cancels the contributions of inactive players, but still captures improvement. Let (u, σ) be some move which appears twice in S, or suppose some (u, σ_u^0) appears in S. Let τ_0 be the index of the first occurrence of (u, σ) in the BR sequence ($\tau_0 = 0$ in the latter case), and let $\tau_1, \tau_2, \ldots$ be all subsequent appearances of $(u, \cdot)$ in the sequence. Suppose τ_m is the second occurrence of (u, σ) in the BR sequence. Then we let $\boldsymbol{q}_{u,\sigma} := \sum_{j=1}^{m} \boldsymbol{\lambda}_{\tau_j}$, noting that the τ_0 is omitted. Let $Q(S, \boldsymbol{\sigma}^0)$ be the matrix whose columns consist of the $\boldsymbol{q}_{u,\sigma}$'s. Observe, for any inactive player w,

$$\boldsymbol{q}_{u,\sigma}\big((u,\sigma')(w,\sigma_w^0)\big) \;=\; \sum_{j=1}^{m} \boldsymbol{\lambda}_{\tau_j}\big((u,\sigma')(w,\sigma_w^0)\big) \;=\; \sum_{j=1}^{m} \mathbb{I}[\sigma_u^{\tau_j} = \sigma'] - \mathbb{I}[\sigma_u^{\tau_j - 1} = \sigma'] \;=\; 0$$

Thus, the $\boldsymbol{q}_{u,\sigma}$'s are all 0 in entries corresponding to edges with inactive players, and therefore the Q matrix does not depend on the initial strategies of the inactive players. Thus, to union bound the possible Q matrices, it suffices to fix the initial strategy of only the active players and the BR sequence. Furthermore, $L \cdot A \in [0, \epsilon]^{\ell} \implies Q \cdot A \in [0, \ell\epsilon]^{d-d_1}$, so it suffices to apply Lemma 7 on the matrix Q, with only polynomial blowup, since $\ell \leq O(nk)$.

Fixing a critical subsequence B, there are at most $(nk)^{\ell(B)}$ choices of the BR sequence, and $k^{p(B)}$ choices of initial strategy profiles for the active players.

Rank Bounds. It remains to show that Q has large rank relative to this smaller union bound. Since we have eliminated inactive players, the high-rank submatrix will consist of interactions between active players. As in [22], construct an auxiliary *directed* graph $G' = (V, E')$, where V is the set of players, and E' is constructed as follows: for any repeating move (u, σ), add the directed edge (u, w) for *every* $w \in V$, such that $\exists \sigma' \in [k] : \boldsymbol{q}_{u,\sigma}\big((u,\sigma)(w,\sigma')\big) \neq 0$. Note that u and w must be connected in the game graph, and we do not need completeness.

Let $P_2 \subseteq V$ be the set of repeating players, and note that they all have non-zero out-degree, since $\boldsymbol{q}_{u,\sigma} \neq \mathbf{0}$ as this would contradict the fact that the sequence is improving. Repeatedly perform the following: choose $r_1 \in P_2$, and let T_1 be the BFS arborescence rooted at r_1 which spans all nodes reachable from r_1 in G'. Delete $V(T_1)$ from G' and repeat, picking an arbitrary root vertex $r_2 \in P_2 \setminus V(T_1)$. Stop when every vertex of P_2 is covered by some arborescence. For all i, let T_i^0 and T_i^1 be a partition of the nodes of T_i which are of even or odd distance from the root, respectively. Let P_i' be the larger of $V(T_i^0) \cap P_2$ and $V(T_i^1) \cap P_2$, and let $P_2' := \bigcup_{i=1}^{\infty} P_i'$, noting that $|P_2'| \geq |P_2|/2 = p_2(S)/2$. We claim that the collection $\mathcal{V} := \{\boldsymbol{q}_{u,\cdot} : u \in P_2'\}$ is linearly independent.

For every $u \in P_2'$, either u was an internal node to the arborescence that covers it, or a leaf. If it is internal, we may associate to u any of its children in the arborescence, which are not contained in P_2', by definition. Let w be the chosen child, then the only $\mathcal{V}$ vectors which have nonzero $((u,\cdot)(w,\cdot))$ entries are the $\boldsymbol{q}_{u,\cdot}$ vectors.

Conversely if u is a leaf, then its out-neighbours must be in previously constructed arborescences. Let w be any such neighbour, then $\boldsymbol{q}_{w,\cdot}$ can not contain a non-zero $((u,\cdot)(w,\cdot))$ entry, as otherwise u would have been in w's arborescence. Therefore, $\boldsymbol{q}_{u,\cdot}$ is the only vector in $\mathcal{V}$ to contain a nonzero $((u,\cdot)(w,\cdot))$ entry. Observe that these matrix entries are necessarily nonzero even if the graph is not complete. The above discussion demonstrates a $|\mathcal{V}| \times |\mathcal{V}|$ diagonal submatrix of $\mathcal{V}$, which implies Q has rank at least $|\mathcal{V}| \geq p_2(S)/2$.

Combining Rank and Union Bounds. This section considers the complete graph case. These bounds will be extended to general graphs in the next section. Section 3.1.1 gives bounds for the case $p_1(B) \geq p_2(B)$, and so we restrict our attention to the case $p_2(B) \geq p_1(B) \implies p_2(B) \geq p(B)/2$.

For any fixed critical subsequence B, we have argued that the probability that $L(B, \boldsymbol{\sigma}^0)$ has all entries in $(0,\epsilon)$ is at most the probability that $Q(B, \boldsymbol{\sigma}^0)$ has all entries in $(0, \ell\epsilon)$. By Lemma 7 and the above rank bounds, this occurs with probability at most $(\ell\phi\epsilon)^{p_2(B)/2}$. Recall that by criticality, $\ell = 2(d(B) - q_0(B)) \leq 2k \cdot p(B)$. Thus, with the above union bound, the probability that all critical subsequences with $p(B)$ active players and $p_2(B) \geq p_1(B)$ have bad improvements is at most $k^{p(B)}(nk)^{2kp(B)}(2k \cdot p(B) \cdot \epsilon\phi)^{p(B)/4} \leq \left(2(nk)^{2k}k^{5/4}(n\phi\epsilon)^{1/4}\right)^{p(S)}$.

3.2 (Quasi-)Polynomial Smoothed Complexity for NetCoordNash

Complete Game Graphs. From Sections, 3.1.1 and 3.1.2, the probability that *all* valid BR sequences of length at least $2nk$ have all improvements in $(0,\epsilon)$ is at most

$$\sum_{p=1}^{n} \left((20n^3k^3\phi^2)^k\epsilon^{1/4}\right)^p + \left(2(nk)^{2k}(nk^5\phi\epsilon)^{1/4}\right)^p$$

by simply taking a union bound over the value of $p(B)$, and whether $p_1(B) \geq p_2(B)$ or the converse hold. Setting $\epsilon = (20\phi^2n^3k^3)^{-4k-4}$, we conclude that this probability is at most $1/(20\phi^2n^3k^4 - 1)$, which concludes the complete-graph portion of Theorem 5 noting that $\phi > \frac{1}{2}$. We omit calculation details and handling edge-cases where all players are active. These are included in the full version [10].

General Game Graphs. For general game graphs, we will use the cyclical-sum construction, as it does not require completeness. Note that it was phrased in terms of critical subsequences, but never used this property. However, the cyclic-sum construction only gives bounds in terms of $p_2(S)$. As in [22], we use the following lemma:

▶ **Lemma 11** ([22], Lemma 3.4). *Any valid BR sequence of length $5nk$ contains a contiguous subsequence S' with $|S'|/(5\log(nk))$ repeating moves (pairs).*

This implies that any $5nk$-length BR sequence S contains a subsequence S' with $p_2(S') \geq |S'|/(5\log(nk))$. Therefore, the probability that all $5nk$-length sequences have improvements in $(0,\epsilon)$ is at most $\sum_{\ell=1}^{5nk} k^n(nk)^\ell(\phi\epsilon)^{\ell/10\log(nk)}$. Setting $\epsilon = \phi^{-1}(2n^2k^3)^{-20k\cdot\log(nk)}$, the probability is at most $1/(nk)^2$. This concludes the general-graph portion of Theorem 5. As above, the details of calculation are omitted.

Performance in Expectation. The performance analysis of BRA in expectation is discussed in the full-version. It is derived as a consequence of the with-high-probability bounds, integrating over the choice of ϵ.

4 Smoothness-Preserving Reduction to Local-Max-Cut and -Bisection

In this section, we refine standard Karp reductions to define *smoothness preserving reductions*, and outline the two reductions of Theorem 2. Recall from Section 2.2 that an algorithm is said to be smoothed-efficient if, on applying independent random perturbations to all inputs of an adversarially chosen instance, the algorithm runs in time polynomial in the input size and inverse perturbation size, with high probability.

▶ **Definition 12** (Strong and Weak Smoothness-Preserving Reductions)**.** *A* weak (randomized) smoothness-preserving reduction *from a search problem $\mathcal{P}$ to problem $\mathcal{Q}$ is defined by poly-time computable functions f_1 and f_2, a full-row-rank, integer, matrix M with polynomially bounded entries, a constant $\eta \geq 1/poly$, and a real probability space $\Omega \subseteq \mathbb{R}^d$; such that the following holds: For any $I = (D, X) \in \mathcal{P}$ and $R \in \Omega$, $J = (f_1(D), \eta M(X \circ R))$ is an instance of $\mathcal{Q}$ whose solutions $\boldsymbol{\sigma}$ map to solutions $f_2(\boldsymbol{\sigma})$ for I. Here, $\circ$ denotes concatenation.*

We require that $|f_1(D)|$, the dimension of R, and the size of M, be polynomial in $|I|$; that the probability density of the entries of R be polynomial in $|I|$ and the density bound on X; and that the entries of R be independently distributed.

If M is a diagonal matrix, then this is a strong *smoothness-preserving reduction.*

The R variables may seem superfluous at first, but are included to ensure that M has full-rank. A key fact to the proof of Lemma 7, the anti-concentration bound at the heart of this paper and previous local-max-cut papers, is the following:

▶ **Proposition 13** ([33])**.** *Let $X \in \mathbb{R}^d$ be a random vector such that the joint probability on any $a \leq d$ coordinates of X is upper-bounded by ϕ^a at all points, and let $M \in \mathbb{R}^{\ell \times d}$ be full-rank, with entries which are multiples of η, for $\ell \leq d$. Then the random variable $Y := MX$ also has bounded joint density $f_Y(y) \leq (\phi/\eta)^\ell$ for all $y \in \mathbb{R}^d$.*

Thus, if the entries of X and R have bounded density, and $|\det(\eta M)| \geq \eta^d$, then the joint distribution on $M(X \circ R)$ has polynomially bounded density. A proof of this statement is provided in the full version of the paper [10].

When M is diagonal, the reduced instance trivially has independent entries, which is sufficient for most smoothed-analysis results to hold. Hence, strong reductions easily extend smoothed efficient algorithms. We conjecture that for many problems, upper-bounding the joint density of the input values suffices for smoothed-efficient algorithms to exist.

▶ **Lemma 14.** *(a) Suppose problem $\mathcal{Q}$ has (quasi-)polynomial smoothed complexity. If $\mathcal{P}$ admits a strong smoothness-preserving reduction to $\mathcal{Q}$, then $\mathcal{P}$ also has (quasi-)polynomial smoothed complexity. (b) If $\mathcal{Q}$ has a smoothed efficient algorithms when the input distribution has joint density bounds as in Proposition 13 and Lemma 7, then if $\mathcal{P}$ admits a weak smoothness-preserving reduction to $\mathcal{Q}$, $\mathcal{P}$ has (quasi-)polynomial smoothed complexity.*

The proof is straightforward modulo technicalities, and is included for completeness in the full version of this paper [10]. It is key that the matrix M has full (row) rank, since this ensures that the joint density on the reduced parameters is sufficiently bounded.

Observe that local-max-cut satisfies the conditions of part (b), since the proofs of [22, 1] simply apply Lemma 7 to the input, similarly to the argument in Section 3. Thus weak reductions to local-max-cut do imply smoothed efficient algorithms. This would not be an interesting notion of reduction if it only held for reductions to max-cut. As mentioned above, we conjecture that many smoothed-analysis results satisfy the conditions for part (b).

As an example, we note that the analyses for the smoothed efficient algorithms for a TSP 2-approximation [21] and for multidimensional bin-packing [28], are robust to this form of input assumption.

The smoothed complexity of local-max-bisection is open, but we believe that the natural local search procedure may admit a similar smoothed analysis to local-max-cut. This would imply a smoothed efficient algorithm for k-NetCoordNash for non-constant k.

4.1 Outline of Reductions

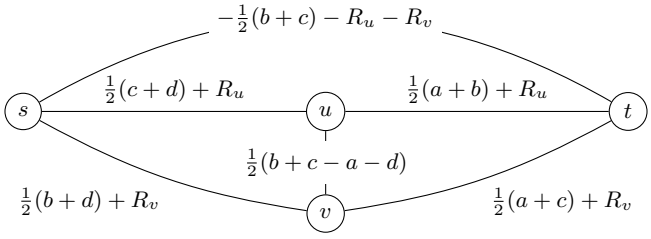
It suffices then, to provide weak smoothness-preserving reductions from NetCoordNash to local-max-cut and -bisection, as stated in Theorem 2. The main technical part involves the construction of M such that its rows are independent, and solutions of the resulting instance map to solutions of the original.

In this writeup, we give only a sketch of the reductions. The formal definitions and rank analyses may be found in the full version of this paper [10]. The reduction from 2-NetCoordNash to local-max-cut will be given first and in more detail, as it is cleaner, and is the basis for the reduction from k-NetCoordNash to local-max-bisection.

2-NetCoordNash reduces to Local-max-cut. Let $G = (V, E)$ be the game graph, with payoff vector A. Construct a weighted cut graph $H = (V', E')$ where $V' = V \cup \{s, t\}$, and $E' = E \cup \bigcup_{u \in V} \{su, ut\}$. We will define edge weights such that (1) every locally maximal cut is an s-t cut, and (2) the value of the cut (S, T) with $s \in S$ and $t \in T$ is equal to the total payoff of the game when $\sigma_u = 1$ if $u \in S$, and 2 if $u \in T$. Thus changing a player's strategy is equivalent to flipping its vertex across the cut. In the reverse direction, local-max-cuts are exactly the local maxima of the game's potential function, and thereby pure NE.

The following figure gives the edge weights for a small 2-player example which achieves the above properties, with the payoff matrix given as follows:

uv game payoffs: $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$



The general construction consists of placing copies of the above gadget on H for every game edge in E, taking the sum of the edge-weights for the su, ut, and st edges.

Observe that the above construction has edge weights which are linear combinations of the payoff values. Furthermore, for all values of R_u and R_v, the cut values are equal to payoff values. The R values are added only to increase the rank of the reduction matrix, and choosing them negative ensures that only s-t cuts are maximal. We show [10] by induction on $|V|$ that the matrix rows are independent, and so the reduction satisfies the necessary conditions. Note that the cut graph is complete if and only if the game graph is.

***k*-NetCoordNash reduces to Local-max-bisection.** The reductions from games with k strategies are not as straightforward. Let $G = (V, E)$ be the game graph with payoff vector A. We construct a weighted cut graph $H = (V', E')$ where $V' = (V \times [k]) \cup \{s_0, s_1, \ldots, s_{n(k-2)}, t\}$, the (player,strategy) pairs, and construct E' as follows: for every node (u, i) and $0 \leq a \leq n(k-2)$, we add an $\{s_a, (u, i)\}$ and $\{(u, i), t\}$ edge; for every $u \in V$

and $i \neq j$, we add a $\{(u,i),(u,j)\}$ edge; and for every $uv \in E$ and $i,j \in [k]$, we add a $\{(u,i),(v,j)\}$ edge. Call a cut (S,T) *valid* if $s_\ell \in S$ for all ℓ, $t \in T$, and S contains exactly one (u,i) node for all $u \in V$. Note that all valid cuts are balanced.

By construction, there is a natural strategy profile associated with each valid cut, namely if node (u,i) is in S then $\sigma_u = i$. We wish to choose edge weights such that (1) all locally maximal bisections are valid, and (2) the cut value is equal to $\Phi(\boldsymbol{\sigma})$. (1) will be achieved by giving low weight to the $\{(u,i),(u,j)\}$ edges, and higher weight to the $\{s_a,(u,i)\}$ edges, using the extra randomness available. This respectively ensures that it is always in our interest to have a small number of $(u,\cdot)$ nodes in S, but not none. As above, we will introduce extra randomness to the edge weights to ensure that M is full-rank. In this case, we will show M is full rank by arguing that it is upper-triangular after basic row operations.

The cut graph is again complete if and only if the game graph is, and thereby we have shown the second part of Theorem 2. The edge weights are not given directly, but are instead found by solving for the total cut values. As it would not be of any value to the reader to be given the values of the edge-weights without the full exposition, the details are left to the full version of this paper [10].

Abstract

Agreement expansion is concerned with set systems for which local assignments to the sets with almost perfect pairwise consistency (i.e., most overlapping pairs of sets agree on their intersections) implies the existence of a global assignment to the ground set (from which the sets are defined) that agrees with most of the local assignments.

It is currently known that if a set system forms a *two-sided* or a *partite* high dimensional expander then agreement expansion is implied. However, it was not known whether agreement expansion can be implied for *one-sided* high dimensional expanders.

In this work we show that agreement expansion can be deduced for one-sided high dimensional expanders assuming that all the vertices' links (i.e., the neighborhoods of the vertices) are agreement expanders. Thus, for one-sided high dimensional expander, an agreement expansion of the large complicated complex can be deduced from agreement expansion of its small simple links.

Using our result, we settle the open question whether the well studied Ramanujan complexes are agreement expanders. These complexes are neither partite nor two-sided high dimensional expanders. However, they are one-sided high dimensional expanders for which their links are partite and hence are agreement expanders. Thus, our result implies that Ramanujan complexes are agreement expanders, answering affirmatively the aforementioned open question.

The local-to-global agreement expansion that we prove is based on the *variance method* that we develop. We show that for a high dimensional expander, if we define a function on its top faces and consider its local averages over the links then the variance of these local averages is much smaller than the global variance of the original function. This decreasing in the variance enables us to construct one global agreement function that ties together all local agreement functions.

1 Introduction

Agreement expansion has been extensively studied. It plays an important role in nearly all PCP constructions, and has found various applications in many recent works (see e.g., [8, 5, 1, 9] and [3]). Previous works could only prove agreement expansion for complexes which are two-sided local spectral expanders or partite one-sided local spectral expanders. However, the question for the general case of one-sided local spectral expanders remained open. In this work we show that all one-sided local spectral expanders are agreement expanders, given that

the local views of their vertices are agreement expanders. In particular, this solves an open question regarding the well studied Ramanujan complexes, which are not two-sided local spectral expanders nor partite, but the local views of their vertices are agreement expanders.

Our main theorem is a local-to-global agreement expansion. We show that agreement expansion of the entire complex can be deduced from agreement expansion of its vertices, i.e., if locally the complex is an agreement expander, then it is also globally expanding. In many cases of high dimensional expanders, the entire complex is a complicated object which is hard to understand, but it is composed of many simple local objects. We show that it is enough to argue regarding the simple local views of the complex, which then implies that the whole complicated complex is also an agreement expander.

The main theorem that we prove is based on the *variance method* that we develop. We show that for one-sided local spectral expanders, the variance of any function decreases as we go down the dimensions. Namely, if we define a function on the top faces of the complex and consider its local averages over the links then the variance of these local averages is much smaller than the global variance of the original function. This decreasing in variance enables us to construct a single global function that stitches together all the local agreement functions.

Agreement tests

Let S a collection of subsets over some ground set V. A *local assignment* is a collection of functions $f = \{f_\sigma\}_{\sigma\in S}$, where each f_σ is a function that specifies a $0,1$ value for each $u \in \sigma$. Any f_σ is local in the sense that it gives values only to the elements in σ, independently of the rest of the functions and the ground set. A *global assignment* is a single function $g : V \to \{0,1\}$ which specifices a value for every vertex in the ground set. We say that a local assignment $f = \{f_\sigma\}$ comes from a global assignment g, if for every $\sigma \in S$ it holds that $f_\sigma = g\big|_\sigma$, i.e., f_σ is just the restriction of g to σ.

Denote by $\mathcal{G}$ the set of all global assignments. An agreement test is specified by a distribution $\mathcal{D}$ on tuples $(\tau, \sigma_1, \sigma_2)$ such that $\sigma_1, \sigma_2 \in S$ and $\tau \subseteq \sigma_1 \cap \sigma_2$. The test picks τ, σ_1, σ_2 according to $\mathcal{D}$ and accepts if f_{σ_1} and f_{σ_2} agree on τ, i.e., if for every $u \in \tau$, $f_{\sigma_1}(\tau) = f_{\sigma_2}(\tau)$.[1] We denote the acceptance probability of the test by

$$\text{agree}_{\mathcal{D}}(f) = \Pr_{\tau,\sigma_1,\sigma_2\sim\mathcal{D}}[f_{\sigma_1}\big|_\tau = f_{\sigma_2}\big|_\tau].$$

It is easy to see that if a local assignment comes from a global assignment then the test accepts with probability 1. Denote by $\text{dist}(f, g)$ the fraction of $\sigma \in S$ for which $f_\sigma \neq g\big|_\sigma$. An agreement theorem states that if $\text{agree}_{\mathcal{D}}(f) \geq 1 - \varepsilon$ then f is $1 - O(\varepsilon)$ close to a global assignment, i.e., there exists a global assignment $g \in \mathcal{G}$ such that $\text{dist}(f, g) \leq O(\varepsilon)$. In other words, an agreement theorem guarantees that the agreement test provides a good approximation for the distance of a local assignment from the global assignments.

High dimensional expanders

A d-dimensional simplicial complex X is a $(d+1)$-hypergraph which is closed under containment: For any $(d+1)$-hyperedge σ in X, all of its subsets $\tau \subset \sigma$ also belong to X. A hyperedge σ is also called a face of the complex, and its dimension is $|\sigma| - 1$. The set of all k-dimensional faces of the complex is denoted by $X(k)$.

[1] A weaker notion of an agreement test, which we do not discuss in this paper, is concerned with an *approximate* global consistency, i.e., that f_σ agrees with $g\big|_\sigma$ on most of the elements in σ.

For any face $\sigma \in X$, its *link* is the subcomplex obtained by all the faces in X which contain σ after removing σ from all of them, and denoted by $X_\sigma = \{\tau \setminus \sigma \mid \sigma \subseteq \tau \in X\}$. Note that if X is of dimension d then X_σ is of dimension $d - |\sigma|$.

▶ **Definition 1.1** (Partite complex). *A d-dimensional complex X is called* partite *if its vertices can be partitioned into $d+1$ sets $X(0) = V_1 \cup V_2 \cup \cdots \cup V_{d+1}$ such that any d-dimensional face $\sigma \in X(d)$ contains a vertex from each V_i, i.e., $|\sigma \cap V_i| = 1$.*

In recent years, several distinct notions of high dimensional expansion have been studied. For a detailed survey regarding high dimensional expanders we refer the reader to [10]. In this work we focus on the spectral expansion of the links of the complex.

▶ **Definition 1.2** (Local spectral expansion). *A d-dimensional complex X is called a* λ-one-sided local spectral expander *(or* λ-two-sided local spectral expander*) if for every $-1 \leq k \leq d-2$ and every $\sigma \in X(k)$, the underlying graph[2] of X_σ is a λ-one-sided spectral expander (or λ-two-sided spectral expander, respectively).*

High dimensional expanders and agreement expansion

The work of [4] initiated the relation of high dimensional expanders to agreement tests. We follow their definition of *agreement expansion*.

▶ **Definition 1.3** (Agreement expansion). *A d-dimensional complex X is called a* c-agreement expander for dimension k *if there exists a distribution $\mathcal{D}$ such that for every local assignment $f = \{f_\sigma\}_{\sigma \in X(k)}$ there exists a global agreement function $g \in \mathcal{G}$ such that*

$$\mathrm{dist}(f, g) \leq c \cdot \mathrm{disagree}_{\mathcal{D}}(f),$$

where $\mathrm{disagree}_{\mathcal{D}}(f) = 1 - \mathrm{agree}_{\mathcal{D}}(f)$ is the rejection probability of the test.

The name "agreement expansion" comes from its similarity to other expansion measures, since X is an agreement expander if and only if

$$\min_f \frac{\mathrm{disagree}_{\mathcal{D}}(f)}{\mathrm{dist}(f, \mathcal{G})} \geq \frac{1}{c},$$

where the minimum is taken over all local assignments that do not come from a global assignment.

In [6], the authors prove that there exists a constant $c > 0$ such that the d-dimensional *complete complex*, which is the complex that contains all possible sets of size $\leq d+1$, is a c-agreement expander for its top dimension. Building on [6], [4] show that there exists a constant $c > 0$ such that a d-dimensional two-sided local spectral expander is a c-agreement expander *for dimension* $k = O(\sqrt{d})$. Their proof goes by a reduction to the complete complex, and therefore they could not prove agreement expansion for the top dimension of the complex, but only for some lower dimension.

In a recent work, Dikstein and Dinur [2] prove that there exists a constant $c > 0$ such that a d-dimensional two-sided local spectral expander or a partite one-sided local spectral expander are c-agreement expanders *for their top dimension*. However, the general question for one-sided local spectral expanders remained open.

[2] The graph whose vertices are $X_\sigma(0)$ and its edges are $X_\sigma(1)$.

Our main theorem in this work is that agreement expansion of a complex can be deduced from the agreement expansion of the links of its vertices. In particular, for any constant $c > 0$ there exists a constant $c' > 0$ *which is dependent only on* c such that a d-dimensional one-sided local spectral expander is a c'-agreement expander *for its top dimension*, given that the links of its vertices are c-agreement expanders for their top dimension.

▶ **Theorem 1.4** (Main Theorem, informal)**.** *For any constant $c > 0$ there exists a constant $c' = c'(c)$ such that if the links of the vertices of a one-sided local spectral expander are c-agreement expanders for their top dimension, then the entire complex is a c'-agreement expander for its top dimension. Moreover, the global agreement function that agrees with most of the local functions is defined by majority decoding.*

Our result extends [2] to general one-sided local expanders, which are not necessarily partite. Moreover, the result of [2] ensures that if the agreement test accepts with probability $1-\varepsilon$ then there exists *some global function* that agrees with $1-c\varepsilon$ of the local functions. The global function that [2] construct is not necessarily the majority function, but rather some conditional majority. We show here that the *majority function* agrees with $1-c'\varepsilon$ of the local functions, *regardless* of which functions agree with the local functions on each vertex. Our proof technique can be used for two-sided local spectral expanders and for partite one-sided local spectral expanders as well: As a first step use [2] to construct a local agreement function for each vertex, and then by our work conclude that the majority function agrees with most of these local agreement functions.

▶ **Corollary 1.5.** *There exists a constant $c > 0$ such that any d-dimensional two-sided local spectral expander and any d-dimensional partite one-sided local spectral expander is a c-agreement expander for its top dimension, where the global agreement function is defined by majority decoding.*

Ramanujan complexes

Much of the motivation for the study of high dimensional expanders comes from the existence of Ramanujan complexes, whose properties are optimal in almost every measure. Ramanujan complexes are the high dimensional analogs of the celebrated LPS Ramanujan graphs [11], which arise from number theory. In [12] the authors describe an explicit construction of a family of bounded degree Ramanujan complexes, i.e., every vertex is contained in a bounded number of faces. Thus, the number of d-dimensional faces in these complexes is linear in the number of vertices.

Ramanujan complexes are known to be one-sided local spectral expanders [7], and their links are also partite. However, Ramanujan complexes are not two-sided local spectral expanders nor partite, so previous works could not show that they are agreement expanders. As a corollary of our theorem, we settle this open question.

▶ **Corollary 1.6.** *There exists a constant $c > 0$ such that Ramanujan complexes are c-agreement expanders for their top dimension.*

The variance method

Our local-to-global agreement theorem is based on the *variance method*. The decreasing in variance idea has first appeared in [4], where the authors proved that in high dimensional expanders, the difference of variances of a function on successive dimensions is decreasing. The authors in [4] proved it *only for two-sided* local spectral expanders, and used it just for

the single purpose of showing that random walks on high dimensional expanders have an optimal convergence rate. We extend their work and show that the same holds for *one-sided* local spectral expanders as well. In addition, we show the general statement that the variance of any function on the top faces of a high dimensional expander decreases by a factor of d when considered on the vertices.

▶ **Theorem 1.7** (The variance method, informal). *Let X be a d-dimensional one-sided local spectral expander. For any function $h : X(d) \to \mathbb{R}$,*

$$\operatorname*{Var}_{u\in X(0)} \operatorname*{\mathbb{E}}_{\sigma\in X_u(d-1)} h(u\sigma) \leq O\left(\frac{1}{d}\right) \operatorname*{Var}_{\sigma\in X(d)} h(\sigma).$$

The small variance is important in order to get a global function that agrees with $1 - O(\varepsilon)$ of the local functions. Recall that we are given a local assignment $f = \{f_\sigma\}$ and a probability distribution $\mathcal{D}$ such that $\text{disagree}_{\mathcal{D}}(f) \leq \varepsilon$ and our goal is to construct a global function g such that $\text{dist}(f, g) \leq O(\varepsilon)$. By a simple union bound argument, it is easy to get $\text{dist}(f, g) \leq O(d\varepsilon)$. In order to get an agreement which is not dependent on d, we must bound the probability of the bad events by $O(\varepsilon/d)$ and then by a union bound to get an agreement of $O(\varepsilon)$. Using the variance method, we can show that the variance on the vertices decreases by a factor of d, and thus the bad events happen with a probability bounded by $O(\varepsilon/d)$. We believe that this method will find many more applications in the future.

Organization

In Section 2 we provide some required preliminaries regarding expander graphs and high dimensional expanders. In Section 3 we introduce the variance method. In Section 4 we prove our main theorem.

2 Preliminaries

2.1 Expander graphs

Let $G = (V, E)$ be a graph with positive weights on the edges $w : E \to \mathbb{R}_{>0}$. Assume without loss of generality that the sum of the weights is 1 (otherwise just normalize), i.e., w is a probability distribution on the edges. These weights induce a probability distribution on the vertices as well, where the probability of a vertex $u \in V$ is given by $\frac{1}{2}\sum_{e\ni u} w(e)$. All the following probabilities are taken according to these distributions.

For any two functions $h, h' : E \to \mathbb{R}$, we define their inner product by

$$\langle h, h'\rangle = \sum_{e\in E} w(e)h(e)h'(e) = \operatorname*{\mathbb{E}}_{e\in E} h(e)h'(e).$$

Similarly, for any two functions $g, g' : V \to \mathbb{R}$, their inner product is defined by

$$\langle g, g'\rangle = \operatorname*{\mathbb{E}}_{u\in V} g(u)g'(u).$$

The adjacency operator $A = A(G) : \mathbb{R}^V \to \mathbb{R}^V$ is defined by $Ag(u) = \mathbb{E}_{uv|u}\, g(v)$, where $uv|u$ denotes the event that the edge $\{u, v\}$ was chosen given that the vertex u was chosen.

Denote the eigenvalues of the adjacency operator of G by $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{|V|}$. It is easy to see that $\lambda_1 = 1$ (with corresponding eigenfunction $\mathbf{1}$) and that $\lambda_{|V|} \geq -1$. Let $0 < \lambda < 1$ be a positive constant. The graph G is said to be a λ-*one-sided spectral expander* if $\lambda_2 \leq \lambda$, and G is said to be a λ-*two-sided spectral expander* if both $\lambda_2 \leq \lambda$ and $\lambda_{|V|} \geq -\lambda$.

2.2 High dimensional expanders

Recall that a d-dimensional simplicial complex X is a $(d+1)$-hypergraph which is closed under containment. Throughout the paper we refer to the probability of choosing a face of the complex, which is given by the following probabilistic process. Consider the random sequence of faces $\sigma_d \supset \sigma_{d-1} \supset \cdots \supset \sigma_0 \supset \emptyset$, where $\sigma_d \in X(d)$ is chosen uniformly at random, and then for each $k = d-1, \cdots, 0$, σ_k is chosen by removing a uniformly random vertex from σ_{k+1}. For any $\sigma \in X(k)$, we denote the probability of choosing σ by

$$\Pr[\sigma] = \Pr[\sigma_d \supset \sigma_{d-1} \supset \cdots \supset \sigma_0 \supset \emptyset \mid \sigma_k = \sigma].$$

For any $-1 \leq k < d$ and a face $\sigma \in X(k)$, its *link* is the $(d-k-1)$-dimensional complex defined by $X_\sigma = \{\tau \setminus \sigma \mid \sigma \subseteq \tau \in X\}$. The probability of choosing a face $\tau \in X_\sigma$ is given by $\Pr[\tau \in X_\sigma] = \Pr[\tau \cup \sigma \mid \sigma_k = \sigma]$.

For the agreement test, we use the $\mathcal{D}_{d,\ell}$ distribution as defined in [2].

▶ **Definition 2.1** (The $\mathcal{D}_{d,\ell}$ distribution)**.** *Let X be a d-dimensional simplicial complex and $\ell < d$ be a positive integer. The $\mathcal{D}_{d,\ell}$ distribution is defined by the following random process:*

1. *Choose $\tau \in X(\ell)$ at random.*
2. *Choose $\sigma_1, \sigma_2 \in X_\tau(d-\ell-1)$ independently at random.*

The tuple that is then returned is $(\tau, \tau \cup \sigma_1, \tau \cup \sigma_2)$.

3 The Variance Method

We show in this section that for one-sided local spectral expanders, the variance of any function decreases as we go down the dimensions of the complex. We first bound the variance in one-sided spectral expander graphs, and then show how to use this bound in order to bound the variance on functions of a complex.

3.1 Bounding the variance in expander graphs

Let $G = (V, E)$ be a weighted graph. Recall that the adjacency operator $A : \mathbb{R}^V \to \mathbb{R}^V$ is defined by $Ag(u) = \mathbb{E}_{uv|u}\, g(v)$. We define the following two additional averaging operators:

- $A^\downarrow : \mathbb{R}^E \to \mathbb{R}^V$ defined by $A^\downarrow h(u) = \mathbb{E}_{e|u}\, h(e)$.
- $A^\uparrow : \mathbb{R}^V \to \mathbb{R}^E$ defined by $A^\uparrow g(e) = \mathbb{E}_{u|e}\, g(u)$.

The following properties are pretty standard.

(1) $A^\downarrow$ and $A^\uparrow$ are adjoint to each other, i.e., for any two vectors $h \in \mathbb{R}^E, g \in \mathbb{R}^V$,

$$\langle A^\downarrow h, g\rangle = \mathop{\mathbb{E}}_{u} \mathop{\mathbb{E}}_{e|u} h(e)g(u) = \mathop{\mathbb{E}}_{e} \mathop{\mathbb{E}}_{u|e} h(e)g(u) = \langle h, A^\uparrow g\rangle.$$

(2) Denote by $\lambda_2(A^\downarrow A^\uparrow)$ and $\lambda_2(A)$ the second largest eigenvalues of $A^\downarrow A^\uparrow$ and A correspondingly. It is easy to check that $A^\downarrow A^\uparrow = (A + I)/2$, where I is the identity operator. Thus,

$$\lambda_2(A^\downarrow A^\uparrow) = \frac{1 + \lambda_2(A)}{2}.$$

(3) $A^\uparrow A^\downarrow$ and $A^\downarrow A^\uparrow$ have the same non-zero eigenvalues. In particular, $\lambda_2(A^\uparrow A^\downarrow) = \lambda_2(A^\downarrow A^\uparrow)$.

(4) By Rayleigh quotient

$$\lambda_2(A^{\uparrow}A^{\downarrow}) = \max_{\substack{h:E\to\mathbb{R}\\ h\perp\mathbf{1}}} \frac{\langle A^{\uparrow}A^{\downarrow}h, h\rangle}{\|h\|^2}.$$

We will use the following lemma, which is immediate from the aforementioned properties.

▶ **Lemma 3.1.** *Let $G=(V,E)$ be a λ-one-sided spectral expander graph. For any function $h: E\to\mathbb{R}$ such that $h\perp\mathbf{1}$ it holds that*

$$\left\|A^{\downarrow}h\right\|^2 \le \frac{1+\lambda}{2}\|h\|^2.$$

Proof. It follows immediately from the properties mentioned above, since

$$\left\|A^{\downarrow}h\right\|^2 = \langle A^{\downarrow}h, A^{\downarrow}h\rangle = \langle A^{\uparrow}A^{\downarrow}h, h\rangle \le \lambda_2(A^{\uparrow}A^{\downarrow})\|h\|^2 = \lambda_2(A^{\downarrow}A^{\uparrow})\|h\|^2 = \frac{1+\lambda_2(A)}{2}\|h\|^2,$$

where we used properties (1), (4), (3) and (2) in that order. ◀

We can now bound the variance of any function on the edges of the graph.

▶ **Lemma 3.2.** *Let $G=(V,E)$ be a λ-one-sided spectral expander graph. For any function $h: E\to\mathbb{R}$ it holds that*

$$\mathop{\mathbb{E}}_{u}\mathop{\mathrm{Var}}_{e|u} h(e) \ge \frac{1-\lambda}{1+\lambda}\mathop{\mathrm{Var}}_{u}\mathop{\mathbb{E}}_{e|u} h(e).$$

Proof. Assume without loss of generality that $\mathbb{E}_e h(e)=0$ (otherwise, define $h'=h-\mathbb{E}_e h(e)$ and continue with h'). Now, note that

$$\mathop{\mathrm{Var}}_{u}\mathop{\mathbb{E}}_{e|u} h(e) = \mathop{\mathbb{E}}_{u}\left(\mathop{\mathbb{E}}_{e|u} h(e)\right)^2 = \left\|A^{\downarrow}h\right\|^2. \tag{1}$$

Note also that

$$\mathop{\mathbb{E}}_{u}\mathop{\mathrm{Var}}_{e|u} h(e) = \mathop{\mathbb{E}}_{u}\left(\mathop{\mathbb{E}}_{e|u} h(e)^2 - \left(\mathop{\mathbb{E}}_{e|u} h(e)\right)^2\right) = \mathop{\mathbb{E}}_{e} h(e)^2 - \mathop{\mathbb{E}}_{u}\left(\mathop{\mathbb{E}}_{e|u} h(e)\right)^2 = \|h\|^2 - \left\|A^{\downarrow}h\right\|^2. \tag{2}$$

Since $\mathbb{E}_e h(e)=0$, by lemma 3.1 we have that

$$\|h\|^2 \ge \frac{2}{1+\lambda}\left\|A^{\downarrow}h\right\|^2. \tag{3}$$

Combining (1), (2) in (3) finishes the proof. ◀

3.2 Bounding the variance in one-sided local spectral expanders

The following lemma follows immediately from lemma 3.2.

▶ **Lemma 3.3.** *Let X be a d-dimensional λ-one-sided local spectral expander. For any $1\le k\le d$ and a function $h: X(k)\to\mathbb{R}$ it holds that*

$$\mathop{\mathbb{E}}_{\sigma\in X(k-1)}\mathop{\mathrm{Var}}_{u\in X_\sigma(0)} h(\sigma u) \ge \frac{1-\lambda}{1+\lambda}\mathop{\mathbb{E}}_{\sigma\in X(k-2)}\mathop{\mathrm{Var}}_{u\in X_\sigma(0)}\mathop{\mathbb{E}}_{v\in X_{\sigma u}(0)} h(\sigma uv).$$

Proof. By definition, for every $\sigma \in X(k-2)$, the underlying graph of X_σ is a λ-one-sided spectral expander. Thus, by lemma 3.2,

$$\mathop{\mathbb{E}}_{u\in X_\sigma(0)} \mathop{\mathrm{Var}}_{v\in X_{\sigma u}(0)} h(\sigma uv) \geq \frac{1-\lambda}{1+\lambda} \mathop{\mathrm{Var}}_{u\in X_\sigma(0)} \mathop{\mathbb{E}}_{v\in X_{\sigma u}(0)} h(\sigma uv).$$

Averaging over all $\sigma \in X(k-2)$ finishes the proof. ◀

We can now prove the following two lemmas for one-sided local spectral expanders.

▶ **Lemma 3.4.** *Let X be a $(d-1)$-dimensional λ-one-sided local spectral expander, where $d \geq k\cdot\ell$ for $k \geq 2$, $\ell \geq 1$. If $\lambda \leq 1/2d$ then for any function $h : X(d-1) \to \mathbb{R}$,*

$$\mathop{\mathrm{Var}}_{\sigma\in X(d-1)} h(\sigma) \leq \frac{k+2}{k-1} \mathop{\mathbb{E}}_{\tau\in X(\ell-1)} \mathop{\mathrm{Var}}_{\sigma\in X_\tau(d-\ell-1)} h(\tau\sigma).$$

Proof. Note that

$$\begin{aligned}
\mathop{\mathrm{Var}}_{\sigma\in X(d-1)} h(\sigma) &= \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)^2 - \Big(\mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Big)^2 \\
&= \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)^2 - \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-1}}\Big(\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Big)^2 + \\
&\quad \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-1}}\Big(\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Big)^2 - \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-2}}\Big(\mathop{\mathbb{E}}_{u_{d-1}}\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Big)^2 + \cdots \\
&\quad \cdots + \mathop{\mathbb{E}}_{u_1}\Big(\mathop{\mathbb{E}}_{u_2}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Big)^2 - \Big(\mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Big)^2 \qquad (4) \\
&= \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-1}}\mathop{\mathrm{Var}}_{u_d} h(u_1\cdots u_d) + \\
&\quad \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-2}}\mathop{\mathrm{Var}}_{u_{d-1}}\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d) + \cdots \\
&\quad \cdots + \mathop{\mathrm{Var}}_{u_1}\mathop{\mathbb{E}}_{u_2}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d),
\end{aligned}$$

where the second equality follows by a telescoping sum argument. Similarly,

$$\begin{aligned}
\mathop{\mathbb{E}}_{\tau\in X(\ell-1)}\mathop{\mathrm{Var}}_{\sigma\in X_\tau(d-\ell-1)} h(\tau\sigma) &= \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-1}}\mathop{\mathrm{Var}}_{u_d} h(u_1\cdots u_d) + \\
&\quad \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{d-2}}\mathop{\mathrm{Var}}_{u_{d-1}}\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d) + \cdots \\
&\quad \cdots + \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_\ell}\mathop{\mathrm{Var}}_{u_{\ell+1}}\mathop{\mathbb{E}}_{u_{\ell+2}}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d).
\end{aligned}$$

For any $1 \leq i \leq k-1$, invoking lemma 3.3 $i\cdot\ell$ times on each of the last ℓ summands of (4) yields

$$\begin{aligned}
&\mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{\ell-1}}\mathop{\mathrm{Var}}_{u_\ell}\mathop{\mathbb{E}}_{u_{\ell+1}}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d) + \cdots + \mathop{\mathrm{Var}}_{u_1}\mathop{\mathbb{E}}_{u_2}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d) \\
&\quad \leq \Big(\frac{1+\lambda}{1-\lambda}\Big)^{i\ell}\Bigg(\mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{(i+1)\ell-1}}\mathop{\mathrm{Var}}_{u_{(i+1)\ell}}\mathop{\mathbb{E}}_{u_{(i+1)\ell+1}}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d) + \cdots \\
&\qquad\qquad \cdots + \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{i\ell}}\mathop{\mathrm{Var}}_{u_{i\ell+1}}\mathop{\mathbb{E}}_{u_{i\ell+2}}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Bigg) \\
&\quad \leq e\Bigg(\mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{(i+1)\ell-1}}\mathop{\mathrm{Var}}_{u_{(i+1)\ell}}\mathop{\mathbb{E}}_{u_{(i+1)\ell+1}}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d) + \cdots \\
&\qquad\qquad \cdots + \mathop{\mathbb{E}}_{u_1}\cdots\mathop{\mathbb{E}}_{u_{i\ell}}\mathop{\mathrm{Var}}_{u_{i\ell+1}}\mathop{\mathbb{E}}_{u_{i\ell+2}}\cdots\mathop{\mathbb{E}}_{u_d} h(u_1\cdots u_d)\Bigg),
\end{aligned}$$

where the last inequality follows since $i \cdot \ell \leq d-1$ and $\lambda \leq 1/2d$. Thus, by invoking lemma 3.3 $i \cdot \ell$ times on the last ℓ summands of (4) for $i = 1, \ldots, k-1$ we get

$$(k-1) \operatorname*{Var}_{\sigma \in X(d-1)} h(\sigma) \leq (k-1+e) \operatorname*{\mathbb{E}}_{\tau \in X(\ell-1)} \operatorname*{Var}_{\sigma \in X_\tau(d-\ell-1)} h(\tau\sigma),$$

which finishes the proof. ◀

▶ **Lemma 3.5.** *Let X be a d-dimensional λ-one-sided local spectral expander. If $\lambda \leq 1/(2d+1)$ then for any function $h : X(\ell) \to \mathbb{R}$, $\ell \leq d$,*

$$\operatorname*{Var}_{u \in X(0)} \operatorname*{\mathbb{E}}_{\sigma \in X_u(\ell-1)} h(u\sigma) \leq \frac{8}{5\ell} \operatorname*{Var}_{\sigma \in X(\ell)} h(\sigma).$$

Proof. Note that

$$\begin{aligned} \operatorname*{Var}_{\sigma \in X(\ell)} h(\sigma) = \operatorname*{\mathbb{E}}_{u_1} \cdots \operatorname*{\mathbb{E}}_{u_\ell} \operatorname*{Var}_{u_{\ell+1}} h(u_1 \cdots u_{\ell+1}) + \\ \operatorname*{\mathbb{E}}_{u_1} \cdots \operatorname*{\mathbb{E}}_{u_{\ell-1}} \operatorname*{Var}_{u_\ell} \operatorname*{\mathbb{E}}_{u_{\ell+1}} h(u_1 \cdots u_{\ell+1}) + \cdots \\ \cdots + \operatorname*{Var}_{u_1} \operatorname*{\mathbb{E}}_{u_2} \cdots \operatorname*{\mathbb{E}}_{u_{\ell+1}} h(u_1 \cdots u_{\ell+1}). \end{aligned} \tag{5}$$

By invoking lemma 3.3 on each summand of (5), where on the ith summand we invoke it $i-1$ times, we get

$$\operatorname*{Var}_{\sigma \in X(\ell)} h(\sigma) \geq \sum_{i=0}^{\ell} \left(\frac{1-\lambda}{1+\lambda}\right)^i \operatorname*{Var}_{u \in X(0)} \operatorname*{\mathbb{E}}_{\sigma \in X_u(\ell-1)} h(u\sigma) \geq \ell(1-e^{-1}) \operatorname*{Var}_{u \in X(0)} \operatorname*{\mathbb{E}}_{\sigma \in X_u(\ell-1)} h(u\sigma),$$

where the last inequality follows since $\lambda \leq 1/(2d+1)$. ◀

▶ **Corollary 3.6.** *By the assumptions of lemma 3.5, if the range of h is $[0,1]$ then*

$$\operatorname*{Var}_{u \in X(0)} \operatorname*{\mathbb{E}}_{\sigma \in X_u(\ell-1)} h(u\sigma) \leq \frac{8}{5\ell} \operatorname*{\mathbb{E}}_{\sigma \in X(\ell)} h(\sigma).$$

Proof. It follows immediately since for h with range in $[0,1]$, $\operatorname{Var}_{\sigma \in X(\ell)} h(\sigma) \leq \mathbb{E}_{\sigma \in X(\ell)} h(\sigma)$. ◀

4 Local-to-Global Agreement Expansion

In this section we state and prove our main theorem.

▶ **Theorem 4.1** (Main Theorem). *For any constant $c > 0$ and two natural numbers $d > \ell \geq 2$ such that $\ell = \Theta(d)$, there exists a constant $c' = c'(c, d/\ell)$ such that the following holds. Let X be a d-dimensional λ-one-sided local spectral expander, $\lambda \leq 1/(2d+1)$. If for every vertex $v \in X(0)$, the link X_v is a c-agreement expander with regard to the $\mathcal{D}_{d-1,\ell-1}$ distribution, then X is a c'-agreement expander with regard to the $\mathcal{D}_{d,\ell}$ distribution. Moreover, the global agreement function is defined by majority decoding.*

The general idea will be to decompose the global agreement probability to local agreements in the links, and to show that with high probability the local functions agree with the global majority function.

Let $f = \{f_\sigma\}_{\sigma \in X(d)}$. Define the majority function $\mathrm{maj} : X(0) \to \{0,1\}$ by

$$\mathrm{maj}(v) = \operatorname*{arg\,max}_{\alpha \in \{0,1\}} \left\{ \Pr_{\sigma \in X_v(d-1)} [f_{v\sigma}(v) = \alpha] \right\}.$$

Denote by $\varepsilon = \mathrm{disagree}(f)$. The proof will follow from the following claims.

▷ Claim 4.2. $\mathop{\mathbb{E}}_{v\in X(0)}\Pr_{\sigma\in X_v(d-1)}[f_{v\sigma}(v)\neq \mathrm{maj}(v)] \le 2\Big(1+\frac{3}{d/\ell-1}\Big)\varepsilon.$

▷ Claim 4.3. $\mathop{\mathbb{E}}_{v\in X(0)}\Pr_{\sigma\in X_v(d-1)}\big[g_v\big|_\sigma \neq \mathrm{maj}\big|_\sigma\big] \le 120\Big(\frac{2d}{\ell}c^2+2c+1+\frac{3}{d/\ell-1}\Big)\varepsilon,$

where $g_v : X_v(0)\to\{0,1\}$ is the function promised by the c-agreement expansion of X_v.

Proof of Main Theorem. Consider a vertex $v\in X(0)$ and a top face in its link $\sigma\in X_v(d-1)$. Note that if the following three events happen then $f_{v\sigma}$ agrees with $\mathrm{maj}\big|_{v\sigma}$:
(1) $f_{v\sigma}(v)=\mathrm{maj}(v)$,
(2) $f_{v\sigma}\big|_\sigma = g_v\big|_\sigma$,
(3) $g_v\big|_\sigma = \mathrm{maj}\big|_\sigma$.
Therefore,

$$\begin{aligned}
\Pr_{\sigma\in X(d)}[f_\sigma\neq\mathrm{maj}\big|_\sigma] &= \mathop{\mathbb{E}}_{v\in X(0)}\Pr_{\sigma\in X_v(d-1)}[f_{v\sigma}\big|_{v\sigma}\neq\mathrm{maj}\big|_{v\sigma}]\\
&\le \mathop{\mathbb{E}}_{v\in X(0)}\Big(\Pr_{\sigma\in X_v(d-1)}[f_{v\sigma}(v)\neq\mathrm{maj}(v)]+\\
&\qquad\Pr_{\sigma\in X_v(d-1)}[f_{v\sigma}\big|_\sigma\neq g_v\big|_\sigma]+\\
&\qquad\Pr_{\sigma\in X_v(d-1)}[g_v\big|_\sigma\neq\mathrm{maj}\big|_\sigma]\Big)\\
&\le 2\Big(1+\frac{3}{d/\ell-1}\Big)\varepsilon + c\varepsilon + 120\Big(\frac{2d}{\ell}c^2+2c+1+\frac{3}{d/\ell-1}\Big)\varepsilon\\
&= \Big(\frac{240d}{\ell}c^2+241c+122+\frac{366}{d/\ell-1}\Big)\varepsilon,
\end{aligned}$$

where the second inequality follows by claims 4.2 and 4.3, and by the c-agreement expansion of the link of every vertex in the complex. Finally, the theorem follows since $d/l=\Theta(1)$. ◀

4.1 Proofs of Claims 4.2 and 4.3

Proof of Claim 4.2. The idea of the proof is by the variance method, as follows. For any vertex $v\in X(0)$ we consider the indicator function on the d-faces whether a local function f_σ agrees with the majority on v. We note that the global variance of this function indicates the disagreement probability of two d-faces on v, and the average over $\tau\in X_v(\ell-1)$ of local variances indicates the disagreement probability of two d-faces on v *with intersection of size at least* ℓ. Since $\ell=\Theta(d)$ we conclude by the variance method that these two distributions are approximately equal. Details follow.

Let $v\in X(0)$. Define the indicator function $h_v : X_v(d-1)\to\{0,1\}$ by

$$h_v(\sigma)=\begin{cases}1 & f_{v\sigma}(v)\neq\mathrm{maj}(v),\\ 0 & f_{v\sigma}(v)=\mathrm{maj}(v).\end{cases}$$

By definition, $\mathbb{E}_{\sigma\in X_v(d-1)}h_v(\sigma)\le 1/2$. Thus,

$$\mathop{\mathbb{E}}_{\sigma\in X_v(d-1)}h_v(\sigma) \le 2\mathop{\mathbb{E}}_{\sigma\in X_v(d-1)}h_v(\sigma)\left(1-\mathop{\mathbb{E}}_{\sigma\in X_v(d-1)}h_v(\sigma)\right). \tag{6}$$

Since h_v is an indicator function

$$\mathop{\mathbb{E}}_{\sigma\in X_v(d-1)}h_v(\sigma)\left(1-\mathop{\mathbb{E}}_{\sigma\in X_v(d-1)}h_v(\sigma)\right) = \mathop{\mathrm{Var}}_{\sigma\in X_v(d-1)}h_v(\sigma). \tag{7}$$

Since X is a λ-one-sided local spectral expander, by lemma 3.4

$$\operatorname*{Var}_{\sigma\in X_v(d-1)} h_v(\sigma) \le \frac{d+2\ell}{d-\ell} \operatorname*{\mathbb{E}}_{\tau\in X_v(\ell-1)} \operatorname*{Var}_{\sigma\in X_{v\tau}(d-\ell-1)} h_v(\tau\sigma). \tag{8}$$

Again, since h_v is an indicator function

$$\operatorname*{Var}_{\sigma\in X_{v\tau}(d-\ell-1)} h_v(\tau\sigma) = \operatorname*{\mathbb{E}}_{\sigma\in X_{v\tau}(d-\ell-1)} h_v(\tau\sigma)\left(1 - \operatorname*{\mathbb{E}}_{\sigma\in X_{v\tau}(d-\ell-1)} h_v(\tau\sigma)\right). \tag{9}$$

Combining (6), (7), (8) and (9) yields

$$\operatorname*{Pr}_{\sigma\in X_v(d-1)}[f_{v\sigma}(v)\neq \mathrm{maj}(v)] \le$$
$$2\frac{d+2\ell}{d-\ell} \operatorname*{\mathbb{E}}_{\tau\in X_v(\ell-1)} \operatorname*{Pr}_{\sigma_1,\sigma_2\in X_{v\tau}(d-\ell-1)}[f_{v\tau\sigma_1}(v)\neq \mathrm{maj}(v)\wedge f_{v\tau\sigma_2}(v)=\mathrm{maj}(v)].$$

Finally, since $f_{v\tau\sigma_1}(v)\neq \mathrm{maj}(v)\wedge f_{v\tau\sigma_2}(v)=\mathrm{maj}(v)$ implies that $f_{v\tau\sigma_1}\big|_{v\tau} \neq f_{v\tau\sigma_2}\big|_{v\tau}$, we can conclude that

$$\begin{aligned}\operatorname*{\mathbb{E}}_{v\in X(0)} \operatorname*{Pr}_{\sigma\in X_v(d-1)}[f_{v\sigma}(v)\neq \mathrm{maj}(v)] &\le 2\frac{d+2\ell}{d-\ell} \operatorname*{\mathbb{E}}_{\tau\in X(\ell)} \operatorname*{Pr}_{\sigma_1,\sigma_2\in X_\tau(d-\ell-1)}[f_{\tau\sigma_1}\big|_\tau \neq f_{\tau\sigma_2}\big|_\tau]\\ &\le 2\Big(1+\frac{3}{d/\ell-1}\Big)\varepsilon.\end{aligned}$$

◁

Before proving Claim 4.3, let us define the following set of "bad neighbors". For any vertex $u\in X(0)$, by the agreement expansion of X_u, there exists a function $g_u : X_u(0)\to\{0,1\}$ that agrees with most of the top faces on u. We say that $v\in X_u(0)$ is a bad neighbor of u if g_u disagrees with many top faces that contain v:

$$B_u = \left\{ v\in X_u(0) \;\middle|\; \operatorname*{Pr}_{\sigma\in X_{uv}(d-2)}[f_{uv\sigma}\big|_{v\sigma}\neq g_u\big|_{v\sigma}] > \frac{3}{10}\right\}.$$

We will use the following two claims, which guarantee that on average almost all of the neighbors are not bad.

▷ Claim 4.4. $\operatorname*{\mathbb{E}}_{u\in X(0)} \operatorname*{Pr}_{v\in X_u(0)}[v\in B_u] \le 160\Big(\frac{d}{\ell}c^2+c\Big)\frac{\varepsilon}{d-1}$.

▷ Claim 4.5. $\operatorname*{\mathbb{E}}_{v\in X(0)} \operatorname*{Pr}_{u\in X_v(0)}[g_u(v)\neq \mathrm{maj}(v) \;\wedge\; v\notin B_u] \le 80\Big(1+\frac{3}{d/\ell-1}\Big)\frac{\varepsilon}{d-1}$.

Proof of Claim 4.3. Note that

$$\begin{aligned}\operatorname*{\mathbb{E}}_{u\in X(0)} \operatorname*{Pr}_{\sigma\in X_u(d-1)}[g_u\big|_\sigma \neq \mathrm{maj}\big|_\sigma] &= \operatorname*{\mathbb{E}}_{u\in X(0)} \operatorname*{Pr}_{\sigma\in X_u(d-1)}[\exists v\in\sigma \text{ s.t. } g_u(v)\neq \mathrm{maj}(v)]\\ &\le d \operatorname*{\mathbb{E}}_{u\in X(0)} \operatorname*{Pr}_{v\in X_u(0)}[g_u(v)\neq \mathrm{maj}(v)].\end{aligned}$$

By the law of total probability

$$\begin{aligned}\operatorname*{\mathbb{E}}_{u\in X(0)} \operatorname*{Pr}_{v\in X_u(0)}[g_u(v)\neq \mathrm{maj}(v)] &= \operatorname*{\mathbb{E}}_{u\in X(0)} \operatorname*{Pr}_{v\in X_u(0)}[g_u(v)\neq \mathrm{maj}(v) \;\wedge\; v\in B_u] +\\ &\quad \operatorname*{\mathbb{E}}_{v\in X(0)} \operatorname*{Pr}_{u\in X_u(0)}[g_u(v)\neq \mathrm{maj}(v) \;\wedge\; v\notin B_u]\\ &\le 160\Big(\frac{d}{\ell}c^2+c\Big)\frac{\varepsilon}{d-1} + 80\Big(1+\frac{3}{d/\ell-1}\Big)\frac{\varepsilon}{d-1}\\ &= 80\Big(\frac{2d}{\ell}c^2+2c+1+\frac{3}{d/\ell-1}\Big)\frac{\varepsilon}{d-1},\end{aligned}$$

where the inequality follows by claims 4.4 and 4.5. Therefore,

$$\mathop{\mathbb{E}}_{u\in X(0)} \Pr_{\sigma\in X_u(d-1)}[g_u\big|_\sigma \neq \mathrm{maj}\big|_\sigma] \leq 120\Big(\frac{2d}{\ell}c^2 + 2c + 1 + \frac{3}{d/\ell - 1}\Big)\varepsilon,$$

where the inequality follows by the assumption that $d \geq 3$. ◁

4.2 Proofs of Claims 4.4 and 4.5

For any $u \in X(0)$, denote by ε_u the disagreement probability conditioned on u:

$$\varepsilon_u = \mathop{\mathbb{E}}_{\tau\in X_u(\ell-1)} \Pr_{\sigma_1,\sigma_2\in X_{u\tau}(d-\ell-1)}[f_{u\tau\sigma_1}\big|_{u\tau} \neq f_{u\tau\sigma_2}\big|_{u\tau}],$$

and define the following set of vertices:

$$S = \left\{ u \in X(0) \;\middle|\; \varepsilon_u \leq \frac{1}{5c} \right\}.$$

The proofs will follow from the following claims.

▷ Claim 4.6. $\Pr_{u\in X(0)}[u \notin S] \leq 160c^2\frac{\varepsilon}{\ell}$.

▷ Claim 4.7. For any vertex $u \in S$,

$$\Pr_{v\in X_u(0)}[v \in B_u \mid u \in S] \leq 160c\frac{\varepsilon_u}{d-1}.$$

Proof of Claim 4.4. Assuming claims 4.6 and 4.7 the proof follows immediately since

$$\begin{aligned}
\mathop{\mathbb{E}}_{u\in X(0)} \Pr_{v\in X_u(0)}[v \in B_u] &\leq \Pr_{u\in X(0)}[u \notin S] + \mathop{\mathbb{E}}_{u\in S} \Pr_{v\in X_u(0)}[v \in B_u] \\
&\leq 160c^2\frac{\varepsilon}{\ell} + 160c\frac{1}{d-1}\mathop{\mathbb{E}}_{u\in S}\varepsilon_u \\
&\leq 160\Big(\frac{d}{\ell}c^2 + c\Big)\frac{\varepsilon}{d-1},
\end{aligned}$$

where the last inequality follows since $\mathbb{E}_{u\in X(0)}\varepsilon_u \leq \varepsilon$. ◁

Proof of Claim 4.5. Consider a vertex $v \in X(0)$ and the sets of top faces which disagree with the majority on v. By the variance method we know that almost all the vertices in the link of v see the right amount of top faces that disagree with the majority on v. Thus, if for a vertex $u \in X_v(0)$, where v is not bad neighbor of u, the function g_u disagrees with the majority on v, it must see a lot of top faces that disagree with the majority. By the variance method we know that this happens with a small probability. Details follows.

For any vertex $v \in X(0)$ define the function $h_v : X_v(d-1) \to \{0,1\}$ by

$$h_v(\sigma) = \begin{cases} 1 & f_{v\sigma}(v) \neq \mathrm{maj}(v), \\ 0 & f_{v\sigma}(v) = \mathrm{maj}(v). \end{cases}$$

Note that $\mathbb{E}_{\sigma\in X_v(d-1)} h_v(\sigma) \leq 1/2$. Note also that for any vertex $u \in X_v(0)$,

$$g_u(v) \neq \mathrm{maj}(v) \quad \wedge \quad v \notin B_u \quad \Rightarrow \quad \mathop{\mathbb{E}}_{\sigma\in X_{uv}(d-2)} h_v(u\sigma) > \frac{7}{10}.$$

Therefore,

$$\Pr_{u\in X_v(0)}[g_u(v) \neq \mathrm{maj}(v) \ \wedge \ v \notin B_u] \leq \Pr_{u\in X_v(0)}\left[\mathop{\mathbb{E}}_{\sigma\in X_{uv}(d-2)} h_v(u\sigma) - \mathop{\mathbb{E}}_{\sigma\in X_v(d-1)} h_v(\sigma) > \frac{1}{5}\right].$$

By corollary 3.6

$$\mathop{\mathrm{Var}}_{u\in X_v(0)} \mathop{\mathbb{E}}_{\sigma\in X_{uv}(d-2)} h_v(u\sigma) \leq \frac{8}{5(d-1)} \mathop{\mathbb{E}}_{\sigma\in X_v(d-1)} h_v(\sigma).$$

Thus, by Chebyshev inequality

$$\Pr_{u\in X_v(0)}\left[\mathop{\mathbb{E}}_{\sigma\in X_{uv}(d-2)} h_v(u\sigma) - \mathop{\mathbb{E}}_{\sigma\in X_v(d-1)} h_v(\sigma) > \frac{1}{5}\right] \leq \frac{40}{d-1} \mathop{\mathbb{E}}_{\sigma\in X_v(d-1)} h_v(\sigma).$$

Averaging over all $v \in X(0)$ yields

$$\begin{aligned}\mathop{\mathbb{E}}_{v\in X(0)} \Pr_{u\in X_v(0)}[g_u(v) \neq \mathrm{maj}(v) \ \wedge \ v \notin B_u] &\leq \frac{40}{d-1} \mathop{\mathbb{E}}_{v\in X(0)} \mathop{\mathbb{E}}_{\sigma\in X_v(d-1)} h_v(\sigma) \\ &\leq 80\Big(1 + \frac{3}{d/\ell - 1}\Big)\frac{\varepsilon}{d-1},\end{aligned}$$

where the last inequality follows by claim 4.2. ◁

4.3 Proofs of Claims 4.6 and 4.7

Both of these claims follow immediately by the variance method. In claim 4.6 we use the small variance of the function that measures the disagreement probability on a face $\tau \in X(\ell)$. Since the variance of the average of this function on the vertices is small, almost all the vertices have disagreement close to the expectation.

In claim 4.7 we use the small variance of the indicator function in the link of a vertex $u \in X(0)$, which indicates whether a top face disagrees with the function g_u. Since the variance of the average of this function on the vertices is small, almost all the vertices in the link of u see a small amount of top faces which disagree with g_u, i.e., almost all the vertices in the link of u are not bad neighbors. Details follow.

Proof of Claim 4.6. Note that $\mathbb{E}_{u\in X(0)} \varepsilon_u \leq \varepsilon$ and assume that $\varepsilon \leq 1/10c$. Thus, for a vertex $u \in X(0)$ to not be in S, it has to deviate from its mean by more than $1/10c$. By corollary 3.6

$$\mathop{\mathrm{Var}}_{u\in X(0)} \varepsilon_u \leq \frac{8}{5\ell} \mathop{\mathbb{E}}_{\tau\in X(\ell)} \Pr_{\sigma_1,\sigma_2\in X_\tau(d-\ell-1)}[f_{\tau\sigma_1}|_\tau \neq f_{\tau\sigma_2}|_\tau] \leq \frac{8\varepsilon}{5\ell}.$$

Thus, by Chebyshev inequality

$$\Pr_{u\in X(0)}[u \notin S] \leq \Pr_{u\in X(0)}\left[\varepsilon_u - \mathop{\mathbb{E}}_{u'\in X(0)} \varepsilon_{u'} > \frac{1}{10c}\right] \leq \frac{160c^2\varepsilon}{\ell}.$$ ◁

Proof of Claim 4.7. Consider a vertex $u \in S$. Since X_u is a c-agreement expander, there exists a local function $g_u : X_u(0) \to \{0,1\}$ such that

$$\Pr_{\sigma\in X_u(d-1)}[f_{u\sigma}|_\sigma \neq g_u|_\sigma] \leq c\varepsilon_u.$$

Define the indicator function $h_u : X_u(d-1) \to \{0,1\}$ by

$$h_u(\sigma) = \begin{cases} 1 & f_{u\sigma}|_\sigma \neq g_u|_\sigma, \\ 0 & f_{u\sigma}|_\sigma = g_u|_\sigma. \end{cases}$$

By the definition of S, $\mathbb{E}_{\sigma\in X_u(d-1)} h_u(\sigma) \le c\varepsilon_u \le 1/5$. Thus, in order for a vertex $v \in X_u(0)$ to be in B_u, it has to deviate from its mean by more than $1/10$. By corollary 3.6

$$\operatorname*{Var}_{v\in X_u(0)} \mathop{\mathbb{E}}_{\sigma\in X_{uv}(d-2)} h_u(v\sigma) \le \frac{8}{5(d-1)} \mathop{\mathbb{E}}_{\sigma\in X_u(d-1)} h_u(\sigma) \le \frac{8c\varepsilon_u}{5(d-1)}.$$

Thus, by Chebyshev inequality

$$\Pr_{v\in X_u(0)}[v \in B_u \mid u \in S] \le \Pr_{v\in X_u(0)}\left[\mathop{\mathbb{E}}_{\sigma\in X_{uv}(d-2)} h_u(v\sigma) - \mathop{\mathbb{E}}_{\sigma\in X_u(d-1)} h_u(\sigma) > \frac{1}{10}\right] \le \frac{160c\varepsilon_u}{d-1}.$$

Abstract

Massively Parallel Computation (MPC) is a model of computation widely believed to best capture realistic parallel computing architectures such as large-scale MapReduce and Hadoop clusters. Motivated by the fact that many data analytics tasks performed on these platforms involve sensitive user data, we initiate the theoretical exploration of how to leverage MPC architectures to enable efficient, privacy-preserving computation over massive data. Clearly if a computation task does not lend itself to an efficient implementation on MPC even without security, then we cannot hope to compute it efficiently on MPC with security. We show, on the other hand, that *any task that can be efficiently computed on MPC can also be securely computed with comparable efficiency*. Specifically, we show the following results:

- any MPC algorithm can be compiled to a *communication-oblivious* counterpart while asymptotically *preserving its round and space complexity*, where communication-obliviousness ensures that any network intermediary observing the communication patterns learn no information about the secret inputs;
- assuming the existence of Fully Homomorphic Encryption with a suitable notion of compactness and other standard cryptographic assumptions, any MPC algorithm can be compiled to a secure counterpart that defends against an adversary who controls not only intermediate network routers but additionally up to $1/3 - \eta$ fraction of machines (for an arbitrarily small constant η) – moreover, this compilation preserves the round complexity tightly, and preserves the space complexity upto a multiplicative security parameter related blowup.

As an initial exploration of this important direction, our work suggests new definitions and proposes novel protocols that blend algorithmic and cryptographic techniques.

1 Introduction

In the past decade, parallel computation has been widely adopted to manipulate and analyze large-scale data-sets, and numerous programming paradigms such as MapReduce, Hadoop, and Spark have been popularized to help program large computing clusters. This has partly served as a driving force for the algorithms community to better understand the power and limitations of such parallel computation models. The first theoretic model capturing modern parallel computation frameworks was proposed by Karloff, Suri, and Vassilvitskii [79]. Since then, a flurry of results have appeared proposing refinements to the model as well as novel algorithms with better asymptotical and practical efficiency [4, 40, 76, 79, 80, 83, 89, 99].

With these amazing efforts, the community has converged on a model called *Massively Parallel Computation* (MPC), which is believed to best capture large computing clusters (e.g., those operated by companies like Google and Facebook) consisting of a network of Random-Access Machines (RAMs), each with a somewhat considerable amount of local memory and processing power – and yet each individual machine is not powerful enough to store the massive amount of data available. In the MPC model of computation, we typically assume a total of N data records where N is rather large (in practice, the data size can range from tens of terabytes to a petabyte). Each machine can locally store only $s = N^{\varepsilon}$ amount of data for some constant $\varepsilon \in (0, 1)$; and the number of machines $m \geq N^{1-\varepsilon}$ such that all machines can jointly store the entire dataset. In many MPC algorithms it is also desirable if $m \cdot s = \widetilde{O}(N)$ or $m \cdot s \leq N^{1+\theta}$ for some small constant $\theta \in (0, 1)$, i.e., the total space consumed should not be too much larger than the dataset itself [2, 5, 79, 83].

In the standard algorithms literature on MPC, a key focus has been the design of algorithms that minimize the *round complexity*, partly by harnessing the reasonably large local memory that is available on each processing unit. Using round complexity as a primary metric, a rich set of computational tasks have been investigated in the MPC model, including graph problems [2, 4–6, 10–13, 15, 19, 20, 29, 36, 40, 52, 60, 63, 81, 83, 93, 97], clustering [16, 17, 46, 61, 107] and submodular function optimization [41, 47, 80, 90]. Interestingly, it is also known that a number of tasks (such as sorting, parity, minimum spanning tree) that either suffered from an almost logarithmic depth lower bound on a classical Parallel Random-Access Machine (PRAM) now can be accomplished in $O(1)$ or sublogarithmic number of rounds on an MPC framework [40, 67, 79, 93]. Note that a PRAM assumes that each processing unit has $O(1)$ local storage and thus PRAM is not the best fit for capturing modern parallel computing clusters.

1.1 Privacy-Preserving Data Analytics on MPC Frameworks

In this paper, we are the first to ask the question, how can we leverage an MPC cluster to facilitate *privacy-preserving*, large-scale data analytics? This question is of increasing importance because numerous data analytics tasks we want to perform on these frameworks involve sensitive user data, e.g., users' behavior history on websites and/or social networks, medical records, or genomic data. We consider two primary scenarios:

Scenario 1: MPC with secure end-points

We may consider an MPC framework where the end-points[1] are secured by trusted processors such as Intel SGX. Without loss of generality, we may assume that data is encrypted in memory or in transit such that all the secure processors can decrypt them inside a hardware-enabled sandbox where computation will take place (to achieve this the secure processors may employ standard cryptographic techniques to perform a secure handshake and establish a shared encryption key). Finally, when the computation result is ready, the secure processors can send encrypt results to an authorized analyst who has a corresponding key to decrypt the results.

In this scenario, we consider a network adversary (e.g., compromised operating systems, intermediate network routers, or system administrators) that can observe the communication patterns between the end-points, and we would like to make sure that the MPC algorithm's *communication pattern leak no information* about the secret data.

Note that in Scenario 1, we make a simplifying assumption that the adversary cannot observe the memory access patterns on end-points: since known works on efficient Oblivious RAM (ORAM) [64, 66, 100, 102] have in principle solved this problem; not only so, in recent work the first secure processor with ORAM support has been taped out [50, 51, 98].

Scenario 2: MPC with insecure end-points

In the second scenario, imagine that the adversary controls not only the intermediate network routers but also some of the end-points. For example, the end-points may be legacy machines without trusted hardware support, and they may have a comprised operating system. The adversary may also be a rogue system administrator who has access to a subset of the machines. We assume, however, that the adversary controls only a small subset of the end-points – such an assumption is reasonable if the end-points are hosted by various organizations, or by the same organization but in different data centers, or if they have diverse hardware/software configurations such that they are unlikely to be all hit by the same virus.

In this scenario, we would like to obtain a guarantee similar to that of cryptographic Secure Multi-Party Computation (SMPC)[2], i.e., an adversary controlling a relatively small subset of the machines cannot learn more information beyond what is implied by the union of the corrupt machine's outputs. Note that in this scenario, all machines' outputs can also be in encrypted format such that only an authorized data analyst can decrypt the result; or alternatively, secret shared such that only the authorized data analyst can reconstruct – in this case, the adversary should not be able to learn anything at all from the computation.

With the aforementioned scenarios in mind, we ask, what computation tasks can be securely and efficiently computed on an MPC architecture? Clearly, if a computation task does not lend itself to efficient computation on MPC *even without security*, we cannot hope to attain an efficient and secure solution on the same architecture. Therefore, the best we can hope for is the following: for computational tasks that indeed have efficient MPC algorithms, we now want to compute the same task securely on MPC while preserving the efficiency of the original insecure algorithm. In other words, we ask the following important question:

> Can we *securely* evaluate a function f on an MPC framework, while paying not too much more overhead than evaluating f *insecurely* on MPC?

[1] By end-points, we mean the machines, as opposed to the communication/network.
[2] In this paper, to avoid confusion, we use SMPC to mean cryptographic Secure Multi-Party Computation; and we use MPC to mean Massively Parallel Computation.

1.2 Our Results and Contributions

Conceptual and definitional contributions

We initiate the exploration of how to leverage Massively Parallel Computation (MPC) to secure large-scale computation. The widespread empirical success of MPC frameworks in practice, as well as the typically sensitive nature of the data involved in the analytics provide strong motivations for our exploration. We hope that the formal definitions and theoretical feasibility results in our work will encourage future work along this direction, and hopefully leading to practical solutions for privacy-preserving large-scale data analytics.

In comparison, although earlier works originating from the cryptography community have explored secure computation on parallel architectures, most known results [3, 24, 25, 32, 34, 35, 37, 38, 87, 92] adopt PRAM as the model of computation. As discussed later in Section 2, known results specialized for PRAMs do not directly lead to the type of results in this paper due to the discrepancy both in model and in metrics. As mentioned, the PRAM model is arguably a mismatch for the parallel computing architectures encountered in most practical scenarios. This is exactly why in the past decade, the algorithms community have focused more on the modern MPC model which better captures the massively parallel computing clusters deployed by companies like Google and Facebook. Therefore, we hope that our work will bring the MPC model to the attention of the cryptography community for exploring parallel secure computation.

We proceed to present a summary of our major results.

Communication-oblivious MPC

To securely compute a function in Scenario 1 and as a stepping stone towards enabling Scenario 2, we first define a notion of *communication obliviousness* for MPC algorithms. Informally speaking, we want that the adversary learns no information about the secret inputs after observing an MPC algorithm's communication patterns. In this paper we require a very strong notion of communication obliviousness, where we simply want that the MPC algorithm's communication patterns be deterministic and input independent[3].

We prove that any MPC algorithm Π can be compiled to a communication-oblivious counterpart while asymptotically preserving its round complexity and space consumption.

▶ **Theorem 1** (Communication-oblivious MPC algorithms). *Suppose that $s = N^\varepsilon$ and that m is upper bounded by a fixed polynomial in N. Given any MPC algorithm Π that completes in R rounds where each of the m machines has s local space, there is a communication-oblivious MPC algorithm $\widetilde{\Pi}$ that computes the same function as Π except with $\exp(-\Omega(\sqrt{s}))$ probability, and moreover $\widetilde{\Pi}$ completes in $O(R)$ rounds, and consuming $O(s)$ space on each of the m machines. Furthermore, only $O(m \cdot s)$ amount of data are communicated in each round in an execution of $\widetilde{\Pi}$.*

Note that numerous interesting MPC algorithms known thus far have total communication at least $\Omega(R \cdot m \cdot s)$ where R denotes the protocol's round complexity (ignoring polylogarithmic factors) [6,59,62,67,77], and for this class of MPC algorithms, our compilation also introduces very little asymptotical communication overhead.

[3] We stress that the algorithm itself can be randomized, we just want its communication patterns to be deterministic and fixed a-priori.

Secure multi-party computation for MPC

We now turn to Scenario 2. In this setting security means that a relatively small corrupt coalition cannot learn anything more beyond the coalition's joint outputs. We now ask the following natural question:

> Can we compile any MPC protocol to a *secure* counterpart (where security is in the above sense), allowing only $O(1)$ blowup in round complexity and security parameter related blowup in the total space[4]?

We answer this question affirmatively assuming that the adversary controls only $\frac{1}{3} - \eta$ fraction of machines for any arbitrarily small constant η. Note that $\frac{1}{3}$ is necessary since the MPC model assumes a point-to-point channel without broadcast, and in this model it is known that secure computation cannot be attained in the presence of $\frac{1}{3}$ or more corruptions [48, 82].

To achieve this result, we need to assume the existence of a common random string and appropriate cryptographic hardness assumptions, including the Learning With Errors (LWE) assumption, enhanced trapdoor permutations, as well as the existence of a Fully Homomorphic Encryption (FHE) scheme with an appropriate notion of *compactness* [55, 58]. It is well-known that such compact FHE schemes are implied by a suitable circularly secure variant of the LWE assumption [58], although our compiler can work in general given any such compact FHE scheme (not necessarily based on LWE). Our result is summarized in the following theorem:

▶ **Theorem 2** (Secure computation for MPC). *Assume the existence of a common random string, the Learning With Errors (LWE) assumption, enhanced trapdoor permutations, as well as the existence of an FHE scheme with a suitable notion of compactness (see Appendix A.1 for a formal definition of compactness). Suppose that $s = N^{\varepsilon}$ and that m is upper bounded by a fixed polynomial in N. Let κ denote a security parameter, and assume that $s \geq \kappa$. Given any MPC algorithm Π that completes in R rounds where each of the m machines has s local space, there is an MPC algorithm $\widetilde{\Pi}$ that securely realizes the same function computed by Π in the presence of an adversary that statically corrupts at most $\frac{1}{3} - \eta$ fraction of the machines for an arbitrarily small constant η. Moreover, $\widetilde{\Pi}$ completes in $O(R)$ rounds, consumes at most $O(s) \cdot \mathsf{poly}(\kappa)$ space per-machine, and incurs $O(m \cdot s) \cdot \mathsf{poly}(\kappa)$ total communication per round.*

Now, one interesting question is whether the cryptographic assumptions we rely on in the above theorem can be avoided. We show that if one can indeed achieve the same result with *statistical* security, then it would imply (at least partial) solutions to long-standing open questions in the cryptography literature. Specifically, in Appendix B, we show that if we could construct such a compiler, it would immediately imply a constant-round Secure Multi-Party Computation protocol for a broad class of circuits that can be computed in small space, achieving *total* communication complexity that is (significantly) sublinear in the circuit size, regardless of the number of parties. As noted in numerous works [26, 39, 44, 45], the existence of such constant-round, sublinear-communication multi-party computation (for circuits) with *statistical* security has been a long-standing open problem, even for special (but nonetheless broad) classes of circuits.

[4] Since many well-known MPC algorithms [2, 4–6, 10–13, 15–17, 19, 20, 29, 36, 40, 41, 46, 47, 52, 60, 61, 63, 80, 81, 83, 90, 93, 97, 107] incur only constant to sub-logarithmic rounds, we would like to preserve the round complexity tightly; and thus we do not allow a security parameter related blowup for round complexity.

Interestingly, we note that barring strong assumptions such as Indistinguishable Obfuscation [53], the only known approach to construct constant-round, sublinear-communication *multi*-party computation for circuits of unbounded polynomial size is also through compact FHE [55, 58]. We stress, however, that even with a compact FHE scheme, constructing our "MPC to SMPC-for-MPC" compiler is non-trivial and require the careful combination of several techniques.

2 Technical Roadmap

We now present a succinct and informal technical roadmap to capture our main ideas and new techniques.

Recall that in the MPC model of computation, there are m machines each with s local space. All machines will jointly compute a function over a large input containing N words. We assume that $s = N^{\varepsilon}$ for some constant $\varepsilon \in (0, 1)$, and that $m \in [N^{1-\varepsilon}, \mathsf{poly}(N)]$. Note that although our results will hold as long as m is upper bounded by some polynomial function in N, in known MPC algorithms typically we desire that $m \cdot s$ is not too much greater than N. At the beginning of the first round, every machine receives an input whose size is bounded by s. In every other round, each machine begins by receiving incoming messages from the network, and it is guaranteed that no more than s words will be received such that the machine can write them down in its local memory – henceforth this is referred to as the *s-receiver-constraint*. After receiving the inputs or the network messages, all machines perform local computation, and then send messages to other machines. These messages will then be received at the beginning of the next round.

As explained earlier, in the algorithms literature on MPC, the primary metric of performance is the algorithm's *round complexity* [2, 4–6, 10–13, 15–17, 19, 20, 29, 36, 40, 41, 46, 47, 52, 60, 61, 63, 80, 81, 83, 90, 93, 97, 107].

2.1 Achieving Communication Obliviousness: Oblivious Routing

Many known MPC algorithms are not communication oblivious, and thus the communication patterns of these algorithms can leak information about the secret inputs. For example, many graph algorithms for MPC have communication patterns that will leak partial information about the structure and properties of the graph, such as the degrees of nodes or the connectivity between vertices [6, 40, 62, 81, 93].

Our goal is to compile an MPC algorithm to a communication-oblivious counterpart while preserving its round and space complexity. To achieve this, we will compile each communication round of the original MPC to a constant-round, oblivious protocol that accomplishes the same message routing. Interestingly, the compiled protocol will respect communication-obliviousness in a very strong sense: *its communication patterns are deterministic and independent of the input.*

Sender and receiver constraints

In the MPC model of computation [6, 40, 93], we typically have that in each round, each machine sends at most s words and receives at most s words – henceforth these are referred to as the s-sender-constraint and the s-receiver-constraint respectively. Note that if a sender wants to send the same word to two machines, it is counted twice.

Oblivious routing

Oblivious routing basically aims to obliviously realize the message routing as long as both the s-sender- and s-receiver-constraints are satisfied.

More specifically, suppose that each machine receives at most s send-instructions as input, where each send-instruction contains an outgoing word to be sent and a destination machine for the outgoing word. The joint inputs of all machines guarantee that each machine will receive no more than s words. How can we design a constant-round, communication-oblivious protocol that routes the outgoing words to the appropriate destinations?

▶ Remark 3. It seems that some MPC works in the algorithms literature respect only the s-receiver constraint but not the s-sender constraint. We think most likely, the folklore understanding is that as long as we assume the s-receiver constraint, whether or not there is an s-sender constraint do not really affect the expressive power of the computation model. For completeness, in Appendix C, we describe a round- and space-preserving transformation that compiles any MPC protocol that satisfies only the s-receiver-constraint to one that satisfies both $O(s)$-receiver- and $O(s)$-sender-constraints. This means that all of our results would be applicable to MPC algorithms that satisfy only the s-receiver-constraint but not the s-sender-constraint.

Background

Our approach is partly inspired by algorithmic techniques from the recent Oblivious RAM and oblivious sorting line of work [7, 33, 49, 96, 101]. Specifically, these works propose a RAM algorithm with a fixed memory access pattern that routes elements to random buckets and succeeds with $1 - \exp(-\Omega(Z))$ probability where Z denotes each bucket's capacity (and assuming that the total number of elements is polynomially bounded). To accomplish this, imagine that initially all N elements are divided into $2N/Z$ buckets each of capacity Z such that each bucket is at most half-loaded. Every element is assigned a random label declaring which bucket it wants to go to. Now, these prior works rely on a *logarithmic-depth*, butterfly network of buckets and move the elements along this butterfly network based on their respective labels, until eventually every element falls into its desired bucket – this is guaranteed to succeed with $1 - \exp(-\Omega(Z))$ probability where a failure can only occur if in the middle some bucket in the butterfly network exceeds its capacity – henceforth this is said to be an overflow event.

In summary, the insight we can gain from this elegant construction is the following: roughly speaking, a butterfly network of super-logarithmically sized buckets can obliviously route elements to their desired buckets in the final layer with a deterministic communication pattern (determined by interconnections in the butterfly network); but to ensure correctness, i.e., to ensure that overflow does not happen except with negligible probability, the elements should have random destination labels to achieve good load-balancing properties.

A first attempt

Our idea is to use such a butterfly-network to route the words to their destinations – specifically, one can imagine that each bucket is relatively small such that every machine holds $\Theta(\frac{s}{Z})$ of the resulting buckets; and moreover, the buckets are numbered $1, 2, \ldots, O(m \cdot s/Z)$ respectively. For convenience, we will use the term "element" to mean an outgoing word to be sent. Since every sender already knows the destination machines for each of its input elements, it can basically assign the element to a random bucket within the destination

machine. Henceforth, by "destination label", we mean the index of the destination bucket (as opposed to the destination machine). We are, however, faced with two challenges which prevent us from adopting the known approach in its current form:

- *Load balancing challenge:* First, in our setting, the destination labels of the input elements are not completely random; and thus the load-balancing properties that hold in earlier works [7, 33, 49] for randomly assigned labels no longer hold in our case;
- *Round complexity challenge:* Second, the natural way to adopt the butterfly network is to assign to each machine an appropriate subset of $\Theta(\frac{s}{Z})$ buckets in each layer of the network. However, if $\frac{s}{Z} = \Theta(1)$, then we will incur logarithmic number $\Omega(\log m)$ of rounds (corresponding exactly to the depth of the butterfly network). Later, we shall set Z to be small enough (e.g., $Z = O(\sqrt{s})$ in size) to reduce the number of rounds.

Overcoming the load balancing challenge

To overcome the load balancing challenge, our idea is to run this butterfly network twice: the first time we use it to route every element a *random* destination bucket just like in the earlier works; and the second time we use it to route every element to a random destination bucket within the destination machine they originally wanted to go to. At the end of the second phase, every element will be routed to the machine it wants to go to.

For the first phase, we can rely on the same load balancing arguments as in the previous works [7, 33, 49] to prove that overflow events happen only with negligible probability. For the second phase, we will prove a new stochastic bound showing that the same load-balancing properties hold with a different starting condition (see Section 4.4): *i)* the starting condition must satisfy the s-receiver-constraint; and *ii)* initially the elements are assigned to random input buckets, which is guaranteed by phase 1.

It remains to overcome the round complexity challenge which we explain below.

Overcoming the round complexity challenge

The earlier works rely on a 2-way butterfly network where in each layer i, a local 2-way routing decision is made for every element based on the i-th bit of its destination label. In our new construction, we will compress r layers of work in the original butterfly to a single round, exploiting the fact that each machine local space to store roughly 2^r buckets, where $2^r = \Theta(\frac{s}{Z})$.[5] In this way our new approach requires $O((\log \frac{N}{Z})/r) = O(1/\varepsilon)$ rounds for $Z = O(\sqrt{s})$ and $s = N^{\varepsilon}$. Effectively, in each round i, each machine would be looking at the i-th r-bit-group of an element's label to make a 2^r-way routing decision for the element.

To make this idea work, the crux is to show that at the end of every round (corresponding to r layers in the old 2-way butterfly), there is a communication-efficient way for the machines to exchange messages and rearrange their buckets such that the interconnections in the graph are "localized" in the next round too. In this way, within each round, each machine can perform 2^r-way routing on its local elements, simulating r layers of the old 2-way butterfly, without communicating with any other machine. Fortunately, we can accomplish this by exploiting the structure of the butterfly network. We defer the algorithmic details and proofs to Section 4.

[5] Our techniques remotely reminiscient of the line of work on external-memory ORAM constructions with large, N^{ϵ} CPU private cache [33, 68, 69, 96, 101] – however, all previous works consider a *sequential* setting.

2.2 SMPC for MPC

2.2.1 Informal Problem Statement

We now turn our attention to Scenario 2 where the adversary controls not just the intermediate network routers but also a subset of the machines involved in large-scale computation. As before, given a computation task f that has an efficient but insecure MPC algorithm, we now would like to *securely* realize f also using the MPC model while preserving its efficiency. Here, our security goal is to guarantee that the adversary learns nothing more than what is already implied by the joint outputs of corrupt machines. Such a notion of security can be formally defined using a standard simulation-based paradigm [30], requiring that the real-world protocol must "securely emulate" an ideal-world protocol where all machines simply forward their inputs to a trusted ideal functionality who performs the desired computation task and forwards the outputs to each machine. Intuitively, we require that for any real-world attack that can be performed by a polynomially bounded adversary, there is an ideal-world adversary that can essentially implement the same attack in the ideal world. We refer the reader to Section 5 for a formal definition. Note that our definition follows the same style as the Universal Composition framework [30]. Henceforth, a secure multi-party computation protocol satisfying the aforementioned security notion is said to be an "SMPC-for-MPC" protocol.

Before we describe how to solve this problem, we need to clarify a few points about the model of execution as we marry SMPC and MPC. Since we now have corrupt machines and corrupt machines are allowed to send arbitrary messages to any machine, we can no longer guarantee that each honest machine receive at most s words. Instead, we require that at the end of the every round $r-1$, every machine can write down in its local memory a receiving schedule for round r of the form $\{(f_j, w_j)\}_j$, where $f_j \in [m]$ denotes the index of a sender to anticipate a message from in round r and w_j denotes the number of words expected from f_j. In this way, an honest machine will only save the first w_j words received from every anticipated sender f_j contained in this receiving schedule; all other received messages are discarded immediately.

▶ Remark 4. Recall that since we showed how to compile any MPC protocol to one that has a fixed communication schedule while asymptotically preserving round and space complexity (Section 2.1), requiring that receivers be able to anticipate their receiving schedule does not reduce the expressive power of the underlying computational model. However, somewhat more subtlely, we do not insist that the communication patterns be deterministic (i.e., fully fixed a-priori) for our SMPC-for-MPC protocols in order not to rule out interesting SMPC-for-MPC protocols – it suffices for an honest machine to anticipate its receiving schedule of some round right before the round starts.

2.2.2 MPC to "SMPC-for-MPC" Compiler

Recall that we would like the compiled SMPC-for-MPC protocol to tightly preserve the original MPC program's round complexity, and for per-machine space we only allow a security parameter related blowup. Although in the cryptography literature, secure multi-party computation (SMPC) techniques have been explored for various models of computation including circuits [21, 55, 65, 105, 106], RAM [1, 54, 56, 57, 71, 85, 86, 104], and PRAM [24, 25, 32, 34, 35, 37, 38, 87, 92], none of the existing approaches can satisfy our efficiency requirements due to a discrepancy in both model and metric of performance.

First, any approach whose round complexity depends at least on the depth of the circuit [9, 22, 65, 78] or on the parallel runtime of a PRAM [24] can be immediately ruled out, since MPC protocols can have high circuit/PRAM depth (e.g., if each machine's local

computation is of a sequential nature). We thus turn our attention to known approaches that achieve small round complexity. For example, a line of works [18, 42, 84] showed a technique where multiple machines jointly garble a circuit/PRAM in constant number of rounds, then each individual machine simply evaluates the garbled circuit/PRAM locally. Although such a protocol would indeed complete in a small number of rounds, the garbled circuit/PRAM's size would be at least linear in the total computation time of all parties (unless we make strong assumptions such as Indistinguishable Obfuscation [53]). This means that the per-machine space blowup will be proportional to the number of machines m. Similarly, other constant-round approaches, including those relying on Threshold Fully Homomorphic Encryption [8] or Multi-Key Fully Homomorphic Encryption [14, 28, 72, 75, 91], also do not directly work due to a linear-in-m blowup in the per-machine space, e.g., due to the need to store all machines' encrypted inputs (although later in our construction we will indeed leverage FHE-based MPC techniques as a building block, although this MPC will only be run among small committees).

Our approach

Henceforth we assume that the adversary controls only $\frac{1}{3} - \eta$ fraction of the machines where η may be an arbitrarily small constant. As explained earlier, this is nearly optimal tolerance in a point-to-point network since an honest fraction of at least $\frac{2}{3}$ is necessary for realizing broadcast in a point-to-point network. Without loss of generality, we may also assume that the original MPC has already been compiled to a communication-oblivious counterpart whose communication patterns are deterministic and input independent.

Our idea is to directly emulate the original (communication-oblivious) MPC round by round, by having a randomly elected small committee emulate each machine's actions in the original MPC. Henceforth the committee acting on behalf of machine i in the original MPC is called the i-th committee. As long as the committee size is polylogarithmic in the security parameter, except with negligible probability each committee must have at least a $\frac{2}{3}$-fraction of honest machines. Therefore, we may employ an SMPC that tolerates less than $\frac{1}{3}$ corruption (and satisfies suitable efficiency requirements to be described below) to securely emulate the following actions – note that in all cases this SMPC protocol will be executed among a small set of polylogarithmically many machines; and thus we call this SMPC building block CommitteeSMPC:

1. *Share input*: initially each machine i secret shares its input with the i-th committee; the secret sharing scheme must be *robust* such that correct reconstruction can be achieved in polynomial time even when corrupt machines provide false shares. Note that to achieve this we may run the aforementioned CommitteeSMPC protocol among machine i and the i-th committee;
2. *Local compute*: in every round's computation step, the i-th committee employ CommitteeSMPC to jointly evaluate what machine i's is supposed to locally compute in the original MPC, and the result is again robustly secret-shared among the committee;
3. *Communicate*: whenever machine i wants to send a message to machine j in the original MPC, now the i-th committee and the j-th committee employ CommitteeSMPC to accomplish this. At the end of this small protocol, every member of the j-th committee will obtain a *fresh* robust secret share of the message.

Instantiating CommitteeSMPC with suitable efficiency requirements

For our compilation to satisfy the stated efficiency goals, the CommitteeSMPC employed must meet certain efficiency requirements:

1. *Constant round:* the protocol must complete in constant number of rounds; and
2. *Weakly space efficient:* the space consumed by each machine in the CommitteeSMPC protocol asypmtotically matches the RAM-space-complexity of the function being evaluated, allowing only a security-parameter-related blowup[6]. In this paper, we assume that the RAM-space-complexity accounts for the space for writing down the RAM program's description and all inputs and outputs.

▶ Remark 5. Note that since the RAM-space-complexity accounts for writing down all machines' inputs and outputs, by definition the RAM-space-complexity of the function being evaluated incur a linear blowup in the number of machines. However, since CommitteeSMPC will only be run among at most 2 committees, the number of machines participating is small in our case. In fact, by the weak space efficiency condition, each machine's space complexity may sometimes need to be sublinear in the circuit size, runtime, or even depth of the function being evaluated (depending on the function being evaluated).

The only known approach for achieving these guarantees simultaneously is through Threshold Fully Homomorphic Encryption (TFHE) [8] or Multi-Key Threshold Fully Homomorphic Encryption (MTFHE) [14, 72, 75] with a suitable notion of *compactness* (to be explained shortly after). Roughly speaking, to perform an SMPC, the following takes place where the encryption scheme employed is (M)TFHE:

(a) possibly after a setup phase, each machine encrypts their local input using the (M)TFHE scheme and computes a zero-knowledge proof attesting to the well-formedness of the ciphertext; now the machine broadcasts the ciphertext as well as the proof;
(b) now each machine homomorphically evaluates an encryption of all machines' outputs;
(c) for every machine involved, compute the partial decryption share for that machine's encrypted output, along with a zero-knowledge proof attesting to the correctness of decryption; now send the partial decryption share and the proof to the corresponding machine.
(d) a machine finally reconstructs the output after collecting enough decryption shares.

If the (M)TFHE scheme employed is *compact* in the sense that the public key, secret key, and ciphertext sizes depend only on the security parameter κ but not the size or the depth of the circuit being evaluated, then we can show that in the above steps each machine needs only $O(m' \cdot s) \cdot \mathsf{poly}(\kappa)$ space where m' denotes the number of machines involved in the CommitteeSMPC protocol and s denotes the RAM-space-complexity of the function being evaluated. Specifically, recall that any RAM machine with space complexity s can be converted to a layered circuit with width s (and moreover the circuit can be generated and written down layer by layer consuming space proportional to the RAM's next-instruction circuit size). Thus in the above, Step (b) can be accomplished using $O(m' \cdot s) \cdot \mathsf{poly}(\kappa)$ space; and it is easy to verify that all other steps indeed consume at most $O(m' \cdot s) \cdot \mathsf{poly}(\kappa)$ too.

In existing (M)TFHE schemes [8, 14, 72], however, the key and ciphertext sizes are dependent on the depth of the circuit being evaluated and thus they do not satisfy the aforementioned compactness requirement. To make these schemes compact, we need to rely on the bootstrapping technique described in the original Gentry work on FHE [55]; and it is

[6] We call this notion weakly space efficient, since one can imagine a stronger notion requiring that the *total* space consumed by *all* parties asyptotically matches the RAM-space-complexity of the function being evaluted.

well-known that to get provable security with bootstrapping, we need to assume that the (M)TFHE scheme employed satisfies *circular security* – informally speaking, ciphertexts must nonetheless remain semantically secure even when we use the encryption scheme to encrypt the secret decryption key.

Since there are relatively few known (M)TFHE constructions [14,72], rather than assuming that the existing constructions are circularly secure, we would like to further hedge our bet. Later in our technical sections, we further relax the assumption and base our scheme instead on LWE and the existence of *any* compact FHE. Note that compact FHE is known to exist assuming circularly secure variants of LWE; but for our purpose, we can work with any compact FHE scheme including ones that depend on different algebraic assumptions.

2.3 Related Work

As mentioned earlier, the cryptography literature has extensively considered secure computation on an parallel architecture but most existing works focus on the PRAM model [3, 24, 25, 32, 34, 35, 37, 38, 87, 92]. Since most real-world large-scale parallel computation is now done on an MPC architecture, we hope that our work will bring the MPC computation model (which has been extensively studied in the algorithms literature) to the attention of the cryptography community. Besides the PRAM model, Parter and Yogev have considered secure computation on graphs in the so-called CONGEST model of computation [94, 95].

3 Preliminaries

3.1 Massively Parallel Computation Model

We now describe the *Massively Parallel Computation* (MPC) model. Let N be the input size in words where each word consists of $w = \Omega(\log N)$ bits, and $\varepsilon \in (0, 1)$ be a constant. The MPC model consists of m parallel machines, where $m \in [N^{1-\varepsilon}, \mathsf{poly}(N)]$ and each machine has a local space of $s = N^{\varepsilon}$ words. Hence, the total space of all machines is $m \cdot s \geq N$ words. Often in the design of MPC algorithms we also want that the total space is not too much larger than N, and thus many works [2, 5, 79, 83] assume that $m \cdot s = \widetilde{O}(N)$, or $m \cdot s = O(N^{1+\theta})$ for some small constant $\theta \in (0, 1)$. Henceforth the m machines are numbered $1, 2, \ldots, m$ respectively. The m machines are pairwise connected and every machine can send messages to every other machine.

In this paper we are interested in *protocols* (also called *algorithms*) in the MPC model. In this model, the computation proceeds in *rounds*. At the beginning of each round, if this is the first round then each machine receives N/m words as input; else each machine receives incoming messages from the network, and a well-formed MPC algorithm must guarantee that each machine receives at most s words since there is no additional space to store more messages. After receiving the incoming messages or inputs, every machine now performs local computation; and we may assume that the local computation is bounded by $\mathsf{poly}(s)$ and the choice of the polynomial poly is fixed once the parameters s and m are fixed. After completing the local computation, every machine may send messages to some other machines through a pairwise channel, and then all messages are received at the beginning of the next round. When the algorithm terminates, the result of computation is written down jointly by all machines, i.e., by concatenating the outputs of all machines. Every machine's output is also constrained to at most s words. An MPC algorithm may be *randomized*, in which case every machine has a sequential-access random tape and can read random coins from the random tape. The size of this random tape is not charged to the machine's space consumption.

In the standard literature on MPC, we are most concerned about the *round complexity* of an MPC algorithm. Specifically, this model has been of interest to the algorithms community since numerous tasks that are known to have logarithmic depth lower bounds on the classical Parallel Random-Access Machine (PRAM) model are known to have sublogarithmic- or even constant-round algorithms in the MPC model [40, 67, 79, 93].

Useful notations and conventions

We introduce a couple useful notations and conventions:

- Given an MPC algorithm Π, we use the notation $(y_1, y_2, \ldots, y_m) \leftarrow \Pi(x_1, x_2, \ldots, x_m)$ to denote a possibly randomized execution of the algorithm where each machine i's input is x_i and its output is y_i for $i \in [m]$.
- When we say the input to an MPC algorithm, we mean the concatenation of all machines' inputs. When we say that an input array I is *evenly spread* across the m machines, we mean that every machine but the last one obtains $\lfloor |I|/m \rfloor$ elements and the last machine obtains $|I| \mod m$ elements where $|I|$ denotes the total number of elements in I.
- We use the term *s-receiver-constraint* to refer to the requirement that a well-formed MPC algorithm must ensure that each machine receives no more than s words in each round. One may also consider, symmetrically, an *s-sender-constraint*, that is, in each round every machine can send at most s words (where sending the same word to two machines counts twice). Many MPC algorithms in the literature respect both constraints. However, it seems that some other works in the MPC literature require only the *s-receiver-constraint* but not the *s-sender-constraint*.

  It turns out that the two modeling approaches are equivalent in terms of expressive power as we show in Appendix C. Therefore, in the main body of the paper, we simply assume that both constraints must be respected, but our results also extend to MPC algorithms that respect only the s-receiver-constraint.
- Like in the standard algorithms literature on MPC, we are concerned about *asymptotical* complexity. For this reason, whenever convenient, we shall assume that each machine is allowed $O(s)$ local space rather than s. Similarly, the s-receiver-constraint is sometimes interpreted as each machine receiving no more than $O(s)$ data per-round.
- We assume that the original MPC protocol to be compiled runs in a *fixed* number of rounds. If not, we can always pad its round complexity to be the worst case. This ensures that no information will be leaked through the number of rounds.

3.2 Communication-Oblivious MPC Algorithms

Communication-oblivious MPC algorithms

To compile an MPC algorithm to a secure counterpart, we go through an important stepping stone where we first compile the original MPC algorithm to a communication-oblivious counterpart. As mentioned earlier in Section 1, communication-oblivious MPC algorithms are also interesting in their own right, e.g., for MPC clusters where the end points are secured with secure processors such as Intel SGX, such that the adversary can observe only the communication patterns.

Intuitively, an MPC algorithm is said to be communication-oblivious, iff an adversary who can observe the communication patterns of the machines learn nothing about the secret input. When we execute an MPC algorithm on some input I, the *communication pattern* incurred in the execution is the concatenation of the following:

1. For each round r, a matrix $P_r \in [s]^{m \times m}$ where $P_r[i,j] \in [s]$ indicates how many words machine i sends to machine j in round r;
2. An ordered list containing the number of words each machine outputs at the end of the algorithm.

In this paper, we define a very strong notion of communication obliviousness: we say that an MPC algorithm is *communication-oblivious*, iff the communication pattern of the algorithm is deterministic, input independent, and known a-priori. Note that this also implies that the algorithm must run for a deterministic number of rounds.

Defining correctness of MPC algorithms

We will define a notion of δ-correctness for an MPC algorithm. Let $(y_1, y_2, \ldots, y_m) \leftarrow \mathcal{F}(x_1, x_2, \ldots, x_m)$ be a (possibly randomized) ideal functionality which, upon receiving inputs $x_1, x_2, \ldots, x_m$, outputs $y_1, y_2, \ldots, y_m$. Here x_i represents machine i's input and y_i represents machine i's output for $i \in [m]$; without loss of generality we may assume that each x_i contains exactly s words (if not we can always pad it with dummies to exactly s words). We say that an MPC algorithm denoted Π δ-correctly realizes the ideal functionality $\mathcal{F}$ iff for any input $I = (x_1, \ldots, x_m)$ the statistical distance between $\Pi(I)$ and $\mathcal{F}(I)$ is at most δ.

▶ **Definition 6** (δ-oblivious realization of an ideal functionality)**.** *We say that an MPC algorithm Π δ-obliviously realizes an ideal functionality $\mathcal{F}$, iff Π is communication-oblivious and moreover Π δ-correctly realizes $\mathcal{F}$.*

▶ Remark 7. One can alternatively consider a weaker notion for an MPC algorithm Π to "δ-oblivious realize" the ideal functionality $\mathcal{F}$, that is, we require that there exists a simulator Sim, such that for any input I of appropriate length, the following distributions must have statistical distance at most δ:

- $\mathbf{Real}^{\Pi}(1^m, 1^s, I)$: outputs the outcome of the MPC algorithm Π on input I and its communication patterns;
- $\mathbf{Ideal}^{\mathcal{F}}(1^m, 1^s, I)$: outputs $\mathcal{F}(I)$ and $\mathsf{Sim}(1^m, 1^s)$. Notice that the simulator Sim is not given the input I.

It is not hard to see that our notion (i.e., Definition 6) implies this weaker notion. This weakened definition would permit the communication patterns to be randomized and also not necessarily known a-priori. In this paper we focus on the stronger notion since we can achieve even the stronger notion in an efficiency-preserving manner.

4 Oblivious Routing and Communication-Oblivious Compiler

4.1 Problem Definition

Recall that our first goal is to obtain an MPC protocol communication oblivious, and the crux of the problem is to realize an oblivious form of routing. Imagine that in the original MPC protocol, in some round, every machine has a list of at most s words that they want to send, and each outgoing word has an intended destination machine. It is also guaranteed that every machine will receive no more than s words. The question is how to route these messages obliviously such that the communication patterns leak no information.

More formally, the $\mathsf{Routing}$ problem has the following syntax:

- **Input.** Every machine $i \in [m]$ has *at most s send instructions* where each send instruction consists of a word to be sent, and the index of the recipient machine. All machines' send instructions must jointly satisfy the s-receiver-constraint, i.e., every machine receives no more than s words.

- **Output.** Every machine outputs the list of words it is supposed to receive as uniquely defined by the joint input (i.e., all machines' send instructions); and moreover, these received words are sorted based on a lexicographically increasing order. If fewer than s words are received, the machine pads the output array with dummies to a length of exactly s.

The above abstraction defines a most natural ideal functionality $\mathcal{F}_{\text{Routing}}$ which implements the routing task correctly.

In the remainder of this section, we will devise an oblivious MPC protocol that accomplishes routing. In the process we will need two intermediate building blocks called "Bucket Route" and "Random Bucket Assignment" respectively.

Notational convention: a global Overflow indicator

Throughout this section, we shall assume that each machine maintains a global variable denoted Overflow. Initially the Overflow bit is set to 0. During the algorithm's execution, a machine may set the Overflow bit to 1. If at the end of the algorithm, all machines' Overflow indicators remain unset, we say that the algorithm is successful; otherwise the algorithm is said to have failed.

4.2 Building Block: Bucket Route

4.2.1 Syntax

The goal is to classify elements into buckets based on each element's label indicating its desired destination bucket. The algorithm is not always guaranteed to succeed; however, should it succeed, the final assignment should be correct. Recall that an algorithm is said to be successful if no machine has set their Overflow indicator by the end of the algorithm. We consider both the input and output configuration as a list of buckets spread evenly across the machines, where each bucket contains either real or dummy elements.

More formally, a $\mathsf{BucketRoute}^Z$ algorithm, parametrized by a bucket size Z, satisfies the following syntax – recall that there are in total m machines each of which has local space $O(s)$; without loss of generality, we may assume that m and s are both powers of 2:

- **Input.** In the beginning, each machine stores 2^r number of buckets each of capacity Z where $2^r \cdot Z = 2s$. Each bucket contains Z elements, some of which are real and others are dummy. Each real element carries an ℓ-bit label where $2^\ell = m \cdot 2^r$ – henceforth if a real element's label is $k \in \{0,1\}^\ell$, we say that the element wants to go to the k-th bucket out of a total of $2^\ell = m \cdot 2^r$ buckets.
- **Output.** The machines jointly output a list of $2^\ell = m \cdot 2^r$ buckets, each of capacity Z. We require that if the algorithm is successful (i.e., no machine's Overflow indicator is set), then every bucket must contain all the real elements wanting to go there plus an appropriate number of dummy elements.

4.2.2 Protocol

We now describe a $\mathsf{BucketRoute}^Z$ algorithm that tries to move every real element to the desired destination bucket but will possibly fail in the middle due to overflow events. Later in Section 4.4, we will show that if the input configuration satisfies certain nice conditions, then the overflow probability can be made negligibly small. Roughly speaking, by "nice conditions", we want that all input buckets are at most half-full; and moreover the input elements' labels are randomly chosen. In this section, we first focus on presenting the algorithm and we will worry about the probability analysis in Section 4.4.

Algorithm 1 Bucket Route.

Input: Let $2^r \cdot Z = 2s$ and let $\ell = \log_2 m + r$. The input consists of 2^ℓ buckets denoted $\mathcal{L} := \{\mathsf{B}_i : i \in [2^\ell]\}$ each with capacity Z, where each real element in a bucket contains an ℓ-bit label. There are $m = 2^{\ell - r}$ parallel machines, each of which has enough memory to store and process 2^r buckets.

1: **procedure** $\mathsf{BucketRoute}^Z(\mathcal{L} := \{\mathsf{B}_i : i \in [2^\ell]\})$ ▷ The input is a list of 2^ℓ buckets.
2: Each bucket in $\mathcal{L}$ receives an empty bit string as its label.
3: **for** $\lfloor \frac{\ell}{r} \rfloor$ sequential iterations **do**
4: Partition the buckets in $\mathcal{L}$ into m groups of equal size 2^r, where the buckets in each group has the same label; a machine is assigned to each group.

▷ *Step 4 requires the machines to exchange their buckets according to a predetermined fashion.*

5: **for** each of m machines in parallel **do**
6: Every machine calls 2^r-way $\mathsf{LocalClassify}^{r,Z}$ on its group of buckets to produce its modified group of buckets (whose labels have lengths increased by r).
7: Update the list $\mathcal{L}$ to be the union of all machines' modified groups of buckets.
8: **if** $t := \ell \mod r \neq 0$ **then**
9: In the last iteration, each machine receives 2^{r-t} sub-groups of buckets, where each sub-group contains 2^t buckets with the same label.
10: **for** each of m machines in parallel **do**
11: Every machine calls 2^t-way $\mathsf{LocalClassify}^{t,Z}$ on every of its sub-groups of buckets.
12: Let $\mathcal{L}$ be the union of all machines' updated buckets.
13: **return** the list $\mathcal{L}$ of 2^r buckets, each of which receives a unique label in $\{0,1\}^r$. Recall that if any instance of multi-way $\mathsf{LocalClassify}$ encounters $\mathsf{Overflow}$, the failure-indicator $\mathsf{Overflow}$ will be set to 1 but the algorithm will continue after truncating the excessive elements in the overflowing bucket(s).

At a very high level, our $\mathsf{BucketRoute}^Z$ algorithm will proceed in iterations such that at the end of the i-th iteration, elements will be sorted based on the first $i \cdot r$ bits of their respective labels. During each iteration i, every machine will obtain a list of buckets containing elements whose labels all share the same $((i-1) \cdot r)$-bit prefix, and the machine will locally further classify these elements into buckets based on the next r bits of their respective labels. This subroutine is henceforth called $\mathsf{LocalClassify}$ which is described more formally below. We will then describe the full $\mathsf{BucketRoute}^Z$ algorithm after specifying this subroutine.

A multi-way LocalClassify subroutine

We introduce a subroutine called a 2^t-way $\mathsf{LocalClassify}^{t,Z}$. The 2^t-way $\mathsf{LocalClassify}^{t,Z}$ subroutine is always performed by a single machine locally which operates on a list of 2^t buckets:

- Imagine that a machine has as input a list of 2^t buckets each of capacity Z where $2^t \cdot Z \leq 2s$. All of the 2^t buckets must have the same bucket-label $x \in \{0,1\}^{|x|}$, where $|x|$ is the bit-length of x. Moreover, every real element contained in the buckets has an ℓ-bit label of the form $x||y$, i.e., the element's label must be prefixed by x, followed by a suffix denoted y (that has length at least r). It is guaranteed that $|x| + r \leq \ell$.
- Now, the machine locally rearranges the input to form 2^t output buckets as follows: for each $i \in \{0,1\}^t$, the i-th output bucket has the bucket-label $x||i$, and contains all the real elements from the input whose label is prefixed with $x||i$, padded with dummies to a capacity of Z. Moreover, in each output bucket the real elements must appear before the dummies.
  If the above rearrange fails due to the overflow of some output bucket, then set the indicator Overflow to 1; moreover, truncate the bucket to a load of Z and continue with the algorithm. Note that if Overflow is set, then some elements can be lost due to the truncation.

The BucketRoute algorithm

We describe the $\mathsf{BucketRoute}^Z$ algorithm in Algorithm 1 which calls LocalClassify as a subroutine. Assuming that no Overflow is encountered, then the algorithm proceeds in the following way: first, using the 2^r-way LocalClassify subroutine, all machines rearrange their local 2^r buckets of elements based on the first r bits of the elements' labels, such that all elements whose labels have the same r-bit prefix fall into the same bucket, and this common r-bit prefix also become the bucket's label. At the end of this iteration, for each r-bit bucket label, there will be $2^{\ell-r}$ buckets with the same bucket label. We will then assign $2^{\ell-2r}$ machines to work on buckets sharing each r-bit bucket label, and each machine now locally calls LocalClassify to further classify the elements based on the next r-bits of their input labels; and this goes on. In general, after the end of the i-th iteration, buckets will acquire labels of length $i \cdot r$ bits, and there will be $2^{\ell-i\cdot r}$ buckets sharing each unique $(i \cdot r)$-bit label; we now assign all buckets with the same label to $2^{\ell-(i+1)\cdot r}$ machines which further classifies the elements based on the next r bits in the input labels. The algorithm will have ended by iteration i if $i \cdot r \geq \ell$, i.e., after $O(\ell/r)$ iterations – at the end, all buckets across all machines will have a unique ℓ-bit label. Algorithm 1 formalizes the above idea and in particular, treats the last iteration more formally for the case when ℓ is not divisible by r.

▶ **Fact 8.** *Using the parameters in Algorithm 1, the number of rounds is* $O(\frac{\ell}{r}) = O(\frac{\log m}{r})$.

▶ **Fact 9** (Communication pattern)**.** *The communication pattern of Algorithm 1 is deterministic, and depends only on the parameters m, ℓ, r and Z. Moreover, in every round, the total communication is upper bounded by $O(m \cdot s)$.*

Proof. Step 4 of Algorithm 1 is where the communication happens, and it is not hard to check that this fact holds. ◀

4.3 Building Block: Oblivious Random Bucket Assignment

Based on the $\mathsf{BucketRoute}^Z$ primitive described above, we realize another intermediate building block called "random bucket assignment". The problem, henceforth denoted $\mathsf{RandBucket}^Z$, is parametrized by an appropriate bucket size Z and is described below:

- **Input.** The input is an array of $m \cdot s$ elements spread evenly across the machines where each machine receives exactly s elements; each element can either be real or dummy. We assume that each element can be stored in $O(1)$ words.

- **Output.** Each machine receives $2^r = 2s/Z$ output buckets each of capacity Z. The contents of the buckets are determined below:
  - Every real element in the input array is assigned to a random bucket out of the $2^r \cdot m$ buckets;
  - If a bucket receives more than Z real elements, choose the Z lexicographically smallest elements to populate the bucket (and the remaining elements are lost);
  - Else if a bucket receives Z or fewer real elements, then the bucket should contain all of these elements, in a lexicographically increasing order, and padded at the end with an appropriate number of dummies to a capacity of Z.

Note that the above abstraction also defines the most natural ideal functionality $\mathcal{F}^Z_{\text{RandBucket}}$ which correctly implements the above task.

Protocol

Using $\mathsf{BucketRoute}^Z$, we can obliviously realize random bucket assignment using the following simple algorithm where we assume that m and s are powers of 2 without loss of generality (if not, we can pad them to the nearest power of 2):

1. Choose r, ℓ based on Z, m, and s, such that $2^r = 2s/Z$ and $2^\ell = m \cdot 2^r$. Henceforth 2^r denotes the number of buckets on each machine, and 2^ℓ denotes the total number of buckets across all machines.
2. Each machine places $Z/2$ elements from the input array to each of its 2^r buckets, and pads each bucket with an additional $Z/2$ dummies to a capacity of Z – note that each bucket is at most half full.
3. Every machine assigns a random ℓ-bit label to each real element in its buckets, indicating which bucket the element wants to go to.
4. Call $\mathsf{BucketRoute}^Z$ (Algorithm 1) to produce the list of output buckets, and for each resulting bucket, sort the elements in it based on a lexicographically increasing order, placing all dummies at the end.

Recall that in the $\mathsf{BucketRoute}^Z$, a machine may encounter a bucket overflow exception which will cause the $\mathsf{Overflow}$ indicator to be set. Below we bound the probability of seeing $\mathsf{Overflow}$ using the fact that the initial labels are randomly chosen and that the initial buckets are at most half full – this allows us to prove good load-balancing properties. We use the standard Chernoff Bound to analyze overflow probability.

▶ **Fact 10** (Chernoff Bound). *Suppose X is a sum of independent $\{0,1\}$-random variables. Then, for any $\beta \geq 2$, $\Pr[X \geq \beta E[X]] \leq \exp(-\frac{\beta E[X]}{6})$.*

▶ **Lemma 11** (Overflow probability for random bucket assignment algorithm). *In the above algorithm, the probability that some machine sets the $\mathsf{Overflow}$ indicator is at most $O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$.*

Proof. Observe that there are $O(\frac{\ell}{r})$ iterations in Algorithm 1. We fix some iteration and some bucket B, and analyze the overflow event of that bucket after that iteration.

Observe that if we assume that all buckets from previous iterations have infinite capacity, then no element will be lost in previous iterations. Hence, the resulting number of elements ending up at bucket B after this iteration in this alternate world will stochastically dominate that in the actual world. The property of no overflow in previous iterations is used to ensure that different elements do not influence one another so that we can apply Chernoff Bound. By stochastic dominance, it suffices to analyze the overflow probability of bucket B after this iteration under this additional assumption.

Suppose after this iteration, this bucket has received a label with k bits. This means that the elements in this bucket could only have come from 2^k possible input buckets, each of which contains at most $\frac{Z}{2}$ elements.

Observe that each such element receives a random ℓ-bit label, whose k-bit prefix coincides with this bucket's label with probability $\frac{1}{2^k}$. Hence, the expected number of elements entering this bucket after this iteration is at most $\frac{Z}{2}$.

Therefore, using Chernoff Bound (Fact 10), after each iteration, each bucket overflows with probability at most $e^{-\frac{Z}{6}}$.

Finally, the union bound over all iterations and all buckets gives the result. ◀

▶ **Lemma 12** (Correctness of random bucket assignment)**.** *The above algorithm, parametrized with Z, δ-correctly realizes $\mathcal{F}^Z_{\text{RandBucket}}$ where $\delta = O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$ (note that the parameters ℓ and r are determined once Z is determined).*

Proof. Follows from Lemma 11 and the fact for every random string ρ assigning real elements to destination buckets, if ρ does not cause Overflow in the algorithm, then the algorithm's output must correctly match that output by the ideal functionality $\mathcal{F}^Z_{\text{RandBucket}}$ consuming the same randomness ρ. ◀

▶ **Fact 13.** *The communication patterns of the algorithm is deterministic and depends only on the parameters m, ℓ, r and Z.*

Proof. The communication pattern of the algorithm stems from that of $\mathsf{BucketRoute}^Z$ since all other steps are performed locally on each machine and incur no communication. The fact now follows directly from Fact 9. ◀

4.4 Putting it Together: Oblivious Routing

Using the building blocks $\mathsf{BucketRoute}^Z$ and $\mathsf{RandBucket}^Z$, we can realize oblivious routing as follows:

(a) Without loss of generality, we may assume that both m and s are powers of 2 and s is a perfect square. Choose the parameter $Z = 2\sqrt{s}$ and $2^r = 2s/Z$, and $\ell := \log_2 m + r$.

(b) Every machine does the following: let X be an input array containing all the words the machine wants to send (also called outgoing words), padded with dummies to a length of s. Each real outgoing word in the input array has a label of the form $x||\rho$ where $x \in \{0,1\}^{\log_2 m}$ encodes the identifier of the recipient machine, and $\rho \xleftarrow{\$} \{0,1\}^{\ell - \log_2 m}$ is chosen at random and indicates the index of the destination bucket within machine x.

(c) Invoke an oblivious $\mathsf{RandBucket}^Z$ algorithm to assign each outgoing word to a random bucket among a total of 2^ℓ buckets, and recall that each machine stores 2^r of these buckets.

We emphasize that the labels selected earlier in Step (b) are not used as destination labels for the $\mathsf{RandBucket}^Z$ algorithm since the $\mathsf{RandBucket}^Z$ algorithm itself internally assigns a random bucket to each element. However, these labels selected earlier will be used in the next step.

(d) Invoke an instance of $\mathsf{BucketRoute}^Z$ to route each outgoing word to the destination bucket encoded in the label chosen in Step (b). Now, every machine looks at the resulting 2^r buckets it stores and outputs all received (real) words in a lexicographically increasing order, padded with an appropriate number of dummies to a length of s.

▶ **Fact 14.** *In the above routing algorithm, the communication pattern is deterministic and depends only on the parameters Z, m, r, ℓ.*

Proof. The communication pattern of the above algorithm is determined by the communication pattern of the $\mathsf{RandBucket}^Z$ algorithm and the $\mathsf{BucketRoute}^Z$ algorithm. The fact now follows directly from Fact 9 and Fact 13. ◀

▶ **Lemma 15** (Correctness of routing). *Suppose that $\mathsf{RandBucket}^Z$ δ-correctly realizes $\mathcal{F}^Z_{\text{randbucket}}$. Then, the above algorithm δ'-correctly realizes $\mathcal{F}_{\text{Routing}}$ for some $\delta' \leq \delta + O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$.*

Proof. We consider a sequence of hybrids.

$\mathbf{Real}^Z(I)$. We will use $\mathbf{Real}^Z(I)$ to denote the outcome of the real-world algorithm.

$\mathbf{Hyb}_1^Z(I)$. We now consider a hybrid execution denoted $\mathbf{Hyb}_1^Z$, which is defined almost the same as the real-world execution, except that we now replace the $\mathsf{RandBucket}^Z$ algorithm with $\mathcal{F}^Z_{\text{randbucket}}$. We define $\mathbf{Hyb}_1^Z(I)$ to output the outcome of this hybrid execution upon the input I.

Since $\mathsf{RandBucket}^Z$ δ-correctly realizes $\mathcal{F}^Z_{\text{randbucket}}$, it holds that for any I, $\mathbf{Hyb}_1^Z(I)$ has at most δ statistical distance from $\mathsf{Real}^Z(I)$.

▶ **Lemma 16.** *For any I, in the execution defined by $\boldsymbol{Hyb}_1^Z(I)$, the probability that some machine sets the $\mathsf{Overflow}$ indicator is bounded by $O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$.*

Proof. To prove this, we instead consider an execution $\mathbf{Hyb}_1^\infty$ where the parameters Z, ℓ, and r are chosen as before; however, we do not impose a Z-capacity limit on any of the buckets, including the buckets in $\mathcal{F}_{\text{randbucket}}$ or any bucket in the hybrid execution $\mathbf{Hyb}_1^Z$. It is not hard to that the probability of seeing $\mathsf{Overflow}$ in $\mathbf{Hyb}_1^Z$ is upper bounded by the probability that there is some bucket storing more than Z real elements in $\mathbf{Hyb}_1^\infty$. This can be formally proven through a standard stochastic domination argument.

Therefore, it suffices for us to prove that in $\mathbf{Hyb}_1^\infty$, the probability that some bucket needs to store more than Z real elements is upper bounded by $O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$, and below we prove this statement.

The analysis is similar to the proof of Lemma 11. We fix some iteration in Algorithm 1 and some bucket B. Let $X_{i,B}$ denote an indicator random variable indicating the contribution of the i-th outgoing word in the input to the load of the bucket B. Our goal is to prove a tail bound for $\sum_i X_{i,B}$ which denotes bucket B's total load. Note that $X_{i,B}$ depends only on the i-th outgoing word's destination bucket and the initial bucket placement chosen by $\mathcal{F}_{\text{RandBucket}}$ for the i-th outgoing word. Therefore, all of the random variables $\{X_{i,B}\}_i$ are independent which will allow us to apply the standard Chernoff bound. To do so, we will first show that the expected number of real elements the bucket contains after this iteration is at most $\frac{Z}{2}$. Hence, in the execution $\mathbf{Hyb}_1^\infty$, we analyze the expected number of elements for this bucket B after this iteration based on the number k of bits of the label received by this bucket after this iteration. Let $\mathcal{L}$ be the list of buckets obtained after $\mathcal{F}_{\text{randbucket}}$.

1. Suppose $k \leq \log_2 m$. The k-bit label indicate a subset of 2^{m-k} destination machines. Then, only elements going to these 2^{m-k} machines can end up in this bucket. There are totally at most $2^{m-k} \cdot s$ such elements.
   Moreover, only elements from 2^k buckets in $\mathcal{L}$ can end up in bucket B after this iteration. Due to $\mathcal{F}_{\text{randbucket}}$, an element is in one of those 2^k buckets independently with probability $\frac{2^k}{2^\ell}$.
   Hence, the expected number of elements in bucket B after this iteration is at most $2^{m-k} \cdot s \cdot \frac{2^k}{2^\ell} = \frac{s}{2^r} = \frac{Z}{2}$.

2. Suppose $k > \log_2 m$. The k-bit label then identifies $2^{\ell-k}$ buckets within a certain destination machine M.
   Recall that at most s elements are supposed to go to machine M. In order for an element to end up in bucket B after this iteration, it has to satisfy the following independent events:
   a. The element is in one of 2^k buckets in $\mathcal{L}$ whose elements can end up in B after this iteration. Due to $\mathcal{F}_{\text{randbucket}}$, this happens with probability $\frac{2^k}{2^\ell}$.
   b. The element has chosen a destination bucket that is among those $2^{\ell-k}$ buckets whose identity agrees with the k-bit label of the bucket B. This happens with probability $\frac{2^{\ell-k}}{2^r}$.
   Hence, the expected of elements that enter this bucket B after this iteration is at most $s \cdot \frac{2^k}{2^\ell} \cdot \frac{2^{\ell-k}}{2^r} = \frac{s}{2^r} = \frac{Z}{2}$, as required.

Finally, we apply a standard Chernoff bound and then a union bound over all iterations and all buckets just like in Lemma 11, which leads to the lemma statement. ◀

Ideal(I). The experiment $\mathbf{Ideal}(I)$ outputs the result of $\mathcal{F}_{\text{Routing}}$ upon the input I

We now show that for any I, $\mathbf{Ideal}(I)$ and $\mathbf{Hyb}_1^Z$ have statistical distance at most $O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$. Note that conditioned on 1) seeing no Overflow in $\mathbf{Hyb}_1^Z$ and 2) that $\mathcal{F}_{\text{randbucket}}$ does not pick bad randomness such that some bucket initially exceeds Z load, then the outcome obtained in $\mathbf{Hyb}_1^Z$ would be the same as the output of $\mathbf{Ideal}(I)$. In Lemma 16, we have shown that the probability of some machine setting the Overflow indicator in $\mathbf{Hyb}_1^Z$ $O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$, therefore it suffices to show that the probability that $\mathcal{F}_{\text{randbucket}}$ internally exceeds Z load is upper bounded by $O(\frac{\ell}{r}) \cdot 2^\ell \cdot e^{-\frac{Z}{6}}$. Due to a simple application of the Chernoff bound, we can show that the probability that some fixed bucket exceeds load Z is at most $e^{-\frac{Z}{6}}$. Now, applying a union bound over all 2^ℓ buckets, the conclusion follows.

In summary, applying a standard hybrid argument, we can complete the proof of this lemma. ◀

▶ **Corollary 17.** *The above algorithm δ-obliviously realizes $\mathcal{F}_{\text{Routing}}$ by Definition 6 for $\delta = \exp(-\Omega(\sqrt{s}))$.*

Proof. Straightforward by Fact 14, Lemma 15 and Lemma 12 and the parameters chosen in the algorithm. ◀

4.5 Oblivious Sorting

Given our oblivious routing primitive, one immediate and interesting application is to construct a constant-round MPC algorithm that obliviously realizes sorting.

To achieve this, recall that Goodrich [67] constructed a non-oblivious MPC algorithm that accomplishes sorting in $O(1)$ rounds; and moreover, his algorithm satisfies both the s-receiver-constraint and the s-sender-constraint.

▶ **Lemma 18** (Constant-round sorting, Theorem 3.5 of Goodrich [67]). *Let $m = N^{1-\varepsilon}$ and $s = O(N^\varepsilon)$ for any constant $\varepsilon \in (0, 1)$. Suppose that each item to be sorted can be stored in $O(1)$ words. There exists a deterministic, comparison-based sorting algorithm that can correctly sort N items stored on m machines each with s local space consuming an a-priori fixed constant number of rounds; and moreover, the algorithm satisfies both the s-sender-constraint and the s-receiver-constraint.*

The idea is to apply our Routing algorithm to realize each round of communication in Goodrich's algorithm. In this way, we obtain the following theorem:

▶ **Theorem 19** (Constant-round oblivious sorting on MPC). *Let $m = N^{1-\varepsilon}$ and $s = O(N^{\varepsilon})$ for any constant $\varepsilon \in (0, 1)$, and suppose that each items to be sorted can be represented in $O(1)$ words. There exists an MPC algorithm that obliviously sorts N items stored on s machines in $O(1)$ number of rounds and the result is correct with $1 - \exp(-\Omega(\sqrt{s}))$ probability.*

Proof. Note that Goodrich's algorithm runs for an apriori-fixed constant number of rounds. Thus, if we apply our oblivious Routing algorithm to realize each round of communication in Goodrich's algorithm, the resulting algorithm has a deterministic communication pattern; and moreover, due to Corollary 17, the resulting algorithm correctly sort the input with $1 - \exp(-\Omega(\sqrt{s}))$ probability. ◀

Although our secure multi-party computation compiler later will not directly rely on oblivious sorting as a building block, we state this result explicitly nonetheless since sorting is such an important and fundamental algorithmic building block.

4.6 Communication-Oblivious Compiler

We can now arrive at Theorem 1 which we restate below for the reader's convenience.

▶ **Theorem 20** (Communication-oblivious MPC algorithms: Restatement of Theorem 1). *Suppose that $s = N^{\varepsilon}$ and that m is upper bounded by a fixed polynomial in N. Given any MPC algorithm Π that completes in R rounds where each of the m machines has s local space, there is a communication-oblivious MPC algorithm $\widetilde{\Pi}$ that computes the same function as Π except with $\exp(-\Omega(\sqrt{s}))$ probability, and moreover $\widetilde{\Pi}$ completes in $O(R)$ rounds, and consuming $O(s)$ space on each of the m machines. Furthermore, only $O(m \cdot s)$ amount of data are communicated in each round in an execution of $\widetilde{\Pi}$.*

Proof. We apply the oblivious Routing algorithm developed earlier in this section to realize every communication round of the original MPC protocol Π. The theorem now follows directly from Corollary 17. ◀

5 Secure Multi-Party Computation for Massively Parallel Computing

In this section, we consider how to perform secure computation on a Massively Parallel Computing (MPC) architecture. As before, we consider a set of m machines each of which is s-space-bounded. Without loss of generality, we consider a setting where each machine receives some input denoted $x_1, x_2, \ldots, x_m$ respectively where each input contains at most s words. Now, these machines would like to jointly evaluate a function $(y_1, y_2, \ldots, y_m) \leftarrow f(x_1, x_2, \ldots, x_m)$ such that at the end, the i-th machine obtains the s-bounded output y_i for $i \in [m]$. We would like to ensure that an adversary controlling a relatively small subset of the machines will not learn anything beyond the outputs of the machines in its control.

The question we are concerned about is the following: suppose that there is an efficient, insecure MPC protocol Π to evaluate the function f. Can we now securely evaluate the function f while preserving the efficiency relative to the insecure protocol Π?

5.1 Execution Model: SMPC for MPC

We consider an MPC protocol Π executing on m machines each with maximum space s. To define Secure Multi-Party Computation (SMPC), we augment the protocol execution model used so-far in the paper as follows to capture a polynomial-time adversary who can corrupt a

subset of the machines. Most of the definitions below directly follow the standard approach in the cryptography literature – there is, however, one subtlety that needs to be clarified when we marry SMPC and MPC: since corrupt machines can send arbitrary messages to honest machines, we must now redefine the s-receiver-constraint (see details in the "communication model" paragraph).

- We now parametrize the protocol's execution with a security parameter denoted κ. Therefore we may write Π as $\Pi(1^\kappa, 1^m, 1^s)$, i.e., it is parametrized by the security parameter κ and the MPC framework's parameters 1^m and 1^s.
- A subset of the machines which are said to be *corrupt* are controlled by an adversary $\mathcal{A}(1^\kappa)$. We assume that corruption is static, i.e., $\mathcal{A}$ decides which machines to corrupt before the protocol execution starts. All protocol messages received by corrupt machines are visible to $\mathcal{A}$, and $\mathcal{A}$ fully controls what messages corrupt machines send.

  Machines that are not in $\mathcal{A}$'s control are said to be honest, and honest machines faithfully follow the prescribed protocol.
- All machines' inputs are chosen by some environment denoted $\mathcal{Z}(1^\kappa)$; and at the end of the protocol, all honest machines send their respective output to $\mathcal{Z}$.
- During the execution $\mathcal{A}$ and $\mathcal{Z}$ may communicate freely.

Communication model

The protocol proceeds in rounds and machines communicate with each other through a pairwise point-to-point network. At the beginning of each round, honest machines receive messages from the network; and afterwards they perform computation and send messages. If an honest machine sends a message in round r, then an honest recipient will receive the message at the beginning of the next round. We assume that honest machines communicate through a pairwise *secure channel* such that the adversary can observe who is communicating with whom, the length of each honest message sent, but not the contents of the message – note that since we can realize secure channels from authenticated channels with key exchange and authenticated encryption, assuming secure channels is without loss of generality.

Recall that in this new setting, some machines can be corrupt and corrupt machines send arbitrary, unwanted messages to honest machines. We cannot guarantee that the s-receiver-constraint is respected in the presence of corrupt nodes; instead, we require the following:

> at the end of the previous round, an honest machine must have written down in a designated location in its memory a *receiving schedule* for the next round, i.e., a list of $\{(f_j, w_j)\}_j$ pairs where $f_j \in [m]$ denotes the index of a sender and $w_j \in [s]$ denotes the number of words the machine is expecting to receiver from machine f_j. Additionally, it must hold[7] that $\sum_j w_j \leq s$.

Every sender whose index appears in this receiving schedule is called an anticipated sender. Now, a machine will save only the first w_j words received from each anticipated sender f_j; it will ignore all words received from unanticipated senders; and also ignore all excessive words received from anticipated senders.

[7] Later on, in our compiled protocol, s will actually be substituted with $O(s) \cdot \mathsf{poly}(\kappa)$ where s is the per-machine space complexity of the original MPC to be compiled.

5.2 Security Definition

Security is defined through (computational) observational equivalence of the environment $\mathcal{Z}$ in an ideal-world and a real-world execution. In the real-world execution, machines run the real protocol Π. In the ideal-world execution, the computation task is performed by an ideal functionality $\mathcal{F}^f$ which computes the intended function f and distributes the results to everyone.

Formally, we define a real-world and an ideal-world execution formally as below:

- $\mathbf{Real}^{\mathcal{A},\mathcal{Z},\Pi}(1^\kappa, 1^m, 1^s)$: $\mathcal{Z}(1^\kappa)$ chooses and provides inputs $x_1, x_2, \ldots, x_m$ for each of the m machines. Now the m machines engage in a protocol execution as explained above, where honest machines will faithfully execute the prescribed protocol Π using the input they obtained from $\mathcal{Z}$ but corrupt machines that are controlled by $\mathcal{A}$ can behave arbitrarily. At the end of the protocol, the honest machines send their output to $\mathcal{Z}$.
- $\mathbf{Ideal}^{\mathcal{S},\mathcal{Z},\mathcal{F}^f}(1^\kappa, 1^m, 1^s)$: The ideal-world execution involves the environment $\mathcal{Z}$ and an ideal-world adversary denoted $\mathcal{S}$. $\mathcal{Z}$ and $\mathcal{S}$ can communicate arbitrarily during the ideal-world execution. Now the execution is defined as below where $\mathsf{Honest} \subseteq [m]$ denotes the set of honest machines; and $\mathsf{Crupt} := [m] \backslash \mathsf{Honest}$ denotes the set of corrupt machines all of which are controlled $\mathcal{S}$:
  1. First, $\mathcal{Z}$ chooses and provides inputs $x_1, x_2, \ldots, x_m$ for each of the m machines.
  2. Every honest machine $i \in \mathsf{Honest}$ sends the input x_i received from $\mathcal{Z}$ to $\mathcal{F}^f$, and $\mathcal{F}^f$ records $\widetilde{x}_i := x_i$;
  3. For a corrupt machine $j \in \mathsf{Crupt}$, $\mathcal{F}^f$ may receive an input x'_j from j, and if so, it records $\widetilde{x}_j := x'_j$. Note that corrupt machines may use arbitrary inputs, and not necessarily the ones provided by $\mathcal{Z}$.
  4. As soon as all m machines have provided input, $\mathcal{F}^f$ computes the outputs $(y_1, y_2, \ldots, y_m) := f(\widetilde{x}_1, \widetilde{x}_2, \ldots, \widetilde{x}_m)$ and gives $\{y_i\}_{i \in \mathsf{Crupt}}$ to $\mathcal{S}$.
  5. Upon receiving `deliver` from the ideal-world adversary denoted $\mathcal{S}$, if any corrupt machine j has not yet provided input, set $\widetilde{x}_j := \perp$ and compute $(y_1, y_2, \ldots, y_m) := f(\widetilde{x}_1, \widetilde{x}_2, \ldots, \widetilde{x}_m)$. Now for $i \in [m]$, give y_i to machine i.
  6. Upon receiving an output from $\mathcal{F}^f$, an honest machine forwards the output to $\mathcal{Z}$.

In this paper, we define a notion of compositional security for multi-party computation analogous to the guarantees of Universal Composability [30]; moreover, our definition captures the requirement of *guaranteed output*, i.e., a small corrupted coalition should not be able to stop honest machines from producing output. The formal definition is provided below – note that the requirement of guaranteed output is captured since we require that the ideal-world adversary $\mathcal{S}$ send `deliver` to the ideal functionality:

▶ **Definition 21** (SMPC for MPC). *We say that an MPC protocol Π securely realizes some ideal functionality $\mathcal{F}^f$ against a t-bounded adversary where $t < m$ iff for any non-uniform polynomial-time adversary $\mathcal{A}$ that statically corrupts at most t out of m machines, there is a non-uniform polynomial-time ideal-world adversary $\mathcal{S}$ which is required to send* `deliver` *to $\mathcal{F}^f$, such that for any non-uniform polynomial-time environment $\mathcal{Z}$,*

$$\left\{ \mathsf{View}^{\mathcal{Z}}(\mathbf{Real}^{\mathcal{A},\mathcal{Z},\Pi}(1^\kappa, 1^m, 1^s)) \right\}_\kappa \approx \left\{ \mathsf{View}^{\mathcal{Z}}(\mathbf{Ideal}^{\mathcal{S},\mathcal{Z},\mathcal{F}^f}(1^\kappa, 1^m, 1^s)) \right\}_\kappa$$

where $\mathsf{View}^{\mathcal{Z}}(\mathbf{Expt})$ denotes the view of $\mathcal{Z}$ in the experiment $\mathbf{Expt}$ and $\approx$ denotes computational indistinguishability of two probability ensembles.

