[23] conjectured that for all monotone functions f, even in the case of exact representation ($\varepsilon = 0$), BuildTopDownDT returns a tree of minimal depth and size "not far from minimal". Theorem 7(a) provides a counterexample to the conjectured bound on size, and the function in Theorem 7(b) disproves the conjecture about depth; see Remark 40.[4]

Stated in the notation of our paper, [44] raised the possibility that $\textsc{TopDownDTSize}(f, \varepsilon) \leq \text{poly}(s, 1/\varepsilon)$ for all size-s monotone decision trees f and $\varepsilon \in (0, \frac{1}{2})$. The author further remarked that "showing $\textsc{TopDownDTSize}(f, \varepsilon) \leq \text{poly}(s)$, even only for constant accuracy ε,[5] would be a huge advance". Theorem 7(b) rules this out.

[4] For clarity of exposition, throughout this overview we discuss our results with decision tree *size* as the complexity measure. There are analogues of all of our results, both upper and lower bounds, for decision tree *depth* as the complexity measure.

[5] That is, a bound of the form $\textsc{TopDownDTSize}(f, \varepsilon) \leq s^{O_\varepsilon(1)}$.

2.1 Algorithmic applications: Properly learning decision trees

Learning decision trees has been a touchstone problem in uniform-distribution PAC learning for more than thirty years. It sits right at the boundary of our understanding of efficient learnability, and continues to be the subject of intensive research. The seminal work of Ehrenfeucht and Haussler [21] gave a $\mathrm{poly}(n^{\log s}, 1/\varepsilon)$-time algorithm for learning decision trees using random examples (see also [8] for an alternative proof based on Rivest's algorithm for learning decision lists [59]);[6] subsequently, Linial, Mansour, and Nisan [45] gave an algorithm that also runs in quasipolynomial time, but achieves polynomial sample complexity; Kusilevitz and Mansour [43], leveraging a novel connection to cryptography [29], gave a polynomial-time algorithm using membership queries; Gopalan, Kalai, and Klivans [30] obtained an *agnostic* analogue of [43]'s algorithm, extending it to tolerate adversarial noise; O'Donnell and Servedio [53] gave a polynomial-time algorithm for learning *monotone* decision trees from random examples; recent work of Hazan, Klivans, and Yuan [33] gives an algorithm agnostically learning decision trees with *polynomial sample complexity*; even more recent work of Chen and Moitra [17] gives an algorithm for learning *stochastic* decision trees.

Properly learning decision trees

When learning decision trees, it is natural to seek a hypothesis that is itself a decision tree. Indeed, it may be natural to seek a decision tree hypothesis even when learning other concept classes. The simple structure of decision trees makes them desirable both in terms of interpretability and explanatory power, which is why they are ubiquitous in empirical machine learning. A further advantage of decision tree hypotheses is that they are very fast to evaluate: evaluating a depth-d decision tree on a given input takes time $O(d)$,[7] whereas evaluating say a degree-d polynomial – another canonical and ubiquitous representation class in learning theory – can take time $\Theta(n^d)$, the number of monomials in the polynomial.

In learning theory, algorithms that return a hypothesis belonging to the concept class are known as *proper*. Understanding the complexity of proper learning (vis-à-vis improper learning) is an important research direction in learning theory [22]; proper learning also has deep connections to proof complexity [2] and property testing [28].

2.1.1 New proper learning algorithms

Among the decision tree learning algorithms discussed at the beginning of this subsection, the only one that is proper is the one of Ehrenfeucht and Haussler [21]. Our upper bounds on TopDownDTSize yield new algorithms for properly learning decision trees under the uniform distribution:

▶ **Theorem 9** (Algorithmic consequence of Theorem 3)**.** *Size-s decision trees can be properly learned under the uniform distribution in time* $\mathrm{poly}(n, s^{\log(s/\varepsilon)\log(1/\varepsilon)})$ *using membership queries.*[8]

---

[6] In fact, the algorithm of [21] learns decision trees in the more challenging setting of *distribution-free* PAC learning. All other results in this discussed in this section, including ours, are specific to uniform-distribution learning, and we focus our exposition on this setting.

[7] Every size-s decision tree is well-approximated by a decision tree of depth $O(\log s)$.

[8] We remark that our algorithm only requires fairly "mild" use of membership queries. Our algorithm only requires *random edge samples* (Definition 43), and hence falls within both the random walk model of Bshouty et al. [16] and the local membership queries model of Awasthi et al. [3]. These (incomparable) models are natural relaxations of the standard model of learning from random examples, and do not allow the learning algorithm unrestricted membership query access to the target function.

Analogously, Theorem 6 yields a new algorithm for learning monotone decision trees using only random examples. The learnability of monotone functions with respect to various complexity measures has been the subject of intensive study in uniform-distribution learning [32, 41, 39, 14, 15, 9, 66, 60, 63, 53, 62, 18, 44, 34, 54].

▶ **Theorem 10** (Algorithmic consequence of Theorems 3 and 6). *Size-s monotone decision trees can be properly learned under the uniform distribution in time*

$$\mathrm{poly}(n, \min(s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}, s^{O(\sqrt{\log s}/\varepsilon)}))$$

using only random examples.

We now compare our results with the prior state of the art for properly learning decision trees.

- **Polynomial-time algorithms for superlogarithmic size.** Theorems 9 and 10 give the first polynomial-time algorithms for properly learning decision trees of size $\omega(\log n)$ to constant accuracy. To see this, we first note that [21]'s runtime of $\mathrm{poly}(n^{\log s}, 1/\varepsilon)$ is superpolynomial time for any $s = \omega(1)$. Alternatively, functions depending on $k \ll n$ variables ("k-juntas") can be properly learned in time $\mathrm{poly}(n, 2^k)$, using random examples for monotone juntas, and membership queries otherwise [10, 49]. Since every size-s decision tree certainly depends on at most $k \leq s$ variables, this runtime is polynomial for decision trees of size $s = O(\log n)$, but becomes superpolynomial once $s = \omega(\log n)$. In contrast, the runtimes of our algorithms in Theorems 9 and 10 remain polynomial for $s = 2^{\Omega(\sqrt{\log n})}$ and $s = 2^{\Omega((\log n)^{2/3})}$ respectively.
- **Dimension-independent hypothesis size.** Related to the above, the sizes of the hypotheses returned by the algorithms of Theorems 9 and 10 are $s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}$ and $s^{O(\sqrt{\log s}/\varepsilon)}$ respectively, independent of n, whereas the size of the hypotheses returned by [21]'s algorithm can be as large as $n^{\Omega(\log s)}$. This is gap can be exponential or even larger for small values of s.
- **Average depth as the complexity measure.** Our algorithms and analyses extend easily to accommodate *average depth* as the complexity measure. The average depth of a decision tree, $\triangle(T)$, is the number of queries T makes on a uniform random input. Average depth is a stronger complexity measure than size since $\triangle(T) \leq \log(\mathrm{size}(T))$.[9]

  ▶ **Theorem 11** (Learning trees with small average depth). *Decision trees of average depth $\triangle$ can be properly learned under the uniform distribution in time* $\mathrm{poly}(n, 2^{\triangle^2/\varepsilon})$ *using membership queries, and monotone decision trees of average depth $\triangle$ can be properly learned in time* $\mathrm{poly}(n, 2^{\triangle^{3/2}/\varepsilon})$ *using random examples.*

  To our knowledge, these represent the first polynomial-time algorithms for properly learning decision trees of superconstant average depth, $\triangle = \omega(1)$. Prior to our work, the fastest algorithm ran in time $\mathrm{poly}(n^{\triangle/\varepsilon})$; this algorithm, which uses random examples, follows implicitly from the results of Mehta and Raghavan [46].

[9] Furthermore, it is easy to construct examples of decision trees T with the largest possible gap between these measures: $\triangle(T) = O(1)$ and $\log(\mathrm{size}(T)) = \Omega(n)$.

2.2 Proper learning with polynomial sample and memory complexity

For our final contribution, we revisit the classic algorithm of Ehrenfeucht and Haussler [21]. As discussed above, this remains the fastest algorithm for properly learning decision trees. We extend it to give the first uniform-distribution proper algorithm that achieves polynomial sample and memory complexity, while matching its state-of-the-art quasipolynomial runtime (Theorem 54).

Table 1 Algorithms for learning size-s decision trees from random examples under the uniform distribution.

[45]	$\mathrm{poly}(n^{\log(s/\varepsilon)})$	$\mathrm{poly}(s, 1/\varepsilon) \cdot \log n$	$\mathrm{poly}(n, s, 1/\varepsilon)$	×
[46]	$\mathrm{poly}(n^{\log(s/\varepsilon)})$	$\mathrm{poly}(s, 1/\varepsilon) \cdot \log n$	$\mathrm{poly}(n^{\log(s/\varepsilon)})$	✓
This work	$\mathrm{poly}(n^{\log s}, 1/\varepsilon)$	$\mathrm{poly}(s, 1/\varepsilon) \cdot \log n$	$\mathrm{poly}(n, s, 1/\varepsilon)$	✓

Ehrenfeucht and Haussler had posed (as the first open problem of their paper) the question of achieving polynomial sample complexity. Such algorithms were subsequently obtained by Linial, Mansour, and Nisan [45] and Mehta and Raghavan [46]. Interestingly, these two algorithms are very different from each other and from [21]: the algorithm of [45], being Fourier-based, is non-proper, whereas the algorithm of [46], which uses dynamic programming, has a large memory footprint. Furthermore, both algorithms have a quasipolynomial dependence on $1/\varepsilon$ in their runtimes, rather than [21]'s polynomial dependence.

This state of affairs raises the question of whether there is a *single* algorithm that achieves "the best of [21], [45], and [46]" in each of the four metrics discussed above; see Table 1. We give such an algorithm in this work (Theorem 54). Our algorithm is a surprisingly simple modification of [21]'s algorithm, but our analysis is more involved. At a high level, the idea is to terminate [21]'s algorithm early to achieve our improved sample and memory complexity. However, incorporating this plan with the inherently bottom-up nature of [21]'s algorithm necessitates a delicate error analysis. (In particular, [21]'s algorithm is an Occam algorithm, whereas ours is not.)[10][11]

We remark that there is an ongoing flurry of research activity on the memory complexity of learning basic concept classes under the uniform distribution, with a specific focus on tradeoffs between memory and sample complexity [64, 65, 57, 42, 47, 58, 48, 4, 26, 27].

[10] Although our algorithm, like the others in Table 1, only uses random examples, to our knowledge there are no known membership query algorithms that achieves our guarantees.

[11] We note that it is possible to combine the ideas in [21] and [46] to give an algorithm that runs in $\mathrm{poly}(n^{\log(s/\varepsilon)})$ time and has sample and memory complexity $\mathrm{poly}(s, 1/\varepsilon) \cdot \log n$ and $\mathrm{poly}(n, s, 1/\varepsilon)$ respectively. We do not provide the details in this paper since our main result (Theorem 54) achieves strictly better guarantees.

3 Discussion and related work

3.1 Relationship to practical machine learning heuristics

Our work is motivated in part by the tremendous popularity and empirical success of top-down decision tree learning heuristics in machine learning practice, such as ID3 [55], its successor C4.5 [56], and CART [11]. The data mining textbook [67] describes C4.5 as "a landmark decision tree program that is probably the machine learning workhorse most widely used in practice to date". In a similar vein, quoting Kearns and Mansour [40], "In experimental and applied machine learning work, it is hard to exaggerate the influence of top-down heuristics for building a decision tree from labeled sample data [...] Dozens of papers describing experiments and applications involving top-down decision tree learning algorithms appear in the machine learning literature each year".

We give a high-level description of how these heuristics work, using the framework of uniform-distribution learning. As we will soon see, they serve as motivation for the heuristic that we study, BuildTopDownDT (Figure 1). These heuristics grow a bare tree T° for a function $f : \{0,1\}^n \to \{0,1\}$ as follows. Consider the progress measure

$$\mathcal{H}(T^\circ) \coloneqq \sum_{\ell \in \text{leaves}(T^\circ)} \Pr_{\boldsymbol{x} \sim \{0,1\}^n}[\,\boldsymbol{x} \text{ reaches } \ell\,] \cdot \mathscr{G}(\mathbb{E}[f_\ell]),$$

where $\mathscr{G} : [0,1] \to [0,1]$ is known as the *impurity function*, and encapsulates the splitting criterion of the heuristic. This carefully chosen function is restricted to be concave, symmetric around $\frac{1}{2}$, and to satisfy $\mathscr{G}(0) = \mathscr{G}(1) = 0$ and $\mathscr{G}(\frac{1}{2}) = 1$. For example, $\mathscr{G}$ is the binary entropy function in ID3 and C4.5; CART uses $\mathscr{G}(p) = 4p(1-p)$, known as the *Gini criterion*; [40] studies the variant $\mathscr{G}(p) = 2\sqrt{p(1-p)}$.[12] Writing $T^\circ_{\ell,i}$ to denote T° with its leaf ℓ replaced with a query to the variable x_i, these heuristics, in a single iteration, grow T° to $T^\circ_{\ell^\star,i^\star}$, where

$$(\ell^\star, i^\star) \text{ is the leaf-variable pair that maximizes } \mathcal{H}(T^\circ) - \mathcal{H}(T^\circ_{\ell^\star,i^\star}). \tag{1}$$

We refer to any such top-down heuristic as an *impurity-based* heuristic, and the progress measure $\mathcal{H}(T^\circ) - \mathcal{H}(T^\circ_{\ell^\star,i^\star})$ as the *purity gain*.

Inherent limitations of impurity-based heuristics

It is easy to see (and has been well known [38]) that impurity-based heuristics can, in general, fare very badly, in the sense of building a decision tree that is much larger than the optimal decision tree. For example, consider $f(x) = x_j \oplus x_k$ for $j, k \in [n]$, the parity of two variables. For such a target function, *regardless of the choice of the impurity function* $\mathscr{G}$, splitting on any of the n variables results in zero purity gain. This is because $\mathbb{E}[f] = \mathbb{E}[f_{x_i=b}]$ for all $i \in [n]$ and $b \in \{0,1\}$. Therefore, *any* impurity-based heuristic may build a tree of size $\Omega(2^n)$ before achieving any non-trivial error $\varepsilon < \frac{1}{2}$, whereas the size of the optimal tree of f is only 4.

One could exclude such "parity-like" examples by considering only *monotone* functions. Monotonicity is a ubiquitous condition in machine learning since many data sets are naturally monotone in their attributes. In the case of monotone functions, it can be shown that for

[12] The work of Dietterich, Kearns, and Mansour [20] gives a detailed experimental comparison of various impurity functions.

any impurity function $\mathscr{G}$, the variable split that results in the most progress in the sense of (1), i.e. the variable x_i that maximizes the purity gain

$$\mathscr{G}(\mathbb{E}[f]) - \tfrac{1}{2}(\mathscr{G}(\mathbb{E}[f_{x_i=0}]) + \mathscr{G}(\mathbb{E}[f_{x_i=1}])),$$

is precisely the most influential variable of f (we prove this in Section 7; see Proposition 41). In other words, in the case of monotone functions, BuildTopDownDT closely models impurity-based heuristics. The works of Fiat and Pechyony [23] and Lee [44] (recall our discussion following Theorem 8) were explicitly motivated by this observation, as are our results on monotone functions (Theorems 6 to 8 and 10).

As we will show, our monotone lower bounds for BuildTopDownDT actually apply to all impurity-based heuristics (Theorem 8), regardless of the choice of the impurity function $\mathscr{G}$ (hence including ID3, C4.5, and CART).[13] Since one could argue that real-world data sets are unlikely to be "parity-like", we view our monotone lower bounds as providing more robust (albeit still only theoretical) evidence of the limitations and potential shortcomings of the impurity-based top-down heuristics used in practice.

Top-down versus bottom-up: from practice to theory?

We find it especially intriguing that the algorithm of Ehrenfeucht and Haussler [21] – which as discussed, remains the fastest algorithm for properly learning decision trees with provable runtime guarantees – builds its hypothesis tree *bottom up*, in exactly the *opposite* order from the top-down heuristics used in practice. It is natural to ask if top-down heuristics can serve as inspiration for the design and analyses of fundamentally different algorithms for properly learning decision trees.

Our algorithmic upper bounds for BuildTopDownDT (Theorems 9 and 10) provide affirmative answers, and as discussed above, these new algorithms even have certain qualitative advantages over [21]. Our lower bounds (Theorems 4 and 7), on the other hand, establish their inherent limitations. They imply that BuildTopDownDT is provably *not* a polynomial-time algorithm for properly learning decision trees using membership queries, or a polynomial-time algorithm for properly learning monotone decision trees using random examples. Either of these results would constitute a major advance in learning theory, and BuildTopDownDT – and other impurity-based variants of it – had been a natural candidate for obtaining them. Indeed, the results of [44] were explicitly motivated by the goal of showing that BuildTopDownDT *is* a polynomial-time algorithm for properly learning monotone decision trees. This is now ruled out by Theorems 7 and 8.[14]

3.2 Related work

Fiat and Pechyony [23] considered linear threshold functions and read-once DNF formulas, and showed that BuildTopDownDT, when run on such functions, returns a decision tree of optimal size computing them exactly. (Stated in the notation of Theorem 3, TopDownDTSize$(f) = s$ for such functions.)

[13] Different impurity functions $\mathscr{G}$ lead to different *orderings* of leaves to split, and hence result in different trees.

[14] Blum et al. [7] gave an information-theoretic lower bound showing that no "statistical query" algorithm can learn decision trees in polynomial time. However, this lower bound does not apply when membership queries are allowed or when the function is assumed to be monotone.

Kearns and Mansour [40] (see also [38, 20]) showed that impurity-based heuristics are *boosting algorithms*, where one views the functions labeling internal nodes of the tree (single variables in our case) as weak learners. At a high level, the proofs of our upper bounds (Theorems 3 and 6) are similar in spirit to their analysis, in the sense that they are all incremental in nature, showing that each split contributes to the accuracy of the decision tree hypothesis. However, our results and analyses are incomparable – for example, [40] does not relate the size of the resulting hypothesis to the size of the optimal decision tree; [40]'s analysis assumes the existence of weak learners for all filtered-and-rebalanced versions of the target distribution, whereas we carry out the entirety of our analyses with respect to the uniform distribution.[15]

Recent work of Brutzkus, Daniely, and Malach [13] studies a variant of ID3 proposed by [40], focusing on learning conjunctions and read-once DNF formulas under product distributions. They provide theoretical and empirical evidence showing that for such functions, the size-t tree grown by [40]'s variant of ID3 achieves optimal or near-optimal error among all trees of size t. Concurrent work by the same authors [12] shows that ID3 efficiently learns $(\log n)$-juntas in the setting of smoothed analysis.

4 Preliminaries

Throughout this paper, we use bold font (e.g. $\boldsymbol{x}$ and $\boldsymbol{S}$) to denote random variables; all probabilities and expectations are with respect to the uniform distribution unless otherwise stated.

For any decision tree T, we say the *size* of T is the number of leaves in T, and the *depth* of T is length of the longest path between the root and a leaf. If a tree has size 1, then it contains a single leaf, computes either the constant $+1$ or constant -1 function, and has depth 0. For a function $f : \{0,1\}^n \to \{\pm 1\}$, the *optimal decision tree size* of f is the smallest s for which there exists a decision tree of size s that exactly computes f, and we write $\mathrm{size}(f)$ to denote this quantity. If T is a decision tree that computes f, then we will often use T interchangeably with f.

Choose any $f, g : \{0,1\}^n \to \{\pm 1\}$. Then, the *error* is defined as

$$\mathrm{error}(f,g) = \Pr_{\boldsymbol{x} \sim \{0,1\}^n}[f(\boldsymbol{x}) \neq g(\boldsymbol{x})].$$

We say that f is an ε-approximation of g if $\mathrm{error}(f,g) \leq \varepsilon$. If T° is a bare tree, then $\mathrm{error}(T^\circ, f)$ is shorthand for $\mathrm{error}(T, f)$ where T is the f-completion of T°. We also use the following shorthand.

$$\mathrm{error}(f, \pm 1) = \min(\mathrm{error}(f,-1), \mathrm{error}(f,1)).$$

The *variance* of $f : \{0,1\}^n \to \{\pm 1\}$, denoted $\mathrm{Var}(f)$, is

$$\mathrm{Var}(f) = 4 \cdot \Pr[f(\boldsymbol{x}) = -1] \cdot \Pr[f(\boldsymbol{x}) = 1].$$

The *total influence* of f, denoted $\mathrm{Inf}(f)$, is

$$\mathrm{Inf}(f) = \sum_{i=1}^{n} \mathrm{Inf}_i(f).$$

[15] Indeed, [40]'s results concern impurity-based heuristics, and as discussed above, statements like Theorem 3 that apply to all functions cannot hold for such heuristics because of parity-like functions.

It is easy to see that for any decision tree $T : \{0,1\}^n \to \{\pm 1\}$,

$$\text{error}(T, \pm 1) \leq \text{Inf}(T)$$

and

$$\frac{\text{Var}(T)}{2} \leq \text{error}(T, \pm 1) \leq \text{Var}(T)$$

always hold.

5 Upper bounds on TopDownDTsize: Proofs of Theorems 3 and 6

Recall that BuildTopDownDT(f, ε) continually grows a bare tree, T°, until the f-completion of T° is an ε-approximation of f. At a high level, the proofs of our upper bounds on TopDownDTSize proceed as follows.

Section 5.1 We define a progress metric, the "cost" of T°, which upper bounds the error of the f-completion of T° with respect to f. Hence, when the "cost" drops below ε, BuildTopDownDT can terminate. We show that whenever BuildTopDownDT grows T°, the "cost" of T° decreases by exactly the score of the leaf selected.

Section 5.2 We lower bound the score of the leaf that BuildTopDownDT selects.

Section 5.3 We put the above together to prove upper bounds on TopDownDTSize. At each step, the "cost" of T° must decrease by at least the lower bounds in Section 5.2, which allows us to upper bound the number of steps until the "cost" falls below ε. This is sufficient since the size of the tree that BuildTopDownDT produces is exactly one more than the number of steps it takes.

5.1 Definition and properties of "Cost"

▶ **Definition 12** (Cost of a bare tree). *Let $f : \{0,1\}^n \to \{\pm 1\}$ be a function and T° be a bare tree. Then the* cost of T° relative to f *is defined as*

$$\text{cost}_f(T^\circ) = \sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot \text{Inf}(f_\ell).$$

This cost function is useful to track because it naturally decreases during BuildTopDownDT and upper bounds the error of the completion.

▶ **Lemma 13** (Properties of cost of a bare tree). *For any $f : \{0,1\}^n \to \{\pm 1\}$ and bare tree T°, the following hold:*

1. $\text{error}(T^\circ, f) \leq \text{cost}_f(T^\circ)$.
2. *Choose any leaf ℓ of T° and variable x_i. Let $(T^\circ)'$ be the bare tree that results from replacing ℓ in T° with a query to x_i. Then,*

$$\text{cost}_f((T^\circ)') = \text{cost}_f(T^\circ) - 2^{-|\ell|} \cdot \text{Inf}_i(f_\ell).$$

At each step, BuildTopDownDT splits the leaf with the largest score, resulting in the cost decreasing by exactly the score selected. Once the cost decreases to below ε, we know the completion of T° is an ε-approximation of f, meaning BuildTopDownDT can terminate.

Proof. The proof of (1) is a simple application of the fact that $\text{error}(g, \pm 1) \leq \text{Inf}(g)$ for any boolean function g:

$$\begin{aligned}\text{error}(T^\circ, f) &= \Pr_{\boldsymbol{x}\sim\{0,1\}^n}[(\text{Completion of } T^\circ)(\boldsymbol{x}) \neq f(\boldsymbol{x})] \\ &= \sum_{\text{leaf } \ell\in T^\circ} \Pr_{\boldsymbol{x}\sim\{0,1\}^n}[\boldsymbol{x} \text{ reaches } \ell] \cdot \text{error}(f_\ell, , \pm 1) \\ &\leq \sum_{\text{leaf } \ell\in T^\circ} 2^{-|\ell|} \cdot \text{Inf}_i(f_\ell) = \text{cost}_f(T^\circ).\end{aligned}$$

The proof of (2) follows from the fact that if T is a tree with x_i at the root, T_0 as its 0-subtree, and T_1 as its 1-subtree, then $\text{Inf}(T) - \text{Inf}_i(T) = \frac{1}{2}(\text{Inf}(T_0) + \text{Inf}(T_1))$. This fact is true because

$$\begin{aligned}\text{Inf}(T) - \text{Inf}_i(T) &= \sum_{j\neq i} \text{Inf}_j(T) \\ &= \sum_{j\neq i} \frac{1}{2}\text{Inf}_j(T_0) + \frac{1}{2}\text{Inf}_j(T_1) \\ &= \frac{1}{2}\left(\sum_{j=1}^{n} \text{Inf}_j(T_0) + \sum_{j=1}^{n} \text{Inf}_j(T_1)\right) \\ &= \frac{1}{2}(\text{Inf}(T_0) + \text{Inf}(T_1)).\end{aligned}$$

◀

5.2 Lower bounds on the score of the leaf BuildTopDownDT selects

We give two different lower bounds. These lower bounds are incomparable, so when proving Theorems 3 and 6, we use whichever is better. Both of these lower bounds rely on a powerful inequality from the analysis of boolean functions due to O'Donnell, Saks, Schramm, and Servedio [52], which we restate in the form most convenient for us.

▶ **Theorem 14** (Corollary of Theorem 1.1 from [52]). *Let f be a size-s decision tree. Then,*

$$\max_i \left(\text{Inf}_i(f)\right) \geq \frac{\text{Var}(f)}{\log s}.$$

We prove our first lower bound on the score of the leaf selected.

▶ **Lemma 15.** *Let f be a size s decision tree. At step j,* BuildTopDownDT(f, ε) *selects a leaf, ℓ^* with score at least*

$$\text{score}(\ell^*) \geq \frac{\varepsilon}{(j+1)\log(s)}.$$

Proof. If BuildTopDownDT has not terminated at step j, then, the completion of T° is not an ε-approximation of f. Equivalently,

$$\sum_{\text{leaf } \ell\in T^\circ} 2^{-|\ell|} \cdot \text{error}(f_\ell, \pm 1) > \varepsilon$$

At step j, there are exactly $j+1$ leaves in T°, so there must be at least one leaf, ℓ, where

$$2^{-|\ell|} \cdot \text{error}(f_\ell, \pm 1) > \frac{\varepsilon}{j+1}.$$

Since $\mathrm{Var}(f_\ell) \geq \mathrm{error}(f_\ell, \pm 1)$, we also know

$$2^{-|\ell|} \cdot \mathrm{Var}(f_\ell) > \frac{\varepsilon}{j+1}.$$

By Theorem 14, we know, for some variable x_i, $\mathrm{Inf}_i(f_\ell) \geq \mathrm{Var}(f_\ell)/\log(\mathrm{size}(f_\ell))$. The optimal size of any restriction of f is certainly at most the optimal size of f itself, so

$$2^{-|\ell|} \cdot \mathrm{Inf}_i(f_\ell) > \frac{\varepsilon}{(j+1)\log(s)}.$$

Since BuildTopDownDT picks a leaf with maximum score, and ℓ has a score at least $\varepsilon/(j+1)\log(s)$, it must pick a leaf with at least that score. ◀

A standard fact from the analysis of boolean functions gives a $\log s$ upper bound on the total influence of a size-s decision tree (see e.g. [53]). In order to prove a second lower bound on the score of the leaf that BuildTopDownDT selects, we will need a refinement of this bound that takes into account the variance of the function. The following lemma is a slight variant of a related (though incomparable) result in [6], which upper bounds the total influence of an s-term DNF formula by $2\mu\log(s/\mu)$, where $\mu \coloneqq \Pr[f(\boldsymbol{x}) = 1]$.

▶ **Lemma 16** (Total influence of size-s DTs). *Let $f : \{0,1\}^n \to \{\pm 1\}$ be computed by a size-s decision tree T. Then*

$$\mathrm{Inf}(f) \leq \mathrm{Var}(f)\log(4s/\mathrm{Var}(f)).$$

Proof. We may assume without loss of generality that $\mu \coloneqq \Pr[f(\boldsymbol{x}) = 1] \leq \frac{1}{2}$, since $\mathrm{Inf}(f) = \mathrm{Inf}(\neg f)$ and if f is a size-s decision tree then so is its negation $\neg f$. Since

$$\begin{aligned}
\mathrm{Inf}(f) &= \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}[\mathrm{sens}_f(\boldsymbol{x})] && (\text{where } \mathrm{sens}_f(x) \coloneqq |\{i \in [n] \colon f(x) \neq f(x^{\oplus i})\}|)\\
&= 2 \cdot \mathbb{E}\left[\mathrm{sens}_f(\boldsymbol{x})\mathbb{1}[f(\boldsymbol{x}) = 1]\right]\\
&\leq 2 \sum_{\text{1-leaves } \ell \in T} 2^{-|\ell|} \cdot |\ell| && (\mathrm{sens}_f(x) \leq |\ell| \text{ for every } x \text{ that reaches } \ell)\\
&\leq 2\mu\log(s/\mu) && (\text{Concavity of } t \mapsto t\log(1/t), \text{ and } \mathrm{size}(T) \leq s)\\
&\leq \mathrm{Var}(f)\log(4s/\mathrm{Var}(f)), && (\mathrm{Var}(f) = 4\mu(1-\mu), \text{ and our assumption that } \mu \leq \tfrac{1}{2})
\end{aligned}$$

the lemma follows. ◀

We now provide a second lower bound on the score of the leaf BuildTopDownDT selects. The lower bound provided below in Lemma 17 is better than the bound provided by Lemma 15 when $\mathrm{cost}_f(T^\circ)$ is large.

▶ **Lemma 17.** *Let f be a size s decision tree. Suppose that* BuildTopDownDT(f, ε) *has already constructed the bare tree T° at step j and that $\mathrm{cost}_f(T^\circ) \geq \varepsilon\log(4s/\varepsilon)$. Then, the next leaf, ℓ^*, that* BuildTopDownDT *picks has score at least*

$$\mathrm{score}(\ell^*) \geq \frac{\mathrm{cost}_f(T^\circ)}{(j+1)\log(4s/\varepsilon)\log(s)}.$$

Proof. We will show that when $\mathrm{cost}_f(T^\circ)$ is large, there is some leaf with high total influence, which means it must have high variance, and finally a variable with high influence.

We define:

$$h_s : [0,1] \to \mathbb{R} \text{ where } h_s(t) = t\log\left(\frac{4s}{t}\right) \text{ and } h_s(0) = 0.$$

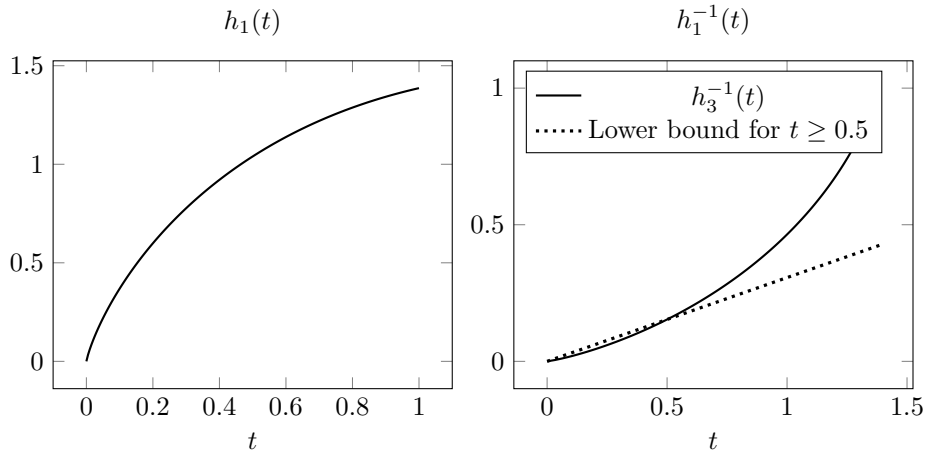

Figure 2 Graphs of the function $h_1(t) = t \cdot \log(\frac{4}{t})$ on the left, and of its inverse, $h_1^{-1}(t)$ on the right. Since the inverse is convex, we can use a linear lower bound as the dotted line in the right plot shows.

Then, for any tree T of size at most s, we have that

$$\mathrm{Inf}(T) \leq h_s(\mathrm{Var}(T)).$$

As long as $s \geq 1$, h_s is an increasing concave function. This means it has a convex inverse, h_s^{-1}, and that for any tree T of size at most s, the following lower bounds the variance.

$$\mathrm{Var}(T) \geq h_s^{-1}(\mathrm{Inf}(T)). \tag{2}$$

Since h_s^{-1} is convex and $h_s^{-1}(0) = 0$, we can lower bound it as follows. Choose arbitrary $a \in \mathbb{R}$. Then, for $t \geq a$ we have that $h_s^{-1}(t) \geq t \cdot \frac{h_s^{-1}(a)}{a}$. Choosing $a = \varepsilon \log(4s/\varepsilon)$, we have that,

$$h_s^{-1}(t) \geq \frac{t}{\log(4s/\varepsilon)} \text{ for all } t \geq \varepsilon \log\left(\frac{4s}{\varepsilon}\right).$$

Consider the bare tree, T°, at step j. By definition, it has cost

$$\sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot \mathrm{Inf}(f_\ell) = \mathrm{cost}_f(T^\circ).$$

We next apply Jensen's inequality.

$$\sum_{\text{leaf } \ell \in T^\circ} 2^{-|\ell|} \cdot h_s^{-1}(\mathrm{Inf}(f_\ell)) \geq h_s^{-1}(\mathrm{cost}_f(T^\circ)).$$

Since, at step j, there are $j+1$ leaves in T°, for at least one of the leaves, ℓ,

$$2^{-|\ell|} \cdot h_s^{-1}(\mathrm{Inf}(f_\ell)) \geq \frac{h_s^{-1}(\mathrm{cost}_f(T^\circ))}{j+1} \geq \frac{\mathrm{cost}_f(T^\circ)}{(j+1)\log(\frac{4s}{\varepsilon})}.$$

By Equation (2), we can lower bound the variance of f_ℓ:

$$2^{-|\ell^*|} \cdot \mathrm{Var}(f_\ell) \geq 2^{-|\ell|} \cdot h_s^{-1}(\mathrm{Inf}(f_\ell)) \geq \frac{\mathrm{cost}_f(T^\circ)}{(j+1)\log(\frac{4s}{\varepsilon})}.$$

Then, using Theorem 14 and the fact that if f is exactly computed by a size s tree, then f_ℓ is exactly computed by a tree of size at most s.

$$2^{-|\ell|} \cdot \max_i \left(\mathrm{Inf}_i[f_\ell]\right) \geq \frac{\mathrm{cost}_f(T^\circ)}{(j+1)\log(\frac{4s}{\varepsilon})\log(s)}.$$

Recall that BuildTopDownDT picks the leaf with largest score, so it will pick a leaf with score at least $\frac{\mathrm{cost}_f(T^\circ)}{(j+1)\log(4s/\varepsilon)\log(s)}$. ◀

5.3 Proofs of Theorems 3 and 6

Armed with the above Lemmas, we are now ready to prove our upper bounds on the size of the tree that BuildTopDownDT produces.

▶ **Theorem 3** (Upper bound for approximate representation). *For every $\varepsilon \in (0, \frac{1}{2})$ and every size-s decision tree f, we have* $\textsc{TopDownDTSize}(f, \varepsilon) \leq s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}$.

Proof. We use C_j to refer to $\mathrm{cost}_f(T^\circ)$ after j steps of BuildTopDownDT. The size of the tree returned is one more than the number of steps BuildTopDownDT takes. Furthermore, if $C_j \leq \varepsilon$, then T° has error at most ε at step j, so BuildTopDownDT will return a tree of size at most $j+1$.

Our analysis proceeds in two phases:

Phase 1: We will show that the larger C_j is, the faster it must decrease at each step. This multiplicative reduction of C_j will allow us to conclude that after at most $k = s^{\log(4s/\varepsilon)\log(1/\varepsilon)}$ steps, that $C_k \leq \varepsilon\log(\frac{4s}{\varepsilon})$.

Phase 2: We will argue that C_j makes additive progress towards 0 once it is less than $\varepsilon\log(\frac{4s}{\varepsilon})$, showing that after $m = s^{2\log(4s/\varepsilon)\log(1/\varepsilon)}$ steps, that $C_m \leq \varepsilon$.

Once $C_m \leq \varepsilon$, the algorithm must terminate.

Phase 1: Based on Lemma 17, we know that during phase 1, BuildTopDownDT will select a leaf with influence at least $\frac{\mathrm{cost}_f(T^\circ)}{(j+1)\log(4s/\varepsilon)\log s}$ at each step j. From Lemma 13, we know that:

$$\begin{aligned} C_j &\leq C_{j-1} - \frac{C_j}{j\log(4s/\varepsilon)\log s} \\ &= C_{j-1} \cdot \left(1 - \frac{1}{j\log(4s/\varepsilon)\log s}\right). \end{aligned}$$

We can use this to bound C_k, the cost after some (k) number of steps, in terms of C_0.

$$\begin{aligned} C_k &\leq C_0 \prod_{j=1}^{k} \left(1 - \frac{1}{j\log(4s/\varepsilon)\log s}\right) \\ &= C_0 \exp\left(\sum_{j=1}^{k} \log\left(1 - \frac{1}{j\log(4s/\varepsilon)\log s}\right)\right). \end{aligned}$$

Using the fact that $\log(1+t) < t$,

$$\begin{aligned} C_k &\leq C_0 \exp\left(-\sum_{j=1}^{k} \frac{1}{j\log(4s/\varepsilon)\log s}\right) \\ &\leq C_0 \exp\left(-\frac{\log k}{\log(4s/\varepsilon)\log s}\right). \end{aligned}$$

We know that $C_0 \leq \log s$ because a size-s decision tree has total influence at most $\log s$ (see e.g. [53]). Choosing

$$k = \exp\big(\log(4s/\varepsilon)\log(s)\log(1/\varepsilon)\big) = s^{\log(4s/\varepsilon)\log(1/\varepsilon)}$$

it must be true that $C_k \leq \varepsilon \log(4s/\varepsilon)$.

Phase 2: This phase combines Lemmas 13 and 15, which together imply that

$$C_{j+1} \leq C_j - \frac{\varepsilon}{(j+1)\log s}.$$

This means that, for $m > k$,

$$C_k - C_m \geq \sum_{j=k+1}^{m} \frac{\varepsilon}{(j+1)\log s} \geq \frac{\varepsilon}{\log s}(\log m - \log k).$$

We are guaranteed to terminate at the first j such that $C_j \leq \varepsilon$, or earlier. Choosing

$$\log m = \frac{\log s}{\varepsilon} C_k + \log k$$

ensures that $C_m \leq 0$, which means BuildTopDownDT must terminate before step m. Plugging in $C_k \leq \varepsilon \log(4s/\varepsilon)$ and $k = s^{\log(4s/\varepsilon)\log(1/\varepsilon)}$ gives that

$$m \leq s^{2\log(4s/\varepsilon)\log(1/\varepsilon)}.$$

Since BuildTopDownDT terminates after at most m steps, it returns a tree of size at most $m + 1$. ◀

The proof of Theorem 6 is mostly the same as Phase 2 from the proof of Theorem 3, except we have a better guarantee on the starting cost. We will use the following upper bound on the total influence of monotone decision trees, due to O'Donnell and Servedio [53]:

▶ **Theorem 18** ([53]). *Let f be a size-s monotone decision tree. Then* $\mathrm{Inf}(f) \leq \sqrt{\log s}$.

▶ **Theorem 6** (Upper bound for approximate representation of monotone functions.). *For every $\varepsilon \in (0, \frac{1}{2})$ and every size-s monotone decision tree f, we have* $\textsc{TopDownDTSize}(f, \varepsilon) \leq s^{O(\sqrt{\log s}/\varepsilon)}$.

Proof. We use C_j to refer to $\mathrm{cost}_f(T^\circ)$ after j steps of BuildTopDownDT. By combining Lemma 15 and Lemma 13, we know that

$$C_{j+1} \leq C_j - \frac{\varepsilon}{(j+1)\log s}.$$

At any step k,

$$C_0 - C_k \geq \sum_{j=0}^{k-1} \frac{\varepsilon}{(j+1)\log s} \geq \frac{\varepsilon \cdot \log k}{\log s}.$$

Since f is a monotone decision tree of size s, it has total influence at most $\sqrt{\log s}$ (Theorem 18). This means that $C_0 \leq \sqrt{\log s}$. We choose

$$k = \exp(\log(s)^{1.5}/\varepsilon) = s^{\sqrt{\log s}/\varepsilon}$$

at which point, $C_k \leq 0 \leq \varepsilon$, so BuildTopDownDTreturns a tree of size $k + 1$. ◀

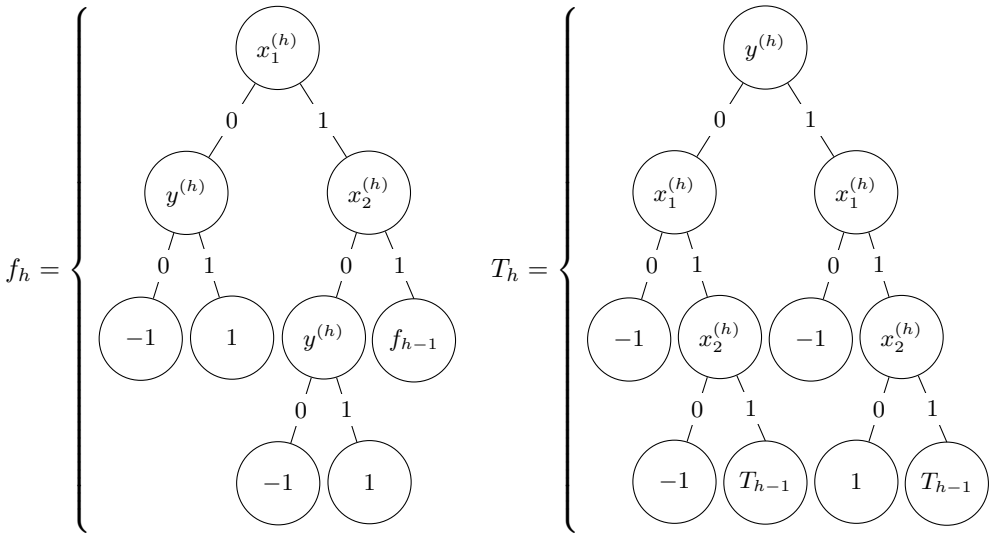

Figure 3 Diagrams exhibiting a function with exponential difference between the optimal decision tree size and TopDownDTSize. The left diagram shows how to compute f_h with a decision tree of size $O(h)$. The right diagram shows T_h, the tree BuildTopDownDT builds, which has size $2^{\Omega(h)}$.

6 Lower bounds on TopDownDTsize for general functions: Proof of Theorem 4

6.1 Size separation for exact representation: Proof of Theorem 4(a)

We begin with a simple family of functions $\{f_h\}_{h\in\mathbb{N}}$ whose BuildTopDownDT tree has exponential size compared to the optimal tree. Each f_h is a function over $3h+1$ boolean variables $x_1^{(1)}, x_2^{(1)}, \ldots, x_1^{(h)}, x_2^{(h)}, y^{(1)}, \ldots, y^{(h)}, z$, and is defined inductively as follows:

$$f_0(z) = z,$$

and for $h \geq 1$,

$$f_h(x,y,z) = \begin{cases} y^{(h)} & \text{if } x_1^{(h)} \vee x_2^{(h)} \\ f_{h-1}(x,y,z) & \text{otherwise.} \end{cases}$$

The structure of BuildTopDownDT(f_h)

We see that $y^{(h)}$ has influence $\frac{3}{4}$, both $x_1^{(h)}$ and $x_2^{(h)}$ have influence $\frac{1}{4}$, and each variable in f_{h-1} has influence $< \frac{1}{4}$. BuildTopDownDT(f_h) therefore queries y_k at the root. In the restrictions of f_h obtained by setting $y^{(h)}$ to a constant, $x_1^{(h)}$ and $x_2^{(h)}$ have equal influence of $\frac{1}{4}$ and each variable in f_{h-1} has influence $< \frac{1}{4}$. By setting either $x_1^{(h)}$ or $x_2^{(h)}$ to a constant, we get a subfunction where the other $x^{(h)}$-variable has influence $\frac{1}{2}$ and each node in f_{h-1} has influence $< \frac{1}{2}$. Thus, BuildTopDownDT(f_h) builds the tree T_h depicted in Figure 3.

We see that each T_h contains two copies of T_{h-1}. It follows that the optimal size of f_h is $O(h)$, whereas the size of T_h is $2^{\Omega(h)}$: a size separation of TopDownDTSize$(f_h) = 2^{\Omega(s)}$ where s denotes the optimal size of f_h.

6.2 Size separation for approximate representation: Proof of Theorem 4(b)

Warmup/intuition: An s versus $s^{\Omega(\log(1/\varepsilon))}$ separation

Before proving Theorem 4(b), we first give a brief, informal description of how a simple modification to the family of functions $\{f_h\}_{h\in\mathbb{N}}$ in Theorem 4(a) above yields a separation of $\textsc{TopDownDTSize}(f,\varepsilon) = s^{\Omega(\log(1/\varepsilon))}$ for approximate representation. Theorem 4(b) – which improves this to a superpolynomial separation even for constant ε – builds on these ideas, but the family of functions and the proof of the lower bound are significantly more involved.

Consider replacing each $y^{(h)}$ variable in the definition of f_h with the parity of k variables $y_1^{(h)} \oplus \cdots \oplus y_k^{(h)}$, i.e. consider the following variant $\tilde{f}_h$ of f_h:

$$\tilde{f}_h(x,y,z) = \begin{cases} y_1^{(h)} \oplus \cdots \oplus y_k^{(h)} & \text{if } x_1^{(h)} \vee x_2^{(h)} \\ \tilde{f}_{h-1}(x,y,z) & \text{otherwise.} \end{cases}$$

Just like the single $y^{(h)}$ variable in f_h, we see that the k many $y_i^{(h)}$ variables are the most influential in $\tilde{f}_h$ (each having influence $\frac{3}{4}$). Furthermore, each $y_i^{(h)}$ variable remains the most influential even under *any* restriction to *any* number of the other $y_j^{(h)}$ variables. Therefore the tree $\tilde{T}_h$ that BuildTopDownDT builds for $\tilde{f}_h$ first queries all k many $y^{(h)}$ variables. At each of the 2^k resulting leaves, $x_1^{(h)}$ and $x_2^{(h)}$ are then queried, followed by a copy of $\tilde{T}_{h-1}$, the tree that BuildTopDownDT recursively constructs for $\tilde{f}_h$, in the branch corresponding to $x_1^{(h)} = x_2^{(h)} = 1$. The fact that there are 2^k copies of $\tilde{T}_{h-1}$ within $\tilde{T}_h$ should be contrasted with the fact that the tree T_h in Theorem 4(a) contains just two copies of T_{h-1}; recall Figure 3.

It is straightforward to see that there is a tree of size $O(h \cdot 2^k)$ that computes $\tilde{f}_h$. This tree is built by first querying the $x^{(h)}$ variables before the $y^{(h)}$ variables, and recursing on just one of the $\Omega(2^k)$ many resulting leaves. On the other hand, by first querying the $y^{(h)}$ variables followed by the $x^{(h)}$ variables, BuildTopDownDT recurses on $\Omega(2^k)$ many branches while only correctly classifying a $\frac{3}{4}$ fraction of inputs. Choosing $h = \Theta(\log(1/\varepsilon))$, we get a separation of $O(h \cdot 2^k)$ versus $2^{\Omega(kh)}$, or equivalently, s versus $s^{\Omega(\log(1/\varepsilon))}$.

6.2.1 Proof of Theorem 4(b)

Before defining the family of functions witnessing the separation, we define a couple of basic boolean functions and state a few of their properties that will be useful for our analyses:

▶ **Definition 19** (Tribes). *For any input length r, let w be the largest integer such that $(1-2^{-w})^{r/w} \leq \frac{1}{2}$. The $\textsc{Tribes}_r : \{0,1\}^r \to \{\pm 1\}$ function is defined to be the function computed by the read-once DNF with $\lfloor \frac{r}{w} \rfloor$ terms (over disjoint sets of variables) of width exactly w:*

$$\textsc{Tribes}_r(z) = (z_{1,1} \wedge \cdots \wedge z_{1,w}) \vee \cdots \vee (z_{t,1} \wedge \cdots \wedge z_{t,w}) \quad \text{where } t := \lfloor \tfrac{r}{w} \rfloor,$$

and where we adopt the convention that -1 represents logical False *and 1 represents logical* True.

The following facts about the Tribes function are standard (see Chapter §4.2 of [51]) and can be easily verified:

▶ **Fact 20** (Properties of $\textsc{Tribes}_r$).

- $\Pr[\textsc{Tribes}_r(\boldsymbol{z}) = 1] = \frac{1}{2} - O\big(\frac{\log r}{r}\big)$.
- $\mathrm{Inf}(\textsc{Tribes}_r) = (1 \pm o(1)) \cdot \ln r$ *and consequently,* $\mathrm{Inf}_i(\textsc{Tribes}_r) = (1 \pm o(1)) \cdot \frac{\ln r}{r}$ *for all* $i \in [n]$.
- $w = \log r - \log \ln r \pm O(1)$.
- $\mathrm{size}(\textsc{Tribes}_r) \leq w^{O(r/w)} = 2^{O(r \log \log r / \log r)}$.