Resilience assumption

Henceforth we will assume that the adversary controls no more than $\frac{1}{3} - \eta$ fraction of the machines for an arbitrarily small constant η. Such a corruption threshold is (almost) the best one can hope for in a pairwise point-to-point network, since it takes at least 2/3 honest to realize broadcast [48, 82] (note that multi-party computation with guaranteed output implies broadcast).

5.3 Building Block: Constant-Round, Weakly Space-Efficient SMPC

We will leverage a universally composable SMPC protocol as a building block, and we would like this protocol to be not only constant round, but also somewhat efficient in space. Specifically, if the function $f(x_1, \ldots, x_{m'})$ evaluated requires $S \geq |x_1| + |x_2| + \ldots |x_{m'}|$ space to compute insecurely on a RAM, then for m' machines to securely compute the function f would require each machine to expend about $O(S)$ space, and moreover, allowing a $\mathsf{poly}(\kappa)$ blowup due to the use of cryptography. While this seems somewhat conserving in terms of space from the perspective of each individual machine, from the perspective of all m' machines, we are expending m' times more total space than the original RAM – for this reason, we call this notion weakly space-efficient. More formally, we require the following efficiency guarantees:

1. *Constant round*: the protocol must complete in $O(1)$ rounds;
2. *Weak space efficiency*: suppose that the function $f(x_1, x_2, \ldots, x_{m'})$ can be computed insecurely on a Random Access Machine (RAM) with S space where S must account for the space needed to write down all m' inputs and outputs, we would then like a protocol running on m' machines that securely realize $\mathcal{F}^f$, requiring only $\mathsf{poly}(\kappa) \cdot O(S)$ space on each machine.
3. *Communication efficiency*: total communication must be asymptotically not more than the total space of all machines;

Note that we cannot directly use this SMPC protocol to compile an MPC protocol to a secure counterpart if we want to preserve the efficiency of the original (insecure) MPC, since weak space efficiency still blows up each machine's space complexity to at least the size of the whole input. Looking ahead, we will run this SMPC building block within a randomly elected poly-logarithmic-sized committee to emulate a MPC machine with small space.

On the other hand, since a machine cannot receive messages of length greater than its space complexity, a constant-round, weakly space efficient SMPC protocol has communication complexity at most $\mathsf{poly}(\kappa) \cdot O(m' \cdot S)$, independent of the time complexity of the functionality f. Constant-round protocols based on garbled circuits or garbled RAM do not achieve desired efficiency. Thus, we consider FHE-based SMPC protocols, and furthermore, we would require the FHE schemes to satisfy a strong notion of *compactness* [55, 58] to avoid dependency on the circuit depth complexity of the functionality (which is the case if standard leveled FHE schemes are used). FHE schemes with this compactness property can be achieved by assuming circular security for standard FHE constructions [55,58] or using indistinguishability obfuscation [31, 53].

There is a long line of work on constant-round FHE-based SMPC that construct SMPC protocols based on threshold FHE (TFHE) or multi-key FHE (MKFHE) [14, 28, 72, 75, 91]. For our purpose, relying on these protocols would requires to assume above-mentioned compactness for TFHE or MKFHE (and trusted setup for some of them). Ideally, we would like to construct a protocol based on any compact (plain) FHE.

To achieve this goal, we follow the approach of constructing SMPC based on threshold FHE (e.g., [8]) and obtain the threshold FHE in use by applying the universal thresholdizer of Boneh et al. [23] to any compact FHE. We show that this yields a constant-round weakly space efficient SMPC protocol, but it requires a trusted setup. We further remove the setup by invoking another constant-round FHE-based SMPC protocol of Badrinarayanan et al. [14] to instantiate the setup. The protocol of [14] does not require a trusted setup. Furthermore, since the setup of threshold FHE has complexity independent of the complexity of the functionality, we do not need to assume compactness for the underlying (multi-key) FHE in the protocol of [14] to achieve weak space efficiency.

Later in our construction, we actually require that each machine receives different output in this SMPC protocol. Namely, the functionality to be securely computed is $f = (f_1, \ldots, f_{m'})$ where each machine M_i receives output $f_i(x_1, \ldots, x_{m'})$. In this case, we consider the space complexity as the maximal space complexity of $f_1, \ldots, f_{m'}$. Formally, we obtain the following theorem, which will serve as the building block of our SMPC for MPC construction. We prove the theorem in Appendix A.

▶ **Theorem 22** (Constant-round, weakly space-efficient, and communication efficient SMPC)**.** *Assume that the LWE assumption holds, the existence of enhanced trapdoor permutations, and the existence of FHE with an appropriate notion of compactness defined in Appendix A.1. Then, for any polynomial-time computable functions $f = (f_1, \ldots, f_{m'})$, there is a constant-round, weakly space-efficient, and communication efficient protocol that securely realizes $\mathcal{F}^f$ on m' machines against a t-bounded adversary as long as $m' \geq 3t + 1$.*

Proof. Deferred to Appendix A. ◀

5.4 Intuition

Given an original insecure MPC protocol that computes some function f over m machines' respective inputs, we would like to compile it to an SMPC protocol that securely realizes the functionality $\mathcal{F}^f$. We would like the compilation to be efficiency-preserving, that is, if the original MPC protocol completes in R rounds consuming s space per machine, then the compiled SMPC protocol completes in $O(R)$ rounds, and consumes $O(s) \cdot \mathsf{poly} \log \lambda \cdot \mathsf{poly}(\kappa)$ space per machine. Specifically, κ and λ denote a computational and a statistical security parameter respectively: the $\mathsf{poly}(\kappa)$ blowup is due to the use of cryptography and the $\mathsf{poly} \log \lambda$ blowup stems from random committee election.

Inspired by Boyle et al. [24, 27], our idea is to randomly elect a small, polylogarithmically sized committee to securely emulate each machine of the original MPC protocol. We use $m' = \mathsf{poly} \log \lambda$ to denote the size of each committee to distinguish from the total number of machines m. Suppose that $(1/3 - \eta)m$ machines are corrupt where η is an arbitrarily small constant, then by Chernoff bound, within each committee, only $t' \leq (1/3 - \eta/2)m'$ are corrupt except with negligible (in both λ and κ) probability.

Without loss of generality, henceforth we may assume that the original MPC protocol is communication-oblivious. If not, we can always take the compiler of Section 4.6 and compile the protocol to a communication-oblivious counterpart incurring only constant round and space blowup.

The state of each machine $i \in [m]$ in the original MPC protocol will now be secret shared among the i-th committee using a t'-out-of-m' robust secret sharing scheme. This means that at the beginning of the protocol, after each machine $i \in [m]$ receives an input it will invoke a protocol to secret share its input among the i-th committee. To accomplish this, machine i and the i-th committee will jointly perform a constant-round, weakly space-efficient,

and communication efficient SMPC (see Section 5.3) that realizes a robust secret-sharing functionality. Within each round, each machine $i \in [m]$ in the original MPC protocol must perform some local computation; in the compiled secure protocol, this computation will now be jointly performed by the i-th committee using a constant-round, weakly space-efficient, and communication efficient SMPC protocol (see Section 5.3). At end of this SMPC protocol, every committee member obtains a robust secret-share of machine i's new state in the original MPC. Finally, for a machine $i \in [m]$ to send a message to a machine $j \in [m]$ in the original MPC protocol, this communication will now also be implemented by an instance of a constant-round, weakly space-efficient SMPC protocol among the i-th and the j-th committees. At the end of the protocol, each member of the j-th committee should receive a robust secret share of the message.

5.5 Assumptions and Notations

5.5.1 Assumptions on the Original MPC

Without loss of generality, we can make the following assumptions on the original MPC to be compiled:

WLOG_1: We assume that the original MPC to be compiled has a deterministic communication pattern; and moreover, in every round every machine sends at most s words (where sending the same word to two machines is counted twice). Not only so, we may assume that in every round, every machine can compute on the fly and write down 1) an ordered list of at most s machines it wants to send words to and 2) an ordered list of at most s machines it is expecting to receive data from; and moreover this can be accomplished in $O(s)$ space.

If this is not the case, we can always apply the oblivious-compiler of Section 4.6 to make it so while incurring only constant blowup in round complexity and space.

WLOG_2: We may in fact assume that in the original MPC, at the end of the computation step in every round, every machine writes down at a designated location in memory (e.g., address 0) a list of at most s words to be sent. Recall that by WLOG_1, the destinations of these outgoing words are deterministic and a-priori known.

WLOG_3: We assume that in each round, after receiving messages from the network, a machine appends the received messages to its local memory in an arbitrary order. This is without loss of generality since during the computation step, the machine can always sort the received messages locally based on any order that is desired.

5.5.2 Notations

We will use the following notations:

- Let $\mathsf{mem}' \leftarrow M_r^i(\mathsf{mem})$ be the description of the RAM corresponding to machine i's computation in the r-th round in the original MPC; it takes in machine i's current memory mem and outputs a new memory state mem'.
- Let $m' = \mathsf{poly}\log\lambda$ denote each small committee's size, let η be an arbitrarily small constant, and let $t' = (1/3 - \eta/2)m'$ such that each committee has at most t' corrupt nodes except with negligible probability (see also the proof of Theorem 23).
- Let $(\mathsf{Share}, \mathsf{Recons})$ denote a t'-out-of-m' robust secret sharing scheme (see Appendix D). If the Share algorithm is provided with a string consisting of multiple words, we always assume that Share will perform secret sharing *word by word*; and similarly Recons will be performed word by word too.

- Later in our protocol, a small committee will be elected to emulate each machine in the original MPC protocol. Henceforth the committee that is emulating machine i in the original MPC is called the i-th committee.

5.5.3 Computing Relevant Committee Information on the Fly

To enable the pseudo-random committee election, a common reference string crs will be distributed to all honest machines at protocol start, and thus crs is common knowledge. In our protocol, committee election relies only on the crs. Specifically, the i-th committee is decided by $\mathsf{PRF}_{\mathsf{crs}}(i)$ where PRF is a pseudorandom function. At this point, it might seem safe to assume that the members of all committees are common knowledge. There is a slight subtlety here in that a machine in fact cannot store the members of all committees since this would consume too much space. Fortunately, by consuming $\mathsf{poly}\log\lambda \cdot O(s)$ additional space, a machine i can always compute on the fly and temporarily store members of committees relevant to itself in some round, including

1. which committees it is serving on, and all members of every committee it is serving on – we will show that every machine serves on at most $\Theta(m') = \mathsf{poly}\log\lambda$ committees except with negligible probability (see proof of Theorem 23);
2. all members of every committee it wants to communicate with in the present round: there are at most $2s$ such committees due to the s-sender-constraint and the s-receiver-constraint – note that to write this information down we rely on the fact that the original MPC to be compiled has a deterministic and fixed communication pattern;
3. all members of the committee emulating machine i itself.

Because of the above observations, later in Section 5.6, for simplicity it is unambiguous to parametrize our ideal functionalities that serve 1 or 2 committees with the relevant committee's indices – if a machine needs interact with some ideal functionality, it can be computed on-the-fly exactly which other machines will also be involved. Except with negligible probability, the additional per-machine space needed to compute on-the-fly and store the committee information relevant to the present round is bounded by $\mathsf{poly}\log\lambda \cdot O(s)$.

5.6 Intermediate Building Blocks

We will adopt the constant-round, weakly space efficient, and communication efficient SMPC protocol of Section 5.3 among one to two small committee(s) to securely realize a few useful ideal functionalities which we can adopt as intermediate building blocks:

- $\mathcal{F}^{\mathsf{share}[i]}$ is the ideal functionality that allows machine i to secret share its state among the i-th committee; $\mathcal{F}^{\mathsf{share}[i]}$ involves $m'+1$ participants among whom at most $t'+1$ can be corrupt;
- $\mathcal{F}^{\mathsf{comp}^r[i]}$ is the ideal functionality that allows the i-th committee to jointly emulate the computation of machine i in the r-th round in the original MPC; $\mathcal{F}^{\mathsf{comp}^r[i]}$ involves m' participants among whom at most t' corruptions; and
- $\mathcal{F}^{\mathsf{send}[i,i']}$ is the ideal functionality that emulates machine i sending a message to machine i' in the original MPC; $\mathcal{F}^{\mathsf{send}[i,i']}$ involves $2m'$ participants (i.e., the sending and receiving committees), among whom at most $2t'$ can be corrupt.

More formally, to define each of $\mathcal{F}^{\mathsf{share}[i]}$, $\mathcal{F}^{\mathsf{comp}^r[i]}$, and $\mathcal{F}^{\mathsf{send}[i,i']}$, we only need to specify what the functions $\mathsf{share}[i]$, $\mathsf{comp}^r[i]$, and $\mathsf{send}[i,i']$ compute respectively and among which players.

1. $\mathsf{share}[i]$: a function that anticipates inputs from machine i as well as members of the i-th committee. The function ignores everyone's input and looks at only machine i's input henceforth denoted x, and computes $(\overline{x}_1, \ldots, \overline{x}_{m'}) \leftarrow \mathsf{Share}(x)$. It outputs $\perp$ to machine i, and $\overline{x}_j$ to the j-th member of the i-th committee for $j \in [m']$.
2. $\mathsf{comp}^r[i]$: the function $\mathsf{comp}^r[i]$ anticipates inputs from members of the i-th committee denoted $\overline{\mathsf{mem}}_1, \overline{\mathsf{mem}}_2, \ldots, \overline{\mathsf{mem}}_{m'}$. It internally evaluates $\mathsf{mem}' \leftarrow M_r^i(\mathsf{Recons}(\{\overline{x}_j\}_{j\in[m']}))$, and $(\overline{\mathsf{mem}}'_1, \ldots, \overline{\mathsf{mem}}'_{m'}) \leftarrow \mathsf{Share}(\mathsf{mem}')$. Now, the j-th member of the i-th committee is supposed to get $\overline{\mathsf{mem}}'_j$ for $j \in [m']$.
3. $\mathsf{send}[i, i']$: this function anticipates inputs from the i-th committee and the i'-th committee. It ignores the inputs from the i'-th committee, and looks at only inputs from the i-th committee henceforth denoted $\overline{x}_1, \ldots, \overline{x}_{m'}$. It internally evaluates $x \leftarrow \mathsf{Recons}(\overline{x}_1, \ldots, \overline{x}_{m'})$, and $\overline{y}_1, \ldots, \overline{y}_{m'} \leftarrow \mathsf{Share}(x)$. Now, $\overline{y}_j$ is meant as the output for the j-th member of the i'-th committee for $j \in [m']$.

5.7 Compilation to a Hybrid Protocol

Since a machine may participate in multiple committees, henceforth when the machine we are concerned with is clear from the context, we often use the notation $\overline{\mathsf{mem}}_j$ a machine's robust secret share pertaining to the j-th committee (assuming that i indeed participates in the j-th committee). Given an original communication-oblivious MPC protocol, our SMPC compiler works as follows where $\mathsf{PRF} : \{0,1\}^\kappa \times [m] \to [m]^{m'}$ denotes a pseudo-random function:

- *Initialize.* At protocol start, a random common reference string denoted $\mathsf{crs} \xleftarrow{\$} \{0,1\}^\kappa$ is chosen which will be used for committee election. Every machine i now receives an input x_i from the environment $\mathcal{Z}$, and each machine is also informed of crs.
- *Committee election.* Now, the pseudo-random string $\mathsf{PRF}_{\mathsf{crs}}(j)$ can be used to determine the m' members of the j-th committee for $j \in [m]$. Note that instead of storing all members of every committee, relying on the observations in Section 5.5.3, machines will instead compute all the relevant committee information on the fly, in all of the subsequent steps of the protocol; and this will not consume too much space. For simplicity, in our description below, we will not explicitly describe how a machine computes the relevant committee information needed in every round.
- *Secret-share input.* Each machine $i \in [m]$ sends its input x_i to $\mathcal{F}^{\mathsf{share}[i]}$. For every committee i serves on, machine i sends $\perp$ to $\mathcal{F}^{\mathsf{share}[i]}$. As a result every member of the i-th committee obtains a robust secret share of x_i from $\mathcal{F}^{\mathsf{share}[i]}$. When a machine i participating in the j-th committee receives a robust secret share $\overline{v}$ from $\mathcal{F}^{\mathsf{share}[j]}$, it sets $\overline{\mathsf{mem}}_j := \overline{v}$.
- *Emulate protocol.* For every round $r \in [R]$ where R denotes the worst-case round complexity of the original MPC protocol, every machine $i \in [m]$ does the following:
  - *Emulate computation:* For each committee $j \in [m]$ the machine i serves on, machine i sends $\overline{\mathsf{mem}}_j$ to $\mathcal{F}^{\mathsf{comp}^r[i]}$. It will obtain from $\mathcal{F}^{\mathsf{comp}^r[i]}$ an updated share of the new memory denoted $\overline{\mathsf{mem}}'$. Machine i overwrites its $\overline{\mathsf{mem}}_j$ variable with $\overline{\mathsf{mem}}'$.
  - *Emulate sending:* For each committee $j \in [m]$ the machine i serves on, do the following: recall that by WLOG_2, shares of the words to be sent are written at a designated location in $\overline{\mathsf{mem}}_j$. By WLOG_1, the total number of words committee j wants to send in this round $s' \le s$ is deterministic and a-priori known; and moreover the s' destination machines can be computed on the fly and written down in $O(s)$ space. Henceforth let $d_1, d_2, \ldots, d_{s'}$ be the $s' \le s$ destination machines' identifiers, and let $\overline{y}_1, \ldots, \overline{y}_{s'}$ denote the shares of the words to send to them respectively. For each d_k where $k \in [s']$, send $\overline{y}_k$ to $\mathcal{F}^{\mathsf{send}[j,d_k]}$.

- *Emulate receiving:* For every committee j' that machine i serves on, if in the original MPC machine $j \in [m]$ is supposed to send message to machine j' (all such j's can be computed and written down on the fly due to WLOG_1), then for every such j:
  1. send $\perp$ to $\mathcal{F}^{\mathsf{send}[j,j']}$ indicating participation as a receiver;
  2. the machine i will receive a secret share $\overline{y}$ from $\mathcal{F}^{\mathsf{send}[j,j']}$, now append $\overline{y}$ to its $\overline{\mathsf{mem}}_j$.
- *Output.* After emulating all rounds of the original MPC in the above manner, machine i does the following: for every committee j it serves on, send $\overline{\mathsf{mem}}_j$ to machine j. When each machine i receives shares from at least $2m'/3$ members of the i-th committee, call Recons with the $2m'/3$ shares received and output the corresponding output.

▶ **Theorem 23.** *Suppose that the PRF scheme employed is secure*[8]*, and that the MPC protocol* Π *to be compiled obliviously realizes the ideal functionality* f *by Definition 6. Then, if we apply the above compiler to* Π *to obtain a hybrid-world protocol* Π_{hyb}*,* Π_{hyb} *must securely realizes* $\mathcal{F}^f$ *by Definition 21, as long as the adversary controls no more than* $1/3 - \eta$ *fraction of the machines (for an arbitrarily small constant* η*).*

Proof. Let $\mathcal{A}$ be a PPT adversary and $\mathsf{Crupt} \subset [m]$ of size $|\mathsf{Crupt}| \leq (1/3 - \eta) \cdot m$ be the set of machines corrupted by $\mathcal{A}$. We first show that except with negligible probability, (i) all the committees elected by $\mathsf{PRF}_{\mathsf{crs}}$ have at most $(1/3 - \eta/2) \cdot m'$ corrupted machines, and (ii) each machine participates in at most $2m'$ committees.[9] Suppose the committees were elected using truly uniform randomness, then the expected corrupted machines in a committee is $m' \cdot |\mathsf{Crupt}|/m \leq (1/3 - \eta) \cdot m'$ and the expected number of committees a machine participate is m'. By a Chernoff Bound and union bound, both (i) and (ii) hold except with probability $e^{-\Omega(m')} = \mathsf{negl}(\lambda)$. Since both properties can be checked efficiently, by the security of PRF, the probability that the committees elected by $\mathsf{PRF}_{\mathsf{crs}}$ violates violate (i) or (ii) is at most $\mathsf{negl}(\kappa) + \mathsf{negl}(\lambda)$. Hence, in the rest of the proof, we assume both (i) and (ii) hold. We proceed to define a simulator $\mathcal{S}$:

- *Initialize and Committee election.* $\mathcal{S}$ simply simulate a random crs. There is no communication in the committee election step.
- *Secret-share input.* In this step, $\mathcal{S}$ extracts the adversary $\mathcal{A}$'s input $\{x_i\}_{\mathsf{Crupt}}$ from $\mathcal{F}^{\mathsf{share}[i]}$ for $i \in \mathsf{Crupt}$. $\mathcal{S}$ sends $\{x_i\}_{\mathsf{Crupt}}$ to the ideal functionality. For the output of $\mathcal{F}^{\mathsf{share}[\cdot]}$ that $\mathcal{A}$ receives, since each committee has at most $(1/3 - \eta/2) \cdot m'$ corrupted machines, $\mathcal{S}$ can simulate the shares outputted by each $\mathcal{F}^{\mathsf{share}[\cdot]}$ by generating a fresh $\mathsf{Share}(0)$.
- *Emulate protocol.* Note both $\mathcal{F}^{\mathsf{comp}^r[\cdot]}$ and $\mathcal{F}^{\mathsf{send}[\cdot,\cdot]}$ also output shares, by the same reason, $\mathcal{S}$ can simulate the shares outputted by each $\mathcal{F}^{\mathsf{comp}^r[\cdot]}$ and $\mathcal{F}^{\mathsf{send}[\cdot,\cdot]}$ to $\mathcal{A}$ by fresh secret sharings $\mathsf{Share}(0)$.
- *Output.* $\mathcal{S}$ sends `deliver` to the ideal functionality and receives the output $\{y_i\}_{i \in \mathsf{Crupt}}$. For each $i \in \mathsf{Crupt}$, $\mathcal{S}$ generates $\mathsf{Share}(y_i)$ and sends the shares that machine i should receive from the honest machines in the i-th committee.

By perfect privacy of the RSS, it is clear that the shares outputted by $\mathcal{F}^{\mathsf{share}[\cdot]}$, $\mathcal{F}^{\mathsf{comp}^r[\cdot]}$ and $\mathcal{F}^{\mathsf{send}[\cdot,\cdot]}$ are simulated perfectly.

---

[8] In fact, this hybrid-world theorem secures against even computationally unbounded adversaries despite the use of the PRF, since the PRF is used to defeat only the polynomial checkable function whether some committee has 1/3 or more corruption.

[9] In fact, property (ii) is not needed for proving security but we will use it to analyze efficiency of the protocol later.

Now, note that our protocol Π_{hyb} emulate the underlying MPC protocol by committees, where all the input and messages are stored by shares of the robust secret sharing scheme (RSS) in each committee. Since all committee has at most $(1/3 - \eta) \cdot m' < m'/3$ corrupted machines, by robustness of RSS, the adversary cannot change the value stored in the RSS. Hence the underlying MPC protocol is emulated correctly, and at the end, each machine $i \in \mathsf{Crupt}$ receives shares of $\mathsf{Share}(y_i)$ from the i-th committee. Hence, $\mathcal{S}$ also simulates the shares in the output step perfectly.

Therefore, Π_{hyb} securely realizes $\mathcal{F}^f$, in fact, with statistical security in this hybrid model. ◀

5.8 Compilation to a Real-World Protocol

In Section 5.7, we compiled a communication-oblivious MPC protocol Π to a secure counterpart Π_{hyb} assuming the existence of ideal functionalities $\mathcal{F}^{\mathsf{share}[i]}$, $\mathcal{F}^{\mathsf{comp}^r[i]}$, and $\mathcal{F}^{\mathsf{send}[i,i']}$. Eventually we would like to replace these ideal functionalities with real-world building blocks. This is easy:

- Let $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$ be SMPC protocols that securely realize (by Definition 21) $\mathcal{F}^{\mathsf{share}[i]}$, $\mathcal{F}^{\mathsf{comp}^r[i]}$, and $\mathcal{F}^{\mathsf{send}[i,i']}$ respectively. Note that $\Pi^{\mathsf{share}[i]}$ is a protocol among machine i and the i-th committee, $\Pi^{\mathsf{comp}^r[i]}$ is a protocol among the i-th committee, and $\Pi^{\mathsf{send}[i,i']}$ is a protocol among the i-th committee and the i'-th committee.
- In the compiled hybrid-world protocol in Section 5.7, whenever a machine invokes some ideal functionality $\mathcal{F}^{\mathsf{share}[i]}$, $\mathcal{F}^{\mathsf{comp}^r[i]}$, or $\mathcal{F}^{\mathsf{send}[i,i']}$ with the input x, it now invokes the corresponding protocol, $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, or $\Pi^{\mathsf{send}[i,i']}$ respectively, also with the input x.
- In the compiled hybrid-world protocol in Section 5.7, whenever a machine is to receive output from the ideal functionality $\mathcal{F}^{\mathsf{share}[i]}$, $\mathcal{F}^{\mathsf{comp}^r[i]}$, or $\mathcal{F}^{\mathsf{send}[i,i']}$, it now instead receives the output from $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, or $\Pi^{\mathsf{send}[i,i']}$ respectively.

Note that due to the observations made in Section 5.5.3, at the beginning of every round, every machine can compute on the fly and temporarily store members of all committees relevant to itself in this round, including committees it serves on and committees it will interact with – and this will only incur $O(s) \cdot \mathsf{poly}\log\lambda$ additional space. Therefore, for every protocol $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, or $\Pi^{\mathsf{send}[i,i']}$ invoked, the machine already knows exactly who are the other machines involved in the protocol. Not only so, in fact, at the beginning of every round, a machine has written down a receiving schedule for this round, again consuming $O(s) \cdot \mathsf{poly}\log\lambda$ additional space. As mentioned, if a machine receives any message from unanticipated senders or excessive messages from anticipated senders, these messages get discarded immediately and will not be stored or processed.

Efficiency of the compiled protocol

Let Π_{real} denote the compiled real-world protocol by applying the compiler described above to an original MPC communication-oblivious protocol Π. Since all of $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$ complete in constant number of rounds, clearly, the round complexity of Π_{real} is only a constant factor more than the original Π.

We now analyze the per-machine space complexity. We will use the fact that $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$ are weakly space efficient. We first focus on the space expended by each machine *for every committee it serves on*. Recall that each robust secret share of a machine's state in the original MPC is only $O(s)$ in size. The dominant part is the space consumed during $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$ protocols. Note that all of the

functions evaluated by $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$ protocols have at most $O(s)$ RAM-space complexity. Now, observe that a RAM consuming space s can be converted to a layered circuit of width s. Recall also that at most $2m'$ machines participate in each of $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$. Thus by weak space efficiency, the space consumed by each $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, or $\Pi^{\mathsf{send}[i,i']}$ instance is at most $O(m' \cdot s) \cdot \mathsf{poly}(\kappa)$. So far we have focused on the space per machine per committee it serves on. The total space consumption of any single machine is at most $2m' \cdot O(m' \cdot s) \cdot \mathsf{poly}(\kappa)$, where $2m'$ is an upper bound on the number of committees a machine can participate in by the proof of Theorem 23 (except for a negligible probability). Since $m' = \mathsf{poly} \log \lambda$, the total space per machine is upper bounded by $\mathsf{poly} \log \lambda \cdot \mathsf{poly}(\kappa) \cdot O(s)$ (for some other suitable polynomial poly).

Finally, the total communication is asymptotically no more than the total space by the communication efficiency requirement.

▶ **Corollary 24.** *Suppose that the PRF employed is secure, and that the* $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, *and* $\Pi^{\mathsf{send}[i,i']}$ *protocols employed securely realize* $\mathcal{F}^{\mathsf{share}[i]}$, $\mathcal{F}^{\mathsf{comp}^r[i]}$, *and* $\mathcal{F}^{\mathsf{send}[i,i']}$ *protocols respectively by Definition 21 as long as at least* $2/3$ *fraction of the machines participating in each protocol instance are honest; and moreover suppose that they are constant-round, weakly space efficiency, and communication efficient as defined in Section 5.3. Suppose that the MPC protocol* Π *obliviously realizes the ideal functionality* f *by Definition 6. Then, if we apply the above compiler to* Π *to obtain a real-world protocol* Π_{real}, Π_{real} *must securely realizes* $\mathcal{F}^f$ *by Definition 21. Moreover,* Π_{real}*'s round complexity is asymptotically the same as* Π*; its per-machine space consumption is at most* $O(s) \cdot \mathsf{poly}(\kappa)$ *where* κ *denotes the security parameter and* s *is the per-machine space of the original* Π*, and its total communication is upper bounded* $O(m \cdot s) \cdot \mathsf{poly}(\kappa)$.

Proof. As shown in the proof of Theorem 23, indeed, in each committee at least $2/3$ fraction of the machines must be honest. Now, security follows from a standard compositional argument: for any real-world adversary $\mathcal{A}$ attacking Π_{real}, we can construct a hybrid-world adversary $\mathcal{A}'$ that basically calls the simulators of all instances of $\Pi^{\mathsf{share}[i]}$, $\Pi^{\mathsf{comp}^r[i]}$, and $\Pi^{\mathsf{send}[i,i']}$, and no polynomial-time environment $\mathcal{Z}$ should be able distinguish whether it is in the real world interacting with $\mathcal{A}$ or the hybrid world interacting with $\mathcal{A}'$. Now, by Theorem 23, for this hybrid-world adversary $\mathcal{A}'$ corresponding to the real-world adversary $\mathcal{A}$, we can construct an ideal-world adversary $\mathcal{S}$, such that no polynomial-time environment $\mathcal{Z}$ can distinguish whether it is in the hybrid world or the ideal world. Thus we can conclude that no polynomial-time environment $\mathcal{Z}$ can distinguish whether it is in the real world interacting with $\mathcal{A}$ or the ideal world interacting with $\mathcal{S}$.

Finally, the efficiency statements follow from the analysis in the paragraph before the corollary. ◀

Main theorem statement for SMPC-for-MPC

Recall that the main theorem statement for our "MPC to SMPC-for-MPC" compiler is Theorem 2. We restate it below for the reader's convenience and complete our presentation with a proof.

▶ **Theorem 25** (Secure computation for MPC: Restatement of Theorem 2)**.** *Assume the existence of a common random string, the Learning With Errors (LWE) assumption, enhanced trapdoor permutations, as well as the existence of an FHE scheme with a suitable notion of compactness (see Appendix A.1 for a formal definition of compactness). Suppose that* $s = N^{\varepsilon}$ *and that* m *is upper bounded by a fixed polynomial in* N*. Let* κ *denote a security parameter,*

and assume that $s \geq \kappa$. Given any MPC algorithm Π that completes in R rounds where each of the m machines has s local space, there is an MPC algorithm $\widetilde{\Pi}$ that securely realizes the same function computed by Π in the presence of an adversary that statically corrupts at most $\frac{1}{3} - \eta$ fraction of the machines for an arbitrarily small constant η. Moreover, $\widetilde{\Pi}$ completes in $O(R)$ rounds, consumes at most $O(s) \cdot \mathsf{poly}(\kappa)$ space per-machine, and incurs $O(m \cdot s) \cdot \mathsf{poly}(\kappa)$ total communication per round.

Proof. We may first apply the communication-oblivious compiler corresponding to Theorem 1 to compile Π to a communication-oblivious counterpart Π', we then apply the compiler corresponding to Corollary 24 on Π'. The theorem then follows in a straightforward fashion due to Theorem 1 and Corollary 24. ◀

A Proof of Theorem 22: the CommitteeMPC Protocol

In this section, we construct a constant-round, weakly space efficient, and communication efficient SMPC protocol as stated in Theorem 22. Starting from a compact FHE, we first apply the universal thresholdizer of Boneh et al. [23] to obtain a compact threshold FHE. We show that the resulting threshold FHE has desired security by Definition 21. Thus we can use it to construct a semi-malicious secure constant-round, weakly space efficient SMPC in a trusted setup model. The protocol can then be converted to a maliciously secure one by a generic transformation [14, 75], and the setup can be removed by invoking the SMPC protocol of Badrinarayanan et al. [14]. We start with the definitions.

Notation

We will use the variable m to denote the number of machines, although keep in mind that when the SMPC protocol in this section is employed in our "MPC to SMPC-for-MPC" compiler, this SMPC building block is in fact applied to at most $2m' = \mathsf{poly}\log\lambda$ number of machines.

A.1 Preliminaries

Fully Homomorphic Encryption

We first define fully homomorphic encryption schemes (FHE) with a strong compactness property. A FHE scheme is a tuple of PPT algorithms $\Pi_{\mathsf{FHE}} = (\mathsf{FHE.KeyGen}, \mathsf{FHE.Enc}, \mathsf{FHE.Eval}, \mathsf{FHE.Dec})$ defined as follows:

- $\mathsf{FHE.KeyGen}(1^\kappa) \to (\mathsf{pk}, \mathsf{sk})$: On input the security parameter κ, the key generation algorithm outputs a public key pk and a secret key sk.
- $\mathsf{FHE.Enc}(\mathsf{pk}, x) \to \mathsf{ct}$: On input a public key pk and a message $x \in \{0,1\}$, the encryption algorithm outputs a ciphertext ct. For convenience, for a message $x \in \{0,1\}^\ell$, we use $\mathsf{FHE.Enc}(\mathsf{pk}, x) = \mathsf{FHE.Enc}(\mathsf{pk}, x_1), \ldots \mathsf{FHE.Enc}(\mathsf{pk}, x_\ell)$ to denote the bit by bit encryptions of x.
- $\mathsf{FHE.Eval}(\mathsf{pk}, C, \mathsf{ct}_1, \ldots, \mathsf{ct}_\ell) \to \hat{\mathsf{ct}}$: On input a public key pk, a circuit $C : \{0,1\}^\ell \to \{0,1\}$ and ciphertexts $\mathsf{ct}_1, \ldots, \mathsf{ct}_\ell$, the homomorphic evaluation algorithm outputs another ciphertext $\hat{\mathsf{ct}}$.
- $\mathsf{FHE.Dec}(\mathsf{sk}, \hat{\mathsf{ct}}) \to \hat{\mu}$: On input a secret key sk and a ciphertext $\hat{\mathsf{ct}}$, the decryption algorithm outputs a bit $\hat{\mu}$.

Correctness

We require that for all $\kappa \in \mathbb{N}$, $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{FHE.KeyGen}(1^\kappa)$, circuit $C : \{0,1\}^\ell \to \{0,1\}$ and corresponding inputs $x_1, \ldots, x_\ell \in \{0,1\}$, it holds that

$$\Pr[\mathsf{FHE.Dec}(\mathsf{sk}, \mathsf{FHE.Eval}(\mathsf{pk}, C, \mathsf{ct}_1, \ldots, \mathsf{ct}_\ell)) \neq C(x_1, \ldots, x_\ell)] \leq \mathsf{negl}(\kappa)$$

where $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{FHE.KeyGen}(1^k)$ and $\mathsf{ct}_i \leftarrow \mathsf{FHE.Enc}(\mathsf{pk}, x_i)$.

Security

We require the usual semantic security. Namely, we require that for all $\kappa \in \mathbb{N}$, $(\mathsf{pk}, \mathsf{Enc}(\mathsf{pk}, 0)) \approx_c (\mathsf{pk}, \mathsf{Enc}(\mathsf{pk}, 1))$, where $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{FHE.KeyGen}(1^k)$.

Compactness

We require the following strong compactness property. There exists a polynomial poly such that the following holds. $|\mathsf{pk}|, |\mathsf{sk}|, |\mathsf{ct}| \leq \mathsf{poly}(\kappa)$ for the public and secret key, and any ciphertext ct generated from the algorithms of FHE. Furthermore, for a layered circuit[10] C with width w, homomorphic evaluation of C can be done in space $\mathsf{poly}(\kappa) \times w$, independent of the size or depth of the circuit.[11]

FHE schemes with this compactness property can be achieved by assuming circular security for standard FHE constructions [55, 58] or using indistinguishability obfuscation [31, 53].

Universal Thresholdizer

The following definition of universal thresholdizer is taken from Boneh et al. [23], who constructed universal thresholdizer based on the learning with error assumption. For our purpose, we do not require the verification algorithm, so we omit it from the definition for simplicity.

▶ **Definition 26.** *Fix a security parameter κ and a data space $\mathcal{X}$. A universal thresholdizer scheme is a tuple of algorithm $\Pi_{\mathsf{UT}} = (\mathsf{UT.Setup}, \mathsf{UT.Eval}, \mathsf{UT.Combine})$ defined as follows:*

- $\mathsf{UT.Setup}(1^\kappa, 1^m, 1^t, 1^d, x) \to (\mathsf{pp}, \{\mathsf{sk}_i\}_{i\in[m]})$*: On input the security parameter κ, a number of users in the system m, a threshold $t \in [m]$, a bound on the depth d, and a secret $x \in \mathcal{X}$, the setup algorithm generates the public parameters pp and a set of secret keys $\mathsf{sk}_1, \ldots, \mathsf{sk}_m$ for each user in the system.*
- $\mathsf{UT.Eval}(\mathsf{pp}, \mathsf{sk}_i, C) \to p_i$*: On input the public parameters pp, a secret key sk_i, and a circuit C, the evaluation algorithm outputs a partial evaluation p_i.*
- $\mathsf{UT.Combine}(\mathsf{pp}, \{p_i\}_{i\in S}) \to \hat{\mu}$*: On input the public parameter pp, and a set of partial evaluations $\{p_i\}_{i\in S}$, the combining algorithm outputs the final evaluation μ.*

Evaluation Correctness

We say that a universal thresholdizer scheme $\Pi_{\mathsf{UT}} = (\mathsf{UT.Setup}, \mathsf{UT.Eval}, \mathsf{UT.Combine})$ satisfies evaluation correctness if the following conditions are true. For all $\kappa, m, t, d \in \mathbb{N}, x \in \mathcal{X}$, let $(\mathsf{pp}, \{sk_i\}_{i\in[m]}) \leftarrow \mathsf{UT.Setup}(1^\kappa, 1^m, 1^t, 1^d, x)$, $S \subset [m]$ of size $|S| = t$, and circuit $C : \mathcal{X} \to \{0, 1\}$ of depth at most d, we have that

$$\Pr[\mathsf{UT.Combine}(\mathsf{pp}, \{\mathsf{UT.Eval}(\mathsf{pp}, \mathsf{sk}_i, C)\}_{i\in S}) = C(x)] = 1 - \mathsf{negl}(\kappa),$$

where the probability is over the randomness of $\mathsf{UT.Setup}, \mathsf{UT.Eval}$, and $\mathsf{UT.Combine}$.

[10] A circuit is layered if the circuit can be represented as a layered graph with no wires crossing the layers.
[11] Here the space complexity measures the working space of $\mathsf{FHE.Eval}$ but not the description size of C. Looking ahead, we will consider uniform circuits whose description can be generated in small space.

Privacy

We say that a universal thresholdizer scheme $\Pi_{\mathsf{UT}} = (\mathsf{UT.Setup}, \mathsf{UT.Eval}, \mathsf{UT.Combine})$ satisfies privacy if there exists a PPT simulator Sim such that for all $\kappa \in \mathbb{N}$, polynomial m, t, d, PPT adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3)$, there exists a negligible function $\mathsf{negl}(\kappa)$ such that

$$\left|\Pr[\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{UT}},\mathcal{A}}(\kappa, m, t, d) = 1] - \Pr[\mathsf{Expt}^{\mathsf{Rand}}_{\Pi_{\mathsf{UT}},\mathcal{A}}(\kappa, m, t, d) = 1]\right| \leq \mathsf{negl}(\kappa)$$

where the experiments $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{UT}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Rand}}_{\Pi_{\mathsf{UT}},\mathcal{A}}$ are defined as follows:

- $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{UT}},\mathcal{A}}(\kappa, m, t, d)$:
  1. $(x^*, \mathsf{st}_1) \leftarrow \mathcal{A}_1(1^\kappa)$.
  2. $(\mathsf{pp}, \{\mathsf{sk}_i\}_{i\in[m]}) \leftarrow \mathsf{UT.Setup}(1^\kappa, 1^m, 1^t, 1^d, \underline{x^*})$.
  3. $(S^*, \mathsf{st}_2) \leftarrow \mathcal{A}_2(\mathsf{pp}, \mathsf{st}_1)$ where $|S^*| = t - 1$.
  4. $b \leftarrow \mathcal{A}_3^{\mathcal{O}_{\mathsf{Eval}}(\underline{\{\mathsf{sk}_i\}_{i\in[m]}}, \cdot, \cdot)}(\{\mathsf{sk}_i\}_{i\in S^*}, \mathsf{st}_2)$.
  5. Output b.
- $\mathsf{Expt}^{\mathsf{Rand}}_{\Pi_{\mathsf{UT}},\mathcal{A}}(\kappa, m, t, d)$:
  1. $(x^*, \mathsf{st}_1) \leftarrow \mathcal{A}_1(1^\kappa)$.
  2. $(\mathsf{pp}, \{\mathsf{sk}_i\}_{i\in[m]}) \leftarrow \mathsf{UT.Setup}(1^\kappa, 1^m, 1^t, 1^d, \underline{0^{|x^*|}})$.
  3. $(S^*, \mathsf{st}_2) \leftarrow \mathcal{A}_2(\mathsf{pp}, \mathsf{st}_1)$ where $|S^*| = t - 1$.
  4. $b \leftarrow \mathcal{A}_3^{\mathsf{Sim}^{\mathcal{O}_{\mathsf{Sim}}(\cdot)}(\underline{\{\mathsf{sk}_i\}_{i\in S^*}}, \cdot, \cdot)}(\{\mathsf{sk}_i\}_{i\in S^*}, \mathsf{st}_2)$.
  5. Output b.

where the oracles $\mathcal{O}_{\mathsf{Eval}}(\{\mathsf{sk}_i\}_{i\in[m]}, \cdot, \cdot)$ and $\mathcal{O}_{\mathsf{Sim}}(\cdot)$ are defined as follows

- $\mathcal{O}_{\mathsf{Eval}}(\{\mathsf{sk}_i\}_{i\in[m]}, C, j)$: On input the set of key $\{\mathsf{sk}_i\}_{i\in[m]}$, a circuit C, and an index $j \in [m]\backslash S^*$, outputs $\mathsf{UT.Eval}(\mathsf{pp}, \mathsf{sk}_j, C)$.
- $\mathcal{O}_{\mathsf{Sim}}(C)$: On input a circuit C, if there exists a query (C, j) for some $j \in [m]\backslash S^*$ previously made by $\mathcal{A}_3$, the algorithm outputs $C(x^*)$. Otherwise, it outputs $\perp$.

A.2 Threshold FHE

We now define a notion of threshold FHE schemes with a simulation security that is sufficient to directly construct a semi-malicious SMPC protocol in a trusted setup model. We then show that applying the above universal thresholdizer to a FHE scheme yields such a threshold FHE scheme.

Syntax

A threshold FHE scheme is a tuple of PPT algorithms $\Pi_{\mathsf{TFHE}} = (\mathsf{TFHE.Setup}, \mathsf{TFHE.SimSetup}, \mathsf{TFHE.Enc}, \mathsf{TFHE.Eval}, \mathsf{TFHE.PartDec}, \mathsf{TFHE.FinDec})$ defined as follows:

- $\mathsf{TFHE.Setup}(1^\kappa, 1^m, 1^t) \to (\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]})$: On input the security parameter κ, a number of users in the system m, and a threshold $t \in [m]$, the setup algorithm generates the public key tpk and a set of secret keys $\mathsf{tsk}_1, \ldots, \mathsf{tsk}_m$ for each user in the system.
- $\mathsf{TFHE.SimSetup}(1^\kappa, 1^m, 1^t) \to (\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]})$: On input the security parameter κ, a number of users in the system m, and a threshold $t \in [m]$, the simulation setup algorithm generates the simulated public key tpk and a set of simulated secret keys $\mathsf{tsk}_1, \ldots, \mathsf{tsk}_m$ for each user in the system.
- $\mathsf{TFHE.Enc}(\mathsf{tpk}, x) \to \mathsf{ct}$: On input a public key tpk and a message $x \in \{0, 1\}$, the encryption algorithm outputs a ciphertext ct.

- $\mathsf{TFHE.Eval}(\mathsf{tpk}, C, \mathsf{ct}_1, \ldots, \mathsf{ct}_\ell) \to \hat{\mathsf{ct}}$: On input a public key tpk, a circuit $C : \{0,1\}^\ell \to \{0,1\}$ and ciphertexts $\mathsf{ct}_1, \ldots, \mathsf{ct}_\ell$, the homomorphic evaluation algorithm outputs another ciphertext $\hat{\mathsf{ct}}$.
- $\mathsf{TFHE.PartDec}(i, \mathsf{tpk}, \mathsf{tsk}_i, \hat{\mathsf{ct}}) \to p_i$: On input an index $i \in [m]$, a secret key tsk_i, and a ciphertext $\hat{\mathsf{ct}}$, the partial decryption algorithm outputs a partial decryption p_i.
- $\mathsf{TFHE.FinDec}(\mathsf{tpk}, \{p_i\}_{i\in S}) \to \hat{\mu}$: On input the public key tpk, and a set of partial decryptions $\{p_i\}_{i\in S}$, the final decryption algorithm outputs the final decryption value $\hat{\mu}$.

Correctness

We require that for all $\kappa, m, t \in \mathbb{N}$, $S \subset [m]$, circuit $C : \{0,1\}^\ell \to \{0,1\}$ and corresponding input $x_1, \ldots, x_\ell \in \{0,1\}$, the following holds except with negligible probability in κ: Let $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]}) \leftarrow \mathsf{TFHE.Setup}(1^\kappa, 1^m, 1^t)$, $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i)$ for $i \in [\ell]$, let $\hat{\mathsf{ct}} = \mathsf{TFHE.Eval}(\mathsf{tpk}, C, \mathsf{ct}_1, \ldots, \mathsf{ct}_\ell)$, let $p_i \leftarrow \mathsf{TFHE.PartDec}(i, \mathsf{tpk}, \mathsf{tsk}_i, \hat{\mathsf{ct}})$, and $\hat{\mu} \leftarrow \mathsf{TFHE.FinDec}(\mathsf{tpk}, \{p_i\}_{i\in S})$. Then $\hat{\mu} = C(x_1, \ldots, x_\ell)$ if $|S| \geq t$, and $\hat{\mu} = \perp$ otherwise.

Compactness

We require the same compactness property as in FHE. There exists a polynomial poly such that the following holds. $|\mathsf{pk}|, |\mathsf{sk}|, |\mathsf{ct}| \leq \mathsf{poly}(\kappa)$ for the public and secret key, and any ciphertext ct generated from the algorithms of TFHE. Furthermore, for a layered circuit C with width w, homomorphic evaluation of C can be done in space $\mathsf{poly}(\kappa) \times w$, independent of the size or depth of the circuit.

Simulation Security

We require the following simulation-based security for the purpose of constructing SMPC protocols. There exists PPT algorithms $\mathsf{Sim}_1, \mathsf{Sim}_2$ such that for all κ, polynomial $m, t, s \in \mathbb{N}$ with $m \geq 3t + 1$, $S \subset [m]$ of size $|S| \leq t$, polynomial size circuits $C_j : \{0,1\}^{m\cdot s} \to \{0,1\}$ for $j \in S$, PPT adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3)$, there exists a negligible function $\mathsf{negl}(\kappa)$ such that

$$\left|\Pr[\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}(\kappa, m, t, S, \{C_j\}_{j\in S}) = 1] - \Pr[\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}(\kappa, m, t, S, \{C_j\}_{j\in S}) = 1]\right| \leq \mathsf{negl}(\kappa)$$

where the experiments $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ are defined as follows:

- $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}(\kappa, m, t, S, \{C_j\}_{j\in S})$:
  1. $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]}) \leftarrow \mathsf{TFHE.Setup}(1^\kappa, 1^m, 1^t)$.
  2. $(\{x_i\}_{i\in[m]\setminus S}, \mathsf{st}_1) \leftarrow \mathcal{A}_1(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in S})$ where $x_i \in \{0,1\}^{\beta s}$.
  3. $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i)$ for $i \in [m]\setminus S$.
  4. $(\{(x_i, r_i^{\mathsf{Enc}})\}_{i\in S}, \mathsf{st}_2) \leftarrow \mathcal{A}_2(\mathsf{st}_1, \{\mathsf{ct}_i\}_{i\in[m]\setminus S})$.
  5. $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i; r_i^{\mathsf{Enc}})$ for $i \in S$; $\hat{\mathsf{ct}}_j \leftarrow \mathsf{TFHE.Eval}(\mathsf{tpk}, C_j, \{\mathsf{ct}_i\}_{i\in[m]})$ for $j \in S$.
  6. $p_{j,i} \leftarrow \mathsf{TFHE.PartDec}(i, \mathsf{tpk}, \mathsf{tsk}_i, \hat{\mathsf{ct}}_j)$ for $i \in [m]\setminus S$ and $j \in S$.
  7. $b \leftarrow \mathcal{A}_3(\mathsf{st}_2, \{p_{j,i}\}_{i\in[m]\setminus S, j\in S})$.
  8. Output b.
- $\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}(\kappa, m, t, S, \{C_j\}_{j\in S})$:
  1. $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]}) \leftarrow \mathsf{TFHE.SimSetup}(1^\kappa, 1^m, 1^t)$.
  2. $(\{x_i\}_{i\in[m]\setminus S}, \mathsf{st}_1) \leftarrow \mathcal{A}_1(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in S})$ where $x_i \in \{0,1\}^{\beta s}$.
  3. $(\{\mathsf{ct}_i\}_{i\in[m]\setminus S}, \mathsf{st}_1) \leftarrow \mathsf{Sim}_1(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in S})$
  4. $(\{(x_i, r_i^{\mathsf{Enc}})\}_{i\in S}, \mathsf{st}_2) \leftarrow \mathcal{A}_2(\mathsf{st}_1, \{\mathsf{ct}_i\}_{i\in[m]\setminus S})$.
  5. $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i; r_i^{\mathsf{Enc}})$ for $i \in S$; $\hat{\mathsf{ct}}_j \leftarrow \mathsf{TFHE.Eval}(\mathsf{tpk}, C_j, \{\mathsf{ct}_i\}_{i\in[m]})$ for $j \in S$.

6. $\{p_{j,i}\}_{i\in[m]\setminus S, j\in S} \leftarrow \mathsf{Sim}_2(\mathsf{st}_1, \{(x_j, r_j^{\mathsf{Enc}})\}_{j\in S}, \{\hat{\mu}_j\}_{j\in S})$, where $\hat{\mu}_j = C_j(x_1, \ldots, x_m)$ for $j \in S$.
7. $b \leftarrow \mathcal{A}_3(\mathsf{st}_2, \{p_{j,i}\}_{i\in[m]\setminus S, j\in S})$.
8. Output b.

Construction

We show that applying the universal thresholdizer to a FHE scheme yields a threshold FHE scheme with above security. Let $\Pi_{\mathsf{FHE}} = (\mathsf{FHE.KeyGen}, \mathsf{FHE.Enc}, \mathsf{FHE.Eval}, \mathsf{FHE.Dec})$ be a FHE scheme with circular security. Let $\Pi_{\mathsf{UT}} = (\mathsf{UT.Setup}, \mathsf{UT.Eval}, \mathsf{UT.Combine})$ be a universal thresholdizer. Formally, we construct a threshold FHE scheme as follows.

- $\mathsf{TFHE.Setup}(1^\kappa, 1^m, 1^t)$: Run $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{FHE.KeyGen}(1^\kappa)$. Let d be the circuit depth of FHE decryption algorithm $\mathsf{FHE.Dec}$. Run $(\mathsf{pp}, \{\mathsf{sk}_i\}_{i\in[m]}) \leftarrow \mathsf{UT.Setup}(1^\kappa, 1^m, 1^{t+1}, 1^d, \mathsf{sk})$. Let $\mathsf{tpk} = (\mathsf{pp}, \mathsf{pk})$ and $\mathsf{tsk}_i = \mathsf{sk}_i$ for $i \in [m]$. Output $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]})$.
- $\mathsf{TFHE.SimSetup}(1^\kappa, 1^m, 1^t)$: Run $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{FHE.KeyGen}(1^\kappa)$. Let d be the circuit depth of FHE decryption algorithm $\mathsf{FHE.Dec}$. Run $(\mathsf{pp}, \{\mathsf{sk}_i\}_{i\in[m]}) \leftarrow \mathsf{UT.Setup}(1^\kappa, 1^m, 1^{t+1}, 1^d, 0^{|\mathsf{sk}|})$. Let $\mathsf{tpk} = (\mathsf{pp}, \mathsf{pk})$ and $\mathsf{tsk}_i = \mathsf{sk}_i$ for $i \in [m]$. Output $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]})$.
- $\mathsf{TFHE.Enc}(\mathsf{tpk}, x)$: Output $\mathsf{ct} \leftarrow \mathsf{FHE.Enc}(\mathsf{pk}, x)$.
- $\mathsf{TFHE.Eval}(\mathsf{tpk}, C, \mathsf{ct}_1, \ldots, \mathsf{ct}_\ell)$: Output $\hat{\mathsf{ct}} \leftarrow \mathsf{FHE.Eval}(\mathsf{pk}, C, \mathsf{ct}_1, \ldots, \mathsf{ct}_\ell)$.
- $\mathsf{TFHE.PartDec}(i, \mathsf{tpk}, \mathsf{tsk}_i, \hat{\mathsf{ct}})$: Output $p_i \leftarrow \mathsf{UT.Eval}(\mathsf{pp}, \mathsf{tsk}_i, \mathsf{FHE.Dec}(\cdot, \hat{\mathsf{ct}}))$.
- $\mathsf{TFHE.FinDec}(\mathsf{tpk}, \{p_i\}_{i\in S})$: Output $\hat{\mu} \leftarrow \mathsf{UT.Combine}(\mathsf{pp}, \{p_i\}_{i\in S})$.

It is clear by inspection that correctness follows by that of the underlying FHE scheme and universal thresholdizer. For compactness, note that universal thresholdizer is applied to evaluate the FHE decryption circuit $\mathsf{FHE.Dec}$, which has a fixed polynomial complexity in κ. Hence, the complexity of universal thresholdizer is upper bounded by a fixed $\mathsf{poly}(\kappa)$ and compactness follows by compactness of the underlying FHE scheme.

Security

We now show that the above construction satisfies simulation security defined above. We define simulators Sim_1, Sim_2 using the simulator of the universal thresholdizer (denoted by $\mathsf{UT.Sim}$) as follows.

- $\mathsf{Sim}_1(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in S})$: Simply run $\mathsf{ct}_i \leftarrow \mathsf{FHE.Enc}(\mathsf{pk}, 0^{\beta s})$ for $i \in [m]\setminus S$, store $\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in S}$ in st_1, and output $(\{\mathsf{ct}_i\}_{i\in[m]\setminus S}, \mathsf{st}_1)$.
- $\mathsf{Sim}_2(\mathsf{st}_1, \{(x_i, r_i^{\mathsf{Enc}})\}_{i\in S}, \{\hat{\mu}_j\}_{j\in S})$: Run $p_{j,i} \leftarrow \mathsf{UT.Sim}^{\mathcal{O}_{\mathsf{Sim}}}(\{\mathsf{sk}_i\}_{i\in S}, C_j, i)$ for $i \in [m]\setminus S$ and $j \in S$, where $\mathcal{O}_{\mathsf{Sim}}$ on input query C' returns $\hat{\mu}_j$ if $C' = C_j$ for $j \in S$, and $\perp$ otherwise. Output $\{p_{j,i}\}_{i\in[m]\setminus S, j\in S}$.

Indistinguishability of $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ follows by considering a hybrid experiment that runs $\mathsf{TFHE.SimSetup}$ and Sim_2 in Step 1 and 6 respectively as the ideal experiment, but still encrypts x_i in Step 3. Formally, we define

- $\mathsf{Expt}^{\mathsf{Hyb}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}(\kappa, m, t, C, S)$:
  1. $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in[m]}) \leftarrow \mathsf{TFHE.SimSetup}(1^\kappa, 1^m, 1^t)$.
  2. $(\{x_i\}_{i\in[m]\setminus S}, \mathsf{st}_1) \leftarrow \mathcal{A}_1(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i\in S})$ where $x_i \in \{0,1\}^{\beta s}$.
  3. $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i)$ for $i \in [m]\setminus S$.
  4. $(\{(x_i, r_i^{\mathsf{Enc}})\}_{i\in S}, \mathsf{st}_2) \leftarrow \mathcal{A}_2(\mathsf{st}_1, \{\mathsf{ct}_i\}_{i\in[m]\setminus S})$.
  5. $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i; r_i^{\mathsf{Enc}})$ for $i \in S$; $\hat{\mathsf{ct}}_j \leftarrow \mathsf{TFHE.Eval}(\mathsf{tpk}, C_j, \{\mathsf{ct}_i\}_{i\in[m]})$ for $j \in S$.
  6. $\{p_{j,i}\}_{i\in[m]\setminus S, j\in S} \leftarrow \mathsf{Sim}_2(\mathsf{st}_1, \{(x_j, r_j^{\mathsf{Enc}})\}_{j\in S}, \{\hat{\mu}_j\}_{j\in S})$, where $\hat{\mu}_j = C_j(x_1, \ldots, x_m)$ for $j \in S$.
  7. $b \leftarrow \mathcal{A}_3(\mathsf{st}_2, \{p_{j,i}\}_{i\in[m]\setminus S, j\in S})$.
  8. Output b.

We claim that indistinguishability of $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Hyb}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ follows directly by privacy of universal thresholdizer. Indeed, observe that the difference between $\mathsf{TFHE.Setup}$ and $\mathsf{TFHE.SimSetup}$ is in the call of $\mathsf{UT.Setup}$, where$\mathsf{TFHE.Setup}$ uses actual FHE secret key sk and $\mathsf{TFHE.SimSetup}$ uses $0^{|\mathsf{sk}|}$. Also in Step 6, partial decryptions $\mathsf{TFHE.PartDec}$ of $\hat{\mathsf{ct}}_j$ for $j \in S$, which in turn are the partial evaluations $\mathsf{UT.Eval}$ on the FHE decryption circuit $\mathsf{FHE.Dec}(\cdot, \mathsf{sk})$, is replaced by the simulator of the universal thresholdizer $\mathsf{UT.Sim}$, where $\mathcal{O}_{\mathsf{Sim}}$ is emulated correctly by returning $\hat{\mu}_j = C_j(x_1, \ldots, x_m)$ when queried by C_j for $j \in S$. Hence, $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Hyb}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ correspond to $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{UT}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Rand}}_{\Pi_{\mathsf{UT}},\mathcal{A}}$ for universal thresholdizer, and the indistinguishability follows by privacy of universal thresholdizer.

Now, observe that the difference between $\mathsf{Expt}^{\mathsf{Hyb}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ is only the messages encrypted in Step 3 and that the FHE secret key is not used in the experiments. Hence, indistinguishability of $\mathsf{Expt}^{\mathsf{Hyb}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}},\mathcal{A}}$ follows directly by semantic security of FHE. This completes the proof of security for the constructed TFHE scheme.

A.3 Semi-Malicious Secure SMPC in a Trusted Setup Model

We proceed to construct a semi-malicious secure constant-round, weakly space efficient SMPC in a trusted setup model using threshold FHE. We consider SMPC protocols over m machines. Henceforth let β denote the bit-width of each word. Each machine holds input $x_i \in \{0,1\}^{\beta s}$ and wishes to learn $f_i(x_1, \ldots, x_m)$ for functions $f_i : \{0,1\}^{m \cdot \beta \cdot s} \to \{0,1\}$.[12] The construction is rather straightforward: We use the setup to run the threshold FHE setup algorithm $\mathsf{TFHE.Setup}$ and distribute the keys. Upon receiving the keys, each machine encrypts its input and output the ciphertext. Then they locally evaluate the output ciphertexts homomorphically, partially decrypt them, and send the partial decryptions to the corresponding machines, who can then learn their own outputs.

Formally, let $\Pi_{\mathsf{TFHE}} = (\mathsf{TFHE.Setup}, \mathsf{TFHE.SimSetup}, \mathsf{TFHE.Enc}, \mathsf{TFHE.Eval}, \mathsf{TFHE.PartDec}, \mathsf{TFHE.FinDec})$ be a threshold FHE scheme. We construct the following SMPC protocol Π_{SMPC} over m machines. Let t be an upper bound on the number of corrupted machines, where $m \geq 3t + 1$.

- **Input and functionality**:
  - Each machine M_i has input $x_i \in \{0,1\}^{\beta s}$ and wishes to learn $f_i(x_1, \ldots, x_m)$ for functions $f_i : \{0,1\}^{m \cdot \beta \cdot s} \to \{0,1\}$.
- **Setup Stage**:
  - Run $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i \in [m]}) \leftarrow \mathsf{TFHE.Setup}(1^\kappa, 1^m, 1^t)$.
  - Send $(\mathsf{tpk}, \mathsf{tsk}_i)$ to each machine M_i for $i \in [m]$.
- **Round** 1: Each machine M_i does the following:
  - Run $\mathsf{ct}_i \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, x_i)$.
  - Broadcast ct_i.
- **Round** 2: Each machine M_i does the following:
  - Record each ct_j received from machine M_j. If M_j aborts, then use $\mathsf{ct}_j \leftarrow \mathsf{TFHE.Enc}(\mathsf{tpk}, 0^{\beta s}; 0^*)$ as a default ciphertext.
  - Compute $\hat{\mathsf{ct}}_j \leftarrow \mathsf{TFHE.Eval}(\mathsf{tpk}, C_j, \{\mathsf{ct}_i\}_{i \in [m]})$ for $j \in [m]$.
  - Compute $p_{j,i} \leftarrow \mathsf{TFHE.PartDec}(i, \mathsf{tpk}, \mathsf{tsk}_i, \hat{\mathsf{ct}}_j)$ for $j \in [m]$.
  - Send $p_{j,i}$ to machine M_j for each $j \in [m]$.

[12] For notational simplicity, we consider functions with one-bit output. It is straightforward to extend the protocol to handle long outputs.

- **Output Computation**: Each machine M_i does the following:
  - Record each $p_{i,j}$ received from machine M_j. Let S_i be the set of partial decryptions received by M_i.
  - Compute $\hat{\mu}_i \leftarrow \mathsf{TFHE.FinDec}(\mathsf{tpk}, \{p_{i,j}\}_{j \in S_i})$.
  - Output $\hat{\mu}_i$.

Correctness

Correctness follows directly from the correctness of TFHE. Furthermore, since the number of honest machines is greater than $t+1$, the honest machines always learn the output.

Weak Space Efficiency

We first note that by compactness, except for the homomorphic evaluation TFHE.Eval, the remaining step takes space at most $\mathsf{poly}(\kappa) \cdot O(ms)$. Let S_{RAM} denote the space complexity for computing $f_1, \ldots, f_m$ using a RAM machine. It is not hard to see that we can emulate the RAM computation by a uniform layered circuit of width $O(S_{\mathsf{RAM}})$: for example, a naïve way is to emulate CPU and memory by circuits and for each RAM computation step, emulate CPU accessing memory by constructing a linear-sized circuit gadget that goes over every memory cell to selects the position requested. Thus, it follows by compactness that TFHE.Eval can be done in space $\mathsf{poly}(\kappa) \cdot O(S_{\mathsf{RAM}})$.

Semi-malicious Security

The security follows directly from the simulation security of TFHE. For completeness, we formally define the simulator $\mathcal{S}$ for Π_{SMPC} as follows. Let Honest and Crupt denote the set of honest and corrupted machines, respectively.

- **Setup Stage**: $\mathcal{S}$ simulates the setup by running TFHE.SimSetup instead of TFHE.Setup. Namely,
  - Run $(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i \in [m]}) \leftarrow \mathsf{TFHE.SimSetup}(1^\kappa, 1^m, 1^t)$.
  - Send $\{(\mathsf{tpk}, \mathsf{tsk}_i)\}_{i \in \mathsf{Crupt}}$ to the adversary $\mathcal{A}$.
- **Round 1**:
  - $\mathcal{S}$ simulates the honest machines' messages by running Sim_1 of TFHE. Namely, $\mathcal{S}$ runs $(\{\mathsf{ct}_i\}_{i \in \mathsf{Honest}}, \mathsf{st}_1) \leftarrow \mathsf{Sim}_1(\mathsf{tpk}, \{\mathsf{tsk}_i\}_{i \in \mathsf{Crupt}})$. $\mathcal{S}$ sends $\{\mathsf{ct}_i\}_{i \in \mathsf{Honest}}$ to $\mathcal{A}$.
  - Upon receiving $(\{(x_i, r_i^{\mathsf{Enc}})\}_{i \in \mathsf{Crupt}}$ from $\mathcal{A}$, $\mathcal{S}$ sends it to the ideal functionality. If any corrupted machine i aborts, then $\mathcal{S}$ sends $x_i = 0^{\beta s}$ to the ideal functionality.
  - $\mathcal{S}$ receives the outputs $\{\hat{\mu}_i\}_{i \in \mathsf{Crupt}}$ from the ideal functionality.
- **Round 2**:
  - $\mathcal{S}$ simulates the honest machines' messages by running Sim_2 of TFHE. Namely, $\mathcal{S}$ runs $\{p_{j,i}\}_{i \in \mathsf{Honest}, j \in \mathsf{Crupt}} \leftarrow \mathsf{Sim}_2(\mathsf{st}_1, \{(x_j, r_j^{\mathsf{Enc}})\}_{j \in \mathsf{Crupt}}, \{\hat{\mu}_j\}_{j \in \mathsf{Crupt}})$. $\mathcal{S}$ sends $\{p_{j,i}\}_{i \in \mathsf{Honest}, j \in \mathsf{Crupt}}$ to $\mathcal{A}$.
  - $\mathcal{S}$ sends `deliver` to the ideal functionality.

It is not hard to see that the real world and ideal world execution of Π_{SMPC} directly corresponds to the experiments $\mathsf{Expt}^{\mathsf{Real}}_{\Pi_{\mathsf{TFHE}}, \mathcal{A}}$ and $\mathsf{Expt}^{\mathsf{Ideal}}_{\Pi_{\mathsf{TFHE}}, \mathcal{A}}$ in the simulation security of TFHE with corresponding adversary. Hence, indistinguishability of the simulation for Π_{SMPC} follows by the simulation security of TFHE.

A.4 Achieving Malicious Security and Removing the Trusted Setup

Finally, we briefly discuss how to upgrade to malicious security and remove the trusted setup in Π_{SMPC}. To upgrade to malicious security, we can apply the standard generic transformation using a simulation-extractable multi-string NIZK which can be constructed from enhanced trapdoor permutations without extra setup [14, 74, 75]. Note that NIZK is used to prove that $\mathsf{TFHE.Enc}$ and $\mathsf{TFHE.PartDec}$ are done correctly, both statements have a fixed $\mathsf{poly}(\kappa)$ complexity. The NIZK proofs can be generated in a fixed $\mathsf{poly}(\kappa)$ space as well. Thus, the transformation preserves weak space efficiency.

To remove the setup, we rely on an SMPC protocol by Badrinarayanan et al. [14]. The protocol of [14] (Theorem 10) is constant-round, achieves guaranteed output delivery, and does not require any setup. We remove the trusted setup by invoking the protocol of Badrinarayanan et al. [14] to securely realize the setup stage in Π_{SMPC}. Note that $\mathsf{TFHE.Setup}$ has a fixed $\mathsf{poly}(\kappa)$ complexity (independent of the functionalities $f_1, \ldots, f_m$). As a result, we obtain a malicious security, constant-round, weakly space efficient and communication efficient SMPC protocol, as required in Theorem 22.

B Potential Barriers Towards Achieving Statistical Security

We have shown how to compile an MPC protocol to a secure counterpart that defends against slightly less than 1/3 corruption while preserving its efficiency; but our compiler relied on a few computational assumptions such as enhanced trapdoor permutations, LWE, and an appropriate notion of compact FHE. One intriguing question is whether we can accomplish the same, but *unconditionally*, i.e., without making any cryptographic hardness assumptions. Such protocols are also said to be *statistically* secure. We now show that if one could achieve the same result unconditionally, it will imply solutions to long-standing open questions in cryptography. Specifically, we prove the following theorem:

▶ **Theorem 27.** *Let κ denote the security parameter. Suppose that there exists an compiler that compiles any MPC protocol Π computing the function f among m machines into an SMPC-for-MPC protocol Π' among m machines that securely realizes $\mathcal{F}^f$ unconditionally, as long as m is polynomially bounded by s and $s \geq \kappa$. Furthermore, suppose that the compiler incurs only $O(1)$ blowup in round complexity and $\mathsf{poly}(\kappa)$ blowup in terms of per-machine space complexity.*

Then, for $m \geq \kappa$, for any m-input, m-output uniform layered circuit C with width m, as long as C's size is a sufficiently large polynomial in m (related to the parameter α later), then there exists a constant-round protocol that allows m parties to securely realize $\mathcal{F}^C$ unconditionally, incurring total communication that is $|C|^\alpha$ for an arbitrarily small constant $\alpha \in (0, 1)$.

Proof. If such a compiler existed, we can use it to compile the following insecure 1-round MPC protocol among m machines each of which has $s = O(m)$ space. Every one now sends their input to the first machine, the first machine computes the circuit C locally, and sends to each machine their respective output. Note that since the circuit is uniform and layered with maximum width m, the first machine can evaluate it in total space $O(m)$.

Now consider the compiled protocol: it will complete in $O(1)$ rounds, and moreover the total communication must be upper bounded by the number of rounds multiplied by $m \cdot O(s) \cdot \mathsf{poly}(\kappa) = O(m^2)$, which can be made $|C|^\alpha$ as long as the circuit size is a sufficiently large polynomial in m where $|C|$ denotes the size of C. ◀

As noted in numerous works in the cryptography literature [26, 39, 44, 45], the existence of such constant-round, sublinear-communication multi-party computation (for circuits) with *statistical* security has been a long-standing open problem, even for the special class of circuits that we consider. To the best of our knowledge, the best known n-party, statistically secure computation protocol achieves the following[13]

- $O(n|C|)$ total communication and d number of rounds without preprocessing [43, 73] where d denotes the circuit depth, and
- $O(n|C|/\log\log|C|)$ total communication and $d/\log\log|C|$ number of rounds with (polynomially-bounded) preprocessing (for layered circuits) [39].

Interestingly, we note that barring strong assumptions such as Indistinguishable Obfuscation [53], the only known approach to construct constant-round, sublinear-communication *multi*-party computation for circuits of unbounded polynomial size is also through compact FHE [55, 58]. In our earlier sections, we essentially showed that making a similar assumption, combined with other standard cryptographic assumptions, we can construct an efficiency-preserving "MPC to SMPC-for-MPC" compiler. From a technical perspective, the main new challenge we encountered is the fact that the machines are now also *space-constrained* (which was not a concern in the standard multi-party computation for circuit literature), and thus we could not just apply existing techniques to the entire set of machines.

Besides the feasibility of achieving statistical security, another interesting direction is to weaken the cryptographic assumption necessary in achieving such a compiler. Similarly, new results in this vein would imply new breakthroughs for constant-round, sublinear-communication *multi*-party computation for circuits too – and even partial results for special classes of circuits (like the family we considered in Theorem 27) would be interesting.

C Removing the Sender Constraint

As mentioned earlier, some works in the MPC literature do not seem to respect the s-sender-constraint, and only respect the s-receiver-constraint. In this section, we generalize our results even to such MPC algorithms.

To achieve this, it suffices to show that given an MPC protocol denoted Π that respects only the s-receiver-constraint, we can compile it to a counterpart denoted Π' that satisfies not just the $O(s)$-receiver-constraint, but also the $O(s)$-sender-constraint. Furthermore, the compilation should preserve both round- and space-complexity; and moreover, the compiled protocol Π' should run in a *fixed* number of rounds (since the oblivious Routing primitive applied to emulate the communication of Π' will not hide total round complexity).

Intuition

The idea is the following: in the first phase (called the replication phase), if a sender wants to send in total μ words in some communication round (where sending the same word to two machines is counted twice), it will *replicate* all of its local memory to $\lceil\mu/s\rceil$ helper-machines where each helper is assigned a unique index from 1 to $\lceil\mu/s\rceil$. This must be accomplished using an s-sender-bounded communication pattern. In the second phase (called the distribution phase), each helper distributes s words on behalf of the sender it represents. Note that in the same round, many machines may be trying to send data simultaneously.

[13] For this reason, in fact even if we relaxed the round complexity blowup in Theorem 27 to poly-logarithmically many rounds or any number that does not depend on circuit depth, having such an MPC-to-SMPC compiler would still imply improving the state-of-the-art for statistically secure MPC.

Thus the above procedure is performed in parallel among all senders. It must be guaranteed that *every machine serves as a helper at most for one sender*. In this way, the distribution phase will satisfy the s-sender-constraint.

C.1 Replication Protocol

A replication protocol allows senders to replicate their local memory to an appropriate number of helpers.

Definition

Formally, replication, henceforth denoted Replicate, is the following problem.

- **Input**. Suppose that among the m machines, some machines are senders and others are non-senders. Each machine i obtains an input pair (β_i, c_i) where $\beta_i \in \{0, 1\}$ is a bit indicating whether machine i is a sender; and if $\beta_i = 1$, $c_i \geq 1$ denotes the total number of machines to replicate machine i's state – henceforth we refer to c_i as sender i's *multiplicity*.

  It is guaranteed that $\sum_{i=1}^{m} \beta_i c_i \leq m$, i.e., in total there are enough machines around to act as receivers.
- **Output**. At the end of the replication protocol, the following output configuration is produced:
  - each sender i has its entire machine state (i.e., a total of s words) replicated on exactly c_i receivers;
  - each machine acts as a receiver for at most 1 sender;
  - suppose sender i has c_i receivers, each of these receivers output i and also a unique index j from the range $[c_i]$, i.e., each of these receiver knows that it acts as the j-th receiver for its sender.

We will next construct a Replicate protocol. Note that the protocol need not be communication-oblivious. The idea is that all machines will first perform a prefix sum computation which allows each sender to discover a range of indices which are meant to become its helpers; moreover, all senders' helpers, identified by the range, are disjoint. It is well-known that prefix sum can be accomplished on MPC in $O(1)$ rounds with an s-sender-bounded communication style. Now, we employ a RangeCast protocol for the sender to replicate its state to the range of machines discovered above. Below we first explain how to construct the RangeCast building block and then describe our Replicate protocol.

Building block: RangeCast

As mentioned, RangeCast allows a sender to replicate its state to a set of machines defined by a range $[a, b] \subseteq [m]$. To realize such a RangeCast primitive, we first realize a weaker form denoted WeakRangeCast which only works if the range's size is at most s. Our RangeCast is similar to the "broadcast" algorithm in the "bulk-synchronous parallel (BSP)" model [103], but we describe it again for completeness.

WeakRangeCast

Input: let a, b be any two machines such that $1 \leq a \leq b \leq m$, let I be an array of s words. The machine a receives the input (I, a, b) where *the range* $[a, b]$ *is small enough such that* $b - a + 1 \leq s$.

Output: every machine $k \in [a, b]$ outputs I.

Protocol:

1. Let $c := b - a + 1$ and $t := \lceil s/c \rceil$. For each $j \in [c]$, let $I_j := I[(j-1)t + 1 : jt]$ be the substring of I where I_j consists of at most t words (if jt or $(j-1)t+1$ is less than s, I_j is by definition a shorter or empty string). In this round, the machine a sends to the machine $a + j - 1$ the message tuple (a, b, I_j) for each $j \in [c]$, while all other machines send nothing.
2. In the next round, machine $a + j - 1$ receives (a, b, I_j) for each $j \in [c]$, and it sends the same message (j, I_j) to every machine $k \in [a, b]$.
3. Every machine $k \in [a, b]$ receives a copy of (j, I_j) for all $j \in [c]$, and it recovers I by concatenating $(I_j)_{j \in [c]}$.

▶ **Lemma 28.** *For any* $1 \leq a \leq b \leq m$ *such that* $b - a + 1 \leq s$, *WeakRangeCast correctly implements range-cast in 2 rounds and satisfies both* $O(s)$*-sender- and* $O(s)$*-receiver-constraints, where each machine takes* $O(s)$ *space and time locally.*

Proof. The correctness, rounds, and local-machine complexity follows directly. The $O(s)$-sender-constraint holds because in Step 1, machine a sends to each machine $O(s/c+2)$ words, and thus the total number of words sent is $O(s + c) = O(s)$. The $O(s)$-receiver-constraint holds because in Step 3, each machine receives c messages each consists of $O(s/c + 1)$ words. ◀

Given WeakRangeCast as a building block, we can construct RangeCast where the range $[a, b]$ may be arbitrary in size. The protocol basically builds a distribution tree of fanout s such that the sender first distributes to s machines, then the s machines distribute to upto s^2 machines, and so on. The protocol can be described formally below.

RangeCast

Input and output: Same as WeakRangeCast but without any constraint on the range $[a, b]$.

Protocol:

1. (Base case.) Let $c := b - a + 1$. If $c \leq 1$, then there is only one machine a and it outputs I directly. Otherwise $c > 1$, continue with the following steps.
2. Let $r := \min(c, s)$. Run WeakRangeCast on the first r machines (i.e., in the range $[a, a + r - 1]$) to copy I from machine a to machines $[a, a + r - 1]$.
3. The machine a computes a partition $[a_1, b_1], [a_2, b_2], \ldots, [a_r, b_r]$ of the range $[a, b]$ such that the ranges $[a_i, b_i]$ are as even as possible (i.e., for any $i_1, i_2 \in [r]$, it holds that $|(b_{i_1} - a_{i_1}) - (b_{i_2} - a_{i_2})| \leq 1$). The pair (a_i, b_i) is sent from machine a to both machines $a + i - 1$ and a_i; Afterwards, machine $a + i - 1$ sends the received I to machine a_i for each $i \in [r]$.
4. For each $i \in [r]$, the machine a_i performs recursively RangeCast on the received I and the range $[a_i, b_i]$.

▶ **Lemma 29.** *For any $1 \leq a \leq b \leq m$, RangeCast correctly implements range-cast in $O(\frac{\log m}{\log s})$ rounds and satisfies both $O(s)$-sender- and $O(s)$-receiver-constraints, where each machine takes $O(s)$ space and time locally.*

Proof. In Step 3, if $c < s$, then $r = c$ and all c machines receive I in $O(1)$ rounds. Else, the first s machines receive I and then forward I to groups of size $\lceil c/s \rceil$, and it takes at most $O(\log_s m) = O(\frac{\log m}{\log s})$ iterations to divide any problem of size $c \leq m$ to a constant size. The correctness follows directly. The local-machine complexity, $O(s)$-sender and $O(s)$-receiver constraints follow by WeakRangeCast. ◀

Protocol Replicate

We are now ready to describe the Replicate protocol. We will use the following terminology: we use the term *ball* to refer to a machine's entire state consisting of upto s words. Each ball is always tagged the ball's identifier denoted $\mathsf{id} \in [m]$, i.e., which machine's state it represents.

The building block PrefixSum is the following primitive: every machine starts with a number, and machine i would like to learn the sum of machine 1 to machine i's numbers. As described by Goodrich et al. [70], this can be accomplished in $O(1)$ rounds with an s-sender-bounded MPC protocol, and consuming $O(m)$ total communication.

1. Each ball is additionally tagged with its outputting range computed as follows.
   a. Given as input (β_i, c_i), each machine $i \in [m]$ sets $c_i = 0$ iff $\beta_i = 0$. All m machines jointly run the PrefixSum protocol on $(c_i)_{i \in [m]}$. As the result, each machine i gets the prefix sum $p_i = \sum_{j \in [i]} c_j$.
   b. Let $p_0 = 0$. Every machine i calculates $p_{i-1} = p_i - c_i$ locally. For each machine i such that $c_i \geq 1$ (i.e., the range $[p_{i-1} + 1, p_i]$ is non-empty), machine i tags the range $[p_{i-1} + 1, p_i]$ to its ball and then sends the ball to machine $p_{i-1} + 1$.
2. Now each ball i is received by the first machine in its outputting range $[p_{i-1} + 1, p_i]$. To replicate the ball i to all machines in the range, for each ball i and the tagged range $[p_{i-1} + 1, p_i]$, the machine $p_{i-1} + 1$ performs RangeCast on the ball i and the range of machines $[p_{i-1} + 1, p_i]$. This RangeCast is performed simultaneously for all balls and hence all machines. To ensure all machines finish at the same round, every instance of RangeCast is programmed to finish at the $O(\frac{\log m}{\log s})$-th round specified in Lemma 29.
3. For each machine i such that has a ball tagged with a range $[a, b]$, let $j := i - a + 1$. Output the ball and j.

▶ **Lemma 30.** *The MPC protocol Replicate is a correct replicate protocol such that takes $O(1)$ rounds and $O(m \cdot s)$ communication, satisfies $O(s)$-sender- and $O(s)$-receiver-constraints, and each machine locally takes $O(s)$ time and $O(s)$ space.*

Proof. The correctness holds as each ball i is replicated exactly c_i copies and the ranges $[p_{i-1} + 1, p_i]$ are disjoint. The complexities follow directly by PrefixSum [70] and RangeCast (Lemma 29). ◀

C.2 Sender-Bounded Compiler

We will now compile any MPC protocol that respects only the s-receiver-constraint to one that respects both the s-receiver- and s-sender-constraints.

Without loss of generality, we may assume that at the end of the local computation stage of each round, there is a *deterministic* polynomial time algorithm[14] that takes each machine's local state as input, and can write down sequentially in a stream a set of *send instructions* where each send instruction contains an outgoing word to be sent and the destination machine's identifier. Note that the sender may not have space to write down all these instructions since each word sent multiple times need to be duplicated multiple times, taking more than $O(s)$ space. However, if the sender replicates its state to enough helpers, every helper can locally repeat the same computation, and write down the range of at most $O(s)$ instructions it is responsible for implementing.

Sender-bounded compiler

Every communication round of the original MPC is replaced with the following protocol:

1. Invoke an instance of the non-oblivious Replicate algorithm: if machine i is trying to send in total μ_i words[15], it replicates its local state onto $\lceil \mu_i/s \rceil$ machines. At the end of this phase, every machine i' may receive the local state of at most one machine i and if so, it also learns that it will act as the j-th helper for machine i.
2. If a machine i' is the j-th helper for machine i, it uses machine i's state to compute the $((j-1)s+1)$-th send instruction through the $\min(j \cdot s, \mu_i)$-th send instruction.
3. Now, every machines executes all send instructions written down in the previous step.

Note that this sender-bounded compiler may not compile each round of the original MPC to a fixed number of rounds. To obtain a compiler that always emits a protocol with a fixed number of rounds, we can simply pad the resulting protocol to the worst-case number of rounds: if there is no more work to be done, just execute empty rounds that do nothing.

▶ **Theorem 31** (Sender-bounded compiler with a fixed number of rounds)**.** *Assume that $s = N^{\varepsilon}$ and m is upper bounded by a fixed polynomial in N. Given any m-machine MPC protocol Π that completes in R rounds in the worst case and consuming s per-machine space, there is an MPC protocol Π' that computes the same function as Π, consuming $O(R)$ rounds, $O(s)$ per-machine space, and $O(m \cdot s)$ total communication per round, and moreover Π' additionally satisfies the $O(s)$-sender-constraint, and executes for a fixed number of rounds. Note that for well-formedness, both Π and Π' must satisfy the s-receiver-constraint.*

Proof. By Lemma 30, the above compiler replaces each round of the original MPC with $O(1)$ rounds of communication, and moreover the resulting protocol satisfies $O(s)$-sender- and $O(s)$-receiver-constraints. The fixed total rounds is guaranteed due the padding mechanism mentioned above. ◀

D Additional Preliminary: Robust Secret Sharing

We recall the notion of robust secret sharing schemes [88]. Here, we only consider robust secret sharing schemes with threshold $t < m/3$.

[14] In the case that the algorithm for generating send instructions is randomized, we may assume that the randomness is pseudo-randomly generated with a small seed using a cryptographically secure pseudo-random generator. This way, the MPC's outputs are computationally indistinguishable no matter whether true randomness or pseudorandomness is used in determining the send instructions.

[15] This can be determined with polynomial-time computation based on its local state.

▶ **Definition 32** (Robust Secret Sharing). *A* t-out-of-m robust secret sharing scheme *over a message space* $\mathcal{M}$ *and share space* $\mathcal{S}$ *is a tuple* $(\mathsf{Share}, \mathsf{Recons})$ *of algorithms defined as follows:*

- $\mathsf{Share}(\mathsf{msg}) \to (s_1, \ldots, s_m)$*: This is a randomized algorithm that takes as input a message* $\mathsf{msg} \in \mathcal{M}$ *and output a sequence of shares* $s_1, \ldots, s_m \in \mathcal{S}$*.*
- $\mathsf{Recons}(s_1, \ldots, s_m) \to \mathsf{msg}'$*: This is a deterministic algorithm that takes as input* m *shares* $(s_1, \ldots, s_m)$ *with* $s_i \in \mathcal{S} \cup \{\perp\}$ *and outputs a message* $\mathsf{msg}' \in \mathcal{M}$*.*

We require the following properties.

- ***Perfect Privacy****: Any* t *out of* m *shares of a secret give no information on the secret itself. Namely, for any* $\mathsf{msg}, \mathsf{msg}' \in \mathcal{M}$ *and* $S \subset [m]$ *of size* $|S| = t$*, the distributions of* $\mathsf{Share}(\mathsf{msg})_S$ *and* $\mathsf{Share}(\mathsf{msg}')_S$ *are identical. Here,* $\mathsf{Share}(\mathsf{msg})_S$ *denotes the set of shares* $\{s_i\}_{i \in S}$ *generated by* $\mathsf{Share}(\mathsf{msg})$*.*
- ***Robustness****: An adversary modifies up to* t *shares can cause the wrong secret to be recovered with probability at most* δ*. Specifically, for any* $\mathsf{msg} \in \mathcal{M}$*,* $S \subset [m]$ *of size* $|S| = t$ *and (unbounded) adversary* $\mathcal{A}$*,*

$$\Pr[\mathsf{Recons}(\mathsf{Share}(\mathsf{msg})_{[m]\setminus S}, \mathcal{A}(\mathsf{Share}(\mathsf{msg})_S)) \neq \mathsf{msg}] \leq \delta.$$

It is known that Shamir's secret sharing scheme is an efficient t-out-of-m robust secret sharing scheme for $t < m/3$.

Choice and Bias in Random Walks

Abstract

We analyse the following random walk process inspired by the power-of-two-choice paradigm: starting from a given vertex, at each step, unlike the simple random walk (SRW) that always moves to a randomly chosen neighbour, we have the choice between *two* uniformly and independently chosen neighbours. We call this process the *choice random walk* (CRW).

We first prove that for any graph, there is a strategy for the CRW that visits any given vertex in expected time $\mathcal{O}(|E|)$. Then we introduce a general tool that quantifies by how much the probability of a rare event in the simple random walk can be boosted under a suitable CRW strategy. We believe this result to be of independent interest, and apply it here to derive an almost optimal $\mathcal{O}(n \log\log n)$ bound for the cover time of bounded-degree expanders. This tool also applies to so-called *biased walks*, and allows us to make progress towards a conjecture of Azar et al. [STOC 1992]. Finally, we prove the following dichotomy: computing an optimal strategy to minimise the hitting time of a vertex takes polynomial time, whereas computing one to minimise the cover time is NP-hard.

1 Introduction

Motivation and Related Work. The power of choice paradigm is the phenomenon that when a random process is offered a choice between two or more uniformly selected options, as opposed to just being supplied with a uniformly random one, then a series of choices can be made to improve overall performance [32]. The power of two choices was first considered for balanced allocation of balls to bins [7, 11, 31]. Here the surprising discovery was made that if each ball is offered two randomly selected bins and the bin containing fewer balls is chosen then the maximum load when assigning n balls to n bins decreases significantly from $\Theta\left(\frac{\log n}{\log\log n}\right)$ to $\Theta(\log\log n)$. The power of choice was later studied for random graphs under the broader class of rule-based random graph processes known as Achlioptas processes. In the standard random graph process, a graph on a fixed vertex set is built up by adding

random edges one by one. Achlioptas suggested that if instead an edge to add is chosen from two random options, this may be done in such a way as to shift the position of the critical window in which a giant component emerges. This is indeed the case and now much is known about the effect of various rules on the phase transition [12, 13, 2, 36, 35]. The effect of the power of choice on the degree distribution in the Preferential Attachment process has also been studied [30, 25].

In this paper we apply the power of two choices to a random walk on a graph with the hope of speeding up the cover and hitting times. One motivation behind this is to improve the efficiency of random walks used in algorithmic applications such as searching, routing, self-stabilization, and query processing in wireless networks, peer-to-peer networks and other distributed systems. One practical setting where routing using the power of choice walk may be advantageous is in relatively slowly evolving dynamic networks such as the internet. For example, say a packet has a target destination v and each node stores a pointer to a neighbour which it believes leads most directly to v. If this network is perturbed then the deterministic scheme may get stuck in "dead ends" whereas a random walk would avoid this fate. The choice random walk which prefers edges pointed to by a node may be the best of both worlds as it would also avoid traps but may see a speed up over the simple random walk when the original paths are still largely intact.

To the best of our knowledge, Avin and Krishnamachari [5] were the first to apply the principle of power of choices to random walks. However, their version only considers a simple choice rule where the vertex with fewer previous visits is always preferred, and ties are broken randomly.

Their results are mainly empirical and suggest a decrease in the variance of the cover time, and a significant improvement in visit load balancing. This is related to the greedy random walk of Orenshtein and Shinkar [34], which chooses uniformly from adjacent vertices that have not yet been visited (if possible). This model is well studied for expanders [10, 15].

Alon, Benjamini, Lubetzky and Sodin [4] studied the mixing rate and asymptotic number of visits made to vertices by the non-backtracking walk. These authors mention the power of two choices paradigm and ask if the number of visits to any vertex can be further reduced by choosing between two independent non-backtracking walks at each step. Fitzner and van der Hofstad [21] obtained more mixing time results and Bordenave, Lelarge and Massoulié have also studied this process in relation to community detection [14].

Perhaps closest to our work, Azar, Broder, Karlin, Linial and Phillips [6] introduced the ε-bias random walk where at each step with probability ε a controller can choose a neighbour of the current vertex, otherwise one is uniformly selected. They obtained bounds on the stationary probabilities and show that optimal strategies for max/minimising stationary probabilities or hitting times can be computed in polynomial time (cf. Section 4.3).

Other related strategies for speeding up the hitting and cover times include degree-biased random walk models [28, 1, 17] or performing multiple walks in parallel [3, 19, 20]. The Power of two choices concept has also been studied in the context of deterministic variants of random walks [16, 8].

Our Results and Techniques. Our first result is a general upper bound of $O(|E|) = O(n^2)$ on the maximum hitting time of a vertex (Theorem 3). This is tight and improves considerably over the well-known $O(n|E|)$ worst-case bound for the simple random walk. This is achieved by approximating the (not necessarily reversible) CRW by a suitable reversible walk.

In Section 4, we present bounds on hitting and cover times in terms of the spectral gap of the lazy random walk. Our general cover time result (Theorem 4) constitutes a significant improvement over the corresponding best possible bound for the simple random walk [33].

In particular, it implies an almost-optimal $O(n \log \log n)$ bound for any bounded-degree expander. The same result also holds for a natural variant of the biased random walk of [6]. Our hitting time result (Theorem 5) is quite different from Theorem 3 and shows that for a large class of graphs that the hitting times of the choice and biased random walk are sublinear. The main technical contribution to derive these bounds is Theorem 6, which shows that any rare event in the simple random walk case can be amplified substantially under a suitable choice (or time-biased) random walk strategy. If one thinks of a simple random walk as running a program with random bits as input then the "tree gadget" used to prove Theorem 6 is a novel way to quantify the effect of the non-determinism added by the power of two choices. We apply the results of this section to a conjecture of Azar et al. [6]; since our approach is orthogonal to theirs, we manage to confirm their conjecture for class of graphs different to those previously treated. As our amplification result applies to arbitrarily defined events and general stochastic processes, we believe this result may find further applications in other areas.

In Section 5, we investigate the complexity of computing optimal strategies for hitting times, cover times and maximising stationary probabilities. Our main insight is a surprising dichotomy, essentially saying that computing complete optimal strategies for hitting times is easy (i.e., polynomial-time), while computing a sequence of optimal choices for cover times, even in an on-line fashion, is NP-hard. To the best of our knowledge, this is the first negative result for processes involving random walks with choice.

2 Notation and Preliminaries

Throughout this paper all graphs will be finite and connected.

Choice Random Walk. The *Choice Random Walk* (CRW) is a discrete time stochastic process $(X_t)_{t \geqslant 0}$ on the vertices of a connected graph $G = (V, E)$, influenced by a controller. The starting state is a fixed vertex; at each time $t \in \mathbb{N}$ the controller is presented with two neighbours $\{c_1^t, c_2^t\}$ of the current state X_t chosen uniformly at random with replacement and must choose one of these neighbours as the next state X_{t+1}. We assume that at each time t the controller knows the graph G, its current position $X_t \in V$, and $\mathcal{H}_t = \left(X_i, \{c_1^i, c_2^i\}\right)_{i=0}^t$ the *history* of the process so far. The controller has access to arbitrary computational resources and an infinite string of random bits ω in order to choose X_{t+1} from $\{c_1^t, c_2^t\}$. A *strategy* for a given task on G is a function which given any t, $\mathcal{H}_t$ and ω outputs a single vertex from c^t where $c^t = \{c_1^t, c_2^t\} \subseteq \Gamma(X_t)$ (here, as is usual, we write $\Gamma(v) := \{w : vw \in E\}$ for the neighbourhood of v).

The aim of the CRW is to make a sequence of choices which most effectively complete a given objective. Examples of objectives may be as follows:

(1) to visit every vertex of the graph;

(2) to hit a given vertex or set of vertices;

(3) to maximise or minimise the stationary probability of a given vertex or set.

Efficacy in tasks (1) and (2) is determined by the expected number of steps taken. Note that an optimal solution to task (1) will necessarily make use of the history of the process, whereas task (3) only applies in the context of strategies which do not change over time. We say that a CRW strategy is *unchanging* if it is independent of both time and the history of the walk. As the walk has access to random bits the strategy may be randomised; we say a strategy is *deterministic* if random bits are not used to make a choice.

For a strategy α and for a vertex v and distinct neighbours i, j let $\alpha^j_{v,i}$ be the probability that when the walk is at v it chooses i when offered $\{i, j\}$ as choices, i.e.

$$\alpha^j_{v,i} := \mathbb{P}\left[\, X_{t+1} = i \mid X_t = v, c^t = \{i, j\} \,\right]$$

(this probability is also conditional on $\mathcal{H}_t$ but we suppress this for notational convenience). These are the only parameters we may vary, but we shall find it convenient to define $\alpha^i_{v,i} := 1/2$ for each i adjacent to v. Thus

$$\text{for each } v \in V: \ \alpha^j_{v,i} \in [0,1] \text{ and } \alpha^i_{v,j} = 1 - \alpha^j_{v,i} \text{ for all } i, j \in \Gamma(v). \tag{1}$$

The transition probabilities $q_{v,i}$ for the strategy α are then given by

$$q_{v,i} = \frac{2\sum_{j\in\Gamma(v)} \alpha^j_{v,i}}{d(v)^2}. \tag{2}$$

Note, any family of parameters $\alpha^j_{v,i}$ satisfying (1) gives a valid set of transition probabilities.

Let $C^{\mathsf{two}}_v(G)$ denote the minimum expected time (taken over all strategies) for the CRW to visit every vertex of G starting from v, and define the *cover time* $t^{\mathsf{two}}_{\mathsf{cov}}(G) := \max_{v\in V} C^{\mathsf{two}}_v(G)$. Analogously, let $H^{\mathsf{two}}_x(y)$ denote the minimum expected time for the CRW to reach y, which may be a single vertex or a set of vertices, starting from a vertex x and define the *hitting time* $t^{\mathsf{two}}_{\mathsf{hit}}(G) := \max_{x,y\in V} H^{\mathsf{two}}_x(y)$.

ε-Biased and ε-Time-Biased Random Walks. Azar et al. [6], building on earlier work [9], introduced the ε-biased random walk (ε-BRW) on a graph G. Each step of the ε-B walk is preceded by an $(\varepsilon, 1-\varepsilon)$-coin flip. With probability $1-\varepsilon$ a step of the simple random walk is performed, but with probability ε the controller gets to select which neighbour to move to. The selection can be probabilistic, but it is time independent. Thus if $\mathbf{P}$ is the transition matrix of a random walk, then the transition matrix $\mathbf{Q}^{\varepsilon\mathrm{B}}$ of the ε-biased random walk is given by

$$\mathbf{Q}^{\varepsilon\mathrm{B}} = (1-\varepsilon)\mathbf{P} + \varepsilon\mathbf{B}, \tag{3}$$

where $\mathbf{B}$ is an arbitrary stochastic matrix chosen by the controller, with support restricted to $E(G)$. In both the ε-Biased and Choice random walks the controller has full knowledge of G.

Azar et al. focused on bias strategies for maximising stationary probabilities and minimising or maximising hitting times of vertices or sets. For each of these tasks one may apply tools from Markov decision theory [18] to show there is a time-independent optimal strategy, so the definition above is sufficient for their purposes. For us a time-dependent version, where the bias matrix $\mathbf{B}_t$ may depend on the time t and the history of the process up to time t, will be useful; we refer to this as the ε-time-biased walk (ε-TBRW). We shall show that the ε-TBRW may be simulated, for suitable ε, by a CRW.

▶ **Proposition 1.** *For any graph G of maximum degree d_{max}, and for any $\varepsilon \leqslant 1/d_{\mathsf{max}}$, the CRW can simulate the ε-TBRW and ε-BRW on G.*

▶ Remark 2. The dependence of ε on d_{max} in Proposition 1 is tight. In the reverse direction, the ε-TB walk can only simulate the CRW if $\varepsilon > 1 - 1/d_{\mathsf{max}}$.

We write $t^{\varepsilon\mathsf{TB}}_{\mathsf{cov}}$ for the cover time of the ε-TBRW under an optimal strategy. There is always a time-independent optimal strategy for hitting a given vertex [6, Thm. 11], thus the maximum hitting times of the ε-TBRW and ε-BRW are the same; we use $t^{\varepsilon\mathsf{B}}_{\mathsf{hit}}$ to denote them. Any unchanging strategy on a finite connected graph results in an irreducible Markov chain and thus, when appropriate, we refer to its stationary distribution as π.

3 A Tight Upper Bound on the Hitting Time in General Graphs

Our first result is the following asymptotically tight bound on the maximal hitting time:

▶ **Theorem 3.** *For any graph G we have $t^{\mathsf{two}}_{\mathsf{hit}}(G) < 3e(G)$ and $t^{\mathsf{two}}_{\mathsf{hit}}(G) < n^2$.*

Both bounds are best possible up to the implied constants: for the path, $t^{\mathsf{two}}_{\mathsf{hit}}$ is about twice the number of edges, and for a clique with a pendant path, where the length of the path is growing much slower than the size of the clique, it is about $3n^2/8$.

We say that an unchanging strategy is *reversible* if it can be realised as a random walk on a weighted graph. The main idea used to prove Theorem 3 is that on any graph the CRW can implement a reversible strategy with a strong drift towards the target vertex. We can then employ tools from reversible Markov chains to bound the hitting time. See Appendix A.2 for a proof. While the reversible strategy constructed gives a bound on the optimal strategy, the latter need not be reversible; for an example, see Appendix A.2.

4 Hitting and Cover Times in Expanders

In this section we prove the following bounds on the cover and hitting times of the ε-TBRW and CRW on a graph G in terms of n, its extremal and average degrees $d_{\mathsf{max}}, d_{\mathsf{min}}$ and d_{avg}, and its relaxation time $t_{\mathsf{rel}} := \frac{1}{1-\lambda_2}$, where λ_2 is the second largest eigenvalue of the transition matrix of the lazy random walk (LRW) on G with loop probability $1/2$.

▶ **Theorem 4.** *For any graph G, and any $\varepsilon \in (0,1)$, we have*

$$t^{\mathsf{two}}_{\mathsf{cov}}(G) = \mathcal{O}\left(n \cdot d_{\mathsf{max}} \cdot \frac{d_{\mathsf{avg}}}{d_{\mathsf{min}}} \cdot \sqrt{t_{\mathsf{rel}}} \cdot \left(1 + \frac{\log t_{\mathsf{rel}}}{\log\log n}\right) \cdot \log\log n\right);$$

$$t^{\varepsilon\mathsf{TB}}_{\mathsf{cov}}(G) = \mathcal{O}\left(n \cdot \varepsilon^{-1} \cdot \frac{d_{\mathsf{avg}}}{d_{\mathsf{min}}} \cdot \sqrt{t_{\mathsf{rel}}} \cdot \left(1 + \frac{\log t_{\mathsf{rel}}}{\log\log n}\right) \cdot \log\log n\right).$$

In particular, the CRW cover time of a bounded degree (not necessarily regular) expander is $\mathcal{O}(n \log\log n)$, significantly less than that of the SRW, which is $\Theta(n \log n)$.

▶ **Theorem 5.** *For any graph G, and any $\varepsilon \in (0,1)$, we have*

$$t^{\mathsf{two}}_{\mathsf{hit}}(G) \leqslant 12\left(\frac{n \cdot d_{\mathsf{avg}}}{d_{\mathsf{min}}}\right)^{1-1/d_{\mathsf{max}}} \cdot t_{\mathsf{rel}} \cdot \ln n \quad \text{and} \quad t^{\varepsilon\mathsf{B}}_{\mathsf{hit}}(G) \leqslant 12\left(\frac{n \cdot d_{\mathsf{avg}}}{d_{\mathsf{min}}}\right)^{1-\varepsilon} \cdot t_{\mathsf{rel}} \cdot \ln n;$$

these bounds hold also for return times.

Theorems 4 and 5 will follow from Theorem 6. Let $G, t \geqslant 0$ and S be a set of trajectories of length t. In the following we use bold characters to denote trajectories in G and if $u \in V(G)$ then u will denote the length 0 trajectory from u. Let $p_{\mathbf{x},S}$ denote the probability that extending a trajectory $\mathbf{x}$ to length t according to the law of a SRW results in a member of S. Let $q_{\mathbf{x},S}(\varepsilon)$ and $\widetilde{q}_{\mathbf{x},S}$ denote the corresponding probabilities under the ε-TBRW or CRW laws respectively; the values of these probabilities will depend on the particular strategies used. These functions can encode probabilities of many events of interest such as "the graph is covered by time t", "the walk is in a set X at time t" or "the walk has hit a vertex x by time t" for example. However, let us emphasise that our result in fact applies to *any* possible event.

▶ **Theorem 6.** *Let G be a graph, $u \in V$, $t > 0$, $0 \leqslant \varepsilon \leqslant 1$ and S be a set of trajectories of length t from u. Then there exist strategies for the ε-TBRW and the CRW such that*

$$q_{u,S}(\varepsilon) \geqslant (p_{u,S})^{1-\varepsilon} \qquad \text{and} \qquad \widetilde{q}_{u,S} \geqslant (p_{u,S})^{1-1/d_{\mathsf{max}}}.$$

By Proposition 1, the results for the CRW in Theorems 4, 5 and 6 follow immediately from those for the ε-TBRW by taking $\varepsilon = 1/d_{\mathsf{max}}$. We shall therefore only consider the ε-TBRW. After stating a technical lemma in Section 4.1, we then explain an alternative way of considering the ε-TBRW in Section 4.2, which enables the proof of Theorem 6 to be completed. The proof of Theorems 4 and 5 via Theorem 6 is given in Appendix A.3.

4.1 The ε-Max/Average Operation

For $0 < \varepsilon < 1$ define the ε-max/average operator $\mathrm{MA}_\varepsilon : [0,\infty)^m \to [0,\infty)$ by

$$\mathrm{MA}_\varepsilon(x_1,\dots,x_m) = \varepsilon \cdot \max_{1\leqslant i\leqslant m} x_i + \frac{1-\varepsilon}{m}\cdot\sum_{i=1}^m x_i.$$

This can be seen as an average which is biased in favour of the largest element, indeed it is a convex combination between the largest element and the arithmetic mean.

For $p \in \mathbb{R}\setminus\{0\}$, the p-power mean M_p of non-negative reals $x_1,\dots,x_m$ is defined by

$$M_p(x_1,\dots,x_m) = \left(\frac{x_1^p+\cdots+x_m^p}{m}\right)^{1/p},$$

and

$$M_\infty(x_1,\dots,x_m) = \max\{x_1,\dots,x_m\} = \lim_{p\to\infty} M_p(x_1,\dots,x_m).$$

Thus we can express the ε-max/ave operator as $\mathrm{MA}_\varepsilon(\cdot) = (1-\varepsilon)M_1(\cdot) + \varepsilon\,\mathrm{M}_\infty(\cdot)$. We use a key lemma, Lemma 7, which could be be described as a multivariate anti-convexity inequality.

▶ **Lemma 7.** *Let $0 < \varepsilon < 1$, $m \geqslant 1$ and $\delta \leqslant \varepsilon/(1-\varepsilon)$. Then for any $x_1,\dots,x_m \in [0,\infty)$,*

$$M_{1+\delta}(x_1,\dots,x_m) \leqslant \mathrm{MA}_\varepsilon(x_1,\dots,x_m).$$

A proof of this Lemma may be found in [26].

▶ Remark 8. The dependence of δ on ε given in Lemma 7 is best possible. This can be seen by setting $x_1 = 0$ and $x_i = 1$ for $2 \leqslant i \leqslant m$, and letting m tend to ∞.

4.2 The Tree Gadget for Graphs

In this section we prove Theorem 6. To achieve this we introduce the *Tree Gadget* which encodes walks of length at most t from u in a rooted graph (G,u) by vertices of an arborescence $(\mathcal{T}_t,\mathbf{r})$, i.e. a tree with all edges oriented away from the root $\mathbf{r}$. Given (G,u) we represent each walk of length $i \leqslant t$ started from u in G as a node at distance i from the root $\mathbf{r}$ in the tree $\mathcal{T}_t$. The root $\mathbf{r}$ represents the walk of length 0 from u. There is an edge from $\mathbf{x}$ to $\mathbf{y}$ in $\mathcal{T}_t$ if $\mathbf{x}$ is obtained from $\mathbf{y}$ by deleting the final vertex.

Also for $\mathbf{x} \in V(\mathcal{T}_t)$ let $\Gamma^+(\mathbf{x}) = \{\mathbf{y} \in V(\mathcal{T}_t) : \mathbf{xy} \in E(\mathcal{T}_t)\}$ be the offspring of $\mathbf{x}$ in $\mathcal{T}$; as usual we write $d^+(\mathbf{x})$ for the number of offspring. Write $|\mathbf{x}|$ for the length of the walk $\mathbf{x}$. To prove Theorem 6 we shall need to discuss simple random walk paths; let $W_u(k) := \bigcup_{i=0}^k \{X_i\}$ be the trajectory of a simple random walk X_i on G up to time k, with $X_0 = u$.

Proof of Theorem 6. To each node $\mathbf{x}$ of the tree gadget $\mathcal{T}_t$ we assign the value $q_{\mathbf{x},S}$ under the the ε-TB strategy of biasing towards a neighbour in G which extends to a walk $\mathbf{y} \in \Gamma^+(\mathbf{x})$ maximising $q_{\mathbf{y},S}$. This is well defined because both the strategy and the values $q_{\mathbf{x},S}$ can be computed in a "bottom up" fashion starting at the leaves, where if $\mathbf{x} \in V(\mathcal{T}_t)$ is a leaf then $q_{\mathbf{x},S}$ is 1 if $\mathbf{x} \in S$ and 0 otherwise.

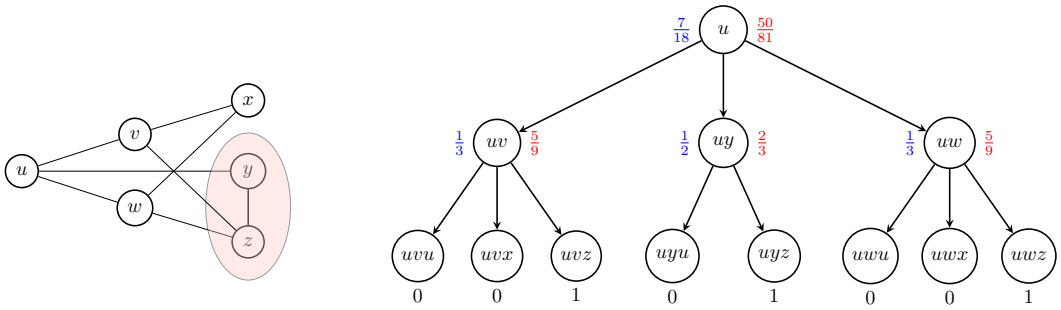

Figure 1 Illustration of a (non-lazy) walk on a non-regular graph starting from u with the objective of being at $\{y, z\}$ at step $t = 2$. The probabilities of achieving this are given in blue (left) for the SRW and in red (right) for the $\frac{1}{3}$-TBRW.

Suppose $\mathbf{x}$ is not a leaf. Then with probability $1 - \varepsilon$ we choose the next step of the walk uniformly at random in which case the probability of reaching S from $\mathbf{x}$ is just the average of $q_{\mathbf{y},S}$ over the offspring $\mathbf{y}$ of $\mathbf{x}$, otherwise we choose a maximal $q_{\mathbf{y},S}$. Thus the value of $\mathbf{x}$ is given by the ε-max/average of its offspring, that is

$$q_{\mathbf{x},S} = \mathrm{MA}_\varepsilon\left(\left(q_{\mathbf{y},S}\right)_{\mathbf{y}\in\Gamma^+(\mathbf{x})}\right). \tag{4}$$

We define the following potential function $\Phi^{(i)}$ on the i^{th} generation of the tree gadget $\mathcal{T}$:

$$\Phi^{(i)} = \sum_{|\mathbf{x}|=i} q_{\mathbf{x},S}^{1+\delta} \cdot \mathbb{P}\left[W_u(i) = \mathbf{x}\right]; \tag{5}$$

note that the sum ranges over all walks of length i. Notice that if $\mathbf{xy} \in E(\mathcal{T}_t)$ then $\mathbb{P}\left[W_u(|\mathbf{y}|) = \mathbf{y}\right] = \mathbb{P}\left[W_u(|\mathbf{x}|) = \mathbf{x}\right]/d^+(\mathbf{x})$. Also since each $\mathbf{y}$ with $|\mathbf{y}| = i$ has exactly one parent $\mathbf{x}$ with $|\mathbf{x}| = i - 1$ we can write

$$\Phi^{(i)} = \sum_{|\mathbf{x}|=i-1} \sum_{\mathbf{y}\in\Gamma^+(\mathbf{x})} q_{\mathbf{y},S}^{1+\delta} \cdot \frac{\mathbb{P}\left[W_u(i-1) = \mathbf{x}\right]}{d^+(\mathbf{x})}. \tag{6}$$

We now show that $\Phi^{(i)}$ is non-increasing in i. By combining (5) and (6) we can see that the difference $\Phi^{(i-1)} - \Phi^{(i)}$ is given by

$$\sum_{|\mathbf{x}|=i-1} \left(q_{\mathbf{x},S}^{1+\delta} - \frac{1}{d^+(\mathbf{x})} \sum_{\mathbf{y}\in\Gamma^+(\mathbf{x})} q_{\mathbf{y},S}^{1+\delta} \right) \mathbb{P}\left[W_u(i-1) = \mathbf{x}\right].$$

Recalling (4), to establish $\Phi^{(i-1)} - \Phi^{(i)} \geqslant 0$ it is sufficient to show the following inequality holds whenever $\mathbf{x}$ is not a leaf:

$$\mathrm{MA}_\varepsilon\left(\left(q_{\mathbf{y},S}\right)_{\mathbf{y}\in\Gamma^+(\mathbf{x})}\right)^{1+\delta} \geqslant \frac{1}{d^+(\mathbf{x})} \sum_{\mathbf{y}\in\Gamma^+(\mathbf{x})} q_{\mathbf{y},S}^{1+\delta}.$$

By taking $(1+\delta)^{\text{th}}$ roots this inequality holds for any $\delta \leqslant \varepsilon/(1-\varepsilon)$ by Lemma 7, and thus for δ in this range $\Phi^{(i)}$ is non-increasing in i.

Observe $\Phi^{(0)} = q_{u,S}^{1+\delta}$. Also if $|\mathbf{x}| = t$ then $q_{\mathbf{x},S} = 1$ if $\mathbf{x} \in S$ and 0 otherwise, it follows that

$$\Phi^{(t)} = \sum_{|\mathbf{x}|=t} q_{\mathbf{x},S}^{1+\delta} \cdot \mathbb{P}\left[W_u(t) = \mathbf{x}\right] = \sum_{|\mathbf{x}|=t} \mathbf{1}_{\mathbf{x}\in S} \cdot \mathbb{P}\left[W_u(t) = \mathbf{x}\right] = p_{u,S}.$$

Thus since $\Phi^{(t)}$ is non-decreasing $q_{u,S}^{1+\delta} = \Phi^{(t)} \geqslant \Phi^{(0)} = p_{u,S}$. The result for the ε-TBRW follows by taking $\delta = \varepsilon/(1-\varepsilon)$. If we let $\varepsilon = 1/d_{\mathsf{max}}$ we can apply the bound on $q_{u,S}$ for the ε-TBRW to the CRW by Proposition 1. ◀

4.3 A Conjecture of Azar et al. for the ε-Biased Walk

Azar, Broder, Karlin, Linial and Phillips [6] make the following conjecture for the ε-BRW.

▶ **Conjecture** ([6, Conjecture 1]). *In any graph, a controller can increase the stationary probability of any vertex from p to $p^{1-\varepsilon}$.*

They prove a weaker bound of $p^{1-O(\varepsilon)}$ for bounded-degree regular graphs. As a corollary of Theorem 5 we obtain a slightly weakened form of the conjecture for any graph where $d_{\mathsf{max}}/d_{\mathsf{min}}$ and t_{rel} are both subpolynomial in n. Our techniques are different and allow us to cover a larger class of graphs, including dense graphs as well as sparse ones, as well as getting closer to the conjectured bound.

▶ **Corollary 9.** *For any family of graphs such that $\log(t_{\mathsf{rel}} \cdot d_{\mathsf{max}}/d_{\mathsf{min}}) = o(\log n)$, a controller can increase the stationary probability of any vertex from p to $p^{1-\varepsilon+o_n(1)}$.*

The corollary follows from Theorem 5 and can be found in [26].

▶ Remark 10. As proven in Theorem 16, the optimal strategy is computable in polynomial time; thus a strategy achieving the above performance bound is also computable in polynomial time.

The original conjecture fails for the graph K_2, as no strategy for the ε-BRW can increase the stationary probability over that of a simple random walk. This motivates weakening the conjecture by replacing $p^{1-\varepsilon}$ by $p^{1-\varepsilon+o_n(1)}$, as in Corollary 9, however this fails for the star on n vertices, and non-bipartite counterexamples may be obtained by adding a small number of extra edges to the star. While these counterexamples have large degree discrepancy, their relaxation time is bounded. We believe the following should hold.

▶ **Conjecture 11.** *For any family of graphs such that $d_{\mathsf{max}}/d_{\mathsf{min}} = o(n)$, a controller can increase the stationary probability of any vertex from p to $p^{1-\varepsilon+o_n(1)}$.*

5 Computing Optimal Choice Strategies

In this section we focus on the following problem: given a graph G and an objective, how can we compute a series of choices for the walk which achieves the given objective in optimal expected time? In particular we consider the following computational problems related to our main objectives of max/minimising hitting times, cover times and stationary probabilities π_v.

`Stat` (G, w):	Find a CRW strategy min/maximising $\sum_{v \in V} w_v \pi_v$ for vertex weights $w_v \geqslant 0$.
`Hit` (G, v, S):	Find a CRW strategy minimising $H_v^{\mathsf{two}}(S)$ for a given $S \subseteq V(G)$ and $v \in V(G)$.
`Cov` (G, v):	Find a CRW strategy minimising $C_v^{\mathsf{two}}(G)$ for a given $v \in V(G)$.

We restrict the strategy in `Stat` to be unchanging so the stationary distribution is well defined. The analogous problems to `Stat` (G, w) and `Hit` (G, v, S) were studied in [6] for the biased random walk. While `Stat` is not one of our primary objectives, we include it here both as a natural problem to consider but also because of its relationship to `Hit` in the case where w is the indicator function of a set S; we shall abuse notation by writing `Stat`(G, S)

for this case. Clearly for `Stat` we must restrict ourselves to unchanging strategies for the stationary probabilities π_v to be well-defined; we shall show that `Hit` also has an unchanging optimal strategy.

For `Hit` and `Cov`, there are two possible interpretations of what it means to "find" a CRW strategy. Perhaps the most natural is to compute a sequence of optimal choices in an on-line fashion, that is at each time step to compute which of the two offered choices to accept. For any particular walk, with suitable memoisation, at most a polynomial number of such computations will be required for either problem: which choice to accept depends only on the current vertex, the two choices, and in the case of `Cov` the vacant set, which can change at most n times. We might alternatively want to compute a complete optimal strategy in advance; for `Hit` this requires only a polynomial number of single-choice computations, but for `Cov` the number of possible situations our strategy must cover will be exponential. However, we shall show that `Cov` is hard even for individual choices.

5.1 A Polynomial-Time Algorithm for `Stat` and `Hit`

First, we show how the (unknown) optimal values $H_x^{\mathsf{two}}(v)$ determine an optimal strategy for $\texttt{Hit}(G,\cdot,v)$. In the following two lemmas we will need to work with a multigraph F; in this context the choice offered at each stage is between two random edges from the current vertex.

▶ **Lemma 12.** *Let F be a multigraph and fix a vertex v. Let $v=v_0,v_1,\dots$ be an ordering of the vertices such that for all $i<j$ we have $H_{v_i}^{\mathsf{two}}(v)\leqslant H_{v_j}^{\mathsf{two}}(v)$. Let β be the deterministic unchanging strategy given by $\beta_{v_i,v_j}^{v_k}=1$ whenever $j<k$. Then β is optimal (among all strategies) for $\texttt{Hit}(F,x,v)$ for every $x\neq v$, and also for the problem of minimising $\mathbb{E}_v[\tau_v^+]$.*

▶ Remark 13. In particular, recalling that for an unchanging strategy $\pi_v=1/\mathbb{E}_v[\tau_v^+]$, it follows that β is an optimal strategy for $\texttt{Stat}(F,\{v\})$. However, this is true in a somewhat stronger sense, since optimality for `Stat` only requires minimising $\mathbb{E}_v[\tau_v^+]$ among unchanging strategies, whereas Lemma 12 shows that β minimises this quantity among all strategies; we shall need this extra strength.

Note that there may be other deterministic unchanging optimal strategies for $\texttt{Hit}(F,x,v)$. For example, if there are multiple vertices with the same optimal hitting time, we may choose between them arbitrarily, and in particular may have a cyclic order of preference which is not consistent with any single ordering. The following lemmas will enable us to show that a good enough approximation to an optimal strategy must itself be optimal.

▶ **Lemma 14.** *Let F be a multigraph with at most n vertices and at most $\binom{n}{2}$ edges, and fix a vertex v. Let α be any unchanging strategy for $\texttt{Stat}(F,\{v\})$. Suppose there exist vertices x,y,z with $y,z\in\Gamma^+(x)$, $H_y^{\mathsf{two}}(v)<H_z^{\mathsf{two}}(v)$ and $\alpha_{x,y}^z\leqslant 1/2$. Then π_v^α differs from the optimal value by at least $n^{-4(n+1)}(H_z^{\mathsf{two}}(v)-H_y^{\mathsf{two}}(v))$.*

▶ **Lemma 15.** *For any simple graph G of order n and every pair of vertices x,y with $H_x^{\mathsf{two}}(S)<H_y^{\mathsf{two}}(S)$ we have $H_y^{\mathsf{two}}(S)-H_x^{\mathsf{two}}(S)>n^{-2n^2}$.*

For any graph G, $v \in V$ and weighting $w : V \to [0, \infty)$ on the vertices of G we can phrase $\texttt{Stat}\,(G, w)$ as an optimisation problem as follows, where we shall encode our actions using the probabilities $\alpha^z_{x,y} = \mathbb{P}\,[\,X_{t+1} = y \mid X_t = x, c = \{y, z\}\,]$ from Section 2.

$$\begin{aligned}
\text{maximize:} \quad & \sum_{v \in V} w_v \pi(v) \\
\text{subject to:} \quad & \pi(x) = \sum_{y \in \Gamma(x)} \pi(y) \cdot \frac{2 \sum_{z \in \Gamma(y)} \alpha^z_{y,x}}{d(x)^2}, && \forall x \in V \\
& \sum_{x \in V} \pi(x) = 1, \\
& \alpha^y_{x,z} \in [0, 1], && \forall xz, xy \in E \\
& \alpha^y_{x,z} = 1 - \alpha^z_{x,y}, && \forall xz, xy \in E
\end{aligned} \tag{7}$$

For minimising the stationary probabilities we maximise -1 times the objective function.

▶ **Theorem 16.** *For any multigraph G and weight function $w : V \to [0, \infty)$ a policy solving the problem $\texttt{Stat}\,(G, w)$ to within an additive ε factor can be computed in time $\mathsf{poly}(|E|, \log(1/\varepsilon))$.*

To prove Theorem 16 the quadratic terms in (7) can be eliminated using the same substitution as [6], we can then solve (7) as a Linear Program.

▶ **Theorem 17.** *For any graph G and any $S \subset V$, a solution to $\texttt{Hit}\,(G, x, S)$ for every $x \in V \setminus S$ can be computed in time $\mathsf{poly}(n)$.*

Proof. Contract S to a single vertex v to obtain a multigraph F; where a vertex x has more than one edge to S in G, retain multiple edges between x and v in F. Note that F has at most n vertices and at most $\binom{n}{2}$ edges. Provided that the CRW on G has not yet reached S, there is a natural correspondence between strategies on G and F with the same transition probabilities, and it follows that $H^{\mathsf{two}}_x(S)$ for G and $H^{\mathsf{two}}_x(v)$ for F are equal for any $x \in V(G) \setminus S$. We compute an optimal strategy to $\texttt{Stat}(F, \{v\})$ to within an additive error of $\varepsilon := n^{-10n^2}$; note that $\log(1/\varepsilon) = o(n^3)$ and so this may be done in time $\mathsf{poly}(n)$ by Theorem 16. Applying Lemma 14 to F and Lemma 15 to G, using the equality of corresponding hitting times, implies that this strategy has $\alpha^z_{x,y} > 1/2$ whenever $H^{\mathsf{two}}_y(v) < H^{\mathsf{two}}_z(v)$, and so rounding each of the probabilities $\alpha^z_{x,y}$ to the nearest integer gives an optimal strategy (on F) for every x, which may easily be converted to an optimal strategy for G. ◀

5.2 A Hardness Result for $\texttt{Cov}\,(G, v)$

We show that in general even the on-line version of $\texttt{Cov}\,(G, v)$ is NP-hard. To that end we introduce the following problem, which represents a single decision in the on-line version. The input is a graph G, a current vertex u, two vertices v and w which are adjacent to u, and a visited set X, which must be connected and contain u.

$\texttt{NextStep}\,(G, u, v, w, X)$: Choose whether to move to v or w so as to minimise the expected time for the CRW to visit every vertex not in X, assuming an optimal strategy is followed thereafter.

Any such problem may arise during a random walk with choice on G starting from any vertex in X, no matter what strategy was followed up to that point, since with positive probability no real choice was offered in the previous walk.

▶ **Theorem 18.** $\texttt{NextStep}$ *is* NP*-hard, even if G is constrained to have maximum degree* 3.

Proof. We give a (Cook) reduction from the NP-hard problem of either finding a Hamilton path in a given graph H or determining that none exists. This is known to be NP-hard even if H is restricted to have maximum degree 3 [22].

We shall find it more convenient to work with the following problem, which takes as input a graph G, a current vertex u and a connected visited set X containing u.

`BestStep`(G, u, X): Choose a neighbour of u to move to so as to minimise the expected time for the CRW to visit every vertex not in X, assuming an optimal strategy is followed thereafter.

We may solve `BestStep`(G, u, X) by computing `NextStep`(G, u, v, w, X) for every pair v, w of neighbours of u; since all optimal neighbours must be preferred to all others, this will identify a set of one or more optimal choices for `BestStep`(G, u, X). Consequently, it is sufficient to reduce the Hamilton path search problem to `BestStep`.

Given an n-vertex graph H, construct the graph G as follows. First replace each edge of H by a path of length $2cn^2$ through new vertices. Next add a new pendant path of length n^3 starting at the midpoint of each path corresponding to an edge of H. Finally, add edges to form a cycle consisting of the end vertices of these pendant paths (in any order). Note that if H has maximum degree 3, so does G.

Fix a starting vertex u and a non-empty unvisited set $Y \subseteq V(H) \setminus \{u\}$, and set $X = V(G) \setminus Y$. (The purpose of the second and third stages of the construction is to make X connected without affecting the optimal strategy.) Suppose that H contains at least one path of length $|Y|$ starting at u which visits every vertex of Y; in particular if $Y = V(H) \setminus \{u\}$ this is a Hamilton path of H. We claim that any optimal next step is to move towards the next vertex on some such path. Assuming the truth of this claim, an algorithm to find a Hamilton path starting at x, if one exists, is to set $u = x$ and $Y = V(H) \setminus \{x\}$, then find the vertex y such that moving towards y is optimal, set $u = y$ and remove y from Y, then continue. If this fails to find a Hamilton path, repeat for other possible choices of x.

To prove the claim, first we argue by induction that there is a strategy to visit every vertex in $|Y|$ in expected time $(4cn^2 + O(n))|Y|$, where the implied constant does not depend on c. This is clearly true for $|Y| = 0$. Let y be the next vertex on a suitable path in H, and let z be the middle vertex of the path corresponding to the edge uy. Attempting to reach z by a straightforward strategy, the distance to z evolves as a random walk with probability $3/4$ of decreasing unless the current location is a branch vertex. We thus reach z in expected time $2cn^2$ plus an additional constant time for each visit to u, of which we expect $O(d(u)) = O(n)$, giving a total expected time of $2cn^2 + O(n)$ (if the walker is forced to a different branch vertex first, the expected time to return from this point is polynomial in n, but this event occurs with exponentially small probability). Similarly, the time taken to reach y from z is $2cn^2 + O(1)$. Once y is reached, there is (by choice of y) a path of length $|Y| - 1$ in H starting from y and visiting all of $Y \setminus \{y\}$. Thus, by induction, the required bound holds. Secondly, suppose that an optimal first step in a strategy from u moves towards a vertex y' of H which is not the first step in a suitable path. Since the expected remaining time decreases whenever an optimal step is taken, two successive optimal steps cannot be in opposite directions unless the walker visits a vertex of Y in between. Thus the optimal strategy is to continue in the direction of y' if possible, and such a strategy reaches y' before returning to u with at least constant probability p, and this takes at least $2cn^2$ steps. Note that the expected time taken to reach another vertex of H from a vertex in H, even if the walker is purely trying to minimise this quantity, is at least $4cn^2$, and from either u or y' at least $|Y|$ such transitions are necessary to cover Y. Thus such a strategy, conditioned on the first step being in the direction of y', has expected time at least $4cn^2 + 2pcn^2$, which, for suitable choice of c, proves the claim. ◀

5.3 Computing $\texttt{Cov}(G, v)$ via Markov Decision Processes

To compute a solution for $\texttt{Cov}(G, v)$ we can encode the cover time problem as a hitting time problem on a (significantly) larger graph. For a proof of the following lemma see [23].

▶ **Lemma 19.** *For any graph $G = (V, E)$ let the (directed) auxiliary graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ be given by $\widetilde{V} = V \times \mathcal{P}(V)$ and $\widetilde{E} = \{((i, S), (j, S \cup j)) \mid ij \in E\}$. Then solutions to $\texttt{Cov}(G, v)$ correspond to solutions to $\texttt{Hit}\big(\widetilde{G}, \widetilde{v}, W\big)$ and vice versa, where $W = \{(u, V) \mid u \in V\}$.*

In light of Lemma 19 it may appear that we can solve $\texttt{Cov}(G, v)$ by converting it to an instance of $\texttt{Hit}\big(\widetilde{G}, \widetilde{v}, W\big)$ and appealing to Theorem 17. This is unfortunately not the case as $\widetilde{G}$ is a directed graph and Theorem 17 cannot handle directed graphs. Lemma 19 is still of use as we can phrase $\texttt{Hit}$ in terms of Markov Decision processes and then standard results tell us that an optimal strategy for the problem can be computed in finite time.

A Markov Decision Process (MDP) is a discrete time finite state stochastic process controlled by a sequence of decisions [18]. At each step a controller specifies a probability distribution over a set of actions which may be taken and this has a direct affect on the next step of the process. Costs are associated with each step/action and the aim of the controller is to minimise the total cost of performing a given task, for example hitting a given state. In our setting the actions are orderings of the vertices in each neighbourhood and the cost of each step/action is one unit of time. $\texttt{Hit}\big(G, u, v\big)$ is then an instance of the optimal first passage problem which can be solved as a linear program. In our setting actions are orderings of neighbourhoods and so the linear program has $\sum_{x \neq v} d(x)!$ many constraints [18, page. 58]. Since, by the construction in Lemma 19, the out degrees of vertices in the directed graph $\widetilde{G}$ are the same as those of the corresponding vertices of G we obtain.

▶ **Corollary 20.** *For any graph G and $v \in V$ an optimal policy for the problem $\texttt{Cov}(G, v)$ can be computed in exponential time.*

▶ Remark 21. Applying the LP from [18, page. 58] to graphs with degrees of order higher than $\mathsf{poly}(\log n)$ will not result in a polynomial time algorithm for $\texttt{Hit}$. This is why we took a different approach to find a polynomial time algorithm in Section 5.1.

6 Summary and Future Work

In this paper we proposed a new random walk process inspired by the power-of-two-choices paradigm. We derived several quantitative bounds on the hitting and cover times, and also presented a surprising dichotomy with regards to computing optimal strategies. Some tools we developed were also applicable to ε-biased walks and we made progress on a long standing conjecture [6].

While we were able to show that on expanders, the CRW significantly outperforms the SRW in terms of its cover time, it is natural to ask whether the cover time is $\Theta(n)$. In fact, it might even be possible for this bound to apply to *any* bounded-degree graph.

We have shown that $\texttt{Cov} \in \mathsf{EXP}$ and that the problem is NP-Hard, it would be interesting to find a complexity class for which the problem is complete.

Our focus here was on hitting and cover times, as well as maximising stationary probabilities, but another natural question is whether we can define a meaningful notion of mixing time and analyse the speed-up achieved by a CRW in comparison to a simple random walk.

A Appendix

A.1 Proofs Omitted from Section 1

Proof of Proposition 1. It is sufficient to provide a strategy to simulate a given bias matrix, since we may then vary the strategy depending on t and $\mathcal{H}_t$ in order to simulate the ε-TBRW. Fix a bias matrix $\mathbf{B}$ with elements $b_{x,y}$ and let the weights $\alpha^z_{x,y}$ for the CRW be given by

$$\alpha^z_{x,y} = \frac{1}{2}\left[1 + \varepsilon d(x)\left(b_{x,y} - b_{x,z}\right)\right]$$

for each $x \in V(G)$ and $y, z \in \Gamma(x)$. Since $\varepsilon \leqslant 1/d_{\mathsf{max}} \leqslant 1/d(x)$, these weights satisfy (1), so this gives a valid CRW strategy.

For adjacent vertices x and y, let $q^{\mathsf{two}}_{x,y}$ and $q^{\varepsilon\mathrm{B}}_{x,y}$ denote the transition probabilities of the CRW and ε-biased walks respectively. By (3) we have

$$q^{\varepsilon\mathrm{B}}_{x,y} = \frac{1-\varepsilon}{d(x)} + \varepsilon b_{x,y},$$

and $\sum_{y\in\Gamma(x)} b_{x,y} = 1$ by definition of $\mathbf{B}$. Also, by (2) we have

$$\begin{aligned} q^{\mathsf{two}}_{x,y} &= \frac{2}{d(x)^2}\sum_{z\in\Gamma(x)} \alpha^z_{x,y} \\ &= \frac{1}{d(x)^2}\sum_{z\in\Gamma(x)} \left(1 + \varepsilon d(x)\left(b_{x,y} - b_{x,z}\right)\right) \\ &= \frac{1}{d(x)} + \varepsilon b_{x,y} - \frac{\varepsilon}{d(x)} \\ &= q^{\varepsilon\mathrm{B}}_{x,y}, \end{aligned}$$

as required. ◀

A.2 Proof of Theorem 3

We first need a lemma establishing that the CRW can simulate random walks on a suitable weighting of G.

▶ **Lemma 22.** *Fix a vertex v, and partition its neighbours into two sets, A and B. There is an unchanging strategy for the CRW such that whenever the walker is at v it moves to a random neighbour according to the probability distribution in which every vertex in B is twice as likely as every vertex in A.*

By considering the strategy at each vertex separately, we immediately obtain the following consequence.

▶ **Corollary 23.** *Let G be a weighted graph with weight function w, having the property that for any two incident edges xy, xz either $w(xy) = w(xz)$, $w(xy) = 2w(xz)$ or $2w(xy) = w(xz)$. Then there is an unchanging strategy for the CRW on G which simulates a random walk according to the weights w.*

For a weighted graph (G, w), write $w(G) = \sum_{e\in E(G)} w(e)$. We need an additional result on edge-crossing times of weighted graphs.

▶ **Lemma 24.** *Let (G, w) be a weighted graph, and let x be a vertex such that every edge incident with x has weight 1. Then for any vertex y adjacent to x, $H_y(x) \leqslant w(G) + w(G \setminus x)$.*

Proofs of the three Lemmas above can be found [23, Sec. 3]. We are now ready to prove the main result of this section.

Proof of Theorem 3. We have to show that the above bounds apply to $H_y^{\mathsf{two}}(x)$ for two arbitrary vertices x, y. Define a weight function $w : E(G) \to \mathbb{Q}^+$ by $w(uv) = 2^{-\min(d(u,x),d(v,x))}$. Note that w satisfies the requirements of Corollary 23, so we can bound $H_y^{\mathsf{two}}(x)$ by the corresponding hitting time of the random walk on (G, w). We will bound that hitting time now.

Write d for the maximum distance of a vertex from x, and V_k for the set of vertices at distance exactly k from x. Note that if $y \in V_{k+1}$ then

$$H_y(x) \leqslant H_y(V_k) + \max_{z \in V_k} H_z(x),$$

and consequently

$$\max_{y \in V(G)} H_y(x) \leqslant \sum_{k=0}^{d-1} \max_{z \in V_{k+1}} H_z(V_k).$$

For each $0 \leqslant k \leqslant d-1$ let G_k be the simple weighted graph obtained by deleting $\bigcup_{i<k} V_i$ and identifying vertices in V_k to give a vertex v_k; if a vertex in V_{k+1} has multiple edges to V_k, delete all but one of them to leave a simple graph. Since removing edges between V_{k+1} and V_k cannot reduce the hitting time of V_k, we have for any $z \in V_{k+1}$ that $H_z^G(V_k) \leqslant H_z^{G_k}(v_k)$. Note that the latter hitting time is unchanged by multiplying all weights by 2^k, and since every $z \in V_{k+1}$ is adjacent to v_k in G_k, by Lemma 24 we have $H_z^{G_k}(v_k) \leqslant 2^k(w(G_k) + w(G_k \setminus v_k))$. Thus

$$\max_{y \in V(G)} H_y(x) \leqslant \sum_{k=0}^{d-1} 2^k(w(G_k) + w(G_k \setminus v_k)).$$

If e is an edge between V_j and V_{j+1} then the contribution of e to the kth term of the above sum is 2^{k-j+1} if $k < j$, at most 1 if $k = j$ and 0 otherwise, so its total contribution is less than 3, and is less than 2 if e is one of the edges deleted to make G_j simple. If e is an edge within V_j then its contribution to the kth term is 2^{k-j+1} if $k < j$ and 0 otherwise, so its total contribution is less than 2. The first bound follows. Note that of the edges of the first type which are not deleted, there is exactly one from each vertex (other than x) to a vertex in a lower layer of G, and so these edges form a tree. Thus there are $n-1$ such edges, whose contribution is bounded by 3, and at most $\binom{n}{2} - (n-1)$ other edges, whose contribution is bounded by 2, giving a bound of $2\binom{n}{2} + n - 1 = n^2 - 1$. ◀

A.3 Deducing Theorems 4 & 5 from Theorem 6

To prove Theorems 4 & 5 from Theorem 6 we need some elementary lemmas concerning random walks. The Proofs of Lemmas 25 & 26 can be found in [23].

▶ **Lemma 25.** *Let $U(t)$ be the number of unvisited vertices at time t by a SRW on a graph and let $T_{n/2^x}$ be the number of SRW steps taken before $U \leqslant n/2^x$. Then*

$$\mathbb{E}\left[\, U(2x \cdot t_{\mathsf{hit}}) \,\right] \leqslant \frac{n}{2^x} \qquad \textit{and} \qquad \mathbb{E}\left[\, T_{n/2^x} \,\right] \leqslant 4(x+1)t_{\mathsf{hit}}.$$

Theorems 4 & 5 bound the hitting/cover times in terms of $t_{\mathsf{rel}} = 1/(1-\lambda_2)$, where λ_2 is the largest non-trivial eigenvalue of the transition matrix of the lazy random walk (LRW). The relaxation time of LRW is more commonly studied than that of the simple random walk

(SRW) since laziness ensures that the walk is an aperiodic Markov chain, and hence the relaxation time is well defined. This provides a further obstacle to overcome since Theorem 6 uses the SRW rather than the LRW; our next lemma resolves this issue.

Let $p^{(t)}_{x,\cdot}$ be the distribution of the simple random walk after t steps, and write $\pi(S)$ for the stationary probability of a set S.

▶ **Lemma 26.** *For any graph G, $S \subset V$ and $x \in V$ there exists $t \leqslant 4t_{\mathsf{rel}} \ln n$ such that $p^{(t)}_{x,S} \geqslant \pi(S)/3$.*

Proof of Theorem 4. We first let a simple random walk cover all but $\alpha = \lfloor n/\log^C n \rfloor$ vertices, for some C to be specified later. By Lemma 25 if we let a simple random walk run for $4t_{hit} \cdot C \log_2 \log n$ steps then the expected size of the unvisited set will be at most $n/\log^C n$ as required. For a simple random walk $t_{hit} = \mathcal{O}\left(\frac{d_{\mathsf{avg}}}{d_{\mathsf{min}}} n\sqrt{t_{\mathsf{rel}}}\right)$ by [33, Thm. 1]. Thus it follows that the expected time τ_1 to complete the first phase is $\mathcal{O}\left(C(\log\log n) \cdot \frac{d_{\mathsf{avg}}}{d_{\mathsf{min}}} n\sqrt{t_{\mathsf{rel}}}\right)$.