▶ **Definition 21** (Threshold). *For any input length* ℓ *and* $t \in \{0, \ldots, \ell\}$*, the* $\textsc{Threshold}_{\ell,t} : \{0,1\}^\ell \to \{\pm 1\}$ *function is defined to be*

$$\textsc{Threshold}_{\ell,t}(x) = 1 \iff \sum_{i=1}^{\ell} x_i \leq t.$$

Defining the family of functions witnessing the separation

Consider the following family of functions $\{f_h\}_{h \in \mathbb{N}}$. Each f_h is a function over $h(\ell + k) + r$ boolean variables $x^{(1)}, x^{(2)}, \ldots, x^{(h)} \in \{0,1\}^\ell$,$y^{(1)}, \ldots, y^{(h)} \in \{0,1\}^k$, and $z \in \{0,1\}^r$, and is defined inductively as follows:

$$f_0(z) = \textsc{Tribes}_r(z),$$

and for $h \geq 1$,

$$f_h(x, y, z) = \begin{cases} \textsc{Parity}_k(y^{(h)}) & \text{if } \textsc{Threshold}_{\ell,1}(x^{(h)}) = 1 \\ f_{h-1}(x, y, z) & \text{otherwise.} \end{cases}$$

▷ Claim 22 (Optimal decision tree size of f_h).

$$\begin{aligned} \mathrm{size}(f_h) &\leq \ell^{O(h)} \cdot (\mathrm{size}(\textsc{Parity}_k) + \mathrm{size}(\textsc{Tribes}_r)) \\ &\leq \ell^{O(h)} \cdot (2^k + 2^{O(r \log \log r / \log r)}). \end{aligned}$$

Proof. Please refer to figure Figure 4. We first build a tree of size $O(\ell^2)$ that evaluates $\textsc{Threshold}_{\ell,1}(x^{(h)})$. Of these leaves, $\ell + 1$ descend into a tree computing $\textsc{Parity}_k(y^{(h)})$, which has size 2^k. The others descend into a tree computing f_{h-1}. This yields the recurrence

$$\begin{aligned} \mathrm{size}(f_h) &\leq O(\ell) \cdot \mathrm{size}(\textsc{Parity}_k) + O(\ell^2) \cdot \mathrm{size}(f_{h-1}) \\ &\leq O(\ell \cdot 2^k) + O(\ell^2) \cdot \mathrm{size}(f_{h-1}) \\ \mathrm{size}(f_0) &= \mathrm{size}(\textsc{Tribes}_r) \leq 2^{O(r \log \log r / \log r)}, \qquad \text{(Recall Fact 20)} \end{aligned}$$

and the claim follows. ◁

In the remainder of this section, we will prove a lower bound on $\textsc{TopDownDTSize}(f, \varepsilon)$. Figure 5 should be contrasted with Figure 4.

The structure of BuildTopDownDT(f_h)

The following helper lemma will be useful in determining the structure of the tree BuildTopDownDT produces.

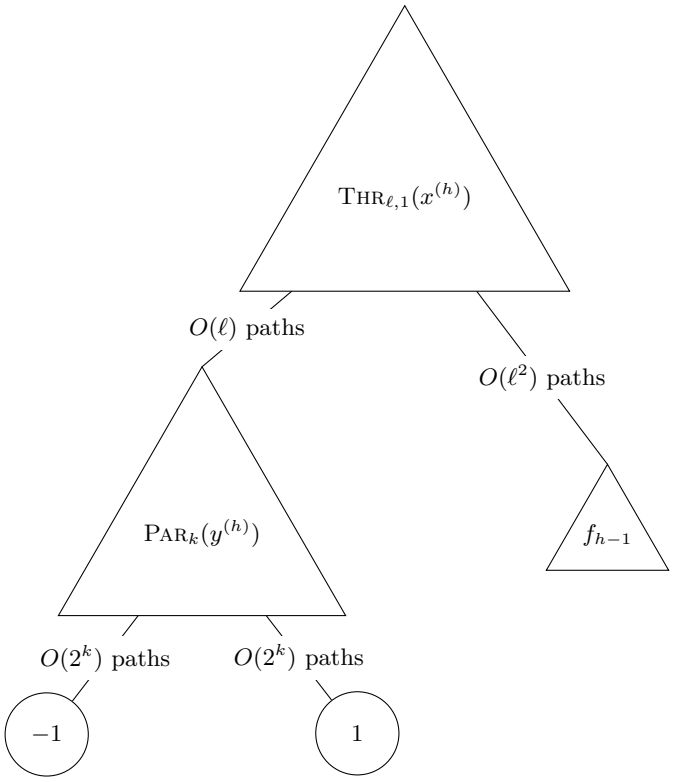

Figure 4 A small decision tree for f_h.

▶ **Lemma 23** (Preservation of influence order). *Let* $f : \{0,1\}^{\overline{S}} \times \{0,1\}^S \to \{\pm 1\}$ *and* $\tilde{f} : \{0,1\}^S \to \{\pm 1\}$ *be two functions satisfying the following: there is a function* $g : \{0,1\}^{\overline{S}} \times \{\pm 1\} \to \{\pm 1\}$ *such that:*

$$f(a,b) = g(a, \tilde{f}(b)) \quad \text{for all } a \in \{0,1\}^{\overline{S}},\ b \in \{0,1\}^S.$$

Then for all variables $v_1, v_2 \in S$,

$$\text{Inf}_{v_1}(\tilde{f}) \geq \text{Inf}_{v_2}(\tilde{f}) \quad \text{if and only if} \quad \text{Inf}_{v_1}(f) \geq \text{Inf}_{v_2}(f).$$

Proof. This holds by noting that for $v \in \{v_1, v_2\}$,

$$\begin{aligned}
\text{Inf}_v(f) &= \Pr_{\boldsymbol{a},\boldsymbol{b}}[f(\boldsymbol{a},\boldsymbol{b}) \neq f(\boldsymbol{a},\boldsymbol{b}^{\oplus v})] \\
&= \Pr_{\boldsymbol{a},\boldsymbol{b}}[g(\boldsymbol{a}, \tilde{f}(\boldsymbol{b})) \neq g(\boldsymbol{a}, \tilde{f}(\boldsymbol{b}^{\oplus v}))] \\
&= \Pr_{\boldsymbol{b}}[\tilde{f}(\boldsymbol{b}) \neq \tilde{f}(\boldsymbol{b}^{\oplus v})] \cdot \Pr_{\boldsymbol{a}}[g(\boldsymbol{a},-1) \neq g(\boldsymbol{a},1)] \\
&= \text{Inf}_v(\tilde{f}) \cdot \Pr_{\boldsymbol{a}}[g(\boldsymbol{a},-1) \neq g(\boldsymbol{a},1)].
\end{aligned}$$

The lemma follows since $\Pr_{\boldsymbol{a}}[g(\boldsymbol{a},-1) \neq g(\boldsymbol{a},1)]$ does not depend on v (and hence is the same regardless of whether $v = v_1$ or $v = v_2$). ◀

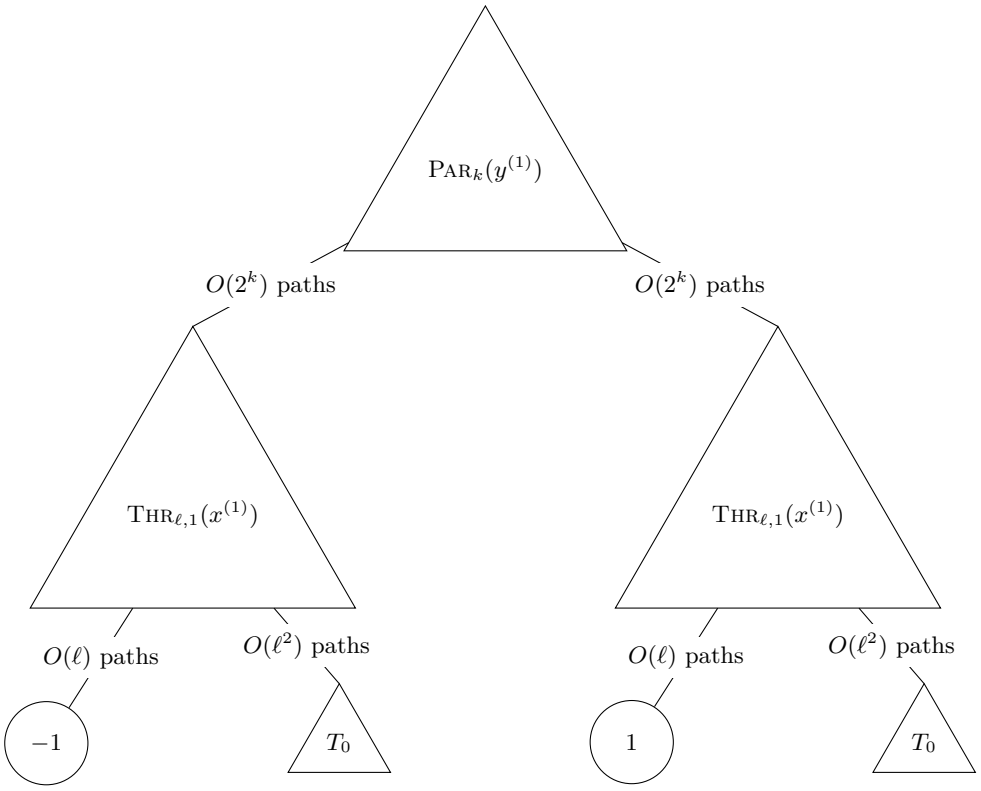

Figure 5 The tree T_1 that BuildTopDownDT builds for f_1. Since $y^{(1)}$ has all the most influential variables, BuildTopDownDT puts them all at the root. As a result, it ends up building a significantly larger tree than optimal (cf. Figure 4). Notice that the size of T_1 is $\Omega(2^k)$ times as large as T_0. This leads to exponential growth of the tree size as a function of h.

Lemma 23 is especially well-suited for our inductively-defined family of functions $\{f_h\}_{h\in\mathbb{N}}$. For each $i \in \{0, 1, \ldots, h\}$, we let S_i denote the relevant variables of f_i. Therefore

$$S_0 = \{z_1, \ldots, z_r\}$$
$$S_{i+1} = S_i \sqcup \{x_1^{(i)}, \ldots, x_\ell^{(i)}, y_1^{(i)}, \ldots, y_k^{(i)}\}$$

▶ **Observation 24.** *For all $i \in \{0, 1, \ldots, h\}$, there exists g_i such that*

$$f_h(a, b) = g_i(a, h_i(b)) \quad \text{for all } a \in \{0,1\}^{S_h \setminus S_i} \text{ and } b \in \{0,1\}^{S_i}. \tag{3}$$

Consequently, we may apply Lemma 23 to get that for all $v_1, v_2 \in S_i$, we have that

$$\mathrm{Inf}_{v_1}(f_i) \geq \mathrm{Inf}_{v_2}(f_i) \quad \text{if and only if} \quad \mathrm{Inf}_{v_1}(f_h) \geq \mathrm{Inf}_{v_2}(f_h).$$

We note the following corollary, which is a straightforward consequence of the observation that the property (3) is preserved under restrictions:

▶ **Corollary 25** (Preservation of influence order under restrictions)**.** *Let π be any restriction. For all $i \in \{0, 1, \ldots, h\}$, we have that*

$$\mathrm{Inf}_{v_1}((f_i)_\pi) \geq \mathrm{Inf}_{v_2}((f_i)_\pi) \quad \text{if and only if} \quad \mathrm{Inf}_{v_1}((f_h)_\pi) \geq \mathrm{Inf}_{v_2}((f_h)_\pi).$$

Lower bounding the size of BuildTopDownDT(f, ε)

Let T_{exact} denote the tree returned by BuildTopDownDT(f_h) and T_{approx} that returned by BuildTopDownDT(f_h, ε). (So T_{exact} computes f_h, and T_{approx} is an ε-approximation of f_h.) Our goal is to lower bound the size of T_{approx}. We will in fact establish something stronger: our lower bound holds for *any pruning* of T_{exact} that is an ε-approximation of T_{exact}, where a pruning of a tree T is any tree obtained by iteratively removing leaves from T in a bottom-up fashion. Since BuildTopDownDT(f, ε) is simply BuildTopDownDT(f_h) terminated early, we have that T_{approx} is indeed a pruning of T_{exact}.

Let V_{exact} be defined as follows:

$$V_{\text{exact}} \coloneqq \{v \colon v \text{ is the first node in a path of } T_{\text{exact}} \text{ that queries a } z\text{-variable}\}.$$

We define $V_{\text{approx}} \subseteq V_{\text{exact}}$ analogously. At a very high level, our proof of Theorem 4(b) will proceed by showing that V_{exact} has large size, and V_{approx} has to contain many nodes in V_{exact}. For the remainder of this proof, we will need that r and ℓ are chosen to satisfy:

$$\frac{2 \ln r}{r} < 2^{-\ell}. \tag{4}$$

▶ **Lemma 26** (All nodes in V_{exact} occur deep within T_{exact})**.** *Fix $v \in V_{\text{exact}}$ and let π denote the path in T_{exact} that leads to v. Then $|\pi| \geq kh$.*

Proof. Suppose without loss of generality that v is a query to z_1. We claim that $y_j^{(i)} \in \pi$ for all $i \in [h]$ and $j \in [k]$, from which the lemma follows. Fix $i \in [h]$. We will prove there are at least k queries to variables in S_i within π, and that the first k of these queries have to be $y_j^{(i)}$ for $j \in [k]$. We prove both these claims simultaneously by induction on k.

- (Base case.) Seeking a contradiction, suppose π does not contain any queries to variables in S_i, in which case $(f_i)_\pi \equiv f_i$. Since z_1 is the variable queried at the root of $(f_h)_\pi$, it is the most influential variable within $(f_h)_\pi$. By Corollary 25, it follows that z is the most influential variable within $(f_i)_\pi \equiv f_i$. This contradicts Equation (4) since

$$\mathrm{Inf}_{y_1^{(i)}}(f_i) = \frac{\ell + 1}{2^\ell} \quad \text{and} \quad \mathrm{Inf}_{z_1}(f_i) < \mathrm{Inf}_{z_1}(\textsc{Tribes}_r) = (1 \pm o(1)) \cdot \frac{\ln r}{r}.$$

  Therefore π has to contain at least one variable in S_i. Let $u \in \pi$ be the first query to a variable in S_i, which we claim must be $y_j^{(i)}$ for some j. Let $\pi_u \subset \pi$ be the path in T_{exact} that leads to u. Again, we have that u must be the most influential variable within $(f_h)_{\pi_u}$, and hence, by Corollary 25, it is the most influential within $(f_i)_{\pi_u}$. Since π_u does not contain any queries to variables in S_i, we have that $(f_i)_{\pi_u} \equiv f_i$, and hence u must be $y_j^{(i)}$ for some j since these are the most influential variables within f_i.
- (Inductive step.) Fix $k' < k$, and suppose we have established that there are at least k' queries to variables in S_i within π, the first k' of which are to $y^{(i)}$-variables. We first claim that there is at least one more query to variable in S_i within π. Suppose not. It follows that z_1 must be the most influential variable within $(f_h)_\pi$, and hence, by Corollary 25, it is the most influential variable within $(f_i)_\pi$. This is a contradiction, since z_1 is less influential than any of the $k - k'$ many $y_j^{(i)}$ variables that are not queried by π.
  Therefore π has to contain at least one more query to a variable in S_i. Let $u \in \pi$ be the $(k+1)^{st}$ query to a variable in S_i, which we claim must be $y_j^{(i)}$ for some j. Let $\pi_u \subset \pi$ be the path in T_{exact} that leads to u. Again, we have that u must be the most

influential variable within $(f_h)_{\pi_u}$, and hence, by Corollary 25, it is the most influential within $(f_i)_{\pi_u}$. Since π_u contains exactly k' queries to variables S_i, and all these queries are to $y^{(i)}$ variables, we have that u must be $y_j^{(i)}$ for one of the remaining $k - k'$ many $y^{(i)}$-variables since these are the most influential variables within $(f_i)_{\pi_u}$.

This completes the inductive proof of Lemma 26. ◀

▶ **Lemma 27.** *Fix $v \in V_{\text{exact}}$ and let π denote that path in T_{exact} that leads to v. Then $(f_h)_\pi \equiv \textsc{Tribes}_r$.*

Proof. Suppose $(f_h)_\pi \not\equiv \textsc{Tribes}_r$. Our proof of Lemma 26 shows that π contains every y-variable, so it must be the case that some x-variable remains relevant (i.e. has nonzero influence) in $(f_h)_\pi$. Let $i^* \geq 1$ be the highest value of i for which there is a relevant $x^{(i)}$-variable in $(f_h)_\pi$. Assume without loss of generality that $x_1^{(i)}$ remains relevant, and that z_1 is that z-variable that is queried at v.

Since z_1 is queried at the root of $(f_h)_\pi$, we have that it must be maximally influential in $(f_h)_\pi$, and in particular,

$$\mathrm{Inf}_{z_1}((f_h)_\pi) \geq \mathrm{Inf}_{x_1^{(i^*)}}((f_h)_\pi).$$

Applying Corollary 25, we infer that

$$\mathrm{Inf}_{z_1}((f_{i^*})_\pi) \geq \mathrm{Inf}_{x_1^{(i^*)}}((f_{i^*})_\pi). \tag{5}$$

Let us say that an input (x, y, z) to f_{i^*} is *z-dependent* if

$$\textsc{Threshold}_{\ell,1}(x^{(i)}) = 0 \quad \text{for all } 1 \leq i \leq i^*.$$

Note that the output of f_{i^*} on any z-dependent input is $\textsc{Tribes}_r(z)$. Since π contains every y-variable, it fixes $\textsc{Parity}_k(y^{(i^*)})$ to either -1 or 1; we assume without loss of generality that $\textsc{Parity}_k(y^{(i^*)})_\pi \equiv 1$. We have that

$$\begin{aligned}
\mathrm{Inf}_{x_1^{(i^*)}}((f_{i^*})_\pi) &\geq \Pr_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})}[(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) \text{ is } z\text{-dependent}] \cdot \Pr_{\boldsymbol{z}}[\textsc{Tribes}_r(\boldsymbol{z}) \neq 1] \\
&\qquad \times \mathrm{Inf}_{x_1^{(i^*)}}\big(\textsc{Threshold}_{\ell,1}(x^{(i^*)})_\pi\big) \\
&\geq \Pr_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})}[(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) \text{ is } z\text{-dependent}] \cdot \tfrac{1}{2} \cdot 2^{-(\ell-1)} \\
&= \Pr_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})}[(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) \text{ is } z\text{-dependent}] \cdot 2^{-\ell}.
\end{aligned}$$

The second inequality uses the fact that $\mathrm{Inf}_{x_1^{(i^*)}}(\textsc{Threshold}_{\ell,1}(x^{(i^*)})_\pi) \geq 2^{-(\ell-1)}$, which holds with equality when exactly one other $x^{(i^*)}$-variable is in π and that variable is set to 1.[16]

On the other hand, we have that

$$\begin{aligned}
\mathrm{Inf}_{z_1}((f_{i^*})_\pi) &\leq \Pr_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})}[(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) \text{ is } z\text{-dependent}] \cdot \mathrm{Inf}_{z_1}[\textsc{Tribes}_r(z)] \\
&< \Pr_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})}[(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) \text{ is } z\text{-dependent}] \cdot \frac{2\ln r}{r}. \qquad \text{(Fact 20)}
\end{aligned}$$

[16] In this derivation, we have assumed that $\textsc{Tribes}_r$ is *perfectly* balanced, i.e. that $\Pr[\textsc{Tribes}_r(\boldsymbol{z}) = 1] = \frac{1}{2}$, when in fact $\Pr[\textsc{Tribes}_r(\boldsymbol{z}) = 1] = \frac{1}{2} \pm o(1)$ (recall Fact 20). The same proof goes through if one carries around the additive $o(1)$ factor.

These bounds on influences, along with Equation (5), imply that $2^{-\ell} < \frac{2\ln r}{r}$. This contradicts our assumption on the relationship between ℓ and r (Equation (4)), and the proof is complete. ◀

We are now ready to lower bound the size of T_{approx}.

▷ Claim 28 (Lower bound on the size of T_{approx}). Fix $\varepsilon \in (0, \frac{1}{2})$ and let $c = (\frac{1}{2} - \varepsilon)/2$. If

$$\left(1 - \frac{\ell+1}{2^\ell}\right)^h \geq (2+c)\varepsilon, \tag{6}$$

then $|V_{\text{approx}}| \geq \Omega(\varepsilon \cdot 2^{kh})$. Consequently, the size of T_{approx} is also at least $\Omega(\varepsilon \cdot 2^{kh})$.

Proof. An input to f_h reaches *some* node in V_{exact} if and only if $\textsc{Threshold}_{\ell,1}(x^{(i)}) = 0$ for all $1 \leq i \leq h$. The fraction of inputs that satisfies this is exactly $(1 - \frac{\ell+1}{2^\ell})^h$, which is at least $(2+c)\varepsilon$ by our choice of parameters given by Equation (6).

Fix $v \in V_{\text{exact}}$. If $v \notin V_{\text{approx}}$, then T_{approx} assigns all inputs reaching v the same -1 or $+1$ value, whereas f_h labels half of them -1 and half of them $+1$ (Lemma 27). Therefore, T_{approx} errors on half of the inputs that each v. On the other hand, if $v \in V_{\text{approx}}$, we have by Lemma 26 that at most a 2^{-kh} fraction of inputs reach this specific v. Combining all of the above observations, it follows that

$$\text{error}(T_{\text{exact}}, T_{\text{approx}}) \geq \tfrac{1}{2}\left((2+c)\varepsilon - |V_{\text{approx}}| \cdot 2^{-kh}\right).$$

Since $\text{error}(T_{\text{exact}}, T_{\text{approx}}) \leq \varepsilon$, it follows that

$$\varepsilon \geq \tfrac{1}{2}\left((2+c)\varepsilon - |V_{\text{approx}}| \cdot 2^{-kh}\right),$$

and the claim follows by rearranging. ◁

Theorem 4(b) now follows from Claim 22 and Claim 28 by setting parameters appropriately:

Proof of Theorem 4(b). Choosing

$$\begin{aligned} h &= \Theta\left(\frac{2^\ell}{\ell} \cdot \log(1/\varepsilon)\right) && \text{(to satisfy Equation (6))} \\ r &= \Theta(\ell 2^\ell) && \text{(to satisfy Equation (4))} \\ k &= \Theta(h \log \ell), \end{aligned}$$

we may apply Claim 22 and Claim 28 to get that

$$\text{size}(f_h) \leq 2^{O(k \log k)} \quad \text{whereas} \quad \textsc{TopDownDTSize}(f, \varepsilon) \geq 2^{\Omega_\varepsilon(k^2/\log\log k)}.$$

This is a separation of s versus $s^{\tilde{\Omega}(\log s)}$. ◀

▶ Remark 29. For our choice of parameters above, we have that $s(n) = \text{size}(f_h) = 2^{\tilde{\Theta}(\sqrt{n})}$, where $n = h(\ell + k) + r$ is the number of variables of f_h. A standard padding argument yields the same s versus $s^{\tilde{\Omega}(\log s)}$ separation for any function $s(n) \leq 2^{\tilde{O}(\sqrt{n})}$.

7 Lower bounds on TopDownDTsize for monotone functions: Proof of Theorem 7

7.1 Size separation for exact representation: Proof of Theorem 7(a)

We will give a family of monotone functions, $\{f_h\}_{h\in\mathbb{N}}$ whose BuildTopDownDT tree has exponential size compared to the optimal tree. First, we define a few terms which will be useful for our monotone constructions.

▶ **Definition 30** (Comparing vectors and upper/lower shadows). *For any $x, y \in \{0,1\}^n$, we use $x \preceq y$ to represent*

$$x \preceq y \iff x_i \leq y_i \text{ for all } i \in [n]$$

and $\succeq$ is defined similarly. For any vector x, the upper shadow *of x is the set of all vectors y such that $x \preceq y$. Similarly, the* lower shadow *of x is the set of all vectors y such that $x \succeq y$.*

Defining the family of functions witnessing the separation

Each f_h in $\{f_h\}_{h\in\mathbb{N}}$ is a function over $5h+1$ boolean variables $x^{(1)}, x^{(2)}, \ldots, x^{(h)} \in \{0,1\}^4$, $y^{(1)}, \ldots, y^{(h)} \in \{0,1\}$, and $z \in \{0,1\}$, and is defined inductively as follows:

$$f_0(z) = z,$$

and for $h \geq 1$, we fix $x^* \coloneqq (0,0,1,1)$ and define

$$f_h(x,y,z) = \begin{cases} f_{h-1}(x,y,z) & \text{if } x^{(h)} = x^* \\ +1 & \text{if } x^{(h)} \succeq x^* \text{ and } x^{(h)} \neq x^* \\ -1 & \text{if } x^{(h)} \preceq x^* \text{ and } x^{(h)} \neq x^* \\ y & \text{otherwise.} \end{cases}$$

It is straightforward to verify that f_h is indeed monotone. We will show that f_h can be computed by a tree of size $O(h)$, but that BuildTopDownDT produces a tree of size $2^{\Omega(h)}$. For the first claim, we construct a decision tree for f_h directly from its definition. We start with a complete tree on the $x^{(h)}$ variables – this complete tree has size 2^4, a constant. At one of the branches, we recursively build a tree for f_{h-1}; at all the other branches, we build a tree of size 1 or 2 computing one of $-1, 1$, or $y^{(h)}$. The result is a tree of size $O(h)$.

On the other hand, we claim that BuildTopDownDT will build a tree of size $2^{\Omega(h)}$, as depicted in Figure 6. In f_h, $y^{(h)}$ has influence $\frac{9}{16}$ and all the other variables have influence at most $\frac{1}{2}$. Hence, $y^{(h)}$ will be placed at root. Then, BuildTopDownDT will query enough of $x^{(h)}$ to determine whether the output should be $-1, +1$, or f_{h-1}. If the output should be f_{h-1}, which will occur once for each choice of y, then the entire tree T_{h-1} will be placed. Hence, the size of T_h is more than double the size of T_{h-1}, and BuildTopDownDT builds a tree of size $2^{\Omega(h)}$.

7.2 Size separation for approximate representation: Theorem 7(b)

For any ε, we will prove there exists a function f with optimal tree size s but for which the tree BuildTopDownDT(f, ε) builds has size $s^{\tilde{\Omega}(\sqrt[4]{\log s})}$. The following function, a biased version of the Tribes function defined in Definition 19, will be used as a building block in our monotone construction.

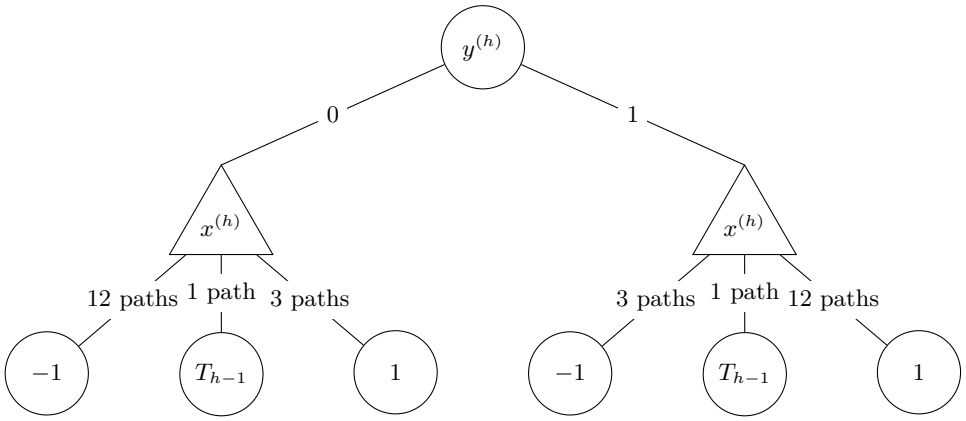

Figure 6 The tree that BuildTopDownDT builds for f_h. It will first query $y^{(h)}$, followed by the variables of $x^{(h)}$. For most choices of $y^{(h)}$ and $x^{(h)}$, the function is determined, and BuildTopDownDT will place a constant leaf equal to ± 1. However, the paths with $y = 0, x^{(h)} = x^*$ and $y = 1, x^{(h)} = x^*$ each include a copy of the tree for T_{h-1}.

▶ **Definition 31** (Biased Tribes). *Fix any input length ℓ and $\delta \in (0,1)$. We define* $\textsc{Tribes}_{\ell,\delta} : \{0,1\}^\ell \to \{\pm 1\}$ *to be the read-once DNF with $\lfloor \frac{\ell}{w} \rfloor$ terms of width exactly w over disjoint sets of variables (with some variables possibly left unused), where $w = w(\ell,\delta) \approx \log(\ell) \pm \log\log(1/\delta)$ is chosen such that $\Pr[\textsc{Tribes}_{\ell,\delta}(\boldsymbol{x}) = 1]$ is as close to δ as possible.*[17]

▶ **Fact 32** (Variable influences in biased Tribes). *All variables in $\textsc{Tribes}_{\ell,\delta}$ and $\textsc{Tribes}_{\ell,1-\delta}$ have influence at most*

$$(2 + o(1)) \cdot \delta \log(1/\delta) \cdot \frac{\log \ell}{\ell}.$$

Proof. We prove the lemma for the case of $\textsc{Tribes}_{\ell,1-\delta}$. (The calculations for $\textsc{Tribes}_{\ell,\delta}$ are very similar, and both claims are special cases of more general facts about variable influences in DNF formulas [61].) Suppose

$$\textsc{Tribes}_{\ell,1-\delta}(x) = T_1(x) \vee \cdots T_{\frac{\ell}{w}}(x),$$

where the T_i's are disjoint terms of width exactly w. We first observe that since

$$\begin{aligned}\delta = \Pr_{\boldsymbol{x}\sim\{0,1\}^n}[\textsc{Tribes}_{\ell,1-\delta}(\boldsymbol{x}) = 1] &= \Pr[\text{all } T_i(\boldsymbol{x}) \text{ are falsified by } \boldsymbol{x}] \\ &= (1 - 2^{-w})^{\ell/w} \approx e^{-\ell/w 2^w},\end{aligned}$$

we have that $w = (1 \pm o(1))(\log \ell - \log\log \ell - \log\log(1/\delta))$. The influence of any variable $i \in [n]$ on $\textsc{Tribes}_{\ell,1-\delta}$ is the probability, over a uniform $\boldsymbol{x}$ that each other variable j in i's term has $\boldsymbol{x}_j = 1$ and all other clauses evaluate to 0 under $\boldsymbol{x}$:

$$\begin{aligned}\mathrm{Inf}_i(\textsc{Tribes}_{\ell,1-\delta}) &= 2^{-(w-1)} \cdot (1 - 2^{-w})^{(\ell/w)-1} \\ &\le 2\delta \cdot 2^{-w} \\ &= (1 \pm o(1)) \cdot 2\delta \log(1/\delta) \cdot \frac{\log \ell}{\ell}.\end{aligned}$$

◀

[17] Although the acceptance probability of $\textsc{Tribes}_{\ell,\delta}$ cannot be made *exactly* δ due to granularity issues, it will be the case that $\textsc{Tribes}_{\ell,\delta} = \delta \pm o(1)$. For clarity, we will assume for the rest of this paper that the acceptance probability of $\textsc{Tribes}_\delta$ is exactly δ, noting that all of our proofs still go through if one carries around the $o(1)$ factor.

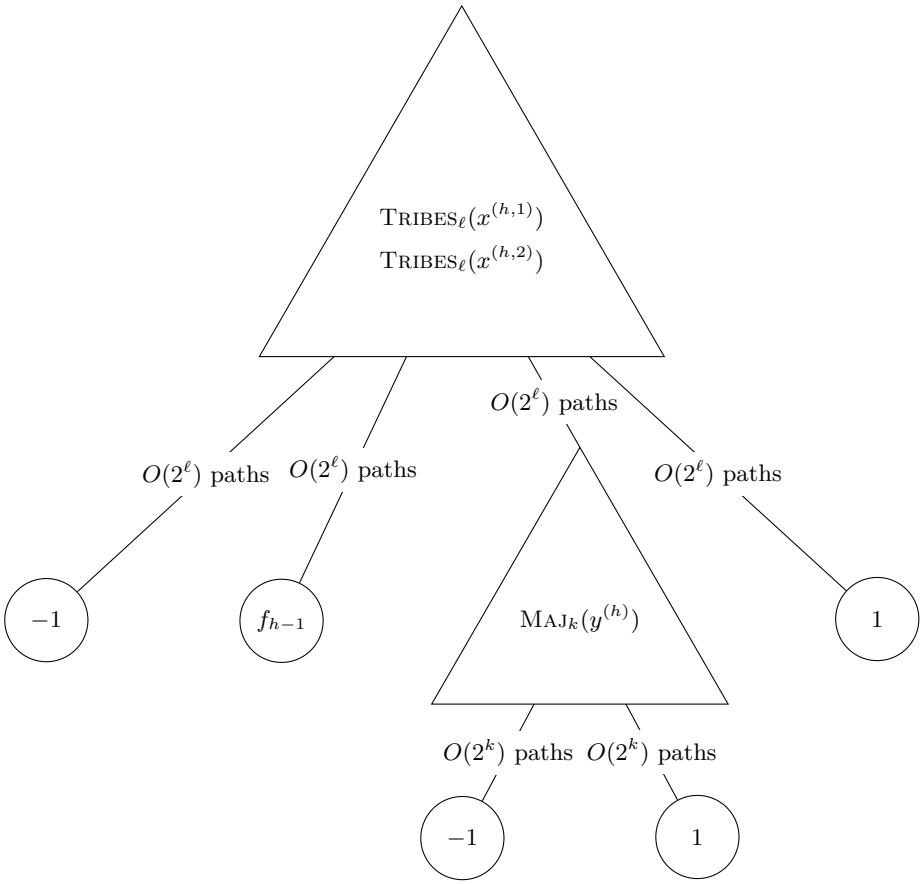

Figure 7 A small decision tree that computes f_h.

Defining the family of functions witnessing the separation

Each f_h in the family $\{f_h\}_{h\in\mathbb{N}}$ is a function over $h(2\ell+k)+r$ boolean variables, $x^{(1,1)}, x^{(1,2)}, \ldots, x^{(h,1)}, x^{(h,2)} \in \{0,1\}^\ell$, $y^{(1)}, \ldots, y^{(h)} \in \{0,1\}^k$, and $z \in \{0,1\}^r$, and is defined inductively as follows:

$$f_0(z) = \textsc{Tribes}_r(z),$$

and for $h \geq 1$,

$$f_h(x,y,z) = \begin{cases} -1 & \text{if } \textsc{Tribes}_{\ell,\delta}(x^{(h,1)}) = \textsc{Tribes}_{\ell,1-\delta}(x^{(h,2)}) = 0 \\ f_{h-1}(x,y,z) & \text{if } \textsc{Tribes}_{\ell,\delta}(x^{(h,1)}) = 0 \text{ and } \textsc{Tribes}_{\ell,1-\delta}(x^{(h,2)}) = 1 \\ \textsc{Maj}_k(y^{(h)}) & \text{if } \textsc{Tribes}_{\ell,\delta}(x^{(h,1)}) = 1 \text{ and } \textsc{Tribes}_{\ell,1-\delta}(x^{(h,2)}) = 0 \\ +1 & \text{otherwise.} \end{cases}$$

Clearly f_h is monotone in $x^{(h,1)}$ and $x^{(h,2)}$. Furthermore, since each of the functions $-1, +1$, and $\textsc{Maj}_k(y^{(h)})$, are monotone, if f_{h-1} is monotone then so is f_h.

▷ Claim 33 (Optimal size of f_h). Choose any integers $\ell, h, r, k > 0$ and let Then, $f_{h,\ell,k,r}$ has optimal decision tree size

$$\begin{aligned}\mathrm{size}(f_h) &\leq (\mathrm{size}(\textsc{Tribes}_{\ell,\delta}) \cdot \mathrm{size}(\textsc{Tribes}_{\ell,1-\delta}))^{O(h)} \cdot (\mathrm{size}(\textsc{Maj}_k) + \mathrm{size}(\textsc{Tribes}_r)) \\ &\leq 2^{O(h\cdot\ell \log\log \ell/\log \ell)} \cdot (2^k + 2^{O(r\log\log r/\log r)}). \qquad \text{(Fact 20)}\end{aligned}$$

Proof. As in the proofs of the previous separations, this upper bound is witnessed by the natural decision tree that one builds by following the definition of f_h. This tree first evaluates $\textsc{Tribes}_{\ell,\delta}(x^{(h,1)})$ followed by $\textsc{Tribes}_{\ell,1-\delta}(x^{(h,2)})$, resulting in a tree of size $(\mathrm{size}(\textsc{Tribes}_{\ell,\delta}) \cdot \mathrm{size}(\textsc{Tribes}_{\ell,1-\delta}))$. At the end of each branch, we either recursively build a tree for f_{h-1}, or a tree for $\textsc{Maj}_k(y^{(h)})$, or place constants $\{\pm 1\}$ as leaves. Please refer to Figure 7. ◁

The remainder of this section is devoted to lower bounding $\textsc{TopDownDTSize}(f_h, \varepsilon)$, the size of the tree T_{approx} that $\textsc{BuildTopDownDT}$ constructs to ε-approximate f_h.

7.2.1 "Mostly precedes"

By choosing parameters appropriately, we will ensure that when T_{approx} begins by querying the variables of $\textsc{Maj}_k(y^{(h)})$. The first technical challenge that arises is the following: unlike $\textsc{Parity}_k(y^{(h)})$ in our proof of Theorem 4(b), the influence of variables in $\textsc{Maj}_k(y^{(h)})$ changes as variables are queried. For example, the influence of the remaining variables of $\textsc{Maj}_k(y^{(h)})$ after $\frac{k}{2}$ variables have been queried is 0 if all of the queried variables are 1 and is $\Theta(\frac{1}{\sqrt{k}})$ if half of the variables queries are 0 and half are 1. Hence, in T_{approx}, the number of nodes from $y^{(h)}$ queried before some non-$y^{(h)}$-variable is queried will vary by path. (In other words, the analogue of Lemma 26 in the proof of Theorem 4(b) is somewhat trickier to establish.)

To handle this, we define the following notion, which will allow us to show that *most* $y^{(h)}$-variables are before other variables in *most* paths of the tree (Corollary 37).

▶ **Definition 34** (Mostly precedes). *Let S be a subset of the relevant variables of f_h. We say that $y^{(i)}$-*variables mostly precede S in T_{approx} *if for every path π in T_{approx} leading to a first query to a variable in S, and every $j \in [k]$,*

$$\mathrm{Inf}_j\big(\textsc{Maj}_k(y^{(i)})_\pi\big) \leq \frac{1}{100\sqrt{k}}.$$

(For some intuition behind Definition 34, we note that *pre-restriction*, the influences of variables in $\textsc{Maj}_k$ are given by:

$$\mathrm{Inf}_j(\textsc{Maj}_k) = \frac{1}{k} \cdot \binom{k}{\frac{k}{2}} \sim \frac{\sqrt{2/\pi}}{\sqrt{k}} \quad \text{for all } j \in [k],$$

which is significantly larger than the $\frac{1}{100\sqrt{k}}$ of Definition 34.)

With Definition 34 in hand, we now begin to formalize the structure of T_{approx} as depicted in Figure 8. For each $i \in [h]$, we define

$$R_i = \{x^{(i,1)}, x^{(i,2)}, \text{ and } z \text{ variables}\}.$$

▶ **Lemma 35.** *There is a universal constant c such that the following holds. Suppose*

$$\frac{c}{\sqrt{k}} \geq \frac{1}{\delta^2} \cdot \max\left\{\frac{\delta \log(1/\delta)\log \ell}{\ell}, \frac{\log r}{r}\right\}. \tag{7}$$

Then for all $i \in [h]$, we have that $y^{(i)}$-variables mostly precede R_i in T_{approx}.

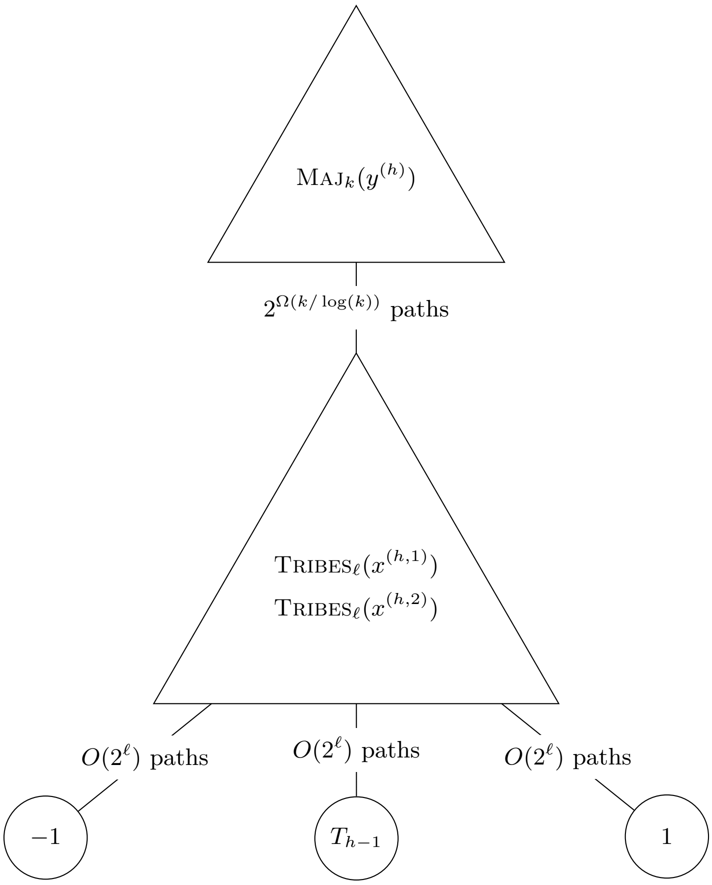

Figure 8 With appropriately chosen parameters, the $y^{(h)}$-variables are the most influential in f_h, so the tree built by BUILDTOPDOWNDT will query them first. Our analysis shows that this leads to a tree of size $2^{\Omega(kh/\log k)}$ (cf. Figure 7).

Proof. Fix $i \in [h]$. Let π be a path in T_{approx} that leads to a first query to a variable in $v \in R_i$. Since v is maximally influential in $(f_h)_\pi$, we may apply Corollary 25 to infer that v is also maximally influential in $(f_i)_\pi$ (and in particular, v is more influential than any $y^{(i)}$ variable). We have that

$$\begin{aligned}\mathrm{Inf}_v((f_i)_\pi) &\le \max\left\{\mathrm{Inf}_j(\mathrm{TRIBES}_{\ell,\delta}(x^{(i,1)})), \mathrm{Inf}_j(\mathrm{TRIBES}_{\ell,1-\delta}(x^{(i,2)})), \mathrm{Inf}_j(\mathrm{TRIBES}_r(z))\right\}\\ &\le \max\left\{(2+o(1))\cdot\delta\log(1/\delta)\cdot\frac{\log\ell}{\ell}, (1+o(1))\cdot\frac{\ln r}{r}\right\}.\end{aligned}$$

(Fact 20 and Fact 32)

On the other hand, for any $j \in [k]$,

$$\begin{aligned}\mathrm{Inf}_{y_j^{(i)}}((f_i)_\pi) &= \Pr\left[\mathrm{TRIBES}_{\ell,\delta}(\boldsymbol{x}^{(h,1)}) = 1, \mathrm{TRIBES}_{\ell,1-\delta}(\boldsymbol{x}^{(h,2)}) = 0\right]\cdot\mathrm{Inf}_j\left(\mathrm{MAJ}_k(y^{(i)})_\pi\right)\\ &= \delta^2\cdot\mathrm{Inf}_j\left(\mathrm{MAJ}_k(y^{(i)})_\pi\right).\end{aligned}$$

Since $\mathrm{Inf}_{y_j^{(i)}}((f_i)_\pi) \le \mathrm{Inf}_v((f_i)_\pi)$, the bounds above imply that

$$\mathrm{Inf}_j\big(\textsc{Maj}_k(y^{(i)})_\pi\big) \le \frac{1}{\delta^2} \cdot \max\left\{(2+o(1))\cdot\delta\log(1/\delta)\cdot\frac{\log\ell}{\ell}, (1+o(1))\cdot\frac{\ln r}{r}\right\}.$$

The lemma follows: by choosing c to be a sufficiently small constant in Equation (7), we can ensure that $\mathrm{Inf}_j\big(\textsc{Maj}_k(y^{(i)})_\pi\big) \le \frac{1}{100\sqrt{k}}$. ◀

▶ **Lemma 36.** *There is a universal constant c such that the following holds. Fix $i \in [h]$ and consider a uniform random $\boldsymbol{y}^{(i)} \in \{0,1\}^k$. The probability there is an input u to f_h consistent with $\boldsymbol{y}^{(i)}$ such that T_{approx}, on input u, queries an R_i-variable before a querying at least $ck/\log k$ many $\boldsymbol{y}^{(i)}$-variables is $O(k^{-2})$.*

Proof. Fix an outcome $y^{(i)}$ of $\boldsymbol{y}^{(i)}$. Suppose that there is an input u consistent with $y^{(i)}$ such that T_{approx}, on input u, queries an R_i-variable after querying only $< ck/\log k$ many $y^{(i)}$-variables. Call such a $y^{(i)}$ outcome *bad*, and let π denote the corresponding path in T_{approx} that leads to the first query to an R_i-variable. Since $y^{(i)}$-variables mostly precede R_i in T_{approx}, we have that

$$\mathrm{Inf}_j\big(\textsc{Maj}_k(y^{(i)})_\pi\big) \le \frac{1}{100\sqrt{k}} \quad \text{for all } j \in [k].$$

For this to hold, it must be the case that among the $t < ck/\log k$ many $y^{(i)}$-variables that occur in π, the discrepancy between the number of 0's and 1's is $\Omega(\sqrt{k})$. We can therefore bound

$$\begin{aligned}
\Pr_{\boldsymbol{y}^{(i)}\in\{0,1\}^k}[\boldsymbol{y}^{(i)} \text{ is bad}] &\le \sum_{t=1}^{ck/\log k} \Pr_{\boldsymbol{b}\sim\mathrm{Bin}(t,\frac{1}{2})}\left[|\boldsymbol{b}-\tfrac{t}{2}| \ge \Omega(\sqrt{k})\right] \\
&\le \sum_{t=1}^{ck/\log k} e^{-\Theta(k/t)} && \text{(Hoeffding's inequality)} \\
&\le \frac{ck}{\log k}\cdot e^{-\Theta((\log k)/c)} \ll \frac{1}{k^2},
\end{aligned}$$

where the final inequality holds by choosing c to be a sufficiently small constant. ◀

By a union bound over $i \in [h]$, we have the following corollary of Lemma 36 (which can be thought of as being roughly analogous to Lemma 26 in the proof of Theorem 4(b)):

▶ **Corollary 37** (Most queries to z-variables are deep within T_{approx})**.** *Let $\boldsymbol{y} = (\boldsymbol{y}^{(1)},\dots,\boldsymbol{y}^{(k)})$ be uniform random. The probability that there is an input u to f_h consistent with $\boldsymbol{y}$ such that T_{approx}, on input u, queries a z-variable before querying at least $(ck/\log k)\cdot h$ many $\boldsymbol{y}$-variables is $O(h/k^2)$.*

We are finally ready to lower bound the size of T_{approx}:

▷ Claim 38 (Lower bound on the size of T_{approx}). Fix $\varepsilon \in (0,\frac{1}{2})$ and let $c = (\frac{1}{2}-\varepsilon)/2$. If

$$(1-\delta)^{2h} \ge (2+c)\varepsilon \tag{8}$$

$$h \le k, \tag{9}$$

then the size of T_{approx} is at least $2^{\Omega(hk/\log k)}$.

Proof. We will call an input to f_h *z-dependent* if it satisfies:

$$\textsc{Tribes}_{\ell,\delta}(x^{(i,1)}) = 0 \text{ and } \textsc{Tribes}_{\ell,1-\delta}(x^{(i,2)}) = 1 \text{ for all } i \in [h].$$

Note that the output of f_h on any z-dependent input is $\textsc{Tribes}_r(z)$. Let us define $\zeta(y^{(1)}, \ldots, y^{(h)})$ to be the $\{0,1\}$-valued indicator of whether there is an input u consistent with $y^{(1)}, \ldots, y^{(h)}$ such that T_{approx} on input u queries a z-variable. For any fixed $y = (y^{(1)}, \ldots, y^{(h)})$,

- If $\zeta(y) = 0$, then T_{approx} must assign the same -1 or $+1$ value to all z-dependent inputs consistent with y;
- The fraction of z-dependent inputs that are consistent with y is

$$\Pr\left[\textsc{Tribes}_{\ell,\delta}(\boldsymbol{x}^{(i,1)}) = 0 \text{ and } \textsc{Tribes}_{\ell,1-\delta}(\boldsymbol{x}^{(i,2)}) = 1 \text{ for all } i \in [h]\right] = (1-\delta)^{2h},$$

  which is at least $(2+c)\varepsilon$ by Equation (8). Furthermore, since output of f_h on any z-dependent input is $\textsc{Tribes}_r(z)$, among the z-dependent inputs that are consistent with y, we have that f_h labels half of them -1 and half of them $+1$.

Therefore,

$$\text{error}(T_{\text{approx}}, f_h) \geq \tfrac{1}{2} \cdot (2+c)\varepsilon \cdot \Pr[\zeta(\boldsymbol{y}) = 0].$$

Since $\text{error}(T_{\text{approx}}, f_h) \leq \varepsilon$, it follows that $\Pr[\zeta(\boldsymbol{y}) = 1] \geq \Omega(1)$. Next, applying Corollary 37 along with our assumption that $h \leq k$ (Equation (9)), we further have that

$$\Pr_{\boldsymbol{y}}\left[\exists\, \boldsymbol{y}\text{-consistent } u \text{ s.t. } T_{\text{approx}}(u) \text{ queries } z\text{-variable after} \geq \tfrac{ck}{\log k} \cdot h \text{ many } \boldsymbol{y}\text{-variables}\right] \geq \Omega(1)$$

On the other hand, for any fixed path π in T_{approx} that queries $\geq \Omega(kh/\log k)$ many y-variables, at most a $2^{-\Omega(kh/\log k)}$ fraction of $\boldsymbol{y}$'s can be consistent with this specific π. We conclude that the size of T_{approx} must be at least $2^{\Omega(kh/\log k)}$, and the proof is complete. ◁

Theorem 7(b) now follows from Claim 33 and Claim 38 by setting parameters appropriately:

Proof of Theorem 7(b). By choosing

$$\begin{aligned}
\delta &= \Theta\left(\sqrt[3]{(\log \ell)^4 \log(1/\varepsilon)/\ell}\right) \\
k &= \Theta\left(\sqrt[3]{\ell^4 \log(1/\varepsilon)^2/(\log \ell)^4}\right) \\
r &= \Theta(k) \\
h &= \Theta\left(\frac{1}{\delta} \cdot \log(1/\varepsilon)\right),
\end{aligned}$$

we satisfy Equations (7) to (9). We may therefore apply Claim 33 to get that the optimal size of f_h is upper bounded by:

$$\text{size}(f_h) \leq \exp\left(O(\sqrt[3]{\ell^4 \log(1/\varepsilon)^2/(\log \ell)^4})\right).$$

On the other hand, by Claim 38, we have that

$$\textsc{TopDownDTSize}(f_h, \varepsilon) \geq 2^{\Omega(kh/\log k)} = \exp\left(\Omega(\sqrt[3]{\ell^5 \log(1/\varepsilon)^4/(\log \ell)^{11}})\right).$$

This is a separation of s versus $s^{\tilde{\Omega}(\sqrt[4]{\log(s)})}$. ◀

▶ Remark 39. For our choice of parameters above, we have that $s(n) = \text{size}(f_h) = 2^{\tilde{\Theta}(n^{4/5})}$, where $n = h(2\ell + k) + r$ is the number of variables of f_h. A standard padding argument yields the same s versus $s^{\tilde{\Omega}(\sqrt[4]{\log s})}$ separation for any function $s(n) \leq 2^{\tilde{O}(n^{4/5})}$.

▶ Remark 40 (Depth separation). The same proof witnesses a separation of d versus $\tilde{\Omega}_\varepsilon(d^{5/4})$ for the optimal *depth* of f_h versus the depth of the tree that BuildTopDownDT(f_h, ε) builds. This disproves the conjecture of Fiat and Pechyony [23] discussed in Section 2, which states that BuildTopDownDT builds a tree of optimal depth for all monotone functions, even in the case of exact representation ($\varepsilon = 0$).

7.3 Lower bounds for all impurity-based heuristics

▶ **Proposition 41** (Splitting on the most influential variable of a monotone function maximizes purity gain). *Let $f : \{\pm 1\}^n \to \{\pm 1\}$ be a monotone boolean function.*[18] *Let $\mathscr{G} : [-1, 1] \to [0, 1]$ be a concave function that is symmetric around 0, and satisfies $\mathscr{G}(-1) = \mathscr{G}(1) = 0$ and $\mathscr{G}(0) = 1$. Suppose $i \in [n]$ maximizes:*

$$\mathscr{G}(\mathbb{E}[f]) - \tfrac{1}{2}(\mathscr{G}(\mathbb{E}[f_{x_i=-1}]) + \mathscr{G}(\mathbb{E}[f_{x_i=1}])), \tag{10}$$

Then $\mathbb{E}[f(\boldsymbol{x})\boldsymbol{x}_i] \geq \mathbb{E}[f(\boldsymbol{x})\boldsymbol{x}_j]$ for all $j \in [n]$.

Proof. For all functions f, not necessarily monotone, $\mathbb{E}[f]$ is precisely the average of $\mathbb{E}[f_{x_i=0}]$ and $\mathbb{E}[f_{x_i=1}]$. Because $\mathscr{G}$ is concave everywhere on its domain, Jensen's inequality ensures that $\mathscr{G}(\mathbb{E}[f])$ is greater than $\frac{1}{2}(\mathscr{G}(\mathbb{E}[f_{x_i=0}]) + \mathscr{G}(\mathbb{E}[f_{x_i=1}])$. Furthermore, again by concavity, we have that this difference increases with the difference between $\mathbb{E}[f_{x_i=1}]$ and $\mathbb{E}[f_{x_i=-1}]$. Therefore the variable $i \in [n]$ that maximizes purity gain (10) also maximizes $|\mathbb{E}[f_{x_i=1}] - \mathbb{E}[f_{x_i=-1}]|$.

For a monotone function $f : \{\pm 1\}^n \to \{\pm 1\}$, we have the following identity for all variables $j \in [n]$:

$$\begin{aligned}\text{Inf}_j(f) &= \Pr[f(\boldsymbol{x}) \neq f(\boldsymbol{x}^{\oplus j})] \\ &= \mathbb{E}[f(\boldsymbol{x})\boldsymbol{x}_j] \\ &= \mathbb{E}[f_{x_j=1}] - \mathbb{E}[f_{x_j=-1}].\end{aligned}$$

Thus, the variable that maximizes purity gain (10) is also the most influential variable of f. ◀

Recall that in Theorem 8, we claimed that our lower bound on TopDownDTSize(f_h, ε) holds not just for the specific algorithm BuildTopDownDT, but in fact *any* impurity-based top-down heuristic. To see this, note that in our proof of Theorem 7(b) described in Section 7.2, we never used any information about *which* leaf BuildTopDownDT chooses to split on at each stage, only that when a leaf *is* split, it is replaced by the most influential variable of the corresponding subfunction. In other words, just like our proof of Theorem 4(b), our proof of Theorem 7(b) applies not just to the specific tree build by BuildTopDownDT(f_h, ε); it in fact lower bounds the size of *any* pruning T_{approx} of $T_{\text{exact}} =$ BuildTopDownDT$(f, \varepsilon = 0)$ that is an ε-approximator to f_h.

By Proposition 41, any tree build by a impurity-based top-down heuristic is a pruning of T_{exact}, and hence our proof of Theorem 7(b) extends to establish Theorem 8.

[18] For this proof, for notational reasons it will be slightly more convenient for us to work with $\{\pm 1\}^n$ instead of $\{0, 1\}^n$ as the domain of f.

8 New proper learning algorithms: Proofs of Theorems 9 and 10

Recall that BuildTopDownDT builds an approximation to f iteratively. It starts with an empty bare tree T° and repeatedly replaces the leaf with the highest score with a query to that leaf's most influential variable. In section Section 5.2, we proved lower bounds on the score of the leaf that BuildTopDownDT selects. Using those lower bounds, in section Section 5.3, we are able to prove upper bounds on the size of the tree BuildTopDownDT needs to produce to guarantee at most ε error. If, instead, we only guaranteed that we would pick a leaf with score a fourth of that guaranteed by the lower bounds in Section 5.2, all of our upper bounds would still hold, up to constant factors in the exponent. In this section, we will show that it is possible to accurately enough estimate influences to guarantee we pick a leaf with score at least a fourth the maximum score. First, we provide a definition of score that takes into account both the leaf and the variable selected.

▶ **Definition 42** (score). *Given any function f, we define the score of a leaf ℓ and variable i as follows.*

$$\operatorname{score}(\ell, i) \coloneqq \Pr_{\boldsymbol{x}\sim\{0,1\}^n}[\boldsymbol{x} \text{ reaches } \ell] \cdot \operatorname{Inf}_i(f_\ell) = 2^{-|\ell|} \cdot \operatorname{Inf}_i(f_\ell).$$

We first show that it is possible to estimate scores sufficiently accurately for monotone functions just from random samples of a function, which proves Theorem 10. Let $\boldsymbol{S}$ be a random sample from a monotone function f, and recall Fact 5. We can estimate the score of a particular leaf and variable as follows.

$$\operatorname{score}(\ell, i, \boldsymbol{S}) = \mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\in\boldsymbol{S}}\left[\mathbb{1}[\boldsymbol{x} \text{ reaches } \ell] \cdot f(\boldsymbol{x})(2\boldsymbol{x}_i - 1)\right].$$

Note that $\mathbb{E}_{\boldsymbol{S}}[\operatorname{score}(\ell, i, \boldsymbol{S}))] = \operatorname{score}(\ell, i)$. Let t be any score threshold and m be the number of examples in $\boldsymbol{S}$. By Chernoff bounds, for any particular leaf ℓ and variable x_i,

$$\Pr_{\boldsymbol{S}}\left[\operatorname{score}(\ell, i, \boldsymbol{S}) \le \tfrac{t}{2}\right] \le e^{-\frac{1}{8}t\cdot m} \quad \text{if } \operatorname{score}(\ell, i) \ge t$$
$$\Pr_{\boldsymbol{S}}\left[\operatorname{score}(\ell, i, \boldsymbol{S}) \ge \tfrac{t}{2}\right] \le e^{-\frac{1}{12}t\cdot m} \quad \text{if } \operatorname{score}(\ell, i) \le t/4.$$

At step j in BuildTopDownDT, there are $j+1$ leaves in T°. If t is the maximum score possible at that step, with probability at least $1-(j+1)e^{-\frac{1}{12}t\cdot m}$, the leaf and variable with maximum empirical score will have true score at least $\frac{t}{4}$. By Lemma 15, BuildTopDownDT(f, ε), at step j, there will always be a leaf with score at least $\frac{\varepsilon}{(j+1)\log(s)}$, where s is the decision tree size of f. Hence, the maximum empirical score will have true score at least $\frac{1}{4}$ the optimal value with probability at least $1-(j+1)e^{-\frac{\varepsilon\cdot m}{12(j+1)\log(s)}}$.

The probability that selecting the maximum empirical score is always within $\frac{1}{4}$ of the optimal value for every step from $j=0$ to $j=k-1$ is at least $1-k^2e^{-\frac{\varepsilon\cdot m}{12k\log(s)}}$. By setting the sample size to

$$m = O\left(\frac{k\log s}{\varepsilon}(\log k + \log(1/\delta))\right) \tag{11}$$

with probability at least $1-\delta$, we choose a sufficiently good leaf for k steps of BuildTopDownDT. Recall that, for monotone functions, BuildTopDownDT builds a decision tree of size at most

$$k = \min(s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}, s^{O(\sqrt{\log s}/\varepsilon)}).$$

Hence, with probability at least $1-\delta$, taking $\min(s^{O(\log(s/\varepsilon)\log(1/\varepsilon))}, s^{O(\sqrt{\log s}/\varepsilon)})\log(1/\delta)$ is enough to learn to accuracy ε. This proves Theorem 10.

If f is not monotone, we cannot accurately estimate influences from just random samples. However, we can estimate influences if given access to *random edges* from f.

▶ **Definition 43** (Random edges). *For any function $f:\{0,1\}^n \to \{\pm 1\}$, a* random edge *is two points of the form $((\boldsymbol{x}, f(\boldsymbol{x})), (\boldsymbol{x}^{\oplus \boldsymbol{i}}, f(\boldsymbol{x}^{\oplus \boldsymbol{i}})))$, where $\boldsymbol{x} \in \{0,1\}^n$ and $\boldsymbol{i} \in [n]$ are both picked uniformly at random. A* random edge sample $\boldsymbol{E}$ *is a collection of random edges. Given random edge sample $\boldsymbol{E}$, we will use $\boldsymbol{E}_i$ to refer to all those edges in $\boldsymbol{E}$ in which the i^{th} bit of x is flipped.*

Given a random edge sample $\boldsymbol{E}$ of a function f, we will be able to accurately estimate influences of the variables in f, and learn f using BuildTopDownDT. We use the following estimate of score:

$$\mathrm{score}(\ell, i, \boldsymbol{E}) = \mathop{\mathbb{E}}_{((\boldsymbol{x}_1,\boldsymbol{y}_1),(\boldsymbol{x}_2,\boldsymbol{y}_2))\in \boldsymbol{E}_i}\left[\mathbb{1}[\boldsymbol{x}_1 \text{ and } \boldsymbol{x}_2 \text{ reach } \ell]\cdot \mathbb{1}[\boldsymbol{y}_1 \neq \boldsymbol{y}_2]\right]$$

If we desire there to be m samples in each $\boldsymbol{E}_i$ with probability at least $1-\delta$, then having $\boldsymbol{E}$ by size $O(n\cdot(m+\log(\frac{1}{\delta}))$ is sufficient, where m is as defined in Equation (11). Since one can certainly general a random edge sample $\boldsymbol{E}$ if given membership query access to f, this proves Theorem 9.

Learning trees with small average depth: Theorem 11

Let f be a monotone function computed by a decision tree T of average depth $\triangle$.

1. We first observe that the total influence of f is at most $\triangle$. To see this, first recall that $\mathrm{Inf}(f) = \mathbb{E}[\mathrm{sens}_f(\boldsymbol{x})]$, where $\mathrm{sens}_f(x) = |\{i\in[n]\colon f(x)\neq f(x^{\oplus i})\}|$, i.e. that total influence is equivalent to average sensitivity. For any x, the sensitivity of f at x is at most the depth of the path that x follows in T, and hence the average sensitivity of f is at most the average depth $\triangle$ of T.
2. Recall Theorem 18, which says that monotone functions with decision tree size s have total influence at most $\sqrt{\log s}$. In fact, [53] proves a stronger statement: if f is monotone, then it has total influence at most $\sqrt{\triangle}$. (This is indeed a stronger statement because $\triangle \leq \log s$.)
3. Similarly, [52] also establishes a stronger version of Theorem 14, showing that f has a variable of influence at least $\mathrm{Var}(f)/\triangle$ (rather than just $\mathrm{Var}(f)/\log s$). Hence an equivalent statement to Lemma 15 holds, where BuildTopDownDT selects a leaf with score at least $\frac{\varepsilon}{(j+1)\triangle}$.

Combining these observations, with the same proof as for Theorem 6, we conclude that BuildTopDownDT produces a tree of size $2^{O(\triangle^2/\varepsilon)}$, and if T is monotone, size only $2^{O(\triangle^{3/2}/\varepsilon)}$. Then, for the same reasons as Theorems 9 and 10 hold, Theorem 11 holds.

9 Proper learning with polynomial sample and memory complexity

In this section we give a quasipolynomial-time algorithm for properly learning decision trees under the uniform distribution, where sample and memory of our algorithm are both polynomial. To our knowledge, this is the first algorithm for properly learning decision trees that achieves polynomial memory complexity. (Recall Table 1.)

Background: Ehrehfeucht–Haussler and Mehta–Raghavan

At the core of most learning algorithms is an algorithm that achieves low error on a set of samples. We will use the following notation in this section:

Notation

A sample, S, is a set of examples of the form (x, y) where $x \in \{0,1\}^n$ and $y \in \{-1, 1\}$. The error of a decision tree, T, with respect to the samples is

$$\text{error}_S(T) = \Pr_{\boldsymbol{x},\boldsymbol{y} \in S}[T(\boldsymbol{x}) \neq \boldsymbol{y}].$$

We say that a set of samples is *exactly fit* by a tree of size s if there exists a zero-error tree with size at most s. Furthermore, we use S_0^v and S_1^v to refer to all the points in the sample S where the variable corresponding to v is 0 and 1 respectively. Lastly, all learning statements in this section are with respect to the uniform distribution.

Ehrenfeucht and Haussler's algorithm makes the following guarantee:

▶ **Theorem 44** (Algorithmic core of [21]). *There is an algorithm that takes in a set of samples, S, over n variables that can be exactly fit by a decision tree of size s and returns a tree of size at most $n^{\log(s)}$ that exactly fits S. Furthermore, that algorithm runs in time $|S| \cdot n^{O(\log s)}$.*

One downside of their algorithm is that it leads to a large hypothesis class – the class of all decision trees of size $n^{\log s}$ – so in order to generalize with high probability, they require $\text{poly}(n^{\log s}, \frac{1}{\varepsilon})$ samples.

Mehta and Raghavan observe that if a function is computable by a tree of size s, then it is also ε-approximated by a tree of depth at most $\log(\frac{s}{\varepsilon})$. They combine this observation with a new algorithm that makes the following guarantee:

▶ **Theorem 45** (Algorithmic core of [46]). *There is an algorithm that takes a sample, S, over n variables as well as budgets for size s and depth d and returns the decision tree of size at most s and depth at most d with minimal error on S.*[19] *Furthermore, the algorithm runs in time $n^{O(d)} \cdot (s^2 + |S|)$.*

Importantly, there are only $2 \cdot (4n)^s$ decision trees of size at most s, a much smaller hypothesis class than for Ehrenfeucht and Haussler's algorithm. As a result, they only need $\text{poly}(s, \frac{1}{\varepsilon}) \cdot \log n$ samples to generalize with high probability. A downside of their work, relative to Ehrenfeucht and Haussler's, is that they need to set $d = O(\log(\frac{s}{\varepsilon}))$, so their algorithm has a runtime of approximately $n^{O(\log(s/\varepsilon))}$ instead of $n^{O(\log s)}$.

Neither [21] nor [46] are able to learn decision trees with only $\text{poly}(n, s, \frac{1}{\varepsilon})$ memory. [21] uses a sample of size approximately $n^{O(\log s)}$ to guarantee generalization, and their algorithm must store all of the samples, so it needs at least that much memory. [46] use a dynamic programming algorithm that stores computation for each restriction of the n variables of size at most $d = O(\log(\frac{s}{\varepsilon}))$. There are $\binom{n}{d} \cdot 2^d = \Theta\binom{n}{\log(s/\varepsilon)}$ such restrictions, resulting in superpolynomial memory complexity.

[19] They also guarantee that if their are multiple trees with minimal error, they return a tree with minimal size among those with minimal error.

Algorithm 1 Our variant of Ehrenfeucht and Haussler's FIND algorithm.

FIND(S, s, d):

Input: A sample S that can be exactly fit by a tree of size s and depth budget d.

Output: A decision tree T with depth at most d that approximately fits S. If S cannot be fit by a tree of size s, may return "None".

1. If all samples in S have the same label, return the single-node tree computing that label.
2. If $s \leq 1$ return "None".
3. If $d = 0$ return the single-node tree computing the majority label of S.
4. For each relevant[20] variable v:
   a. Let $T_0^v = \text{FIND}(S_0^v, \frac{s}{2}, d-1)$ and $T_1^v = \text{FIND}(S_1^v, \frac{s}{2}, d-1)$.
   b. If both T_0^v and T_1^v are not "None", return the tree with root labeled v, 0-subtree T_0^v and 1-subtree T_1^v.
   c. If one of T_0^v and T_1^v is "None" and the other is not:
      i. Reexecute the recursive call for the side that was "None" with size $s-1$ instead of size $\frac{s}{2}$. For example, if T_1^v was "None", set $T_1^v = \text{FIND}(S_1^v, s-1, d-1)$
      ii. If the reexecuted call still returns "None", return "None".
      iii. Return the tree with root labeled v, 0-subtree T_0^v and 1-subtree T_1^v.
5. Return "None".

Our algorithm: proper learning with polynomial sample and memory complexity

We introduce a new algorithm that makes more assumptions about its input than either [21]'s or [46]'s algorithms. It requires the samples it receives to be *well-distributed*, a property we will later define (Definition 48). In exchange, it only uses polynomial memory. The following should be contrasted with Theorems 44 and 45:

▶ **Theorem 46** (Core of our algorithm). *There is an algorithm (Algorithm 1) that when given a depth budget d and a well-distributed sample S that can be exactly fit by a tree of size s returns a tree with depth at most d and error at most $(\frac{3}{4} + o(1))^d \cdot s$ on the samples. Furthermore, the algorithm runs in time $|S| \cdot n^{O(\log s)}$ and uses $\text{poly}(2^d, \log n, |S|)$ memory.*

Note that if the goal is to learn the sample to accuracy ε, we can set $d = O(\log(\frac{s}{\varepsilon}))$. The result is an algorithm that runs in time $|S| \cdot n^{O(\log s)}$ and uses memory $\text{poly}(n, s, 1/\varepsilon, |S|)$. Furthermore, the well-distributed requirement turns out to be true for nearly all uniformly random samples that are sufficiently large. The result is, to the best of our knowledge, the first polynomial memory proper learning algorithm for decision trees.

Our algorithm (Algorithm 1) is a surprisingly simple modification of [21]'s algorithm, but our analysis is quite a bit more involved. A key difference is that [21]'s algorithm is an Occam algorithm, whereas ours is not. The original [21] algorithm breaks down when in cannot fully fit the sample; the analysis showing that our algorithm *is* able to handle a sample it cannot fully fit is subtle.

▶ **Lemma 47** (Correctness of FIND). *If S can be exactly fit by a tree of size s, then* FIND(S, s, d) *will not return "None".*

Proof. By induction. If $s = 1$ and S can be fit by a tree of size s, then all samples in S will have the same label. Hence, FIND will return a tree on line 1, and not return "None".

For $s \geq 2$, there are only two spots where FIND could return "None":

Line 4.c.ii FIND returns "None" on line 4.c.ii only if a call of the form $\text{FIND}(S_a^v, s-1, d-1)$ returns "None" where $a = \pm 1$ and v is relevant. Let T_S be a minimal size tree that fits S, which by assumption, has size at most s. Since v is relevant, a node labeled with it must appear somewhere in that tree. This means that there is a size $s-1$ tree that will exactly fit S_a^v. By induction, this means that $\text{FIND}(S_a^v, s-1, d-1)$ will not return "None".

Line 5. FIND returns "None" on line 5 only if there was not a single relevant variable v for which either of the calls $\text{FIND}(S_0^v, \frac{s}{2}, d-1)$ or $\text{FIND}(S_1^v, \frac{s}{2}, d-1)$ on line 4.a succeeded (i.e. did not return "None"). Once again, let T_S be a minimal size tree that fits S. Then, every node in T_S must be relevant for S. Furthermore, T_S has some root variable v^* and subtrees $(T_S)_0$ and $(T_S)_1$. At least one of $(T_S)_0$ or $(T_S)_1$ must have size at most $\frac{s}{2}$. If $(T_S)_0$ has size at most $\frac{s}{2}$, then by the inductive hypothesis, $\text{FIND}(S_0^v, \frac{s}{2}, d-1)$ does not return "None". Otherwise $\text{FIND}(S_1^v, \frac{s}{2}, d-1)$ does not return "None". Hence, FIND won't return "None" on line 5. ◀

We hope to prove that FIND will produce low error trees, but it turns out to be difficult to guarantee this for arbitrary samples. One particular sample we can guarantee this for is the sample containing all possible points. If S contains all 2^n possible points, then FIND will return a tree with error at most $\frac{1}{4} \cdot (\frac{3}{4})^d$, which we will prove in Lemma 49. The following property allows us to quantify how close S is to the full sample.

▶ **Definition 48** (Well-distributed samples). *We say that a sample of points S is c-well-distributed to depth d if, for any restriction α where $|\alpha| \leq d$,*

$$||(S_\alpha)| - \mu| \leq c\mu$$

where $\mu = 2^{-|\alpha|} \cdot |\boldsymbol{S}|$ is the expected size of $\boldsymbol{S}_\alpha$ if $\boldsymbol{S}$ is chosen uniformly at random.

For example, if S contains all possible 2^n points, then S is 0-*well-distributed* to any depth.

▶ **Lemma 49** (Error of FIND on well-distributed samples). *Let S be c-well-distributed to depth d. If $\text{FIND}(S, s, d)$ does not return "None", it returns a tree with error at most $\frac{1}{4}(\frac{3}{4} + \frac{c}{4})^d \cdot s$ with respect to S.*

Proof. By induction on the d; If $d = 0$ and $s \geq 2$, then this lemma requires the error to be less than $\frac{1}{2}$, which FIND satisfies since it places the majority node. If $s = 1$ and FIND doesn't return "None", it must have returned a zero-error tree on Line 1, satisfying the desired error bound.

Next, consider $d \geq 1$. If all samples have the same label, FIND returns a 0 error tree. Otherwise, it returns a tree, T, with 0-subtree T_0^v and 1-subtree T_1^v for some variable v. Let ℓ_0 and ℓ_1 be the number of points in S_0^v and S_1^v respectively. Then, we can relate the errors of the trees as follows:

$$\text{error}(T) = \frac{\ell_0}{\ell_0 + \ell_1} \cdot \text{error}(T_0^v) + \frac{\ell_1}{\ell_0 + \ell_1} \cdot \text{error}(T_1^v)$$

At least one of T_0^v and T_1^v was generated using a recursive call to FIND with size parameter $\frac{s}{2}$. Without loss of generality, let that tree be T_0^v. The other tree, T_1^v was generated by a recursive call with size at most s. By the inductive hypothesis,

$$\text{error}(T) \leq \frac{\ell_0}{\ell_0 + \ell_1} \cdot \frac{1}{4}\left(\frac{3}{4} + \frac{c}{4}\right)^d \cdot \frac{s}{2} + \frac{\ell_1}{\ell_0 + \ell_1} \cdot \frac{1}{4}\left(\frac{3}{4} + \frac{c}{4}\right)^d \cdot s \tag{12}$$

Since S is c-well-distributed to depth d, $(1-c)\mu \leq \ell_0, \ell_1 \leq (1+c)\mu$, where $\mu = \frac{|S|}{2}$. Choosing $\ell_0 = (1-c)\mu$ and $\ell_1 = (1+c)\mu$ maximizes equation Equation (12) and so results in a valid upper bound.

$$\begin{aligned}\text{error}(T) &\leq \frac{\mu(1-c)}{2\mu} \cdot \frac{1}{4}\left(\frac{3}{4}+\frac{c}{4}\right)^{d-1} \cdot \frac{s}{2} + \frac{\mu(1+c)}{2\mu} \cdot \frac{1}{4}\left(\frac{3}{4}+\frac{c}{4}\right)^{d-1} \cdot s \\ &= \frac{1}{4} \cdot \left(\frac{3}{4}+\frac{c}{4}\right)^{d-1} \cdot \left(\frac{3}{4}+\frac{c}{4}\right) \cdot s \\ &= \frac{1}{4}\left(\frac{3}{4}+\frac{c}{4}\right)^{d} \cdot s\end{aligned}$$

◀

The above Lemma shows that if a sample is sufficiently well-distributed, FIND will return a tree with low error. We next show that, with high probability, sufficiently large samples will be well-distributed.

▶ **Lemma 50** (Well-distributed samples are common). *Choose any* $0 < c < 1.0, \delta > 0$. *Then for*

$$m = O\left(\frac{2^d}{c^2} \cdot (d\log(n) + \log(1/\delta))\right),$$

a sample of size m *chosen uniformly at random from* $\{0,1\}^n$ *is* c*-well-distributed to depth* d *with probability at least* $1-\delta$

Proof. Consider an arbitrary restriction α of length $h \leq d$. By Chernoff bounds,

$$\Pr[||\boldsymbol{S}_\alpha| - \mu| \geq c\mu] \leq 2e^{-\mu c^2/3}$$

where $\mu = \mathbb{E}[|\boldsymbol{S}_\alpha|] = m \cdot 2^{-h}$. Since $h \leq d$, we can upper bound the probability as follows.

$$\Pr[||\boldsymbol{S}_\alpha| - \mu| \geq c\mu] \leq 2e^{-m\cdot 2^{-d}c^2/3}$$

$\boldsymbol{S}$ is c-well-distributed if $||\boldsymbol{S}_\alpha| - \mu| \leq c\mu$ for all possible restrictions α of size at most d. There are $\sum_{i=0}^{d}\binom{n}{i}2^i = n^{O(d)}$ such restrictions. Thus, by a union bound:

$$\Pr[\boldsymbol{S} \text{ is } c\text{-well-distributed}] \geq 1 - n^{O(d)} \cdot e^{-m\cdot 2^{-d}c^2/3}.$$

We set the right-hand side of the above equation to be at least $1-\delta$ and solve for m, which proves this Lemma. ◀

Our analysis of the time complexity of FIND is very similar to Ehrenfeucht and Haussler's:

▶ **Lemma 51** (Time complexity of FIND). FIND(S,s,d) *takes time* $|S| \cdot (n+1)^{2\log(s)}$.

Proof. Fix a total number of variables n and sample size m. Let $T(i,s)$ be the maximum time needed by FIND(S,s,d) where S has size at most m, i is the number of relevant variables in S, and d is arbitrary.

If $i = 0$ or $s = 1$, then FIND must return on Line 1 or 2, using only $O(m)$ time. Otherwise, the FIND makes at most $2i$ recursive calls on line 4.(a) each of which takes time at most $T(i-1, \frac{s}{2})$ It also makes zero or one recursive call on line 4.(c).i which takes time up

to $T(i-1, s-1) \leq T(i-1, s)$. In addition to these recursive calls, all of the auxiliary computations can be done in $O(mn)$ time. Hence, we have the following recurrence relation:

$$T(i, s) \leq 2i \cdot T\left(i-1, \tfrac{s}{2}\right) + T(i-1, s) + O(mn).$$

If we substitute $r = \log(s)$, then equivalently, we have the relation:

$$\tilde{T}(i, r) \leq 2i \cdot \tilde{T}(i-1, r-1) + \tilde{T}(i-1, r) + O(mn).$$

The above relation is shown to be upper bounded by $\tilde{T}(i, r) = O(m \cdot (n+1)^{2r})$ in [21]. Substituting back $r = \log(s)$ gives that $T(i, s) \leq O(m \cdot (n+1)^{2\log(s)})$. ◀

▶ **Lemma 52** (Memory complexity of FIND). FIND(S, s, d) *takes memory* $O(2^d(|S| + \log n))$.

Proof. Each call to FIND with depth d will only ever need simultaneously need to run up to 2 calls to FIND, each with depth $d-1$. Hence, there are at most 2^d copies of FIND that need to be stored in memory at any one time. At worst, each copy stores the sample as well as pointers to it and the n different variables. This means each copy uses $O(|S| + \log n)$ memory, for a total of $O(2^d(|S| + \log n))$ memory. ◀

The last step in this analysis is a standard generalization argument relying on Chernoff bounds.

▶ **Lemma 53** (Generalization). *Choose any $\delta, \varepsilon \geq 0$. Suppose that $\boldsymbol{S}$ is a uniformly random sample from a function, f, that can be computed by a decision tree of size at most s and depth at most d. If the number of samples in $\boldsymbol{S}$ is at least*

$$m = O\left(\frac{2^d \log(n) + \log(\frac{1}{\delta})}{\varepsilon}\right)$$

and FIND$(\boldsymbol{S}, s, d)$ *returns a decision tree that fits $\boldsymbol{S}$ with error at most $\frac{\varepsilon}{4}$. Then, with probability at least $1-\delta$, the decision tree returned by* FIND *has error at most ε on f.*

Proof. We will upper bound the number of different decision trees FIND could return when given depth limit d. There up to 2^d spots where a decision tree of depth $\leq d$ could have a node. In each of these spots, the decision tree could either have one of n variables, a leaf that is either $+1$ or -1, or nothing. Thus, the number of decision trees of depth at most d is at most $(n+3)^{2^d}$.

We call a decision tree, T, "bad", if T has error at least ε on f. For any particular bad tree T, the probability it will have error less than $\frac{\varepsilon}{4}$ on $\boldsymbol{S}$ can be upper bounded using a Chernoff Bound:

$$\Pr_{\boldsymbol{S}}\left[\text{error}_{\boldsymbol{S}}(T) \leq \tfrac{\varepsilon}{4}\right] \leq \exp(-\tfrac{9}{32}\varepsilon m).$$

Since there are most $(n+3)^{2^d}$ bad trees, the probability that any bad tree has error at most $\frac{\varepsilon}{4}$ is at most $(n+3)^{2^d} \cdot \exp(-\frac{9}{32}\varepsilon m)$. Setting this equal to δ and solving for m completes the proof of this lemma. ◀

Finally, we are able to put all these pieces together to prove our main theorem of this section, and show how FIND is used to learn decision trees:

▶ **Theorem 54** (Proper learning with polynomial sample and memory complexity)**.** *Let f be any function over n variables computable by a size s decision tree. Choose any $\varepsilon, \delta > 0$. There is an algorithm that*

- *runs in time* $\text{poly}(n^{\log s}, \frac{1}{\varepsilon}, \log(\frac{1}{\delta}))$
- *requires memory* $\text{poly}(s, \log n, \frac{1}{\varepsilon}, \log(\frac{1}{\delta}))$
- *uses* $\text{poly}(s, \log n, \frac{1}{\varepsilon}, \log(\frac{1}{\delta}))$ *random samples from f*

and with probability at least $1 - \delta$ returns a decision tree that is an ε-approximation of f.

Proof. Choose any constant $0 < c < 1$ and set $d = \log(\frac{s}{\varepsilon})/(-\log(\frac{3+c}{4}))$. Then, by taking a uniformly random sample, $\boldsymbol{S}$, of size

$$m = O\left(\frac{2^d}{\varepsilon c^2} \cdot (d \log(n) + \log(1/\delta))\right)$$

we have the following holds:

1. $\boldsymbol{S}$ is c-well-distributed with probability at least $1 - \frac{\delta}{2}$.
2. If $\boldsymbol{S}$ is c-well-distributed, then $\textsc{Find}(\boldsymbol{S}, s, d)$ returns a tree, T, with error at most $\frac{1}{4}(\frac{3+c}{4})^d \cdot s = \frac{\varepsilon}{4}$ on $\boldsymbol{S}$.
3. If T has error less than $\frac{\varepsilon}{4}$, then with probability at least $1 - \frac{\delta}{2}$, T is a ε-approximation for f.

Furthermore, this procedure meets the time constraints by Lemma 51 and memory constraints by Lemma 52. ◀

Abstract

Given a metric (V, d) and a root $\in V$, the classic k-TSP problem is to find a tour originating at the root of minimum length that visits at least k nodes in V. In this work, motivated by applications where the input to an optimization problem is uncertain, we study two stochastic versions of k-TSP.

In Stoch-Reward k-TSP, originally defined by Ene-Nagarajan-Saket [13], each vertex v in the given metric (V, d) contains a stochastic reward R_v. The goal is to adaptively find a tour of minimum *expected* length that collects at least reward k; here "adaptively" means our next decision may depend on previous outcomes. Ene et al. give an $O(\log k)$-approximation adaptive algorithm for this problem, and left open if there is an $O(1)$-approximation algorithm. We totally resolve their open question, and even give an $O(1)$-approximation *non-adaptive* algorithm for Stoch-Reward k-TSP.

We also introduce and obtain similar results for the Stoch-Cost k-TSP problem. In this problem each vertex v has a stochastic cost C_v, and the goal is to visit and select at least k vertices to minimize the expected *sum* of tour length and cost of selected vertices. Besides being a natural stochastic generalization of k-TSP, this problem is also interesting because it generalizes the Price of Information framework [33] from deterministic probing costs to metric probing costs.

Our techniques are based on two crucial ideas: "repetitions" and "critical scaling". In general, replacing a random variable with its expectation leads to very poor results. We show that for our problems, if we truncate the random variables at an ideal threshold, then their expected values form a good surrogate. Here, we rely on running several repetitions of our algorithm with the same threshold, and then argue concentration using Freedman's and Jogdeo-Samuels' inequalities. Unfortunately, this ideal threshold depends on how far we are from achieving our target k, which a non-adaptive algorithm does not know. To overcome this barrier, we truncate the random variables at various different scales and identify a "critical" scale.

1 Introduction

Consider a scenario where a salesperson must sell some quota of brushes in order to win a trip to Hawaii. The salesperson knows the time it takes to travel between different cities and the demand at each city. What is the best route to take to sell the quota while spending the least amount of time? This exact scenario was described by Awerbuch et al. [4] to motivate the study of TSP problems where the algorithm has to also decide which cities to visit. A cleaner version of this problem, first introduced by Ravi et al. [31], is the k-TSP problem where we assume that each city has a unit demand. Formally, given a metric (V, d) with a root $\in V$ and a *target* $k \in \mathbb{Z}_{\geq 0}$, the k-TSP problem is to find a tour that originates at the root and visits at least k vertices, while minimizing the total travel time. There is a long line of work trying to design better approximation algorithms for the k-TSP problem [4, 30, 8, 16, 2, 1], and the state-of-the-art is a 2-approximation algorithm due to Garg [17][1].

In this work we consider stochastic versions of the k-TSP problem: what if the salesperson does not know the exact demand in each city, or what if the salesperson need to spend some uncertain time in each city to complete the city's demand? Indeed, there is a long line of work studying classical optimization problems where we begin only with estimates (probability distributions) on the input parameters. The algorithm has to *adaptively probe* parameters (inspect elements) by paying some "cost" before realizing their exact values; here "adaptively" means that our decisions may depend on the outcomes of already probed elements. Such stochastic probing problems have been well-studied in both maximization and minimization settings [11, 18, 19, 22, 20, 23, 5, 24, 6, 29, 3, 25, 13, 15, 33, 9, 21].

There are two natural ways of defining the stochastic k-TSP problem, depending on the type of input uncertainty. In the Stoch-Reward k-TSP problem, first introduced by Ene-Nagarajan-Saket [13], we incorporate uncertainty in the vertex demands. Formally, we assume that the demand at each vertex is drawn independently from a known distribution, and the goal is to *adaptively* find a tour Π that obtains the target demand k, while minimizing the total *expected* travel time[2].

We also study Stoch-Cost k-TSP where each city still has a unit demand, but the salesperson will have to spend an additional *completion* time (drawn from a known distribution) at each vertex before meeting its unit demand. The goal is to adaptively find a tour Π that completes the target demand k, while minimizing the expected *sum* of total travel and completion times. Notice, our algorithm finds the exact completion time of a vertex only after visiting it, and may choose not to complete it (i.e., not meet its unit demand) if the completion time seems too long. This idea of studying stochastic completion times at vertices is not new, and has been previously used in the study of stochastic Orienteering problems, which in some sense is the dual to our Stoch-Cost k-TSP problem [23, 6].

A common theme in the study of stochastic probing problems is to understand the power of adaptivity. Indeed, while the optimal algorithms can fully adapt to the outcomes, and hence may not even have a polynomial-size representation, a *non-adaptive* algorithm makes all its decisions upfront independent of the observed outcomes (except perhaps the stopping time). Being non-adaptive has several benefits like they are simpler to find, easily parallelizable, and have a poly-size representation. So ideally for a probing problem we would like to design non-adaptive algorithms with performance close to the optimal adaptive

[1] A closely-related variant is called the k-MST problem. Both problems are equivalent up to a constant approximation factor.

[2] Our Stoch-Reward k-TSP problem is called the "Stochastic k-TSP" problem in [13]. We rename it to differentiate it from Stoch-Cost k-TSP.

algorithms, or in other words design non-adaptive algorithms with a small *adaptivity gap*. The main results of our work is to show that both the above Stoch-Reward k-TSP and Stoch-Cost k-TSP problems have a constant adaptivity-gap. That is, there exist fixed-tours starting at the root which the algorithm can take until it obtains the target demand k, which guarantee an expected total time at most a constant factor more than the expected total time of the optimal adaptive tour. Moreover, for distributions with polynomial support, we give poly-time algorithms to find such tours.

Our constant adaptivity-gap for Stoch-Reward k-TSP answers the main open question of [13], who showed an $O(\log^2 k)$ bound on the adaptivity gap. The constant adaptivity gap result for Stoch-Cost k-TSP might also seem surprising because it is known that the related Stochastic Orienteering problem has a super-constant adaptivity gap [6].

In the rest of this section we first formally state our problems and results, and then discuss our high-level techniques and other related work.

1.1 Stoch-Reward k-TSP

The following Stoch-Reward k-TSP was first defined by Ene et al. [13].

Stoch-Reward k-TSP. We are given a metric (V, d) with a root $\in V$ and each vertex $v \in V$ has an independent integral[3] stochastic[4] reward $R_v \in \mathbb{Z}_{\geq 0}$. All reward distributions are given as input but the actual reward instantiation R_v is only known when the algorithm visits vertex v. Given a target value $k \in \mathbb{Z}_{\geq 0}$, the goal is to adaptively find a tour Π originating at root that collects at least k reward (i.e., $\sum_{v \in \Pi} R_v \geq k$) while minimizing the expected tour length.

This problem captures several well-studied problems; e.g., it captures the problem of Stoch-Knapsack Cover where the metric (V, d) is a weighted star: given a target k and n items where item $i \in [n]$ has both a deterministic cost $C_i \in \mathbb{R}_{\geq 0}$ and an independent stochastic reward $R_i \in \mathbb{Z}_{\geq 0}$, the Stoch-Knapsack Cover problem is to adaptively obtain a total reward of at least k at the minimum expected cost. This problem was studied by Deshpande et al. [12], and they gave an *adaptive* 2-approximation algorithm. However, even in this special case, it was not know if there is a non-adaptive constant factor approximation algorithm.

The first non-trivial results for the Stoch-Reward k-TSP problem were obtained by Ene et al. [13]. They gave an $O(\log^2 k)$-approximation non-adaptive algorithm and an $O(\log k)$-approximation adaptive algorithm. On the hardness side, however, they only gave a lower bound of e on the adaptivity gap. This left open closing the wide gap on the adaptivity gap for Stoch-Reward k-TSP. We resolve their open question by giving a non-adaptive $O(1)$-approximation algorithm.

▶ **Theorem 1.** *The Stoch-Reward k-TSP problem has a non-adaptive $O(1)$-approximation algorithm.*

The difficulty in Stoch-Reward k-TSP arises because the expected reward is a poor indicator of how much we care about a node. An extreme example is a vertex with a large expected reward, but which is non-zero with nearly zero probability. It is therefore reasonable to truncate the reward distributions at the remaining target reward. However, it is not clear why such an approach would work, and moreover this approach is adaptive as it depends on the remaining target.

[3] This is without loss of generality. Our result also generalizes to the case where rewards are real numbers via re-scaling.

[4] We assume that the distribution is discrete and is given explicitly.

1.2 Stoch-Cost k-TSP

We formally define the Stoch-Cost k-TSP problem.

Stoch-Cost k-TSP. We are given a metric (V, d) with a root $\in V$ and each vertex $v \in V$ has an independent stochastic cost $C_v \in \mathbb{R}_{\geq 0}$. All cost distributions are given as input but the actual cost instantiation C_v is only known when vertex v is visited. Suppose a vertex v can only be *selected* if: (1) v is visited and (2) we are currently[5] at vertex v. The goal is to adaptively find a tour Π originating at root that selects a set S of k visited vertices while minimizing the expected *total* cost, which is the sum of the tour length and the cost of the selected vertices:

$$\mathbb{E}\Big[d(\Pi) + \sum_{v \in S} C_v\Big].$$

Apart from being a natural generalization of the classical k-TSP problem, Stoch-Cost k-TSP is also motivated due to its connections to price of information [33]. In particular, it generalizes the Minimization k-Pandora's Box problem studied in [28, 33]. In this problem we are given a target k and n items, where each item $i \in [n]$ has a known probing price $\pi_i \in \mathbb{R}_{\geq 0}$ and an independent stochastic cost C_i. The exact cost C_i is only revealed after we pay price π_i. The goal is to adaptively probe and select k of the probed items to minimize the expected total selection cost plus probing price. Stoch-Cost k-TSP captures this problem on a star metric where node i is at a distance $\pi_i/2$ from the root. Thus, we can view the Stoch-Cost k-TSP problem as generalizing the price of information framework to a *metric* setting, where the price of probing is not fixed but given by a general metric. Our next result gives a non-adaptive $O(1)$-approximation algorithm for Stoch-Cost k-TSP.

▶ **Theorem 2.** *The Stoch-Cost k-TSP problem has a non-adaptive $O(1)$-approximation algorithm.*

Our main techniques in the proof of Theorem 2 are similar to those for Stoch-Reward k-TSP. In fact, in Section 3 we present a generic framework that can be used to solve both these problems. It will be interesting to find other applications of our framework in future work.

1.3 High-level Techniques

We assume that after re-scaling, the distance between any pair of vertices is at least 1.

Stoch-Reward k-TSP. A standard idea in the design of approximation algorithms on a metric is to operate in phases, where in phase i our algorithm is allowed a budget of 2^i. Intuitively, this corresponds to the algorithm imagining that the optimal adaptive tour has length $\Theta(2^i)$. In each phase, a naïve algorithm would be to collect as much *expected* reward as possible within budget 2^i (say, by solving an instance of the Orienteering problem). However, in general the performance of such a naïve algorithm can be arbitrarily bad. E.g., suppose $k - \sqrt{k}$ reward is easy to get, now for the remaining reward the naïve algorithm prefers a vertex having a reward of k with probability $10/\sqrt{k}$ and 0 otherwise, as opposed to a vertex with a deterministic reward of $\sqrt{k}$ (assuming both are at the same distance).

[5] Up to a factor of 2, this version of the problem is equivalent to the version where restriction (2) is removed.

A natural fix to the above issue is to *truncate* the reward distributions at the *remaining* target reward and then take expectations. Not only is this algorithm *adaptive*, it is not even clear why it would work. Indeed, Ene et al. [13] give an example (see Example 2 in [13]) where this algorithm has an $\Omega(\log k)$-approximation factor. Our first idea is to run $O(1)$ *repetitions* of a bi-criteria Orienteering algorithm using the *same* truncation (i.e., the initial remaining target) for all these repetitions. Our analysis applies Freedman's [14] and Jogdeo-Samuels [27] inequalities to argue concentration, and relies crucially on not updating the remaining target for these $O(1)$ repetitions.

Nevertheless, the above approach depends on the remaining target, which is unknown to a *non-adaptive* algorithm. One could bypass this by truncating the reward distributions at $\log k$ different *scales*, where scale j corresponds to the remaining target being roughly $k/2^j$, applying the previous $O(1)$ repetitions idea at each scale, and visiting the union of all tours. Unfortunately, this immediately loses a $\log k$ approximation factor. Our second idea is "critical scaling" in which we identify a "critical" scale j_{crit} among the $\log k$ possible scales, and only include tours for scales $j_{\mathsf{crit}} - 1$ and j_{crit}. This critical scale j_{crit} roughly (but not quite) corresponds to a "phase transition" from an underestimation to an overestimation of the remaining target. A priori it is not clear why such a "critical" scale can be found non-adaptively, but the concentration properties of the above $O(1)$ repetitions allow us to find it efficiently.

Stoch-Cost k-TSP. We obtain our result for Stoch-Cost k-TSP in a similar way. An immediate challenge, however, is how should we truncate the cost distributions C_v, say even if the remaining target k' is known? One natural way is by looking at $\mathbb{P}[C_v \leq O(2^i/k')]$, where $O(2^i/k')$ is the "average" cost per remaining reward in phase i. But such an approach would fail when some vertices in the optimal tour have costs much smaller than $O(2^i/k')$, while the other vertices have much higher costs. We overcome this by considering $\mathbb{P}[C_v \leq O(2^{i-j})]$ for all possible scales $j \in \{0, \cdots, i + \log n\}$, identifying a "critical" scale j_{crit}, and again only including the tours for scales $j_{\mathsf{crit}} - 1$ and j_{crit}. To identify the critical scale, we need to evaluate the maximum target a tour at a given scale can get within cost budget 2^i with constant probability. We show this can be approximately computed via dynamic programming.

1.4 Further Related Work

There is a long line of work studying the classic k-TSP and the related k-MST problem; we refer the readers to Garg's beautiful 2-approximation paper and the references therein [17].

A formal study on the benefits of adaptivity for stochastic combinatorial optimization problems started with the seminal work of Dean et al. [11]. They showed that for the stochastic knapsack problem, where items sizes are independently drawn and we need to fit them in a knapsack of size B, there is an $O(1)$-approximation non-adaptive algorithm. This factor was later improved to a $(2 + \epsilon)$-approximation in [7, 29]. The minimization version of the stochastic knapsack problem, which is known as the Stoch-Knapsack Cover problem, was studied by Deshpande et al. [12], and is a special case of Stoch-Reward k-TSP as we mentioned before. The unbounded version of Stoch-Knapsack Cover (each item has infinite number of copies) was studied by [26] and they provide an FPTAS for this problem.

Gupta et al. [23] generalized the stochastic knapsack problem to the stochastic orienteering problem, where each stochastic item now resides on a vertex of a given metric, and we need to fit both the tour length and the item sizes inside our budget B. They give an $O(\log \log B)$-approximation non-adaptive algorithm for this problem. Bansal and Nagarajan [6] later showed that this problem has no constant-approximation non-adaptive algorithm. These

works inspired Ene et al. [13] to study Stoch-Reward k-TSP, a natural minimization variant of the stochastic orienteering problem. Prior to our work, it was conceivable that this minimization problem also has a super-constant adaptivity gap, like stochastic orienteering.

Motivated by different applications that solve discrete problems under an uncertain input, other related stochastic probing models have been studied. We refer the readers to Singla's Ph.D. Thesis for a survey [32]. Of particular interest to us is the Price of Information model [33], which was inspired from the work on Pandora's box [34, 28]. Their Minimization k-Pandora's Box problem inspired us to define Stoch-Cost k-TSP, which generalizes the probing costs from being fixed to being on a metric. Although an optimal strategy is known for Minimization k-Pandora's Box, the problem becomes APX-hard on a metric as it generalizes k-TSP.

Organization

We start with some preliminary definitions and lemmas in Section 2. In Section 3, we describe our general framework for both Stoch-Reward k-TSP and Stoch-Cost k-TSP, and prove some key lemmas that will be used throughout the paper. We give our non-adaptive $O(1)$-approximation algorithm for Stoch-Reward k-TSP that proves Theorem 1 in Section 4. The non-adaptive $O(1)$-approximation algorithm for Stoch-Cost k-TSP that proves Theorem 2 is in Section 5.

2 Preliminaries

2.1 Adaptive vs Non-Adaptive Algorithms

Any feasible solution to our stochastic problems can be described by a *decision tree*, where nodes correspond to vertices that are visited and branches correspond to instantiations of the observed random variables. Even if the degree of every vertex is a constant, the size of such decision trees can be exponentially large in its height. These solutions are called *adaptive* because the choice of the next vertex to visit depends on the outcomes of the already visited nodes.

We also consider the special class of *non-adaptive* solutions that is described simply by an ordered list of vertices: the policy involves visiting vertices in the given order until a certain stopping criterion is met. Such non-adaptive solutions are often preferred over adaptive solutions because they are easier to implement.