We then have α different phases, labelled $\alpha, \alpha-1, \ldots, 1$, where in each phase we reduce the number of uncovered vertices by one. Consider any phase i where a set of i vertices are still uncovered; call this set $S_i \subseteq V$. By Lemma 26 there is some $T \leqslant 4t_{\mathsf{rel}} \log n$ and $t \leqslant T$ such that $p^{(t)}_{x,S} \geqslant \pi(S)/3 \geqslant d_{\mathsf{min}} \cdot i/(3nd_{\mathsf{avg}})$ and thus $q^{(t)}_{u,S_i} \geqslant (d_{\mathsf{min}} \cdot i/(3nd_{\mathsf{avg}}))^{1-\varepsilon}$ by Theorem 6. By considering independent trials with walks of length T the expected time until at least one vertex in S_i is visited is at most

$$\mathcal{O}\left(\left(\frac{n \cdot d_{\mathsf{avg}}}{i \cdot d_{\mathsf{min}}}\right)^{1-\varepsilon} \cdot t_{\mathsf{rel}} \cdot \log n\right).$$

Hence the expected time τ_2 to complete all α phases satisfies

$$\begin{aligned}\tau_2 &= \sum_{i=1}^{n/\log^C n} \mathcal{O}\left(\left(\frac{nd_{\mathsf{avg}}}{id_{\mathsf{min}}}\right)^{1-\varepsilon} t_{\mathsf{rel}} \log n\right) \\ &= \mathcal{O}\left(\left(\frac{nd_{\mathsf{avg}}}{d_{\mathsf{min}}}\right)^{1-\varepsilon} t_{\mathsf{rel}} \log n\right) \sum_{i=1}^{n/\log^C n} i^{\varepsilon-1}.\end{aligned}$$

Then, since $\sum_{i=1}^{n/\log^C n} i^{\varepsilon-1} \leqslant \left(n/\log^C n\right)^{\varepsilon} \cdot \sum_{i=1}^{n/\log^C n} i^{-1} \leqslant \left(n/\log^C n\right)^{\varepsilon} \cdot \log n$,

$$\begin{aligned}\tau_2 &= \mathcal{O}\left(\left(\frac{nd_{\mathsf{avg}}}{d_{\mathsf{min}}}\right)^{1-\varepsilon} t_{\mathsf{rel}} \log n\right) \cdot \mathcal{O}\left(\left(\frac{n}{\log^C n}\right)^{\varepsilon} \cdot \log n\right) \\ &= \mathcal{O}\left(n \cdot \left(\frac{d_{\mathsf{avg}}}{d_{\mathsf{min}}}\right)^{1-\varepsilon} \cdot t_{\mathsf{rel}} \cdot \frac{\log^2 n}{\log^{C\varepsilon} n}\right).\end{aligned}$$

Now if we let $C = \left(2 + \frac{\log t_{\mathsf{rel}}}{\log\log n}\right)/\varepsilon$ then $\log^{C\varepsilon} n = t_{\mathsf{rel}} \cdot \log^2 n$ and thus $\tau_2 = o(\tau_1)$. It follows that the contribution from the first phase dominates the second. Thus the total time is $\mathcal{O}(\tau_1)$ and for C above this is given by $\tau_1 = \mathcal{O}\left(n \cdot \varepsilon^{-1} \cdot \frac{d_{\mathsf{avg}}}{d_{\mathsf{min}}} \cdot \sqrt{t_{\mathsf{rel}}} \cdot \left(2 + \frac{\log t_{\mathsf{rel}}}{\log\log n}\right) \cdot \log\log n\right)$. ◀

Proof of Theorem 5. Let $T = 4 \cdot t_{\mathsf{rel}} \cdot \ln n$ then for any $x, v \in V$ there exists some $t \leqslant T$ such that $p^{(t)}_{x,y} \geqslant \pi(y)/3$ by Lemma 26. By Theorem 6 for any $x, y \in V$ there exists an ε-TB strategy and some $t \leqslant T$ such that $q^{(t)}_{x,y} \geqslant (\pi(y)/3)^{1-\varepsilon} \geqslant (d_{\mathsf{min}}/nd_{\mathsf{avg}})^{1-\varepsilon}/3$. Thus for any target vertex y and start vertex x we need in expectation at most $3\,(nd_{\mathsf{avg}}/d_{\mathsf{min}})^{1-\varepsilon}$ attempts to hit y in at most $T = 4t_{\mathsf{rel}} \ln n$ steps, the result follows. ◀

A.4 Proofs from section 5.1

Proof of Theorem 16. We prove the simple graph case; this proof may be easily extended for multigraphs with suitably adapted notation. The optimisation problem (7) above can be rephrased as a Linear Program by making the substitution $r_{x,y,z} = \pi(x) \cdot \alpha^z_{x,y}$. Either the Ellipsoid method or Karmarkar's algorithm will approximate the solution to within an additive $\varepsilon > 0$ factor in time which is polynomial in the dimension of the problem and $\log(1/\varepsilon)$, see for example [29, 24]. ◀

Proof of Lemma 12. Fix an optimal strategy α for $\texttt{Hit}(F, x, v)$, and for each $y \in \Gamma(x)$ write q_y for the probability that the first step under this strategy is from x to y. Recall that $q_y = \sum_{z \in \Gamma x} \frac{2\alpha^z_{x,y}}{d(x)^2}$. Now given that the first step is at y, an optimal strategy for the remaining steps is precisely an optimal strategy for $\texttt{Hit}(F, y, v)$, and thus

$$H^{\mathsf{two}}_x(v) = \sum_{y \in \Gamma(x)} q_y H^{\mathsf{two}}_y(v).$$

Suppose there exist $y, z \in \Gamma(x)$ with $H^{\mathsf{two}}_y(v) < H^{\mathsf{two}}_z(v)$ but $\alpha^z_{x,y} < 1$ at the first step. By instead (at time 1 only) always choosing y in preference to z, the expected hitting time is decreased by $\frac{2}{d(x)^2}(1 - \alpha^z_{x,y})(H^{\mathsf{two}}_z(v) - H^{\mathsf{two}}_y(v))$, a contradiction. Thus we have $\alpha^z_{x,y} = 1$ if $H^{\mathsf{two}}_y(v) < H^{\mathsf{two}}_z(v)$ and $\alpha^z_{x,y} = 0$ if $H^{\mathsf{two}}_y(v) > H^{\mathsf{two}}_z(v)$. If $H^{\mathsf{two}}_y(v) = H^{\mathsf{two}}_z(v)$ then the expected hitting time does not depend on $\alpha^z_{x,y}$, and so any strategy satisfying these conditions at time 1, and thereafter following an optimal strategy, is itself optimal.

It follows by induction that following β for k turns and thereafter following α is optimal; since this gives arbitrarily good approximations of the expected hitting time under β, β is itself optimal for $\texttt{Hit}(F, x, v)$, and, since the definition of β does not depend on x, for $\texttt{Hit}(F, y, v)$ for any $y \neq v$.

Next we show that β is also an optimal strategy for minimising $\mathbb{E}_v[\,\tau^+_v\,]$. Suppose not, and let γ be an optimal strategy. Write q^γ_x for the probability of moving from v to x at time 1 under γ, and $H^\gamma_v(v^+)$ for $\mathbb{E}_v[\,\tau^+_v\,]$ under γ. Now

$$\begin{aligned} H^\gamma_v(v^+) &= \sum_{x \in \Gamma(v)} q^\gamma_x H^\gamma_x(v) \\ &\geqslant \sum_{x \in \Gamma(v)} q^\gamma_x H^\beta_x(v), \end{aligned}$$

by optimality of β for $\texttt{Hit}(F, x, v)$. Suppose $\gamma^y_{v,x} \neq \beta^y_{v,x}$ for some $x, y \in \Gamma(v)$. Replacing $\gamma^y_{v,x}$ and $\gamma^x_{v,y}$ by $\beta^y_{v,x}$ and $\beta^x_{v,y}$ respectively changes $\sum_{x \in \Gamma(v)} q^\gamma_x H^\beta_x(v)$ by $\frac{2}{d(v)^2}(\beta^y_{v,x} - \gamma^y_{v,x})(H^{\mathsf{two}}_x(v) - H^{\mathsf{two}}_y(v))$, which is non-positive by choice of β. Thus after a sequence of such changes we obtain

$$\begin{aligned} H^\gamma_v(v^+) &\geqslant \sum_{x \in \Gamma(v)} q^\gamma_x H^\beta_x(v) \\ &= H^\beta_v(v^+). \end{aligned}$$ ◀

Proof of Lemma 14. First we bound $H^\alpha_v(v^+) - H^\beta_v(v^+)$, where β is as described in Lemma 12. Consider the strategy of following α until the first time the walk either reaches v or is at x and offered a choice between y and z, and in the latter case following β until v is reached. The difference between this strategy and following α is $p(\alpha^z_{x,y} H^\alpha_y(v) + \alpha^y_{x,z} H^\alpha_z(v) - H^\beta_y(v))$, where p is the probability of the latter event occurring before the walk returns to v. Note

that

$$\begin{aligned}\alpha^z_{x,y}H^\alpha_y(v) + \alpha^y_{x,z}H^\alpha_z(v) - H^\beta_y(v) &\geqslant (\alpha^z_{x,y}-1)H^\beta_y(v) + \alpha^y_{x,z}H^\beta_z(v)\\ &= (1-\alpha^z_{x,y})(H^{\mathsf{two}}_z(v) - H^{\mathsf{two}}_y(v))\\ &\geqslant (H^{\mathsf{two}}_z(v) - H^{\mathsf{two}}_y(v))/2\end{aligned}$$

by Lemma 12 and the assumptions. Further,

$$p \geqslant 2\left(\frac{1}{\Delta(F)^2}\right)^{d(v,x)+1} \geqslant \binom{n}{2}^{-2n},$$

since with at least this probability the walk is forced along a specific shortest path to x, then offered a choice of y or z.

Thus the difference in $\mathbb{E}_v[\tau^+_v]$ between α and this hybrid strategy is at least

$$\zeta := \frac{1}{2}\binom{n}{2}^{-2n}(H^{\mathsf{two}}_z(v) - H^{\mathsf{two}}_y(v)),$$

and since β minimises this quantity among all strategies by Lemma 12, the same bound applies to the difference between α and β, giving

$$\pi_\alpha(v)^{-1} \geqslant \pi_\beta(v)^{-1} + \zeta,$$

and consequently

$$\pi_\alpha(v) \leqslant \pi_\beta(v) - \zeta\frac{\pi_\beta(v)^2}{1+\pi_\beta(v)\zeta}. \tag{8}$$

We have $1 \geqslant \pi_\beta(v) \geqslant \binom{n}{2}^{-1}$ by comparison with a simple random walk. Also we may crudely bound $t^{\mathsf{two}}_{\mathsf{hit}}F$ by noting that a SRW has probability at least $\binom{n}{2}^{1-n}$ of reaching any given vertex in at most $n-1$ steps, giving $\zeta < 1$. Combining these bounds with (8) gives the required result. ◀

Proof of Lemma 15. Note that the hitting times $(h_x)_{x\in V}$ for any given unchanging strategy are uniquely determined by the equations

$$h_x = \begin{cases} 1 + \sum_y \mathbf{P}_{xy}\cdot h_y & \text{if } x \notin S\\ 0 & \text{if } x \in S,\end{cases}$$

where $\mathbf{P}$ is the transition matrix for the strategy. This set of equations can be written as $\mathbf{Ah} = \mathbf{b}$, where $\mathbf{A} := (\mathbf{I} - \mathbf{Q})$, $\mathbf{Q}_{i,j} = \mathbf{P}_{x,y}$ if $i,j \notin S$ and 0 otherwise, and $\mathbf{b}$ is a 0-1 vector. Notice that since $S \neq \emptyset$ we have $\|\mathbf{Q}\| < 1$ and so $\mathbf{A}^{-1}$ exists [27, Cor. 5.6.16.] For any non-random strategy, and in particular for the optimal strategy described above, every transition probability from x is a multiple of $d(x)^{-2}$. Thus all the elements of $\mathbf{A}$ can be put over a common denominator D, where $D := \mathrm{LCM}(d(x)^2)_{x\in V} < (n!)^2 < n^{2n}/2$.

We have $\mathbf{h} = \mathbf{A}^{-1}\mathbf{b} = |\mathbf{A}|^{-1}\mathbf{C}^\mathsf{T}\mathbf{b}$, where $\mathbf{C}$ is the matrix of cofactors. Each entry in $\mathbf{C}$ can be put over a common denominator which is at most D^n, and so the same applies to each entry of $\mathbf{C}^\mathsf{T}\mathbf{b}$. Also, $|\mathbf{A}| < 2^n$ by Hadamard's inequality [27, Thm. 7.8.1]. It follows that if two hitting times differ, they differ by at least $(2D)^{-n}$. ◀

Graph Spanners in the Message-Passing Model

Abstract

Graph spanners are sparse subgraphs which approximately preserve all pairwise shortest-path distances in an input graph. The notion of approximation can be additive, multiplicative, or both, and many variants of this problem have been extensively studied. We study the problem of computing a graph spanner when the edges of the input graph are distributed across two or more sites in an arbitrary, possibly worst-case partition, and the goal is for the sites to minimize the communication used to output a spanner. We assume the message-passing model of communication, for which there is a point-to-point link between all pairs of sites as well as a coordinator who is responsible for producing the output. We stress that the subset of edges that each site has is not related to the network topology, which is fixed to be point-to-point. While this model has been extensively studied for related problems such as graph connectivity, it has not been systematically studied for graph spanners. We present the first tradeoffs for total communication versus the quality of the spanners computed, for two or more sites, as well as for additive and multiplicative notions of distortion. We show separations in the communication complexity when edges are allowed to occur on multiple sites, versus when each edge occurs on at most one site. We obtain nearly tight bounds (up to polylog factors) for the communication of additive 2-spanners in both the with and without duplication models, multiplicative $(2k-1)$-spanners in the with duplication model, and multiplicative 3 and 5-spanners in the without duplication model. Our lower bound for multiplicative 3-spanners employs biregular bipartite graphs rather than the usual Erdős girth conjecture graphs and may be of wider interest.

1 Introduction

In modern computational settings, graphs are often stored in a distributed setting with edges living across multiple servers. This may happen when traditional, single-server methods for representing and processing massive graphs are no longer feasible and require parallel processing capability to complete. In other real world settings, different sites collect

information in different locations, naturally leading to a computational setting with an input graph distributed across servers. For example, the sites may correspond to sensor networks, different network servers, etc. Furthermore, the bottleneck in these settings is often in the *communication* between the servers, rather than the computation time within each of the servers. Computing synopses of distributed graphs in a communication-efficient manner has therefore become increasingly important.

We consider the problem of efficiently constructing a *graph spanner* in the message-passing model of communication. A graph spanner is a subgraph of the input graph, for which shortest path distances are approximately preserved in the subgraph. This property can immediately be used to approximately answer shortest path queries, diameter queries, connectivity queries, etc. Spanners have applications to internet routing [49, 22, 23, 47], using protocols in unsynchronized networks to simulate synchronized networks [46], distributed and parallel algorithms for shortest paths [19, 20, 27], and for constructing distance oracles [50, 12].

There are various notions of approximation provided by a spanner, such as *additive*, for which there is an integer $\beta \geq 1$ and one wants for all pairs u, v of vertices, that $d_H(u,v) \leq d_G(u,v) + \beta$, as well as *multiplicative*, in which case there is an integer $\alpha \geq 1$ and one wants for all pairs u, v of vertices, that $d_H(u,v) \leq \alpha \cdot d_G(u,v)$.

Message-Passing Model

In the message-passing model (see, e.g., [48, 55, 14, 56, 36]) there are s players, denoted $P^1, P^2, \ldots, P^s$, and each player holds part of the input. In our context, player P^i holds a subset E_i of a set of edges on a common vertex set V, and we define the graph G with vertex set V and edgeset $\bigcup_i E_i$. We focus on two input models, the *without duplication* edge model in which the E_i are pairwise disjoint, and the *with duplication* edge model in which the E_i are allowed to overlap.

In this model there is also a coordinator C who is required to compute a function defined on the union of the inputs of the players. The communication channels in this model are point-to-point. For example, if C is communicating with P^i, then the remaining $s-1$ players do not see the contents of the message between C and P^i. We also do not allow the players to talk directly with each other; rather, all communication happens between the coordinator and a given player at any given time[1]. The coordinator C is responsible for producing the output.

The main resource measure we study is the *communication complexity*, that is, the total number of bits required to be sent between the servers in order to output such a spanner with high probability. While graph spanners have been studied in the offline model, as well as in various distributed models such as the CONGEST and LOCAL models, e.g., [16, 28, 25, 34, 15, 45] as well as in the local computation algorithms model [44], they have not been systematically studied in the message-passing model. The few related results we are aware of in the message-passing model are given in [56], where (1) the problem of testing graph connectivity was studied, which can be viewed as a very special case of a spanner, and (2) a result on additive 2-spanners which we discuss more and improve upon below. There is also work in related models such as [41], but such models require that the edges be randomly distributed, which may not be a realistic assumption in certain applications, e.g., if data is collected at sensors with different input distributions.

[1] This model only mildly increases the communication cost over a complete point-to-point network in which each pair of players can communicate with each other. Indeed, if P^i wishes to speak to P^j, then P^i can forward a message through the coordinator who can send it to P^j. Thus the communication increases by a multiplicative factor of 2 and an additive $O(\log s)$ per message to specify where to forward the message. As these factors are small in our context, we will focus on the coordinator model.

Table 1 Our results.

	With duplication		Without duplication	
Spanner	LB	UB	LB	UB
$+2$	$\Omega(sn^{\frac{3}{2}})$	$\tilde{O}(sn^{\frac{3}{2}})$	$\Omega(\sqrt{s}n^{\frac{3}{2}} + sn)$	$\tilde{O}(\sqrt{s}n^{\frac{3}{2}} + sn)$
$+k$	$\Omega(sn^{\frac{4}{3}-o(1)})$	$\tilde{O}(sn^{\frac{3}{2}})$	$\Omega(n^{\frac{4}{3}-o(1)} + sn)$	$\tilde{O}(\sqrt{\frac{s}{k}}n^{\frac{3}{2}} + snk)$
$\times 3$	$\Omega(sn^{\frac{3}{2}})$	$\tilde{O}(sn^{\frac{3}{2}})$	$\Omega(s^{\frac{1}{2}}n^{\frac{3}{2}} + sn)$	$\tilde{O}(s^{1/2}n^{\frac{3}{2}} + sn)$
$\times 5$	$\Omega(sn^{\frac{4}{3}})$	$\tilde{O}(sn^{\frac{4}{3}})$	$\Omega(s^{\frac{1}{3}}n^{\frac{4}{3}} + sn)$	$\tilde{O}(s^{\frac{1}{3}}n^{\frac{4}{3}} + sn)$
$\times(2k-1)$, $k \geq 3$	$\Omega(sn^{1+\frac{1}{k}})$	$\tilde{O}(sn^{1+\frac{1}{k}})$	$\Omega(s^{\frac{1}{2}-\frac{1}{2k}}n^{1+\frac{1}{k}} + sn)$	$\tilde{O}(ks^{1-\frac{2}{k}}n^{1+\frac{1}{k}} + snk)$
$\times(2k-1)$, (sim.)	$\Omega(sn^{1+\frac{1}{k}})$	$\tilde{O}(sn^{1+\frac{1}{k}})$	$\Omega(sn^{1+\frac{1}{k}})$	$\tilde{O}(sn^{1+\frac{1}{k}})$

We also study a variant of the communication complexity in the message-passing model known as the *simultaneous communication complexity* for the multiplicative $(2k-1)$-spanner problem, in which each server is only allowed to send one round of communication to the coordinator [9, 52].

Turnstile Streaming Model

Finally, we present some simple results in the *turnstile streaming model*, in which the input graph is presented as a stream of insertion and deletion updates of edges. That is, we view our graph as an $\binom{n}{2}$-dimensional vector x starting with the zero vector, and we receive updates of the form $(e_i, \Delta_i) \in [\binom{n}{2}] \times \{\pm 1\}$ and increment the e_ith entry of x by Δ_i. Our input graph is then the graph that has the edge e iff $\sum_{i:e_i=e} \Delta_i > 0$. We assume that the input graph has no self-loops. In this model, we wish to design algorithms using low space and low number of passes through the stream. The study of graph problems in this model were pioneered by [2] and were subsequently studied by many other works, including [3, 4, 40, 38, 39].

1.1 Our Results

We summarize our results in Table 1. Note that the $\tilde{O}$ and $\tilde{\Omega}$ notation hides $\text{poly}(\log n)$ factors. Often our upper bounds are stated in terms of edges, but since each edge can be represented using $O(\log n)$ bits, we obtain the same upper bound in terms of bits up to an $O(\log n)$ factor. We study both the with duplication and without duplication edge models, and in all cases we consider a worst-case distribution of edges.

We give a number of communication versus approximation quality tradeoffs for additive spanners and multiplicative spanners. We describe each type of spanner we consider in the sections below, together with the results that we obtain. We obtain qualitatively different results depending on whether edges are allowed to be duplicated across the players, or if each edge is an input to exactly one player.

We point out some particular notable aspects of our results. First, we obtain nearly tight bounds (up to $\text{poly}(\log n)$ factors) for the communication of additive 2-spanners in both the with and without duplication models, multiplicative $(2k-1)$-spanners in the with duplication model, and multiplicative 3 and 5-spanners in the without duplication model. Second, in proving our tight lower bound for 3-spanners in the without duplication model (Theorem 16), we employ results from extremal graph theory on *biregular bipartite graphs*, which, to the best of our knowledge, is the first explicit use of such graphs in the context of lower bounds for spanners. All other lower bounds that we are aware of are obtained from

extremal graphs given by the Erdős girth conjecture (e.g., lower bounds in the streaming [10], local computation algorithm [44], and distributed [16, 28, 25, 34, 15, 45] models), and we believe that our use of biregular bipartite graphs may inspire tight lower bounds in other models in the future as well.

We note that our results slightly differ from traditional results on spanners, in that the sparsity of our spanner may be far from optimal. For instance, we show an algorithm for computing an additive 2-spanner in the without duplication model with near-optimal communication complexity of $\tilde{O}(\sqrt{s}n^{3/2})$ bits of communication, but the size of this spanner is $\tilde{O}(\sqrt{s}n^{3/2})$ edges, which may be much larger than the optimal $O(n^{3/2})$ edges when the number of servers s is very large. It is an interesting question to characterize the communication complexity of computing spanners of optimal size.

1.1.1 Additive Spanners

In the case of additive spanners, one is given an arbitrary graph G on a set V of n vertices and an integer parameter $\beta \geq 1$, and we want to output a subgraph H containing as few edges as possible so that $d_H(u, v) \leq d_G(u, v) + \beta$ for all pairs of vertices $u, v \in V$. The first such spanner was constructed by Aingworth et al. [5], which was slightly improved in [26, 29]. They showed, surprisingly, that for $\beta = 2$, it is always possible to achieve $|H| = O(n^{3/2})$. The next additive spanner was constructed in [11], where it was shown that for $\beta = 6$ one can achieve $O(n^{4/3})$ edges; see also [54] where the time complexity was optimized. Recently, it was shown in [18] how to achieve an additive spanner with $\tilde{O}(n^{7/5})$ edges for $\beta = 4$. In a breakthrough work [1], an $\Omega(n^{4/3-o(1)})$ lower bound was shown for any constant β.

The one previous result we are aware of for computing spanners in the message-passing model is for additive 2-spanners given in [56], for which an $\tilde{O}(sn^{3/2})$ upper bound was given which works with edge duplication. We first show that with edge duplication, the algorithm of [56] is *optimal*, by proving a matching $\Omega(sn^{3/2})$ lower bound. Our lower bound is a reduction from the s-player set disjointness problem [14]. We next consider the case when there is no edge duplication, and perhaps surprisingly, show that one can achieve an additive 2-spanner with $\tilde{O}(\sqrt{s}n^{3/2})$ communication, improving upon the $\tilde{O}(sn^{3/2})$ bound of [56], and given our lower bound in the case of edge duplication, providing a separation for additive spanners in the models with and without edge duplication. Our upper bound is based on observing that the dominant cost in implementing additive spanner algorithms in a distributed setting is that of performing a breadth-first search. We instead perform fewer breadth first searches to obtain a better overall communication cost than one would obtain by naïvely implementing an offline additive spanner algorithm, as is done in [56]. This algorithm is the starting point for our technically more involved upper bound, where we show that it is possible to obtain an additive k-spanner with $\tilde{O}(\sqrt{s/k}n^{3/2} + snk)$ total communication. We complement this result with a lower bound of $\Omega(n^{4/3-o(1)})$ for this problem.

We note that we are not able to obtain constant additive spanners with fewer than $n^{3/2}$ edges, as the dominant cost comes from having to do breadth first search trees, which is communication-intensive in the message-passing model. We conjecture that $\Theta(n^{3/2})$ may be the optimal communication bound for any additive spanner with constant distortion, unlike in the offline model where an $O(n^{4/3})$ edge bound is achievable.

1.1.2 Multiplicative Spanners

In the case of multiplicative spanners, we are given an arbitrary graph G on a set V of n vertices and an integer parameter $\alpha \geq 1$, and wish to output a subgraph H containing as few edges as possible so that $d_H(u, v) \leq \alpha \cdot d_G(u, v)$ for all pairs of vertices $u, v \in V$. For odd

integers $\alpha = 2k-1$, for any graph G on n vertices there exists a α-spanner with $O(n^{1+1/k})$ edges, for any integer $k \geq 1$ [7]. Further, this is known to be optimal for $k \in \{1,2,3,5\}$ [51, 53], while for general k the best known bounds are $\Omega(n^{1+2/(3k-3)})$ for odd k and $\Omega(n^{1+2/(3k-2)})$ for even k [42, 43].

Under a standard conjecture of Erdős [31], this bound of $O(n^{1+1/k})$ is in fact optimal for every k. Recall that the girth of an unweighted graph is the minimum length cycle in the graph. Erdős's conjecture is that there exist graphs G with $\Omega(n^{1+1/k})$ edges for which the girth is $2k+2$. Note that given such a G, if one were to delete any edge $\{u,v\}$ in G, then the distance from u to v would increase from 1 to $2k+1$, and therefore G is the only $2k-1$-spanner of itself, giving the $\Omega(n^{1+1/k})$ edge lower bound. Notice that G is also the only $2k$-spanner of itself, and so the $\Omega(n^{1+1/k})$ lower bound also holds for even integers $\alpha = 2k$, which is also optimal since, as mentioned above, there always exist $(2k-1)$-spanners with $O(n^{1+1/k})$ edges.

1.1.2.1 Message-Passing Model

We show that for computing a multiplicative $(2k-1)$-spanner with s players, in the edge model with duplication on n-node graphs, there is an $\Omega(s \cdot OPT_k)$ communication lower bound, where OPT_k is the maximum size of a $(2k-1)$-spanner of any graph. Our lower bound is again based on a reduction from the multiplayer set disjointness communication problem. A greedy algorithm shows that this bound is optimal, that is, we provide a matching $\tilde{O}(s \cdot OPT_k)$ upper bound.

If instead each edge occurs on exactly one server, note that the additive 2-spanner algorithm already gives a separation in the s parameter by providing a $\tilde{O}(\sqrt{s}n^{3/2} + sn)$ algorithm. We show that this is optimal up to polylog factors by showing a lower bound of $\Omega(\sqrt{s}n^{3/2})$ for multiplicative 3-spanners. This then gives near optimal lower bounds for additive 2-spanners as well. Our lower bound here uses for the first time, to the best of our knowledge, the theory of *biregular bipartite cages*, which may be of wider interest. For $k \geq 3$, we again show that there is a separation in the s parameter between the models with and without edge duplication, by showing that carefully balancing the complexity of a lesser known variant of the classic algorithm of [13], the cluster-cluster joining variant, can be implemented to use only $\tilde{O}(ks^{1-2/k}n^{1+1/k} + snk)$ communication. We complement this result with a lower bound of $\Omega(s^{1/2-1/2k}n^{1+1/k} + sn)$ communication via a reduction from the edge model with duplication, essentially by splitting vertices to transform the input instance with duplication into one without duplication. This bound is off by a factor of $O(s^{1/2-3/2k})$. For $k = 3$, the exponent on s is exactly correct, giving a nearly tight characterization of $\tilde{\Theta}(s^{1/3}n^{4/3})$ communication for the problem of computing multiplicative 5-spanners.

1.1.2.2 Simultaneous Communication

In the simultaneous communication model, we show an upper bound of $\tilde{O}(sn^{1+1/k})$ in the with duplication model and a lower bound of $\Omega(sn^{1+1/k})$ without duplication model under the Erdős girth conjecture, showing that the complexity is $\tilde{\Theta}(sn^{1+1/k})$ in all cases. The upper bound simply comes from locally computing a multiplicative $(2k-1)$-spanner of size $\Theta(n^{1+1/k})$ at each server, while the lower bound comes from constructing s edge-disjoint graphs on n vertices and $\Omega(n^{1+1/k})$ edges, a constant fraction of which must be sent to the server in the simultaneous communication model, as we show.

1.1.2.3 Turnstile Streaming Model

Finally, we note that implementing the cluster-cluster joining algorithm of [13] in the turnstile streaming model gives an algorithm for computing a multiplicative $(2k-1)$-spanner with $(\lfloor k/2 \rfloor + 1)$ passes and $\tilde{O}(n^{1+1/k})$ space. Our algorithm follows the techniques of [3], but implements a different version of the Baswana-Sen algorithm than they do, which allows us to save on the number of passes. Previously, in the regime of a small constant number of passes, [40] gave an algorithm for computing multiplicative spanners with distortion 2^k in $\tilde{O}(n^{1+1/k})$ space with two passes. Our result improves upon this in the distortion for $k = 3$, achieving an optimal space-distortion tradeoff.

2 Preliminaries

We use $[n]$ to denote $\{1, \ldots, n\}$. We often use capital letters X, Y, ... for sets, vectors, or random variables, and lower case letters x, y, ... for specific values of the random variables X, Y, ... For a set S, we use $|S|$ to denote the size of S.

Let $G = (V, E)$ be an undirected graph, where V is the vertex set and E is the edgeset. Let $n = |V|$ and $m = |E|$ denote the number of vertices and the number of edges, respectively. For a pair of vertices u, v in G, the distance between u and v is denoted by $d_G(u, v)$, which indicates the length of the shortest path connecting u to v. The results in this paper are for unweighted graphs, thus the length of a path is equal to the number of edges is contains.

We will also assume in this paper that $s \ll n$, e.g. $s = O(n^{\varepsilon})$ for a small constant ε: this is typically the case in practice, as well as the interesting regime for most of our bounds.

As for messages and communication, we assume that all communication is measured in terms of bits. All logarithms in this paper are base 2.

We make use of the Set Disjointness problem in the message-passing model, see, e.g., [17].

▶ **Definition 1** ($\text{DISJ}_{n,s}$). *There are s players and each of them holds a set $X_i \subseteq [n]$, and the goal is to determine whether $\bigcap_{i=1}^{s} X_i$ is empty or not.*

Recently in [14], the authors obtained a tight lower bound for this problem.

▶ **Theorem 2** ([14], Theorem 1.1). *For every $\delta > 0$, $n \geq 1$ and $s = \Omega(\log n)$, the randomized communication complexity of set disjointness in the message-passing model is $\Omega(sn)$ bits. That is, for every randomized protocol which succeeds with probability at least $2/3$ on any given set of inputs, there exists a set of inputs and random coin tosses of the players which causes the sum of message lengths of the protocol to be $\Omega(sn)$ bits. Further, for any $s \geq 2$, the randomized communication complexity of set disjointness is $\Omega(n)$ ([37]).*

3 Additive Spanners

In this section we study how to compute additive spanners of graphs in the message-passing model. Recall the definition of additive spanners.

▶ **Definition 3** (Additive spanners). *Given a graph G, a subgraph H is an* additive β-spanner for G *if for all $u, v \in V$, $d_G(u, v) \leq d_H(u, v) \leq d_G(u, v) + \beta$, where $d_G(u, v)$ and $d_H(u, v)$ are lengths of the shortest paths in G and H, respectively.*

3.1 Additive 2-Spanners with Duplication

As a warmup, we first consider the case when $\beta = 2$, and edge duplication is allowed. We will show the following:

▶ **Theorem 4.** *The optimal communication cost of the additive 2-spanner problem with edge duplication in the message passing model is $\tilde{\Theta}(sn^{3/2})$ bits.*

The following lemma is well known and follows from Theorem 2 of [33].

▶ **Lemma 5.** *For every n, there is a family of graphs on n vertices with $\Theta(n^{3/2})$ edges and girth at least 6.*

It is easy to see that if a graph G has girth 6, then G is the only possible spanner for G. Thus, we can tell whether a subgraph H of G is all of G or not just by looking at a valid spanner of H. We use this fact to reduce the set disjointness problem to the problem of computing spanners. We state our reduction in the following general lemma:

▶ **Lemma 6.** *Let R be a binary relation between graphs and members of a set $\mathcal{P}$. Suppose there is a family of graphs $\{G_n\}_n$ such that G_n has n vertices and $f(n)$ edges, and:*
1. *p_n is the unique member of $\mathcal{P}$ with $(G_n, p_n) \in R$*
2. *for any proper subgraph H of G_n, $(H, p_n) \notin R$*

Then for a graph G on n vertices, the communication complexity in the edge duplication case of computing p such that $(G, p) \in R$ is $\Omega(sf(n))$ bits.

For concreteness, in this example we may think of $\mathcal{P}$ as the set of all graphs, and define R to be the set of pairs (G, S) such that S is an additive 2-spanner of G.

Proof. We reduce from the set disjointness problem in the message-passing model. Given an instance of set disjointness with s players each holding $X_i \subseteq [f(n)]$, we create a graph G_n on n vertices. We give player i the edge indexed by j if $j \notin X_i$. If the coordinator outputs $p = p_n$, we output that $\bigcap_i X_i \neq \varnothing$, otherwise we output that $\bigcap_i X_i = \varnothing$. The coordinator outputs p_n if and only if all the edges of G_n are present among the players, which is the case if and only if $\bigcap_i X_i \neq \varnothing$. Therefore this procedure correctly decides set disjointness. Theorem 2 implies a $\tilde{\Omega}(sf(n))$ bit lower bound for the communication cost of computing p. ◀

Together, these pieces yield the following:

Proof of Theorem 4. For the lower bound, we observe that for a graph G as in Lemma 5 removing any edge (u, v) increases the distance from u to v to at least 5, and thus the only additive-2 spanner of G is G itself. By Lemma 6 with $\mathcal{P}$ as the set of all graphs and R as the set of pairs (G, H) such that H is an additive 2-spanner of G, we immediately have that the communication cost of finding a subgraph that is an additive 2-spanner is $\tilde{\Omega}(s|E(G)|) = \tilde{\Omega}(sn^{3/2})$.

For the upper bound, one can show that the well known algorithm of [26] for computing additive 2-spanners can be implemented in the message passing model with $\tilde{O}(sn^{3/2})$ bits of communication, even in the case of edge duplication. See the proof of Theorem 5 of [56] for details. ◀

3.2 Additive k-Spanners with Duplication

Unfortunately, we are not able to design algorithms with improved communication over the above additive 2-spanners even if we allow for larger additive distortion, despite the existence of algorithms for additive 6-spanners that achieve $O(n^{4/3})$ edges [11, 54]. In this section, we show a lower bound of $\Omega(sn^{4/3-o(1)})$ on the communication of additive k-spanners via a similar argument to the lower bound in Theorem 4.

▶ **Theorem 7.** *The randomized communication complexity of the additive k-spanner problem with edge duplication is $\Omega(sn^{4/3-o(1)})$.*

Proof. The proof follows essentially from applying Lemma 6 on the extremal graph of [1], with minor modifications. The details are in the appendix of the full version of the paper. ◀

3.3 Additive 2-Spanners without Duplication

We next show how to improve the upper bound of Theorem 4 when edges are not duplicated across servers. We note that we can assume all servers know the degree of every vertex, since this involves exchanging at most n numbers per player or $O(ns \log n)$ bits of communication. This is negligible compared to the rest of the communication assuming $s \ll n$.

First we write down some simple lemmas that we will make use of multiple times. The proofs of these can be found in the full version.

▶ **Lemma 8.** *Let $\mathcal{C}$ be a collection of sets over a ground set $\mathcal{U}$ each of size at least t. If we sample $\frac{|\mathcal{U}|}{t} \log |\mathcal{C}/\delta|$ elements from $\mathcal{U}$ uniformly with replacement, with probability at least $1-\delta$ we sample at least one element from each set in $\mathcal{C}$.*

▶ **Lemma 9.** *The deterministic communication complexity of computing a BFS (breadth first search) tree from a given node in the message passing model (with our without duplication) is $\tilde{O}(sn)$.*

We are ready to state the main algorithm of this section:

▶ **Theorem 10.** *The randomized communication complexity of the additive-2 spanner problem without edge duplication is $\tilde{O}(\sqrt{s}n^{3/2})$.*

Algorithm 1 $+2$ spanner without edge duplication.

Input: $G = (V, E)$.
Output: H, $+2$ spanner of G.

1: $V_1 = \{x \in V : \text{degree of } x \leq \sqrt{sn}\}$.
2: Each player sends the coordinator all edges adjacent to V_1. The coordinator aggregates these and compiles the set $E_1 = \{(u, v) \in E : u \in V, v \in V_1\}$.
3: The coordinator samples $2 \log n \cdot \sqrt{\frac{n}{s}}$ vertices uniformly at random with replacement from V, and let $\mathcal{R}$ denote the sampled vertex set.
4: Grow a BFS tree T_x from each $x \in \mathcal{R}$, let $E(T_x)$ be its edge set.
5: $F = E_1 \cup \bigcup_{x \in \mathcal{R}} E(T_x)$.
6: **return** $H = (V, F)$.

Proof. First we will show this algorithm provides a $+2$ spanner of G with constant probability.

Consider the set $V \setminus V_1$ of vertices with degree $\geq \sqrt{sn}$. Let $\mathcal{E}$ denote the event that $\mathcal{R}$ contains at least one vertex from the neighborhood of every vertex in this set. Applying Lemma 8 with $\mathcal{U} = V$, with $\mathcal{C}$ as the collection of neighborhoods of vertices in $V \setminus V_1$, and with $t = \sqrt{sn}$, we have that $\mathcal{E}$ occurs with probability at least $1 - o(1)$.

Now for an arbitrary pair of vertices u, v, let us consider the shortest path P connecting them in G. Suppose an edge $(x, y) \in P$ is missing from E_1. This implies that both x and y are in $V \setminus V_1$ and have degree strictly larger than $\sqrt{sn}$. If $\mathcal{E}$ holds, then x has a neighbor w sampled in $\mathcal{R}$. Then:

$$\begin{aligned} d_H(u, v) &\leq d_H(u, w) + d_H(w, v) \leq d_G(u, w) + d_G(w, v) \\ &\leq d_G(u, x) + 1 + d_G(x, v) + 1 = d_G(u, v) + 2 \end{aligned} \tag{1}$$

Above the first and third line follow from the triangle inequality, the second holds since H includes a BFS-tree rooted at w, and the last line since x is on the shortest path between u and v.

Next we bound the communication. Line 2 requires $\tilde{O}(\sqrt{s}n^{3/2})$ communication since each edge is in $N(V_1)$ is sent exactly once. By Lemma 9, growing $\log n\sqrt{n/s}$ BFS trees on line 4 requires $\tilde{O}(sn \cdot \sqrt{n/s} = \sqrt{s}n^{3/2})$ communication as well. Thus the total communication is $\tilde{O}(\sqrt{s}n^{3/2})$. ◀

We will later show that this is nearly optimal by showing a lower bound of $\Omega(\sqrt{s}n^{3/2})$ for the weaker problem of computing a multiplicative 3-spanner in Theorem 16 later in the paper.

3.4 Additive k-Spanners without Duplication

We now study the additive spanner problem with larger distortion in the without duplication model. Unfortunately, we are not able to get tight tight results in this setting, and closing this gap remains and outstanding question.

A lower bound of $\Omega(n^{4/3-o(1)})$ on the communication complexity follows from the strong incompressibility result of additive spanners in Theorem 2 of [1], the proof for which can be found in the full version.

▶ **Theorem 11.** *The randomized communication complexity of the additive k-spanner problem without edge duplication is $\Omega(n^{4/3-o(1)} + sn)$.*

On the algorithms side, we generalize the additive 2-spanner algorithm, showing that the communication drops off by a factor of $\sqrt{k}$ for larger additive distortions k.

▶ **Theorem 12.** *The randomized communication complexity of the additive k-spanner problem without edge duplication is $\tilde{O}(\sqrt{s/k}n^{3/2} + snk)$.*

Algorithm 2 $+k$ spanner without edge duplication.

Input: $G = (V, E)$
Output: H, $+s$ spanner of G

1: $V_1 = \{x \in V : \text{degree of } x \leq \sqrt{sn/k}\}$, $E_1 = \{(u, v) \in E : u \in V, v \in V_1\}$
2: Uniformly sample $\tilde{O}(\sqrt{n/sk}) + \tilde{O}(k)$ vertices from V, and let $\mathcal{R}_1$ denote the set of sampled vertices.
3: Grow a BFS tree T_x from every $x \in \mathcal{R}_1$, $E_2 = \{e \in E : e \in T_x \text{ for some } x \in \mathcal{R}_1\}$.
4: Uniformly sample $\tilde{O}(\sqrt{kn/s})$ vertices from V, and let $\mathcal{R}_2$ denote the sampled vertices.
5: Grow a truncated BFS tree T_x from every $x \in \mathcal{R}_2$, such that $|T_x| = n/k$. (In the last level of building the tree, arbitrarily include edges until $|T_x| = n/k$.) Let $E_3 = \{e \in E : e \in T_x \text{ for some } x \in \mathcal{R}_2\}$
6: $F \leftarrow E_1 \cup E_2 \cup E_3$
7: **return** $H = (V, F)$

Proof. We will first show that Algorithm 2 gives an additive k-spanner with probability at least $1 - o(1)$, then argue that it achieves the stated communication complexity. We may assume that $k \geq 6$, since otherwise Theorem 10 directly implies the claim. For convenience, let $N_\ell(e)$ denote the set of vertices within ℓ hops of either of the endpoints of e. Suppose

we have added only the edges E_1 which are adjacent to vertices of degree at most $\sqrt{sn/k}$, which is the case at the end of line 3, and consider the shortest path P in G between an arbitrary pair of vertices u, v. Let D be the set of edges of P missing from E_1.

- **Case 1**: $|D| \geq k$
  Since P is a simple path and we have already included all edges adjacent to low-degree vertices, there are collectively at least $k\sqrt{sn/k}/2 = \Omega(\sqrt{snk})$ vertices in the union of the $N_1(e)$ for all e missing from P. Let $\mathcal{E}_1$ be the event that $\mathcal{R}_1$ contains a vertex from this neighborhood for every choice of u, v with at least k missing path edges. If $\mathcal{E}_1$ holds, since in line 5 we include a BFS tree from each sampled vertex, this implies that the returned H is a $+2$ spanner for each such pair of u, v by the same reasoning as in the proof of Theorem 10.
- **Case 2**: $|D| < k$
  In what follows, we will argue that our construction either bridges each missing $e = (u', v') \in D$ with a 2-hop path, or places the root of a full BFS within distance 3 of P. If all $e \in D$ are bridged by 2-hop paths, we will argue that these paths are contained in truncated BFS trees included in line 5. Since there are at most k edges missing from P, and since the distance between the endpoints of e changes from $d_G(u', v') = 1$ to $d_H(u', v') = 2$, we will have that $d_H(u, v) \leq d_G(u, v) + k$. On the other hand if there is a BFS tree center a within distance 3 of u', then by the triangle inequality

$$\begin{aligned} d_H(u, v) &\leq d_H(u, a) + d_H(a, v) \\ &\leq d_G(u, u') + d_G(u', a) + d_G(a, u') + d_G(u', v) \\ &\leq d_G(u, u') + d_G(u', v) + 3 + 3 = d_G(u, v) + 6 \end{aligned} \tag{2}$$

  and since we may assume that $k \geq 6$, we will again have that $d_H(u, v) \leq d_G(u, v) + k$. Let $\mathcal{E}_2$ denote the event that $\mathcal{R}_2$ samples a vertex u_e in $N_1(e)$ for every missing edge e. Furthermore, let $\mathcal{E}_3$ denote the event that $\mathcal{R}_1$ samples at least one vertex v_e from $N_2(u_e)$ for every edge e for which $|N_2(u_e)| \geq n/k$. If $\mathcal{E}_2$ and $\mathcal{E}_3$ both hold, then:
  - **Case a**: for all $e \in D$, we have $N_2(u_e) \leq n/k$
    By $\mathcal{E}_2$, there is a truncated BFS center in $N_1(e)$ for all $e \in D$ that reaches both endpoints of e. So all missing edges have 2-hop paths.
  - **Case b**: For some $e \in D$, we have $N_2(u_e) > n/k$
    By $\mathcal{E}_3$, there is a full BFS center v_e in $N_2(u_e)$, which is at a distance at most

$$d_G(P, v_e) \leq d_G(P, u_e) + d_G(u_e, v_e) \leq 1 + 2 = 3 \tag{3}$$

    of P.

  By the arguments above, this sub-case analysis implies that H is a $+s$ spanner for all u, v for which at most s edges are missing from P.

It remains to show that $\mathcal{E}_1$, $\mathcal{E}_2$ and $\mathcal{E}_3$ hold simultaneously with probability $1 - o(1)$. All three can be made to hold individually with probability $1 - o(1)$ by applying Lemma 8, and this will determine the $\tilde{O}$ factors in Algorithm 2. By a union bound all three events hold simultaneously with probability $1 - o(1)$.

We now consider the communication complexity. Identifying the vertices of degree at most $\sqrt{sn/k}$ and communicating their incident edges in line 2 requires $\tilde{O}(\sqrt{s/k}n^{3/2})$ communication. By Lemma 9 the full BFS trees constructed in line 3 require $\tilde{O}(\sqrt{s/k}n^{3/2} + snk)$ communication. Similarly, the truncated BFS trees found in step 8 require $\tilde{O}(sn/k)$ communication each, for a total of $\tilde{O}(\sqrt{s/k}n^{3/2})$. Adding, we obtain an upper bound of $\tilde{O}(\sqrt{s/k}n^{3/2} + snk)$. ◀

4 Multiplicative Spanners

In this section we study how to compute multiplicative spanners of graphs in the message-passing model. Recall the definition of multiplicative spanners.

▶ **Definition 13** (Multiplicative spanners). *Given a graph G, a subgraph H is a* multiplicative α-spanner for G *if for all vertex pairs $u, v \in V$, $d_H(u,v) \leq \alpha \cdot d_G(u,v)$. where $d_G(u,v)$ and $d_H(u,v)$ are the shortest path distances in G and H respectively.*

4.1 Multiplicative $(2k-1)$-Spanners with Duplication

One can show that the classic greedy algorithm for computing multiplicative $(2k-1)$-spanners can be implemented to match the a lower bound that follows the same techniques as Theorem 4:

▶ **Theorem 14.** *The communication cost of the multiplicative $(2k-1)$-spanner problem with edge duplication is $\tilde{O}(sn^{1+1/k})$. Under Erdős' girth conjecture [30], the bound is tight, in other words the cost is $\tilde{\Theta}(sn^{1+1/k})$.*

The details can be found in the full version.

4.2 Multiplicative $(2k-1)$-Spanners without Duplication

For $k = 2$, the additive 2-spanner algorithm of Theorem 10 immediately gives us a multiplicative $(2k-1) = 3$-spanner algorithm with $\tilde{O}(\sqrt{s}n^{3/2})$ communication. We show that this bound is in fact tight. We will use the following fact about bipartite biregular graphs follows from Theorem 2 of [57] by taking an appropriate subgraph of their construction:

▶ **Corollary 15.** *Let s, n be such that $\sqrt{sn}$ be a prime power and $\sqrt{n/s}$ is an integer. Then, there exists a bipartite biregular graph of girth 6 on $\Theta(n)$ vertices where one side has size $\Theta(n/s)$ with common degree $\sqrt{sn}$ and one side with size $\Theta(n)$ with common degree $\sqrt{n/s}$.*

Using this extremal graph, we obtain the following theorem:

▶ **Theorem 16.** *The randomized communication cost of the multiplicative 3-spanner problem without edge duplication is $\Omega(\sqrt{s}n^{3/2})$.*

Proof. Recall the graph Z from Corollary 15 and let U be the partite set with $\Theta(n/s)$ vertices and common degree $\sqrt{sn}$ and let V be the partite set with $\Theta(n)$ vertices and common degree $\sqrt{n/s}$. Note that this graph has $m := \Theta(n^{3/2}/\sqrt{s})$. We will reduce s player set disjointness on m elements to the problem of finding multiplicative 3-spanners without edge duplication.

Consider s copies of the vertex sets $U^1, U^2, \ldots, U^s$, each belonging to each of the s players, as well as one copy of the vertex set V belonging to the coordinator. Now given an instance of set disjointness with s players each holding a set $X_i \subseteq [m]$, we define our input graph G by giving the ith player the edge indexed by $j \in [m]$ if and only if $j \notin X_i$. That is, if $\{a, b\} \in Z$ is the edge indexed by j, then we give P^i the edge $\{(a,i), b\}$, where $(a,i) \in U^i$ is the copy of the vertex $a \in U$ and b is the single copy of the vertex $b \in V$ that belongs to the coordinator. Note that this graph consists of $\Theta(n)$ vertices for the one copy of V and $\Theta(s \cdot n/s) = \Theta(n)$ for the s copies of U, and $\Theta(\sqrt{s}n^{3/2})$ edges without duplication.

We now show that the s sets X_i simultaneously intersect if and only if there is an edge $\{a, b\} \in Z$ that is missing from all s copies of the graph Z in the spanner H. It's clear that if $j \in \bigcap_{i=1}^{s} X_i$, then the edge $\{a, b\} \in Z$ indexed by j cannot be in the spanner H. Now

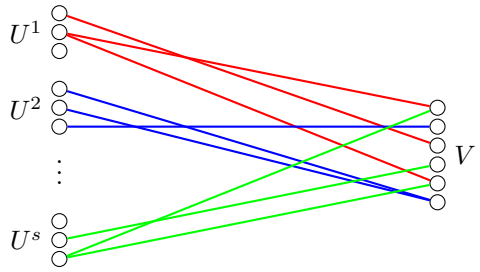

Figure 1 Our hard input instance.

suppose that no copy of the edge $\{a, b\} \in Z$ indexed by j is in the spanner H and suppose for contradiction that $j \notin X_i$ for some i, that is, the edge $\{a, b\} \in G$ belonged to some player P^i. We claim that there is no path of length at most 3 in the spanner H, contradicting that H is a multiplicative 3-spanner. Indeed, suppose for contradiction that a path $(a, i), v_1, (v_2, i'), b$ were in the spanner. Then $v_1 \neq b$ since we assumed that there were no copies of $\{a, b\}$ in the spanner, and similarly, $v_2 \neq a$. Then since $\{a, b\}$ is also an edge of Z, this implies that there is a 4-cycle a, v_1, v_2, b in Z, which contradicts that Z is of girth 6.

We thus conclude that the randomized communication complexity of this problem is

$$\Omega(sm) = \Omega\left(s\frac{n^{3/2}}{\sqrt{s}}\right) = \Omega(\sqrt{s}n^{3/2}), \tag{4}$$

as desired. ◀

▶ Remark 17. For bipartite biregular graphs of larger girth, the optimal size of the graph is unknown. However, a simple counting argument known as the *Moore bound* gives a lower bound on the number of vertices of a bipartite biregular graph of prescribed bidegree and girth [35, 32, 6], which shows limitations of the above technique for proving communication lower bounds for multiplicative spanners of larger distortion. More specifically, let $g = 2k + 2$ be the girth and let the two degrees be $\{d, sd\}$ (as we require one side of the bipartite graph to be of size $\Theta(n/s)$ in our proof technique). Then the Moore bound states that when k is odd, then the number of vertices is at least

$$n = \Omega\Big((sd)^{(k+1)/2}d^{(k-1)/2}\Big) = \Omega(s^{(k+1)/2}d^k) \tag{5}$$

which implies that we can't get a bound better than $\Omega(sdn) = \Omega(s^{1/2-1/2k}n^{1+1/k})$. We will in fact be able to show this bound under the Erdős girth conjecture for all k, as we show next. On the other hand, when k is even, then the Moore bound is

$$n = \Omega((sd)^{k/2}d^{k/2}) = \Omega(s^{k/2}d^k) \tag{6}$$

which implies that the best we can do is $\Omega(sdn) = \Omega(s^{1/2}n^{1+1/k})$, which is slightly better than the previous bound. However, it is known that these Moore bounds are not tight everywhere, and counterexamples exist in some limited parameter regimes, e.g. Theorem 4 of [24].

Finally, we note that more robust versions of the Moore bound have been shown for bipartite biregular graphs [35], where an analogue of the above bound holds even for irregular graphs.

For $k \geq 3$, one can implement the multiplicative spanner algorithm of [13] to get asymptotically better dependence on the number of servers s than the lower bound of Theorem 14. This separates the with edge duplication model from the without duplication model for all k, given the lower bound of Theorem 14.

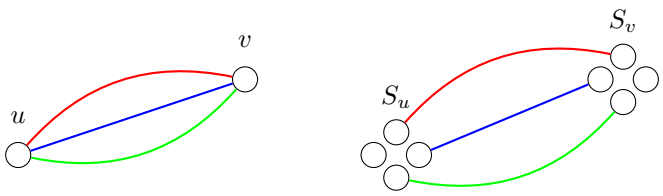

Figure 2 Converting an instance with edge duplication to one without.

▶ **Theorem 18.** *For $k \geq 3$, the randomized communication complexity of the multiplicative $(2k-1)$-spanner problem without edge duplication is $\tilde{O}(ks^{1-2/k}n^{1+1/k} + snk)$.*

Furthermore, this algorithm can be made deterministic with small modifications, essentially by having the players send $\tilde{O}(s^{1-2/k}n^{1+1/k})$ edges that allows for the coordinator to do the randomized part by themselves, which can then in turn be done deterministically by brute force.

▶ **Theorem 19.** *For $k \geq 3$, the deterministic communication complexity of the multiplicative $(2k-1)$-spanner problem without edge duplication is $\tilde{O}(ks^{1-2/k}n^{1+1/k} + snk)$.*

The details for both of these algorithms can be found in the full version.

We also show that in this model, a polynomial dependence on the parameter s is necessary. Specifically, we prove a $\Omega(s^{1/2-1/2k}n^{1+1/k})$ lower bound via a reduction from the lower bound for the multiplicative $(2k-1)$-spanner problem *with* duplication. The lower bound matches the algorithm of Theorem 18 exactly for $k = 3$ up to polylog factors, giving a communication complexity of $\tilde{\Theta}(s^{1/3}n^{4/3})$ in this case. For general k, the bounds are off by a factor of $\tilde{O}(s^{1/2-3/2k})$. Interestingly, this technique is not able to get us tight results for $k = 2$, giving a lower bound of $\Omega(s^{1/4}n^{3/2})$ instead.

▶ **Theorem 20.** *Under Erdős' girth conjecture, the randomized communication cost of the multiplicative $(2k-1)$-spanner problem without edge duplication is $\Omega(s^{1/2-1/2k}n^{1+1/k} + sn)$.*

Figure 2 illustrates the main idea of the proof: we can split vertices into $\sqrt{s}$ different vertices so that an instance with edge duplication on n vertices can be converted into one with $\sqrt{s}n$ vertices without duplication. Proofs for the lower and upper bounds are detailed in the full version.

4.3 Simultaneous Communication of Multiplicative $(2k-1)$-Spanners

We now prove our results for simultaneous communication for multiplicative $(2k-1)$-spanners.

Our algorithm comes from observing that for multiplicative spanners, each server can just locally compute a multiplicative $(2k-1)$-spanner of size $O(n^{1+1/k})$ and send it to the server for a $\tilde{O}(sn^{1+1/k})$ communication algorithm, which turns out to be optimal.

▶ **Theorem 21.** *The deterministic simultaneous communication complexity of multiplicative $(2k-1)$-spanners problem with duplication is $\tilde{O}(sn^{1+1/k})$.*

To prove the lower bound, we will make use of the following lemma.

▶ **Lemma 22.** *Let $s = o(n^{1/3-1/3k})$. Then under the Erdős girth conjecture, there exist s pairwise edge-disjoint graphs $E_1, E_2, \ldots, E_s$ on n vertices and $\Theta(n^{1+1/k})$ edges, each of girth $2k+2$.*

Proof. Under the Erdős girth conjecture, there exists a graph G on n vertices with $\Theta(n^{1+1/k})$ edges and girth $2k+2$. We now choose the s pairwise edge-disjoint graphs on n vertices as follows. First draw a random permutation of G for each server P^j for $j \in [s]$ by drawing a random permutation $\pi_j : [n] \to [n]$ of the vertices and giving the server P^j the edge set $\{\{\pi_j(u), \pi_j(v)\} : \{u, v\} \in E(G)\}$. To get pairwise edge-disjoint graphs, we now just delete any shared edges to produce our final edges E_j for $j \in [s]$.

Note that any subgraph of G also has girth at least $2k-1$, so E_j has girth at least $2k+2$ for all $j \in [s]$. It remains to show that in our parameter regime, this yields graphs of the desired size. Fix two distinct players P^i, P^j and edges $e_1 \in E_i$ and $e_2 \in E_j$. Then, the probability that e_1 collides with e_2 is $(n-2)!/n! = 1/n(n-1)$ and thus the expected number of edges shared between P^i and P^j is $n^{1+1/k}n^{1+1/k}/n(n-1) = \Theta(n^{2/k})$. By Markov's inequality, we delete $O(s^2n^{2/k})$ edges between these two players with probability at least $1-O(s^{-2})$. By the union bound, this is true simultaneously for all pairs of players with positive probability. In this event, each player deleted at most $s \cdot O(s^2n^{2/k}) = O(s^3n^{2/k}) = o(n^{1-1/k}n^{2/k}) = o(n^{1+1/k})$ edges, so each player still has a graph of size $\Theta(n^{1+1/k})$. ◀

Our lower bound now comes from either giving each of the players the above graphs with probability $1/2$, or giving only one player one of the above graphs with probability $1/2$. The intuition is as follows. When a player is the only one with a graph, then they must send their entire graph, while this is not the case when everyone has a graph. However, the players do not know whether everyone else has a graph or not, and therefore must always send their input graph whenever they get one.

▶ **Theorem 23.** *The randomized simultaneous communication complexity of multiplicative $(2k-1)$-approximate distance oracle problem without duplication is $\Omega(sn^{1+1/k})$.*

The above intuition is formalized in the full version.

4.4 Multiplicative $(2k-1)$-Spanners in the Dynamic Streaming Model

Finally, we note that implementing the Baswana-Sen cluster-cluster joining algorithm [13] in the turnstile streaming model gives a $(\lfloor k/2 \rfloor + 1)$-pass algorithm.

▶ **Theorem 24.** *There exists an algorithm for constructing a multiplicative $(2k-1)$-spanner using $\tilde{O}(n^{1+1/k})$ space and $\lfloor k/2 \rfloor + 1$ passes in the dynamic streaming model.*

The space-distortion tradeoff here is optimal under the Erdős girth conjecture, as graphs given by this conjecture must output themselves as spanners, which takes $\Omega(n^{1+1/k})$ bits of space.

5 Conclusions

We initiated the study of communication versus spanner quality in the message-passing model of communication, in which the edges of a graph are arbitrarily distributed, with or without duplication, across two or more players, and the players wish to execute a low communication protocol to compute a spanner. We believe there are several surprising aspects of these problems illustrated by our work, illustrating separations between models with and without edge duplication.

One open question is whether it is possible to obtain an additive spanner with constant distortion with $O(n^{4/3})$ communication for constant s. We show it is possible to obtain $O(n^{3/2})$ communication and constant distortion, but in the non-distributed setting it is

possible to obtain an additive 6-spanner with $O(n^{4/3})$ edges. Since known constructions involve computing many partial breadth-first search trees, we are not able to implement them in the message-passing model, nor are we able to exploit any of the literature for computing distributed BFS trees (see, e.g., [8]), without spending $\Omega(n^2)$ communication in the message-passing model. Yet another question is to extend our techniques to other notions of spanners, such as distance preservers [21] or mixed additive and multiplicative spanners [29]; see also the $(k, k-1)$ spanners in [11].

Abstract

Given a random $n \times n$ symmetric matrix $\boldsymbol{W}$ drawn from the Gaussian orthogonal ensemble (GOE), we consider the problem of certifying an upper bound on the maximum value of the quadratic form $\boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x}$ over all vectors $\boldsymbol{x}$ in a constraint set $\mathcal{S} \subset \mathbb{R}^n$. For a certain class of normalized constraint sets we show that, conditional on a certain complexity-theoretic conjecture, no polynomial-time algorithm can certify a better upper bound than the largest eigenvalue of $\boldsymbol{W}$. A notable special case included in our results is the hypercube $\mathcal{S} = \{\pm 1/\sqrt{n}\}^n$, which corresponds to the problem of certifying bounds on the Hamiltonian of the Sherrington-Kirkpatrick spin glass model from statistical physics. Our results suggest a striking gap between optimization and certification for this problem.

Our proof proceeds in two steps. First, we give a reduction from the detection problem in the *negatively-spiked Wishart model* to the above certification problem. We then give evidence that this Wishart detection problem is computationally hard below the classical spectral threshold, by showing that no low-degree polynomial can (in expectation) distinguish the spiked and unspiked models. This method for predicting computational thresholds was proposed in a sequence of recent works on the sum-of-squares hierarchy, and is conjectured to be correct for a large class of problems. Our proof can be seen as constructing a distribution over symmetric matrices that appears computationally indistinguishable from the GOE, yet is supported on matrices whose maximum quadratic form over $\boldsymbol{x} \in \mathcal{S}$ is much larger than that of a GOE matrix.

1 Introduction

An important phenomenon in the study of the computational aspects of random problems is the appearance of *statistical-to-computational gaps*, wherein a problem may be solved by an inefficient algorithm – typically a brute-force search – but empirical evidence, heuristic formal calculations, and negative results for classes of powerful algorithms all suggest that the same problem cannot be solved by any algorithm running in polynomial time. Many examples of this phenomenon arise from Bayesian estimation tasks, in which the goal is to recover a planted *signal* from noisy observations. Bayesian problems exhibiting statistical-to-computational gaps in certain regimes include graph problems such as community detection [16], estimation for models of structured matrices and tensors [42, 30], statistical problems arising from imaging and microscopy tasks [53, 10], and many others. A different family of examples comes from random optimization problems that are *signal-free*, where there is no "planted" structure to recover; rather, the task is simply to optimize a random objective function as effectively as possible. Notable instances of problems of this kind that exhibit statistical-to-computational gaps include finding a large clique in a random graph [33], finding a submatrix of large entries of a random matrix [25], or finding an approximate solution to a random constraint satisfaction problem [1].

In this paper, we study a problem from the latter class, namely the problem of maximizing the quadratic form $\boldsymbol{x}^\top \boldsymbol{W}\boldsymbol{x}$ over a constraint set $\boldsymbol{x} \in \mathcal{S} \subset \mathbb{R}^n$, where $\boldsymbol{W}$ is a random matrix drawn from the Gaussian orthogonal ensemble,[1] $\boldsymbol{W} \sim \mathsf{GOE}(n)$. Unlike previous works that have studied whether an efficient algorithm can *optimize* and find $\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{W})$ that achieves a large objective value, we study whether an efficient algorithm can *certify* an upper bound on the objective over all $\boldsymbol{x} \in \mathcal{S}$. In the notable case of the *Sherrington-Kirkpatrick (SK) Hamiltonian* [59, 49], where $\mathcal{S} = \{\pm 1/\sqrt{n}\}^n$, while there is an efficient algorithm believed to optimize arbitrarily close to the true maximum [46], we give evidence – based on the *low-degree likelihood ratio* recently studied in the sum-of-squares literature [9, 31, 29, 28], which we describe in Section 2.4 – that there is *no* efficient algorithm to certify an upper bound that improves on a simple spectral certificate. Thus, the certification task for this problem appears to exhibit a statistical-to-computational gap, while the optimization task does not.

1.1 Computational tasks in random optimization problems

To formalize the above discussion, consider a generic random optimization problem:

$$\begin{array}{ll} \text{maximize} & f_\omega(\boldsymbol{x}) \\ \text{subject to} & \boldsymbol{x} \in \mathcal{S} \\ \text{where} & \omega \sim \mathbb{P}, \end{array} \tag{1}$$

for $\mathbb{P}$ a probability distribution over some set of problem instances Ω. We will contrast two important computational tasks in this setting. The first, most obvious task is that of *optimization*, producing an algorithm that computes $\mathsf{alg}_{\mathsf{opt}} : \Omega \to \mathcal{S}$ such that $f_\omega(\mathsf{alg}_{\mathsf{opt}}(\omega))$ is as large as possible (say, in expectation, or with high probability as the size of the problem diverges).

Another task is that of *certification*, producing instead an algorithm that computes a scalar $\mathsf{alg}_{\mathsf{cert}} : \Omega \to \mathbb{R}$, such that *for all* $\omega \in \Omega$ and all $\boldsymbol{x} \in \mathcal{S}$ we have $f_\omega(\boldsymbol{x}) \le \mathsf{alg}_{\mathsf{cert}}(\omega)$. The main challenge specific to certification is that $\mathsf{alg}_{\mathsf{cert}}$ must produce a valid upper bound on

[1] Gaussian orthogonal ensemble (GOE): $\boldsymbol{W}$ is symmetric with $W_{ij} = W_{ji} \sim \mathcal{N}(0, 1/n)$ for $i \neq j$ and $W_{ii} \sim \mathcal{N}(0, 2/n)$, all independent.

f_ω for *every* possible instance $\omega \in \Omega$, no matter how unlikely ω is to occur under $\mathbb{P}$. Subject to this requirement, we seek to minimize $\mathsf{alg}_{\mathsf{cert}}(\omega)$ (again, in a suitable probabilistic sense when $\omega \sim \mathbb{P}$). *Convex relaxations* are a common approach to certification, where $\mathcal{S}$ is relaxed to a convex superset $\mathcal{S}' \supset \mathcal{S}$ over which it is possible to optimize exactly and efficiently using convex optimization. Often, such algorithms admit an alternative interpretation of *proving* a bound on $f_\omega(\boldsymbol{x})$ in some limited proof system (see, e.g., [27] for such discussion of sum-of-squares algorithms).

If $\boldsymbol{x}^\star = \boldsymbol{x}^\star(\omega)$ is the true maximizer of f_ω, then for any pair of optimization and certification algorithms as above, we have

$$f_\omega(\mathsf{alg}_{\mathsf{opt}}(\omega)) \leq f_\omega(\boldsymbol{x}^\star) \leq \mathsf{alg}_{\mathsf{cert}}(\omega). \tag{2}$$

Thus, in the case of a maximization problem, optimization algorithms approximate the true value $f_\omega(\boldsymbol{x}^\star)$ from below, while certification algorithms approximate it from above. We are then interested in how tight either inequality can be for random problems of growing dimension. Of course, we can achieve "perfect" optimization and certification (equality on either side of (2)) by exhaustive search over all $\boldsymbol{x} \in \mathcal{S}$, but we are interested in whether this is still possible when we restrict our attention to computationally-efficient algorithms.

To make these definitions concrete, we review an instance of each type of algorithm for the problem of optimizing the Sherrington-Kirkpatrick Hamiltonian.

▶ **Example 1.1.** The "SK problem" is the random optimization problem

$$\begin{array}{ll} \text{maximize} & \boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \\ \text{subject to} & \boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n \\ \text{where} & \boldsymbol{W} \sim \mathsf{GOE}(n). \end{array} \tag{3}$$

Here, two related *spectral algorithms* give simple examples of algorithms for both optimization and certification. For certification, writing $\lambda_{\max}$ for the largest eigenvalue of $\boldsymbol{W}$, we may use the bound

$$\boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \leq \lambda_{\max} \cdot \|\boldsymbol{x}\|^2 = \lambda_{\max} \approx 2 \tag{4}$$

for all $\boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n$, whereby $\lambda_{\max}$ is a certifiable upper bound on (3). From classical random matrix theory (see, e.g., [5]), it is known that $\lambda_{\max} \approx 2$ as $n \to \infty$.

For optimization, for $\boldsymbol{v}_{\max}$ the eigenvector of $\lambda_{\max}$, we may take $\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{W}) := \mathrm{sgn}(\boldsymbol{v}_{\max})/\sqrt{n}$ where sgn denotes the $\{\pm 1\}$-valued sign function, applied entrywise. The vector $\boldsymbol{v}_{\max}$ is distributed as an uniform random unit vector in $\mathbb{R}^n$, so the quality of this solution may be computed as

$$\boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} = \lambda_{\max} \cdot \langle \boldsymbol{x}, \boldsymbol{v}_{\max} \rangle^2 + O\left(\frac{1}{\sqrt{n}}\right) = \lambda_{\max} \cdot \frac{\|\boldsymbol{v}_{\max}\|_1^2}{n} + O\left(\frac{1}{\sqrt{n}}\right) \approx \frac{4}{\pi} \approx 1.2732 \tag{5}$$

with high probability as $n \to \infty$. (The error in the first equation is obtained as $\sum_i \lambda_i \langle \boldsymbol{v}_i, \boldsymbol{x} \rangle^2 \approx \frac{1}{n} \mathrm{Tr}(\boldsymbol{W})(1 - \langle \boldsymbol{v}_{\max}, \boldsymbol{x} \rangle^2)$, where the sum is over all eigenvectors $\boldsymbol{v}_i$ except $\boldsymbol{v}_{\max}$. This analysis appeared in [3], an early rigorous mathematical work on the SK model.)

On the other hand, deep results of statistical physics imply that the true optimal value approaches

$$\boldsymbol{x}^{\star\top} \boldsymbol{W} \boldsymbol{x}^\star \approx 2\mathsf{P}_* \approx 1.5264 \tag{6}$$

as $n \to \infty$, where the constant P_* is expressed via the celebrated Parisi formula for the free energy of the SK model [50, 49, 62]. The approximate value we give above was estimated with numerical experiments in previous works (see, e.g., [51, 15]).

Thus, neither for optimization nor for certification does the naive spectral algorithm achieve the optimal value, which suggests the question: can more sophisticated algorithms improve on the spectral algorithm for either task? For optimization, the recent result of [46] implies, assuming a widely-believed conjecture from statistical physics, that for any $\varepsilon > 0$ there exists a polynomial-time optimization algorithm achieving with high probability a value of $2\mathsf{P}_* - \varepsilon$ on the SK problem.[2] On the other hand, there are few results addressing certification in the SK problem. The only previous work we are aware of in this direction is [48], where a simple semidefinite programming relaxation (which coincides with degree-2 sum-of-squares) is shown to achieve the same value as the spectral certificate (4). More recently (after the initial appearance of this paper) the same was shown for degree-4 sum-of-squares [39, 45].

1.2 Our contributions

The main result of this paper, which we now state informally, gives formal evidence that for the SK certification problem, the simple spectral certificate (4) is optimal among efficient algorithms. See Corollary 3.8 for the precise statement.

▶ **Theorem 1.2** (Informal). *Conditional on the correctness of the low-degree likelihood ratio method (see Section 2.4), for any $\varepsilon > 0$, there is no polynomial-time algorithm that certifies the upper bound $2 - \varepsilon$ on the SK problem* (3) *with probability $1 - o(1)$ as $n \to \infty$.*

In fact, we expect that there is not even a subexponential-time algorithm; see Remark 3.6. Theorem 1.2 reveals a striking gap between optimization and certification: it is possible to efficiently give a tight lower bound on the maximum objective value by exhibiting a solution $\boldsymbol{x}$, but it seems impossible to efficiently give a tight upper bound. In other words, an algorithm can efficiently find a near-optimal solution, but cannot be sure that it has done so. The same result also holds for a wide variety of constraints other than $\boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n$ (see Corollary 3.8). Due to the high-dimensional setting of the problem, we expect the value of an optimal certification algorithm to concentrate tightly; thus we expect Theorem 1.2 to still hold if $1 - o(1)$ is replaced by any positive constant.

Our result has important consequences for convex programming. A natural approach for optimizing the SK problem (3) would be to use a convex programming relaxation such as a semidefinite program based on the sum-of-squares hierarchy [60, 52, 41] (see [55] for a survey). Such a method would relax the constraints of the SK problem to weaker ones for which the associated optimization problem can be solved efficiently. One can either hope that the relaxation is *tight* and gives a valid solution $\boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n$ (with high probability), or use a *rounding* procedure to extract a valid solution from the relaxation. The optimal value of any convex relaxation of (3) provides an upper bound on the optimal value of (3) and therefore gives a certification algorithm. Thus Theorem 1.2 implies that (conditional on the correctness of the low-degree likelihood ratio method) no polynomial-time convex relaxation of (3) can have value $\leq 2 - \varepsilon$ (resolving a question posed by [32]) and in particular cannot be tight.[3] As a result, we expect that natural relax-and-round approaches for optimization should fail to find a solution of value close to $2\mathsf{P}_*$. This would suggest a fundamental weakness of convex programs: even the most powerful convex programs (such as sum-of-squares relaxations)

[2] The work [46] builds on that of [2, 61], and these works taken together formalize the heuristic idea from statistical physics that optimization is tractable for certain optimization problems exhibiting *full replica symmetry breaking*.

[3] Our results suggest that $\Omega(n^{1-o(1)})$ rounds of sum-of-squares are required to certify a value $2 - \varepsilon$; see Remark 3.6.

seem to fail to optimize (3), even though other methods succeed (namely, the message-passing algorithm of [46]).[4] An explanation for this suboptimality is that convex relaxations are actually solving a fundamentally harder problem: certification.

1.3 Related work

A related example of an optimization–certification gap comes from random constraint satisfaction problems (CSPs).

▶ **Example 1.3.** In random MAX-3SAT, the decision variable is a boolean vector $\boldsymbol{x} \in \{0,1\}^n$, and the optimization task is to maximize the number of satisfied *clauses* $C_1, \ldots, C_m$, each of which is a boolean expression of the form $C_i = a_{i_1} \vee a_{i_2} \vee a_{i_3}$ where each a_{i_j} is chosen uniformly among the x_i and their boolean negations. Let $s_{\boldsymbol{C}}(\boldsymbol{x})$ denote the number of clauses satisfied by $\boldsymbol{x}$.

If $m/n \to \infty$ as $n \to \infty$, the optimal value $\max_{\boldsymbol{x}} s_{\boldsymbol{C}}(\boldsymbol{x})$ is $(7/8 + o(1))m$ with probability $1 - o(1)$ [11]. This is achieved by the trivial optimization algorithm that chooses a uniformly random assignment $\boldsymbol{x}$. On the other hand, sum-of-squares lower bounds suggest that it is hard to certify even $s_{\boldsymbol{C}}(\boldsymbol{x}) < m$ unless $m \gg n^{3/2}$ [26, 58, 38]. Along similar lines, a well-known conjecture of Feige asserts this cannot be certified (by *any* certification algorithm) in polynomial time for m/n an arbitrarily large constant [22].

As in the SK problem, there is an efficient algorithm for near-perfect optimization, while there does not seem to be such an algorithm for near-perfect certification. However, here the optimization algorithm is trivial (a random guess), so arguably a more natural optimization task would be to achieve the best possible advantage over random guessing, assessing the quality of a solution on a finer scale.

Prior work has used *sum-of-squares lower bounds* to argue for hardness of certification in problems such as random CSPs [26, 58, 38], planted clique [19, 44, 9], tensor injective norm [30, 29], graph coloring [8], community detection in hypergraphs [37], and others. These results prove that the sum-of-squares hierarchy (at some degree) fails to certify. If sum-of-squares fails at every constant degree (e.g., [9, 38, 29]), this suggests that all polynomial-time algorithms should also fail. In our case, it appears difficult to prove such sum-of-squares lower bounds for the SK problem, although recent work (appearing after the initial version of this paper) has shown lower bounds at degree 4 [39, 45]. We instead take a new approach based on a related heuristic for computational hardness, which we explain in Section 2.4. One advantage of this approach over sum-of-squares is that it is substantially simpler. Perhaps the prior work that is closest to our approach is [63], which also gives a reduction from a hypothesis testing problem to a certification problem.

Overview of techniques

The proof of Theorem 1.2 has two parts. First, we give a reduction from hypothesis testing in the *negatively-spiked Wishart model* [34, 6, 7, 54] to the SK certification problem. We then use a method introduced in the sum-of-squares literature based on the *low-degree likelihood ratio* [9, 31, 29, 28] to give formal evidence that detection in that negatively-spiked Wishart model is computationally hard.

[4] In contrast, simple rounded convex relaxations are believed to approximate many similar problems optimally in the worst-case (rather than average-case) setting [36].

In the spiked Wishart model, we observe either N i.i.d. samples $\boldsymbol{y}_1, \dots, \boldsymbol{y}_N \sim \mathcal{N}(0, \boldsymbol{I}_n)$, or N i.i.d. samples $\boldsymbol{y}_1, \dots, \boldsymbol{y}_N \sim \mathcal{N}(0, \boldsymbol{I}_n + \beta \boldsymbol{x}\boldsymbol{x}^\top)$ where the "spike" $\boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n$ is a uniformly random hypercube vector, and $\beta \in [-1, \infty)$. The goal is to distinguish between these two cases with probability $1 - o(1)$ as $n \to \infty$. In the *negatively-spiked* ($\beta < 0$) case with $\beta \approx -1$, this task amounts to deciding whether there is a hypercube vector $\boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n$ that is nearly orthogonal to all of the samples $\boldsymbol{y}_i$. When $N = \Theta(n)$, a simple spectral method succeeds when $\beta^2 > n/N$ [6, 7], and we expect the problem to be computationally hard when $\beta^2 < n/N$.

Let us now intuitively explain the relation between the negatively-spiked Wishart model and the SK certification problem. Suppose we want to certify that

$$\mathsf{SK}(\boldsymbol{W}) := \max_{\boldsymbol{x} \in \{\pm 1/\sqrt{n}\}^n} \boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \leq 2 - \varepsilon$$

where $\boldsymbol{W} \sim \mathsf{GOE}(n)$, for some small constant $\varepsilon > 0$. Since the eigenvalues of $\boldsymbol{W}$ approximately follow the semicircle distribution on $[-2, 2]$ [64], we need to certify that the top δn-dimensional eigenspace of $\boldsymbol{W}$ does not (approximately) contain a hypercube vector, for a small $\delta > 0$ depending on ε. In particular, we need to distinguish a uniformly random δn-dimensional subspace (the distribution of the actual top eigenspace of $\boldsymbol{W} \sim \mathsf{GOE}(n)$) from a δn-dimensional subspace that contains a hypercube vector. Equivalently, taking orthogonal complements, we need to distinguish a uniformly random $(1-\delta)n$-dimensional subspace from a $(1-\delta)n$-dimensional subspace that is orthogonal to a hypercube vector. This is the problem of detection in the negatively-spiked Wishart model with $\beta \approx -1$ and $N = (1-\delta)n$, and these parameters lie in the "hard regime" $\beta^2 < n/N$.

Formally, we construct a distribution $\mathcal{D}(n)$ over $n \times n$ symmetric matrices with $\mathsf{SK}(\boldsymbol{W}) \geq 2 - \varepsilon/2$ when $\boldsymbol{W} \sim \mathcal{D}(n)$. This $\mathcal{D}(n)$ also has the property that, conditional on the hardness of the above detection problem, it is computationally hard to distinguish $\boldsymbol{W} \sim \mathcal{D}(n)$ from $\boldsymbol{W} \sim \mathsf{GOE}(n)$. The existence of such $\mathcal{D}(n)$ implies hardness of certification for the SK problem, because if an algorithm could certify that $\mathsf{SK}(\boldsymbol{W}) \leq 2 - \varepsilon$ when $\boldsymbol{W} \sim \mathsf{GOE}(n)$, then it could distinguish $\mathcal{D}(n)$ from $\mathsf{GOE}(n)$.

Borrowing terminology from [65, 66], we refer to this idea of "planting" a hidden solution (in our case, a hypercube vector $\boldsymbol{x}$) in such a way that it is difficult to detect, as *quiet planting*[5]. Our quiet planting scheme $\mathcal{D}(n)$ draws $\boldsymbol{W} \sim \mathsf{GOE}(n)$ and then rotates the top eigenspace of $\boldsymbol{W}$ to align with a random hypercube vector $\boldsymbol{x}$, while leaving the eigenvalues of $\boldsymbol{W}$ unchanged. (The more straightforward planting scheme, $\boldsymbol{W} + (2 - \varepsilon/2)\boldsymbol{x}\boldsymbol{x}^\top$ with $\boldsymbol{W} \sim \mathsf{GOE}(n)$, is not quiet because it changes the largest eigenvalue of $\boldsymbol{W}$ [23].) The question of how to design optimal quiet planting schemes in general remains an interesting open problem.

The final ingredient in our proof is to give formal evidence (in the form of the low-degree likelihood ratio) that detection in the spiked Wishart model is computationally hard below the spectral threshold. This consists of a calculation involving the projection of the likelihood ratio (between the "null" and "planted" distributions) onto the subspace of low-degree polynomials. This method suggests that the correct strategy for quiet planting is to match the low-degree moments of the distributions $\mathcal{D}(n)$ and $\mathsf{GOE}(n)$. We discuss the details of this method further in Section 2.4.

Our results on hardness in the spiked Wishart model may be of independent interest: our low-degree calculations suggest that, for a large class of spike priors, no polynomial-time algorithm can successfully distinguish the spiked and unspiked models below the classical

[5] However, our notion of quiet planting is not quite the same as that of [65, 66].

spectral threshold [6, 7], both in the negatively-spiked and positively-spiked regimes. (For positive spikes there was existing evidence for this based on failure of approximate message passing [24]; no such evidence was known for negative spikes.)

2 Background

2.1 Probability Theory

Our asymptotic notation (e.g., $O(\cdot), o(\cdot)$) always pertains to the limit $n \to \infty$. Parameters of the problem (e.g., $\beta, \gamma, \mathcal{X}, \mathcal{S}$) are held fixed as $n \to \infty$. Thus the constants hidden by $O(\cdot)$ and $o(\cdot)$ do not depend on n but may depend on the other parameters. When A_n is a sequence of events in probability spaces with measures $\mathbb{P}_n$, we say A_n holds *with high probability* if $\mathbb{P}_n[A_n] = 1 - o(1)$.

▶ **Definition 2.1.** *A real-valued random variable π with $\mathbb{E}[\pi] = 0$ is* subgaussian *if there exists $\sigma^2 \geq 0$ (the* variance proxy*) such that, for all $t \in \mathbb{R}$, $M(t) := \mathbb{E}[\exp(t\pi)] \leq \exp(\sigma^2 t^2/2)$.*

The name *subgaussian* refers to the fact that if $\pi \sim \mathcal{N}(0, \sigma^2)$, then $M(t) = \exp(\sigma^2 t^2/2)$. A random variable with law $\mathcal{N}(0, \sigma^2)$ is therefore subgaussian. Any bounded centered random variable is also subgaussian: if $\pi \in [a, b]$ almost surely, then π is subgaussian with $\sigma^2 = \frac{1}{4}(b-a)^2$ (see, e.g., [56]).

We next give some background facts from random matrix theory (see, e.g., [5]).

▶ **Definition 2.2.** *The* Gaussian orthogonal ensemble $\mathsf{GOE}(n)$ *is a probability distribution over symmetric matrices $\boldsymbol{W} \in \mathbb{R}^{n \times n}$, under which $W_{ii} \sim \mathcal{N}(0, 2/n)$ and $W_{ij} \sim \mathcal{N}(0, 1/n)$ when $i \neq j$, where the entries W_{ij} are independent for distinct pairs (i, j) with $i \leq j$.*

Our scaling of the entries of $\mathsf{GOE}(n)$ ensures a spectrum of constant width.

▶ **Proposition 2.3.** *Let $\boldsymbol{W}_n \sim \mathsf{GOE}(n)$. Then, almost surely, $\lambda_{\min}(\boldsymbol{W}_n) \to -2$ and $\lambda_{\max}(\boldsymbol{W}_n) \to 2$ as $n \to \infty$. In particular, for any $\varepsilon > 0$, $\|\boldsymbol{W}_n\| \leq 2 + \varepsilon$ with high probability. Also, the empirical distribution of eigenvalues of $\boldsymbol{W}_n$ converges weakly to a semicircle distribution supported on $[-2, 2]$.*

2.2 Constrained PCA

▶ **Definition 2.4.** *A* constraint set *is a sequence $\mathcal{S} = (\mathcal{S}_n)_{n \in \mathbb{N}}$ where $\mathcal{S}_n \subset \mathbb{R}^n$. The* constrained principal component analysis (PCA) problem with constraint set $\mathcal{S}$*, denoted* $\mathsf{PCA}(\mathcal{S})$*, is*

$$\begin{array}{ll} \textit{maximize} & \boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \\ \textit{subject to} & \boldsymbol{x} \in \mathcal{S}_n \\ \textit{where} & \boldsymbol{W} \sim \mathsf{GOE}(n). \end{array}$$

We will work only with constraint sets supported on vectors of approximately unit norm. General problems of this kind have been studied previously in, e.g., [20].

▶ **Example 2.5.** Problems that may be described in the constrained PCA framework include:

- the Sherrington-Kirkpatrick (SK) spin glass model: $\mathcal{S}_n = \{\pm 1/\sqrt{n}\}^n$ [59, 49],
- the Wigner sparse PCA null model: $\mathcal{S}_n = \{\boldsymbol{x} \in \mathbb{R}^n \ : \ \|\boldsymbol{x}\| = 1, \|\boldsymbol{x}\|_0 \leq \rho\}$ [17, 43],
- the spherical $2p$-spin spin glass model: $\mathcal{S}_{pn} = \{\boldsymbol{x}^{\otimes p} \ : \ \boldsymbol{x} \in \mathbb{R}^n, \|\boldsymbol{x}\| = 1\}$ [14, 13],
- the positive PCA null model: $\mathcal{S}_n = \{\boldsymbol{x} \in \mathbb{R}^n \ : \ x_i \geq 0, \|\boldsymbol{x}\| = 1\}$ [47].

Our results apply to the first two examples: the SK model, and sparse PCA when $\rho = \Theta(n)$.

▶ **Definition 2.6.** *Let f be a (randomized) algorithm*[6] *that takes a square matrix $\boldsymbol{W}$ as input and outputs a number $f(\boldsymbol{W}) \in \mathbb{R}$. We say that f* certifies *a value B on $\mathsf{PCA}(\mathcal{S})$ if*
1. *for* any *symmetric matrix $\boldsymbol{W} \in \mathbb{R}^{n \times n}$, $\max_{\boldsymbol{x} \in \mathcal{S}_n} \boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \le f(\boldsymbol{W})$, and*
2. *if $\boldsymbol{W}_n \sim \mathsf{GOE}(n)$ then $f(\boldsymbol{W}_n) \le B + o(1)$ with high probability.*

2.3 Spiked Wishart Models

▶ **Definition 2.7.** *A* normalized spike prior *is a sequence $\mathcal{X} = (\mathcal{X}_n)_{n \in \mathbb{N}}$ where $\mathcal{X}_n$ is a probability distribution over $\mathbb{R}^n$, such that if $\boldsymbol{x} \sim \mathcal{X}_n$ then $\|\boldsymbol{x}\| \to 1$ in probability as $n \to \infty$.*

▶ **Definition 2.8** (Spiked Wishart model)**.** *Let $\mathcal{X}$ be a normalized spike prior, let $\gamma > 0$, and let $\beta \in [-1, \infty)$. Let $N = \lceil n/\gamma \rceil$. We define two probability distributions over $(\mathbb{R}^n)^N$:*
1. *Under $\mathbb{Q}$, the* null *model, draw $\boldsymbol{y}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n)$ independently for $i \in [N]$.*
2. *Under $\mathbb{P}$, the* planted *model, draw $\boldsymbol{x} \sim \mathcal{X}_n$. If $\beta\|\boldsymbol{x}\|^2 \ge -1$, then draw $\boldsymbol{y}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n + \beta \boldsymbol{x}\boldsymbol{x}^\top)$ independently for $i \in [N]$. Otherwise, draw $\boldsymbol{y}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n)$ independently for $i \in [N]$.*

Taken together, $\mathbb{P}$ and $\mathbb{Q}$ form the spiked Wishart model $(\mathbb{P}, \mathbb{Q}) =: \mathsf{Wishart}(n, \gamma, \beta, \mathcal{X})$*. For fixed γ and β we denote the sequence $(\mathsf{Wishart}(n, \gamma, \beta, \mathcal{X}))_{n \in \mathbb{N}}$ by $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$.*

Several remarks on this definition are in order. First, we make the explicit choice $N = \lceil n/\gamma \rceil$ for concreteness, but our results apply to any choice of $N = N(n)$ for which $n/N \to \gamma$ as $n \to \infty$. Second, often the Wishart model is described in terms of the distribution of the sample covariance matrix $\frac{1}{N}\sum_{i=1}^N \boldsymbol{y}_i \boldsymbol{y}_i^\top$. We instead work directly with the samples $\boldsymbol{y}_i$ so as not to restrict ourselves to algorithms that only use the sample covariance matrix. (This modification only makes our results on computational hardness of detection more general.) Finally, the definition of $\mathbb{P}$ has two cases to ensure that the covariance matrix $\boldsymbol{I}_n + \beta \boldsymbol{x}\boldsymbol{x}^\top$ is positive semidefinite. We will work in the setting $\beta > -1$ where the first case ($\beta\|\boldsymbol{x}\|^2 \ge -1$) occurs with high probability.

We consider the algorithmic task of distinguishing between $\mathbb{P}$ and $\mathbb{Q}$ in the following sense.

▶ **Definition 2.9.** *For sequences of distributions $\mathbb{P} = (\mathbb{P}_n)_{n \in \mathbb{N}}$ and $\mathbb{Q} = (\mathbb{Q}_n)_{n \in \mathbb{N}}$ over measurable spaces $(\Omega_n, \mathcal{F}_n)_{n \in \mathbb{N}}$, an algorithm $f_n : \Omega_n \to \{0, 1\}$ achieves* strong detection *between $\mathbb{P}$ and $\mathbb{Q}$ if*

$$\mathbb{Q}_n[f_n(\boldsymbol{y}) = 0] = 1 - o(1) \qquad \text{and} \qquad \mathbb{P}_n[f_n(\boldsymbol{y}) = 1] = 1 - o(1).$$

The celebrated BBP transition [6] implies a spectral algorithm for strong detection in the spiked Wishart model whenever $\beta^2 > \gamma$.

▶ **Theorem 2.10** ([6, 7])**.** *Let $\mathcal{X}$ be any normalized spike prior. If $\beta^2 > \gamma$ then there exists a polynomial-time algorithm for strong detection in $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$.*

The algorithm thresholds the largest eigenvalue (if $\beta > 0$) or smallest eigenvalue (if $\beta < 0$) of the sample covariance matrix $\frac{1}{N}\sum_{i=1}^N \boldsymbol{y}_i \boldsymbol{y}_i^\top$. This eigenvalue converges almost surely to a limiting value which is different under $\mathbb{P}$ and $\mathbb{Q}$.

[6] We allow f to be randomized; i.e., it may use randomness in its computations, but the output B must be an upper bound almost surely. We do not expect certification algorithms to require randomness, but it may be convenient, e.g., to randomly initialize an iterative optimization procedure.

We will give evidence that (see Corollary 3.5) if $\mathcal{X}$ has i.i.d. subgaussian entries with suitable scaling, then no polynomial-time algorithm achieves strong detection below the BBP threshold ($\beta^2 < \gamma$). Exponential-time strong detection is possible below the BBP threshold for some priors, such as i.i.d. Rademacher when $\beta < -0.84$ [54]. Very sparse priors with $\boldsymbol{x}$ supported on $O(\sqrt{n})$ entries give rise to the *sparse PCA* regime, where polynomial-time strong detection is possible below the BBP threshold [35, 4, 18]; our results will not apply in this setting (although see [29, 21] for some related work that addresses this regime).

2.4 The Low-Degree Likelihood Ratio

Inspired by the sum-of-squares hierarchy (e.g., [60, 52, 41]) and in particular the pseudo-calibration approach [9], recent works [31, 29, 28] have proposed a strikingly simple method for predicting computational hardness of Bayesian inference problems. This method recovers widely-conjectured computational thresholds for high-dimensional inference problems such as planted clique [9, 28], community detection [31, 28], sparse PCA [21], tensor PCA [29, 28, 40], and the spiked Wigner matrix model [40]. We now give an overview of this method (see also [40] for a survey).

Consider the problem of distinguishing two simple hypotheses $\mathbb{P}_n$ and $\mathbb{Q}_n$ which are probability distributions on some domain $\Omega_n = \mathbb{R}^{d(n)}$ (where typically the dimension $d(n)$ grows with n). One example is the spiked Wishart model $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$ for some fixed choice of the parameters $\beta, \gamma, \mathcal{X}$. The idea is to take low-degree polynomials as a proxy for polynomial-time algorithms and consider whether there are such polynomials that can distinguish $\mathbb{P}_n$ from $\mathbb{Q}_n$.

▶ **Definition 2.11.** *Let $D : \mathbb{N} \to \mathbb{N}$. We say that distinguishing $\mathbb{P}_n$ from $\mathbb{Q}_n$ is $D(n)$-low-degree easy if there exists a sequence of nonzero polynomials $f_n \in \mathbb{R}[y_1, \ldots, y_{d(n)}]$ with $\deg f_n \leq D(n)$ such that*

$$\lim_{n\to\infty} \frac{\mathbb{E}_{\boldsymbol{y}\sim\mathbb{P}_n} f_n(\boldsymbol{y})}{\sqrt{\mathbb{E}_{\boldsymbol{y}\sim\mathbb{Q}_n} f_n(\boldsymbol{y})^2}} = +\infty, \tag{7}$$

and $D(n)$-low-degree hard otherwise.

We view $\mathbb{Q}_n$ as the "null" distribution, which is often i.i.d. Gaussian (as in the Wishart model) or i.i.d. Rademacher (± 1-valued). $\mathbb{Q}_n$ induces an inner product on L^2 functions $f : \Omega_n \to \mathbb{R}$ given by $\langle f, g\rangle_{L^2(\mathbb{Q}_n)} = \mathbb{E}_{\boldsymbol{y}\sim\mathbb{Q}_n}[f(\boldsymbol{y})g(\boldsymbol{y})]$, and a norm $\|f\|^2_{L^2(\mathbb{Q}_n)} = \langle f, f\rangle_{L^2(\mathbb{Q}_n)}$. For $D \in \mathbb{N}$, let $\mathbb{R}[\boldsymbol{y}]_{\leq D}$ denote the polynomials $\Omega_n \to \mathbb{R}$ of degree at most D. For $f : \Omega_n \to \mathbb{R}$, let $f^{\leq D}$ denote the orthogonal projection (with respect to $\langle\cdot,\cdot\rangle_{L^2(\mathbb{Q}_n)}$) of f onto $\mathbb{R}[\boldsymbol{y}]_{\leq D}$. The following relates low-degree hardness to the *low-degree likelihood ratio*.

▶ **Theorem 2.12** ([31])**.** *Let $\mathbb{P}_n$ and $\mathbb{Q}_n$ be probability distributions on Ω_n for each $n \in \mathbb{N}$. Suppose $\mathbb{P}_n$ is absolutely continuous with respect to $\mathbb{Q}_n$, so that the likelihood ratio $L_n = \frac{d\mathbb{P}_n}{d\mathbb{Q}_n}$ is defined. Then*

$$\max_{f\in\mathbb{R}[\boldsymbol{y}]_{\leq D}\setminus\{0\}} \frac{\mathbb{E}_{\boldsymbol{y}\sim\mathbb{P}_n} f(\boldsymbol{y})}{\sqrt{\mathbb{E}_{\boldsymbol{y}\sim\mathbb{Q}_n} f(\boldsymbol{y})^2}} = \|L_n^{\leq D}\|_{L^2(\mathbb{Q}_n)}. \tag{8}$$

Proof. The objective can be rewritten as $\langle f, L_n\rangle_{L^2(\mathbb{Q}_n)}/\|f\|_{L^2(\mathbb{Q}_n)}$, so by basic Hilbert space theory, the maximum is attained by taking $f = L_n^{\leq D}$. ◀

▶ **Corollary 2.13.** *In the setting of Theorem 2.12,*

1. *if $\|L_n^{\leq D(n)}\|_{L^2(\mathbb{Q}_n)} = O(1)$, then distinguishing $\mathbb{P}_n$ from $\mathbb{Q}_n$ is $D(n)$-low-degree hard;*
2. *if $\|L_n^{\leq D(n)}\|_{L^2(\mathbb{Q}_n)} = \omega(1)$, then distinguishing $\mathbb{P}_n$ from $\mathbb{Q}_n$ is $D(n)$-low-degree easy.*

We take $O(\log n)$-degree polynomials $\Omega_n \to \mathbb{R}$ as a proxy for functions computable in polynomial-time. One justification for this is that many polynomial-time algorithms compute the leading eigenvalue of a matrix $\boldsymbol{M}$ whose entries are constant-degree polynomials in the data; in fact, there is formal evidence that such *low-degree spectral methods* are as powerful as the sum-of-squares hierarchy [29]. Typically, $O(\log n)$ rounds of power iteration are sufficient to compute the leading eigenvalue accurately, which amounts to evaluating the $O(\log n)$-degree polynomial $\mathrm{Tr}(\boldsymbol{M}^{2q})$ for some $q = O(\log n)$. This argument can be made formal: if $\|L_n^{\leq D}\|_{L^2(\mathbb{Q}_n)} = O(1)$ then all low-degree spectral methods must fail in a certain sense [40]. This motivates the following informal conjecture, which is based on [31, 29, 28], particularly Conjecture 2.2.4 of [28].

▶ **Conjecture 2.14** (Informal). *For "nice" distributions $\mathbb{P}_n$ and $\mathbb{Q}_n$, if distinguishing $\mathbb{P}_n$ and $\mathbb{Q}_n$ is $\log^{1+\Omega(1)}(n)$-low-degree hard, then there is no randomized polynomial-time algorithm for strong detection between $\mathbb{P}$ and $\mathbb{Q}$.*

This conjecture is useful because the norm of the low-degree likelihood ratio, $\|L_n^{\leq D}\|_{L^2(\mathbb{Q}_n)}$, can be computed (or at least bounded) for various distributions such as the stochastic block model [31] and the spiked tensor model [29, 28]. More generally, Hypothesis 2.1.5 of [28] conjectures that degree-D polynomials are a proxy for time-$n^{\widetilde{\Theta}(D)}$ algorithms.

▶ Remark 2.15. We do not expect the converse of Conjecture 2.14 to hold. If detection is $O(\log n)$-low-degree easy then we expect an $n^{O(\log n)}$-time algorithm but not necessarily a polynomial-time algorithm, because not every $O(\log n)$-degree polynomial can be evaluated in polynomial time.

Conjecture 2.14 is informal in that we do not specify what is meant by "nice" distributions. See Conjecture 2.2.4 of [28] for a precise variant of Conjecture 2.14; however, this variant uses the more refined notion of *coordinate degree* and so does not apply to the calculations we will perform. Roughly speaking, "nice" distributions $\mathbb{P}$ and $\mathbb{Q}$ should satisfy the following:

1. $\mathbb{Q}$ should be a product distribution, e.g., i.i.d. Gaussian or i.i.d. Rademacher;
2. $\mathbb{P}$ should be sufficiently symmetric with respect to permutations of its coordinates; and
3. we should be able to add a small amount of noise to $\mathbb{P}$, ruling out distributions with brittle algebraic structure (such as random satisfiable instances of XOR-SAT, which can be identified using Gaussian elimination [12]).

We refer the reader to [31, 28, 40] for further details and evidence in favor of Conjecture 2.14.

3 Main Results

3.1 Spiked Wishart Models

We now study the low-degree hardness of the spiked Wishart model. The following technical definitions will be important to specify the priors to which our results apply.

▶ **Definition 3.1.** *Let $\beta \in (-1, \infty)$ and let $\mathcal{X}$ be a normalized spike prior. We say that $\mathcal{X}$ is* β-good *if when $\boldsymbol{x} \sim \mathcal{X}_n$ then $\beta\|\boldsymbol{x}\|^2 > -1$ almost surely.*

We consider spike priors having i.i.d. entries, and will sometimes need to slightly modify the spike prior to ensure that it is β-good and has bounded norm.

▶ **Definition 3.2.** *Let π be a probability distribution over $\mathbb{R}$ such that $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Let $\mathsf{iid}(\pi/\sqrt{n})$ denote the normalized spike prior $\mathcal{X} = (\mathcal{X}_n)$ that draws each entry of $\boldsymbol{x}$ independently from $\frac{1}{\sqrt{n}}\pi$. (We do not allow π to depend on n.)*

▶ **Definition 3.3.** *For a normalized spike prior $\mathcal{X}$, let the β-truncation* $\mathrm{trunc}_\beta(\mathcal{X})$ *of $\mathcal{X}$ denote the following normalized spike prior. To sample $\boldsymbol{x}$ from* $(\mathrm{trunc}_\beta(\mathcal{X}))_n$*, first sample $\boldsymbol{x}' \sim \mathcal{X}_n$. Then, let $\boldsymbol{x} = \boldsymbol{x}'$ if $\beta\|\boldsymbol{x}'\|^2 > -1$ and $\|\boldsymbol{x}'\|^2 \le 2$, and let $\boldsymbol{x} = \boldsymbol{0}$ otherwise.*

If $\beta > -1$ then since $\mathcal{X}$ is normalized ($\|\boldsymbol{x}'\| \to 1$ in probability), the first case of Definition 3.3 occurs with high probability. The upper bound $\|\boldsymbol{x}'\| \le 2$ is for technical convenience, and the constant 2 is not essential. Note also that the β-truncation of an i.i.d. prior is no longer i.i.d.

▶ **Theorem 3.4.** *Fix constants $\gamma > 0$ and $\beta > -1$.*

1. *Suppose $\beta^2 < \gamma$. Let $\mathcal{X} = \mathrm{trunc}_\beta(\mathsf{iid}(\pi/\sqrt{n}))$ where π is subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. For any $D = o(n/\log n)$, distinguishing $\mathbb{P}_n$ from $\mathbb{Q}_n$ is $D(n)$-low-degree hard.*
2. *Suppose $\beta^2 > \gamma$. Let $\mathcal{X} = \mathsf{iid}(\pi/\sqrt{n})$ be β-good with π symmetric about zero, $\mathbb{E}[\pi] = 0$, and $\mathbb{E}[\pi^2] = 1$. For any $D = \omega(1)$, distinguishing $\mathbb{P}_n$ from $\mathbb{Q}_n$ is $D(n)$-low-degree easy.*

We prove Theorem 3.4 in Section 5. Part 1 of Theorem 3.4, combined with Conjecture 2.14, suggests that for i.i.d. subgaussian priors, strong detection is hard below the BBP threshold.

▶ **Corollary 3.5.** *Suppose Conjecture 2.14 holds for the spiked Wishart model. Fix constants $\gamma > 0$ and $\beta > -1$. Let π be subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Let $\mathcal{X}$ be either $\mathsf{iid}(\pi/\sqrt{n})$ or $\mathrm{trunc}_\beta(\mathsf{iid}(\pi/\sqrt{n}))$. If $\beta^2 < \gamma$, then there is no randomized polynomial-time algorithm for strong detection in $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$.*

Proof. The case $\mathcal{X} = \mathrm{trunc}_\beta(\mathsf{iid}(\pi/\sqrt{n}))$ follows immediately from Part 1 of Theorem 3.4. If strong detection is impossible for $\mathcal{X} = \mathrm{trunc}_\beta(\mathsf{iid}(\pi/\sqrt{n}))$, then strong detection is also impossible for $\mathcal{X} = \mathsf{iid}(\pi/\sqrt{n})$, as these two spike priors differ with probability $o(1)$ (under the natural coupling). ◀

▶ Remark 3.6. We make some technical remarks regarding Theorem 3.4 and Corollary 3.5.

1. Even if Conjecture 2.14 does not hold, note that Theorem 3.4 still implies unconditional lower bounds against low-degree polynomials in the sense of Definition 2.11.
2. Part 2 of Theorem 3.4 serves only to check that we do not predict computational hardness when $\beta^2 > \gamma$ (as polynomial-time strong detection is possible in this regime; see Theorem 2.10). The assumption that π is symmetric about zero should not be essential.
3. In Part 1 of Theorem 3.4 and in Corollary 3.5, the requirement that $\mathcal{X}$ be a β-truncated i.i.d. prior can be relaxed. We only require that $\mathcal{X}$ is the β-truncation of a normalized prior admitting a *local Chernoff bound* (see Definition 5.11).
4. Part 1 of Theorem 3.4 holds for any $D = o(n/\log n)$, much larger than the $D = \log^{1+\Omega(1)}(n)$ required by Conjecture 2.14. Since Hypothesis 2.1.5 of [28] conjectures that degree-D polynomials are a proxy for $n^{\widetilde{\Theta}(D)}$-time algorithms [28], this suggests that the conclusion of Corollary 3.5 also holds for $2^{n^{1-\delta}}$-time algorithms, for any $\delta > 0$. In other words, strong detection requires nearly-exponential time.

3.2 Constrained PCA

The following result gives a reduction from strong detection in the spiked Wishart model to certification in the constrained PCA problem.

▶ **Theorem 3.7.** *Let $\mathcal{S}$ be a constraint set and let $\mathcal{X}$ be a normalized spike prior such that if $\boldsymbol{x} \sim \mathcal{X}_n$ then $\boldsymbol{x} \in \mathcal{S}_n$ with high probability. Suppose there exists $\varepsilon > 0$ and a randomized polynomial-time algorithm that certifies the value $2 - \varepsilon$ on $\mathsf{PCA}(\mathcal{S})$. Then there exist $\gamma > 1$ and $\beta \in (-1, 0)$ such that there is a randomized polynomial-time algorithm for strong detection in $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$.*

We give the proof in Section 4. Note for the parameters γ, β above, $\beta^2 < \gamma$ (the "hard regime").

▶ **Corollary 3.8.** *Suppose Conjecture 2.14 holds for the spiked Wishart model. Let π be subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Let $\mathcal{S}$ be a constraint set such that, if $\boldsymbol{x} \sim \mathsf{iid}(\pi/\sqrt{n})$, then $\boldsymbol{x} \in \mathcal{S}_n$ with high probability. Then, for any $\varepsilon > 0$, there is no randomized polynomial-time algorithm to certify the value $2 - \varepsilon$ on $\mathsf{PCA}(\mathcal{S})$.*

Proof. The result is immediate from Theorem 3.4 and Theorem 3.7. ◀

In particular, we obtain the hardness of improving on the spectral certificate in the SK model.

▶ **Corollary 3.9.** *If Conjecture 2.14 holds for the spiked Wishart model, then for any $\varepsilon > 0$, there is no randomized polynomial-time algorithm to certify the value $2 - \varepsilon$ on the SK problem* (3)*.*

Proof. Apply Corollary 3.8 with π having the Rademacher distribution and $\mathcal{S}_n = \{\pm 1/\sqrt{n}\}^n$. ◀

4 Proof of Reduction from Spiked Wishart to Constrained PCA

Our proof will rely on the following crucial invariance property of $\mathsf{GOE}(n)$.

▶ **Proposition 4.1.** *For any orthogonal matrix $\boldsymbol{Q} \in \mathcal{O}(n)$, if $\boldsymbol{W} \sim \mathsf{GOE}(n)$, then the law of $\boldsymbol{Q}\boldsymbol{W}\boldsymbol{Q}^\top$ is also $\mathsf{GOE}(n)$.*

Proof of Theorem 3.7. Let $\mathcal{S}$ be a constraint set and let $\mathcal{X}$ be a normalized spike prior such that, if $\boldsymbol{x} \sim \mathcal{X}_n$, then $\boldsymbol{x} \in \mathcal{S}_n$ with high probability. Suppose that for some $\varepsilon > 0$ there is a randomized polynomial-time algorithm f that certifies the value $2 - \varepsilon$ on $\mathsf{PCA}(\mathcal{S})$. We will show that this implies that there is a polynomial-time algorithm for strong detection in $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$ with certain parameters $\gamma > 1$ and $\beta \in (-1, 0)$ (depending on ε). Note that these parameters lie in the "hard" regime $\beta^2 < \gamma$.

Our algorithm for detection in the Wishart model is as follows. Fix $\gamma > 1$, to be chosen later. Since $n/N \to \gamma$ we have $n > N$ (for sufficiently large n). Given samples $\boldsymbol{y}_1, \dots, \boldsymbol{y}_N \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n + \beta \boldsymbol{x}\boldsymbol{x}^\top)$, let $V = \mathrm{span}\{\boldsymbol{y}_1, \dots, \boldsymbol{y}_N\} \subseteq \mathbb{R}^n$ and let $V^\perp$ be its orthogonal complement. We sample $\boldsymbol{W} \in \mathbb{R}^{n \times n}$ having the distribution $\mathsf{GOE}(n)$ conditioned on the event that the span of the top $n - N$ eigenvectors of $\boldsymbol{W}$ is $V^\perp$. Concretely, we can obtain a sample in the following way. Let $\boldsymbol{v}_1, \dots, \boldsymbol{v}_N$ be a uniformly random orthonormal basis for V and let $\boldsymbol{v}_{N+1}, \dots, \boldsymbol{v}_n$ be a uniformly random orthonormal basis for $V^\perp$. Sample $\boldsymbol{W}' \sim \mathsf{GOE}(n)$ and let $\lambda_1 < \cdots < \lambda_n$ be the eigenvalues of $\boldsymbol{W}'$. Then, let $\boldsymbol{W} := \sum_{i=1}^n \lambda_i \boldsymbol{v}_i \boldsymbol{v}_i^\top$. Finally, run the certification algorithm f for $\mathsf{PCA}(\mathcal{S})$ on $\boldsymbol{W}$. The detection algorithm $\widetilde{f} : (\mathbb{R}^n)^N \to \{0, 1\}$ then thresholds $f(\boldsymbol{W})$:

$$\widetilde{f}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N) = \begin{cases} 0 \text{ (report } \mathbb{Q}_n) & \text{if } f(\boldsymbol{W}) \le 2 - \varepsilon/2, \\ 1 \text{ (report } \mathbb{P}_n) & \text{if } f(\boldsymbol{W}) > 2 - \varepsilon/2. \end{cases} \tag{9}$$

We now prove that $\widetilde{f}$ indeed achieves strong detection in $\mathsf{Wishart}(\gamma, \beta, \mathcal{X})$. First, if the samples $\boldsymbol{y}_i$ are drawn from the null model $\mathbb{Q}_n$, then V is a uniformly random N-dimensional subspace of $\mathbb{R}^n$, so by Proposition 4.1 the law of $\boldsymbol{W}$ constructed above is $\mathsf{GOE}(n)$. Thus $f(\boldsymbol{W}) \le 2 - \varepsilon/2$ with high probability by assumption, and therefore $\widetilde{f}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N) = 0$ with high probability, i.e., our algorithm correctly reports that the samples were drawn from the null model.

Next, suppose the samples $\boldsymbol{y}_i$ are drawn from the planted model $\mathbb{P}_n$ with planted spike $\boldsymbol{x} \sim \mathcal{X}_n$. We will choose $\gamma > 1$ and $\beta \in (-1, 0)$ so that $\boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \geq 2 - \varepsilon/3$ with high probability. Since $\boldsymbol{x} \in \mathcal{S}_n$ with high probability, this would imply $f(\boldsymbol{W}) \geq 2 - \varepsilon/3$, so we will have $\widetilde{f}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N) = 1$ with high probability, i.e., our algorithm will correctly report that the samples were drawn from the planted model.

It remains to show that $\boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} \geq 2 - \varepsilon/3$. Let $\lambda_1 < \cdots < \lambda_n$ be the eigenvalues of $\boldsymbol{W}$ and let $\boldsymbol{v}_1, \dots, \boldsymbol{v}_n$ be the corresponding (unit-norm) eigenvectors. By Proposition 2.3, with high probability, for all $i \in [n]$, $\lambda_i \in [-2 - o(1), 2 + o(1)]$. Furthermore, by the semicircle law [64], with high probability, $\lambda_{N+1} \geq 2 - g(\gamma)$ where $g(\gamma) > 0$ is a function satisfying $g(\gamma) \to 0$ as $\gamma \to 1^+$ (recalling that $n/N \to \gamma$). Letting $\|\boldsymbol{x}\|_V$ denote the norm of the orthogonal projection of $\boldsymbol{x}$ onto V, we have, with high probability,

$$\begin{aligned}
\boldsymbol{x}^\top \boldsymbol{W} \boldsymbol{x} &= \boldsymbol{x}^\top \left(\sum_{i=1}^n \lambda_i \boldsymbol{v}_i \boldsymbol{v}_i^\top \right) \boldsymbol{x} \\
&= \sum_{i=1}^n \lambda_i \langle \boldsymbol{x}, \boldsymbol{v}_i \rangle^2 \\
&\geq \lambda_1 \|\boldsymbol{x}\|_V^2 + \lambda_{N+1} \|\boldsymbol{x}\|_{V^\perp}^2 \\
&\geq (-2 - o(1)) \|\boldsymbol{x}\|_V^2 + (2 - g(\gamma))(\|\boldsymbol{x}\|^2 - \|\boldsymbol{x}\|_V^2) \\
&= (2 - g(\gamma)) \|\boldsymbol{x}\|^2 + (-4 + g(\gamma) - o(1)) \|\boldsymbol{x}\|_V^2 \\
&\geq 2 - g(\gamma) - 4\|\boldsymbol{x}\|_V^2 - o(1). \qquad (10)
\end{aligned}$$

Thus we need to upper bound $\|\boldsymbol{x}\|_V^2$. Let $\boldsymbol{P}_V$ denote the orthogonal projection matrix onto V. Since V is the span of $\{\boldsymbol{y}_1, \dots, \boldsymbol{y}_N\}$, we have $\boldsymbol{P}_V \preceq \frac{1}{\mu} \boldsymbol{Y}$ where

$$\boldsymbol{Y} = \frac{1}{N} \sum_{i=1}^N \boldsymbol{y}_i \boldsymbol{y}_i^\top$$

and μ is the smallest nonzero eigenvalue of $\boldsymbol{Y}$. (Here $\preceq$ denotes Loewner order.) Since $\boldsymbol{Y}$ is a spiked Wishart matrix, it follows from Theorem 1.2 of [7] that its smallest nonzero eigenvalue converges almost surely to $(1 - \sqrt{\gamma})^2$ as $n \to \infty$. Thus we have $\mu = (1 - \sqrt{\gamma})^2 + o(1)$. Therefore,

$$\|\boldsymbol{x}\|_V^2 = \|\boldsymbol{P}_V \boldsymbol{x}\|^2 = \boldsymbol{x}^\top \boldsymbol{P}_V \boldsymbol{x} \leq \frac{1}{\mu} \boldsymbol{x}^\top \boldsymbol{Y} \boldsymbol{x} = \frac{1}{\mu N} \sum_{i=1}^N \langle \boldsymbol{x}, \boldsymbol{y}_i \rangle^2.$$

We have $\boldsymbol{y}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n + \beta \boldsymbol{x}\boldsymbol{x}^\top)$ and so $\langle \boldsymbol{x}, \boldsymbol{y}_i \rangle \sim \mathcal{N}(0, \boldsymbol{x}^\top (\boldsymbol{I}_n + \beta \boldsymbol{x}\boldsymbol{x}^\top) \boldsymbol{x}) = \mathcal{N}(0, \|\boldsymbol{x}\|^2 + \beta \|\boldsymbol{x}\|^4)$. Therefore, letting $a_N^2 = \sum_{i=1}^N g_i^2$ for g_i i.i.d. standard gaussian random variables, so that a_N^2 has the χ^2 distribution with N degrees of freedom, we have conditional on $\boldsymbol{x}$ the distributional equality

$$\boldsymbol{x}^\top \boldsymbol{Y} \boldsymbol{x} \stackrel{(d)}{=} (\|\boldsymbol{x}\|^2 + \beta \|\boldsymbol{x}\|^4) \frac{a_N^2}{N}.$$

Standard concentration inequalities imply $a_N^2 / N \in [1 - o(1), 1 + o(1)]$ with high probability, and therefore $\boldsymbol{x}^\top \boldsymbol{Y} \boldsymbol{x} = 1 + \beta + o(1)$ with high probability. Thus, with high probability, we find

$$\|\boldsymbol{x}\|_V^2 = \frac{1 + \beta}{(1 - \sqrt{\gamma})^2} + o(1). \qquad (11)$$

Finally, we choose $\gamma > 1$ close enough to 1 so that $g(\gamma) \le \varepsilon/8$. By (11), we can also choose $\beta \in (-1, 0)$ close enough to -1 so that $\|\boldsymbol{x}\|_V^2 \le \varepsilon/32$ with high probability. Combining these, from (10) it follows that $\boldsymbol{x}^\top \boldsymbol{W}\boldsymbol{x} \ge 2 - \varepsilon/4 - o(1) \ge 2 - \varepsilon/3$ with high probability, completing the proof. ◀

▶ Remark 4.2. We remark that we have ignored issues of numerical precision by assuming a model of computation where eigendecomposition computations can be done exactly in polynomial time. However, we believe all the operations we have used are stable, so that our reduction should also hold for weaker models of computation. (In particular, if we want to compute polynomially-many bits of precision of the $\mathsf{PCA}(\mathcal{S})$ instance, this should require only polynomially-many bits of precision in the eigendecomposition computation.)

5 Proofs for Spiked Wishart Models

5.1 Preliminaries

Spiked Wishart model statistics

The following formulae pertaining to the spiked Wishart model are derived in [54]. (Recall that in the spiked Wishart model, the parameter N is determined by n and γ as $N = \lceil n/\gamma \rceil$.)

▶ **Proposition 5.1.** *Suppose $\gamma > 0$, $\beta \in [-1, \infty)$, and $\mathcal{X}$ is a β-good normalized spike prior. Then, the likelihood ratio of the null and planted probability distributions of Definition 2.8 is*

$$L_{n,\gamma,\beta,\mathcal{X}}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N) := \frac{d\mathbb{P}_n}{d\mathbb{Q}_n}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N) = \mathop{\mathbb{E}}_{\boldsymbol{x} \sim \mathcal{X}_n} \left[\left(1 + \beta \|\boldsymbol{x}\|^2\right)^{-N/2} \prod_{i=1}^{N} \exp\left(\frac{1}{2} \frac{\beta}{1 + \beta\|\boldsymbol{x}\|^2} \langle \boldsymbol{x}, \boldsymbol{y}_i \rangle^2 \right) \right]. \quad (12)$$

If furthermore $\|\boldsymbol{x}\|^2 < 1/|\beta|$ almost surely when $\boldsymbol{x} \sim \mathcal{X}_n$, then the second moment of the likelihood ratio is given by

$$\mathop{\mathbb{E}}_{\boldsymbol{y} \sim \mathbb{Q}_n} \left(L_{n,\gamma,\beta,\mathcal{X}}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N)\right)^2 = \mathop{\mathbb{E}}_{\boldsymbol{x}^1, \boldsymbol{x}^2 \sim \mathcal{X}_n} \left[(1 - \beta^2 \langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle^2)^{-N/2} \right] \quad (13)$$

where $\boldsymbol{x}^1, \boldsymbol{x}^2$ are drawn independently from $\mathcal{X}_n$.

Hermite polynomials

We recall the classical one-dimensional Hermite polynomials.

▶ **Definition 5.2.** *The polynomials $h_k \in \mathbb{R}[x]$ for $k \ge 0$ are defined by the recursion*

$$h_0(x) = 1,$$
$$h_{k+1}(x) = x h_k(x) - h_k'(x),$$

and we define normalized versions

$$\widehat{h}_k(x) = \frac{1}{\sqrt{k!}} h_k(x).$$

▶ **Proposition 5.3.** *The $\widehat{h}_k$ are an orthonormal polynomial system for the standard Gaussian measure:*

$$\mathop{\mathbb{E}}_{g \sim \mathcal{N}(0,1)} \left[\widehat{h}_k(g) \widehat{h}_\ell(g) \right] = \delta_{k\ell}.$$

Similarly, we define the product Hermite polynomials. It is helpful to first define some notations for vectors of indices, which will also be used in the later derivations.

▶ **Definition 5.4.** *Let* $\mathbb{N} = \{n \in \mathbb{Z} : n \geq 0\}$. *For* $\boldsymbol{\alpha} \in \mathbb{N}^n$ *and* $\boldsymbol{x} \in \mathbb{R}^n$, *let*

$$|\boldsymbol{\alpha}| := \sum_{i=1}^{n} \alpha_i,$$
$$\boldsymbol{\alpha}! := \prod_{i=1}^{n} \alpha_i!,$$
$$\boldsymbol{x}^{\boldsymbol{\alpha}} := \prod_{i=1}^{n} x_i^{\alpha_i}.$$

▶ **Definition 5.5.** *For* $\boldsymbol{\alpha} \in \mathbb{N}^n$ *and* $\boldsymbol{x} \in \mathbb{R}^n$,

$$H_{\boldsymbol{\alpha}}(\boldsymbol{x}) := \prod_{i=1}^{n} h_{\alpha_i}(x_i),$$
$$\widehat{H}_{\boldsymbol{\alpha}}(\boldsymbol{x}) := \prod_{i=1}^{n} \widehat{h}_{\alpha_i}(x_i) = \frac{1}{\sqrt{\boldsymbol{\alpha}!}} H_{\boldsymbol{\alpha}}(\boldsymbol{x}).$$

▶ **Proposition 5.6.** *The* $\widehat{H}_{\boldsymbol{\alpha}}$ *are an orthonormal polynomial system for the product measure of* n *standard Gaussian measures:*

$$\mathop{\mathbb{E}}_{\boldsymbol{g} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n)} \left[\widehat{H}_{\boldsymbol{\alpha}}(\boldsymbol{g}) \widehat{H}_{\boldsymbol{\beta}}(\boldsymbol{g}) \right] = \delta_{\boldsymbol{\alpha}\boldsymbol{\beta}}.$$

Combinatorics

We will also need the (ordinary) generating function of the central binomial coefficients.

▶ **Proposition 5.7.** *For any* $x \in \mathbb{R}$ *with* $|x| < \frac{1}{4}$,

$$(1 - 4x)^{-1/2} = \sum_{k \geq 0} \binom{2k}{k} x^k.$$

5.2 Norm of the Low-Degree Projection

In this section, we describe the formulas for the norm of the low-degree likelihood ratio in the spiked Wishart model, $\|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}$. The full calculations are given in Appendix A.

The following result, the main technical one of this portion of the argument, computes the norm of the projection of the likelihood ratio onto a single Hermite polynomial.

▶ **Lemma 5.8.** *Let* $\boldsymbol{\alpha} \in (\mathbb{N}^n)^N$, *and let* $\boldsymbol{\alpha}_i \in \mathbb{N}^n$ *denote the* i*th component. Let* $|\boldsymbol{\alpha}| = \sum_{i=1}^{N} |\boldsymbol{\alpha}_i|$. *Suppose* $\gamma > 0$, $\beta \in [-1, \infty)$, *and* $\mathcal{X}$ *is a* β*-good normalized spike prior. Then,*

$$\langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}} \rangle_{L^2(\mathbb{Q}_n)}^2 = \begin{cases} \beta^{|\boldsymbol{\alpha}|} \cdot \prod_{i=1}^{N} \frac{(|\boldsymbol{\alpha}_i|-1)!!^2}{\boldsymbol{\alpha}_i!} \cdot \left(\mathbb{E}_{\boldsymbol{x} \sim \mathcal{X}_n} \boldsymbol{x}^{\sum_{i=1}^{N} \boldsymbol{\alpha}_i} \right)^2 & \text{if } |\boldsymbol{\alpha}_i| \text{ even for all } i \in [N], \\ 0 & \text{otherwise,} \end{cases} \tag{14}$$

where when $\beta = 0$ *and* $\boldsymbol{\alpha} = \boldsymbol{0}$ *we interpret* $0^0 = 1$.

Note in particular that the quantity in question does not depend on the sign of β; thus the calculation of the norm of the low-degree projection of the likelihood ratio will not distinguish between the positively and negatively spiked Wishart models. Interestingly, in our proof, which involves generalized Hermite polynomials that form families of orthogonal polynomials with respect to Gaussian measures of different variances, this corresponds to the fact that an "umbral" analogue of the Hermite polynomials corresponding to a fictitious Gaussian measure with *negative* variance satisfies many of the same identities as the ordinary Hermite polynomials.

Combining these quantities, we may give a simple description of the norm of the low-degree projection of the likelihood ratio.

▶ **Lemma 5.9.** *Suppose $\gamma > 0$, $\beta \in [-1, \infty)$, and $\mathcal{X}$ is a β-good normalized spike prior. Define*

$$\varphi_N(x) := (1-4x)^{-N/2}, \tag{15}$$

$$\varphi_{N,k}(x) := \sum_{d=0}^{k} x^d \sum_{\substack{d_1,\dots,d_N \\ \sum d_i = d}} \prod_{i=1}^{N} \binom{2d_i}{d_i}, \tag{16}$$

so that $\varphi_{N,k}(x)$ is the Taylor series of φ_N around $x = 0$ truncated to degree k (as may be justified by Proposition 5.7). Then,

$$\|L^{\le D}_{n,\gamma,\beta,\mathcal{X}}\|^2_{L^2(\mathbb{Q}_n)} = \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2 \sim \mathcal{X}_n} \left[\varphi_{N,\lfloor D/2 \rfloor} \left(\frac{\beta^2 \langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle^2}{4} \right) \right] \tag{17}$$

where $\boldsymbol{x}^1, \boldsymbol{x}^2$ are drawn independently from $\mathcal{X}$.

▶ Remark 5.10. The squared norm of the low-degree likelihood ratio (17) is closely related via Taylor expansion to the squared norm (or second moment) of the full likelihood ratio (13), which is recovered by taking $D \to \infty$ while n and N remain fixed.

5.3 Asymptotics as $n \to \infty$

In this section, we use the formula from Lemma 5.9 to prove Part 1 of Theorem 3.4 (the case $\beta^2 < \gamma$). The proof of Part 2 ($\beta^2 > \gamma$) is deferred to Appendix B.4.

The following concentration result is the key property that we require from the spike prior $\mathcal{X}$.

▶ **Definition 5.11.** *A normalized spike prior $\mathcal{X}$ admits a* local Chernoff bound *if for every $\eta > 0$ there exist $\delta > 0$ and $C > 0$ such that, for all n,*

$$\Pr\left\{ |\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle| \ge t \right\} \le C \exp\left(-\frac{1}{2}(1-\eta) n t^2 \right) \quad \text{for all } t \in [0, \delta] \tag{18}$$

where $\boldsymbol{x}^1, \boldsymbol{x}^2$ are drawn independently from $\mathcal{X}_n$.

▶ **Proposition 5.12.** *If π is subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$ then $\mathsf{iid}(\pi/\sqrt{n})$ and $\mathrm{trunc}_\beta(\mathsf{iid}(\pi/\sqrt{n}))$ (for any $\beta > -1$) each admit a local Chernoff bound.*

We defer the proof to Appendix B.1.

Proof of Theorem 3.4 (Part 1). Let $\beta^2 < \gamma$. We decompose the norm of the low-degree likelihood ratio into two parts, which we will bound separately:

$$\|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}^2 = \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\varphi_{N,\lfloor D/2\rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right] = R_1 + R_2$$

where

$$R_1 := \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\varphi_{N,\lfloor D/2\rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right],$$

$$R_2 := \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|>\varepsilon}\,\varphi_{N,\lfloor D/2\rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right].$$

Here $\varepsilon > 0$ is a small constant to be chosen later. We call R_1 the *small deviations* and call R_2 the *large deviations*.

The following two lemmas bound these two terms, respectively. First, we bound the large deviations.

▶ **Lemma 5.13** (Large Deviations). *Let $\beta^2 < \gamma$. Suppose $\mathcal{X}$ is a β-good normalized spike prior that admits a local Chernoff bound. Suppose that for any n, $\boldsymbol{x} \sim \mathcal{X}_n$ satisfies $\|\boldsymbol{x}\|^2 \leq 2$ almost surely. If $D = o(n/\log n)$ and $\varepsilon > 0$ is any constant, then $R_2 = o(1)$.*

We give a proof summary, with the full proof deferred to Appendix B.2. Since $\|\boldsymbol{x}^1\|^2 \leq 2$ and $\|\boldsymbol{x}^2\|^2 \leq 2$,

$$R_2 \leq \Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle| > \varepsilon\right\}\varphi_{N,\lfloor D/2\rfloor}(\beta^2).$$

By the local Chernoff bound, $\Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle| > \varepsilon\right\}$ decays exponentially in n. To complete the proof, we use elementary combinatorial bounds to control the polynomial expression (16) for $\varphi_{N,\lfloor D/2\rfloor}(\beta^2)$. Its growth is roughly of order $O(n^D)$, which is counteracted by the exponential decay of $\Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle| > \varepsilon\right\}$ so long as $D = o(n/\log n)$.

Next, we bound the small deviations. For this part of the argument, it is irrelevant that the likelihood ratio is truncated to its low-degree component, and we essentially reuse an existing argument for the full likelihood ratio from [54].

▶ **Lemma 5.14** (Small Deviations). *Let $\beta^2 < \gamma$. Suppose $\mathcal{X}$ is a β-good normalized spike prior that admits a local Chernoff bound. Let $D = D(n)$ be any function of n. If $\varepsilon > 0$ is a sufficiently small constant then $R_1 = O(1)$.*

We again give a proof summary, with the full proof deferred to Appendix B.3. As mentioned above, unlike in the proof of Lemma 5.13, here we simply bound $\varphi_{N,\lfloor D/2\rfloor} \leq \varphi_N$ in the expression for R_1. To bound the resulting expression, we borrow an argument from [54]. This step crucially uses the local Chernoff bound, and amounts to showing that the exponential decay from the Chernoff bound sufficiently counteracts the exponential growth of the likelihood ratio term $\varphi_N(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2)$ when $\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle$ is small.

Combining Proposition 5.12 with Lemmas 5.13 and 5.14 completes the proof of Part 1 of Theorem 3.4. (The proof of Part 2 is deferred to Appendix B.4.) ◀

A Proofs for Computing the Low-Degree Likelihood Ratio

A.1 Generalized and Umbral Hermite Polynomials

We introduce some calculations with a useful generalization of the Hermite polynomials. While the usual Hermite polynomials are a family of orthogonal polynomials for the Gaussian measure with variance 1, and a straightforward generalization yields orthogonal polynomials for the Gaussian measure with any positive variance, we will use the surprising further generalization to fictitious Gaussian measures with *negative* variance, as described by the so-called *umbral calculus*. We follow the presentation of [57] (specifically, Section 2.1 of Chapter 4).

▶ **Definition A.1.** *For any $v \in \mathbb{R}$, the* Hermite polynomials with variance v *are defined by the recursion*

$$h_0(x; v) = 1, \tag{19}$$
$$h_{k+1}(x; v) = x h_k(x; v) - v \partial_x [h_k](x; v). \tag{20}$$

The next facts are useful for translating between different versions of the basic recursion and other properties of the Hermite polynomials.

▶ **Proposition A.2** (Differentiation Identity)**.** *For any $v, x \in \mathbb{R}$,*

$$\partial_x [h_k](x; v) = k h_{k-1}(x; v). \tag{21}$$

▶ **Proposition A.3** (Alternate Recursion)**.** *For any $v \in \mathbb{R}$, the Hermite polynomials are equivalently defined by the recursion*

$$h_0(x; v) = 1, \tag{22}$$
$$h_{k+1}(x; v) = x h_k(x; v) - v k h_{k-1}(x; v). \tag{23}$$

The following is yet another common way of defining the Hermite polynomials, in terms of the derivatives of the corresponding Gaussian density (or, in the negative variance case, a suitable generalization thereof).

▶ **Proposition A.4** (Rodrigues Formula)**.** *Let $v \in \mathbb{R}$ with $v \neq 0$. Then,*

$$\frac{d^k}{dx^k}\left[\exp\left(-\frac{1}{2v}x^2\right)\right] = (-v)^{-k} h_k(x; v) \exp\left(-\frac{1}{2v}x^2\right). \tag{24}$$

The next fact shows how the generalized Hermite polynomials transform under scaling.

▶ **Proposition A.5** (Scaling Identity)**.** *Let $v, w, x \in \mathbb{R}$, then*

$$h_k(wx; v) = w^k h_k\left(x; \frac{v}{w^2}\right). \tag{25}$$

Finally, the following is a generalized version of Gaussian integration by parts. We only provide the version of this identity for the standard Hermite polynomials, which is the only one we will use, but analogous statements hold for the generalized and umbral Hermite polynomials.

▶ **Proposition A.6** (Integration by Parts)**.** *Let $f \in \mathcal{C}^k(\mathbb{R})$ have $|f^{(i)}(x)| \leq e^{Cx}$ for all $i \in \{0, 1, \ldots, k\}$ and some $C > 0$. Then,*

$$\mathop{\mathbb{E}}_{g \sim \mathcal{N}(0,1)} [h_k(g; 1) f(g)] = \mathop{\mathbb{E}}_{g \sim \mathcal{N}(0,1)} \left[f^{(k)}(g)\right]. \tag{26}$$

While the above results are standard, we now give two results we will use in our calculation that do not seem to appear explicitly in the previous literature, although they are straightforward to obtain from the preceding facts. First, we will use the following slightly more general version of the Rodgrigues formula (Proposition A.4) in our calculations.

▶ **Proposition A.7** (Multidimensional Rodrigues Formula). *Let $\boldsymbol{x} \in \mathbb{R}^n$, $\boldsymbol{\alpha} \in \mathbb{N}^n$, and $v \in \mathbb{R}$ with $v \neq 0$. Then,*

$$\partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}} \left[\exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \right] = (-v)^{-|\boldsymbol{\alpha}|} \boldsymbol{x}^{\boldsymbol{\alpha}} h_{|\boldsymbol{\alpha}|}(\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) \exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right). \tag{27}$$

Proof. We proceed by induction on $|\boldsymbol{\alpha}|$. Clearly the result holds for $\boldsymbol{\alpha} = \mathbf{0}$. Suppose the result holds for all $|\boldsymbol{\alpha}'| \leq k$, and $|\boldsymbol{\alpha}| = k + 1 > 0$. Let $\boldsymbol{\alpha}'$ having $|\boldsymbol{\alpha}'| = k$ differ from $\boldsymbol{\alpha}$ only in coordinate i, so that $\alpha'_i = \alpha_i - 1$ and $\alpha'_j = \alpha_j$ for all $j \neq i$. Then,

$$\begin{aligned}
&\partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}} \left[\exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \right] \\
&\quad = \partial_{y_i} \left[\partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}'} \left[\exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \right] \right] \\
&\quad = (-v)^{-k} \boldsymbol{x}^{\boldsymbol{\alpha}'} \partial_{y_i} \left[h_k(\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) \exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \right] \\
&\quad = (-v)^{-k} \boldsymbol{x}^{\boldsymbol{\alpha}'} \left(x_i \partial_x[h_k](\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) - v^{-1} \langle \boldsymbol{x}, \boldsymbol{y} \rangle x_i h_k(\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) \right) \exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \\
&\quad = (-v)^{-(k+1)} \boldsymbol{x}^{\boldsymbol{\alpha}} \left(\langle \boldsymbol{x}, \boldsymbol{y} \rangle h_k(\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) - v \partial_x[h_k](\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) \right) \exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \\
&\quad = (-v)^{-(k+1)} \boldsymbol{x}^{\boldsymbol{\alpha}} h_{k+1}(\langle \boldsymbol{x}, \boldsymbol{y} \rangle; v) \exp\left(-\frac{1}{2v} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right),
\end{aligned}$$

completing the proof. ◀

Second, we will need the following calculation evaluating the expectation of any Hermite polynomial under any centered Gaussian measure.

▶ **Proposition A.8** (Expectation Under Mismatched Variance). *Let $v \in \mathbb{R}$ and $k \geq 0$. Then,*

$$\mathbb{E}_{g \sim \mathcal{N}(0, \sigma^2)} \left[h_k(g; v) \right] = \begin{cases} 0 & \text{if } k \text{ odd,} \\ (k-1)!!(\sigma^2 - v)^{k/2} & \text{if } k \text{ even.} \end{cases}$$

Proof. The result for odd k holds since $h_k(\cdot\,; v)$ is an odd function for any $v \in \mathbb{R}$ in this case. For even k, we argue by induction on k. The result clearly holds for $k = 0$. If the result holds for a given k, then we may compute

$$\begin{aligned}
\mathbb{E}_{g \sim \mathcal{N}(0,\sigma^2)}[h_{k+2}(g; v)] &= \mathbb{E}_{g \sim \mathcal{N}(0,1)}[h_{k+2}(\sigma g)] \\
&= \sigma \mathbb{E}_{g \sim \mathcal{N}(0,1)}[g h_{k+1}(\sigma g; v)] - v(k+1) \mathbb{E}_{g \sim \mathcal{N}(0,1)}[h_k(\sigma g)] \\
&= \sigma^2 \mathbb{E}_{g \sim \mathcal{N}(0,1)}[\partial_x[h_{k+1}](\sigma g; v)] - v(k+1) \mathbb{E}_{g \sim \mathcal{N}(0,1)}[h_k(\sigma g)] \\
&= (k+1)\sigma^2 \mathbb{E}_{g \sim \mathcal{N}(0,1)}[h_k(\sigma g; v)] - v(k+1) \mathbb{E}_{g \sim \mathcal{N}(0,1)}[h_k(\sigma g)] \\
&= (k+1)(\sigma^2 - v) \mathbb{E}_{g \sim \mathcal{N}(0,1)}[h_k(\sigma g)] \\
&= (k+1)(\sigma^2 - v) \mathbb{E}_{g \sim \mathcal{N}(0,\sigma^2)}[h_k(g)]
\end{aligned}$$

completing the proof. ◀

We note two interesting features of this result. First, it generalizes two simple cases, on the one hand $v = \sigma^2$ where the expectation is zero unless $k = 0$, as may be seen from the orthogonality relations, and on the other $v = 0$ where it recovers the moments of a Gaussian measure. Second, the quantities appearing on the right-hand side formally resemble the moments of a Gaussian measure of suitable variance, but the formula in fact still holds for $\sigma^2 < v$, in which case case these quantities may be viewed as the moments of a fictitious Gaussian measure of negative variance (the same as inspired the umbral Hermite polynomials).

A.2 Individual Hermite Components of the Likelihood Ratio

Proof of Lemma 5.8. By Proposition A.6, we find

$$\begin{aligned}
&\langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}} \rangle^2 \\
&= \frac{1}{\boldsymbol{\alpha}!} \left(\mathop{\mathbb{E}}_{\boldsymbol{y} \sim \mathbb{Q}_n} \partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}} L_{n,\gamma,\beta,\mathcal{X}}(\boldsymbol{y}_1, \dots, \boldsymbol{y}_N) \right)^2 \\
&= \frac{1}{\boldsymbol{\alpha}!} \left(\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \mathcal{X}_n, \boldsymbol{y} \sim \mathbb{Q}_n} \left(1 + \beta \|\boldsymbol{x}\|^2\right)^{-N/2} \partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}} \prod_{i=1}^N \exp\left(\frac{1}{2} \frac{\beta}{1 + \beta \|\boldsymbol{x}\|^2} \langle \boldsymbol{x}, \boldsymbol{y}_i \rangle^2 \right) \right)^2 \\
&= \frac{1}{\prod_{i=1}^N \boldsymbol{\alpha}_i!} \left(\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \mathcal{X}_n} \left(1 + \beta \|\boldsymbol{x}\|^2\right)^{-N/2} \prod_{i=1}^N \mathop{\mathbb{E}}_{\boldsymbol{y} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n)} \left[\partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}_i} \exp\left(\frac{1}{2} \frac{\beta}{1 + \beta \|\boldsymbol{x}\|^2} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \right] \right)^2
\end{aligned} \tag{28}$$

where the $\boldsymbol{\alpha}_i \in \mathbb{N}^n$ are the components of $\boldsymbol{\alpha}$ corresponding to $\boldsymbol{y}_i$, for each $i \in [N]$. When $\beta = 0$, our result follows from the above, giving $\langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}} \rangle^2 = \delta_{0,|\boldsymbol{\alpha}|}$. (Indeed, in this case the null and planted models are identical, so $L_{n,\gamma,\beta,\mathcal{X}} = 1$ is a constant, which is compatible with the above.) Let us suppose $\beta \neq 0$ below.