In this work we only study minimization problems. We compare the performance of our algorithm with that of the optimal *adaptive* algorithm, which is denoted by OPT. We abuse notation and also use OPT to denote the expected objective of the optimal adaptive algorithm. We say an algorithm is α-approximation for $\alpha \geq 1$ if the expected objective of the algorithm is at most $\alpha \cdot \mathsf{OPT}$. Ideally, we want to design non-adaptive algorithms whose performance is comparable to the optimal adaptive algorithm. Since this is not always possible, it is important to bound the *adaptivity gap*, which is the worst-case ratio between the expected objectives of the optimal non-adaptive and the optimal adaptive algorithms.

2.2 Probability Inequalities

Our proofs will require the following probability inequalities. We start with a bound on the median of independent Bernoulli random variables due to Jogdeo and Samuels [27]. Given n independent Bernoulli random variables $X_1, \cdots, X_n$ where X_i has success probability $p_i \in [0, 1]$, let $X := \sum_{i=1}^{n} X_i$ be their sum. Define the median of X to be any integer $m \in \mathbb{Z}_{\geq 0}$ such that $\min\{\mathbb{P}[X \geq m], \mathbb{P}[X \leq m]\} \geq 1/2$.

▶ **Theorem 3** (Theorem 3.2 and Corollary 3.1 [27]). *Let $X = \sum_{i=1}^{n} X_i$ be the sum of n independent Bernoulli random variables where X_i has success probability $p_i \in [0,1]$. If $\mathbb{E}[X]$ is an integer k, then the median of X is also k. If $k < \mathbb{E}[X] < k+1$ for some integer k, then the median of X is either k or $k+1$.*

We will also need the following martingale inequality due to Freedman [14].

▶ **Theorem 4** (Freedman's Inequality, Theorem 1.6 in [14]). *Consider a real-valued martingale sequence $\{X_t\}_{t\geq 0}$ such that $X_0 = 0$, and $\mathbb{E}[X_{t+1}|\mathcal{F}_t] = 0$ for all t, where $\{\mathcal{F}_t\}_{t\geq 0}$ is the filtration defined by the martingale. Assume that the sequence is uniformly bounded, i.e., $|X_t| \leq M$ almost surely for all t. Now define the predictable quadratic variation process of the martingale to be $W_t = \sum_{j=1}^{t} \mathbb{E}[X_j^2|\mathcal{F}_{j-1}]$ for all $t \geq 1$. Then for all $\ell \geq 0$ and $\sigma^2 > 0$ and any stopping time τ, we have*

$$\mathbb{P}\Big[\Big|\sum_{j=0}^{\tau} X_j\Big| \geq \ell \wedge W_\tau \leq \sigma^2 \text{for some stopping time } \tau\Big] \leq 2\exp\Big(-\frac{\ell^2/2}{\sigma^2 + M\ell/3}\Big).$$

▶ **Theorem 5** (Chernoff Bound). *Let $X_1, X_2, \cdots, X_n$ be independent random variables taking values in $[0,1]$ and define $X := \sum_{i\in[n]} X_i$. Then for any $\delta \in [0,1]$, we have*

$$\mathbb{P}\left[X \leq (1-\delta)\cdot\mathbb{E}[X]\right] \leq \exp\left(-\delta^2\cdot\mathbb{E}[X]/2\right).$$

2.3 A Bi-Criteria Algorithm $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ for Orienteering

We formally define the well-known Orienteering problem.

Orienteering. Given a metric (V,d) with root $\in V$, a *profit*[6] $R_v > 0$ for each $v \in V$, and a budget $B > 0$, the goal is to find a tour originating at root of length at most B that maximizes the collected profit.

The state-of-the-art for this NP-hard Orienteering problem is a $(2+\epsilon)$-approximation algorithm [10]. We denote this algorithm as $\mathsf{ALG}_{\mathsf{Orient}}$ and denote the profit of the optimal Orienteering tour as $\mathsf{OPT}_{\mathsf{Orient}}$. For our purposes, however, we also need to find profit at least $\mathsf{OPT}_{\mathsf{Orient}}$ minus an arbitrarily small additive error. To achieve this, the tour found by our algorithm has length $O(1)\cdot B$.

▶ **Lemma 6** (Bi-criteria Orienteering). *There is an efficient algorithm $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ that finds a tour of length $O(1)\cdot B$ while collecting at least $(\mathsf{OPT}_{\mathsf{Orient}} - \epsilon)$ profit, where $\epsilon = 1/\mathrm{poly}(n)$ can be made arbitrarily small.*

3 Our Approach via Critical Scaling and Repetitions

3.1 A Meta-Algorithm and Critical Scaling

Our non-adaptive $O(1)$-approximation algorithms for both the problems, Stoch-Reward k-TSP and Stoch-Cost k-TSP, have the same structure described in Meta-Algorithm $\mathsf{ALG}_{\mathsf{Meta}}$ (Algorithm 1). This algorithm operates in phases where it gets a budget of $O(1)\cdot\gamma^i$ in phase $i \geq 0$ for some constant $\gamma \in (1,2)$.

[6] We use the word "profit" for Orienteering to avoid confusion with the "reward" in Stoch-Reward k-TSP.

In each phase i, $\mathsf{ALG}_{\mathsf{Meta}}$ explores multiple different "scales" in the remaining graph after excluding the set Π of vertices found in the previous phases. Recall, each scale corresponds to truncating the random variables at a different threshold. This is crucial because our non-adaptive algorithm doesn't know the remaining reward to reach the target k. For each different scale, $\mathsf{ALG}_{\mathsf{Meta}}$ obtains a tour of length $O(1) \cdot \gamma^i$ via a sub-procedure $\mathsf{ALG}_{\mathsf{Rep}}$ to which it sends the truncated random variables as arguments (discussed in Section 3.2). Eventually, $\mathsf{ALG}_{\mathsf{Meta}}$ identifies a "critical" scale j_{crit} and appends at the end of Π the two tours corresponding to the scales j_{crit} and $j_{\mathsf{crit}} - 1$. Since we only append two tours, $\mathsf{ALG}_{\mathsf{Meta}}$ uses budget at most $O(1) \cdot \gamma^i$ in phase i.

Algorithm 1 A Meta-Algorithm $\mathsf{ALG}_{\mathsf{Meta}}$.

Pre-processing stage:
set $\gamma \in (1,2), \Pi \leftarrow \emptyset$ and $\ell \leftarrow \mathsf{polylog}(k,n)$;
for *phase* $i = 0, 1, \cdots$ **do**
  set $\Pi_{i,-1} \leftarrow \emptyset$;
  for *scale* $j = 0, \cdots, \ell$ **do**
    set $X_v^j \in [0,1]$ to be the truncation of X_v at scale j for $v \in V \setminus \Pi$, and zero for $v \in \Pi$;
    find tour $\Pi_{i,j} \leftarrow \mathsf{ALG}_{\mathsf{Rep}}\big(\{X_v^j\}_{v \in V \setminus \Pi}\ ,\ i\big)$ of length $O(1) \cdot \gamma^i$;
  end
  identify a "critical" scale j_{crit} and set $\Pi_i \leftarrow \Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}$;
  append tour Π_i to Π, i.e., $\Pi \leftarrow \Pi \circ \Pi_i$;
end

Probing stage:
for *phase* $i = 0, 1, \cdots$ **do**
  visit vertices in the order of Π_i and apply certain Selection and Stopping Criteria;
end
Return set of vertices selected

To analyze the algorithm, we need some notation for any phases $i, i' \geq 1$:

- σ_{i-1}: outcome of vertices visited by $\mathsf{ALG}_{\mathsf{Meta}}$'s in the first $i-1$ phases of the probing stage.
- $u_{i'}(\sigma_{i-1})$: probability that $\mathsf{ALG}_{\mathsf{Meta}}$ enters phase $i'+1$ in the probing stage, conditioning on σ_{i-1}.
- $u^*_{i'}(\sigma_{i-1})$: probability that the cost of OPT is more than $\gamma^{i'}$, conditioning on σ_{i-1}.

Notice $u_{i-1}(\sigma_{i-1})$ denotes the indicator variable that $\mathsf{ALG}_{\mathsf{Meta}}$ enters phase i in the probing stage. The following Lemma 7 is the key to our theorems. Roughly, it says that $\mathsf{ALG}_{\mathsf{Meta}}$ is a constant approximation algorithm if it can ensure that whenever $u^*_i(\sigma_{i-1})$ is small (i.e., OPT has a large success probability within budget γ^i) then $\mathsf{ALG}_{\mathsf{Meta}}$ also succeeds with a constant probability in the first i phases (i.e., only using $O(1) \cdot \gamma^i$ budget). The proof of Lemma 7 is standard (e.g., [13]), and we defer it to Appendix B.

▶ **Lemma 7** (Key Lemma). *If for some universal constants $C > 0$, $\gamma > 1$, any phase $i \geq 1$, and any possible σ_{i-1}, the algorithm ALG_{Meta} satisfies*

$$u_i(\sigma_{i-1}) \leq C \cdot u^*_i(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2},$$

then ALG_{Meta} is a non-adaptive $O(1)$-approximation algorithm.

All our effort will go in designing $\mathsf{ALG}_{\mathsf{Meta}}$ that satisfies the precondition of Lemma 7.

3.2 $\mathsf{ALG}_{\mathsf{Rep}}$: Constant Repetitions of $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ Suffice

For a fixed scale j in phase i, $\mathsf{ALG}_{\mathsf{Meta}}$ uses $\mathsf{ALG}_{\mathsf{Rep}}$ (Algorithm 2) as a key sub-procedure to find a tour of length $O(1) \cdot \gamma^i$. To achieve this, $\mathsf{ALG}_{\mathsf{Rep}}$ runs a constant number of repetitions of $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ on an Orienteering instance where each vertex v has a profit $w_v = \mathbb{E}[X_v]$ for input random variable $X_v \in [0,1]$ (recall, X_v is the truncated random variable at scale j for vertices outside Π). In each repetition, $\mathsf{ALG}_{\mathsf{Rep}}$ excludes vertices found in previous repetitions.

Algorithm 2 $\mathsf{ALG}_{\mathsf{Rep}}\big(\{X_v\}_{v\in V}\ ,\ i\big)$.

Input: random variables $X_v \in [0,1]$ corresponding to vertex profits and phase i;
Main stage:
set $\gamma \in (1,2)$, $\epsilon \leftarrow 1/10^5$, $C \leftarrow O(1)$, and $w_v = \mathbb{E}[X_v]$;
set $\Pi_i \leftarrow \emptyset$;
for *repetition* $s = 1, \cdots, C$ **do**
  use $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ to find a tour π_s with budget γ^i, profit $\{w_v\}_{v\in V}$, and error ϵ;
  append tour π_s to Π_i, i.e., $\Pi_i \leftarrow \Pi_i \circ \pi_s$;
  reset $w_v = 0$ for $v \in \Pi_i$;
end
Return Π_i

Intuition. In the following, we prove two important properties of $\mathsf{ALG}_{\mathsf{Rep}}$. Recall from Algorithm 2 that Π_i denotes the union of the C repetitions of $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$. The first property (Lemma 8) roughly says that if an Orienteering tour of budget γ^i cannot obtain much profit outside Π_i, then OPT also cannot obtain much reward outside Π_i within budget γ^i. The second property (Lemma 9) roughly says that if on the other hand lots of profit can be found by an Orienteering tour outside Π_i, then the tour Π_i obtains a large amount of *expected* reward in its C repetitions, much more than what OPT obtains within budget γ^i. This follows from the property that $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ obtains profit close to the optimal Orienteering tour.

To formally state the above two properties, we need some notation. Consider the Orienteering instance in the remaining graph $V \setminus \Pi_i$ where the budget is γ^i and each vertex $v \in V \setminus \Pi_i$ has profit $\mathbb{E}[X_v]$. Denote $\pi \subseteq V \setminus \Pi_i$ the optimal Orienteering tour for this instance and let

$$T := \sum_{v\in\pi} \mathbb{E}[X_v] \tag{1}$$

be the Orienteering profit obtained by π. For any adaptive strategy ADAP, let $\Pi_i(\mathsf{ADAP}) \subseteq \Pi_i$ denote the random set of vertices visited by ADAP inside the tour Π_i and let $\overline{\Pi}_i(\mathsf{ADAP}) \subseteq V \setminus \Pi_i$ denote the random set of vertices visited by ADAP outside the tour Π_i.

▶ **Lemma 8.** *Suppose we are given independent random variables $X_v \in [0,1]$. Let T be as defined in (1). Then for any adaptive strategy* ADAP *which uses at most γ^i budget and any constant $\alpha > 1$, we have*

$$\mathbb{P}\Big[\sum_{v\in\overline{\Pi}_i(\mathsf{ADAP})} X_v \geq \alpha T\Big] \ \leq\ 2\cdot\exp\left(-\frac{(\alpha-1)^2 T/2}{1+(\alpha-1)/3}\right).$$

Proof of Lemma 8. We construct a martingale for the (random) set $\overline{\Pi}_i(\mathsf{ADAP})$ of vertices visited by ADAP in $V \setminus \Pi_i$ as follows: When ADAP visits a vertex $v \in \overline{\Pi}_i(\mathsf{ADAP})$, the martingale proceeds for one step with martingale difference defined by

$$Z_v \;:=\; X_v - \mathbb{E}[X_v] \;\in\; [-1,1],$$

and the martingale doesn't move when ADAP visits a vertex $v \in \Pi_i$. The stopping time τ is naturally defined as the martingale step when ADAP finishes. Since each $X_v \in [0,1]$, the quadratic variance of the above martingale $W_\tau = \sum_{j=1}^{\tau} \mathbb{E}[X_j^2|\mathcal{F}_{j-1}]$ is bounded by its expectation $\sum_{j=1}^{\tau} \mathbb{E}[X_j|\mathcal{F}_{j-1}]$ which is at most T, i.e., $\sum_{v\in\overline{\Pi}_i(\mathsf{ADAP})} \mathbb{E}[X_v] \le T$. Therefore, applying Freedman's inequality (Theorem 4), we have

$$\begin{aligned}\mathbb{P}\Big[\sum_{v\in\overline{\Pi}_i(\mathsf{ADAP})} X_v \ge \alpha T\Big] \;&\le\; \mathbb{P}\Big[\Big|\sum_{v\in\overline{\Pi}_i(\mathsf{ADAP})} Z_v\Big| \ge (\alpha-1)T \wedge W_\tau \le T\Big] \\ &\le\; 2\cdot\exp\left(-\frac{(\alpha-1)^2T/2}{1+(\alpha-1)/3}\right).\end{aligned}$$

This finishes the proof of Lemma 8. ◀

▶ **Lemma 9.** *Suppose we are given independent random variables $X_v \in [0,1]$. Let T be as defined in (1). Then for any adaptive strategy* ADAP *which uses budget at most γ^i, we have*

$$\sum_{v\in\Pi_i\setminus\Pi_i(\mathsf{ADAP})} \mathbb{E}[X_v] \;\ge\; (C-1)(T-\epsilon)-\epsilon.$$

Proof of Lemma 9. Since ADAP uses budget at most γ^i, the set $\Pi_i(\mathsf{ADAP}) \subseteq \Pi_i$ can always be visited by a tour of length at most γ^i. Consider the first tour π_1 found by Algorithm 2. Since the tour with length at most γ^i that visits the set $\Pi_i(\mathsf{ADAP})$ is a valid Orienteering tour when π_1 is found, it follows from Lemma 6 that $\sum_{v\in\Pi_i(\mathsf{ADAP})} \mathbb{E}[X_v] \le \epsilon + \sum_{v\in\pi_1} \mathbb{E}[X_v]$. For any $s \in \{2,3,\cdots,C\}$, since π is an Orienteering tour in $V\setminus\Pi_i$ of length at most γ^i with $\sum_{v\in\pi} \mathbb{E}[X_v] = T$, Lemma 6 implies that $\sum_{v\in\pi_s} \mathbb{E}[X_v] \ge T-\epsilon$. Therefore, a simple calculation gives

$$\sum_{v\in\Pi_i\setminus\Pi_i(\mathsf{ADAP})} \mathbb{E}[X_v] \;=\; \sum_{v\in\Pi_i} \mathbb{E}[X_v] - \sum_{v\in\Pi_i(\mathsf{ADAP})} \mathbb{E}[X_v] \;\ge\; (C-1)(T-\epsilon)-\epsilon,$$

which finishes the proof of Lemma 9. ◀

4 Stoch-Reward k-TSP

In this section we prove Theorem 1, which is restated below for convenience.

▶ **Theorem 1.** *The Stoch-Reward k-TSP problem has a non-adaptive $O(1)$-approximation algorithm.*

To prove this theorem we carefully choose the parameters of our Meta-Algorithm from last section.

4.1 The Algorithm

Algorithm 3 $\mathsf{ALG}_{\text{Stoch-Reward}}$ for Stoch-Reward k-TSP problem.

Pre-processing stage:
set $\gamma \leftarrow 1.1, \epsilon \leftarrow 1/10^5, \Pi \leftarrow \emptyset$, $\ell = \lfloor \log k \rfloor$, and $C \leftarrow 6000$;
for *phase* $i = 0, 1, \cdots$ **do**
  set $\Pi_{i,-1} \leftarrow \emptyset$;
  for *scale* $j = 0, \cdots, \ell$ **do**
    set profit $w_v^j = \mathbb{E}\left[\min\left\{R_v \cdot 2^j/k, 1\right\}\right] \cdot \mathbf{1}[v \in V \setminus \Pi]$; /* Scale j truncates at $k/2^j$ */
    set $\Pi_{i,j} \leftarrow \emptyset$;
    for *repetition* $s = 1, 2, \cdots, C$ /* Constant repetitions of $\mathsf{ALG}_{\text{Bicrit-Orient}}$ */ **do**
      use $\mathsf{ALG}_{\text{Bicrit-Orient}}$ to find tour $\pi_{i,j,s}$ with budget γ^i, profit $\{w_v^j\}_{v \in V}$, and error ϵ ;
      append tour $\pi_{i,j,s}$ to $\Pi_{i,j}$, i.e., $\Pi_{i,j} \leftarrow \Pi_{i,j} \circ \pi_{i,j,s}$;
      reset $w_v^j = 0$ for $v \in \Pi_{i,j}$;
    end
    /* Check whether j is a "critical" scale */
    use $\mathsf{ALG}_{\text{Orient}}$ to find tour $\pi_{i,j}^{\text{Ori}}$ with budget γ^i and profit $\{w_v^j\}_{v \in V}$;
    set $T_{i,j} \leftarrow \sum_{v \in \pi_{i,j}^{\text{Ori}}} w_v^j$;
    if $T_{i,j} \geq 1/300$ *or* $j = \ell$ **then**
      append tour $\Pi_i := \Pi_{i,j} \cup \Pi_{i,j-1}$ to Π, i.e., $\Pi \leftarrow \Pi \circ \Pi_i$;
      Break ;
    end
  end
end

Probing stage:
for *phase* $i = 0, 1, \cdots$ **do**
  visit vertices in the order of Π_i and apply the following selection and stopping criteria ;
  Selection Criterion: select every vertex visited ;
  Stopping Criterion: total reward reaches k ;
end
Return set of vertices selected

We assume without loss of generality that the stochastic reward $R_v \leq k$ almost surely for each vertex $v \in V$. Our algorithm $\mathsf{ALG}_{\text{Stoch-Reward}}$ for Stoch-Reward k-TSP problem is given in Algorithm 3. It is an instantiation of the Meta-Algorithm $\mathsf{ALG}_{\text{Meta}}$ (Algorithm 1) by setting the phase parameter $\gamma = 1.1$, number of scales $\ell = \lfloor \log k \rfloor$, and number of repetitions $C = 6000$. For each scale j in phase i, we set the random variable X_v^j for any vertex $v \in V \setminus \Pi$ in $\mathsf{ALG}_{\text{Meta}}$ to be the stochastic reward R_v truncated at $k/2^j$ and then scaled down to $[0, 1]$. We identify the "critical" scale j_{crit} in $\mathsf{ALG}_{\text{Meta}}$ as follows: For each scale j in phase i, denote $\Pi_{i,j}$ the $C = 6000$ repetitions of $\mathsf{ALG}_{\text{Bicrit-Orient}}$ and let $T_{i,j}$ be the profit obtained by the 3-approximation Orienteering algorithm $\mathsf{ALG}_{\text{Orient}}$ in $V \setminus (\Pi \cup \Pi_{i,j})$. The "critical" scale j_{crit} is the smallest scale j such that $T_{i,j} \geq 1/300$, i.e., sufficient profit remains outside even after C repetitions. We add the two tours corresponding to the "rich" scale j_{crit} and the "poor"

scale $j_{\mathsf{crit}} - 1$ into Π. In the case when there is no scale j with $T_{i,j} \geq 1/300$, we simply set j_{crit} to be the last scale ℓ. In the probing stage, the selection and the stopping criteria are straightforward: we collect reward from every visited vertex and stop when the total reward reaches k.

4.2 Proof of Theorem 1

Recall from Section 3.1 that to prove Theorem 1, we only need to prove the precondition in Lemma 7. The remainder of this section proves this precondition for $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ as given in the following Lemma 10.

▶ **Lemma 10.** *For $\gamma = 1.1$, any phase $i > 0$ in the probing stage of $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ satisfies*

$$u_i(\sigma_{i-1}) \leq 100 \cdot u_i^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}. \tag{2}$$

Before proving Lemma 10, we discuss the high-level intuition of our proof.

Intuition. Assume without loss of generality that $u_i^*(\sigma_{i-1}) < 0.01$, i.e., OPT finds k reward within budget γ^i with probability at least 0.99, as otherwise the lemma trivially holds. Now the plan is to show that with constant probability, $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ finds more reward than OPT restricted to budget γ^i, even when all rewards in σ_{i-1} are given to OPT for free. This allows us to focus on the remaining graph with vertex set $V_i := V \setminus \sigma_{i-1}$ where we repeat $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ for different scales.

Our arguments rely on the notion of "richness". We call a scale j "rich" if $T_{i,j} \geq 1/300$ and otherwise "poor". A scale being poor indicates that not much reward can be collected outside the C repetitions of $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ for that scale, in which case we can use Lemma 8 to argue that OPT cannot find much reward outside. A scale being rich implies that each repetition of $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ for that scale finds a significant amount of reward, in which case we can apply Lemma 9 to argue that $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ finds much more reward than OPT in the C repetitions for that scale. Our critical scale j_{crit} corresponds to the transition from poor to rich scales. Since the algorithm includes both j_{crit} and $j_{\mathsf{crit}} - 1$, roughly the reason why our analysis works is that we use the poor scale $j_{\mathsf{crit}} - 1$ to argue OPT cannot find much reward outside our tours and we use the rich scale j_{crit} to argue OPT cannot find much more reward inside. The final analysis has to do some case analysis depending on whether the transition ever happens or not.

Proof of Lemma 10. We fix any outcome σ_{i-1} of vertices visited by $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ in the first $i-1$ phases in its probing stage. The lemma trivially holds in the case where $u_i^*(\sigma_{i-1}) \geq 0.01$ as we have $100u_i^*(\sigma_{i-1}) \geq 1$. If $u_{i-1}(\sigma_{i-1}) = 0$ which means that $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ already collects reward k before entering phase i in the probing stage, then $u_i(\sigma_{i-1}) = 0$ and again the lemma trivially holds. We therefore assume that $u_i^*(\sigma_{i-1}) < 0.01$ and that $u_{i-1}(\sigma_{i-1}) = 1$. Now proving Lemma 10 is equivalent to proving

$$u_i(\sigma_{i-1}) \leq 100u_i^*(\sigma_{i-1}) + 1/\gamma^2. \tag{3}$$

To prove (3), we need the following notation. Denote $V_i \coloneqq V \setminus \sigma_{i-1}$ the vertex set of the remaining graph where vertices in σ_{i-1} are excluded. Denote $\overline{\Pi}_i(\mathsf{OPT}) \subseteq V_i \setminus \Pi_i$ the (random) set of vertices visited by OPT outside $\sigma_{i-1} \cup \Pi_i$ within budget γ^i, and denote $\Pi_i(\mathsf{OPT}) \subseteq \Pi_i$ the (random) set of vertices visited by OPT inside Π_i. We consider three cases:

Case (1): (Scale 0 is rich) $T_{i,0} \geq 1/300$. In this case, our algorithm appends tour $\Pi_i := \Pi_{i,0}$ to Π (recall that $\Pi_{i,-1} = \emptyset$), and these will be the phase i vertices visited in the probing stage. We show that $T_{i,0} \geq 1/300$ implies that each repetition of $\mathsf{ALG}_{\text{Bicrit-Orient}}$ has large expected reward (notice the random rewards are not truncated at scale 0). As we repeat $\mathsf{ALG}_{\text{Bicrit-Orient}}$ for $C = 6000$ times, the tour $\Pi_{i,0}$ has expected reward much larger than the target k.

Since $T_{i,0}$ is the profit of a valid Orienteering tour with length at most γ^i, for each $s \in \{1, \ldots, C\}$ we have $T_{i,0,s} \geq T_{i,0} - \epsilon \geq 1/300 - \epsilon$, where $\epsilon = 1/10^5$ is the small error term for $\mathsf{ALG}_{\text{Bicrit-Orient}}$ in Lemma 6. Thus,

$$\sum_{v \in \Pi_{i,0}} \mathbb{E}\left[\min\left\{R_v/k, 1\right\}\right] \quad \geq \quad 20 - 6000\epsilon \quad \geq \quad 19.$$

Notice that $R_v/k \in [0,1]$, so applying Chernoff bound (Theorem 5) we have

$$1 - u_i(\sigma_{i-1}) \quad \geq \quad \mathbb{P}\Big[\sum_{v \in \Pi_{i,0}} R_v \geq k\Big] \quad = \quad \mathbb{P}\Big[\sum_{v \in \Pi_{i,0}} \min\left\{R_v/k, 1\right\} \quad \geq \quad 1\Big] \quad \geq \quad 0.9,$$

which means $u_i(\sigma_{i-1}) \leq 0.1 \leq 1/\gamma^2$. This proves (3) and finishes the proof of Lemma 10 in this case.

Case (2): (Scale ℓ is poor) $T_{i,j} \leq 1/300$ for every scale $j = 0, \cdots, \ell$. In this case, our algorithm adds $\Pi_i := \Pi_{i,\ell} \cup \Pi_{i,\ell-1}$ to Π, and these will be the phase i vertices visited in the probing stage. We argue that the assumption of $T_{i,\ell} \leq 1/300$ implies that with constant probability OPT finds *no* reward outside $\sigma_{i-1} \cup \Pi_i$ within budget γ^i. If OPT still manages to find k reward, then all k reward must come from vertices in $\sigma_{i-1} \cup \Pi_i$, in which case $\mathsf{ALG}_{\text{Stoch-Reward}}$ also finds k reward. In this case our argument already works with the vertices $\Pi_{i,\ell}$ added to Π, i.e., we do not even need vertices in $\Pi_{i,\ell-1}$.

Since $\mathsf{ALG}_{\text{Orient}}$ is a 3-approximation Orienteering algorithm, for any set of vertices $S \subseteq V_i \setminus \Pi_i$ that can be visited within budget γ^i, we have $\sum_{v \in S} \mathbb{E}\left[\min\left\{R_v \cdot 2^\ell/k, 1\right\}\right] \leq 3T_{i,\ell} \leq 0.01$. Since $\ell = \lfloor \log k \rfloor$, we have $k/2^\ell \in [1,2]$, and therefore

$$\sum_{v \in S} \mathbb{E}[\min\{R_v, 1\}] \quad \leq \quad \sum_{v \in S} \mathbb{E}\left[\min\left\{2 \cdot R_v \cdot 2^\ell/k, 1\right\}\right] \quad \leq \quad 0.02. \tag{4}$$

Recall that $\overline{\Pi}_i(\mathsf{OPT}) \subseteq V_i \setminus \Pi_i$ denotes the (random) set of vertices visited by OPT outside $\sigma_{i-1} \cup \Pi_i$ within budget γ^i. Since each $\min\{R_v, 1\} \in \{0,1\}$, the best probability of obtaining truncated reward at least 1 in $V_i \setminus \Pi_i$ within budget γ^i is achieved by a non-adaptive strategy. Therefore, Markov's inequality together with (4) implies that

$$\mathbb{P}\Big[\sum_{v \in \overline{\Pi}_i(\mathsf{OPT})} \min\{R_v, 1\} \geq 1\Big] \;\leq\; 0.02.$$

Since $u_i^*(\sigma_{i-1}) < 0.01$, we have that with probability at least $1 - 0.01 - 0.02 = 0.97$, OPT finds k reward in V but 0 reward outside $\sigma_{i-1} \cup \Pi_i$. In this case, $\mathsf{ALG}_{\text{Stoch-Reward}}$ also finds k reward among vertices visited in the first i phases. So we have $u_i(\sigma_{i-1}) \leq 1 - 0.97 = 0.03 \leq 1/\gamma^2$, which establishes (3) in this case.

Case (3): (Transition from poor to rich scale at j_{crit}) $T_{i,0} \leq 1/300$ but $T_{i,j} > 1/300$ for some $j \in [\ell]$. In this case, let $j_{\text{crit}} = \min\left\{j \in [\ell] : T_{i,j} > 1/300\right\}$ be our critical scale. The algorithm appends $\Pi_i := \Pi_{i,j_{\text{crit}}-1} \cup \Pi_{i,j_{\text{crit}}}$ to Π. To prove that $\mathsf{ALG}_{\text{Stoch-Reward}}$ will not continue to phase $i+1$ with constant probability, we show that the following two events happen with constant probability:

1. OPT doesn't find too much reward outside $\sigma_{i-1} \cup \Pi_i$ within budget γ^i.
2. $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ finds much more reward inside Π_i than OPT does since it is restricted to budget γ^i.

We show that the first event follows from $T_{i,j_{\mathsf{crit}}-1} \leq 1/300$ while the second event follows from $T_{i,j_{\mathsf{crit}}} \geq 1/300$. From these we conclude that with constant probability, $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ obtains at least as much reward as OPT restricted to budget γ^i.

We first argue that OPT doesn't find too much reward outside $\sigma_{i-1} \cup \Pi_i$. Specifically, we prove that

$$\mathbb{P}\Big[\sum_{v \in \overline{\Pi}_i(\mathsf{OPT})} R_v < k/2^{j_{\mathsf{crit}}-1}\Big] \;\geq\; 0.5. \tag{5}$$

Notice that $T_{i,j_{\mathsf{crit}}-1} \leq 1/300$ together with the fact that $\mathsf{ALG}_{\mathsf{Orient}}$ is a 3-approximation for $\mathsf{Orienteering}$ implies that for any set of vertices $S \subseteq V_i \setminus \Pi_i$ that can be visited within distance γ^i, we have

$$\sum_{v \in S} \mathbb{E}\left[\min\left\{R_v \cdot 2^{j_{\mathsf{crit}}-1}/k, 1\right\}\right] \leq 0.01.$$

Since the random variables $\min\left\{R_v \cdot 2^{j_{\mathsf{crit}}-1}/k, 1\right\} \in [0,1]$, applying Lemma 8 we have

$$\mathbb{P}\Big[\sum_{v \in \overline{\Pi}_i(\mathsf{OPT})} \min\left\{R_v \cdot 2^{j_{\mathsf{crit}}-1}/k, 1\right\} \geq 1\Big] \quad\leq\quad 2\exp\left(-\frac{0.99^2/2}{0.01 + 0.99/3}\right) \quad\leq\quad 0.5,$$

which immediately implies (5).

Now we argue that inside Π_i, we find much more reward than OPT does when it's restricted to budget γ^i. Specifically, we prove that

$$\mathbb{P}\Big[\sum_{v \in \Pi_i \setminus \Pi_i(\mathsf{OPT})} R_v \geq k/2^{j_{\mathsf{crit}}-1}\Big] \;\geq\; 0.8, \tag{6}$$

where recall that $\Pi_i(\mathsf{OPT}) \subseteq \Pi_i$ is the (random) set of vertices visited by OPT inside Π_i within budget γ^i. Notice that $T_{i,j_{\mathsf{crit}}} > 1/300$ together with Lemma 9 implies that

$$\sum_{v \in \Pi_i \setminus \Pi_i(\mathsf{OPT})} \mathbb{E}[\min\{R_v \cdot 2^{j_{\mathsf{crit}}}/k, 1\}] \quad\geq\quad (6000-1) \cdot (T_{i,j_{\mathsf{crit}}} - \epsilon) - \epsilon \quad\geq\quad 19.$$

Applying Chernoff bound (Theorem 5), we have

$$\mathbb{P}\Big[\sum_{v \in \Pi_i \setminus \Pi_i(\mathsf{OPT})} \min\{R_v \cdot 2^{j_{\mathsf{crit}}}/k, 1\} \geq 2\Big] \;\geq\; 0.8,$$

which implies (6).

Now we complete the proof of (3) in this final case. From (5) and (6) and our assumption that $u_i^*(\sigma_{i-1}) < 0.01$, we have that with probability at least $1 - 0.5 - 0.2 - 0.01 \geq 1/4$, all the following three events hold: (1) $\sum_{v \in \overline{\Pi}_i(\mathsf{OPT})} R_v < k/2^{j_{\mathsf{crit}}-1}$, (2) $\sum_{v \in \Pi_i \setminus \Pi_i(\mathsf{OPT})} R_v \geq k/2^{j_{\mathsf{crit}}-1}$, and (3) OPT obtains at least k reward within budget γ^i. When all these three events hold, $\mathsf{ALG}_{\mathsf{Stoch\text{-}Reward}}$ also finds at least k reward before visiting any vertex from phase $i+1$. Therefore, $u_i(\sigma_{i-1}) \leq 3/4 \leq 1/\gamma^2$, and this completes the proof of Lemma 10. ◀

5 Stoch-Cost k-TSP

In this section we prove Theorem 2, which is restated below for convenience. Throughout this section, we will remove the restriction that a vertex v can only be selected if we are currently at v because this is equivalent to the original problem up to a factor of 2.

▶ **Theorem 2.** *The Stoch-Cost k-TSP problem has a non-adaptive $O(1)$-approximation algorithm.*

Recall, an additional challenge for Stoch-Cost k-TSP is that there is no obvious way to truncate the cost distributions C_v, even if the remaining target k' is known. Truncating at the "average" cost per remaining reward (i.e., $\mathbb{P}[C_v \le O(\gamma^i/k')]$) will fail when some vertices in the optimal tour have costs much smaller than $O(\gamma^i/k')$, while the other vertices have much higher costs. We overcome this by considering $\mathbb{P}[C_v \le O(\gamma^i/2^j)]$ for all possible scales $j \in \{0, \cdots, i \cdot \log\gamma + \log n\}$. To identify a "critical" scale, we evaluate the maximum target a tour at a given scale can get with constant probability within cost budget 2^i. We show this can be approximately computed via dynamic programming.

The rest of this section is devoted to proving Theorem 2.

5.1 The Algorithm

Our algorithm $\mathsf{ALG}_{\text{Stoch-Cost}}$ for Stoch-Cost k-TSP is given in Algorithm 4. $\mathsf{ALG}_{\text{Stoch-Cost}}$ is an instantiation of our Meta-Algorithm $\mathsf{ALG}_{\text{Meta}}$ in Algorithm 1 by setting the phase parameter $\gamma = 1.1$ and number of repetitions $C = 6000$. The number of scales in phase $i \ge 0$ will be $\ell_i = \lfloor i \cdot \log\gamma + \log n \rfloor$. (Notice, unlike Stoch-Reward k-TSP, the number of scales changes with phase.) For scale j in phase i, we set a random variable X_v^j for vertex $v \in V \setminus \Pi$ in $\mathsf{ALG}_{\text{Meta}}$ to be the indicator variable that cost $C_v \le \gamma^i/2^j$.

We identify a "critical" scale $\widetilde{j}_{\text{crit}}$ as follows: For any phase $i \ge 0$ and scale $j \in \{0, \cdots, \ell_i\}$, define $Y_{i,j} \in \mathbb{Z}_{\ge 0}$ to be the maximum number of vertices that can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ with probability at least 0.2 within cost budget $3\gamma^i$. Ideally, we want to compute $Y_{i,j}$ for every scale $j \in \{0, \cdots, \ell_i\}$ and set the critical scale to be the one that maximizes $Y_{i,j}$. Unfortunately, $Y_{i,j}$ cannot be computed efficiently as the corresponding problem is NP-Hard. To get around this issue, we compute an approximate value $\widetilde{Y}_{i,j}$ in Step 15 of $\mathsf{ALG}_{\text{Stoch-Cost}}$ via a dynamic programming sub-procedure ALG_{DP}. We discuss the details of ALG_{DP} in Section 5.3, where we prove the following Lemma 11 which roughly says that the $\widetilde{Y}_{i,j}$ computed by $\mathsf{ALG}_{\text{Stoch-Cost}}$ is a reasonably good approximation of $Y_{i,j}$.

▶ **Lemma 11.** *For any phase $i \ge 0$ and any scale $j \in \{0, \cdots, \ell_i\}$, the approximate value $\widetilde{Y}_{i,j}$ computed in Step 15 of $\mathsf{ALG}_{\text{Stoch-Cost}}$ satisfies that (1) $\widetilde{Y}_{i,j} \ge Y_{i,j}$, and (2) $\widetilde{Y}_{i,j}$ vertices can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ within cost budget $6\gamma^i$ with probability at least 0.2.*

After computing $\widetilde{Y}_{i,j}$ for each scale $j \in \{0, \cdots, \ell_i\}$, we simply set $\widetilde{j}_{\text{crit}}$ to be the scale that maximizes $\widetilde{Y}_{i,j}$ and add the two tours corresponding to scales $\widetilde{j}_{\text{crit}} - 1$ and $\widetilde{j}_{\text{crit}}$ into Π.

In the probing stage, the Stopping Criterion is natural: we stop whenever the number of selected vertices reaches k. The selection process needs some care since not all vertices visited in the previous phases are selected. Our algorithm therefore runs two selection processes consecutively: In Selection-Process 1, we select as many unselected vertices from those visited in the previous phases within total cost γ^i. This is to ensure that we select from σ_{i-1} at least as many vertices as OPT restricted to budget γ^i. In Selection-Process 2, we select as many vertices as possible from Π_i within total cost $6\gamma^i$. The above Lemma 11 guarantees that at least $\widetilde{Y}_{i,\widetilde{j}_{\text{crit}}}$ vertices can be selected in this process with probability at least 0.2.

Algorithm 4 $\mathsf{ALG}_{\textsf{Stoch-Cost}}$ for Stoch-Cost k-TSP problem.

Pre-processing stage:
set $\gamma \leftarrow 1.1$, $\epsilon \leftarrow 1/10^5$, $\Pi \leftarrow \emptyset$ and $C \leftarrow 6000$;
for *phase* $i = 0, 1, \cdots$ **do**
  set $\Pi_{i,-1} \leftarrow \emptyset$;
  for *scale* $j = 0, \cdots, \ell_i$, *where* $\ell_i = \lfloor i \cdot \log \gamma + \log n \rfloor$ **do**
    set profit $w_v^j = \mathbb{P}[C_v \le \gamma^i / 2^j] \cdot 1[v \in V \setminus \Pi]$; /* Scale j "truncates" at $\gamma^i/2^j$ */
    set $\Pi_{i,j} \leftarrow \emptyset$;
    for *repetition* $s = 1, 2, \cdots, C$ /* *Constant repetitions of* $\mathsf{ALG}_{\textit{Bicrit-Orient}}$ */ **do**
      use $\mathsf{ALG}_{\textsf{Bicrit-Orient}}$ to find tour $\pi_{i,j,s}$ with budget γ^i, profit $\{w_v^j\}_{v \in V}$ and error ϵ ;
      append tour $\pi_{i,j,s}$ to $\Pi_{i,j}$, i.e., $\Pi_{i,j} \leftarrow \Pi_{i,j} \circ \pi_{i,j,s}$;
      reset $w_v^j = 0$ for $v \in \Pi_{i,j}$;
    end
    /* Approximately compute the maximum number of vertices that can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ within cost budget $3\gamma^i$ and with probability at least 0.2 */
    find the largest integer $\widetilde{Y}_{i,j} \le n$ such that $\mathsf{ALG}_{\mathsf{DP}}(\widetilde{Y}_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \ge 0.2$;
  end
  /* Identify a "critical" scale */
  set $\widetilde{j}_{\mathsf{crit}} \leftarrow \arg\max_j \widetilde{Y}_{i,j}$ and $\Pi_i \leftarrow \Pi_{i,\widetilde{j}_{\mathsf{crit}}} \cup \Pi_{i,\widetilde{j}_{\mathsf{crit}}-1}$;
  append tour Π_i to Π, i.e., $\Pi \leftarrow \Pi \circ \Pi_i$;
end

Probing stage:
for *phase* $i = 0, 1, \cdots$ **do**
  set $\sigma_{i-1} \leftarrow \bigcup_{t=0}^{i-1} \Pi_t$;
  visit vertices in the order of Π_i and apply the following selection and stopping criteria ;
  /* Select (unselected) vertices visited in previous phases */
  Selection-Process 1: select as many vertices as possible from σ_{i-1} within total cost γ^i ;
  /* Select vertices visited in the current phase */
  Selection-Process 2: select as many vertices as possible from Π_i within total cost $6\gamma^i$;
  Stopping Criterion: total number of vertices selected reaches k ;
end
Return the set of selected vertices

5.2 Proof of Theorem 2

Recall from Section 3.1 that to prove Theorem 2, we only need to prove the precondition in Lemma 7. The remainder of this section proves this precondition for $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$ as stated in the following Lemma 12.

▶ **Lemma 12.** *For $\gamma = 1.1$, any phase $i > 0$ in the probing stage of Stoch-Cost k-TSP satisfies*

$$u_i(\sigma_{i-1}) \leq 100u_i^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}. \tag{7}$$

Before proving Lemma 12, we need some notation.

Notation. For any (possibly adaptive) algorithm ADAP, we say ADAP has a *distance budget* of B if it is allowed to travel a total distance of at most B; we say ADAP has a *cost budget* of B if it is allowed to select vertices up to a total cost of B; we say ADAP has a *total budget* of B if its total distance travelled *plus* the total cost of selecting vertices is restricted to be at most B. An algorithm satisfying a budget constraint is said to be *within* that budget. For any phase i, denote $V_i := V \setminus \sigma_{i-1}$ the set of vertices in the remaining graph where vertices in σ_{i-1} are excluded. For any fixed outcome σ_{i-1} and any target $Y \in \mathbb{Z}_{\geq 0}$, denote $p^*_{i,Y}(\sigma_{i-1})$ the probability that OPT selects at least Y vertices from V_i within total budget γ^i and $p_{i,Y}(\sigma_{i-1})$ the probability that the tour $\Pi_i \subseteq V_i$ found by $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$ contains Y vertices which can be selected within cost budget $6\gamma^i$.

The proof of Lemma 12 relies on the following Lemma 13, which says that if OPT selects Y vertices in V_i within total budget γ^i with probability at least 0.9, then we can select Y vertices in Π_i within cost budget $6\gamma^i$ with probability at least 0.2. The proof of Lemma 12 from Lemma 13 is standard, see Appendix C.

▶ **Lemma 13.** *For any phase $i \geq 0$, any target $Y \in \mathbb{Z}_{\geq 0}$ and any outcome σ_{i-1} of vertices visited in the previous $i-1$ phases, if $p^*_{i,Y}(\sigma_{i-1}) \geq 0.9$ then we have $p_{i,Y}(\sigma_{i-1}) \geq 0.2$.*

We need some notation to prove Lemma 13.

Notation. We say a vertex $v \in V$ is *qualified* for scale $j \in \{0, \cdots, \ell_i\}$ if its cost $C_v \leq \gamma^i/2^j$. For each scale $j \in \{0, \cdots, \ell_i\}$, denote $\pi^*_{i,j}$ the optimal Orienteering tour in $V_i \setminus \Pi_{i,j}$ with budget γ^i where each vertex $v \in V_i \setminus \Pi_{i,j}$ has profit $\mathbb{P}[C_v \leq \gamma^i/2^j]$. Define $T^*_{i,j} := \sum_{v \in \pi^*_{i,j}} \mathbb{P}[C_v \leq \gamma^i/2^j]$ and $T_{i,j} := \sum_{v \in \Pi_{i,j}} \mathbb{P}[C_v \leq \gamma^i/2^j]$ to be the total Orienteering profit of tour $\pi^*_{i,j}$ and $\Pi_{i,j}$, respectively. Denote $\overline{\Pi}_{i,j}(\mathsf{OPT}) \subseteq V_i \setminus (\Pi_{i,j} \cup \Pi_{i,j-1})$ the (random) set of vertices visited by OPT outside $\sigma_{i-1} \cup (\Pi_{i,j} \cup \Pi_{i,j-1})$ within total budget γ^i, and $\Pi_{i,j}(\mathsf{OPT}) \subseteq \Pi_{i,j} \cup \Pi_{i,j-1}$ the (random) set of vertices visited by OPT inside $\Pi_{i,j} \cup \Pi_{i,j-1}$ within total budget γ^i.

Intuition. We discuss our high-level proof strategy for Lemma 13. Our arguments again rely on the notion of "richness". Recall from above that $T_{i,j}$ denotes the Orienteering profit of tour $\Pi_{i,j}$ at scale j. We call a scale j "rich" if $T_{i,j} \geq Y$ and otherwise "poor". A scale j being poor roughly (but not quite) indicates that OPT cannot find enough low-cost vertices qualified for scale j outside the tour $\Pi_{i,j}$. A scale j being rich implies that $\Pi_{i,j}$ contains enough vertices that are qualified for scale j, which is an immediate consequence of Jogdeo-Samuels inequality (Theorem 3). We plan to find a critical scale j_{crit} that corresponds to the transition from rich to poor scales. Notice that such a critical scale j_{crit} might be different from the critical scale $\widetilde{j}_{\mathsf{crit}}$ found by our algorithm, but we show that it suffices to argue about j_{crit} since $\widetilde{j}_{\mathsf{crit}}$ is only better.

To argue about j_{crit}, we consider the tours corresponding to both scales j_{crit} and $j_{\mathsf{crit}}-1$. Roughly we use the poor scale j_{crit} to argue that OPT cannot find enough low-cost vertices outside these tours and we use the rich scale $j_{\mathsf{crit}}-1$ to argue that we have enough replacements for these low-cost vertices without paying too much cost. Our final analysis is a case analysis depending on whether the transition ever happens or not. The proof here is more involved than that in Section 4 as we also need to take into account the amount of $\mathsf{Orienteering}$ profit outside the $C = 6000$ repetitions of $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ for each scale j.

Proof of Lemma 13. Recall that for any phase $i \geq 0$ and scale $j \in \{0, \cdots, \ell_i\}$, we defined $Y_{i,j}$ to be the maximum number of vertices that can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ with probability at least 0.2 within cost budget $3\gamma^i$. We show in the following that $p^*_{i,Y}(\sigma_{i-1}) \geq 0.9$ implies there exists a "critical" scale $j_{\mathsf{crit}} \in \{0, \cdots, \ell_i\}$ with $Y_{i,j_{\mathsf{crit}}} \geq Y$. This critical scale j_{crit} might be different from the critical scale $\widetilde{j}_{\mathsf{crit}}$ identified by $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$. But since $\widetilde{j}_{\mathsf{crit}}$ maximizes $\widetilde{Y}_{i,j}$ among all scales $j \in \{0, \cdots, \ell_i\}$, it follows from property (1) in Lemma 11 that $\widetilde{Y}_{i,\widetilde{j}_{\mathsf{crit}}} \geq \widetilde{Y}_{i,j_{\mathsf{crit}}} \geq Y_{i,j_{\mathsf{crit}}} \geq Y$. Now using property (2) in Lemma 11 we have that $\widetilde{Y}_{i,\widetilde{j}_{\mathsf{crit}}} \geq Y$ vertices can be selected from $\Pi_{i,\widetilde{j}_{\mathsf{crit}}} \cup \Pi_{i,\widetilde{j}_{\mathsf{crit}}-1}$ within cost budget $6\gamma^i$ with probability at least 0.2. It follows that $p_{i,Y}(\sigma_{i-1}) \geq 0.2$. Therefore, the existence of a critical scale j_{crit} with $Y_{i,j_{\mathsf{crit}}} \geq Y$ would imply Lemma 13.

In the following, we consider three different cases and prove the existence of such a critical scale j_{crit} with $Y_{i,j_{\mathsf{crit}}} \geq Y$ in each case.

Case (1): (Scale 0 is poor) $T_{i,0} < Y$. We show in this case that $p^*_{i,Y}(\sigma_{i-1}) \geq 0.9$ implies that scale 0 is a "critical" scale with $Y_{i,0} \geq Y$. Notice that any vertex $v \in V_i$ not qualified for scale 0 has cost $C_v > \gamma^i$. Therefore, OPT cannot select any vertex that is not qualified for scale 0 within total budget γ^i.

We start by showing that $T^*_{i,0} \leq 0.1$. To prove this, we assume for the purpose of contradiction that $T^*_{i,0} > 0.1$. It follow from Lemma 8 that

$$\mathbb{P}\Big[\,\big|\{v \in \overline{\Pi}_{i,0}(\mathsf{OPT}) : C_v \leq \gamma^i\}\big| \leq 200T^*_{i,0}\Big] \;\geq\; 0.9. \tag{8}$$

From Lemma 9 we have that

$$\sum_{v \in \Pi_{i,0} \setminus \Pi_{i,0}(\mathsf{OPT})} \mathbb{P}[C_v \leq \gamma^i] \quad\geq\quad (6000-1)\cdot(T^*_{i,0}-\epsilon)-\epsilon \quad\geq\quad 5000T^*_{i,0}.$$

So it follows from Chernoff bound (Theorem 5) that

$$\mathbb{P}\Big[\,\big|\{v \in \Pi_{i,0} \setminus \Pi_{i,0}(\mathsf{OPT}) : C_v \leq \gamma^i\}\big| \geq 500T^*_{i,0}\Big] \;\geq\; 0.9. \tag{9}$$

Since $T_{i,0} < Y$, from Theorem 3 we have that

$$\mathbb{P}\Big[\,\big|\{v \in \Pi_{i,0} : C_v \leq \gamma^i\}\big| \leq Y\Big] \;\geq\; 0.5. \tag{10}$$

Now we count the number of vertices found by OPT that are qualified for scale 0 within total budget γ^i. It follows from union bound that with probability at least 0.2, all three events in (8), (9) and (10) hold, in which case OPT finds at most $Y - 300T^*_{i,0}$ vertices qualified for scale 0 within total budget γ^i. Therefore, in order to select at least Y vertices, OPT needs to select vertices that are not qualified for scale 0 within total budget γ^i, which is a contradiction to the assumption that $p^*_{i,Y}(\sigma_{i-1}) \geq 0.9$.

Therefore we must have $T^*_{i,0} \le 0.1$. Applying Markov's inequality, the probability that OPT finds any vertex qualified for scale 0 in $V_i \setminus \Pi_{i,0}$ is upper bounded by $T^*_{i,0} \le 0.1$. When this happens and when OPT selects Y vertices within total budget γ^i, all vertices selected by OPT are from $\Pi_{i,0}$. Therefore, with probability at least $p^*_{i,Y}(\sigma_{i-1}) - 0.1 \ge 0.8$, we can select Y vertices from $\Pi_{i,0}$ within cost budget γ^i which implies that $Y_{i,0} \ge Y$.

Case (2): (All scales are rich) $T_{i,j} \ge Y$ for every scale $j = 0, \cdots, \ell_i$. In this case we show that ℓ_i is a "critical" scale with $Y_{i,\ell_i} \ge Y$. Notice that selecting any Y vertices qualified for scale ℓ_i has cost at most $Y \cdot \gamma^i/2^{\ell_i} \le 2 \le 6\gamma^i$. Since $T_{i,\ell_i} \ge Y$, it follows from Theorem 3 that with probability no less than 0.5, at least Y vertices in Π_{i,ℓ_i} are qualified for scale ℓ_i (notice we don't even need the tour Π_{i,ℓ_i-1} in this case). This implies that $Y_{i,\ell_i} \ge Y$.

Case (3): (Transition from rich to poor scale at j_{crit}) $T_{i,0} \ge Y$ but $T_{i,j} < Y$ for some $j \in [\ell_i]$. In this case, let $j_{\mathsf{crit}} = \arg\min_j \{j \in [\ell_i] : T_{i,j} < Y\}$. We show in the following that j_{crit} is a "critical" scale with $Y_{i,j_{\mathsf{crit}}} \ge Y$. To prove this, we show that the following two events happen with constant probability:

1. $T_{i,j_{\mathsf{crit}}} < Y$ implies that OPT doesn't find enough vertices *qualified* for scale j_{crit}. This gives a lower bound on the cost of the set of vertices selected by OPT within total budget γ^i.
2. $T_{i,j_{\mathsf{crit}}-1} \ge Y$ implies that $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$ finds enough vertices *qualified* for scale $j_{\mathsf{crit}} - 1$. This can be used to upper bound the cost of $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$.

We first consider the sub-case where $T^*_{i,j_{\mathsf{crit}}} \le 0.1$. This is the case where not many vertices qualified for scale j_{crit} can be found outside $\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}$. In this case, we have $\sum_{v \in \overline{\Pi}_{i,j_{\mathsf{crit}}}(\mathsf{OPT})} \mathbb{P}[C_v \le \gamma^i/2^{j_{\mathsf{crit}}}] \le T^*_{i,j_{\mathsf{crit}}}$. It follows from Markov's inequality that with probability at least 0.9, OPT finds no vertex in $V_i \setminus (\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1})$ that is qualified for scale j_{crit}, in which case any vertex $v \in V_i \setminus (\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1})$ selected by OPT has cost $C_v > \gamma^i/2^{j_{\mathsf{crit}}}$. Since $T_{i,j_{\mathsf{crit}}-1} \ge Y$, it follows from Theorem 3 that with probability at least 0.5, we have $\left|\left\{v \in \Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1} : C_v \le \gamma^i/2^{j_{\mathsf{crit}}-1}\right\}\right| \ge Y$. Furthermore, $p^*_Y \ge 0.9$ implies that with probability at least 0.9, OPT selects Y vertices within total budget γ^i. It follows from union bound that all three events above happen with probability at least 0.2, in which case we can select Y vertices from $\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}$ within cost budget $2\gamma^i$. This implies that $Y_{i,j_{\mathsf{crit}}} \ge Y$.

Now we deal with the other sub-case where $T^*_{i,j_{\mathsf{crit}}} > 0.1$. This represents the situation where many vertices qualified for scale j_{crit} can be found outside $\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}$. Roughly, Lemma 8 implies in this case that OPT finds at most $200T^*_{i,j_{\mathsf{crit}}}$ low-cost vertices in $V_i \setminus (\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1})$. In general, these vertices might have very tiny cost. However, we show in the following Claim 14 that increasing the cost of each one of these low-cost vertices to $\gamma^i/2^{j_{\mathsf{crit}}}$ will increase their total cost by at most $O(\gamma^i)$. This allows us to lower bound the cost of the set of vertices selected by OPT within total budget γ^i.

▷ Claim 14. We have $200T^*_{i,j_{\mathsf{crit}}} \cdot \gamma^i/2^{j_{\mathsf{crit}}} \le \gamma^i/2$.

Before proving Claim 14, we complete the proof of Lemma 13. Since $T^*_{i,j_{\mathsf{crit}}} > 0.1$, from Lemma 8 we have

$$\mathbb{P}\left[\left|\left\{v \in \overline{\Pi}_{i,j_{\mathsf{crit}}}(\mathsf{OPT}) : C_v \le \gamma^i/2^{j_{\mathsf{crit}}}\right\}\right| \le 200T^*_{i,j_{\mathsf{crit}}}\right] \ \ge \ 0.9. \tag{11}$$

Since $T_{i,j_{\mathsf{crit}}-1} \geq Y$, it follows from Theorem 19 that

$$\mathbb{P}\Big[\,\big|\big\{v \in \Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1} : C_v \leq \gamma^i/2^{j_{\mathsf{crit}}-1}\big\}\big| \geq Y\Big] \;\geq\; 0.5. \tag{12}$$

Together with the assumption that $p^*_{i,Y} \geq 0.9$, we have from union bound that with probability at least 0.2, both events in (11) and (12) hold and that OPT selects at least Y vertices within total budget γ^i. When all three events happen, we can replace $Y - |\Pi_{i,j_{\mathsf{crit}}}(\mathsf{OPT})|$ vertices in $\overline{\Pi}_{i,j_{\mathsf{crit}}}(\mathsf{OPT})$ by $Y - |\Pi_{i,j_{\mathsf{crit}}}(\mathsf{OPT})|$ vertices in $(\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}) \setminus \Pi_{i,j_{\mathsf{crit}}}(\mathsf{OPT})$ that are qualified for scale $j_{\mathsf{crit}}-1$. Claim 14 together with (11) imply that after such replacements, we reach a subset of Y vertices in $\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}$ with total cost at most $2(\gamma^i + \gamma^i/2) = 3\gamma^i$. So we conclude that with probability at least 0.2, we can select at least Y vertices from $\Pi_{i,j_{\mathsf{crit}}} \cup \Pi_{i,j_{\mathsf{crit}}-1}$ within cost budget $3\gamma^i$. This implies that $Y_{i,j_{\mathsf{crit}}} \geq Y$ and finishes the proof of Lemma 13. ◀

Now we are left to prove Claim 14.

Proof of Claim 14. We consider the tour $\Pi_{i,j_{\mathsf{crit}}}$. Denote respectively $\Pi'_{i,j_{\mathsf{crit}}}(\mathsf{OPT}) \subseteq \Pi_{i,j_{\mathsf{crit}}}$ and $\overline{\Pi}'_{i,j_{\mathsf{crit}}}(\mathsf{OPT}) \subseteq V_i \setminus \Pi_{i,j_{\mathsf{crit}}}$ the (random) set of vertices visited by OPT inside and outside $\Pi_{i,j_{\mathsf{crit}}}$ within total budget γ^i. Since $T_{i,j_{\mathsf{crit}}} < Y$, it follows from Theorem 3 that

$$\mathbb{P}\Big[\,\big|\big\{v \in \Pi_{i,j_{\mathsf{crit}}} : C_v \leq \gamma^i/2^{j_{\mathsf{crit}}}\big\}\big| \leq Y\Big] \;\geq\; 0.5. \tag{13}$$

Since $T^*_{i,j_{\mathsf{crit}}} > 0.1$, Lemma 8 gives

$$\mathbb{P}\Big[\,\Big|\Big\{v \in \overline{\Pi}'_{i,j_{\mathsf{crit}}}(\mathsf{OPT}) : C_v \leq \gamma^i/2^{j_{\mathsf{crit}}}\Big\}\Big| \leq 200T^*_{i,j_{\mathsf{crit}}}\Big] \;\geq\; 0.9. \tag{14}$$

Lemma 9 followed by Chernoff bound gives

$$\mathbb{P}\Big[\,\big|\big\{v \in \Pi_{i,j_{\mathsf{crit}}} \setminus \Pi'_{i,j_{\mathsf{crit}}}(\mathsf{OPT}) : C_v \leq \gamma^i/2^{j_{\mathsf{crit}}}\big\}\big| \geq 600T^*_{i,j_{\mathsf{crit}}}\Big] \;\geq\; 0.9. \tag{15}$$

From the assumption that $p^*_{i,Y} \geq 0.9$, we have

$$\mathbb{P}\Big[\,\big\{\mathsf{OPT} \text{ selects at least } Y \text{ vertices within total budget } \gamma^i\big\}\,\Big] \;\geq\; 0.9. \tag{16}$$

By union bound, all four events in (13)-(16) happen with positive probability, in which case OPT selects at least $400T^*_{i,j_{\mathsf{crit}}}$ vertices that are not qualified for scale j_{crit} within total budget γ^i. This implies that $400T^*_{i,j_{\mathsf{crit}}} \cdot \gamma^i/2^{j_{\mathsf{crit}}} \leq \gamma^i$ from which Claim 14 immediately follows. ◁

5.3 The Dynamic Programming Sub-procedure $\mathsf{ALG}_{\mathsf{DP}}$

In this section, we give our dynamic program $\mathsf{ALG}_{\mathsf{DP}}$ and prove Lemma 11 restated below for convenience.

▶ **Lemma 11.** *For any phase $i \geq 0$ and any scale $j \in \{0, \cdots, \ell_i\}$, the approximate value $\widetilde{Y}_{i,j}$ computed in Step 15 of $\mathsf{ALG}_{\mathit{Stoch\text{-}Cost}}$ satisfies that (1) $\widetilde{Y}_{i,j} \geq Y_{i,j}$, and (2) $\widetilde{Y}_{i,j}$ vertices can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ within cost budget $6\gamma^i$ with probability at least 0.2.*

Recall, our dynamic program $\mathsf{ALG}_{\mathsf{DP}}$ is used to approximately compute the maximum number of vertices that can be selected from a certain tour with probability at least 0.2 within cost budget $3\gamma^i$. Essentially, $\mathsf{ALG}_{\mathsf{DP}}$ solves the following sub-problem: We are given a target $T \in \mathbb{Z}_{\geq 0}$, a budget $B \geq 0$ and n independent non-negative stochastic costs. The goal is to find the probability $P_{T,B}$ that there exists a subset S of size T with sum of its costs at most B. Since this general problem is NP-hard, we give a dynamic program that finds something between $P_{T,B}$ and $P_{T,2B}$. Lemma 11 follows immediately from the following Lemma 15.

▶ **Lemma 15.** *Given n independent non-negative random variables $V = \{C_1, C_2, ..., C_n\}$, a target $T \in \mathbb{Z}_{\geq 0}$ and a budget $B \geq 0$. Let $P_{T,B}$ denote the probability that there exists a subset $S \subseteq V$ of size at least T and $\sum_{i \in S} C_i \leq B$. Then there's an efficient dynamic programming $\mathsf{ALG}_{DP}(T, B, V)$ that outputs a value $\widetilde{P}_{T,B}$ s.t. $P_{T,B} \leq \widetilde{P}_{T,B} \leq P_{T,2B}$.*

Proof of Lemma11. We first prove property (1). Recall that $Y_{i,j}$ is the maximum number of vertices that can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ with probability at least 0.2 within cost budget $3\gamma^i$, and $\widetilde{Y}_{i,j}$ is the largest integer such that $\mathsf{ALG}_{\mathsf{DP}}(\widetilde{Y}_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2$. Consider the set of stochastic costs in $\Pi_{i,j} \cup \Pi_{i,j-1}$. By definition, we have $P_{Y_{i,j}, 3\gamma^i} \geq 0.2$. It follows from Lemma 15 that $\mathsf{ALG}_{\mathsf{DP}}(Y_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2$. This implies that $\widetilde{Y}_{i,j} \geq Y_{i,j}$ and proves property (1).

Now we prove property (2). Applying Lemma 15 we have $P_{\widetilde{Y}_{i,j}, 6\gamma^i} \geq \mathsf{ALG}_{\mathsf{DP}}(\widetilde{Y}_{i,j}, 3\gamma^i, \Pi_{i,j} \cup \Pi_{i,j-1}) \geq 0.2$. It follows that $\widetilde{Y}_{i,j}$ vertices can be selected from $\Pi_{i,j} \cup \Pi_{i,j-1}$ within cost budget $6\gamma^i$ with probability at least 0.2. This establishes property (2) and finishes the proof of Lemma 11. ◀

Proof of Lemma 15. We begin by discretizing each C_i to be $\overline{C}_i := \lfloor C_i \cdot n/B \rfloor \in \mathbb{N}$ and define $\overline{P}_{T,n}$ the probability that there exists a subset $S \subseteq V$ s.t. $|S| \geq T$ and $\sum_{i \in S} \overline{C}_i \leq n$. Notice that $\sum_{i \in S} \overline{C}_i \leq n$ implies that $\sum_{i \in S} C_i \leq 2B$. Therefore we have $P_{T,B} \leq \overline{P}_{T,n} \leq P_{T,2B}$. In the following, we give a dynamic programming $\mathsf{ALG}_{\mathsf{DP}}$ that computes the value $\overline{P}_{T,n}$ and we will set $\widetilde{P}_{T,B}$ in the statement of the lemma to be $\overline{P}_{T,n}$. Assume without loss of generality that $\overline{C}_i \leq n+1$ as one can truncate the distribution of $\overline{C}_i$ at $(n+1)$ without changing $\overline{P}_{T,n}$.

Denote $A(i,j)$ the jth smallest value among the first i random variables. We build a DP table where each entry $P[i,j,\ell,m]$ (for $i \in \{1, \cdots, n\}, j \in \{1, \cdots, T\}$, $\ell \in \{0, \cdots, n\}$ and $m \in \{0, \cdots, n\}$) denotes the probability that the smallest j values among the first i random variables sum up to ℓ and the jth smallest value among the first i random variables is equal to m, i.e. $\sum_{s=1}^{j} A[i,s] = \ell$ and $A[i,j] = m$.

Initial values: $\mathsf{ALG}_{\mathsf{DP}}$ initializes certain entries of the DP table as follows.

- **Case 1 (impossible events):** set $P[i,j,\ell,m]$ to be 0 if $j > i$, $m > \ell$ or $m \cdot j < \ell$.
- **Case 2 ($j = 1$):** set $P[i,1,\ell,m] = \prod_{s \in [i]} \mathbb{P}[\overline{C}_s \geq \ell] - \prod_{s \in [i]} \mathbb{P}[\overline{C}_s > \ell]$ if $\ell = m$, and 0 otherwise.

Note that all the entries corresponding to $i = 1$ are already included in the two cases above.

Recursion: $\mathsf{ALG}_{\mathsf{DP}}$ uses the following recursion.

$$P[i,j,\ell,m] = \mathbb{P}[\overline{C_i} > m] \cdot P[i-1,j,\ell,m] + \sum_{u=0}^{m-1} \mathbb{P}[\overline{C_i} = u] \cdot P[i-1,j-1,\ell-u,m]$$
$$+\mathbb{P}[\overline{C_i} = m] \cdot \Big(\sum_{u=0}^{m} P[i-1,j-1,\ell-m,m-u] - \sum_{u=1}^{m} P[i-1,j,\ell-u,m-u] \Big). \tag{17}$$

Output: after computing all the entries of the DP table, $\mathsf{ALG}_{\mathsf{DP}}$ outputs $\overline{P}_{T,n}$ that equals $\sum_{\ell=0}^{n} \sum_{m=0}^{\ell} P[n,T,\ell,m]$.

Now we prove the correctness of $\mathsf{ALG}_{\mathsf{DP}}$. Given the definition of $P[i,j,\ell,m]$, we can immediately verify that the assignment of initial values and the final output are correct if all the entries of the DP table computed from (17) are also correct. To see the correctness of the recursion, we consider the outcome of $\overline{C}_i$. When $\overline{C}_i > m$, in order to satisfy $\sum_{s=1}^{j} A[i,s] = \ell$

and $A[i,j] = m$, one must have that $\overline{C}_i$ is not in the j smallest values among the first i random variables. This verifies the first term in (17). When $\overline{C}_i = u < m$, in order to satisfy $\sum_{s=1}^{j} A[i,s] = \ell$ and $A[i,j] = m$, one must have that $\overline{C}_i$ is one of the jth smallest values among the first i random variables. Also notice that in this case, the $(j-1)$th smallest value among the first $(i-1)$ random variables is still m and that $\sum_{s=1}^{j-1} A[i-1,s] = \ell - \overline{C}_i$. This gives the second term in (17).

Now we verify the last term in (17, which corresponds to the case where $\overline{C}_i = m$. In this case, we might as well select $\overline{C}_i$ as one of the j smallest values among the first i random variables. In order to satisfy $\sum_{s=1}^{j} A[i,s] = \ell$ and $A[i,j] = m$, we need the smallest $(j-1)$ values among the first $(i-1)$ random variables to sum up to $\ell - m$ and the $(j-1)$th smallest value to be at most m, i.e. $\sum_{s=1}^{j-1} A[i,s] = \ell - m$ and $A[i,j-1] \leq m$. The probability of this event is exactly $\sum_{u=0}^{m} P[i-1, j-1, \ell-m, m-u]$. However, in order to ensure that $A[i,j] = m$, we also need the jth smallest value among the first $(i-1)$ random variables to be at least m (i.e. $A[i-1,j] \geq m$) and the outcomes that don't satisfy this condition needs to be excluded from the previous event. Putting everything together, we have the following:

$$\begin{aligned}
&\mathbb{P}\Big\{ \sum_{s=1}^{j-1} A[i-1,s] = \ell - m, A[i-1,j-1] \leq m, A[i-1,j] \geq m \Big\} \\
&= \mathbb{P}\Big\{ \sum_{s=1}^{j-1} A[i-1,s] = \ell - m, A[i-1,j-1] \leq m \Big\} \\
&\qquad - \mathbb{P}\Big\{ \sum_{s=1}^{j-1} A[i-1,s] = \ell - m, A[i-1,j-1] \leq m, A[i-1,j] < m \Big\} \\
&= \sum_{u=0}^{m} P[i-1, j-1, \ell-m, m-u] - \sum_{u=1}^{m} P[i-1, j, \ell-u, m-u].
\end{aligned}$$

This immediately gives the last term in (17) and finishes the proof of Lemma 15. ◀

A Missing Proofs in Section 2

▶ **Lemma 6** (Bi-criteria Orienteering). *There is an efficient algorithm* $\mathsf{ALG}_{\textit{Bicrit-Orient}}$ *that finds a tour of length* $O(1) \cdot B$ *while collecting at least* $(\mathsf{OPT}_{\textit{Orient}} - \epsilon)$ *profit, where* $\epsilon = 1/\mathrm{poly}(n)$ *can be made arbitrarily small.*

Proof of Lemma 6. Assume without loss of generality that $\mathsf{OPT}_{\mathsf{Orient}} > 0$. Denote $\rho = 3$ the approximation factor of k-TSP algorithm $\mathsf{ALG}_{k\text{-}\mathsf{TSP}}$ from [8]. Denote $R_{\max} := \max_{v \in V} R_v$ and $R_{\min} := \min_{v \in V} R_v$ the maximum and minimum profit in the Orienteering instance. Notice, $\mathsf{OPT}_{\mathsf{Orient}} \in [R_{\min}, n \cdot R_{\max}]$.

$\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ applies binary search in $[R_{\min}, n \cdot R_{\max}]$, starting with profit target $(R_{\min} + n \cdot R_{\max})/2$. For each profit target λ, $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ runs $\mathsf{ALG}_{k\text{-}\mathsf{TSP}}$ with target reward λ to obtain a tour Π_λ whose length is denoted as $\ell(\Pi_\lambda)$. $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ performs binary search over $\lambda \in [R_{\min}, n \cdot R_{\max}]$ until finding two values $\lambda_l < \lambda_h \le \lambda_l + \epsilon$ such that $\ell(\Pi_{\lambda_l}) \le \rho B$ and $\ell(\Pi_{\lambda_h}) > \rho B$, in which case $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ returns the tour Π_{λ_l}. Here we assumed without loss of generality that $\ell(\Pi_{n \cdot R_{\max}}) > \rho B$ as otherwise $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ can simply return the tour $\Pi_{n \cdot R_{\max}}$. Notice that $\ell(\Pi_{\lambda_h}) > \rho B$ implies that $\mathsf{OPT}_{\mathsf{Orient}} < \lambda_h$ and therefore $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ finds reward at least $\lambda_l \ge \lambda_h - \epsilon > \mathsf{OPT}_{\mathsf{Orient}} - \epsilon$. The length of the tour found by $\mathsf{ALG}_{\mathsf{Bicrit\text{-}Orient}}$ is $\ell(\Pi_{\lambda_l}) \le \rho B = O(1) \cdot B$. This finishes the proof of Lemma 6. ◀

B Missing Proofs in Section 3

▶ **Lemma 7** (Key Lemma). *If for some universal constants* $C > 0$, $\gamma > 1$, *any phase* $i \ge 1$, *and any possible* σ_{i-1}, *the algorithm* $\mathsf{ALG}_{\textit{Meta}}$ *satisfies*

$$u_i(\sigma_{i-1}) \le C \cdot u_i^*(\sigma_{i-1}) + \frac{u_{i-1}(\sigma_{i-1})}{\gamma^2},$$

then $\mathsf{ALG}_{\textit{Meta}}$ *is a non-adaptive* $O(1)$*-approximation algorithm.*

Proof of Lemma 7. For any phase $i \ge 0$, denote u_i the probability that $\mathsf{ALG}_{\mathsf{Meta}}$ enters phase $i+1$ in the probing stage and u_i^* the probability that OPT has cost more than γ^i. Taking expectation over σ_{i-1} for the pre-condition of Lemma 7, we have $u_i \le C \cdot u_i^* + u_{i-1}/\gamma^2$. It follows that

$$\sum_{i \ge 1} u_i \cdot \gamma^i \le C \cdot \sum_{i \ge 1} u_i^* \cdot \gamma^i + u_0/\gamma + 1/\gamma \cdot \sum_{i \ge 1} u_i \cdot \gamma^i,$$

which gives

$$(1-1/\gamma)\cdot\sum_{i\geq 1}u_i\cdot\gamma^i \;\leq\; O(1)\cdot\sum_{i\geq 1}u_i^*\cdot\gamma^i+1/\gamma. \tag{18}$$

We also notice that

$$\mathsf{OPT} \;\geq\; \sum_{i\geq 0}(u_i^*-u_{i+1}^*)\cdot\gamma^i \;=\; (1-1/\gamma)\cdot\sum_{i\geq 1}u_i^*\cdot\gamma^i+1,$$

and that

$$\mathsf{ALG}_{\mathsf{Meta}} \;\leq\; O(1)\cdot\sum_{i\geq 0}(u_i-u_{i+1})\cdot\gamma^{i+1} \;=\; O(1)\cdot\sum_{i\geq 0}u_i\cdot\gamma^i.$$

It follows from (18) that $\mathsf{ALG}_{\mathsf{Meta}}\leq O(1)\cdot\mathsf{OPT}$. This finishes the proof of Lemma 7. ◀

C Missing Proofs in Section 5

▶ **Lemma 12.** *For $\gamma=1.1$, any phase $i>0$ in the probing stage of Stoch-Cost k-TSP satisfies*

$$u_i(\sigma_{i-1})\leq 100u_i^*(\sigma_{i-1})+\frac{u_{i-1}(\sigma_{i-1})}{\gamma^2}. \tag{7}$$

Proof of Lemma 12. We fix any outcome σ_{i-1} of vertices visited by $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$ in the first $i-1$ phases of its probing stage. The lemma trivially holds in the case where $u_i^*(\sigma_{i-1})\geq 0.01$ as we have $100u_i^*(\sigma_{i-1})\geq 1$. If $u_{i-1}(\sigma_{i-1})=0$ which means that $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$ already selects k vertices before entering phase i in the probing stage, then $u_i(\sigma_{i-1})=0$ and again the lemma trivially holds. We therefore assume that $u_i^*(\sigma_{i-1})<0.01$ and that $u_{i-1}(\sigma_{i-1})=1$. Now proving Lemma 12 is equivalent to proving

$$u_i(\sigma_{i-1})\leq 100u_i^*(\sigma_{i-1})+1/\gamma^2. \tag{19}$$

Denote $k(\sigma_{i-1})$ the remaining target at the beginning of phase i in the probing stage of $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$. We first consider Selection-Process 1 and denote $N_{\mathsf{old}}(\sigma_{i-1})$ the number of vertices selected from σ_{i-1} in this process. We assume without loss of generality that $N_{\mathsf{old}}(\sigma_{i-1})<k(\sigma_{i-1})$, as otherwise our algorithm has already selected k vertices after Selection-Process 1 and (19) immediately follows. Since Selection-Process 1 uses cost budget γ^i to select as many unselected vertices from σ_{i-1} as possible, OPT can select at most $N_{\mathsf{old}}(\sigma_{i-1})+k-k(\sigma_{i-1})$ vertices from σ_{i-1} within total budget γ^i. Denote $N_{\mathsf{new}}(\sigma_{i-1}):=k(\sigma_{i-1})-N_{\mathsf{old}}(\sigma_{i-1})$ the remaining target for $\mathsf{ALG}_{\mathsf{Stoch\text{-}Cost}}$ after Selection-Process 1. It follows that in order to select k vertices within total budget γ^i, OPT needs to select at least $N_{\mathsf{new}}(\sigma_{i-1})$ vertices from V_i within total budget γ^i. Therefore, $u_i^*(\sigma_{i-1})<0.01$ implies that OPT selects at least $N_{\mathsf{new}}(\sigma_{i-1})$ vertices from V_i within total budget γ^i with probability at least 0.99. Applying Lemma 13 with $Y=N_{\mathsf{new}}(\sigma_{i-1})$, it follows that our algorithm finds at least $N_{\mathsf{new}}(\sigma_{i-1})$ vertices from V_i which can be selected within cost budget $6\gamma^i$ with probability at least 0.2. This implies that $u_i(\sigma_{i-1})\leq 0.8\leq 1/\gamma^2$ and (19) is established. ◀

Strategic Payments in Financial Networks

Abstract

In their seminal work on systemic risk in financial markets, Eisenberg and Noe [13] proposed and studied a model with n firms embedded into a network of debt relations. We analyze this model from a game-theoretic point of view. Every firm is a rational agent in a directed graph that has an incentive to allocate payments in order to clear as much of its debt as possible. Each edge is weighted and describes a liability between the firms. We consider several variants of the game that differ in the permissible payment strategies. We study the existence and computational complexity of pure Nash and strong equilibria, and we provide bounds on the (strong) prices of anarchy and stability for a natural notion of social welfare. Our results highlight the power of financial regulation – if payments of insolvent firms can be centrally assigned, a socially optimal strong equilibrium can be found in polynomial time. In contrast, worst-case strong equilibria can be a factor of $\Omega(n)$ away from optimal, and, in general, computing a best response is an NP-hard problem. For less permissible sets of strategies, we show that pure equilibria might not exist, and deciding their existence as well as computing them if they exist constitute NP-hard problems.

1 Introduction

The last major financial crisis and its aftermath have highlighted the systemic risks and resulting hazards for society that arise in financial markets, which are characterized by different, highly interconnected financial institutions. Over the last decade an increased research effort has been underway to analyze, understand, and manage the systemic risks in financial markets. Main aspects of interest are contagion effects and cascading defaults, as well as recommendations for suitable regulation on a national and international level.

A prominent approach in the area of systemic risk stems from the seminal work by Eisenberg and Noe [13]. Here the set V of financial institutions (or *firms*) is the node set of a directed graph $G = (V, E)$. The directed and weighted edges $e \in E$ express the debt

relations among firms. In addition, each firm has non-negative *external assets*, which capture the value of property rights (such as real-estate, gold, business and mortgage loans, etc.) that the firm has acquired from non-financial institutions. Eisenberg and Noe discuss a clearing mechanism for such a market, in which every firm v uses its available assets to pay its debt. The clearing follows basic balance sheet identities and evolves rather mechanically. It is commonly assumed that payments are distributed among all creditors in a pro-rata fashion, i.e., for each interbank debt (i.e., each outgoing edge) firm v allocates a proportional share of its available assets. Similarly, a firm receives the payments for its incoming edges (so-called *internal assets*), which in turn are also paid proportionally to outgoing edges (until all debt is paid or all assets are distributed). In this way, clearing payments constitute a fixed point of the system. Eisenberg and Noe discuss existence and uniqueness issues of such fixed point payments.

While the model has been studied intensively over the last two decades, there are a plethora of open questions, especially towards understanding strategic and game-theoretic issues. In this paper, our focus are the strategic incentives and their consequences for clearing mechanisms in financial markets. For example, rather than using pro-rata payments, financial institutions often put priority on clearing certain debts first. In this way, a firm v could profit substantially when using a suitable priority-based payment scheme – by clearing certain debt first, the money propagates through the network and returns to v in the form of additional internal assets. In the Eisenberg-Noe model, it is easy to see that the intuitive pro-rata clearing mechanism is not always incentive compatible, and strategic incentives of this kind can arise frequently.

In this paper, we study the properties of priority-based clearing mechanisms for financial markets. We focus on payment schemes that constitute a pure Nash or even a strong equilibrium in the underlying strategic payment game for the firms. In this way, firms have no unilateral or coalitional incentives to deviate from the payment schemes proposed by the clearing mechanism. Depending on the granularity of priorities, the resulting games have different properties. In particular, if priorities are implemented over debt contracts, existence of a pure Nash or a strong equilibrium becomes strongly NP-hard to decide. Instead, if firms can assign each unit of money arbitrarily to any open debt, a strong equilibrium always exists and can be computed in strongly polynomial time. Moreover, in this case, there is even a strong equilibrium that maximizes the sum of all assets of all firms.

Our results imply interesting insights for bankruptcy settlement of insolvent firms. It turns out that only insolvent firms face a potential strategic decision about where to allocate money in order to maximize the internal assets through network effects (or, equivalently, minimize the remaining debt after clearing the network). In case there is a benevolent and centralized bankruptcy settlement, we show that it can implement a clearing mechanism with monotone payment strategies that leads to a socially optimal clearing state. It comes with the additional guarantee of giving no coalition of firms an incentive to pay their debts differently.

Instead, if clearing payments are determined by suitable negotiation in a decentralized fashion resulting in some arbitrary Nash or strong equilibrium, the total amount of internal assets available to the firms in the system can deteriorate drastically. Similar problems arise if a centralized clearing mechanism is restricted to payment schemes based on priorities over single loans (rather than units of money). This can lead to non-existence of pure equilibria in the resulting games. Even if equilibria exist, they can be undesirable since the total amount of internal assets of all firms can be drastically smaller than in an optimal solution. This shows a marked contrast between centralized and decentralized bankruptcy settlement and highlights how the structure of permissible payment strategies impacts the performance and the structural properties of the clearing mechanism.

1.1 Contribution

In this paper, we study the properties of priority-based clearing mechanisms for financial markets. We assume the network of liabilities is given, but insolvency resolution is driven by strategic considerations. In particular, we analyze payment schemes that constitute a pure Nash or even a strong equilibrium in the underlying strategic payment game for the firms.

Below, we introduce basic preliminaries of the Eisenberg-Noe model. In addition, we introduce two classes of priority-based payment strategies for the firms and analyze the resulting clearing mechanisms. For an *edge-ranking strategy*, a firm ranks its debt contracts and assigns its assets in order of the ranking. As a superset of strategies, we consider *coin-ranking strategies*, where money is considered in units ("coins"). Instead of contracts, each firm ranks single coin payments to the contracts. By letting the value of a coin approach zero, coin-ranking strategies become equivalent to monotone strategies, where the payments of a firm are simply a monotone function of its total available assets.

In Section 2 we present structural insights on the clearing states for a strategy profile in an edge- or coin-ranking game. In such a profile, each firm is choosing an edge- or coin-ranking strategy to pay its debt. For each such profile, we prove that the possible clearing states form a lattice with respect to the vector of assets of each firm (Theorem 3). In particular, there is a unique clearing state that pointwise maximizes the assets available to each firm (given this strategy profile). In the full version [6] we show that it can be computed in strongly polynomial time. We assume that this state defines the assets and, thus, the utility of each firm in the strategy profile. Similar properties were shown in [13] for profiles composed of pro-rata payment strategies.

In Section 3 we study coin-ranking games and strategic choice of payments. Our interest lies in the existence, computational complexity, and social quality of equilibria. We show that there always is a strategy profile that represents a strong equilibrium, in which no coalition of firms has an incentive to deviate. Furthermore, it maximizes social welfare, i.e., the sum of all assets or total revenue available to all firms. Such a strong equilibrium can be computed in strongly polynomial time (Theorem 6). It can be represented compactly, even though the strategy shall rank all (possibly pseudo-polynomially many) coins that a firm might have available. In contrast, it is strongly NP-hard to find a best-response strategy for a single firm in a given arbitrary strategy profile of a coin-ranking game (Theorem 9).

For worst-case equilibria and the strong price of anarchy, we show that the deterioration of social welfare in a strong equilibrium compared to a social optimum is tightly characterized by the min-max length of cycles in any social optimum (Theorem 11). This implies that networks with optimal money circulation composed of small cycles yield a small inefficiency in strong equilibria. In contrast, a worst-case Nash equilibrium, which is stable only against unilateral deviations, can be arbitrarily worse than a social optimum, even in simple games with a constant number of firms (Proposition 10).

In Section 4 we study equilibria in edge-ranking games, where all firms are restricted to play edge-ranking strategies. Restricting the strategy space to rankings over contracts can have devastating consequences for the existence and social quality of equilibria. In edge-ranking games, pure Nash and strong equilibria can be absent, and deciding their existence is strongly NP-hard (Theorem 14). The same hardness applies for computing a social optimum, and for computing a pure Nash or strong equilibrium when it is guaranteed to exist. Even the best strong equilibrium can be a factor of $\Omega(n)$ worse than the social optimum in terms of social welfare (Proposition 16). For pure Nash equilibria, even the best one can be arbitrarily worse than a social optimum (Proposition 17).

1.2 Related Work

Financial Networks. On a conceptual level, we study issues of strategic choice and computational complexity in financial networks. There have been works addressing computational complexity of diverse issues, such as pricing options with [3] and without information asymmetry [7], finding clearing payments with credit default swaps [27], or estimating the number of defaults when providing a shock in the financial system [20]. In addition, many extensions to the model by Eisenberg and Noe have been proposed in the literature on financial markets. However, even models including cross-holdings of equity [28], default costs [26], or debt contracts of different maturities [15] follow the idea of the basic approach that all contracts have to be cleared consistently, i.e., clearing payments locally adhere to the rather mechanical clearing rule and constitute a fixed point solution globally. Indeed, Barucca et al. [5] have recently shown that many of the above models can be unified in terms of self-consistent network valuations. A well-known result of such models is the "robust-yet-fragile" property exhibited by financial networks, i.e., contagion arises in an all-or-nothing fashion akin to the formation of a giant connected component in random graph models [17]. This provides important insights into systemic risk and advises the need for macro-prudential regulation.

Accordingly, the rather mechanical pro-rata payments are also usually presumed in models studying contagion effects arising from overlapping portfolios [8, 9]. In this case, distressed firms are selling assets which in turn decreases the value of these assets by market impact. Here, it is commonly assumed that firms mechanically sell all their assets in a pro-rata fashion. In turn, the resulting market impact is modeled as a known function parametrized by the market depth or liquidity of each asset. In contrast, especially decisions regarding the portfolio composition of financial firms yield substantial potential for strategic consideration in reality.

To our knowledge, strategic aspects are currently reflected mostly in models of network formation [14, 1]. A three period economy is assumed where firms can invest into risky assets. To do so, they strategically decide to borrow funds from outside investors as well as other firms. Thereby a network of financial cross-holdings is endogenously formed as each firm maximizes their expected profit. The results show that risk-seeking firms tend to over-connect leading to stronger contagion and systemic risk as compared to the socially optimal risk-sharing allocation. Note that in this case, strategic aspects only play a role in the formation of inter-bank relations whereas the clearing mechanism is assumed to follow the same process as in [13]. Another strategic variant of the model by Eisenberg and Noe has been considered in [2] in the form of a two-period model. Firms strategically store some amount from their first period endowment with an interest rate in order to increase the available assets in the second period. The clearing in both rounds is based on pro-rata payments. Each firm optimizes a function of the remaining debts in both periods.

Flow Games. On a more technical level, our game-theoretic approach is related to a number of existing game-theoretic models based on flows in networks. In cooperative game theory, there are several notions of flow games based on a directed flow network. Existing variants include games, where edges are players [12, 21, 22, 18, 11, 4], or each player owns a source-sink pair [25, 24]. The total value of a coalition C is the profit from a maximum (multi-commodity) flow that can be routed through the network if only the players in C are present. There is a rich set of results on structural characterizations and computability of solutions in the core, as well as other solution concepts for cooperative games. In contrast to our work, these games are non-strategic. Instead, here we consider each player as a single node with a strategic decision about flow allocation.

More recently, a class of strategic flow games has been proposed in [23, 19]. There is a capacitated flow network with a set of sources nodes. At each source node, a given amount of flow enters the network. Each node of the network is owned by a single player. Each player always owns a designated sink node, as well as one or more additional nodes from the network. A player can choose a flow strategy for each of her nodes. The flow strategy specifies, for every node v and every $x \geq 0$, how an incoming flow of x at v is distributed onto the outgoing edges (if any). Each flow strategy needs to fulfill flow conservation constraints at every node, subject to capacity on the outgoing edges. Each player aims to maximize the incoming flow at its sink node.

For these games there exist a number of Σ_2^p-completeness results for, e.g., determining the value of a game in a two-player Stackelberg variant, or determining the existence of a pure Nash equilibrium in a multi-player variant. In the latter game, computing a best response can also be NP-hard. Our approach is related to these games. However, motivated by financial networks we assume each firm is a single (source) node. The firm optimizes the incoming flow at its node (without it being a sink node). We study the computational complexity and social quality of equilibria. Moreover, strategic incentives arise mainly from cycles in the network – a condition absent in the existing work on max-flow games [23, 19] where the network is assumed to be acyclic.

The problem of calculating a clearing state for a given strategy profile in our games is closely related to the notion of a stable flows. In the stable flow problem, each node is equipped with an externally given preference order over both incoming and outgoing arcs. There always exists a stable flow, and the set of stable flows forms a lattice [16]. In fact, there is an augmenting path algorithm for computing a stable flow with polynomial running time [10].

1.3 Financial Networks with Payment Strategies

Network Model. We consider a financial network model due to Eisenberg and Noe [13]. There is a network $G = (V, E)$ with node set V of *institutions* or *firms*. Each firm $v \in V$ has *external assets* of value $a_v^x \geq 0$. Moreover, the firms are related via a set E of *liabilities*. Each liability $(u, v) \in E$ is a directed edge from firm $u \in V$ to firm $v \in V$. The *weight* $c(e) \geq 0$ of some edge $e = (u, v)$ is the amount of money that u owes to v. We follow standard notation in graph theory and denote by $E^+(v) = \{(v, u) \in E\}$ and by $E^-(v) = \{(u, v) \in E\}$ the set of outgoing and incoming edges of $v \in V$, respectively. The *total liabilities* $\ell(v)$ of firm v is the total amount of money firm v owes to other firms, i.e.,

$$\ell(v) = \sum_{e \in E^+(v)} c(e).$$

We strive to understand issues of computational complexity. As such, we will assume that all numbers in the input, i.e., all a_v^x and $c(e)$, are integer numbers.

We consider clearing mechanisms based on strategic payments decisions. A *money flow* g_e on edge e satisfies $0 \leq g_e \leq c(e)$. Given a money flow on each edge, the *internal assets* of firm v are the total incoming money from other firms, i.e.,

$$a_v^i = \sum_{e \in E^-(v)} g_e.$$

The *total assets* of v are the sum of external and internal assets $a_v = a_v^x + a_v^i$. A firm is *insolvent* if its total assets are strictly smaller than its total liabilities, i.e., $a_v < \ell(v)$.

Eisenberg and Noe define a clearing mechanism with money flows given by *pro-rata* payments. In their clearing mechanism, each firm v distributes its total assets a_v proportionally on its outgoing edges until all debt is paid. More formally, every edge $e \in E^+(v)$ is assigned a money flow of $g_e(a_v) = \min\left\{c(e), a_v \cdot \frac{c(e)}{\ell(v)}\right\}$. Firm v keeps the surplus $a_v - \ell(v) \geq 0$ for itself, if any.

Payment Strategies. In this paper, we analyze incentives when firms strategically manipulate their payments. As such, we study *money flow games* defined as follows. Each firm $v \in V$ chooses as a *strategy* a parametrized flow function $f_e(y)$ for every outgoing edge $e \in E^+(v)$ and every $y \geq 0$. The strategy $\mathbf{f}^v = (f_e(y))_{e \in E^+(v)}$ must satisfy for every $y \geq 0$

$$0 \leq f_e(y) \leq c(e) \qquad \text{(capacity constraint)} \tag{1}$$

$$\sum_{e \in E^+(v)} f_e(y) = \min\{y, \ell(v)\} \qquad \text{(no-fraud constraint)} \tag{2}$$

Intuitively, the strategy specifies, for every possible value $y \geq 0$ of total assets available to firm v, how v will allocate these assets to pay its debts. The capacity constraint ensures that no debt is overpaid, the no-fraud constraint requires that v does not embezzle assets as long as there is unpaid debt. This definition includes pro-rata payments as one possible strategy profile. Given a *strategy profile* $\mathbf{f} = (\mathbf{f}^v)_{v \in V}$, a *clearing state* $\mathbf{a} = (a_v)_{v \in V}$ is a vector of assets such that

$$a_v = a_v^x + \sum_{e=(u,v) \in E^-(v)} f_e(a_u) \qquad \text{(fixed point constraint)} \tag{3}$$

holds for all nodes $v \in V$. Equivalently, this ensures that for a given strategy profile $\mathbf{f}$, there is a clearing state $\mathbf{a}$ such that the flow $\mathbf{g}$ defined by $g_e = f_e(a_u)$ is in fact a money flow. The *utility* of firm v is a_v, i.e., v's goal is to choose a strategy to maximize its total assets in the clearing state.

▶ **Proposition 1.** *If all $f_e(y)$ are continuous, there exists at least one clearing state.*

The proof is a straightforward application of Brouwer's fixed point theorem and thus omitted. If strategies are not continuous, it is easy to construct examples where no clearing state exists. Still, even for a continuous strategy profile $\mathbf{f}$, there could be multiple clearing states $\mathbf{a}$ (even for pro-rata profiles). Given sufficiently complex strategy profiles with compact representation, computation of a clearing state might even become computationally difficult.

In the rest of the paper, we focus on a set of rich and meaningful strategy spaces, for which we can single out a unique clearing state with a simple algorithm. An intuitive and well-motivated class of strategies can be derived via *rankings* or *seniorities*.

Edge-Ranking Games. In an *edge-ranking game*, each player $v \in V$ spends its assets to pay its debts according to a strict and total order over $E^+(v)$, which we represent by a permutation $\pi_v = (e_1, e_2, \ldots)$. v first pays all debt of edge $e_1 = \pi_v(1)$, then $e_2 = \pi_v(2)$, etc. until all debt is paid or it runs out of assets. Formally, $f_{e_i}(y) = \min\{c(e_i), \max\{0, y - \sum_{j<i} c(e_j)\}\}$. The *edge-ranking strategy* of v is fully described by the ranking π_v, hence we denote a strategy profile in edge-ranking games by $\boldsymbol{\pi} = (\pi_v)_{v \in V}$.

Coin-Ranking Games. As a strict superset of such strategies, consider the case where each player $v \in V$ can spend its assets to pay its debts in a monotone fashion. In coin-ranking games, we rely on integrality of all values for c_e and a_v^x, and interpret money flow as being

discretized into "coins" of value 1. Thus, for a *coin-ranking strategy*, the parametrized flow functions $f_e(y)$ for every outgoing edge $e \in E^+(v)$ are defined on the non-negative integer numbers $f_e(y) : \mathbb{N}_0 \to \mathbb{N}_0$. They are characterized by capacity and no-fraud constraints, and, for every $y, y' \in \mathbb{N}_0$ with $y \geq y'$

$$f_e(y) \geq f_e(y') \qquad \text{(monotonicity constraint)} \tag{4}$$

Note that, by letting the value of a coin tend to 0, coin-ranking strategies become arbitrary *monotone strategies* $f_e(y) : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$.

Coin-ranking strategies generalize edge-ranking strategies. Maybe counterintuitively, every coin-ranking game is also a special edge-ranking game – replacing each edge e with weight $c(e)$ many multi-edges of unit weight expands a coin-ranking game into an equivalent edge-ranking game. There is a one-to-one correspondence between coin-ranking strategies in the original game and edge-ranking strategies in the expanded game. Intuitively, for a coin-ranking strategy in the original game, a player v pays the first coin of assets to the multi-edge $\pi_v(1)$, the second coin to $\pi_v(2)$, etc. in the expanded edge-ranking game until all debt is paid or v runs out of assets. The expansion of the game implies a pseudo-polynomial blowup in representation size, but nevertheless, the structural equivalence is very useful for characterizing and analyzing solutions to coin-ranking games.

Note that the representation of a coin-ranking strategy might require pseudo-polynomial size even in the original non-expanded game. We discuss this issue below in Section 3.1. It turns out that in every coin-ranking game, we can restrict attention to a subset of compactly representable coin-ranking strategies.

Clearing States and Utilities. For a given strategy profile $\boldsymbol{\pi}$ in an edge- or coin-ranking game, we determine the utility using a clearing state $\hat{\mathbf{a}}$, where we choose the one that maximizes the total revenue in the network, i.e., the sum of total assets available to all firms

$$\textsc{Rev}(\boldsymbol{\pi}, \mathbf{a}) = \sum_{v \in V} a_v = \sum_{v \in V} a_v^x + \sum_{e=(u,v) \in E} f_e(a_u) = \sum_{v \in V} a_v^x + \sum_{e \in E^+(v)} f_e(a_v).$$

Note that the choice of $\hat{\mathbf{a}}$ and thus, the resulting revenue significantly depends on the strategy profile $\boldsymbol{\pi}$. In many cases, for a fixed strategy profile $\boldsymbol{\pi}$, the clearing state $\hat{\mathbf{a}}$ is unique, and there is no choice based on maximum revenue. Moreover, in case there are several clearing states for a strategy profile $\boldsymbol{\pi}$ in an edge-ranking game, it turns out that they can be arranged into a lattice with coordinate-wise maximum inducing a partial order. We choose the coordinate-wise maximal clearing state, since it maximizes $\textsc{Rev}(\boldsymbol{\pi}, \mathbf{a})$ as a natural measure of social welfare. In this sense, the properties of edge-ranking games mirror the conditions shown for pro-rata payments in [13]. We prove these conditions in the subsequent section.

2 Clearing States

2.1 Circulation Structure in Money Flow Games

We observe a useful *circulation representation* of clearing states in money flow games. Given a strategy profile $\mathbf{f}$, the fixed point and no-fraud constraints imply for any clearing state $\mathbf{a}$ the conservation of money flow. Now using an auxiliary source s, we can represent all money flows in $\mathbf{a}$ in the form of a circulation. We build a *circulation network* G' by adding node s, for every $v \in V$ we add an auxiliary edge (v, s) with capacity $c((v, s)) = \infty$, and for every

$v \in V$ with $a_v^x > 0$ we add an auxiliary edge (s, v) with $c((s, v)) = a_v^x$. In this way, external assets of v become internal assets via a flow on edge (s, v). Surplus assets of w become a flow on edge (w, s), i.e., the internal assets of s.

▶ **Proposition 2.** *For every clearing state* $\mathbf{a}$ *of a strategy profile* $\mathbf{f}$ *in a money flow game, the flow in* G' *can be decomposed and represented as a circulation. The auxiliary source* s *has assets of* $a_s = \sum_{v \in V} a_v^x$*, and all auxiliary edges* (s, v) *are saturated.*

Proof. This is a simple consequence of fixed point and no-fraud constraints. Surplus at firm $v \in E$ exists only if v pays all debt

$$\sum_{e \in E^+(v)} f_e(a_v) = \min(a_v, \ell(v)) \ .$$

Moreover, the total external assets constitute the total net revenue:

$$\begin{aligned} \sum_{v \in V} a_v^x &= \sum_{v \in V} a_v^x + \sum_{v \in V} \sum_{e=(u,v) \in E^-(v)} f_e(a_u) - \sum_{v \in V} \sum_{e=(u,v) \in E^-(v)} f_e(a_u) \\ &= \sum_{v \in V} a_v - \sum_{e \in E^+(v)} f_e(a_v) \quad = \quad \sum_{v \in V} \max\{0, a_v - \ell(v)\} \end{aligned}$$

The net revenue of every firm gets routed to the auxiliary source s and constitutes the assets a_s. Thus $a_s = \sum_{v \in V} \max\{0, a_v - \ell(v)\} = \sum_{v \in V} a_v^x$, and all auxiliary edges (s, v) are saturated. Overall, by routing the surplus assets to s, we obtain exact flow conservation at every node. As such, the flow can be decomposed and represented as a circulation. ◀

2.2 Structure for Monotone Strategies

Lattice Structure. Consider an arbitrary money-flow game and a strategy profile $\mathbf{f}$ of monotone strategies. Let $\mathcal{A}$ be the set of feasible clearing states for a strategy profile $\mathbf{f}$. We show that $(\mathcal{A}, \geq)$ forms a lattice with the coordinate-wise comparison. Formally, $\mathbf{a} \geq \mathbf{a}'$ iff $a_v \geq a'_v$ for all v; and $\mathbf{a} > \mathbf{a}'$ iff $a_v \geq a'_v$ for all v and $a_v > a'_v$ for at least one v.