In this case, using Proposition A.7, we have

$$\begin{aligned}
&\partial_{\boldsymbol{y}}^{\boldsymbol{\alpha}_i} \exp\left(\frac{1}{2} \frac{\beta}{1 + \beta \|\boldsymbol{x}\|^2} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right) \\
&\quad = \left(\frac{1 + \beta \|\boldsymbol{x}\|^2}{\beta} \right)^{-|\boldsymbol{\alpha}_i|} \boldsymbol{x}^{\boldsymbol{\alpha}_i} h_{|\boldsymbol{\alpha}_i|}\left(\langle \boldsymbol{x}, \boldsymbol{y} \rangle; -\frac{1 + \beta \|\boldsymbol{x}\|^2}{\beta} \right) \exp\left(\frac{1}{2} \frac{\beta}{1 + \beta \|\boldsymbol{x}\|^2} \langle \boldsymbol{x}, \boldsymbol{y} \rangle^2 \right).
\end{aligned} \tag{29}$$

(Note that the sign of the spike, or equivalently the sign of β, is the opposite of the sign of the variance of the Hermite polynomials that appear; thus, it is the negatively spiked case that corresponds to the more natural positive variance Hermite polynomials.) Since when $\boldsymbol{y} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_n)$ then $\langle \boldsymbol{x}, \boldsymbol{y} \rangle \sim \mathcal{N}(0, \|\boldsymbol{x}\|^2)$, we find

$$\begin{aligned}
\langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}} \rangle^2 = &\frac{\beta^{2|\boldsymbol{\alpha}|}}{\prod_{i=1}^N \boldsymbol{\alpha}_i!} \left(\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \mathcal{X}_n} \frac{\boldsymbol{x}^{\sum_{i=1}^N \boldsymbol{\alpha}_i}}{(1 + \beta \|\boldsymbol{x}\|^2)^{|\boldsymbol{\alpha}| + N/2}} \right. \\
&\left. \prod_{i=1}^N \mathop{\mathbb{E}}_{g \sim \mathcal{N}(\boldsymbol{0}, \|\boldsymbol{x}\|^2)} h_{|\boldsymbol{\alpha}_i|}\left(g; -\frac{1 + \beta \|\boldsymbol{x}\|^2}{\beta} \right) \exp\left(\frac{1}{2} \frac{\beta}{1 + \beta \|\boldsymbol{x}\|^2} g^2 \right) \right)^2.
\end{aligned} \tag{30}$$

We next focus on the innermost expectation. We may rewrite:

$$\begin{aligned}
&\mathop{\mathbb{E}}_{g\sim\mathcal{N}(\mathbf{0},\|\boldsymbol{x}\|^2)} h_{|\boldsymbol{\alpha}_i|}\left(g; -\frac{1+\beta\|\boldsymbol{x}\|^2}{\beta}\right)\exp\left(\frac{1}{2}\frac{\beta}{1+\beta\|\boldsymbol{x}\|^2}g^2\right)\\
&= \frac{1}{\sqrt{2\pi\|\boldsymbol{x}\|^2}}\int_{-\infty}^{\infty} h_{|\boldsymbol{\alpha}_i|}\left(g; -\frac{1+\beta\|\boldsymbol{x}\|^2}{\beta}\right)\exp\left(-\frac{1}{2}\left(\frac{1}{\|\boldsymbol{x}\|^2}-\frac{\beta}{1+\beta\|\boldsymbol{x}\|^2}\right)g^2\right)dg\\
&= \frac{(1+\beta\|\boldsymbol{x}\|^2)^{1/2}}{\sqrt{2\pi\|\boldsymbol{x}\|^2(1+\beta\|\boldsymbol{x}\|^2)}}\int_{-\infty}^{\infty} h_{|\boldsymbol{\alpha}_i|}\left(g; -\frac{1+\beta\|\boldsymbol{x}\|^2}{\beta}\right)\exp\left(-\frac{1}{2\|\boldsymbol{x}\|^2(1+\beta\|\boldsymbol{x}\|^2)}g^2\right)dg\\
&= (1+\beta\|\boldsymbol{x}\|^2)^{1/2}\mathop{\mathbb{E}}_{g\sim\mathcal{N}(0,\|\boldsymbol{x}\|^2(1+\beta\|\boldsymbol{x}\|^2))} h_{|\boldsymbol{\alpha}_i|}\left(g; -\frac{1+\beta\|\boldsymbol{x}\|^2}{\beta}\right). \qquad (31)
\end{aligned}$$

By Proposition A.8, this quantity will be zero unless $|\boldsymbol{\alpha}_i|$ is even, and thus $\langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}}\rangle^2$ will be zero unless $|\boldsymbol{\alpha}_i|$ is even for all i. In this case, by Proposition A.8,

$$\mathop{\mathbb{E}}_{g\sim\mathcal{N}(\mathbf{0},\|\boldsymbol{x}\|^2)} h_{|\boldsymbol{\alpha}_i|}\left(g; -\frac{1+\beta\|\boldsymbol{x}\|^2}{\beta}\right)\exp\left(\frac{1}{2}\frac{\beta}{1+\beta\|\boldsymbol{x}\|^2}g^2\right) = (|\boldsymbol{\alpha}_i|-1)!!\frac{(1+\beta\|\boldsymbol{x}\|^2)^{|\boldsymbol{\alpha}_i|+1/2}}{\beta^{|\boldsymbol{\alpha}_i|/2}}. \qquad (32)$$

Substituting into (30), we find many cancellations after which we are left with

$$\langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}}\rangle^2 = \frac{\prod_{i=1}^N (|\boldsymbol{\alpha}_i|-1)!!^2}{\prod_{i=1}^N \boldsymbol{\alpha}_i!}\beta^{|\boldsymbol{\alpha}|}\left(\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\mathcal{X}_n} \boldsymbol{x}^{\sum_{i=1}^N \boldsymbol{\alpha}_i}\right)^2, \qquad (33)$$

the final result. ◀

A.3 Norm of the Low-Degree Likelihood Ratio

Proof of Lemma 5.9. Recall that

$$\|L^{\le D}_{n,\gamma,\beta,\mathcal{X}}\|^2_{L^2(\mathbb{Q}_n)} = \sum_{\substack{\boldsymbol{\alpha}\in(\mathbb{N}^n)^N\\ |\boldsymbol{\alpha}|\le D}} \langle L_{n,\gamma,\beta,\mathcal{X}}, \widehat{H}_{\boldsymbol{\alpha}}\rangle^2. \qquad (34)$$

We substitute in the result of Lemma 5.8, which, after introducing independent replicas $\boldsymbol{x}^1, \boldsymbol{x}^2 \sim \mathcal{X}_n$, may be rewritten as

$$\begin{aligned}
\|L^{\le D}_{n,\gamma,\beta,\mathcal{X}}\|^2_{L^2(\mathbb{Q}_n)} &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \sum_{\substack{\boldsymbol{\alpha}_i\in\mathbb{N}^n, i\in[N]\\ |\boldsymbol{\alpha}_i| \text{even}\\ \sum_{i=1}^N|\boldsymbol{\alpha}_i|\le D}} \prod_{i=1}^N \frac{(|\boldsymbol{\alpha}_i|-1)!!^2}{\boldsymbol{\alpha}_i!}\beta^{|\boldsymbol{\alpha}_i|}(\boldsymbol{x}^1)^{\boldsymbol{\alpha}_i}(\boldsymbol{x}^2)^{\boldsymbol{\alpha}_i}\\
&= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \sum_{d=0}^D \beta^d \sum_{\substack{d_1,\dots,d_N \text{ even}\\ \sum d_i = d}} \left(\prod_{i=1}^N \frac{(d_i-1)!!^2}{d_i!}\right) \sum_{\substack{\boldsymbol{\alpha}_i\in\mathbb{N}^n, i\in[N]\\ |\boldsymbol{\alpha}_i|=d_i}} \prod_{i=1}^N \binom{d_i}{\boldsymbol{\alpha}_i} \prod_{j=1}^n (x_j^1 x_j^2)^{\boldsymbol{\alpha}_i(j)}.
\end{aligned}$$

By the multinomial theorem,

$$\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^{d_i} = \sum_{\substack{\boldsymbol{\alpha}\in\mathbb{N}^n\\ |\boldsymbol{\alpha}|=d_i}} \binom{d_i}{\boldsymbol{\alpha}} \prod_{j=1}^n (x_j^1 x_j^2)^{\boldsymbol{\alpha}(j)},$$

and therefore

$$\begin{aligned}\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^{\sum_{i=1}^N d_i} &= \prod_{i=1}^N \langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^{d_i} \\ &= \prod_{i=1}^N \sum_{\substack{\boldsymbol{\alpha}\in\mathbb{N}^n \\ |\boldsymbol{\alpha}|=d_i}} \binom{d_i}{\boldsymbol{\alpha}} \prod_{j=1}^n (x_j^1 x_j^2)^{\boldsymbol{\alpha}(j)} \\ &= \sum_{\substack{\boldsymbol{\alpha}_i\in\mathbb{N}^n, i\in[N] \\ |\boldsymbol{\alpha}_i|=d_i}} \prod_{i=1}^N \binom{d_i}{\boldsymbol{\alpha}_i} \prod_{j=1}^n (x_j^1 x_j^2)^{\boldsymbol{\alpha}_i(j)}.\end{aligned}$$

In our case, this shows

$$\begin{aligned}\|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}^2 &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \sum_{\substack{0\leq d\leq D \\ d \text{ even}}} \beta^d \sum_{\substack{d_1,\dots,d_N \text{ even} \\ \sum d_i = d}} \left(\prod_{i=1}^N \frac{(d_i-1)!!^2}{d_i!}\right)\left(\prod_{i=1}^N \langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^{d_i}\right) \\ &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \sum_{\substack{0\leq d\leq D \\ d \text{ even}}} \beta^d \langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^d \sum_{\substack{d_1,\dots,d_N \text{ even} \\ \sum d_i = d}} \prod_{i=1}^N \frac{d_i!}{d_i!!^2} \\ &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \sum_{\substack{0\leq d\leq D \\ d \text{ even}}} 2^{-d}\beta^d \langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^d \sum_{\substack{d_1,\dots,d_N \text{ even} \\ \sum d_i = d}} \prod_{i=1}^N \binom{d_i}{d_i/2}\end{aligned}$$

where we have used the identities $n! = n!! \cdot (n-1)!!$ and $(2n)!! = 2^n \cdot n!$. We now pass to a notation making the restriction to even degrees clearer:

$$\|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}^2 = \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \sum_{0\leq d\leq \lfloor D/2\rfloor} \left(\frac{\beta^2\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^2}{4}\right)^d \sum_{\substack{d_1,\dots,d_N \\ \sum d_i = d}} \prod_{i=1}^N \binom{2d_i}{d_i}.$$

The remaining function may be understood in terms of the generating function of the central binomial coefficients: using Proposition 5.7, we have that for any $x \in (-\frac{1}{4}, \frac{1}{4})$,

$$\varphi_N(x) := (1-4x)^{-N/2} = \left(\sum_{d\geq 0} \binom{2d}{d} x^d\right)^N = \sum_{d\geq 0} x^d \sum_{\substack{d_1,\dots,d_N \\ \sum d_i = d}} \prod_{i=1}^N \binom{2d_i}{d_i}.$$

Writing $\varphi_{N,k}(x)$ for the truncation of this Taylor series to degree k, we see that

$$\|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}^2 = \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n} \left[\varphi_{N,\lfloor D/2\rfloor}\left(\frac{\beta^2\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^2}{4}\right)\right],$$

the final result. ◀

B Proofs for Bounding the Low-Degree Likelihood Ratio

B.1 Local Chernoff Bound

Proof of Proposition 5.12. It is sufficient to show that $\mathsf{iid}(\pi/\sqrt{n})$ admits a local Chernoff bound. Since π is subgaussian, $\pi^2 - \mathbb{E}[\pi^2]$ is subexponential (see, e.g., [56]), i.e., the moment-generating function $M(t) = \mathbb{E}[\exp(t(\pi^2 - \mathbb{E}[\pi^2]))]$ satisfies $M(t) \leq \exp(\frac{t^2}{2s^2})$ for all $|t| \leq s$ for

a suitable choice of a constant $s > 0$. In particular, $\mathbb{E}[\exp(t\pi^2)] < \infty$ for all $|t| \le s$ for this choice of $s > 0$.

Let $\Pi = \pi\pi'$, the product of two independent copies of π. Let σ^2 be the variance proxy of π (see Definition 2.1). The moment-generating function of Π is

$$M(t) = \mathbb{E}[\exp(t\Pi)] = \mathbb{E}_\pi \mathbb{E}_{\pi'}[\exp(t\pi\pi')] \le \mathbb{E}_\pi \left[\exp\left(\sigma^2 t^2 \pi^2/2\right)\right] < \infty$$

provided $\frac{1}{2}\sigma^2 t^2 < s$, i.e., $|t| < \sqrt{2s/\sigma^2}$. Thus $M(t)$ exists in an open interval containing $t = 0$, which implies $M'(0) = \mathbb{E}[\Pi] = 0$ and $M''(0) = \mathbb{E}[\Pi^2] = 1$ (this is the defining property of the moment-generating function: its derivatives at $t = 0$ are the moments of Π).

Let $\eta > 0$ and $f(t) = \exp\left(\frac{t^2}{2(1-\eta)}\right)$. Since $M(0) = 1, M'(0) = 0, M''(0) = 1$ and $f(0) = 1, f'(0) = 0, f''(0) = \frac{1}{1-\eta} > 1$, there exists $\delta > 0$ such that for all $t \in [-\delta, \delta]$, $M(t)$ exists and $M(t) \le f(t)$.

We now apply the standard Chernoff bound argument to $\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle = \frac{1}{n}\sum_{i=1}^n \Pi_i$, where $\Pi_1, \ldots, \Pi_n$ are i.i.d. copies of Π. For any $\lambda > 0$,

$$\begin{aligned}
\Pr\left\{\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle \ge t\right\} &= \Pr\left\{\exp(\lambda\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle) \ge \exp(\lambda t)\right\} \\
&\le \exp(-\lambda t)\mathbb{E}[\exp(\lambda\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle)] && \text{(by Markov's inequality)} \\
&= \exp(-\lambda t)\mathbb{E}[\exp(\lambda n^{-1}\sum_{i=1}^n \Pi_i)] \\
&= \exp(-\lambda t)[M(\lambda/n)]^n \\
&\le \exp(-\lambda t)[f(\lambda/n)]^n && \text{(provided } \lambda/n \le \delta\text{)} \\
&\le \exp(-\lambda t)\exp\left(\frac{\lambda^2}{2(1-\eta)n}\right).
\end{aligned}$$

Taking $\lambda = (1-\eta)nt$,

$$\Pr\left\{\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle \ge t\right\} \le \exp\left(-(1-\eta)nt^2 + \frac{1}{2}(1-\eta)nt^2\right) = \exp\left(-\frac{1}{2}(1-\eta)nt^2\right)$$

as desired. This holds provided $\lambda/n \le \delta$, i.e., $t \le \delta/(1-\eta)$. The same argument (with $-\Pi$ instead of Π) holds for the other tail bound $\Pr\left\{\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle \le -t\right\}$. ◀

B.2 Bounding the Large Deviations

Proof of Lemma 5.13. Recall that

$$\varphi_{N,\lfloor D/2 \rfloor}(x) = \sum_{d=0}^{\lfloor D/2 \rfloor} x^d \sum_{\substack{d_1,\ldots,d_N \\ \sum d_i = d}} \prod_{i=1}^N \binom{2d_i}{d_i}.$$

Note that the first sum above has $\lfloor D/2 \rfloor + 1$ terms and the second sum has at most $N^d \le N^{\lfloor D/2 \rfloor} \le N^{D/2}$ terms. It is combinatorially clear that $\binom{2d_i}{d_i}\binom{2d_j}{d_j} \le \binom{2(d_i+d_j)}{d_i+d_j}$, and therefore

$$\prod_{i=1}^N \binom{2d_i}{d_i} \le \binom{2\sum_{i=1}^N d_i}{\sum_{i=1}^N d_i} = \binom{2d}{d} \le (2d)^d \le D^{D/2}.$$

Since $\|\boldsymbol{x}^1\|^2 \le 2$ and $\|\boldsymbol{x}^2\|^2 \le 2$ we have $\frac{1}{4}\beta^2\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle^2 \le \beta^2$. Since $d \le D/2$ we have $(\beta^2)^d \le (1+\beta^2)^{D/2}$, and therefore

$$\varphi_{N,\lfloor D/2 \rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1, \boldsymbol{x}^2 \rangle^2\right) \le (D/2+1)(1+\beta^2)^{D/2} N^{D/2} D^{D/2} \le (1+\beta^2)^{D/2} D N^{D/2} D^{D/2}.$$

Combining these bounds,

$$\begin{aligned} R_2 &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|>\varepsilon}\,\varphi_{N,\lfloor D/2\rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right] \\ &\leq \Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|>\varepsilon\right\}(1+\beta^2)^{D/2}DN^{D/2}D^{D/2}. \end{aligned}$$

Since R_2 increases as ε decreases, we can assume without loss of generality that ε is small enough that we may apply the local Chernoff bound (18):

$$\begin{aligned} &\leq \exp\left(-\frac{1}{3}n\varepsilon^2\right)(1+\beta^2)^{D/2}DN^{D/2}D^{D/2} \\ &= \exp\left(-\frac{1}{3}n\varepsilon^2+\frac{D}{2}\log(1+\beta^2)+\log D+\frac{D}{2}\log N+\frac{D}{2}\log D\right) \\ &= o(1) \end{aligned}$$

provided $D=o(n/\log n)$, completing the proof. ◀

B.3 Bounding the Small Deviations

Proof of Lemma 5.14. We use the argument from Appendix K of [54]. Since the Taylor series for $\varphi_N(x)$ has nonnegative coefficients, we have $\varphi_{N,\lfloor D/2\rfloor}(x)\leq\varphi_N(x)$ for all $x\in[0,1/4)$. Taking $\varepsilon<1/|\beta|$, we have

$$\begin{aligned} R_1 &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\varphi_{N,\lfloor D/2\rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right] \\ &\leq \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\varphi_{N}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right] \\ &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\left(1-\beta^2\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)^{-N/2}\right] \\ &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\exp\left(-\frac{N}{2}\log\left(1-\beta^2\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right)\right]. \end{aligned}$$

By the convexity of $t\mapsto-\log(1-\beta^2 t)$, we have $-\log(1-\beta^2 t)\leq-\frac{t}{\varepsilon^2}(1-\beta^2\varepsilon^2)$ for all $t\in[0,\varepsilon^2]$. Letting $c:=-\frac{N}{2\varepsilon^2}\log(1-\beta^2\varepsilon^2)>0$, we proceed bounding

$$\begin{aligned} &\leq \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2\sim\mathcal{X}_n}\left[\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\exp\left(c\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)\right] \\ &= \int_0^\infty \Pr\left\{\mathbb{1}_{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon}\,\exp\left(c\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)>u\right\}du \\ &= \int_0^\infty \Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon \quad\text{and}\quad \exp\left(c\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)>u\right\}du \\ &\leq 1+\int_1^\infty \Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon \quad\text{and}\quad \exp\left(c\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2\right)>u\right\}du. \end{aligned}$$

Applying the change of variables $u=\exp(ct)$,

$$\begin{aligned} &= 1+\int_0^\infty \Pr\left\{|\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle|\leq\varepsilon \quad\text{and}\quad \langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2>t\right\}c\exp(ct)\,dt \\ &\leq 1+\int_0^{\varepsilon^2} \Pr\left\{\langle \boldsymbol{x}^1,\boldsymbol{x}^2\rangle^2>t\right\}c\exp(ct)\,dt. \end{aligned}$$

Provided ε is sufficiently small, we can apply the local Chernoff bound (18):

$$\leq 1 + Cc \int_0^{\varepsilon^2} \exp\left(-\frac{1}{2}(1-\eta)nt + ct\right) dt.$$

Let $\widehat{\gamma} := n/N$, so that $\widehat{\gamma} \to \gamma$ as $n \to \infty$. Letting $c =: \widehat{c}n$ where $\widehat{c} = -\log(1-\beta^2\varepsilon^2)/(2\varepsilon^2\widehat{\gamma})$,

$$\leq 1 + C \cdot \widehat{c}n \int_0^{\varepsilon^2} \exp\left[\left(-\frac{1}{2}(1-\eta) + \widehat{c}\right) nt\right] dt.$$

We have $\lim_{\varepsilon \to 0^+} \widehat{c} = \frac{\beta^2}{2\widehat{\gamma}}$. Since $\beta^2 < \gamma$, we have that for sufficiently large n, $\frac{\beta^2}{2\widehat{\gamma}} < \frac{1}{2}$. Thus we can choose ε and η small enough so that for sufficiently large n, $-\frac{1}{2}(1-\eta) + \widehat{c} \leq -\alpha$ for some $\alpha > 0$. Now

$$\begin{aligned}
&\leq 1 + C \cdot \widehat{c}n \int_0^{\infty} \exp\left(-\alpha nt\right) dt \\
&= 1 + \frac{C \cdot \widehat{c}}{\alpha} \\
&= O(1),
\end{aligned}$$

completing the proof. ◀

B.4 Above the BBP Threshold

Proof of Theorem 3.4 (Part 2). Let $\beta^2 > \gamma$. Recall

$$\begin{aligned}
\|L^{\leq D}_{n,\gamma,\beta,\mathcal{X}}\|^2_{L^2(\mathbb{Q}_n)} &= \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2 \sim \mathcal{X}_n} \left[\varphi_{N,\lfloor D/2 \rfloor}\left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^2\right)\right] \\
&= \sum_{d=0}^{\lfloor D/2 \rfloor} \mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2 \sim \mathcal{X}_n} \left(\frac{\beta^2}{4}\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^2\right)^d \sum_{\substack{d_1,\ldots,d_N \\ \sum d_i = d}} \prod_{i=1}^{N} \binom{2d_i}{d_i}. \qquad (35)
\end{aligned}$$

Since each term in the outer summation of (35) is nonnegative, it sufficies to fix a single $d \leq D/2$ and show that the corresponding term is $\omega(1)$. We can write $\langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle = \frac{1}{n}\sum_{i=1}^n \Pi_i$ where $\Pi_1, \ldots, \Pi_n$ are i.i.d. with distribution of the product $\Pi = \pi\pi'$ of two independent copies of π. This means

$$\mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2 \sim \mathcal{X}_n} \langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^{2d} = \mathbb{E}\left(\frac{1}{n}\sum_{i=1}^n \Pi_i\right)^{2d} = n^{-2d} \sum_{i_1,\ldots,i_{2d} \in [n]} \mathbb{E}[\Pi_{i_1}\Pi_{i_2}\cdots\Pi_{i_{d2}}].$$

Since π is symmetric about zero, Π is also symmetric about zero, so all moments $\mathbb{E}[\Pi^k]$ are nonnegative. This means each term in the remaining sum is nonnegative, so we can obtain a lower bound by only considering terms where each index occurring among the $i_1, \ldots, i_{2d}$ occurs exactly twice:

$$\mathop{\mathbb{E}}_{\boldsymbol{x}^1,\boldsymbol{x}^2 \sim \mathcal{X}_n} \langle \boldsymbol{x}^1, \boldsymbol{x}^2\rangle^{2d} \geq n^{-2d}\binom{n}{d}\frac{(2d)!}{2^d}\left(\mathbb{E}[\Pi^2]\right)^d = n^{-2d}\binom{n}{d}\frac{(2d)!}{2^d}.$$

Next, we bound the inner summation of (35) below by taking only the terms with $d_i \in \{0, 1\}$ for all $i \in [N]$:

$$\sum_{\substack{d_1,\ldots,d_N \\ \sum d_i = d}} \prod_{i=1}^{N} \binom{2d_i}{d_i} \geq \binom{N}{d} 2^d.$$

Combining these bounds, we find that for any fixed $0 \leq d \leq \lfloor D/2 \rfloor$,

$$\begin{aligned} \|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}^2 &\geq \frac{\beta^{2d}}{4^d} n^{-2d} \binom{n}{d} \frac{(2d)!}{2^d} \binom{N}{d} 2^d \\ &= \left(\frac{\beta^2}{4n^2}\right)^d \frac{(2d)!\, n!\, N!}{(d!)^2\, (n-d)!\, (N-d)!} \\ &\geq \left(\frac{\beta^2 (n-d)(N-d)}{4n^2}\right)^d \binom{2d}{d}. \end{aligned}$$

Using the standard bound $\binom{2d}{d} \geq 4^d/(2\sqrt{d})$,

$$\|L_{n,\gamma,\beta,\mathcal{X}}^{\leq D}\|_{L^2(\mathbb{Q}_n)}^2 \geq \frac{1}{2\sqrt{d}} \left(\frac{\beta^2 (n-d)(N-d)}{n^2}\right)^d.$$

This final expression will be $\omega(1)$ provided that $1 \ll d \ll n$, since $n/N \to \gamma$ and $\beta^2 > \gamma$. ◀

Abstract

A pseudo-deterministic algorithm is a (randomized) algorithm which, when run multiple times on the same input, with high probability outputs the same result on all executions. Classic streaming algorithms, such as those for finding heavy hitters, approximate counting, ℓ_2 approximation, finding a nonzero entry in a vector (for turnstile algorithms) are not pseudo-deterministic. For example, in the instance of finding a nonzero entry in a vector, for any known low-space algorithm A, there exists a stream x so that running A twice on x (using different randomness) would with high probability result in two different entries as the output.

In this work, we study whether it is inherent that these algorithms output different values on different executions. That is, we ask whether these problems have low-memory pseudo-deterministic algorithms. For instance, we show that there is no low-memory pseudo-deterministic algorithm for finding a nonzero entry in a vector (given in a turnstile fashion), and also that there is no low-dimensional pseudo-deterministic sketching algorithm for ℓ_2 norm estimation. We also exhibit problems which do have low memory pseudo-deterministic algorithms but no low memory deterministic algorithm, such as outputting a nonzero row of a matrix, or outputting a basis for the row-span of a matrix.

We also investigate multi-pseudo-deterministic algorithms: algorithms which with high probability output one of a few options. We show the first lower bounds for such algorithms. This implies that there are streaming problems such that every low space algorithm for the problem must have inputs where there are many valid outputs, all with a significant probability of being outputted.

1 Introduction

Consider some classic streaming problems: heavy hitters, approximate counting, ℓ_p approximation, finding a nonzero entry in a vector (for turnstile algorithms), counting the number of distinct elements in a stream. These problems were shown to have low-space randomized algorithms in [4, 27, 7, 2, 20, 26], respectively. All of these algorithms exhibit the property that when running the algorithm multiple times on the same stream, different outputs may result on the different executions.

For the sake of concreteness, let's consider the problem of ℓ_2 approximation: given a stream of poly(n) updates to a vector (the vector begins as the zero vector, and updates are of the form "increase the i^{th} entry by 1" or "decrease the j^{th} entry by 1"), output an approximation of the ℓ_2 norm of the vector. There exists a celebrated randomized algorithm for this problem [2]. This algorithm has the curious property that running the same algorithm multiple times on the same stream may result in different approximations. That is, if Alice runs the algorithm on the same stream as Bob (but using different randomness), Alice may get some approximation of the ℓ_2 norm (such as 27839.8), and Bob (running the same algorithm, but with your own randomness) may get a different approximation (such as 27840.2). The randomized algorithm has the guarantee that both of the approximations will be close to the true value. However, interestingly, Alice and Bob end up with slightly different approximations. Is this behavior inherent? That is, could there exist an algorithm which, while being randomized, for all streams with high probability both Alice and Bob will end up with the *same* approximation for the ℓ_2 norm?

Such an algorithm, which when run on the same stream multiple times outputs the same output with high probability is called *pseudo-deterministic*. The main question we tackle in this paper is:

What streaming problems have low-memory pseudo-deterministic algorithms?

1.1 Our Contributions

This paper is the first to investigate pseudo-determinism in the context of streaming algorithms. We show certain problems have pseudo-deterministic algorithms substantially faster than the optimal deterministic algorithm, while other problems do not.

1.1.1 Lower Bounds

1.1.1.1 Find-Support-Elem

We show pseudo-deterministic lower bounds for finding a nonzero entry in a vector in the turnstile model. Specifically, consider the problem Find-Support-Elem of finding a nonzero entry in a vector for a turnstile algorithm (the input is a stream of updates of the form "increase entry i by 1" or "decrease entry j by 1", and we wish to find a nonzero entry in the final vector). We show this problem does not have a low-memory pseudo-deterministic algorithm:

▶ **Theorem 1.** *There is no pseudo-deterministic algorithm for* Find-Support-Elem *which uses* $\tilde{o}(n)$ *memory.*

This is in contrast with the work of [26], which shows a randomized algorithm for the problem using polylogarithmic space.

Theorem 1 can be viewed as showing that any low-memory algorithm A for Find-Support-Elem must have an input x where the output $A(x)$ (viewed as a random variable depending on the randomness used by A) must have at least a little bit of entropy. The algorithms we know for Find-Support-Elem have a very high amount of entropy in their outputs (the standard algorithms, for an input which is the all 1s vector, will find a uniformly random entry). Is this inherent, or can the entropy of the output be reduced? We show that this is inherent: for every low memory algorithm there is an input x such that $A(x)$ has high entropy.

▶ **Theorem 2.** *Every randomized algorithm for* Find-Support-Elem *using* $o(s)$ *space must have an input* x *such that* $A(x)$ *has entropy at least* $\log\left(\frac{n}{s\log n}\right)$.

So, in particular, an algorithm using $n^{1-\varepsilon}$ space must have outputs with entropy $\Omega(\log n)$, which is maximal up to constant factors.

We also show analogous lower bounds for the problem Find-Duplicatein which the input is a stream of $3n/2$ integers between 1 and n, and the goal is to output a number k which appears at least twice in the stream:

▶ **Theorem 3.** *Every randomized algorithm for* Find-Duplicate *using* $o(s)$ *space must have an input* x *such that* $A(x)$ *has entropy at least* $\log\left(\frac{n}{s\log n}\right)$.

1.1.1.2 Techniques

To prove a pseudo-deterministic lower bound for Find-Support-Elem, the idea is to show that if a pseudo-deterministic algorithm existed for Find-Support-Elem, then there would also exist a pseudo-deterministic one-way communication protocol for the problem One-Way-Find-Duplicate, where Alice has a subset of $[n]$ of size $3n/4$, and so does Bob, and they wish to find an element which they share.

To prove a lower bound on the one-way communication problem One-Way-Find-Duplicate, we show that if such a pseudo-deterministic protocol existed, then Bob can use Alice's message to recover many $(n/10)$ elements of her input (which contains much more information than one short message). The idea is that using Alice's message, Bob can find an element they have in common. Then, he can remove the element he found that they have in common from his input, and repeat to find another element they have in common (using the original message Alice sent, so Alice does not have to send another message). After repeating $n/10$ times, he will have found many elements which Alice has.

It may not be immediately obvious where pseudo-determinism is being used in this proof. The idea is that because the algorithm is pseudo-deterministic, the element which Bob finds as the intersection with high probability does not depend on the randomness used by Alice. That is, let $b_1, b_2, \ldots$ be the sequence of elements which Bob finds. Because the algorithm is pseudo-deterministic, there exists a specific sequence $b_1, b_2, \ldots$ such that with high probability this will be the sequence of elements which Bob finds. Notice that a randomized (but not pseudo-deterministic) algorithm for One-Way-Find-Duplicatewould result in different sequences on different executions.

When the sequence $b_1, b_2, \ldots$ is determined in advance, we can use a union bound and argue that with high probability, one of Alice's messages will likely work on all of Bob's inputs. If $b_1, b_2, \ldots$ is not determined in advance, then it's not possible to use a union bound.

Proving a lower bound on the entropy of the output of an algorithm for Find-Support-Elem uses a similar idea, but is more technically involved. It is harder to ensure that Bob's later inputs will be able to succeed with Alice's original message. The idea, at a very high level, is to have Alice send many messages (but not too many), so that Bob's new inputs will not strongly depend on any part of Alice's randomness, and also to have Alice send additional messages to keep Bob from going down a path where Alice's messages will no longer work.

This lower bound technique may seem similar to the way one would show a deterministic lower bound. It's worth noting that for certain problems, deterministic lower bounds do not generalize to pseudo-deterministic lower bounds; see our results on pseudo-deterministic upper bounds for some examples and intuition for why certain problems remain hard in the pseudo-deterministic setting while others do not.

1.1.1.3 Sketching lower bounds for pseudo-deterministic ℓ_2 norm estimation

The known randomized algorithms (such as [2]) for approximating the ℓ_2 norm of a vector x in a stream rely on *sketching*, i.e., storing $\boldsymbol{S}x$ where $\boldsymbol{S}$ is a $d \times n$ random matrix where $d \ll n$ and outputting the ℓ_2 norm of $\boldsymbol{S}x$. More generally, an abstraction of this framework is the setting where one has a distribution over matrices $\mathcal{D}$ and a function f. One then stores a *sketch* of the input vector $\boldsymbol{S}x$ where $\boldsymbol{S} \sim \mathcal{D}$ and outputs $f(\boldsymbol{S}x)$. By far, most streaming algorithms fall into this framework and in fact some recent work [24, 1] proves under some caveats and assumptions that low-space turnstile streaming algorithms imply algorithms based on low-dimensional sketches. Since sketching-based streaming algorithms are provably optimal in many settings, it motivates studying whether there are low-dimensional sketches of x from which the ℓ_2 norm can be estimated pseudo-deterministically.

We prove a lower bound on the dimension of sketches from which the ℓ_2 norm can be estimated pseudo-deterministically:

▶ **Theorem 4.** *Suppose $\mathcal{D}$ is a distribution over $d \times n$ matrices and f is a function from $\mathbb{R}^d$ to $\mathbb{R}$ such that for all $x \in \mathbb{R}^n$, when $\boldsymbol{S} \sim \mathcal{D}$:*

- *$f(\boldsymbol{S}x)$ approximates the ℓ_2 norm of x to within a constant factor with high probability,*
- *$f(\boldsymbol{S}x)$ takes a unique value with high probability.*

Then d must be $\Omega(n)$.

As an extension, we also show that

▶ **Theorem 5.** *For every constant $\varepsilon, \delta > 0$, every randomized sketching algorithm A for ℓ_2 norm estimation using a $O(n^{1-\delta})$-dimensional sketch, there is a vector x such that the output entropy of $A(x)$ is at least $1 - \varepsilon$. Furthermore, there is a randomized algorithm using a $O(\operatorname{poly}\log n)$-dimensional sketch with output entropy at most $1 + \varepsilon$ on all input vectors.*

1.1.1.4 Techniques

The first insight in our lower bound is that if there is a pseudo-deterministic streaming algorithm A for ℓ_2 norm estimation in k space, then that means there is a fixed function g such that $g(x)$ approximates $\|x\|_2$ and A is a randomized algorithm to compute $g(x)$ with high probability. The next step uses a result in the work of [17] to illustrate a (randomized) sequence of vectors $\boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(t)}$ only depending on g such that any linear sketching-based

algorithm that uses sublinear dimensional sketches outputs an incorrect approximation to the ℓ_2 norm of some vector in that sequence with constant probability, thereby implying a dimension lower bound.

1.1.2 Upper Bounds

On the one hand, all the problems considered so far were such that

1. There were "low-space" randomized algorithms.
2. The pseudo-deterministic and deterministic space complexity were "high" and equal up to logarithmic factors.

This raises the question if there are natural problems where pseudo-deterministic algorithms outperform deterministic algorithms (by more than logarithmic factors). We answer this question in the affirmative.

We illustrate several natural problems where the pseudo-deterministic space complexity is strictly smaller than the deterministic space complexity.

The first problem is that of finding a nonzero row in a matrix given as input in a turnstile stream. Our result for this problem has the bonus of giving a natural problem where the pseudo-deterministic streaming space complexity is strictly sandwiched between the deterministic and randomized streaming space complexity.

In the problem Find-Nonzero-Row, the input is an $n \times d$ matrix A streamed in the turnstile model, and the goal is to output an i such that the i^{th} row of the matrix A is nonzero.

▶ **Theorem 6.** *The randomized space complexity for* Find-Nonzero-Row *is* $\widetilde{\Theta}(1)$*, the pseudo-deterministic space complexity for* Find-Nonzero-Row *is* $\widetilde{\Theta}(n)$*, and the deterministic space complexity for* Find-Nonzero-Row *is* $\widetilde{\Theta}(nd)$*.*

The idea behind the proof of Theorem 6 is to sample a random vector x, and then deterministically find a nonzero entry of Ax. With high probability, if a row of A is nonzero, then the corresponding entry of Ax will be nonzero as well.

1.1.2.1 Discussion

Roughly speaking, in this problem there is a certain structure that allows us to use randomness to "hash" pieces of the input together, and then apply a deterministic algorithm on the hashed pieces. The other upper bounds we show for pseudo-deterministic algorithms also have a structure which allows us to hash, and then use a deterministic algorithm. It is interesting to ask if there are natural problems which have faster pseudo-deterministic algorithms than the best deterministic algorithms, but for which the pseudo-deterministic algorithms follow a different structure.

The next problems we show upper bounds for are estimating frequencies in a length-m stream of elements from a large universe $[n]$ up to error εm, and that of estimating the inner product of two vectors x and y in an insertion-only stream of length-m up to error $\varepsilon \cdot \|x\|_1 \cdot \|y\|_1$. We show a separation between the deterministic and (weak) pseudo-deterministic space complexity in the regime where $m \ll n$.

▶ **Theorem 7.** *There is a pseudo-deterministic algorithm for point query estimation and inner product estimation that uses* $O\left(\frac{\log m}{\varepsilon} + \log n\right)$ *bits of space. On the other hand, any deterministic algorithm needs* $\Omega\left(\frac{\log n}{\varepsilon}\right)$ *bits of space.*

1.2 Related work

Pseudo-deterministic algorithms were introduced by Gat and Goldwasser [9]. Such algorithms have since been studied in the context of standard (sequential algorithms) [15, 30], average case algorithms [18], parallel algorithms [12], decision tree algorithms [11, 10], interactive proofs [13], learning algorithms [31], approximation algorithms [31, 6], and low space algorithms [16]. In this work, we initiate the study of pseudo-determinism in the context of streaming algorithms (and in the context of one-way communication complexity).

The problem of finding duplicates in a stream of integers between 1 and n was first considered by [14], where an $O(\log^3 n)$ bits of space algorithm is given, later improved by [22] to $O(\log^2 n)$ bits. We show that in contrast to these low space randomized algorithms, a pseudo-deterministic algorithm needs significantly more space in the regime where the length of the stream is, say, $3n/2$. [23] shows optimal lower bounds for randomized algorithms solving the problem.

The method of ℓ_p-sampling to sample an index of a turnstile vector with probability proportional to its ℓ_p mass, whose study was initiated in [26], is one way of outputting an element from the support of a turnstile stream. A line of work [8, 26, 22, 3], ultimately leading to an optimal algorithm in [21] and tight lower bounds in [23], characterizes the space complexity of randomized algorithms to output an element from the support of a turnstile vector as $\Theta(\operatorname{poly}\log n)$, in contrast with the space lower bounds we show for algorithms constrained to a low entropy output.

1.3 Open Problems

Morris Counters

In [27], Morris showed that one can approximate (up to a multiplicative error) the number of elements in a stream with up to n elements using $O(\log\log n)$ bits of space. Does there exist an $O(\log\log n)$ bits of space pseudo-deterministic algorithm for the problem?

ℓ_2-norm estimation

In this work, we show that there are no low-dimensional pseudo-deterministic sketching algorithms for estimating the ℓ_2-norm of a vector. However, we do not show a turnstile streaming lower bound for pseudo-deterministic algorithms, which motivates the following question. Does there exist a $O(\operatorname{poly}\log n)$ space pseudo-deterministic algorithm for ℓ_2-norm estimation?

Multi-pass streaming lower bounds

All the streaming lower bounds we prove are in the single pass model, i.e., where the algorithm receives the stream exactly once. How do these lower bounds extend to the multi-pass model, where the algorithm receives the stream multiple times? All of the pseudo-deterministic streaming lower bounds in this paper do not even extend to 2-pass streaming algorithms.

1.4 Table of complexities

In the below table, we outline the known space complexity of various problems considered in our work.

Table 1 Table of space complexities.

Problem	Randomized	Deterministic	Pseudo-deterministic
Morris Counters	$\Theta(\log\log n)$	$\Theta(\log n)$	$O(\log n)$, $\Omega(\log\log n)$
Find-Duplicate	$\Theta(\log n)$	$\Theta(n)$	$\widetilde{\Theta}(n)$
ℓ_2-approximation (streaming)	$\Theta(\log n)$	$\widetilde{\Theta}(n)$	$\widetilde{\Theta}(n)$
ℓ_2-approximation (sketching)			$\widetilde{O}(n)$, $\widetilde{\Omega}(\log n)$
Find-Nonzero-Row	$\widetilde{\Theta}(1)$	$\widetilde{\Theta}(nd)$	$\widetilde{\Theta}(n)$

2 Preliminaries

A randomized algorithm is called *pseudo-deterministic* if for every valid input x, when running the algorithm twice on x, the same output is obtained with probability at least $2/3$. Equivalently (up to amplification of error probabilities), one can think of an algorithm as pseudo-deterministic if for every input x, there is a unique value $f(x)$ such that with probability at least $2/3$ the algorithm outputs $f(x)$ on input x

▶ **Definition 8** (Pseudo-deterministic). *A (randomized) algorithm A is called pseudo-deterministic if for all valid inputs x, the algorithm A satisfies*

$$\Pr_{r_1,r_2}[A(x,r_1) = A(x,r_2)] \geq 2/3.$$

An extension of pseudo-determinism is that of k-entropy randomized algorithms [16]. Such algorithms have the guarantee that for every input x, the distribution $A(x,r)$ (over a random choice of randomness r) has low entropy, in particular bounded by k.

Another extension of pseudo-determinism is that of m-pseudo-deterministic algorithms, from [10]. Intuitively speaking, any algorithm is k-pseudo-deterministic if for every valid input, with high probability the algorithm outputs one of k options (so, a 1-pseudo-deterministic algorithm is the same as a standard pseudo-deterministic algorithm, since it outputs the one unique option with high probability):

▶ **Definition 9** (k-pseudo-deterministic). *We say that an algorithm A is k-pseudo-deterministic if for all valid inputs x, there is a set $S(x)$ of size at most k, such that $\Pr_r[A(x,r) \in S(x)] \geq \frac{k+1}{k+2}$*

For the purposes of this work, we define a simple notion that we call a *k-concentrated algorithm.*

▶ **Definition 10.** *We say that an algorithm A is k-concentrated if for all valid inputs x, there is some output $F(x)$ such that $\Pr_r[A(x,r) = F(x)] \geq \frac{1}{k}$.*

The reason for making this definition is that any $\log k$-entropy randomized algorithm, and any $(k+2)$-pseudo-deterministic algorithm is k-concentrated. Thus, showing an impossibility result for k-concentrated algorithms also shows an impossibility result for $\log k$-entropy and $(k+2)$-pseudo-deterministic algorithms. Indeed, in this work, we use space lower bounds against k-concentrated algorithms to simultaneously conclude space lower bounds against low entropy and multi-pseudo-deterministic algorithms.

▶ **Definition 11.** *A turnstile streaming algorithm is one where there is a vector v, and the input is a stream of updates of the form "increase the i^{th} coordinate of v by r" or "decrease the i^{th} coordinate of v by r'". The goal is to compute something about the final vector, after all of the updates.*

We use a pseudorandom generator for space-bounded computation due to Nisan [29], which we recap below.

▶ **Theorem 12.** *There is a function* $G : \{0,1\}^{s \log r} \to \{0,1\}^r$ *such that*

1. *Any bit of* $G(x)$ *for any input* x *can be computed in* $O(s \log r)$ *space.*
2. *For all functions* f *from* $\{0,1\}^r$ *to some set* A *such that* f *is computable by a finite state machine on* 2^s *states, the total variation distance between the random variables* $f(\boldsymbol{x})$ *and* $f(G(\boldsymbol{y}))$ *where* $\boldsymbol{x}$ *is uniformly drawn from* $\{0,1\}^r$ *and* $\boldsymbol{y}$ *is uniformly drawn from* $\{0,1\}^{s \log r}$ *is at most* 2^{-s}.

3 Find-Duplicate: Pseudo-deterministic lower bounds

Consider the following problem: the input is a stream of $3n/2$ integers between 1 and n. The goal is to output a number k which appears at least twice in the stream. Call this problem Find-Duplicate. Recall that this problem has been considered in the past literature, specifically in [14, 22, 23], where upper and lower bounds for randomized algorithms have been shown.

Indeed, we know the following is true from [14, 22].

▶ **Theorem 13.** Find-Duplicate *has an algorithm which uses* $O(\text{poly} \log n)$ *memory and succeeds with all but probability* $\frac{1}{\text{poly}(n)}$.

We formally define a *pseudo-deterministic streaming algorithm* and show a pseudo-deterministic lower bound for Find-Duplicate to contrast with the randomized algorithm from Theorem 13.

▶ **Definition 14** (Pseudo-deterministic Streaming Algorithm)**.** *A pseudo-deterministic streaming algorithm is a (randomized) streaming algorithm* A *such that for all valid input streams* $s = \langle x_1, \ldots, x_m \rangle$*, the algorithm* A *satisfies* $\Pr_{r_1,r_2}[(A(x,r_1) = A(x,r_2)] \geq 2/3$.

One can also think of a pseudo-deterministic streaming algorithm as an algorithm A such that for every valid input stream s, there exists some valid output $f(s)$ such that the algorithm A outputs $f(s)$ with probability at least $2/3$ (one would have to amplify the success probability using repetition to see that this alternate notion is the same as the definition above).

▶ **Definition 15** (Find-Duplicate)**.** *Define* Find-Duplicate *to be the streaming problem where the input is a stream of length* $3n/2$ *consisting of up to* n*, and the output must be an integer which has occured at least twice in the string.*

▶ **Theorem 16.** Find-Duplicate *has no pseudo-deterministic algorithm with memory* $o(n)$.

Proof Overview

In order to prove Theorem 16, we introduce two communication complexity problems – One-Way-Find-Duplicate and One-Way-Partial-Recovery:

In the One-Way-Find-Duplicate problem, Alice has a list of $3n/4$ integers between 1 and n, and so does Bob. Alice sends a message to Bob, after which Bob must output an integer which is in both Alice's and Bob's list. Formally:

▶ **Definition 17** (One-Way-Find-Duplicate)**.** *Define* One-Way-Find-Duplicate *to be the one-way communication complexity problem where Alice has input* $S_A \subseteq [n]$ *and Bob has input* $S_B \subseteq [n]$*, where* $|S_A|, |S_B| \geq 3n/4$*. The goal is for Bob to output an element in* $S_A \cap S_B$.

The idea is that one can reduce One-Way-Find-Duplicate to Find-Duplicate. So, our new goal will be to show that One-Way-Find-Duplicate requires high communication. To do so, we will show that it is possible to reduce a different problem, denoted One-Way-Partial-Recovery(defined below), to One-Way-Find-Duplicate. Informally, in the One-Way-Partial-Recovery problem, Alice has a list of $3n/4$ integers between 1 and n. Bob does not have an input. Alice sends a message to Bob, after which Bob must output $n/10$ distinct elements which are all in Alice's list. Formally:

▶ **Definition 18** (One-Way-Partial-Recovery)**.** *Define* One-Way-Partial-Recovery *to be the one-way communication complexity problem where Alice has input $S_A \subseteq [n]$ and Bob has no input. The goal is for Bob to output a set S satisfying $S \subseteq S_A$ and $|S| \geq n/10$.*

We will show in Claim 19 that a low memory pseudo-deterministic algorithm for Find-Duplicate implies a low-communication pseudo-deterministic algorithm for One-Way-Find-Duplicate, and in Claim 20 that a low-communication pseudo-deterministic algorithm for One-Way-Find-Duplicate implies a low communication algorithm for One-Way-Partial-Recovery. Finally, in Claim 21, we show that One-Way-Partial-Recovery cannot be solved with low communication. Combining the claims yields Theorem 16.

Proof of Theorem 16.

▷ Claim 19. A pseudo-deterministic algorithm for Find-Duplicate with space S and success probability p implies a pseudo-deterministic communication protocol for One-Way-Find-Duplicate with communication S and success probability at least p.

Proof. To prove the above claim, we construct a protocol for One-Way-Find-Duplicate from a streaming algorithm for Find-Duplicate. Given an instance of One-Way-Find-Duplicate, Alice can stream her input set of integers in increasing order, and simulate the streaming algorithm for Find-Duplicate. Then, she sends the current state of the algorithm (which is at most S bits) to Bob, who continues the execution of the streaming algorithm. At the end, the streaming algorithm outputs a repetition with probability p, which means the element showed up in both Alice and Bob's lists. Note that for a given input to Alice and Bob, Bob outputs a unique element with high probability because the streaming algorithm is pseudo-deterministic. ◁

▷ Claim 20. A pseudo-deterministic one-way communication protocol for One-Way-Find-Duplicate with S communication and failure probability $O\left(\frac{1}{n^2}\right)$ implies a pseudo-deterministic communication protocol for One-Way-Partial-Recovery with S communication and $O\left(\frac{1}{n}\right)$ failure probability.

Proof. We will show how to use a protocol for One-Way-Find-Duplicate to solve the instance of One-Way-Partial-Recovery.

Suppose we have an instance of One-Way-Partial-Recovery. Alice sends the same message to Bob as if the input was an instance of One-Way-Find-Duplicate, which is valid since in both of these problems, Alice's input is a list of length $3n/4$ of integers between 1 and n.

Now, Bob's goal is to use the message sent by Alice to recover $n/10$ elements of Alice. Let X be the (initially empty) set of elements of Alice's input that Bob knows and let B be a set of $3n/4$ elements in $\{1, \ldots, n\}$ disjoint from X, where we initially set B to $\{1, 2, \ldots, n\}$. While the size of X is less than $n/10$, Bob simulates the protocol of One-Way-Find-Duplicate with Alice's message and input B. This will result in Bob finding a single element x in Alice's input that is (i) in B, and (ii) not in X. Bob adds x to X, and deletes x from B. Once the size of X is $n/10$, Bob outputs X.

If Alice has the set A as her input, define $f_A(B)$ to be the output which the pseudo-deterministic algorithm for One-Way-Find-Duplicate outputs with high probability when Alice's input is A and Bob's input is B. Now, set $B_0 = \{1, 2, \ldots, n\}$, and $B_i = B_{i-1} \setminus \{f_A(B)\}$. Note that these B_i (for $i = 0$ through $n/10$) are the sets which, assuming the pseudo-deterministic algorithm never errs during the reduction (where we say the algorithm errs if it does not output the unique element which is guaranteed to be output with high probability), Bob will use as his inputs for the simulated executions of One-Way-Find-Duplicate. The pseudo-deterministic algorithm does not err on any of the B_i except with probability at most $1/n$, by a union bound. If Bob succeeds on all of the B_i, that means that the sequence of inputs which will be his inputs for the simulated executions of One-Way-Find-Duplicate are indeed $B_0, B_1, \ldots, B_{n/10}$. So, since we have shown with high probability the algorithms succeeds on all of the B_i, and therefore with high probability the B_i are also Bob's inputs for the simulated executions of One-Way-Find-Duplicate, we see that with high probability Bob will succeed on all of the $n/10$ inputs he tries to simulate executions of One-Way-Find-Duplicate with.

Note that we used the union bound over all the B_i for $i = 1$ through $n/10$. All of these B_i are a function of A. In particular, notice that by definition, the B_i do not depend on the randomness chosen by Alice. ◁

▷ Claim 21. Every pseudo-deterministic One-Way-Partial-Recovery protocol which succeeds with probability at least $\frac{2}{3}$ requires $\Omega(n)$ bits of communication.

Proof. We prove this lower bound by showing that a protocol for One-Way-Partial-Recovery can be used to obtain a protocol with exactly the same communication for the problem where Alice is given a string x in $\{0,1\}^{Cn}$ as input, she sends a message to Bob, and Bob must exactly recover x from Alice's message with probability at least $2/3$. This problem has a lower bound of $\Omega(n)$ bits of communication.

Suppose there exists a pseudo-deterministic algorithm for One-Way-Partial-Recovery. Given such a pseudo-deterministic protocol that succeeds with probability at least $2/3$, there is a function F such that $F(S)$ (a set with $n/10$ elements) is Bob's output after the protocol with probability at least $2/3$ when Alice is given S as input.

We will construct sets $S_1, \ldots, S_t$ to be subsets of $[n]$ of size $3n/4$ such that for any $i \neq j$, $F(S_i)$ is not a subset of S_j. To do so, we use the probabilistic method: set $S_1, \ldots, S_t$ be random subsets of $[n]$ of size $3n/4$. The probability that $F(S_i)$ is contained S_j for fixed $i \neq j$ is at most $\left(\frac{3}{4}\right)^{n/10}$. Thus, by a union bound, the probability that for any $i \neq j$, $F(S_i)$ is contained S_j is at most $t^2 \left(\frac{3}{4}\right)^{n/10}$, a quantity which is strictly less than 1 when t is $\left(\frac{4}{3}\right)^{n/100}$, so $S_1, \ldots, S_t$ satisfying the desired guarantee exist.

Alice and Bob can (ahead of time) agree on an encoding of $\lfloor \log t \rfloor$-bit strings that is an injective function G from $\{0,1\}^{\lfloor \log t \rfloor}$ to $\{S_1, \ldots, S_t\}$. Now, if Alice is given a $\lfloor \log t \rfloor$-bit string x as input, she can send a message to Bob according to the pseudo-deterministic protocol for One-Way-Partial-Recovery by treating her input as $G(x)$. Bob then recovers $F(G(x))$ with probability at least $2/3$, and can use it to recover $G(x)$ since there is unique S_i in which $F(G(x))$ is contained. Since G is injective, Bob can also recover x with probability $2/3$.

This reduction establishes a lower bound of $\Omega(\lfloor \log t \rfloor)$ on the pseudo-deterministic communication complexity of One-Way-Partial-Recovery, which is an $\Omega(n)$ lower bound. ◁

Combining Claim 19, Claim 20 and Claim 21 completes the proof of Theorem 16. ◀

It is worth noting that the problem has pseudo-deterministic algorithms with sublinear space if one allows multiple passes through the input. Informally, a p-pass streaming algorithm is a streaming algorithm which, instead of seeing the stream only once, gets to see the stream p times.

▷ Claim 22. There is a p-pass deterministic streaming algorithm that uses $\widetilde{O}(n^{1/p})$ memory for the Find-Duplicate problem.

Proof. At the start of t-th pass, the algorithm maintains a candidate interval I of width $n^{1-(t-1)/p}$ from which it seeks to find a repeated element. At the very beginning, this candidate interval is $[1, n]$. In the t-th pass, first partition the interval into $n^{1/p}$ equal sized intervals $I'_1, \ldots, I'_{n^{1/p}}$, each of whose width (the width of an interval $[a, b]$ is $b - a$) is $n^{1-t/p}$ and count the number of elements of the stream that lie in each such subinterval – this count must exceed the width of at least one subinterval I'_t. Update I to I'_t and proceed to the next pass. After p passes, this interval will contain at most 1 integer. ◁

4 Entropy Lower Bound for Find-Duplicate

▶ **Theorem 23.** *Every zero-error randomized algorithm for* Find-Duplicate *that is* $\frac{n}{s}$*-concentrated must use* $\Omega\left(\frac{s}{\log n}\right)$ *space.*

By *zero error*, we mean that the algorithm never outputs a number k which is not repeated. With probability one it either outputs a valid output, or $\perp$.

Proof. We use a reduction similar to that of the pseudo-deterministic case (cf. Proof of Claim 20). Using the exact same reduction from the proof of Claim 19, we get that a $\frac{n}{s}$-concentrated streaming algorithm for Find-Duplicate using T space must give us a $\frac{n}{s}$-concentrated protocol for One-Way-Find-Duplicate with communication complexity T. If we can give a way to convert such a protocol for One-Way-Find-Duplicate into an $O\left(\frac{Tn \log n}{s}\right)$-communication protocol for One-Way-Partial-Recovery, the desired lower bound on T follows from the lower bound on communication complexity of One-Way-Partial-Recovery from Claim 21. We will now show how to make such a conversion by describing a protocol for One-Way-Partial-Recovery.

Alice sends Bob $\Theta(n \log n/s)$ messages according to the protocol for One-Way-Find-Duplicate (that is, she simulates the protocol for One-Way-Find-Duplicate a total of $\Theta(n \log n/s)$ times). Bob's goal is to use these $\Theta(n \log n/s)$ messages to recover at least $n/10$ input elements of Alice. Towards this goal, he maintains a set of elements recovered so far, X (initially empty), and a family of "active sets" $\mathcal{B}$ (initially containing the set $\{1, 2, \ldots, n\}$). While the size of X is smaller than $n/10$, Bob simulates the remainder of the One-Way-Find-Duplicate protocol on every possible pair (B, M) where B is a set in $\mathcal{B}$ and M is one of the messages of Alice. For each such pair (B, M) where the protocol is successful in finding a duplicate element x, Bob adds x to X, removes B from $\mathcal{B}$ and adds $B \setminus \{x\}$ to $\mathcal{B}$.

We now wish to prove that this protocol indeed lets Bob recover $n/10$ elements of Alice. Suppose Alice has input A. For each set S, define $f_A(S)$ be an element of $A \cap S$ that has probability at least s/n of being outputted by Bob on input S at the end of a One-Way-Find-Duplicate protocol. Let $S_0 := \{1, 2, \ldots, n\}$ and $S_i := S_{i-1} \setminus \{f_A(S_i)\}$ be defined for $0 \leq i \leq n/10$. Note that S_i are predetermined: it is a function of Alice's input (and, in particular, not a function of the randomness she uses when choosing her messages). For a fixed i, the probability of failure to recover $f_A(S_i)$ from any of Alice's messages is at most

$1/n^2$. A failure to fill in X with $n/10$ elements implies that for some i, Bob failed to recover $f_A(S_i)$ from all of Alice's messages. The probability that such a failure happens for a specific i is at most $(1-s/n)^{\Theta(n\log n/s)}$. By setting the constant in the Θ to be large enough, we can have this be at most $\frac{1}{n^2}$, and so by a union bound the probability that there is an i such that $f_A(S_i)$ is not recovered by Bob is at most $1/n$.

Thus, we obtain a protocol for One-Way-Partial-Recovery with communication complexity $O(Tn\log n/s)$, and so $T \le s/\log n$, completing the proof. ◀

We obtain the following as immediate corollaries:

▶ **Corollary 24.** *Any zero-error* $\log\left(\frac{n}{s}\right)$*-entropy randomized algorithm for* Find-Duplicate *must use* $\Omega\left(\frac{s}{\log n}\right)$ *space.*

▶ **Corollary 25.** *Any zero-error* $O\left(\frac{n}{s}\right)$*-pseudo-deterministic algorithm for* Find-Duplicate *must use* $\Omega\left(\frac{s}{\log n}\right)$ *space.*

Below we show that the above lower bound is tight up to log factors.

▶ **Theorem 26.** *For all* s*, there exists a zero-error randomized algorithm for* Find-Duplicate *using* $\widetilde{O}(s)$ *space (where* $\widetilde{O}$ *hides factors polylogarithmic in* n*) that is* $O\left(\frac{n}{s}\right)$*-concentrated.*

Proof. Define the following algorithm A for Find-Duplicate: pick a random number i in $[3n/2]$, then remember the i^{th} element a of the stream, and see if a appears again later in the stream. If it does, return x. Otherwise return $\perp$.

The $O\left(\frac{n}{s}\right)$-concentrated algorithm algorithm is as follows: Run $s\log n$ copies of Algorithm A independently (in parallel), and then output the minimum of the outputs.

We are left to show that this algorithm is indeed $O\left(\frac{n}{s}\right)$-concentrated.

Define f to be a function where $f(i)$ is the total number of times which i shows up in the stream, and define $g(i) = \max((f(i)-1), 0)$. Note that then, the probability that i is outputted by algorithm A is $g(i)/(3n/2)$, since i will be outputted if A chooses to remember one of the first $i-1$.

Consider the smallest a such that $\sum_{i=1}^{a} g(i) \ge n/(2s)$. We will show that the probability that the output is less than a with high probability. It will follow that the algorithm is s-concentrated, since of the $a-1$ smallest elements, at most $\sum_{i=1}^{a-1} g(i)$ outputs are possible (since if $g(i)=0$, then i is not a possible output). So, we will see that with high probability, one of at most $\sum_{i=1}^{a-1} g(i) + 1 \le n/(2s)$ outputs (namely, the valid outputs less than or equal to a) will be outputted with high probability. And hence, at least one of them will be outputted with probability at least $\frac{s}{n}$.

The probability that the output is at most a in a single run of algorithm A is $\frac{3n}{2}\sum_{i=1}^{a} g(i)$ $\ge 3/(4s)$. So, the probability that in $s\log n$ runs of algorithm, in at least one of them an element which is at most a is outputted is $1-(1-\frac{3}{4s})^{s\log n}$, which is polynomially small in n. Hence, with high probability an element which is at most a (and there are $n/(2s)$ valid outputs less than a) will be outputted. ◀

4.1 Getting Rid of the Zero Error Requirement

A downside of Theorem 23 is that it shows a lower bound only for zero-error algorithms. In this section, we strengthen the theorem by getting rid of that requirement:

▶ **Theorem 27.** *Every randomized algorithm for* Find-Duplicate *that is* $\frac{n}{s}$*-concentrated and errs with probability at most* $\frac{1}{n^2}$ *must use* $\tilde{\Omega}\left(s^{1-\epsilon}\right)$ *space (for all* $\epsilon > 0$*).*

Proof overview

We begin by outlining why the approach of Theorem 23 does not work without the zero-error requirement. Recall that the idea in the proof was to have Alice send many messages (for One-Way-Find-Duplicate) to Bob, and Bob simulates the One-Way-Find-Duplicate algorithm (using simulated inputs he creates for himself) using these messages to find elements in Alice's input.

The problem is that the elements we end up removing from Bob's simulated input[1] depend on Alice's messages, and therefore we can't use a union bound to bound the probability that the protocol failed for a certain simulated input. So, we want the elements we remove from Bob's fake input not to depend on the inputs Alice sent. One idea to achieve this is to have Alice send a bunch of messages (for finding a shared element), and then Bob will remove the element that gets output the largest number of times (by simulating the protocol with each of the many messages Alice sent). The issue with this is that if the two most common outputs have very similar probability, the outputted element depends not only on Alice's input, but also on the randomness she uses when choosing what messages to send to Bob. This makes it again not possible to use a union bound.

There are two new ideas to fix this issue. The first is to use the following "Threshold" technique: Bob will pick a random "threshold" T between $ks/(2n)$ and $ks/(4n)$ (where we wish to show a lower bound on n/s-concentrated algorithms, and k is the total number of messages Alice sends to Bob). He simulates the algorithm for One-Way-Find-Duplicate with all k messages Alice sent him, and gets a list L of k outputs. Then, he will consider the "real" output to be the lexicographically first output $y \in L$ where there are more than T copies of y in the list L (note that since the algorithm is n/s-concentrated, its very unlikely for no such element to exist).

Now, it follows that with high probability, the shared element does not really depend on the messages. This is because with all but probability approximately $1/\sqrt{ks/n}$, the threshold is far (more than $\sqrt{ks/n}\log^2 ks/n$ away) from the the frequency of every element in L. We note that we pick $\sqrt{ks/n}\log^2 ks/n$ since from noise we would expect to have the frequencies of elements in L change by up to $\sqrt{ks/n}\log^2 ks/n$, depending on the randomness of A. We want the threshold to be further than that from the expected frequencies, so that with high probability there will be no element which sometimes has frequency more than T and sometimes has frequency less than T, depending on Alice's messages (recall that the goal is to make the outputs depend as little as possible on Alice's messages, but to only depend on shared randomness and on Alice's input).

This is still not enough for us: we still cannot use a union bound, as $1/\sqrt{ks/n}$ fraction of the time Bob's output will depends on Alice's message (and not just her input). The next idea resolves this. What Alice will do is send $n/\sqrt{ks/n}$ additional pieces of information: telling Bob where the chosen thresholds are bad, and what threshold to use instead. We assume that we have shared randomness so Alice knows all of the thresholds that will be chosen by Bob (note heavy-recovery is hard, even in the presence of shared randomness, so the lower bound is sufficient with shared randomness). Now, Alice can tell for which executions there the threshold chosen will be too close to the likelihood of an element. So, Alice will send approximately $n/\sqrt{ks/n}$ additional pieces of information: telling Bob where the chosen thresholds are bad, and what threshold to use instead. By doing so, Alice has guaranteed that a path independent of her messages will be taken.

[1] recall that Bob simulates an input to the One-Way-Find-Duplicate problem, and then he repeatedly finds elements he shares with Alice, removes them from the "fake" input, and reconstructs a large fraction Alice's inputs

To recap, idea 1 is to use the threshold technique so that with probability $1 - 1/\sqrt{ks/n}$ what Bob does doesn't depend on Alice's messages (only on her input). Idea 2 is to have Alice tell Bob where these $1/\sqrt{ks/n}$ bad situations are, and how to fix them.

The total amount of information Alice sends (ignoring logs) is $\tilde{\Theta}(kb + n/\sqrt{ks/n})$, (where b is the message size we are assuming exists for pseudo-deterministically finding a shared element, and k is the number of messages Alice sends). The factor $n/\sqrt{ks/n}$ follows since $1/\sqrt{ks/n}$ of the times, short messages will be sent to Bob due to a different threshold. A threshold requires $\log n$ bits to describe, which can be dropped since we are ignoring log factors. Setting $n/s \ll k \ll n/b$, we conclude that Alice sends a total of $\tilde{o}(n)$ bits. This establishes a contradiction, since we need $\tilde{\Theta}(n)$ bits to solve One-Way-Partial-Recovery. So, whenever $s = \tilde{\omega}(b)$, we can pick a k such that we get a contradiction.

Proof. Below we write the full reduction written out as an algorithm for One-Way-Find-Duplicate.

- Alice Creates $k = n/\sqrt{sb}$ messages for One-Way-Find-Duplicate, and sends them to Bob (Call these messages of type A).
- Additionally, Alice looks at the thresholds in the shared randomness. every time there is a threshold that is close (within $\sqrt{ks/n}\log^2 ks/n$) of the expected number of times a certain y will be outputted on the corresponding input (that is, for each fake input Bob will try, Alice checks if the probability of outputting some y is close to T – to be precise, say she checks if its probability of being outputted, assuming a randomly chosen message by Alice, is close to T), she sends a message to Bob informing him about the bad threshold, and suggests a good threshold to be used instead (call these messages of type B). Notice that these messages do not depend on the messages of type A that Alice sends, and that each such message is of size $O(\log n)$.
- Bob sets B to be the simulated input $\{1, ..., n\}$
- Bob uses each of the messages of type A that Alice sent, along with B, to construct a list of outputs.
- Bob looks at the shared randomness to find a threshold T (if Alice has informed him it is a bad threshold, use the threshold Alice suggests instead), and consider the lexicographically minimal output y that is contained in the multiset more than T times.
- Bob removes y from the fake input and repeat the last three steps of the algorithm (this time using a new threshold).

▷ Claim 28. The above protocol solves One-Way-Partial-Recoverywith high probability using $\tilde{o}(n)$ bits.

Proof. First we show that the total number of bits communicated is $\tilde{o}(n)$. Notice that the total number of messages of type A that are sent is $n/\sqrt{sb}$. We assume that each of these is of size at most b, giving us a total of $n\sqrt{b}/\sqrt{s}$ bits sent in messages of type A. Under the assumption that $b = \tilde{o}(n)$, we see that this is $\tilde{o}(n)$ total bits for messages of type A.

We now count the total number of bits communicated in messages of type B. Each message of type B is of size $O(\log n)$ (it is describing a single element, and a number corresponding to which execution the message is relevant for, each requiring $O(\log n)$ bits). So, we wish to show that with high probability the total number of messages of type B is $\tilde{o}(n)$. The total number of messages of type B that will be sent is $O(\frac{n}{\sqrt{ks/n}})$, since for every input, the probability that the randomly chosen threshold (which is sampled using public randomness) is more than $\sqrt{ks/n}\log^2 ks/n$ away from the frequency of every output is $O(\frac{1}{\sqrt{ks/n}})$. Note that $\frac{n}{\sqrt{ks/n}} = \tilde{o}(n)$ since $ks = n\sqrt{\frac{s}{b}}$, and we assume $b = \tilde{o}(s)$.

We are now left to show the protocol correctly solves One-Way-Partial-Recovery with high probability. We will first show that, after fixing Alice's input and the public randomness, with high probability there will be a single sequence of inputs that Bob will try that will occur with high probability (that is, there is a sequence of y's that Bob goes through with high probability). To do this, consider a certain input that Bob tries. We will bound the probability that there are two values y and y' such that both y and y' have probability at least $\frac{1}{n}$ of being outputted. Suppose there exists two such y and y' that means that at least one of them (say y, without loss of generality) has to be the output of more than T of the k executions with probability more than $\frac{1}{n}$, but less than $\frac{n-1}{n}$. Additionally, we know that the expected number of times that y will be outputted of the k times is more than $\sqrt{ks/n}\log^2 ks/n$ away from T (otherwise Alice will pick a different value of T such that this will be true, and send that value to Bob in a message of type B). However, the probability of being more than $\sqrt{ks/n}\log^2 ks/n = \Theta((\frac{s}{b})^{1/4}\log^2 s/b) = \Theta(n^{\varepsilon/4}\log^2 n)$ away from the expectation, by a Chernoff bound, is (asymptotically) less than $\frac{1}{n}$.

Notice also, that by the assumption that the algorithm in n/s-concentrated, there will always be an output $y_{\max}$ which is expected to appear at least $\frac{s}{n}$ of the time. Also, since the threshold T is at most $ks/2n$, the probability that $y_{\max}$ appeared fewer than T times is exponentially low in $ks/n = \sqrt{s/b} = \tilde{\Theta}(n^{\epsilon/2})$, and so with high probability there will always exist a y which was outputted on more than T of the executions, so in the second to last step, the multiset will always have an element that appears at least T_1 times.

Hence, by a union bound over all inputs that Bob tries, with high probability there will be a single sequence of inputs which Bob goes through (which depends only only on the public thresholds and Alice's input).

We will show that each y generated by Bob is an element in Alice's input with high probability. Notice that the y that Bob picks has appeared more than T times out of k, where T is at least $ks/(4n)$. If y is not a valid output then its probability of being outputted is $\frac{1}{n^2}$. The probability it is outputted at least once is at most $\frac{k}{n^2} \leq \frac{1}{n}$. Taking a union bound over the inputs that Bob tries (of which there are $n/10$), we get that the probability that there is an invalid y at any point is at most $1/10$. So, with probability $9/10$, no invalid y is ever outputted. ◁

◀

5 Entropy lower bounds for finding a support element

Consider the turnstile model of streaming, where a vector $z \in \mathbb{R}^n$ starts out as 0 and receives updates of the form "increment z_i by 1" or "decrement z_i by 1", and the goal of outputting a nonzero coordinate of z. This is a well studied problem and a common randomized algorithm to solve this problem in a small amount of space is known as ℓ_0 sampling [8]. ℓ_0 sampling uses polylogarithmic space and outputs a uniformly random coordinate from the support of z. A natural question one could ask is whether the output of any low space randomized algorithm is necessarily close to uniform, i.e., has high entropy. We answer this affirmatively and show a nearly tight tradeoff between the space needed to solve this problem and the entropy of the output of a randomized algorithm under the assumption that the algorithm is not allowed to output anything outside the support[2]

[2] We note that using similar ideas to those in Subsection 4.1, the zero error requirement could be removed. We omit this adaptation since it is very similar to that of Subsection 4.1.

▶ **Theorem 29.** *Every zero-error randomized algorithm for* Find-Support-Elem *that is* $\frac{n}{s}$*-concentrated must use* $\Omega\left(\frac{s}{\log n}\right)$ *space.*

We only provide a sketch of the proof and omit details since they are nearly identical to the proof of Theorem 23.

Proof Sketch. Let $\mathcal{A}$ be such an algorithm that uses T space. Just like the proof of Theorem 23, the way we show this lower bound is by illustrating that $\mathcal{A}$ can be used to obtain an $O\left(\frac{Tn\log n}{s}\right)$-communication protocol for One-Way-Partial-Recovery, which combined with Claim 21 yields the desired result.

For every element a in Alice's input set A, she streams "increment z_a by 1" and runs $\Theta\left(\frac{n}{s}\log n\right)$ independent copies of $\mathcal{A}$ on the input. She then sends the states of each these independent runs of $\mathcal{A}$ to Bob, which is at most $\frac{Tn\log n}{s}$ bits, to Bob. Bob maintains a set of states $\mathcal{M}$, initially filled with all of Alice's messages. While he has not yet recovered $n/10$ elements, Bob picks a message $M \in \mathcal{M}$ and recovers x in A using algorithm $\mathcal{A}$. And for each $M \in \mathcal{M}$, Bob resumes $\mathcal{A}$ on state M and streams "decrement z_x by 1" and adds the new state to $\mathcal{M}$, and deletes M from $\mathcal{M}$.

The proof of correctness for why Bob indeed eventually recovers $n/10$ elements of A is identical to that in the proof of Theorem 23, thus giving a protocol for One-Way-Partial-Recovery and proving the statement. ◀

We can immediately conclude the following.

▶ **Corollary 30.** *Any zero-error* $\log\left(\frac{n}{s}\right)$*-entropy randomized algorithm for* Find-Support-Elem *must use* $\Omega\left(\frac{s}{\log n}\right)$ *space.*

▶ **Corollary 31.** *Any zero-error* $O\left(\frac{n}{s}\right)$*-pseudo-deterministic algorithm for* Find-Support-Elem *must use* $\Omega\left(\frac{s}{\log n}\right)$ *space.*

This lower bound is also tight up to polylogarithmic factors due to an algorithm nearly identical to the one from Theorem 26. In particular, we have:

▶ **Theorem 32.** *For all* s*, there exists a zero-error randomized algorithm for* Find-Duplicate *using* $O(s)$ *space that is* $O\left(\frac{n}{s}\right)$*-concentrated.*

6 Space complexity of pseudo-deterministic ℓ_2-norm estimation

In this section, we once again consider the pseudo-deterministic complexity of ℓ_2 norm estimation in the *sketching model*. The algorithmic question here is to design a distribution $\mathcal{D}$ over $s \times n$ matrices along with a function $f : \mathbb{R}^s \to \mathbb{R}$ so that for any $x \in \mathbb{R}^n$:

$$\Pr_{\boldsymbol{S}\sim\mathcal{D}}[f(\boldsymbol{S}x) \notin \left[\frac{1}{\alpha}\|x\|_2, \alpha\|x\|_2\right] \leq \frac{1}{\text{poly}(n)}.$$

Further, we want $f(\boldsymbol{S}x)$ to be a pseudo-deterministic function; i.e., we want $f(\boldsymbol{S}x)$ to be a unique number with high probability.

▶ **Theorem 33.** *The pseudo-deterministic sketching complexity of* ℓ_2 *norm estimation is* $\Omega(n)$*.*

The following query problem is key to our lower bound.

▶ **Definition 34** (ℓ_2 adaptive attack)**.** *Let $\alpha > 0$ be some constant. Let S be an $s \times n$ matrix with real-valued entries and $f : \mathbb{R}^s \to \mathbb{R}$ be some function. Now, consider the query model where an algorithm is allowed to specify a vector $x \in \mathbb{R}^n$ as a query and is given $f(Sx)$ as a response. The goal of the algorithm is to output y such that*

$$f(Sy) \notin \left[\frac{1}{\alpha}\|y\|_2, \alpha\|y\|_2\right]$$

*in as few queries as possible. We call this algorithmic problem the ℓ_2-*adaptive attack problem.

We use a theorem on adaptive attacks on ℓ_2 sketches proved in [17].

▶ **Theorem 35.** *There is a $\mathrm{poly}(n)$-query protocol to solve the ℓ_2 adaptive attack problem with probability at least $9/10$, i.e., the problem in Definition 34 when $s = o(n)$.*

Proof of Theorem 33. Suppose $\mathcal{D}$ is a distribution over $s \times n$ sketching matrices and f is a function mapping $\mathbb{R}^s$ to $\mathbb{R}$ with the property that the pair $(\mathcal{D}, f)$ gives a pseudo-deterministic sketching algorithm for ℓ_2 norm estimation. Henceforth, we use $\boldsymbol{S}$ to denote a random matrix sampled from $\mathcal{D}$. Then there is a function $g : \mathbb{R}^n \to \mathbb{R}$ such that:

1. g is an α-approximation of the ℓ_2 norm.
2. On every input x, $f(\boldsymbol{S}x) = g(x)$ with probability at least $1 - \frac{1}{n^c}$ for some constant c.

We will show that s must be $\Omega(n)$ by deducing a contradiction when $k = o(n)$. Let r be a parameter to be chosen later. Let $\boldsymbol{x}^{(1)}, \boldsymbol{x}^{(2)}, \ldots, \boldsymbol{x}^{(r)}$ be the (random) sequence of vectors in $\mathbb{R}^n$ obtained by the adaptive query protocol from Theorem 35 based on responses $g(\boldsymbol{x}^{(0)}), \ldots, g(\boldsymbol{x}^{(r)})$ where $r = \mathrm{poly}(n)$, and let $\boldsymbol{y}$ be the (random) output of the protocol. Note that the guarantee that $r = \mathrm{poly}(n)$ hinges on assuming $s = o(n)$. From the guarantees of Theorem 35, for any fixed matrix B and function h such that $h(B\boldsymbol{x}^{(i)}) = g(\boldsymbol{x}^{(i)})$ for all i, it is true with probability at least $9/10$ that $h(B\boldsymbol{y}) \neq g(\boldsymbol{y})$. On the other hand, for any sequence of $r + 2$ fixed vectors $v_0, \ldots, v_{r+1}$, $f(\boldsymbol{S}v_i) = g(v_i)$ for all i with probability at least $1 - \frac{1}{\mathrm{poly}(n)}$. Call the event $\{f(\boldsymbol{S}\boldsymbol{x}^{(0)}) = g(\boldsymbol{x}^{(0)}), \ldots, f(\boldsymbol{S}\boldsymbol{x}^{(r)}) = g(\boldsymbol{x}^{(r)}), f(\boldsymbol{S}\boldsymbol{y}) = g(\boldsymbol{y})\}$ as $\mathcal{E}$. Let p_S be the probability density function of $\boldsymbol{S}$ and let p_T be the probability density function of $(\boldsymbol{x}^{(0)}, \ldots, \boldsymbol{x}^{(r)}, \boldsymbol{y})$. This results in the following two estimates of $\Pr[\mathcal{E}]$.

On the one hand,

$$\begin{aligned}\Pr[\mathcal{E}] &= \int_{\boldsymbol{S}} \Pr[\mathcal{E}|\boldsymbol{S}] p_S(\boldsymbol{S}) \\ &\leq \int_{\boldsymbol{S}} \frac{1}{10} p_S(\boldsymbol{S}) \\ &= \frac{1}{10},\end{aligned}$$

and on the other hand,

$$\begin{aligned}\Pr[\mathcal{E}] &= \int_{\boldsymbol{x}^{(0)},\ldots,\boldsymbol{x}^{(r)},\boldsymbol{y}} \Pr[\mathcal{E}|\boldsymbol{x}^{(0)}, \ldots, \boldsymbol{x}^{(r)}, \boldsymbol{y}] p_T(\boldsymbol{x}^{(0)}, \ldots, \boldsymbol{x}^{(r)}, \boldsymbol{y}) \\ &\geq \int_{\boldsymbol{x}^{(0)},\ldots,\boldsymbol{x}^{(r)},\boldsymbol{y}} \left(1 - \frac{1}{\mathrm{poly}(n)}\right) p_T(\boldsymbol{x}^{(0)}, \ldots, \boldsymbol{x}^{(r)}, \boldsymbol{y}) \\ &= 1 - \frac{1}{\mathrm{poly}(n)}.\end{aligned}$$

The contradiction arises since $\Pr[\mathcal{E}]$ cannot simultaneously be at least $1 - \frac{1}{\mathrm{poly}(n)}$ and at most $\frac{1}{10}$, and hence s cannot be $o(n)$. ◀

▶ **Corollary 36.** *For any constant $\delta > 0$, any $(2-\delta)$-concentrated sketching algorithm that where the sketching matrix is $s \times n$ can be turned into a pseudo-deterministic one by running $\log n$ independent copies of the sketch and outputting the majority answer. Thus, as an upshot of Theorem 33 we obtain a lower bound of $\Omega\left(\frac{n}{\log n}\right)$ on $(2-\delta)$-concentrated algorithms for pseudo-deterministic ℓ_2-norm estimation in the sketching model.*

In contrast to Corollary 36 which says that $(2-\delta)$-concentrated algorithms for ℓ_2 estimation in the sketching model need near linear dimension, we show that there is an $O(\text{poly}\log n)$-dimension $(2+\delta)$-concentrated sketching algorithm to solve the problem, thus exhibiting a "phase transition".

▶ **Theorem 37.** *There is a distribution $\mathcal{D}$ over $s \times n$ matrices and a function $f : \mathbb{R}^s \to \mathbb{R}$ when $s = O(\text{poly}\log n)$ For every constant $\delta > 0$, there is an $O(\text{poly}(\log n, \log m))$-space $(2+\delta)$-concentrated sketching algorithm for ℓ_2-norm estimation.*

Proof. Let the true ℓ_2 norm of the input vector be r. Run the classic sketching algorithm of [2] for randomized ℓ_2 norm estimation with error $\min\{1/2^{20}, \varepsilon^4\}$ and failure probability $\frac{1}{\text{poly}(n)}$ where $(1+\varepsilon)$ is the desired approximation ratio. This uses a sketch of dimension $O(\text{poly}\log n)$. Now, we describe the function f we use. Take the output of the sketching algorithm of [2] and return the number obtained by zeroing out all its bits beyond the first $\max\{2\log\left(\frac{1}{\varepsilon}\right), 5\}$ significant bits.[3] First, the outputted number is a $(1+\varepsilon)$ approximation. Further, for each input, the output is one of two candidates with probability $1 - \frac{1}{\text{poly}(n)} > 1-\delta$ for every constant δ. This is because [2] produces a $(1+\varepsilon^4)$-approximation to r, and there are only two candidates for the $2\log\left(\frac{1}{\varepsilon}\right)$ most significant bits of any real number that lies in an interval $[(1-\varepsilon^4)r, (1+\varepsilon^4)r]$. ◀

7 Pseudo-deterministic Upper Bounds

7.1 Finding a nonzero row

Given updates to an $n \times d$ matrix A (where we assume $d \leq n$) that is initially 0 in a turnstile stream such that all entries of A are always in range $[-n^3, n^3]$, the problem Find-Nonzero-Row is to either output an index i such that the ith row of A is nonzero, or output `none` if A is the zero matrix.

▶ **Theorem 38.** *The randomized space complexity for* Find-Nonzero-Row *is $\widetilde{\Theta}(1)$, the pseudo-deterministic space complexity for* Find-Nonzero-Row *is $\widetilde{\Theta}(n)$, and the deterministic space complexity for* Find-Nonzero-Row *is $\widetilde{\Theta}(nd)$.*

Proof. We first will show a randomized $\widetilde{\Theta}(1)$ space algorithm for the problem, then we will show pseudo-deterministic upper and lower bounds, and then show the deterministic lower bound.

Randomized algorithm for Find-Nonzero-Row. A randomized algorithm for this problem is given below. Note that the version of the algorithm as stated below does not have the desirable $\widetilde{O}(1)$ space guarantee, but we will show how to use a pseudorandom generator of Nisan [29] to convert the below algorithm to one that uses low space.

[3] The parameters $1/2^{20}, 5$ and ε^4 are chosen purely for *safety* reasons.

1. Sample a random d-dimensional vector $\boldsymbol{x}$ where each entry is an independently drawn integer in $[-n^3, n^3]$ and store it.
2. Simulate a turnstile stream which maintains $A\boldsymbol{x}$. In particular, consider the n-dimensional vector y, which is initially 0, and for each update to A of the form "add Δ to A_{ij}", add $\Delta \boldsymbol{x}_j$ to y_i. We run an ℓ_0-sampling algorithm [8] on this simulated stream updating y, and return the output of the ℓ_0-sampler, which is close in total variation distance to a uniformly random element in the support of y.

In the above algorithm, step 1 is not low-space as stated. Before we give a way to perform step 1 in $\widetilde{O}(1)$ space, we prove the correctness of the above algorithm. Suppose A_i is a nonzero row of A, then let j be an index where A_i is nonzero. Suppose all coordinates of $\boldsymbol{x}$ except for the j-th coordinate have been sampled, there is at most one value C for $\boldsymbol{x}_j$ for which $\langle A_i, \boldsymbol{x}\rangle$ is 0, and there is at most a $1/n^3$ probability that $\boldsymbol{x}_j$ equals C, which means if i is a nonzero row, then $(A\boldsymbol{x})_i$ is nonzero except with probability at most $1/n^3$. In fact, by taking a union bound over all nonzero rows we can conclude that the set of nonzero rows and the set of nonzero indices of $A\boldsymbol{x}$ are exactly the same, except with probability bounded by $1/n^2$.

Now we turn our attention to implementing step 1 in low space. Towards doing so we use Nisan's pseudorandom generator for space bounded computation in a very similar manner to [19].

Instead of sampling $3d \log n + 1$ bits to store $\boldsymbol{x}$, we sample and store a uniformly random seed $\boldsymbol{w}$ of length $O(\text{poly}\log(n, d))$ and add $\Delta G(\boldsymbol{w})_j$ to y_i when an update "add Δ to A_{ij}" is received, where G is the function from Theorem 12 that maps the random seed to a sequence $3d \log n + 1$ bits. To prove the algorithm is still correct if we use the pseudorandom vector $G(\boldsymbol{w})$ instead of the uniformly random vector $\boldsymbol{x}$, we must show that when A_i is nonzero, then $\langle A_i, G(\boldsymbol{w})\rangle$ is nonzero with probability at least $1 - O(1/n^3)$. Towards this, for a fixed d-dimensional vector q, consider the following finite state machine. The states are labeled by pairs (i, a) where i is in $\{0, 1, \ldots, d\}$ and a is in $[-n^6 d, n^6 d]$. The FSM takes a d-dimensional vector r as input, starts at state $(0, 0)$, and transitions from state (i, a) to $(i+1, a+q_{i+1} \cdot r_{i+1})$ until it reaches a state (d, ℓ). The FSM then outputs ℓ. This establishes that for a fixed q, the function $f(x) \coloneqq \langle q, x\rangle$ is computable by an FSM on $\text{poly}(d, n)$ states, and hence from Theorem 12, $f(\boldsymbol{x})$ and $f(G(\boldsymbol{w}))$ are $1/dn^6$ close in total variation distance, which means when A_i is nonzero, then $\langle A_i, G(\boldsymbol{w})\rangle$ is nonzero except with probability bounded by $O(1/n^3)$.

A pseudo-deterministic algorithm and lower bound for Find-Nonzero-Row. The pseudo-deterministic algorithm is very similar to the randomized algorithm from the previous section.

1. Sample a random d-dimensional vector $\boldsymbol{x}$ where each entry is an independently drawn integer in $[-n^3, n^3]$. Store $\boldsymbol{x}$ and maintain $A\boldsymbol{x}$.
2. Output the smallest index i such that $(A\boldsymbol{x})_i$ is nonzero.

Storing $\boldsymbol{x}$ takes $O(d \log n)$ space, and maintaining $A\boldsymbol{x}$ takes $O(n \log n)$ space. Recall from the discussion surrounding the randomized algorithm that the set of nonzero indices of $A\boldsymbol{x}$ and the set of nonzero rows were equal with probability $1 - 1/n^2$, which establishes correctness of the above pseudo-deterministic algorithm. The space complexity is thus $O((d + n) \log n)$, which is equal to $O(n \log n)$ from the assumption that $d \leq n$.

A pseudo-deterministic lower bound of $\widetilde{\Omega}(n)$ follows immediately from Corollary 31 since Find-Nonzero-Row specialized to the $d = 1$ case is the same as Find-Support-Elem.

Lower Bound for deterministic algorithms. An $\Omega(nd \log n)$ bit space lower bound for deterministic algorithms follows from a reduction to the communication complexity problem of EQUALITY. Alice and Bob are each given $nd \log n$ bit strings as input, which they interpret as $n \times d$ matrices, A and B respectively, where each entry is a chunk of length $\log n$. Suppose a deterministic algorithm $\mathcal{A}$ takes S bits of space to solve this problem. We will show that this can be converted to a S-bit communication protocol to solve EQUALITY. Alice runs $\mathcal{A}$ on a turnstile stream updating matrix X initialized at 0 by adding A_{ij} to X_{ij} for all (i, j) in $[n] \times [d]$. Alice then sends the S bits corresponding to the state of the algorithm to Bob and he continues running $\mathcal{A}$ on the updates "add $-B_{ij}$ to X_{ij}". $\mathcal{A}$ outputs `none` if and only if $A = B$ and thus Bob outputs the answer to EQUALITY depending on the output of $\mathcal{A}$. Due to a communication complexity lower bound of $\Omega(nd \log n)$ on EQUALITY, S must be $\Omega(nd \log n)$. ◀

7.2 Point Query Estimation and Inner Product Estimation

In this section, we give pseudo-deterministic algorithms that beat the deterministic lower bounds for two closely related streaming problems – point query estimation and inner product estimation.

Point Query Estimation

Given a parameter ε and a stream of m elements where each element comes from a universe $[n]$, followed by a query $i \in [n]$, output f_i' such that $|f_i - f_i'| \leq \varepsilon m$ where f_i is the frequency of element i in the stream.

Inner Product Estimation

Given a parameter ε and a stream of m updates to (initially 0-valued) n-dimensional vectors x and y in an insertion-only stream[4], output estimate e satisfying $|e - \langle x, y \rangle| < \varepsilon \cdot \|x\|_1 \cdot \|y\|_1$. In the above problems, we will be interested in the regime where $m \ll n$.

Our main result regarding a pseudo-deterministic algorithm for point query estimation is:

▶ **Theorem 39.** *There is an $O\left(\frac{\log m}{\varepsilon} + \log n\right)$-space pseudo-deterministic algorithm $\mathcal{A}$ for point query estimation with the following precise guarantees. For every sequence $s_1, \ldots, s_m$ in $[n]^m$, there is a sequence $f_1', \ldots, f_n'$ such that*

1. *For all i, $|f_i' - f_i| \leq \varepsilon m$ where f_i is the frequency of i in the stream.*
2. *Except with probability $1/m$, for all $i \in [n]$ $\mathcal{A}$ outputs f_i' on query i.*

We remark that the deterministic complexity of the problem is $\Omega(\frac{\log n}{\varepsilon}$ (see Theorem 44). Towards establishing Theorem 39, we recall two facts.

▶ **Theorem 40** (Misra–Gries algorithm [25])**.** *Given a parameter ε and a length-m stream of elements in $\{1, \ldots, d\}$, there is a deterministic $O\left(\frac{\log d + \log m}{\varepsilon}\right)$-space algorithm that given any query $s \in [d]$, outputs f_s' such that $|f_s' - f_s| \leq \varepsilon m$ where f_s is the number of occurrences of s in the stream. An additional guarantee that the algorithm satisfies is the following, which we call* permutation invariance*. Consider the stream*

$$s_1, s_2, \ldots, s_m$$

[4] A stream where only increments by positive numbers are promised.

and for any permutation $\pi : [d] \to [d]$, consider the stream

$$\pi(s_1), \pi(s_2), \ldots, \pi(s_m).$$

When the algorithm is given the first stream as input, let f'_s denote its output on query s, and when the algorithm is given the second stream as input, let $g'_{\pi(s)}$ denote its output on query $\pi(s)$. The algorithm has the guarantee that $f'_s = g'_{\pi(s)}$.

▶ **Theorem 41** (Pairwise independent hashing, [32, Corollary 3.34]). *Assume $d \ll n$. There is a pairwise independent hash function $h : [n] \to [d]$, which can be sampled using $O(\log n)$ random bits and also can be stored in $O(\log n)$ bits.*

Proof of Theorem 39. The algorithm is as follows.

- Sample a random pairwise independent hash function $h : [n] \to [m^3]$, which can be sampled and stored in $O(\log n)$ bits.
- Run the Misra–Gries algorithm with the following simulated stream as input: for each s streamed as input, stream $h(s)$ to the simulation.
- Given any query s, perform query $h(s)$ to the Misra–Gries algorithm running on the simulated stream, and return its output.

Let S be the collection of elements of $[n]$ that occur in the input stream $s_1, \ldots, s_m$. Assuming h maps S into $[m^3]$ without any collisions[5], it follows from the permutation invariance property of the Misra–Gries algorithm from Theorem 40 the output of the above algorithm on any query q is equal to $F(s_1, \ldots, s_m, q)$ for a *fixed* function F. Thus if we show that h indeed maps S into $[m^3]$ injectively pseudo-determinism of the given algorithm would follow.

Given $i, j \in S$, due to pairwise independence of h, the probability that $h(i) = h(j)$ is equal to $1/m^3$. A union bound over all pairs of elements in S tells us that h is collision-free except with probability at most $1/m$, which implies that the above algorithm is indeed pseudo-deterministic. ◀

▶ **Theorem 42.** *There is a (weakly) pseudo-deterministic algorithm for inner product estimation that uses $O\left(\frac{\log m}{\varepsilon} + \log n\right)$ space.*

The algorithm for inner product estimation is based on point query estimation, and towards stating the algorithm we first state a known result that helps relate the two problems.

▶ **Lemma 43** (Easily extracted from the proof of [28, Theorem 1]). *Let x, y, x', y' be vectors such that $\|x - x'\|_\infty \le \varepsilon \|x\|_1$ and $\|y - y'\|_\infty \le \varepsilon \|y\|_1$. Now, let x'' (and respectively y'') denote x' with everything except the maximum $1/\varepsilon$ entries zeroed out. Then the following holds:*

$$|\langle x'', y'' \rangle - \langle x, y \rangle| \le \varepsilon \cdot \|x\|_1 \cdot \|y\|_1.$$

Proof of Theorem 42. Given a stream of updates to x and y, run two instances of the point query estimation algorithm from Theorem 39 – one for updates to x and one for updates to y. There are x' and y' that only depend on the stream such that

$$\|x - x'\|_\infty \le \varepsilon \cdot \|x\|_1 \quad \text{and} \quad \|y - y'\|_\infty \le \varepsilon \cdot \|y\|_1$$

and except with probability $O(1/m)$ both point query algorithms respond to any query i with x'_i (and y'_i respectively). Maintaining these two instances takes $O\left(\frac{\log m}{\varepsilon} + \log n\right)$ space.

[5] I.e. the restriction of h to domain S is an injective function.

Next, enumerate over elements of $[n]$ and for each $i \in [n]$ query both instances with i, and store the running max-$1/\varepsilon$ answers to queries to each instance along with the hashed identities of the indices of entries that are part of the running max. Storing the running max takes $O\left(\frac{\log m}{\varepsilon}\right)$ space, and storing a counter to enumerate over $[n]$ takes $\log n$ space. Thus, at the end of this routine, except with probability $O(1/m)$ our two lists are equal to $(x'_{i_1}, h(i_1)), \ldots, (x'_{i_{1/\varepsilon}}, h(i_{1/\varepsilon}))$ and $(y'_{j_1}, h(j_1)), \ldots, (y'_{j_{1/\varepsilon}}, h(j_{1/\varepsilon}))$ respectively where $x'_{i_1}, \ldots, x_{i_{1/\varepsilon}}$ are the max-$1/\varepsilon$ entries of x' and $y'_{j_1}, \ldots, y_{j_{1/\varepsilon}}$ are the max-$1/\varepsilon$ entries of y'.

Finally, if there is t, u such that $h(i_t) = h(i_u)$ or $h(j_t) = h(j_u)$, return "fail"; otherwise output

$$\sum_{\ell \in \{h(i_t)\}_{t=1,\ldots,1/\varepsilon} \cap \{h(j_t)\}_{t=1,\ldots,1/\varepsilon}} x'_\ell y'_\ell.$$

With probability at least $1 - 2/m$, the above quantity is equal to $\langle x'', y'' \rangle$ from Lemma 43, which lets us conclude via Lemma 43 that the output is within $\varepsilon \cdot \|x\|_1 \cdot \|y\|_1$ of the true inner product. ◀

Finally, we remark that the following lower bounds can be proved for deterministic algorithms.

▶ **Theorem 44.** *Any deterministic algorithm for point query estimation and inner product estimation needs* $\Omega\left(\frac{\log n}{\varepsilon}\right)$ *space.*

Proof. We prove a lower bound for point query estimation via a reduction from EQUALITYin communication complexity. Alice encodes a $\log \binom{n}{1/(3\varepsilon)}$ bit string as a subset S of $[n]$ of size $1/(3\varepsilon)$ and runs the point query streaming algorithm on the input where she streams each element of this subset $3\varepsilon m$ times. She then sends the state of the algorithm to Bob, who can query every index in the universe and learn S (the element corresponding to the query is in S if and only if the response to the query is at least $2\varepsilon \cdot m$), decode S back to a $\log \binom{n}{1/(3\varepsilon)}$ and check if it is equal to his own input. The space lower bound from the theorem statement then follows since $\log \binom{n}{1/(3\varepsilon)} = \Omega\left(\frac{\log n}{\varepsilon}\right)$.

A space lower bound for inner product estimation follows from the lower bound for point query estimation since the latter is a special case of the former when x is the vector of frequencies and y is a standard unit vector e_i corresponding to query i. ◀

7.3 Retrieving a Basis of a Row-space

We now work in a "mixed" model, where an input $n \times d$ matrix A of rank-$\leq k$ is given to us via a sequence of updates in a turnstile stream, and each entry at all times in the stream can be represented by an $O(\log n)$-bit word. During this phase, there is an upper bound T on the number of bits of space an algorithm is allowed to use. In the "second phase", we are allowed to perform arbitrary computation and the goal is to output a basis for the row-span of A

We show a lower bound on T of $\widetilde{\Omega}(nd)$ for deterministic algorithms, and a pseudo-deterministic algorithm that uses $\widetilde{O}(\text{poly}(k) \cdot d)$ space in the streaming phase.

▶ **Theorem 45.** *Any deterministic streaming algorithm for* RECOVERBASIS *needs* $\widetilde{\Omega}(nd)$ *space.*

Proof. Suppose the matrix A is 0, then the algorithm would have to output the empty set. A T space streaming algorithm for this problem could be used to solve the communication complexity problem of equality EQUALITY using T bits of communication. In particular,

Alice and Bob could encode their respective inputs x and y as matrices M_x and M_y. Alice can then run the T-space algorithm on adding M_x in a turnstile stream, and send Bob the state of the algorithm. Bob can then resume running the algorithm from Alice's state on updates that subtract M_y. If Bob outputs the empty set, then $x = y$ and Bob outputs "yes". Otherwise, Bob outputs "no". ◀

While the deterministic complexity is $\widetilde{\Omega}(nd)$, there is a pseudo-deterministic streaming algorithm which uses only $\widetilde{O}(\text{poly}(k) + k \cdot d)$ in its streaming phase:

▶ **Theorem 46.** *There is a pseudo-deterministic algorithm for* RecoverBasis *that uses* $\widetilde{O}(\text{poly}(k) + k \cdot d)$ *space in its streaming phase, where the* $\widetilde{O}(\cdot)$ *hides factors of* $\text{poly}\log n$.

Towards giving a pseudo-deterministic algorithm, we first state a result about pseudorandom matrices that is a special case of [5, Lemma 3.4].

▶ **Theorem 47.** *There is a distribution* $\mathcal{D}$ *over* $m \times n$ *matrices where* $m = O(k \log n)$ *with* ± 1 *entries such that for any* $n \times m$ *matrix* U *with orthonormal columns and* $\boldsymbol{S} \sim \mathcal{D}$*, the following holds with probability* $1 - 1/\text{poly}(n)$*:*

$$\|U^T \boldsymbol{S}\boldsymbol{S}^T U - I\|_2 \leq 1/2.$$

Further, the rows of $\boldsymbol{S}$ *are independent and each row can be generated by a* $(k + \log n)$*-wise independent hash family.*

▶ **Theorem 48** (t-wise independent hash families [32, Corollary 3.34])**.** *There is a* t*-wise independent hash family* $\mathcal{H}$ *of functions from* $[n] \to \{\pm 1\}$ *such that sampling a uniformly random* h *from* $\mathcal{H}$ *can be done using a* $\text{poly}(\log n, t)$*-length random seed, and* $h(x)$ *for any* $x \in [n]$ *can be computed in* $\text{poly}(\log n, t)$ *time and space from the random seed used to sample it.*

As a consequence we have:

▶ **Corollary 49.** *Let* A *be a* $n \times d$ *matrix of rank* k *and let* $\mathcal{D}$ *be the distribution over* $O(k \log n) \times n$ *matrices from the statement of Theorem 47. Then, for* $\boldsymbol{S} \sim \mathcal{D}$*,* $\boldsymbol{S}A$ *has rank* k *with probability* $1 - 1/\text{poly}(n)$*.*

Proof. We start by writing A in its singular value decomposition $U\Sigma V^T$. Since A has rank k, U is a $n \times k$ matrix with orthonormal columns and ΣV^T surjectively maps $\mathbb{R}^d$ to $\mathbb{R}^k$. From Theorem 47, $\boldsymbol{S}A$ is also full rank, which means the collection of vectors

$$\{\boldsymbol{S}Ax : x \in \mathbb{R}^d\} = \{\boldsymbol{S}U\Sigma V^T x : x \in \mathbb{R}^d\} = \{\boldsymbol{S}Ux : x \in \mathbb{R}^k\}$$

is a k-dimensional space, and hence $\boldsymbol{S}A$ has rank k. ◀

Proof of Theorem 46. Begin by sampling $\boldsymbol{S} \sim \mathcal{D}$ via a seed $\boldsymbol{s}$ of length $O(\text{poly}(k) \cdot \text{poly}\log(n))$ from which entries of $\boldsymbol{S}$ can be efficiently computed where $\mathcal{D}$ is the distribution over matrices given by Corollary 49, and maintain the sketch $\boldsymbol{S}A$ in the stream.

The row-span of $\boldsymbol{S}A$ is exactly the same as that of A assuming the two matrices have equal rank, which happens with probability $1 - 1/\text{poly}(n)$.

$\boldsymbol{S}A$ is an $O(k) \times d$ matrix and each entry is a signed combination of at most n entries of A and hence there is a bit complexity bound of $\widetilde{O}(kd)$ on the space used to store $\boldsymbol{S}A$.

In the second phase (i.e., after the stream is over) of the algorithm, we first find an orthonormal basis Q for the row-span of $\boldsymbol{S}A$ and compute $\widetilde{\Pi}_A = QQ^T$. And finally, use a deterministic algorithm to compute the singular value decomposition $\widetilde{U}\widetilde{\Sigma}\widetilde{V}^T$ of $\widetilde{\Pi}_A$ and output the rows of $\widetilde{V}^T$.

The row-span of $\boldsymbol{S}A$ and A are equal except with probability $1/\text{poly}(n)$; assuming this happens, $\widetilde{\Pi}_A$ is exactly equal to Π_A, the unique projection matrix onto the row-span of A. Write Π_A in its singular value decomposition $U\Sigma V^T$. If $\widetilde{\Pi}_A = \Pi_A$, $\widetilde{V}^T$ is exactly equal to V^T. Since V^T is given by a deterministic function of A, and the output of the algorithm $\widetilde{V}$ is equal to V^T with high probability, our algorithm is pseudo-deterministic. ◀

Abstract

There have been many successes in constructing explicit non-malleable codes for various classes of tampering functions in recent years, and strong existential results are also known. In this work we ask the following question:

When can we rule out the existence of a non-malleable code for a tampering class $\mathcal{F}$?

First, we start with some classes where positive results are well-known, and show that when these classes are extended in a natural way, non-malleable codes are no longer possible. Specifically, we show that no non-malleable codes exist for any of the following tampering classes:

- Functions that change $d/2$ symbols, where d is the distance of the code;
- Functions where each input symbol affects only a single output symbol;
- Functions where each of the n output bits is a function of $n - \log n$ input bits.

Furthermore, we rule out constructions of non-malleable codes for certain classes $\mathcal{F}$ via reductions to the assumption that a distributional problem is hard for $\mathcal{F}$, that make black-box use of the tampering functions in the proof. In particular, this yields concrete obstacles for the construction of efficient codes for NC, even assuming average-case variants of $P \not\subseteq \mathsf{NC}$.

1 Introduction

Since the introduction of non-malleable codes (NMC) by Dziembowski, Pietrzak, and Wichs in 2010, there has been a long line of work constructing non-malleable codes for various classes [43]. A plethora of upper bounds, explicit and implicit (to varying degrees), have been shown for a wealth of classes of tampering functions. However, to our knowledge, relatively little is known about when non-malleability is impossible. In this work, we initiate the study of the limits to non-malleability.

Non-malleability for a class $\mathcal{F}$ is defined via the following "tampering" experiment:
Let $f \in \mathcal{F}$ denote a tampering function.

1. Encode message m using a (public) randomized encoding algorithm: $c \leftarrow \mathsf{E}(m)$,
2. Tamper the codeword: $\tilde{c} = f(c)$,
3. Decode the tampered codeword (with public decoder): $\tilde{m} = \mathsf{D}(\tilde{c})$.

Roughly, the encoding scheme, (E, D), is non-malleable for a class $\mathcal{F}$, if for any $f \in \mathcal{F}$ the result of the above experiment, $\tilde{m}$, is either identical to the original message, or completely unrelated. More precisely, the outcome of a $\mathcal{F}$-tampering experiment should be simulatable without knowledge of the message m (using a special flag "same" to capture the case of unchanged message).

[43] showed that, remarkably, this definition is achievable for any $\mathcal{F}$ such that $\text{loglog}|\mathcal{F}| < n - 2 \cdot \log(1/\epsilon)$, where n is the length of the codeword (the input/output of functions in $\mathcal{F}$), and ϵ parameterizes the quality of simulation possible (see Definition 3). However the definition is not achievable in general. It is easy to observe that if $\mathcal{F}$ is the class of all functions, there is a trivial tampering attack: decode, maul, and re-encode. This same observation rules out the possibility of *efficient* codes against efficient tampering, as this attack only requires that decoding and outputting constants conditioned on the result is in the tampering class. By a similar argument, the decoding function of a non-malleable code with respect to the distribution formed by encoding a random one-bit message can be seen as existence of hard decision problem for the tampering class. (This, in turn, informs us of where to hope for unconditional constructions.)

In this work, we give a variety of impossibility results for non-malleable codes, in disparate tampering regimes. We present 3 unconditional impossibility results for various classes, which hold even for *inefficient* NMC. These impossibility results apply to classes that are simple and natural extensions of classes with well-known and efficient NMC constructions. Additionally, we rule out constructions of NMC for a wide range of complexity classes with security reductions that are only given black-box access to the tampering function. This result is more technically complex than the previous ones, and requires the introduction of a new notion of fine-grained black-box reductions appropriate for the non-malleability setting, as we explain below. This result allows us to study the minimal assumptions necessary for achieving NMC for complexity classes contained in P (e.g., NC^1), and to rule out such NMC constructions (with black-box reductions) from minimal average-case hardness assumptions.

To our knowledge, the only previously-known impossibility results beyond the simple observations above, are related to other variants of NMC. These include bounds on locality of locally decodable and updatable NMC, bounds on continuous NMC, and impossibility of "look-ahead" or "block-wise" NMC (which also follows from a simple observation). There are also several bounds related to the *rate* of NMC. We discuss these and other related works in Section 1.4. In contrast, our results hold regardless of rate. In fact, our lower bounds rule out even message spaces of size two or three.

1.1 Strictly Impossible

We identify 3 tampering regimes where non-malleability is strictly impossible.

On tampering functions that change $d/2$ symbols, where d is the distance of the code

It is common to present non-malleable codes as a strict relaxation of error-correcting codes (ECC). It is easy to see that ECC are NMC against tampering that changes up to the allowed fraction of symbols, but since NMC only require correctness of decoding in the absence of errors, they can provide "security" for tampering functions that ECC cannot, in particular functions that can modify most, or even all, symbols of the codeword. This suggests that we could potentially construct NMC for tampering classes that are strictly larger than any class for which ECC could exist. However, no such construction is known: all NMC results that allow to modify more symbols, also require that the computation of the tampering function is restricted in some way. In contrast, ECC do not place any restrictions on the tampering adversary beyond the limit to the number of modified symbols.

In the current work we ask whether this trade-off is in fact necessary. Specifically, can we construct NMC that allow for modifying more symbols of the codeword than ECC *without* placing any other restrictions on the tampering? Note that for ECC it is known that if the distance of the code is d, it is not possible to correct when $d/2$ symbols are modified, but there are constructions that allow for error correction after arbitrary modification of at most $d/2 - 1$ symbols (e.g., Reed-Solomon ECC achieve this bound). Indeed, for the case of potentially inefficient coding schemes, the above is tight: A coding scheme with distance d implies error correction against $d/2 - 1$ errors. Thus, fixing a message space $\mathcal{M}$ and a codeword space $\mathcal{C}$, we consider the optimal ECC for this message and codeword space, which has some distance d (and therefore can correct $d/2 - 1$ errors). We then ask whether one can construct a non-malleable code with message space $\mathcal{M}$ and codeword space $\mathcal{C}$ against the class of functions that may arbitrarily tamper with $d/2$ codeword symbols.

We fully resolve our question. We show that for message space of size 2, non-malleable codes that tolerate arbitrary modification of even up to $d - 1$ symbols are *possible* (via a repetition code, see Section 3). On the other hand, for message space of size greater than 2, it is *impossible* to construct non-malleable codes with distance d for tampering functions that arbitrarily modify $d/2$ codeword symbols. This indicates that for message space larger than 2, in order to obtain improved parameters beyond what is possible with error correcting codes, imposing some additional restrictions on the tampering function is *necessary*.

On tampering functions where each input symbol affects at most one output symbol

In their recent work, Ball et al. [17] presented unconditional NMC for the class of output-local functions, where each output symbol depends on a bounded number of input symbols. As an intermediate step, they also considered the class of functions that are both input and output

local. The class of input-local functions is the class of functions where each input symbol affects a bounded number of output symbol. A natural question is whether non-malleable codes can be constructed for the class of input-local functions, where for codeword length n, each input bit affects $\ll n$ output bits.

In this work, we answer this question negatively in a very strong sense. We show that even achieving NMC for 1-input local functions (where each input bit affects at most one output bit) is impossible. In fact, our proof shows an even stronger result: the impossibility holds even if each input symbol can only affect the same single output symbol. That is, it is impossible to construct NMC for the tampering class that allows to change only one codeword symbol in a way that depends on the input (while the other symbols may be changed into constant values). Stated like this, this result can also be viewed as an extension of our first result above on the maximum number of symbols that can be modified in a non-malleable code.

On tampering functions where each output symbol depends on $n - \log(1/(4\epsilon))$ input symbols

Here we move on to consider achieving NMC for output-local tampering functions. The prior work of [17] constructed efficient NMC for tampering functions with locality n^c, for constant $c < 1$. The size of the class of all output-local tampering functions (with locality sufficiently smaller than n) is also bounded in size and therefore NMC for this class follow from the existential results of [43]. A natural question is how large can the output-locality be?

We prove the impossibility of ϵ-non-malleable codes (see Definition 3) for the class of $(n - \log(1/(4\epsilon)))$-output-local tampering functions. In addition to the above motivation, parity over n bits is average-case hard for this class.[1] Therefore, our impossibility result can be viewed as a "separation" between average-case hardness and non-malleability, as it exhibits a class for which we have average-case hardness bounds, but cannot construct non-malleable codes for. Furthermore, the class $\mathcal{F}'$ constructed in our lower bound proof has size only $4^n \cdot 2^{2^{n-\log(1/(4\epsilon))}}$, which in turn means that $\log\log|\mathcal{F}'| = n - \log(1/(4\epsilon)) = n - \log(1/\epsilon) + 2$. On the other hand, the aforementioned result of Dziembowski et al. [43] shows existence of an ϵ-non-malleable code for any class $\mathcal{F}$ such that $\log\log|\mathcal{F}| \leq n - 2\log(1/\epsilon)$. Thus, our lower bound result is close to matching the existential upper bound.

Remark: deterministic vs. randomized decoding

The standard (and original) definition of NMC requires deterministic decoding and perfect correctness, although some later work took advantage of randomized decoding.[2] We note that our lower bound for the class of input-local functions holds for standard schemes (with deterministic decoding and perfect correctness). Our lower bound (with $\epsilon = \frac{1}{4n}$) for the class of $n - \log(n)$ output-local functions holds even for coding schemes that have *randomized* decoding and perfect correctness. The lower bound for the class of functions that change $d/2$ symbols holds even for coding schemes with *randomized* decoding and *imperfect* correctness.

---

[1] Note that, even arbitrary decision trees of depth $n - 1$ have no advantage in computing the parity of n bits with respect to the uniform distribution. [22]

[2] For the class of output-local functions (where each output depends on at most ℓ inputs) we have explicit constructions with randomized decoding (and $\epsilon = \mathsf{negl}(n)$) for $\ell < n/\log n$ [17], whereasconstructions with deterministic decoding are known for locality up to $n^{1/2-\epsilon}$ for small ϵ. [28, 15].

1.2 Impossibility of Black-Box Security Reductions

In recent work, unconditional constructions of non-malleable codes for progressively larger tampering classes, such as NC^0 [17, 29, 15] and AC^0 [29, 15], have been presented. In fact, the construction of [15] remains secure for circuit depths as large as $\Theta(\log(n)/\log\log(n))$. Moreover, due to the impossibility of efficient NMC for all of P, extending their result to obtain unconditional NMC for circuits with asymptotically larger depth would require separating P from NC^1, a problem that is well out of reach with current complexity-theoretic techniques. However, rather than ruling out such constructions entirely, in this regime we ask what are the minimal assumptions necessary for achieving non-malleable codes for NC^1, as well as other classes $\mathcal{F}$ that are believed to be strictly contained in P.

The above question was partially addressed by Ball et al. [18, 16] in their recent work, where they presented a general framework for construction of NMC for various classes $\mathcal{F}$ in the CRS model and under cryptographic assumptions. Instantiating their framework for NC^1 yields a computational, CRS-model construction of 1-bit NMC for NC^1, assuming there is a distributional problem that is hard for NC^1, but easy for P. Moreover, such distributional problems for NC^1 can be based on worst-case assumptions.[3]

In this work, we ask whether 1-bit non-malleable codes for NC^1 in the standard (no-CRS) model can be constructed from the assumption that there are distributional problems that are hard for NC^1 but easy for P. Recall that this assumption is minimal, since the decoding function of a 1-bit non-malleable code for NC^1 w.r.t. the distribution of random encodings of 1 bit messages yields such a distributional problem.

We provide a negative answer, showing that, under black-box reductions (restricting use of the tampering function in the security proof to be black-box), this is impossible.

Specifically, we define a notion of black-box reductions for the setting of 1-bit non-malleable codes (E, D) against a complexity class $\mathcal{F}$ to a distributional problem (Ψ, L) that is hard for $\mathcal{F}$. This type of reduction is required to use the "adversary" – i.e. the tampering function in our setting – in a black-box manner, but is not restricted in its use of the underlying assumptions. To motivate our new notion, we begin by recalling the notions of reductions in complexity theory and cryptography, and how they are used.

Reductions in Complexity Theory

A reduction is a technique in complexity theory that is used to show that *Problem 1* is as hard as *Problem 2*. For example, the famous Cook-Levin theorem showed that SAT (Boolean satisfiability) is as hard as any problem in NP, by showing a reduction from any problem in NP to SAT. In more detail, a reduction R, is an algorithm that receives as input an algorithm A that solves Problem 1 and uses it to solve Problem 2. Typically, R will only access A in an input/output manner as a subroutine (also known as oracle access and denoted as R^A). When a reduction R uses a solver A in this way, R is known as a black-box reduction. Intuitively, in this case, R does not care *how* A solves Problem 1, it just cares that A exhibits the correct input-output behavior. Therefore, the reduction R should still be able to solve Problem 2, even when A is computationally unbounded. In fact, in the Cook-Levin theorem, only a single oracle query is made by the reduction to the algorithm solving SAT.

When is a reduction R between two problems useful? Note that if R is in a complexity class that can solve Problem 2, then existence of such a reduction R is tautological, since R can simply ignore its oracle and solve Problem 2 on its own (so no relationship is demonstrated

[3] Assuming $\oplus\mathsf{L}/\,\mathrm{poly} \not\subseteq \mathsf{NC}^1$ yields a distributional problem since randomized encodings for $\oplus\mathsf{L}/\,\mathrm{poly}$ are known to exist [13, 21, 41, 14].

about the relative hardness of the problems). This is why in the Cook-Levin theorem the reduction is required to be *polynomial time*. Reductions are also useful since they allow us to draw conclusions about the relationships between different complexity classes. For example, using the Cook-Levin theorem, we conclude that if there exists a polynomial time algorithm for solving SAT then there exists a polynomial time algorithm for all of NP (i.e. P = NP). Note that there is actually a subtlety here: In order for the above to hold, we need that whenever A is polynomial time, R^A is also polynomial time. This holds trivially for the case of polynomial time, since the class P is closed under composition. However, as we will see later, this closure does not necessarily hold in some of the settings we consider. Many variations on reductions beyond the setting of the Cook-Levin Theorem and NP-completeness have been considered in complexity theory. For example, polynomial time reductions have no utility when P is the object of study. Instead, the theory of P-completeness uses NC-computable reductions to argue about whether or not problems in P can be parallelized. Another such example is the theory of fine-grained complexity, which seeks to understand the *exact* (or, more exact) complexity of problems in P. Fine-grained reductions allow one to argue that a problem cannot be solved in, for example, $O(n^{2-\epsilon})$ time (for any $\epsilon > 0$), by reduction from another problem believed to require $\Omega(n^{2-o(1)})$ time. For this reasoning to hold, such a fine-grained reduction must run in sub-quadratic time, and moreover it can make at most $n^{o(1)}$ queries to an oracle defined on instances of length n if it is to remain useful. As we will see, this tension between the length of the inputs queried to the oracle and the number of such queries will also be relevant in our setting.

Reductions in Cryptography

Reductions in cryptography are exactly like reductions in complexity theory. For example, the seminal result of [54] proves by reduction that *breaking a pseudorandom function* (Problem 1) is as hard as *breaking a pseudorandom generator* (Problem 2). In order to prove this, they present a reduction R such that that given an algorithm A that breaks the constructed pseudorandom function, R^A breaks the underlying pseudorandom generator. Note that since R only has oracle access to A, again R does not care how A works, as long as it exhibits input-output behavior that qualifies it as a valid distinguisher between a pseudorandom and random function. Thus, R is black-box. As before, R is only useful if it is polynomial time, since otherwise R can break the pseudorandom generator on its own. Furthermore, we again want to use the existence of the reduction to draw conclusions about the security relationship between the pseudorandom function and the pseudorandom generator. Here we want to show that if there exists a polynomial-time algorithm that breaks the pseudorandom function, then there exists a polynomial-time algorithm that breaks the pseudorandom generator. Therefore, we want it to be the case that whenever A is polynomial time, R^A is also polynomial time. This trivially holds, as before, since P is closed under composition. However, in the following we will consider cases where this type of closure does not necessarily hold. For example, when A and R are in NC^1, R^A may no longer be in NC^1 (in fact R^A could have depth up to $\log^2(n)$). We therefore need to include a notion of closure under composition as one of the requirements of a black-box reduction in our setting.

A fine-grained setting: Security reductions for non-malleable codes

What would a security reduction in the setting of non-malleable codes look like? In this case, we want to show that *breaking the non-malleable code* (Problem 1) is as hard as *breaking distributional problem* (Ψ, L) (Problem 2). Here, an algorithm that breaks the non-malleable

code simply consists of a *tampering function* f. A reduction R is provided black-box access to the tampering function f and must use it to break the distributional problem (Ψ, L). First, note that since we assume R is black-box, R is only allowed to use f as a subroutine (gives it inputs and obtains its output), regardless of *how* f performs its computation. Thus, as in all the cases discussed above, we require that R^f break the distributional problem (Ψ, L), even in the case that f is not contained in $\mathcal{F}$. Note that the distributional problem (Ψ, L) is *easy* for polynomial-time. Therefore, for the reduction to be non-trivial, R must be in a complexity class that does not contain P. Indeed, since we only assume that (Ψ, L) is hard for $\mathcal{F}$, R must be contained in $\mathcal{F}$ in order for us to draw any conclusions (otherwise, we cannot rule out the possibility that R simply ignores its oracle and solves (Ψ, L) on its own). Furthermore, as discussed above, the point of the reduction is to be able to conclude that if there is a tampering function f in $\mathcal{F}$ that breaks the non-malleable code, then there exists an algorithm in $\mathcal{F}$ that breaks the distributional problem (Ψ, L). Therefore, it is not enough that $R \in \mathcal{F}$, and we actually need that whenever $f \in \mathcal{F}$, $R^f \in \mathcal{F}$. We will then use the fact that R^f breaks (Ψ, L) and is used to obtain a contradiction to the hardness of (Ψ, L) for $\mathcal{F}$.

Overall, at a high level (skipping some technical details), we require two properties of a black-box reduction R from (E, D) to (Ψ, L):

- If the tampering function f succeeds in breaking the non-malleable code, the reduction, R^f, should succeed, regardless of whether $f \in \mathcal{F}$. This represents the fact that R uses f in a black-box manner.
- For any $f \in \mathcal{F}$, R^f must also be in $\mathcal{F}$, and in particular, R itself must be in $\mathcal{F}$. This represents the fact that the black-box reduction R should allow one to obtain a contradiction to the assumption that (Ψ, L) is hard for $\mathcal{F}$, in the case that (E, D) is malleable by $\mathcal{F}$.

Note that for arbitrary classes $\mathcal{F}$ (unlike the usual polynomial-time adversaries typically used in cryptography), the fact that $R \in \mathcal{F}$ and $f \in \mathcal{F}$ does not necessarily imply that $R^f \in \mathcal{F}$. This introduces some additional complexity in our definitions and also requires us to restrict our end results to classes $\mathcal{F}$ that behave appropriately under composition.

We present general impossibility results for constructing 1-bit non-malleable codes for a class $\mathcal{F}$ from a distributional problem that is hard for $\mathcal{F}$ but easy for P. We present three types of results: results ruling out *security parameter preserving* reductions for tampering class $\mathcal{F}$ that behave nicely under composition; results ruling out *"approximate" security parameter preserving* reductions for tampering class $\mathcal{F}$ with slightly stronger compositional properties; and results ruling out *non-security parameter preserving* reductions for tampering class $\mathcal{F}$ that are fully closed under composition. See Definitions 21, 22 and Lemmas 31, 35, 37 for the formal statements.

Briefly, security parameter preserving reductions have the property that the reduction only queries the adversary (in our case the tampering function) on the same security parameter that it receives as input. The security parameter preserving reductions have been used in constructions of leakage resilient circuit compilers [11]. The notion of "approximate" security parameter preserving reductions is new to this work. Such reductions are parameterized by polynomial functions $\ell(\cdot), u(\cdot)$ and on input security parameter n, the reduction may query the adversary on any security parameter in the range $\ell(n)$ to $u(n)$. This notion is somewhat less restrictive than a security parameter preserving reduction. Finally, in a non-security parameter preserving reduction, the reduction receives security parameter n as input and may query the adversary on arbitrary security parameter n'. Note that $n'(n)$ must be in $O(n^c)$ for some constant c, since the reduction must be polynomial time. This notion allows us to rule out the most general type of black-box reduction discussed above.

We can instantiate the tampering class $\mathcal{F}$ from our generic lemma statements with various classes of interest. Our results on security parameter preserving and approximate security parameter preserving reductions apply to the class NC^1 as a special case. Our result ruling out non-security parameter preserving reductions applies to the class (non-uniform) NC as a special case. See Corollaries 32, 36, 38 for the formal statements. As the proofs are already quite involved, we make the simplifying assumption of deterministic decoding and perfect correctness. However, this is not inherent to the proof and we expect the results to extend to coding schemes with imperfect correctness and randomized decoding.

Do reductions for NMC take the above form?

So far, in the non-malleable codes setting, results have either been *unconditional* (e.g. [43, 4]) or have been based on polynomial-hardness assumptions (e.g. [64, 2]). The results that are based on polynomial-hardness assumptions have all used black-box security reductions, in the standard polynomial-time sense [69]. Our notion is new since it captures a fine-grained setting where the underlying distributional problem is, in fact, *easy* for polynomial-time algorithms. As discussed above, this is the minimal computational hardness assumption necessary to construct non-malleable codes for classes $\mathcal{F}$ for which we cannot prove unconditionally that $\mathsf{P} \not\subseteq \mathcal{F}$. While this type of reduction implicitly arises in the work of [18], our work is the first to formally define and explore this notion of fine-grained black-box reductions in a cryptographic setting.

1.3 Technical Overview

In order to prove impossibility of constructing non-malleable codes in different scenarios, we need to show that any such code is malleable. Recall that for single-bit messages, non-malleability is equivalent to showing that when applying the tampering function to a randomly generated encoding of a random bit, the decoded value flips with probability at most $1/2 + \mathsf{negl}(n)$. Thus, proving that something is malleable, corresponds to showing that the decoded value flips with probability at least $1/2 + 1/\operatorname{poly}(n)$. We will use this fact in the following exposition.

1.3.1 On tampering functions that change $d/2$ symbols, where d is the distance of the code

We observe that for any coding scheme, there must be some message, x^*, such that *every* encoding of that message is at most distance $d/2$ from something that is likely to decode to something other than x^*. Our tampering function will only modify encodings of x^*, and it will do so by moving each encoding to one of these nearby points that decodes differently. We claim that if there are at least 3 messages in the message space, then the output of decoding with the tampering function described above depends on the input message (and thus cannot be simulated). Indeed, when starting with message x^* (which is encoded, tampered, and decoded) there must be some other message $y^* \neq x^*$ that is not output a majority of the times by this process. On the other hand, when starting with y^*, since the tampering does not change anything in this case, correctness of decoding means that y^* should be output a majority of times.

This argument falls apart if there are only two possible messages, and in this case a repetition code with a decoding that outputs a fixed value on invalid codewords is, in fact, non-malleable with respect to tampering functions that can change up to $n - 1$ symbols.

1.3.2 On tampering functions where each input symbol affects at most one output symbol

Consider any two codewords c_x and c_y corresponding to distinct messages, x and y. Now consider any sequence of n codewords between c_x and c_y, made by altering one symbol at a time. There must be two adjacent codewords, c_i, c_{i+1}, (differing on a single bit) in this sequence that decode differently. Therefore, to tamper, simply output c_i if the input is an encoding of 0, and c_{i+1} otherwise. Because c_i and c_{i+1} just differ on a single bit, the tampering function has input locality 1.

1.3.3 On tampering functions where each output symbol depends on $n - \log(1/(4\epsilon))$ input symbols

We begin by considering a simpler argument, that only rules out tampering functions of output locality $n-1$ (each output bit can depend on at most $n-1$ input bits), where n is the bit length of the codeword. To illustrate the idea in the locality $n-1$ case, we also assume that the decoding algorithm is deterministic. We consider two cases and show that each case leads to a different tampering attack:

- **Case 1:** Given the first $n-1$ bits of the codeword, the codeword decodes to the same bit b, regardless of whether the final bit is 0 or 1. In this case, the tampering function contains a hardwired valid codeword encoding 0 and a valid codeword encoding 1. The tampering function derives the bit b, given only the first $n-1$ bits (since the decoded bit b is independent of the final bit) and replaces the codeword with the hardwired encoding of $1-b$.
- **Case 2:** Given the first $n-1$ bits of the codeword, the codeword decodes to 0 if the final bit is set to b and decodes to 1 if the final bit is set to $1-b$. In this case, the tampering function just flips the final bit, causing the decoding to flip.

The key observation is that we can extend the attacks for Cases 1 and 2 above to tampering functions of output locality $n - \log(1/(4\epsilon))$. We will sketch the special case corresponding to extending to $\epsilon = \frac{1}{4n}$ (and locality $(n - \log(n))$), to rule out non-malleable codes with negligible error. Case 1 now corresponds to the case that, for a randomly generated codeword, when the first $n - \log(n)$ bits of the codeword are fixed and the remaining $\log(n)$ bits are set at random, the decoded value *remains the same* with probability at least $1/2 + 1/(4n)$ In this case, the tampering function gets the first $n - \log(n)$ bits, randomly sets the final $\log(n)$ bits and decodes to obtain a bit b. Then, the tampering function succeeds in flipping the encoding with probability $1/2 + 1/(4n)$ by replacing the codeword with the hardwired encoding of $1 - b$.

Case 2 now corresponds to the case that for a randomly generated codeword, when the first $n - \log(n)$ bits of the codeword are fixed and the remaining $\log(n)$ bits are set at random, the decoded value *flips* with probability at least $1/2 - 1/(4n)$. Note that the decoded value *never flips* when the randomly chosen $\log(n)$ bits happen to be the same as the original value, which occurs with probability $1/n$. Thus, if the final $\log(n)$ bits are chosen at random, conditioned on being different from the original value, then the decoded value must flip with probability at least $\frac{1/2 - 1/(4n)}{1 - 1/n} \geq 1/2 + 1/(4n)$. In this case, the tampering function ignores the first part of the codeword and simply sets the final $\log(n)$ bits at random, *conditioned on the value being different from the original value*. Then, the tampering function succeeds in flipping the value of the encoding with probability at least $1/2 + 1/(4n)$.

Our final argument for $n - \log(1/(4\epsilon))$-locality holds even for *randomized* decoding.

1.3.4 Impossibility of Black-Box Security Reductions

We begin by describing our proof showing the impossibility of a black-box, security-parameter preserving reduction, from NMC against the tampering class NC^1, to a distributional problem that is hard for NC^1. The proof for approximately security parameter preserving reductions is essentially the same, and so we subsequently describe the extension to impossibility of a black-box, *non*-security-parameter preserving reduction, from non-malleable codes against the tampering class NC, to a distributional problem that is hard for NC.

Our proof proceeds via the meta-reduction technique. Specifically, consider a black-box reduction R, reducing the security of a single-bit non-malleable code against NC^1 to a distributional problem that is hard for NC^1. The form that this reduction takes, is that it submits codewords c to the tampering function f and gets back (tampered) codewords y as responses. The main idea is to begin with a tampering function f, which is not in NC^1. This tampering function receives a codeword c, decodes it to obtain the bit b and then submits a randomly generated encoding of the bit $1-b$. In the proof, we assume the existence of a reduction R such that R^f breaks the underlying distributional problem (this follows from the definition of a black-box reduction). We then switch from f to a tampering function f' that *is* in NC^1, which behaves as follows: Upon receiving a codeword c, f simply responds with a (hardcoded) random codeword c' that encodes a random bit, independent of the bit that is obtained when the decoding algorithm is applied to c. This switch is desirable, since then $R^{f'}$ will be in NC^1 (note that we are guaranteed that $R^{f'}$ is in NC^1, since one of the properties of R is that whenever the tampering function f' is in NC^1, then $R^{f'}$ must also be in NC^1). It remains, however, to show that $R^{f'}$ succeeds in breaking the underlying distributional problem, which then implies that the underlying distributional problem is not hard for NC^1. In order to ensure this, we use a hybrid argument, where responses to queries from R are switched one by one, from responses according to f to responses according to f'. In each step, we must show that the reduction remains successful in breaking the underlying distributional problem. Importantly, in the i-th hybrid, the first $i-1$ responses are answered according to f, the i-th response and on are answered according to f'. Since R is in NC^1, we argue that if R can distinguish the $(i-1)$-st and i-th hybrids, then we obtain a *tampering attack in* NC^1 *on the non-malleable code*. To do this, we construct a tampering function that hardwires the input to R, the transcript (queries and responses) and entire state of R for the first $i-1$ queries made from R to f, the i-th query along with the value b that it decodes to, and the responses to the queries $i+1$ and on. Then, given an input codeword c', the tampering function inserts this value as the response to the i-th query, runs the reduction R from this point on (given the state of R at the point of the response to the i-th query) and responds with the random hardwired queries upon any future queries from R. If R distinguishes between Hybrids $i-1$ and i, then the above yields a distinguisher between randomly generated encodings of the bit b, versus randomly generated encodings of a random bit. It is not hard to see that such a distinguisher immediately yields a tampering attack, since it can be used to predict the underlying encoded value and the tampering attack can then replace the codeword with an encoding of a bit which is the opposite of the predicted bit.

In the above, note that it is crucial that the reduction is security parameter preserving. Indeed, if R queries codewords c' that are very short (say length $\log^2(n)$) then we can no longer use R to obtain a valid tampering function against the non-malleable code. This is because R has size $\mathrm{poly}(n)$ and depth $\log(n)$, which is not in NC^1 relative to input length $\log^2(n)$. To deal with this problem, we take advantage of the fact that R must be successful even for tampering functions f that work only for very sparse input lengths $\{1, 2, 2^2, 2^{2^2}, \ldots\}$.

In this way, we can essentially guarantee that the reduction queries at most a single input length ℓ which is greater than $\log(n)$ and at most $\text{poly}(n)$. We now consider two cases: Either for this input length ℓ it is the case that NC circuits can distinguish encodings of 0 and 1 with probability at least $3/4$, or for this input length ℓ it is the case that NC circuits can distinguish encodings of 0 and 1 with probability at most $1 - 1/\text{poly}(n)$. If we are in the first case, then we can actually honestly run the attack using a NC circuit (in this case we just use the distinguisher to guess the value of the encoding and succeed with probability $3/4$). If we are in the second case, then we can use Impagliazzo's Hard Core Set [55] to find a set of encodings such that a NC circuit can distinguish random encodings of 0 and 1 from this set with probability at most $1/2 + 1/\text{poly}(n)$. In this case, we modify the tampering function to hardcode random encodings *from the hard core set* and return these in response to the queries from R. Note that to obtain contradiction to the security of the constructed non-malleable code, we now require that when the reduction R is composed with any tampering circuit in NC, then the composed circuit is still in NC. This property holds for NC, but not NC^1, which is why our result on ruling out non-security preserving reductions holds only for NC.

1.4 Related Work

Non-Malleable Codes

Non-malleable codes (NMC) were introduced in the seminal work of Dziembowski, Pietrzak and Wichs [43]. In the same paper they pointed out the simple impossibility result for NMC for all polynomial tampering functions. Since then NMC have been studied in the information-theoretic as well as computational settings. Liu and Lysyanskaya [64] studied the split-state classes of tampering functions and constructed computationally secure NMC for split-state tampering. A long line of work followed in both the computational [2] as well as information theoretic setting with a series of advances – reduced number of states, improved rate, or adding desirable features to the scheme [42, 4, 31, 3, 8, 2, 26, 58, 62, 63, 7]. Recently efficient NMC have been constructed for tampering function classes other than split-state tampering [17, 9, 29, 45, 18, 15, 16, 19, 32] in both the computational and information-theoretic setting. Additionally, [43, 33, 48] present various inefficient, existential or randomized constructions for more general classes of tampering functions. These results are sometimes presented as efficient constructions in a random-oracle or CRS model. Other works on non-malleable codes include [46, 34, 24, 6, 57, 40, 47, 3, 25, 23, 60, 38, 5, 39, 59, 65, 61, 44, 27, 30, 68, 35].

Bounds on Non-Malleable Codes

Surprisingly, understanding the limitations and bounds on NMC has received relatively less attention. While there have been a few previous works exploring the lower and upper bounds on NMC and its variants [43, 33, 23, 38, 37], most of the effort has been focused on understanding and/or improving the bounds on the rates of NMC [2, 9, 8, 58, 63, 35]

Perhaps the closest to this work are the results of [33, 38, 37]. Cheragachi and Guruswami [33] studied the "capacity" of non-malleable codes in order to understand the optimal bounds on the efficiency of non-malleable codes. They showed that information theoretically secure efficient NMC exist for tampering families $\mathcal{F}$ of size $|\mathcal{F}|$ if $\text{loglog}|\mathcal{F}| \leq \alpha n$ for $0 \leq \alpha < 1$, moreover these NMC have optimal rate of $1 - \alpha$ with error $\varepsilon \in O(1/\mathsf{poly}(n))$. Dachman-Soled, Kulkarni, and Shahverdi [38] studied the bounds on the locality of locally decodable and updatable NMC. They showed that for any locally decodable and updatable NMC which allows rewind attacks, the locality parameter of the scheme must be $\omega(1)$, and

gave an improved version of [40] construction to match the lower bound in computational setting. Recently, Dachman-Soled and Kulkarni [37] studied the bounds on continuous non-malleable codes (CNMC), and showed that 2-split-state CNMC cannot be constructed from any falsifiable assumption without CRS. They also gave a construction of 2-split-state CNMC from injective one-way functions in CRS model. Faust et al. [46] showed the impossibility of constructing information-theoretically secure 2-split-state CNMC.

Black-Box Separations

Impagliazzo and Rudich [56] showed the impossibility of black-box reductions from key agreement to one-way function. Their oracle separation technique subsequently led to sequence of works, ruling out black-box reductions between different primitives. Notable examples are [71] separating collision resistant hash functions from one way functions, and [53] ruling out oblivious transfer from public key encryption. The meta-reduction technique (cf. [36, 66, 51, 49, 67, 52, 1, 70, 20, 50]) has been used for ruling out larger classes of reductions – where the construction is arbitrary (non-black-box), but the reduction uses the adversary in a black-box manner. The meta-reduction technique is often used to provide evidence that construction of a cryptographic primitive is impossible under "standard assumptions" (e.g. falsifiable or non-interactive assumptions).

2 Preliminaries

2.1 Notation

For any positive integer n, $[n] := \{1, \ldots, n\}$. For a vector $x \in \chi$ of length n, we denote its *hamming weight* by $\| x \|_0 := |\{x_i : x_i \neq 0 \text{ for } i \in [n]\}|$, where $|S|$ is the cardinality of set S, and x_i denotes the i-th element of x. For $x, y \in \{0,1\}^n$ define their distance to be $d(x,y) := \| x - y \|_0$. (I.e. x and y are ε-far if $d(x,y) \geq \varepsilon$.) We denote the *statistical distance* between two random variables, X and Y, over a domain S to be $\Delta(X,Y) := 1/2 \sum_{s \in S} |\Pr[X = s] - \Pr[Y = s]|$, where $|\cdot|$ denotes the absolute value. We say X and Y are ε-close, denoted by $X \approx_\varepsilon Y$, if $\Delta(X,Y) \leq \varepsilon$.

2.2 Non-Malleable Codes

▶ **Definition 1** (Coding Scheme [43]). *A* Coding scheme, (E, D), *consists of a (possibly randomized) encoding function* $\mathsf{E} : \{0,1\}^k \to \{0,1\}^n$ *and a deterministic decoding function* $\mathsf{D} : \{0,1\}^n \to \{0,1\}^k \cup \{\perp\}$ *such that* $\forall m \in \{0,1\}^k, \Pr[\mathsf{D}(\mathsf{E}(m)) = m] = 1$ *(over randomness of* E*).*

We define the distance of a *randomized* coding scheme by considering the minimum distance of all codes formed as follows: for each message $x \in \{0,1\}^k$ choosing an arbitrary codeword corresponding to that message, $c_x \in \{\mathsf{E}(x;r)\}_{r \in \{0,1\}^*}$. We take the distance of the randomized encoding scheme to be the maximum of all such minimum distances (i.e. the distance of the best sub-code).

▶ **Definition 2** (Distance of a Coding Scheme). *The* distance *of a (randomized) coding scheme,* (E, D)*, is*

$$\max_{\substack{S \subset \{c = \mathsf{E}(x;r) : x \in \{0,1\}^k, r \in \{0,1\}^*\}: \\ \forall x \in \{0,1\}^k, \exists c_x \in S : \Pr[\mathsf{D}(c_x) = x] > 1/2}} \min_{\substack{c_x, c_y \in S: \\ x \neq y \in \{0,1\}^k}} \|c_x - c_y\|_0$$

Note that this definition can be extended to arbitrary alphabets. Moreover, it is clear that the minimum distance any coding scheme with K messages and codeword space Σ^n is upper bounded by the maximum of the traditional notion of minimum distance in (non-randomized) codes with the same parameters: the minimum distance between codewords from a code (over Σ^n with K distinct code words).

▶ **Definition 3** (ε-Non-malleability [43]). *Let $\mathcal{F}$ be some family of functions. For each function $f \in \mathcal{F}$, and $m \in \{0,1\}^k$, define the tampering experiment:*

$$\mathbf{Tamper}_m^f \stackrel{\text{def}}{=} \left\{ \begin{array}{c} c \leftarrow \mathsf{E}(m), \tilde{c} := f(c), \tilde{m} := \mathsf{D}(\tilde{c}). \\ \textit{Output}: \ \tilde{m}. \end{array} \right\},$$

where the randomness of the experiment comes from E. *We say a coding scheme (E, D) is ε-non-malleable with respect to $\mathcal{F}$ if for each $f \in \mathcal{F}$, there exists a distribution D^f over $\{0,1\}^k \cup \{\mathsf{same}^*, \perp\}$ such that for every message $m \in \{0,1\}^k$, we have*

$$\mathbf{Tamper}_m^f \approx_\varepsilon \left\{ \begin{array}{c} \tilde{m} \leftarrow D^f. \\ \textit{Output}: m \textit{ if } \tilde{m} = \mathsf{same}^*; \\ \textit{otherwise } \tilde{m}. \end{array} \right\}$$

Here the indistinguishability can be either statistical or computational.

▶ **Lemma 4** (Lemma 2 [42]). *Let (E, D) be a coding scheme with $\mathsf{E} : \{0,1\} \to \mathcal{X}$ and $\mathsf{D} : \mathcal{X} \to \{0,1\}$. Let $\mathcal{F}$ be a set of functions $f : \mathcal{X} \to \mathcal{X}$. Then (E, D) is ε-non-malleable with respect to $\mathcal{F}$ if and only if for every $f \in \mathcal{F}$,*

$$\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b] \leq \frac{1}{2} + \varepsilon,$$

where the probability is over the uniform choice of b and the randomness of E.