▶ **Theorem 3.** *For every strategy profile* $\mathbf{f}$ *in a money-flow game with monotone strategies, the pair* $(\mathcal{A}, \geq)$ *forms a lattice.*

Proof. Consider $A = \left\{ \mathbf{a} \;\middle|\; 0 \leq a_v \leq a_v^x + \sum_{e \in E^-(v)} c(e), \quad \forall v \in V \right\}$, a superset of all possible asset vectors. Obviously, $(A, \geq)$ forms a lattice with the coordinate-wise comparison defined above. For a given strategy profile $\mathbf{f}$, the map $g : A \to A$ with $g(\mathbf{a})_v = a_v^x + \sum_{e=(u,v) \in E^-(v)} f_e(a_u)$ is a monotone function for every firm $v \in V$, since for every edge $e = (u, v) \in E$ the strategy of firm u implies that f_e is monotone in a_u. Obviously, the set of clearing states $\mathcal{A}$ is the set of fixed-point asset vectors of g. The result follows by applying the Knaster-Tarski theorem. ◀

Solvent Firms. The previous result implies uniqueness of $\hat{\mathbf{a}}$ for a given monotone strategy profile $\mathbf{f}$. We observe another interesting property, which shows that in monotone money flow games the maximal clearing state $\hat{\mathbf{a}}$ is unique as long as all insolvent firms stick to their strategy. Since every strategy satisfies capacity and no-fraud constraints, the payments of solvent firms remain the same if they receive the same assets, and vice versa. Consequently, strategies of solvent firms have no impact on the asset vector $\hat{\mathbf{a}}$. For any solvent firm v, every strategy constitutes a best response.

▶ **Proposition 4.** *For a given money flow game, consider any monotone strategy profile* $\mathbf{f}$*, the corresponding clearing state* $\hat{\mathbf{a}}$*, and any solvent firm* v *with* $\hat{a}_v \geq \ell(v)$*. Every strategy* $\mathbf{f}'^v$ *is a best response for* v *against the other strategies* $\mathbf{f}_{-v}$ *and results in the same clearing state* $\hat{\mathbf{a}}$*.*

Proof. Consider a deviation $\mathbf{f}'^v$, the resulting state $\mathbf{f}' = (\mathbf{f}'^v, \mathbf{f}^{-v})$ and the resulting revenue-maximizing clearing state $\mathbf{a}'$. Suppose that $\hat{\mathbf{a}} \neq \mathbf{a}'$. Firm v is solvent under $\hat{\mathbf{a}}$, thus $\sum_{e \in E^+(v)} f_e(\hat{a}_v) = l(v)$ and $f_e(\hat{a}_v) = c(e)$. Using Theorem 3 we can assume w.l.o.g. that $\hat{\mathbf{a}} > \mathbf{a}'$ (i.e., $\hat{a}_u \geq a'_u$ for all firms u, and $\hat{a}_w > a'_w$ for at least one firm w). We construct an equivalent game, in which we remove all edges in $E^+(v)$ and instead increase external assets to $\bar{a}^x(u) = a^x_u + c(e)$ for all u with $(v,u) \in E^+(v)$. Observe that $\hat{\mathbf{a}}$ is still a feasible clearing state in the constructed game. However, any clearing state $\mathbf{a}$ in the original game with $a_v \geq l(v)$ induces $f(a_v) = c(e)$ independent of the chosen strategies of v due to the non-fraud condition. Thus, any clearing state $\mathbf{a}$ with $a_v \geq l(v)$ in the new game is still a feasible clearing state in the old game. We conclude that $\hat{\mathbf{a}}$ is a feasible clearing state under $\mathbf{f}'$. This is a contradiction to the maximality of $\mathbf{a}'$. ◀

3 Coin-Ranking Games

3.1 Representation

An instance of a money flow game is given by the network G and integer numbers for edge weights $c(e)$ and external assets a^x_u. Hence, the representation of the instance is logarithmic in input numbers for $c(e)$ and a^x_u. In contrast, if we consider arbitrary coin-ranking strategies $\mathbf{f}^v$ for firm v, this specifies a ranking over all *coins* of value 1. This is linear in $\sum_{e \in E^+(v)} c(e)$ and, thus, only pseudo-polynomial in the instance representation. Our first observation is that in every coin-ranking game, we can restrict attention to threshold-ranking strategies with a polynomial representation. A *threshold-ranking* strategy $\pi^t_v = (\pi_v, \tau_v)$ is composed of a permutation π_v over $E^+(v)$ and a vector of thresholds $\tau_v = (\tau_e)_{e \in E^+(v)}$ with $0 \leq \tau_e \leq c(e)$ for every $e \in E^+(v)$.

The interpretation is as follows. In π^t_v, firm v first pays τ_e to every edge $e \in E^+(v)$, sequentially in the order given by π_v. Then, it pays the remaining $c(e) - \tau_e$ to every edge in the order given by π_v. That is, v first considers edge $\pi_v(1)$ and pays the first $\tau_{\pi_v(1)}$ coins to this edge. The next $\tau_{\pi_v(2)}$ coins are paid to edge $\pi_v(2)$ etc. until $\sum_{j=1}^{|E^+(v)|} \tau_{\pi_v(j)}$ coins are paid to the edges (or v runs out of assets). Then, the remaining $c(\pi_v(1)) - \tau_{\pi_v(1)}$ coins are paid to edge $\pi_v(1)$, then the next $c(\pi_v(2)) - \tau_{\pi_v(2)}$ coins to $\pi_v(2)$ etc.

Indeed, we can restrict attention to threshold-ranking strategies in coin ranking games. The formal proof is deferred to the full version [6].

▶ **Proposition 5.** *For every strategy profile* $\mathbf{f}$ *in a coin-ranking game with clearing state* $\hat{\mathbf{a}}$ *and every firm* v*, there is a threshold-ranking strategy* π^t_v *such that the profile* $(\pi^t_v, \boldsymbol{\pi}_{-v})$ *has the same clearing state* $\hat{\mathbf{a}}$ *and, thus, the same utilities for all firms.*

3.2 Existence and Computation of Equilibria

Our first result is that in every coin-ranking game there is a strong equilibrium that maximizes the total revenue of all firms. This strong equilibrium can be computed in polynomial time. In particular, consider the instance (G, c, a^x) as a money flow game and an arbitrary clearing state, i.e., a circulation of maximum value in the circulation network G'. This circulation is also a clearing state of a strong equilibrium in threshold-ranking strategies.

▶ **Theorem 6.** *For every coin-ranking game, there is a strong equilibrium with money flows that maximize the total revenue in the network. The strong equilibrium can be computed in polynomial time.*

Proof. Consider the circulation network $G' = (V, E')$. An optimal circulation $\mathbf{f}^*$ that maximizes the total flow value saturates all outgoing auxiliary edges from s. Hence, it maximizes the total assets of all firms

$$\sum_{e \in E'} f^*_e = 2 \sum_{v \in V} a^x_v + \sum_{e \in E} f^*_e = \sum_{v \in V} a^x_v + \textsc{Rev}(\mathbf{f}^*) \ .$$

$\mathbf{f}^*$ can be computed in strongly polynomial time [29]. Since all edge weights are integral, we can assume all f^*_e are integral. We can turn this circulation into a clearing state for a strategy profile with threshold-ranking strategies. Every firm v chooses an arbitrary order π_v over $E^+(v)$ and sets thresholds $\tau_e = f^*_e$. Clearly, in this strategy profile the optimal circulation corresponds to the maximum-revenue clearing state $\hat{\mathbf{a}}$.

Let us prove that this strategy profile $\boldsymbol{\pi}$ is a strong equilibrium. A coalition $C \subseteq V$ of firms has a profitable deviation $\boldsymbol{\pi}'_C = (\pi'_v)_{v \in C}$ if upon joint deviation of C to π'_C, the resulting assets $\mathbf{a}'$ in the new profile $(\boldsymbol{\pi}'_C, \boldsymbol{\pi}_{-C})$ are strictly better, i.e., $a'_v > \hat{a}_v$ for every $v \in C$. We will show that no coalition $C \subseteq V$ has a profitable deviation.

Suppose for contradiction that there is a coalition C with a profitable deviation. Examine the new profile $(\boldsymbol{\pi}'_C, \boldsymbol{\pi}_{-C})$ and consider a firm $v \in C$. Since $a'_v > \hat{a}_v$, there must be an edge $(u, v) \in E^-(v)$ that has strictly more incoming flow in the new profile $f'_e(a'_u) > f_e(a_u)$. Now consider node u. If $u \in C$, then $a'_u > a_u$, so there is again some edge $E^-(u)$ that has strictly more incoming flow in the new profile. Otherwise, if $u \notin C$, then u still plays the threshold-ranking strategy obtained from $\mathbf{f}^*$. Since this is a monotone strategy, a higher flow on (u, v) can only occur if u has larger assets. Thus, $a'_u > a_u$, so there is again some edge $E^-(u)$ that has more incoming flow in the new profile.

We can repeat this argument indefinitely. As such, there must be a cycle of edges that all have more flow under $(\boldsymbol{\pi}'_C, \boldsymbol{\pi}_{-C})$ than under $\boldsymbol{\pi}$. Such a cycle, however, can be used to increase the flow circulation. This contradicts that $\hat{\mathbf{a}}$ represents an optimal circulation. ◀

▶ Remark 7. For the profitable deviation, we can even allow arbitrary continuous strategies and any choice of clearing state for the deviation profile. As such, the strategy profile obtained from $\mathbf{f}^*$ is a strong equilibrium even in general money flow games (with suitable choice of clearing state).

▶ Remark 8. If one allows deviations that weakly improve the coalition (i.e., $a'_u \geq \hat{a}_u$ for all $u \in C$ and $a'_v > \hat{a}_v$ for at least one $v \in C$), it is a simple exercise to see that there are coin-ranking games, in which no stable state (termed super-strong equilibrium) exists.

While it is computationally easy to compute a socially optimal strong equilibrium, computing a best-response strategy for a general strategy profile can be strongly NP-hard, since best responses can provide answers to computationally hard decision problems. For the following result, we assume the coin-ranking game is given in the edge-ranking representation as a network with unit-weight multi-edges. Note that the edge weights in our instances of interest can be restricted to the set $\{0, 1\}$. Thus, our construction needs no multi-edges, and the representation incurs no overhead. A proof of the following theorem is given in the full version [6].

▶ **Theorem 9.** *For a given strategy profile* $\mathbf{f}$ *of a coin-ranking game, deciding whether a given firm* v *has a best response resulting in assets at least* k *is strongly NP-complete. This holds even in coin-ranking games without external assets and all edge weights in* $\{0, 1\}$.

3.3 Total Revenue of Equilibria

In this section, we analyze the total revenue in pure Nash and strong equilibria. We relate this value to the social optimum, i.e., the total sum of assets for all firms in the best strategy profile. Clearly, since we proved existence of a system optimal strong equilibrium, the price of stability for Nash and strong equilibria are both 1. We bound the prices of anarchy for Nash and strong equilibria. The proof of the next Proposition is given in the full version [6].

▶ **Proposition 10.** *The price of anarchy for Nash equilibria is unbounded, even in coin-ranking games without external assets.*

The total revenue depends crucially on the emergence of cycles in the strategy profile. This requires an effort that is inherently coalitional, as such it might be unsurprising that in general Nash equilibria fail to provide good revenue guarantees.

To analyze the quality of strong equilibria, we again consider the coin-ranking game in the form of unit-weight multi-edges. Consider an optimal circulation $\mathbf{f}^*$ of maximum total revenue in the circulation network G'. Since we have unit-weight edges, we can assume that the optimal circulation has binary flows on each edge. Let $\mathcal{C}(\mathbf{f}^*) = \{C_1, \dots, C_k\}$ be a decomposition of $\mathbf{f}^*$ into cycles of unit flow. We denote by

$$d = \min_{\mathbf{f}^*, \mathcal{C}(\mathbf{f}^*)} \max_{C \in \mathcal{C}(\mathbf{f}^*)} |C_i|$$

the min-max size of any cycle, in any decomposition $\mathcal{C}(\mathbf{f}^*)$ of any optimal circulation $\mathbf{f}^*$.

▶ **Theorem 11.** *In coin-ranking games, the strong price of anarchy is at most d.*

Proof. Consider an optimal circulation $\mathbf{f}^*$ and a decomposition $\mathcal{C}(\mathbf{f}^*)$ such that all flow cycles $C_i \in \mathcal{C}(\mathbf{f}^*)$ have size at most $|C_i| \leq d$. The total revenue in $\mathbf{f}^*$ is given by

$$\textsc{Rev}(\mathbf{f}^*) = \sum_{C_i \in \mathcal{C}(\mathbf{f}^*)} |C_i| - \sum_{v \in V} a_v^x$$

since the circulation also accounts for the assets of the auxiliary source s.

Now consider a strong equilibrium $\boldsymbol{\pi}$ in the coin-ranking game with clearing state $\hat{\mathbf{a}}$. It yields a binary money flow in the network. Suppose there is a cycle $C_i \in \mathcal{C}(\mathbf{f}^*)$ such that $f_e(\hat{a}_u) = 0$ for all $e = (u, v) \in C_i$. Then the firms in this cycle have an incentive to jointly deviate and place the edges of C_i on first position in their ranking. Then the clearing state $\hat{\mathbf{a}}$ will emerge as before, adding a flow of 1 along the cycle C_i. This is a profitable deviation for the firms of C_i.

Consequently, for every cycle $C_i \in \mathcal{C}(\mathbf{f}^*)$ there must be at least one edge $e = (u, v) \in C_i$ such that $f_e(a_u) = 1$. Thus, the revenue in the strong equilibrium $\boldsymbol{\pi}$ is

$$\textsc{Rev}(\boldsymbol{\pi}, \hat{\mathbf{a}}) \geq \sum_{C_i \in \mathcal{C}(\mathbf{f}^*)} 1$$

and the ratio is at most d. ◀

▶ **Proposition 12.** *For every $d \geq 2$, there is a coin-ranking game with strong price of anarchy of $d - 1$.*

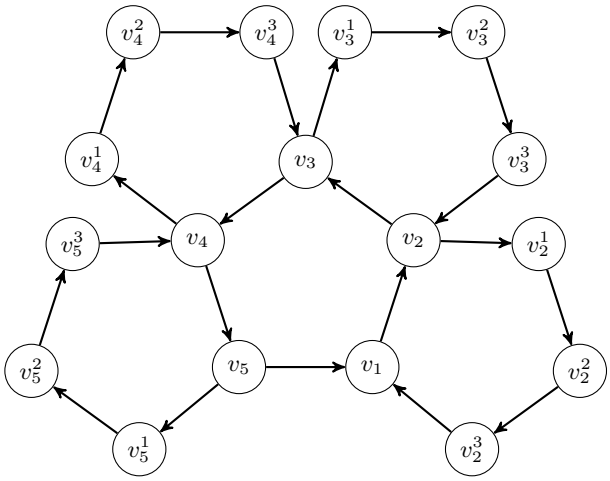

Figure 1 A coin-ranking game with $d = 5$ and a strong price of anarchy of $d - 1 = 4$.

Proof. The game is given by a graph G with $d + (d-1)(d-2)$ firms. G is constructed as follows. The firms $v_1, \dots, v_d$ are called *central firms* and they form a cycle of length d. For each $i = 1, \dots, d-1$, there are firms $(v_{i,j})_{j=1,\dots,d-2}$ that form additional cycles of length d with the edge (v_i, v_{i+1}). Thus, the set of edges is given by

$$E = \{(v_i, v_{i+1}) \mid i \in \{1, \dots, d-1\}\} \cup \{(v_d, v_1)\}$$
$$\cup \bigcup_{i=2,\dots,d} \left((v_i, v_i^1) \cup \{(v_i^j, v_i^{j+1}) \mid j = 1, \dots, d-3\} \cup (v_i^{d+2}, v_{i-1})\right) .$$

All edges have unit weight. An example of the instance with $d = 5$ is depicted in Figure 1. Observe that only firms v_i, $i = 2, \dots, d$ have multiple outgoing edges. We claim that $\pi_i = \big((v_i, v_{i+1}), (v_i, v_i^1)\big)$ and $\pi_d = \big((v_d, v_1), (v_d, v_d^1)\big)$ is a strong equilibrium. In order to see this, let $\hat{\mathbf{a}}$ be the clearing state corresponding to $\boldsymbol{\pi}$. The clearing state is given by

$$\hat{a}_v = \begin{cases} 1 & \text{if } v = v_1, v_2, \dots, v_d \ , \\ 0 & \text{otherwise} \ , \end{cases}$$

that is, $\textsc{Rev}(\boldsymbol{\pi}, \hat{\mathbf{a}}) = d$. Now, assume there is a non-empty coalition of player $S \subseteq (v_2, \dots, v_d)$ that all strictly increase their assets by a joint deviation. Note that v_d only has a single incoming edge, so $v_d \notin S$. Thus, the cycle $v_d, v_d^1, \dots, v_d^{d-2}, v_{d-1}$ cannot carry any flow. We conclude that v_{d-1} has only a single edge that can carry flow. Iterating this argument yields $S = \emptyset$, a contradiction.

However, the optimal flow emerges with the strategy profile $\pi_i = \big((v_i, v_i^1), (v_i, v_{i+1})\big)$ and $\pi_d = \big((v_d, v_d^1), (v_d, v_1)\big)$. It is easy to observe that this yields a total revenue of $(d-1)d$. Thus, the strong price of anarchy in this instance is $d - 1$. ◀

4 Edge-Ranking Games

4.1 Existence and Computation of Equilibria

With coin-ranking strategies we assume that firms have flexibility in allocation of single units of assets. In this section, we focus on a more restricted class of strategies, in which firms simply rank their outgoing edges and allocate assets in order of this ranking until they run

Table 1 Utility matrix for firms v_2 and v_3 in the proof of Proposition 13.

π_{v_2} \ π_{v_3}	$((v_3,v_1),(v_3,v_8))$	$((v_3,v_8),(v_3,v_1))$
$((v_2,v_1),(v_2,v_5))$	4 4	3 4
$((v_2,v_5),(v_2,v_1))$	2 5	3 3

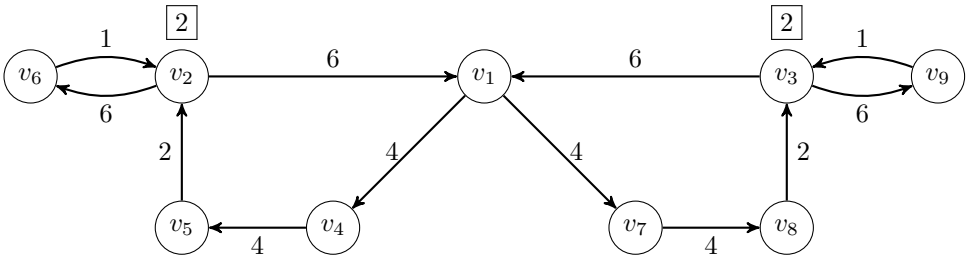

Figure 2 An edge-ranking game without a pure Nash equilibrium.

out of assets of all debts are paid for. In contrast to coin-ranking games, the restriction to rankings over edges (with different weights) can destroy the existence of (optimal) stable states. In fact, there are even games without a single pure Nash equilibrium.

▶ **Proposition 13.** *There is an edge-ranking game without a pure Nash equilibrium.*

Proof. Consider the game in Figure 2. The capacities of the edges are depicted next to the edges. Firms v_2 and v_3 each have external assets of 2, the other firms have 0 external assets. Firms v_1, v_2 and v_3 are the only ones with multiple outgoing edges. The strategy choices of the other firms are fixed. Due to the symmetry of the network, we can assume w.l.o.g. $\pi_{v_1} = ((v_1,v_4),(v_1,v_7))$. There are two possible strategy choices for each of the nodes v_2 and v_3. Checking all four resulting strategy profiles yields the utility matrix shown in Table 1 for firms v_2 and v_3. Inspecting the utilities, we see that there is no pure Nash equilibrium. ◀

The following theorem shows that a number of natural decision and optimization problems in edge-ranking games are indeed computationally intractable. Note that for coin-ranking games, these problems are either trivial (a strong equilibrium always exists) or can be solved in polynomial time (a strong equilibrium, which also represents a profile with maximum total revenue, can be computed in strongly polynomial time). The proof of the following theorem is deferred to the full version [6].

▶ **Theorem 14.** *Given an edge-ranking game the following problems are strongly NP-hard:*

1. *Deciding whether a pure Nash equilibrium exists or not.*
2. *Deciding whether a strong equilibrium exists or not.*
3. *Computing a pure Nash equilibrium, when it is guaranteed to exist.*
4. *Computing a strong equilibrium, when it is guaranteed to exist.*
5. *Computing a strategy profile with maximum total revenue.*

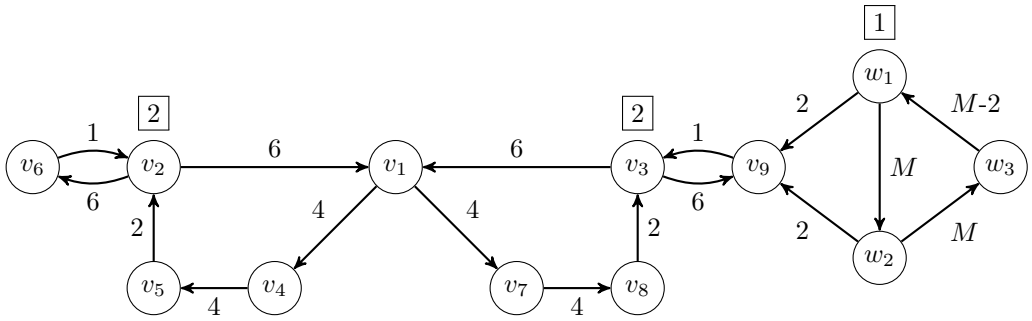

Figure 3 Edge-Ranking Game with unbounded Price of Stability.

▶ Remark 15. It is unclear whether the problem of deciding existence of a pure Nash equilibrium in an edge-ranking game is in NP or not, due to NP-hardness of verification that a firm plays a best response (see Theorem 9). It is easy to see that the decision problem is in Σ_2^p. The problem could be Σ_2^p-complete, similar to related decision problems in strategic max-flow games [23, 19]. Proving such a result is an interesting open problem.

4.2 Total Revenue of Equilibria

For edge-ranking games, the lower bound on the price of anarchy observed for coin-ranking games does apply, i.e., the price of anarchy can be unbounded. The restriction to edge-ranking strategies can have a drastic effect even on the quality of the best equilibrium in case it exists. In particular, in edge-ranking games the strong price of stability can be as high as $\Omega(n)$, and the price of stability might even be unbounded.

▶ **Proposition 16.** *For every $\varepsilon > 0$, there is an edge-ranking game with strong price of stability of at least $n/2 - \varepsilon$.*

Proof. We consider a slight modification of the instance in Proposition 12. In contrast to the instance described in the proof of Proposition 12, the edges $(v_1, v_n), (v_n, v_1), (v_1, v_2)$ have a weight $M + 1$ and all other edges a weight of M. The only node with more than a single outgoing edge is still v_1. If $\pi_{v_1} = ((v_1, v_n), (v_1, v_2))$, player v_1 gets assets of $M + 1$, which is optimal. The total revenue for $\boldsymbol{\pi}$ is $2M + 2$. $\boldsymbol{\pi}$ is the only Nash equilibrium and the only strong equilibrium.

In contrast, for profile $\boldsymbol{\pi}'$ with $\pi'_{v_1} = ((v_1, v_2), (v_1, v_n))$, firm v_1 only gets a revenue of M, but the total revenue is nM. Thus, the strong price of stability is $nM/(2M + 2) = n/2 - n/(2M + 2)$, which is at least $n/2 - \varepsilon$ for $M \geq n/(2\varepsilon) - 1$. ◀

▶ **Proposition 17.** *There is an edge-ranking game with unbounded price of stability.*

Proof. Consider the game in Figure 3, which uses the game without pure equilibrium from Figure 2. We add three firms. w_1 has external assets equal to 1, w_2 and w_3 no external assets. These firms have a cycle C of edges (w_1, w_2) and (w_2, w_3) with weight $M \gg 2$, as well as edge (w_3, w_1) with weight $M - 2$. In addition, there are edges (w_1, v_9) and (w_2, v_9) of weight 2.

In an optimal circulation, w_1 and w_2 prioritize the edges of C, leading to total revenue of $\Theta(M)$. In contrast, a pure Nash equilibrium can only exist if the w-firms ensure that the external assets of w_1 are routed to v_9, in which case a Nash equilibrium can exist (as observed

in the proof of Theorem 14). Clearly, both w_1 and w_2 have an incentive to deviate towards C. Hence, if *either* w_1 *or* w_2 places the edge to v_9 in first rank and the other does not, a unilateral deviation suffices to close C – thereby leaving the v-nodes with instability. However, if *both* w_1 *and* w_2 play strategies $\pi_{w_1} = ((w_1, v_9), (w_1, w_2))$ and $\pi_{w_2} = ((w_2, v_9), (w_2, w_3))$, no unilateral deviation can lead to flow along C. In this case, a pure Nash equilibrium evolves. Obviously the total revenue in this equilibrium is at most a constant. Hence, the price of stability is as large as $\Omega(M)$. ◀

5 Conclusions

In this paper, we have studied clearing mechanisms for financial networks and analyzed their properties from a computational and game-theoretic perspective. Our main results show that in these games, solvent firms have no strategic incentives, i.e., the game is played exclusively among insolvent firms. If firms are using coin-ranking strategies, every social optimum that maximizes the sum of all assets in the network constitutes a strong equilibrium. Moreover, it can be computed in strongly polynomial time. This result implies that a centralized bankruptcy settlement can achieve a clearing state, in which the social welfare is maximized and no coalition of firms gets incentivized to deviate. In contrast, when considering decentralized clearing and arbitrary strong equilibria, the social welfare depends on the length of cycles in the money circulation of a social optimum. For pure Nash equilibria, the deterioration in social welfare can be severe due to the lack of coordination among firms. Alternatively, when restricting the strategy spaces to edge-ranking strategies, we show that pure Nash and strong equilibria can be absent, hard to compute, and highly undesirable in terms of social welfare.

There are many open problems that arise from our work. For example, real-life markets involve a number of complex financial products (such as derivatives, credit-default swaps, etc.). Their impact on stability and computational complexity of financial markets is only beginning to attract attention in the literature. In this context, there are a variety of important game-theoretic aspects with respect to pricing, information revelation, or network creation, which are crucial for understanding financial markets and represent interesting avenues for future work.

Abstract

In the past decade, the design of *fault tolerant data structures* for networks has become a central topic of research. Particular attention has been given to the construction of a subgraph H of a given digraph D with as fewest arcs/vertices as possible such that, after the failure of any set F of at most $k \geq 1$ arcs, testing whether $D - F$ has a certain property $\mathcal{P}$ is equivalent to testing whether $H - F$ has that property. Here, reachability (or, more generally, distance preservation) is the most basic requirement to maintain to ensure that the network functions properly. Given a vertex $s \in V(D)$, Baswana et al. [STOC'16] presented a construction of H with $\mathcal{O}(2^k n)$ arcs in time $\mathcal{O}(2^k nm)$ where $n = |V(D)|$ and $m = |E(D)|$ such that for any vertex $v \in V(D)$: if there exists a path from s to v in $D - F$, then there also exists a path from s to v in $H - F$. Additionally, they gave a tight matching lower bound. While the question of the improvement of the dependency on k arises for special classes of digraphs, an arguably more basic research direction concerns the dependency on n (for reachability between a pair of vertices $s, t \in V(D)$) – which are the largest classes of digraphs where the dependency on n can be made sublinear, logarithmic *or even constant*? Already for the simple classes of directed paths and tournaments, $\Omega(n)$ arcs are mandatory. Nevertheless, we prove that "almost acyclicity" suffices to eliminate the dependency on n *entirely* for a broad class of dense digraphs called *bounded independence digraphs*. Also, the dependence in k is only a polynomial factor for this class of digraphs. In fact, our sparsification procedure extends to preserve parity-based reachability. Additionally, it finds notable applications in Kernelization: we prove that the classic Directed Feedback Arc Set (DFAS) problem as well as Directed Edge Odd Cycle Transversal (DEOCT) (which, in sharp contrast to DFAS, is W[1]-hard on general digraphs) admit polynomial kernels on bounded independence digraphs. In fact, for any $p \in \mathbb{N}$, we can design a polynomial kernel for the problem of hitting all cycles of length ℓ where ($\ell \mod p = 1$). As a complementary result, we prove that DEOCT is NP-hard on tournaments by establishing a combinatorial identity between the minimum size of a feedback arc set and the minimum size of an edge odd cycle transversal. In passing, we also improve upon the running time of the sub-exponential FPT algorithm for DFAS in digraphs of bounded independence number given by Misra et at. [FSTTCS 2018], and give the first sub-exponential FPT algorithm for DEOCT in digraphs of bounded independence number.

1 Introduction

In most real-life applications, even the most reliable networks are highly prone to unexpected failures of a small number of links that connect their nodes. In the past decade, the design of *fault tolerant data structures* for networks has become a central topic of research [7, 9, 13, 47, 44, 12, 16, 17, 18, 11, 26, 45, 46]. Generally, the scenario under study concerns the design of a structure that, after the failure of any set F of at most $k \geq 1$ arcs (representing links) in a given digraph D (representing a network), should provide a fast answer to certain types of queries that address the properties of $D - F$. The most common queries of this form address the *reachability* between two vertices, or, more generally, the length of a shortest path existent, if any, between them. Indeed, reachability (or, more generally, distance preservation) is the most basic requirement to maintain to ensure that the network functions properly. In this context, particular attention has been given to the case where the data structure should consist of a subgraph or a minor of D with as fewest arcs/vertices as possible [7, 47, 9, 11, 8, 45, 13]. Then, queries can be answered by standard means as the usage of BFS or Dijkstra's algorithm. In particular, these simple data structures are of interest as they also double as *sparsifiers*. The study of various graph sparsifiers – such as *flow-sparsifiers* [38] which are closely related to the aforementioned data structures – is a fundamental, active area of research in computer science and structural graph theory [22, 5, 29, 38, 15].

More concretely, in the Fault-Tolerance (S,T)-Reachability problem (or FTR(S,T) for short), we are given a digraph D, two (not necessarily disjoint) terminals sets $S, T \subseteq V(D)$, and a positive integer k. The objective is to construct a subgraph H of D with minimum number of arcs/vertices such that, after the failure of any set of at most k arcs in D, the following property is preserved for any two vertices $s \in S$ and $t \in T$: if there still exists a directed path from s to t in D, then there also still exists a directed path from s to t in H. Clearly, a trivial lower bound on the number of arcs in H is $m = \Omega(n^2)$. For the case where $|S| = 1$ and $T = V(D)$, Baswana et al. [9] presented a construction of a subgraph H with $\mathcal{O}(2^k n)$ arcs in time $\mathcal{O}(2^k nm)$ where $n = |V(D)|$ and $m = |E(D)|$. Additionally, they gave a tight matching lower bound: for any $n, k \in \mathbb{N}$ where $n \geq 2^k$, there exists a digraph on n vertices where H must have $\Omega(2^k n)$ arcs.

Naturally, the question of the improvement of the dependency on k arises for special classes of digraphs. However, an arguably more radical research direction to pursue concerns the dependency on n.

Which are the largest classes of digraphs for which FTR(S,T) admits subgraphs whose size dependency on n can be made sublinear, logarithmic *or even constant*?

At first glance, when we consider the simplest sparsest digraph existent, this pursuit seems futile. Indeed, already in the case where $S = \{s\}$, $T = \{t\}$, $k = 1$ and D is a directed path from s to t, the only solution is to choose $H = D$. At second glance, when we consider the simplest densest digraph existent, again we reach a dead-end: for S, T and k as before, define D as the tournament obtained by adding, to a directed path $s = v_1 \to v_2 \to \ldots \to v_n = t$, all arcs going from v_i to v_j for every $j + 1 < i$; then, to construct H, we must select the entire path.

We show that "almost acyclicity" suffices to eliminate the dependency on n *entirely* for a broad class of dense digraphs called *bounded independence number digraphs*. Furthermore, one can achieve a polynomial dependence in terms of k for this digraph class.

To step beyond the strict confinement of tournaments where *all* relations (arcs) between the input entities (vertices) must be both *present* and *known*, Fradkin and Seymour [33] initiated the study of bounded independence digraphs. Formally, for any integer $\alpha \geq 1$, the class of α-bounded independence digraphs, denoted by $\mathcal{D}_\alpha$, is defined as follows.

$$\mathcal{D}_\alpha = \{D \mid D \text{ is a digraph and the maximum size of an independent set in } D \text{ is at most } \alpha\}.$$

chitnis2014directedFor this class of digraphs, Fradkin and Seymour [33] studied the k-Disjoint Paths problem, and showed that it admits a polynomial time algorithm for any fixed value of k. Observe that $\mathcal{D}_\alpha$ is *hereditary*, and for $\alpha = 1$, it coincides with the class of tournaments. Furthermore, even for $\alpha = 2$, it contains digraphs with a linear fraction of vertex pairs that have no arc between them – thus, it can accommodate the lack of a large number of links/relations.

Our main technical contribution is the following combinatorial lemma.

▶ **Lemma 1.1.** *Given a digraph $D \in \mathcal{D}_\alpha$, positive integers k and ℓ, and $S \subseteq V(D)$ such that every strongly connected component of $D - S$ has at most ℓ vertices, the* Fault-Tolerance (S,S)-Reachability (FTR(S,S)) *problem admits a solution H on $|S|^2(k\ell)^{\mathcal{O}(4^{\alpha\ell^2})}$ vertices. Furthermore, such a solution H can be found in polynomial time.*

In particular, when $D - S$ is acyclic, $\ell = 1$. Thus, if $|S|$ and ℓ are independent of n (such as the case where $|S| = |T| = \ell = 1$ discussed earlier), the dependency on n is eliminated. (We remark that a solution for Fault-Tolerance (S,T)-Reachability where $S \neq T$ is subsumed by a solution for Fault-Tolerance $(S \cup T, S \cup T)$-Reachability.) Note that we extend the class of digraphs dealt with beyond acyclicity at two fronts: enabling S to be a modulator, thus $D - S$ rather than D should be "almost acyclic"; enabling the strongly connected components to be of size that is ("small" but) larger than 1.

In fact, our result generalizes to *parity reachability*. More precisely, in the Fault-Tolerance (S,T)-Parity Reachability problem, we are given a digraph D, two terminal sets $S, T \subseteq V(D)$, positive integers k and p, and a non-negative integer r. The objective is to construct a subgraph H of D with as few arcs/vertices as possible, such that, after the failure of any set of at most k arcs in D, the following property is preserved for any two vertices $s \in S$ and $t \in T$: if there exists a directed path from s to t in D whose length q satisfies $(q \mod p = r)$, then there also exists a directed path from s to t in H whose length q' satisfies $(q' \mod p = r)$. For this problem, we prove the following combinatorial lemma.

▶ **Lemma 1.2.** *Given a digraph $D \in \mathcal{D}_\alpha$, positive integers k, ℓ, p, a non-negative integer r, and $S \subseteq V(D)$ such that every strongly connected component of $D - S$ has at most ℓ vertices, the* Fault-Tolerance (S,S)-Parity Reachability *problem admits a solution H on $(|S|\alpha\ell pk)^{\mathcal{O}(4^{\alpha\ell^2})}$ vertices. Furthermore, such a solution H can be found in polynomial time.*

1.1 Applications in Kernelization

Directed Feedback Arc Set. From the perspective of Parameterized Complexity, with the exception of Directed Multicut, the Directed Feedback Arc/Vertex Set (DFA/VS) problem is the most well studied parameterized problem on digraphs. (On general digraphs, the vertex and arc versions of the problem are equivalent [23].) Formally, this problem is defined as follows.

Directed Feedback Arc Set (DFAS)	**Parameter:** k
Input: A digraph D and a non-negative integer k.	
Question: Does there exist $S \subseteq E(D)$ of size at most k such that $D - S$ is a DAG?	

We remark that this problem is among Karp's 21 original NP-complete problems [35]. Already a decade ago, the DFAS problem has been shown to be *fixed-parameter tractable (FPT)* parameterized by the solution size k [19]. Specifically, Chen et al. [19] developed an algorithm that solves DFAS in time $\mathcal{O}(k!4^k k^4 mn)$, based on the powerful machinery of important separators [23]. Since then, the quest to assert the existence of a polynomial kernel for this problem has been unfruitful. Over the years, it has been repeatedly posed as a major challenge in the subfield of Kernelization [23, 28, 42, 41] (also see [1] for a number of workshops and schools where it was posed as an open problem). In fact, the two specific problems whose polynomial kernelization complexity is completely unknown and their resolution is raised most frequently are DFAS and Multiway Cut [23, 28]. At the front of parameterized algorithms, the recent work by Lokshtanov et al. [39] improved upon the polynomial factor of the aforementioned algorithm by the design of an $\mathcal{O}(k!4^k k^5(m+n))$-time algorithm. It is known that unless the Exponential Time Hypothesis (ETH) is false, parameterized by the treewidth tw of the underlying undirected graph, DFAS cannot be solved in time $2^{o(\mathsf{tw}\log \mathsf{tw})} \cdot n^{\mathcal{O}(1)}$. However, it is unknown whether DFAS is solvable in time $2^{o(k \log k)} \cdot n^{\mathcal{O}(1)}$. In this regard, the only lower bound known is of $2^{\Omega(k)} \cdot n^{\mathcal{O}(1)}$ under the ETH [23, 39].

Particular attention has been given to the parameterized complexity of DFAS on tournaments. The classical complexity (NP-hardness) of DFAS on tournaments has a curious history. More than two decades ago, this problem was conjectured to be NP-hard by Bang-Jensen and Thomassen [6]. In 2008, Ailon et al. [2] proved that this problem does not admit a polynomial-time algorithm unless NP$\subseteq$BPP. Later, the reduction of Ailon et al. [2] was derandomized independently by Alon [3] and Charibt et al. [14], to prove that DFAS on tournaments is NP-hard. With respect to Parameterized Complexity, Alon et al. [4] proved that DFAS on tournaments admits a sub-exponential time parameterized algorithm (with running time $2^{\mathcal{O}(\sqrt{k}\log^2 k)} \cdot n^{\mathcal{O}(1)}$), to which end they introduced the method of chromatic coding. Later, the $\log^2 k$ factor in the exponent was shaved in independent works by Feige [30] and Karpinski and Schudy [36]. Fomin and Pilipczuk [32] presented a general approach, based on a bound on the number of k-cuts in transitive tournaments, to achieve the same running time for DFAS on tournaments. Based on this approach, Misra et al. [43] developed a sub-exponential time parameterized algorithm for DFAS on digraphs in $\mathcal{D}_\alpha$, with running time $2^{\mathcal{O}(\alpha^2\sqrt{k}\log(\alpha k))} \cdot n^{\mathcal{O}(\alpha)}$. Yet, the (arguably more) intriguing question

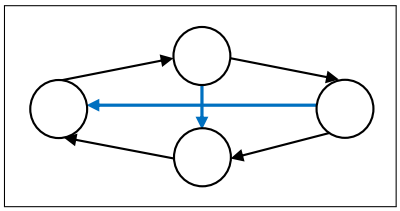

Figure 1 A directed edge odd cycle transversal (in blue) that is not a directed feedback arc set.

of the existence of a polynomial kernel for DFAS on digraphs in $\mathcal{D}_\alpha$ remained unsolved. On tournaments, Bessy et al. [10] have proved that DFAS admits a linear-vertex kernel (improving upon polynomial kernels given in [4, 27]). Based on our combinatorial lemma (Lemma 1.1), we establish the following theorem.

▶ **Theorem 1.3.** DFAS *on* $\mathcal{D}_\alpha$ *admits a kernel of size* $k^{\mathcal{O}(4^\alpha)}$.

In addition to its rich history in theoretical studies, the elimination of directed feedback loops is highly relevant to rank aggregation, Voting Theory, the resolution of inconsistencies in databases, and the prevention of deadlocks [48, 10, 34, 37, 19, 31]. While in a wide-variety of applications, *most* relations between the entities in a network are both present and known, it is generally unrealistic (in real-world partial and noisy data) that *all* relations will be so. Then, the usage of a bounded independence digraphs naturally comes into play. In passing, using Theorem 1.3, we also improve the running time for DFAS on digraphs in $\mathcal{D}_\alpha$, given by Misra et al. [43], by eliminating the dependence of α in the exponent of n. That is, we have the following theorem.

▶ **Theorem 1.4.** DFAS *on* $\mathcal{D}_\alpha$ *can be solved in* $2^{f(\alpha)\sqrt{k}\log k} \cdot n^{\mathcal{O}(1)}$, *where* $f(\alpha)$ *is some function of* α *and* n *is the number of vertices in* D.

Directed Edge Odd Cycle Transversal. The Directed Edge Odd Cycle Transversal (DEOCT) problem is the parity-based version of DFAS, formally defined as follows. (On general digraphs, the vertex and arc versions of the problem are equivalent [40]).

Directed Edge Odd Cycle Transversal (DEOCT)	**Parameter:** k
Input: A digraph D and a non-negative integer k.	
Question: Does there exist $S \subseteq E(D)$ of size at most k such that $D-S$ has no odd cycle?	

Observe that a tournament has no directed cycle if and only if it has no directed triangle (a cycle on three vertices). In turn, this simple observation implies that, given a tournament D, any subset S of the *vertices* of D has the following property: $D - S$ is a DAG if and only if it has no directed odd cycle. Thus, the vertex versions of DFAS and DEOCT on tournaments are equivalent. However, for DFAS and DEOCT the situation is not so clear. Indeed, it is not difficult to come up with a tournament D and a subset of *arcs* S of D such that $D - S$ is not a DAG, yet it has no directed odd cycle (see, e.g., Fig. 1). Nonetheless, we are able to prove that given a tournament D and a subset S of the *arcs* of D such that $D - S$ has no directed odd cycle, there exists a subset of arcs S' of D such that $D - S'$ is a DAG and $|S'| \leq |S|$. In particular, we thus establish the following result.

▶ **Theorem 1.5.** DEOCT *on tournaments is* NP*-hard.*

The question of the parameterized complexity of DEOCT was explicitly stated as an open problem [24] for the first time in 2007, immediately after the announcement of the first parameterized algorithm for DFAS. Since then, the problem has been re-stated several

times [20, 21, 42, 41]. Recently, Lokshtanov et al. [40] proved that DEOCT is W[1]-hard. Specifically, this means that DEOCT is highly unlikely to be FPT or admit a kernel of any size (even exponential in k). Based on the parity-based generalization of our combinatorial lemma (Lemma 1.2), we establish a polynomial kernel for DEOCT on $\mathcal{D}_\alpha$, which stands in sharp contrast to its aforementioned status on general digraphs.

▶ **Theorem 1.6.** DEOCT *on* $\mathcal{D}_\alpha$ *admits a kernel of size* $(\alpha k)^{\mathcal{O}(4^{4\alpha^3})}$.

In fact, we present combinatorial results stronger than Lemma 1.2 that yield a polynomial kernel for a more general version of DEOCT, where instead of hitting directed odd cycles, the objective is to hit directed cycles whose length ℓ satisfies $(\ell \mod p = 1)$ for an integer $p \in \mathbb{N}$ given as input.[1]

Modulo p Directed Cycle Transversal (mod(p)-DCT) **Parameter:** k
Input: A digraph D and non-negative integers k and p.
Question: Does there exist $S \subseteq E(D)$ of size at most k such that $D - S$ has no cycle of length $1 \mod p$?

▶ **Theorem 1.7.** mod(p)-DCT *on* $\mathcal{D}_\alpha$ *admits a kernel of size* $(p\alpha k)^{\mathcal{O}(4^{\alpha^3 p^2})}$.

Having Theorem 1.6 at hand, we also show how to employ the general approach of Fomin and Pilipczuk [32] to derive a sub-exponential time parameterized algorithm for DEOCT on digraphs in $\mathcal{D}_\alpha$.

▶ **Theorem 1.8.** DEOCT *on* $\mathcal{D}_\alpha$ *admits an algorithm with running time* $2^{\mathcal{O}(f(\alpha)\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$, *where* $f(\alpha)$ *is a function of* α *and* n *is the number of vertices in* D.

1.2 Towards the proof of Lemmas 1.1: Cut Preserving Sets

The most central notion in this paper is of a *cut preserving set*. Informally, for a digraph D, a pair of vertices s, t and an integer k, a set $\mathcal{Z} \subseteq V(D)$ is called a k-cut preserving set[2] for (s, t) in D if it preserves all (s, t)-arc cuts of size at most k. That is, A is an (s, t)-arc cut with at most k arcs in D if and only if A is a such a cut in $D[\mathcal{Z}]$. Observe that the graph induced on such a k-cut preserving set $\mathcal{Z}$ is a candidate solution for FTR($\{s\}, \{t\}$) problem. Clearly $V(D)$ is a k-cut preserving set for any pair of vertices s, t. The intent is to have such a set of "small" size. Towards this, let us discuss some properties that suffice for $\mathcal{Z}$ to be a k-cut preserving set for (s, t) in D.

Since $\mathcal{Z} \subseteq V(D)$, any (s, t)-arc cut of D is an (s, t)-arc cut of $D[\mathcal{Z}]$. For the other direction, we need the property that, for any $A \subseteq E(D)$ of size at most k, the existence of an (s, t)-path in $D - A$ implies the existence of an (s, t)-path in $D[\mathcal{Z}] - A$. Let us now see which properties suffice to imply the above property. We begin with a special case. Suppose there is a "large" flow from s to t in D. In particular, suppose there are at least $k + 1$ internally vertex-disjoint (s, t)-paths in D. Then, in $\mathcal{Z}$ it is enough to keep the vertices of some $k + 1$ vertex-disjoint (s, t)-paths, as no arc set of size at most k can hit all these paths. The more involved case occurs when the flow from s to t in D is at most k. Consider any (s, t)-path P in D. Ideally (if we did not have a size constraint on $\mathcal{Z}$) we would have preserved all the

[1] Note that a fundamental difference between this result and Lemma 1.2 is that the latter only works for any modulo and not just 1.

[2] This is not the way it is defined later. However, for the sake of exposition, we start with this definition and refine it to have properties that also guarantee this property implicitly.

vertices of P in $\mathcal{Z}$. Clearly, this can be expensive in terms of the size of $\mathcal{Z}$. Nevertheless, we can merge the ideas above (the "large-flow idea" and the "keep-full-path idea") to get the desired result. To see this, let P be a (s,t)-path in D. Let $\mathcal{Z}$ be a set of vertices such that, either all the vertices of P are in $\mathcal{Z}$ or if the vertices of a (u,v)-subpath of P are not in $\mathcal{Z}$, then there are $k+1$ internally vertex-disjoint (u,v)-paths in $D[\mathcal{Z}]$. That is, if the vertices of a subpath are missing in $\mathcal{Z}$, then $\mathcal{Z}$ contains a witness of a large flow for the endpoints of this subpath. Observe that such a set $\mathcal{Z}$ suffices to be a k-cut preserving set for (s,t) in D. This is because if P is an (s,t)-path in $D-A(A \subseteq E(D)$ and $|A| \leq k)$, then either all the vertices of P are in $\mathcal{Z}$ or for any missing (u,v)-subpath of P, since there are $k+1$ vertex-disjoint (u,v)-paths in $D[\mathcal{Z}]$, at least one still remains in $D[\mathcal{Z}]-A$. Thus, in $D[\mathcal{Z}]-A$, one can find an (s,t)-path: for the missing subpaths of P in $\mathcal{Z}$, there exists some (other) path between the same endpoints in $D[\mathcal{Z}]-A$ which together yield an (s,t)-walk (and hence an (s,t)-path) in $D[\mathcal{Z}]-A$. These properties are formalized in Definition 3.1.

1.2.1 About Computing k-Cut Preserving Sets

Next we give an intuition for how one can compute such k-cut preserving sets for a digraph $D \in \mathcal{D}_\alpha$, each of whose strongly connected component has size at most ℓ. For exposition purposes, consider (for now), only the case where D is acyclic (i.e. $\ell = 1$). With a certain technical argument, the general case reduces to this one. Moreover, we use the definition of a k-cut preserving set from the beginning of this section for this illustration as it allows us to convey our ideas in a clearer manner.

The proof will use induction on α. As the base case, consider the case when $\alpha = 1$, that is, D is a transitive tournament. As D is transitive, there exists a topological ordering of the vertices of D. Consider the set S of vertices between s and t in this ordering. Note that any path from s to t only uses vertices in S. So, either S is smaller than $k+1$, and then $S \cup \{s,t\}$ is a k-cut preserving set for (s,t), or it can be seen that there is no arc-cut for (s,t) of size at most k. In the latter case, the union of $\{s,t\}$ and any subset of $k+1$ vertices of S is a k-cut preserving set for (s,t); indeed, in the subgraph induced by the union there is still no arc-cut for (s,t) of size at most k.

Now, let us hint at how the inductive step of the proof works. First, we note that, if $P_1, \ldots, P_{k+1}$ are $k+1$ internally vertex-disjoint (s,t)-paths, then $\mathcal{Z} = \cup_{i \in [k+1]} P_i$ is a k-cut preserving set for the pair (s,t), because there is no arc-cut of (s,t) in both D and $D[\mathcal{Z}]$ of size at most k. Moreover, since D is acyclic and $D \in \mathcal{D}_\alpha$, if these paths exist, then Observation 2.1 implies that we can assume that all these paths are shorter than $2\alpha+1$ and thus $|\mathcal{Z}| \leq k(2\alpha+1)$.

The last argument means that we can assume the existence of a (s,t)-vertex cut of size at most k. For simplicity, suppose that $\{c_1, c_2\}$ is a minimal (s,t)-vertex -cut. Since $\{c_1, c_2\}$ is a vertex cut, any path from s to t in D can be decomposed as a path from s to c_i, a path from c_i to c_j and then a path from c_j to t, where i and j are two indices (possibly equal) in $\{1,2\}$. Here, we mean that none of the three paths contains c_i (or c_j) as an internal vertex. For $i \in \{1,2\}$, let S_i be the union of the set of vertices of the paths from s to c_i that intersect $\{c_1, c_2\}$ only on the last vertex, and T_i be the union of the set of vertices of the paths from c_i to t that intersect $\{c_1, c_2\}$ only on the first vertex. Finally, for distinct $i, j \in \{1,2\}$, let $C_{i,j}$ be the union of the set of vertices of the paths from c_i to c_j. Because of the last remark on how any path from s to t can be decomposed, taking the union of six k-cut preserving sets-namely, for each $i, j \in \{1,2\}$, $i \neq j$, for (s, c_i) in $D[S_i]$, (c_i, t) in $D[T_i]$ and (c_i, c_j) in $D[C_{i,j}]$- gives a k-cut preserving set for (s,t) in D. Now, the question is how to use the induction hypothesis to find a k-cut preserving set for each of these pairs. Consider first

the digraph induced by the vertices in S_1. Because $\{c_1, c_2\}$ is a minimal (s,t)-vertex cut, the only vertices of S_1 that can possibly have "outgoing arcs towards" t in S_1 are s and c_1. Moreover, since $\{c_1, c_2\}$ is a minimal (s,t)-vertex cut, there exists a path from c_1 to t in D and thus t is reachable from any vertex of S_1. However, since D is acyclic, this means that there is no arc from t to any of the vertices of S_1, else we would get a closed walk and thus a cycle. This implies that $D[S_1 \setminus \{s, c_1\}] \in \mathcal{D}_{\alpha-1}$ as any independent set of $S_1 \setminus \{s, c_1\}$ can be extended with t. We cannot apply the induction hypothesis to find a k-cut preserving set for (s, c_1) in S_1 because the independence number of $D[S_1]$ could be equal to α, however the above shows the spirit of the arguments that will be used to find subgraphs with smaller independence number where we can apply the induction hypothesis. A similar argument would also give that the independence number of $D[T_1 \setminus \{c_1, t\}]$ is at most $\alpha - 1$ as any independent set can be extended using s.

The previous argument does not apply to $C_{1,2}$, because the vertices of $C_{1,2}$ can be adjacent to s or t (some vertices of $C_{1,2}$ can be adjacent to s and some can be adjacent to t). This is the case that requires a stronger and more technical definition for a k-cut preserving set. In particular, we need to understand what happens to the vertices of D that are on a path from s to t but do not belong to a k-cut preserving set for this pair.

1.3 Deriving Polynomial Kernels for DFAS

Let us now briefly explain how to derive a polynomial kernel for DFAS when the input digraph belongs to $\mathcal{D}_\alpha$, from our result on fault-tolerant subgraphs. First note that if $D \in \mathcal{D}_\alpha$ then every induced cycle in D has length at most $2\alpha+1$. Let (D, k) be an instance of DFAS, and consider a maximal set of arc disjoint induced cycles in D. If this set consists of more than k cycles, then any solution to (D, k) has to pick one arc per cycle, and (D, k) is a NO instance. If not, let S be the union of these cycles. S is a set of less than $(2\alpha+1) \cdot k$ vertices such that $D - S$ is acyclic. Therefore, we can apply our result to find a solution H to the problem of Fault-Tolerance (S, S)-Reachability of size at most $|S|^2 k^{\mathcal{O}(4^\alpha)}$. We claim that H is the desired kernel. Indeed, suppose that A is a set of arcs such that $H - A$ is acyclic, but $D - A$ contains a cycle. By construction of S, this cycle must use vertices of S. However, we know that if a path exists between two vertices of S in $D - A$, then such a path also exists in $H - A$. This implies the existence of a closed walk in $H - A$, a contradiction.

2 Preliminaries

For standard notations and terminology that is not defined here, we refer to [25].

Sets. For positive integer i, j, $[i]$ denotes the set $\{1, \ldots, i\}$ and $[i, j]$ denote the set $\{i, i+1, \ldots, j\}$. For a set S, S^2 denotes the set of ordered pairs of S, that is $S^2 = \{(u, v) \mid u \in S, v \in S\}$.

Digraphs. For a digraph D, $V(D)$ denotes the vertex set of D and $E(D)$ denotes the arc set of D. For any $X \subseteq V(D)$ (resp. $X \subseteq E(D)$), $D - X$ denotes the digraph obtained by deleting the vertices (resp. edges) of X. For any $v \in V(D)$, $N^+_D(v)$ (resp. $N^-_D(v)$) denotes the set of out-neighbours (resp.in-neighbours) of v in D, that is $N^+_D(v) = \{u \in V(D) \mid (v, u) \in E(D)\}$ (resp. $N^-_D(v) = \{u \in V(D) \mid (u, v) \in E(D)\}$). Whenever the digraph D is clear from the context, we drop the subscript D in $N^+_D(v)$ (resp. $N^-_D(v)$). For any $X, Y \subseteq V(D)$, $E(X, Y)$ denotes the set of arcs of D with tail in X and head in Y, that is, $E(X, Y) = \{(u, v) \in E(D) \mid u \in X, v \in Y\}$. A digraph D is called *strongly connected* if for each $u, v \in V(D)$ there

is a path from u to v and, a path from v to u in D. A set $X \subseteq V(D)$ is called a *strongly connected component* of D if $D[X]$ is a strongly connected digraph and for each $X' \supseteq X$, $D[X']$ is not a strongly connected digraph. A *tournament* is a digraph where there is exactly one arc between each pair of vertices. A digraph with no cycles is called a *directed acyclic graph (dag)*. A tournament with no cycles is called a *transitive tournament*.

Paths. A *path* P is a graph such that there exists an ordering $(v_1, \ldots, v_q)$ of its vertex set $V(P)$ such that $E(P) = \{(v_i, v_{i+1}) \mid i \in [q-1]\}$. Such a path is called a (v_1, v_q)-*path*, v_1, v_q are called the *end-points of* P and $v_2, \ldots, v_{q-1}$ are called the *internal vertices of* P. A path P is *even* (resp. odd) if the number of arcs/edges in it is even (resp. odd). We say that P is a path in the digraph D if P is a subgraph of D. We say that P is an *induced path* in D if P is an induced subgraph of D. For paths P and P', by $P \circ P'$ we denote the composition of P and P', that is, the path obtained by appending P' after P. For paths $P, P_1, P_2, \ldots, P_q$ such that $P = P_1 \circ P_2 \circ \ldots \circ P_q$, we say that $P_1 \circ P_2 \circ \ldots \circ P_q$ is a *partition* of P. For a digraph D and $X \subseteq V(D)$, we say that a (u, v)-path P in D is X-*free* if none of the internal vertices of P are from X. The X-*based partition of* P in D is the partition $P = P_1 \circ \ldots \circ P_q$ such the union of the end-points of P_i, $i \in [q]$, is exactly the set $(X \cap V(P)) \cup \{u, v\}$. A *semi-$X$-based partition* of P, $P = P_1 \circ \ldots \circ P_q$, is such that the end-points of the paths P_i, $i \in [q]$, are a subset of $(X \cap V(P)) \cup \{u, v\}$. Paths $\{P_1, \ldots, P_q\}$ are *internally vertex-disjoint* if for all distinct $i, j \in [q]$, the sets of internal vertices of P_i and P_j are disjoint.

Vertex and Arc Cuts. For a digraph D and $u, v \in V(D)$, a (u, v)-*arc cut* is a set of arcs of D, say X, such that $D - X$ has no (u, v)-path. A (u, v)-*vertex cut* is a set of vertices of D, say Y, such that $D - Y$ has no (u, v)-path and $u, v \notin Y$ if $(u, v) \notin E(D)$.

▶ **Observation 2.1.** *Let $D \in \mathcal{D}_\alpha$. The length of the shortest cycle in D is at most $2\alpha + 1$. Also, the length of any induced path in D is at most $2\alpha + 1$.*

In this article, we focus of the proof of Lemma 1.1 alone. The proofs of Lemma 1.2 and Theorems 1.6, 1.8, 1.5, 1.6, 1.7, 1.8 will be made available later in the full version of the paper.

3 Finding Small k-Cut Preserving Sets

We give the precise definition of a k-cut preserving set here.

▶ **Definition 3.1** (k-Cut Preserving Set). *For digraph D, an ordered pair (u, v) of vertices of D and a positive integer k, $\{u, v\} \subseteq \mathcal{Z} \subseteq V(D)$ is a* k-cut preserving set for (u, v) in D *if the following holds. For any (u, v)-path P in D, there exists a semi-$\mathcal{Z}$-based partition $P_1 \circ \ldots \circ P_d$ of P with the following two properties. For each $i \in [d]$, P_i is an (s_i, t_i)-path in D with $s_i, t_i \in \mathcal{Z}$. Moreover, either $V(P_i) \subseteq \mathcal{Z}$ or there exists a list $\mathcal{L}_i$ of $k+1$ internally vertex-disjoint $(V(D) \setminus \mathcal{Z})$-free (s_i, t_i)-paths. A list $\mathcal{L}_i$ with the above property is called a* replacement kit for P_i in $\mathcal{Z}$. *Such a semi-$\mathcal{Z}$-based partition of P is called a* $\mathcal{Z}$-replacement witness for P.

Before moving to the computational aspects of a k-cut preserving set, we give the following lemma that can be considered as the main utility of k-cut preserving sets, and relate to the intuition we gave in the previous section.

▶ **Lemma 3.2.** *Let D be a digraph, $u, v \in V(D)$ and $\mathcal{Z}$ be a k-cut preserving set for (u, v) in D. For any set $A \subseteq E(D)$ of at most k arcs, if there exists a (u, v)-path in $D - A$, then there also exists one in $D[\mathcal{Z}] - A$.*

Proof. Consider some $A \subseteq E(D)$ such that $|A| \leq k$. Suppose there exists a (u,v)-path P in $D - A$. Since $\mathcal{Z}$ is a k-cut preserving set for the pair (u,v), there exists a semi-$\mathcal{Z}$-based partition $P = P_1 \circ \ldots \circ P_d$ such that for each $j \in [d]$, P_j is an (s_j, t_j)-path, $s_j, t_j \in \mathcal{Z}$ and, either $V(P_j) \subseteq \mathcal{Z}$, in which case P_j is a path in $D[\mathcal{Z}] - A$, or there exist $k+1$ internally vertex- disjoint (s_j, t_j)-paths in $D[\mathcal{Z}]$. In the later case, at least one of the $k+1$ paths is in $D[\mathcal{Z}] - A$ (because $|A| \leq k$). This implies the existence of a walk from u to v (and hence also a (u,v)-path) in $D[\mathcal{Z}] - A$. This concludes the proof. ◀

The main goal of this section is to prove the following lemma.

▶ **Lemma 3.3** (k-Cut Preserving Lemma)**.** *Let D be an acyclic digraph, and $u, v \in V(D)$ be such that $N^-(u) = N^+(v) = \emptyset$. Additionally, let $D - \{u,v\} \in \mathcal{D}_\alpha$. Then there exists a k-cut preserving set for (u,v) in D of size at most $f(\alpha)$, where $f(1) = k^3 + 5k^2 + 3k$ and for $\alpha > 1$, $f(\alpha) = k^2 g(\alpha) + 2kh(\alpha)$, $g(\alpha) = (2k + (k + kf(\alpha-1))^2) f(\alpha-1)$ and $h(\alpha) = (k^2+k)g(\alpha) + kf(\alpha-1)$. Moreover, such a set can be found in time $n^{\mathcal{O}(1)}$, where $n = |V(D)|$.*

Note that $V(D)$ is always a k-cut preserving set for any pair of vertices (u,v) in D, for any k. We now define a notation, for the sake of convenience, that will be used throughout this section. For any digraph D, $u, v \in V(D)$ and $X \subseteq V(D)$, let $ver_D(u, v; X)$ denote the union of the sets of vertices of all X-free (u,v)-paths in D. Observe that $ver_D(u,v;X) \cap X \subseteq \{u,v\}$. We begin by making an observation that forms the base line for computing small sized k-cut preserving sets using an appropriate induction.

▶ **Observation 3.4.** *Let D be a digraph, $u, v \in V(D)$, $\mathcal{Z} \subseteq V(D)$ and k be a positive integer. Let P be a (u,v)-path in D, and $P = P_1 \circ \ldots \circ P_d$ be a semi-$\mathcal{Z}$-based partition of P. If for each $i \in [d]$, there is a $\mathcal{Z}_i$-replacement witness for P_i in D_i, for some $\mathcal{Z}_i \subseteq \mathcal{Z}$ and D_i subgraph of D, then there is a $\mathcal{Z}$-replacement witness for P.*

Proof. For each $i \in [d]$, let $P_I = P_{i,1} \circ \ldots \circ P_{i,c_i}$ be a $\mathcal{Z}_i$-replacement witness for $\mathcal{Z}_i$ in D_i. Then, consider the semi-$\mathcal{Z}$-based partition $P = P_{1,1} \circ \ldots \circ P_{1,c_1} \circ P_{2,1} \circ \ldots \circ P_{2,c_2} \circ \ldots \circ P_{d,1} \circ \ldots \circ P_{d,c_d}$. Then, for each $i \in [d]$ and $j \in [c_i]$, either $V(P_{i,j}) \subseteq \mathcal{Z}_i \subseteq \mathcal{Z}$, or there exists a list $\mathcal{Z}_{i,j}$ containing $k+1$ internally vertex-disjoint $(V(D_i) \setminus \mathcal{Z}_i)$-free $(x_{i,j}, y_{i,j})$-paths in D_i such that $P_{i,j}$ is a $(x_{i,j}, y_{i,j})$-path. Since $\mathcal{Z}_i \subseteq \mathcal{Z}$ and D_i is a subgraph of D, the paths in $\mathcal{L}_{i,j}$ are $(V(D) \setminus \mathcal{Z})$-free and exist in D. ◀

Next, we give two lemmas (Lemmas 3.5 and 3.6) that basically use Observation 3.4 in a more concrete setting required to prove the k-Cut Preserving Lemma by induction on the size of the maximum independent set in the digraph.

▶ **Lemma 3.5.** *Let D be a digraph, $u, v \in V(D)$ and k be a positive integer. Let C be some (u,v)-vertex cut in D. For each $c \in C$, let $\mathcal{Z}(u,c)$ (resp. $\mathcal{Z}(c,v)$) be a k-cut preserving set for (u,c) (resp. (c,v)) in $D[ver_D(u,c;C)]$ (resp. $D[ver_D(c,v;C)]$). For each $(c,c') \in C^2$, $c \neq c'$, let $\mathcal{Z}(c,c')$ be a k-cut preserving set for (c,c') in $D[ver_D(c,c';C)]$. Then, $\mathcal{Z} := \bigcup_{c \in C} (\mathcal{Z}(u,c) \cup \mathcal{Z}(c,v)) \cup \bigcup_{(c,c') \in C^2, c \neq c'} \mathcal{Z}(c,c')$ is a k-cut preserving set for (u,v) in D.*

Proof. First observe, from the definition of a k-cut preserving set and the construction of $\mathcal{Z}$, that $C \subseteq \mathcal{Z}$. Consider any (u,v)-path P in D. Let $P = P_1 \circ \ldots \circ P_q$ be the C-based partition of P. Since $C \subseteq \mathcal{Z}$, $P_1 \circ \ldots \circ P_q$ is a semi-$\mathcal{Z}$-based partition of P. Then P_1 is a C-free (u, c_1)-path in D for some $c_1 \in C$, P_q is a C-free (c_2, v)-path in D for some $c_2 \in C$, and for each $i \in [2, q-1]$, P_i is a C-free $(c_{j_i}, c_{j_{i'}})$-path in D, for some

$c_{j_i}, c_{j_i'} \in C$, $j_i \neq j_i'$. Thus, P_1 is a (u, c_1)-path in $D[ver_D(u, c_1; C)]$, P_q is a (c_2, v)-path in $D[ver_D(c_2, v; C)]$, and for each $i \in [2, q-1]$, P_i is a $(c_{j_i}, c_{j_i'})$-path in $D[ver_D(c_{j_i}, c_{j_i'}; C)]$. Since $\mathcal{Z}(u, c_1), \mathcal{Z}(c_2, v), \cup_{i \in [2,q-1]} \mathcal{Z}(c_{j_i}, c_{j_i'}) \subseteq \mathcal{Z}$, we are done by Observation 3.4. ◀

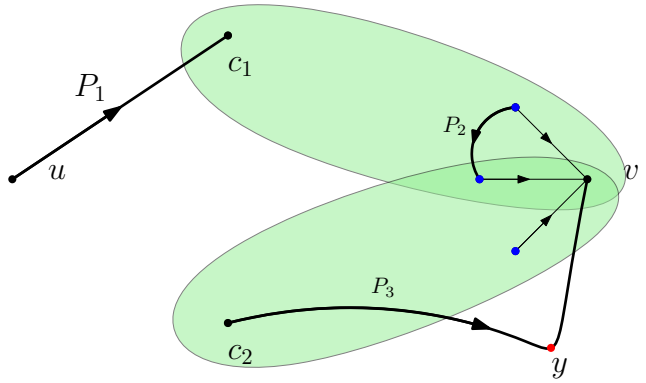

Figure 2 (c_1, c_2) is a (u, v) vertex-cut, the green parts correspond to the $\mathcal{Z}(c_i, v)$ and the blue vertices are the vertices of X. P_1 is a path of Type $(u, \square)$, P_2 is a path of Type $(\boxtimes, \boxtimes)$ and P_3 is a path of Type $(\square, \boxminus, v)$ with $y \in Y$.

▶ **Lemma 3.6.** *Let D be a digraph, $u, v \in V(D)$, and k be a positive integer. Let C be some (u, v)-vertex cut in D. For each $c \in C$, let $\mathcal{Z}(u, c)$ (resp. $\mathcal{Z}(c, v)$) be a k-cut preserving set for (u, c) (resp. (c, v)) in $D[ver_D(u, c; C)]$ (resp. $D[ver_D(c, v; C)]$). Let $X = N_D^-(v) \cap \bigcup_{c \in C} \mathcal{Z}(c, v)$. For each $(\mathtt{a}, \mathtt{b}) \in (C \cup X)^2$, $\mathtt{a} \neq \mathtt{b}$, let $\mathcal{Z}(\mathtt{a}, \mathtt{b})$ be a k-cut preserving set for $(\mathtt{a}, \mathtt{b})$ in $D[ver_D(\mathtt{a}, \mathtt{b}; C \cup N_D^-(v))]$. Then, $\mathcal{Z} := \bigcup_{c \in C} (\mathcal{Z}(u, c) \cup \mathcal{Z}(c, v)) \cup \bigcup_{(\mathtt{a},\mathtt{b}) \in (C \cup X)^2, \mathtt{a} \neq \mathtt{b}} \mathcal{Z}(\mathtt{a}, \mathtt{b})$ is a k-cut preserving set for (u, v) in D.*

Proof. First observe that $\{u, v\} \cup C \cup X \subseteq \mathcal{Z}$. Let $Y = N_D^-(v) \setminus X$. We begin by defining some special types of paths (see Figure 2).

1. A path P *is of Type* $(u, \square)$ *(resp.* $(\square, v)$*)* if it is a C-free (u, c)-path (respectively (c, v)-path) in D for some $c \in C$.
2. A path P *is of Type* $(\boxtimes, \boxtimes)$ if it is a $(C \cup N_D^-(v))$-free $(\mathtt{a}, \mathtt{b})$-path in D for some $(\mathtt{a}, \mathtt{b}) \in (C \cup X)^2$.
3. A path P *is of Type* $(\square, \boxminus, v)$ if it is a (c, v)-path in D for some $c \in C$ and there exists $y \in V(P) \cap Y$ such that the (c, y)-subpath of P is C-free.[3]

We now begin with the proof of the lemma. Let P be some (u, v)-path. We need to show that there is a $\mathcal{Z}$-replacement witness for P. Let $P = P_1' \circ \ldots \circ P_q'$ be the $(C \cup X)$-based partition of P. If P is not Y-free, that is, $V(P) \cap Y \neq \emptyset$, let $s' \in [q]$ be the least integer such that $V(P_{s'}'] \cap Y \neq \emptyset$. If P is Y-free, let $s' = q$. Let $s \leq s'$ be the largest integer such that P_s is an $(\mathtt{a}, \mathtt{b})$-path, where $\mathtt{a} \in C$ and $\mathtt{b} \in C \cup X \cup \{v\}$. WE first show that such a s always exists. From the definition of s', either there exists some $y \in Y$ in $V(P_{s'}')$ or $v \in V(P_{s'}')$. In the later case, since C is a (u, v)-vertex cut, there exists $c \in C$ such that c appears on P. Since $P = P_1' \circ \ldots \circ P_q'$ is a $C \cup X$-based partition of P, there exists $s \leq s'$ such that P_s is a $(\mathtt{a}, \mathtt{b})$-path where $\mathtt{a} \in C$. In the former case again, since $y \in Y \subseteq N_D^-(v)$ and C is a (u, v)-vertex cut using previous arguments the existence of the desired s is guaranteed.

[3] Specifically, if there exists $y \in V(P) \cap Y$ with this property, then the first vertex of P that belongs to Y also has that property.

Consider the partition $P = P_1 \circ \ldots \circ P_s$, such that $P_i = P'_i$, if $i < s$ and $P_s = P'_s \circ P'_{s+1} \circ \ldots \circ P'_q$. Observe that, since $C \cup X \subseteq \mathcal{Z}$, $P = P_1 \circ \ldots \circ P_s$ is a semi-$\mathcal{Z}$-based partition of P.

▷ Claim 3.7. P_1 is a Type $(u, \square)$ path, for each $i \in [2, s-1]$, P_i is a Type $(\boxtimes, \boxtimes)$ path and, P_s is either a Type $(\square, v)$ or Type $(\square, \boxminus, v)$ path.

Proof. Recall that $P = P'_1 \circ \ldots \circ P'_q$ is the $(C \cup X)$-based partition of P. Thus, we have the following.

1. For each $i \in [q]$, P'_i is $(C \cup X)$-free path.
2. For each $i \in [2, q-1]$, P'_i is a $(\mathtt{a}, \mathtt{b})$-path, where $(\mathtt{a}, \mathtt{b}) \in (C \cup X)^2$.
3. Since C is a (u, v)-vertex cut in D and $X \subseteq N_D^-(v)$, P'_1 is a (u, c)-path for some $c \in C$.
4. From the choice of s, for each $i \in [s-1]$, $V(P'_i) \cap Y = \emptyset$. Since for $i \in [s-1]$, $P_i = P'_i$ and $X \cup Y = N_D^-(v)$, P_i is $(C \cup N_D^-(v))$-free.

Thus, from Points 2 and 4, for each $i \in [s-1]$, P_i is of Type $(\boxtimes, \boxtimes)$. Also, from Points 3 and 4, P_1 is of Type $(u, \square)$. We now show that P_s is of Type $(\square, v)$ or $(\square, \boxminus, v)$. From the choice of s and the construction of P_s, P_s is a (c, v)-path for some $c \in C$. If P is Y-free, then P_s is of Type $(\square, v)$, otherwise, P_s is of Type $(\square, \boxminus, v)$. ◁

For each $i \in [s]$, define $\mathcal{Z}_i$ and D_i as follows.

$$\mathcal{Z}_i = \begin{cases} \mathcal{Z}(u, c) & \text{if } i = 1,\ P_1 \text{ is a } (u, c)\text{-path}, c \in C \\ \mathcal{Z}(\mathtt{a}, \mathtt{b}) & \text{if } i \in [2, s-1],\ P_i \text{ is a } (\mathtt{a}, \mathtt{b})\text{-path}, (\mathtt{a}, \mathtt{b}) \in (C \cup X)^2 \\ \mathcal{Z}(c, v) & \text{if } i = s,\ P_s \text{ is a } (c, v)\text{-path}, c \in C \end{cases}$$

$$D_i = \begin{cases} D[ver_D(u, c; C)] & \text{if } i = 1, P_1 \text{ is a } (u, c)\text{-path}, c \in C \\ D[ver_D(\mathtt{a}, \mathtt{b}; (C \cup N_D^-(v))] & \text{if } i \in [2, s-1],\ P_i \text{ is a } (\mathtt{a}, \mathtt{b})\text{-path}, (\mathtt{a}, \mathtt{b}) \in (C \cup X)^2 \\ D[ver_D(c, v)] & \text{if } i = s,\ P_s \text{ is a } (c, v)\text{-path}, c \in C \end{cases}$$

Recall the construction of $\mathcal{Z}$ from the lemma statement. Observe that for each $i \in [s]$, $\mathcal{Z}_i \subseteq \mathcal{Z}$. From Observation 3.4, to give a $\mathcal{Z}$-replacement witness for P, it is enough to give a $\mathcal{Z}_i$-replacement witness for each P_i, in D_i, $i \in [s]$. Thus, the following claim will finish the proof of the lemma.

▷ Claim 3.8. For each $i \in [s]$, P_i has a $\mathcal{Z}_i$-replacement witness in D_i.

Proof. We prove the claim using the following cases.

- **Case $i = 1$:** From Claim 3.7, P_1 is a C-free (u, c)-path in D for some $c \in C$. Thus, P_1 is a (u, c)-path in D_1. Since Z_1 is a k-cut preserving set for (u, c) in D_i, there exists a $\mathcal{Z}_1$-replacement witness for P_1 in D_1.
- **Case $i \in [2, s-1]$:** From Claim 3.7, when $i \in [2, s-1]$, then P_i is a $(C \cup N_D^-(v))$-free $(\mathtt{a}, \mathtt{b})$-path in D for some $(\mathtt{a}, \mathtt{b}) \in (C \cup X)^2$. Thus, P_i is an $(\mathtt{a}, \mathtt{b})$-path in D_i. Since Z_i is a k-cut preserving set for $(\mathtt{a}, \mathtt{b})$ in D_i, there exists a $\mathcal{Z}_i$-replacement witness for P_i in D_i.
- **Case $i = s$:** From Claim 3.7, P_s is of either Type $(\square, v)$ or Type $(\square, \boxminus, v)$.
  - **P_s is of Type $(\square, v)$:** From the definition of Type $(\square, v)$, P_s is a C-free (c, v)-path in D, for some $c \in C$. Thus, P_s is a (c, v)-path in D_s. Since $\mathcal{Z}_s$ is a k-cut preserving set for (c, v) in D_s, there exists a $\mathcal{Z}_s$-replacement witness for P_s in D_s.

- P_s **is of Type** $(\square, \boxminus, v)$**:** From the definition of Type $(\square, \boxminus, v)$, P_s is a (c, v)-path in D, for some $c \in C$, and there exists $y \in V(P) \cap Y$ such that the (c, y)-subpath of P is C-free. Let $P_s^\dagger$ be the (c, y)-subpath of P. Recall that $Y = N_D^-(v) \setminus X$. Consider the (c, v)-path in D, denoted by $\widetilde{P_s}$, obtained by appending the arc (y, v) at the end of $P_s^\dagger$. That is, $\widetilde{P_s} = P_s^\dagger \circ (y, v)$. Since $P_s^\dagger$ is a C-free path, so is $\widetilde{P_s}$. Thus $\widetilde{P_s}$ is a (c, v)-path in D_s. Since $\mathcal{Z}_s$ is a k-cut preserving set for (c, v) in D_s, there exists a semi-$\mathbb{Z}_s$-based partition of $\widetilde{P_s}$ which is a $\mathcal{Z}_s$-replacement witness for $\widetilde{P_s}$ in D_s. Let $\widetilde{P_s} = \widetilde{P_{s,1}} \circ \ldots \circ \widetilde{P_{s,r}}$ be one such partition. Since $y \in Y = N_D^-(v) \setminus X$ and $\mathcal{Z}_s \subseteq X$, $y \notin \mathcal{Z}_s$. Thus, y is an internal vertex of $\widetilde{P_{s,r}}$. Let $\widetilde{P_{s,r}}$ be an (x, v)-path. Clearly, $x \in \mathcal{Z}_s$ because $\widetilde{P_s} = \widetilde{P_{s,1}} \circ \ldots \circ \widetilde{P_{s,r}}$ is a semi-$\mathcal{Z}_s$-based partition. Let $P_{s,r}^\dagger$ be the (x, v)-subpath of $P_{s,r}$. We claim that $P_s = \widetilde{P_{s,1}} \circ \ldots \circ \widetilde{P_{s,r-1}} \circ P_{s,r}^\dagger$ is a semi-$\mathcal{Z}_s$-based partition of P_s and is also a $\mathcal{Z}_s$-replacement witness for P_s in D_s. It is clear from the discussion above that $P_s = \widetilde{P_{s,1}} \circ \ldots \circ \widetilde{P_{s,r-1}} \circ P_{s,r}^\dagger$ is a semi $\mathcal{Z}_s$-based partition of P_s. We will now show that it is a $\mathcal{Z}_s$-replacement witness for P_s in D_s.
  Since $\widetilde{P_s} = \widetilde{P_{s,1}} \circ \ldots \circ \widetilde{P_{s,r}}$ is a $\mathcal{Z}_s$-replacement witness for $\widetilde{P_s}$, we have that for each $j \in [r]$, either $V(\widetilde{P_{s,j}}) \subseteq \mathcal{Z}_s$ or there exists a list $\mathcal{L}_j$ containing $k+1$ vertex disjoint paths from the start vertex of $\widetilde{P_{s,j}}$ to its end vertex. Also, since $y \notin \mathcal{Z}_s$ and y is an internal vertex of $\widetilde{P_{s,r}}$, $V(\widetilde{P_{s,r}}) \not\subseteq \mathcal{Z}_s$. Thus, there is a list $\mathcal{L}_r$ containing $k+1$ vertex disjoint (x, v)-paths (recall x and v are the start and end vertices, respectively, of $\widetilde{P_{s,r}}$). Since $P_s = \widetilde{P_{s,1}} \circ \ldots \circ \widetilde{P_{s,r-1}} \circ P_{s,r}^\dagger$, and $P_{s,r}^\dagger$ is an (x, v)-path, from the above discussion for each $j \in [r-1]$, either $V(\widetilde{P_{s,j}}) \subseteq \mathcal{Z}_s$ or there exists a list $\mathcal{L}_j$ containing $k+1$ vertex disjoint paths from the start vertex of $\widetilde{P_{s,j}}$ to its end vertex. Also, there exists a list, $\mathcal{L}_r$, containing $k+1$ vertex disjoint paths from the start vertex of $P_{s,r}^\dagger$ to its end vertex. This completes the proof of the claim. ◁

As argued earlier, this completes the proof of the lemma. ◀

3.1 Finding a Small k-Cut Preserving Set for a Pair with Large Flow

As explained in Section 1.2, the proof of Lemma 3.3 will distinguish whether there is a k vertex-cut for (s, t) or not. The case where there is a no k vertex-cut is the easiest one, and will be dealt with the following lemma by simply keeping $k+1$ vertex disjoint paths.

▶ **Lemma 3.9.** *Let $D \in \mathcal{D}_\alpha$ be an acyclic digraph and $u, v \in V(D)$ be such that each (u, v)-vertex cut in D has size at least $k+1$. Then, a k-cut preserving set for (u, v) in D of size at most $(2\alpha - 1)(k+1) + 2$ exists and is computable in $n^{\mathcal{O}(1)}$ time, where $n = |V(D)|$.*

Proof. Since every (u, v)-vertex cut in D has size at least $k+1$, from Menger's Theorem, there are at least $k+1$ vertex-disjoint (u, v)-paths in D. Let $Q'_1, \ldots, Q'_{k+1}$ be a collection of some $k+1$ of these paths. We will now obtain a collection of $Q_1, \ldots Q_{k+1}$ vertex disjoint paths where the length of each Q_i is at most $2\alpha + 1$. To this end, we define each Q_i as some shortest (u, v)-path using the vertices of $V(Q'_i)$. We first claim that the length of Q_i is at most $2\alpha + 1$. For the sake of contradiction, suppose not. Then, from Observation 2.1, there exist $x, y \in V(Q_i)$ such that $(x, y) \in E(D)$. Since D is acyclic, x appears before y in the path Q_i. This contradicts that Q_i is a shortest (u, v)-path in $V(Q'_i)$. Let $\mathcal{Z} = \bigcup_{i \in [k+1]} V(Q_i)$. Clearly, $\{u, v\} \subseteq \mathcal{Z}$ and $|\mathcal{Z}| \leq (2\alpha - 1)(k+1) + 2$. The size bound follows because the length of each Q_i is at most $2\alpha + 1$, and u, v are the vertices common in each Q_i. To show that $\mathcal{Z}$ is a k-cut preserving set for (u, v) in D, consider the semi-$\mathcal{Z}$-based partition of P that is P itself. Then, $\{Q_1, \ldots, Q_{k+1}\}$ is the list for P containing $k+1$ internally vertex-disjoint $(V(D) \setminus \mathcal{Z})$-free (u, v)-paths. ◀

3.2 Finding a Small k-Cut Preserving Set of a Pair in a Tournament

As explained before, the proof of Lemma 3.3 will use induction on α. The next lemma handles the base case where $\alpha = 1$. It is somewhat more complicated compared to the arguments in Section 1.2; the reason for the complication is that we consider the digraph D such that the $D - \{u, v\} \in \mathcal{D}_\alpha$. Thus D is not "exactly" a tournament. This is required in the inductive case for the proof of Lemma 3.3.

▶ **Lemma 3.10.** *Let D be an acyclic digraph. Let $u, v \in V(D)$ be such that $N^+(u) = N^-(v) = \emptyset$ and $D - \{u, v\}$ is a tournament. Then, a k-cut preserving set for (u, v) in D of size at most $k^3 + 5k^2 + 3k$ exists and is computable in polynomial time.*

Proof. If all (u, v)-vertex cuts in D have size at least $k+1$, then the correctness follows from Lemma 3.9. Thus, for the rest of the proof assume that there is a (u, v)-vertex-cut in D of size at most k. Let $C = \{c_1, \ldots, c_\ell\}$ be a minimal (u, v)-vertex cut in D of size $\ell \leq k$.

▷ Claim 3.11. $C \subseteq N_D^+(u) \cup N_D^-(v)$.

Proof. Suppose not. Then, there exists $c_i \in C$ such that $c_i \notin N^+(u) \cup N^-(v)$. Since C is a minimal (u, v)-vertex cut in D, there exists a path, say P, from u to v in $D - (C \setminus \{c_i\})$. Let u' be the first vertex on P after u and v' be the last vertex of P before v. Since $D - \{u, v\}$ is an acyclic tournament, $(u', v') \in E(D)$. Since $u', v' \notin C$, we get a (u, v)-path in $D - C$, contradicting that C is a (u, v)-vertex cut in D. ◁

Let $I = \{i \in [\ell] \mid c_i \in N_D^-(v)\}$ and $J = \{j \in [\ell] \mid c_j \in N_D^+(u)\}$. For all $i \in I$, let $U_i = ver_D(u, c_i; C)$ and $D_i = D[U_i]$. For all $j \in J$, let $V_j = ver_D(c_j, v; C)$ and $D_j = D[V_j]$. For all $(i, j) \in [\ell]^2$, $i \neq j$, let $Q_{i,j} = ver_D(c_i, c_j; \emptyset)$ and $D_{i,j} = D[Q_{i,j}]$.

For each $i \in I$ (resp. $j \in J$, resp. $(i, j) \in [\ell]^2$, $i \neq j$), we will compute a k-cut preserving set $\mathcal{Z}_i$ (resp. $\mathcal{Z}_j$, resp. $\mathcal{Z}_{i,j}$) of (u, c_i) (resp. (c_j, v), resp. (c_i, c_j)) in D_i (resp. D_j, resp. $D_{i,j}$) of size at most $2k + 3$ (resp. $2k + 3$, resp. $k + 3$). The procedure to do so is as follows.

- **Computing $\mathcal{Z}_i$, $i \in I$:** First observe that U_i is a candidate for $\mathcal{Z}_i$. Thus, if $|U_i| \leq 2(k+1)$, set $\mathcal{Z}_i = U_i$. Otherwise, we have that $|U_i| \geq 2k + 3$. Since $D - \{u, v\}$ is an acyclic tournament, let π be the unique topological ordering of $D - \{u, v\}$. We divide this case further into two cases.
  - **Case 1: $|N^+(u) \cap U_i| \leq k$:** Let $\widetilde{U_i}$ be the last $k + 1$ vertices of U_i in π. Observe that $\widetilde{U_i} \subseteq N^-(c_i) \cap U_i$. Define $\mathcal{Z}_i = (N^+(u) \cap U_i) \cup \widetilde{U_i} \cup \{u, c_i\}$. Clearly, $|\mathcal{Z}_i| \leq 2k + 3$. To prove that $\mathcal{Z}_i$ is a k-cut preserving set for (u, c_i) in D_i, consider some (u, c_i)-path P in D_i, such that $V(P) \not\subseteq \mathcal{Z}_i$. We will show a $\mathcal{Z}_i$-replacement witness for P in D_i. Consider the semi-$\mathcal{Z}_i$-based partition of P, $P = P_1 \uplus P_2$, where P_1 is the arc $(u, x) \in E(P)$, for some $x \in N^+(u) \cap U_i$ and P_2 is the (x, c_i)-subpath of P. Clearly, $V(P_1) \subseteq \mathcal{Z}_i$. We claim that there are $k + 1$ vertex-disjoint (x, c_i)-paths in $\mathcal{Z}_i$. To see this, consider the following argument. Since $V(P) \not\subseteq \mathcal{Z}_i$, there exists a vertex $y \in V(P)$ such that $y \notin \mathcal{Z}_i$. Then, $y \in V(P_2)$. Since $y \notin \mathcal{Z}_i$, it in particular holds that $y \notin \widetilde{U_i}$. Thus, all the vertices of $\widetilde{U_i}$ appear after y in π. Since there is a (x, y)-path in D_i, x appears before y in π. Thus, x appears before all the vertices of $\widetilde{U_i}$ in π. Thus, because $D - \{u, v\}$ is a tournament, $\widetilde{U_i} \subseteq N^+(x) \cap U_i$. Since $\widetilde{U_i} \subseteq N^-(c_i) \cap U_i$, there are $|\widetilde{U_i}|$ many vertex disjoint (x, c_i)-paths in $\mathcal{Z}$. This completes the proof.
  - **Case 2: $|N^+(u) \cap U_i| > k$:** First observe that all the vertices of $N^+(u) \cap U_i$ appear before c_i in π. Since π is a topological ordering of $D - \{u, v\}$, there are $|N^+(u) \cap U_i| > k$ vertex-disjoint (u, c_i)-paths in $\mathcal{Z}_i$. Thus, each (u, c_i)-vertex-cut in D_i has size at least

$k+1$. In this case, let $\mathcal{Z}_i$ be the k-cut preserving set for (u, c_i) in D_i obtained from Lemma 3.9. Observe that $|\mathcal{Z}_i| \leq k+3$.

- **Computing $\mathcal{Z}_j$, $j \in J$:** $\mathcal{Z}_j$ can be computed using arguments symmetric to the previous case.
- **Computing $\mathcal{Z}_{i,j}$, $(i,j) \in [\ell]^2$, $i \neq j$:** First observe that all the vertices of $Q_{i,j} \setminus \{c_i, c_j\}$ appear after c_i and before c_j in π. Thus, there are $|Q_{i,j} \setminus \{c_i, c_j\}|$ many vertex-disjoint (c_i, c_j)-paths in $D_{i,j}$. If $|Q_{i,j}| \leq k-2$, then set $\mathcal{Z}_i = Q_{i,j}$, otherwise let $\mathcal{Z}_i$ be the k-cut preserving set for (c_i, c_j) in $D_{i,j}$ obtained from Lemma 3.9. In either case, $|\mathcal{Z}_i| \leq k+3$.

Let $\mathcal{Z} := \bigcup_{i \in I} \mathcal{Z}_i \cup \bigcup_{j \in J} \mathcal{Z}_j \cup \bigcup_{(i,j) \in [\ell]^2, i \neq j} \mathcal{Z}_{i,j}$. Observe that $C \subseteq \mathcal{Z}$. First note that $|\mathcal{Z}| \leq |I|(2k+3) + |J|(2k+3) + \ell^2(k+3) \leq k^3 + 5k^2 + 3k^2$ (the last inequality holds because $|I| + |J| = \ell$ and $\ell \leq k$). We will now show that $\mathcal{Z}$ is a k-cut preserving set for (u, v) in D. To see this, consider some(u, v)-path P, in D. Since C is a (u, v)-vertex-cut in D there exists a vertex of C on P. Let c_i be the first vertex of C on P and c_j be the last vertex of C on P (c_i could be the same as c_j). Let P_1 be the (u, c_i)-subpath of P, P_2 be the (c_i, c_j)-subpath of P and P_3 be the (c_j, v)-subpath of P (if c_i is the same as c_j, then P_2 is empty). Thus, $P = P_1 \circ P_2 \circ P_3$ is a semi-$\mathcal{Z}$-based partition of P (as $C \subseteq \mathcal{Z}$). Since $\mathcal{Z}_i$ is a k-cut preserving set for (u, c_i) in D_i, $\mathcal{Z}_i$ is a k-cut preserving set for (c_j, v) in D_j and $\mathcal{Z}_{i,j}$ is a k-cut preserving set for (c_i, c_j) in $D_{i,j}$, and $\mathcal{Z}_i, \mathcal{Z}_j, \mathcal{Z}_{i,j} \subseteq \mathcal{Z}$, from Observation 3.4, $\mathcal{Z}$ is a k-cut preserving set for (u, v) in D. ◀

3.3 Finding a small k-cut preserving set for a pair in a $D \in \mathcal{D}_\alpha$

We are now ready to prove Lemma 3.3.

▶ **Lemma 3.3** (k-Cut Preserving Lemma). *Let D be an acyclic digraph, and $u, v \in V(D)$ be such that $N^-(u) = N^+(v) = \emptyset$. Additionally, let $D - \{u, v\} \in \mathcal{D}_\alpha$. Then there exists a k-cut preserving set for (u, v) in D of size at most $f(\alpha)$, where $f(1) = k^3 + 5k^2 + 3k$ and for $\alpha > 1$, $f(\alpha) = k^2 g(\alpha) + 2kh(\alpha)$, $g(\alpha) = (2k + (k + kf(\alpha-1))^2) f(\alpha-1)$ and $h(\alpha) = (k^2+k)g(\alpha) + kf(\alpha-1)$. Moreover, such a set can be found in time $n^{\mathcal{O}(1)}$, where $n = |V(D)|$.*

Proof. We prove this lemma using induction on α. When $\alpha = 1$, the proof follows from Lemma 3.10.

▷ Claim 3.12. Let $x, y \in V(D) \setminus \{x, y\}$. Then, a k-cut preserving set for (x, y) of size $g(\alpha)$ in any digraph D' that is a subgraph of D where $u, v \notin V(D')$, can be found in polynomial time.

Proof. Let W be a minimum (x, y)-vertex-cut in D'. If $|W| > k$, then the claim follows from Lemma 3.9. Thus, we are now in the case where $|W| \leq k$. For each $w \in W$, let $\mathcal{Z}(x, w)$ (resp. $\mathcal{Z}(w, y)$) be a k-cut preserving set for (x, w) (resp. (w, y)) in $D'[ver_{D'}(x, w; W)]$ (resp. $D'[ver_{D'}(w, y; W)]$). Let $B = N^-_{D'}(y) \cap \bigcup_{w \in W} \mathcal{Z}(w, y)$. For each $(\mathtt{a}, \mathtt{b}) \in (W \cup B)^2$, let $\mathcal{Z}(\mathtt{a}, \mathtt{b})$ be a k-cut preserving set for $(\mathtt{a}, \mathtt{b})$ in $D'[ver'_D(\mathtt{a}, \mathtt{b}; W \cup N^-(y))]$. Then, from Lemma 3.6, $\mathcal{Z}(x, y) := \bigcup_{w \in W} (\mathcal{Z}(x, w) \cup \mathcal{Z}(w, y)) \cup \bigcup_{(\mathtt{a},\mathtt{b}) \in (W \cup B)^2} \mathcal{Z}(\mathtt{a}, \mathtt{b})$ is a k-cut preserving set for (x, y) in D'.

We will now show that for any $w \in W$ and $(\mathtt{a}, \mathtt{b}) \in (W \cup B)^2$, each digraph among $D'[ver_{D'}(x, w; W)]$, $D'[ver_{D'}(w, y; W)]$ and $D'[ver_{D'}(\mathtt{a}, \mathtt{b}; W \cup N^-_{D'}(y))]$ has independence number strictly smaller than α. Then, from induction hypothesis and the expression for $\mathcal{Z}(x, y)$ written above, we will conclude that a k-cut preserving set for (x, y) in D' of size $g(\alpha)$ can be found in polynomial time. To see that the independence number of $D'[ver_{D'}(x, w; W)]$

is strictly less than α, observe that y is not adjacent to any vertex in $ver_{D'}(x, w; W)$, as W is an (x, y)-vertex cut in D'. Thus, any independent set of $D'[ver_{D'}(x, w; W)]$ together with y is an independent set of D' and hence of D. Since $y \notin \{u, v\}$, $u, v \notin V(D')$ and the independence number of $D - \{u, v\}$ is α, we have that the independence number of $D'[ver_{D'}(x, w; W)]$ is strictly smaller than α. A similar argument holds for $D'[ver_{D'}(w, y; W)]$ as in this case x is not adjacent to any vertex of $ver_{D'}(w, y; W)$. For $D'[ver_{D'}(\mathtt{a}, \mathtt{b}; W \cup N^-_{D'}(y))]$, since $ver_{D'}(\mathtt{a}, \mathtt{b}; W \cup N^-_{D'}(y)) \cap N^-_{D'}(y) = \emptyset$, $u, v \notin V(D')$ and $N^+_{D'}(y) = \emptyset$, any independent set of $D'[ver_{D'}(\mathtt{a}, \mathtt{b}; W \cup N^-_{D'}(y))]$ together with y is an independent set in $D - \{x, y\}$. Since $D - \{x, y\}$ has independence number α, $D'[ver_{D'}(\mathtt{a}, \mathtt{b}; W \cup N^-_{D'}(y))]$ has independence number strictly smaller than α. ◁

Let C be a minimum (u, v)-vertex-cut in D. If $|C| > k$, then the lemma follows from Lemma 3.9. Thus, for the remainder of the proof we assume that $|C| \leq k$. For each $c \in C$, let $U_c = ver_D(u, c; C)$, $V_c = ver_D(c, v; C)$, $\mathcal{Z}(u, c)$ be a (u, c) k-cut preserving set in $D[U_c]$, and $\mathcal{Z}(c, v)$ be a (c, v) k-cut preserving set in $D[V_c]$. For each $(c, c') \in C^2$, $c \neq c'$, let $Q_{c,c'} = ver_D(c, c'; C)$, and $\mathcal{Z}(c, c')$ be a k-cut preserving set in $D[Q_{c,c'}]$. Then from Lemma 3.5, $\mathcal{Z} := \bigcup_{c \in C} \mathcal{Z}(u, c) \cup \mathcal{Z}(c, v) \cup \bigcup_{(c,c') \in C^2, c \neq c'} \mathcal{Z}(c, c')$ is a k-cut preserving set for (u, v) in D. Since $C \cap \{u, v\} = \emptyset$, from Claim 3.12, for each $(c, c') \in C^2$, $c \neq c'$, $\mathcal{Z}(c, c')$ of size $g(\alpha)$ can be computed in polynomial time. In the remainder of the proof, we will show how to compute $\mathcal{Z}(u, c)$ and $\mathcal{Z}(c, v)$, for any $c \in C$, of the desired size. We will only give the proof of construction of $\mathcal{Z}(u, c)$ as the proof for $\mathcal{Z}(c, v)$ is symmetrical.

▷ Claim 3.13. For any $c \in C$, $\mathcal{Z}(u, c)$ of size $h(\alpha)$ can be computed in polynomial time.

Proof. For ease of notation, let $\widehat{D} = D[U_c]$. Let A be a minimum (u, c)-vertex-cut in $\widehat{D}$. First note that $A \cap \{u, v\} = \emptyset$. If $|A| > k$, then the claim follows from Lemma 3.9. Thus, for the remainder of the proof, assume that $|A| \leq k$.