▶ **Definition 5** (ε-Malleable Code). *Let (E, D) be a coding scheme with $\mathsf{E} : \{0,1\} \to \mathcal{X}$ and $\mathsf{D} : \mathcal{X} \to \{0,1\}$. Let $\mathcal{F}$ be a set of functions $f : \mathcal{X} \to \mathcal{X}$. Then (E, D) is ε-malleable with respect to $\mathcal{F}$, if $\exists f \in \mathcal{F}$ such that,*

$$\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b] \geq \frac{1}{2} + \varepsilon,$$

where the probability is over the uniform choice of b and the randomness of E.

2.3 Input/Output Local Functions

We next define input and output local functions. In input local functions, each input bit can affect a bounded number of output bits. In output local functions, each output bit is affected by a bounded number of input bits. Loosely speaking, an input bit x_i affects the output bit y_j if for any boolean circuit computing f, there is a path in the underlying DAG from x_i to y_j. The formal definitions are below, and our notation follows that of [12].

▶ **Definition 6** ([17]). *We say that a bit x_i* affects *the boolean function f, if $\exists \{x_1, x_2, \cdots x_{i-1}, x_{i+1}, \cdots x_n\} \in \{0,1\}^{n-1}$ such that, $f(x_1, x_2, \cdots x_{i-1}, 0, x_{i+1}, \cdots x_n) \neq f(x_1, x_2, \cdots x_{i-1}, 1, x_{i+1}, \cdots x_n)$.*

Given a function $f = (f_1, \ldots, f_n)$ (where each f_j is a boolean function), we say that input bit x_i affects *output bit y_j, or that output bit y_j* depends *on input bit x_i, if x_i affects f_j.*

▶ **Definition 7** (Input Locality [17]). *A function $f : \{0,1\}^n \to \{0,1\}^n$ is said to have* input locality ℓ *if every input bit f_i is affects at most ℓ output bits.*

▶ **Definition 8** (Output Locality [17]). *A function $f : \{0,1\}^n \to \{0,1\}^n$ is said to have* output locality m *if every output bit f_i is dependent on at most m input bits.*

▶ **Definition 9** (Input Local Functions [12]). *A function $f : \{0,1\}^n \to \{0,1\}^n$ is said to be* ℓ-input local, $f \in \text{Local}_\ell$, *if it has input locality ℓ.*

▶ **Definition 10** (Output Local Functions [12]). *A function $f : \{0,1\}^n \to \{0,1\}^n$ is said to be* m-output local, $f \in \text{Local}^m$, *if it has output locality m.*

Recall that NC^1 is the class of functions where each output bit can be computed by a efficiently and uniformly generated $\text{poly}(n)$ size boolean circuit with $O(\log n)$ depth and constant fan-in, where n is the input size. NC is the class of functions where each output is computed by a uniformly and efficiently generated $\text{poly}\log(n)$ depth $\text{poly}(n)$ size circuit. $\mathsf{nu}-\mathsf{NC}$ is the class of functions computed by a $\text{poly}\log(n)$ depth $\text{poly}(n)$ size circuit.

▶ **Definition 11** (Pseudorandom Generator [41]). *Let $n, n' \in \mathbb{N}$ such that $n' > n$, and let $\mathsf{PRG} = \{\mathsf{prg}_n : \{0,1\}^n \to \{0,1\}^{n'}\}$ be a family of deterministic functions which can be computed in computational class $\mathcal{C}_1$. We say PRG is a $\mathcal{C}_1$-*pseudorandom generator for $\mathcal{C}_2$ *if for any $D := \{D_n : \{0,1\}^{n'} \to \{0,1\}\} \in \mathcal{C}_2$:*

$$|\Pr[D_n(\mathsf{prg}_n(x)) = 1] - \Pr[D_n(r) = 1]| \leq \mathsf{negl}(n),$$

where $x \leftarrow \{0,1\}^n$ and $r \leftarrow \{0,1\}^{n'}$ are sampled uniform randomly.

For class $\mathcal{C}$, if $\mathcal{C}_1 = \mathcal{C}_2 = \mathcal{C}$ then we simply call it $\mathcal{C}$-pseudorandom generator.

2.4 Distributional Problems

▶ **Definition 12** (Distributional Problem). *A* distributional problem *is a decision problem along with ensembles $(\Psi = \{\Psi_n\}_{n=1}^\infty, L = \{L_n\}_{n=1}^\infty)$ for $n \in \mathbb{N}$, where Ψ_n is probability distribution over $\{0,1\}^n$. The decision problem is to decide whether $s \in L_n$ where, $s \leftarrow \Psi_n$. For a string $s \in \{0,1\}^n$, we define $L(s)$ to output 1, if and only if $s \in L_n$.*

Note that length of s need not be n.

We say distributional problem $(\Psi = \{\Psi_n\}_{n=1}^\infty, L = \{L_n\}_{n=1}^\infty)$ is in P if $L \in \mathsf{P}$. We say it is efficiently samplable if there is a randomized poly-time algorithm that on input 1^n samples Ψ_n.

▶ **Definition 13** ($\varepsilon(n)$-Hard Distributional Problem). *Let $(\Psi = \{\Psi_n\}_{n=1}^\infty, L = \{L_n\}_{n=1}^\infty)$ be a distributional problem, we say that (Ψ, L) is $\varepsilon(n)$-hard for family of boolean circuits $\mathcal{C} = \{C_n\}_{n=1}^\infty$, if and only if for every circuit $C_n \in \mathcal{C}$,*

$$\Pr_{x \leftarrow \Psi_n}[C_n(x) = L_n(x)] \leq \frac{1}{2} + \varepsilon(n)$$

▶ **Definition 14** ($\varepsilon(n)$-Easy Distributional Problem). *Let $(\Psi = \{\Psi_n\}_{n=1}^\infty, L = \{L_n\}_{n=1}^\infty)$ be a distributional problem, we say that (Ψ, L) is $\varepsilon(n)$-easy for family of boolean circuits $\mathcal{C} = \{C_n\}_{n=1}^\infty$, if there exists some circuit $C_n \in \mathcal{C}$,*

$$\Pr_{x \leftarrow \Psi_n}[C_n(x) = L_n(x)] \geq \frac{1}{2} + \varepsilon(n)$$

2.5 Hardness of Boolean Functions and Composition

▶ **Definition 15** (δ-hardness of boolean function). *Let $f : \{0,1\}^n \to \{0,1\}$ be a boolean function, and U_n be uniform distribution over $\{0,1\}^n$. Also let $0 < \delta < \frac{1}{2}$, and $n \leq s \leq \frac{2^n}{n}$. We say f is* δ-hard for size s *if for any boolean circuits C of size at most s*

$$\Pr_{x \leftarrow U_n}[C(x) = f(x)] \leq 1 - \delta.$$

▶ **Definition 16** (ε-hard-core function). *Let $f : \{0,1\}^n \to \{0,1\}$ be a boolean function, and D_S be a distribution over $\{0,1\}^n$ induced by the characteristic function of set $S \subset \{0,1\}^n$*[4]*. We call f* ε-hard-core *on S for size s (where $n \leq s \leq \frac{2^n}{n}$), if for any boolean circuits C of size at most s*

$$\Pr_{x \leftarrow D_S}[C(x) = f(x)] < \frac{1}{2} \cdot (1 + \varepsilon).$$

We also present the following theorem from [55].

▶ **Theorem 17** (Theorem 1 [55]). *Let $f : \{0,1\}^n \to \{0,1\}$ be boolean function that δ-hard for size s. Also, let $\varepsilon > 0$. Then $\exists$ set $S \subseteq \{0,1\}^n$ and constant c, such that $|S| \geq \delta \cdot 2^n$ and f is ε-hard-core on S for circuits of size $s' \leq c \cdot \varepsilon^2 \cdot \delta^2 \cdot s$.*

▶ **Definition 18** (Hard Core Set (HCS) Amenable). *We say that $\mathcal{F} = \{\mathcal{F}_n\}_{n=1}^{\infty}$ is HCS-Amenable if for any polynomial $p(\cdot)$, it holds that if $C_1, \ldots, C_{p(n)} \in \mathcal{F}_n$ then* $\mathsf{MAJ}(C_1, \ldots, C_{p(n)}) \in \mathcal{F}_n$.

We now present definitions of functionalities Unroll and Replace which will then allow us to define the appropriate notions of composition and closure for function classes.

▶ **Definition 19** (Unroll functionality.). *Let $F := \{f_n\}_{n=1}^{\infty} \in \mathcal{F}$, where $f_n : \{0,1\}^n \to \{0,1\}$ and $G = \{g_m\}_{m=1}^{\infty} \in \mathcal{G}$, where $g_m : \{0,1\}^m \to \{0,1\}^m$, be function families. Also let t, p be polynomials. Let $m \in \mathrm{poly}(n)$. Let F^G denote families functions $f_n : \{0,1\}^n \to \{0,1\} \in F$ which contains at most $t(n)$ oracle gates computing $g_m : \{0,1\}^m \to \{0,1\}^m \in G$ and get string of length $p(n)$ as non-uniform advice. On an n-bit input, consider the DAG whose left side consists of the circuit of f_n and whose right side consists of circuits $g_{n_1}, \ldots, g_{n_{t(n)}}$. The values of wires going from the left to the right correspond to (a topological ordering of) the oracle queries $x_1, \ldots, x_{t(n)}$ of lengths $n_1, \ldots, n_{t(n)}$, made in each of the $t(n)$ queries. For $i \in [t(n)]$, circuit g_{n_i} takes as input x_i and returns y_i. The values of wires going from the right to the left correspond to the responses $y_1, \ldots, y_{t(n)}$. We say that this DAG, denoted* $\mathsf{Unroll}(F^G)$, *is an unrolling of $F^G(x)$.*

▶ **Definition 20** (Replace Functionality.). *Consider replacing each g_{n_i}, $i \in [t(n)]$, in* $\mathsf{Unroll}(F^G)$ *with a circuit g'_{n_i} that takes input $(x_1, \ldots, x_i)$ and produces output y_i. This is denoted by* $\mathsf{Replace}(\mathsf{Unroll}(F^G), g'_{n_1}, \ldots, g'_{n_{t(n)}})$.

▶ **Definition 21** ($(\mathcal{G}, t, \ell, u)$-closure of $\mathcal{F}$). *Let $F := \{f_n\}_{n=1}^{\infty} \in \mathcal{F}$, where $f_n : \{0,1\}^n \to \{0,1\}$ and $G = \{g_m\}_{m=1}^{\infty} \in \mathcal{G}$, where $g_m : \{0,1\}^m \to \{0,1\}^m$, be function families. Also let t, ℓ, u be polynomials, and $\ell(n) \leq m \leq u(n)$. Let ${f_n}^{g_m}$ denote function $f_n : \{0,1\}^n \to \{0,1\}$ which has access to the output of $g_m : \{0,1\}^m \to \{0,1\}^m$ on at most $t(n)$ inputs of its choice.*

We say that $\mathcal{F}$ is $(\mathcal{G}, t, \ell, u)$-closed under compositions if for every $F \in \mathcal{F}$ such that for all $G \in \mathcal{G}$, $\mathsf{Unroll}(F^G) \in \mathcal{F}$, *we have that for all $G' \in \mathcal{G}$ and all $g'_{n_1}, \ldots, g'_{n_{t(n)}} \in G'$,* $\mathsf{Replace}(\mathsf{Unroll}(F^G), g'_{n_1}, \ldots, g'_{n_{t(n)}}) \in \mathcal{F}$.

[4] Characteristic function of set S outputs 1 if the input to the function is in set S.

▶ **Definition 22** ($(\mathcal{G},t)$-closure of $\mathcal{F}$ under Strong Composition)**.** *Let $F := \{f_n\}_{n=1}^{\infty} \in \mathcal{F}$, where $f_n : \{0,1\}^n \to \{0,1\}$ and $G = \{g_m\}_{m=1}^{\infty} \in \mathcal{G}$, where $g_m : \{0,1\}^m \to \{0,1\}^m$, be function families. Also let t, p be polynomials. Let $m \in \text{poly}(n)$. Let F^G denote families functions $f_n : \{0,1\}^n \to \{0,1\} \in F$ which contains at most $t(n)$ oracle gates computing $g_m : \{0,1\}^m \to \{0,1\}^m \in G$*

We say that $\mathcal{F}$ is $(\mathcal{G},t)$-closed under compositions if for every $F \in \mathcal{F}$ we have that for all $G, G' \in \mathcal{G}$ and all $g'_1, \ldots, g'_{t(n)} \in G'$, $\mathsf{Replace}(\mathsf{Unroll}(F^G), g'_1, \ldots, g'_{t(n)}) \in \mathcal{F}$.

2.6 Black Box Reductions

▶ **Definition 23** (Black-Box-Reduction)**.** *We say R is an (F, ϵ, δ)-*black-box reduction from a (single bit) non-malleable code, $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^{\infty}$, to a distributional problem, $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^{\infty}$, *if the following hold:*

1. *For every set of circuits $\{f_n\}_{n=1}^{\infty}$ parameterized by input length n such that f_n achieves $\epsilon(n)$-malleability, for non-negligible ϵ, i.e.*

$$\Pr_{b \xleftarrow{u} \{0,1\}}[\mathsf{D}_n(f_n(\mathsf{E}_n(b))) = 1 - b] > \frac{1}{2} + \epsilon(n),$$

then R^f solves $\{(\Psi_n, L_n)\}_{n=1}^{\infty}$ with advantage $\delta(n)$, where δ is non-negligible. I.e.

$$\Pr_{x \leftarrow \Psi_n}[L_n(x) = R^{\{f_k\}_{k=1}^{\infty}}(x)] > \frac{1}{2} + \delta(n).$$

2. *If $\{f_n\}_{n=1}^{\infty} \in F$, then $R^{\{f_k\}_{k=1}^{\infty}}(x) \in F$.*

We say a reduction R is length-preserving *if R, on input of length n is only allowed to make queries to oracles with security parameter n. Namely,*

$$\Pr_{x \leftarrow \Psi_n}[L_n(x) = R^{f_n}(x)] > \frac{1}{2} + \delta(n).$$

We say a reduction R is approximately length-preserving *if there are polynomials $p(\cdot), q(\cdot)$ such that R, on input of length n is only allowed to make queries to oracles with security parameter $k \in [p(n), q(n)]$. Namely,*

$$\Pr_{x \leftarrow \Psi_n}[L_n(x) = R^{\{f_k\}_{k=p(n)}^{q(n)}}(x)] > \frac{1}{2} + \delta(n).$$

We say a reduction is in NC^1 if it can be written as a family of circuits of $O(\log n)$-depth, $\text{poly}(n)$-size.

3 2-Message NMC against $d-1$ arbitrary errors

In this section, we show that when the message space has size 2 (i.e. single bit messages), non-malleable codes are possible against $d-1$ arbitrary errors, whereas error correcting codes can tolerate at most $(d-1)/2$ arbitrary errors. In the next section, we will show that if the message space is increased to 3 or more, then non-malleable codes are impossible even against $d/2$ errors.

The construction is simply a repetition code (E, D). On input a bit b, E outputs the string b^d (the bit b repeated d times). On input a string $b_1, \ldots, b_d$, D outputs 1 if there is some $i \in [d]$ such that $b_i = 1$. Otherwise, D outputs 0. Note that this code has distance d.

We next prove that (E, D) is a 0-non-malleable code (i.e. the two distributions in the security definition for non-malleable codes–see Definition 3–are identical). Applying Lemma 4, it is sufficient to show that for every tampering function f that modifies at most $d-1$ symbols,

$$\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b] \leq \frac{1}{2},$$

We will use the fact that for the decode algorithm defined above,

$$\Pr[\mathsf{D}(f(\mathsf{E}(1))) = 0] = 0,$$

since a tampering function that modifies at most $d-1$ bits cannot flip a 1 codeword to a tampered codeword that decodes to 0 under D.

Therefore,

$$\begin{aligned}\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b] &= \frac{1}{2}\Pr[\mathsf{D}(f(\mathsf{E}(0))) = 1] + \frac{1}{2}\Pr[\mathsf{D}(f(\mathsf{E}(1))) = 0] \\ &= \frac{1}{2}\Pr[\mathsf{D}(f(\mathsf{E}(0))) = 1] \\ &\leq \frac{1}{2}.\end{aligned}$$

This completes the proof.

4 Unconditional Negative Results

In this section we demonstrate that non-malleable codes are impossible to construct for 3 different classes. The first impossibility result holds for message spaces of size greater than 2 (which is tight, given the result in Section 3), the second and third impossibility results hold even for a single bit.

4.1 Functions that Modify Half the Max Minimum Distance

Let (E, D) be a coding scheme with distance d. Define the class of functions $\mathcal{F}_{d/2-1} = \{f : f$ changes $< d/2$ codeword symbols $\}$. We know that ECC exist, and thus NMC also exist, for $\mathcal{F}_{d/2-1}$ (e.g. Reed Solomon Codes achieve this bound).

We now define the slightly larger class $\mathcal{F}_{d/2} = \{f : f$ changes $\leq d/2$ symbols$\}$. In Theorem 24 we show that even inefficient NMC do not exist for $\mathcal{F}_{d/2}$. Recall that distance for randomized coding schemes is upper bounded by the notion of distance for (non-randomized) codes with the same message/codeword-space parameters. Specifically, for a set of codewords S, we define the distance of S ($\mathsf{dist}(S)$) as the minimum pairwise distance over all pairs of codewords in S. Let $\mathcal{S}$, be the set that consists of all sets S that contain exactly one codeword for each message in the message space. Then the distance of the code is defined as $\max_{S \in \mathcal{S}} \mathsf{dist}(S)$. Refer to definition 2 for formal definition of distance of coding scheme, presented earlier. Intuitively, we want that a code with distance d, ensures that any 2 codewords which are at least d distance apart decode to distinct messages. Therefore, first consider a set of codewords which contains at least one codeword corresponding to each message in the message space such that decoding that specific codeword returns the corresponding message with probability greater than 1/2. Now consider the minimum of pairwise distances for the codewords in this set (say d'). Note that, if the distance of the code is set to d', then for this particular set, we will ensures that any 2 codewords which are at least d' apart decode to distinct messages with high probability. Further, if we take the

maximum over all such distances d' corresponding to each set of codewords and call that value d as the distance of the code, then for any 2 codewords which are at least d apart decode to distinct messages with high probability.

▶ **Theorem 24.** *Let* (E, D) *be a coding scheme with message space of size greater than* 2*, alphabet* Σ *and distance* d*. Then, for any* $\epsilon > 0$*,* (E, D) *is not a* $\frac{1}{8} - \epsilon$*-NMC for* $\mathcal{F}_{d/2}$*.*

Proof. We begin with some notation Given $\alpha, \beta \in \Sigma^n$, we denote by $\|\alpha - \beta\|_0$ the number of positions $i \in [n]$ such that $\alpha_i \neq \beta_i$.

Let $(\mathsf{E} : U \to V, \mathsf{D} : V \to U)$ be a randomized encoding scheme, where $U \subseteq \Sigma^k, V \subseteq \Sigma^n$ and $|U| > 2$.

▷ Claim 25. $\exists x \in U$ such that $\forall c_x \in \mathsf{E}(x)$ there is a $z = z(c_x) \in V$:
1. $\|c_x - z\|_0 \leq \frac{d}{2}$
2. $\Pr[\mathsf{D}(z) \neq x] =\geq \frac{1}{2}$.

Assuming the claim, consider the following tampering function $f \in \mathcal{F}_{d/2}$. Let z_c be the z for each $c \in \mathsf{E}(x^*)$ guaranteed to exist for some $x^* \in U$ by the above claim.

$$f(c) := \begin{cases} z_c & \text{if } c \in \mathsf{E}(x^*) \\ c & \text{otherwise} \end{cases}$$

Let $\Pr_{c_{x^*} \leftarrow \mathsf{E}(x^*)}[\mathsf{D}(z(c_{x^*})) \neq x^*] = p \geq \frac{1}{2}$. Then, $\exists y^* \neq x^* \in U$ such that $\Pr_{c_{x^*} \leftarrow \mathsf{E}(x^*)}[\mathsf{D}(z(c_{x^*})) = y^*] \leq \frac{p}{|U|-1}$, but $\Pr[\mathsf{D}(f(\mathsf{E}(y^*))) = y^*] = 1$. This means that a distribution $D^f_{x^*}$ that exactly agrees with $\mathsf{D}(f(\mathsf{E}(\cdot)))$ on x^* must output same^* or x^* with probability $1-p$ and y^* with probability at most $\frac{p}{|U|-1}$. A distribution $D^f_{y^*}$ that exactly agrees with $\mathsf{D}(f(\mathsf{E}(\cdot)))$ on y^* must output same^* or y^* with probability 1. Thus, any distribution D^f can only agree with $\mathsf{D}(f(\mathsf{E}(\cdot)))$ for both x^* and y^* at most $(1-p) + \frac{p}{|U|-1} \leq 3/4$ fraction of the time (and must have statistical distance at least $1/8$ from one of them), since $p \geq 1/2$ and $|U| > 2$.

Next we prove the claim.

Proof. Suppose for the sake of contradiction that $\forall x \in U, \exists c_x \in \mathsf{E}(x)$ such that $\forall z \in V$ with $\|c_x - z\|_0 \leq \frac{d}{2}$ it is the case that $\Pr[\mathsf{D}(z) \neq x] < \frac{1}{2}$. Fix any such set of codewords corresponding to all messages $S = \{c_x : \forall z \in V \, \|c_x - z\|_0 \leq \frac{d}{2} \implies \Pr[\mathsf{D}(z) \neq x] < \frac{1}{2}\}_{x \in U}$. Note that the distance of S ($\min_{c_x \neq c_y \in S} \|c_x - c_y\|_0$) is at most d (by definition of the distance of a randomized code). Let $c_x \neq c_y \in U$ be two such codewords such that $\|c_x - c_y\| \leq d$. Then, $\exists z \in V$ such that $\|z - c_x\|_0 \leq d/2$ and $\|z - c_y\|_0 \leq d/2$. But then by assumption it follows that $\Pr[\mathsf{D}(z) = x] > \frac{1}{2}$ and $\Pr[\mathsf{D}(z) = y] > \frac{1}{2}$, which is a contradiction because $x \neq y$. ◁

◀

We observe that a randomized coding scheme with message space $\mathcal{M}$, codeword space $\mathcal{C}$ and distance d (as defined above for randomized coding schemes), implies a (possibly inefficient) error correcting code with the same message/codeword space that can correct up to $d/2 - 1$ errors. To see this, note that one can take the set $S \in \mathcal{S}$ (as in the definition of distance for randomized coding schemes) achieving the maximum $\mathsf{dist}(S)$. Since $S \subseteq \mathcal{C}$ contains exactly one codeword for each message in the message space, the set S itself comprises a code with message space $\mathcal{M}$, codeword space $\mathcal{C}$ and distance d. This, in turn, implies a (possibly inefficient) error correcting code with message space $\mathcal{M}$ and codeword space $\mathcal{C}$ that can correct up to $d/2 - 1$ errors. We thus obtain the following corollary:

▶ **Corollary 26.** *Fix a message space $\mathcal{M}$ and a codeword space $\mathcal{C}$. If the optimal (inefficient) error-correcting code for $(\mathcal{M}, \mathcal{C})$ can correct at most t errors, then there is no non-malleable code with message space $\mathcal{M}$ and codeword space $\mathcal{C}$ against tampering class $\mathcal{F}_{t+1}$.*

4.2 Input-Local Functions

We rule out non-malleable codes for *input*-local functions (see Section 2.3 for formal definition), where each input symbol affects ℓ output symbols and ℓ is the locality parameter. We show that even for $\ell = 1$, non-malleability is impossible to achieve. The specific tampering functions used in our proof fix all but one of the codeword symbols to constant values. So we can alternately view this result as building on the previous impossibility result: If one allows fixing codeword symbols to constants, then one cannot achieve non-malleability against functions where even a single output symbol's value depends on the input.

▶ **Theorem 27.** *Let (E, D) be a coding scheme with message space of at least 2 and alphabet Σ. Then, for any $\epsilon > 0$, (E, D) is not a $1/2 - \epsilon$-NMC for $Local_1$.*

Proof. Let $U \subseteq \{0,1\}^k$, $V \subseteq \{0,1\}^n$ where $|U| > 1$. Let $(\mathsf{E} : U \to V, \mathsf{D} : V \to U)$ be non-malleable code. Take $x \neq y \in U$. Consider $c_x = \mathsf{E}(x), c_y = \mathsf{E}(y)$ for some fixed randomness. By correctness $c_x \neq c_y$ and moreover, $\mathsf{D}(c_x) \neq \mathsf{D}(c_y)$. Also let $d := d(c_x, c_y)$ be the distance between c_x and c_y, note that $0 < d \leq n$. Consider $d+1$ codewords starting with, $c_0 = c_x, c_1, \ldots, c_d = c_y$ where $\forall i \in \{0, \ldots, d-1\}$, $d(c_i, c_{i+1}) = 1$. Notice that

$$\mathsf{D}(c_0) \neq \mathsf{D}(c_d) \implies \exists j \in \{0, \ldots, d-1\} : \mathsf{D}(c_j) \neq \mathsf{D}(c_{j+1}).$$

Let $x = \mathsf{D}(c_j)$ and let $y = \mathsf{D}(c_{j+1})$, where $x \neq y$. Now, consider the following $f \in \text{Local}_1$,

$$f(c) = \begin{cases} c_j & \text{if } c \in \mathsf{E}(y) \\ c_{j+1} & \text{otherwise} \end{cases}$$

(Note that all symbols except a single one are constant.) Because they have disjoint support, either $\mathsf{D}(f(\mathsf{E}(x)))$ or $\mathsf{D}(f(\mathsf{E}(y)))$ will be at least 1/2-far from any distribution D^f. ◀

4.3 Functions with Large Output Locality

A function $f : \{0,1\}^n \to \{0,1\}^n$ is $(n - \log(n))$-output-local if each output bit depends on at most $n - \log(n)$ input bits (see Section 2.3 for formal definition). The particular class $\mathcal{F}'$ that we use in our lower bound proof is a subclass of all $(n - \log(n))$-local tampering functions $\mathcal{F}$. Each $f \in \mathcal{F}'$ has the following structure: First, $f_1, \ldots, f_{n-\log(n)}$ (the functions that output the first $n - \log(n)$ bits) are all the same, except that two different bits from $\{0,1\}$ are hardcoded in each. Second, $f_{n-\log(n)+1}, \ldots, f_n$ are also the same, except that a different value from $\{0,1\}$ is hardcoded in each. Finally, the set of input bits upon which $f_1, \ldots, f_{n-\log(n)}$ depend and the set of input bits upon which $f_{n-\log(n)+1}, \ldots, f_n$ depend are fixed. Taken together, this means that the total number of functions f in $\mathcal{F}$ is at most $4^n \cdot 2^{2^{n-\log(n)}}$, so $\log\log|\mathcal{F}'| = n - \log(n)$. On the other hand, Dziembowski et al. [43] showed existence of a $1/n$-non-malleable code for any class $\mathcal{F}$ such that $\log\log|\mathcal{F}| \leq n - 2\log(n)$. Thus, our lower bound result is nearly tight matching the existential upper bound. In our theorem, we prove a more general statement:

▶ **Theorem 28.** *Let (E, D) be a coding scheme with $\mathsf{E} : \{0,1\} \to \{0,1\}^n$ and $\mathsf{D} : \{0,1\}^n \to \{0,1\}$. Let $\mathcal{F}$ be the class of $(n - \log(1/\epsilon) + 2)$-output- local functions, where $1/8 \geq \epsilon \geq 1/2^n$. Then (E, D) is ϵ-malleable with respect to $\mathcal{F}$.*

Note that the parameters discussed above can be obtained by setting $\epsilon = \frac{1}{4n}$.

Additionally, note that non-malleable codes whose decode function D may output values in $\{0, 1, \perp\}$ *imply* non-malleable codes whose decode function D may only output values in $\{0, 1\}$. Thus, ruling out the latter *implies* ruling out the former and only makes our result stronger.

Proof. Fix an arbitrary (E, D) with $\mathsf{E} : \{0,1\} \to \{0,1\}^n$ and $\mathsf{D} : \{0,1\}^n \to \{0,1\}$. Our analysis considers two cases and shows that for each case, there exists $f \in \mathcal{F}$ such that

$$\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b] \geq \frac{1}{2} + \epsilon.$$

By Definition 5, this is sufficient to prove Theorem 28.

We begin with some notation and the proceed to the case analysis. For codeword $c = c_1, \ldots, c_n$, let c^{top} (resp. c^{bot}) denote the first $n - \log(1/\epsilon) + 2$ bits (resp. last $\log(1/\epsilon) - 2$ bits) of c. I.e. $c^{\mathsf{top}} := c_1, \ldots, c_{n-\log(1/\epsilon)+2}$ ($c^{\mathsf{bot}} := c_{n-\log(1/\epsilon)+3}, \ldots, c_n$). For $t \in \mathbb{N}$, let S_t denote the set of all t-bit strings and let U_t denote the uniform distribution over t bits. Assume $n \geq 2$.

Case 1.

$$\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(c^{\mathsf{top}}||r) = b \mid c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}] \geq 1/2 + \epsilon.$$

Let $c^{*,0} = c_1^{*,0}, \ldots, c_n^{*,0}$ (resp. $c^{*,1} = c_1^{*,1}, \ldots, c_n^{*,1}$) be the lexicographically first string that decodes to 0 (resp. 1) under D (i.e. $\mathsf{D}(c^{*,0}) = 0$ and $\mathsf{D}(c^{*,1}) = 1$.

In this case we consider the following distribution over tampering circuits $f = f_1, \ldots, f_n$, where f_i outputs the i-th bit of f:

Sample $r \leftarrow U_{\log(1/\epsilon)-2}$, construct circuits f_i for each $i \in [n]$, which take input c^{top} and output c'_i. Each f_i does the following:

- Compute $d := \mathsf{D}(c^{\mathsf{top}}||r)$.
- Output $c'_i = c_i^{*,1-d}$.

We now analyze $\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b]$.

$$\begin{aligned}
\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1 - b] &= \Pr_{b \leftarrow \{0,1\}}[f(\mathsf{E}(b)) \text{ outputs } c^{*,1-b}] \\
&= \Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(c^{\mathsf{top}}||r) = b \mid c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}] \\
&\geq 1/2 + \epsilon,
\end{aligned}$$

where the two equalities follow from the definition of the tampering function f, and the inequality follows since we are in Case 1. This implies the ϵ-malleability of (E, D).

Case 2.

$$\Pr_{b \leftarrow \{0,1\}}[\mathsf{D}(c^{\mathsf{top}}||r) = 1 - b \mid c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}] \geq 1/2 - \epsilon.$$

In this case we consider the following distribution over tampering circuits $f = f_1, \ldots, f_n$, where f_i outputs the i-th bit of f:

The first $n - \log(1/\epsilon) + 2$ circuits $(f_1, \ldots, f_{n-\log(1/\epsilon)+2})$ simply compute the identity function: I.e. f_i for $i \in [n - \log(1/\epsilon) + 2]$ takes c_i as input and produces c_i as output.

We next describe the distribution over circuits f_i for $i \in \{n - \log(1/\epsilon) + 3, \ldots, n\}$. Sample $r' \leftarrow [1/(4\epsilon) - 1]$. Construct circuits f_i for each $i \in \{n - \log(1/\epsilon) + 3, \ldots, n\}$ that take input c^{bot} and produce output c'_i. Each f_i does the following:

- Let $r := r_{n-\log(1/\epsilon)+3}, \ldots, r_n$ be the r'-th lexicographic string in the set $S_{\log(1/\epsilon)-2} \setminus \{c^{\mathsf{bot}}\}$[5].
- Output $c'_i = r_i$.

We now analyze $\Pr_{b\leftarrow\{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1-b]$.
Since we are in Case 2 we have that:

$$\begin{aligned}
1/2-\epsilon &\leq \Pr_{b\leftarrow\{0,1\}}[\mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}] \\
&= \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} c^{\mathsf{bot}} = r \mid \\ c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \cdot \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} \mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid \\ c^{\mathsf{bot}} = r \wedge c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \\
&\quad + \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} c^{\mathsf{bot}} \neq r \mid \\ c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log n}\end{array}\right] \cdot \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} \mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid \\ c^{\mathsf{bot}} \neq r \wedge c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \\
&= \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} c^{\mathsf{bot}} = r \mid \\ c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \cdot 0 \\
&\quad + \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} c^{\mathsf{bot}} \neq r \mid \\ c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \cdot \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} \mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid \\ c^{\mathsf{bot}} \neq r \wedge c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \\
&= \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} c^{\mathsf{bot}} \neq r \mid \\ c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \cdot \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} \mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid \\ c^{\mathsf{bot}} \neq r \wedge c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] \\
&= (1-4\epsilon) \cdot \Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} \mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid \\ c^{\mathsf{bot}} \neq r \wedge c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right].
\end{aligned}$$

Note that

$$\Pr_{b\leftarrow\{0,1\}}\left[\begin{array}{c} \mathsf{D}(c^{\mathsf{top}}||r) = 1-b \mid \\ c^{\mathsf{bot}} \neq r \wedge c \leftarrow \mathsf{E}(b), r \leftarrow U_{\log(1/\epsilon)-2}\end{array}\right] = \Pr_{b\leftarrow\{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1-b].$$

Thus, we have that

$$1/2-\epsilon \leq (1-4\epsilon) \Pr_{b\leftarrow\{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1-b].$$

Since

$$\begin{aligned}
(1/2+\epsilon)\cdot(1-4\epsilon) &= 1/2+\epsilon-2\epsilon-4\epsilon^2 \\
&\leq 1/2-\epsilon,
\end{aligned}$$

we have that

$$\begin{aligned}
\Pr_{b\leftarrow\{0,1\}}[\mathsf{D}(f(\mathsf{E}(b))) = 1-b] &\geq \frac{1/2-\epsilon}{1-4\epsilon} \\
&\geq 1/2+\epsilon.
\end{aligned}$$

This implies the ϵ-malleability of (E,D). ◀

5 On NMC via BB Reductions

For the formal definition of a (F,ϵ,δ)-*black-box reduction from a (single bit) non-malleable code,* $(\mathsf{E},\mathsf{D}) = \{(\mathsf{E}_n,\mathsf{D}_n)\}_{n=1}^{\infty}$*, to a distributional problem,* $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^{\infty}$, see Definition 23 in Section 2.6.

[5] Recall that, $t \in \mathbb{N}$, let S_t denote the set of all t-bit strings and let U_t denote the uniform distribution over t bits.

A crucial component of our impossibility result will be a lookup circuit that responds to queries submitted by the reduction with hardwired responses. However, we need the lookup circuit to maintain consistency: If the reduction queries the same query multiple times, the same response should be given each time. Such a lookup circuit is trivial to implement with polynomial-size circuits. However, in our case, we require that this lookup circuit is implementable in NC^1. In the following, we first formally define such a lookup circuit and then prove that it is implementable in NC^1.

▶ **Definition 29** (Look-Up Circuit.)**.** *A $(\ell(n), p(n))$ lookup circuit consists of $\ell(n)$ hardwired values of length $p(n)$ bits, denoted $y_1, \ldots, y_{\ell(n)}$. The lookup circuit receives as input $x_1, \ldots, x_{\ell(n)}$, where each x_i has length $p(n)$ bits. The circuit outputs $\ell(n)$ number of $p(n)$-bit strings: $y_{i_1}, \ldots, y_{i_{\ell(n)}}$, where for $j \in [\ell(n)]$, i_j is set to the first index $k \in [\ell(n)]$ such that $x_j = x_k$. For example, on input $x_1, x_2, x_3, x_4, \ldots$, where $x_1 = x_3$ and $x_2 = x_4$, the circuit outputs y_1, y_2, y_1, y_2.*

▶ **Proposition 30.** *For $p(n)$, $\ell(n) = O(n^c)$ for some fixed constant c, there exist polynomial size look-up circuits of depth $O(\log n)$.*

Sketch. The inputs, $x_1, \ldots, x_{\ell-1}$, can be put in sorted order via a circuit of size $O(n^c \log n)$ and depth $O(\log n)$ [10]. Then each sorted x_i can determine if it is the first of that value (if $x_1, \ldots, x_{\ell-1}$ are in sorted order then x_j is determining that there does not exist $x_i = x_j$ such that $i < j$), by comparing only to one neighboring value. This can be done in parallel. Finally, compare x_ℓ to all x_i that pass this test in parallel. If there is such an x_i such that $x_i = x_\ell$, the circuit will output y_i. Otherwise, the circuit will output y_ℓ. ◀

We now present the central technical lemma of the section.

▶ **Lemma 31.** *Assume that $\mathcal{F}$ is $(\mathcal{F}, t, p(n), p(n))$-closed under composition (see Definition 21), and contains $(t(n), p(n))$ look-up circuits for polynomials $t(\cdot)$, $p(\cdot)$.[6] If there is an $(\mathcal{F}, 1/2, \delta(n))$-black-box-reduction making $t(n)$ security parameter-preserving queries from a (single bit) non-malleable code for $\mathcal{F}$, $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^{\infty}$, to a distributional problem, $(\Psi, L) = \{(= \Psi_n, L_n)\}_{n=1}^{\infty}$, then one of the following must hold:*

1. *(E, D) is $\frac{\delta(n)}{2t(n)}$-malleable by $\mathcal{F}$.*
2. *(Ψ, L) is $(\delta(n)/2)$-easy for $\mathcal{F}$.*

Moreover, if (E, D) is efficient, then it suffices that $\mathcal{F}$ contains such look-up circuits generated in uniform polynomial time.

Proof. Let R be such a security parameter-preserving $(\mathcal{F}, 1/2, \delta(n)$-reduction, for a non-malleable code (E, D) and distributional problem (Ψ, L). Moreover, for security parameter n, let $p(n)$ be the length of the codeword generated by E, where $p(\cdot)$ is a polynomial.

Consider the following tampering functions $\{f_{p(n)}\}_{p(n)}$ whose behavior on a given codeword c is defined as follows (where H is a random function $H : \{0,1\}^{p(n)} \to \{0,1\}^*$ and $H(c)$ is the randomness used by encoding algorithm):

$$f_{p(n)}(c) := \begin{cases} \mathsf{E}_n(1; H(c)) & \text{if } \mathsf{D}_n(c) = 0 \\ \mathsf{E}_n(0; H(c)) & \text{if } \mathsf{D}_n(c) = 1 \end{cases}$$

Since, NMC are perfectly correct, we have (for any choice of H)

$$\Pr_{b \xleftarrow{u} \{0,1\}} [\mathsf{D}_n(f_{p(n)}(\mathsf{E}(b))) = 1 - b] = 1.$$

[6] $p(n)$ corresponds to the length of the codeword outputted by E_n.

Therefore, by our assumption on R we have that for all n,

$$\Pr_{x \leftarrow \Psi_n}[L_n(x) = R^{f_{p(n)}}(x)] \geq \frac{1}{2} + \delta(n).$$

Now, for the j-th oracle query, we define $f'^{,j}_{p(n)}$, a stateful simulation of the output of the tampering function $f_{p(n)}$ on the j-th query. Each $f'^{,j}_{p(n)}$ is a $(j, p(n))$ lookup circuit (with j number of inputs/outputs of length $p(n)$) that hardcodes a random codeword (sampled from $\mathsf{E}(b)$ where b is uniform) as the y_j value.

By our assumption on $\mathcal{F}$ (and R), we have that $\mathsf{Replace}(\mathsf{Unroll}(R^{f_{p(n)}}), f'^{,1}_{p(n)}, \ldots, f'^{,t(n)}_{p(n)}) \in \mathcal{F}$. We will abuse notation and denote the resulting circuit by $R^{f'_{p(n)}}$. So, it suffices to show that the behavior of $R^{f'_{p(n)}}(x)$ is close that of $R^{f^H_{p(n)}}(x)$, for any x, which will imply that $R^{f'_{p(n)}}(x) \in \mathcal{F}$ breaks the distributional problem w.h.p., since $R^{f^H_{p(n)}}(x)$ does. More accurately, if (E, D) is $\frac{\delta(n)}{2t(n)}$-non-malleable by $\mathcal{F}$, then we will show that

$$\forall n \in \mathbb{N}, \forall x \in \{0,1\}^n, \Delta(R^{f'_n}(x); R^{f_n}(x)) \leq \delta(n)/2.$$

By the above, this then implies that (Ψ, L) is $(\delta(n)/2)$-easy for $\mathcal{F}$.

To show that the outputs of $R^{f'_{p(n)}}(x)$ and $R^{f^H_{p(n)}}(x)$ are close, we will use a hybrid argument, reducing to the $\frac{\delta(n)}{2t(n)}$-non-malleablity of (E, D) at every step.

In the i-th hybrid, the function $f^{(i),j}_{p(n)}$ responding to the j-th query is a $(j, p(n))$ look-up circuit that hardcodes values $y^i_1, \ldots, y^i_j$. For $k \in [t = t(n)]$, the y^i_k values are sampled as follows: For $k \in [t - i]$, y^i_k is sampled as by $f^H_{p(n)}$. For $k > t - i$, y^i_k is a random encoding of a random bit. The concatenation of the t circuits for each query is denoted by $f^{(i)}_{p(n)}$. Clearly, $f^{(0)}_{p(n)} \equiv f_{p(n)}$ and $f^{(t)}_{p(n)} \equiv f'_{p(n)}$.

We will show that for all $x \in \{0,1\}^n$ (and any fixing of random coins r for R) $\Delta(R^{f^{(i)}_{p(n)}}(x); R^{f^{(i-1)}_{p(n)}}(x)) \leq \frac{\delta(n)}{2t(n)}$ (for $i \in [t(n)]$), which proves the claim above.($R^{f^{(0)}_{p(n)}}(x)$ has advantage $\delta(n)$ and in each of the subsequent $t(n)$ hybrids we lose at most an $\epsilon(n)$ factor.)

Suppose not, then there exists an x (and random coins r, if R is randomized) such that R's behavior differs with respect to $f^{(i)}_{p(n)}$ and $f^{(i-1)}_{p(n)}$: $|\Pr[R^{f^{(i)}_{p(n)}}(x) = 1] - \Pr[R^{f^{(i-1)}_{p(n)}}(x) = 1]| \geq \frac{\delta(n)}{2t(n)}$.

Note that for fixed random function H (that generates the random coins used to sample the y_j values) $f^{(i)}_{p(n)}$ and $f^{(i-1)}_{p(n)}$ differ solely on the response to $(t-i)$-th query. So, fix x, H and all but the $(t-i)$-th value y^i_{t-i} and "hardcode" all other y_k values in both cases. The reason that we can hardcode the y_j values except for the $(t-i)$-th response is the following: Clearly, up to the $(t-i)$-th query, the responses can be fully hardcoded since x is fixed and so all the queries and responses can also be fixed. The y_j values hardcoded in the $(t-i+1)$-st lookup circuit and on can also be fixed, since in both $f^{(i)}_{p(n)}$ and $f^{(i-1)}_{p(n)}$, the $(t-i+1)$-st value of y_j and on is a random codeword, that does not depend on the value encoded in the query submitted by the reduction. Let $s_{H,x}$ denote the value encoded in the $(t-i)$-th query in this hardcoded variant of the hybrid. Note that the value of $s_{H,x}$ is also fixed.

1. In $R^{f^{(i-1)}_{p(n)}}(x)$ all values up to the $(t-i)$-th response are hardcoded. The $(t-i)$-th response, which will be a random encoding of bit $1 - s_{H,x}$, is not hardcoded. All the other responses are computed by lookup circuits with hardwired y_j values.

2. In $R^{f^{(i)}_{p(n)}}(x)$, all values up to the $(t-i)$-th response are hardcoded. The $(t-i)$-th response, which will be a random encoding of a random bit, is not hardcoded. All the other responses are computed by lookup circuits with hardwired y_j values.

Thus, we will treat the above as a new function $R'_{H,x}(\cdot)$ that takes as input just the response to the $(t-i)$-th query and returns some value. Note that $R'_{H,x}(\cdot)$ is in $\mathcal{F}$, since it can be viewed as the circuit $R^{f^{(i)}_{p(n)}}$, with queries/responses to $f^{(i),j}$, $j \in [t-i-1]$ hardcoded, the $(t-i)$-th query hardcoded, the $(t-i)$-th value y^i_{t-i} as the input to the circuit, and for $j > t-i$, the $f^{(i),j}$ functions as lookup circuits contained in $\mathcal{F}$. Moreover, by the above, $R'_{H,x}(\cdot)$ distinguishes random codewords that encode the bit $1-s_{H,x}$ from random codewords that encode a random bit with advantage $\epsilon(n)$. Specifically,

$$\Pr[R'_{H,x}(c)=1 \mid c \leftarrow \mathsf{E}_n(1-s_{H,x})] - \Pr[R'_{H,x}(c)=1 \mid c \leftarrow \mathsf{E}_n(b), b \leftarrow \{0,1\}] \geq \frac{\delta(n)}{2t(n)}.$$

By standard manipulation, the above is equivalent to:

$$\frac{1}{2}\cdot\Pr[R'_{H,x}(c)=1 \mid c \leftarrow \mathsf{E}_n(1-s_{H,x})] + \frac{1}{2}\cdot\Pr[R'_{H,x}(c)=0 \mid c \leftarrow \mathsf{E}_n(s_{H,x})] \geq \frac{1}{2} + \frac{\delta(n)}{2t(n)}.$$

This implies that we can use $R'_{H,x}$ to construct a distribution over tampering functions in $\mathcal{F}$ that successfully break (E,D). Details follows.

Let $c_{s_{H,x}}$ be a codeword encoding bit $s_{H,x}$ and let $c_{1-s_{H,x}}$ be a codeword encoding bit $1-s_{H,x}$. Define $\hat{f}_{H,x}$ as follows: $\hat{f}_{H,x}$ hardcodes $c_{s_{H,x}}$ and $c_{1-s_{H,x}}$. On input (codeword) c,

- If $R'_{H,x}(c)=1$, output $c_{s_{H,x}}$;
- Otherwise, output $c_{1-s_{H,x}}$.

We now analyze

$$\Pr_{b\leftarrow\{0,1\}}[\mathsf{D}_n(\hat{f}_{H,x}(\mathsf{E}_n(b))) = 1-b].$$

$$\begin{aligned}
\Pr_{b\leftarrow\{0,1\}}[\mathsf{D}(\hat{f}_{H,x}(\mathsf{E}(b))) = 1-b] &= \Pr[b = 1-s_{H,x}]\cdot\Pr[R'_{H,x}(c)=1 \mid c\leftarrow\mathsf{E}_n(1-s_{H,x})] \\
&\quad + \Pr[b=s_{H,x}]\cdot\Pr[R'_{H,x}(c)=0 \mid c\leftarrow\mathsf{E}_n(s_{H,x})] \\
&= \frac{1}{2}\cdot\Pr[R'_{H,x}(c)=1 \mid c\leftarrow\mathsf{E}_n(1-s_{H,x})] \\
&\quad + \frac{1}{2}\cdot\Pr[R'_{H,x}(c)=0 \mid c\leftarrow\mathsf{E}_n(s_{H,x})] \\
&\geq \frac{1}{2} + \frac{\delta(n)}{2t(n)}.
\end{aligned}$$

But, the above implies that (E,D) is $\frac{\delta(n)}{2t(n)}$-malleable for $\mathcal{F}$.

Therefore, we conclude that either (E,D) is $\frac{\delta(n)}{2t(n)}$-malleable for $\mathcal{F}$ or the distributional problem, $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^{\infty}$ is $(\delta(n)/2)$-easy for $\mathcal{F}$. ◀

The following corollary holds since NC^1 is $(\mathsf{NC}^1, t, p(n), p(n))$-closed under composition (for all polynomials $p(\cdot)$), and NC^1 contains $(t(n), p(n))$ lookup circuits for any polynomials $t(\cdot)$, $p(\cdot)$.

▶ **Corollary 32.** *If there is an* $(\mathsf{NC}^1, 1/2, \delta(n))$*-black-box-reduction making* $t(n)$ *security parameter preserving queries from a (single bit) non-malleable code for* NC^1*,* $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^{\infty}$*, to a distributional problem,* $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^{\infty}$*, then one of the following must hold:*

1. (E, D) *is* $\frac{\delta(n)}{2t(n)}$*-malleable by* NC^1*.*
2. (Ψ, L) *is* $(\delta(n)/2)$*-easy for* NC^1*.*

▶ Note 33. The proof of Lemma 31 (as well as the other proofs in this section), does not extend to cases in which the reduction R is outside in the class of tampering functions $\mathcal{F}$. Specifically, in the hybrid arguments, we require that $R'_{H,x}(\cdot)$ is in $\mathcal{F}$. In particular, our proof approach does not extend to proving impossibility of constructing a (single bit) non-malleable code for $\mathcal{F}$, from a distributional problem, (Ψ, L) that is hard for some larger class $\mathcal{F}$. E.g. our techniques do not allow us to rule out constructions of non-malleable codes for NC^1 from a distributional problem that is hard for NC^2. Our techniques also do not rule out constructions of non-malleable codes for $\mathcal{F}$ from an "incompressibility"-type assumption, such as those used in the recent work of [16]. Briefly, if a function ψ is incompressible by circuit class $\mathcal{F}$, it means that for $t \ll n$, for any *computationally unbounded* Boolean function $D : \{0,1\}^t \to \{0,1\}$ and any $F : \{0,1\}^n \to \{0,1\}^t \in \mathcal{F}$, the output of $D \circ F(x_1, \ldots, x_n)$ is uncorrelated with $\psi(x_1, \ldots, x_n)$ (over uniform choice of $x_1, \ldots, x_n$). In our case, this would mean that the reduction R is allowed oracle access to a computationally unbounded Boolean function D, since the hardness assumption would still be broken by the reduction as long as $R \in \mathcal{F}$ and the query made to D has length $t \ll n$. Since R composed with D is clearly outside the tampering class $\mathcal{F}$, our proof approach does not apply in the incompressibility setting.

▶ Note 34. We can extend Lemma 31 to rule out $(u(n), \ell(n))$*-approximately* security parameter preserving reductions by allowing our reduction access to a greater range of inefficient/simulated tampering functions (defined in the same manner as above): $\{f_k\}_{k=\ell(n)}^{u(n)}$ and $\{f'_k\}_{k=\ell(n)}^{u(n)}$. In this case, we can, WLOG, conflate the security parameter queried to the oracle with the length of the query made to the oracle. However, we now require for our proof that $\mathcal{F}$ is $(\mathcal{F}, t, \ell, u)$-closed under composition and contains look-up circuits with $t(n)$ inputs, consisting of $\ell(n)$ to $u(n)$ number of bits, for polynomials $t(\cdot)$, $\ell(\cdot), u(\cdot)$.

▶ **Lemma 35.** *Assume* $\mathcal{F}$ *is* $(\mathcal{F}, t, \ell, u)$*-closed under composition (see Definition 21) and contains* $(t(n), p(n))$ *look-up circuits for polynomials* $t(\cdot)$*,* $p(\cdot)$*. If there is an* $(\mathcal{F}, 1/2, \delta(n))$*-black-box-reduction making* $t(n)$ *number of* $(\ell(n), u(n))$*-approximately length preserving queries, from a (single bit) non-malleable code for* $\mathcal{F}$*,* $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^{\infty}$*, to a distributional problem,* $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^{\infty}$*, then one of the following must hold:*

1. (E, D) *is* $\frac{\delta(n)}{2t(n)}$*-malleable by* $\mathcal{F}$*.*
2. (Ψ, L) *is* $(\delta(n)/2)$*-easy for* $\mathcal{F}$*.*

Moreover, if (E, D) *is efficient, then for the conclusion to hold it suffices that* $\mathcal{F}$ *contains such look-up circuits generated that are generated uniform polynomial time.*

The following corollary holds since NC^1 is $(\mathsf{NC}^1, t, \ell, u)$-closed under composition, where $\ell(n) = n^\gamma$, for any constant $\gamma \leq 1$, $u(n) = n^c$, for any constant $c \geq 1$ and NC^1 contains look-up circuits with $t(n)$ number of inputs of length $\ell(n)$ to $u(n)$-bits for polynomials $t(\cdot)$, $\ell(\cdot), u(\cdot)$.

▶ **Corollary 36.** *Fix constants $\gamma \leq 1$, $c \geq 1$. If there is an $(\mathsf{NC}^1, 1/2, \delta(n))$-black-box-reduction making $t(n)$ (n^γ, n^c)-approximately length preserving queries from a (single bit) non-malleable code for NC^1, $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^\infty$, to a distributional problem, $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^\infty$, then one of the following must hold:*

1. *(E, D) is $\frac{\delta(n)}{2t(n)}$-malleable by NC^1.*
2. *(Ψ, L) is $(\delta(n)/2)$-easy for NC^1.*

We extend to non-security parameter preserving reductions, but require a stronger compositional property for the tampering class $\mathcal{F}$. As for approximate security parameter preserving reductions, WLOG we may conflate the security parameter queried to the oracle with the length of the query made to the oracle.

▶ **Lemma 37.** *Let $\mathcal{F}$ be closed under strong composition (see Definition 22) and contain $(t(n), u(n))$ lookup circuits. If for every non-negligible ϵ, there is an $(\mathcal{F}, \epsilon, \delta(n))$-black-box-reduction (for some non-negligible δ) making $t(n)$ queries from an (single bit) $\epsilon(n)$-non-malleable code for $\mathcal{F}$, $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^\infty$, to a distributional problem, $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^\infty$, then (Ψ, L) is not $(\delta(n) - t(n) \cdot \epsilon(n))$-hard for $\mathcal{F}$.*

Proof. Let $\mathcal{S} := \{1, 2^1, 2^{2^1}, 2^{2^{2^1}}, \ldots\}$. Let $\epsilon(n)$ be the following non-negligible function:

$$\epsilon(n) := \begin{cases} \frac{1}{4} & \text{if } n \in \mathcal{S} \\ 0 & \text{if } n \notin \mathcal{S} \end{cases}$$

Assume there is some reduction R that succeeds with non-negligible probability $\delta := \delta(n)$ for this ϵ. Since δ is non-negligible, there must be an infinite set $\mathcal{S}'$ such that $\delta(n) \geq 1/n^c$ for some constant c and for all $n \in \mathcal{S}'$.

WLOG, we may assume that the reduction R, on input of length n, queries at most a single input length $\ell(n) \in \omega(\log(n))$, whereas all other queries are of input length $O(\log(n))$ (since we may assume the oracle simply returns strings of all 0's on any input of length $k \notin \mathcal{S}$). Additionally, we may assume that (1) $\ell(n)$ is polynomial in n (since otherwise the reduction does not have time to even write down the query) and (2) for any $k \in \mathbb{N}$, the size of the set $\ell^{-1}(k) \cap \mathcal{S}'$ is finite (otherwise we can hardcode all possible query/responses for a particular input length k into the reduction–which is constant size since k is constant–and obtain a circuit that breaks the underlying hard problem on an infinite number of input lengths). Moreover, we assume WLOG that $\ell(n) < n$, since otherwise our previous proof holds.

Since by assumption $\mathcal{F}$ is HCS-amenable, it means that Impagliazzo's hardcore set holds for adversaries in $\mathcal{F}$. Specifically, for random codewords $c \leftarrow \mathsf{E}_{\ell(n)}(b), b \leftarrow \{0,1\}$ of length $\ell = \ell(n)$ s.t. $\ell(n) < n$, there are two possible cases:

1. For infinitely many $n \in \mathcal{S}'$ (this set of values is denoted by $\mathcal{S}'' \subseteq \mathcal{S}'$), there is some adversary in $\mathcal{F} := \{\mathcal{F}_n\}_{n \in \mathbb{N}}$ that outputs $\mathsf{D}_{\ell(n)}(c)$ with probability at least $3/4$[7].
2. For infinitely many $n \in \mathcal{S}'$ (this set of values is denoted by $\mathcal{S}'' \subseteq \mathcal{S}'$), there is some hardcore set $\mathcal{H}$ of size at least $\epsilon'(n) \cdot 2^\ell$, where $\epsilon'(n) = \frac{1}{2 \cdot n^c \cdot t(n)}$ such that every adversary in $\mathcal{F} := \{\mathcal{F}_n\}_{n \in \mathbb{N}}$ outputs $\mathsf{D}_{\ell(n)}(c)$ with probability at most $1/2 + \epsilon'(n)$, when c is chosen at random from $\mathcal{H}$[8].

[7] Note that $\mathsf{D}_{\ell(n)}(c)$ takes inputs of length $\ell(n)$, whereas $\mathcal{F}_n$ takes inputs of length n. We can easily resolve this discrepancy by padding inputs of length $\ell(n)$ up to n.

[8] Again, the input c to $\mathsf{D}_{\ell(n)}$ has length $\ell(n)$ while $\mathcal{F}_n$ takes inputs of length n. As above, we resolve the discrepancy by padding inputs of length $\ell(n)$ up to n.

In Case 1, we set the tampering function $\{f_k\}_k$ to use the circuit described above to decode a random codeword with prob 3/4 and then chooses a random encoding of 0 or 1 appropriately. Additionally, f_k only responds if $k \in \mathcal{S}$. Clearly, f_k succeeds with non-negligible probability ϵ. Since the ϵ function remains the same, we know that δ and ℓ, $\mathcal{S}$, $\mathcal{S}'$ remain the same.

In this case, as in the previous proof, we can switch to a simulated tampering function Sim, which responds with $f_{\ell(n)}$ on query input length $\ell(n)$ and hardcodes all responses for all possible queries R makes to f_k with input lengths $k = k(n) \in O(\log(n))$.

Note that since we are in Case 1, for infinitely many input lengths–input lengths $n \in \mathcal{S}''$–to R, R^{Sim}, is a circuit in $\mathcal{F}_n$, since $\mathcal{F}_n$ strongly composes. Additionally, the behavior of R^{Sim} is identical to the behavior of $R^{\{f_k\}_k}$. Moreover, since f_k succeeds with non-negligible ϵ, by assumption on R, it means that for all $n \in \mathcal{S}'$, $R^{f_{\ell(n)}}$ agrees with (Ψ, L) with probability $1/2+1/n^c$. But then we must have that for infinitely many $n \in \mathcal{S}'$–input lengths $n \in \mathcal{S}''$–R^{Sim} agrees with (Ψ, L) with probability $1/2 + 1/n^c$ and $R^{\mathsf{Sim}} \in \mathcal{F}_n$. So (Ψ, L) is $(\delta'(n))$-easy for $\mathcal{F}$, where

$$\delta'(n) := \begin{cases} \frac{1}{n^c} & \text{if } n \in \mathcal{S}'' \\ 0 & \text{if } n \notin \mathcal{S}'' \end{cases}$$

In Case 2, we set the tampering function $\{f_k\}_k$ to decode the query submitted by the reduction R and respond with a random encoding from the hardcore set described above (if it exists), which decodes to 0 or 1 as appropriate. Specifically, the hardcore set $\mathcal{H}$ is defined as follows: f_k sets n^* to be equal to the lexicographically first element in the (finite) set $\ell^{-1}(k) \cap \mathcal{S}''$[9], and chooses the lexicographically first set $\mathcal{H}$ of size $\epsilon'(n^*) \cdot 2^{\ell(n^*)} = \epsilon'(n^*) \cdot 2^k$ for which every adversary in $\mathcal{F}_n$ outputs $\mathsf{D}_{\ell(n^*)}(c)$ with probability at most $1/2 + \epsilon'(n^*)$, when c is chosen at random from $\mathcal{H}$. If $\ell^{-1}(k) \cap \mathcal{S}' = \emptyset$ or there is no such hardcore set $\mathcal{H}$, then f_k applies the trivial breaking strategy described above (decoding the input and responding with a random encoding of 0 or 1 as appropriate). Moreover, f_k responds only if $k \in \mathcal{S}$. Since the ϵ function remains the same in this case as well, the δ function also remains the same. Thus, for $n \in \mathcal{S}'$, $R^{f_{\ell(n)}}$ must still agree with (Ψ, L) with probability $1/2 + 1/n^c$.

In this case, as in the previous proof, we can switch to a simulated tampering function Sim that does not decode but rather chooses a random codeword from the hardcode set $\mathcal{H}$ (which again we can hardcode in using lookup circuits as before). Moreover, for queries R makes to Sim with input lengths $k = k(n) \in O(\log(n))$, all responses for all possible queries c are hardcoded into Sim. Now, for infinitely many $n \in \mathcal{S}'$–input lengths $n \in \mathcal{S}''$–R's behavior should be $t(n) \cdot \epsilon'(n)$-close when interacting with $\{f_k\}_k$ versus Sim, since otherwise in each hybrid step we can construct a distinguishing circuit in $\mathcal{F}_n$ (as in the previous proof) contradicting the guaranteed hardness of the hardcore set. Finally, we must argue that for infinitely many $n \in \mathcal{S}'$–input lengths $n \in \mathcal{S}''$–R composed with Sim is in the class $\mathcal{F}$. But due to the fact that $\mathcal{F}$ is $(\mathcal{F}, t)$-closed under strong composition, this occurs whenever the reduction is instantiated with security parameter $n \in \mathcal{S}''$, where n is the lexicographically first element in the set $\ell^{-1}(\ell(n)) \cap \mathcal{S}''$. Since n is always contained in $\ell^{-1}(\ell(n))$, since the size of $\ell^{-1}(\ell(n)) \cap \mathcal{S}'$ is finite and since the size of $\mathcal{S}''$ is infinite, there will be infinitely many $n \in \mathcal{S}''$ for which this event occurs. Thus, for infinitely many $n \in \mathcal{S}''$ (denote this set of values by $\widetilde{\mathcal{S}}$, $R^{\{f_k\}_k}$ agrees with (Ψ, L) with probability $1/2 + 1/n^c$ and R^{Sim} is $t(n) \cdot \epsilon'(n) \leq 1/2n^c$-close to $R^{\{f_k\}_k}$. So we conclude that (Ψ, L) is $(\delta'(n))$-easy for $\mathcal{F}$, where

$$\delta'(n) := \begin{cases} \frac{1}{2n^c} & \text{if } n \in \widetilde{\mathcal{S}} \\ 0 & \text{if } n \notin \widetilde{\mathcal{S}} \end{cases}$$

◀

[9] Note that it is finite since $\ell^{-1}(k) \cap \mathcal{S}'$ is finite and $\mathcal{S}'' \subseteq \mathcal{S}'$.

The following corollary holds since NC is (NC, t)-closed under strong composition and Impagliazzo's HCS holds for NC.

▶ **Corollary 38.** *If for every non-negligible $\epsilon = \epsilon(\cdot)$, there is an $(\mathsf{nu}-\mathsf{NC}, \epsilon, \delta)$-black-box-reduction, for some non-negligible $\delta = \delta(\cdot)$, making $t(n)$ queries from a (single bit) non-malleable code for $\mathsf{nu}-\mathsf{NC}$, $(\mathsf{E}, \mathsf{D}) = \{(\mathsf{E}_n, \mathsf{D}_n)\}_{n=1}^{\infty}$, to a distributional problem, $(\Psi, L) = \{(\Psi_n, L_n)\}_{n=1}^{\infty}$, then (Ψ, L) is $(\delta'(n))$-easy for NC, for some non-negligible $\delta' = \delta'(\cdot)$.*

Abstract

Reductions between problems, the mainstay of theoretical computer science, efficiently map an instance of one problem to an instance of another in such a way that solving the latter allows solving the former.[1] The subject of this work is "lossy" reductions, where the reduction loses some information about the input instance. We show that such reductions, when they exist, have interesting and powerful consequences for lifting hardness into "useful" hardness, namely cryptography.

Our first, conceptual, contribution is a definition of lossy reductions in the language of mutual information. Roughly speaking, our definition says that a reduction C is t-lossy if, for any distribution X over its inputs, the mutual information $I(X;\mathsf{C}(X)) \leq t$. Our treatment generalizes a variety of seemingly related but distinct notions such as worst-case to average-case reductions, randomized encodings (Ishai and Kushilevitz, FOCS 2000), homomorphic computations (Gentry, STOC 2009), and instance compression (Harnik and Naor, FOCS 2006).

We then proceed to show several consequences of lossy reductions:

1. We say that a language L has an f-reduction to a language L' for a Boolean function f if there is a (randomized) polynomial-time algorithm C that takes an m-tuple of strings $X = (x_1, \ldots, x_m)$, with each $x_i \in \{0,1\}^n$, and outputs a string z such that with high probability,

   $$L'(z) = f(L(x_1), L(x_2), \ldots, L(x_m))$$

   Suppose a language L has an f-reduction C to L' that is t-lossy. Our first result is that one-way functions exist if L is worst-case hard and one of the following conditions holds:
   - f is the OR function, $t \leq m/100$, and L' is the same as L
   - f is the Majority function, and $t \leq m/100$
   - f is the OR function, $t \leq O(m \log n)$, and the reduction has no error

   This improves on the implications that follow from combining (Drucker, FOCS 2012) with (Ostrovsky and Wigderson, ISTCS 1993) that result in *auxiliary-input* one-way functions.
2. Our second result is about the stronger notion of t-compressing f-reductions – reductions that only output t bits. We show that if there is an average-case hard language L that has a t-compressing Majority reduction to some language for $t = m/100$, then there exist collision-resistant hash functions.

   This improves on the result of (Harnik and Naor, STOC 2006), whose starting point is a cryptographic primitive (namely, one-way functions) rather than average-case hardness, and whose assumption is a compressing OR-reduction of SAT (which is now known to be false unless the polynomial hierarchy collapses).

[1] Such reductions are called many-one or Karp reductions. To be sure, there are more general types of reductions, such as oracle reductions (or Cook reductions), which we do not deal with in this paper.

Along the way, we define a non-standard one-sided notion of average-case hardness, which is the notion of hardness used in the second result above, that may be of independent interest.

1 Introduction

Consider a polynomial-time reduction R from a language L to another L'.[2] That is, R takes as input $x \in \{0,1\}^n$ for any n and produces an output $y \in \{0,1\}^{m(n)}$ for some polynomial m such that $x \in L$ if and only if $y \in L'$. Such a reduction relates the computational complexities of L and L'; its existence says that the complexity of L is at most the complexity of L', upto some additional polynomial running time. In general, the reduction says little more than this. If the reduction has certain additional properties, however, it tells us more about the complexity of L and starts becoming more useful. This work is about an important such class of reductions, namely *lossy reductions* that forget information about the input instance.

Losing Information through Compression. One way to lose information about the input instance is by compressing it. Continuing the discussion above, if $m(n) = O(\log n)$, the reduction enables L to be decided in non-uniform polynomial-time. More generally, L can be decided on n-bit inputs by a circuit of size roughly $2^{m(n)}$. Such *instance compressing*

[2] Much of our discussion also applies to promise problems and search problems.

reductions, those that have $m(n) \ll n$, have been an important part of the study of fixed parameter tractable algorithms, where they are called kernelizations (see [11] and the references therein). A classical example is the vertex cover problem on n-node graphs parameterized by the size of the cover k, where there is a $\mathsf{poly}(n)$-time algorithm that takes the graph as input and outputs a smaller graph of size $\mathsf{poly}(k)$ which has a cover of size k if and only if the original graph does.

Harnik and Naor [18] showed a variety of cryptographic applications of such compressing reductions. For example, assuming that the Boolean Satisfiability problem (SAT) has good enough instance compression, they showed how to construct a collision-resistant hash function starting from any one-way function, a task known to be impossible to do in a black-box manner [28]. Furthermore, if this compression has some additional properties, they also show how to get public-key encryption schemes and oblivious transfer protocols from one-way functions. However, Fortnow and Santhanam [14] and later Drucker [12] showed that, unless the polynomial hierarchy collapses, such instance compression algorithms for SAT cannot exist.

This Work: Losing Information without Compression. Compression is one way to lose information, but not the only one. In this paper, we study cryptographic implications of *lossy reductions* – randomized algorithms that forget information about the input instance but not necessarily by compressing them. Such reductions are abundant in the study of average-case complexity and cryptography.

An example is a reduction $\mathsf{R}(x)$ that outputs a sample from a distribution that is (almost) completely determined by whether x is contained in L (and, as before, $\mathsf{R}(x) \in L'$ if and only if $x \in L$). Such a reduction loses all information about x other than its membership in L. Thus, it relates the complexity of deciding L in the *worst-case* to the complexity of deciding L' *on average* over a specific distribution[3]. In other words, a reduction that loses all information about its input except membership in L is a *worst-case to average-case reduction* from L to L'.

From a different vantage point, such reductions are equivalent to *randomized encodings* [19], a powerful and versatile notion in cryptography (see the survey by Applebaum [1] and the references therein). In particular, randomized encodings have been used to delegate computations [3], for secure computation [31, 7, 20], for parallel cryptography [2], for key-dependent message security and much more.

Given this relevance to cryptography of reductions that lose all information except membership, both as average-case reductions and as randomized encodings, we ask whether anything similar can be said of reductions that are almost this way. That is, *are reductions that lose* almost *all other information except membership useful for cryptography*?

Lossy Reductions and Cryptography. Our first contribution is a definition of such lossy reductions through the lens of mutual information. For a function $t : \mathbb{N} \to \mathbb{R}^+$, we say that a reduction C from a language L to a language L' is *t-lossy* if for any random variable X over bit-strings of length n (capturing an input distribution), the mutual information $I(X; \mathsf{C}(X))$ is at most $t(n)$. Note that this definition does not fix an input distribution, rather quantifies over all of them. In this sense, it is reminiscent of the prior-free information complexity definition of [10]. Roughly speaking, if X has little entropy, we don't care; if X has more than $t(n)$ bits of entropy, we want the reduction to reveal at most $t(n)$ of it.

[3] The distribution is given by picking any $x_N \notin L$ and any $x_Y \in L$, and taking the equal convex combination of the distributions sampled by $\mathsf{R}(x_N)$ and $\mathsf{R}(x_Y)$.

Whereas Harnik and Naor showed that instance compression can be used to construct other cryptographic primitives *from* one-way functions, we investigate the possibility of using compression or information loss to construct one-way functions from simpler hardness properties. Some results along these lines are already known, or are implicit in prior work: (1) Drucker [12] showed that the existence of certain kinds of compression for a language L implies that L has a statistical zero-knowledge proof.[4] Together with a result of Ostrovsky [25], this implies that if such a language is *average-case hard*, then one-way functions exist; (2) Replacing average-case with worst-case hardness in the above gives us *auxiliary input* one-way functions, a weaker object [26]; (3) on the other hand, if the reduction is a randomized encoding, then replacing average-case with worst-case hardness in the above gives us one-way functions [5].

We demonstrate a number of other similar sufficient conditions to elevate worst-case hardness to one-way functions. To give the reader a taste of what is to come, one of our results is a way to achieve the best of (1), (2) and (3) above, showing how to elevate worst-case hardness of L into one-way functions if L has a lossy reduction to L'.

▶ **Informal Theorem 1.1.** *Suppose there is a perfect reduction from L to L' that is $O(\log n)$-lossy on n-bit inputs. If L is worst-case hard, then One-Way Functions exist.*

The above follows as a corollary to Informal Theorem 1.4 described later. As noted earlier, randomized encodings may be seen roughly as a 1-lossy reduction from L to some problem L', and the worst-case hardness of a problem that has randomized encodings implies the existence of a one-way function. The above theorem says that it is in fact sufficient for the reduction to be $O(\log n)$-lossy (rather than 1-lossy) for this conclusion to hold, if it has the additional property that it does not make any errors – that is, a YES instance of L is never mapped to a NO instance of L', and also the other way round. This may also be interpreted as saying that the implication to OWFs for randomized encodings still holds if the privacy guarantee of the encodings is much weaker, as long as the correctness is perfect.

f-Reductions and OWFs. Our main theorems are about the implications of lossy reductions for the composition of a simple Boolean function with membership in a language. Let $f = \{f^n\}$ denote a family of (partial) Boolean functions, where for some polynomial m, the function f^n takes $m(n)$ bits as input. We denote by $f \circ L$ the composition of f with L – on $m(n)$ inputs $x_1, \ldots, x_{m(n)} \in \{0,1\}^n$, this function is computed as $f(L(x_1), \ldots, L(x_{m(n)}))$. We refer to a reduction from $f \circ L$ to some problem as an f-reduction of L.

Such f-reductions that are also compressing (in terms of bit length) have been the subject of considerable past work in the study of parametrized complexity [18, 9, 14, 13] (see also further references in [13]), especially for simple functions f like AND and OR. Most relevant to our work are the results of Drucker [13], who showed that if there is a sufficiently compressing reduction from $\mathrm{OR}_m \circ L$ to any problem L', then L is contained in SZK (where m is some polynomial and OR_m is the family of OR function on $m(n)$ inputs). As noted earlier, this implied membership in SZK lets us lift the average-case hardness of L to a one-way function, or its worst-case hardness to an auxiliary-input OWF.

Our starting point is the observation that Drucker's proofs still work if the reduction were just lossy and not necessarily compressing. We prove the following theorems that show three different sufficient conditions for lossy reductions to be useful in lifting worst-case

[4] Drucker's results were stated for the stronger notion of compression in terms of bit-length, but his proofs imply the same results for notion of lossy reductions as well.

hardness directly to one-way functions. Each of the three imply OWFs along different paths, as described briefly below. These paths and the pointers to the relevant parts of the paper are presented in Figure 1.

▶ **Informal Theorem 1.2.** *Suppose, for some polynomial m, and promise problem L, there is a reduction from $\mathrm{OR}_m \circ L$ to L that is $(m(n)/100)$-lossy on $(n \cdot m(n))$-bit inputs. If L is worst-case hard, then One-Way Functions exist.*

We prove this by first showing that Drucker's techniques actually imply a certain kind of worst-case to average-case reduction to L'. And if L is worst-case hard, then this reduction lets us conclude that L' is *one-sided average-case hard*, a notion explained later in this section. Thus, if L' is L itself, then it is both contained in SZK and is one-sided average-case hard. Finally, we show that the existence of any such problem implies the existence of a OWF.

The next theorem we prove is that a similarly lossy Majority-reduction for L by itself lets us lift the worst-case hardness of L to a OWF, without worrying about what it reduces to.

▶ **Informal Theorem 1.3.** *Suppose, for some polynomial m, and promise problem L, there is a reduction from $\mathrm{MAJ}_m \circ L$ to some problem that is $(m(n)/100)$-lossy on $(n \cdot m(n))$-bit inputs. If L is also worst-case hard, then One-Way Functions exist.*

In this case, we extend Drucker's techniques to show that such a reduction from $\mathrm{MAJ}_m \circ L$ implies a *two-sided* average-case reduction from L to some problem L' – where the YES and NO parts of the distribution over instances of L' that L is reduced to can be sampled separately. In different terms, this implies that L has statistical randomized encodings, and the conclusion follows from the fact that the worst-case hardness of a problem that has randomized encodings implies one-way functions [5].

Finally, the following theorem says that we can make do with OR_m-reductions that are not as lossy as before – only $O(m(n)\log n)$-lossy instead of $m(n)/100$ – if the reduction is perfect, meaning that it never maps YES instances of $\mathrm{OR}_m \circ L$ to NO instances of L', and also the other way. Note that a reduction that is $\Omega(m(n)\log n)$-lossy could still preserve some information about all of its $m(n)$ inputs – for instance, whether each x_i is a YES or NO instance of L, etc..

▶ **Informal Theorem 1.4.** *Suppose, for some polynomial m, and promise problems L and L', there is a* perfect *reduction from $\mathrm{OR}_m \circ L$ to L' that is $O(m(n)\log n)$-lossy on $(n \cdot m(n))$-bit inputs. If L is worst-case hard, then One-Way Functions exist.*

We prove this by showing that a perfect reduction from $\mathrm{OR}_m \circ L$ implies a one-sided average-case reduction that is perfect in the sense that the NO and YES distributions that are generated by the reduction are disjoint. On the other hand, the hardness that is implied by the reduction is quite weak due to it not being lossy enough – it only says that the NO distribution is no better than $(1 - 1/\mathsf{poly}(n))$-distinguishable from the YES distribution for a given algorithm. However, the perfectness lets us show that the sampler for the NO distribution itself is a weak one-way function (with the input as its random string).

Collision-Resistance from Compression. Finally, we show that compressing reductions – a strong form of lossy reductions where the output length is smaller than the input length – can be used to lift one-sided average-case hardness to collision-resistant hash functions.

▶ **Informal Theorem 1.5.** *Suppose, for some polynomial m, and promise problem L, there is a perfect reduction from $\mathrm{OR}_m \circ L$ to some problem that compresses $(n \cdot m(n))$-bit inputs to $m(n)/100$ bits. If L is also one-sided average-case hard with perfect sampling*[5]*, then Collision-Resistant Hash Functions exist.*

Our construction builds directly on the construction of collision-resistant hash functions from homomorphic commitments by Ishai et al [21]. In our construction, the keys of the hash function for hashing strings of length m correspond to a set of $2m$ instances (grouped into m pairs) sampled from the NO distribution. Each bit of an input x is used to select an instance from the corresponding pair, and the hash function is computed by running the compressing OR-reduction on this set.

The construction in [21] may be seen to use essentially the same approach, where instead of using a compressing OR-reduction for a hard problem, they use the homomorphism of a commitment scheme. The security of the commitment scheme there is the analogue of the one-sided average-case hardness of L, and our observation is that, while homomorphism is one way to compress (XOR-compression in their case), it is not necessary, and any compressing OR-reduction is sufficient to use with the construction.

One-Sided Average-Case Hardness. In the process of studying the implications of OR-compression of a problem to itself, we introduce the notion of one-sided average-case hardness, which we describe next. Recall that the worst-case hardness of a problem L says that for any polynomial-time algorithm A that attempts to decide L, there exists some input x on which it is wrong. Perhaps the simplest notion of average-case hardness flips the quantifiers here and says that there exists a (samplable) distribution over inputs such that any algorithm fails to decide L with large advantage when inputs are sampled from this distribution.

A stronger notion of average-case hardness that we call *two-sided* average-case hardness (and one that directly relates to one-way functions), says that there are two (samplable) distributions, one over the just the YES instances of L and another over just the NO instances, such that no algorithm A can distinguish between them. One-sided average-case hardness is a notion between this and worst-case hardness, and says that there exists one samplable distribution N over (mostly) NO instances such that for any algorithm A, there exists a distribution Y_A over (mostly) YES instances such that A cannot distinguish between N and Y_A.

One-sided average-case hardness implies worst-case hardness, is implied by two-sided average-case hardness, and does not seem to be related in this manner to plain average-case hardness. Ostrovsky [25] proved that plain average-case hardness of a problem in SZK implies OWFs. We prove the following theorem that, to our knowledge, is incomparable to it.

▶ **Informal Theorem 1.6.** *If there is a problem in SZK that is one-sided average-case hard, then One-Way Functions exist.*

The theorem is proven using a reduction to (the complement of) the Statistical Difference problem that is complete for SZK [27]. We also show that the existence of an analogous notion of worst-case to average-case reduction – called one-sided average-case reduction – from a problem L to any other problem implies that L is contained in SZK. Thus, along with the worst-case hardness of L, they imply auxiliary-input OWFs analogous to how two-sided average-case hardness implies OWFs. Such reductions are closely related to the notion of semi-private randomized encodings [4].

[5] The perfect sampling condition implies that the YES and NO distributions that come up in the definition of the hardness are contained completely within the YES and NO parts of the problem.

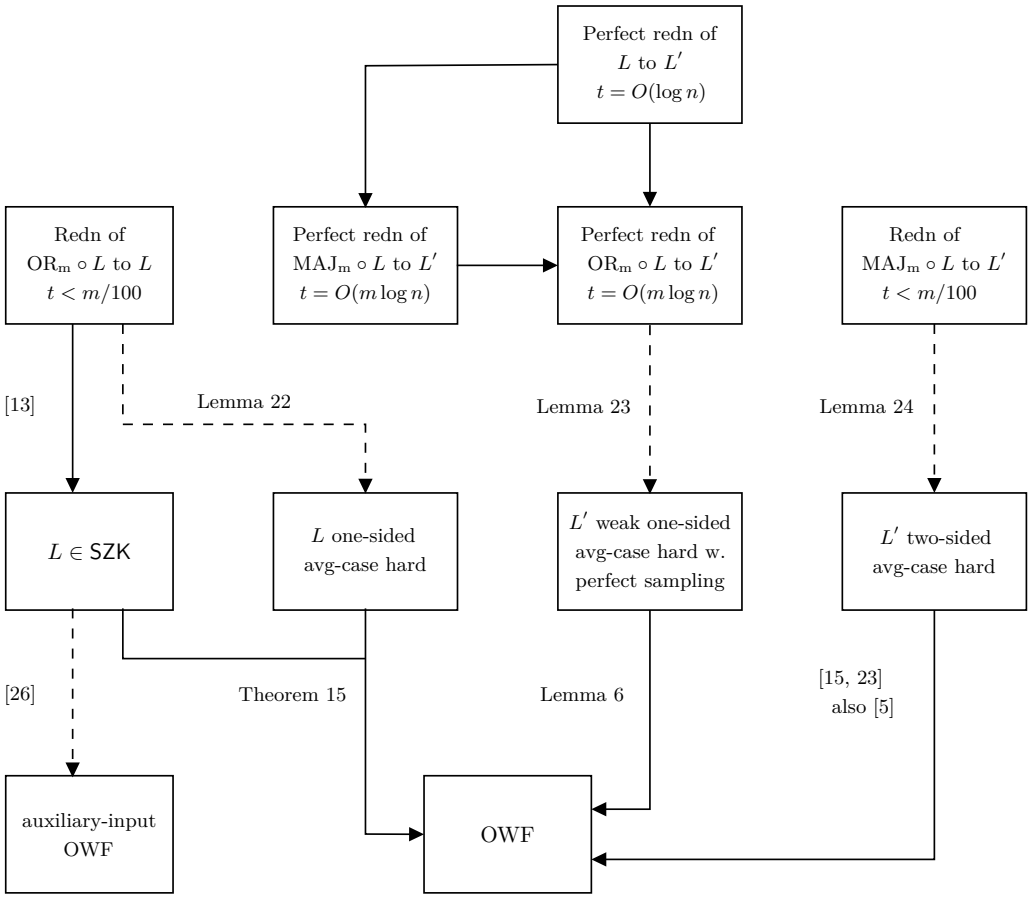

Figure 1 The many paths to One-Way Functions. L and L' are promise problems. The solid arrows denote implications, and the dashed arrows denote implication conditioned on the worst-case hardness of L. In all cases, m and t are polynomials in n, and the reductions lose all but $t(n)$ bits of information on a set of $m(n)$ inputs of size n – that is, t-lossy according to Definition 21 (when reducing L to L', $m(n)$ is set to 1).

1.1 Notation

We will always deal with promise problems and partial functions rather than languages and total functions, as these come up naturally in our discussions, and are also more general. Given a promise problem L, we denote by L_Y and L_N the corresponding sets of YES and NO inputs. Abusing notation, we also denote by L the partial function indicating membership in this promise problem. In the other direction, note that any partial Boolean function $f : \{0,1,\perp\}^n \to \{0,1,\perp\}$ has a corresponding promise problem, which we also sometimes denote by f. The symbol $\perp$ is set to be the output of a partial function on an input on which it is otherwise undefined. In general, we take U_S to be the random variable distributed uniformly over the set S, where S is clear from context we simply write U.

Random variables are capitalized (X), and algorithms are sans serif (A). $\mathsf{A}(X)$ denotes the random variable resulting from sampling x according to X and running A on it. $\mathrm{H}(X)$ is the Shannon entropy of X, and $\mathrm{I}(X;Y)$ is the mutual information between X and Y. We take $\Delta(X;Y)$ to denote the total variation distance between X and Y.

Unless otherwise specified, all algorithms in our work are non-uniform, and assumptions and claims of hardness are also against non-uniform algorithms. Further, we always use notions of hardness that are strong in the following sense – when we say, for instance, that a problem L is hard against polynomial-time algorithms, we mean that for any polynomial-time algorithm A, there is an $n_{\mathsf{A}} \in \mathbb{Z}$ such that for any $n \geq n_{\mathsf{A}}$, the algorithm A fails to decide L correctly on some instance of size n. This is to be contrasted against the more standard notion of hardness, infinitely-often hardness, which would say that there is an infinite sequence of n's such that A fails to decide L on some instance of size n. All of our lemmas and theorems, however, may also be stated in terms of infinitely-often hardness and follow from the same proofs, resulting in infinitely-often cryptographic objects as well.

1.2 Outline of the Paper

In Section 2, we define the various kinds of computational hardness that we will be using, the corresponding reductions, and some lemmas relating the reductions, the hardness, and one-way functions. In Section 3, we prove define the class SZK and prove that one-sided average-case hardness in SZK implies one-way functions, and some associated lemmas. In Section 4, we define our notion of lossy reductions, and prove that certain kinds of lossy reductions along with worst-case hardness imply one-way functions. In Section 5, we prove that one-sided average-case hardness and OR-compressing reductions imply collision-resistance hash functions.

2 Computational Hardness

In this section, we define the various kinds of computational hardness of promise problems that we will be employing in later discussions, and also different kinds of reductions between problems that have implications for such hardness. The proofs of the lemmas in this section are in Appendix A. We start by defining the weakest and simplest form of hardness.

▶ **Definition 1** (Worst-Case Hardness). *A problem L is* worst-case hard *if, for any polynomial-time algorithm A and all large enough n, there is an input $x \in (L_Y \cup L_N) \cap \{0,1\}^n$ such that $\Pr[\mathsf{A}(x) = L(x)] < 2/3$.*

Worst-case hardness says that for any algorithm A (and large enough instance size n), there is an input x on which it is wrong. We next define perhaps the simplest form of average-case hardness, which mostly just swaps these quantifiers. It says that there is a distribution over inputs x such that any algorithm A is wrong on average over this distribution.

▶ **Definition 2** (Average-Case Hardness). *A problem L is* average-case hard *if there is a polynomial-time sampling algorithm D such that:*

- *D mostly samples instances from L_Y and L_N. That is, for all large enough n,*

$$\Pr_{x \leftarrow \mathsf{D}(1^n)}[x \notin L_Y \cup L_N] \leq 0.1$$

- *The membership in L of most instances drawn from D is hard to decide. That is, for any polynomial-time algorithm A, for all large enough n,*

$$\Pr_{x \leftarrow \mathsf{D}(1^n)}[\mathsf{A}(x) = L(x) \vee L(x) = \perp] \leq \frac{1}{2} + 0.15$$

Note that the constant 2/3 in Definition 1 is somewhat arbitrary – if there is an algorithm A that does in fact decide L in the worst-case with success probability bounded away from 1/2 for all n, this can be amplified by repetition to get an algorithm A' with success probability close to 1.

In Definition 2, however, the constants are not arbitrary, at least in this straighforward sense. There are known hardness amplification theorems (see [6, Chapter 19]) that can take a problem L that is somewhat average-case hard as above, and obtain another problem L' and a distribution under which L' is much harder, but these do not say that L itself is any harder than initially supposed. Our choice of the constants we use in our definitions are such that the hardness is mild enough to be implied by the hypotheses that we later start with, and are yet strong enough to have interesting implications for cryptography, as shown by our theorems.

We next define a stronger and natural notion of average-case hardness that is known to be closely related to One-Way Functions. It separates the hard distribution into YES and NO parts, and asks that each of these parts be efficiently samplable.

▶ **Definition 3** (Two-Sided Average-Case Hardness). *A problem L is* two-sided average-case hard *if there are two polynomial-time sampling algorithms Y and N such that:*

- *Y and N mostly sample instances from L_Y and L_N, respectively. That is, for all large enough n,*

$$\Pr_{x \leftarrow \mathsf{Y}(1^n)}[x \notin L_Y] \leq 0.1$$
$$\Pr_{x \leftarrow \mathsf{N}(1^n)}[x \notin L_N] \leq 0.1$$

- *The outputs of Y and N are computationally indistinguishable. That is, for any polynomial-time algorithm A, for all large enough n,*

$$\left| \Pr_{x \leftarrow \mathsf{Y}(1^n)}[\mathsf{A}(x) = 1] - \Pr_{x \leftarrow \mathsf{N}(1^n)}[\mathsf{A}(x) = 1] \right| \leq 0.3$$

It is known that any two-sided average-case hard problem implies the existence of a One-Way Function. This follows from the fact that such hardness implies the existence of a family of statistically far distributions that are computationally indistinguishable (N and Y). Goldreich [15] showed that this is equivalent to the existence of OWFs if the indistinguishability was with negligible advantage, and this was later extended by Naor and Rothblum [23] to hold for weaker indistinguishability that covers the constants used above (see [8] for an alternative proof), leading to the following lemma. A theorem that is roughly equivalent to the combination of Lemmas 4 and 9 was also proven by Applebaum and Raykov [5].

▶ **Lemma 4.** *There is a problem that is two-sided average-case hard if and only if One-Way Functions exist.*

Further, note that the existence of a OWF also implies (as can be seen by the PRG that can be constructed from it) that there is some language that is two-sided average-case hard, but with much stronger guarantees – with negligible functions (in n) in place of the constants 0.1 and 0.3 in Definition 3. In this sense, for the purposes of its relevance to cryptography, the constants in the definition above are also somewhat arbitrary.

Finally, we introduce a notion of average-case hardness that is intermediate between worst-case and two-sided average-case hardness and, to our knowledge, is incomparable to plain average-case hardness. Recall that average-case hardness was obtained by swapping

the quantifiers in worst-case hardness, and two-sided average-case hardness then came out of separating and fixing the YES and NO parts. The following definition fixes just the NO distribution, and requires that for any algorithm A, there exists some YES distribution that it cannot distinguish from this fixed NO distribution.

▶ **Definition 5** (One-Sided Average-Case Hardness). *A problem L is* one-sided average-case hard *if there is a polynomial-time sampling algorithm N such that:*

- N *mostly samples instances from L_N. That is, for all large enough n,*

$$\Pr_{x \leftarrow \mathsf{N}(1^n)} [x \notin L_N] \leq 0.1$$

- *For any polynomial-time algorithm, there is some distribution that is mostly over L_Y that it cannot distinguish from the output of N. That is, for every polynomial-time algorithm A, there is a (possibly inefficient) sampler Y_A such that:*
  - Y_A *mostly samples instances from L_Y. That is, for all large enough n,*

$$\Pr_{x \leftarrow \mathsf{Y}_\mathsf{A}(1^n)} [x \notin L_Y] \leq 0.1$$

  - *The outputs of N and Y_A are indistinguishable to A. That is, for all large enough n,*

$$\left| \Pr_{x \leftarrow \mathsf{N}(1^n)} [\mathsf{A}(x) = 1] - \Pr_{x \leftarrow \mathsf{Y}_\mathsf{A}(1^n)} [\mathsf{A}(x) = 1] \right| \leq 0.3$$

We say that the hardness is strong *if the distinguishing advantage is negligible in n, and* weak *if it is only required to be less than $(1 - 1/n^c)$ for some constant c. We say that L is one-sided average-case hard with* perfect sampling *if N and Y_A only output samples in L_N and L_Y, respectively.*

This kind of hardness turns out to be somewhat related to a weaker kind of OWF called auxiliary-input OWF – see Corollary 17. We do not know how to amplify this kind of hardness, so the choice of constants in its definition is not arbitrary.

We consider separately the weak one-sided average-case hardness with perfect sampling, which requires that the YES and NO distribution be contained completely within the respective parts of the problem, but places a much weaker requirement on their indistinguishability. This variant implies the existence of OWFs, though following an approach different from that taken in Lemma 4.

▶ **Lemma 6.** *If there is a problem that is weak one-sided average-case hard with perfect sampling, then One-Way Functions exist.*

2.1 Reductions

Reductions relate the complexities of different problems, and while there are more involved forms of reductions that still do so, in our work we will be using the simple notion of Karp reductions. Roughly, a Karp reduction from L to L' takes an instance x and produces an instance x' whose membership in L' is completely determined by that of x in L. Later definitions below also ask for some additional properties.

▶ **Definition 7** (Karp Reduction). *A polynomial-time algorithm R is a* Karp reduction *from a problem L to a problem L' if for all large enough n:*

$$x \in L_Y \cap \{0,1\}^n \implies \Pr[\mathsf{R}(x) \in L'_Y] \geq 0.9$$
$$x \in L_N \cap \{0,1\}^n \implies \Pr[\mathsf{R}(x) \in L'_N] \geq 0.9$$

In this case, L is said to reduce *to L'. If the above probabilities are both 1, then A is said to be a* perfect *Karp reduction.*

A worst-case reduction like the one above from L to L' allows us to conclude that L' is worst-case hard if L is worst-case hard. Throughout the rest of this work, we will be drawing conclusions about the two-sided and one-sided average-case hardness of L' that follow from analogous notions of worst-to-average-case reductions defined below.

▶ **Definition 8** (Two-Sided Average-Case Karp Reduction). *A polynomial-time algorithm* R *is a* two-sided average-case Karp reduction *from a problem* L *to a problem* L' *if there are two polynomial-time samplers* Y *and* N *such that the following hold for all large enough* n*:*

- Y *and* N *mostly sample instances from* L'_Y *and* L'_N*, respectively. That is,*

$$\Pr_{x \leftarrow \mathsf{Y}(1^n)}[x \notin L'_Y] \leq 0.1$$

$$\Pr_{x \leftarrow \mathsf{N}(1^n)}[x \notin L'_N] \leq 0.1$$

- *For any* $x \in L_N \cap \{0,1\}^n$*, the output of* $\mathsf{R}(x)$ *is close to that of* $\mathsf{N}(1^n)$*. That is, for such* x*,*

$$\Delta\left(\mathsf{R}(x); \mathsf{N}(1^n)\right) \leq 0.1$$

- *For any* $x \in L_Y \cap \{0,1\}^n$*, the output of* $\mathsf{R}(x)$ *is close to that of* $\mathsf{Y}(1^n)$*. That is, for such* x*,*

$$\Delta\left(\mathsf{R}(x); \mathsf{Y}(1^n)\right) \leq 0.1$$

A two-sided average-case reduction from L to L' allows us to conclude that L' is two-sided average-case hard if L is worst-case hard.

▶ **Lemma 9.** *Suppose there is a two-sided average-case Karp reduction from a language* L *to a language* L'*, and* L *is worst-case hard. Then,* L' *is two-sided average-case hard.*

Finally, we define one-sided average-case reductions, which similarly relate one-sided average-case hardness to worst-case hardness.

▶ **Definition 10** (One-Sided Average-Case Karp Reduction). *A polynomial-time algorithm* R *is a* one-sided average-case Karp reduction *from a problem* L *to a problem* L' *if there is a polynomial-time sampler* N *such that the following hold for all large enough* n*:*

- N *mostly samples instances from* L'_N*. That is,*

$$\Pr_{x \leftarrow \mathsf{N}(1^n)}[x \notin L'_N] \leq 0.1$$

- *For any* $x \in L_N \cap \{0,1\}^n$*, the output of* $\mathsf{R}(x)$ *is close to that of* $\mathsf{N}(1^n)$*. That is, for such* x*,*

$$\Delta\left(\mathsf{R}(x); \mathsf{N}(1^n)\right) \leq 0.1$$

- *For any* $x \in L_Y \cap \{0,1\}^n$*, the output of* $\mathsf{R}(x)$ *is mostly contained in* L'_Y*. That is, for such* x*,*

$$\Pr_{x' \leftarrow \mathsf{R}(x)}[x' \notin L'_Y] \leq 0.1$$

The reduction is said to be strong *if for any* $x \in L_N \cap \{0,1\}^n$*, the distance* $\Delta\left(\mathsf{R}(x); \mathsf{N}(1^n)\right)$ *is negligible in* n*, and is* weak *if this is at most* $1 - 1/n^c$ *for some constant* c*. The reduction is said to have* perfect sampling *if the probability that the outputs of* N *or* $\mathsf{R}(x)$ *when* $x \in L_Y$ *are not in* L'_N *and* L'_Y*, respectively, are* 0*.*

▶ **Lemma 11.** *Suppose there is a one-sided average-case Karp reduction from a language L to a language L', and L is worst-case hard. Then, L' is one-sided average-case hard. Further, if the reduction is weak and has perfect sampling, then the hardness is also weak and has perfect sampling.*

3 Statistical Zero Knowledge

One of the paths we take to showing the existence of OWFs is through a one-sided average-case hard problem that also has a statistical zero-knowledge proof. The class SZK of problems that have statistical zero-knowledge proofs has been widely studied in the past, partly owing to its connections to cryptography (see [29] and discussions and references therein). Due to a completeness theorem of Sahai and Vadhan [27], we may equivalently define this class in the following manner that is more convenient for us.

▶ **Definition 12** (Statistical Zero Knowledge [27])**.** Statistical Zero Knowledge *(*SZK*) is the class of promise problems which have a perfect Karp reduction to the* Statistical Difference problem *(*SD*), which is defined over pairs of circuits (C_0, C_1), as follows:*

$$\mathrm{SD}_Y = \{(C_0, C_1) \mid \Delta(C_0(U)); C_1(U))) > 2/3\}$$
$$\mathrm{SD}_N = \{(C_0, C_1) \mid \Delta(C_0(U)); C_1(U))) < 1/3\}$$

where n is the output length of both C_0 and C_1, and the U's above represent uniform distributions over the appropriate input domains.

We will also use the following two results regarding SZK.

▶ **Lemma 13** (Polarization [27])**.** *There exists an efficient procedure* Polarize *that when given two circuits C_0, C_1 and a parameter 1^λ as input outputs C_0', C_1' such that*

- *If $\Delta(C_0(U); C_1(U)) > 2/3$, then $\Delta(C_0'(U); C_1'(U)) > 1 - 2^{-\lambda}$.*
- *If $\Delta(C_0(U); C_1(U)) < 1/3$, then $\Delta(C_0(U); C_1(U)) < 2^{-\lambda}$.*

▶ **Theorem 14** (SZK closed under complement [24])**.** *If $\Pi = (\Pi_Y, \Pi_N) \in \mathsf{SZK}$, then $\overline{\Pi} = (\overline{\Pi}_Y, \overline{\Pi}_N) \in \mathsf{SZK}$ where $\overline{\Pi}_Y = \Pi_N$ and $\overline{\Pi}_N = \Pi_Y$.*

As noted in Lemma 4, two-sided average-case hardness of any problem implies the existence of OWFs. Ostrovsky [25] showed that *plain* average-case hardness of any problem in SZK also implies the existence of OWFs. Furthermore, Ostrovsky and Wigderson [26] observe that the *worst-case* hardness of any problem in SZK implies the existence of *auxiliary-input* one-way functions.[6] We show the following incomparable theorem.

▶ **Theorem 15.** *If there is a problem in* SZK *that is one-sided average-case hard, then One-Way Functions exist.*

[6] Roughly, auxiliary-input one-way functions (against non-uniform adversaries) exist if there is polynomial p such that for every family of poly size circuits, $\{\mathsf{A}_n\}_{n\in\mathbb{N}}$ there is family of circuits of size $p(n)$, $\{\mathsf{F}_n\}_{n\in\mathbb{N}}$, such that A_n fails to invert F_n when given a description of F_n as an auxiliary input. Contrast this with the notion of non-uniform one-way functions we use throughout: a (fixed) family of poly-sized circuits, $\{\mathsf{F}_n\}_{n\in\mathbb{N}}$ is a non-uniform one-way function if for *any* poly-sized circuit family $\{\mathsf{F}_n\}$ is hard to invert. So far as we know, the latter is strictly stronger. Interestingly however, if one is concerned with security against *uniform* adversaries, the quantifiers can be switched via diagonalization arguments and the two notions are equivalent.

Proof. We show that such hardness implies the existence of two samplable distributions that are α-statistically far but β-computationally indistinguishable, where there is a noticeable gap between α and β. (Here, we will take $\alpha = 4/5 - \text{negl}(n)$ and $\beta = 3/4$.) The rest follows from the results of Goldreich and Naor-Rothblum [15, 23].

The completeness of the complement of Statistical Difference(by Theorem 14) implies that for any problem L in SZK, there is a reduction R that takes input x and outputs two circuits that sample distributions that are far if $x \in L_N$, and negligibly close if $x \in L_Y$. Let L be the one-sided average-case hard problem in SZK and let N be the sampler for its fixed NO distribution. The two distributions we want are sampled by the samplers D_0 and D_1 below given security parameter n:

- $\mathsf{D}_0(1^n)$: Sample $x \leftarrow \mathsf{N}(1^n)$. Compute $(C_0, C_1) \leftarrow \mathsf{R}(x)$. Compute circuits $(C'_0, C'_1) \leftarrow \text{Polarize}(1^n, C_0, C_1)$. Pick random r of appropriate length and output $((C'_0, C'_1), C_0(r))$.
- $\mathsf{D}_1(1^n)$: Same as above, but output $((C'_0, C'_1), C'_1(r))$ at the end.

By definition, the event that $\mathsf{N}(1^n)$ outputs something not in L_N happens with probability at most $1/10$. By the definition of $\overline{\text{SD}}$, conditioned on this event not happening, for any fixed output C_0, C_1 we have that $\Delta(C_0(U); C_1(U)) > 2/3$. If this is the case, it follows from Lemma 13 that $\Delta(C'_0(U); C'_1(U)) > 1 - 2^{-n}$ It follows that, *conditioned on this event not happening*, we have $\Delta(\mathsf{D}_0(1^n); \mathsf{D}_1(1^n)) > 1 - \text{negl}(n)$. By standard manipulations[7], we get that $\Delta(\mathsf{D}_0(1^n); \mathsf{D}_1(1^n)) > .8 - \text{negl}(n)$.

To see that these distributions are 3/4-computationally indistinguishable, consider any distinguisher A for them. Suppose A has more than 3/4 advantage in distinguishing $\mathsf{D}_0(1^n)$ from $\mathsf{D}_1(1^n)$. But then consider A' that attempts to solve L by on input x running the reduction,R, and polarization procedure, $\text{Polarize}(1^n, \cdot, \cdot)$ to get C'_0, C'_1, flipping a coin $b \leftarrow U_{\{0,1\}}$, and outputting 1 if $\mathsf{A}(C'_0, C'_1, C'_b(U)) = b$. If A' is given inputs from $N(1^n)$, then what it feeds A is identically distributed to either $D_0(1^n)$ (if $b = 0$) or $D_1(1^n)$ (if $b = 1$). It follows from A's advantage that $Pr[\mathsf{A}'(N(1^n))] > \frac{1+3/4}{2} = .875$.

On the other hand, by virtue of the fact that L is one-sided average case hard there is a distribution $\mathsf{Y}_{\mathsf{A}'}$ which is .3-indistinguishable from N to A'. Consider $\mathsf{A}'(\mathsf{Y}_{\mathsf{A}'})$. First of all $\Pr[\mathsf{Y}_{\mathsf{A}'} \in L_Y] \geq .9$. Moreover, for any such $x \in L_Y$, $\mathsf{R}(x) \in \overline{\text{SD}}_N$. In this case, $\text{Polarize}(1^n)$ will output (C'_0, C'_1) such that $\Delta(C'_0(U); C'_1(U)) < 2^{-n}$. Therefore, with probability at least .9, the two circuits A' gives to A correspond to distributions with negligible distance from one another. It follows from standard manipulations that A, regardless of efficiency, can distinguish with probability at most $.1 + \text{negl}(n)$. Thus, $\Pr[\mathsf{A}'(\mathsf{Y}_{\mathsf{A}'}) = 1] \leq \frac{1+.15}{2} = .575$.

But then $\Pr[\mathsf{A}'(\mathsf{N}_{\mathsf{A}'}) = 1] - \Pr[\mathsf{A}'(\mathsf{Y}_{\mathsf{A}'}) = 1] > .3$, which violates the assumption on $\mathsf{Y}_{\mathsf{A}'}$ following from the average-case hardness of L. ◀

The above theorem talks about the implication of a problem that is both one-sided hard and is in SZK. The following lemma, which was implicitly used by Drucker [13], says that membership of a problem in SZK is implied by the existence of any one-sided average-case reduction *from* it. A stronger version of this lemma (in different terminology) was also proven by Applebaum and Raykov [5].

▶ **Lemma 16.** *If there is a one-sided average-case Karp reduction from a problem L to any other problem, then L is in* SZK.

[7] For any random variables X, Y, Z and any event E, $\Delta(X;Y) \in [\Pr[Z \in E]\Delta(X|Z \in E; Y|Z \in E) \pm \Pr[Z \notin E]]$.

Proof of Lemma 16. We show this by reduction to the Statistical Difference problem, and appealing to its completeness of SZK and the closure of the class under complement. Suppose R is the one-sided average-case Karp reduction and N is the canonical NO distribution from Definition 10. The reduction is, given input x for L, to output the pair of circuits $(\mathsf{N}(1^n;\cdot), \mathsf{R}(x;\cdot))$ – each of these takes the randomness for the respective algorithm as input and produces the corresponding output. The properties of the one-sided reduction guarantee that if $x \in L_N$, then $\Delta(\mathsf{N}(1^n); \mathsf{R}(x))$ is at most 0.1, while if $x \in L_Y$, then this is at least 0.9. ◀

Because worst-case hard languages in SZK imply auxiliary-input one-way functions [26], the following is an immediate consequence of Lemma 16. We refer the reader to [26] for the definition of auxiliary-input one-way functions.

▶ **Corollary 17.** *If L is worst-case hard and there is a one-sided average-case Karp reduction from L to any other problem, then auxiliary-input one-way functions exist.*

Starting with a stronger hypothesis – a *two-sided* average-case reduction from L – we show membership in SRE, which is the class of problems that have statistical randomized encodings (and is a subset of SZK). We refer the reader to [5] for the definitions of randomized encodings and this class.

▶ **Lemma 18.** *If there is a two-sided average-case Karp reduction from a problem L to any other problem, then L is in* SRE*.*

This lemma is proven in the same way as Lemma 16, with the two fixed distributions of the randomized encodings taken to be Y and N from the two-sided average-case reduction (see Definition 8).

4 Lossy Reductions

In this section, we define our notions of lossy reductions, and show their implications for OWFs. We start with a definition of what it means for a generic algorithm to lose information about its input. All algorithms in this section are randomized and non-uniform unless specified otherwise.

▶ **Definition 19** (Lossy Algorithm)**.** *An algorithm* C *is said to* t-lossy on n-bit inputs *for some $n \in \mathbb{N}$ and $t \in \mathbb{R}^+$ if, for any random variable X over $\{0,1\}^n$,*

$$\mathrm{I}(X; \mathsf{C}(X)) \leq t$$

Note that being t-lossy means, in a sense, that the algorithm loses $(n - t(n))$ bits of information. For convenience, we overload the above terminology for the following special cases of reductions.

▶ **Definition 20** (Lossy Reduction)**.** *For a function $t : \mathbb{N} \to \mathbb{R}^+$, a Karp reduction from a problem L to a problem L' is said to be* t-lossy *if, for every $n \in \mathbb{N}$, it is $t(n)$-lossy on n-bit inputs.*

For a polynomial m, consider a family $f = \left\{f_n : \{0,1,\perp\}^{m(n)} \to \{0,1,\perp\}\right\}$ of partial functions. Define the problem $f \circ L$ on inputs from $\{0,1\}^{n \times m(n)}$ as the composition of f with $m(n)$ copies of L; that is, for $x_1, \ldots, x_{m(n)} \in \{0,1\}^n$, define $(f \circ L)(x_1, \ldots, x_{m(n)}) = f(L(x_1), \ldots, L(x_{m(n)}))$. We also overload the terminology for reductions from such compositions as follows.

▶ **Definition 21** (Lossy f-Reduction). *Let $m : \mathbb{N} \to \mathbb{N}$ and $t : \mathbb{N} \to \mathbb{R}^+$ be polynomials, and $f = \left\{f_n : \{0,1,\bot\}^{m(n)} \to \{0,1,\bot\}\right\}$ be a family of partial functions. For a problem L, a Karp reduction from $f \circ L$ to a problem L' is said to be* t-lossy *if, for every $n \in \mathbb{N}$, it is $t(n)$-lossy on $(n \cdot m(n))$-bit inputs. We say in this case that L has a t-lossy f-reduction to L'.*

In the last two definitions, the problem L is said to have a t-lossy *self-reduction* (or self-f-reduction) if L' is the same as L. During many of our discussions, the size parameter n will be fixed, and when it is, we will use just t and m to denote the numbers $t(n)$ and $m(n)$.

We first consider the family of OR functions – for some polynomial m, the family $\mathrm{OR}_m = \left\{\mathrm{OR}^n : \{0,1,\bot\}^{m(n)} \to \{0,1,\bot\}\right\}_{n\in\mathbb{N}}$, where OR^n is a function from $\{0,1,\bot\}^{m(n)}$ to $\{0,1,\bot\}$ that is the Boolean OR of its inputs if they are all from $\{0,1\}$, and is $\bot$ if any of its inputs is $\bot$. Drucker [13] showed that any problem that is OR_m-compressible to $O(m(n)\log n)$ bits is contained in SZK, where his notion of compression to t bits was that the output length of the reduction is at most t bits (similar to Definition 31). We observe that his proof works almost as is for reductions that are lossy in the sense of Definition 21 (but that may not be compressing). We isolate the following lemma that is implicit in [13], which will be useful for us, and state it in terms of average-case Karp reductions.

▶ **Lemma 22.** *Suppose, for some polynomial m and problems L, L', there is a reduction from $\mathrm{OR}_m \circ L$ to L'. If this reduction is $(m/100)$-lossy and $m(n) > 100$ for all large enough n, then there is a one-sided average-case Karp reduction from L to L'.*

As noted above, Drucker shows membership in SZK as long as the compression (or loss) is to $O(m \log n)$ bits, but the implication of the one-sided average-case reduction as in Lemma 22 seems to follow only if the loss is to somewhat less than m bits. In the case where the reduction from $\mathrm{OR}_m \circ L$ does not make any errors, however, we can recover a weak one-sided average-case reduction with perfect sampling even if the loss is only to $O(m \log n)$ bits.

▶ **Lemma 23.** *Suppose, for some polynomial m and problems L, L', there is a* perfect *reduction from the problem $\mathrm{OR}_m \circ L$ to L'. If this reduction is $O(m \log n)$-lossy, then there is a weak one-sided average-case Karp reduction with perfect sampling from L to L'.*

Define MAJ_m in the same way as OR_m, but with the Majority function. We extend Drucker's results and show the following stronger conclusion from lossy Majority-reduction – that it implies a two-sided average-case reduction (or a randomized encoding, following Lemma 18).

▶ **Lemma 24.** *Suppose, for some polynomial m and problems L, L', there is a reduction from the problem $\mathrm{MAJ}_m \circ L$ to L'. If this reduction is $m/100$-lossy and $m(n) > 100$ for all large enough n, then there is a two-sided average-case Karp reduction from L to L'.*

The proofs of these lemmas are in Appendix B.

4.1 Lossy Reductions and One-Way Functions

We now state and prove our main theorems, showing that certain lossy reductions for a problem L can be used to lift its worst-case hardness to a One-Way Function. Each of our three theorems is proven by following a different path, as explained in the respective proofs. The first says that good enough lossy self-OR-reduction implies a OWF.

▶ **Theorem 25.** *Suppose, for some polynomial m and a problem L, there is a reduction from $\mathrm{OR}_m \circ L$ to L that is $(m/100)$-lossy. If L is worst-case hard and $m(n) > 100$ for all large enough n, then One-Way Functions exist.*

Proof of Theorem 25. This theorem is proven by showing that the hypothesis implies that L is both one-sided average-case hard and contained in SZK which, as seen in Section 3, implies a OWF. The proof is as follows:

- Lemma 22 implies that there is a one-sided average-case reduction from L to itself.
- Lemma 16 and the one-sided reduction imply that $L \in \mathsf{SZK}$.
- Together with the worst-case hardness of L and the one-sided reduction, Lemma 11 implies that L is one-sided average-case hard.
- Theorem 15, along with the above two conclusions, implies that OWFs exist. ◀

Our second theorem uses an incomparable hypothesis – that there is a lossy MAJ-reduction, but not necessarily to L itself.

▶ **Theorem 26.** *Suppose, for some polynomial m and a problem L, there is a reduction from $\mathrm{MAJ}_m \circ L$ to some problem that is $(m/100)$-lossy. If L is worst-case hard and $m(n) > 100$ for all large enough n, then One-Way Functions exist.*

Proof of Theorem 26. This theorem is proven by showing that such a reduction implies the existence of a two-sided average-case reduction from L, and using this to go from worst-case hardness of L to OWFs. Suppose the reduction is to a problem L'. The proof is as follows:

- Lemma 24 implies that there is a two-sided average-case reduction from L to L'.
- Together with the worst-case hardness of L and the two-sided reduction, Lemma 9 implies that L' is two-sided average-case hard.
- Lemma 4, along with the above two-sided hardness, implies that OWFs exist. ◀

The third theorem also uses a hypothesis incomparable to the other two – it assumes that the lossy reduction is perfect, but works even if the loss is to more bits than the number of instances it takes as input.

▶ **Theorem 27.** *Suppose, for a polynomial m and a problem L, there is a* perfect *reduction from $\mathrm{OR}_m \circ L$ to some problem that is $O(m \log n)$-lossy. If L is also worst-case hard, then One-Way Functions exist.*

We draw the following interesting corollaries of this theorem, both of which follow from a direct implication of lossy perfect OR-reduction by their respective hypotheses. The first is a statement along the lines of Lemma 4, but incomparable to it. Lemma 4 may be rephrased as saying that a 1-lossy reduction from a worst-case hard language implies OWFs, and Corollary 28 relaxes the requirement to $O(\log n)$-lossiness, but requires the reduction to be perfect.

▶ **Corollary 28.** *Suppose there is a* perfect *reduction from a problem L to another problem that is $O(\log n)$-lossy. If L is also worst-case hard, then One-Way Functions exist.*

The second corollary is the analogue of Theorem 27 for Majority reductions.

▶ **Corollary 29.** *Suppose, for a polynomial m and a problem L, there is a* perfect *reduction from $\mathrm{MAJ}_m \circ L$ to some problem that is $O(m \log n)$-lossy. If L is also worst-case hard, then One-Way Functions exist.*

Proof of Theorem 27. This theorem is proven by showing that a perfect lossy OR-reduction leads to a weak one-sided average-case reduction with perfect sampling, which along with worst-case hardness leads to OWFs. Suppose the reduction is to a problem L'. The proof is as follows:

- Lemma 23 implies that there is a weak one-sided average-case reduction from L to L' with perfect sampling.
- Together with the worst-case hardness of L and the above reduction, Lemma 11 implies that L' is weak one-sided average-case hard with perfect sampling.
- Lemma 6, along with the above hardness, implies that OWFs exist. ◀

5 Collision Resistance

In this section, we show that that one-sided average-case hardness of a language L combined with compressiblility of $\mathrm{OR}_m \circ L$ (in the standard sense of compressed output length), implies the existence of *collision-resistant hash functions.*

The reduction builds directly on the construction of collision-resistant hash functions from homomorphic encryption due to Ishai, Kushilevitz, and Ostrovsky [21] (more generally, from any one-round private information retrieval (PIR) protocol, or homomorphic one-way commitments). Indeed, these cryptographic notions can be viewed precisely as providing compressing reductions for related languages whose average-case hardness is implied by security: e.g., additively homomorphic encryption corresponds directly to self-compression from $(\mathrm{XOR}_m \circ L)$ to L, for the (average-case hard) language L where L_Y is the set of ciphertexts encrypting the bit 1, and L_N is the set of ciphertexts of 0.

We begin by formally defining collision-resistant hash function families and the required form of output-length compression.

▶ **Definition 30.** Collision-resistant hash functions *exist if there exist* $\ell, \ell' : \mathbb{N} \to \mathbb{N}$ *with* $\ell(n) > \ell'(n)$*, an index set* $I \subseteq \{0,1\}^*$*, and probabilistic polynomial-time algorithms of the form:*

- $\mathit{Gen}(1^n)$*, which outputs an index* $s \in I$*,*
- $\mathit{Eval}(s, y)$*, which given index* $s \in I$ *and input* $y \in \{0,1\}^{\ell(n)}$*, outputs* $h_s(y) \in \{0,1\}^{\ell'(n)}$*,*

for which finding collisions is computationally hard. That is, for every polynomial-time (non-uniform) A*, there exists a negligible function* ν *for which*

$$\Pr_{\substack{s \leftarrow \mathit{Gen}(1^n) \\ (y,y') \leftarrow \mathsf{A}(s)}} [(y \neq y') \wedge (\mathit{Eval}(s,y) = \mathit{Eval}(s,y'))] \leq \nu(n).$$

▶ **Definition 31** (Compressing Reduction)**.** *An algorithm* C *is said to* compress n-bit inputs to t bits *for some* $n, t \in \mathbb{N}$ *if for any* $x \in \{0,1\}^n$ *the output bit length is* $|\mathsf{C}(x)| \leq t$*.*

For a function $t : \mathbb{N} \to \mathbb{N}$*, a Karp reduction from a problem* L *to a problem* L' *is said to* t-compressing *if, for every* $n \in \mathbb{N}$*, it is* $t(n)$*-compressing on* n*-bit inputs.*

We now present the main theorem of the section. Note for simplicity, we present the reduction with respect to a *perfect* compressing reduction of $\mathrm{OR}_m \circ L$ (see Definition 7), as well as assuming *perfect* sampling for the one-sided average-case hard language L (that is, for any polynomial-time A, the probability that the outputs of N or Y_A are not in L_N and L_Y, respectively, are set to 0).

▶ **Theorem 32.** *Suppose, for some polynomial* m *and a problem* L*, there is a perfect reduction from* $\mathrm{OR}_m \circ L$ *to* L' *that compresses to* $m/100$ *bits. If* L *is strongly one-sided average-case hard with perfect sampling and* $m(n) > 100$ *for all large enough* n*, then Collision-Resistant Hash Functions exist.*

Recall that existence of a compressing reduction from $(\mathrm{MAJ}_{2m+1} \circ L)$ to L', or from $(\mathrm{AND}_m \circ L)$ to L', each directly imply equivalent compressing reduction from $(\mathrm{OR}_m \circ L)$ to L', up to constant factors of compression. This yields the following corollary.

▶ **Corollary 33.** *The following variations of Theorem 32 additionally hold. Let m be polynomial and L a problem. Then collision-resistant hash functions exist assuming existence of a compressing reduction of the following corresponding kinds (to $m/100$ bits), in addition to the specified hardness requirements on L:*

1. *If there is a compressing reduction from $\mathrm{MAJ}_m \circ L$ to L' and L is strongly one-sided average-case hard with perfect sampling.*
2. *If there is a compressing reduction from $\mathrm{AND}_m \circ L$ to L' and the complement language $\mathsf{co}L$ is strongly one-sided average-case hard with perfect sampling.*

At a high level, the construction mirrors the approach of [21], as follows. Each hash function in the family will be keyed by a collection s of $2m$ randomly sampled no-instances of L (via N). The corresponding hash function $\mathsf{Eval}(s, \cdot)$ takes as input a bit-string $y \in \{0,1\}^m$, and outputs the $m/100$-bit instance of L' generated by applying the compressing reduction on the $(OR_m \circ L)$ instance defined by the m no-instances selected by the bits of y. A successful collision-finder can be used to gain contradictorily high advantage in deciding L (more specifically, in distinguishing a sample of N from the (possibly inefficient) Y_A), by embedding the challenge instance x into a random location $i^* \in [m]$ of the key, and seeing whether the colliding inputs $y \neq y'$ differ in this index i^*. If x was sampled from N, then the concocted key is properly distributed, independent of i^*, and thus y, y' must differ in position i^* with noticeable probability. On the other hand, if x was sampled from Y_A, then any $(\mathrm{OR}_m \circ L)$ instance containing x is a *yes* instance, whereas any instance not containing x is (by construction) a *no* instance; by perfect correctness of the compressing reduction, it thus cannot be the case that any two such inputs y, y' that differ in position i^* could collide to an identical output in L'.

Proof of Theorem 32. Given such a pair of languages L, L', we construct the desired collision-resistant hash function family.

Denote by R the weakly compressing reduction from $(\mathrm{OR}_m \circ L)$ to L'. By one-sided average-case hardness of L (as per Definition 5), there exists a polynomial-time sampling algorithm N which samples instances from L_N. Let $\ell(n) = m$ and $\ell'(n) = m/100$ be the input and (compressed) output length of the hash function. Consider the following algorithms.

- $\mathsf{Gen}(1^n)$: Independently sample $\ell(n) = m$ instances from N. That is, for $(i, b) \in [m] \times \{0,1\}$, let $x_{i,b} \leftarrow \mathsf{N}(1^n)$. Output $s = (x_{i,b})_{i \in [m], b \in \{0,1\}}$.
- $\mathsf{Eval}(s, y)$: Parse $s = (x_{i,b})_{i \in [m], b \in \{0,1\}}$ and $y = (y_1, \ldots, y_m) \in \{0,1\}^m$. Output the R-compression of the $\mathrm{OR}_m \circ L$ instance selected by y. That is, output $\mathsf{R}\left((x_{i,y_i})_{i \in [\ell]}\right) \in \{0,1\}^{m/100}$.

We prove that the above constitutes a collision-resistant hash function family, by showing that any successful collision finder would violate one-sided average-case hardness of L.

Suppose there exists a (non-uniform) polynomial-time algorithm A for which

$$\Pr_{\substack{s \leftarrow \mathsf{Gen}(1^n) \\ (y,y') \leftarrow \mathsf{A}(s)}} [(y \neq y') \wedge (\mathsf{Eval}(s, y) = \mathsf{Eval}(s, y'))] = \epsilon.$$

Consider the following associated algorithm A', which receives as input a bit string $x \in \{0,1\}^n$ and outputs a bit (corresponding to a prediction for $x \in L_Y$ or L_N). Intuitively, A' embeds the input x into a random index of the hash function description, runs the collision-finder A, and outputs 1 if A successfully finds a collision which differs in the embedded index.

Algorithm 1 Algorithm $\mathsf{A}'(x)$.

1. Select a random index $(i^*, b^*) \leftarrow [m] \times \{0,1\}$; let $x_{i^*,b^*} := x$.
   For every $(i,b) \neq (i^*,b^*)$, sample $x_{i,b} \leftarrow \mathsf{N}$. Set $s = (x_{i,b})_{i\in[m],b\in\{0,1\}}$.
2. Execute $(y, y') \leftarrow \mathsf{A}(s)$.
3. If it holds that: (1) $y \neq y'$, (2) $\mathsf{Eval}(s,y) = \mathsf{Eval}(s,y')$, and (3) $y_{i^*} \neq y'_{i^*}$, then output 1.
   Else, output a randomly selected bit $c \leftarrow \{0,1\}$.

By the strong one-sided average-case hardness of L, there exists a negligible function ν' and (possibly inefficient) sampler algorithm $\mathsf{Y}_{A'}$ corresponding to A', for which

$$\left| \Pr_{x\leftarrow\mathsf{N}(1^n)}[\mathsf{A}'(x)=1] - \Pr_{x\leftarrow\mathsf{Y}_{\mathsf{A}'}(1^n)}[\mathsf{A}'(x)=1] \right| \leq \nu'(n). \tag{1}$$

Claim 1: $\Pr_{x\leftarrow\mathsf{N}(1^n)}[\mathsf{A}'(x)=1] \geq \epsilon/m$. Given $x \leftarrow \mathsf{N}(1^n)$, the value of s as generated by A' is identically distributed to that of $\mathsf{Gen}(1^n)$, independent of the selected choice of $i^* \in [m]$. This implies that

$$\begin{aligned}\Pr_{x\leftarrow\mathsf{N}(1^n)}[\mathsf{A}'(x)=1] &= \Pr_{\substack{s\leftarrow\mathsf{Gen}(1^n)\\(y,y')\leftarrow\mathsf{A}(s)}}[(y\neq y') \wedge (\mathsf{Eval}(s,y)=\mathsf{Eval}(s,y')) \wedge (y_{i^*}\neq y'_{i^*})] \\ &\geq \Pr_{\substack{s\leftarrow\mathsf{Gen}(1^n)\\(y,y')\leftarrow\mathsf{A}(s)}}[(y\neq y') \wedge (\mathsf{Eval}(s,y)=\mathsf{Eval}(s,y'))] \cdot \frac{1}{m} = \frac{\epsilon}{m}.\end{aligned}$$

Claim 2: $\Pr_{x\leftarrow\mathsf{Y}_{\mathsf{A}'}(1^n)}[\mathsf{A}'(x)=1] = 0$. Assuming perfect correctness $\Pr_{x\leftarrow\mathsf{Y}_{\mathsf{A}'}}[x \in L_Y] = 1$ and $\Pr_{x\leftarrow\mathsf{N}}[x \in L_N] = 1$, then the embedded instance satisfies $x_{i^*,b^*} \in L_Y$, whereas the ambient instances are in $x_{i,b} \in L_N$ for $(i,b) \neq (i^*,b^*)$. This means for any $y, y' \in \{0,1\}^m$ in which $y_{i^*} \neq y'_{i^*}$, the corresponding selected $\mathrm{OR}_m \circ L$ instances *necessarily* disagree: $(x_{i,y_i})_{i\in[m]} \in (\mathrm{OR}_m \circ L)_Y$ and $(x_{i,y'_i})_{i\in[m]} \in (\mathrm{OR}_m \circ L)_N$, or vice versa. However, by perfect correctness of the compression algorithm R, this implies $\mathsf{R}((x_{i,y_i})_{i\in[m]}) \neq \mathsf{R}((x_{i,y'_i})_{i\in[m]})$. Thus, for any $y, y' \in \{0,1\}^m$ with $y_{i^*} \neq y'_{i^*}$, it must be the case that $\mathsf{Eval}(s,y) \neq \mathsf{Eval}(s,y')$.

Combining the two above claims together with Equation (1) implies that the collision-finding success probability ϵ of A must be bounded above by a negligible value. The theorem follows. ◀

A OWFs and One/Two-Sided Average-Case Hardness

In this section, we restate and prove the lemmas stated in Section 2 about average-case hardness and reductions, and their connections to one-way functions.

A.1 Proof of Lemma 6

▶ **Lemma 6.** *If there is a problem that is weak one-sided average-case hard with perfect sampling, then One-Way Functions exist.*

Proof. Let L be weak one-sided average-case hard with perfect sampling, and N the poly-time sampling algorithm, such that there is a constant c such that for any poly-time distinguisher D there is Y_D such that for almost all n, $|\Pr_r[\mathsf{D}(\mathsf{N}(1^n;r))=1] - \Pr[\mathsf{Y}_D(1^n;r)=1]| < 1 - 1/n^c$. Moreover, $\mathrm{Supp}(\mathsf{N}) \subseteq L_N$ and $\mathrm{Supp}(\mathsf{Y}) \subseteq L_Y$.

Let F be defined for output length n as $\mathsf{F}_n(x) := \mathsf{N}(1^n; x)$. We will show that F is a weak-one-way function. The lemma then follows from classical results. [30, 17, 16]

Suppose, for the sake of contradiction, there exists an efficient A that can invert F_n with probability $> 1 - 1/n^c$, for infinitely many n. Then, consider the (efficient) distinguisher D that simply checks if A was succesful. In particular, D on input x simply:

1. $y \leftarrow \mathsf{A}(x)$
2. If $\mathsf{F}_n(y) = x$, output 1. Otherwise, output 0.

Because A has advantage $1 - 1/n^c$ on F_n, $\Pr_r[\mathsf{A}(\mathsf{N}(1^n; r)) = 1] > 1 - 1/n^c$, for infinitely many n. Now by our assumption on L, there exists Y_D such that $|\Pr_r[\mathsf{D}(\mathsf{N}(1^n; r)) = 1] - \Pr_r[\mathsf{D}(\mathsf{Y}_D(1^n; r)) = 1]| < 1 - 1/n^c$ and $\mathrm{Supp}(\mathsf{Y}_D) \cap \mathrm{Supp}(\mathsf{N}) = \emptyset$, for almost all n. It follows from the latter condition that A will never find preimages (under F) for outputs from Y_D, because they don't exist. It follows that $\Pr_r[\mathsf{D}(Y_D(1^n; r))] = 0$.

But then, $\Pr[\mathsf{D}(\mathsf{N}) = 1] - \Pr[\mathsf{D}(\mathsf{Y}_D) = 1] > 1 - 1/n^c$ for infinitely many n, which contradicts the weak one-sided average-case hardness of L. ◀

A.2 Proof of Lemma 9

▶ **Lemma 9.** *Suppose there is a two-sided average-case Karp reduction from a language L to a language L', and L is worst-case hard. Then, L' is two-sided average-case hard.*

Let Y, N be the samplers guaranteed by the two-sided-ness of the reduction from L to L', R. Let Y, N denote the random variable distributed according to Y and N evaluated on random inputs, respectively.

It suffices to show that for every efficient A, $|\Pr[\mathsf{A}(Y) = 1] - \Pr[\mathsf{A}(Y) = 1]| \leq 3/10$ (for almost all n).

Suppose not, and let A be a counter-example to the above in that $\Delta(\mathsf{A}(Y); \mathsf{A}(N)) > 3/10$ for infinitely many n. Moreover, suppose without loss of generality that $\Pr[\mathsf{A}(Y) = 1] > \Pr[\mathsf{A}(N) = 1]$. Then define A' to be the algorithm for L that on input x: (i) runs the reduction to get $z \leftarrow \mathsf{R}(x)$, then (ii) runs $b \leftarrow \mathsf{A}(z)$, and finally (iii) outputs b. Let R_x be the random variable distributed according to $\mathsf{R}(x)$. By definition, it is the case that $\Delta(R_x; Y) \leq 1/10$ for all $x \in L_Y$ and similarly $\Delta(R_x; N) \leq 1/10$ for all $x \in L_N$. It follows that $\Delta(\mathsf{A}(R_x); \mathsf{A}(N)) \leq 1/10$ for all $x \in L_Y$ and similarly $\Delta(\mathsf{A}(R_x); \mathsf{A}(Y)) \leq 1/10$ for all $x \in L_N$.

Consequently,

$$\begin{aligned} x \in L_Y &\implies \Pr[\mathsf{A}'(x) = 1] = \Pr[\mathsf{A}(R_x) = 1] \geq \Pr[\mathsf{A}(Y) = 1] - 1/10 \\ x \in L_N &\implies \Pr[\mathsf{A}'(x) = 1] = \Pr[\mathsf{A}(R_x) = 1] \leq \Pr[\mathsf{A}(N) = 1] + 1/10 \\ &\qquad\qquad \leq \Pr[\mathsf{A}(Y) = 1] - 2/10. \end{aligned}$$

It follows from standard amplification that L is not worst-case hard, contradicting our assumption on L.

A.3 Proof of Lemma 11

▶ **Lemma 11.** *Suppose there is a one-sided average-case Karp reduction from a language L to a language L', and L is worst-case hard. Then, L' is one-sided average-case hard. Further, if the reduction is weak and has perfect sampling, then the hardness is also weak and has perfect sampling.*

Let R be the one-sided average-case Karp reduction from L to L' with a corresponding NO-instance sampler N. In order to show that L' is one-sided average-case hard, we need to show a NO-instance sampler for L' and, for any polynomial-time A, a YES-distribution Y_A that it cannot distinguish from it. Our NO-instance sampler will be the N from the reduction itself, which satisfies the property that its samples are in L'_N except with probability 0.1.

Given a polynomial-time algorithm A, we claim that, for all large enough n, there exists an $x_y \in L_Y \cap \{0,1\}^n$ such that A cannot distinguish between $\mathsf{R}(x_y)$ and $\mathsf{N}(1^n)$ with advantage more than 0.3. If this were not the case, that is, if for every $x \in L_Y \cap \{0,1\}^n$, the algorithm A could distinguish between $\mathsf{R}(x)$ and $\mathsf{N}(1^n)$ with advantage more than 0.3, then the algorithm A' that, on input x, estimates the probability that $\mathsf{A}(\mathsf{R}(x)) = 1$ up to error say 0.01 could be used to decide L on all instances $x \in (L_Y \cup L_N) \cap \{0,1\}^n$, as for all $x \in L_N$, the reduction promises that $\mathsf{R}(x)$ is at most 0.1-far from $\mathsf{N}(1^n)$. The distribution $\mathsf{Y}_\mathsf{A}(1^n)$ is simply $\mathsf{R}(x_y)$ for such an x_y, and the reduction guarantees that $\mathsf{R}(x_y)$ is contained in L_Y except with probability 0.1, as necessary.

Note that if R is a weak one-sided average-case reduction with perfect sampling, then for any $x \in L_Y, \Pr[\mathsf{R}(x) \notin L'_Y] = 0$, $\Pr[\mathsf{N}(1^n) \notin L'_N] = 0$, and there is a constant c such that for any $x \in L_N$, $\Delta(\mathsf{N}(1^n); \mathsf{R}(x)) \leq 1 - n^{-c}$. Then, again, for any efficient A it follows that $\Delta(\mathsf{A}(\mathsf{N}(1^n)); \mathsf{A}(\mathsf{R}(x))) \leq 1 - n^{-c}$, for any $x \in L_Y$. Now, we can modify the A' above to approximate $\Pr[\mathsf{A}(\mathsf{R}(x)) = 1]$ to within a $\frac{1}{2n^c}$ factor. We claim, as above, that there is some $x_y \in L_Y$ $\Delta(\mathsf{A}(\mathsf{R}(x)); \mathsf{A}(\mathsf{N}(1^n))) \leq 1 - \frac{1}{4n^c}$. If not then for every $x \in L_Y \cup L_N$, $\Delta(\mathsf{A}(\mathsf{R}(x)); \mathsf{A}(\mathsf{N}(1^n))) > 1 - \frac{1}{4n^c}$ and A' will output such that $\mathsf{A}'(x) = L(x)$ with overwhelming probability. It follows that such an x_y exists and again we can take $\mathsf{Y}_A(1^n) = \mathsf{R}(x_y)$. Because $x \in L_Y, \Pr[\mathsf{R}(x) \notin L'_Y] = 0$, it follows that $\Pr[\mathsf{Y}_A(1^n) \notin L'_Y] = 0$.

B Proofs for Section 4

In this section, we restate and prove the lemmas used in Section 4. The proofs of Lemmas 22 and 23 are based on the following lemma that is implicit in [13], in particular following from the proofs of Theorem 7.1 and Claim 7.2 there. While the statement there is in terms of the compression (where the output length of the reduction itself is restricted to t bits), it may be verified that the proof only uses lossiness as in Definitions 19 and 21.

▶ **Lemma 34** ([13]). *Suppose, for some polynomials $m : \mathbb{N} \to \mathbb{N}$ and $t : \mathbb{N} \to \mathbb{R}$, a problem L has a t-lossy OR_m-reduction to a problem L', and the reduction has error $\epsilon(n) < 0.5$. Let*

$$\delta(n) = \min\left\{\sqrt{\frac{\ln 2}{2} \cdot \frac{t(n)+1}{m(n)}}, 1 - 2^{-\frac{t(n)}{m(n)}-3}\right\}$$

Then, for any constant c, there are polynomial-time algorithms A and B such that:

- $\Pr[\mathsf{A}(1^n) \notin L'_N] \leq \epsilon$
- *For any $x \in L_N \cap \{0,1\}^n$, $\Delta(\mathsf{A}(1^n); \mathsf{B}(x)) \leq \delta(n) + n^{-c}$*
- *For any $x \in L_Y \cap \{0,1\}^n$, $\Pr[\mathsf{B}(x) \notin L'_Y] \leq \epsilon$*

We now use this to prove the following lemmas.

▶ **Lemma 22.** *Suppose, for some polynomial m and problems L, L', there is a reduction from $\mathrm{OR}_m \circ L$ to L'. If this reduction is $(m/100)$-lossy and $m(n) > 100$ for all large enough n, then there is a one-sided average-case Karp reduction from L to L'.*

Proof of Lemma 22. The reduction from the hypothesis has error at most 0.1, and is t-lossy for $t = m/100$. Applying Lemma 34 with $c = 1$ gives us algorithms A and B as in its statement, with $\delta(n) < \sqrt{\ln 2/100}$ for large enough n. We get a one-sided Karp reduction from L to L' with the algorithm B as the reduction and A the corresponding NO-instance sampler. ◀

▶ **Lemma 23.** *Suppose, for some polynomial m and problems L, L', there is a* perfect *reduction from the problem $\mathrm{OR}_m \circ L$ to L'. If this reduction is $O(m \log n)$-lossy, then there is a weak one-sided average-case Karp reduction with perfect sampling from L to L'.*

Proof of Lemma 23. Here, the reduction has error 0, and is t-lossy for $t = c'm \log n$ for some constant c'. Applying Lemma 34 with $c = c' + 2$, we get $\delta(n) = 1 - 2^{-(c' \log n + 3)}$, which is less than $1 - 1/n^{c-1}$ for large enough n. We get a weak-perfect one-sided reduction from L to L' with the algorithm B as the reduction and A as the corresponding NO-instance sampler. ◀

Closely along the lines of Drucker [13], we show the following analogue of Lemma 34 for Majority reductions, and use it to prove Lemma 24. We defer the proof of this lemma to Appendix B.1.

▶ **Lemma 35.** *Suppose, for some polynomials $m : \mathbb{N} \to \mathbb{N}$ and $t : \mathbb{N} \to \mathbb{R}$, a problem L has a t-lossy MAJ_m-reduction to a problem L', and the reduction has error $\epsilon(n) < 0.5$. Let*

$$\delta(n) = \min\left\{\sqrt{\frac{(t+1)\ln 2}{m+1}}, 1 - 2^{-\frac{2t}{m+2}-3}\right\}$$

Then, for any constant c, there are polynomial-time algorithms Y, N and R such that:

- $\Pr[\mathsf{N}(1^n) \notin L'_N] \leq \epsilon$
- $\Pr[\mathsf{Y}(1^n) \notin L'_Y] \leq \epsilon$
- *For any $x \in L_N \cap \{0,1\}^n$, $\Delta(\mathsf{N}(1^n); \mathsf{R}(x)) \leq \delta(n) + n^{-c}$*
- *For any $x \in L_Y \cap \{0,1\}^n$, $\Delta(\mathsf{Y}(1^n); \mathsf{R}(x)) \leq \delta(n) + n^{-c}$*

▶ **Lemma 24.** *Suppose, for some polynomial m and problems L, L', there is a reduction from the problem $\mathrm{MAJ}_m \circ L$ to L'. If this reduction is $m/100$-lossy and $m(n) > 100$ for all large enough n, then there is a two-sided average-case Karp reduction from L to L'.*

Proof of Lemma 24. The reduction we start with has error 0.1 and is t-lossy for $t = m/100$ bits. Applying Lemma 35 with $c = 1$, we get algorithms R, Y and N with $\delta < \sqrt{\ln 2/100}$ for all large enough n. We get a two-sided Karp reduction from L to L' with the algorithm Y as the YES-instance sampler, N as the NO-instance sampler, and R as the reduction. ◀

B.1 Proof of Lemma 35

Throughout this subsection, we will be concerned with a (possibly randomized) mapping $\mathsf{F} : (\{0,1\}^n)^m \to \{0,1\}^*$ for some odd m and $n \in \mathbb{N}$. The following notation will be useful in our discussions. Suppose D_0 and D_1 are distributions over $\{0,1\}^n$. By $\mathsf{F}(D_0^k, D_1^\ell)$, we denote the execution of F on m inputs, k of which are sampled from D_0, and ℓ from D_1, and the whole set of samples is randomly permuted before being input to F. For an $x \in \{0,1\}^n$, $\mathsf{F}(D_0^k, D_1^\ell, x)$ is similar, except along with the $(k + \ell)$ samples, x is also inserted. We will use the following concept of distributional stability that is similar to the one used by Drucker [13], but specialised for pairs of distirbutions.

▶ **Definition 36.** *Let $m, n, k \in \mathbb{N}$, with $m = 2k + 1$, and $\delta \in [0, 1]$. A (possibly randomized) mapping $\mathsf{F} : (\{0,1\}^n)^m \to \{0,1\}^*$ is said to be* δ-distributionally stable *(denoted δ-DS) over a pair of distributions (D_0, D_1) over $\{0,1\}^n$ if the following holds:*

$$\mathop{\mathbb{E}}_{x \leftarrow D_0} \left[\Delta\left(\mathsf{F}(D_0^k, D_1^k, x); \mathsf{F}(D_0^{k+1}, D_1^k)\right)\right] \leq \delta$$

The proof of Lemma 35 follows from the following propositions.

▶ **Proposition 37.** *Let $m, n, k \in \mathbb{N}$, and $t \in \mathbb{R}^+$, with $m = 2k + 1$. Any (possibly randomized) mapping $\mathsf{F} : (\{0,1\}^n)^m \to \{0,1\}^*$ that is t-lossy on nm-bit inputs is δ-distributionally stable over any pair of distributions (D_0, D_1) over $\{0,1\}^n$, where $\delta = \min\left\{\sqrt{\frac{(t+1)\ln 2}{m+1}}, 1 - 2^{-\frac{2t}{m+2}-3}\right\}$.*

▶ **Proposition 38.** *Let $m, n, k \in \mathbb{N}$, with $m = 2k + 1$. Suppose $\mathsf{F} : (\{0,1\}^n)^m \to \{0,1\}^*$ is δ-DS over all pairs of distributions over $\{0,1\}^n$. For any pair of disjoint sets $S_0, S_1 \subseteq \{0,1\}^n$, any $\ell > 0$, and any $\nu \in (0, 1)$, there exists a distibution K over $S_0^\ell \times S_1^\ell$ such that:*

- *K is samplable in time $\mathsf{poly}(n, \ell, 1/\nu^2)$*
- *For any $x \in S_0$,*

$$\mathop{\mathbb{E}}_{(T_0,T_1)\leftarrow K} \left[\Delta\left(\mathsf{F}(U_{T_0}^k, U_{T_1}^k, x); \mathsf{F}(U_{T_0}^{k+1}, U_{T_1}^k)\right)\right] \leq \delta + 2m/\ell + \nu$$

- *For any $x \in S_1$,*

$$\mathop{\mathbb{E}}_{(T_0,T_1)\leftarrow K} \left[\Delta\left(\mathsf{F}(U_{T_1}^k, U_{T_0}^k, x); \mathsf{F}(U_{T_1}^{k+1}, U_{T_0}^k)\right)\right] \leq \delta + 2m/\ell + \nu$$

where U_T is the uniform distribution over the multiset T.

Proof of Lemma 35. Given a reduction A from $\mathrm{MAJ}_m \circ L$ to L' that is t-lossy and the constant c, we construct the algorithms Y, N, and R as required by the lemma. Fix a value of n and, for convenience, denote $m(n)$ and $t(n)$ by just m $(= 2k + 1)$ and t.

First, we apply Proposition 37 to A, which tells us that it is δ-DS over any pair of distributions over $\{0,1\}^n$, with δ as in the statement. This lets us apply Proposition 38 taking the sets S_0 and S_1 to be $L_N \cap \{0,1\}^n$ and $L_Y \cap \{0,1\}^n$, respectively, and with $\ell = 4mn^c$ and $\nu = 1/2n^c$ there. Proposition 38 then gives us a samplable distribution K over $L_N^\ell \times L_Y^\ell$.

The algorithm N, on input 1^n, samples (T_0, T_1) from the K obtained as above, and outputs a sample from $\mathsf{A}(U_{T_0}^{k+1}, U_{T_1}^k)$. The algorithm R is the same, except it outputs $\mathsf{A}(U_{T_1}^{k+1}, U_{T_0}^k)$. The algorithm R, on input x, similarly samples (T_0, T_1) and outputs $\mathsf{A}(U_{T_0}^k, U_{T_1}^k, x)$.

That the outputs of $\mathsf{N}(1^n)$ and $\mathsf{Y}(1^n)$ are contained in L'_N except with error ϵ follows from the fact that $T_0 \subseteq L_N$, $T_1 \subseteq L_Y$, and A has error at most ϵ.

Next, for any $x \in L_N \cap \{0,1\}^n$, we are interested in the following distance:

$$\begin{aligned}
\Delta\left(\mathsf{N}(1^n); \mathsf{R}(x)\right) &= \Delta\left(\mathsf{A}(U_{T_0}^{k+1}, U_{T_1}^k); \mathsf{A}(U_{T_0}^k, U_{T_1}^k, x)\right) \\
&\leq \Delta\left((T_0, T_1, \mathsf{A}(U_{T_0}^{k+1}, U_{T_1}^k)); (T_0, T_1, \mathsf{A}(U_{T_0}^k, U_{T_1}^k, x))\right) \\
&= \mathop{\mathbb{E}}_{(T_0,T_1)\leftarrow K} \left[\Delta\left(\mathsf{A}(U_{T_0}^{k+1}, U_{T_1}^k); \mathsf{A}(U_{T_0}^k, U_{T_1}^k, x)\right)\right] \\
&\leq \delta + 2m/\ell + \nu = \delta + 3/4n^c
\end{aligned}$$

where the first inequality follows from the data processing inequality, and the second from Proposition 38. The analogous guarantee for $x \in L_Y \cap \{0,1\}^n$ and $\mathsf{Y}(1^n)$ is shown in the same way. This proves the lemma. ◀

Proof of Proposition 37. We prove this by reduction to the simpler distributional stability lemma proved by Drucker [13]. Recall that $\mathsf{F}(D_0^{k+1}, D_1^k)$ is computed by sampling $x_1, \ldots, x_{k+1} \leftarrow D_0$ and $y_1, \ldots y_k \leftarrow D_1$, and a random permutation π over $[2k+1]$, and then computing the output as $\mathsf{F}(\pi(x_1, \ldots, x_{k+1}, y_1, \ldots, y_k))$. Alternatively, we can write this as the random variable $F(\Pi(\overline{X}, \overline{Y}))$. Similarly, we can write $\mathsf{F}(D_0^k, D_1^k, x)$ as $\mathsf{F}(\Pi(x, \overline{X'}, \overline{Y'}))$. The distance we are interested in is now:

$$\Delta\left(\mathsf{F}(\Pi(\overline{X}, \overline{Y})); \mathsf{F}(\Pi(x, \overline{X'}, \overline{Y}))\right)$$

We split the process of sampling Π into two parts. First, we sample the part of the permutation that maps the last k inputs (corresponding to $\overline{Y}$) to get an intermediate random variable $\widehat{\Pi}$, which is uniform over the set of permutations that all map their last k inputs to the same places, and then sample the final permutation π from this variable. We have:

$$\begin{aligned}\Delta\left(\mathsf{F}(\Pi(\overline{X}, \overline{Y})); \mathsf{F}(\Pi(x, \overline{X'}, \overline{Y}))\right) &\leq \Delta\left((\widehat{\Pi}, \mathsf{F}(\Pi(\overline{X}, \overline{Y}))); (\widehat{\Pi}, \mathsf{F}(\Pi(x, \overline{X'}, \overline{Y})))\right) \\ &= \mathop{\mathbb{E}}_{\widehat{\pi} \leftarrow \widehat{\Pi}} \left[\Delta\left(\mathsf{F}(\Pi_{\widehat{\pi}}(\overline{X}, \overline{Y})); \mathsf{F}(\Pi_{\widehat{\pi}}(x, \overline{X'}, \overline{Y}))\right)\right]\end{aligned}$$

where the first inequality is by the data processing inequality, and in the last expectation $\Pi_{\widehat{\Pi}}$ represents Π sampled conditioned on the last k inputs being mapped according to $\widehat{\pi}$.

For any $\widehat{\pi}$ sampled from $\widehat{\Pi}$, define the mapping $\mathsf{G}_{\widehat{\pi}}$ on input $(x_1, \ldots, x_{k+1})$ as the one obtained by sampling $(y_1, \ldots, y_k) \leftarrow \overline{Y}$, and running F with the y_i's in the positions assigned by $\widehat{\pi}$, and the x_i's in lexicographic order in the rest. We can now apply [13, Lemma 6.2], which is paraphrased below, to the quantity inside the first expectation with $\mathsf{G}_{\widehat{\pi}}$ as the mapping to get the proposition.

▶ **Proposition 39** ([13, Lemma 6.2])**.** *Let $m, n \in \mathbb{N}$, and $t \in \mathbb{R}^+$. Any (possibly randomized) mapping $\mathsf{F} : (\{0,1\}^n)^m \to \{0,1\}^*$ that is t-lossy on nm-bit inputs satisfies the following for any distribution D over $\{0,1\}^n$:*

$$\mathop{\mathbb{E}}_{x \leftarrow D}\left[\Delta\left(\mathsf{F}(D^k, x); \mathsf{F}(D^{k+1})\right)\right] \leq \delta$$

where $\delta = \min\left\{\sqrt{\frac{\ln 2}{2} \cdot \frac{t+1}{m}}, 1 - 2^{-\frac{t}{m}-3}\right\}$.

While the lemma in [13] was stated for compression as measured by output length, it may be verified that its proof there only uses lossiness. ◀

In order to prove Proposition 38, we need the following proposition that is proven in the same way as [13, Lemma 6.3].

▶ **Proposition 40.** *Suppose F is δ-DS over all pairs of distributions over $\{0,1\}^n$. For a pair of distributions (D_0, D_1), denote by $\widehat{D}_{0,\ell}$ (respectively $\widehat{D}_{1,\ell}$) the empirical distribution formed by taking ℓ samples from D_0 (respectively D_1). (Note that these are themselves random variables.) Then,*

$$\mathop{\mathbb{E}}_{\substack{\widehat{D}_{0,\ell}, \widehat{D}_{1,\ell} \\ x \leftarrow D_0}}\left[\Delta\left(\mathsf{F}(\widehat{D}_{0,\ell}^k, \widehat{D}_{1,\ell}^k, x); \mathsf{F}(\widehat{D}_{0,\ell}^{k+1}, \widehat{D}_{1,\ell}^k)\right)\right] \leq \delta + 2m/\ell$$

Proof of Proposition 38. We proceed by considering the following two-player zero-sum game:

- Player 1 chooses a pair of multisets $T_0 \subseteq S_0$ and $T_1 \subseteq S_1$, both of size ℓ
- Player 2 chooses a string $x \in S_0 \cup S_1$

- If $x \in S_0$, Player 2 gets a payoff of $\Delta\left(\mathsf{F}(U^k_{T_0}, U^k_{T_1}, x); \mathsf{F}(U^{k+1}_{T_0}, U^k_{T_1})\right)$, and if $x \in S_1$, it gets a payoff of $\Delta\left(\mathsf{F}(U^k_{T_1}, U^k_{T_0}, x); \mathsf{F}(U^{k+1}_{T_1}, U^k_{T_0})\right)$

The rest of the proof follows that of [13, Lemmas 6.4 and 6.5]. For any randomized strategy of Player 2, which is a distribution X over $S_0 \cup S_1$, consider the randomized strategy of Player 1 (T_0, T_1) where each element of T_0 (respectively T_1) is sampled from the distribution X restricted to S_0 (respectively S_1), denoted $X|_{S_0}$ (denoted $X|_{S_1}$). In the case where X is not supported in S_0 (respectively S_1), the set T_0 is chosen arbitrarily from S_0 (respectively T_1 from S_1). The payoff of this strategy for Player 2 is calculated as follows:

$$\begin{aligned}\Pr_{x \leftarrow X}\left[x \in S_0\right] \mathop{\mathbb{E}}_{x \leftarrow X|_{S_0}, T_0, T_1} \left[\Delta\left(\mathsf{F}(U^k_{T_0}, U^k_{T_1}, x); \mathsf{F}(U^{k+1}_{T_0}, U^k_{T_1})\right)\right] \\ + \Pr_{x \leftarrow X}\left[x \in S_1\right] \mathop{\mathbb{E}}_{x \leftarrow X|_{S_1}, T_0, T_1} \left[\Delta\left(\mathsf{F}(U^k_{T_1}, U^k_{T_0}, x); \mathsf{F}(U^{k+1}_{T_1}, U^k_{T_0})\right)\right]\end{aligned}$$

Noting that the elements of T_0 and T_1 are sampled from $X|_{S_0}$ and $X|_{S_1}$, respectively, and that F is δ-DS over all pairs of distributions over $\{0,1\}^n$, Proposition 40 implies that both the expectations above are at most $\delta + 2m/\ell$.

Thus, for any strategy of Player 2, there is a strategy of Player 1 such that Player 2's payoff is at most $\delta + 2m/\ell$. By the minimax theorem, there is a randomized strategy of Player 1 – a distribution over multisets (T_0, T_1) – such that for every move $x \in S_0 \cup S_1$ of Player 2, its payoff is at most $\delta + 2m/\ell$. Further, by the results of Lipton and Young [22, Theorem 2], there is a randomized strategy of Player 1 that corresponds to uniformly sampling from a set of pure strategies of size $O(n/\nu^2)$ and restricts Player 2's payoff to $\delta + 2m/\ell + \nu$. This proves the proposition. ◀

Affine Determinant Programs: A Framework for Obfuscation and Witness Encryption

Abstract

An *affine determinant program* $\mathsf{ADP} : \{0,1\}^n \to \{0,1\}$ is specified by a tuple $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ of square matrices over $\mathbb{F}_q$ and a function $\mathsf{Eval} : \mathbb{F}_q \to \{0,1\}$, and evaluated on $\mathbf{x} \in \{0,1\}^n$ by computing $\mathsf{Eval}(\det(\mathbf{A} + \sum_{i\in[n]} x_i \mathbf{B}_i))$.

In this work, we suggest ADPs as a new framework for building general-purpose obfuscation and witness encryption. We provide evidence to suggest that constructions following our ADP-based framework may one day yield secure, practically feasible obfuscation.

As a proof-of-concept, we give a candidate ADP-based construction of indistinguishability obfuscation ($i\mathcal{O}$) for all circuits along with a simple witness encryption candidate. We provide cryptanalysis demonstrating that our schemes resist several potential attacks, and leave further cryptanalysis to future work. Lastly, we explore practically feasible applications of our witness encryption candidate, such as public-key encryption with near-optimal key generation.

1 Introduction

Program obfuscation "scrambles" a program, preserving functionality while hiding implementation details. A theoretical study of program obfuscation was initiated by Barak et al. [6], who demonstrated that the natural notion of virtual black-box (VBB) obfuscation is impossible to achieve for all circuits. This initially led to skepticism that general cryptographically useful program obfuscation might not be realizable.

The situation changed several years ago when Garg et al. [17] gave the first candidate construction of *indistinguishability obfuscation* – a weaker notion not subject to the impossibility – and, along with subsequent work [32], showed how to use this weaker notion in a multitude of cryptographically useful ways. In fact, today indistinguishability obfuscation (iO) is widely regarded as "crypto complete," capable of achieving essentially any cryptographic task.[1]

Initially all candidate obfuscators required cryptographic multilinear maps [16, 13, 20], a powerful new mathematical tool. Very recently, two new lines of work have emerged on constructing obfuscation without multilinear maps. The first line of work builds upon the connection between obfuscation and functional encryption (see [1] and the references therein); the second builds on a number of new mathematical methods [21]. While these new directions expand the set of methodologies for achieving general-purpose obfuscation, the set of viable approaches for building general-purpose obfuscation remains extremely limited.

We view the situation as being reminiscent of the early days of public key cryptography, which also required new mathematical tools for the time. Some, such as Diffie-Hellman and RSA, have withstood the test of time, whereas others, such as the Merkle–Hellman knapsack cryptosystem, were ultimately found to be insecure. But even the failures yielded interesting insights, such as new cryptanalysis techniques. Therefore, given the importance of obfuscation, we believe it is crucial to investigate many potential lines of inquiry for realizing obfuscation. Furthermore, we believe it is particularly important to emphasize *simplicity* in our search for new approaches, since even successful cryptanalyses of simple proposals are likely to inform the scientific quest for secure and efficient obfuscation. (This perspective is part of a larger research agenda exploring new sources of hardness in cryptography [31].)

This Work

In this work, we propose a new framework for building obfuscation through *affine determinant programs* (ADP). An ADP consists of a tuple of square matrices $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ over $\mathbb{F}_p$, where evaluation on an input $\mathbf{x} \in \{0,1\}^n$ involves computing the affine combination $\mathbf{A} + \sum_{i \in [n]} x_i \mathbf{B}_i$ and taking the determinant. While ADPs have appeared before in the literature (e.g. to build randomized encodings [28]), to the best of our knowledge no prior work has considered their application to general obfuscation. We believe ADPs are a promising route toward obfuscation for several reasons:

- ADPs are conceptually very simple.
- We can interpret the recent work of Bartusek et al. [8] as an ADP for conjunction obfuscation, with provable security under the LPN assumption. Thus, ADPs certainly provide security for obfuscation in some situations.
- As we will show, ADPs may offer a route toward implementable applications.

[1] To be slightly more precise, building cryptography from iO also requires one-way functions.

Therefore, we initiate the study of ADPs for obfuscation, giving the following results:

- **A New Framework for Building Obfuscation.** We suggest ADPs as a route toward building obfuscation without multilinear maps. To facilitate this approach, we provide a number of techniques for protecting ADPs against attacks, and study the security of these techniques by developing new cryptanalysis techniques.
- **A Candidate Witness Encryption Scheme.** We examine a special case of obfuscation, called witness encryption, and give a very simple candidate construction. As an application, we use our scheme to build a public key encryption scheme with low-complexity key generation. Our approach yields for the first time *implementable* applications of witness encryption.
- **Towards Candidate iO Constructions.** We then turn to the much more difficult problem of constructing full indistinguishability obfuscation. We develop some initial ideas, including cryptanalytic methods, leading to an initial candidate construction.

1.1 Technical Overview

One of the main approaches to general-purpose program obfuscation, pioneered in [17], can be seen as following a particular recipe:

1. Construct an algebraic randomized encoding for the input program, which can be seen as offering a sort of "one-time" security.
2. Place the algebraic encoding "in the exponent" of a multilinear map, using the multilinear map operations to evaluate the encoding.

In most of the literature, the randomized encoding used is a matrix branching program, which can be obtained using Barrington's theorem and Kilian re-randomization. Another common example due to [37] converts a circuit into an algebraic circuit.

Affine Determinant Programs

In this work, we consider another variant of randomized encodings from the literature (though not yet considered in the *obfuscation* literature) which we call *Affine Determinant Programs* (ADPs). Here, the program consists of a matrix M whose entries are affine functions mapping inputs x to a field $\mathbb{F}_p$. We will denote by $M(x)$ the entry-wise evaluation of M on input x. There is also a fixed evaluation function $\mathsf{Eval} : \mathbb{F} \to \{0, 1\}$. To evaluate the program on input x, we simply compute $\mathsf{Eval}(\det(M(x))$.

We note that, just like Barrington's theorem or the algebraic circuit approach to constructing algebraic randomized encodings, ADPs can also plausibly be used in conjunction with multilinear maps (and appropriate re-randomization) to yield secure obfuscation[2]. However, the central question we consider in this work is:

Can we obfuscate with ADP*s in the clear, without using multilinear maps?*

Witness Encryption – An Initial Idea

As a starting point, we consider the easier task of constructing a secure *witness encryption* [19] scheme. In witness encryption, a ciphertext c is encrypted with respect to an instance x of some NP language L. The ciphertext may be decrypted using any witness π that attests

[2] There is a potential issue that the standard multilinear map interface does not allow for efficiently computing determinants over encoded values. However, the first two multilinear map candidates [16, 13] *do* allow for determinant computations.

that $x \in L$. Security stipulates that, for any false instance $x \notin L$, encryptions relative to x completely hide the message from computationally bounded adversaries. Note that the instance x is considered public.

We build a new framework for witness encryption for the NP-complete subset-sum problem, where instances x are vector/scalar pairs $(v, t) \in \mathbb{Z}^n \times \mathbb{Z}$, and witnesses are 0/1 vectors $w \in \{0,1\}^n$ such that $v \cdot w = t$. Under standard NP reductions, our construction extends to any NP language.

Testing the validity of a subset-sum witness can be trivially expressed as an ADP of dimension one: $M_{v,t}(w) = -t + v \cdot w$ is an affine function that is 0 if and only if w is a witness for (v, t). We can introduce randomization and extend this to a matrix program by choosing a random $R \in \mathbb{F}^{k \times k}$ and setting $M_{v,t}(w) = (-t + v \cdot w)R$. Then, with overwhelming probability over the choice of R, for $w \in \{0,1\}^n$, $\det(M_{v,t}(w)) = 0$ if and only if w is a valid witness.

While the above allows for testing if a witness is valid, we need a way to actually encode a message in the output. There are many ways to do this, but perhaps the simplest is to encrypt 0 by sampling the distribution above, and encrypting 1 by sampling a uniformly random ADP. Let $M_{v,t,m}$ be the resulting ADP. A random ADP over a large field will have $\det(M(w)) \neq 0$ with high probability for *any* w. Therefore for valid witnesses w, we have that $\det(M_{v,t,m}(w)) = 0$ if and only if $m = 0$.

Witness Encryption – Resisting Attacks Through Structured "Noise"

It is not difficult to see that the idea so far is completely insecure. The attacker can learn m by, for example, choosing a w^* that satisfies $v \cdot w^* = t$, but where w^* now consists of arbitrary field elements rather than 0/1. Such a w^* can be found trivially using linear algebra. In this case, we will still have that $\det(M(w)) = 0$ if and only if $m = 0$, thus revealing m. We call attacks of this form *invalid input attacks*.

Alternatively, one could simply inspect a single entry of M and notice that in the case $m = 0$, the entry is a multiple of the (known) function $(-t + v \cdot w)$, whereas if $m = 1$ the entry is a random affine function and is most likely not a multiple of $(-t + v \cdot w)$.

To remedy these issues, we will *add* as "noise" a randomized "all-accept" ADP M_{AA}, which is an ADP that accepts every 0/1 input, but rejects (with high probability) any input that is not 0/1. The encryption of 0 will then be

$$M(w) = M_{AA}(w) + M_{v,t,m}(w).$$

Since the all-accept program rejects any input that is not 0/1, meaning $M_{AA}(w)$ is full rank, it is also the case that $M(w)$ is full rank with high probability. Therefore, our witness encryption scheme will reject any invalid inputs, just as a random ADP will. This shows that our witness encryption scheme is at least immune to invalid input attacks.

Of course, as suggested by our noise analogy above, the security of this proposal depends on how "noisy" the all-accept program M_{AA} is. In Section 5 we discuss two simple approaches, and how these approaches evade our attempts at cryptanalysis.

Applications

As suggested in [19], one application of witness encryption is to build a public key encryption scheme where public keys are extremely short and generated by a lightweight process. In particular, given a PRG G, the secret key will be a seed s and the public key will be the output $x = G(s)$. To encrypt a message m, simply witness encrypt m to the statement "x

has a pre-image under G". Correctness is immediate, and security follows from a simple two-step hybrid: first replace x with a random string, which with overwhelming probability will not be in the image of G. Then invoke witness encryption security to show that m is hidden. Under a stronger assumption of *extractable* witness encryption due to [23], G can even be taken to be an arbitrary one-way function.

We show how to optimize our witness encryption candidate for use with Goldreich's one-way function, which is a very simple one-way function where every output bit depends on only 5 input bits. Thus, public-key generation is *linear-time* in the secret key length. For a plausible setting of parameters, we obtain 300-bit public keys, and 50 megabyte ciphertexts. We note that while our ciphertexts are too large for any practical use, they are well within the realm of implementability. In contrast, existing approaches to building witness encryption using multilinear maps are extremely impractical and their concrete efficiency has never even been estimated, to the best of our knowledge.

Indistinguishability Obfuscation

We now turn to the task of using ADPs to build general-purpose indistinguishability obfuscation ($i\mathcal{O}$). We note that this case is much more challenging than witness encryption. First, there is the obvious question of converting general computations into ADPs. Second, the security requirements for witness encryption are much weaker: it only needs security to hold in the evasive setting, where the adversary cannot find accepting inputs, and the adversary is allowed to know almost the entire program, save for a single message bit.

Fortunately, there are multiple ways to convert a circuit in NC^1 into an ADP, outlined in Section 4, and $i\mathcal{O}$ for NC^1 can be bootstrapped into $i\mathcal{O}$ for all circuits following known techniques [17]. However, simply taking such a program and adding an all-accept program as in our witness encryption construction is insufficient, as doing so leads to various attacks, which we outline in Section 9.

As mentioned earlier, the common approach starting with [17] to obfuscating circuits in NC^1 first applies Barrington's theorem [7] to obtain a representation of the circuit as a polynomial-size branching program. Then, the branching program is represented as a *matrix branching program*, and the matrix entries are encoded in the exponent of a multilinear map.

In this work, we still make use of branching programs as the underlying computational model, but instead appeal to the works of [28, 4], which give a representation of any deterministic branching program as an ADP $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$. In particular, this representation has the property that for any binary input $\mathbf{x} \in \{0,1\}^n$, $\det(\mathbf{A} + \sum_i x_i \mathbf{B}_i) = 1$ if $\mathbf{x}$ induces an accepting path in the branching program, and $\det(\mathbf{A} + \sum_i x_i \mathbf{B}_i) = 0$ otherwise.

We argue that this ADP representation of branching programs has several qualitative advantages over the matrix branching program approach. Notably, the earlier matrix branching program approach gives rise to so-called "mixed input" attacks, since multiple matrices are associated with each input bit. In contrast, the ADP encoding associates a single matrix with each input bit.

In this work, we initiate a systematic study of various randomization strategies that can be applied to ADPs that encode branching programs, in the hope that such safeguards will lead to a secure obfuscation scheme. As a first attempt, we left- and right-randomize with matrices $\mathbf{R}, \mathbf{S}$ over $\mathbb{F}_p$ such that $\det(\mathbf{R}) \cdot \det(\mathbf{S}) = 1$, preserving the correctness property of the ADP, while scrambling the individual matrix entries. However, this safeguard is not sufficient, due to the existence of "polynomial extension attacks," discussed in Section 9.1. Thus, we consider methods of scrambling the underlying ADP encoding first, before applying the left and right randomization as a final step.

In particular, we make use of the fact that on honest evaluation, the determinant will always be in $\{0, 1\}$. This motivates the possibility of adding random *even-valued* noise to the matrices in the ADP, which shifts the determinant by an even value on every input. Correctness is then preserved by simply having the evaluator compute the parity of the determinant. Parameters must be set carefully so that the size of the field over which these determinant calculations are being carried out is large enough so that determinants on honest inputs do not wrap around the modulus. This is discussed in detail in Section 8.1.

Unfortunately, as we show in Section 9.3, this even-valued error does not yet give a secure obfuscation scheme. In particular, there exist attacks on $i\mathcal{O}$ that use the fact that the adversary may know the underlying structure of the branching program it is attacking to learn non-trivial information about the random even-valued error. This in turn motivates the need to inject entropy into the structure of the branching program itself, before encoding it as an ADP and applying the safeguards described above. We term this process "random local substitution," where each individual "step" of the branching program is randomized, and discuss one concrete method of doing this in Section 8.1.1. However, we stress that there is a vast space of transformations to explore here, and our proposal is only the first of many simple possibilities to explore.

In summary, we present the following generic recipe for obfuscating a deterministic branching program BP:

- Apply random local *functionality-preserving* transformations to BP, producing BP'.
- Represent BP' as an ADP, following [28, 4].
- Add random even-valued error to each matrix in ADP, fixing the evaluation function to compute the parity of the determinant.
- Left- and right-randomize with matrices $\mathbf{R}, \mathbf{S}$ such that $\det(\mathbf{R}) \cdot \det(\mathbf{S}) = 1$.

In the body, we give an instantiation of the above recipe, resulting in a candidate $i\mathcal{O}$ scheme for all circuits (noting that it suffices to obfuscate the class NC^1, which can be simulated by polynomial-size branching programs). However, we view the recipe itself as the main contribution of this section, and hope that it will motivate other candidates and more cryptanalysis, with the eventual goal of obtaining efficient and secure obfuscation without the use of multilinear maps.

2 Preliminaries

Let $\mathbb{Z}, \mathbb{N}$ be the set of integers and positive integers respectively. For $n \in \mathbb{N}$, we let $[n]$ denote the set $\{1, \ldots, n\}$. For $p \in \mathbb{N}$, denote $\mathbb{Z}/p\mathbb{Z}$ by $\mathbb{Z}_p$, and denote the finite field of order p by $\mathbb{F}_p$. A vector $\mathbf{v} \in \mathbb{F}_p^n$ (represented in column form by default) is written as a bold lower-case letter and we denote its ith element by $v_i \in \mathbb{F}_p$. A matrix $\mathbf{A} \in \mathbb{F}_p^{n \times m}$ is written as a bold capital letter and we denote the entry at position (i, j) by $(\mathbf{A})_{i,j}$. For any set of matrices $\mathbf{A}_1, \ldots, \mathbf{A}_n$ of potentially varying dimensions, let $\mathsf{diag}(\mathbf{A}_1, \ldots, \mathbf{A}_n)$ be the block diagonal matrix with the $\mathbf{A}_i$ on the diagonal, and zeros elsewhere.

We use the usual Landau notations. A function $f(n)$ is said to be negligible if it is $n^{-\omega(1)}$ and we denote it by $f(n) := \mathsf{negl}(n)$. A probability $p(n)$ is said to be overwhelming if it is $1 - n^{-\omega(1)}$. We write $D_1 \approx_S D_2$ if there exists a negligible function $\mathsf{negl}(n)$ such that the statistical distance between D_1 and D_2, denoted $SD(D_1, D_2)$, is bounded above by $\mathsf{negl}(n)$. Recall for any two distribution D_1 and D_2 taking values in some set $\mathcal{S}$ the statistical distance or $SD(D_1, D_2)$ is defined as:

$$SD(D_1, D_2) = 1/2 \sum_{x \in \mathcal{S}} |\Pr[D_1 = x] - \Pr[D_2 = x]|$$

We write $D_1 \approx_C D_2$ if no computationally-bounded adversary can distinguish between D_1 and D_2 except with advantage $\mathsf{negl}(n)$.

2.1 Randomized Encodings

A randomized encoding of the function $f(x)$ is a function $\hat{f}(x,r)$ such that a sample from the output distribution of $\hat{f}(x,r)$ for a uniformly chosen r reveals $f(x)$ and no additional information about x. We formalize and generalize this below.

▶ **Definition 1** (Randomized Encodings [5]). *Let $f : \{0,1\}^n \to \{0,1\}^\ell$ be a function. We say that $\hat{f} : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}^s$ is a δ-correct, ϵ-private randomized encoding of f, if it satisfies the following:*

- *δ-**correctness**. There exists an algorithm B, called a decoder, such that for any input $\mathbf{x} \in \{0,1\}^n$,*

$$\Pr[B(\hat{f}(x, U_m)) \neq f(x)] \leq \delta.$$

- *ϵ-**privacy**. There exists a randomized simulator algorithm Sim such that for any $\mathbf{x} \in \{0,1\}^n$,*

$$SD(\mathsf{Sim}(f(x)), \hat{f}(x, U_m)) \leq \epsilon.$$

2.2 Witness Encryption

The following definition is taken almost verbatim from [19].

▶ **Definition 2.** *A witness encryption scheme for an NP language L (with corresponding witness relation R) consists of the following two polynomial-time algorithms:*

- *$\mathsf{Encrypt}(1^\lambda, x, m)$ takes as input a security parameter 1^λ, an unbounded-length string x, and a message $m \in \{0,1\}$, and outputs a ciphertext ct.*
- *$\mathsf{Decrypt}(ct, w)$ takes as input a ciphertext ct and an unbounded-length string w, and outputs a message m or the symbol $\perp$.*

These algorithms satisfy the following two conditions:

- ***Correctness.** For any security parameter λ, for any $m \in \{0,1\}$, and for any $x \in L$ such that $R(x,w)$ holds, we have that*

$$\Pr[\mathsf{Decrypt}(\mathsf{Encrypt}(1^\lambda, x, m), w) = m] = 1.$$

- ***Soundness Security.** For any PPT adversary $\mathcal{A}$, there exists a negligible function $\mathsf{negl}(\cdot)$ such that for any $x \notin L$, we have:*

$$|\Pr[\mathcal{A}(\mathsf{Encrypt}(1^\lambda, x, 0)) = 1] - \Pr[\mathcal{A}(\mathsf{Encrypt}(1^\lambda, x, 1)) = 1]| < \mathsf{negl}(\lambda).$$

We also consider an "extractable" version of witness encryption, introduced by [23]. In extractable witness encryption, if an adversary that can break semantic security for an instance x, an extractor can extract the witness for x. Formally, in an extractable witness encryption, the following definition (taken verbatim from [23]) replaces the standard soundness security notion.

- **Extractable Security.** A witness encryption scheme for a language $L \in \mathsf{NP}$ is secure if for all PPT adversary $\mathcal{A}$ and all polynomials q, there exists a PPT extractor E and a polynomial $p(\cdot)$ such that for all auxiliary inputs z and for all $x \in \{0,1\}^*$, the following holds:

$$\Pr[m \leftarrow \{0,1\}; ct \leftarrow \mathsf{WE.Encrypt}(1^\lambda, x, m) : \mathcal{A}(x, ct, z) = b] \geq \frac{1}{2} + \frac{1}{q(|x|)}$$
$$\implies \Pr[\mathsf{E}(x, z) = w : (x, w) \in R_L] \geq \frac{1}{p(|x|)}.$$

2.3 Indistinguishability Obfuscation

▶ **Definition 3** (Indistinguishability Obfuscator [6]). *A uniform PPT machine $i\mathcal{O}$ is an indistinguishability obfuscator for a circuit class $\{\mathcal{C}_\lambda\}$ if the following conditions are satisfied:*

- *(Strong Functionality Preservation) For all security parameters $\lambda \in \mathbb{N}$, for all $C \in \mathcal{C}_\lambda$,*

$$\Pr_{C' \leftarrow i\mathcal{O}(\lambda, C)}[\forall x,\ C'(x) = C(x)] \geq 1 - \mathsf{negl}(\lambda).$$

- *For any non-uniform PPT distinguisher D, there exists a negligible function α such that the following holds: for all $\lambda \in \mathbb{N}$, for all pairs of circuits $C_0, C_1 \in \mathcal{C}_\lambda$, we have that if $C_0(x) = C_1(x)$ for all inputs x and $|C_0| = |C_1|$ (where $|C|$ denotes the size of a circuit), then*

$$|\Pr[D(i\mathcal{O}(\lambda, C_0)) = 1] - \Pr[D(i\mathcal{O}(\lambda, C_1)) = 1]| \leq \alpha(\lambda).$$

3 Affine Determinant Programs: Syntax and Definitions

An *affine determinant program* $(\mathsf{ADP}) : \{0,1\}^n \to \{0,1\}$ is parameterized by an input length n, a width k, and a finite field $\mathbb{F}_p$. An ADP is comprised of an affine function $\mathsf{M} : \{0,1\}^n \to \mathbb{F}_p^{k \times k}$ along with an evaluation function $\mathsf{Eval} : \mathbb{F}_p \to \{0,1\}$. The affine function M is specified by an $(n+1)$-tuple of $k \times k$ matrices $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ over $\mathbb{F}_p$ so that

$$\mathsf{M}(\mathbf{x}) := \mathbf{A} + \sum_{i \in [n]} x_i \mathbf{B}_i.$$

On input $\mathbf{x} \in \{0,1\}^n$, $\mathsf{ADP}_{\mathsf{M},\mathsf{Eval}}(\mathbf{x})$ is computed as

$$\mathsf{Eval}(\det(\mathsf{M}(\mathbf{x}))).$$

We will typically use one of the following Eval functions.

- $\mathsf{Eval}_0(y) = \begin{cases} 1 & \text{if } y = 0 \\ 0 & \text{if } y \neq 0 \end{cases}$.
- $\mathsf{Eval}_{\neq 0}(y) = \begin{cases} 1 & \text{if } y \neq 0 \\ 0 & \text{if } y = 0 \end{cases}$.
- $\mathsf{Eval}_{\text{parity}}(y) = y \bmod 2$.

3.1 Encoding Functions as ADPs

We will consider a randomized procedure ADP-Encode which takes as input a description $\langle f \rangle$ of a function $f : \{0,1\}^n \to \{0,1\}$ and produces $\mathsf{ADP}_{\mathsf{M},\mathsf{Eval}}$ such that $\mathsf{ADP}_{\mathsf{M},\mathsf{Eval}} \equiv f$. Formally, the algorithm works as follows.

- $\mathsf{ADP\text{-}Encode}(1^\lambda, \langle f \rangle)$: This algorithm takes in a security parameter 1^λ and a canonical description $\langle f \rangle$ of a function $f \in \mathcal{F}_n$. It outputs width-k $\mathsf{ADP}_{\mathsf{M},\mathsf{Eval}}$ over $\mathbb{F}_p$ where $k = \mathsf{poly}(\lambda, |\langle f \rangle|)$ and $p = 2^{\mathsf{poly}(\lambda)}$.

In this work, Eval will be fixed as part of the description of ADP-Encode and will be independent of the particular input $\langle f \rangle$. We will therefore view ADP-Encode as an algorithm outputting $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ where $\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n \in \mathbb{F}_p^{k \times k}$.

3.2 One-time Security

We say that ADP-Encode satisfies *one-time security* if the matrix $\mathsf{M}(\mathbf{x})$ can be simulated given only $f(x)$.

▶ **Definition 4** (One-time Security)**.** ADP-Encode *is* one-time secure *for* $\mathcal{F}_n$ *if there exists a PPT simulator* Sim *such that for any* $f \in \mathcal{F}_n$ *and any* $\mathbf{x} \in \{0,1\}^n$*,*

$$\mathsf{M}(\mathbf{x}) \approx_S \mathsf{Sim}(f(x))$$

where $\mathsf{M} \leftarrow \mathsf{ADP\text{-}Encode}(1^\lambda, \langle f \rangle)$.

We stress that while $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$, the simulator is only required to simulate a single evaluation of $\mathsf{M}(\mathbf{x}) = \mathbf{A} + \sum_{i \in [n]} x_i \mathbf{B}_i$.

▶ **Theorem 5** ([28])**.** *There exists an algorithm* ADP-Encode *which satisfies correctness and one-time security for all branching programs.*

▶ Remark 6. One-time security implies that $\mathsf{M}(\mathbf{x})$ is a randomized encoding [27] of $f(x)$.

Achieving One-time Security Generically

When the evaluation function is Eval_0 or $\mathsf{Eval}_{\neq 0}$, there is a simple generic transformation that turns any functionality-preserving ADP-Encode procedure into one that additionally satisfies one-time security.

We first import the following lemma from [26].

▶ **Lemma 7** ([26])**.** *For any fixed* $\mathbf{A} \in \mathbb{F}_q^{k \times k}$ *and uniformly random invertible* $\mathbf{R}, \mathbf{S} \leftarrow \mathbb{F}_q^{k \times k}$*, the distribution of* $\mathbf{R} \cdot \mathbf{A} \cdot \mathbf{S}$ *depends only on* $\mathrm{rank}(\mathbf{A})$.

Let ADP-Encode be an encoding procedure which uses Eval_0 or $\mathsf{Eval}_{\neq 0}$, and outputs

$$\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n) \in (\mathbb{F}_p^{k \times k})^{n+1}.$$

▷ Claim 8 (One-Time Security for $\mathsf{Eval}_0, \mathsf{Eval}_{\neq 0}$). Suppose ADP-Encode has the property that when $\det(\mathsf{M}(\mathbf{x})) = 0$, then $\mathrm{rank}(\mathsf{M}(\mathbf{x})) = k'$ for some fixed $k' < k$. Furthermore, ADP-Encode uses Eval_0 or $\mathsf{Eval}_{\neq 0}$. Let $\mathsf{ADP\text{-}Encode}'$ be an algorithm which runs ADP-Encode, samples uniformly random invertible $\mathbf{R}, \mathbf{S} \leftarrow \mathbb{F}_p^{k \times k}$, and outputs

$$\mathbf{R} \cdot \mathsf{M} \cdot \mathbf{S} := (\mathbf{R} \cdot \mathbf{A} \cdot \mathbf{S}, \mathbf{R} \cdot \mathbf{B}_1 \cdot \mathbf{S}, \ldots, \mathbf{R} \cdot \mathbf{B}_n \cdot \mathbf{S}).$$

Then $\mathsf{ADP\text{-}Encode}'$ has identical functionality to ADP-Encode, and is additionally one-time secure.

Proof. Identical functionality holds since $\det(\mathsf{M}(\mathbf{x})) = 0$ implies $\det(\mathbf{R} \cdot \mathsf{M}(\mathbf{x}) \cdot \mathbf{S}) = 0$, and $\det(\mathsf{M}(\mathbf{x})) \neq 0$ implies $\det(\mathbf{R} \cdot \mathsf{M}(\mathbf{x}) \cdot \mathbf{S}) \neq 0$ since $\mathbf{R}, \mathbf{S}$ are invertible.

One-time security follows from the fact that given $f(x)$, $\mathbf{R} \cdot \mathsf{M}(\mathbf{x}) \cdot \mathbf{S}$ can be simulated by either drawing a random matrix of rank k' or of rank k (by Lemma 7) ◁

3.3 $i\mathcal{O}$ Security

In contrast to one-time security, $i\mathcal{O}$ security holds even if the adversary is free to evaluate M on as many inputs $\mathbf{x}$ of its choosing. In particular, we ask that $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ be an $i\mathcal{O}$ of the input program f.

▶ **Definition 9.** ADP-Encode *is* $i\mathcal{O}$-secure *for* $\mathcal{F}_n$ *if for any two functions* $f_1, f_2 \in \mathcal{F}_n$ *such that* $f_1 \equiv f_2$ *and* $|\langle f_1 \rangle| = |\langle f_2 \rangle|$*, then*

$$\mathsf{M}_1 \approx_C \mathsf{M}_2$$

where $\mathsf{M}_1 \leftarrow \mathsf{ADP\text{-}Encode}(1^\lambda, \langle f_1 \rangle)$ *and* $\mathsf{M}_2 \leftarrow \mathsf{ADP\text{-}Encode}(1^\lambda, \langle f_2 \rangle)$.

4 Constructing ADPs

4.1 Obfuscating Simple Functionalities with ADPs

In this section we describe simple ADP-based obfuscations of point functions and conjunctions. These constructions have appeared before in the literature, but we recast them in the language of our ADP framework.

Point Functions

Consider the class of point functions $\{\mathcal{I}_\mathbf{y}\}_\mathbf{y}$ over $\{0,1\}^n$, where for any $\mathbf{x} \in \{0,1\}^n$, $\mathcal{I}_\mathbf{y}(\mathbf{x})$ outputs 1 if and only if $\mathbf{x} = \mathbf{y}$, and outputs 0 otherwise. There exists a simple ADP encoding scheme for point functions due to [9] where each ADP matrix is 1×1 (i.e. a scalar).

On input point $\mathbf{y}$, the ADP encoding of $\mathcal{I}_\mathbf{y}$ is generated as follows. Fix a superpolynomial-size modulus p, draw uniformly random $b_1, \ldots, b_n \leftarrow \mathbb{Z}_p$, and set

$$a = -\sum_{i \in [n] : y_i = 1} b_i.$$

The resulting scalar ADP is $\mathsf{M} = (a, b_1, \ldots, b_n)$. To evaluate M on input $\mathbf{x} \in \{0,1\}^n$, compute the scalar sum $\mathsf{M}(\mathbf{x}) = a + \sum_{i \in [n]} x_i b_i$ and output 1 if and only if the resulting scalar is 0. Correctness holds with high probability on any input since the modulus p is superpolynomial. Observe that this ADP construction fits into the more general framework of taking a determinant of an affine combination of matrices, since the determinant is simply the identity for 1×1 matrices.

If the accepting point $\mathbf{y}$ is chosen from a distribution with sufficient entropy, this ADP information-theoretically hides $\mathbf{y}$ (this follows immediately from the Leftover Hash Lemma).

Conjunctions

Point functions can be naturally extended to *conjunctions*, a more expressive class of functionalities that allow for "wildcard" positions (which we denote by $*$) indicating locations where the input bit can be either 0 or 1. Formally, a conjunction $\mathcal{C}_\mathsf{pat}$ is parameterized by a pattern string $\mathsf{pat} \in \{0, 1, *\}^n$. On input $\mathbf{x} \in \{0,1\}^n$, $\mathcal{C}_\mathsf{pat} = 1$ if and only if $\mathbf{x}$ matches pat at all indices i where $\mathsf{pat}_i \in \{0,1\}$. Bartusek et al. [8] give a simple ADP-based obfuscation for conjunctions, which we recall here.

For $\mathsf{pat} \in \{0,1,*\}^n$, the corresponding ADP will consist of square matrices of width n over $\mathbb{F}_p$ where p is a superpolynomial-size prime. We use the notation $\mathsf{colspan}(\mathbf{M})$ to denote the linear subspace spanned by the columns of $\mathbf{M}$.

1. Sample a uniformly random rank-$(n-1)$ matrix $\mathbf{L} \in \mathbb{F}_p^{n \times n}$.
2. For each index $i \in [n]$ where $\mathsf{pat}_i \in \{0,1\}$, sample a uniformly random rank-one matrix $\mathbf{B}_i \in \mathbb{F}_p^{n \times n}$.
3. For each index $i \in [n]$ where $\mathsf{pat}_i = *$, sample a uniformly random rank-one matrix $\mathbf{B}_i$ conditioned on $\mathsf{colspan}(\mathbf{B}_i) \subseteq \mathsf{colspan}(\mathbf{L})$. Since a rank-one $\mathbf{B}_i$ can be written as $\mathbf{u}_i \mathbf{v}_i^\top$, this is equivalent to sampling $\mathbf{v}_i$ uniformly at random from $\mathbb{F}_p^n$, sampling $\mathbf{w}_i$ uniformly at random from $\mathbb{F}_p^n$, and setting $\mathbf{u}_i := \mathbf{L}\mathbf{w}_i$.
4. Set $\mathbf{A} = \mathbf{L} - \sum_{i \in [n], \mathsf{pat}_i = 1} \mathbf{B}_i$, and output

$$\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$$

To evaluate the ADP M on input $\mathbf{x} \in \{0,1\}^n$, compute

$$\mathsf{M}(\mathbf{x}) = \mathbf{A} + \sum_{i \in [n] : x_i = 1} \mathbf{B}_i$$

and accept (output 1) if and only if $\det(\mathsf{M}(\mathbf{x})) = 0$.

Correctness follows since for any input $\mathbf{x}$ that agrees with pat on all 0/1 positions, $\mathsf{colspan}(\mathsf{M}(\mathbf{x})) \subseteq \mathsf{colspan}(\mathbf{L})$. Since $\mathbf{L}$ is rank-$(n-1)$, $\det(\mathsf{M}(\mathbf{x}))$ will be 0. On any input $\mathbf{x}$ that disagrees with pat on a 0/1 position, $\mathsf{M}(\mathbf{x})$ is the sum of a random rank-$(n-1)$ matrix and at least one independent random rank-one matrix, which yields a full-rank with overwhelming probability.

Bartusek et al. [8] prove that this construction statistically hides pat assuming that pat has sufficient entropy on its 0/1 entries. The entropy of pat is used to argue that $\mathbf{A} = \mathbf{L} - \sum_{i \in [n], \mathsf{pat}_i = 1} \mathbf{B}_i$ is statistically close to a uniformly random matrix. This means $\mathbf{L}$ is statistically hidden, and so for all $i \in [n]$, $\mathbf{B}_i$ is statistically close to uniformly random rank-one matrix. At this point, the distribution of $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ is independent of pat.

4.2 ADPs for Log-depth Boolean Formulas

We now give a simple construction that directly converts any log-depth formula into a functionally equivalent ADP. In contrast to the point function and conjunction setting, we have been unable to prove that this ADP encoding achieves any meaningful notion of obfuscation security. Nevertheless, this encoding procedure will be useful for one of our candidate witness encryption constructions (see Section 5), as well as to develop general intuition for the ADP framework.

We describe the construction recursively, associating an ADP with each wire in the formula and demonstrating how to construct an output ADP given two input ADPs to either an OR gate or an AND gate.

Fix a superpolynomial-size prime p. For this ADP construction, evaluation is done by computing the determinant of $\mathsf{M}(\mathbf{x}) := \mathbf{A} + \sum_{i \in [n] : x_i = 1} \mathbf{B}_i$ over $\mathbb{F}_p$ and accepting if and only if the result is 0.

Throughout this construction, we maintain the invariant that (with overwhelming probability) on an accepting input $\mathsf{M}(\mathbf{x})$ will be rank-deficient by 1, and on a rejecting input $\mathsf{M}(\mathbf{x})$ will be full-rank.

- Positive Input Wire: An ADP for the (positive) input wire $f(x_1, \ldots, x_n) = x_j$ consists of $n+1$ scalars (i.e. a width-1 ADP) $(a, b_1, \ldots, b_n)$ set as follows. Sample a uniformly random $r \leftarrow \mathbb{F}_p$ and set $a = -r$ and $b_j = r$. For all $i \neq j$, set $b_i = 0$.

- Negated Input Wire: An ADP for the (negated) input wire $f(x_1, \ldots, x_n) = \neg x_j$ consists of $n+1$ scalars $(a, b_1, \ldots, b_n)$ set as follows. Sample a uniformly random $r \leftarrow \mathbb{F}_p$ and set $b_j = r$. Set $a = 0$ and $b_i = 0$ for all $i \neq j$.

For any input $\mathbf{x} \in \{0,1\}^n$, correctness of the input wire ADP constructions holds with high probability over the randomness of r.

The ADP M that computes the AND of two n-bit input ADPs $\mathsf{M}_1, \mathsf{M}_2$ with widths w_1, w_2 respectively is constructed as follows. Define $k \coloneqq k_1 + k_2$. Sample a uniformly random matrix $\mathbf{R} \leftarrow \mathbb{F}_q^{(k-1)\times k}$ and a uniformly random matrix $\mathbf{S} \leftarrow \mathbb{F}_q^{k\times(k-1)}$. Output

$$\mathsf{M}(\mathbf{x}) = \mathbf{R} \cdot \begin{pmatrix} \mathsf{M}_1(\mathbf{x}) & 0 \\ 0 & \mathsf{M}_2(\mathbf{x}) \end{pmatrix} \cdot \mathbf{S}.$$

We briefly sketch correctness of the AND construction.

- (Both input wires accept) If $\det(\mathsf{M}_1(\mathbf{x})) = 0$ and $\det(\mathsf{M}_2(\mathbf{x})) = 0$, then

$$\begin{pmatrix} \mathsf{M}_1(\mathbf{x}) & 0 \\ 0 & \mathsf{M}_2(\mathbf{x}) \end{pmatrix}$$

is a $k \times k$ matrix which is rank-deficient by 2. Left- and right-multiplying by random matrices $\mathbf{R} \leftarrow \mathbb{F}_q^{(k-1)\times k}, \mathbf{S} \leftarrow \mathbb{F}_q^{k\times(k-1)}$ yields $\mathsf{M}(\mathbf{x})$ which is rank deficient by 1 with overwhelming probability.

- (Some input wire rejects) If either of $\det(\mathsf{M}_1(\mathbf{x})) \neq 0$ or $\det(\mathsf{M}_2(\mathbf{x})) \neq 0$ holds, then

$$\begin{pmatrix} \mathsf{M}_1(\mathbf{x}) & 0 \\ 0 & \mathsf{M}_2(\mathbf{x}) \end{pmatrix}$$

is a $k \times k$ matrix which is rank-deficient by at most 1. Left- and right-multiplying by random matrices $\mathbf{R} \leftarrow \mathbb{F}_q^{(k-1)\times k}, \mathbf{S} \leftarrow \mathbb{F}_q^{k\times(k-1)}$ yields $\mathsf{M}(\mathbf{x})$ which is full-rank with overwhelming probability.

An ADP M which computes the OR of two n-bit input ADPs $\mathsf{M}_1, \mathsf{M}_2$ with widths w_1, w_2 respectively can be constructed as follows. Define $k \coloneqq k_1 + k_2$. Sample a uniformly random matrix $\mathbf{R} \leftarrow \mathbb{F}_q^{k\times k}$ and a uniformly random matrix $\mathbf{S} \leftarrow \mathbb{F}_q^{k\times k}$. Sample a uniformly random affine function $\mathbf{T} : \{0,1\}^n \to \mathbb{F}_q^{k_1 \times k_2}$. Output

$$\mathsf{M}(\mathbf{x}) = \mathbf{R} \cdot \begin{pmatrix} \mathsf{M}_1(\mathbf{x}) & \mathbf{T}(\mathbf{x}) \\ 0 & \mathsf{M}_2(\mathbf{x}) \end{pmatrix} \cdot \mathbf{S}.$$

We briefly sketch correctness of the OR construction.

- (Either input wire accepts) If $\det(\mathsf{M}_1(\mathbf{x})) = 0$ or $\det(\mathsf{M}_2(\mathbf{x})) = 0$, then

$$\begin{pmatrix} \mathsf{M}_1(\mathbf{x}) & \mathbf{T}(\mathbf{x}) \\ 0 & \mathsf{M}_2(\mathbf{x}) \end{pmatrix}$$

is a $k \times k$ matrix which is rank-deficient by 1; even if both $\det(\mathsf{M}_1(x)) = 0$ and $\det(\mathsf{M}_2(x)) = 0$ hold, the random $\mathbf{T}(\mathbf{x})$ will ensure the rank is only deficient by 1 with overwhelming probability. Left- and right-multiplying by random matrices $\mathbf{R} \leftarrow \mathbb{F}_q^{k\times k}, \mathbf{S} \leftarrow \mathbb{F}_q^{k\times k}$ yields $\mathsf{M}(\mathbf{x})$ which is still rank deficient by 1 with overwhelming probability.

- (Both input wires reject) If both $\det(\mathsf{M}_1(\mathbf{x})) \neq 0$ and $\det(\mathsf{M}_2(\mathbf{x})) \neq 0$ hold, then

$$\begin{pmatrix} \mathsf{M}_1(\mathbf{x}) & \mathbf{T}(\mathbf{x}) \\ 0 & \mathsf{M}_2(\mathbf{x}) \end{pmatrix}$$

is a full-rank $k \times k$ matrix. Left- and right-multiplying by random matrices $\mathbf{R} \leftarrow \mathbb{F}_q^{k\times k}, \mathbf{S} \leftarrow \mathbb{F}_q^{k\times k}$ still yields a full-rank $\mathsf{M}(\mathbf{x})$ with overwhelming probability.

4.3 Encoding Branching Programs as ADPs

In this section we describe a way to represent branching programs as ADPs. This representation is implicit in [28] (see also [4]). Different notions of branching programs (e.g., deterministic vs. non-deterministic vs. counting) correspond to different choices of the field and evaluation Eval.

We start by defining the most expressive notion and then specialize it to the weaker notions on which we will rely.

▶ **Definition 10** (Counting Branching Programs [28]). *A $\mathbb{Z}$-arithmetic branching program computing $f : \{0,1\}^n \to \mathbb{Z}$ is specified by a directed acyclic graph $G = (V, E)$ and a labeling $\phi(\cdot,\cdot)$ where each edge (u, v) is labeled with a literal $\phi(u, v) = x_i$ or $\phi(u, v) = \neg x_i$, or the constant 1. Two of the vertices are labeled s, t. Its size is $|V| - 1$. Any input x induces a subgraph G_x limited to edges consistent with x (i.e. edges that evaluate to 1 on x). An accepting path on input x is a directed $s - t$ path in G_x. A $\mathbb{Z}$-arithmetic branching program (ABP) computes the function $f : \{0,1\}^n \to \mathbb{Z}$ such that $f(x)$ is the number of accepting paths. It computes a boolean function $f : \{0,1\}^n \to \{0,1\}$ if the number of accepting paths is equal to $f(x) \in \{0,1\}$.*

▶ **Lemma 11** ([28, 4]). *Suppose there is a $\mathbb{Z}$-arithmetic branching program (ABP) of size ℓ computing a boolean function f. Suppose $L(x)$ satisfies the following*

- *$L(x)$ has -1 along the second diagonal (right below the main diagonal).*
- *$L(x)$ is 0 below the second diagonal.*
- *Each entry of $L(x)$ is a degree (at most) 1 polynomial in a single input variable x_i.*

More precisely, $L(x)$ is defined as follows. Fix a topological ordering of the vertices in V, and label the columns / rows (from left to right / top to bottom) according to this ordering of vertices. In particular we want s labeled 1 and t labeled ℓ. We first define a matrix $A(x)$ of dimension $\ell \times \ell$. For entry (i, j) of $A(x)$, write $\phi(i, j)$ if (i, j) is an edge in G and 0 otherwise. Note that $A(x)$ will be 0 on and below the main diagonal. Now consider $A(x) - I$, and delete its first column and last row to obtain the $(\ell - 1) \times (\ell - 1)$ dimensional matrix $L(x)$.

Then for all $x \in \{0,1\}^n$, we have $\det(L(x)) = f(x)$. (If f is boolean, we say $f(x)$ accepts if $\det(L(x))$ is non-zero.)

This immediately gives us an ADP for $\mathbb{Z}$-arithmetic branching programs. Namely, $\mathsf{M} = L$ and Eval is simply the identity function (if f is boolean). This ADP can also be implemented over a finite field $\mathbb{F}_p$ if the number of accepting paths is at most $p - 1$. Simply compute $f(x) = \det(L(x)) \mod p$.

Example

Suppose we have vertices in the order s, v_1, v_2, t. We can write a point function that accepts on $x = 010$ with an edge from s to v_1 labeled with $1 - x_1$, an edge from v_1 to v_2 labeled with x_2, and an edge from v_2 to t labeled with $1 - x_3$. So the resulting $A(x) - I$ and $L(x)$ matrices are

$$A(x) = \begin{pmatrix} -1 & 1 - x_1 & 0 & 0 \\ 0 & -1 & x_2 & 0 \\ 0 & 0 & -1 & 1 - x_3 \\ 0 & 0 & 0 & -1 \end{pmatrix},$$

$$L(x) = \begin{pmatrix} 1-x_1 & 0 & 0 \\ -1 & x_2 & 0 \\ 0 & -1 & 1-x_3 \end{pmatrix}.$$

Thus the resulting ADP is of the following form:

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 \\ -1 & 0 & 0 \\ 0 & -1 & 1 \end{pmatrix}, \mathbf{B}_1 = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$\mathbf{B}_2 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \mathbf{B}_3 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

Then, as done in [4] and described above, the resulting program can be "re-randomized" by left- and right-multiplying by uniformly random matrices $\mathbf{R}, \mathbf{S}$ such that $\det(\mathbf{R}) = \det(\mathbf{S}) = 1$.

5 Witness Encryption

5.1 Definitions

In this section we will use ADPs to construct *witness encryption* [18]. Since our focus will not be on encoding *functions* as ADPs, we will ignore the Eval part of our ADP formalism. For the remainder of this section, a width-k ADP M over $\mathbb{F}_p$ will refer to a tuple of $n+1$ matrices $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$, where each matrix is in $\mathbb{F}_p^{k \times k}$. Since we will not have a dedicated Eval function, the evaluation of $\mathsf{M}(\cdot)$ on an input $\mathbf{x} \in \{0,1\}^n$ will refer to the matrix

$$\mathsf{M}(\mathbf{x}) \coloneqq \mathbf{A} + \sum_{i \in [n]} x_i \mathbf{B}_i.$$

Consider the NP-complete subset sum problem (or more generally, *vector* subset sum).

▶ **Definition 12.** *The* VECTOR-SUBSET-SUM *language consists of instances* $(\mathbf{H}, \boldsymbol{\ell})$ *where* $\mathbf{H} \in \mathbb{Z}^{d \times n}, \boldsymbol{\ell} \in \mathbb{Z}^d$*, such that there exists* $\mathbf{w} \in \{0,1\}^n$ *satisfying* $\mathbf{H} \cdot \mathbf{w} = \boldsymbol{\ell}$ *(over the integers).*

We refer to d as the *dimension* of the instance. When $d = 1$, we simply refer to this as SUBSET-SUM.

Vector Subset Sum Encoding

A dimension $d = 1$ instance $(\mathbf{h}, \ell)$ can be represented as an ADP of arbitrary width k as follows. Sample a uniformly random matrix $\mathbf{R} \leftarrow \mathbb{F}_p^{k \times k}$ and set $\mathbf{A} = -\ell\mathbf{R}$ and $\mathbf{B}_i = h_i\mathbf{R}$ for all $i \in [n]$. This ADP accepts on input $\mathbf{w} \in \{0,1\}^n$ if and only if

$$\det(\mathbf{A} + \sum_{i \in [n]} w_i \mathbf{B}_i) = \det((-\ell + \sum_{i \in [n]} w_i h_i)\mathbf{R}) = 0.$$

We can generalize this approach to any instance $(\mathbf{H}, \boldsymbol{\ell})$ of dimension $d \geq 1$ as follows. We define the procedure VSS.Encode, which takes an instance $(\mathbf{H}, \boldsymbol{\ell})$ of VECTOR-SUBSET-SUM instance and outputs a width-k ADP over $\mathbb{F}_p$.

- VSS.Encode$((\mathbf{H} \in \mathbb{Z}^{d \times n}, \boldsymbol{\ell} \in \mathbb{Z}^d), p, k)$: Interpret each entry of $\mathbf{H}$ and $\boldsymbol{\ell}$ as the corresponding element over $\mathbb{F}_p$; for correctness we will require $p > \max_{\mathbf{x} \in \{0,1\}^n} ||\mathbf{H} \cdot \mathbf{x}||_\infty$. For each $j \in [d]$, draw uniformly random $\mathbf{R}_j \leftarrow \mathbb{F}_p^{k \times k}$. Set $\mathbf{A} \coloneqq -\sum_{j \in [d]} \ell_j \mathbf{R}_j$ and $\mathbf{B}_i \coloneqq \sum_{j \in [d]} H_{j,i} \mathbf{R}_j$ for each $i \in [n]$. Output

  $$\mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n).$$

An Insecure Witness Encryption

Consider the following *insecure* construction of witness encryption for VECTOR-SUBSET-SUM. To "encrypt" a bit b with respect to an instance $(\mathbf{H}, \boldsymbol{\ell})$:

1. Fix a width k and a prime $p > \max_{\mathbf{x}\in\{0,1\}^n} ||\mathbf{H}\cdot\mathbf{x}||_\infty$ such that p is at least super-polynomial in the security parameter.
2. Sample
$$\mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} \leftarrow \mathsf{VSS.Encode}((\mathbf{H},\boldsymbol{\ell}), p, k).$$
3. Sample uniformly random $\mathbf{S} \leftarrow \mathbb{F}_p^{k\times k}$ and output the ciphertext
$$\mathsf{M}_{\mathbf{H},\boldsymbol{\ell},b} \coloneqq \mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} + (b\mathbf{S}, \mathbf{0}, \ldots, \mathbf{0}).$$

To decrypt a ciphertext of the form $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ using a witness $\mathbf{w} \in \{0,1\}^n$, we compute

$$\det(\mathbf{A} + \sum_{i\in[n]} w_i\mathbf{B}_i).$$

If this determinant is a non-zero element in $\mathbb{F}_p$, then $b = 1$ and if the result is zero then $b = 0$.

Correctness holds since if $\mathbf{w} \in \{0,1\}^n$ is a witness for $(\mathbf{H}, \boldsymbol{\ell}) \in$ VECTOR-SUBSET-SUM, then $\mathbf{H}\cdot\mathbf{w} = \boldsymbol{\ell}$, so

$$\mathbf{A} + \sum_{i\in[n]} w_i\mathbf{B}_i = b\mathbf{S}.$$

Since $\mathbf{S}$ is a random matrix in $\mathbb{F}_p$, where p is super-polynomial in the security parameter, its determinant is nonzero with overwhelming probability.

However, this construction is insecure; given an instance $(\mathbf{H}, \boldsymbol{\ell}) \notin$ VECTOR-SUBSET-SUM, an adversary can potentially find $\mathbf{x} \in \mathbb{F}_p^n$ (where $\mathbf{x} \notin \{0,1\}^n$) such that $\mathbf{H}\cdot\mathbf{x} = \boldsymbol{\ell}$. The same correctness argument used for *valid* witnesses $\mathbf{w} \in \{0,1\}^n$ will also imply that for such an $\mathbf{x} \in \mathbb{F}_p^n$, the "encrypted" bit b can be recovered as

$$b = \mathsf{Eval}_{\neq 0}(\det(\mathsf{M}_{\mathbf{H},\boldsymbol{\ell},b}(\mathbf{x}))).$$

Preventing Invalid Evaluations

For this approach to have any hope for security, we will need to modify the ciphertext $\mathsf{M}_{\mathbf{H},\boldsymbol{\ell},b}$ so that $\det(\mathsf{M}_{\mathbf{H},\boldsymbol{\ell},b}(\mathbf{x}))$ does not leak the value of b on inputs $\mathbf{x} \notin \{0,1\}^n$.

Our approach is to add "noise" to $\mathsf{M}_{\mathbf{H},\boldsymbol{\ell},b}$ which will prevent the adversary from gaining information on non-binary inputs. This noise will take the form of another ADP $\mathsf{M}_{\mathsf{noise}}$ which will satisfy the following properties:

- (Zero on binary inputs) For all $\mathbf{x} \in \{0,1\}^n$, $\det(\mathsf{M}_{\mathsf{noise}}(\mathbf{x})) = 0$,
- (Non-zero on non-binary inputs): For all $\mathbf{x} \in \mathbb{F}_p^n \setminus \{0,1\}^n$, $\Pr[\det(\mathsf{M}_{\mathsf{noise}}(\mathbf{x})) = 0] = \mathsf{negl}(n)$,

where the probability is taken over the randomness used to generate $\mathsf{M}_{\mathsf{noise}}$. In the construction, we will simply add $\mathsf{M}_{\mathsf{noise}}$ to $\mathsf{M}_{\mathbf{H},\boldsymbol{\ell},b}$, so the "non-zero on non-binary inputs" property will intuitively block the attack described above. We set $\mathsf{M}_{\mathsf{noise}}$ to be the result of sampling from an "All-Accept" encoding scheme, defined as follows.

An All-Accept ADP encoding scheme AllAcc.Gen is a randomized procedure that takes an input length n and field $\mathbb{F}_p$, and outputs M of width k with the following properties:

- (Correctness) For all $\mathbf{x} \in \{0,1\}^n$,
$$\Pr[\det(\mathsf{M}(\mathbf{x})) = 0 : \mathsf{AllAcc.Gen}(n, \mathbb{F}_p) \to (\mathsf{M}, k)] = 1.$$
- (Rejection of Invalid Inputs) For all non-binary $\mathbf{x}$, i.e. $\mathbf{x} \in \mathbb{F}_p^n \setminus \{0,1\}^n$,
$$\Pr[\det(\mathsf{M}(\mathbf{x})) = 0 : \mathsf{AllAcc.Gen}(n, \mathbb{F}_p) \to (\mathsf{M}, k)] = \mathsf{negl}(n).$$

An All-Accept ADP from a Boolean Formula Encoding

A natural attempt to construct such an encoding scheme would be to use the formula encoding scheme described in Section 4.2 to encode any formula that accepts all boolean inputs $\mathbf{x} \in \{0,1\}^n$. Unfortunately, this does not in general guarantee rejection of invalid inputs. However, it turns out that encoding the simple boolean formula

$$f(x_1, \ldots, x_n) = (x_1 \vee \neg x_1) \wedge \cdots \wedge (x_n \vee \neg x_n)$$

via the procedure described above does guarantee rejection of invalid inputs. This sampling procedure is equivalent to the concrete procedure given here.

$\mathsf{AllAcc.Gen}^{\mathsf{FORM}}(n, \mathbb{F}_p)$:

- Draw uniformly at random 4 sets of n vectors of dimension $n+1$:

  $$\{\mathbf{u}_i\}_{i\in[n]}, \{\mathbf{v}_i\}_{i\in[n]}, \{\mathbf{s}_i\}_{i\in[n]}, \{\mathbf{t}_i\}_{i\in[n]},$$

  along with n^2 scalars $\{c_j^{(i)}\}_{i,j\in[n]}$ over $\mathbb{F}_p$.
- Let

  $$\mathbf{A} = \sum_{i\in[n]} \mathbf{u}_i \mathbf{v}_i^\top,$$
  $$\mathbf{B}_i = -\mathbf{u}_i \mathbf{v}_i^\top + \mathbf{s}_i \mathbf{t}_i^\top + \sum_{j\in[n]} c_i^{(j)} \mathbf{u}_j \mathbf{t}_j^\top,$$

  and output $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$.

Correctness and security follow by fixing the field size $p = \omega(\mathsf{poly}(n))$ and rewriting an evaluation on input $\mathbf{x} \in \mathbb{F}_p^n$ as follows, setting $k_i \coloneqq \sum_{j\in[n]} x_j c_j^{(i)}$:

$$\begin{aligned}
\mathbf{A} + \sum_{i\in[n]} x_i \mathbf{B}_i &= \sum_{i\in[n]} \Big((1-x_i)\mathbf{u}_i \mathbf{v}_i^\top + x_i \mathbf{s}_i \mathbf{t}_i^\top + k_i \mathbf{u}_i \mathbf{t}_i^\top \Big) \\
&= \sum_{i\in[n]:x_i=0} \mathbf{u}_i \Big(\mathbf{v}_i^\top + k_i \mathbf{t}_i^\top \Big) + \sum_{i\in[n]:x_i=1} \Big(\mathbf{s}_i + k_i \mathbf{u}_i \Big) \mathbf{t}_i^\top \\
&\quad + \sum_{i\in[n]:x_i\notin\{0,1\}} \mathbf{u}_i \Big((1-x_i)\mathbf{v}_i^\top + k_i \mathbf{t}_i^\top \Big) + x_i \mathbf{s}_i \mathbf{t}_i^\top .
\end{aligned}$$

Thus when $\mathbf{x}$ is binary, $\mathbf{A} + \sum_{i\in[n]} x_i \mathbf{B}_i$ can be written as a sum of n rank one matrices (recall the dimension is $n+1$). Otherwise, it can be written as a sum of at least $n+1$ rank one matrices which do not share column or row spans (with overwhelming probability over the sampling randomness). Since the field size is $p = \omega(\mathsf{poly}(n))$, the resulting matrix will be full rank except with probability negligible in the input length n.

We now describe a slight generalization of the above sampling procedure, which will help with security of the eventual witness encryption candidate. We replace the vectors $\mathbf{u}_i, \mathbf{v}_i, \mathbf{s}_i, \mathbf{t}_i$ with matrices $\mathbf{U}_i, \mathbf{V}_i, \mathbf{S}_i, \mathbf{T}_i$ of width $q(n)$ (where $q(\cdot)$ is now a parameter for the encoding procedure). In the sampling procedure given above, $q(n)$ is implicitly set to always output 1. In general, the resulting dimension of the output program will be set to $k = nq(n) + 1$. This more general sampling procedure is used in the concrete candidate we give in Section 5.2.

An All-Accept ADP from "Nearly Skew Symmetric" Matrices

To state our next construction of an all-accept ADP, it will be helpful to define a "nearly-skew-symmetric" matrix.

▶ **Definition 13** (Nearly Skew Symmetric Matrices). *A matrix* $\mathbf{N} \in \mathbb{F}_p^{k \times k}$ *is nearly-skew-symmetric (*NSS*) if* $\mathbf{N}_{i,j} = -\mathbf{N}_{i,j}$ *for all* $i, j > 1$ *such that* $i \neq j$*, and* $\mathbf{N}_{i,1} + \mathbf{N}_{1,i} + \mathbf{N}_{i,i} = 0$ *for all* i*.*

Observe that any nearly-skew-symmetric matrix will have $\mathbf{N}_{1,1} = 0$. Furthermore, the bottom-right $(k-1) \times (k-1)$ supmatrix of any NSS matrix is skew-symmetric. Setting $n = k - 1$, note that it is easy to sample a random NSS by choosing uniformly random field elements $a_1, \ldots, a_n, d_1, \ldots, d_n$, as well as a uniformly random width-n skew-symmetric matrix B, and outputting

$$\begin{pmatrix} 0 & 0 & \cdots & 0 \\ 0 & & & \\ \vdots & & B & \\ 0 & & & \end{pmatrix} + \begin{pmatrix} 0 & a_1 & \cdots & a_n \\ -a_1 - d_1 & d_1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ -a_n - d_n & 0 & \cdots & d_n \end{pmatrix}.$$

The above formulation makes it clear that for any finite field $\mathbb{F}_p$ and matrix width k, the set of all NSS matrices lies in a known linear subspace. Let $\mathsf{NSS.Sample}(p, k)$ be the procedure that produces a uniformly random sample from this subspace, i.e. outputs a random nearly-skew-symmetric matrix $\mathbf{N}$ of width k over $\mathbb{F}_p$.

We define the following all-accept encoding procedure.

$\mathsf{AllAcc.Gen}^{\mathsf{NSS}}(n, \mathbb{F}_p)$:

- Let $k = n + 1$, and draw a uniformly random full rank matrix $\mathbf{T} \leftarrow \mathbb{F}_p^{k \times k}$.
- For each $i \in [k]$, draw $\mathbf{N}_i \leftarrow \mathsf{NSS.Sample}(k)$ and set $\mathbf{C}_i = \mathbf{T}^{-1} \cdot \mathbf{N}_i$.
- Let $\mathbf{A}$ be the $k \times k$ matrix obtained by concatenating the first column of each of the $\mathbf{C}_i$ matrices, and let $\mathbf{B}_i$ be the $k \times k$ matrix obtained by concatenating the $i+1$st columns of each of the $\mathbf{C}_i$ matrices. Output $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$.

To show correctness, fix any $\mathbf{x} \in \{0,1\}^n$, and let $\mathbf{x}' = [1 \mid \mathbf{x}^\top]^\top$. Denote the jth column of a matrix $\mathbf{M}$ by $(\mathbf{M})_j$. Then for all $j \in [n+1]$,

$$\mathbf{T} \cdot (\mathbf{A} + \sum_{i \in [n]} x_i \mathbf{B}_i)_j = \mathbf{T} \cdot \mathbf{C}_j \cdot \mathbf{x}' = \mathbf{N}_j \cdot \mathbf{x}'.$$

Now we claim that for all $j, \mathbf{x}'^\top \cdot \mathbf{N}_j \cdot \mathbf{x}' = 0$, which implies that $\mathbf{x}'^\top \cdot \mathbf{T}$ is in the kernel of $\mathbf{A} + \sum_{i \in [n]} x_i \mathbf{B}_i$, and thus that $\det(\mathsf{M}(\mathbf{x})) = 0$. In fact, for any NSS matrix $\mathbf{N}$, and any vector $\mathbf{x}' = [1 \mid \mathbf{x}^\top]^\top$, where $\mathbf{x} \in \{0,1\}^n$, it holds that $\mathbf{x}'^\top \cdot \mathbf{N} \cdot \mathbf{x}' = 0$. To see this, treat each entry of $\mathbf{x}$ as a distinct formal variable, and expand out the expression as a quadratic polynomial over $x_1, \ldots, x_n$. Since $\mathbf{x}$ is binary, we know that $x_i^2 = x_i$. Thus, the coefficient on x_i is equal to $\mathbf{N}_{1,i} + \mathbf{N}_{i,1} + \mathbf{N}_{i,i} = 0$, and the coefficient on $x_i x_j$ for $i \neq j$ is equal to $\mathbf{N}_{i,j} + \mathbf{N}_{j,i} = 0$, which establishes the claim.

To argue security, we take n to be the security parameter, and fix the field size to be $p = \omega(\mathsf{poly}(n))$. Fix any $\mathbf{x} \notin \{0,1\}^n$ and again let $\mathbf{x}' = [1 \mid \mathbf{x}^\top]^\top$. We want to bound the probability that there exists some vector $\mathbf{v} \neq \mathbf{0}$ such that $\mathbf{v}^\top \cdot (\mathbf{A} + \sum_i x_i \mathbf{B}_i) = 0$. Setting $\mathbf{w}'^\top = \mathbf{v}^\top \cdot \mathbf{T}^{-1}$, we have that

$$\mathbf{v}^\top \cdot (\mathbf{A} + \sum_i x_i \mathbf{B}_i) = 0 \Leftrightarrow \mathbf{w}'^\top \cdot \mathbf{N}_i \cdot \mathbf{x}' = 0 \ \forall i \in [n+1].$$

We will union bound over all vectors $\mathbf{w'}^\top$ to show that there does not exist such a vector with high probability. Note that it suffices to union bound over all $\mathbf{w'}$ with first entry equal to 0 or 1, for a total of $2p^n$ vectors.

First consider the case where $\mathbf{w'}^\top = [0 \mid \mathbf{w}^\top]$ for some $\mathbf{w} \in \mathbb{F}_p^n$. Recall that each $\mathbf{N}_i$ is generated by choosing random values $a_1, \ldots, a_n, d_1, \ldots, d_n$ and a skew-symmetric $\mathbf{B}$ and arranging in a matrix as described above. Now treat these values as formal variables, and consider the linear polynomial over these variables induced by the expression $[0 \mid \mathbf{w}^\top] \cdot \mathbf{N}_i \cdot [1 \mid \mathbf{x}^\top]^\top$. We argue that this polynomial must not be identically zero. The coefficient on the variable a_i is exactly $-w_i$. Since $\mathbf{w'} \neq \mathbf{0}$, it must be the case that $\mathbf{w} \neq \mathbf{0}$, so there must be some i such that $w_i \neq 0$.

Now consider the case where $\mathbf{w'}^\top = [1 \mid \mathbf{w}^\top]$ for some $\mathbf{w} \in \mathbb{F}_p^n$. The coefficient on a_i is exactly $w_i(x_i - 1)$ and the coefficient on d_i is exactly $x_i(w_i - 1)$. But by assumption, there must be some i such that $x_i \notin \{0, 1\}$, implying that the coefficient on either a_i or d_i is non-zero. Thus, for each of the $2p^n$ vectors $\mathbf{w'}$ that we consider, the probability that $\mathbf{w'}^\top \cdot \mathbf{N}_i \cdot \mathbf{x'} = 0$ is at most $1/p$ over the randomness of sampling $\mathbf{N}_i$. This holds simultaneously for each $i \in [n+1]$ with probability at most $1/p^{n+1}$. So by a union bound, there exists a $\mathbf{w'}$ orthogonal to each $\mathbf{N}_i \cdot \mathbf{x'}$ with probability at most $2/p = \mathsf{negl}(n)$.

5.2 Candidate Witness Encryption Constructions

Generic Candidate

Given the above definitions, we can define a general paradigm for constructing witness encryption (encrypting a single bit b) for VECTOR-SUBSET-SUM. Instantiating the framework with any AllAcc.Gen and VSS.Encode procedures will result in a correct witness encryption.

- $\mathsf{WE.Enc}(b, (\mathbf{H}, \boldsymbol{\ell}))$: Let $d \times n$ be the dimension of $\mathbf{H}$.
  1. Choose a prime $p > \max_{\mathbf{x} \in \{0,1\}^n} ||\mathbf{H} \cdot \mathbf{x}||_\infty$. Additionally we require $p = \omega(\mathsf{poly}(n))$.
  2. Sample $(\mathsf{M_{AA}}, k) \leftarrow \mathsf{AllAcc.Gen}(n, \mathbb{F}_p)$.
  3. Sample $\mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} \leftarrow \mathsf{VSS.Encode}((\mathbf{H}, \boldsymbol{\ell}), \mathbb{F}_p, k)$.
  4. Sample $\mathbf{S} \leftarrow \mathbb{F}_p^{k \times k}$.
  5. Output $\mathsf{M_{AA}} + \mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} + (b\mathbf{S}, \mathbf{0}, \ldots, \mathbf{0})$.
- $\mathsf{WE.Dec}(\mathsf{M}, w)$: output $\mathsf{Eval}_{\neq 0}(\det(\mathsf{M}(w)))$.

Concrete Candidate

We now give a simple, self-contained instantiation of the general witness encryption framework described above.

This candidate will be a witness encryption for SUBSET-SUM, with instances $(\mathbf{h} \in \mathbb{Z}^n, \ell \in \mathbb{Z})$. Given an instance $(\mathbf{h} \in \mathbb{Z}^n, \ell \in \mathbb{Z})$, define the instance $(\mathbf{H} \in \mathbb{Z}^{(n+1) \times 2n}, \boldsymbol{\ell} \in \mathbb{Z}^{n+1})$ of VECTOR-SUBSET-SUM where

$$\mathbf{H} \coloneqq \begin{pmatrix} h_1 & h_2 & \cdots & h_n & 0 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 & 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 0 & 0 & \cdots & 1 \end{pmatrix}, \boldsymbol{\ell} \coloneqq \begin{pmatrix} \ell \\ 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix}.$$

As discussed in Section 7, this transformation will help with security. In particular, an instance $((h_1, \ldots, h_n), \ell) \notin \mathsf{SUBSET\text{-}SUM}$ could potentially have many $h_i = 0$, so encoding without the above transformation will leak many $\mathbf{B}_i$ of the all-accept encoding in the clear.

The following instantiation combines the $\mathsf{VSS.Encode}$ scheme described above with the all-accept encoding $\mathsf{AllAcc.Gen}^{\mathsf{FORM}}$, with parameter $q(n) = n^\epsilon$ for some constant $\epsilon > 0$. As discussed in Section 7.1, setting $q(\cdot)$ to be a super-constant function of n will help defend against MQ-style attack strategies. Note that the encryption scheme below takes as input a one-dimensional $\mathsf{SUBSET\text{-}SUM}$ instance and first follows the above conversion to a $\mathsf{VECTOR\text{-}SUBSET\text{-}SUM}$ instance. Then, it encrypts under this $\mathsf{VECTOR\text{-}SUBSET\text{-}SUM}$ instance following the generic paradigm above.

- $\mathsf{WE.Enc}(b, ((h_1, \ldots, h_n), \ell))$. Choose $p > \max_{\mathbf{x}\in\{0,1\}^n} |\sum_i x_i h_i|$ such that $p = \omega(\mathsf{poly}(n))$, and fix the field $\mathbb{F}_p$.
  1. For each $i \in [2n]$, draw 4 uniformly random matrices
  $$\mathbf{U}_i, \mathbf{V}_i, \mathbf{S}_i, \mathbf{T}_i \leftarrow \mathbb{F}_p^{(2n^{1+\epsilon}+1)\times n^\epsilon}.$$
  2. For each $i, j \in [2n]$, draw a uniformly random scalar
  $$c_j^{(i)} \leftarrow \mathbb{F}_p.$$
  3. Draw $2n$ uniformly random matrices
  $$\mathbf{R}_0, \mathbf{R}_1, \ldots, \mathbf{R}_n, \mathbf{S} \leftarrow \mathbb{F}_p^{(2n^{1+\epsilon}+1)\times(2n^{1+\epsilon}+1)}.$$
  4. Define
  $$\mathbf{A} := \sum_{i\in[2n]} \mathbf{U}_i\mathbf{V}_i^\top - \ell\mathbf{R}_0 - \sum_{i\in[n]} \mathbf{R}_i + b\mathbf{S}.$$
  For $\ell \in [n]$, define
  $$\mathbf{B}_\ell := -\mathbf{U}_\ell\mathbf{V}_\ell^\top + \mathbf{V}_\ell\mathbf{T}_\ell^\top + \sum_{j\in[2n]} c_\ell^{(j)}\mathbf{U}_j\mathbf{T}_j^\top + h_\ell\mathbf{R}_0 + \mathbf{R}_\ell$$
  For $\ell \in \{n+1, \ldots, 2n\}$, define
  $$\mathbf{B}_\ell := -\mathbf{U}_\ell\mathbf{V}_\ell^\top + \mathbf{S}_\ell\mathbf{T}_\ell^\top + \sum_{j\in[2n]} c_\ell^{(j)}\mathbf{U}_j\mathbf{T}_j^\top + \mathbf{R}_\ell.$$
  5. Finally, output
  $$\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_{2n}).$$
- $\mathsf{WE.Dec}(\mathsf{M}, w)$. Let $\widehat{w}$ be such that each $\widehat{w}_i = 1 - w_i$. Output $\mathsf{Eval}_{\neq 0}(\det(\mathsf{M}([w \mid \widehat{w}])))$.

6 Applications of ADP-Based Witness Encryption

6.1 Public-Key Encryption with Short Public Keys

In this section, we show how to use our witness encryption candidate to construct a public key encryption scheme with extremely short public keys and with fast key generation.

6.1.1 A Generic Framework

We recall from [19] the generic construction of public-key encryption from a witness encryption scheme WE and any pseudo-random generator $g : \{0,1\}^\lambda \to \{0,1\}^{n(\lambda)}$.

- $\mathsf{PKE.Gen}(1^\lambda)$. Sample a uniformly random $\mathsf{sk} \leftarrow \{0,1\}^\lambda$, and set $\mathsf{pk} = g(\mathsf{sk})$. Output $(\mathsf{pk}, \mathsf{sk})$.
- $\mathsf{PKE.Encrypt}(\mathsf{pk}, m \in \{0,1\})$. Define the boolean circuit $C[g, \mathsf{pk}](\cdot)$, which on input $\mathbf{x} \in \{0,1\}^\lambda$, outputs 1 if and only if $g(\mathbf{x}) = \mathsf{pk}$. Interpreting $C[g, \mathsf{pk}](\cdot)$ as an instance of CIRCUIT-SAT, apply a deterministic reduction from CIRCUIT-SAT to SUBSET-SUM and obtain an instance $(\mathbf{h}, \ell)$. Output $c \leftarrow \mathsf{WE.Enc}(1^\lambda, (\mathbf{h}, \ell), m)$.
- $\mathsf{PKE.Decrypt}(\mathsf{sk}, (\mathbf{h}, \ell), c)$. Run the reduction from CIRCUIT-SAT to SUBSET-SUM to transform the witness sk for $C[g, \mathsf{pk}](\cdot)$ to a subset-sum witness $\mathbf{w}$ for $(\mathbf{h}, \ell)$. Return $m \leftarrow \mathsf{WE.Dec}(c, \mathbf{w})$.

▶ Remark 14. The choice of g is fixed in the specification of the public-key encryption scheme and is not included in pk. Notice that 1^λ is an input to WE.Enc since there is no set-up/gen algorithm in witness encryption, but it is not an explicit input to PKE.Encrypt; however, it can be easily obtained by inspecting the length of pk.

The following claim captures the fact that security of this construction can be proved assuming either the standard security notion for witness encryption [19], or the stronger extractable security notion given by [23]; in the latter case the requirement on g can be weakened to one-wayness.

▷ Claim 15 (Security of Witness-Encryption-based PKE). The above public-key encryption scheme satisfies CPA-security if

- WE is secure under the standard [19] security notion for witness encryption, and $g : \{0,1\}^\lambda \to \{0,1\}^{n(\lambda)}$ is a pseudo-random generator with $n(\lambda) \geq 2\lambda$, OR
- WE is secure under the stronger [23] security notion for *extractable* witness encryption, and $g : \{0,1\}^\lambda \to \{0,1\}^{n(\lambda)}$ is a one-way function.

Proof. In the case where we use the standard [19] security notion for witness encryption, an encryption with respect to pk which is not generated as the output of g computationally hides the encrypted message. Therefore, an adversary that can distinguish encryptions of 0 and 1 also distinguishes between outputs of g and uniformly random strings, breaking the pseudorandomness of g.

If we rely on the [23] extractable security notion, then an adversary which can distinguish encryptions of 0 and 1 implies the existence of an extractor which outputs a witness that pk is in the image of g; this breaks the one-wayness of g. ◀

6.1.2 A Concrete Instantiation from Goldreich's PRG

For an arbitrary one-way function, the CIRCUIT-SAT to SUBSET-SUM reduction may be costly. Thus, we give a concrete instantiation of the above approach using Goldreich's PRG [22, 3] in place of g, along with a custom reduction to VECTOR-SUBSET-SUM. We first recall the construction of Goldreich's PRG.

▶ **Definition 16** (Goldreich's PRG with locality k). *Fix a boolean predicate $P : \{0,1\}^k \to \{0,1\}$, and a list $S_1, \ldots, S_m \in [n]^k$ of k-tuples of indices. Write S_i as $(i_1, \ldots, i_k)$. On input $\mathbf{x} \in \{0,1\}^n$, the jth bit of the output is set to $P(x_{i_1}, \ldots, x_{i_k})$.*

For this work, we will exclusively focus on the locality $k = 5$ setting with the TSA ("Tri-Sum-And") predicate, defined as

$$\mathrm{TSA}(x_1, x_2, x_3, x_4, x_5) = x_1 + x_2 + x_3 + x_4 x_5 \mod 2.$$

Hereinafter, "Goldreich's PRG" will refer to the instantiation with the TSA predicate. For a list $S = (S_1, \ldots, S_m)$ where each $S_i \in [n]^5$, let $g_S : \{0,1\}^n \to \{0,1\}^m$ be Goldreich's PRG instantiated with the TSA predicate, parameterized by index sets $S_1, \ldots, S_m$.

▶ **Definition 17.** *The* GOLDREICH *language consists of instances* $(n, \mathbf{y}, (S_1, \ldots, S_m))$ *such that each* $S_i \in [n]^5$*, and* $\mathbf{y}$ *is in the image of* g_S *where* $S = (S_1, \ldots, S_m)$*.*

▶ **Lemma 18** (GOLDREICH to VECTOR-SUBSET-SUM)**.** *There is a Karp reduction which takes* $(n, \mathbf{y}, (S_1, \ldots, S_m))$ *in* GOLDREICH *and outputs* $(\mathbf{H}, \boldsymbol{\ell})$ *in* VECTOR-SUBSET-SUM*, where* $\mathbf{H} \in \mathbb{Z}^{m \times (n+2m)}$ *and* $\boldsymbol{\ell} \in \mathbb{Z}^m$*.*

Proof. Given a list $S = (S_1, \ldots, S_m)$ with corresponding Goldreich PRG $g_S : \{0,1\}^n \to \{0,1\}^m$, along with a string $\mathbf{y} \in \{0,1\}^m$, we construct an instance $(\mathbf{H}, \boldsymbol{\ell})$ where $\mathbf{H} \in \mathbb{Z}^{m \times (n+2m)}$ and $\boldsymbol{\ell} \in \mathbb{Z}^m$ such that there exists $\mathbf{w} \in \{0,1\}^{n+2m}$ satisfying $\mathbf{H} \cdot \mathbf{w} = \boldsymbol{\ell}$ if and only there exists $\mathbf{x} \in \{0,1\}^n$ satisfying $G_S(\mathbf{x}) = \mathbf{y}$.

We define $n + 2m$ variables by allocating 1 variable for each input position $j \in [n]$, and 2 variables a_i, b_i for each output position $i \in [m]$. We generate m equations as follows. For each $i \in [m]$, write $S_i = (i_1, i_2, i_3, i_4, i_5)$ and consider the pair (S_i, y_i).

- If $y_i = 0$, the associated equation is

$$2x_{i_1} + 2x_{i_2} + 2x_{i_3} - x_{i_4} - x_{i_5} - 4a_i + b_i = 0.$$

- If $y_i = 1$, the associated equation is

$$2x_{i_1} + 2x_{i_2} + 2x_{i_3} + x_{i_4} + x_{i_5} - 4a_i - b_i = 2.$$

Since each equation is a linear equation over $n + 2m$ variables, writing the coefficients of each of the m equations as a matrix yields the matrix $\mathbf{H} \in \mathbb{Z}^{m \times (n+2m)}$. Correspondingly, $\boldsymbol{\ell} \in \mathbb{Z}^m$ is specified by the right-hand-side values of the m equations.

We can extend a pre-image $\mathbf{x} \in \{0,1\}^n$ into a vector $\mathbf{w} \in \{0,1\}^{n+2m}$ satisfying $\mathbf{H} \cdot \mathbf{w} = \boldsymbol{\ell}$ as follows. For each $i \in [m]$:

- If $y_i = 0$, set $a_i = 1$ if and only if $x_{i_1} + x_{i_2} + x_{i_3} \geq 2$.
- If $y_i = 1$, set $a_i = 1$ if and only if $x_{i_1} + x_{i_2} + x_{i_3} + x_{i_4} x_{i_5} \geq 3$.
- Regardless of y_i, set $b_i = 1$ if and only if $x_{i_4} + x_{i_5} = 1$.

It can be verified that if any constraint i is not satisfied, then there is no $\{0,1\}$ setting of the a_i, b_i variables that can result in a satisfying VECTOR-SUBSET-SUM witness. ◀

6.1.3 Optimizations and Parameter Size Estimates

In this section, we describe an extension of the above witness encryption candidate for one-bit messages that allows for encoding an h-bit message in a single ADP. We will make use of the NSS based all-accept, and will first generalize the $\mathsf{AllAcc.Gen}^{\mathsf{NSS}}$ algorithm to output wide rectangular matrices of dimension $k \times (k + r)$. We include the parameter r in the input to the sampling procedure, noting that the procedure given before implicitly set $r = 0$.

$\mathsf{AllAcc.Gen}^{\mathsf{NSS}}(n, r, \mathbb{F}_p)$:

- Let $k = n + 1$, and draw a uniformly random full rank matrix $\mathbf{T} \leftarrow \mathbb{F}_p^{k \times k}$.
- For each $i \in [k + r]$, draw $\mathbf{N}_i \leftarrow \mathsf{NSS.Sample}(k)$ and set $\mathbf{C}_i = \mathbf{T}^{-1} \cdot \mathbf{N}_i$.
- Let $\mathbf{A}$ be the $k \times (k + r)$ matrix obtained by concatenating the first column of each of the $\mathbf{C}_i$ matrices, and let $\mathbf{B}_i$ be the $k \times (k + r)$ matrix obtained by concatenating the $i + 1$st column of each of the $\mathbf{C}_i$ matrices. Output $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$.

It is also straightforward to generalize the $\mathsf{VSS.Encode}$ procedure to take in an additional input r and produce an ADP with matrices of width $k \times (k + r)$. Simply draw the random $\mathbf{R}_i$ matrices over $\mathbb{F}_p^{k \times (k+r)}$.

The optimized witness encryption algorithm will additionally take as input a parameter λ which determines the correctness of the encryption, and the input message will now be $\mathbf{m} \in \{0, 1\}^h$. It operates as follows.

- $\mathsf{WE.Enc}(1^\lambda, \mathbf{m}, (\mathbf{H}, \boldsymbol{\ell}))$: Let $d \times n$ be the dimension of $\mathbf{H}$, and h be the bit length of $\mathbf{m}$.
  1. Choose a prime $p > \max_{\mathbf{x} \in \{0,1\}^n} ||\mathbf{H} \cdot \mathbf{x}||_\infty$.
  2. Set $t = \lceil h / \log(p) \rceil$ and $r = \lambda + t$.
  3. Sample $(\mathsf{M_{AA}}, k) \leftarrow \mathsf{AllAcc.Gen}^{\mathsf{NSS}}(n, r, \mathbb{F}_p)$.
  4. Sample $\mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} \leftarrow \mathsf{VSS.Encode}((\mathbf{H}, \boldsymbol{\ell}), \mathbb{F}_p, k, r)$.
  5. Encode $\mathbf{m} \in \{0, 1\}^h$ as a vector $\hat{\mathbf{m}} \in \mathbb{F}_p^t$. Let $\mathbf{X}_{\hat{\mathbf{m}}}$ be the matrix of dimension $k \times (k+r)$ whose only non-zero entries consist of the vector $\hat{\mathbf{m}}$, placed in the last t positions of the first row.
  6. Output $\mathsf{M_{AA}} + \mathsf{M}_{\mathbf{H},\boldsymbol{\ell}} + \mathbf{X}_{\hat{\mathbf{m}}}$.
- $\mathsf{WE.Dec}(\mathsf{M}, \mathbf{w})$: Compute $\mathbf{A}_\mathbf{w} = \mathbf{A} + \sum_i w_i \mathbf{B}_i$. If the first $k + \lambda$ columns of $\mathbf{A}_\mathbf{w}$ do not form a matrix of rank exactly $k - 1$, abort. Otherwise, find a rank $k - 1$ submatrix $\mathbf{A}'_\mathbf{w}$ of dimension $k \times (k - 1)$ among the first $k + \lambda$ columns of $\mathbf{A}_\mathbf{w}$. Let $\mathbf{X}$ be the matrix of all zeros except for a formal variable x in the top right corner. Now, for each $i \in [t]$, let $\hat{m}_i$ be the solution to the linear equation $\det([\mathbf{A}'_\mathbf{w} \mid (\mathbf{A}_\mathbf{w})_{k+\lambda+i}] - \mathbf{X}) = 0$ over the variable x. Assemble the $\hat{m}_i$ into a vector $\hat{\mathbf{m}} \in \mathbb{F}_p^t$ and recover the message $\mathbf{m} \in \{0, 1\}^h$.

To argue correctness of decryption on input a valid witness $\mathbf{w}$, first note that since $\mathbf{A}'_\mathbf{w}$ has full rank $k - 1$, each equation $\det([\mathbf{A}'_\mathbf{w} \mid (\mathbf{A}_\mathbf{w})_{k+\lambda+i}] - \mathbf{X}) = 0$ will be linear with a non-zero coefficient on variable x. Hence, each element of $\hat{\mathbf{m}}$ can easily be recovered. It is left to argue that the decryption function aborts with negligible probability. Let $\overline{\mathbf{A}}_\mathbf{w}$ be the first $k + \lambda$ columns of $\mathbf{A}_\mathbf{w}$. We claim that the rank of $\overline{\mathbf{A}}_\mathbf{w}$ is $k - 1$, except with negligible probability. We know it is not full rank, since by the properties of the NSS all-accept scheme, the vector $[1 \mid \mathbf{w}] \cdot \mathbf{T}$ must be in its left kernel. Similar to the proof of security of the original NSS all accept, we can union bound over all other possible vectors, concluding that $\overline{\mathbf{A}}_\mathbf{w}$ is rank deficient by at least 2 with probability at most $1/p^\lambda$, which is negligible in λ, even for constant size fields.

Now we estimate the ciphertext size of the public key encryption scheme that results from combining the optimized witness encryption scheme with our reduction from $\mathsf{GOLDREICH}$ to $\mathsf{VECTOR\text{-}SUBSET\text{-}SUM}$. We will set $\lambda = 80$ to be the security and correctness parameter. Note that for any public key encryption scheme, it suffices to encrypt a security parameter number of bits and then appeal to key encapsulation to encrypt arbitrarily long messages. We set $p = 11$ to be the smallest prime satisfying $p > \max_{\mathbf{x} \in \{0,1\}^n} ||\mathbf{H} \cdot \mathbf{x}||_\infty$ for $\mathbf{H}$ output by the reduction from $\mathsf{GOLDREICH}$.

We will make use of Goldreich's PRG[3] with input length $n = 300$ and output length $m = 300$ [15]. Plugging in these parameters, the optimized witness encryption will output $n + 2m = 900$ matrices of dimension 900×1007 over the field of size 11. Assuming 4 bits per field element, this comes to a ciphertext of size about 400 MB. Again, the *public key* size will be extremely small: 300 bits. Perhaps even more impressively, the key generation can be done by a Boolean circuit with 300 AND gates and 900 XOR gates. This can be useful for fast distributed generation of keys via secure multiparty computation. We are not aware of any other (practically feasible) public-key encryption schemes whose key generation is nearly as efficient.

7 Cryptanalysis of the Witness Encryption Candidate

Recall that in our generic witness encryption framework of Section 5, we encrypt a bit b with respect to an instance $(\mathbf{h}, \ell)$ by sampling the following 3 ADPs.

- An instance-encoding ADP

$$\mathsf{M}_{\mathbf{h},\ell} = (\mathbf{A}^{(\mathbf{h},\ell)}, \mathbf{B}_1^{(\mathbf{h},\ell)}, \ldots, \mathbf{B}_n^{(\mathbf{h},\ell)}).$$

- A bit-encoding ADP

$$\mathsf{M}_b = (b\mathbf{S}, 0, \ldots, 0).$$

- An all-accept ADP

$$\mathsf{M}_{\mathsf{AA}} = (\mathbf{A}^{(\mathsf{AA})}, \mathbf{B}_1^{(\mathsf{AA})}, \ldots, \mathbf{B}_n^{(\mathsf{AA})}) \leftarrow \mathsf{AllAcc.Gen}(n, \mathbb{F}_p).$$

The ciphertext is the ADP

$$\mathsf{M}_{\mathbf{h},\ell} + \mathsf{M}_b + \mathsf{M}_{\mathsf{AA}} = (\mathbf{A}^{(\mathbf{h},\ell)} + b\mathbf{S} + \mathbf{A}^{(\mathsf{AA})}, \mathbf{B}_1^{(\mathbf{h},\ell)} + \mathbf{B}_1^{(\mathsf{AA})}, \ldots, \mathbf{B}_n^{(\mathbf{h},\ell)} + \mathbf{B}_n^{(\mathsf{AA})}).$$

A described in Section 5, $\mathsf{M}_{\mathbf{h},\ell} + \mathsf{M}_b$ on its own would be insufficient for security, since given any vector $\mathbf{w} \in \mathbb{F}_p^n$ such that $\mathbf{h} \cdot \mathbf{w} = \ell$, it is possible to recover b. For security, recovering b should only be possible when the vector $\mathbf{w}$ additionally satisfies $\mathbf{w} \in \{0,1\}^n$.

We therefore include the "all-accept" ADP M_{AA} such that for any $\mathbf{x} \notin \{0,1\}^n$, $\det(\mathsf{M}_{\mathsf{AA}}(\mathbf{x})) \neq 0$ with overwhelming probability, and for any $\mathbf{x} \in \{0,1\}^n$, $\det(\mathsf{M}_{\mathsf{AA}}(\mathbf{x})) = 0$. We note that both $\mathsf{M}_{\mathbf{h},\ell} + \mathsf{M}_b$ and M_{AA} on their own are "insecure" in the sense that we can show *randomness recovery* attacks on the procedures used to sample them. However, security relies on the idea that adding these ADPs to each other may block such attacks.

First, we show how to mount a randomness recovery attack on M_{AA}. On its own, this will not constitute an attack on the witness encryption ciphertext. However, we will show that this attack strategy can be extended to a full attack on a simplified version of our concrete witness encryption candidate, without the additional safeguards.

Indeed, to obtain secure witness encryption for VECTOR-SUBSET-SUM, we need semantic security of ciphertexts to hold for *any* instance $(\mathbf{h}, \ell)$ that is not in the language. A toy NO instance to consider is

$$\mathbf{h} = (0, \ldots, 0, 1), \ell = 2.$$

[3] This function is conjectured to be *one-way* when the output length is equal to the input length. Here we use it as a one-way function, which by Claim 15 suffices if our WE candidate is extractable. The latter assumption is only sufficient but not necessary; in fact, the security of this PKE candidate is a relatively clean and falsifiable assumption that can serve as a good target for cryptanalysis.

Intuitively, such an instances is particularly vulnerable since the resulting $\mathsf{M}_{\mathbf{h},\ell} + \mathsf{M}_b + \mathsf{M}_{\mathsf{AA}}$ will give out all but 2 of the matrices of M_{AA} in the clear.

Attacks on this instance motivate the concrete candidate given in Section 5, in which we first encode the instance $(\mathbf{h}, \ell)$ into a VECTOR-SUBSET-SUM instance $(\mathbf{H}, \boldsymbol{\ell})$ where $\mathbf{H}$ consists of many linearly independent rows.

7.1 Formula-Based All-Accept

We will consider two attacks on the $\mathsf{AllAcc.Gen}^{\mathsf{FORM}}$ sampling procedure, where the width of each $\mathbf{u}_i, \mathbf{v}_i, \mathbf{s}_i, \mathbf{t}_i$ is set to 1. The second attack in particular will motivate the need to consider a more general width parameter $q(\cdot)$.

7.1.1 Correlated Span Attack

We first show a polynomial-time algorithm that given $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n) \leftarrow \mathsf{AllAcc.Gen}(n, \mathbb{F}_p)$, recovers all $4n$ vectors $\{\mathbf{u}_i, \mathbf{v}_i, \mathbf{s}_i, \mathbf{t}_i\}_{i\in[n]}$ up to scalings. The high-level intuition for the attack is that for any $\mathbf{x} \in \{0,1\}^n$, the matrix $\mathbf{A} + \sum_i x_i \mathbf{B}_i$ is rank-deficient. Moreover, if we look at the kernel of this matrix for many different choices of $\mathbf{x} \in \{0,1\}^n$, correlations between these kernels will allow us to recover the original randomness used to sample $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$. We refer to this as a *correlated span attack*.

More precisely, the algorithm proceeds in the following steps.

1. Observe that $\mathbf{A}$ is rank deficient by 1. Thus, we can find vectors $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ such that $\mathbf{A} \cdot \boldsymbol{\alpha} = \mathbf{0}$ and $\boldsymbol{\beta}^\top \cdot \mathbf{A} = \mathbf{0}$.
2. Observe that with high probability $\boldsymbol{\alpha} \perp \mathbf{v}_i$ for all $i \in [n]$. Similarly, $\boldsymbol{\beta} \perp \mathbf{u}_i$ for all $i \in [n]$.
3. Now to recover $\mathbf{t}_i$ up to a scalar, compute $\boldsymbol{\beta}^\top \cdot \mathbf{B}_i$. Since $\boldsymbol{\beta}$ is perpendicular to $\mathbf{u}_i$ for all $i \in [n]$, $\boldsymbol{\beta}^\top \cdot \mathbf{B}_i = (\boldsymbol{\beta}^\top \cdot \mathbf{s}_i) \cdot \mathbf{t}_i$.
4. Now find a vector $\boldsymbol{\gamma}$ that is perpendicular to $\mathbf{t}_i$ for $i \in [n]$. Then, one can compute $\mathbf{B}_i \cdot \boldsymbol{\gamma}$ to find a vector that is a scalar multiple of $\mathbf{u}_i$. Continuing this way, one can recover all vectors $\mathbf{u}_i, \mathbf{v}_i, \mathbf{s}_i, \mathbf{t}_i$ for $i \in [n]$ up to scalar multiples.

Note that this attack crucially relies on access to the rank deficient matrix $\mathbf{A} + \sum_i x_i \mathbf{B}_i$ for various choices of $x \in \{0,1\}^n$. In the witness encryption candidate, it appears difficult to recover such a matrix when the instance is not in the language SUBSET-SUM, which is crucial for security.

7.1.2 Linearization Attack

Next we discuss linearization-style attacks [29, 14]. At a high level, a linearization attack first models the problem to be solved as a system of non-linear equations. Then, it attempts to find certain structures within the equations that enable solving them with just linear algebra. Generally, one derives new variables and re-expresses the system as a larger system of linear equations. Note that in general, systems of quadratic equations are difficult to solve. However, certain systems may be vulnerable to this style of attack.

For concreteness, we give a particular witness encryption instance that we are interested in attacking. We describe the output of encrypting a bit b under the SUBSET-SUM NO instance $(\mathbf{h}, \ell) = ((0, \ldots, 0, 1), 2)$, without first applying the transformation to VECTOR-SUBSET-SUM instance $(\mathbf{H}, \boldsymbol{\ell})$.

- $\mathsf{WE.Enc}(b, ((0,\ldots,0,1),2))$. Fix a large enough field $\mathbb{F}_p$ and draw at random 4 sets of n vectors of dimension $n+1$: $\{\mathbf{u}_i\}_{i\in[n]}, \{\mathbf{v}_i\}_{i\in[n]}, \{\mathbf{s}_i\}_{i\in[n]}, \{\mathbf{t}_i\}_{i\in[n]}$, along with n^2 scalars $\{c_j^{(i)}\}_{i,j\in[n]}$ over $\mathbb{F}_p$. Also draw uniformly random matrices $\mathbf{R}, \mathbf{S} \in \mathbb{F}_p^{(n+1)\times(n+1)}$. Let

$$\mathbf{A} = \sum_{i\in[n]} \mathbf{u}_i\mathbf{v}_i^\top - 2\mathbf{R} + b\mathbf{S},$$
$$\mathbf{B}_1 = -\mathbf{u}_1\mathbf{v}_1^\top + \mathbf{s}_1\mathbf{t}_1^\top + \sum_{j\in[n]} c_1^{(j)}\mathbf{u}_j\mathbf{t}_j^\top,$$
$$\vdots$$
$$\mathbf{B}_{n-1} = -\mathbf{u}_{n-1}\mathbf{v}_{n-1}^\top + \mathbf{s}_{n-1}\mathbf{t}_{n-1}^\top + \sum_{j\in[n]} c_{n-1}^{(j)}\mathbf{u}_j\mathbf{t}_j^\top,$$
$$\mathbf{B}_n = -\mathbf{u}_n\mathbf{v}_n^\top + \mathbf{s}_n\mathbf{t}_n^\top + \sum_{j\in[n]} c_n^{(j)}\mathbf{u}_j\mathbf{t}_j^\top + \mathbf{R}.$$

  Output

$$\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n).$$

First, observe that $\mathbf{A}$ and $\mathbf{B}_n$ are masked by $\mathbf{R}$, so we will attempt to extract information only from $\mathbf{B}_1, ..., \mathbf{B}_{n-1}$. Our goal is to recover vectors $(\mathbf{u}_1, ..., \mathbf{u}_n, \mathbf{s}_1)$. In the end, we will be left with $\Omega(n^6)$ equations of degree 3 over the the $O(n^2)$ variables that constitute these vectors. As discussed at the end of the section, these asymptotics fall in the range where successful linearization attacks may be mounted. Thus, we view this as evidence that the above simplified scheme requires the safeguards described in Section 5.2.

The idea can now be described as follows.

1. Compute $\mathbf{M}_i = \mathbf{B}_1 \cdot \mathbf{B}_i^{-1}$ for $i \in \{2,\ldots,n-1\}$. Denote matrix $\mathbf{P} = [\mathbf{u}_1, ..., \mathbf{u}_n, \mathbf{s}_1]$ and $\mathbf{Q} = [\mathbf{t}_1, ..., \mathbf{t}_n, -\mathbf{v}_1]^\top$. In this notation, $\mathbf{B}_1$ can be written as $\mathbf{P}\cdot\mathbf{D}_1\cdot\mathbf{Q}$ where $\mathbf{D}_1 \in \mathbb{F}_p^{(n+1)\times(n+1)}$ is:

$$\mathbf{D}_1 = \begin{bmatrix} c_1^{(1)} & 0 & \ldots & 0 & 1 \\ 0 & c_1^{(2)} & \ldots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \ldots & c_1^{(n)} & 0 \\ 1 & 0 & \ldots & 0 & 0 \end{bmatrix}$$

2. Now for $i \in \{2,\ldots,n-1\}$, $\mathbf{B}_i$ can be expressed as $\mathbf{P}\cdot\mathbf{D}_i\cdot\mathbf{Q} + \mathsf{LowRank}_i$. Here, $\mathbf{D}_i$ is described below, and $\mathsf{LowRank}_i$ is a matrix with rank at most 2.

$$\mathbf{D}_i = \begin{bmatrix} c_i^{(1)} & 0 & \ldots & 0 & 0 \\ 0 & c_i^{(2)} & \ldots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \ldots & c_i^{(n)} & 0 \\ 0 & 0 & \ldots & 0 & 0 \end{bmatrix}$$

3. Calculate $\mathbf{D}'_i \coloneqq \mathbf{D}_1^{-1} \cdot \mathbf{D}_i$ as

$$\mathbf{D}'_i = \begin{bmatrix} 0 & 0 & \dots & 0 & 0 \\ 0 & (c_1^{(2)})^{-1} c_i^{(2)} & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & (c_1^{(n)})^{-1} c_i^{(n)} & 0 \\ 0 & 0 & \dots & 0 & 0 \end{bmatrix}$$

4. Now, define $\mathbf{M}_i \coloneqq \mathbf{B}_1^{-1} \cdot \mathbf{B}_i$. Note that the attacker can compute all $\mathbf{M}_i$ for $i \in \{2, \dots, n-1\}$ in the clear. Observe that

$$\mathbf{Q} \cdot \mathbf{M}_i = \mathbf{Q} \cdot \mathbf{B}_1^{-1} \cdot \mathbf{B}_i = \mathbf{Q} \cdot \mathbf{Q}^{-1} \cdot \mathbf{D}'_i \cdot \mathbf{Q} + \mathbf{Q} \cdot \mathsf{LowRank}_i = \mathbf{D}'_i \cdot \mathbf{Q} + \mathsf{LowRank}'_i,$$

   where $\mathsf{LowRank}'_i$ is a matrix of rank at most 2.

5. Defining $\mathbf{Q}'_i \coloneqq \mathbf{D}'_i \cdot \mathbf{Q}$, we have that $\mathbf{Q} \cdot \mathbf{M}_i - \mathbf{Q}'_i$ has rank at most 2. Then, for any i, letting $\mathbf{Q}$ and $\mathbf{Q}'_i$ be matrices of formal variables, the attacker can set up $O(n^6)$ degree 2 equations over $2n^2$ variables. These arise by setting the determinant of each of the $O(n^6)$ submatrices of size 3×3 in $\mathbf{Q} \cdot \mathbf{M}_i - \mathbf{Q}'_i$ equal to zero.

   We also have more equations that arise from the fact that $\mathbf{Q}'_i$ has the following structure:

$$\mathbf{Q}'_i = \begin{bmatrix} 0 & 0 & \dots & 0 \\ (c_1^{(2)})^{-1} c_i^{(2)} \mathbf{Q}_{2,1} & (c_1^{(2)})^{-1} c_i^{(2)} \mathbf{Q}_{2,2} & \dots & (c_1^{(2)})^{-1} c_i^{(2)} \mathbf{Q}_{2,n+1} \\ \vdots & \vdots & & \vdots \\ (c_1^{(n)})^{-1} c_i^{(n)} \mathbf{Q}_{n,1} & (c_1^{(n)})^{-1} c_i^{(n)} \mathbf{Q}_{n,2} & \dots & (c_1^{(n)})^{-1} c_i^{(n)} \mathbf{Q}_{n,n+1} \\ 0 & 0 & \dots & 0 \end{bmatrix}$$

   Thus, for every $i_1, i_2 \in [2, \dots, n-1]$ and $j_1, j_2 \in [n+1], \mathbf{Q}'_{i,j_1} \cdot \mathbf{Q}_{i,j_2} = \mathbf{Q}'_{i,j_2} \cdot \mathbf{Q}_{i,j_1}$. Similarly, one can set up new equations for every $i \in [n]$. We can further impose that $\sum_i \mathbf{Q}_{i,i} = 1$ to ensure non-triviality.

6. It is not immediately clear that there are enough linearly independent equations to mount an attack. As long as we have a unique solution, Kipnis and Shamir [29] suggest that (heuristically) it should be possible to solve for $\mathbf{Q}$ and $\mathbf{D}'_i$ (up to scaling factors).[4] This argument can be generalized to any constant degree d. For a degree 3 system with n^2 variables, we need $0.1 \cdot n^6$ equations. A rudimentary counting argument suggests that if $\mathbf{B}_i$ are random, such a solution should not exist. We leave a more refined analysis of this attack to future work.

This attack suggests that we should set parameters so that $\mathsf{LowRank}$ matrices have a super-constant rank, or alternatively, that we do not allow the attacker to see many $\mathbf{B}_i$ matrices in the clear. The construction in Section 5.2 incorporates safeguards that address both, generalizing the width of the $\mathbf{u}_i, \mathbf{v}_i, \mathbf{s}_i, \mathbf{t}_i$ vectors via the parameter $q(\cdot)$, and encoding SUBSET-SUM instances into VECTOR-SUBSET-SUM instances with many linearly independent vectors.

[4] More specifically, for a degree-2 system of equation over n variables, roughly $0.1 \cdot n^2$ linearly independent quadratic equations suffice to recover an over-determined solution in polynomial time [29, 35].

7.2 NSS-Based All-Accept

One potential advantage that the NSS-based construction has over the formula-based construction is in the amount of randomness used to generate a sample. For dimension n, the formula-based sampling procedure uses $4(n+1)n + n^2 = O(n^2)$ uniformly random field elements to produce $n+1$ matrices of dimension $(n+1) \times (n+1)$. On the other hand, the NSS-based sampling procedure generates a fresh NSS matrix for each $i \in [n]$, each of which requires about $n^2/2$ fresh random variables. Thus the sampling procedure overall uses $O(n^3)$ random field elements to produce $n+1$ matrices of dimension $(n+1) \times (n+1)$.

However, the NSS matrices are very structured, which leads to randomness recovery attacks in certain settings, even when the attacker is not given the entire all-accept sample. Consider a sample $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n) \leftarrow \mathsf{AllAcc.Gen}^{\mathsf{NSS}}(n, \mathbb{F}_p)$, recalling that the width k of each matrix is $n+1$. The goal will be to recover the random matrix $\mathbf{T}$ drawn during the sampling procedure. First assume that just $\mathbf{B}_1$ and $\mathbf{B}_2$ are given in the clear. This means we have the 2nd and 3rd column of each $\mathbf{C}_i$ matrix for $i \in [k]$, where $\mathbf{N}_i = \mathbf{T} \cdot \mathbf{C}_i$ and each $\mathbf{N}_i$ is NSS. The symmetric properties of each $\mathbf{N}_i$ immediately give us k linear equations over the $2k$ variables comprising the 2nd and 3rd row of $\mathbf{T}$. Generalizing, if we started with s matrices $\mathbf{B}_i$ in the clear, we could form $\binom{s}{2}$ linear equations over $2s$ variables of $\mathbf{T}$ and eventually the linear system will be over-determined.

We can use this structure to attack the $(\mathbf{h}, \ell) = ((1, 0, \ldots, 0), 2)$ instance of SUBSET-SUM as follows (note this is the same instance considered above but relabeled for convenience). Encryption of the bit 0 results in the set of matrices $\mathbf{A}' = \mathbf{A} + 2\mathbf{R}, \mathbf{B}'_1 = \mathbf{B}_1 + \mathbf{R}, \mathbf{B}_2, \ldots, \mathbf{B}_n$, where $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n) \leftarrow \mathsf{AllAcc.Gen}^{\mathsf{NSS}}(n, \mathbb{F}_p)$ and $\mathbf{R}$ is a uniformly random matrix. Using $\mathbf{B}_2, \ldots, \mathbf{B}_n$, recover all but the first two rows of $\mathbf{T}$ as described above, and call this matrix $\widetilde{\mathbf{T}} \in \mathbb{F}_p^{(k-2)\times k}$. We will be interested in solving for the first and second rows of $\mathbf{T}$, denoted $\mathbf{t}^{(1)}$ and $\mathbf{t}^{(2)}$, using $\widetilde{\mathbf{T}}$ and the matrices $\mathbf{A}'$ and $\mathbf{B}'_1$.

Note that $\widetilde{\mathbf{T}}$ and $\mathbf{B}_2, \ldots, \mathbf{B}_n$ reveal the bottom right $(k-2) \times (k-2)$ submatrix of each $\mathbf{N}_i$, and in particular the diagonal entries of each of these submatrices. Now let $\mathbf{d}_i$ be the column vector that consists of the final $k-2$ elements on the diagonal of $\mathbf{N}_i$, and arrange the k columns $\mathbf{d}_i$ into a matrix $\widetilde{\mathbf{N}}$ of dimension $(k-2)$ by k. Using the symmetries present in the $\mathbf{N}_i$, we see that

$$\widetilde{\mathbf{T}} \cdot \mathbf{A} = \begin{bmatrix} -\mathbf{t}^{(1)} \cdot \mathbf{B}_2 \\ \vdots \\ -\mathbf{t}^{(1)} \cdot \mathbf{B}_n \end{bmatrix} - \widetilde{\mathbf{N}} := \widetilde{\mathbf{T}}^{(1)} - \widetilde{\mathbf{N}} \quad \text{and} \quad \widetilde{\mathbf{T}} \cdot \mathbf{B}_1 = \begin{bmatrix} -\mathbf{t}^{(2)} \cdot \mathbf{B}_2 \\ \vdots \\ -\mathbf{t}^{(2)} \cdot \mathbf{B}_n \end{bmatrix} := \widetilde{\mathbf{T}}^{(2)},$$

and we can then compute

$$\widetilde{\mathbf{T}}(\mathbf{A}' + 2\mathbf{B}'_1) = \widetilde{\mathbf{T}}(\mathbf{A} - 2\mathbf{R} + 2\mathbf{B}_1 + 2\mathbf{R}) = \widetilde{\mathbf{T}}(\mathbf{A} + 2\mathbf{B}_1) = \widetilde{\mathbf{T}}^{(1)} - 2\widetilde{\mathbf{T}}^{(2)} - \widetilde{\mathbf{N}}.$$

This gives k^2 linear equations over the $2k$ variables comprising $\mathbf{t}^{(1)}$ and $\mathbf{t}^{(2)}$.

This attack again highlights the danger of giving the adversary many $\mathbf{B}_i$ matrices in the clear. This motivates the need for encoding the SUBSET-SUM instance $(\mathbf{h}, \ell)$ into a VECTOR-SUBSET-SUM instance $(\mathbf{H}, \boldsymbol{\ell})$ where $\mathbf{H}$ contains many linearly independent rows, as described in the concrete candidate above. Now an adversary attacking the $(\mathbf{h}, \ell) = ((1, 0, \ldots, 0), 2)$ instance can recover matrices $\mathbf{B}_1 - \mathbf{B}_{n/2+1}, \ldots, \mathbf{B}_{n/2} - \mathbf{B}_n$ in the clear, and about half the information in $\mathbf{T}$, but it is unclear how to use this limited information to mount a full randomness recovery or message distinguishing attack.

8 Candidate Obfuscation for Branching Programs

As discussed in Section 4.3, the ADP model is powerful enough to capture different types of branching programs. In this section, we describe a general paradigm for taking an arbitrary deterministic branching program BP and producing an ADP that is plausibly an *indistinguishability obfuscation* ($i\mathcal{O}$) of BP. Since polynomial-size deterministic branching programs are powerful enough to simulate the class NC^1 (by Barrington's theorem) or even log-space computations, our construction directly yields a candidate $i\mathcal{O}$ for NC^1 and log-space. As shown in [17], this suffices to obtain a candidate $i\mathcal{O}$ for all polynomial-size circuits.

8.1 Functionality-Preserving Transformations

In this section, we describe three generic transformations that can be applied to affine determinant programs satisfying specific conditions. Our candidate NC^1 obfuscation will be the result of applying these three transformations in sequence to an ADP encoding of [28, 4].

8.1.1 Transformation 1: Random Local Substitutions

Recall the ADP encoding of counting branching programs described in Section 4.3. Consider any such branching program, specified by a directed acyclic graph $G = (V, E)$, and fix a topological ordering on the vertices $v_1, \ldots, v_{|V|}$. Each pair of ordered vertices (v_j, v_k), for $j < k$, is labeled by a function x_i, $\neg x_i$, 1, or 0 (no edge). Given such a branching program, our first transformation will perform what we term a *random local substitution* for each vertex pair (v_j, v_k). We describe in Section 9.3 an attack strategy that motivates the need for random local substitutions.

Viewing the branching program as $\mathsf{ADP} = (\mathsf{M}, \mathsf{Eval})$, where $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$, we see that each vertex pair (v_j, v_k), for $j < k$, defines a width-1 ADP. For concreteness, these matrices can be thought to be over some finite field $\mathbb{F}_p$ and Eval is just the identity function. In particular, each pair gives rise to the $(j, k-1)$th entry of each matrix $\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n$, which we denote by $a^{(j,k)}, b_1^{(j,k)}, \ldots, b_n^{(j,k)}$, as follows. If the label is the bit 0 or 1, then $a^{(j,k)}$ is equal to the bit, and all $b_i^{(j,k)} = 0$. If the label is x_i, then $a^{(j,k)} = 0, b_i^{(j,k)} = 1$, and $b_{i'}^{(j,k)} = 0$ for $i' \neq i$. If the label is $\neg x_i$, then $a^{(j,k)} = 1, b_i^{(j,k)} = -1$, and $b_{i'}^{(j,k)} = 0$ for $i' \neq i$.

We will inject entropy into the branching program by replacing each of these width-1 ADPs with a random width-2 ADP computing the same function. There are many possible such local substitution operations and generalizations, but we present here a particularly simple realization, which maintains the property that the resulting matrices have all entries in $\{-1, 0, 1\}$.

In the graph representation of the original branching program, the effect of replacing each each width-1 ADP with a width-2 ADP amounts to adding a vertex $v_{j,k}$ for each pair (v_j, v_k). Thus, if the width of the original ADP was ℓ, the width of the resulting ADP $\mathbf{A}', \mathbf{B}'_1, \ldots, \mathbf{B}'_n$ will be $\ell + \binom{\ell+1}{2}$. With this view it is easy to see what transformations are possible. For any pair (v_j, v_k), we consider the set of 2×2 submatrices of $\mathbf{A}', \mathbf{B}'_1, \ldots, \mathbf{B}'_n$ with rows indexed by $v_j, v_{j,k}$ and columns indexed by $v_{j,k}, v_k$. Denote this set of 2×2 matrices as $\mathbf{A}'^{(j,k)}, \mathbf{B}_1'^{(j,k)}, \ldots, \mathbf{B}_n'^{(j,k)}$. If the label of (v_j, v_k) was 0, we set all $\mathbf{B}_i'^{(j,k)} = \mathbf{0}$, and have the following possibilities for $\mathbf{A}'^{(j,k)}$:

$$\mathbf{A}_1^{(0)} = \begin{bmatrix} 0 & 0 \\ -1 & 0 \end{bmatrix}, \mathbf{A}_2^{(0)} = \begin{bmatrix} 1 & 0 \\ -1 & 0 \end{bmatrix}, \mathbf{A}_3^{(0)} = \begin{bmatrix} 0 & 0 \\ -1 & 1 \end{bmatrix}.$$

If the label of (v_j, v_k) was 1, we set all $\mathbf{B}_i^{(j,k)} = \mathbf{0}$, and have the following possibilities for $\mathbf{A}^{(j,k)}$:

$$\mathbf{A}_1^{(1)} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \mathbf{A}_2^{(1)} = \begin{bmatrix} 1 & 1 \\ -1 & 0 \end{bmatrix}, \mathbf{A}_3^{(1)} = \begin{bmatrix} 0 & 1 \\ -1 & 1 \end{bmatrix}, \mathbf{A}_4^{(1)} = \begin{bmatrix} 1 & 0 \\ -1 & 1 \end{bmatrix}.$$

If the label of (v_j, v_k) was x_i, we can set $\mathbf{A}'^{(j,k)}$ to be $\mathbf{A}_c^{(0)}$ for some $c \in \{1, 2, 3\}$, and $\mathbf{B}_i'^{(j,k)}$ to be $\mathbf{A}_d^{(1)} - \mathbf{A}_c^{(0)}$ for some $d \in \{1, 2, 3, 4\}$. This gives a total of 12 possible substitutions. Finally, if the label of (v_j, v_k) was $1 - x_i$, we again obtain 12 possible substitutions by fixing $\mathbf{A}'^{(j,k)}$ to be $\mathbf{A}_c^{(1)}$ for some $c \in \{1, 2, 3, 4\}$, and $\mathbf{B}_i'^{(j,k)}$ to be $\mathbf{A}_d^{(0)} - \mathbf{A}_c^{(1)}$, for some $d \in \{1, 2, 3\}$.

The operation we perform will, for each vertex pair, pick uniformly at random from the set of possibilities described above. For convenience, we denote this *random local substitution* operation by $\mathsf{ADP}' = \mathsf{RLS}(\mathsf{ADP})$.

We stress that our particular method of performing random local substitutions is only one potential candidate, and there are many possible transformations to explore. Our candidate was designed specifically to thwart attacks on iO described in Section 9.3, which take advantage of the fact that the structure of the underlying branching program is known.

8.1.2 Transformation 2: Small Even-Valued Noise

Our next transformation assumes the following about the input $\mathsf{ADP} = (\mathsf{M}, \mathsf{Eval})$.

- $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ is such that each entry of $\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n$ is in $\{-1, 0, 1\}$.
- $\mathsf{Eval} = \mathsf{Eval}_{\neq 0}$, and furthermore, on any input $\mathbf{x} \in \{0,1\}^n$, $\det(\mathbf{A} + \sum_i x_i \mathbf{B}_i) \in \{0, 1\}$.

Note that any ADP output by the [28, 4] encoding and then subjected to the random local substitution above satisfies these properties.

$\mathsf{AddNoise}(\mathsf{ADP})$:

- Let ℓ be the width of the matrices in ADP and n be the input length. Based on n, ℓ, fix a prime modulus p and error distribution χ as explained below. Consider each matrix $\mathbf{A}, \mathbf{B}_i$ as now being over $\mathbb{F}_p^{\ell \times \ell}$.
- Sample matrices $\mathbf{U}, \mathbf{V}$ randomly in $\mathbb{F}_p^{\ell \times \ell}$ such that $\det(\mathbf{U}) \cdot \det(\mathbf{V}) = 1$.
- Sample matrices $\mathsf{Err}_i \leftarrow \chi^{\ell \times \ell}$.
- Set $\mathbf{A}' = \mathbf{U} \cdot (\mathbf{A} + 2 \cdot \mathsf{Err}_0) \cdot \mathbf{V}$ and $\mathbf{B}'_j = \mathbf{U} \cdot (\mathbf{B}_j + 2 \cdot \mathsf{Err}_j) \cdot \mathbf{V}$ for all $j \in [n]$.
- Finally, in the resulting ADP, set $\mathsf{M} = (\mathbf{A}', \mathbf{B}'_1, ..., \mathbf{B}'_n)$ and set $\mathsf{Eval} = \mathsf{Eval}_{\text{parity}}$.

Parameters

We set χ to be the distribution that samples uniformly from the range $[-B(\ell), +B(\ell)]$, where $B(\ell) = \ell^{\omega(1)}$. We set p to be a prime modulus such that p is $\Theta((n \cdot B(\ell) \cdot \sqrt{\ell})^\ell)$. This can be done by setting the bit length of p as $\ell^{1+\epsilon}$ for any constant $\epsilon > 0$, assuming $\ell > n$.

Correctness

Let $\mathbf{x}$ be any input in $\{0,1\}^n$ and let $L(\mathbf{x}) \coloneqq \mathbf{A} + \sum_i x_i \mathbf{B}_i$ be the branching program that is being obfuscated. Observe that

$$\begin{aligned} \det(\mathsf{M}(\mathbf{x})) &= \det(\mathbf{U} \cdot (L(\mathbf{x}) + 2 \cdot \mathsf{Err}_0 + \sum_i x_i \cdot 2 \cdot \mathsf{Err}_i) \cdot \mathbf{V}) \\ &= \det(\mathbf{U}) \det(\mathbf{V}) \det(L(\mathbf{x}) + 2 \cdot \mathsf{Err}_0 + \sum_i x_i \cdot 2 \cdot \mathsf{Err}_i) \\ &= \det(L(\mathbf{x}) + 2(\mathsf{Err}_0 + \sum_i x_i \cdot \mathsf{Err}_i)). \end{aligned}$$

Correctness follows from the following observations.

- The value of $\det(L(\mathbf{x}) + 2(\mathsf{Err}_0 + \sum_i x_i \cdot \mathsf{Err}_i))$ over the integers is of the form $L(\mathbf{x}) + 2z$ for some $z \in \mathbb{Z}$.
- The number of monomials in the degree ℓ polynomial defined by the determinant is (loosely) bounded by ℓ^ℓ.
- Each entry in $L(\mathbf{x}) + 2(\mathsf{Err}_0 + \sum_i x_i \cdot \mathsf{Err}_i)$ is bounded by $n \cdot B(\ell) + 1$ in absolute value, so the determinant is smaller than $(n \cdot B(\ell)+1)^\ell \cdot \ell^\ell$ in absolute value. If $p > (n \cdot B(\ell)+1)^\ell \cdot \ell^\ell$, correctness holds.

One can also carry out a more refined calculation as follows. For a boolean input x, let $Q_x = L(\mathbf{x}) + 2(\mathsf{Err}_0 + \sum_i x_i \cdot \mathsf{Err}_i)$. With overwhelming probability over the choice of x, Q_x has entries bounded by $n^{1/2+\delta}B(\ell)$ in absolute value for any $\delta > 0$. This can be shown using a Chernoff bound. The signs of the entries of this matrix Q_x, are random and independent, so one can use the matrix Bernstein inequality (see for example, Theorem 6.6.1 [36]) to bound the maximum eigenvalue and hence the determinant (as determinant is the product of eigenvalues), to be $(n^{1/2+\delta} \cdot B(\ell) \cdot \ell^{1/2+\delta})^\ell$. This implies that p can be a $\Theta(\ell^{1+\epsilon})$ bit prime for any $\epsilon > 0$.

8.1.3 Transformation 3: Block-Diagonal Matrices

Ideally, the obfuscation of a circuit over n bits should not leak anything other than its input/output behavior on $\mathbf{x} \in \{0,1\}^n$. However, consider evaluating the ADP that results from the above transformation on a short but non-binary input $\mathbf{x}$. Due to the setting of parameters necessary for correctness, the determinant of the matrix $\mathbf{A} + \sum_i x_i \mathbf{B}_i$ will not be large enough to wrap around the modulus. Intuitively, the even-valued noise should ensure that the only useful information gained from this determinant is the evaluation of the circuit on input $\mathbf{x}$ mod 2. However, the fact that the determinant does not wrap around p is nevertheless worrisome, and we present a simple method to potentially block any attacks that might make use of short non-binary evaluations, such as the polynomial extension attacks described in Section 9.1.

The idea will be to post-process any $\mathsf{M} = (\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ in a way that forces the determinant on non-binary inputs to be large and random. This can be accomplished using $2n$ random matrices $\{\mathbf{G}_i, \mathbf{H}_i\}_{i\in[n]}$ of determinant 1. We will append each $\mathbf{G}_i$ to $\mathbf{A}$ along the diagonal, and then append $\mathbf{H}_i - \mathbf{G}_i$ to $\mathbf{B}_i$ in the ith slot along the diagonal. After appending, we rerandomize as before with $\mathbf{U}$ and $\mathbf{V}$. The determinant on any binary input will be the product of the determinant of the original ADP times the product of the determinant of $\mathbf{G}_i$ or $\mathbf{H}_i$ for each i, which are both 1. On any non-binary input, some block diagonal will be a linear combination of $\mathbf{G}_i$ and $\mathbf{H}_i$ that results in a large and random determinant. The following transformation also takes as input a parameter d, which determines the size of the random $\mathbf{G}_i, \mathbf{H}_i$ matrices. In our obfuscation construction, it is reasonable to set $d = 2$.

$\mathsf{AddBlockDiagonals}(\mathsf{ADP}, d)$:

- Let ℓ be the width of the matrices in ADP and n be the input length.
- Sample $2n$ matrices $\{\mathbf{G}_i, \mathbf{H}_i\}_{i\in[n]}$ uniformly from $\mathbb{F}_p^{d\times d}$ conditioned on their determinant being equal to 1.
- Sample $\mathbf{U}, \mathbf{V}$ uniformly from $\mathbb{F}_p^{(\ell+nd)\times(\ell+nd)}$ conditioned on $\det(\mathbf{U}) \cdot \det(\mathbf{V}) = 1$.
- Set $\mathbf{A}' = \mathbf{U} \cdot \mathsf{diag}(\mathbf{A}, \mathbf{G}_1, \ldots, \mathbf{G}_n) \cdot \mathbf{V}$, and $\mathbf{B}'_i = \mathbf{U} \cdot \mathsf{diag}(\mathbf{B}_i, \mathbf{0}, \ldots, \mathbf{0}, \mathbf{H}_i - \mathbf{G}_i, \mathbf{0}, \ldots, \mathbf{0}) \cdot \mathbf{V}$, and return the resulting ADP, consisting of $\mathsf{M} = (\mathbf{A}', \mathbf{B}'_1, \ldots, \mathbf{B}'_n)$ and $\mathsf{Eval} = \mathsf{Eval}_{\text{parity}}$.

In summary, to obfuscate a deterministic (alternatively, $\mathbb{F}_2$ counting) branching program, we first convert it into an ADP as described in Section 4.3. We then output $\mathsf{AddBlockDiagonals}(\mathsf{AddNoise}(\mathsf{RLS}(\mathsf{ADP})), 2)$ as the final obfuscation.

8.2 Extensions of the Basic Construction

8.2.1 Obfuscating Affine $\mathbb{F}_2$ Counting Branching Programs

Motivated by the goal of improved concrete efficiency, we extend the branching program model to allow labeling of edges by any *affine function* over the input bits. This is captured by the following notion of Affine $\mathbb{F}_2$ Counting Branching Programs.

▶ **Definition 19** (Affine Counting Branching Programs [28]). *An Affine $\mathbb{F}_2$ Counting Branching Program computing $f : \{0,1\}^n \to \{0,1\}$ is specified by a directed acyclic graph $G = (V, E)$ and a labeling $\phi(\cdot,\cdot)$ where each edge $(u, v) \in E$ is labeled with an affine function $\phi(u, v) = f_{u,v}(\mathbf{x})$, and two special source and sink vertices are labeled s and t respectively. $f_{u,v}$ has the form*

$$f_{u,v}(\mathbf{x}) = \sum_{i \in S_{u,v}} x_i + c_{u,v} \mod 2,$$

where $c_{u,v} \in \mathbb{F}_2$. Its size is $|V| - 1$. Any input $\mathbf{x} \in \{0,1\}^n$ induces a sub-graph $G_{\mathbf{x}}$ limited to edges consistent with $\mathbf{x}$ (i.e. edges that evaluate to 1 on $\mathbf{x}$). An accepting path on input $\mathbf{x}$ is a directed $s - t$ path in $G_{\mathbf{x}}$. An Affine $\mathbb{F}_2$ Counting Branching Program computes the function $g : \{0,1\}^n \to \{0,1\}$ such that $g(\mathbf{x})$ is the number of accepting paths in $G_{\mathbf{x}}$ mod 2.

We now import the following theorem.

▶ **Lemma 20** ([28, 4]). *Suppose there is an Affine $\mathbb{F}_2$ Counting Branching Program of size ℓ computing a boolean function f. Suppose $L(\mathbf{x})$ satisfies the following*

- *$L(\mathbf{x})$ has -1 along the second diagonal (right below the main diagonal).*
- *$L(\mathbf{x})$ is 0 below the second diagonal.*
- *Each entry of $L(\mathbf{x})$ is a degree (at most) 1 polynomial in a single input variable x_i. More precisely, $L(\mathbf{x})$ is defined as follows. Fix a topological ordering of the vertices in V, and label the columns / rows (from left to right / top to bottom) according to this ordering of vertices. In particular we want s labeled 1 and t labeled ℓ. We first define a matrix $A(\mathbf{x})$ of dimension $\ell \times \ell$. For entry (i, j) entry of $A(\mathbf{x})$ write affine function $\phi(i, j)$ (written as a degree one polynomial over the reals) if (i, j) is an edge in G and 0 otherwise. Note that $A(\mathbf{x})$ will be 0 on and below the main diagonal. Now consider $A(\mathbf{x}) - I$, and delete its first column and last row to obtain the $(\ell - 1) \times (\ell - 1)$ dimensional matrix $L(\mathbf{x})$.*

Then for all $\mathbf{x} \in \{0,1\}^n$, we have $\det(L(\mathbf{x})) \mod 2 = f(\mathbf{x})$.

Observe that this class of branching programs contain $\mathbb{Z}$ branching programs, since the evaluation of a $\mathbb{Z}$ branching program is exactly its evaluation modulo 2. What we observe is that in this case, our obfuscation scheme described in Section 8 is already capable of obfuscating affine $\mathbb{F}_2$ counting branching programs. The idea is that we can apply transformation 2 given in Section 8 to the matrix $L(\mathbf{x})$ representing an Affine $\mathbb{F}_2$ Counting Branching Program as follows: Each edge in $L(\mathbf{x})$ is an affine function of the form $f(\mathbf{x}) = \sum_{i \in S} x_i + c \mod 2$. We construct a new matrix $L'(\mathbf{x})$ where the edge is replaced by $f'(\mathbf{x}) = \sum_{i \in S} x_i + c$, and the computation is now over integers. The range of this new affine function is $[0, n + 1]$. If the parameters are chosen appropriately, what we end up computing by the evaluation procedure is $\det(L'(\mathbf{x})) \bmod 2$. We set p so that this can be computed without a wrap-around. Note that $\det(L(\mathbf{x})) \mod 2 = \det(L'(\mathbf{x})) \bmod 2$ as the error that is added to the matrices is even. This ensures correctness.

In the next section, we refine the notion of random local substitution and propose another alternative safeguard that relies on the ideas developed in this section.

8.2.2 Using Embedded Affine $\mathbb{F}_2$ Branching Programs

In Section 8.1.1, we discussed the notion of random local substitutions, which is our safeguard for preventing attacks such as the one described in Section 9.3. However, that solution incurs a quadratic blow up in the size of the branching program. In this section, we propose an alternate safeguard. Let $\mathsf{BP} : \{0,1\}^n \to \{0,1\}$ be a $\mathbb{Z}$ branching program with ℓ vertices, including source s and target t. First, sample a $\mathsf{BP}' : \{0,1\}^n \to \{0,1\}$ as follows:

- Fix ℓ vertices, and select two vertices s', t' among these ℓ vertices to act as the source vertex and target vertex of BP'.
- Induce a random directed acyclic graph among these vertices. This is done by connecting all vertices $i \in [\ell]$ to vertices j where $j \geq i+1$. In this numbering, the starting vertex s' is the 1st vertex and t' is the ℓ^{th} vertex. For every edge u, v sample a random affine function $f_{u,v}(\mathbf{x})$ which is used to label the edges.

We now combine BP and BP' into the final transformed BP'' as follows. BP'' consists of $2\ell+2$ vertices: the ℓ vertices of BP, the ℓ vertices of BP', and a new source s'' and target t''. Form edges from s'' to s, from s'' to s', and from t to t'', all with label 1. Note that there will be no edge between t' and t''. Observe that BP'' computes the same function as BP'. Indeed, any additional paths that go via BP' are never connected to the target vertex t''. There can be either 0 or 1 path going via BP since we started with a deterministic $\mathbb{Z}$ branching program. This resulting new BP'' can now be input to transformations 2 and 3 outlined in Section 8.

9 Cryptanalysis and Parameter Estimation for the Branching Program Obfuscation Candidate

9.1 Polynomial Extension Attacks

As an instructive example, consider the ADP obfuscation of a point function $\mathcal{I}_v$, without the even-valued error. Recall that on input $\mathbf{x} \in \{0,1\}^n$, $\mathcal{I}_v$ outputs 1 if $\mathbf{x} = \mathbf{v}$ and 0 otherwise. A simple branching program computing $\mathcal{I}_v$ contains $n+1$ vertices, with a single edge from each vertex i to vertex $i+1$ that is either set to v_i or $1-v_i$. Thus, $L(\mathbf{x})$ can be written as the following matrix:

$$\begin{bmatrix} 1+2v_1x_1-v_1-x_1 & 0 & \dots & \dots & 0 \\ -1 & 1+2v_2x_2-v_2-x_2 & \dots & \dots & 0 \\ 0 & -1 & \ddots & \ddots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & -1 & 1+2v_nx_n-v_n-x_n \end{bmatrix}$$

Hence, for $\mathbf{x} \in \{0,1\}^n$, $\det(L(\mathbf{x}))$ is 1 if $\mathbf{x} = \mathbf{v}$ and 0 otherwise. Writing

$$L(\mathbf{x}) = L_0 + x_1L_1 + \ldots + x_nL_n,$$

we see that an attacker given

$$\mathsf{ADP} = (\mathbf{A} = \mathbf{U} \cdot L_0 \cdot \mathbf{V}, \mathbf{B}_1 = \mathbf{U} \cdot L_1 \cdot \mathbf{V}, ..., \mathbf{B}_n = \mathbf{U} \cdot L_n \cdot \mathbf{V}),$$

can evaluate

$$\det(\mathbf{A} + \sum_i x_i\mathbf{B}_i) = \det(\mathbf{U} \cdot L(\mathbf{x}) \cdot \mathbf{V}) = \det(L(\mathbf{x})).$$

Thus, the attacker has input-output access to the polynomial $\det(L(\mathbf{x}))$ over the field $\mathbb{F}_p$, and is not restricted to evaluation on binary inputs $\mathbf{x} \in \{0,1\}^n$. This leads to the following attack.

1. Observe that $\det(\mathbf{A} + \sum_i x_i \mathbf{B}_i)$ is the unique multilinear polynomial over $\mathbb{F}_p^n$ agreeing with $\prod_{i\in[n]}(1 + 2v_i x_i - v_i - x_i)$ on inputs from $\{0,1\}^n$. This implies

$$\det(\mathbf{A} + \sum_i x_i \mathbf{B}_i) = \prod_{i\in[n]} (1 + 2v_i x_i - v_i - x_i)$$

   over $\mathbb{F}_p^n$.
2. To recover v_1, compute

$$\det(\mathbf{A} + x_1 \cdot \mathbf{B}_1 + \sum_{i\geq 2} 2^{-1}\mathbf{B}_i) = (1 - 2^{-1})^{n-1}(1 + 2v_1 x_1 - v_1 - x_1).$$

   We can find $x_1 = 1 - v_1$ by equating this quantity to 0. This recovers the first bit of the point function, and the others can be computed in the same way.

The reason that this particular attack succeeds is that the polynomial extending the boolean function $\det(L(\mathbf{x}))$ is *multilinear*. Read-once branching programs give rise to such polynomials. More generally, Klivans and Shpilka [30] showed that *any* read-once, oblivious branching program can be learned efficiently. In their model, the attacker is given membership and equivalence query access to an unknown polynomial P computed by a read once branching program over a field $\mathbb{F}_p$. This means the attacker is able to evaluate the program on any input $\mathbf{x} \in \mathbb{F}_p^n$, as well as submit a hypothesis H and learn that either H is equal to P or receive a point $\mathbf{y}$ on which $H(\mathbf{y}) \neq P(\mathbf{y})$. In our setting, we just argued that the attacker has membership query access to the polynomial computed by the branching program, and equivalence queries can be simulated by evaluation on random points and appealing to Schwartz-Zippel.

For our construction to satisfy the security notion of indistinguishablity obfuscation, we need to be able to successfully obfuscate simple classes of functions computable by read once branching programs. Thus, we have to include some noise in the obfuscation procedure that destroys the read once nature of any such program. One can view the random even-valued error as adding an edge between every pair of vertices in the branching program, labeled with a random, small, even linear combination of the entire input vector. The resulting program is very far from read-once, as evaluating every edge requires reading the entire input. Thus, learning results that apply to restricted classes on branching programs will not apply. As an example, [30] state that their techniques would not apply to a polynomial as simple as $f(x_1, \ldots, x_n) = \prod_{i=2}^n (x_1 + x_i)$.

9.2 The Need for Super-polynomial Error and Modulus

Now we present a contrived example consisting of two ADPs which will motivate the need for super-polynomial noise for transformation 2. While these specific ADPs will not arise from the [28] transformation, we will set our error-size to err on the side of caution.

The attack works as follows. Suppose we have an ADP $\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n$ that is in one of the two following forms.

- In the first form, $\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n = \mathbf{0}$.
- In the second form, $\mathbf{A} = \mathbf{0}$, and $\mathbf{B}_i$ for $i \in [n]$ is the matrix

$$\begin{bmatrix} 1 & 1 & \ldots & 1 \\ 0 & 0 & \ldots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \ldots & 0 \end{bmatrix}.$$

Now consider applying the AddNoise operation to one of the ADPs, hoping that the choice of ADP is masked by this operation. Assume that the even-valued error added by the AddNoise operation is actually chosen in $\{-2, 2\}$, so that each entry of the matrices $\mathsf{Err}_0, \mathsf{Err}_1, \ldots, \mathsf{Err}_n$ is uniform in $\{-1, +1\}$. Observe that in both cases $\det(\mathbf{A} + \sum_i x_i \mathbf{B}_i) = 0$ for all $\mathbf{x} \in \{0,1\}^n$, so the parity of the determinant will not reveal which ADP was chosen. A relevant result of [33] states that the determinant of a matrix where the entries are chosen uniformly at random from $\{-1, +1\}$ concentrates in absolute value around $\sqrt{n!}$. This fact can be used to estimate the determinant of the matrix $\mathbf{A} + \sum_i \mathbf{B}_i$ in both cases, which is the ADP evaluated on input $x = [1, \ldots, 1]$.

Case 1: The value $\det(\mathbf{A} + \sum_i \mathbf{B_i})$ is exactly $\det(2(\mathsf{Err}_0 + \sum_i x_i \cdot \mathsf{Err}_i))$, whose entries are independently signed, with standard deviation about $\sqrt{n}$. Thus, the determinant will concentrate around $\sqrt{n!} \cdot (\sqrt{n})^n$ in absolute value.

Case 2: To estimate the value $\det(\mathbf{A} + \sum_i \mathbf{B_i})$ in this case, we apply a Chernoff bound and find that the elements in the top row are typically in the range $[n - \sqrt{n}\log^2 n, n + \sqrt{n}\log^2 n]$. If we divide the top row by $\sqrt{n}$, we are left with a matrix whose entries are distributed as the matrix in case 1, with the only difference being that the top row is positively signed. Heuristically, this will result in $\det(\mathbf{A} + \sum_i \mathbf{B_i})$ being a $\sqrt{n}$ factor larger.

Thus, the magnitude of the determinant on input $[1, \ldots, 1]$ will give a distinguisher. Note however that neither ADP considered here is a valid [28, 4] encoding of a branching program. We chose these particular ADPs for simplicity, to illustrate the need for super-polynomial error; similar attacks can be carried out on ADPs that result from encodings of real branching programs.

Setting the Modulus

Once we fix the noise bound $B(\ell)$, we can choose p in a more refined manner as follows. Let $L = (L_0, ..., L_n)$ be the branching program to obfuscate. We would like to add noise to the matrices of L to form an ADP $(\mathbf{A}, \mathbf{B}_1, \ldots, \mathbf{B}_n)$, in such a way that for all $y_0, y_1, ..., y_n \in \{0,1\}$,

$$\left(\det(y_0\mathbf{A} + \sum_i y_i \mathbf{B}_i) \mod p\right) \mod 2 = \det(y_0 L_0 + \sum_i y_i L_i) \mod 2.$$

Let $t = \mathsf{poly}(\ell)$ be a parameter, and set $p = \Theta(t^\ell \cdot B(\ell)^\ell \cdot \sqrt{\ell!} \cdot \ell)$. Then we observe the following:

- If $t \geq n^2$, then with overwhelming probability we can correctly evaluate any boolean combination $y_0, y_1, ..., y_n \in \{0,1\}^{n+1}$. To see this, first note that the entries of $y_0\mathbf{A} + \sum_i y_i \mathbf{B}$ are randomly signed, and typically lie in $[-2 \cdot \sqrt{n+1}\log^2 n \cdot B(\ell), +2 \cdot \sqrt{n+1}\log^2 n \cdot B(\ell)]$ due to a Chernoff bound. Then, we can appeal to Theorem 1.1 from [33], stating that the determinant of any matrix $\mathbf{M}$ of dimension ℓ, with entries chosen uniformly at randomly from $\{-1, +1\}$, satisfies

$$\sqrt{\ell!} \cdot e^{-c\sqrt{\ell \log \ell}} \leq |\det(\mathbf{M})| \leq \sqrt{\ell!} \cdot \ell,$$

with overwhelming probability. Here $c > 0$ is any constant. In this case, the determinant will thus heuristically satisfy

$$|\det(y \cdot \mathbf{A} + \sum_i y_i \cdot \mathbf{B}_i)| \leq (2 \cdot B(\ell) \cdot \sqrt{n+1} \log^2 n)^\ell \sqrt{\ell!} \cdot \ell \leq p.$$

- Now, consider more general (non-binary) linear combinations $(y_0, y_1, \ldots, y_n)$. If the ℓ_1 norm of the combination satisfies $|y_0| + \sum_i |y_i| > t^3$, then it holds that

$$|\det(y_0\mathbf{A} + \sum_i y_i\mathbf{B}_i)| \geq p.$$

This overflow will hopefully help with security against attacks that evaluate the ADP on non-binary inputs. We can again observe heuristically from theorem 1.1 in [33]. If the weight is greater than t^3, then typically we expect each entries of the matrix to be randomly signed and having values larger than $t^{1.4} \cdot B(\ell)$. Thus with high probability,

$$|\det(y_0\mathbf{A} + \sum_i y_i\mathbf{B}_i)| \geq (t^{1.4} \cdot B(\ell))^\ell \sqrt{\ell!} \cdot e^{-c\sqrt{\ell \log \ell}} \geq p.$$

We set t to be n^2 to allow correct evaluation of boolean inputs. The above describes that setting the modulus appropriately can protect against attacks that involves evaluating programs on inputs of large (polynomial) weight. If the weight of the combination is bounded by some polynomial t, we claim the following.

▷ Claim 21. Fix any ADP $\mathbf{A}, \mathbf{B}_1, ..., \mathbf{B}_n$ of width ℓ with entries in $\{-1, 0, 1\}$. For any $x = (x_0, ..., x_n) \in \mathbb{Z}^{n+1}$, Let $L(\mathbf{x}) = x_0\mathbf{A} + \sum_i x_i\mathbf{B}_i$, and let $\mathsf{ADP}' = \mathsf{AddNoise}(\mathsf{ADP})$. Let $\mathsf{Err}_0, \mathsf{Err}_1, \ldots, \mathsf{Err}_n$ be the matrices drawn during the real $\mathsf{AddNoise}$ procedure (with a super-polynomial bound), and for $x \in Z^{n+1}$, let $\mathsf{Err}(x) := x_0 \cdot 2\mathsf{Err}_0 + \sum_i x_i \cdot 2\mathsf{Err}_i$. Then for any $x \in \mathbb{Z}^{n+1}$ where $\|x\|_1 < t$,

$$\Pr\left[\frac{|\det(x_0\mathbf{A}' + \sum_i x_i\mathbf{B}'_i)| - |\det(L(\mathbf{x})) \mod 2 + \det(\mathsf{Err}(x))|}{|\det(\mathsf{Err}(x))|} \leq \mathsf{negl}(\ell)\right] \geq 1 - \mathsf{negl}(\ell).$$

where the probability is taken over the randomness of generating $\mathsf{Err}_0, \mathsf{Err}_1, \ldots, \mathsf{Err}_n$.

This also shows that if the error is chosen from a super-polynomially large error distribution, then a distinguishing attack which only uses the magnitude of $\det(\mathsf{M}(\mathbf{x}))$ will not apply.

Proof. This follows from a result of Ipsen and Rehman [25] who showed that for any non-singular matrices $\mathbf{M}_1, \mathbf{M_2} \in \mathbb{R}^{\ell \times \ell}$,

$$|\det(\mathbf{M}_1 + \mathbf{M}_2) - \det(\mathbf{M}_1)|/|\det(\mathbf{M_1})| \leq \cdot \left(\kappa \cdot \frac{\|\mathbf{M}_2\|_2}{\|\mathbf{M}_1\|_2} + 1\right)^\ell - 1,$$

were $\|\mathbf{M}\|_2$ is the largest singular value of the matrix $\mathbf{M}$ and $\kappa := \|\mathbf{M}_1\|_2 \cdot \|\mathbf{M}_1^{-1}\|_2$ (κ is sometimes referred to as the condition number of $\mathbf{M}_1$). For a random matrix of size $\ell \times \ell$, the condition number is expected to be around $O(\ell)$ [12]. Now, we can substitute $\mathbf{M}_1$ as $\mathsf{Err}(x)$, $\mathbf{M}_2$ as $L(\mathbf{x})$. Observe that the maximum singular value of $\mathsf{Err}(x)$ will be at least $\Omega(B(\ell)\sqrt{\ell})$ (see Excercise 14, [34]). Since branching programs have small entries, their singular values are also bounded by $\|x\|_1 \cdot O(\ell) = O(t \cdot \ell)$. Thus, the right hand side of the previous equation is

$$\left(\kappa \cdot \frac{\|L(\mathbf{x})\|_2}{\|\mathsf{Err}(x)\|_2} + 1\right)^\ell - 1 = \left(O(\ell) \cdot \frac{O(t \cdot \ell)}{\Omega(B(\ell) \cdot \sqrt{\ell})} + 1\right)^\ell - 1.$$
$$\approx O(\ell^2 \cdot t \cdot B(\ell)^{-1})$$

Since $B(\ell)$ is super-polynomial in ℓ, this concludes the argument. Although above we talked about learning for any $\mathbf{y} \in \mathbb{Z}^{n+1}$ determinants of the form $\det(y_0\mathbf{A} + \sum_i y_i\mathbf{B}_i)$, however, in $\mathbb{Z}$ branching programs, whenever $y = 0 \mod 2$, then $\det(y_0 L_0 + \sum_i y_i L_i) = 0 \mod 2$ and thus such combinations should not reveal anything useful. Heuristically, Claim 21 suggests that the magnitude of $\det(y_0\mathbf{A} + \sum_i y_i\mathbf{B}_i)$ should only reveal information about $\det((y_0 \mod 2)L_0 + \sum_i (y_i \mod 2)L_i)$. ◀

9.3 The Need for Random Local Substitutions

Consider any fixed branching program $L(\mathbf{x}) = \mathbf{A} + \sum_i x_i\mathbf{B}_i$ of width ℓ. Suppose we obfuscate $L(\mathbf{x})$ but skip the random local substitution step. Let $\mathsf{Err}^{(0)}, \mathsf{Err}^{(1)}, \ldots, \mathsf{Err}^{(n)}$ be the $n+1$ error matrices drawn by the $\mathsf{AddNoise}$ transformation. Write each $\mathsf{Err}^{(i)}_{j,k} = 2e^{(i)}_{j,k}$. We can recover the parity of each $e^{(i)}_{j,k}$ as follows. Let $\mathbf{A}', \mathbf{B}'_1, \ldots, \mathbf{B}'_n$ be the ADP after obfuscation. For any input $\mathbf{x}$,

$$\det(\mathbf{A}' + \sum_i x_i\mathbf{B}'_i) \equiv \det(L(\mathbf{x})) + \sum_{j,k}(\sum_i x_i 2e^{(i)}_{j,k}) \det(L(\mathbf{x})_{(j,k)}) \bmod 4,$$

where $L(\mathbf{x})_{(j,k)}$ is the (j,k) minor of $L(\mathbf{x})$. Note that everything is known except the parities of $e^{(i)}_{j,k}$, so this gives a linear equation mod 2 over these $(n+1)\ell^2$ parities. We have an exponential number of equations of this form, and can eventually obtain $(n+1)\ell^2$ linearly independent equations.

This readily gives an attack on $i\mathcal{O}$. To distinguish between two known and functionally equivalent branching programs L_1, L_2, simply run the above attack assuming the underlying BP is L_1 and see if there exists a solution or not. Now, the random local substitution is meant to randomize the underlying branching program $L(\mathbf{x})$, so an attacker does not know all of the $L(\mathbf{x})_{(j,k)}$ values. Without these, the attacker cannot set up and solve the above system of linear equations.

10 Applications and Future Work

In future work, we aim to explore applications of optimized variants of our candidates. We give some of the more promising directions below. Since our focus here is on concrete efficiency, we make a heuristic leap of faith of treating our $i\mathcal{O}$ candidates as *ideal* obfuscation schemes for the purpose of these applications.

Concretely Efficient Obfuscation for Circuits

If the safeguards described are secure, then in order to obfuscate a branching program of size ℓ, we need about $O(\ell^{4+\epsilon})$ bits for any $\epsilon > 0$. In concrete terms, if the size of the branching program exceeds 2^{13} vertices, the size is already around 100 terabytes. This motivates the study of efficient bootstrapping mechanisms and simple "obfuscation complete" families of branching programs. In particular, we would like to understand if the SNARG-based bootstrapping approach from [11] or the PRF-based approach from [24, 2] are practically feasible for our candidates.

Obfuscating PRFs

Efficiently obfuscating PRFs and simple computations that employ them is a highly desirable goal for both theoretical and practical applications. For instance, the bootstrapping theorems of [24, 2] reduce the obfuscation of a circuit to multiple obfuscations of simple functions that each use a constant number of PRF calls. This and other applications motivate PRF

candidates that have small *affine* branching programs, which can be efficiently handled by our construction. One such candidate could be based on the work of [10]. They propose a weak PRF[5] candidate based on Learning With Rounding (LWR) modulo a constant-size composite, which can be computed by a linear-size deterministic branching program. They also suggest a heuristic for converting a weak PRF into a strong one by evaluating the weak PRF on a suitable encoding of the input; for this particular weak PRF candidate, a linear encoding over a prime that does not divide the LWR modulus seems like a natural choice. For instance, one could use a linear code over $\mathbb{F}_2$ and LWR modulo 15 or linear code over $\mathbb{F}_3$ and LWR modulo 10. This approach yields (strong) PRF candidates that can be evaluated by a linear-size *affine* branching program.

Optimally-Succinct Non-Interactive Arguments

The ability to efficiently obfuscate a PRF would give several compelling applications. One example, due to Sahai and Waters [32], is a succinct non-interactive argument (SNARG) with proof length that is the best one could hope for; namely, an s-bit proof suffices to obtain (roughly) 2^{-s} soundness error.

To give slightly more detail, we briefly recall the obfuscation-based SNARG of [32]. Given a PRF and relation circuit $R_{\mathcal{L}}$ for language $\mathcal{L}$, the crs consists of the obfuscations of two programs $C_{\mathcal{P}}$ and $C_{\mathcal{V}}$. $C_{\mathcal{P}}$ takes as input an instance witness pair (x, w) and outputs $\mathsf{PRF}_k(x)$ (where k is a hard-coded PRF key) if and only if $\mathcal{R}_{\mathcal{L}}(x, w) = 1$. $C_{\mathcal{V}}$, which has the same k hard-coded, takes as input (x, π) and outputs 1 if and only if $\mathsf{PRF}_k(x) = \pi$. A prover wishing to prove that $x \in \mathcal{L}$ simply evaluates $\mathsf{Obf}(C_{\mathcal{P}})$ on (x, w) to obtain $\pi = \mathsf{PRF}_k(x)$. The verifier on input x and proof π runs $\mathsf{Obf}(C_{\mathcal{V}})$ on (x, π) and accepts if the output is 1.

If the obfuscation is an *ideal* obfuscation, then forging a proof on $x \notin \mathcal{L}$ requires predicting $\mathsf{PRF}(k, x)$. If the PRF is exponentially-secure, then the SNARG soundness error is (within polynomial factors of) 2^{-s}.

OV Graphs Are (Probably) Hard Instances

Abstract

A graph G on n nodes is an Orthogonal Vectors (OV) graph of dimension d if there are vectors $v_1, \ldots, v_n \in \{0,1\}^d$ such that nodes i and j are adjacent in G if and only if $\langle v_i, v_j \rangle = 0$ over $\mathbb{Z}$. In this paper, we study a number of basic graph algorithm problems, except where one is given as input the vectors defining an OV graph instead of a general graph. We show that for each of the following problems, an algorithm solving it faster on such OV graphs G of dimension only $d = O(\log n)$ than in the general case would refute a plausible conjecture about the time required to solve sparse MAX-k-SAT instances:

- Determining whether G contains a triangle.
- More generally, determining whether G contains a directed k-cycle for any $k \geq 3$.
- Computing the square of the adjacency matrix of G over $\mathbb{Z}$ or $\mathbb{F}_2$.
- Maintaining the shortest distance between two fixed nodes of G, or whether G has a perfect matching, when G is a dynamically updating OV graph.

We also prove some complementary results about OV graphs. We show that any problem which is NP-hard on constant-degree graphs is also NP-hard on OV graphs of dimension $O(\log n)$, and we give two problems which can be solved faster on OV graphs than in general: Maximum Clique, and Online Matrix-Vector Multiplication.

1 Introduction

Two of the most studied conjectures in fine-grained complexity are the Strong Exponential Time Hypothesis (SETH), and the Orthogonal Vectors Conjecture (OVC). SETH was introduced by Impagliazzo, Paturi and Zane [17] regarding the complexity of k-SAT:

▶ **Hypothesis 1** (Strong Exponential Time Hypothesis). *For every $\varepsilon > 0$, there is an integer $k \geq 3$ such that k-SAT on n variables cannot be solved in $O(2^{(1-\varepsilon)n})$ (randomized) time.*

OVC concerns the Orthogonal Vectors (OV) problem: Given as input a set $A \subseteq \{0,1\}^d$ of $|A| = n$ vectors, determine whether there are $a, b \in A$ such that $\langle a, b \rangle = 0$ (all inner products in this paper, including this one, are taken over $\mathbb{Z}$ unless stated otherwise).

▶ **Hypothesis 2** (Orthogonal Vectors Conjecture). *For every $\varepsilon > 0$, there is a $c > 0$ such that OV in dimension $d = c \log n$ cannot be solved in $O(n^{2-\varepsilon})$ (randomized) time.*

Williams [28] showed that SETH implies OVC. Most of the known fine-grained implications of SETH use this result and are actually proved assuming OVC instead; see [27] for a survey of the many applications of OVC to graph algorithms, string algorithms, nearest neighbors problems, and more.

In this paper, we study a mathematical object inspired by OVC which we call an OV graph: a graph G on n nodes is an OV graph of dimension d if there are n vectors $v_1, \ldots, v_n \in \{0,1\}^d$ such that nodes i and j are adjacent in G if and only if $\langle v_i, v_j \rangle = 0$. Given as input the vectors $v_1, \ldots, v_n \in \{0,1\}^d$ defining G, there are a number of natural algorithmic questions one might ask, including:

- OV: does G have any edges?
- OVΔ: does G contain any triangles?
- OV-DIR-k-CYCLE: given a partition of the nodes of G into k parts, is there a k-cycle containing one node from each part?

Detecting triangles and more generally, k-cycles are among the most basic algorithmic questions one can ask about graphs. OV graphs of low dimension $d \ll n$ make up a small fraction of all graphs: there are only $2^{O(nd)}$ such graphs on n nodes, compared to $2^{\Theta(n^2)}$ total graphs on n nodes. However, in this paper we will show that solving these problems on OV graphs of dimension only $d = O(\log n)$ may be just as hard as solving them in general graphs. Somewhat analogously to how Williams showed that faster algorithms for OV in dimension $O(\log n)$ would lead to breakthroughs in solving k-SAT, we will show that faster algorithms for OVΔ or OV-DIR-k-CYCLE on OV graphs of dimension $O(\log n)$ would lead to breakthroughs in solving MAX-k-SAT.

MAX-k-SAT

In the MAX-k-SAT problem for an integer $k \geq 2$, given as input a k-CNF formula ϕ, the goal is to determine the maximum number of clauses of ϕ which can be satisfied by a single assignment.

MAX-k-SAT on n variables and m clauses can be solved in $O(2^n m)$ time by exhaustive search. Williams [28, 29] showed that MAX-2-SAT has a much faster, $2^{\omega n/3}\text{poly}(n)$ time algorithm, where $\omega < 2.373$ is the exponent of matrix multiplication [26, 13]. This running time for MAX-2-SAT has remained unchallenged for over 15 years. It is an interesting open problem whether a faster algorithm exists.

Williams' techniques for MAX-2-SAT do not carry over to MAX-k-SAT for $k \geq 3$ (see [19] for a discussion), and there is no known $O((2-\varepsilon)^n)$ time algorithm for MAX-k-SAT for any $k \geq 3$ and $\varepsilon > 0$.

Unlike with k-SAT [16], there is no known sparsification lemma for MAX-k-SAT, so that in principle MAX-k-SAT on formulas with $O(n)$ clauses might be easier than the general case of MAX-k-SAT that might have n^k clauses. This has led researchers to investigate the complexity of such sparse instances of MAX-k-SAT (e.g. [11, 9, 3]).

The fastest known algorithms for MAX-k-SAT on n variables and cn clauses for constant c run in time $2^{n(1-1/O(\log^2 c))}\text{poly}(n)$ when $k \leq 4$, or in time $2^{n(1-1/O(c^{1/3}))}\text{poly}(n)$ when $k > 4$ [3]. Unfortunately, as c grows, these running times go to 2^n, the brute force running time. Thus the following hypothesis is fully consistent with the state-of-the art of MAX-k-SAT algorithms:

▶ **Hypothesis 3** (Sparse MAX-3-SAT Hypothesis). *For every $\varepsilon > 0$, there exists a $c > 0$ so that n variable MAX-3-SAT on cn clauses cannot be solved in time $O(2^{n(1-\varepsilon)})$.*

The hypothesis above strengthens an earlier hypothesis that MAX-3-SAT requires $2^{n(1-o(1))}$ time (see e.g. [27, 19]); it would be equivalent to that hypothesis if a sparsification lemma for MAX-3-SAT can be proven. We will base some of our hardness results on our strengthened hypothesis. We will also use an analogous hypothesis for Sparse MAX-2-SAT:

▶ **Hypothesis 4** (Sparse MAX-2-SAT Hypothesis). *For every $\varepsilon > 0$, there exists a $c > 0$ so that n variable MAX-2-SAT on cn clauses cannot be solved in time $O(2^{n(\omega/3-\varepsilon)})$.*

1.1 Our Results

Triangle Finding and Matrix Multiplication

The best known algorithm for finding a triangle in a graph on n nodes runs in time $n^{\omega+o(1)}$, where $\omega \leq 2.373$ is the matrix multiplication exponent [26, 13]. Our first result is that if there is a faster algorithm that finds triangles in *OV graphs*, then Hypothesis 4 would be violated and sparse MAX-2-SAT would have faster algorithms.

▶ **Theorem 5.** *Suppose OVΔ in OV graphs with n nodes and dimension $O(\log n)$ can be solved in time $n^{\omega-\varepsilon+o(1)}$ for some constant $\varepsilon > 0$. Then, for any constants $a, \delta > 0$, MAX-2-SAT on n variables and $a \cdot n$ clauses can be solved in time $2^{(\omega/3-\varepsilon/3+\delta)n}$.*

The best known algorithm for triangle finding in a general graph G works by reducing to the *Boolean matrix multiplication* of two copies of the adjacency matrix of G. In Boolean matrix multiplication, given as input two matrices $A, B \in \{0,1\}^{n\times n}$, the goal is to compute their product over the (AND,OR) semiring, i.e. the matrix $C \in \{0,1\}^{n\times n}$ given by $C[i,j] = \bigvee_{k=1}^{n} A[i,k] \wedge B[k,j]$. This can be solved in time $n^{\omega+o(1)}$ using a simple reduction to matrix multiplication over either $\mathbb{F}_2$ or $\mathbb{Z}$.

Similarly, OVΔ in OV graphs with n nodes and dimension d has a simple linear-time reduction to Boolean matrix multiplication of $n \times n$ matrices which are the adjacency matrices of *OV* graphs of dimension d. In other words, these are matrices $A \in \{0,1\}^{n\times n}$ for which there are vectors $v_1, \ldots, v_n \in \{0,1\}^d$ such that $A[i,j] = 1$ if and only if $\langle v_i, v_j \rangle = 0$. If such matrices for $d = O(\log n)$ can be multiplied in $n^{\omega-\varepsilon+o(1)}$ time for some constant $\varepsilon > 0$, it would lead to a corresponding speedup for MAX-2-SAT on n variables and $O(n)$ clauses as well. In other words, this small set of only $O(2^{nd}) = O(2^{n \log n})$ matrices with such efficient descriptions may be just as difficult to multiply as arbitrary $\{0,1\}$ matrices (of which there are $2^{\Theta(n^2)}$).

Consequences of the n^ω hardness of OVΔ for dynamic algorithms

Because of its simplicity, triangle detection has been reduced to many other problems. For instance, Abboud and Vassilevska Williams [1] present several clean reductions from triangle detection to a variety of dynamic problems. We next show that, as a consequence of the hardness of OVΔ, many of the triangle-based lower bounds in [1] also hold for OV graphs with $O(\log n)$ dimension.

Typically, in dynamic graph algorithms one supports edge insertions and deletions. In OV graphs, however, the edge relation is captured by the labels on the vertices of the graph. Thus, in dynamic OV graphs, we instead support vertex label updates as above. One could also consider an alternate model where the updates may only change one bit of a vertex label, but update times in these two models differ by at most a fairly negligible $O(d)$ factor.

Although changing a vertex label can change all the incident edges to the vertex, our lower bounds apply even when each update changes at most a *single* edge. Hence the lower bounds would also apply in the standard dynamic graph algorithms model if one maintains the OV graph as a graph, rather than as a set of vectors.

Assuming that OVΔ requires $n^{\omega-o(1)}$ time (as follows from Hypothesis 4), we obtain the following conditional lower bounds:

- Dynamic s-t OV Shortest Paths, maintaining the distance between two fixed vertices s and t in an n node OV graph with dimension $O(\log n)$ under vertex relabel updates (change the vector representing a node) requires either $n^{\omega-o(1)}$ preprocessing time, or $n^{\omega-1-o(1)}$ amortized update time; the lower bound holds even if the updates insert or delete at most a single edge. The same lower bounds hold for $5/3-\varepsilon$-approximating the s-t distance when arbitrary label updates are allowed, even when the preprocessing time can be arbitrary.
- Dynamic bipartite perfect matching in OV graphs on n nodes and dimension $O(\log n)$ under vertex relabel updates requires either $n^{\omega-o(1)}$ preprocessing time, or $n^{\omega-1-o(1)}$ amortized update time. The lower bound holds even if the updates insert or delete at most a single edge. If the updates can be arbitrary, the lower bound holds for arbitrary preprocessing time.

In the full version of the paper we present more such reductions. Because of the structure of our reductions, the lower bounds we prove in which the relabelings change only a single edge also hold for incremental algorithms (where edges are only inserted), but the lower bound is only for worst case update time.

Directed k-Cycle

The fastest known algorithm for finding a k-cycle for any constant $k \geq 3$ in a general directed n-node graph runs in $n^{\omega+o(1)}$ time via color-coding and matrix multiplication [6]. Our next result is that under Hypothesis 4, this running time is essentially tight even in OV graphs:

▶ **Theorem 6.** *Let $k \geq 3$ be any constant. Suppose that k-Cycle in directed OV graphs with n nodes and dimension $O(\log n)$ can be solved in time $n^{\omega-\varepsilon+o(1)}$ for some constant $\varepsilon > 0$. Then, for any constants $a, \delta > 0$, MAX-2-SAT on n variables and $a \cdot n$ clauses can be solved in time $2^{(\omega/3-\varepsilon/3+\delta)n}$.*

As our MAX-3-SAT Hypothesis 3 is potentially more believable than our MAX-2-SAT Hypothesis 4, we further investigate what it implies for k-Cycle detection. We show that unless Hypothesis 3 fails, there is no constant k for which k-cycle in an n node OV graph with dimension $O(\log n)$ can be found in $O(n^{3/2-\varepsilon})$ time for any $\varepsilon > 0$. The statement of our directed k-cycle results under Hypothesis 3 are strongest for $k = 4$:

▶ **Theorem 7.** *Suppose that OV-DIR-4CYCLE in OV graphs with n nodes and dimension $O(\log n)$ can be solved in time $n^{2-\varepsilon+o(1)}$ for some constant $\varepsilon > 0$. Then, for any constants $a, \delta > 0$, MAX-3-SAT on n variables and $a \cdot n$ clauses can be solved in time $2^{(1-\varepsilon/2+\delta)n}$, and Hypothesis 3 fails.*

If $\omega = 2$, the above would give an essentially tight lower bound under a better hypothesis. While the lower bounds we obtain under Hypothesis 3 are not nearly as strong as the tight results we get under Hypothesis 4, they are conditioned on a slightly more believable hypothesis. Moreover, the techniques seem to be slightly more flexible, so that there might be hope that a similar result might hold for k-cycle in *undirected* graphs. When k is odd,

our hardness results already hold for k-cycle in undirected OV graphs, but when k is even, k-cycle in general undirected graphs can be solved in $O(n^2)$ time regardless of k [30]. Hence our $n^{\omega-o(1)}$ lower bound from Hypothesis 4 may not extend to undirected graphs if $\omega > 2$. A strengthening of our MAX-3-SAT-based reductions to undirected graphs might still be possible, and would be significant as it would be tight, at least for 4-cycles.

Constant Degree Graphs have low OV dimension

Next, we study the complexity of various NP-hard graph problems when they are restricted to graphs on n nodes with OV dimension $O(\log n)$. We begin with problems which are known to be NP-hard on constant-degree graphs, including Hamiltonian Path and Minimum Vertex Cover. It follows from prior work [5] that constant-degree graphs have OV dimension $O(\log n)$. However, the proof of this is nonconstructive, and uses the probabilistic method. We nonetheless show how to derandomize this proof, giving a deterministic polynomial-time algorithm for finding a representation of a constant-degree graph as an OV graph of dimension $O(\log n)$. We hence show:

▶ **Theorem 8.** *Any problem which is NP-hard on graphs of constant maximum degree is also NP-hard on OV graphs of dimension $O(\log n)$.*

We also show that at least one NP-hard problem, the Max Clique problem, seems to become easier on OV graphs of dimension $d \ll n$, by reducing to a set packing problem:

▶ **Theorem 9.** *Given as input vectors $V = \{v_1, \ldots, v_n\} \subseteq \{0,1\}^d$ defining a dimension d OV graph G_V, a maximum size clique in G_V can be found in time $2^d \cdot n^{O(1)}$.*

Online Matrix-Vector Multiplication

Finally, we study the Online Matrix-Vector Multiplication (OMV) problem: preprocess a matrix $M \in \mathbb{F}_2^{n \times n}$ so that, given as input a query vector $v \in \mathbb{F}_2^n$, one can quickly return the product $M \cdot v$. The best known algorithms in general answer queries in time $n^{2-o(1)}$ [18]. We show that faster algorithms are possible when the matrix M is the adjacency matrix of a graph with OV dimension $c \log n$:

▶ **Theorem 10.** *For $c > 0$, we can preprocess vectors $u_1, \ldots, u_n, v_1, \ldots, v_n \in \{0,1\}^{c \log n}$, which define a matrix $M \in \mathbb{F}_2^{n \times n}$ as $M[i,j] = 1$ if and only if $\langle u_i, v_j \rangle = 0$, in preprocessing time $\tilde{O}(n^2)$ with high probability, such that given as input a vector $v \in \mathbb{F}_2^n$, we can compute the product $M \cdot v$ in time $n^{2-1/O(\log c)}$.*

Data structures for OMV have many applications. For instance, by multiplying the adjacency matrix of a graph G by an indicator vector for a subset $S \subseteq \{1, 2, \ldots, n\}$ of the nodes of G, one gets the neighborhood of S. Similar to [18, Corollary 1.1], our Theorem 10 thus yields a data structure with $\tilde{O}(n^2)$ preprocessing time for OV graphs G of dimension $c \cdot \log n$ which, given as a query a subset S of the nodes of G, can answer whether S is independent, dominating, or a vertex cover, in time $n^{2-1/O(\log c)}$.

Our data structure for Theorem 10 works by expressing the matrix M as the sum of a matrix of rank $n^{0.1}$ and a sparse matrix with $n^{2-1/O(\log c)}$ nonzero entries. It does this by combining the algorithm for OV by Abboud et al. [2], which makes use of the "polynomial method in algorithm design", together with known techniques for converting polynomial method constructions into "matrix rigidity" upper bounds [4].

1.2 Other Related Work

OV graphs have been studied in a number of other settings in mathematics and computer science.

The Edge Clique Cover Number (ECCN) of a graph G is the minimum number of cliques needed to cover the edges of G. We can see that a graph G is an OV graph of dimension d if and only if the ECCN of the *complement* of G is d. A line of work in the combinatorics community has shown that a number of simple classes of graphs have low ECCN; see e.g. [12, 5, 15, 24, 23].

The complexity of determining the ECCN of an input graph has also been studied. The problem is known to be NP-hard in general, but Gramm et al. [14] gave a parameterized algorithm running in time $2^{2^{O(k)}} \cdot \text{poly}(n)$ on an n node graph with ECCN k. Such a doubly-exponential dependence on k may be optimal: Cygan et al. [10] showed that a $2^{2^{o(k)}} \cdot \text{poly}(n)$ time algorithm would refute the Exponential Time Hypothesis (a weak version of SETH).

Representations of graphs by the orthogonality relations of vectors have also been studied in other areas. For instance, Lovász [20] describes "orthonormal representations" where each node must be assigned a unit vector in Euclidean space, and the vectors corresponding to nonadjacent vertices must be orthogonal. In this language, if G is a graph with low OV dimension, then the complement of G has low $\{0,1\}$-faithful orthogonality dimension; see e.g. [22, 21].

2 Preliminaries

2.1 Notation

For a positive integer d, write 0^d for the all-zeroes vector of dimension d. Write $||$ to denote concatenation of vectors.

Define $AND : \{0,1\}^d \times \{0,1\}^d \to \{0,1\}^d$, the bit-wise AND function by, for $x, y \in \{0,1\}^d$ and $\ell \in \{1, \ldots, d\}$, $AND(x,y)[\ell] = x[\ell] \cdot y[\ell]$.

2.2 OV Graphs

▶ **Definition 11** (OV Graph). *For positive integers n, d and vectors $V = \{v_1, \ldots, v_n\} \subseteq \{0,1\}^d$, the OV graph G_V is the graph on n nodes where nodes i and j are adjacent if and only if $\langle v_i, v_j \rangle = 0$, where the inner product is over $\mathbb{Z}$. The OV dimension of a graph G is the smallest nonnegative integer d such that G can be written as the OV graph of vectors in $\{0,1\}^d$.*

▶ **Definition 12** (Generalized Inner Product). *For any positive integers n, d and vectors $v_1, \ldots, v_n \in \mathbb{Z}^d$, we define the generalized inner product*

$$IP(\{v_1, \ldots, v_n\}) = \langle v_1, \ldots, v_n \rangle = \sum_{\ell=1}^{d} v_1[\ell] \cdot v_2[\ell] \cdots v_n[\ell].$$

The sum (as well as all inner products in this paper) is taken over $\mathbb{Z}$.

▶ **Definition 13** (k-Uniform OV Hypergraph). *For positive integers n, d and vectors $V = \{v_1, \ldots, v_n\} \subseteq \{0,1\}^d$, the k-uniform OV hypergraph $G_{V,k}$ is the k-uniform hypergraph on n nodes where, for distinct nodes $i_1, i_2, \ldots, i_k$, the hyperedge $(i_1, \ldots, i_k)$ is in $G_{V,k}$ if and only if $\langle v_{i_1}, v_{i_2}, \ldots, v_{i_k} \rangle = 0$.*

▶ **Definition 14** (OV dimension of a matrix). *The OV dimension of a matrix $M \in \{0,1\}^{n \times n}$ is the smallest nonnegative integer d such that there are $2n$ vectors $u_1, \ldots, u_n, v_1, \ldots, v_n \in \{0,1\}^d$ with the property that, for any $i, j \in \{1, 2, \ldots, n\}$, we have $M[i,j] = 1$ if and only if $\langle u_i, v_j \rangle = 0$. Equivalently, the OV dimension of M is the rank of $\bar{M}$ (the all 1s matrix minus M) over the OR, AND (Boolean) semiring.*

▶ Remark 15. The adjacency matrix of an OV graph of dimension d is a matrix of OV dimension d.

2.3 Algorithmic Problems

▶ **Definition 16.** *We define some problems. For positive integers n, d:*

- *OV$_{n,d}$: Given $A, B \subseteq \{0,1\}^d$ with $|A| = |B| = n$, determine whether there is an $(a,b) \in A \times B$ with $\langle a, b \rangle = 0$.*
- *EXACT-IP$_{n,d}$: Given $A, B \subseteq \{0,1\}^d$ with $|A| = |B| = n$, and an integer $0 \leq m \leq d$, determine whether there is an $(a,b) \in A \times B$ with $\langle a, b \rangle = m$.*
- *OV$\Delta_{n,d}$: Given $V \subseteq \{0,1\}^d$ with $|V| = n$, determine whether there are distinct $a, b, c \in V$ with $\langle a, b \rangle = \langle b, c \rangle = \langle c, a \rangle = 0$.*
- *EXACT-IP$\Delta_{n,d}$: Given $A, B, C \subseteq \{0,1\}^d$ with $|A| = |B| = |C| = n$, and three integers $0 \leq m_{AB}, m_{BC}, m_{CA} \leq d$, determine whether there is a $(a,b,c) \in A \times B \times C$ with $\langle a, b \rangle = m_{AB}$, $\langle b, c \rangle = m_{BC}$, and $\langle c, a \rangle = m_{CA}$.*
- *OV-HYPERGRAPH$_{n,d,\ell,k}$ (for $\ell > k \geq 2$): Given $V \subseteq \{0,1\}^d$ with $|V| = n$, determine whether there is a $T \subseteq V$ of size $|T| = \ell$ such that for all $S \subseteq T$ of size $|S| = k$ we have IP$(S) = 0$.*
- *DIRECTED-CYCLE$_{n,d,k}$: Given $V_1, \ldots, V_k \subseteq \{0,1\}^d$ with $|V_1| = \cdots = |V_k| = n$, determine whether there is a $v_i \in V_i$ for each $i \in \{1, 2, \ldots, k\}$ such that $\langle v_i, v_{i+1} \rangle = 0$ for all such i (with $v_{k+1} = v_1$).*
- *MAX-k-SAT$_{n,m}$: Given a k-CNF formula ϕ on n variables and m clauses, determine the maximum number of clauses of ϕ which can be satisfied by an assignment.*

3 Reduction from MAX-2SAT to Finding Triangles in OV Graphs

▶ **Lemma 17.** *There is a polynomial-time reduction from MAX-2-SAT$_{n,m}$ to $O(m^3)$ instances of EXACT-IP$\Delta_{3 \cdot 2^{\lceil n/3 \rceil}, m}$.*

Proof. Partition the input variables into three groups X, Y, Z of $n/3$ variables each. Let S be the set of clauses of ϕ. Partition S into six sets $S_X, S_Y, S_Z, S'_X, S'_Y, S'_Z$ such that:

- S'_X contains the clauses which consist only of literals of variables from X, and S'_Y and S'_Z are defined similarly.
- $S_X \subseteq S \setminus (S'_X \cup S'_Y \cup S'_Z)$ contains the clauses which contain one literal from Y and one from Z, and S_Y and S_Z are defined similarly.

For each of the $O(m^3)$ choices of $0 \leq m_X, m_Y, m_Z \leq m$, we will determine whether it is possible to find an assignment to ϕ which satisfies all but m_X clauses of $S'_Y \cup S_Z$, all but m_Y clauses of $S'_Z \cup S_X$, and all but m_Z clauses of $S'_X \cup S_Y$. From this we can compute the desired answer.

For any assignment $\alpha : X \to \{0,1\}^{n/3}$, define the vector $v_\alpha \in \{0,1\}^m$, whose entries are indexed by clauses c in S, by

$$v_\alpha[c] = \begin{cases} 0 & \text{if } c \in S'_X \cup S_Y \cup S_Z \text{ and } \alpha \text{ satisfies a literal in } c, \\ 0 & \text{if } c \in S'_Z \cup S_X, \\ 1 & \text{otherwise.} \end{cases}$$

Similarly, for any assignment $\beta : Y \to \{0,1\}$, define $v_\beta \in \{0,1\}^m$ by

$$v_\beta[c] = \begin{cases} 0 & \text{if } c \in S_X \cup S'_Y \cup S_Z \text{ and } \alpha \text{ satisfies a literal in } c, \\ 0 & \text{if } c \in S'_X \cup S_Y, \\ 1 & \text{otherwise.} \end{cases}$$

and for any assignment $\gamma : Z \to \{0,1\}$, define $v_\gamma \in \{0,1\}^m$ by

$$v_\gamma[c] = \begin{cases} 0 & \text{if } c \in S_X \cup S_Y \cup S'_Z \text{ and } \alpha \text{ satisfies a literal in } c, \\ 0 & \text{if } c \in S'_Y \cup S_Z, \\ 1 & \text{otherwise.} \end{cases}$$

Note that for any assignment s to all the variables, letting $\alpha = s|_X$, $\beta = s|_Y$, and $\gamma = s|_Z$, we have that $\langle v_\alpha, v_\beta \rangle$ counts the number of clauses in $S'_Y \cup S_Z$ which are unsatisfied by s, $\langle v_\beta, v_\gamma \rangle$ counts the number of clauses in $S'_Z \cup S_X$ which are unsatisfied by s, and $\langle v_\gamma, v_\alpha \rangle$ counts the number of clauses in $S'_X \cup S_Y$ which are unsatisfied by s. In other words, our goal is to determine whether there is an $\alpha : X \to \{0,1\}$, $\beta : Y \to \{0,1\}$, and $\gamma : Z \to \{0,1\}$ with $\langle v_\alpha, v_\beta \rangle = m_X$, $\langle v_\beta, v_\gamma \rangle = m_Y$, and $\langle v_\gamma, v_\alpha \rangle = m_Z$. This is exactly an instance of EXACT-IP$\Delta_{3 \cdot 2^{\lceil n/3 \rceil}, m}$, as desired. ◀

▶ **Theorem 18** (Reduction from EXACT-IP to OV implicit in [8, Proof of Lemma 4.2])**.** *For any positive integer n, and any $c, \varepsilon > 0$, set $s := n^{\varepsilon \log(c/\varepsilon)}$ and $d := O(2^{c/\varepsilon} \log n)$. There is a pair of maps*

$$r_1, r_2 : \{0,1\}^{c \log n} \times \{1, 2, \ldots, s\} \times \{0, 1, \ldots, c \log n\} \to \{0,1\}^d$$

which can be computed in deterministic time $O(s \cdot 2^{c/\varepsilon} \log n)$ such that for any $x, y \in \{0,1\}^{c \log n}$, and any $m \in \{0, 1, \ldots, c \log n\}$, we have $\langle x, y \rangle = m$ if and only if there is an $i \in \{1, 2, \ldots, s\}$ such that $\langle r_1(x, i, m), r_2(y, i, m) \rangle = 0$ (over $\mathbb{Z}$).

▶ **Lemma 19.** *For every $c, \varepsilon > 0$, there is a reduction from an EXACT-IP$\Delta_{n, c \log n}$ instance to $n^{3\varepsilon \log(c/\varepsilon)}$ many instances of OV$\Delta_{n, O(2^{c/\varepsilon} \log n)}$. The EXACT-IP$\Delta$ instance is a yes instance if and only if at least one of the OVΔ instances is a yes instance. The reduction takes time $2^{O(\varepsilon \log(c/\varepsilon) \log n + c/\varepsilon)}$.*

Proof. In our EXACT-IP$\Delta_{n, c \log n}$ instance, we are given $A, B, C \subseteq \{0,1\}^{c \log n}$ with $|A| = |B| = |C| = n$ and three nonnegative integers m_{AB}, m_{BC}, m_{CA}, and our goal is to determine whether there is a $(a, b, c) \in A \times B \times C$ such that $\langle a, b \rangle = m_{AB}$, $\langle b, c \rangle = m_{BC}$, and $\langle c, a \rangle = m_{CA}$.

Set $s := n^{\varepsilon \log(c/\varepsilon)}$ and $d := O(2^{c/\varepsilon} \log n)$, and let r_1, r_2 be the maps from Theorem 18. Then, our goal is equivalently to determine whether there is a choice of $(a, b, c) \in A \times B \times C$ and $i_{AB}, i_{BC}, i_{CA} \in \{1, 2, \ldots, s\}$ such that $\langle r_1(a, i_{AB}, m_{AB}), r_2(b, i_{AB}, m_{AB}) \rangle = \langle r_1(b, i_{BC}, m_{BC}), r_2(c, i_{BC}, m_{BC}) \rangle = \langle r_1(c, i_{CA}, m_{CA}), r_2(a, i_{CA}, m_{CA}) \rangle = 0$.

For each fixed choice of $i_{AB}, i_{BC}, i_{CA} \in \{1, 2, \ldots, s\}$, this is very nearly an instance of $\mathsf{OV}\Delta_{n,d}$, which would complete the proof. To convert it into an instance of $\mathsf{OV}\Delta_{n,3d}$, simply map:

$$a \to r_1(a, i_{AB}, m_{AB})||0^d||r_2(a, i_{CA}, m_{CA}),$$

$$b \to r_2(b, i_{AB}, m_{AB})||r_1(b, i_{BC}, m_{BC})||0^d,$$

$$c \to 0^d||r_2(c, i_{BC}, m_{BC})||r_1(c, i_{CA}, m_{CA}),$$

for each $a \in A$, $b \in B$, $c \in C$, where $||$ denotes concatenation of vectors, and 0^d is the all-0s vector of length d. ◀

▶ **Theorem 20.** *Suppose that $\mathit{OV}\Delta_{N,c\log N}$ can be solved in (deterministic) time $N^{\tau+o(1)}$ for some constant $\tau \geq 0$ and all constants $c > 0$. Then, for any constant $a > 0$, MAX-2-$\mathit{SAT}_{n,an}$ can be solved in (deterministic) time $O(2^{(\tau/3+\delta)n})$ for every $\delta > 0$.*

Proof. Let $\varepsilon > 0$ be a small constant to be set later. Lemma 17 gives a reduction from $\mathsf{MAX\text{-}2\text{-}SAT}_{n,an}$ to $O(n^3)$ instances of $\mathsf{EXACT\text{-}IP}\Delta_{O(2^{n/3}),an}$. Lemma 19 then reduces each of those to $2^{O(n\varepsilon\log(a/\varepsilon))}$ instances of $\mathsf{OV}\Delta_{O(2^{n/3}),O(n\cdot 2^{3a/\varepsilon})}$. The total time for computing all these reductions is $2^{O(n\varepsilon\log(a/\varepsilon)+a/\varepsilon)}$.

For any $\delta > 0$, we can pick a sufficiently small $\varepsilon > 0$ so that the combination is a reduction from $\mathsf{MAX\text{-}2\text{-}SAT}_{n,an}$ to $2^{\delta n/2}$ instances of $\mathsf{OV}\Delta_{O(2^{n/3}),O(n)}$, which can be computed in $2^{\delta/2}$ time. Each of those instances can be solved in time $2^{\tau n/3+o(n)}$ using the given algorithm with $N = O(2^{n/3})$, as desired. ◀

Finally, we can extend Theorem 20 from showing hardness just for $\mathsf{OV}\Delta_{n,O(\log n)}$ to showing hardness for $\mathsf{DIRECTED\text{-}CYCLE}_{n,O(\log n),k}$ for any integer $k \geq 3$ (the two problems coincide when $k = 3$) via a simple reduction:

▶ **Lemma 21.** *For any integer $k \geq 3$, there is a linear-time reduction from $\mathit{OV}\Delta_{n,O(\log n)}$ to $\mathit{DIRECTED\text{-}CYCLE}_{n,O(\log n),k}$.*

Proof. $\mathsf{OV}\Delta_{n,O(\log n)}$ reduces to $\mathsf{DIRECTED\text{-}CYCLE}_{n,O(\log n),3}$ by simply repeating the given input set three times (unless it contains the all-zeroes vector, in which case we include it in only one of the three sets). We next show how to reduce from $\mathsf{DIRECTED\text{-}CYCLE}_{n,O(\log n),k-1}$ to $\mathsf{DIRECTED\text{-}CYCLE}_{n,O(\log n),k}$ for any $k \geq 4$, which will complete the proof.

We are given as input $k-1$ sets $V_1, \ldots, V_{k-1} \subseteq \{0,1\}^d$ for $d = O(\log n)$ and $|V_i| = n$ for all $i \in \{1, 2, \ldots, k-1\}$. For each i write $V_i = \{v_{i,j}\}_{j\in\{1,\ldots,n\}}$.

Next, for a sufficiently large $d' = O(\log n)$, pick $2n$ vectors $\alpha_1, \ldots, \alpha_n, \beta_1, \ldots, \beta_n \in \{0,1\}^{d'}$ such that, for $i, j \in \{1, 2, \ldots, n\}$ we have

$$\langle \alpha_i, \beta_j \rangle = \begin{cases} 0 & \text{if } i = j \\ \geq 1 & \text{otherwise.} \end{cases}$$

This can be done, for instance, by picking each α_i to be a different vector with exactly half its entries 1, and picking β_i to be $\bar{\alpha_i}$ (i.e. the all 1s vector minus α_i). We thus can pick the smallest $d' = O(\log n)$ such that $\binom{d'}{d'/2} \geq n$.

We will now pick sets $V'_1, \ldots, V'_k \subseteq \{0,1\}^{2d+d'}$ for our $\mathsf{DIRECTED\text{-}CYCLE}_{n,O(\log n),k}$ instance. We will pick $V'_i = \{v'_{i,j}\}_{j\in\{1,2,\ldots,n\}}$, where the $v'_{i,j}$ vectors are defined as follows: If $i \in \{1, 2, \ldots, k-2\}$ then set $v'_{i,j} = v_{i,j}||v_{i,j}||0^{d'}$. Then, set $v'_{k-1,j} = 0^d||v_{k-1,j}||\alpha_j$ and $v'_{k,j} = v_{k-1,j}||0^d||\beta_j$.

We can see with these choices that the vectors $(v_{1,j_1}, v_{2,j_2}, \ldots, v_{k-1,j_{k-1}})$ formed a $k-1$ cycle in the original instance of DIRECTED-CYCLE$_{n,O(\log n),k-1}$ if and only if the k vectors $(v'_{1,j_1}, v'_{2,j_2}, \ldots, v'_{k-1,j_{k-1}}, v'_{k,j_{k-1}})$ form a k cycle in the new instance we created of DIRECTED-CYCLE$_{n,O(\log n),k}$. Moreover, $\langle v'_{k-1,j}, v'_{k,j'}\rangle = 0$ if and only if $j = j'$, so these are the only possible k cycles in the new instance, as desired. ◀

▶ **Corollary 22.** *Suppose for any $k \geq 3$ that DIRECTED-CYCLE$_{n,O(\log n),k}$ can be solved in (deterministic) time $N^{\tau+o(1)}$ for some constant $\tau \geq 0$. Then, for any constant $a > 0$, MAX-2-SAT$_{n,an}$ can be solved in (deterministic) time $O(2^{(\tau/3+\delta)n})$ for every $\delta > 0$.*

4 Hypercliques in OV Hypergraphs and Directed Cycles

A straightforward generalization of the above argument shows:

▶ **Theorem 23.** *Suppose, for integers $\ell > k \geq 2$, that OV-HYPERGRAPH$_{N,O(\log N),\ell,k}$ can be solved in (deterministic) time $N^{\tau+o(1)}$ for some constant $\tau \geq 0$. Then, for any constant $a > 0$, MAX-k-SAT$_{n,an}$ can be solved in (deterministic) time $O(2^{(\tau/\ell+\delta)n})$ for every $\delta > 0$.*

Following the reduction from finding hypercliques in hypergraphs to finding directed cycles of [19], we can also reduce to finding directed cycles in OV graphs, with some care to ensure that the OV dimension does not increase too much:

▶ **Theorem 24.** *Let $k \geq 4$ be a constant integer. There is a $\tilde{O}(d \cdot n^{k-\lceil k/3\rceil})$ time deterministic reduction from OV-HYPERGRAPH$_{n,d,k,3}$ to DIRECTED-CYCLE$_{n^{k-\lceil k/3\rceil},d+O(\log n),k}$.*

The proof of the theorem is a bit technical, so we first present the special case for $k = 4$ and then highlight some changes.

▶ **Theorem 25** ($k = 4$ case of Theorem 24)**.** *There is a $O(d \cdot n^2 \log n)$ time deterministic reduction from OV-HYPERGRAPH$_{n,d,4,3}$ to DIRECTED-CYCLE$_{\binom{n}{2},d+O(\log n),4}$.*

Proof. In OV-HYPERGRAPH$_{n,d,4,3}$, we are given as input a size-n set $V = \{v_1, \ldots, v_n\} \subseteq \{0,1\}^d$, and we want to determine whether there is a $T \subseteq V$ of size $|T| = 4$ such that, for all $S \subseteq T$ of size $|S| = 3$, we have $\mathsf{IP}(S) = 0$.

We first give some definitions. Define $AND : \{0,1\}^d \times \{0,1\}^d \to \{0,1\}^d$ by, for $x, y \in \{0,1\}^d$ and $\ell \in \{1, \ldots, d\}$, $AND(x,y)[\ell] = x[\ell] \cdot y[\ell]$. Next, similar to Lemma 21, for a sufficiently large $d' = O(\log n)$, pick $2n$ vectors $\alpha_1, \ldots, \alpha_n, \beta_1, \ldots, \beta_n \in \{0,1\}^{d'}$ such that, for $i, j \in \{1, 2, \ldots, n\}$ we have

$$\langle \alpha_i, \beta_j \rangle = \begin{cases} 0 & \text{if } i = j \\ \geq 1 & \text{otherwise.} \end{cases}$$

As before, we can pick the smallest $d' = O(\log n)$ such that $\binom{d'}{d'/2} \geq n$. Finally, define $\chi : \{1,2,3,4\}^2 \times \{1,2,\ldots,n\}^2 \to \{0,1\}^{d'}$ by

$$\chi(p,q,i,j) = \begin{cases} \alpha_j & \text{if } p = q \\ \beta_i & \text{if } p = q+1 \pmod 4 \\ 0^{d'} & \text{otherwise.} \end{cases}$$

Our reduction constructs sets $V_1, V_2, V_3, V_4 \subseteq \{0,1\}^{d+4d'}$, each of size $\binom{n}{2}$, as follows. For each $p \in \{1,2,3\}$, and $1 \leq i < j \leq n$, put into set V_p the vector

$$v_{i,j,p} := AND(v_i, v_j)||\chi(p,1,i,j)||\chi(p,2,i,j)||\chi(p,3,i,j)||\chi(p,4,i,j),$$

where $||$ denotes vector concatenation. Finally, for each $1 \leq i < j \leq n$, put into V_4 the vector

$$v_{j,i,4} := AND(v_i, v_j)||\chi(4,1,j,i)||\chi(4,2,j,i)||\chi(4,3,j,i)||\chi(4,4,j,i).$$

We picked the function χ so that, for $a, b, c, d \in \{1, 2, \ldots, n\}$,

- for $p \in \{1, 2, 3\}$, we have $\langle v_{a,b,p}, v_{c,d,p+1}\rangle = 0$ if and only if $a < b = c < d$ and

$$\langle AND(v_{i_a}, v_{i_b}), AND(v_{i_b}, v_{i_d})\rangle = \langle v_{i_a}, v_{i_b}, v_{i_d}\rangle = 0.$$

- For $p = 4$, we have $\langle v_{a,b,4}, v_{c,d,1}\rangle = 0$ if and only if $a > b = c < d$ and $\langle v_{i_a}, v_{i_b}, v_{i_d}\rangle = 0$.

In other words, there are $a, b, c, d \in \{1, 2, \ldots, n\}$ such that $\langle v_{a,b,1}, v_{b,c,2}\rangle = \langle v_{b,c,2}, v_{c,d,3}\rangle = \langle v_{c,d,3}, v_{d,a,4}\rangle = \langle v_{d,a,4}, v_{a,b,1}\rangle = 0$ if and only if $1 \leq a < b < c < d \leq n$ and, for every $S \subseteq \{v_{i_a}, v_{i_b}, v_{i_c}, v_{i_d}\}$ of size $|S| = 3$ we have $\mathsf{IP}(S) = 3$. In other words, the sets V_1, V_2, V_3, V_4 form the desired instance of $\mathsf{DIRECTED\text{-}CYCLE}_{\binom{n}{2}, d+4d', 4}$. ◀

Now we highlight the main changes to the above proof needed to obtain Theorem 24.

Sketch of the proof of Theorem 24. We start with $\mathsf{OV\text{-}HYPERGRAPH}_{n,d,k,3}$ where we are given as input a size-n set $V = \{v_1, \ldots, v_n\} \subseteq \{0,1\}^d$, and we want to determine whether there is a $T \subseteq V$ of size $|T| = k$ such that, for all $S \subseteq T$ of size $|S| = 3$, we have $\mathsf{IP}(S) = 0$.

Let $\gamma = k - \lceil k/3 \rceil$.

The reduction from k-hyperclique in 3-uniform hypergraphs to k-hypercycle in 3-uniform hypergraphs from [19] carries over to our case and we see (details in the full version) that $\mathsf{OV\text{-}HYPERGRAPH}_{n,d,k,3}$ reduces to the following OV Hypercycle problem: given k sets of vectors $W_1, \ldots, W_k$ where $W_i \subseteq \{0,1\}^d$ with $|Q_i| = n$, are there $a_1 \in W_1, \ldots, a_k \in Q_k$ so that for every $j \in \{1, \ldots, k\}$, we have that $\langle a_j, a_{j+1}, \ldots, a_{j+\gamma}\rangle = 0$, where indices are taken mod k.

We now take this hypercycle problem with generalized inner product over $(\gamma+1)$-tuples and reduce it to k-cycle in a graph with roughly n^γ vertices extending our construction for 4-cycle.

We extend the definition of AND to take the bitwise AND of a γ-tuple of d length bit vectors. We then select for sufficiently high d', $2n^{\gamma-1}$ vectors $\alpha_1, \ldots, \alpha_{n^{\gamma-1}}, \beta_1, \ldots, \beta_{n^{\gamma-1}} \in \{0,1\}^{d'}$ such that, for $i, j \in \{1, 2, \ldots, n\}^{\gamma-1}$ we have

$$\langle \alpha_i, \beta_j\rangle = \begin{cases} 0 & \text{if } i = j \\ \geq 1 & \text{otherwise.} \end{cases}$$

This can be done as before by picking each α_i to be a different vector with exactly half its entries 1, and picking β_i to be $\bar{\alpha_i}$. Then we get $d' = O(\log n)$ by picking the smallest d' with $\binom{d'}{d'/2} \geq n^{\gamma-1}$. We define $\chi : \{1, 2, \ldots, k\}^2 \times \{1, 2, \ldots, n\}^\gamma \to \{0,1\}^{d'}$ by the below, where $i_1, \ldots, i_\gamma \in \{1, \ldots, n\}$:

$$\chi(p, q, i_1, \ldots, i_\gamma) = \begin{cases} \alpha_{i_2, \ldots, i_\gamma} & \text{if } p = q \\ \beta_{i_1, \ldots, i_{\gamma-1}} & \text{if } p = q + 1 \pmod k \\ 0^{d'} & \text{otherwise.} \end{cases}$$

Our reduction constructs sets $V_1, V_2, \ldots, V_k \subseteq \{0,1\}^{d+kd'}$, each of size roughly n^γ, as follows. For each $p \in \{1, 2, \ldots, k\}$, and each γ-tuple $i_1, \ldots, i_\gamma \in \{1, \ldots, n\}$ put into set V_p the vector

$$v_{i_1,\ldots,i_\gamma,p} := AND(v^p_{i_1}, \ldots, v^p_{i_\gamma}) || \chi(p, 1, v^p_{i_1}, \ldots, v^p_{i_\gamma}) || \chi(p, 2, v^p_{i_1}, \ldots, v^p_{i_\gamma}) || \ldots || \chi(p, k, v^p_{i_1}, \ldots, v^p_{i_\gamma}),$$

where $||$ denotes vector concatenation and v^p_j is the jth node of W_p from the hypercycle instance.

We picked the function χ so that,

$$\langle v_{i_1,\ldots,i_\gamma,p}, v_{j_1,\ldots,j_\gamma,p+1} \rangle = 0$$

if and only if $(v^p_{i_2}, \ldots, v^p_{i_\gamma}) = (v^{p+1}_{i_1}, \ldots, v^{p+1}_{i_{\gamma-1}})$ and

$$\langle AND(v^p_{i_1}, \ldots, v^p_{i_\gamma}), (v^{p+1}_{j_1}, \ldots, v^{p+1}_{j_\gamma}) \rangle = \langle v^p_1, v^p_2, \ldots, v^p_\gamma, v^{p+1}_\gamma \rangle = 0.$$

In other words, there is an OV k-cycle if and only if there was an OV k-hypercycle. ◀

We obtain the following corollary:

▶ **Corollary 26.** *Suppose that there is some $\varepsilon > 0$ so that DIRECTED-CYCLE$_{n,O(\log n),k}$ can be solved in*

- *$O(n^{3/2-\varepsilon})$ time for some $k \geq 6$ divisible by 3, or*
- *$O(n^{3/2+1/(2\ell)-\varepsilon})$ time for some $k = 3\ell + 1 \geq 4$, or*
- *$O(n^{3/2+1/(4\ell+2)-\varepsilon})$ time for some $k = 3\ell + 2 \geq 5$.*

Then, for any constant $a > 0$, MAX-3-SAT$_{n,an}$ can be solved in (deterministic) time $O(2^{(1-\varepsilon/4+\delta)n})$ for every $\delta > 0$.

In particular, if DIRECTED-CYCLE$_{n,O(\log n),4}$ can be solved in time $n^{2-\varepsilon}$ time for some $\varepsilon > 0$, then MAX-3-SAT$_{n,an}$ has a faster algorithm.

5 Consequences for dynamic problems

In this section we will give two reductions that show that under Hypothesis 4, dynamic graph problems are hard even in OV graphs. We will need two tools to prove our theorems.

The first is from the previous section. It says that for any n we can construct $2n$ Boolean vectors of length $O(\log n)$, $\alpha_1, \ldots, \alpha_n, \beta_1, \ldots, \beta_n$ so that $\langle \alpha_i, \beta_j \rangle = 0$ if and only if $i = j$.

The second tool is a way to make an OV graph "layered".

▷ Claim 27. For any $\ell \geq 2$, there exist ℓ nonzero Boolean vectors $a_1, \ldots, a_\ell$ of length $2 + (\ell - 2)(\ell - 1)/2$ so that for each i, j, $\langle a_i, a_j \rangle = 0$ if and only if $j = i + 1$ or $i = j + 1$.

Proof. We proceed by induction. For $\ell = 2$, the vectors are $[1, 0]$ and $[0, 1]$. Suppose the vectors for ℓ are $a_1, \ldots, a_\ell$ and have length L, then for every $j < \ell$, replace a_j with a_j concatenated with the length $\ell - 1$ bit vector that is all 0 except in position j in which it is 1. Replace a_ℓ with a_ℓ concatenated with the length $\ell - 1$ all 0s vector. Finally set $a_{\ell+1}$ to be the length L all 0s vector concatenated with the length $\ell - 1$ all 1s vector.

After the vector replacement, $\langle a_j, a_{\ell+1} \rangle > 0$ for all $j < \ell$, and $\langle a_i, a_j \rangle$ is the same as before the replacement for $i, j \leq \ell$, and $\langle a_\ell, a_{\ell+1} \rangle = 0$. The length of the vectors goes up by $\ell - 1$. If we assume inductively that $L = 2 + (\ell - 2)(\ell - 1)/2$, adding $\ell - 1$, we complete the proof as $(\ell - 2)(\ell - 1)/2 + (\ell - 1) = (\ell - 1)\ell/2$. ◁

▶ Remark 28. In fact, we will see in Theorem 32 below that the bound $2+(\ell-2)(\ell-1)/2$ in Claim 27 can be replaced by only $O(\log \ell)$. However, such an improvement is unimportant for the results in this section, in which we will always pick ℓ to be a constant.

First let us consider the dynamic *s-t* OV Shortest Paths which asks to maintain the distance between two fixed vertices s and t in an n node OV graph with dimension $O(\log n)$ under vertex relabel updates (change the vector representing a node).

▶ **Theorem 29.** *Under Hypothesis 4, dynamic s-t OV Shortest Paths with vertex label updates that change at most one edge at a time requires either $n^{\omega-o(1)}$ preprocessing time, or $n^{\omega-1-o(1)}$ amortized update time. If arbitrary vertex label updates are supported, then $5/3-\varepsilon$-approximating the s-t distance requires $n^{\omega-1-o(1)}$ amortized update time even when starting with an empty graph (all vectors are all 1s).*

Proof. Suppose we are given an instance of OVΔ with n vectors V of dimension $d = O(\log n)$.

We will start with the proof for vertex label updates that change at most a single edge.

Let us create 4 sets of vectors V_1, V_2, V_3, V_4, using the vectors $a_1, a_2, \ldots, a_6$ from Claim 27: for each $i \in \{1, \ldots, 4\}$ and for every $v \in V$, put in V_j the vector v^j that concatenates v with a_{j+1}. In addition, create two new vectors, s and t, where s is the d-length all 1s vector concatenated with a_1 and t is the d-length all 1s vector concatenated with a_6.

By construction, s and t are non-orthogonal with all other vectors, and a vector $v^j \in V_j$ and a vector $u^k \in V_k$ for $j \leq k$ are orthogonal if and only if $k = j+1$ and u and v are orthogonal in the original OVΔ instance.

We will use the length $d' = O(\log n)$ vectors $\alpha_1, \ldots, \alpha_n, \beta_1, \ldots, \beta_n$ from our first tool. For every vector $v^j \in V^j$ for $j \in \{2, 3\}$, we concatenate the length d' all 0s vector to its end. For a vector $v^j_q \in V^j$ for $j \in \{1, 4\}$ (where v_q is the qth vector of V) we concatenate β_q to the end of it. This does not change the orthogonality of the vectors. We also concatenate the length d' all zeros vector to the ends of both s and t.

This completes the preprocessing stage.

Now, the updates are as follows. We have n stages, one for each vector $v_q \in V$. In the stage for v_q, we replace the last d' bits of s and t with α_q and the first d bits with the all 0 vector. This has the effect of inserting the edges (s, v^1_q) and (v^4_q, t) and leaving all other edges unchanged.

Then, the distance between s and t in the new OV graph is 5 if and only if there are vectors $a, b \in V$ such that $\langle v_q, a\rangle = \langle a, b\rangle = \langle b, v_q\rangle = 0$. At the end of the stage for v_q, we undo the relabeling of s and t and we move on to the next vector in V. This effectively deletes the two edges that were inserted.

The number of stages is n, and so if the preprocessing time is $O(n^{\omega-\varepsilon})$ for $\varepsilon > 0$, then the total time of all n update stages needs to be $n^{\omega-o(1)}$ under our Hypothesis, and hence the amortized time per update is $n^{\omega-1-o(1)}$.

Now we present a simpler proof where the updates are arbitrary relabelings. In the previous proof since the edges in the initial graph would be too expensive to insert one by one using single edge updates, we needed preprocessing. Here there will be no need for preprocessing since we can simply label all vertices as needed one by one.

Create just two sets of vectors V_1, V_2, using the vectors a_1, a_2, a_3, a_4 from Claim 27: for each $i \in \{1, 2\}$ and for every $v \in V$, put in V_j the vector v^j that concatenates v with a_{j+1}. In addition, create two new vectors, s and t, where s is the d-length all 1s vector concatenated with a_1 and t is the d-length all 1s vector concatenated with a_4. Then we will have n stages one for each vector $v_q \in V$ in which we will change s and t as follows. In the stage for v_q, we replace the first d bits of s and t with v_q. Now, s will only be orthogonal to the vectors in V_1

corresponding to original vectors that are orthogonal to v_q and t will be orthogonal to the vectors in V_2 corresponding to original vectors that are orthogonal to v_q. Thus the distance between s and t is 3 if there is a triangle in the OV graph, and it is at least 5 otherwise. ◀

The second dynamic problem we will prove hardness for is dynamic bipartite perfect matching in OV graphs: given an OV graph maintain whether it has a perfect matching, under vertex relabel updates.

▶ **Theorem 30.** *Dynamic bipartite perfect matching in OV graphs on n nodes and dimension $O(\log n)$ under vertex relabel updates that change only a single edge at a time requires either $n^{\omega-o(1)}$ preprocessing time, or $n^{\omega-1-o(1)}$ amortized update time. If arbitrary vertex relabelings are supported, the same lower bound holds but with arbitrary preprocessing.*

Proof. The proof is similar to the proof of the previous theorem.

We start with an instance of OVΔ, and make it layered with 10 layers, $s, V^{1,1}, V^{1,2}, V^{2,1}, V^{2,2}, V^{3,1}, V^{3,2}, V^{4,1}, V^{4,2}, t$. Here s and t are vertices and the rest contain vectors corresponding to the vectors in V. The layering is accomplished using Claim 27 as in the previous theorem. This adds a constant number of coordinates to the vectors.

For a particular j, the edges between $V^{j,1}$ and $V^{j,2}$ are just a matching between the vectors $v_q^{j,1}$ and $v_q^{j,2}$ corresponding to a vector $v_q \in V$. This is accomplished using the vectors α_i and β_i from our first tool.

The edges between $V^{j,2}$ and $V^{j+1,1}$ are between vectors $v_q^{j,2}$ and $v_r^{j+1,1}$ that correspond to $v_q, v_r \in V$ that are orthogonal.

The above two tasks are accomplished as follows. Let $L = O(1)$ be the length of the vectors a_j for $j \in \{1, \ldots, 12\}$ from Claim 27 . Let $d = O(\log n)$ be the length of the vectors from the original OVΔ instance and let $d' = O(\log n)$ be the length of the vectors $\alpha_1, \ldots, \alpha_n, \beta_1, \ldots, \beta_n$ from our first tool. Let 0_t denote the length-t all 0s vector. Each of the vectors $v_q^{j,b}$ for $j \in \{1,2,3,4\}, b \in \{1,2\}$ is of length $L + 2d' + 2d$ as follows. If j is odd, a vector $v_q^{j,1}$ is the concatenation of a_{2j+2}, $0_{d'}$, α_q, v_q and 0_d, and a vector $v_q^{j,2}$ is the concatenation of a_{2j+3}, $0_{d'}$, β_q, 0_d and v_q. On the other hand, if j is even, a vector $v_q^{j,1}$ is the concatenation of a_{2j+2}, α_q,$0_{d'}$, 0_d and v_q, and a vector $v_q^{j,2}$ is the concatenation of a_{2j+3}, β_q, $0_{d'}$, v_q and 0_d.

We make s and t orthogonal to each other but not to anything else. This can be done by letting s be a_1 followed by $0_{2d'+2d}$ and t be a_2 followed by $0_{2d'+2d}$. Since all other vectors start with a_k for $k \geq 4$, s and t are not orthogonal to any of the other vectors but are orthogonal to each other.

This completes the preprocessing stage. At this point there is a perfect matching consisting of (s,t) and the perfect matchings between $V^{j,1}$ and $V^{j,2}$ for $j \in \{1,2,3,4\}$.

There is a stage for each $v_q \in V$. In the stage for v_q, we make s be in layer 1 and only orthogonal to $v_q^{1,1}$, and t be in layer 10 and only orthogonal to $v_q^{4,2}$. This effectively deletes the edge (s,t) and inserts edges $(s, v_q^{1,1})$ and $(v_q^{4,2}, t)$. (These updates are undone at the end of the stage.)

Since $v_q^{1,1}$ is the concatenation of $a_4, \alpha_q, 0_{d'}, 0_d, v_q$ and $v_q^{4,2}$ is the concatenation of $a_{11}, \beta_q, 0_{d'}, v_q, 0_d$, we only need to set s to be the concatenation of $a_3, \beta_q, 0_{d'}, 0_d, 0_d$ and t to be the concatenation of $a_{12}, \alpha_q, 0_{d'}, 0_d, 0_d$.

Now the only way that for there to be a perfect matching is if there are $v_a, v_b \in V$ so that v_q, v_a, v_b form a triangle in the original OV graph. The number of updates is $O(n)$, and hence we get the same conditional lower bound as in the previous theorem. ◀

6 Problems still NP-hard on OV graphs

We begin by recalling Alon's original proof that graphs with low maximum degree can be written as OV graphs of low dimension:

▶ **Lemma 31** ([5, Lemma 3.2]). *For any graph G with n nodes and maximum degree d, there are n vectors in $\{0,1\}^{O(d^2 \log n)}$ whose OV graph is G.*

Proof. (We give here the original proof of [5].) Let $k = \lceil 2e^2(d+1)^2 \ln n \rceil$. We begin by picking n vectors $v_1, \ldots, v_n \in \{0,1\}^k$ at random: for each $i \in \{1,2,\ldots,n\}$ and each $\ell \in \{1,2,\ldots,k\}$ we set $v_i[\ell] = 1$ independently with probability $1/(d+1)$, and $v_i[\ell] = 0$ otherwise. Next, we perform a "correction": for each $i,j \in \{1,2,\ldots,n\}$ which are adjacent nodes in G, and each $\ell \in \{1,2,\ldots,k\}$ such that $v_i[\ell] = v_j[\ell] = 1$, we set both $v_i[\ell]$ and $v_j[\ell]$ to 0. After this correction, every edge in G is also an edge in the OV graph for $V = \{v_1, \ldots, v_n\}$.

Now, consider any $i,j \in \{1,2,\ldots,n\}$ which are not adjacent in G. They are also not adjacent in the OV graph of V so long as there is an $\ell \in \{1,2,\ldots,k\}$ such that (1) $v_i[\ell] = v_j[\ell] = 1$ before the correction phase, and (2) for every $i' \in \{1,2,\ldots,n\} \setminus \{i,j\}$ which is adjacent to i or j (there are at most $2d$ such i's), $v_{i'}[\ell] = 0$ before the correction phase. For a fixed $\ell \in \{1,2,\ldots,k\}$, this happens with probability

$$\frac{1}{(d+1)^2}\left(1 - \frac{1}{d+1}\right)^{2d} \geq \frac{1}{e^2(d+1)^2}.$$

Thus, for a fixed pair $i,j \in \{1,2,\ldots,n\}$ which are not adjacent in G, the probability that they are adjacent in the OV graph of V is at most

$$\left(1 - \frac{1}{e^2(d+1)^2}\right)^k \leq e^{-k/e^2(d+1)^2} \leq \frac{1}{n^2}.$$

It follows that the expected number of $i,j \in \{1,2,\ldots,n\}$ which are not adjacent in G but are adjacent in the OV graph of V is at most $\binom{n}{2} \cdot n^{-2} < 1/2$. Hence, by the probabilistic method, there is a choice of randomness for which there are no such i,j, and hence the OV graph of V is exactly our graph G, as desired. ◀

▶ **Theorem 32.** *Given a graph G with n nodes and maximum degree d, there is a deterministic algorithm running in time $n^{O(d^2)}$ to find n vectors in $\{0,1\}^{O(d^2 \log n)}$ whose OV graph is G.*

Proof. We will derandomize the construction from Lemma 31. We first note that, for a fixed ℓ, when picking $v_i[\ell]$ for all i before the correction phase, it is sufficient to pick them $(2d+2)$-wise independently, rather than fully independently as we did in the original proof. Indeed, in the proof that any $i,j \in \{1,2,\ldots,n\}$ which are not adjacent in G are also not adjacent in the OV graph of V, we only needed to consider $v_{i'}[\ell]$ for $(2d+2)$ choices of i'. For a fixed ℓ, we can thus draw the required $v_i[\ell]$ before the correction phase for all i, $(2d+2)$-wise independently, to be 1 with probability $1/(d+1)$, and 0 otherwise, using $O(d \log n)$ random bits via standard constructions.

Next, rather than independently sample such a vector for each ℓ, we use the standard derandomization trick of using a random walk on a constant-degree expander graph (see e.g. [25, Section 4.2]). We saw above that for a given $i,j \in \{1,2,\ldots,n\}$ which are not adjacent in G, the required vector entries for a particular ℓ can be drawn with $O(d \log n)$ random bits, and will cause them to be not adjacent in the OV graph of V with probability $1/O(d^2)$. Hence, using an expander random walk, we can draw the vector entries for $t = O(d^2 \log n)$ different ℓs using $O(t + d \log n) = O(d^2 \log n)$ random bits. As before, there is a choice of randomness for which the resulting OV graph is G. We can iterate over all $2^{O(d^2 \log n)} = n^{O(d^2)}$ choices of randomness to find such an OV graph as desired. ◀

This immediately gives a polynomial-time reduction from algorithmic problems on sparse graphs to algorithmic problems on OV graphs of dimension $O(\log n)$. For instance:

▶ **Corollary 33.** *Any problem which is NP-hard on graphs of constant maximum degree is also NP-hard on OV graphs of dimension $O(\log n)$.*

Finally, we note that some NP-hard graph problems do become easier on OV graphs:

▶ **Theorem 34.** *Given as input vectors $V = \{v_1, \ldots, v_n\} \subseteq \{0,1\}^d$ defining a dimension d OV graph G_V, a maximum size clique in G_V can be found in time $2^d \cdot n^{O(1)}$.*

Proof. A clique in G_V of size s corresponds to a subset $S \subseteq V$ of size $|S| = s$ such that, for each $i \in \{1, 2, \ldots, d\}$, there is at most one $v \in V$ such that $v[i] = 1$. Equivalently, if we view each $v \in V$ as a subset of $U := \{1, 2, \ldots, d\}$ (i.e. $i \in v$ if and only if $v[i] = 1$), then $S \subseteq V$ is a clique if and only if it is a collection of disjoint subsets of U. Finding the maximum size clique is hence the set packing problem in a universe of size d, which can be solved in $2^d \cdot n^{O(1)}$ time [7]. ◀

7 OV Matrices and Online Matrix-Vector Multiplication

▶ **Theorem 35.** *For any real numbers a, c with $c > 2a > 0$, and any matrix $M \in \mathbb{F}_2^{n \times n}$ of OV dimension $c \cdot \log n$, we can write $M = L \cdot R + S$ where $L, R^T \in \mathbb{F}_2^{n \times r}$ for $r = n^{a \log(c/a) + o(1)}$, and $S \in \mathbb{F}_2^{n \times n}$ has at most $O(n^{2-a})$ entries equal to 1. Moreover, given the vectors $u_1, \ldots, u_n, v_1, \ldots, v_n \in \{0,1\}^{c \log n}$ such that $M[i,j] = 1$ if and only if $\langle u_i, v_j \rangle = 0$ (over $\mathbb{Z}$), we can compute L, R and S in randomized time $\tilde{O}(n^2)$ with high probability.*

Proof. We use the polynomial method similar to [2, Theorem 1.1]. Let $d = c \log n$. For every subset $S \subseteq \{1, 2, \ldots, d\}$, define the polynomial $p_S : \mathbb{F}_2^d \to \mathbb{F}_2$ by $p_S(x) = \sum_{\ell \in S} x[\ell]$. Notice that, when $x = 0^d$, then $p_S(x) = 0$ for all S, and when $x \neq 0^d$, then $p_S(x) = 1$ for half of all S.

Let $m = a \log n$. We begin by picking m independent, uniformly random subsets $S_1, \ldots, S_m \subseteq \{1, 2, \ldots, d\}$. We then compute the set E of all pairs $(i,j) \in \{1, \ldots, n\}^2$ such that $AND(u_i, v_j) \neq 0^d$ but $p_{S_t}(AND(u_i, v_j)) = 0$ for all $t \in \{1, \ldots, m\}$. This can be computed in $O(n^2 md) = \tilde{O}(n^2)$ time. From the above discussion, a given (i,j) will be in E with probability $2^{-m} = n^{-a}$, and so the expected size of E is n^{2-a}. Hence, by Markov's inequality, $|E| \leq 100 \cdot n^{2-a}$ with probability at least 0.99; if this is not the case, repeat independently until it is.

Now, consider the polynomial $p : \mathbb{F}_2^d \to \mathbb{F}_2$ given by, for $z \in \mathbb{F}_2^d$, $p(z) = 1 + \prod_{t=1}^m (1 + p_{S_t}(z))$. Since p is over $\mathbb{F}_2$, with $x^2 = x$ for all $x \in \mathbb{F}_2$, we can assume that p is *multilinear* by reducing any exponent larger than 1 to 1. Hence, we can expand p into a sum of multilinear monomials, and the number r of monomials will be at most[1]

$$r \leq \sum_{g=0}^{m} \binom{d}{g} \leq O\left(\frac{d}{m}\right)^m = O\left(\frac{c \log n}{a \log n}\right)^{a \log n} \leq n^{a \log(c/a) + o(1)}.$$

[1] Here we use the fact, from Stirling's inequality, that for any $1 \leq k \leq n$ we have $\binom{n}{k} \leq \frac{n^k}{k!} \leq \left(\frac{e \cdot n}{k}\right)^k \leq O(n/k)^k$.

In particular, since for $x, y \in \mathbb{F}_2^d$ the vector $AND(x, y)$ consists of a single monomial in terms of x and y in each entry, i.e. $AND(x, y)[\ell] = x[\ell] \cdot y[\ell]$, we can write

$$p(AND(x, y)) = \sum_{w=1}^{r} \prod_{\ell \in T_w} x[\ell] \cdot y[\ell]$$

for some subsets $T_1, \ldots, T_r \subseteq \{1, 2, \ldots, d\}$. Define the map $V : \mathbb{F}_2^d \to \mathbb{F}_2^r$ by $V(x)[w] = \prod_{\ell \in T_w} x[\ell]$. Hence, $p(AND(x, y)) = \langle V(x), V(y) \rangle$ (where the inner product is over $\mathbb{F}_2$).

Finally, we can define our matrices L, R, S as follows: $L \in \mathbb{F}_2^{n \times r}$ is the matrix whose ith row is $V(u_i)$, $R \in \mathbb{F}_2^{r \times n}$ is the matrix whose jth column is $V(v_j)$, and $S \in \mathbb{F}_2^{n \times n}$ is the matrix whose entry $S[i, j]$ is 1 if and only if $(i, j) \in E$. Hence, we can see that $(L \cdot R)[i, j] = p(AND(u_i, v_j))$, and we have defined E so that $S[i, j] = 1$ if and only if $p(AND(u_i, v_j)) \neq M[i, j]$. ◀

▶ **Corollary 36.** *For $c > 0$, given vectors $u_1, \ldots, u_n, v_1, \ldots, v_n \in \{0,1\}^{c \log n}$ which define a matrix $M \in \mathbb{F}_2^{n \times n}$ of OV dimension $c \log n$, we can compute matrices $L \in \mathbb{F}_2^{n \times n^{0.1}}$, $R \in \mathbb{F}_2^{n^{0.1} \times n}$ and $S \in \mathbb{F}_2^{n \times n}$ in time $\tilde{O}(n^2)$ with high probability such that S has at most $n^{2-1/O(\log c)}$ nonzero entries and $M = L \cdot R + S$.*

Proof. Apply Theorem 35 with $a = 1/O(\log c)$ so that $a \log(c/a) < 0.1$. ◀

▶ **Corollary 37.** *For $c > 0$, we can preprocess vectors $u_1, \ldots, u_n, v_1, \ldots, v_n \in \{0,1\}^{c \log n}$ which define a matrix $M \in \mathbb{F}_2^{n \times n}$ of OV dimension $c \log n$, in preprocessing time $\tilde{O}(n^2)$ with high probability, such that given as input a vector $v \in \mathbb{F}_2^n$, we can compute the product $M \cdot v$ in time $n^{2-1/O(\log c)}$.*

Proof. In preprocessing we compute the matrices L, R, S from Corollary 36. Then, on input v, we compute $L \cdot (R \cdot v)$ in $O(n^{1.2})$ time and $S \cdot v$ in $n^{2-1/O(\log c)}$ time, and sum the results. ◀

Abstract

Say that we are given samples from a distribution ψ over an n-dimensional space. We expect or desire ψ to behave like a product distribution (or a k-wise independent distribution over its marginals for small k). We propose the problem of enumerating/list-decoding all large subcubes where the distribution ψ deviates markedly from what we expect; we refer to such subcubes as skewed subcubes. Skewed subcubes are certificates of dependencies between small subsets of variables in ψ. We motivate this problem by showing that it arises naturally in the context of algorithmic fairness and anomaly detection.

In this work we focus on the special but important case where the space is the Boolean hypercube, and the expected marginals are uniform. We show that the obvious definition of skewed subcubes can lead to intractable list sizes, and propose a better definition of a minimal skewed subcube, which are subcubes whose skew cannot be attributed to a larger subcube that contains it. Our main technical contribution is a list-size bound for this definition and an algorithm to efficiently find all such subcubes. Both the bound and the algorithm rely on Fourier-analytic techniques, especially the powerful hypercontractive inequality.

On the lower bounds side, we show that finding skewed subcubes is as hard as the sparse noisy parity problem, and hence our algorithms cannot be improved on substantially without a breakthrough on this problem which is believed to be intractable. Motivated by this, we study alternate models allowing query access to ψ where finding skewed subcubes might be easier.

1 Introduction

Assume that we observe samples from a distribution ψ over points in n-dimensional space $\mathcal{D}^n$. Our prior belief is that each attribute has a marginal distribution μ_i and that the various attributes are nearly independent (or at least k-wise independent for small k), hence ψ is close to the product distribution $\mu = \prod_i \mu_i$. Our goal is to find significant deviations between our hypothesis μ and the observed distribution ψ, manifested as significant dependencies between small sets of variables. The distribution μ might represent either a prior model for

[1] Work done while an intern at VMware Research.

ψ, or it might be represent a target distribution that we wish ψ to be close to. This problem arises naturally in several machine learning applications as we detail in Section 1.1, but first we formulate the problem with more detail.

To formulate a precise statement, we first define the notion of subcubes. Assume that $\mathcal{D}$ is ordered and bounded, the two canonical examples are $\mathcal{D}^n = \{0,1\}^n$ and $\mathcal{D}^n = [0,1]^n$. Let $K \subseteq [n]$ be a set of k coordinates. For $x \in \mathcal{D}^n$, x_K denotes the projection of x onto coordinates in K. For each $j \in K$, let $I_j \subsetneq \mathcal{D}$ be an interval in $\mathcal{D}$. We call the set of points $C = \{x \in \mathcal{D}^n : x_K \in \prod_{j \in K} I_j\}$ a subcube of codimension k. We have

$$\mu(C) := \Pr_{\mathbf{x} \sim \mu}[\mathbf{x} \in C] = \prod_{j \in K} \Pr_{\mathbf{x}_j \sim \mu_j}[\mathbf{x}_j \in I_j] = \prod_{j \in K} \mu_j(I_j).$$

If we similarly define $\psi(C) := \Pr_{\mathbf{x} \sim \psi}[\mathbf{x} \in C]$, then our goal is to find subcubes such that $|\mu(C) - \psi(C)| \geq \gamma$. Motivated by our applications, we add two more desiderata to our problem formulation (that will be justified shortly): we restrict to large subcubes, and we want algorithms that enumerate all subcubes that satisfy our conditions.

One way to restrict to large subcubes is to only consider subcubes with $\mu(C) \geq \eta$ for some $\eta \in [0,1]$. Alternately, we could bound the codimension by k. The advantage of the latter is that we only need that μ is k-wise independent for the equality $\mu(C) = \prod_{j \in K} \mu_j(I_j)$ to hold. In the discrete case $\mathcal{D}^n = \{0,1\}^n$, the two notions coincide since $\mu(C) = 2^{-k}$ for subcubes of codimension k.

Rather then phrasing this as an optimization question where the goal is to find the subcube that maximizes the deviation γ, our goal will be to come up with a *list-decoding* style algorithm that enumerates over all subcubes of codimension k such that $|\mu(C) - \psi(C)| \geq \gamma$.

In addition to being a natural algorithmic question in its own right, this problem comes up in recent work in machine learning, on anomaly detection and fairness.

1.1 Motivation

Fairness in Machine Learning

Assume there is a base population P of individuals, each described by n attributes. We naturally view P as inducing a distribution μ on the attribute space $\mathcal{D}^n$. Suppose that small subsets of the attributes are nearly independent, so that μ is close to being k-wise independent for some k which is small compared to n. We are given a distribution ψ over this population. Our goal is to discover significant biases in the distribution that are not present in the original population P. For instance the population P might be the set of students that apply to a university, and ψ might represent the set of successful applicants. Or P might be the training data for a machine learning algorithm while ψ represents the misclassified inputs. The latter setting has received a fair amount of attention in the context of algorithmic bias and fairness in Machine learning, where the most commonly studied notion is that of intersectionality bias [4]: we are interested in biases where we restrict the values of some small subset of attributes, which are typically discrete. See for instance a recent study showing that facial recognition software has higher error rates for women of color [3]. Our motivation for considering subcubes is that it captures intersectionality in the discrete setting.

Enumerating over all subcubes is more appropriate than optimization in this setting since not all intersectionalities might be equally important. The fact that college applications submitted during certain days of the week are less likely to be accepted might not be as significant as the fact that certain zipcodes are less likely to be accepted; even if the deviation

is lower in the latter case. We ask for algorithms that enumerate over all biased subcubes and leave it to subject experts to decide how interesting these are, just as in list-decoding we do not worry about how the receiver chooses from the list of possible codewords returned by the decoder. Another reason to favor enumeration is that in real-world datasets, we may not expect ψ to be truly k-wise independent; we might expect correlations between certain sets of attributes. But even so, an exhaustive list of significant correlations might lead us to discover interesting new properties of the distribution and refine our model for ψ. The restriction to subcubes of bounded codimension is natural since intersectionalities of few attributes are more interesting.

Anomaly Detection

Anomaly detection is a ubiquitous unsupervised learning problem [5]. Isolation based methods for anomaly detection have proven to be extremely effective in practice [15, 7, 11]. Building on this, the recent work of [10] proposes an approach to anomaly detection based on a notion called Partial Identification. It assigns a score denoted $\mathrm{PIDScore}(x, P)$ to each point $x \in P$ which measures how easy it is to distinguish x from other points in P. They give a heuristic to compute $\mathrm{PIDScore}(x, P)$, and show that the resulting anomaly detection algorithm outperforms several popular anomaly detection methods, across a broad range of benchmarks.

Formally, given a set of points $P \subseteq \mathcal{D}^n$ and a subcube $C \in \mathcal{D}^n$, define the sparsity of C as

$$\rho(C) = \frac{\mathrm{vol}(C)}{|C \cap P|}$$

The PIDScore of a point $x \in P$ is the maximum value of $\rho(C)$ over all subcubes that contain it.

$$\mathrm{PIDScore}(x, P) = \max_{C \ni x} \rho(C).$$

Anomalous points are those for which $\mathrm{PIDScore}(x, P) \geq t$ for some threshold t. Equivalently, it suffices to find all C such that $\rho(C) \geq t$, and then take all the points contained in them.

To relate this to our problem, let us take μ to be the uniform measure over $\mathcal{D}^n$ and ψ to be the measure induced by P. Rescaling ρ by a factor of $|P|/\mathrm{vol}(\mathcal{D}^n)$, we get

$$\rho'(C) = \frac{\mathrm{vol}(C)}{\mathrm{vol}(\mathcal{D}^n)} \frac{|P|}{|C \cap P|} \approx \frac{\mu(C)}{\psi(C)}.^{2}$$

If we also scale the threshold t by the same factor, then the set of outliers stays the same. But $\rho'(C) \geq t'$ implies $\psi(C) \leq \mu(C)/t'$, hence

$$\frac{\mu(C) - \psi(C)}{\mu(C)} \geq 1 - \frac{1}{t'}.$$

Thus this is an instance of the problem that we consider, where our goal is to find non-empty subcubes that are underrepresented in ψ, when compared to μ. Enumeration over all sparse subcubes is natural in this setting, since we wish to list all points with high scores.

[2] Actually $|C \cap P|/|P| = \psi(C)$ only in expectation, but since subcubes have small VC dimension, we get tight concentration.

2 Our Results

In this paper, we focus on the case when $\mathcal{D}^n = \{\pm 1\}^n$ and μ is the uniform distribution. We believe that several of our techniques apply to more general product distributions. A subcube of codimension k is obtained by restricting the values of some subset K of coordinates. For subcubes $C \subseteq D$ we refer to C as a child of D and D as a parent of C.

As a warm-up we first consider the following problem:

▶ **Problem 1** (Finding skewed subcubes). *Given sample access to a distribution ψ over $\{\pm 1\}^n$ and $\gamma \in (0, 2^k - 1]$ find all subcubes C with codimension $j \leq k$ such that*

$$\left| \frac{\Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 2^{-j}}{2^{-j}} \right| \geq \gamma.$$

There is a trivial $\tilde{O}(n^k)$ algorithm that enumerates over all subcubes. To beat this naive bound, we first need to bound the list-size of the output, or rather a bound on the number of skewed subcubes. However, we show in Lemma 12 that there exist distributions where the number of skewed subcubes is $\Omega((n/k)^k)$, which is not far from the trivial upper bound.

The proof of Lemma 12 demonstrates that one source for the abundance of skewed subcubes is that skew is easily inherited by children from their parents: if a subcube C of codimension j is skewed, for every choice of $k - j$ additional coordinates, by simple averaging, there is at least one restriction that results in a skewed subcube. So even if we consider the uniform distribution over points with $x_1 = 1$, there are $\Omega(n^{k-1})$ skewed subcubes by this definition, while really the only interesting subcube is the $x_1 = 1$ subcube. Our first contribution is a definition which captures only those subcubes that do not inherit their skew from a parent.

▶ **Problem 2** (Finding minimal skewed subcubes). *Given sample access to a distribution ψ over $\{\pm 1\}^n$, $\gamma \in (0, 2^k - 1]$ and $\epsilon \in (0, 1)$ find all subcubes C with codimension $j \leq k$ such that*

$$\left| \frac{\Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 2^{-j}}{2^{-j}} \right| \geq \gamma.$$

and for every parent $C' \supsetneq C$ of codimension i,[3]

$$\left| \frac{\Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 2^{-i}}{2^{-i}} \right| \leq \gamma(1 - \epsilon).$$

We refer to such a subcube as a (γ, ϵ)-minimal skewed subcube. This notion is motivated by our applications: if we already know that $\Pr_{\mathbf{x}\sim\psi}[(\mathbf{x}_1 = 1) \wedge (\mathbf{x}_2 = 1)] = 3/4$ (rather than $1/4$), then knowing that $\Pr_{\mathbf{x}\sim\psi}[(\mathbf{x}_1 = 1) \wedge (\mathbf{x}_2 = 1) \wedge (\mathbf{x}_3 = 1)] = 3/8$ should not surprise us, given our prior.

A natural question to ask is whether focusing in minimal skewed subcubes suffices to make the problem (or at least the list size) more tractable. Our second contribution is a bound on the number of minimal skewed subcubes which is independent of the dimension n. Instead we have a dependence on the max norm of the probability distribution defined below.

[3] The formal definition of minimal skewed subcubes (Definition 13) is a little more involved, we only care about those parents of C which are skewed the same way as C.

Given a distribution ψ on $\{\pm 1\}^n$, let $\|\psi\|_\infty := 2^n \cdot \max_{x\in\{\pm1\}^n} \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} = x]$. The parameter $\|\psi\|_\infty$ lies in the range $[1, 2^n]$ and is a measure of how well-spread the distribution is. It is referred to as the smoothness of a distribution in the literature on boosting, and is closely related to min-entropy. The uniform distribution has $t = 1$, whereas $t = 2^n$ when the entire distribution is concentrated on a single point.

▶ **Theorem 1.** *For a distribution ψ on $\{\pm1\}^n$, the number of (γ, ϵ)-minimal skewed subcubes of codimension at most k is bounded by $k^{O(k)} \left(\ln(e\,\|\psi\|_\infty)\,\mathrm{poly}(1/\epsilon, 1/\gamma)\right)^k$.*

For constant ϵ, γ, the asymptotic dependence on n is never worse than $O(n^k)$, which happens when ψ is concentrated on a point. But when $\|\psi\|_\infty = O(1)$, the above bound is $O_k(1)$ and when $\|\psi\|_\infty = \mathrm{poly}(n)$, the bound is $O_k(\ln(n)^k)$ improving substantially over the $O(n^k)$ bound.

There are two key elements in the proof of Theorem 1. We first use a novel Fourier based algorithm to reduce the problem to that of finding large, low-degree Fourier coefficients in a series of restrictions of the distribution ψ to various subcubes. We then use the powerful hypercontractive inequality to bound the number of such coefficients in any distribution in terms of $\|\psi\|_\infty$. This latter bound generalizes the level-k inequalities for indicators of small sets in the Boolean hypercube [16, Chapter 9], and the proof follows similar lines. We also construct distributions showing that for various values of ϵ, γ, the dependency of $(\ln(\|\psi\|_\infty))^k$ is optimal. The distributions are constructed using the Tribes function and BCH codes.

We now turn to the algorithmic problem of finding the list of minimal skewed subcubes. We observe that even when the list-size is constant, there is a significant algorithmic barrier to a $n^{o(k)}$ algorithm, namely the k-sparse noisy parity problem [8, 18]. In this problem, we are given points x and labels y which are the XOR of some k-subset S with random noise of rate η added. There is a simple reduction from this problem to finding skewed subcubes, if we consider the distribution of $(x, y) \in \{\pm1\}^{n+1}$ the only skewed subcubes involve the coordinates $S \cup \{n + 1\}$.

▶ **Theorem 2.** *For $\eta \in (0, 1/2)$, an algorithm that given a distribution ψ and k can find a $(1 - 2\eta, 1)$-minimal skewed subcube of co-dimension k in time $T(n, k, \eta)$ can be used to solve the k-sparse noisy parity problem with noise rate η in time $T(n, k, \eta)$.*

Given this reduction, there are two *lower bounds* on the running time of any list-decoder: the list-size given in Theorem 1, and the running time of the best known algorithm for the k-sparse noisy parity problem, which is $O(n^{0.8k})$ due to [18]. We give an algorithm that nearly gets the sum of these two bounds.

▶ **Theorem 3.** *For any measure ψ on $\{\pm1\}^n$, integer $k \le n$, and parameters $0 \le \gamma \le 2^k - 1$ and $0 \le \epsilon \le 1$, there are algorithms that return all (γ, ϵ)-minimal skewed subcubes of codimension at most k in time*

$$\tilde{O}\left(n^{0.8k}\right) + \tilde{O}\left(n^{k/3}\right) \cdot \frac{k^{O(k)}}{(\epsilon\gamma)^{4/\lambda+2k}} \left(\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^k$$

Finally, to circumvent the noisy parity problem, we consider stronger models where we have query access to the distribution ψ: in addition to random samples, we can also query the value of $\psi(x)$ for any $x \in \{\pm1\}^n$. The noisy parity problem becomes trivial to solve once one has query access. In this model, we are able to get an algorithm whose running time is is $\mathrm{poly}(n, \|\psi\|_\infty)$. Thus when $\|\psi\|_\infty < n^{\alpha k}$ for some $\alpha > 0$, this improves over the trivial algorithm. We show some dependence on $\|\psi\|_\infty$, possibly of the form $\ln(\|\psi\|_\infty)^k$ is inherent even in the query model, by constructing a distribution ψ (with large $\|\psi\|_\infty$) where the query model and random samples model are equivalent, and where finding skewed subcubes lets us solve the k-sparse noisy parity problem.

2.1 Related Work

In nearby work, [1] study the problem of testing whether a distribution is δ close in statistical distance to (ϵ, k)-wise uniform. In our language, a distribution D is said to be (ϵ, k)-wise uniform if all subcubes of codimension $j \leq k$ have skew no greater than $2^j\epsilon$. They provide a sample complexity upper bound of $O((k \log n)/\epsilon^2\delta^2)$. They then provide evidence, based on the conjectured hardness of finding planted cliques, that no polynomial in n time algorithm for this problem exists (one can also base this hardness on sparse noisy parity, as we do here). Indeed, their testing algorithm essentially reduces the problem to the optimization version: find the subcube of codimension k such that the skew is maximized.

Fourier analytic techniques have found widespread use in a variety of supervised learning problems under the uniform distribution [16]. Our work differs from this in that the problem we consider is an unsupervised learning problem, and that we use Fourier analysis over the uniform distribution to reason about the deviation from an arbitrary distribution. In this aspect, our work is similar to the work of [1, 17].

Finally, there have been a line of recent results in machine learning which have a list-decoding flavor to them, see for instance [6, 12].

Outline of the paper. Section 3 introduces definitions and notation. Section 4 contains Fourier analytic results that are required for our results. Section 5 proves our main combinatorial bounds on the number of skewed subcubes, and gives examples that show these bounds are tight. Section 6 describes the efficient algorithm for enumerating minimal skewed subcubes. Section 7 gives lower bounds due to the reduction from the noisy parity problem. Section 8 considers the problem in the membership query model. Some proofs are deferred from the main body to the Appendix 9.

3 Definitions

In this section we present basic definitions and facts.

Distributions

We denote the n-dimensional Hamming cube by $\{\pm 1\}^n$. Given a probability distribution ψ on $\{\pm 1\}^n$, it is convenient to identify it with the probability measure $\psi : \{\pm 1\}^n \to \mathbb{R}^{\geq 0}$ which satisfies

$$\mathop{\mathbb{E}}_{\mathbf{x}\sim\{\pm 1\}^n}[\psi(\mathbf{x})] = 1.$$

We write $\mathbf{x} \sim \psi$ to denote $\mathbf{x}$ is a random variable with the distribution

$$\Pr_{\mathbf{x}\sim\psi}[\mathbf{x} = x] = \frac{\psi(x)}{2^n}$$

Henceforth, we will interchangeably refer to ψ as a distribution and a measure. We will use μ to denote the uniform distribution over $\{\pm 1\}^n$, where $\mu(x) = 1$ for all $x \in \{\pm 1\}^n$. Given functions $f, g : \{\pm 1\}^n \to \mathbb{R}$, we define their inner product by $\langle f, g\rangle := \mathbb{E}_{\mathbf{x}\sim\mu}[f(\mathbf{x})g(\mathbf{x})]$. We define $\|f\|_p := \mathbb{E}_{\mathbf{x}\sim\mu}[f(\mathbf{x})^p]^{1/p}$. For two probability measures ψ, θ, we have

$$\langle \psi, \theta\rangle = \sum_{x\in\{\pm 1\}^n} \frac{\psi(x)\theta(x)}{2^n} = \mathop{\mathbb{E}}_{\mathbf{x}\sim\psi}[\theta(\mathbf{x})] = \mathop{\mathbb{E}}_{\mathbf{x}\sim\theta}[\psi(\mathbf{x})].$$

Let $A \subseteq \{\pm 1\}^n$ and let $\alpha = |A|/2^n$ denote its fractional density. We use μ_A to denote the uniform distribution over A. The corresponding measure is defined as

$$\mu_A(\mathbf{x}) = \begin{cases} \frac{1}{\alpha} & \text{if } x \in A \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

For a distribution ψ, we define

$$\|\psi\|_\infty = \max_{x \in \{\pm 1\}^n} \psi(x)$$

It follows from the definition that

$$\|\psi\|_\infty = 2^n \max_{x \in \{\pm 1\}^n} \Pr_{\mathbf{x} \sim \psi}[\mathbf{x} = x] = \max_{x \in \{\pm 1\}^n} \frac{\Pr_{\mathbf{x} \sim \psi}[\mathbf{x} = x]}{\Pr_{\mathbf{x} \sim \mu}[\mathbf{x} = x]}$$

A bound on $\|\psi\|_\infty$ implies that no point is too likely.

Subcubes

A subcube is a subset of $\{\pm 1\}^n$ obtained by fixing some subset of bits to a particular value. Formally, a subcube $C \subseteq \{\pm 1\}^n$ is specified by a pair (K, y) where $K \subseteq [n]$ and $y \in \{\pm 1\}^K$. We have

$$C = \{x \in \{\pm 1\}^n \text{ s.t. } x_i = y_i \ \forall\ i \in K\}.$$

We refer to coordinates in K as the fixed coordinates of C, and to the rest as the free coordinates of C. For $C = (K, y)$ we define the codimension of C to be $|K|$ and denote it $\mathrm{codim}(C)$. We use $\mathcal{C}^{\leq k}$ to denote the set of all subcubes of codimension at most k. By Equation (1), μ_C the uniform measure over C is given by

$$\mu_C(x) = \begin{cases} 2^{\mathrm{codim}(C)} & \text{if } x \in C \\ 0 & \text{if } x \notin C \end{cases}$$

For subcubes $C = (K, y), D = (L, z)$, we have $D \subset C$ iff $K \subset L$ and $z_i = y_i$ for all $i \in K$. We refer to D as a child of C and C as a parent of D.

▶ **Definition 4** (Restriction). *For a distribution ψ on $\{\pm 1\}^n$ and a subcube $C \subseteq \{\pm 1\}^n$ such that ψ assigns non-zero probability to C we define $\psi|_C : C \to \mathbb{R}^{\geq 0}$, the restriction of ψ to C, as*

$$\psi|_C(x) = \frac{\psi(x)}{\langle \psi, \mu_C \rangle}.$$

Since $\langle \psi, \mu_C \rangle = \mathbb{E}_{x \sim \mu_C}[\psi(x)]$, ψ assings non-zero probaility to C iff $\langle \psi, \mu_C \rangle > 0$. The restriction is itself a legal probability measure; it satisfies $\mathbb{E}_{x \in C}[\psi|_C] = 1$. This definition immediately implies the relationship:

▶ **Fact 5.** *For a distribution ψ on $\{\pm 1\}^n$ and a subcube $C \subset \{\pm 1\}^n$*

$$\|\psi|_C\|_\infty = \frac{\|\psi\|_\infty}{\langle \psi, \mu_C \rangle}$$

▶ **Lemma 6.** *Given subcubes C and D such that $D \subseteq C \subseteq \{\pm 1\}^n$, and a density function ψ, it holds that:*

$$\langle \psi, \mu_D \rangle = \langle \psi, \mu_C \rangle \cdot \langle \psi|_C, \mu_D|_C \rangle$$

3.1 Skewed subcubes

▶ **Definition 7** (Skew). *We define the **skew** of a subcube C with respect to measure ψ as*

$$\textsc{Skew}_\psi(C) = \langle \psi, \mu_C \rangle - 1$$

The next two lemmas state some simple facts about the skew of subcubes. First we show the skew of a subcube measures the deviation of the measure on the subcube from the uniform distribution.

▶ **Lemma 8.** *Let $\mathrm{codim}(C) = k$. We have*

$$\begin{aligned}\textsc{Skew}_\psi(C) &= 2^k \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 1 \\ &= \frac{1}{\Pr_{x\sim\mu}[\mathbf{x} \in C]} \left(\Pr_{x\sim\psi}[\mathbf{x} \in C] - \Pr_{x\sim\mu}[\mathbf{x} \in C] \right).\end{aligned}$$

▶ **Corollary 9.** *For any distribution ψ, $\textsc{Skew}_\psi(C)$ lies in the range $[-1, 2^k - 1]$.*

If $\textsc{Skew}_\psi(C) < 0$, we say that C is negatively skewed while if $\textsc{Skew}_\psi(C) > 0$ we say that it is positively skewed. An averaging argument shows that the existence of negatively skewed subcubes implies the existence of positively skewed subcubes and vice versa.

▶ **Lemma 10.** *For any $K \subseteq [n]$, we have*

$$\sum_{\substack{D=(K,w) \\ w\in\{\pm 1\}^K}} \textsc{Skew}(D) = 0.$$

Given a cube $C = (K, y)$ of codimension k, we can partition it into 2^ℓ subcubes of codimension $k + \ell$, where we pick a set L of ℓ additional coordinates outside of K to fix and enumerate over all settings of these coordinates.

▶ **Lemma 11.** *If $\{C_1, \ldots, C_{2^\ell}\}$ is a partition of C, then*

$$\textsc{Skew}_\psi(C) = \frac{1}{2^\ell} \sum_{i=1}^{2^\ell} \textsc{Skew}_\psi(C_i).$$

Having established basic properties of the skew function, we next turn to bounding the number of subcubes with a given skew. We show that this number may be quite large in the worst case.

▶ **Lemma 12.** *Let $\gamma = 2^f - 1$ for $f \in \{1, \ldots, k\}$. There exists a distribution ψ such that there are $\Omega((n/k)^k)$ many subcubes of codimension k with $\textsc{Skew}(C) \geq \gamma$.*

Proof. Let C be the subcube where the first $t \geq f$ bits are fixed to 1, and let μ_C be the uniform distribution over it. Consider any subcube D where we choose f indices from $[t]$ and $k - f$ indices from $[n] \setminus [t]$, and set them to 1. We have

$$\langle \mu_C, \mu_D \rangle = \mathop{\mathbb{E}}_{\mu_C}[\mu_D] = 2^k \Pr_{\mathbf{x}\sim\mu_C}[\mathbf{x} \in D] = 2^k \frac{1}{2^{k-f}} = 2^f \geq 1 + \gamma$$

since a point from μ_C lies in D iff the $k - f$ bits from $[n] \setminus [t]$ are all set to 1. We now optimize the choice of t. Let $\alpha = f/k$ for $\alpha \leq 1$. We choose $t = \alpha n$ (ignoring floors and ceilings which will not affect the asymptotics). The number of choices for D is given by

$$\binom{t}{f} \cdot \binom{n-t}{k-f} = \binom{\alpha n}{\alpha k} \cdot \binom{(1-\alpha)n}{(1-\alpha)k} \geq \left(\frac{n}{k}\right)^{\alpha k} \cdot \left(\frac{n}{k}\right)^{(1-\alpha)k} \geq \left(\frac{n}{k}\right)^k. \qquad \blacktriangleleft$$

While the above bound is proved for positive skew, Lemma 10 can be used to derive a similar bound for negative skew. Given that this bound is not too far from the trivial upper bound of $\binom{n}{k}$, we need to refine our notion of skew, and also to restrict the set of distributions we consider.

3.2 Minimal skewed subcubes

Lemma 11 tells us that if there exists $C = (J, y)$ such that $|J| = j < k$ and $\textsc{Skew}(C) \geq \gamma$, then for any $L \subseteq [n] \setminus J$ of size $k - j$, there exists some further restriction of bits in L such that the resulting subcube $D \subseteq C$ has $\textsc{Skew}(D) \geq \gamma$. This suggests that we ought to ignore subcubes such as D that can be viewed as *inheriting* skew from some parent C, and instead focus on subcubes whose skew is larger than any parent. One technical issue is that we now need to handle the case of positive and negative skew separately. This motivates the following definitions.

▶ **Definition 13.** *Let $\gamma \in (0, 2^k - 1]$ and $\epsilon \in (0, 1]$. A subcube $C \subseteq \{\pm 1\}^n$ is a (γ, ϵ)-minimally skewed subcube if $\textsc{Skew}(C) \geq \gamma$ and for all its parent subcubes $D \supsetneq C$, we have*

$$\textsc{Skew}_\psi(D) \leq (1 - \epsilon)\gamma. \tag{2}$$

Let $\gamma \in (0, 1]$ and $\epsilon \in (0, 1]$. A subcube $C \subseteq \{\pm 1\}^n$ is a $(-\gamma, \epsilon)$-minimally skewed subcube if $\textsc{Skew}(C) \leq -\gamma$ and for all its parent subcubes $D \supsetneq C$, we have

$$\textsc{Skew}_\psi(D) \geq -(1 - \epsilon)\gamma. \tag{3}$$

Note that our convention is to always use $\gamma > 0$ for the magnitude of the skew, and specify its sign explicitly. Note that the allowable values of γ are different for the case of positive and negative skew. We restrict $\epsilon \in (0, 1]$. The case $\epsilon = 1$ corresponds to the case where every subcube of C has no skew.

The crux of this definition is that minimal skew cannot be inherited from a parent. Given a minimal skewed subcube C, and a parent $D \supsetneq C$, we show that C has noticeable skew in the restriction $\psi|_D$.

▶ **Lemma 14.** *If C is a (γ, ϵ)-minimal skewed subcube and $D \supseteq C$ is a parent of C, then*

$$\textsc{Skew}_{\psi|_D}(C) \geq \frac{\epsilon\sqrt{\gamma}}{2}.$$

If C is a $(-\gamma, \epsilon)$-minimal skewed subcube and $D \supseteq C$ is a parent of C, then

$$\textsc{Skew}_{\psi|_D}(C) \leq -\epsilon\gamma.$$

Proof. We first consider the case when $\gamma > 0$. By Lemma 6

$$\langle \psi|_D , \mu_C|_D \rangle = \frac{\langle \psi, \mu_C \rangle}{\langle \psi, \mu_D \rangle} = \frac{1 + \textsc{Skew}_\psi(C)}{1 + \textsc{Skew}_\psi(D)} \geq \frac{1 + \gamma}{1 + (1 - \epsilon)\gamma}. \tag{4}$$

We have

$$\textsc{Skew}_{\psi|_D}(C) = \langle \psi|_D , \mu_C|_D \rangle - 1 \geq \frac{\epsilon\gamma}{1 + (1 - \epsilon)\gamma} \geq \frac{\epsilon\gamma}{2\sqrt{(1 - \epsilon)\gamma}} \geq \frac{\epsilon\sqrt{\gamma}}{2}$$

where the first inequality is by Equation (4) and the second is by the AM-GM inequality.

Next we consider the case where $\gamma < 0$. By Lemma 6

$$\langle \psi|_D , \mu_C|_D \rangle = \frac{\langle \psi, \mu_C \rangle}{\langle \psi, \mu_D \rangle} = \frac{1 + \textsc{Skew}_\psi(C)}{1 + \textsc{Skew}_\psi(D)} \leq \frac{1-\gamma}{1-(1-\epsilon)\gamma}.$$

Hence

$$\textsc{Skew}_{\psi|_D}(C) = \langle \psi|_D , \mu_C|_D \rangle - 1 \leq \frac{1-\gamma}{1-(1-\epsilon)\gamma} - 1 = \frac{\epsilon\gamma}{1-(1-\epsilon)\gamma} \leq -\epsilon\gamma. \quad \blacktriangleleft$$

4 Fourier Analysis

Given $S \subseteq [n]$, let $\chi_S : \{\pm 1\}^n \to \{\pm 1\}$ be given by $\chi_S(x) = \prod_{i \in S} x_i$. These functions form a basis so we can write $\psi = \sum_S \widehat{\psi}(S)\chi_S$, where the Fourier coefficients of ψ are given by

$$\widehat{\psi}(S) = \mathop{\mathbb{E}}_{\mathbf{x}\sim\mu}[\psi(\mathbf{x})\chi_S(\mathbf{x})] = \sum_{x \in \{\pm 1\}^n} \frac{\psi(x)\chi_S(x)}{2^n} = \sum_{x \in \{\pm 1\}^n} \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} = x]\chi_S(x) = \mathop{\mathbb{E}}_{\mathbf{x}\sim\psi}[\chi_S(\mathbf{x})]$$

which is simply the bias of χ_S under the distribution ψ. Thus we have

$$\psi(x) = \sum_{S \subseteq [n]} \widehat{\psi}(S)\chi_S(x)$$

where $\widehat{\psi}(\emptyset) = \mathbb{E}_{\mathbf{x}\sim\psi}[\psi(x)] = 1$. Given two distributions ψ and ω, their inner product is given by

$$\langle \psi, \omega \rangle = \mathop{\mathbb{E}}_{\mathbf{x}\sim\{\pm 1\}^n}[\psi(\mathbf{x})\omega(\mathbf{x})] = \sum_{x \in \{\pm 1\}^n} \frac{\psi(x)\omega(x)}{2^n} = 1 + \sum_{\emptyset \neq S \subseteq [n]} \widehat{\psi}(S)\widehat{\omega}(S)$$

Skew implies heavy low-degree coefficients

We show that large skew in the subcube (K, y) implies non-trivial Fourier mass on subsets of K.

▶ **Lemma 15.** *For $C = (K, y)$,*

$$\textsc{Skew}_\psi(C) = \sum_{\emptyset \neq S \subseteq K} \widehat{\psi}(S)\chi_S(y).$$

Proof. Given $C = (K, y)$, μ_C the uniform measure over C is given by

$$\mu_C(x) = \prod_{i \in K}(1 + x_i y_i) = 1 + \sum_{\emptyset \neq S \subseteq K} \chi_S(y)\chi_S(x).$$

Hence we have

$$\langle \psi, \mu_C \rangle = 1 + \sum_{\emptyset \neq S \subseteq [n]} \widehat{\psi}(S)\widehat{\mu}_A(S) = 1 + \sum_{\emptyset \neq S \subseteq K} \widehat{\psi}(S)\chi_S(y)$$

from which the claim follows. ◀

Given the above lemma, our approach is to reduce bounding the number of skewed subcubes to bounding the number of large Fourier coefficients of ψ at level k.

We define

$$W^{\leq k}(\psi) = \sum_{\substack{S\subseteq[n]\\|S|\leq k}} \widehat{\psi}(S)^2.$$

A trivial bound is obtained from Parseval's identity:

$$W^{\leq k}(\psi) \leq \sum_{S\subseteq[n]} \widehat{\psi}(S)^2 = \mathop{\mathbb{E}}_{\mathbf{x}\sim\{\pm1\}^n}[\psi(\mathbf{x})^2] \leq \|\psi\|_\infty \mathop{\mathbb{E}}_{\mathbf{x}\sim\{\pm1\}^n}[\psi(\mathbf{x})] = \|\psi\|_\infty$$

If we restrict the summation to sets S of cardinality at most k, then a much stronger bound of $O(\ln(\|\psi\|_\infty)^k)$ holds, it is proved using the powerful HyperContractivity Theorem. These bounds generalize the Level-k inequalities for the Fourier spectrum of small-sets, indeed the proof is identical.

For a $f : \{\pm1\}^n \to \mathbb{R}$ and $0 \leq \rho \leq 1$ set

$$T_\rho f = \sum_S \rho^{|S|} \widehat{f}(S)\chi_S$$

T_ρ is known as the noise operator. Recall that for $p > 0$ we have $\|f\|_p = \mathbb{E}[f^p]^{1/p}$. The hypercontractive inequality quantifies the extent to which the noise operater reduces the norm of a function. See for instance. [16, Chapter 2] for a detailed exposition.

▶ **Theorem 16.** *Let $f : \{\pm1\}^n \to \mathbb{R}$ and $\rho \in [0, 1]$. Then*

$$\|T_\rho f\|_2 \leq \|f\|_{1+\rho^2}.$$

We use the hypercontractive inequality to bound the mass of the low level coefficients.

▶ **Theorem 17.** *Let ψ be a distribution. Then*

$$W^{\leq k}(\psi) \leq e^2(\ln(e\,\|\psi\|_\infty))^k.$$

Proof. By Theorem 16, we have

$$\begin{aligned}
\|T_\rho\psi\|_2 &\leq \|\psi\|_{1+\rho^2} \\
&= \left(\mathop{\mathbb{E}}_{\mathbf{x}\sim\{\pm1\}^n}[\psi(x)^{\rho^2}\psi(x)]\right)^{1/(1+\rho^2)} \\
&\leq \|\psi\|_\infty^{\rho^2/(1+\rho^2)} \mathop{\mathbb{E}}_{\mathbf{x}\sim\{\pm1\}^n}[\psi(x)]^{1/(1+\rho^2)} \\
&= \exp\left(\frac{\ln(\|\psi\|_\infty)\rho^2}{1+\rho^2}\right)
\end{aligned}$$

where we used Holder's inequality with $p = \infty$, $q = 1$. Taking $\rho = \min(1, 1/\sqrt{\ln(\|\psi\|_\infty)})$, we have

$$\|T_\rho\psi\|_2 \leq \exp(1/(1+\rho^2)) \leq e$$

But note that

$$\|T_\rho\psi\|_2 \geq (\rho^{2k} W^{\leq k}(\psi))^{1/2}$$

Hence we conclude that

$$W^{\leq k}(\psi)) \leq e^2(1/\rho)^{2k} = e^2 \max(1, \ln\|\psi\|_\infty)^k \leq e^2(\ln(e\,\|\psi\|_\infty))^k.$$ ◀

We also need a bound for the Fourier mass at level k where we do not count coordinates from some set $J \subseteq [n]$ in the degree of a coefficient.

$$W^{\leq k}(\psi, J) = \sum_{T \subseteq J} \sum_{\substack{S \subseteq [n] \setminus J \\ |S| \leq k}} \widehat{\psi}(S \cup T)^2.$$

▶ **Corollary 18.** *For $J \subseteq [n]$ and a distribution ψ over $\{\pm 1\}^n$,*

$$W^{\leq k}(\psi, J) \leq 2^{|J|} e^2 (\ln(e \|\psi\|_\infty))^k.$$

Projection, Extension, Restriction

Given $x \in \{\pm 1\}^n$ and a set of coordinates $P \subseteq [n]$, let x_P denote the projection of x onto coordinates in P. Given a distribution ψ over $\{\pm 1\}^n$ and a set of coordinates $P \subseteq [n]$, let ψ_P denote the marginal distribution over the set P. The Fourier expansion is especially convenient for marginals, we simply restrict the sum to subsets of P.

▶ **Lemma 19.** *For $P \subseteq [n]$ and a distribution ψ over $\{\pm 1\}^n$, the restriction ψ_P is given by*

$$\psi_P(y) = \sum_{S \subseteq P} \widehat{\psi}(S) \chi_S(y).$$

Coversely we can *extend* a distribution ψ' defined on $\{\pm 1\}^P$ for $P \subseteq [n]$ to all of $\{\pm 1\}^n$ while preserving its important properties.

▶ **Lemma 20.** *Let $P \subsetneq [n]$. Let ψ' be a distribution on $\{\pm 1\}^P$. Define a distribution ψ on $\{\pm 1\}^n$ by $\psi(x) = \psi'(x_P)$. Then*

1. *ψ is the product distribution of ψ' with the uniform distribution on $\{\pm 1\}^{\bar{P}}$.*
2. *$\|\psi\|_\infty = \|\psi'\|_\infty$.*
3. *C is a minimal skewed subcube under ψ iff it is a minimal skewed subcube under ψ'.*

Finally, we derive an expression for the Fourier expansion of $\psi|_C$ in terms of the coefficients of ψ.

▶ **Lemma 21.** *Let $C = (J, z)$. Then*

$$\psi|_C(x) = \sum_{S \subseteq [n] \setminus J} \chi_S(x) \frac{\sum_{T \subseteq J} \widehat{\psi}(S \cup T) \chi_T(z)}{\langle \psi, \mu_C \rangle}.$$

5 A Combinatorial Bound for minimal skewed subcubes

In this section, we show bounds on the number of minimal skewed subcubes that is dimension independent.

▶ **Theorem 22** (Combinatorial Bound for Positive Skew). *For any measure ψ on $\{\pm 1\}^n$, integer $k \leq n$, and $\gamma \in (0, 2^k - 1]$ and $\epsilon \in (0, 1]$, the number of (γ, ϵ)-minimal skewed subcubes of codimension at most k is bounded by*

$$k^{O(k)} \left(\frac{1}{\epsilon^2 \gamma} \ln(e \|\psi\|_\infty) \right)^k.$$

▶ **Theorem 23** (Combinatorial Bound for Negative Skew). *For any measure ψ on $\{\pm 1\}^n$, integer $k \leq n$, and $\gamma \in (0,1]$ and $\epsilon \in (0,1]$, the number of $(-\gamma,\epsilon)$-minimal skewed subcubes of codimension at most k is bounded by*

$$k^{O(k)} \left(\frac{1}{\epsilon^2 \gamma^2} \ln \left(\frac{e \, \|\psi\|_\infty}{\epsilon \gamma} \right) \right)^k .$$

We now outline our approach for proving these bounds.

1. We give an algorithm to enumerate all minimal skewed subcubes, given the list of large, low-degree Fourier coefficients in an adaptively chosen sequence of restrictions of the original distribution ψ. The algorithm recursively "grows" skewed subcubes by finding heavy Fourier coefficients and restricting the bits in that coefficient, and showing that this algorithm discovers all minimal skewed subcubes.
2. We bound the number of large low-degree Fourier coefficients of ψ using Theorem 17.

The details of the algorithm in Step 1 are different for the cases of positive and negative skew, so we present them in Subsections 5.1 and 5.2. To go from a combinatorial bound to an efficient algorithm, we need to make Step 2 algorithmic. We will consider this problem under different learning models in Sections 6 and 8.

5.1 Positive skew

We first present an algorithm FindSkew$^+$ for enumerating minimal skewed subcubes where the skew is positive.

To prove the combinatorial bound, we allow the algorithm to make certain *guesses* in Lines 6 and 7. We think of the set of all possible outputs over all possible guesses as the list that is returned by the algorithm. In Lemma 24, we will show that all minimal skewed subcubes are contained in this list. We bound the list size in Lemma 26. Together, these complete the proof of Theorem 22.

We start the recursion with $R_0 = \emptyset$ and $z_0 = \emptyset$ the null string. The routine either returns FAIL or returns $S_t \subset [n]$ and $z_t \in \{\pm 1\}^{S_t}$ such that (R_t, z_t) is a γ-skewed subcube. The algorithm also takes as inputs the input the distribution ψ, a bound k on the codimension, and skew parameters $\gamma \in (0, 2^k - 1]$ and $\epsilon \in (0,1]$. These stay constant through the recursion, so we suppress the dependence on them. Consider the list of all possible choices returned by the algorithm.

Algorithm 1 FindSkew$^+(R_t, y_t)$.

1: Let $D_t = (R_t, y_t)$. Let $\psi_t = \psi|_{D_t}$. Let $k_t = k - |R_t|$.
2: **if** $\text{Skew}_\psi(D_t) > \gamma(1-\epsilon)$ **then**
3: **return** D_t
4: **if** $\langle \psi, \mu_{D_t} \rangle < (1+\gamma) \cdot 2^{-k_t}$ **then**
5: **return** FAIL
6: Pick S_t such that $|S_t| \leq k_t$ and

$$|\widehat{\psi_t}(S_t)| \geq \frac{\epsilon\sqrt{\gamma}}{k_t \cdot \binom{k_t}{|S_t|}}. \tag{5}$$

7: Pick $z_t \in \{\pm 1\}^{S_t}$.
8: **return** FindSkew$^+(R_t \cup S_t, y_t \circ z_t)$.

We need some notation for the analysis. Let the sequence of subcubes produced by the algorithm be $D_0 \supsetneq D_1 \cdots \supsetneq D_\ell$. Let $s_t = |S_t|$.

▶ **Lemma 24.** *For every (γ, ϵ)-minimal skewed subcube C with $\mathrm{codim}(C) \le k$ there are sequences of choices of S_t and z_t (in Lines 6 and 7) so that C is returned by* FindSkew$^+$.

Proof. For every $C = (K^*, z^*)$ that is a (γ, ϵ)-minimal skewed subcube where $\mathrm{codim}(C) \le k$, we will show that for every t, if $D_t \supsetneq C$ is parent of C, and is not equal to C there is a choice of S_t, z_t that leads to a parent D_{t+1} of C with a larger codimension. Since $t \le \mathrm{codim}(D_t) \le \mathrm{codim}(C) \le k$, in $\ell \le k$ steps we must have $D_t = C$, at which point we return at Line 3. Thus the claim implies the lemma.

At $t = 0$, we have $D_0 = \{\pm 1\}^n$ so the parent condition holds trivially. Assume that we have $D_t \supsetneq C$.

By the definition of a minimal skewed subcube, $\textsc{Skew}(D_t) \le (1-\epsilon)\gamma$, hence the procedure will not return at Line 3.

Next we show that $\langle \psi, \mu_{D_t} \rangle \ge (1+\gamma)2^{-k_t}$, the algorithm will not return FAIL at Line 5:

$$\begin{aligned}
\langle \psi, \mu_{D_t} \rangle &= \Pr_{\mathbf{x}\sim\psi}[\mu_{D_t}(\mathbf{x})] = 2^{k-k_t} \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in D_t] \\
&\ge 2^{k-k_t} \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] \\
&\ge 2^{-k_t} \langle \psi, \mu_{C_t} \rangle \\
&\ge (1+\gamma)2^{-k_t}.
\end{aligned}$$

The first inequality holds because $D_t \supset C$, the second because $\mathrm{codim}(C) \le k$ and the last because we assume that $\textsc{Skew}(C) \ge \gamma$.

Recall that $\psi_t = \psi|_{D_t}$, and let $K_t = K \setminus S_t$. By Lemma 15,

$$\textsc{Skew}_{\psi_t}(C) = \sum_{\emptyset \ne S \subseteq K_t} \widehat{\psi_t}(S)\chi_S(y) = \sum_{k'} \sum_{\substack{\emptyset \ne S \subseteq K_t \\ |S|=k'}} \widehat{\psi_t}(S)\chi_S(y)$$

By Lemma 14, $\textsc{Skew}_{\psi_t}(C) \ge \epsilon\sqrt{\gamma}/2$ which implies that for some $k' \le k_t$, we have

$$\sum_{\substack{\emptyset \ne S \subseteq K_t \\ |S|=k'}} \widehat{\psi_t}(S)\chi_S(y) \ge \epsilon\sqrt{\gamma}/k_t$$

which in turn implies that for at least one $\emptyset \ne S_t \subseteq K_t$, we have

$$|\widehat{\psi_t}(S_t)| \ge \epsilon\sqrt{\gamma} / \left(k_t \cdot \binom{k_t}{k'}\right).$$

Assume that we pick this S_t in Line 6 and $z_t = z^*|_S$ in Line 7. This ensures that D_{t+1} is a parent of C of larger codimension. ◀

We next bound the number of all possible outputs of the algorithm. The crux of the argument is to bound the number of large low-degree Fourier coefficients using Theorem 17. This in turn requires a bound on the infinity norm of ψ_t which comes from passing the test in Line 4.

▶ **Lemma 25.** *The number of choices for S_t satisfying Equation* (5) *is bounded by*

$$\frac{e^2}{\epsilon^2\gamma}(\ln(2^{k_t} e \|\psi\|_\infty))^{s_t} k_t^{4s_t+2}.$$

Proof. We bound $\|\psi_t\|_\infty$ as

$$\|\psi_t\|_\infty = \left\|\psi|_{D_t}\right\|_\infty \leq \frac{\|\psi\|_\infty}{\langle\psi, \mu_{D_t}\rangle} \leq \frac{\|\psi\|_\infty}{(1+\gamma)2^{-k_t}} \leq \|\psi\|_\infty 2^{k_t}$$

where the first inequality is from Fact 5 and we have $\langle\psi, \mu_{D_t}\rangle \geq (1+\gamma)2^{-k_t}$ since we check for this condition in Line 5. We now use Theorem 17 which gives

$$W^{\leq s_t}(\psi) \leq e^2(\ln(e\|\psi\|_\infty \cdot 2^{k_t}))^{s_t}.$$

Hence the number of choices for S_t satisfying (5) is bounded by

$$W^{\leq s_t}(\psi_t)\left(\frac{k_t\binom{k_t}{s_t}}{\epsilon\sqrt{\gamma}}\right)^2 \leq \frac{e^2}{\epsilon^2\gamma}(\ln(2^{k_t}e\|\psi\|_\infty))^{s_t}k_t^{4s_t+2}.$$ ◀

▶ **Lemma 26.** *The total number of subcubes of codimension k output by* FindSkew$^+$ *is at most:*

$$k^{O(k)}\left(\frac{\ln(e\|\psi\|_\infty)}{\epsilon^2\gamma}\right)^k.$$

Proof. Since $\sum_{t\leq\ell} s_t = k$, the sequence $\{s_t\}_{t=1}^{\ell}$ is a partition of k, and there are at most k^k of them. Let us fix the sequence. The number of choices for S_t is bounded by Lemma 25. Since $z_t \in \{\pm 1\}^{S_t}$, the number of choices for z is 2^{s_t}. Taking the product over all t, the number of possible outputs for FindSkew$^+$ is bounded by

$$\prod_{t=1}^{\ell}\frac{e^2}{\epsilon^2\gamma}(\ln(2^{k_t}e\|\psi\|_\infty))^{s_t}k_t^{4s_t+2}\cdot 2^{s_t}$$

We can bound

$$\prod_{t=1}^{\ell}(\ln(2^{k_t}e\|\psi\|_\infty))^{s_t} \leq \ln(2^k e\|\psi\|_\infty)^k \leq (k+\ln(e\|\psi\|_\infty))^k \leq (2k)^k(\ln(e\|\psi\|_\infty))^k.$$

$$\prod_{t=1}^{\ell}k_t^{4s_t+2}2^{s_t} \leq k^{5k+2}.$$

Including the k^k choices for $s_1, \ldots, s_t$, the output list size is bounded by

$$\left(\frac{e^2}{\epsilon^2\gamma}\right)^k(\ln(e\|\psi\|_\infty))^k k^{7k+2} = k^{O(k)}\left(\frac{\ln(e\|\psi\|_\infty)}{\epsilon^2\gamma}\right)^k.$$ ◀

Together Lemma 24 and Lemma 26 complete the proof of Theorem 22.

5.2 Negative Skew

We now present an algorithm FindSkew$^-$ for the negative skewed case. The algorithm takes as input $\gamma \in (0,1]$ and $[\epsilon \in (0,1]$ and the goal is to list all $(-\gamma,\epsilon)$-minimal negatively skewed subcubes.

The main differences from FindSkew$^+$ are that once the skew is less than $-\gamma(1-\epsilon)$, we can return. Thus we can combine the Return statement (Line 3, and the the check in Line 5. Also, the bound on the coefficient size in Equation(6) now reflects the bound for the negative skew case in Lemma 14.

We have the following claim about the correctness of FindSkew$^-$.

Algorithm 2 FindSkew$^-(R_t, y_t)$.

1: Let $D_t = (S_t, z_t)$. Let $\psi_t = \psi|_{D_t}$. Let $k_t = k - |S_t|$.
2: **if** $\mathrm{Skew}_\psi(D_t) < -\gamma(1-\epsilon)$ **then**
3: **return** D_t
4: Pick S_t such that $|S_t| \le k_t$ and

$$|\widehat{\psi_t}(S_t)| \ge \frac{\epsilon\gamma}{k_t \cdot \binom{k_t}{|S_t|}}. \tag{6}$$

5: Pick $z_t \in \{\pm 1\}^{S_t}$.
6: **return** FindSkew$^-(R_t \cup S_t, y_t \circ z_t)$.

▶ **Lemma 27.** *For every (γ,ϵ)-minimal skewed subcube C with $\mathrm{codim}(C) \le k$ there are choices of subsets S_t and z_t (in Lines 6 and 7) so that C is returned by* FindSkew$^-$.

We prove this by showing that for every t, if $D_t \supsetneq C$ is parent of C, and is not equal to C there is a choice of S_t, z_t that gives a parent D_{t+1} of C with a larger codimension. Indeed, we know that for any parent of C, inner product $\langle \psi, \mu_{D_t}\rangle$ is large enough to pass the test in Line 3. The rest of the proof is identical to that of Lemma 24 for the case of positive skew, so we do not repeat it.

The crux of the proof is to bound the number of choices for S_t satisfying Equation (6).

▶ **Lemma 28.** *The number of choices for S_t satisfying Equation* (6) *is bounded by*

$$\frac{e^2}{\epsilon^2\gamma^2}\left(\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^{s_t} k^{2s_t+2}.$$

Proof. To pass Line 3, it must hold that $\mathrm{Skew}_\psi(D_t) \ge -\gamma(1-\epsilon)$, hence

$$\langle \psi, \mu_{D_t}\rangle \ge 1 - \gamma(1-\epsilon) \ge \epsilon\gamma$$

since $\gamma \le 1$. So we bound $\|\psi_t\|_\infty$ as

$$\|\psi_t\|_\infty = \left\|\psi|_{D_t}\right\|_\infty = \frac{\|\psi\|_\infty}{\langle \psi, \mu_{D_t}\rangle} \le \frac{\|\psi\|_\infty}{\gamma\epsilon}.$$

Using Theorem 17 gives

$$W^{\le s_t}(\psi_t) \le e^2\left(\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^{s_t}.$$

Hence the number of choices for S_t satisfying Equation (6) is bounded by

$$\begin{aligned}\frac{W^{\le s_t}\cdot\left(k_t\cdot\binom{k_t}{|S_t|}\right)^2}{\epsilon^2\gamma^2} &\le e^2\left(\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^{s_t}\frac{\left(k_t\cdot\binom{k_t}{|S_t|}\right)^2}{\epsilon^2\gamma^2}\\ &\le \frac{e^2}{\epsilon^2\gamma^2}\left(\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^{s_t} k^{2s_t+2}.\end{aligned}$$

◀

We can now conclude as before.

▶ **Lemma 29.** *The total number of subcubes of codimension k output by* FindSkew$^-$ *is bounded by*

$$k^{O(k)}\left(\frac{1}{\epsilon^2\gamma^2}\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^k.$$

Proof. Using Lemma 28 and the fact that there are are 2^{s_t} choices for z_t and k^k choices of the partition $s_1, \ldots, s_t$, the overall list size is bounded by

$$k^k \prod_{t=1}^{\ell} \frac{e^2}{\epsilon^2\gamma^2} \left(\ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^{s_t} k^{2s_t+2}2^{s_t} \leq k^{O(k)} \left(\frac{1}{\epsilon^2\gamma^2} \ln\left(\frac{e\,\|\psi\|_\infty}{\epsilon\gamma}\right)\right)^k. \quad \blacktriangleleft$$

Combining Lemmas 27 and 29 completes the proof of Theorem 23.

5.3 Tightness of our bounds

We show that the dependence on $\|\psi\|_\infty$ in Theorem 22 is nearly optimal. To simplify our constructions, we will construct distributions on n variables where $n = n(\|\psi\|_\infty, k)$. But one can then use Lemma 20 to extend the construction to all larger values of n.

▶ **Theorem 30.** *There exists a distribution μ_C on $\{\pm1\}^n$ which has $\Omega_k((\ln(\|\mu_C\|_\infty))^k)$ many $(2^k, 1/2)$-minimal skewed subcubes of codimension k.*

Proof. Let C be the subcube where all the bits are fixed to 1, and let μ_C be the uniform distribution over it. It follows that $\|\mu_C\|_\infty = 2^n$ hence $\ln(\|\mu_C\|_\infty) = n$. We claim that all $\binom{n}{k}$ subcubes where a k out of the first t bits are fixed to 1 are $(2^k - 1, 1/2)$-minimal skewed subcubes. Fix one such cube D. We have

$$\textsc{Skew}_{\mu_C}(D) = 2^k \Pr_{\mathbf{x}\sim\mu_C}[\mathbf{x} \in D] - 1 = 2^k - 1.$$

Since the maximum skew of any subcube of codimension $k-1$ is at most $2^{k-1} - 1$, D satisfies the definition of (γ, ϵ)-minimal skew for $\gamma = 2^k - 1$ and ϵ such that $\gamma(1-\epsilon) \geq 2^{k-1} - 1$. In particular, we can take $\epsilon = 1/2$.

Thus the number of $(2^k - 1, 1/2)$-minimal skewed subcubes is $\binom{n}{k} = \Omega_k(n^k)$. The only dependence on n in Theorem 22 comes from the $\|\mu_C\|_\infty$ since ϵ is a constant and $\gamma \leq 2^k$. Thus the number of cubes is $\Omega((\ln(\|\mu_C\|_\infty))^k)$. $\blacktriangleleft$

For Theorem 23 dealing with negative skew, we show a similar bound, though with a smaller value of $\epsilon = 1/k$. The distribution we use is derived from the Tribes function.

▶ **Theorem 31.** *There exists a distribution τ on $\{\pm1\}^n$ which has $\Omega_k((\ln(\|\tau\|_\infty))^k)$ many $(-1, 1/k)$-minimal skewed subcubes of codimension k.*

Proof. Let $n = tk$. We label the coordinates as $\{x_{i,j}\}_{i\in[k],j\in[t]}$. Consider the DNF formula

$$\text{Tribes}(x) = \bigvee_{i=1}^{k} \bigwedge_{j=1}^{t} x_{i,j}$$

We now define a distribution τ where we pick a $i^* \in [k]$ at random, set $x_{i^*,j} = 1$ for all $j \in [t]$ and set all the other variables randomly. Clearly the distribution τ is supported on the satisfying assignments of Tribes(x). It is also easy to see that

$$\|\tau\|_\infty = \tau(1^{tk}) = 2^{tk} \sum_{i=1}^{k} \frac{1}{k} 2^{-(k-1)t} = 2^t.$$

Now consider the set of minimal 0 certificates of Tribes, which are subcubes where we pick a single variables from each term and set it to 0. There are t^k such subcubes, fix one such subcube C. Clearly $\Pr_{\mathbf{x}\sim\tau}[\mathbf{x} \in C] = 0$, hence $\textsc{Skew}_\tau(C) = -1$. Now consider any parent subcube D of C. Assume it has codimension $\ell < k$, and let $L \subset [k]$ denote the set of terms that it sets to 0. For $\mathbf{x} \sim \tau$ to lie in L, two events need to happen:

- $i^* \notin L$, which happens with probability $1 - \ell/k$.
- The variables in L which are set to 0 in D are also set to 0 by the random assignment, which happens with probability $2^{-\ell}$.

As these two events are independent, we have $\Pr_{\mathbf{x}\sim\tau}[\mathbf{x} \in D] = 2^{-\ell}(1 - \ell/k)$ hence

$$\textsc{Skew}_\tau(D) = 2^\ell \Pr_{\mathbf{x}\sim\tau}[\mathbf{x} \in D] - 1 = -\frac{\ell}{k}.$$

Thus the maximum skew of any parent D is $-1 + 1/k$. Hence C is $(-1, 1/k)$-minimally skewed.

As before we note that $\gamma = 1$ and $\epsilon = 1/k$, hence the only dependence on t comes from $\log(\|\tau\|_\infty) = t$, which gives the claimed bound. ◀

Finally, we present a distribution that has a large number of $(-1, 1)$ and $(1, 1)$ minimally skewed subcubes. Recall that $\epsilon = 1$ means that every parent of the cube has skew 0.

The construction is based on (dual) BCH codes. We think of linear codes as subsets of $\mathbb{F}_2^n$ where $\mathbb{F}_2 = \{0, 1\}$ which we can identify with $\{\pm 1\}^n$ via the usual mapping $x \to (-1)^x$. For $x \in \mathbb{F}_2^n$ let the weight of x denoted $\mathrm{wt}(x)$ be the number of 1s in x. Let $\mathrm{supp}(x) \subseteq [n]$ denote the set of cordinates where x is non-zero. We will use the following fact about BCH codes communicated to us by Sergey Yekhanin [19].

▶ **Lemma 32** ([19]). *Let $d \geq 2$ be even and let $n + 1 = 2^l \geq d$. There exists a $\mathbb{F}_2$-linear code $\mathcal{C}_{BCH} \subseteq \{0, 1\}^n$ with minimum distance d, which contains $\Omega(n^{d/2+1})$ minimum weight codewords.*

▶ **Theorem 33.** *For any even $k \geq 2$ and large enough n, there exists a distribution ψ_k on $\{\pm 1\}^n$ where the numbers of $(-1, 1)$-minimal skewed subcubes and $(1, 1)$-minimal skewed subcubes of codimension k are both $\Omega_k((\log(\|\psi_k\|_\infty))^{k/2+1})$.*

Proof. Set $k = d$, and take n as in Lemma 32. Let ψ^k be the uniform distribution on the dual space to $\mathcal{C}_{BCH}$. Using standard facts about the Fourier expansion of a subspace, we can write

$$\psi^k = \sum_{\substack{c \in \mathcal{C}_{BCH} \\ S = \mathrm{supp}(c)}} \chi_S(x). \tag{7}$$

Since $\mathcal{C}_{BCH}$ has minimum distance k, ψ^k is $(k-1)$-wise independent, so for any subcube C where $\mathrm{codim}(C) \leq k - 1$, we have $\textsc{Skew}_{\psi^k}(C) = 0$. This relies on a standard construction of k-wise independent spaces from codes [2, Chapter 16], it can also be seen using Lemma 15 combined with Equation (7).

Fix $S \subset [n]$ to be the support of a minimum weight codeword in $\mathcal{C}_{BCH}$. By Lemma 19 and Equation (7), the projection of ψ^k to coordinates in S is given by $\psi^k_S(x) = 1 + \chi_S(x)$. Hence it is uniform over the 2^{k-1} settings $y \in \{\pm 1\}^S$ such that $\chi_S(y^+) = 1$.

For every such y and $D^+ = (S, y)$, we have $\Pr_{\mathbf{x}\sim\psi^k}[\mathbf{x} \in D^+] = 2^{-(k-1)}$ hence

$$\textsc{Skew}_{\psi^k}(D^+) = 2^k \Pr_{\mathbf{x}\sim\psi^k}[\mathbf{x} \in D^+] - 1 = 1.$$

On the other hand, for every $y \in \{\pm 1\}^S$ such that $\chi_S(y) = -1$ and $D^- = (S, y)$, we have $\Pr_{\mathbf{x}\sim\psi^k}[\mathbf{x} \in D^-] = 0$ hence

$$\textsc{Skew}_{\psi^k}(D^-) = 2^k \Pr_{\mathbf{x}\sim\psi^k}[\mathbf{x} \in D^-] - 1 = -1.$$

Since every parent of D^+ has 0 skew, every such D^+ is a $(1, 1)$-minimal skewed subcube, and similary for every D^-.

Trivially, we have $\|\psi^k\|_\infty \le 2^n$, hence $\log(\|\psi^k\|_\infty) \le n$ (in fact it equals $n - O(\log(n))$. Since the number of minimal weight codewords is $\Omega_k(n^{k/2+1})$ by Lemma 32, and γ, ϵ are both 1, the number of codewords is $\Omega_k((\log(\|\psi^k\|_\infty))^{k/2+1})$. Hence the number of minimal skewed subcubes is as claimed. ◀

6 Algorithms for Finding Skewed Subcubes

In this section, we present an algorithm that find skewed subcubes efficiently in the random sample model, where we have access to random samples from ψ.

To make Algorithm 1 efficient, we need to replace the step of guessing S (Line 6 in Algorithm 1, and Line 4 in Algorithm 2) with an algorithm to find large low degree Fourier coefficients[4]. We restate the problem below:

▶ **Problem 3** (Finding large low-degree biases). *Given a distribution ψ on $\{\pm 1\}^n$, an integer k and $\rho \ge 0$, find all $S \subseteq [n]$ such that $|S| \le k$ and*

$$\hat{\psi}(S) := \mathop{\mathbb{E}}_{\mathbf{x}\sim\psi}[\chi_S(x)] \ge \rho.$$

Our main result is the following pair of theorems.

▶ **Theorem 34** (Algorithm for Positive Skew). *Given sample access to a distribution ψ on $\{\pm 1\}^n$, integer $k \le n$, and parameters $\gamma \in (0, 2^k - 1]$, $\epsilon \in (0, 1]$ and $\lambda \in [0, 1]$, there is an algorithm that returns all (γ, ϵ)-minimal skewed subcubes of codimension at most k in time:*

$$\tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + k^{O(k)} \cdot (\ln(e\,\|\psi\|_\infty))^k \left(\frac{\tilde{O}(n^{k/3})}{(\epsilon\sqrt{\gamma})^{4/\lambda}} + \frac{\mathrm{poly}(n)}{(\epsilon\sqrt{\gamma})^{2k}}\right)$$

where ω is the matrix multiplication exponent, and $\tilde{O}$ hides $\mathrm{poly}\log n$ factors.

▶ **Theorem 35** (Algorithm for Negative Skew). *Given sample access to a distribution ψ on $\{\pm 1\}^n$, integer $k \le n$, and parameters $\gamma \in (0, 1]$, $\epsilon \in (0, 1]$ and $\lambda \in [0, 1]$, there is an algorithm that returns all $(-\gamma, \epsilon)$-minimal skewed subcubes of codimension at most k in time:*

$$\tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + k^{O(k)} \cdot (\ln(e\,\|\psi\|_\infty))^k \left(\frac{\tilde{O}(n^{k/3})}{(\epsilon\gamma)^{4/\lambda}} + \frac{\mathrm{poly}(n)}{(\epsilon\gamma)^{2k}}\right)$$

where ω is the matrix multiplication exponent, and $\tilde{O}$ hides $\mathrm{poly}\log n$ factors.

Theorem 3 follows from using (a), setting $\lambda = 0.01$ and $\omega \le 2.38$.

In both algorithms, we will find large low-degree biases using a breakthrough algorithm of [18] for detecting pairs of vectors that are highly correlated from a set of weakly correlated vectors. The algorithm was subsequently improved by [13]).

▶ **Theorem 36** ([13]). *Given two sets of vectors $V_1, V_2 \subseteq \{\pm 1\}^n$ for which there are at most q pairs $(v_1, v_2) \in V_1 \times V_2$ with correlation larger than τ, and a parameter $\rho \ge \tau^{1/\lambda}$ (for $\lambda \in [0, 1]$), there is an algorithm $\textsc{FindCorr}(V_1, V_2, \rho, \tau)$ that with high probability outputs all pairs $(v_1, v_2) \in V_1 \times V_2$ with correlation at least ρ. Furthermore, algorithm runs in time*

$$\tilde{O}\left(n^{\frac{2\omega}{3-\lambda}} + qdn^{\frac{2(1-\lambda)}{3-\lambda}}\right).$$

[4] We note that technically to implement the algorithm we also need to estimate $\langle \psi, \mu_C \rangle$ for every C to an additive accuracy of $\min(\gamma, 2^{-k})$. If done via sampling, these only incur $2^{2k} k \log n/\gamma^2$ additional cost per call, and will be absorbed into our runtime bounds anyway.

The essence of the reduction is as follows. For each set $S \subseteq [n]$ less than $k/2$ we associate a vector y_S, for which each coordinate is a random sample of $\chi_S(x)$ where x is drawn from ψ. If $Q, R \subseteq [n]$ are disjoint, the correlation coefficient $\mathbb{E}[y_Q \cdot y_R]/d$ is precisely the value of the Fourier coefficient $\widehat{\psi}(Q \cup R)$. Thus as long as the algorithm of [13] succeeds and is not overwhelmed by sample error, every ρ correlated pair (y_Q, y_R) corresponds to a Fourier coefficient $\widehat{\psi}(Q \cup R)$ of size less than k and absolute value ρ. We now describe this more formally.

Algorithm 3 FindFourierCoefficients(ψ, k, ρ, λ).

$\mathcal{S} \leftarrow \emptyset$
$\tau \leftarrow (\rho/2)^{1/\lambda}$
Draw a set of $d = O(k \log n/\tau^2)$ samples $x_1, \ldots x_d$ from ψ.
for $T = O(k^{3/2} \log n)$ rounds **do**
  Randomly partition $[n]$ into two subsets N_1 and N_2.
  For every subset $S \subseteq N_1$ of size $\leq \lceil k/2 \rceil$, form a vector $y_S \in [-1, 1]^d$ for which the ith bit is set to $\chi_S(x_i)$. Call this set of vectors V_1.
  Do the same for N_2 for sets of size $\leq \lfloor k/2 \rfloor$, and call the set of vectors V_2.
  Run FindCorr$(V_1, V_2, \rho/2, \tau)$ from [13] to find all pairs y_Q and y_R such that $Q \subseteq N_1$, $R \subseteq N_2$, and y_Q and y_R are $\rho/2$ correlated. For each of these, add $Q \cup R$ to $\mathcal{S}$.
return $\mathcal{S}$.

We first prove some simple lemmas using standard concentration of measure results.

▶ **Lemma 37.** *For every $Q \in N_1$ and $R \in N_2$, w.h.p. $\left|\langle y_Q, y_R \rangle / d - \widehat{\psi}(Q \cup R)\right| \leq \tau/2$.*

Proof. For a single $x \sim \{\pm 1\}^n$ and disjoint $Q, R \subseteq N$, we have $\mathbb{E}[\chi_Q(x) \cdot \chi_R(x)] = \widehat{\psi}(Q \cup R)$. Applying the Hoeffding bound with our choice of $d = 32k \log n/\tau^2$, we have that $\langle y_Q, y_R \rangle / d$ is within $\tau/2$ of $\widehat{\psi}(Q \cup R)$ with probability at least $1 - n^{-2k}$. By a union bound, this hold for all $O(n^k)$ choices of pairs (Q, R) with probability $1 - n^{-k}$. ◀

▶ **Lemma 38.** *For every $S \subseteq [n]$ with $|S| \leq k$, w.h.p. in at least one round $t \in [T]$ there are $Q \subseteq N_1$, $R \subseteq N_2$ with $Q \cap R = \emptyset$ such that $Q \cup R = S$.*

Proof. Fix a set S of size ℓ. For a random bipartition of $[n]$, the probability S is perfectly bisected is at least $1/(8\sqrt{\ell}) \geq 1/(8\sqrt{k})$. The probability it is never bisected over $T = 16k^{3/2} \log n$ rounds is upper bounded by

$$\left(1 - \frac{1}{8\sqrt{k}}\right)^T \leq e^{-2k \log n} = n^{-2k}.$$

By a union bound, every S of size $\leq k$ is bisected at least once with high probability. ◀

▶ **Lemma 39.** *The algorithm* FindFourierCoefficients(ψ, k, ρ, λ) *returns all Fourier coefficients of ψ of degree at most k of absolute value at least ρ in time*

$$\tilde{O}\left(n^{k\omega/(3-\lambda)}\right) + \tilde{O}(n^{k/3}) 2^{O(k)} (\ln(e \|\psi\|_\infty))^k \rho^{-4/\lambda}.$$

Proof. Consider any set $S \subseteq [n]$ of size $\leq k$ of magnitude at least ρ. By Lemma 38, w.h.p. for some round $t \in [T]$, the algorithm will form two vectors y_Q and y_R such that $Q \subseteq N_1$, $R \subseteq N_2$ and $Q \cup R = S$. Furthermore, by Lemma 37, we have $\langle y_Q, y_R \rangle / d \geq \rho - \tau \geq \rho/2$. In turn, this means that FindCorr$(V_1, V_2, \rho/2, \tau)$ will detect these w.h.p.

To bound the running time, we need a bound on the number q of pairs with correlation higher than τ. By Lemma 37, we have $\langle y_Q, y_R \rangle / d \geq \tau$ implies $\hat{\psi}(Q \cup R) \geq \tau/2$. The number of such coefficients is bounded by

$$\frac{W^{\leq k}(\psi)}{(\tau/2)^2} \leq 2^8 \left(\ln(e \|\psi\|_\infty)\right)^k \rho^{-2/\lambda}.$$

For each such coefficient S, there are 2^k ways to write it as $S = Q \cup R$ for disjoint Q, R. Hence

$$q \leq 2^{k+8} (\ln(e \|\psi\|_\infty))^k \rho^{-2/\lambda}.$$

Observe that $\log_\tau \rho \geq \lambda$ by our choice of τ. By Theorem 36, [13] will find a list containing all $\rho/2$ correlated pairs in time at most

$$\begin{aligned}
&\tilde{O}\left(\left(n^{k/2}\right)^{2\omega/(3-\lambda)} + qd\left(n^{k/2}\right)^{(2-2\lambda)/(3-\lambda)}\right) \\
&\leq \tilde{O}\left(n^{k\omega/(3-\lambda)} + 2^{O(k)}(\ln(e\|\psi\|_\infty))^k \rho^{-2/\lambda} k \cdot \log(n) \cdot \rho^{-2/\lambda} n^{k(1-\lambda)/(3-\lambda)}\right) \\
&\leq \tilde{O}\left(n^{k\omega/(3-\lambda)}\right) + \tilde{O}(n^{k/3}) 2^{O(k)} (\ln(e\|\psi\|_\infty))^k \rho^{-4/\lambda}.
\end{aligned}$$

◀

We relegate the remainder of the proofs of Theorem 34 to the appendix.

7 Reduction from Noisy Parity

Recall that given $S \subseteq [n]$, a parity function $\chi_S : \{\pm 1\}^n \to \{\pm 1\}$ is given by $\chi_S(x) = \prod_{i \in S} x_i$. A noisy parity is a parity function with random noise of rate η added to it. In other words, we say $f : \{\pm 1\}^n \to \{\pm 1\}$ is an η-noisy parity if $\Pr[f(x) = \chi_S(x)] = 1 - \eta$ an $\Pr[f(x) = -\chi_S(x)] = \eta$. In the sparse noisy parity problem, we are given access to samples $(\mathbf{x}, f(\mathbf{x}))$ where $\mathbf{x} \sim \mu$ is sampled uniformly from $\{\pm 1\}^n$ and f is noisy parity χ_S with $|S| = k$. The goal is to recover the parity function, or equivalently the set S.

Given a set $S' \subseteq [n]$, we have

$$\mathop{\mathbb{E}}_{\mathbf{x} \sim \mu}[\widehat{f}(S')] = \begin{cases} 0 & \text{if } S' \neq S \\ 1 - 2\eta & \text{if } S' = S \end{cases}$$

This leads to a naive enumeration algorithm that runs in time $O(n^k)$. The current best algorithm due to [18] runs in time $O(n^{0.8k})\,\mathrm{poly}(1/(1-2\eta)))$. A series of reductions due to [8] show that efficient algorithms for sparse noisy parity imply algorithms with similar running times for learning k-juntas, decision trees and DNFs under the uniform distribution. This suggests the following conjecture (which we consider to be folklore).

▶ **Conjecture.** *There is no algorithm for the sparse noisy parity problem which runs in time* $n^{o(k)}$.

We now prove Theorem 2 which we restate below.

▶ **Theorem 2.** *For $\eta \in (0, 1/2)$, an algorithm that given a distribution ψ and k can find a $(1-2\eta, 1)$-minimal skewed subcube of co-dimension k in time $T(n, k, \eta)$ can be used to solve the k-sparse noisy parity problem with noise rate η in time $T(n, k, \eta)$.*

Proof. Finding a noisy parity reduces to finding a minimal skewed subcube. Given an instance of sparse noisy parity, consider the distribution ψ on $\{\pm 1\}^{n+1}$ obtained by appending the label to the sample. Thus $\psi = (\mathbf{x}, f(\mathbf{x}))_{\mathbf{x}\sim\mu}$. We show that all skewed subcubes must restrict the set $S \cup \{n+1\}$, hence they are all minimal, and finding any skewed subcube solves the noisy parity problem.

For any $z \in \{\pm 1\}^S$, consider the subcube $D^+(z)$ given by $x_S = z$, $x_{n+1} = \chi_S(z)$. We have

$$\textsc{Skew}(D^+(z)) = 2^{k+1}\left(\Pr_{\mathbf{x}'\sim\psi}[\mathbf{x}' \in D] - \Pr_{\mathbf{x}'\sim\mu}[\mathbf{x}' \in D]\right) = 2^{k+1}\left(\frac{1-\eta}{2^k} - \frac{1}{2^{k+1}}\right) = 1 - 2\eta.$$

Similarly if we define $D^-(z)$ by $x_S = z$ and $x_{n+1} = -\chi_S(z)$, then

$$\textsc{Skew}(D^-(z)) = 2^{k+1}\left(\Pr_{\mathbf{x}'\sim\psi}[\mathbf{x}' \in D] - \Pr_{\mathbf{x}'\sim\mu}[\mathbf{x}' \in D]\right) = 2^{k+1}\left(\frac{\eta}{2^k} - \frac{1}{2^{k+1}}\right) = -(1-2\eta).$$

It is easy to verify that if the set of restricted variables is not $S \cup \{n+1\}$, then the skew is 0, which shows that the subcubes above all $(\pm(1-2\eta), 1)$-minimal skewed subcubes. ◀

This shows the hardness of finding subcubes with skew $(1-2\eta) < 1$. The reduction could be extended to show the hardness of finding subcubes with larger skew, simply by concatenating ℓ different samples of ψ. Now an algorithm that finds a subcube of skew $(2(1-\eta))^\ell - 1$ and codimension k can be used to solve a k/ℓ-sparse noisy parity problem.

8 The Membership Query Model

Theorem 2 suggests that a much better algorithm does not exist in the model where we only get random samples from ψ. However, noisy parity becomes trivial when we are given query access to f, by repeatedly querying the function at x and $x \cdot e_i$. This motivates us to consider the query model where in addition to getting random samples from ψ, we are allowed to query $\psi(x)$ for points x of our choosing. As we will see, this does make finding skewed subcubes easier for distributions where $\|\psi\|_\infty$ is small. We first show how this improvement arises, and then give evidence that queries do not add too much power over random samples when $\|\psi\|_\infty$ is large.

Algorithmically, all we need is a procedure to find all large low-degree Fourier coefficients of ψ under the query model. Such a procedure is given by a classic result [14] of Kushilevitz and Mansour, which uses the algorithm of Goldreich and Levin [9] to compute large Fourier coefficients when given a query access to a function.

▶ **Theorem 40** ([9]). *Given query access to $f : \{\pm 1\}^n \to [-t, t]$ and a parameter $\rho > 0$, there is an algorithm running in time poly$(n, t/\rho)$ that with high probability outputs a list containing all subsets S, such that $\widehat{f}(S) \geq \tau$.* [5]

If we apply it to ψ, then we get an algorithm whose running time is poly$(n, \|\psi\|_\infty, \rho)$. Thus, the algorithm is faster than the trivial exhaustive search algorithm only when $\|\psi\|_\infty < n^{\alpha k}$ for some $\alpha > 0$. The polynomial dependence on $\|\psi\|_\infty$ in the running time is inevitable since the algorithm finds all $\widehat{\psi}(S) \geq \rho$, and not just those with $|S| \leq k$. The number of such coefficients can be $\|\psi\|_\infty / \rho^2$. In contrast, when we restrict to $|S| \leq k$, the list-size only grows as $\ln(e\|\psi\|_\infty)^k/\rho^2$. This raises the following natural open question:

[5] The theorem is typically stated for functions with range $\{\pm 1\}$, however a similar bound is true for the range $[-1, 1]$. The version stated here follows by scaling the function by t so it lies in the range $[-1, 1]$, and replacing ρ by ρ/t.

▶ **Problem 4.** *Given query access to a probability measure, ψ such parameter $\rho > 0$, does there exist an algorithm that can find all S such that $|S| \leq k$ and $|\widehat{\psi}(S)| \geq \rho$ in time* $\mathrm{poly}(n, 1/\rho, \ln(\|\psi\|_\infty)^k)$*?*

We conclude by observing that some dependence on $\|\psi\|_\infty$ (at least logarithmic) seems inevitable, even in cases where the list-size is 1. This is seen by a reduction from sparse noisy parity. A sample of size $O(k \log n/\epsilon^2)$ from an instance of noisy parity preserves all correlations of sets of k variables up to an additive ϵ. Define ψ to be the uniform measure of these samples alone. Finding S such that $|S| \leq k+1$ and $\widehat{\psi}(S) \geq 1 - 2\eta$ will solve the noisy parity problem. Note that for ψ the query model and the random samples model are equivalent as we have the support explicitly. So if we believe that sparse noisy parity requires time $n^{\Omega(k)}$ time, then any algorithm for finding large low-degree Fourier coefficients in ψ must require as much time. Since $\|\psi\|_\infty = \epsilon^2 2^n/k \log(n)$, we have $\ln(\|\psi\|_\infty) = n - O(\log(1/\epsilon)$. This is consistent with a dependence of $\ln(\|\psi\|_\infty)^{\Omega(k)}$.

9 Missing Proofs

▶ **Lemma 6.** *Given subcubes C and D such that $D \subseteq C \subseteq \{\pm 1\}^n$, and a density function ψ, it holds that:*

$$\langle \psi, \mu_D \rangle = \langle \psi, \mu_C \rangle \cdot \left\langle \psi|_C, \mu_D|_C \right\rangle$$

Proof. We have

$$\langle \psi, \mu_D \rangle = \langle \psi, \mu_C \rangle \cdot \left\langle \frac{\psi}{\langle \psi, \mu_C \rangle}, \mu_D \right\rangle = \langle \psi, \mu_C \rangle \cdot \left\langle \psi|_C, \mu_D|_C \right\rangle$$ ◀

where the second equality follows from $D \subseteq C$.

▶ **Lemma 8.** *Let $\mathrm{codim}(C) = k$. We have*

$$\begin{aligned}\textsc{Skew}_\psi(C) &= 2^k \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 1 \\ &= \frac{1}{\Pr_{x\sim\mu}[\mathbf{x} \in C]} \left(\Pr_{x\sim\psi}[\mathbf{x} \in C] - \Pr_{x\sim\mu}[\mathbf{x} \in C] \right).\end{aligned}$$

Proof. We have

$$\begin{aligned}\langle \psi, \mu_C \rangle &= \mathop{\mathbb{E}}_{\mathbf{x}\in\mu_C}[\psi(\mathbf{x})] \\ &= \sum_{x\in C} \frac{\psi(x)}{2^{n-k}} \\ &= 2^k \sum_{x\in C} \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} = x] \\ &= 2^k \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C].\end{aligned}$$

Hence

$$\begin{aligned}\langle \psi, \mu_C \rangle - 1 &= 2^k \Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 1 \\ &= \frac{\Pr_{\mathbf{x}\sim\psi}[\mathbf{x} \in C] - 2^{-k}}{2^{-k}}.\end{aligned}$$

Since $\Pr_{\mathbf{x}\sim\mu}[\mathbf{x} \in C] = 2^{-k}$, the claim follows. ◀

▶ **Lemma 10.** *For any $K \subseteq [n]$, we have*

$$\sum_{\substack{D=(K,w)\\ w\in\{\pm1\}^K}} \textsc{Skew}(D) = 0.$$

Proof. Consider the sum:

$$\sum_{\substack{D=(K,w)\\ w\in\{\pm1\}^K}} \textsc{Skew}(D) = \sum_{\substack{D=(K,w)\\ w\in\{\pm1\}^K}} 2^k \left(\Pr_{x\sim\psi}[\mathbf{x}\in D] - \Pr_{x\sim\mu}[\mathbf{x}\in D] \right) = 0.$$

The first equality comes from Lemma 8, the second follows since the set of cubes D form a partition of $\{\pm1\}^n$. ◀

▶ **Lemma 11.** *If $\{C_1,\ldots,C_{2^\ell}\}$ is a partition of C, then*

$$\textsc{Skew}_\psi(C) = \frac{1}{2^\ell}\sum_{i=1}^{2^\ell} \textsc{Skew}_\psi(C_i).$$

Proof. We have

$$\begin{aligned}
\textsc{Skew}_\psi(C) &= 2^k \left(\Pr_{\mathbf{x}\sim\psi}[\mathbf{x}\in C] - \frac{1}{2^k} \right) \\
&= \frac{2^{k+\ell}}{2^\ell} \left(\sum_{i=1}^{2^\ell} \left(\Pr_{\mathbf{x}\sim\psi}[\mathbf{x}\in C_i] - \frac{1}{2^{k+\ell}} \right) \right) \\
&= \frac{1}{2^\ell} \left(\sum_{i=1}^{2^\ell} 2^{k+\ell} \left(\Pr_{\mathbf{x}\sim\psi}[\mathbf{x}\in C_i] - \frac{1}{2^{k+\ell}} \right) \right) \\
&= \frac{1}{2^\ell}\sum_{i=1}^{2^\ell} \textsc{Skew}_\psi(C_i).
\end{aligned}$$

◀

▶ **Corollary 18.** *For $J\subseteq[n]$ and a distribution ψ over $\{\pm1\}^n$,*

$$W^{\le k}(\psi, J) \le 2^{|J|} e^2 (\ln(e\,\|\psi\|_\infty))^k.$$

Proof. Recall that

$$W^{\le k}(\psi, J) = \sum_{T\subseteq J} \sum_{\substack{S\subseteq[n]\setminus J\\ |S|\le k}} \widehat{\psi}(S\cup T)^2$$

We will show that for any $T\subseteq J$, we have

$$\sum_{\substack{S\subseteq[n]\setminus J\\ |S|\le k}} \widehat{\psi}(S\cup T)^2 \le e^2(\ln(e\,\|\psi\|_\infty))^k. \tag{8}$$

The claim will then follow by summing over all $2^{|J|}$ choices of $T\subseteq J$. To prove Equation (8), we define $\psi^{(T)}:\{\pm1\}^{[n]\setminus J}\to\mathbb{R}$ as

$$\psi^{(T)}(x) = \mathop{\mathbb{E}}_{\mathbf{z}\sim\{\pm1\}^J}[\psi(x\circ\mathbf{z})\chi_T(\mathbf{z})].$$

Note that unlike ψ, $\psi^{(T)}$ can be negative. By orthogonality of characters, we have

$$\psi^{(T)}(x) = \sum_{S \subseteq [n] \setminus J} \widehat{\psi}(S \cup T)\chi_S(x).$$

Since $\psi^{(T)}$ is a signed average of ψ which is non-negative, we have $\left\|\psi^T\right\|_\infty \leq \|\psi\|_\infty$ and

$$\begin{aligned}\left\|\psi^T\right\|_1 &= \mathop{\mathbb{E}}_{\mathbf{x} \in \{\pm 1\}^{[n]\setminus J}} \left[\left| \mathop{\mathbb{E}}_{\mathbf{z} \sim \{\pm 1\}^J} [\psi(x \circ \mathbf{z})\chi_T(\mathbf{z})] \right|\right] \\ &\leq \mathop{\mathbb{E}}_{\mathbf{x} \in \{\pm 1\}^{[n]\setminus J}} \left[\left| \mathop{\mathbb{E}}_{\mathbf{z} \sim \{\pm 1\}^J} [|\psi(x \circ \mathbf{z})|] \right|\right] = \mathop{\mathbb{E}}_{\mathbf{x} \in \{\pm 1\}^n} [|\psi(\mathbf{x})|] = 1.\end{aligned}$$

The proof of Theorem 17 only uses bounds on the 1 and ∞ norms of ψ. Hence we can repeat the same proof with $\psi^{(T)}$ to get an identical bound. This proves Equation (8). ◀

▶ **Lemma 19.** *For $P \subseteq [n]$ and a distribution ψ over $\{\pm 1\}^n$, the restriction ψ_P is given by*

$$\psi_P(y) = \sum_{S \subseteq P} \widehat{\psi}(S)\chi_S(y).$$

Proof. Let $|P| = p < n$. For $x \in \{\pm 1\}^P$, we have

$$\psi_P(y) = 2^p \Pr_{\mathbf{x} \sim \psi}[\mathbf{x}_P = y] = \sum_{z \in \{\pm 1\}^{\bar{P}}} \frac{\psi(y \circ z)}{2^{n-p}} = \mathop{\mathbb{E}}_{\mathbf{z} \sim \mu_{\bar{P}}} [\psi(y \circ \mathbf{z})].$$

where the last expectation is over the bits $\mathbf{z}$ assigned to $\bar{P}$ being chosen uniformly at random. Using the Fourier expansion of ψ,

$$\mathop{\mathbb{E}}_{\mathbf{z} \sim \mu_{\bar{P}}} [\psi(y \circ \mathbf{z})] = \sum_{S \subseteq [n]} \widehat{\psi}(S) \mathop{\mathbb{E}}_{\mathbf{z} \sim \mu_{\bar{P}}} \chi_S(y \circ \mathbf{z}) = \sum_{S \subseteq P} \widehat{\psi}(S)\chi_S(y).$$ ◀

▶ **Lemma 20.** *Let $P \subsetneq [n]$. Let ψ' be a distribution on $\{\pm 1\}^P$. Define a distribution ψ on $\{\pm 1\}^n$ by $\psi(x) = \psi'(x_P)$. Then*

1. *ψ is the product distribution of ψ' with the uniform distribution on $\{\pm 1\}^{\bar{P}}$.*
2. *$\|\psi\|_\infty = \|\psi'\|_\infty$.*
3. *C is a minimal skewed subcube under ψ iff it is a minimal skewed subcube under ψ'.*

Proof. It follows that ψ is a distribution since it is non-negative and $\|\psi\|_1 = 1$. Since the uniform distribution on $\{\pm 1\}^{(\bar{P})}$ is given by $\mu_{\bar{P}}(y) = 1$ for all $y \in \{\pm 1\}^{\bar{P}}$, it follows that $\psi = \psi' \times \mu_{\bar{P}}$ is the product of ψ' and $\mu_{\bar{P}}$.

Claim (2) follows trivially from the definition of ψ.

For claim (3), we show that if $C = (K, y)$ is a minimal skewed subcube under ψ, then $K \subseteq P$. Indeed, suppose $i \in K \setminus P$. Consider the parent subcube $D \supsetneq C$ obtained by *freeing* the coordinate i. Then $\Pr_{\mathbf{x} \in \psi}[\mathbf{x} \in C] = \Pr_{\mathbf{x} \in \psi}[\mathbf{x} \in D]/2$, whereas $\operatorname{codim}(C) = \operatorname{codim}(D) + 1$, hence

$$\textsc{Skew}_\psi(C) = 2^{\operatorname{codim}(C)} \Pr_{\mathbf{x} \in \psi}[\mathbf{x} \in C] - 1 = \textsc{Skew}_\psi(D).$$

This violates the definition of minimality. In the other direction, it is easy to see that a minimal skewed subcube under ψ' is also a minimal skewed subcube under ψ. ◀

▶ **Lemma 21.** *Let $C = (J, z)$. Then*

$$\psi|_C(x) = \sum_{S \subseteq [n] \setminus J} \chi_S(x) \frac{\sum_{T \subseteq J} \widehat{\psi}(S \cup T)\chi_T(z)}{\langle \psi, \mu_C \rangle}.$$

Proof. Recall that $\psi|_C(x) = \psi(x)/\langle \psi, \mu_C \rangle$ for $x \in C$. For $x \in \{\pm 1\}^{[n]\setminus J}$ let $x \circ z$ denote the string obtained by setting coordinates in J to z and those in $[n] \setminus J$ to x. Then

$$\begin{aligned}
\psi|_C(x) &= \frac{\psi(x \circ z)}{\langle \psi, \mu_C \rangle} \\
&= \frac{1}{\langle \psi, \mu_C \rangle} \sum_{S \subset [n]\setminus J} \sum_{T \subset J} \chi_{S \cup T}(x \circ z)\widehat{\psi}(S \cup T) \\
&= \frac{1}{\langle \psi, \mu_C \rangle} \sum_{S \subset [n]\setminus J} \sum_{T \subset J} \chi_S(x)\chi_T(z)\widehat{\psi}(S \cup T) \\
&= \sum_{S \subset [n]\setminus J} \chi_S(x) \frac{\sum_{T \subset J} \chi_T(z)\widehat{\psi}(S \cup T)}{\langle \psi, \mu_C \rangle}
\end{aligned}$$

◀

▶ **Lemma 32** ([19]). *Let $d \geq 2$ be even and let $n + 1 = 2^l \geq d$. There exists a $\mathbb{F}_2$-linear code $\mathcal{C}_{BCH} \subseteq \{0,1\}^n$ with minimum distance d, which contains $\Omega(n^{d/2+1})$ minimum weight codewords.*

Proof. Let $d = 2e + 2$ for $e \geq 0$. We use the fact that BCH codes are $[n, n - el - 1, 2e + 2)]$ codes [2, Theorem 16.21]. We need to show that there are many minimum weight codewords. For this, let us consider the parity check matrix H which has dimension $(el + 1) \times n$ so that $\mathcal{C}_{BCH} = \{x \in \mathbb{F}_2^n : Hx = 0\}$.

Now let us consider the mapping $x \to Hx$ for all $x : \mathrm{wt}(x) = e + 1$. This maps each x to a vector $y \in \{0,1\}^{el+1}$. For each $y \in \{0,1\}^{el+1}$, let $b_y = |\{x : \mathrm{wt}(x) = e + 1, Hx = 0\}|$ be the number of vectors of weight $e + 1$ mapped to y. Then we have $\sum_y b_y = \binom{n}{e+1}$, hence

$$\sum_y b_y^2 \geq \frac{\left(\sum_y b_y\right)^2}{2^{el+1}} = \frac{\binom{n}{e+1}^2}{2(n+1)^e}.$$

For $x_1 \neq x_2$ both of weight $e + 1$, if $Hx_1 = Hx_2$ then $H(x_1 + x_2) = 0$, hence $x_1 + x_2$ is a non-zero codeword of weight at most $2e + 2$, hence it is in fact a minimum weight codeword. Since there are $\binom{2e+2}{e+1} < 2^{2e+2}$ ways to write each vector of weight $2e + 2$ as such as sum, hence the number of vectors of codewords of weight $2e + 2$ is at least

$$\frac{1}{2^{2e+2}} \sum_y \binom{b_y}{2} = \frac{1}{2^{2e+3}} \sum_y (b_y^2 - b_y) \geq \frac{1}{2^{2e+3}} \left(\frac{\binom{n}{e+1}^2}{2(n+1)^e} - \binom{n}{e+1} \right) = \Omega_e(n^{e+2}).$$ ◀

▶ **Theorem 34** (Algorithm for Positive Skew). *Given sample access to a distribution ψ on $\{\pm 1\}^n$, integer $k \leq n$, and parameters $\gamma \in (0, 2^k - 1]$, $\epsilon \in (0, 1]$ and $\lambda \in [0, 1]$, there is an algorithm that returns all (γ, ϵ)-minimal skewed subcubes of codimension at most k in time:*

$$\tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + k^{O(k)} \cdot (\ln(e \|\psi\|_\infty))^k \left(\frac{\tilde{O}(n^{k/3})}{(\epsilon\sqrt{\gamma})^{4/\lambda}} + \frac{\mathrm{poly}(n)}{(\epsilon\sqrt{\gamma})^{2k}} \right)$$

where ω is the matrix multiplication exponent, and $\tilde{O}$ hides $\mathrm{poly}\log n$ *factors.*

▶ **Theorem 35** (Algorithm for Negative Skew). *Given sample access to a distribution ψ on $\{\pm 1\}^n$, integer $k \leq n$, and parameters $\gamma \in (0,1]$, $\epsilon \in (0,1]$ and $\lambda \in [0,1]$, there is an algorithm that returns all $(-\gamma,\epsilon)$-minimal skewed subcubes of codimension at most k in time:*

$$\tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + k^{O(k)} \cdot (\ln(e\,\|\psi\|_\infty))^k \left(\frac{\tilde{O}(n^{k/3})}{(\epsilon\gamma)^{4/\lambda}} + \frac{\mathrm{poly}(n)}{(\epsilon\gamma)^{2k}}\right)$$

where ω is the matrix multiplication exponent, and $\tilde{O}$ hides $\mathrm{poly}\log n$ *factors.*

The algorithm is FindSkew$^+(\emptyset,\emptyset)$ in the positive case and FindSkew$^-(\emptyset,\emptyset)$ in the negative case with the nondeterminism replaced. In the positive case, one could replace the enumeration of Fourier coefficients (this is Line 6 in Algorithm 1 and Line 4 in Algorithm 2) by a call to FindFourierCoefficients. However this would naively yield a running time bound of $O(n^{0.8k}) \cdot k^{O(k)} \left(\ln(e\,\|\psi\|_\infty/\epsilon\gamma)\right)^k/(\epsilon\gamma)^{2k+O(1)}$. We show the stronger bound claimed in the theorem by making the following modification. Instead of running FindFourierCoefficients at every recursive call, we run it once at the top level to get the list L of heavy coefficients for ψ, and "deduce" the heavy Fourier coefficients for each restricted distribution $\psi|_C$ from the original list L. To do so efficiently, we require a data structure which we now explain.

We preprocess L by creating a graph G_L. Vertices of this graph are indexed by elements of the power set $2^{[n]}$. For each coefficient $S \in L$, and each subset $T \subset S$, add the directed edge $T \to S$. Furthermore, each T stores k lists, where the i^{th} list contains all sets S in the out-neighborhood of T such that $|S \backslash T| = i$. Since $2^k|L|$ is a bound on both the total number of edges and the total number of vertices in the graph, creating the graph takes $O(2^k|L|)$ time. Creating the partitions of the out-neighborhoods also takes $O(2^k|L|)$ times since each edge in the graph need only be processed once.

We summarize the algorithm below for reference.

Algorithm 4 PreprocessCoefficients(L).

```
V, E ← ∅
for S ∈ L do
    for T ⊆ S do
        V ← V ∪ {S, T}
        E ← E ∪ {(T → S)}
for edge (T → S) ∈ E do
    Let i = |S\T|, and add S to the i^th list stored at T.
return G_L = (V, E)
```

Next, given G_L the preprocessed form of L, a target subcube $C = (J, z)$ and a threshold τ, we show how to output all Fourier coefficients $\widehat{\psi|_C}(S)$ such that $\widehat{\psi|_C}(S) \geq \tau$.

▶ **Lemma 41.** *Let $L = \{S \subseteq [n] : |S| \leq k, |\widehat{\psi}(S)| \geq \tau/4^k\}$, and G_L be the output of* Preprocess(L). *Then* DeduceSubcubeCoefficients(G_L, C, τ) *returns the list of Fourier coefficients of $\psi|_C$ of degree at most k and magnitude at least τ. Furthermore,* DeduceSubcubeCoefficients(G_L, C, τ) *runs in time*

$$\mathrm{poly}(n) \cdot O(|L'|) \leq \mathrm{poly}(n) \cdot 2^{O(k)} \cdot \frac{(\ln(e\,\|\psi\|_\infty))^{k-|J|}}{\tau^2}.$$

Algorithm 5 DeduceSubcubeCoefficients(G_L, C, τ).

1: Let J be the coordinates fixed by C.
2: $L' \leftarrow \emptyset$
3: **for** $T \subseteq J$ **do**
4: | **for** S out-neighbor of T in G_L with $|S \backslash T| \leq k - |J|$ **do**
5: | | Check by sampling if $\left|\widehat{\psi|_C}(S \backslash J)\right| \geq 3\tau/4$ to accuracy $\tau/4$. If so, add $S \backslash J$ to L'.
6: **return** L'.

Proof. The output L' consists only of sets S' such that $S' \cup J \in L$, $S' \cap J = \emptyset$ and $|S'| \leq k - |J|$. Furthermore it contains all S' meeting these criteria such that $\left|\widehat{\psi|_C}(S')\right| \geq \tau$, note that for any set $H \in L$ such that $|H| \leq k$, if T is chosen to be $H \cap J$, then $|H \backslash J| = |H \backslash T| \leq k - |J|$ and thus the algorithm will add $H \backslash J$ to the output.

To obtain the claim of the lemma, we need to argue that for every Fourier coefficient $\widehat{\psi|_C}(S)$ of absolute value at least τ, the set S must appear in L'. We need the following consequence of Lemma 21: let ψ be a distribution on $\{\pm 1\}^n$ and let $C = (J, z)$ be a subcube. Then

$$\widehat{\psi|_C}(S) = \sum_{T \subseteq J} \frac{\chi_T(z)\widehat{\psi}(S \cup T)}{\langle \psi, \mu_C \rangle}.$$

It follows that every coefficient $\widehat{\psi|_C}(S)$ is the signed sum of at most 2^k coefficients $\widehat{\psi}(R) = \widehat{\psi}(S \cup T)$, which is then scaled by $1/\langle \psi, \mu_C \rangle$ (at most 2^k). Furthermore, if $|S| \leq k - |J|$, then each such coefficient has $|R| \leq |S| + |T| \leq k$. Thus if $\widehat{\psi|_C}(S) \geq \tau$, there is at least one $R \subseteq J$ with $|R| \leq k$ such that $|\widehat{\psi}(R)| \geq \tau/4^k$, which means that $R \in L$.

Finally, the running time claim follows from Corollary 18 and the fact that for every $S \in L$ we have $\widehat{\psi}(S) \geq \tau/4^k$. ◀

We are now ready to prove our main theorem. We start with the positive case.

Proof of Theorem 34. We start by running FindFourierCoefficients$(\psi, k, \rho^+, \lambda)$ once, with $\rho^+ = \epsilon\sqrt{\gamma}/16^k$. This outputs a list L^+ containing all S where $|S| \leq k$ and $\widehat{\psi}(S) \geq \epsilon\sqrt{\gamma}/4^k$. Subsequently, we compute $G_{L^+} \leftarrow$ PreprocessCoefficients(L^+) using the output. This set up phase has running time R^+ bounded by

$$R^+ \leq \tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + \frac{k^{O(k)}\tilde{O}\left(n^{k/3}\right)\ln(e\,\|\psi\|_\infty)^k}{(\epsilon\sqrt{\gamma})^{4/\lambda}}.$$

Next we run FindSkew$^+(\emptyset, \emptyset)$ but we replace the nondeterministic enumeration of Fourier coefficients (this is Line 6 in Algorithm 1) by DeduceSubcubeCoefficients(G_{L^+}, C, τ^+) where $\tau^+ := \epsilon\sqrt{\gamma}/\left(k_t \cdot \binom{k_t}{|S_t|}\right)$. We also replace the nondeterministic choice of z (Line 7 in Algorithm 1) by simple enumeration over all possible choices. Correctness follows from Lemma 24 together with Lemmas 39 and 41 and it remains to show the running time bound.

By Lemma 41, at every subcube C the algorithm spends time at most

$$\mathrm{poly}(n) \cdot 2^{O(k)} \cdot \frac{(\ln(e\,\|\psi\|_\infty))^{k-|J|}}{(\tau^+)^2} = \mathrm{poly}(n) \cdot 2^{O(k)} \cdot \frac{(\ln(e\,\|\psi\|_\infty))^{k-|J|}}{(\epsilon\sqrt{\gamma})^2}$$

to run DeduceSubcubeCoefficients.

On the other hand, the proof of Lemma 26 requires that the branching factor of FindSkew$^+$ be bounded as in Lemma 25. Since this bound is at least $(\ln(e\,\|\psi\|_\infty))^{k-|J|}/(\epsilon\sqrt{\gamma})$ (and we may assume WLOG that the branching factor is *at least* this threshold), we may amortize the cost of each call to DeduceSubcubeCoefficients by charging to each child call the average running time per child. The time spent per child is $\mathrm{poly}(n)\cdot 2^{O(k)}$, and we argued in Lemma 26 that the total number of recursive calls to FindSkew$^+$ is at most

$$k^{O(k)}\left(\frac{\ln(e\,\|\psi\|_\infty)}{\epsilon^2\gamma}\right)^k.$$

Thus we may bound the running time of FindSkew$^+(\emptyset,\emptyset)$ by this expression as well.

To conclude, the final running time of the algorithm in the positive skew case is:

$$\begin{aligned}
&R^+ + \mathrm{poly}(n,k^k)\cdot k^{O(k)}\left(\frac{\ln(e\,\|\psi\|_\infty)}{\epsilon^2\gamma}\right)^k\\
&\le \tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + \frac{k^{O(k)}\tilde{O}\left(n^{k/3}\right)\ln(e\,\|\psi\|_\infty)^k}{(\epsilon\sqrt{\gamma})^{4/\lambda}} + \mathrm{poly}(n,k^k)\cdot k^{O(k)}\left(\frac{\ln(e\,\|\psi\|_\infty)}{\epsilon^2\gamma}\right)^k\\
&\le \tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + k^{O(k)}\cdot(\ln(e\,\|\psi\|_\infty))^k\left(\frac{\tilde{O}\left(n^{k/3}\right)}{(\epsilon\sqrt{\gamma})^{4/\lambda}} + \frac{\mathrm{poly}(n)}{(\epsilon\sqrt{\gamma})^{2k}}\right).
\end{aligned}$$

◀

The negative case is identical, but with a different setting of parameters.

Proof of Theorem 35. In this case we run FindFourierCoefficients(ψ,k,ρ^-,λ) with $\rho^- = \epsilon\gamma/16^k$. This outputs the list L^-, and we set $G_{L^-} \leftarrow$ PreprocessCoefficients(L^-). This all has running time R^- bounded by

$$R^- \le \tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + \frac{k^{O(k)}\tilde{O}\left(n^{k/3}\right)\ln(e\,\|\psi\|_\infty)^k}{(\epsilon\gamma)^{4/\lambda}}.$$

Now we run FindSkew$^-(\emptyset,\emptyset)$, with Fourier coefficient enumeration (Algorithm 2 in Algorithm 2) replaced with DeduceSubcubeCoefficients(G_{L^-},C,τ^-), and we set $\tau^- = \epsilon\gamma/\left(k_t\cdot\binom{k_t}{|S_t|}\right)$. The analysis is identical to the positive case, and the final running time is:

$$\tilde{O}\left(n^{k\left(\frac{\omega}{3-\lambda}\right)}\right) + k^{O(k)}\cdot(\ln(e\,\|\psi\|_\infty))^k\left(\frac{\tilde{O}\left(n^{k/3}\right)}{(\epsilon\gamma)^{4/\lambda}} + \frac{\mathrm{poly}(n)}{(\epsilon\gamma)^{2k}}\right).$$

Abstract

A code is called a *q-query locally decodable code* (LDC) if there is a randomized decoding algorithm that, given an index i and a received word w close to an encoding of a message x, outputs x_i by querying only at most q coordinates of w. Understanding the tradeoffs between the dimension, length and query complexity of LDCs is a fascinating and unresolved research challenge. In particular, for 3-query binary LDC's of dimension k and length n, the best known bounds are: $2^{k^{o(1)}} \geq n \geq \tilde{\Omega}(k^2)$.

In this work, we take a second look at binary 3-query LDCs. We investigate a class of 3-uniform hypergraphs that are equivalent to *strong* binary 3-query LDCs. We prove an upper bound on the number of edges in these hypergraphs, reproducing the known lower bound of $\tilde{\Omega}(k^2)$ for the length of strong 3-query LDCs. In contrast to previous work, our techniques are purely combinatorial and do not rely on a direct reduction to 2-query LDCs, opening up a potentially different approach to analyzing 3-query LDCs.

1 Introduction

A code $\mathcal{C}$ is said to be a *q-query locally decodable code (LDC)* if it is possible to recover any symbol x_i of a message x by querying $\mathcal{C}(x)$ on at most q locations, such that even if a constant fraction of $\mathcal{C}(x)$ is corrupted, the decoder returns x_i with high probability. LDCs already appeared in the PCP literature (e.g., implicitly in [1]) but they were first explicitly formulated by Katz and Trevisan in [10]. LDCs have attracted attention not only because of their immediate relevance to data transmission and data storage but also because of their surprising connections to complexity theory and cryptography ([3, 13, 8, 11]). In more recent years, the analysis of LDCs has led to a greater understanding of basic problems in incidence geometry, the construction of design matrices and the theory of matrix scaling, e.g. [2, 7, 6].

Although LDCs have been studied now for two decades, some basic questions remain stubbornly open. In particular, we have the following open question for 3-query LDCs:

▶ **Open Question 1.** *What is the length of the shortest* 3*-query LDC that can encode all* k*-bit binary messages?*

A wild variety of techniques have been used to study the problem. For a while, it was believed that the length n should be exponential in k for 3-query LDCs (indeed, for any constant number of queries). This belief was shattered by a breakthrough work of Yekhanin that designed 3-query LDCs of length subexponential in k (conditional on some number-theoretic conjectures). Subsequent work ([9, 5] reformulated the construction in terms of *matching vector codes* and established an unconditional upper bound of $\exp\left(\exp(O(\sqrt{\log k \log\log k}))\right) = \exp(k^{o(1)})$ on the length.

As for lower bounds on the length of 3-query LDCs, which is the focus of this work, Katz and Trevisan [10] first gave a super linear lower bound of $\Omega(k^{3/2})$, which was then improved to $\Omega\left(k^2/(\log k)^2\right)$ by Kerenedis and de Wolf [12] using quantum information theoretic techniques. The current state-of-the-art is due to Woodruff [14] from over a decade ago where he showed that $n \geq \Omega(k^2/\log k)$.

Given the state of affairs, it is natural to try to prove lower bounds for stronger variants[1] of LDCs where the task should be easier. In this work, we study a restricted form of LDCs which seem to capture most of the challenges associated with general LDCs.

▶ **Definition 2.** *For a given $\delta \in (0,1)$, a code $\mathcal{C} : \{\pm 1\}^k \to \{\pm 1\}^n$ is a* $(3,\delta)$-strong LDC *if for every $i \in [k]$, there exists a set M_i of $\geq \delta n$ disjoint triples in $\binom{[n]}{3}$ such that for every $x \in \{\pm 1\}^k$ and for every triple $(j_1, j_2, j_3) \in M_i$, $x_i = \mathcal{C}(x)_{j_1} \cdot \mathcal{C}(x)_{j_2} \cdot \mathcal{C}(x)_{j_3}$. Moreover, if $i \neq i'$, a triple in M_i intersects a triple in $M_{i'}$ in at most 1 coordinate.*

Known constructions of 3-query LDCs are strong. Conceptually, the main[2] restriction that the above definition makes is that each triple in the matching M_i successfully decodes x_i for *every* x. On the other hand, Katz and Trevisan [10] show that general LDCs yield matchings $M_1, \ldots, M_k$ such that each triple in the matching M_i sucessfully decodes x_i for most (not all) x's.

We show a combinatorial proof of the known $\Omega(k^2/\log k)$ lower bound for the length of code words of 3-query strong LDCs. Here is the main theorem stating the lower bound.

▶ **Theorem 3.** *Let $C : \{\pm 1\}^k \mapsto \{\pm 1\}^n$ be a $(3,\delta)$-strong LDC. Then, $n \geq \Omega_\delta(k^2/\log k)$.*

1.1 Proof Overview

As we already noted, Theorem 3 follows from [14]. Of more interest is our proof technique. Woodruff's lower bound reduces 3-query LDCs to 2-query LDCs and applies known analytic proofs giving tight bounds for 2-query LDCs [12]. On the other hand, our proof is purely combinatorial and does not seem to be a reduction to 2 queries.

Our starting point is the observation that strong 3-query LDCs are equivalent to *even-colored 3-uniform hypergraphs*. A 3-uniform hypergraph is called *linear* if any two edges intersect in at most one vertex.

▶ **Definition 4.** *An* (n,k,δ)-even-colored 3-uniform hypergraph *is a linear edge-colored hypergraph H on n vertices with each edge having a color in $\{1,\ldots,k\}$ such that:*

- **(i)** *For each $i \in [k]$, the edges of color i form a matching of size at least δn, and*
- **(ii)** *If H' is a subgraph of H such that every vertex has even degree in H', then there are an even number of edges of each color in H'.*

[1] For instance, Woodruff in [15] gave an $\Omega(k^2)$ lower bound for the special case of *linear* 3-query LDCs.

[2] The decoding scheme of taking the product (xor) of the codeword bits is without loss of generality (see [14]). The additional condition in Definition 2 about triples in different matchings intersecting only at single coordinates is made for technical convenience and should be avoidable.

Given a $(3, \delta)$-strong LDCs, define the hypergraph H which is the union of the matchings $M_1, \ldots, M_k$ given by Definition 2, and let the color of an edge be the matching it comes from. Then, it is easy to check that both conditions (i) and (ii) are met (see Claim 5). The correspondence naturally goes in the other direction too, although this is not needed in the present work.

We prove an upper bound $k^2 \leq O_\delta(n \log n)$ for (n, k, δ)-even-colored 3-uniform hypergraphs, proving our main theorem. To motivate our proof, let us sketch the corresponding argument for 2-query LDCs (which is also new to the best of our knowledge). Suppose we have a (2-uniform) graph which is the union of k matchings, with edges from the i'th matching having color i. Analogously to condition (ii) of Definition 4, also suppose that any cycle contains an even number of edges of each color. Then, we prove that the number of vertices n is at least $\exp(k)$. For simplicity, suppose the matchings of each color are perfect. Our argument is through coding (ironically!). Fix an arbitrary vertex s. For any vertex $v \neq s$, let its *signature* $S(v)$ be defined as $(n_1, \ldots, n_k)$ where n_i is the parity of the number of edges of color i on a path P from s to v. We claim that $S(v)$ does not depend on the path chosen. This is because if two paths from s to v gave different signatures, this would yield a cycle in which some color occurred an odd number of times. On the other hand, there are at least 2^k different signatures because for any signature $(s_1, \ldots, s_k) \in \{0, 1\}^k$, there is a path from s with exactly s_i edges of color i (since the matchings are perfect). Hence, the number of vertices is at least $\exp(k)$.

Our proof for 3-uniform hypergraphs is in a similar spirit. Instead of a path to define a signature, we use a sequence of *cherries*, borrowing an idea from [4]. A cherry is a pair of hyperedges which uniquely intersect at a hyperedge; see Figure 1. We observe that if the number of edges is sufficiently large, then there are many cherries. We then use this structure to show that there are even subgraphs (i.e., subgraphs in which all vertices have even degrees) which have an odd number of edges of some color. Namely, we construct a "cycle of cherries" in which we know there is a color that appears on a unique edge, yielding the contradiction. More details follow.

Formally, given an (n, k, δ)-even colored hypergraph H which is a union of matchings $M_1, \ldots, M_k$, define the *signature graph* $G = (V', E')$ as follows. The vertex set $V' = V \times V$, and there is an edge in G between the vertices (u_1, v_1) and $(u_2, v_2) \in V'$ whenever there exists a $w \in V$ such that $\{u_1, u_2, w\}$ and $\{v_1, v_2, w\}$ are hyperedges forming a cherry in H. Moreover, such an edge is labeled by the pair of colors $\{i_1, i_2\}$ if $\{u_1, u_2, w\} \in M_{i_1}$ and $\{v_1, v_2, w\} \in M_{i_2}$. The signature graph enjoys the following useful structural property:

> For any vertex x in G and for any color $i \in [k]$, there are at most 4 edges incident to x that have i in their label. $(\star)$

The proof of $(\star)$ follows from the definition of G in terms of cherries (see Claim 8) .

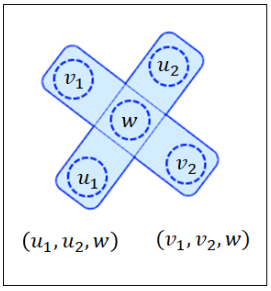

Figure 1 A cherry formed from the edges $\{u_1, w, u_2\}$ and $\{v_1, w, v_2\}$ intersecting at w.

For the sake of contradiction, assume that $k \geq \sqrt{Cn \log n}$ for some large constant C. This, along with a standard averaging argument, implies that there exists a large subgraph G' of the signature graph with minimum degree at least $k^2 n/4n^2 \geq (C/4)\log n$. Now fixing an arbitrary vertex $r \in V(G')$ as root, we iteratively grow a sequence of trees $T_1, T_2, \ldots, T_{\ell+1}$ using edges in G', while maintaining the following *rainbow* condition: For any vertex $x \in V(T_i)$, no color appears more than once among the colors labeling the unique path from r to x in T_i.

We explain how to construct T_{i+1} from T_i so that the above rainbow condition is met. Let L_i denote the leaves of the tree T_i, and let N_i denote the neighbors y of vertices $x \in L_i$ so that the colors labeling the edge (x, y) do not occur on the path from the root r to x in T_i. A short argument (Claim 9) allows us to deduce that N_i must be disjoint from $V(T_i)$, because otherwise, condition (ii) of Definition 4 is violated. Hence, the next tree T_{i+1} can be built by letting $L_{i+1} = N_i$ and adding one edge from each vertex in L_{i+1} to a vertex in L_i.

We continue this process until $|L_\ell| < 2|L_{\ell-1}|$ for some iteration ℓ. We now sketch how to arrive at a contradiction. From the stopping criteria, we know that for every $i < \ell - 1$ we have $|L_{i+1}| \geq 2|L_i| \geq 2^{i+1}$, and therefore the depth of the tree is at most $\ell = O(\log n)$. Therefore, for any $x \in L_{\ell-1}$, the number of colors labeling the path from r to x is at most $O(\log n)$. From property $(\star)$, we get that there are at least $(C/4)\log n - O(\log n) = C' \log n$ neighbors of x that are in L_ℓ (for some other constant C'). Since $|L_\ell| < 2|L_{\ell-1}|$, there exists a vertex $w \in L_\ell$ with at least $(C'/2)\log n$ neighbors in $L_{\ell-1}$. Again, invoking property $(\star)$, for C' large enough, there will be a neighbor $w' \in L_{\ell-1}$ such that that the colors labeling (w, w') do not appear among the $O(\log n)$ labels of the path from r to w. From here, we can conclude that the unique path between w and w' in T_ℓ along with the edge (w, w') forms a cycle in G in which some color appears exactly once. This structure corresponds to a subgraph in H that violates condition (ii) of Definition 4.

In the rest of the paper, we present the argument formally with all the details. It is unclear currently how to extend the analysis to q-query LDCs or how to improve the analysis for 3-query LDCs. But we remain hopeful that by looking at more intricate combinatorial structures than cherries, we can make some progress.

2 Preliminaries

In this section and later, we do not invoke the notion of even-colored subgraphs, and we define objects directly in reference to strong 3-query LDCs.

Given a $(3, \gamma)$-strong LDC, we define the *recovery hypergraph* H, where $V(H) = [n]$ and $E(H) := \cup_{i \in [k]} M_i$ to be the 3-uniform hypergraph which is the union of matchings $M_1, M_2, \ldots, M_k$. For any edge $e \in E(H)$, we say that the color of the hyperedge e is i if e belongs to matching M_i. We use the notation $\mathsf{col}(e)$ to denote the color of the hyperedge e. We additionally assume that H is linear, i.e. no two hyperedges of H intersect in more than one element.

Let L be a hypergraph. Then we define an *augmentation* L' of L as follows: $V(L') = V(L)$ and $E(L')$ is a multiset where each member $e \in E(L')$ also belongs to $E(L)$ but can possibly have a higher multiplicity than the multiplicity of e in $E(L)$. With respect to a hypergraph L where a hyperedge e is allowed to have multiplicity greater than 1, we denote by $\mathsf{mult}_L(e)$ the multiplicity of e in $E(L)$. We may drop the subscript L, if the hypergraph under consideration is clear from the context. Also for $v \in V(L), \deg_L(v) := \sum_{e \in E(L): v \in e} \mathsf{mult}_L(e)$. If for all $v \in V(L), \deg_L(v)$ is even, then L is called an *even hypergraph*. We use $\mathsf{col}(L)$ to denote the multiset of colors associated with edges in $E(L)$.

If L is an augmentation of the recovery hypergraph H, for $1 \leq i \leq k$, we define

$$\lambda_L(i) := \sum_{e \in E(L): \mathsf{col}(e) = i} \mathsf{mult}_L(e).$$

▷ Claim 5. Let L be an augmentation of the recovery hypergraph H. If L is even, then for $1 \leq i \leq k$, $\lambda_L(i)$ is even.

Proof. Suppose for contradiction that there exists i, $1 \leq i \leq k$ such that $\lambda_L(i)$ is odd. Recall that the indices of the code word bits correspond to the vertices of the recovery hypergraph. Let us assume that $y = (y_1, y_2, \ldots, y_n)$ is the code word of a message $(x_1, x_2, \ldots, x_k)$, where $x_i = -1$ and $x_j = 1$ for $j \neq i$. For an edge $e = \{a, b, c\}$ of the recovery hypergraph, $Y^e = y_a.y_b.y_c$. Now it is clear that $\prod_{e \in E(L)} Y^e = 1$, since L is an even augmentation of H.

On the other hand, by definition of the recovery hypergraph, if $\mathsf{col}(e) = t$, then $Y^e = x_t$ for $1 \leq t \leq k$. Therefore $\prod_{e \in E(L)} Y^e = \prod_{1 \leq t \leq k} x_t^{\lambda_L(t)}$. Clearly since for the selected message $x_j = 1$ for $j \neq i$, we infer that $\prod_{e \in E(L)} Y^e = x_i^{\lambda_L(i)} = -1$, if $\lambda_L(i)$ is odd. This is a contradiction. We conclude that for $1 \leq i \leq k$, $\lambda_L(i)$ is even. ◁

The Signature Graph

We define a graph called the *signature graph* G as follows: $V(G) = \{(u, v) : u, v \in V(H); u \neq v\}$ and an edge exists between two vertices (u_1, v_1) and (u_2, v_2) of G if and only if $\{u_1, v_1\} \cap \{u_2, v_2\} = \emptyset$ and there exists a vertex $w \in V(H)$ such that $\{u_1, u_2, w\}, \{v_1, v_2, w\} \in E(H)$. Note that since the recovery hypergraph H is linear, if there exists an edge between two vertices (u_1, v_1) and (u_2, v_2), there is a unique vertex w such that $\{u_1, u_2, w\}, \{v_1, v_2, w\} \in E(H)$. We may say that the vertex w *causes* the edge $((u_1, v_1), (u_2, v_2))$. Given an edge $e \in E(G)$, we define $T(e) = (\{u_1, u_2, w\}, \{v_1, v_2, w\})$ if w causes the edge e. We may abuse the notation and use $T(e)$ to denote the corresponding unordered set. We define $\mathsf{col}(e) = \{i_1, i_2\}$ if $(u_1, u_2, w) \in M_{i_1}$ and $(v_1, v_2, w) \in M_{i_2}$. Note that $i_1 \neq i_2$ since w cannot be in two different edges of the same matching.

▷ Claim 6. The number of edges in the signature graph G is at least $12\gamma^2 nk^2$.

Proof. Since each matching is of size at least γn, the number of hyperedges m in H is at least γnk. It follows that $\sum_{v \in V(H)} \deg(v) = 3m \geq 3\gamma nk$. For any vertex $w \in V(H)$ consider a pair of incident edges, say $\{u_1, u_2, w\}$ and $\{v_1, v_2, w\}$. Since H is linear, $\{u_1, u_2\} \cap \{v_1, v_2\} = \emptyset$. It is easy to see that based on this pair of incident edges, w can *cause* 4 distinct edges of the signature graph G. Therefore the vertex w *causes* $4\binom{d(v)}{2}$ distinct edges of G, where $d(v) = \deg(v)$. As we have mentioned earlier, two different vertices w and w' cannot cause the same edge in G. Therefore $|E(G)| \geq 4\sum_{v \in V(H)} \binom{d(v)}{2} = 2\sum_{v \in V(H)} (d(v)^2 - d(v))$. Recall that $\sum_{v \in V(H)} d(v) = 3m$. Using Cauchy-Schwarz inequality, [3] we get $\sum_{v \in V(H)} (d(v)^2) \geq \frac{9m^2}{n}$. It follows that $|E(G)| \geq \frac{6m}{n}(3m - n) \geq \frac{12m^2}{n} \geq 12\gamma^2 nk^2$. Here we have used $m \geq \gamma nk$ and $m \geq n$, since $\gamma k \geq 1$. ◁

For a subgraph J of the signature graph G, we define H_J to be the augmentation of H, with $V(H_J) = V(H)$ and $E(H_J) = \cup_{e \in E(J)} T(e)$. Note that when we take the union here, we retain multiple copies of a hyperedge if that hyperedge appears in multiple sets $T(e)$ taking part in the union operation. Thus $E(H_J)$ is by definition a multi-set. We extend some of the notation used for hypergraphs to subgraphs of signature graphs also in the following way: We use $\mathsf{col}(J)$ to denote the multiset $\mathsf{col}(H_J)$. A hypergraph H' is *rainbow colored* with respect to an edge coloring if there exist no two hyperedges having the same color. (In

[3] For vectors X, Y, the Cauchy-Schwarz inequality states that $\|X\| \cdot \|Y\| \geq X^\top Y$. Now take $X = (d(v_1), d(v_2), \ldots, d(v_n))^\top$, where $V(H) = \{v_1, v_2, \ldots, v_n\}$ and $Y = (1, 1, \ldots, 1)^T$ to get the required lower bound.

particular, there will not be any hyperedge with multiplicity greater than 1.) A subgraph J of the signature graph is rainbow colored, if H_J is rainbow colored. We may also say J (or H) is *rainbow*, shortening the phrase *rainbow colored*.

▷ Claim 7. Let J be an even subgraph of the signature graph G, i.e. $\forall v \in V(J)$, $\deg(v)$ is even. Then H_J is an *even* augmentation of H.

Proof. Recall that each edge $e = ((u_1, v_1), (u_2, v_2)) \in E(G)$ corresponds to exactly 2 edges in $E(H_J)$, namely the two edges of $T(e) = \{\{u_1, u_2, w\}, \{v_1, v_2, w\}\}$, where w is the unique vertex which *caused* the edge e. We say that w appears in the role of an intermediate vertex and u_1, v_1, u_2 and v_2 appear in the role of signature vertices in $T(e)$. It is easy to see that since in $T(e)$ itself the $degree(w)$ is even, each vertex plays the role of an intermediate vertex an even number of times. Noting that in $T(e)$ each vertex appears in the role of a signature vertex exactly once, it is easy to see that if $x = (u, v)$ is a vertex of J, then u (also v) plays the role of a signature vertex in $\cup_{e \in E_J(x)} T(e)$ (where $E_J(x)$ denotes the set of edges incident on x in J) exactly $\deg_J(x)$ times. Since $\deg_J(x)$ is even, it follows that $\deg_{H_J}(u)$ and $\deg_{H_J}(v)$ are even numbers. ◁

▷ Claim 8. Let x be a vertex of the signature graph G and let $E(x)$ be the set of edges incident on x in G. Let $\mathcal{C} \subseteq [k]$ be a subset of colors. Let $E(x, \mathcal{C}) = \{e \in E(x) : \mathsf{col}(e) \cap \mathcal{C} \neq \emptyset\}$. Then $|E(x, \mathcal{C})| \leq 4|\mathcal{C}|$.

Proof. Let $x = (u, v)$. For an edge $e \in E(x)$, $T(e)$ contains 2 hyperedges, exactly one of which contains u and the other one contains v: Let us denote by $T(e)_1$ and $T(e)_2$ the hyperedges in $T(e)$ that contain u and v respectively. For $1 \leq i \leq k$, $E(x, \mathcal{C}) = \cup_{i \in \mathcal{C}} E_1^i \cup E_2^i$, where $E_j^i = \{e \in E(x) : \mathsf{col}(T(e)_j) = i\}$ for $j = 1, 2$. First we will show that $|E_1^i| \leq 2$. To see this, note that if $\mathsf{col}(T(e)_1) = i$, then $T(e)_1 \in M_i$ and $T(e)_1$ contains u as mentioned earlier. There is a unique hyperedge with these properties since M_i is a matching. Let $T(e)_1 = (u, a, b)$. Then either a or b could have *caused* the edge e. If a caused the edge e, then $T(e)_2$ contains both v and a, and there is a unique edge in $E(H)$ that is a superset of $\{v, a\}$ since H is linear. Similarly if b caused e, then $T(e)_2$ is uniquely determined, since it should contain both v and b. It follows that $|E_1^i| \leq 2$ for all i, $1 \leq i \leq k$. A similar argument shows that $|E_2^i| \leq 2$. It follows that $|E(x, \mathcal{C})| \leq 4|\mathcal{C}|$. ◁

Now we are ready to prove Theorem 3.

3 Proof of Theorem 3

For contradiction, we shall assume that $k^2 > Cn \log n$ where $C = C(\gamma)$ is a sufficiently large constant. We can then lower bound the average degree of G as follows. From claim 6, we know that $|E(G)| \geq 12\gamma^2 nk^2$. On the other hand, the number of vertices in G is at most n^2. Therefore, for $k^2 \geq Cn \log n$, for C large enough, the average degree of G is at least $(2C') \log n$ so that we can find a subgraph $G' \subseteq G$ with minimum degree at least $C' \log n$, where C' is a sufficiently large constant.

Now we fix a vertex $r \in V(G')$, and we grow a rainbow tree rooted at r in G' level by level as follows. Let T_0 be the tree consisting only of the root r and T_1 be the tree consisting of r and all its neighbors. At the ith stage, we will have a tree T_i where $V(T_i) = \dot{\cup}_{i=0}^{i} L_i$ where L_i is the set of vertices in level i. Note that $V_0 = L_0 = \{r\}$ and T_1 consists of 2 levels, $L_0 = \{r\}$ and $L_1 = N_{G'}(r)$. For two vertices x and y, the unique path in T_i from x to y will be denoted by $P(x, y)$.

Moreover at the ith stage, we will make sure that the tree T_i satisfies the following property:

For any vertex $x \in V(T_i)$, $P(r, x)$ is a rainbow path. (1)

▷ Claim 9. If T_i satisfies property (1), and if $e = (x, y)$ is an edge of G' such that $x \in L_i$ and $y \in L_j$, where $i \geq j$, then $\mathsf{col}(e) \cap \mathsf{col}(P(r, x)) \neq \emptyset$.

Proof. Suppose not. Let z be the least common ancestor of x and y in T_i. Since $P(z, x) \subseteq P(r, x)$ is a rainbow path by property (1), $P(z, x) \cup \{(x, y)\}$ is also rainbow. Since $|P(z, y)| \leq |P(z, x)|$, clearly we have $|\mathsf{col}(P(z, x) \cup \{(x, y)\})| > |\mathsf{col}(P(z, y)|$. It follows that there is at least one matching color, say i in the cycle $C = P(z, x) \cup \{(x, y)\} \cup P(y, z)$, such that $\lambda_{H_C}(i) = 1$. But since C is an even subgraph of G, H_C is an even augmentation of H by Claim 7. Then by Claim 5, $\lambda_{H_C}(i)$ should be an even number, a contradiction. ◁

Now we describe how to construct T_{i+1} from T_i by adding a new level L_{i+1}. For a vertex $x \in L_i$ define $N'(x) = \{y \in N_{G'}(x) : \mathsf{col}(x, y) \cap \mathsf{col}(P(r, x)) = \emptyset\}$. Observe that $N'(x) \cap V(T_i) = \emptyset$: This follows from Claim 9, since if there is an edge in G' from a vertex $x \in L_i$ to a vertex $y \in L_j$, $j \leq i$ then $\mathsf{col}(x, y) \cap \mathsf{col}(P(r, x)) \neq \emptyset$, and therefore $y \notin N'(x)$. Define $L_{i+1} = \cup_{x \in L_i} N'(x)$. Clearly $L_{i+1} \cap V(T_i) = \emptyset$. If $L_{i+1} \neq \emptyset$, define a bipartite graph $B_i = (L_i, L_{i+1})$ such that for $x \in L_i$ and $y \in L_{i+1}$, $(x, y) \in E(B_i)$ if and only if $y \in N'(x)$. Now for each $y \in L_{i+1}$, select one vertex y' from L_i such that $(y, y') \in E(B_i)$ to be its parent thus obtaining the new tree T_{i+1}. From the way we defined $N'(x)$ for $x \in L_i$, it is clear that property (1) is satisfied by T_{i+1}. If $|L_{i+1}| \geq 2|L_i|$, we proceed to add the next level. Otherwise we stop the procedure and define the final tree T to be T_{i+1}.

Let L_ℓ be the last level added to the tree. Clearly $\ell > 2$. We observe that $\ell \leq \log n + 1$. Otherwise $|L_{\ell-1}| \geq 2^{t-1} > n$, since $|L_{i+1}| \geq 2|L_i|$ for $i \leq \ell - 2$. Now consider the bipartite graph $B_{\ell-1}$: For each vertex $x \in L_{\ell-1}$, we know by applying Claim 8 with $\mathcal{C} = \mathsf{col}(P(r, x))$ that $E(x, \mathcal{C}) \leq 4|\mathsf{col}(P(r, x))| \leq 8 \log n$. But $|E_{G'}(x)| = \deg_{G'}(x) \geq C' \log n$ and therefore $|N'(x)| \geq (C' - 8) \log n$. Therefore $B_{\ell-1}$ has at least $|L_{\ell-1}|(C' - 8) \log n$ edges. Since $|L_\ell| < 2|L_{\ell-1}|$, there exists a vertex $w \in L_\ell$ such that its degree in $B_{\ell-1}$ is at least $(C'/2 - 4) \log n$. Again by applying Claim 8, this time with $\mathcal{C} = \mathsf{col}(P(r, w))$, at most $8(\log n + 1)$ of these edges can have a common color with any edge in $P(r, w)$. It follows that if C is taken large enough, w has a neighbor $w' \in L_{\ell-1}$ such that $\mathsf{col}(w, w') \cap \mathsf{col}(P(r, w)) = \emptyset$. This contradicts Claim 9 applied to the tree $T = T_\ell$. The situation is depicted in Figure 2. Thus we infer that $k^2 \leq Cn \log n$, which in turn implies that $n = \Omega\left(\frac{k^2}{\log k}\right)$.

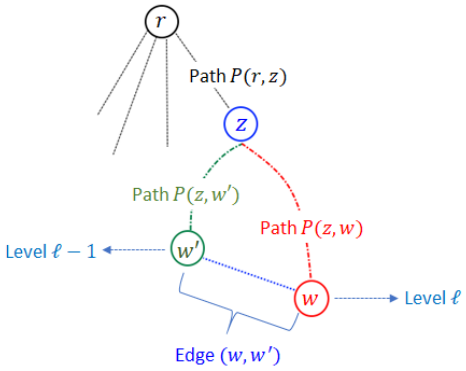

Figure 2 The cycle formed by the concatenation of $P(z, w'), P(z, w)$, and (w, w') corresponds to an even subgraph in H with an odd number of edges having a particular color.

Abstract

Garbling schemes, also known as decomposable randomized encodings (DRE), have found many applications in cryptography. However, despite a large body of work on constructing such schemes, very little is known about their limitations.

We initiate a systematic study of the DRE complexity of Boolean functions, obtaining the following main results:

- **Near-quadratic lower bounds**. We use a classical lower bound technique of Nečiporuk [Dokl. Akad. Nauk SSSR '66] to show an $\Omega(n^2/\log n)$ lower bound on the size of any DRE for many explicit Boolean functions. For some natural functions, we obtain a corresponding upper bound, thus settling their DRE complexity up to polylogarithmic factors. Prior to our work, no superlinear lower bounds were known, even for non-explicit functions.
- **Garbling-friendly PRFs.** We show that any exponentially secure PRF has $\Omega(n^2/\log n)$ DRE size, and present a plausible candidate for a "garbling-optimal" PRF that nearly meets this bound. This candidate establishes a barrier for super-quadratic DRE lower bounds via natural proof techniques. In contrast, we show a candidate for a *weak* PRF with near-exponential security and linear DRE size.

Our results establish several qualitative separations, including near-quadratic separations between computational and information-theoretic DRE size of Boolean functions, and between DRE size of weak vs. strong PRFs.

1 Introduction

Originating from Yao's garbled circuit construction [65], garbling schemes have played an important role in different sub-areas of cryptography. A garbled representation of $f(x)$ is a randomized function $\hat{f}(x;r)$ such that: (1) a sample from the output of $\hat{f}(x;r)$ reveals $f(x)$ and no additional information about x; and (2) each output bit of $\hat{f}$ depends on at most *one* bit of x (but can depend arbitrarily on r); equivalently, each bit of x acts as a selector between two strings that are determined by r. We refer to such a garbled representation $\hat{f}$ for f as a *decomposable randomized encoding* (DRE)[1] of f, and refer to the output length of $\hat{f}$ as its *size*.

Garbling schemes were initially motivated by the goal of efficient secure computation [65, 44, 30, 40]. This still serves as a primary motivation for their study, which has led to many optimized constructions (see, e.g., [12] and references therein).

Over the years, different flavors of garbling schemes have found applications in many other areas of cryptography, including parallel cryptography [8], one-time programs and leakage-resilient cryptography [36], verifiable computation [33, 10], key-dependent message security [13, 5], identity-based encryption [29], and more. See [18, 39, 6] for surveys.

Despite the large body of work on constructing and applying such garbling schemes, very little is known about their *limitations*. Previous relevant works show very limited lower bounds for more liberal notions of garbling. These include either conditional lower bounds that apply to computationally efficient garbling of intractable functions [5, 1] or linear size lower bounds for so-called "2-party PSM protocols" [30, 25, 7].

In this work, we initiate a complexity theoretic study of standard ("DRE-style") garbling schemes, providing *lower bounds* in both *information-theoretic* and *computational settings*.

[1] This notion of garbling roughly corresponds to a *projective garbling scheme* in the terminology of Bellare et al. [18]. We use the DRE terminology when we want to emphasize that we are not interested in the process of "garbling" a given representation of f, but only in the *existence* of a garbled representation $\hat{f}$ with a given complexity.

1.1 Our Contribution

We make two types of contributions: (1) obtaining the first super-linear lower bounds on the DRE size of Boolean functions (with some matching upper bounds), and (2) studying the minimal DRE size of (strong and weak) pseudorandom functions. We now detail both types of results.

1.1.1 Near-quadratic lower bounds and matching upper bounds

We adapt a classical lower bound technique of Nečiporuk [49] to show an $\Omega(n^2/\log n)$ lower bound on the size of any DRE for many explicit Boolean functions $f : \{0,1\}^n \to \{0,1\}$. Nečiporuk showed that functions with many subfunctions cannot have small formulas or branching programs. We provide matching lower bounds on DRE for the same class. In particular, this yields $\Omega(n^2/logn)$ lower bounds on DRE size for almost all functions, including the explicit examples of Element Distinctness, Indirect Storage Access, Clique, Determinant, Matching, and others. These bounds hold in both the information theoretic setting and the exponentially-secure computational setting, provided the DRE admits a sub-exponential decoding algorithm in the latter case.

For the explicit example of Element Distinctness, we obtain a corresponding upper bound, thus settling its DRE complexity up to polylogarithmic factors. Furthermore, since some of the functions that admit nearly quadratic lower bounds on DRE size can be computed by linear-size circuits, our lower bounds establish a near-quadratic gap between the size of computationally secure and information-theoretic DRE in a setting where the input size is polynomially bigger than the computational security parameter. In fact, given that our nearly quadratic lower bounds also apply to computational DREs with security parameter nearly that of the input size, this means, in a concrete sense, that a tradeoff between DRE size and security parameter is inherent!

The only previous lower bounds we are aware of are *linear* lower bounds that also apply to the more liberal 2-party Private Simultaneous Messages (PSM)[2] setting [30, 25, 7] and quadratic lower bounds for *non-Boolean* functions $f : \{0,1\}^n \to \{0,1\}^n$ that follow from the input locality lower bounds of [9]. In contrast to the other classes lower bounded by Nečiporuk's method, such as formulas and branching programs, no superlinear lower bounds on DRE size were known prior to our work, even for a *non-explicit* (e.g., random or worst-case) Boolean function.

1.1.2 Garbling-friendly PRFs

There is a recent line of work on "MPC-friendly" block ciphers [3, 37, 54, 28, 27, 2] and pseudorandom functions (PRFs) [48, 32, 37, 19]. In this context, DRE size is a highly relevant complexity measure that is often used as a benchmark. The question of minimizing the DRE size of PRFs is motivated by the goal of securely evaluating a PRF in a setting where the input (and possibly also the key) is secret-shared between two or more parties. This is useful for natural applications that involve secure keyword search and distributed forms of searchable symmetric encryption; see [19] for discussion.

[2] A DRE can be viewed as an n-party PSM protocol in which each party holds just one bit. Any 2-party PSM lower bound implies a similar DRE lower bound, but the converse is not true.

For the case of exponentially secure (strong) PRFs, we show that the DRE size must be $\Omega(n^2/\log n)$.[3] Finally, we conjecture that a candidate PRF based on the "hidden shift problem" is exponentially secure PRF with almost matching DRE size $O(n^2)$. That is, the function outputs the quadratic character of a hidden shift of the input, determined by the secret key. To defeat known attacks (both quantum and classical), we restrict inputs bounded interval rather than the entire domain. A similar PRF (without the input restriction) has been proposed in [37] as an attractive candidate for MPC-friendly PRF, but in an interactive setting of arithmetic MPC, rather than in the context of garbling. We also present a similar PRF construction with $\Omega(n)$ bits of output, for which we can still obtain a near-quadratic DRE size upper bound.[4] Consequently, modulo the validity of the conjectured security, these PRFs are nearly garbling-optimal.

Interpreted differently, our garbling-friendly PRF candidate establishes a barrier for super-quadratic DRE lower bounds on *explicit* Boolean functions via *natural proof* techniques [53]. In contrast, we show that a recent candidate for a *weak* PRF with near-exponential security due to Boneh et al. [19] has a *linear* DRE size.

Our results imply several qualitative separations, including near-quadratic separations between computational and information-theoretic DRE size of Boolean functions, and between the DRE size of weak vs. strong PRFs.

2 Preliminaries

2.1 Cryptography

▶ **Definition 1** (Pseudorandom Functions [35]). *An* $(s(\cdot), \delta(\cdot))$-secure pseudorandom function (PRF) family *is an ensemble* $\mathcal{F} = \{\mathcal{F}_\lambda\}_{\lambda\in\mathbb{Z}^+}$*, where each* $\mathcal{F}_\lambda$ *is a keyed family of functions* $\mathcal{F}_\lambda = \{f_k : \{0,1\}^{n(\lambda)} \to \{0,1\}^{m(\lambda)}\}_{k\in\{0,1\}^{\kappa(\lambda)}}$*, satisfying the following security property:*

Pseudorandomness. *For every* $\lambda \in \mathbb{Z}^+$ *and every size-*s *(ensemble) of oracle circuits* $\mathcal{A}$ *(with output in* $\{0,1\}$*),*

$$\left| \mathop{\mathbb{E}}_{\substack{k\leftarrow\{0,1\}^{\kappa(\lambda)} \\ U:\{0,1\}^{n(\lambda)}\to\{0,1\}^{m(\lambda)}}} [\mathcal{A}^{f_k}(1^\lambda) - \mathcal{A}^{U}(1^\lambda)] \right| \leq \delta(\lambda).$$

$n(\cdot)$*,* $m(\cdot)$*, and* $\kappa(\cdot)$ *are respectively called the* input length*,* output length*, and* key length *of* $\mathcal{F}$*.*

▶ **Definition 2** (Weak PRFs [34]). *An* $(s(\cdot), \delta(\cdot))$-secure weak PRF family *is a relaxation of a PRF family as in Definition 1, with the "pseudorandomness" security property replaced by the following notion of "weak pseudorandomness":*

Weak Pseudorandomness. *For every* λ*, the tuples*

$$\big(X_1, \ldots, X_{s(\lambda)}, f_K(X_1), \ldots, f_K(X_{s(\lambda)})\big)$$

[3] This is almost immediate in the non-uniform setting, given our lower bounds. In the appendix we give a constructive proof for this fact in the uniform setting by exhibiting a sublinear test for an average-case variant of the natural property used in Nečiporuk's method.

[4] For this case, multi-bit output, we use input locality bounds of [9] to prove a slightly stronger (and nearly tight) quadratic lower bound (contrast with our $\Omega(n^2/\log n)$ bounds for single bit output).

and

$$\left(X_1, \ldots, X_{s(\lambda)}, Y_1, \ldots, Y_{s(\lambda)}\right)$$

are $(s(\lambda), \delta(\lambda))$*-indistinguishable in the probability space defined by sampling*

$$\begin{aligned} &K \leftarrow \{0,1\}^{\ell(\lambda)} \\ &X_1, \ldots, X_{s(\lambda)} \leftarrow \{0,1\}^{n(\lambda)} \\ &Y_1, \ldots, Y_{s(\lambda)} \leftarrow \{0,1\}^{m(\lambda)}. \end{aligned}$$

▶ **Definition 3.** *Random variables* X *and* Y *are* (s, ϵ)*-indistinguishable if the advantage of every size-*s *circuit in distinguishing* X *from* Y *is at most* ϵ*. We denote this by* $X \approx^{(s,\epsilon)} Y$*.*

2.2 Information Theory

▶ **Definition 4.** *The* min-entropy *of a random variable* X *is* $H_\infty(X) \stackrel{\text{def}}{=} \min_{x \in \text{Supp}(X)} \log_2 \left(\frac{1}{\Pr[X=x]}\right)$.

2.3 Decomposable Randomized Encodings

▶ **Definition 5** (Randomized Encodings)**.** *A* randomized encoding *for a function* $f : \{0,1\}^n \to \mathcal{Y}$ *consists of a "randomness" distribution* $\mathcal{R}$*, an encoding function* $\mathsf{Enc} : \{0,1\}^n \times \mathcal{R} \to \{0,1\}^\ell$*, and a decoding function* $\mathsf{Dec} : \{0,1\}^\ell \to \mathcal{Y}$*.* ℓ *is called* the size of the randomized encoding*.*

A randomized encoding $(\mathcal{R}, \mathsf{Enc}, \mathsf{Dec})$ *for function* $f : \{0,1\}^n \to \mathcal{Y}$ *should satisfy:*

Correctness. *For any input* $x \in \{0,1\}^n$*,*

$$\Pr_{R \leftarrow \mathcal{R}}[\mathsf{Dec}(\mathsf{Enc}(x, R)) = f(x)] = 1.$$

Security. *For all* $x, y \in \{0,1\}^n$ *with* $f(x) = f(y)$*, the distribution of* $\mathsf{Enc}(x, R)$ *is identical to the distribution of* $\mathsf{Enc}(y, R)$ *when sampling* $R \leftarrow \mathcal{R}$*.*

The security can be relaxed to require only that $\mathsf{Enc}(x, R)$ *and* $\mathsf{Enc}(y, R)$ *cannot be effectively distinguished by small circuits.*

(s, δ)***-Security.*** *For all* $x, y \in \{0,1\}^n$ *such that* $f(x) = f(y)$*, for any circuit* $\mathcal{A} : \{0,1\}^\ell \to \{0,1\}$ *of size at most* s*,*

$$\left| \Pr_{R \leftarrow \mathcal{R}}[\mathcal{A}(\mathsf{Enc}(x, R)) = 1] - \Pr_{R \leftarrow \mathcal{R}}[\mathcal{A}(\mathsf{Enc}(y, R)) = 1] \right| \leq \delta.$$

In this paper, we focus on decomposable randomized encoding (DRE)*, which is a randomized encoding that also satisfies an additional property:*

Decomposability. *Each output bit of* $\mathsf{Enc}(x, r)$ *is determined by* r *and 1 bit of input* x*.*

To ease presentation, we also introduce an equivalent definition of DRE. The equivalent definition is used when we prove lower bounds on the size of DRE.

▶ **Definition 6.** *An* (s, δ)*-secure* decomposable randomized encoding (DRE) for a function $f : \{0,1\}^n \to \{0,1\}$ *is a family of random variables*

$$\mathcal{X} = \begin{pmatrix} \mathcal{X}_0^1, \ldots, \mathcal{X}_0^n \\ \mathcal{X}_1^1, \ldots, \mathcal{X}_1^n \end{pmatrix}$$

such that

Correctness. *There is an algorithm* Dec *such that for every* $x \in \{0,1\}^n$,

$$\Pr[\mathsf{Dec}(\mathcal{X}^1_{x_1}, \ldots, \mathcal{X}^n_{x_n}) = f(x)] = 1.$$

3 Lower Bounds on DRE Size

Over 50 years ago, Nečiporuk published a two-page note titled "On a boolean function." [49] Within these two pages, Nečiporuk introduced an elegant combinatorial measure of a function related to the number of ways a function can be restricted distinctly. To this day, Nečiporuk's method still provides the strongest lower bounds known for formulas over arbitrary finite bases, deterministic branching programs, non-deterministic branching programs, parity branching programs, switching networks, span programs, and more [16].

In this section we recall Nečiporuk's measure and add decomposable randomized encoding (DRE) size to the list of complexity measures that are lower bounded by Nečiporuk's measure. Specifically, we show that for any function f, the DRE complexity of f is at least Nečiporuk's measure (which for explicit functions is as large as $n^2/\log n$). Prior to this work no super linear lower bounds on DRE size were known.

3.1 Technical Overview

To lower bound the DRE size of a function $f : \{0,1\}^n \to \{0,1\}$, we first consider all possible restrictions of f, using notation as in Definition 7. For simplicity, suppose that

$$\mathcal{X} = \begin{pmatrix} \mathcal{X}^1_0, \ldots, \mathcal{X}^n_0 \\ \mathcal{X}^1_1, \ldots, \mathcal{X}^n_1 \end{pmatrix}$$

is a *perfect* DRE for f. Then for all $S \subseteq [n]$ (with complement denoted by $\bar{S}$), we observe that:

1. The distribution of $(\mathcal{X}^i_{z_i})_{i\in\bar{S}}$ does not depend on $z \in \{0,1\}^{\bar{S}}$ (as long as $f_{S|z}$ is non-constant). This follows from DRE security.
2. Given $(\mathcal{X}^i_{z_i})_{i\in\bar{S}}$, the values $(X^i_b)_{i\in S, b\in\{0,1\}}$ are sufficient to reconstruct the truth table of $f_{S|z}$. This follows from DRE correctness.

Together, these properties imply that the size of the support of $(X^i_b)_{i\in S,b\in\{0,1\}}$ is at least the number of non-constant truth tables of the form $f_{S|z}$ for some $z \in \{0,1\}^{\bar{S}}$. We obtain a bound on the size of $\mathcal{X}$ by partitioning $[n]$ into sets $S_1,\ldots,S_m$, and lower bounding the size of each $(\mathcal{X}^i_b)_{i\in S_j,b\in\{0,1\}}$. The maximum bound on the *bit length* of $\mathcal{X}$ that can be achieved in this way is essentially Nečiporuk's measure of f.

We elaborate further below, defining a somewhat more general computational analogue of Nečiporuk's measure (that will suffice for lower bounds on computationally secure DREs).

3.2 Nečiporuk's Measure

Let $f : \{0,1\}^n \to \{0,1\}$ be any boolean function. For any subset $S \subseteq [n]$, let $\bar{S}$ denote $[n] \setminus S$, and define

$$g_S(f) \stackrel{\text{def}}{=} \log(\#\{f_{S|z} : z \in \{0,1\}^{\bar{S}}\}).$$

Let $V = (V_1,\ldots,V_m)$ denote a partition of $[n]$. That is, $V_1,\ldots,V_m$ are pairwise disjoint subsets of $[n]$ whose union is $[n]$. Then, the Nečiporuk measure of f is

$$G(f) \stackrel{\text{def}}{=} \max_V \sum_{V_i\in V} g_{V_i}(f).$$

▶ Remark 8. It is well known that for any function f, $G(f) \le n^2/\log n$ [57].

3.3 Functions with Maximal Measure

We recall several functions whose Nečiporuk measures are known to be as high as possible ($\Omega(n^2/\log n)$, where n is the bit-length of the input).

Element Distinctness

Element Distinctness is a function $\mathrm{ED}_m : [m^2]^m \to \{0,1\}$ which given a vector $(x_1,\ldots,x_m) \in [m^2]^m$ and outputs 1 if all x_i are distinct and 0 otherwise ($\exists i \neq j$ such that $x_i = x_j$).

Others

Clique, matching, and determinant all have measure $\Omega(n^2/\log n)$ [57].

Random

Finally, and perhaps unsurprisingly, we note that a random function has measure at least $\frac{n(n-2)}{\log n}$) with overwhelming probability (for n large enough). See Appendix B for proof.

3.4 DRE Size Lower Bounds via Nečiporuk

We define a pseudo-min-entropic analogue of Nečiporuk's measure, with an additional non-constantness restriction that is tailored for use in DRE lower bounds.

▶ **Definition 9.** *The* (s,ϵ)-pseudo min-entropy *of a random variable* X*, which we will denote by* $\tilde{H}_\infty^{(s,\epsilon)}(X)$*, is the supremum of* $H_\infty(\tilde{X})$ *over all random variables* $\tilde{X}$ *that are* (s,ϵ)*-indistinguishable from* X*.*

▶ **Definition 10.** *For any function* $f:\{0,1\}^n\to\{0,1\}$ *and any subset* $\emptyset\neq V\subseteq[n]$*, define*

$$\tilde{G}_V^{(s,\epsilon)}(f) \stackrel{\mathsf{def}}{=} \sup\left(\tilde{H}_\infty^{(s,\epsilon)}(f_{V|Z})\right),$$

where the supremum is taken over all $\{0,1\}^{\bar{V}}$*-valued random variables* Z *whose support only consists of values* z *that make* $f_{V|z}$ *non-constant.*

We define $\tilde{G}^{(s,\epsilon)}(f)$ *to be the maximum over all partitions* $[n]=V_1\cup\cdots\cup V_m$ *of* $\sum_{i\in[m]}\tilde{G}_{V_i}^{(s,\epsilon)}(f)$*.*

▶ Remark 11. If not for the non-constantness constraint on $f_{V|Z}$, the measure $\tilde{G}^{(\infty,0)}$ is the same as Nečiporuk's original measure. Reducing s or increasing ϵ only increases this measure. Taking the non-constantness restriction into account, our measure cannot be smaller than Nečiporuk's measure by more than $O(n)$ (so superlinear lower bounds on Nečiporuk's measure imply an asymptotically identical lower bound on our measure).

Beyond a certain threshold, increasing s no longer changes the value of $\tilde{G}^{(s,\epsilon)}$:

▷ Claim 12. For any function $f:\{0,1\}^n\to\{0,1\}$ and any subset $V\subseteq[n]$, we have $\tilde{G}_V^{(\infty,\epsilon)}(f)=\tilde{G}_V^{\left(2^{2^{|V|}},\epsilon\right)}(f)$.

Proof. Any function of n bits can be computed by a circuit of size 2^n. In fact this can be strengthened to $O(\frac{2^n}{n})$ [59, 45], but we prefer the simpler bound 2^n. Apply this to the (s,ϵ)-indistinguishability in the definition of pseudo-min-entropy of $f_{V|Z}$ (which is a truth table of bit length $n=2^{|V|}$). ◁

Our main lower bound is given by the following theorem.

▶ **Theorem 13.** *Let* $f:\{0,1\}^n\to\{0,1\}$ *be a function, and let* $\mathcal{X}$ *be a* $(s^*_{\mathsf{DRE}},\frac{1}{3})$*-secure DRE for* f *with a decoding algorithm of size* s_{Dec}*.*

Then for all $V\subseteq[n]$*, we have*

$$|\mathcal{X}^V|\geq\min\left(\log_2\left(\frac{s^*_{\mathsf{DRE}}}{s_{\mathsf{Dec}}\cdot 2^{|V|}}\right),\tilde{G}_V^{(s^*_{\mathsf{DRE}},\frac{1}{3})}(f)-2\right).$$

Proof. Suppose otherwise – that $|\mathcal{X}^V|<\log_2\left(\frac{s^*_{\mathsf{DRE}}}{s_{\mathsf{Dec}}\cdot 2^{|V|}}\right)$ and $|\mathcal{X}^V|<\tilde{G}_V^{(s^*_{\mathsf{DRE}},\frac{1}{3})}(f)-2$.

Let Z be a $\{0,1\}^{\bar{V}}$-valued random variable that maximizes $\tilde{H}_\infty^{(s^*_{\mathsf{DRE}},\frac{1}{3})}(f_{V|Z})$, supported by values z for which $f_{V|z}$ is non-constant, and let $\tilde{F}_V$ denote a random variable that is $(s^*_{\mathsf{DRE}},\frac{1}{3})$-indistinguishable from $f_{V|Z}$ and satisfies $H_\infty(\tilde{F}_V)=\tilde{H}_\infty^{(s^*_{\mathsf{DRE}},\frac{1}{3})}(f_{V|Z})$. Let Z' be an independent copy of Z.

We first claim that $(\mathcal{X}_Z^{\bar{V}},f_{V|Z})\approx^{(s^*_{\mathsf{DRE}},\frac{1}{3})}(\mathcal{X}_{Z'}^{\bar{V}},f_{V|Z})$. To see why, suppose for contradiction that there is size-s^*_{DRE} circuit $\mathcal{A}$ that distinguishes $(\mathcal{X}_Z^{\bar{V}},f_{V|Z})$ from $(\mathcal{X}_{Z'}^{\bar{V}},f_{V|Z})$ with advantage better than $\frac{1}{3}$. Then in particular there exist $z,z'\in\{0,1\}^{\bar{V}}$ such that $\mathcal{A}$ distinguishes $(\mathcal{X}_z^{\bar{V}},f_{V|z})$ from $(\mathcal{X}_{z'}^{\bar{V}},f_{V|z})$ with the same advantage. Hardwiring $f_{V|z}$ into $\mathcal{A}$, this gives a circuit $\mathcal{B}$ of size[5] $|\mathcal{B}|\leq|\mathcal{A}|$ for distinguishing $\mathcal{X}_z^{\bar{V}}$ from $\mathcal{X}_{z'}^{\bar{V}}$ with the same advantage. But this contradicts the $(s^*_{\mathsf{DRE}},\frac{1}{3})$-indistinguishability that is guaranteed by DRE security.

[5] Recall that the size of a circuit is measured in number of gates, and all gates of $\mathcal{A}$ whose inputs are the hard-wired value $f_{V|z}$ can be simplified or eliminated.

We also know that $(\mathcal{X}_{Z'}^{\bar{V}}, f_{V|Z}) \approx^{(s^*_{\mathsf{DRE}}, \frac{1}{3})} (\mathcal{X}_{Z'}^{\bar{V}}, \tilde{F}_V)$, so together with the previous claim, we have $(\mathcal{X}_{Z}^{\bar{V}}, f_{V|Z}) \approx^{(s^*_{\mathsf{DRE}}, \frac{2}{3})} (\mathcal{X}_{Z'}^{\bar{V}}, \tilde{F}_V)$. However, there is a distinguisher that contradicts this. Specifically, try all possible values of $\left(\mathcal{X}_b^i\right)_{i\in V, b\in\{0,1\}}$ (there are at most $\frac{s^*_{\mathsf{DRE}}}{s_{\mathsf{Dec}}\cdot 2^{|V|}}$ possibilities), and apply the DRE decoding algorithm ($2^{|V|}$ times per possibility) to see whether any possibility "explains" the given truth table.

By correctness of the DRE, there will always exist a value that explains $f_{V|Z}$ given $\mathcal{X}_Z^{\bar{V}}$, but because $H_\infty(\tilde{F}_V) > \log_2 |\mathcal{X}^V| + 2$, the probability that any value explains $\tilde{F}_V$ is at most $\frac{1}{4}$. Hence the distinguisher succeeds with probability $\frac{3}{4} > \frac{2}{3}$, which is a contradiction. ◀

3.5 The Nečiporuk Measure of PRFs

In this section, we prove lower bounds on the Nečiporuk measure of PRFs (of varying security levels), which imply corresponding lower bounds on the size of DREs.

▶ **Proposition 14.** *If $E : \{0,1\}^{\kappa+n} \to \{0,1\}$ is an (s,ϵ)-secure PRF with key length κ and input length n satisfying $s \geq 4$ and $\epsilon \leq \frac{1}{6}$, then for any subset $V \subseteq [\kappa+1, \kappa+n]$ with $|V| \geq 2$, we have $\tilde{G}_V^{(s,\epsilon')}(E) = 2^{|V|}$ for $\epsilon' = 3\epsilon + 2^{-s+1} + 2^{-2^{|V|}+1}$.*

Proof. Let Z' be a $\{0,1\}^{\bar{V}}$-valued random variable whose first κ coordinates are independent and uniformly random, and the rest of whose coordinates are 0. By PRF security, the probability that $E_{V|Z'}$ is constant is at most $\delta \stackrel{\mathsf{def}}{=} \epsilon + 2^{-\min(s,2^{|V|})+1} \leq \epsilon + 2^{-s+1} + 2^{-2^{|V|}+1} \leq \frac{1}{2}$.

Let $\mathcal{A}$ be an arbitrary size-s circuit. Suppose for contradiction that $\mathcal{A}$ distinguishes $E_{V|Z'}$ from a uniformly random truth table with advantage greater than ϵ. Then each input wire of $\mathcal{A}$ can be replaced by an oracle gate to yield a circuit that distinguishes oracle access to $E(K,\cdot)$ (for uniform K) from oracle access to a uniformly random function with the same advantage ϵ. This contradicts (s,ϵ)-security of the PRF. So $E_{V|Z'}$ is (s,ϵ)-indistinguishable from a uniformly random truth table.

Conditioned on $E_{V|Z'}$ being non-constant, the advantage of any $\mathcal{A}$ in distinguishing $E_{V|Z'}$ from a uniformly random truth table can increase to at most

$$\frac{\frac{1}{2}+\epsilon}{1-\delta} - \frac{1}{2} \leq (\frac{1}{2}+\epsilon)\cdot(1+2\delta) - \frac{1}{2} = \epsilon + \delta + 2\epsilon\cdot\delta \leq 3\epsilon + 2^{-s+1} + 2^{-2^{|V|}+1}.$$

Thus if Z denotes the random variable Z' conditioned on $E_{V|Z'}$ being non-constant, we have $\tilde{H}^{(s,\epsilon')}(E_{V|Z}) = 2^{|V|}$ for $\epsilon' = 3\epsilon + 2^{-s+1} + 2^{-2^{|V|}+1}$. ◀

▶ **Corollary 15.** *If $E : \{0,1\}^{\kappa+n} \to \{0,1\}$ is the evaluation algorithm for an (s,ϵ)-secure PRF family with key length κ and input length n satisfying $s \geq 4$ and $\epsilon \leq \frac{1}{6}$, then $\tilde{G}^{(\infty,\epsilon')}(E) \geq \Omega\left(\frac{n\log s}{\log\log s}\right)$ for $\epsilon' = 3\epsilon + 2^{-s+2}$. In particular, if the PRF family is exponentially secure, then $\tilde{G}^{(\infty,\epsilon')}(E) \geq \Omega\left(\frac{n^2}{\log n}\right)$.*

Proof. For every $V \subseteq [\kappa+1, n]$ of size $|V| = \log\log s$, Proposition 14 implies that there exists a random variable Z such that $\tilde{H}^{(s,\epsilon')}(E_{V|Z}) = 2^{|V|} = \log s$ for $\epsilon' = 3\epsilon + 2^{-s+2}$. But by Claim 12, $\tilde{H}^{(s,\epsilon')}(E_{V|Z}) = \tilde{H}^{(\infty,\epsilon')}(E_{V|Z})$.

The lower bound on $\tilde{G}^{(\infty,\epsilon')}(E)$ follows by partitioning $[\kappa+n]$ into $V_0 \cup V_1 \cup \cdots \cup V_{n/\log\log s}$, where $V_0 = [\kappa]$ and each V_i has size $|V_i| = \log\log s$ for $1 \leq i \leq n/\log\log s$. ◀

▶ Remark 16. We obtain a similar result to Corollary 15 in Appendix A that applies to uniformly secure PRFs.

▶ **Corollary 17.** *If E is the evaluation algorithm for an exponentially secure PRF family with input length n, then any statistically secure DRE for E has size at least $\Omega\left(\frac{n^2}{\log n}\right)$.*

3.6 A Truly Quadratic Lower Bound

We observe that for exponentially secure PRFs with n-bit output, even computationally secure DREs require size $\Omega(n^2)$.

▶ **Theorem 18.** *Any computational DRE of an exponentially-secure PRF with n-bits of output must have size $\Omega(n^2)$.*

To prove this theorem we will rely on the following result of Applebaum et al. [9].

▶ **Theorem 19.** *Let $S(k, x, r)$ be a one-time MAC with key k, message x, and randomness r. Let $\ell(n)$ denote the input locality of $S_k(x, r)$ and let $s(n)$ denote the length of a tag, where n is the security parameter. (A function has input locality ℓ if no input bit affects more than ℓ output bits.) Then, there is an efficient attack on $S(k, x, r)$ that succeeds with probability $1/\binom{s(n)}{\ell(n)} \cdot 2^{-\ell(n)}$.*

Proof. Recall that an exponentially secure PRF $f_k : \{0,1\}^n \to \{0,1\}^n$ is also an exponentially secure one-time MAC [42]. Moreover, a DRE of a MAC preserves unforgeability [9]. Because $1/\binom{n}{\ell(n)} \cdot 2^{-\ell(n)} \leq 2^{\ell(n)}$, it follows Theorem 19 that any DRE of an exponentially-secure f_k must have input locality $\Omega(n)$. By decomposability, any such DRE must have size $\Omega(n^2)$. ◀

4 Upper Bounds on DRE Size

In this section we present nearly matching upper bounds for some of the explicit functions to which our lower bounds apply. We explicitly conjecture two variants of the "hidden shift problem" are exponentially secure PRFs and show that they admit nearly quadratic size (efficient, perfect) DREs. Finally, we show a recent *weak* PRF candidate due to Boneh et al. [19], conjectured to be nearly exponentially-secure, admits a linear-size (efficient and perfect) DRE

4.1 Almost Tight Quadratic Upper Bounds

Partial Decomposability

We introduce the notation of a *partially decomposable randomized encoding*, so that later we can construction DRE by composing a randomized encoding and a partially decomposable randomized encoding. A randomized encoding $(\mathsf{Enc}, \mathsf{Dec})$ for a function $f : \{0,1\}^n \times \mathcal{W} \to \mathcal{Y}$ is a *partially decomposable randomized encoding (PDRE)* if every bit of $\mathsf{Enc}(x, w, r)$ is determined by $w \in \mathcal{W}, r \in \mathcal{R}$ and only 1 bit of $x \in \{0,1\}^n$.

▶ **Lemma 20** (Composition of randomized encodings)**.** *Let $\mathsf{Enc} : \{0,1\}^n \times \mathcal{W} \to \{0,1\}^\ell$ be (the encoding function of) a randomized encoding $(\mathsf{Enc}, \mathsf{Dec})$ for function $f : \{0,1\}^n \to \mathcal{Y}$. Let $\mathsf{Enc}' : (\{0,1\}^n \times \mathcal{W}) \times \mathcal{R} \to \{0,1\}^{\ell'}$ be the encoding function of a PDRE $(\mathsf{Enc}', \mathsf{Dec}')$ for function Enc. Then $\mathsf{Enc}' : \{0,1\}^n \times (\mathcal{W} \times \mathcal{R}) \to \{0,1\}^{\ell'}$ is the encoding function of a DRE for function f.*

Proof. The corresponding decoding function is $\mathsf{Dec}''(c) := \mathsf{Dec}(\mathsf{Dec}'(c))$. It's easy to verify $(\mathsf{Enc}', \mathsf{Dec}'')$ is a DRE, as each bit of $\mathsf{Enc}'(x, r, w)$ is determined by (r, w) and only 1 bit of x.

A DRE for Element Distinctness

Choose an $O(\log n)$-bit prime p with $p > \binom{n}{2}$. For all $1 \le i < i' \le n$, define indicator $\delta_{i,i'} \in \{0,1\}$ that captures whether $x_i = x_{i'}$,

$$\delta_{i,i'} := \begin{cases} 1, & \text{if } x_i = x_{i'}, \\ 0, & \text{if } x_i \neq x_{i'}. \end{cases}$$

Sample $a \leftarrow \mathbb{Z}_p \setminus \{0\}$ for the CRS. For all $1 \le i < i' \le n$, sample random $r_{i,i'} \in \mathbb{Z}_p$ from CRS such that $\sum_{1 \le i < i' \le n} r_{i,i'} = 0$. Define $\hat{r}_{i,i'} \in \mathbb{Z}_p$ as $\hat{r}_{i,i'} := r_{i,i'} + a \cdot \delta_{i,i'}$.

Then a DRE for element distinctness is induced by composing the following two claims:

▷ Claim 21. $(\hat{r}_{i,i'})_{1 \le i < i' \le n}$ is a randomized encoding of the functionality output.

Proof. It's obvious that $(\hat{r}_{i,i'})_{1 \le i < i' \le n}$ is a randomized encoding of $a \cdot \sum_{1 \le i < i' \le n} \delta_{i,i'}$. The later is a randomized encoding of the functionality output because: when $(x_i)_{1 \le i \le n}$ are all distinct, $a \cdot \sum_{1 \le i < i' \le n} \delta_{i,i'}$ is zero; when there is a collision, $a \cdot \sum_{1 \le i < i' \le n} \delta_{i,i'}$ is uniformly random in $\mathbb{Z}_p \setminus \{0\}$. ◁

▷ Claim 22. For all $1 \le i < i' \le n$, there exists a PDRE for $\hat{r}_{i,i'}$ of size $O(\log^4 n)$.

Proof. For any $v \in \mathbb{Z}_p$, let $v[k]$ denote the k-th bit of its binary representation. Then the k-th bit of $r_{i,i'}$ can be computed from

$$\begin{aligned} \hat{r}_{i,i'}[k] &= \begin{cases} r_{i,i'}[k], & \text{if } \delta_{i,i'} = 0 \\ (r_{i,i'} + a)[k], & \text{if } \delta_{i,i'} = 1 \end{cases} \\ &= r_{i,i'}[k] \oplus (r_{i,i'}[k] \oplus (r_{i,i'} + a)[k]) \cdot \bigvee_{j=1}^{\log p} (x_i[j] \oplus x_{i'}[j]), \end{aligned}$$

which, as a function of $(x_i, x_{i'})$, is a binary branching program of size $O(\log n)$. Thus there is a PDRE for $\hat{r}_{i,i'}$ of size $O(\log^3 n)$ [8][6]. As $\hat{r}_{i,i'}$ has $\log n$ bits, there exists a PDRE for $\hat{r}_{i,i'}$ of size $O(\log^4 n)$. ◁

4.2 A PRF Candidate With A Nearly Optimal DRE

Now we can present the almost-optimally-garble-able candidate PRF. Modulo a conjecture on its hardness, this simple algebraic PRF candidate admits a (perfect) DRE of size at most a $\log n$ factor from the minimum. Moreover, a simple generalization of this candidate yields linear output length with the same DRE complexity. Thus, if this candidate is exponentially secure, it is indeed optimally-garble-able.

In addition to applications in efficient MPC, this candidate can be conversely interpreted through Razborov and Rudich's natural proof framework as barrier to proving super quadratic bounds on DRE size [53].

[6] For a branching program of size s and has t input bits, there is a DRE for the branching program of size $s^2 t$.

An Exponentially-Secure PRF Candidate

Our starting point is an algebraic object that has received considerable attention in both cryptography and mathematics: Legendre sequences. A Legendre sequence is a sequence of the form:

$$(x+1)^{(p-1)/2}, (x+2)^{(p-1)/2}, (x+3)^{(p-1)/2}, \ldots$$

where all operations are over $\mathbb{Z}_p$ for some prime p.

The pseudorandomness of sequences of quadratic characters have a long history in both cryptography and mathematics [4, 20, 24, 26, 38, 46, 47, 52, 55]. These sequences have been shown to behave as if random with respect to a variety of statistical tests designed for randomness.

Recent work has considered the so-called "hidden shift problems" and their generalizations. In the quadratic character variant of the hidden shift problem, algorithms are given oracle access to a function $\phi_k : \mathbb{Z}_p \to \{-1, 0, +1\}$ where $\phi_k(x) = (k+x)^{(p-1)/2}$ from some $k \in \mathbb{Z}_p$. The task is then to recover k. Efficient quantum algorithms for this problem are known [61, 62, 63, 56, 41]. However, the best classical algorithms to date are still just subexponentional (under an assumption on the density of smooth integers) [20, 56, 43]. Indeed, Dam, Hallgren, and Ip [63] have explicitly conjectured that ϕ_k is a PRF with respect to polytime classical algorithms. Grassi et al. [37] additionally proposed this function specifically as an "MPC-friendly" PRF. Recently, cryptanalytic bounties have been announced on this PRF [31].

With the known attacks in mind, we give a twist on the hidden shift problem restricting evaluation to a short interval. So far as we know this confounds all existing techniques (including quantum algorithms) and the best algorithm[7] runs in $2^{(1+o(1))n}$-time [60].

We actually make two conjectures: (1) restricted hidden shift yields an exponentially-secure PRF with one bit of output, (2) a natural generalization is an exponentially-secure PRF with many bits of output. But first, we define the restricted hidden shift function.

For any $m \in \mathbb{Z}^+$, let $p \equiv 1 \pmod m$ be a prime with $p \geq 2^{2n}$, and let $\langle \zeta_m \rangle$ denote the group of m^{th} roots of unity in $\mathbb{Z}_p^\times$. For $k \in \mathbb{Z}_p$ define

$$\begin{aligned} \mathsf{Char}_k^{p,m,n} &: [0, 2^n - 1] \to \langle \zeta_m \rangle \\ \mathsf{Char}_k^{p,m,n} &: x \mapsto (k+x)^{\frac{p-1}{m}} \pmod p. \end{aligned}$$

Note that $\mathsf{Char}_k^{p,2,n}(x) = 0$ for $k + x = p$. In order to achieve single bit output (just two possible output values) we restrict the key space in addition to the input space, so that this equation cannot be satisfied.

▶ **Conjecture 23.** *Let $p = p(n)$ be any prime sequence satisfying $p \equiv 1 \pmod m$, $p > 2^{n+1}$. Then, $\left\{ \left\{ \mathsf{Char}_k^{p,2,n} \right\}_{k \in \{1,\ldots,2^n\}} \right\}_{n \in \mathbb{Z}^+}$ is, for some $s(n) = 2^{\Omega(n)}$, an $(s(\cdot), s(\cdot)^{-1})$-secure PRF family.*

Next, we present a variant with long output by applying an input restriction to the "hidden power problem" [21] or "hidden root problem" [64]. In this problem, the goal is to recover k using query access to $x \mapsto (k+x)^e$ for more general $e | p-1$ (the shift problem

[7] The algorithm is to simply guess k and test on enough x. However it is worth noting that even this is not known to work, and requires making a conjecture on the distribution of Legendre sequences generated by random k [60]. The best *provable* distinguisher that we know of runs in time $2^{(3/2+o(1))n}$-time by simply exhaustively enumerate all sequences of length $2^{n/2}$ and comparing [60]

discussed above is simply the specific case of $e = \frac{p-1}{2}$). Notably, [21] demonstrated (classical) algorithms for this problem that make $O(1)$ queries and recover k in time $e^{1+\epsilon}\log^{O(1)} p$. With this in mind, we make the following conjecture.

▶ **Conjecture 24.** *Let $p = p(n)$ be any prime sequence and $m = m(n)$ be any positive integer sequence satisfying $p \equiv 1 \pmod m$, $p \geq 2^{2n}$, and $\frac{p}{m} \geq 2^n$. Then $\left\{\left\{\mathsf{Char}_k^{p,m,n}\right\}_{k\in\mathbb{Z}_p}\right\}_{n\in\mathbb{Z}^+}$ is, for some $s(n) = 2^{\Omega(n)}$, an $(s(\cdot), s(\cdot)^{-1})$-secure PRF family.*

An $O(n^2)$ DRE for the Candidate PRF

We now show that there is a DRE for $\mathsf{Char}_{(\cdot)}^{n,m,p}(\cdot)$ of size $O(n^2)$. Assuming the above conjectures, it follows from Corollary 32 that this DRE has essentially optimal size, not just for $\mathsf{Char}_{(\cdot)}^{n,m,p}(\cdot)$, but among DREs for *any* exponentially-secure PRF.

For clarity, we present a DRE for $\mathsf{Char}_k^{p,2,n}$ and note that the construction can easily be extended to the multi-bit output case.

Our starting point is a simple perfect randomized encoding for quadratic residue[8]:

$$\mathsf{Enc} : x \mapsto x \cdot r^2, \text{ for uniformly sampled } r \leftarrow \mathbb{Z}_p$$
$$\mathsf{Dec} : y \mapsto y^{(p-1)/2}$$

Security follows from the fact that any quadratic residue is mapped to a uniformly random quadratic residue, and any non-residue is mapped to a uniformly random non-residue. Note that this randomized encoding has size $O(n)$.

However, we would like a randomized encoding of the quadratic residuosity of $x + k$ and moreover we would like it to be decomposable. This is easily remedied via bit decomposition and the fact that the above encoding is linear with respect to the input.

$$\begin{aligned}\mathsf{Enc} : x_i &\mapsto x_i \cdot 2^{i-1} \cdot r^2 + s_i \\ k_i &\mapsto k_i \cdot 2^{i-1} \cdot r^2 + t_i \\ &\text{where } r, s_1, \ldots, s_n, t_1, \ldots, t_{2n+1} \text{ are drawn uniformly from } \mathbb{Z}_p \\ &\text{such that } s_1 + \cdots + s_n + t_1 + \cdots + t_{2n+1} = 0.\end{aligned}$$
$$\mathsf{Dec} : y_1, \ldots, y_{3n+1} \mapsto \left(\sum y_i\right)^{(p-1)/2}$$

Similarly, correctness and security follow from the fact that an encoding is simply $3n + 1$ random elements, conditioned on the fact that their sum is a random element with the quadratic residuosity of x. Note that because the encoding consists of $3n + 1$ elements, each of bit length $2n + 1$, the size of this DRE is $O(n^2)$.

4.3 A WPRF Candidate With A Nearly Optimal DRE

In this section, we observe that a recent weak pseudorandom function candidate put forward by Boneh et al. admits a DRE of quasi-linear size [19].

Boneh et al. [19] have put forward the following WPRF candidate related to both the learning parity with noise problem (with "deterministic" noise) and learning with rounding problem (over constant-size modulus). Given a key $k \in \{0,1\}^n$, they define

[8] A similar randomization technique for quadratic characters was previously used in related contexts in [30, 5, 1, 37].

Protocol Let S_6 and f act on $\mathbb{Z}_6$ on the right in the natural way. Let $\sigma \in S_6$ denote the permutation that maps x to $x+1$. Let $L = 0 \in \mathbb{Z}_6$.

Randomness

- Sample $r_1, \ldots, r_{n-1} \leftarrow S_6$.
- Define $(R_{1,0}, R_{1,1}) = (L \cdot r_1, L \cdot \sigma \cdot r_1)$
- For $2 \le i \le n-1$, define $(R_{i,0}, R_{i,1}) = (r_{i-1}^{-1} \cdot r_i, r_{i-1}^{-1} \cdot \sigma \cdot r_i)$
- Define $(R_{n,0}, R_{n,1}) = (r_{n-1}^{-1} \cdot f, r_{n-1}^{-1} \cdot \sigma \cdot f)$

Encoding For $1 \le i \le n$, $\mathsf{Enc}_i(z_i, R_i) = M_i = R_{i,z_i}$

Decoding $M_1 \cdots M_n$

Figure 1 A DRE for a function of a sum mod 6 [17].

$$\mathsf{LWR}_k^6 : \{0,1\}^n \to \{0,1\}$$
$$\mathsf{LWR}_k^6(x) = \begin{cases} 0 & \text{if } \langle x, k\rangle \equiv 0,\ 1,\ \text{or } 2 \pmod 6 \\ 1 & \text{if } \langle x, k\rangle \equiv 3,\ 4,\ \text{or } 5 \pmod 6. \end{cases}$$

This candidate was proposed with efficient secure function evaluation protocols in mind; however, the protocol presented in [19] requires two phases of interaction: first it applies a DRE-based subprotocol for computing shares of the mod-6 inner product, and then another subprotocol for rounding. Here we show that LWR^6 has a DRE of size $O(n)$.[9]

Let $\lfloor \cdot \rceil : \mathbb{Z}_6 \to \{0,1\}$ denote the function

$$\lfloor x \rceil = \begin{cases} 0 & \text{if } x \in \{0,1,2\} \\ 1 & \text{otherwise.} \end{cases}$$

We obtain our DRE for LWR_k^6 by composing two DREs ([8, 11]); the first is for a function that maps $(z_1, \ldots, z_n) \mapsto \left\lfloor \sum_i z_i \pmod 6 \right\rceil$ for $z_1, \ldots, z_n \in \{0,1\}$, and the second is for the AND function mapping $(k_i, x_i) \in \{0,1\}^2$ to $k_i \cdot x_i$.

The DRE for the first function is obtained as a special case of a result on symmetric functions due to Beimel et al. [17, Theorem 7.2, Figure 9] that refines a group-based DRE due to Kilian [44]:

▶ **Imported Theorem 25** ([17]). *For any function $f : \mathbb{Z}_6 \to \{0,1\}$, the scheme of Figure 1 is a size-$O(n)$ DRE of the function h that maps $(z_1, \ldots, z_n) \mapsto f\big(\sum z_i \pmod 6\big)$.*

The second function is constant-sized, and thus has a constant-sized DRE by Barrington's theorem [14] and Kilian's rerandomization.

Springer, 2015. doi:10.1007/978-3-662-47672-7_1.

[9] In contrast to the PRF candidate proposed above, this WPRF candidate is at most $2^{n/\log n}$-secure. Assuming it is indeed $2^{n/\log n}$ secure, an $O(\lambda \log \lambda)$ size DRE is needed to get 2^λ security.

A PRF Bounds in the Uniform Setting

In this appendix, we give improved lower bounds on the complexity of garbling pseudorandom functions (PRFs). In particular, the attack presented here is uniform, as opposed to non-uniform bounds in Corollary 15. Our results follow from applying the natural proof framework of [53]. However, we achieve improved bounds by demonstrating the existence of a property tester for a relaxation of Nečiporuk's measure. By combining our results with those of Section 3.4 we show any exponentially-secure PRF has DRE size $\Omega(n^2/\log n)$.

We then discuss a candidate PRF with a DRE construction of size almost matching the lower bound.

A.1 PRFs are complex under (average-case) Nečiporuk

Intuitively, because a random function has high measure under Nečiporuk, so should a pseudorandom function.[10] In fact, Servedio and Tan have recently shown how to exactly learn functions with low ($O(n^{1.99})$) measure under Nečiporuk in time $2^{n-n^{\delta}}$ (via membership and equivalence queries) [58]. We show that the much simpler task of simply distinguishing a function with low measure can be done much more quickly (and without equivalence queries, which do not fit into the usual PRF game).

We accomplish this via an average case variant of Nečiporuk. Recall that Nečiporuk is ultimately statement about the number of functions that can be generated under some restriction. Viewed differently, this can be framed as a statement about the *maximum entropy* of the random variable defined by sampling a restricted function uniformly at random. Our observation is that for the special case of distinguishing from a random function it suffices to look at the *Shannon entropy* of the same variable. Consequently, instead of bounding the support size we can focus on much easier task of bounding the entropy.

An "average-case" notion of Nečiporuk

We begin by introducing our average-case variant of Nečiporuk's measure that relies on Shannon entropy as opposed to maximum entropy.

For a function $f : \{0,1\}^n \to \{0,1\}$, and a set $S \subset [n]$, let $Z^{f,S}$ denote the variable distributed according to $f_{S|z}$ for uniformly drawn $z \leftarrow \{0,1\}^{\bar{S}}$. Define,

$$h_S(f) \stackrel{\mathsf{def}}{=} H(Z^{f,S}).$$

Notice that $H_{\max}(Z^{f,S}) = g_S(f)$, thus it follows that $h_S(f) \leq g_S(f)$.

Random functions are complex (under h_S)

Next we observe that random functions have high complexity with respect to the average-case variant of Nečiporuk we defined above.

▶ **Proposition 26.** *For any set $S \subseteq [n]$ and a uniformly random function $F : \{0,1\}^n \to \{0,1\}$,*

$$\Pr[h_S(F) \leq 2^{|S|} - t] < \exp(-\frac{2t^2}{|\bar{S}| + \ln(2)})$$

We can apply the same style of balls/bins argument used for Nečiporuk's original measure again here.

[10] Statements of this form indeed were at the heart of Razoborov and Rudich's natural proof framework and its recent extensions [53, 22, 23, 51]. Unfortunately, because Nečiporuk's measure seems to behave poorly under known pseudorandom function generators, its not clear how to apply their framework here to get strong bounds on pseudorandom generators with simple DREs.

Proof. First, we bound $\mathbb{E}[H(Z^{F,S})]$ from below. We will omit S from the superscript in this proof ($Z^F = Z^{F,S}$). Additionally, we will take Z^F_ϕ to denote $\Pr_F[Z^F = \phi]$. Note that for any ϕ, $\mathbb{E}[Z^F_\phi] = 1/\#\{\phi : \{0,1\}^{|S|} \to \{0,1\}\} = 2^{-2^{|S|}}$.[11]

$$\begin{aligned}
\mathbb{E}_F[H(Z)] &= \mathbb{E}_F\left[\sum_\phi Z^F_\phi \log(1/Z^F_\phi)\right] \\
&= \sum_\phi \mathbb{E}_F[Z^F_\phi \log(1/Z^F_\phi)] \\
&\geq \sum_\phi \mathbb{E}_F[Z^F_\phi] \log(1/\mathbb{E}_F[Z^F_\phi]) \\
&= 2^{2^{|S|}} \cdot \frac{1}{2^{2^{|S|}}} \log(2^{2^{|S|}}) \\
&= 2^{|S|}
\end{aligned}$$

Note that the third line follows from Jensen's inequality.

Next, we show concentration around the mean in the standard way. Consider $H(Z^F)$ as a Doob martingale on the independent random variables $F_{S|z}$ for $z \in \{0,1\}^{\bar{S}}$. Clearly, if F and F' only differ on single restriction of f to z, then $|H(Z^F) - H(Z^{F'})| \leq \frac{\log(2^{|\bar{S}|})+\ln(2)}{2^{|\bar{S}|}}$. Moreover, because F is random, these variables are independent. So, we can apply McDiarmid/Azuma's inequality to get, for any $t > 0$:

$$\Pr_F[\mathbb{E}[H(Z^F)] - H(Z^F) \geq t] \leq \exp(\tfrac{2t^2}{|\bar{S}|+\ln(2)}).$$ ◀

Plugging $|S| = \log n$ and $t = n/2$ into the above proposition we immediately get the following corollary.

▶ **Corollary 27.** *For any set $S \subseteq [n]$ such that $|S| = \log n$, if $F : \{0,1\}^n \to \{0,1\}$ is a uniformly random function, then*

$$\Pr[h_S(F) \leq n/2] < \exp(-\frac{n^2}{2(n - \log n + \ln(2))}) < \exp(-n/2).$$

A.2 Low Nečiporuk measure can be distinguished from random

Next, we use the above to show that any function with Nečiporuk measure that is slightly less than maximal can be distinguished from a random function in time $O(2^{n/10})$. It immediately follows that none of the classes whose functions have bounded Nečiporuk measure can contain exponentially-secure PRFs.

The following theorem is implicit in Batu et al. [15].

▶ **Imported Theorem 28.** *There is an algorithm that given sample access to a distribution X supported on $[N]$, promised to either have "high" entropy (at least $N/2$) or "low" entropy (at most $N/21$), runs in time $\tilde{O}(N^{1/100})$ and distinguishes which is the case with overwhelming probability.*

[11] In more detail: Let $M = \#\{0,1\}^{\bar{S}}$ (number of balls) and $N = \#\{0,1\}^{\{0,1\}^S}$ (number of bins). Then, for $k \in \mathbb{N}$ we can see that $\Pr[Z^F_\phi = k/M]$ is the probability that exactly k out M balls (or restrictions $z \in \{0,1\}^{\bar{S}}$) hit the bin ϕ (which happens with probability $1/N$). Thus, $\Pr[Z^F_\phi = k/M] = \binom{M}{k} N^{-k}(1 - \frac{1}{N})^{M-k}$. Because this is simply a rescaled binomial distribution it follows that $\mathbb{E}[Z^F_\phi] = \frac{1}{M} \cdot \frac{M}{N} = \frac{1}{N}$.

▶ Remark 29. Batu et al. actually show how to multiplicatively approximate entropy within a factor of $(1+2\epsilon)\gamma$ ($\gamma > 1, \epsilon \in (0, 1/2]$) given sample access in time $O(N^{1/\gamma^2}/\epsilon^2 \log n)$ with constant failure probability when the distribution has entropy at least $\Omega(\gamma/\eta)$ for some small constant η ([15, Theorem 2]).

To apply this to the low entropy case, it suffices to suffices to show min-entropy is greater than the constant assumed above. For these parameters, empirical estimates are more than efficient enough. In fact, [15, Lemma 2] says just that. Finally, correctness of these estimates can be amplified by taking the median/majority after $\operatorname{poly}\log n$ repetitions.

▶ **Theorem 30.** *There is an algorithm running in time $\tilde{O}(2^{n/100})$ that given oracle access to either a random function $F : \{0,1\}^n \to \{0,1\}$ or any $f : \{0,1\}^n \to \{0,1\}$ such that $G(f) < \frac{n^2}{21 \log n}$ can distinguish between the two cases with overwhelming advantage.*

Proof. Note that if $G(f) < \frac{n^2}{21 \log n}$, then in particular $\sum_{V_i} g_{V_i}(f) < \frac{n^2}{21 \log n}$ for the partition $(V_1, \ldots, V_{n/\log n})$ of $[n]$ into consecutive $\log n$-bit blocks. Moreover, there must be some V_i such that $h_{V_i}(f) \le g_{V_i}(f) < n/21$.

In contrast, Corollary 27 implies that for a uniformly random F, it holds with overwhelming probability that for all i, $h_{V_i}(F) \ge n/2$.

Additionally, for any i, it is possible to efficiently sample Z^{f,V_i} by simply drawing $z \leftarrow \{0,1\}^{|\bar{V}_i|}$ uniformly at random and evaluating $f_{V_i|z}$ on all $x \in \{0,1\}^{V_i}$. Because $|V_i| = \log n$, this procedure takes time $\operatorname{poly}(n)$.

It follows that we can run the procedure from Imported Theorem 28 on all V_i in time $\tilde{O}(2^{n/100})$. If the procedure outputs "High" on all V_i, then output "F." Otherwise, output "f." By Theorem 28 and the above observations, the procedure described will err with at most negligible probability. ◀

▶ Remark 31. We note that for $\epsilon > 0$ the above distinguisher can be modified to test on the partition $V = (V_1, \ldots, V_m)$ where each V_i is a block of size $\epsilon \log n$ ($m = \frac{n}{\epsilon n}$) and again distinguish entropy that differs by constant factor in any block from $n^\epsilon/2$, taking time $O(2^{n^\epsilon})$ overall. By Proposition 26 a random function will have Nečiporuk measure $h_{V_i}(f) \ge n^\epsilon/2$ for all V_i with high probability. It follows that an $O(2^{n^\epsilon})$-secure PRF must have DRE complexity $\Omega(n^{1+\epsilon}/\log n)$.

PRFs have high complexity

From Theorem 30, it almost immediately follows that there can be no exponentially-secure PRFs in any class to which Nečiporuk applies. This yields a host of lower bounds on PRF complexity that, to our knowledge, were not known before now.

▶ **Corollary 32.** *No exponentially-secure PRF has*

- *Decomposable Randomized Encodings of size $o(n^2/\log n)$,*
- *Binary formulas of size $o(n^2/\log n)$ over arbitrary basis,*
- *Deterministic branching programs of size $o(n^2/\log^2 n)$,*
- *Switching networks of size $o(n^2/\log^2 n)$,*
- *Non-deterministic branching programs of size $o(n^{3/2}/\log n)$,*
- *Parity branching programs of size $o(n^{3/2}/\log n)$,*
- *Span programs of size $o(n^{3/2}/\log n)$,*
- *Switching-and-rectifier networks of size $o(n^{3/2}/\log n)$.*

B Deferred Proofs

▶ **Proposition 33.** *For any set* $S \subseteq [n]$ *and a random function* $f : \{0,1\}^n \to \{0,1\}$, $\Pr_f[2^{g_S(f)} \leq 2^{n-|S|} - t] < \exp(-\frac{2t^2}{2^{n-|S|}})$

This follows from a standard balls & bins argument, reproduced here for completeness.

Proof. Recall that $2^{g_V(f)} = \#\{f_{S|z} : z \in \{0,1\}^{\bar{S}}\}$. If we let Y_ϕ for $\phi : \{0,1\}^S \to \{0,1\}$ be the indicator random variable such that

$$Y_\phi := \begin{cases} 1 & \text{if } \exists z \in \{0,1\}^{\bar{S}} : f_{S|z} = \phi \\ 0 & \text{otherwise} \end{cases}$$

Then we can rewrite the above as,

$$2^{g_S(f)} = \sum_{\phi:\{0,1\}^S \to \{0,1\}} Y_\phi.$$

By linearity of expectation,

$$\mathbb{E}[2^{g_S(f)}] = \mathbb{E}[\sum_\phi Y_\phi] = \sum_\phi \mathbb{E}[Y_\phi] = 2^{2^{|S|}} \cdot \frac{2^{|\bar{S}|}}{2^{2^{|S|}}} = 2^{n-|S|}.$$

Finally, we consider $2^{g_S(f)}$ as a doob martingale on the independent random variables $f_{S|z}$ for $z \in \{0,1\}^{\bar{S}}$. Clearly, if f and f' only differ on single restriction of f to z, then $|g_S(f) - g_S(f')| \leq 1$. Moreover, because f is random, these variables are independent. So, we can apply McDiarmid/Azuma's inequality to get, for any $t > 0$:

$$\Pr_f[\mathbb{E}[2^{g_S(f)}] - 2^{g_S(f)} \geq t] \leq \exp(\tfrac{2t^2}{2^{|\bar{S}|}}).$$ ◀

In particular, if we take $|S| = \log n$ and $t = 2^{n-\log n-1}$, then $\Pr_f[g_S(f) \leq n - \log n - 1] \leq \exp(-2^{n-\log n-1})$. This yields the following corollary via a union bound.

▶ **Corollary 34.** *For a random function* f, $\Pr_f[G(f) \leq n^2/\log n - 2n] \leq \frac{n}{\log n} \cdot \exp(-2^{n-1})$.