For each $a \in A$, let $\widehat{U_a} = ver_{\widehat{D}}(u, a; A)$, $\widehat{V_a} = ver_{\widehat{D}}(a, c; A)$, $\widehat{\mathcal{Z}}(u, a)$ be a (u, a) k-cut preserving set in $\widehat{D}[\widehat{U_a}]$ and $\widehat{\mathcal{Z}}(a, c)$ be a (a, c) k-cut preserving set in $\widehat{D}[\widehat{V_a}]$. For each $(a, a') \in A^2$, $a \neq a'$, let $R_{a,a'} = ver_{\widehat{D}}(a, a'; A)$ and $\widehat{\mathcal{Z}}(a, a')$ be a k-cut preserving set in $\widehat{D}[R_{a,a'}]$. Then from Lemma 3.5, $\mathcal{Z}(u, c) := \bigcup_{a \in A}(\widehat{\mathcal{Z}}(u, a) \cup \widehat{\mathcal{Z}}(a, c)) \cup \bigcup_{(a,a') \in A^2, a \neq a'} \widehat{\mathcal{Z}}(a, a')$ is a k-cut preserving set for (u, c) in D. Since $A \cap \{u, v\} = \emptyset$ and $c \in \{u, v\}$, from Claim 3.12, for each $a \in A$, $(a, a') \in A^2$, $a \neq a'$, $\widehat{\mathcal{Z}}(a, c)$ and $\widehat{\mathcal{Z}}(a, a')$ of size $g(\alpha)$ can be computed in polynomial time. Moreover, the independence number of $\widehat{D}[\widehat{U_a}] - \{u, a\}$ is strictly smaller than α because $c(\neq v)$ is not adjacent to any vertex in $\widehat{U_a}$, besides possibly u and a. Thus, for each $a \in A$, a set $\widehat{\mathcal{Z}}(u, a)$ of size $f(\alpha - 1)$ can be computed in polynomial time by the induction hypothesis. This finishes the proof of the claim. ◁

Thus, from the previous arguments and Claim 3.13, we have that $\mathcal{Z}$ is a k-cut preserving set for (u, v) in D of size at most $k^2 g(\alpha) + 2kh(\alpha)$. ◀

A rough computation gives that, for any k, $g(\alpha) \leq 6k^2 f(\alpha - 1)$ and $h(\alpha) \leq 8k^4 f(\alpha - 1)$. This imply that $f(\alpha) \leq 22k^5 f(\alpha - 1)^3$. By noting that $f(1) \leq 22k^5$, we can show the following observation.

▶ **Observation 3.14.** *For any α and k, there exists a k-cut preserving set of size smaller than $f(k, \alpha) = (22k^5)^{4^\alpha}$.*

3.4 k-Cut Preserving Sets for a Set of Vertices

Below we also define a notion of k-cut preserving sets for a set of vertices. Such a notion will come handy in our applications. Given a digraph D and $X \subseteq V(D)$, for each $(u,v) \in X^2$, we define the digraph $D^X_{(u,v)}$ as follows (note that u could be equal to v). Let $R = V(D) - X$. Then, $D^X_{(u,v)}$ is the supergraph of $D[R]$ obtained by adding two new vertices u^+ and v^- together with the following set of additional arcs: $\{(u^+, x) : x \in R, (u,x) \in E(D)\} \cup \{(x, v^-) : x \in R, (x,v) \in E(D)\}$.

▶ **Definition 3.15** (k-Cut Preserving Set for a Set of Vertices). *For any digraph D, a positive integer k and $X \subseteq V(D)$, we say that $X \subseteq \mathcal{Z} \subseteq V(D)$ is a* k-cut preserving set for X, *if for all $(u,v) \in X^2$, $\mathcal{Z}$ is a k-cut preserving set for (u,v) in $D^X_{(u,v)}$.*

▶ **Lemma 3.16.** *For any digraph $D \in \mathcal{D}_\alpha$, a positive integer k, and $S \subseteq V(D)$ such that $D - S$ is a acyclic, a k-cut preserving set for S of size at most $|S|^2 f(k,\alpha)$ can be found in polynomial time, where $f(k,\alpha) \leq (22k^5)^{4^\alpha}$.*

Proof. For each pair $(u,v) \in S^2$ (u and v could be equal), let $\mathcal{Z}_{(u,v)}$ be the a k-cut preserving set for (u^+, v^-) in $D^S_{(u,v)}$ obtained from Lemma 3.3. From the definition of k-cut preserving set for S, $\mathcal{Z} = \bigcup_{(u,v)\in S^2} \mathcal{Z}_{(u,v)}$ is a k-cut preserving set for S. From Observation 3.14, for any $(u,v) \in S^2$, $|\mathcal{Z}_{(u,v)}| \leq f(k,\alpha)$. Thus, we conclude the correctness of the lemma. ◀

4 Fault-Tolerant (S,S)-Reachability

In this section, we prove Lemma 1.1. Recall that (D, S, ℓ, k) is an instance of FTR(S,S) where $D \in \mathcal{D}_\alpha$, $S \subseteq V(D)$ and ℓ, k are positive integers such that each strongly connected component of $D - S$ has size at most ℓ. The goal is to compute a subgraph H of D of size $k^{2^{\mathcal{O}(\alpha)}}$ such that, for any $A \subseteq E(D)$ of size at most k, for any $s,t \in S$, if $D - A$ has an (s,t)-path, then so does $H - A$. It is not difficult to see from Lemma 3.2 that if $\mathcal{Z}$ is a k-cut preserving set for S in D, then $H = D[\mathcal{Z}]$ is a solution for (D, S, ℓ, k) (for any ℓ). When $\ell = 1$, $D - S$ is acyclic and hence a k-cut preserving set for S can be computed using Lemma 3.16. When $\ell > 1$, in order to use Lemma 3.16 we modify the digraph D to turn $D - S$ acyclic. We now describe the operation, which we call dagify, that is used to turn $D - S$ acyclic. Informally, for each strongly connected component SC of D we turn it into an independent set while preserving the paths in D that use the vertices of SC. This is achieved by creating a new vertex for every ordered pair of vertices (say, (u,v)) in SC. Such a vertex represents the existence of a (u,v)-path in the strongly connected component SC. In fact, in the path in the modified graph, each new vertex corresponding to some pair (u,v) can be replaced by some (u,v)-path from the strongly connected component SC to yield a path in the original graph. Then, arcs between two vertices in this newly constructed vertex set are put in such a way that the concatenation of the paths corresponding to these new vertices gives a path in D. This idea is formalized below.

▶ **Definition 4.1** (dagify(D,R)). *Let D be a digraph, $R \subseteq V(D)$ and $S = V(D) \setminus R$. Let $SC_1, \ldots, SC_d$ be the strongly connected components of $D[R]$. For $a \in [d]$, let $V(SC_a) = \{v^a_1, \ldots, v^a_{n_a}\}$, where $n_a = |V(SC_a)|$. Then, $D^\dagger_R :=$ dagify(D,R) is the digraph defined as:*

Vertex set of $D^\dagger_R$: *For each $a \in [d]$, let $SC^\dagger_a = \{\mathbf{v}^a_{ij} \mid (v^a_i, v^a_j) \in \{SC_a\}^2, i,j \in [n_a]\}$. Let $R^\dagger = \cup_{a\in[d]} SC^\dagger_a$ and $V(D^\dagger_R) = R^\dagger \cup S$.*

Arc set of $D^\dagger_R$: *It contains all the arcs of D with both end-points in S. For each $a \in [d]$, ${SC^\dagger}_a$ is an independent set in $D^\dagger_R$. For any $a \in [d]$, $s \in S$ and $i,j \in [n_a]$, $(s, \mathbf{v}^a_{ij}) \in E(D^\dagger_R)$ if and only if $(s, v^a_i) \in E(D)$. Similarly, $(\mathbf{v}^a_{ij}, s) \in E(D^\dagger_R)$ if and only if $(v^a_j, s) \in E(D)$. We put the arcs between $SC^\dagger_a$ and $SC^\dagger_b$, for distinct $a,b \in [d]$ as follows. For any $i,j \in [n_a]$ and $i',j' \in [n_b]$, $(\mathbf{v}^a_{ij}, \mathbf{v}^b_{i'j'}) \in E(D^\dagger_R)$ if and only if $(v^a_j, v^b_{i'}) \in E(D)$.*

For a set of vertices of $X^\dagger \subseteq D_R^\dagger$, $full\text{-}comp(X^\dagger)$ denotes the set of vertices of $V(D)$ such that, for each $\mathbf{v}_{i,j}^a \in X^\dagger$, all the vertices of SC_a belong to full-comp$(X^\dagger)$. Also all the vertices of S that belong to $X^\dagger$, belong to $full\text{-}comp(X^\dagger)$. Observe that $|full\text{-}comp(X^\dagger)| \leq \ell^2 \cdot |X^\dagger|$, where ℓ is the upper bound on the size of each SC_a. Note from the construction above that, for any $s,t \in S$ and an (s,t)-path $P^\dagger$ in $D_R^\dagger$, there exists an (s,t)-path P in D such that $V(P) \subseteq full\text{-}comp(P^\dagger)$. The following observations state a few properties of the digraph $D_R^\dagger$ that would be useful when we want to find a k-cut preserving set for $D_R^\dagger$ using Lemma 3.16.

▶ **Observation 4.2.** *$D_R^\dagger[R^\dagger]$ is acyclic.*

Proof. Recall, from the construction of $D_R^\dagger$, that $R^\dagger = \bigcup_{a\in[d]} SC_a^\dagger$ and each $SC_a^\dagger$ is an independent set in $D_R^\dagger$. Without loss of generality, let $SC_1, \ldots, SC_d$ be the strongly connected components of $D[R]$ ordered as in their topological ordering. Then, there is no arc from a vertex of SC_b to a vertex of SC_a, for any $b > a$, in D. Thus, from the construction of $D_R^\dagger$, there is no arc from any $\mathbf{v}_{ij}^b$ to any $\mathbf{v}_{i'j'}^a$ $(b > a)$. This shows that $D_R^\dagger[R^\dagger]$ is acyclic. ◀

▶ **Observation 4.3.** *If $D \in \mathcal{D}_\alpha$ and every strongly connected component of $D[R]$ has size at most ℓ, then $D_R^\dagger \in \mathcal{D}_{\ell^2\alpha}$.*

Proof. Recall that $R^\dagger = \bigcup_{a\in[d]} {SC^\dagger}_a$ and $D_R^\dagger[SC_a^\dagger]$ has no arc. From the construction of $D_R^\dagger$, for each $a \in [d]$, $|SC_a^\dagger| \leq \ell^2$. Finally, since $D \in \mathcal{D}_\alpha$, from the construction of $D_R^\dagger$, the size of any maximum independent set in $D_R^\dagger$ is at most $\max_{a\in[d]} |SC_a^\dagger| \cdot \alpha \leq \ell^2\alpha$. ◀

We define some terminology that would come handy later. For any $A \subseteq E(D)$, we say that a vertex $v \in V(D)$ *is affected by* A if there exists some arc of A that is incident on v. The *set affected by A in $D_R^\dagger$* is the set of vertices of $D_R^\dagger$ containing the union of the vertices in $SC_a^\dagger$, for each $a \in [d]$ such that a vertex in SC_a is affected by A in D.

▶ **Observation 4.4.** *Let D be a digraph, $R \subseteq V(D)$ and $S = V(D) \setminus R$. Let $A \subseteq E(D)$ of size at most k. Let $\mathcal{A}^\dagger$ be the set affected by A in $D_R^\dagger$. Recall the construction of $D_R^\dagger$ from Definition 4.1. For some $\mathbf{v}_{ij}^a, \mathbf{v}_{i'j'}^b \in R^\dagger$, let $P^\dagger$ be an $\mathcal{A}^\dagger$-free $(\mathbf{v}_{ij}^a, \mathbf{v}_{i'j'}^b)$-path in $D_R^\dagger$. Then there exists a $(v_i^a, v_{j'}^b)$-path P in D such that: $V(P) \subseteq full\text{-}comp(P^\dagger)$ and, P does not use any arc of A.*

Proof. Recall the construction of dagify(D,R). Consider any path P obtained from $P^\dagger$ by replacing all the vertices of $R^\dagger$ as follows. If for any $c \in [d]$, $i^*, j^* \in [n_c]$, $\mathbf{v}_{i^*j^*}^c \in V(P^\dagger)$, then replace $\mathbf{v}_{i^*j^*}^c$ in $P^\dagger$ by any $(v_{i^*}^c, v_{j^*}^c)$-path in the strongly connected component SC_c. Clearly, the path P obtained is a $(v_i^a, v_{j'}^b)$-path in D and $V(P) \subseteq full\text{-}comp(P^\dagger)$. Also from the definition of $\mathcal{A}^\dagger$ and the fact that $P^\dagger$ is $\mathcal{A}^\dagger$-free, we get that P cannot use an arc of A. ◀

From the construction in Definition 4.1, for any $s,t \in S$, for an (s,t)-path P in D, we can associate a unique (s,t)-path $P^\dagger$ in $D_R^\dagger$. This is elaborated below. Consider the digraph $D_R^\dagger$ obtained by dagify(D,R). $(v_i^a, v_j^a) \in SC_a^2$ for some component SC_a of $D[R]$. Let $s,t \in S$. Let P be an S-free (s,t)-path in D. For any such path P, we define the notion of a *reduced path* of P in $D_R^\dagger$ as follows. Consider the unique partition $P = P_s \circ P_{i_1} \circ \ldots \circ P_{i_q} \circ P_t$ such that P_s is an arc (s,u) where $u \in V(SC_{i_1})$, P_t is an arc (v,t) where $v \in V(SC_{i_q})$ and for each $j \in [q]$, $V(P_{i_j}) \subseteq V(SC_{i_j})$, where $i_1, \ldots, i_j \in [d]$ and $i_1 < \ldots < i_q$. For each $j \in [q]$, let P_{i_j} be a $(v_{p_j}^{i_j}, v_{r_j}^{i_j})$-path. Consider the vertex $\mathbf{v}_{p_j,r_j}^{i_j}$ in $V_{i_j} \subseteq R^\dagger \subseteq V(D_R^\dagger)$. From the construction of $D_R^\dagger$, we get the (s,t)-path $P^\dagger = s \circ \mathbf{v}_{p_1,r_1}^{i_1} \circ \mathbf{v}_{p_2,r_2}^{i_2} \circ \ldots \circ \mathbf{v}_{p_q,r_q}^{i_q} \circ t$ in $D_R^\dagger$. This (s,t)-path $P^\dagger$ in $D_R^\dagger$ is called the *reduced path of P in $D_R^\dagger$*.

Proof of Lemma 1.1. Recall (D, S, ℓ, k) is an instance of FTR(S, S). Let $R = V(D) \setminus S$. Let $D^\dagger_R$ be obtained by dagify(D, R). From Observations 4.2 and 4.3, Lemma 3.16 can be used to compute a $(2k\ell^2 + 1)$-cut preserving set for S in $D^\dagger_R$. Let $\mathcal{Z}^\dagger$ be such a set. Let $\mathcal{Z} = \mathit{full\text{-}comp}(\mathcal{Z}^\dagger)$. We claim that $H = D[\mathcal{Z}]$ is a solution to the instance (D, S, ℓ, k). (First note that the size bound on H follows from Lemma 3.16 and the fact that each strongly connected component of R has size at most ℓ.)

Towards this let $A \subseteq E(D)$ of size at most k, $s, t \in S$ and P be an (s, t)-path in $D - A$. We need to show that there is some (s, t)-path in $H - A$ too. Let $P = P_1 \circ \ldots \circ P_q$ be the S-based partition of P such that each P_i is an (s_i, t_i)-path. Then it suffices to show that for each fixed $i \in [q]$, there is some (s_i, t_i) path in $H - A$ (these paths would yield a closed walk from s to t in $H - A$ and hence an (s, t)-path in $H - A$). In the remaining part of the proof, we focus on proving this. Note that each P_i is S-free. Fix any $i \in [q]$. For the ease of notation, let us call the path P_i as P, vertices s_i, t_i as s, t respectively.

Let $P^\dagger$ be the reduced path corresponding of P in $D^\dagger_R$. Since $\mathcal{Z}^\dagger$ is a $(2k\ell^2 + 1)$-cut preserving set for $P^\dagger$ in $D^\dagger_R$, consider a $\mathcal{Z}^\dagger$-witnessing replacement $P^\dagger = P^\dagger_1 \circ \ldots \circ P^\dagger_r$. Recall the notation from the construction in Definition 4.1.

For an arbitrary $c \in [r]$, let $P^\dagger_c$ be a $(\mathbf{v}^a_{ij}, \mathbf{v}^b_{i',j'})$-path (or $(s, \mathbf{v}^a_{ij})$-path or $(\mathbf{v}^a_{ij}, s)$-path). Observe that, since $P^\dagger$ is the reduced path of P, to finish the proof of the lemma, it is enough to show a (v^a_i, v^b_j)-path (or (s, v^a_i)-path or (v^a_i, s)-path) exists in $H - A$. Without loss of generality, let $P^\dagger_c$ be a $(\mathbf{v}^a_{ij}, \mathbf{v}^b_{i',j'})$-path, the other cases hold due to similar arguments.

As $P^\dagger = P^\dagger_1 \circ \ldots \circ P^\dagger_d$ is a $\mathcal{Z}^\dagger$-witnessing replacement, one of the following cases arises.

1. $V(P^\dagger_c) \subseteq \mathcal{Z}^\dagger$. Since $P^\dagger$ is the reduced path of P, consider the (v^a_i, v^b_j)-subpath, say P'_c, of P. Then, $V(P'_c) \subseteq \mathit{full\text{-}comp}(P^\dagger_c) \subseteq \mathcal{Z}$ (because $V(P^\dagger_c) \subseteq \mathcal{Z}^\dagger$). Also since P does not have an arc in A, so does P'_c. Thus, by the construction of H, P'_c is a path in $H - A$.
2. There is a list $\mathcal{L}_i$ of $2k\ell^2 + 1$ internally vertex-disjoint $(\mathbf{v}^a_{ij}, \mathbf{v}^b_{i'j'})$-paths in $D^\dagger_R[\mathcal{Z}^\dagger]$. Let $\mathcal{A}^\dagger$ be the set of affected vertices of A in $D^\dagger_R$. Clearly, $|\mathcal{A}^\dagger| \leq 2k\ell^2$. Then there exists a path in $\mathcal{L}_i$ that is $\mathcal{A}^\dagger$-free. Then from Observation 4.4, there exists a (v^a_i, v^b_j)-path, say P'_c, such that $V(P'_C) \subseteq \mathit{full\text{-}comp}(P^\dagger_c) \subseteq \mathcal{Z}$ and, that does not use an arc of A. From the construction of H, P'_c is a path in $H - A$.

This finishes the proof of the lemma. ◀

5 Conclusion

In this paper, we presented a sparsification procedure for the class of acyclic digraphs (or more generally, "almost" acyclic) of bounded independence, to preserve the (both normal and parity-based) reachability from a given terminal set S to a given terminal set T under the failure of any set of at most k arcs. In particular, it outputs a digraph whose size is completely *independent* of n and polynomial in k, while even the simple classes of directed paths and tournaments admit no sparsifier whose output is a digraph of less than $n - 1$ arcs already when $k = 1$. Apart from being interesting on its own from the perspective of fault tolerance, we also showed that our sparsification procedure finds applications in Kernelization. Specifically, we proved that the classic Directed Feedback Arc Set problem as well as Directed Edge Odd Cycle Transversal (which, in sharp contract, is W[1]-hard on general digraphs) admit polynomial kernels on bounded independence number digraphs. In fact, for any $p \in \mathbb{N}$, we designed a polynomial kernel for hitting all cycles of length ℓ where (ℓ mod $p = 1$). Additionally, we derived complementary results that assert the NP-hardness of DEOCT on tournaments, as well as its admittance of a sub-exponential time parameterized algorithm on digraphs of bounded independence.

We conclude the paper with a few directions for further research. Our result, currently, holds when the input digraph D is "almost acyclic" and has bounded independence number. From the example of the tournament described in the introduction (the one that is obtained by taking a transitive tournament and reversing the arcs along the Hamiltonian path defined by its topological ordering), it seems that some notion of "almost acyclic" might be necessary to have fault tolerant subgraphs whose size avoid the dependence on n. On the other hand, it might be possible to ask for something weaker than bounded independence number. For example, forbidding the existence of an induced P_α, the directed path on α vertices.

Question 1. Does $\mathrm{FTR}(S, S)$ admit a subgraph of size independent of n on digraphs that are "almost acyclic" and have no induced P_α, for some fixed positive integer α?

It is not very difficult to observe that our results (Lemmas 1.1 and 1.2) also hold when the input graph is undirected and has bounded independence number. It would be interesting (because of the arguments discussed earlier) if one could obtain similar results when the input undirected graph has no induced P_α.

Question 2. Does $\mathrm{FTR}(S, S)$ admit a subgraph of size independent of n when the input graph is undirected and has no induced P_α, for some fixed positive integer α?

It would also be interesting to discover other (di)graph classes where the dependence on n of the size of the output subgraph can be sublinear, for example, $\log n$, for $\mathrm{FTR}(S, S)$ and also for other fault tolerant graph properties.

Abstract

Biological neural computation is inherently asynchronous due to large variations in neuronal spike timing and transmission delays. So-far, most theoretical work on neural networks assumes the *synchronous* setting where neurons fire simultaneously in discrete rounds. In this work we aim at understanding the barriers of asynchronous neural computation from an algorithmic perspective. We consider an extension of the widely studied model of synchronized spiking neurons [Maass, Neural Networks 97] to the asynchronous setting by taking into account edge and node delays.

- **Edge Delays:** We define an asynchronous model for spiking neurons in which the latency values (i.e., transmission delays) of non self-loop edges *vary* adversarially over time. This extends the recent work of [Hitron and Parter, ESA'19] in which the latency values are restricted to be fixed over time. Our first contribution is an impossibility result that implies that the assumption that self-loop edges have no delays (as assumed in Hitron and Parter) is indeed necessary. Interestingly, in real biological networks self-loop edges (a.k.a. autapse) are indeed free of delays, and the latter has been noted by neuroscientists to be crucial for network synchronization.

  To capture the computational challenges in this setting, we first consider the implementation of a single NOT gate. This simple function already captures the fundamental difficulties in the asynchronous setting. Our key technical results are space and time upper and lower bounds for the NOT function, our time bounds are *tight*. In the spirit of the distributed synchronizers [Awerbuch and Peleg, FOCS'90] and following [Hitron and Parter, ESA'19], we then provide a general synchronizer machinery. Our construction is very modular and it is based on efficient circuit implementation of threshold gates. The complexity of our scheme is measured by the overhead in the number of neurons and the computation time, both are shown to be polynomial in the largest latency value, and the largest incoming degree Δ of the original network.
- **Node Delays:** We introduce the study of asynchronous communication due to variations in the response rates of the neurons in the network. In real brain networks, the *round duration* varies between different neurons in the network. Our key result is a simulation methodology that allows one to transform the above mentioned synchronized solution under edge delays into a synchronized under node delays while incurring a small overhead w.r.t space and time.

1 Introduction

Understanding how the brain works, as a computational device, is a central challenge of modern neuroscience, artificial intelligence, and lately also in theoretical computer science and distributed computing [18, 19, 20, 17, 16, 32, 6, 39, 37]. This line of work usually assumes a simple synchronized model [23, 24] in which neurons fire simultaneously in discrete rounds in response to their neighboring neurons that fired in the previous round. This model, while being very convenient for algorithm design, does not take into account the inherent *asynchronous* nature of neural communication. In the neuroscience literature it has been noted that the asynchronous nature of these networks mostly stems from two independent sources [29]: *edge delays* (known as response latency[1].) [35, 5] and *node delays* (known as refractory period) [34, 3]. In this paper, we aim at understanding the computational cost incurred by such asynchronous communication. The overhead is measured by the overhead in the number of neurons and computation time required to compute a certain function. We believe that understanding the computational power, limitations and the connections between these models go beyond the setting of spiking neurons, and might also be relevant for the theory of digital logic design and circuit computation in general.

The Standard Synchronous Model [23, 24]. Before describing our asynchronous models, we first revise the standard synchronous model formally defined by Maass. In this model, the network evolves in discrete, synchronous *rounds* as a Markov chain where each neuron u in the network is a probabilistic threshold gate with a threshold (or bias) value $b(u)$. In every round t, the firing probability of neuron u only depends on the firing status of its incoming neighbors in the preceding round $t-1$. Formally, the potential $\text{pot}_t(u)$ of neuron u in round t is defined by the weighted sum over its incoming neighbors that fired in round $t-1$. The neuron u fires in round t with probability that depends on the quantity $\text{pot}_t(u) - b(u)$.

1.1 Asynchronous Computation with Bounded Edge Delays

We define an asynchronous model with edge delays bounded[2] by some given integer L. The dynamic of the network $\mathcal{N}$ is specified by a latency function $\ell : V \times V \times \mathbb{N} \to \mathbb{N}_{\leq L}$ interpreted as follows: For every neuron u firing in round τ, its spike reaches its outgoing neighbor v within $\ell(u, v, \tau)$ rounds where $\ell(u, v, \tau) \in [1, L]$ might be chosen adversarially for every $u \neq v$, and every round τ. The network solution $\mathcal{N}$ should then output the desired solution for *any* adversarial choice of the latency function ℓ. Setting $L = 1$ yields the standard synchronous model.

Asynchronous computation with edge delays was recently introduced by Hitron and Parter [12]. Their model is similar to ours only that in their model, the edge latencies are required to be *fixed* over time, whereas in our model the adversary is allowed to change it from round to round. The model of Hitron and Parter includes an additional restriction on the adversary (that sets the latency values) by requiring that self-spikes, i.e., of the form $\langle u, u, \tau \rangle$ have no latency and arrive within a single round to their destination. This assumption is justified in [12] by the experimental evidence that self-spikes in brain networks have almost no delays [14]. It is commonly believed in the neuroscience community that this no-delay property of self-edges is in fact essential for network synchronization [33, 21, 40, 8].

[1] Throughout, we use the terms edge-delay and latency interchangeably.

[2] This bound is crucial as will be later implied by our lower bound results that depend on L. E.g., both the computation time and the size of the network in this model *must* depend on L.

In this work, we provide a theoretical support for this hypothesis by showing that without such an assumption, one cannot even implement a single AND gate in this model. This impossibility result holds already in a setting where $L = 2$, the edge latencies are fixed over time (as assumed in [12]), and the computation time and network size are allowed to be unbounded. For this reason, we will mostly consider in this paper *nice* latency functions in which all self-spikes have a latency value of one round.

1.2 Asynchronous Computation with Bounded Node Delays

We next turn to consider an alternative source for asynchronous communication due to variations in the response timing of the individual neurons in the network. In real brain networks, for every neuron u there is a predefined time interval between two consecutive spikes of u. The length of this interval, which we call *round*, varies considerably among different neurons in the network [34, 3]. This poses the challenge of creating a synchronized response at the network level. To account this behavior, we consider a model in which network's evolution proceeds in *seconds*. A second in this context is simply the smallest measurable time unit. For a given integer $T \geq 1$, the dynamics is specified by a node-delay function $t : V \to \mathbb{N}_{\leq T}$ interpreted as follows: the round duration of each neuron v consists of $t(v)$ seconds. Specifically, the i^{th} round of v is defined by the time interval $R_i(v) = [(i-1)t(v)+1, i \cdot t(v)]$ for every $i \geq 1$. The neuron u fires in the second $i \cdot t(v)$ (i.e., at the end of its i^{th} round) only if the total potential due to spikes arriving in the interval $R_i(v)$ is sufficiently large. The network solution $\mathcal{N}$ should then output the desired solution for *any* adversarial choice of the node-delay function t. The input parameter T sets a bound on the differences between the round duration over all neurons in the network. Setting $T = 1$ yields the standard synchronous model.

Observe that the edge and node delay models do not imply one another. In the edge latency model, even though the spikes arrive in adversarially chosen rounds, all neurons in round τ still depend only on the spikes arriving in round τ. Thus, the duration of a round for all the neurons in the network is the same: a single tick (or a second) of the global clock. In contrast, in the node delay model, the adversary selects the round duration for each neuron which has two physical interpretations. First, it determines the time duration over which the potential due to arriving spikes is accumulated. In addition, it also determines the time interval between two consecutive spikes by the given neuron. In one of our most technically involved results, we show a non-trivial reduction between the edge delay and the node delay models, provided that the input network satisfies certain properties.

Finally, we note that this model has several variations which are in fact supported by our simulation results (from edge delays to node delays). In particular, one can consider a more elaborated setting in which the duration of each round per node varies in an adversarial manner *over time*, i.e., the node-delay function in such a model is of the form $t : V \times \mathbb{N}_{\geq 1} \to \mathbb{N}_{\leq T}$ interpreted as follows: the i^{th} round duration on each neuron v consists of $t(v, i)$ seconds. For example, in such a model the i^{th} round of node u can consists of 2 seconds while its $(i+1)^{th}$ round might consist of 100 seconds. In another variation, both edge and node delays are combined and the dynamic is specified by an L-bounded edge latency function $\ell : V \times V \times \mathbb{N}_{\geq 1} \to \mathbb{N}_{\leq L}$ and a T-bounded node-delay function $t : V \times \mathbb{N}_{\geq 1} \to \mathbb{N}_{\leq T}$.

1.3 Synchronizers

In the spirit of Awerbuch and Peleg's synchronizers for distributed networks [2] and the recent work of [12], our primary goal with respect to upper bound results is to provide a general simulation methodology that takes any n-neuron network $\mathcal{N}$ that *solves* the problem

in the standard synchronized setting (i.e., in which all spikes arrive within a single round) and transforms it into an "analogous" network $\mathsf{Sync}(\mathcal{N})$ in the edge delay setting while incurring a small overhead in the number of neurons and the computation time (w.r.t the base network $\mathcal{N}$).

For the setting in which the edge latencies are fixed over time and bounded by some integer L, Hitron and Parter [12] showed such a simulation using their efficient constructions for neural timers and counters. Their synchronized network solution $\mathsf{Sync}(\mathcal{N})$ has $O(n + L \log L)$ neurons and $O(rL^3)$ rounds where r is the computation time of the base network $\mathcal{N}$. While being quite efficient in terms of space and time, the synchronizers of [12] are heavily built up on the strong assumption that the latency values of the edges are fixed over time. In this paper, we aimed at understanding the edge latency setting in its most general form, and ask:

> *Can one provide a general synchronization scheme in a setting that allows the latency of the network edges to vary in an adversarial manner in each round?*

A priori it is not so clear if one can compute even basic Boolean functions without assuming that the latency values are fixed. We answer this question in the affirmative by presenting a modular syncronization scheme using a different approach than that taken in [12]. The benefit of this approach is in its modularity. We start by understanding the implementation of a single NOT gate in this model in terms of upper and lower bounds on the space and the time of the computation. We then use this synchronized NOT solution as a building block in the final synchronized network solution. Specifically, the synchronized NOT gates are used to build synchronized circuits (and hence threshold gates) which in turn combined into a whole synchronized network solution. The space and time overheads incurred by our solution are polynomial in L (the bound on the latency) and Δ, the maximal incoming degree in the base network $\mathcal{N}$.

We next turn to consider synchronizers for the node delay model. Our approach is based on showing a *simulation* result that takes any synchronized solution $\mathsf{sync}_E(\mathcal{N}, L)$ obtained by the synchronizer in the L-bounded *edge* latency model, and transforms it into a synchronized solution $\mathsf{sync}_V(\mathcal{N}, T)$ that works in the T-bounded *node* delay model for $L = \Theta(T^2)$.

▶ Remark. It is noteworthy that in contrast to the *distributed* setting of Awerbuch and Peleg [2] where the network size does not depend on the latencies, in the neural setting it is not the case. As our lower bound constructions, both the computation time and the network size must depend (in fact, polynomially) on the largest edge latency. For this reason, for any practical purposes, the study of asynchronous communication, in general, must assume bounded delays.

1.4 Our Results

We study the cost and limitations of asynchronous neural computation in a biologically plausible yet simple model of spiking neural networks. Our main focus is in the edge latency model where the dynamic is specified by an L-bounded function $\ell : V \times V \times \mathbb{N} \to \mathbb{N}_{\leq L}$. The node delay model is concerned only towards the end of the paper (Appendix C), as it is handled via reduction to the edge delay setting. In the first part of the paper, we show several negative results for the L-bounded model. This includes an impossibility results for delay on self-loop edges, as well as size and time lower bound on an implementation of a NOT gate in this model. In the second part, we consider the construction of synchronizers in this generalized setting. We note that these constructions are self-contained and are technically different from [13].

Negative Results. We first show that without assuming a minimal latency value on the self-loop edges, one cannot compute $AND(x, y)$ given two Boolean inputs x and y, even when the edge latency values are fixed over time and the largest latency is $L = 2$.

▶ **Theorem 1** (Impossibility for Arbitrary Latency Functions). *There exists no network that computes $AND(x, y)$ in a setting that allows the adversary to pick latencies in $\{1, 2\}$ for* all *edges in the network.*

The proof goes by showing that for any given candidate network solution $\mathcal{N}$, there exists a bad latency function ℓ under which $\mathcal{N}$ fails to compute $AND(x, y)$. This holds even when the latencies are fixed over time. From that point on, we restrict attention to *nice* latency functions, that assign latency value 1 to the self-loop edges in the network.

▶ **Definition 2.** *A latency function is* nice *if $\ell(u, u, \tau) = 1$ for every $u \in V$ and round τ.*

Our key technical contributions are lower bounds on the network size and the computation time for computing the $NOT(x)$ function in the L-bounded setting. Informally speaking, the $NOT(x)$ function appears to be a "complete" function for the purpose of synchronization in this asynchronous model. Indeed, our $NOT(x)$ implementation captures most of the essence of the L-bounded model. To obtain the final synchronization scheme we mainly glue together synchronized NOT units. For this reason, we spend much attention into understanding the tightness of our constructions by providing nearly matching lower bound results.

▶ **Lemma 3** (Size and Time Lower Bounds for Async. Computation of $NOT(x)$). *Any network that computes $NOT(x)$ in the L-bounded asynchronous setting must use $\Omega(L)$ neurons and $\Omega(L^3)$ time (the time lower bound is tight).*

This should be compared with the size lower bound of $\Omega(\log L)$ shown by [13] for their simplified asynchronous setting.

Positive Results. Our end result is a synchronizer that given any network $\mathcal{N}$ in the standard synchronous setting and an integer L, computes a network $\mathsf{sync}_E(\mathcal{N}, L)$ that performs the "same" computation as $\mathcal{N}$ in the L-bounded edge delay setting.

▶ **Theorem 4** (Synchronizers for Edge Delays). *There exists a synchronizer that given a network $\mathcal{N}$ with n neurons, maximum in-degree Δ, and maximum edge latency L, constructs a network $\mathsf{sync}_E(\mathcal{N}, L)$ that has an "analogous" execution in the L-bounded edge-delay setting with a total number of $\widetilde{O}(L^4 \cdot \mathrm{poly}(\Delta) \cdot n)$ neurons and a time overhead[3] of $\widetilde{O}(L^5 \cdot \log \Delta)$.*

Although the construction is inspired by the work of Awerbuch and Peleg [2], the implementation is very different as our neurons, unlike processors in a distributed network, are memoryless. Thus, they cannot aggregate the incoming messages as in [2]. Our construction is also different than that of [13], as the latter crucially depends on having fixed latencies over time.

For the node delay model, in Appendix C we show that given a network $\mathcal{N}$ in the standard synchronous setting and an integer T, one can compute an analogous network $\mathsf{sync}_V(\mathcal{N}, T)$ in the node-delay model with bounded node delay T by taking the following approach. Apply the algorithm of Theorem 4 with $\mathcal{N}$ and $L = \Theta(T^2)$. This results with a network $\mathsf{sync}_E(\mathcal{N}, L)$

[3] The $\widetilde{O}$ hides a factor of $\mathrm{poly}(\log(n \cdot r))$, where r is the number of simulation rounds.

that performs the same computation as $\mathcal{N}$ in the L-bounded edge delay model. The desired network $\mathsf{sync}_V(\mathcal{N}, T)$ is then obtained by multiplying the edge weights of a carefully defined edge *subset* in $\mathsf{sync}_E(\mathcal{N}, L)$ by a factor of T. The quite delicate analysis then shows that the network $\mathsf{sync}_V(\mathcal{N}, T)$ indeed simulates the original network $\mathcal{N}$ upon any selection of the node-delay function $t : V \to \mathbb{N}_{\leq T}$. By setting $L = O(T^2)$ in Theorem 4, we show the following for the node delay model:

▶ **Theorem 5** (Synchronizers for Node Delays)**.** *There exists a synchronizer that given a network $\mathcal{N}$ with n neurons, maximum in-degree Δ, and maximum node delay T, constructs a network $\mathsf{sync}_V(\mathcal{N}, T)$ that has an "analogous" execution in the T-bounded node-delay setting with a total number of $\widetilde{O}(T^8 \cdot \mathrm{poly}(\Delta) \cdot n)$ neurons and a time overhead of $\widetilde{O}(T^{10} \cdot \log \Delta)$.*

We note that our preference to take a modular approach rather then an optimized one inevitably leads to suboptimal space and time bounds in both Theorems 4 and 5. For example, Theorem 5 is shown via a simulation result, which further deepens our understanding of the connections between these models. We believe that by employing a more direct approach for building synchronizers in the node-delay model, one should get a considerably improved dependency in the delay bound T.

1.5 Our Approach in a Nutshell

We next provide the high level ideas for the key contributions. Throughout, unless stated otherwise we consider the edge delay model where the dynamics is specified by an arbitrary latency function.

Size and Time Lower Bound for Computing $NOT(x)$. A network $\mathcal{N}$ with input neuron x and an output neuron z computes the function $NOT(x)$ in the asynchronous setting if the following holds: when $x = 0$, the output z fires in at *least* one round regardless of the latency function; and when $x = 1$ the output z never fires for any latency function. To show a size lower bound of $\Omega(L)$ we take the following approach. First, we reduce any network $\mathcal{N}$ that computes $NOT(x)$ into a simpler and yet not larger network $\mathcal{N}_{simple}$. In the latter network the only inhibitor is the input x which also has a self-loop of large positive weight, and outgoing edges of very large negative weight to all the excitatory neurons in $\mathcal{N}$. The second part of the proof shows a lower bound for $\mathcal{N}_{simple}$ using its specialized structure. We will assume towards a contradiction that the in-degree of each neuron in $\mathcal{N}_{simple}$ is less than L and exhibit two conflicting latency functions ℓ_0, ℓ_1 that satisfy the following. If $\mathcal{N}_{simple}$ computes $NOT(x)$ with ℓ_0 and with $x = 0$, then it must fail to compute $NOT(x)$ with the function ℓ_1 and $x = 1$. To compute these latency functions, we partition the simulation into blocks $T_0, \ldots,$ each containing L rounds. In each phase i, we set the latency values for all the edges and all the rounds in block T_i. Throughout, we will keep the invariant that there exists *no* neuron that fires when $x = 0$ and with ℓ_0, but does not fire when $x = 1$ and with ℓ_1. By the correctness of the network, the output neuron must fire at least once when $x = 0$, thus leading to the contradiction. In the very high level, the fact that the in-degree of each vertex is small is used in order to spread over the at most L incoming spikes of each neuron u in a balanced manner over the L rounds of the block. This will prevent the firing of a neuron z when $x = 0$. Our lower bound is complemented by an upper bound of $O(L^2)$ as described next.

The Generalized Synchronization Scheme. The scheme is based on gradual steps.

Step I: Synchronization of NOT and OR Gates. We start by considering the asynchronous computation of simple Boolean functions $NOT(x)$ and $OR(x_1, \ldots, x_\ell)$ with a small number of neurons. The key challenge is in implementing the NOT gate. When $x = 1$, the output gate is required not to fire (i.e., output 0) throughout the *entire* execution. In contrast, when $x = 0$ the output gate should fire at least once during the execution. The construction is combinatorial and uses a similar logic to the lower bound arguments. It contains a collection of $L + 1$ neurons with outgoing edges to the output z. The above mentioned lower bound result shows that the incoming degree of z must be at least $L - 2$.

Step II: Synchronization of a Boolean Circuit. Any Boolean circuit $\mathcal{A}$ can be implemented by NOT and OR gates. To simulate the computation of $\mathcal{A}$ in the asynchronous setting, we replace each gate g_i in $\mathcal{A}$ by its synchronized implementation $\mathsf{Sync}(g_i)$ constructed in Step (I). For a gate g_i in layer j with incoming gates $g_{i,1}, \ldots, g_{i,k}$, the input to the sub-network $\mathsf{Sync}(g_i)$ are the output neurons of the sub-networks $\mathsf{Sync}(g_{i,1}), \ldots, \mathsf{Sync}(g_{i,k})$. The synchronization between the layers of the circuit is governed by a directed chain of $O(dL^3)$ neurons. The head of the chain fires in the first round of the simulation and activates the network. The sub-networks $\mathsf{Sync}(g_i)$ of gates g_i in layer j are activated by the $\Theta(j \cdot L^3)$ neuron in this chain. These parameters are set so that we can be sure that the modules of layer j are activated, only *after* the spikes from the output neurons of the previous layer have reached the input of this layer. Overall the synchronized transformed network $\mathsf{Sync}(\mathcal{A})$ has $O(d \cdot L^3 + m \cdot L^2)$ neurons, where d is the depth of $\mathcal{A}$ and m is the number of gates. The overtime in the computation is $O(d \cdot L^4)$ rounds.

Step III: Synchronization of a Single (Probabilistic) Threshold Gate. To synchronize a single deterministic threshold gate, we use the fact that a threshold gate with incoming degree Δ can be implemented by a Boolean circuit with $\text{poly}(\Delta)$ neurons and depth $O(\log \Delta)$. This allows us to use the synchronized construction of the previous step. Turning to probabilistic threshold gates, here it is much less clear how to implement such a gate by a Boolean circuit. We take the following approach. First, we use the fact from [20] that a spiking neuron[4] u with bias $b(u)$ is equivalent to a *deterministic* neuron u' whose bias is sampled from the Logistic distribution with mean $b(u)$. Therefore our key challenge is in sampling a value from a given Logistic distribution. To do that, we use a collection of k (input-less) spiking neurons each fires independently with probability half. These neurons provide us the random bits for this process of sampling. In fact, these fair coins tosses allows one to sample a value *almost* uniformly at random in the range $[0, 2^k]$. We will then use the method of inverse transform sampling to convert this almost-uniform sampled value to a value that is sampled from the Logistic distribution up to a small error in the sampling. Using Taylor expansion of the natural log function, we implement this Uniform to Logistic transformation by a collection of simple arithmetic operations applied on a collection of Boolean neurons. The total error in our sampling is set to be small enough so that the output distribution of the Boolean circuit is almost indistinguishable from that of the probabilistic threshold gate.

Grand Finale: Synchronization of a Spiking Neural Network. Finally, given an SNN network $\mathcal{N}$ of (probabilistic) threshold gates the synchronized network $\mathsf{sync}(\mathcal{N})$ is obtained as follows. Each threshold gate g_i in $\mathcal{N}$ is replaced by its synchronized implementation $\mathsf{Sync}(g_i)$.

[4] The probabilistic threshold gates of SNN.

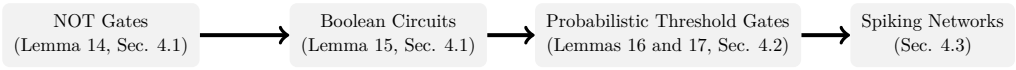

Figure 1 A road-map for synchronizing spiking neural networks.

The key challenge is in synchronizing these modules so that every neuron v in $\mathcal{N}$ (i.e., not only the output neuron) has an equivalent neuron v' in $\mathsf{sync}(\mathcal{N})$ that simulates v for any possible latency function throughout the entire simulation. See Fig. 1 for an illustration.

From Edge Delays to Node Delays. Given a network $\mathcal{N}$ to be simulated and an integer T, our goal is to build a synchronizer $\mathsf{sync}_V(\mathcal{N}, T)$ that *simulates* $\mathcal{N}$ in the T-bounded node-delay model. To do that, we first compute a network $\mathsf{sync}_E(\mathcal{N}, L)$ that simulates $\mathcal{N}$ in the L-bounded edge-delay model for $L = \Theta(T^2)$. Then the output network $\mathsf{sync}_V(\mathcal{N}, T)$ is obtained by dividing some of the edge weights in $\mathsf{sync}_E(\mathcal{N}, L)$ by a factor of T. The correctness argument is based on showing that for every node-delay function $t : V \to \mathbb{N}_{\leq T}$, there exists an edge-delay function $\ell : V \times V \times \mathbb{N}_{\geq 0} \to \mathbb{N}_{\leq L}$ such that the execution of the network $\mathsf{sync}_E(\mathcal{N}, L)$ with the edge-delay function ℓ (in the edge-delay model) is *similar* to the execution of the network $\mathsf{sync}_V(\mathcal{N}, T)$ with the node-delay function t (in the node-delay model). Since the network $\mathsf{sync}_E(\mathcal{N}, L)$ simulates the original network $\mathcal{N}$ for any edge-delay function, it will imply that the network $\mathsf{sync}_V(\mathcal{N}, T)$ simulates the original network $\mathcal{N}$ for any node-delay function as desired.

Additional Related Work. Asynchronized communication in spiking neural networks has been studied in several settings. Maass [22, 25] considered a quite elaborated model for deterministic neural networks with *arbitrary* response *functions* for the edges, and a vector firing times for all neuron. The approach of [22] mostly concerned the computational power of this model upon choosing the best parameters for the network. I.e., showing feasibility results for various functions. In contrast, in this work our goal is to *bound* the computation time and the network size under this asynchronous setting. Khun et al. [15] studied the asynchronous dynamics under the stochastic model of DeVille and Peskin [7].

Turning to the setting of logical circuits, there is a long line of work on the asynchronous setting under various model assumptions [1, 11, 36, 4] that do not quite fit the memory-less setting of spiking neurons. A more related work to our setting is by Martin, Manohar and Moses [28, 26, 27] who studied the computational power of asynchronous digital circuits. In particular, they characterize the necessary and sufficient conditions for a valid operation of a given circuit in the asynchronous setting. For example, they showed that if all edges and nodes suffer from an unbounded delay then the computational power of the circuit must be very limited. The focus in our work is quite different. Instead of studying the computational power of the asynchronous setting, we bound the computational overhead for solving concrete problems.

2 The Synchronous and Asynchronous SNN Models

A deterministic neuron u is modeled by a *deterministic* threshold gate. Letting $b(u)$ to be the threshold value of u, then u outputs 1 if the weighted sum of its incoming neighbors exceeds $b(u)$. A *spiking neuron* is modeled by a probabilistic threshold gate which fires with a sigmoidal probability that depends on the difference between its weighted incoming sum and $b(u)$.

Neural Network Definition. A *Neural Network* (NN) $\mathcal{N} = \langle X, Z, Y, w, b\rangle$ consists of n input neurons $X = \{x_1, \ldots, x_n\}$, m output neurons $Y = \{y_1, \ldots, y_m\}$, and k auxiliary neurons $Z = \{z_1, ..., z_k\}$. In spiking neural network (SNN), the neurons can be either deterministic threshold gates or probabilistic threshold gates. The directed weighted synaptic connections between $V = X \cup Z \cup Y$ are described by the weight function $w : V \times V \to \mathbb{R}$. A weight $w(u, v) = 0$ indicates that a connection is not present between neurons u and v. Finally, for any neuron v, the value $b(v) \in \mathbb{R}$ is the threshold value (activation bias). The in-degree of every input neuron x_i is zero, i.e., $w(u, x) = 0$ for all $u \in V$ and $x \in X$. Additionally, each neuron is either inhibitory or excitatory: if v is inhibitory, then $w(v, u) \leq 0$ and if v is excitatory, then $w(v, u) \geq 0$ for every u. This restriction arises from the biological structure of the neurons.

Network Dynamics in the Synchronous Setting. The network evolves in discrete, synchronous rounds as a Markov chain. The firing probability of every neuron in round τ depends on the firing status of its neighbors in round $\tau - 1$, via a standard sigmoid function, with details given below. For each neuron u, and each round $\tau \geq 0$, let $\sigma_\tau(u) = 1$ if u fires (i.e., generates a spike) in round τ. Let $\sigma_0(u)$ denote the initial firing state of the neuron. The firing state of each input neuron x_j in each round is the input to the network. For each non-input neuron u and every round $\tau \geq 1$, let $\text{pot}(u, \tau)$ denote the membrane potential at round τ and $p(u, \tau)$ denote the firing probability ($\Pr[\sigma_\tau(u) = 1]$), calculated as $\text{pot}(u, \tau) = \sum_{v \in V} w(v, u) \cdot \sigma_{\tau-1}(v) - b(u)$ and $p(u, \tau) = \frac{1}{1+e^{-\text{pot}(u,\tau)/\lambda}}$ where $\lambda > 0$ is a *temperature parameter* which determines the steepness of the sigmoid. Clearly, λ does not affect the computational power of the network, thus we set $\lambda = 1$.

2.1 Network Dynamics in the Edge Delay Setting

The dynamic of the network is governed by a latency function $\ell : V \times V \times \mathbb{N} \to \mathbb{N}$ interpreted as follows. For every directed edge $e = (u, v)$ and round τ, a spike generated by u in round τ arrived at v after $\ell(u, v, \tau)$ rounds. In the synchronous setting, $\ell(u, v, \tau) = 1$ for every u, v, τ.

For every neuron v and round τ, let $A(u, \tau) = \{(v, \tau') |\ v \in V,\ \tau' + \ell(v, u, \tau') = \tau\}$ denote all the spike events that if occur, arrive to u at round τ. The state of u in round τ is given by:

$$\text{pot}(u, \tau) = \sum_{(v,\tau') \in A(v,\tau)} w(v, u) \cdot \sigma_{\tau'}(v) \ - \ b(u) \ \text{ and } \ \sigma_\tau(u) = 1 \text{ iff } \text{pot}(v, \tau) \geq 0 \ . \qquad (1)$$

If u is a probabilistic threshold gate then it fires with probability $p(u, \tau) = \frac{1}{1+e^{-\text{pot}(u,\tau)}}$. When $\ell(u, v, \tau) = \ell(u, v, \tau')$ for every u, v and $\tau' \neq \tau$, we may omit τ and write $\ell(u, v)$.

▶ **Definition 6** (The L-bounded Edge-Delay Setting)**.** *Given is a network $\mathcal{N}$ and an integer L. It is assumed the network contains a special neuron, the* starter*, that fires in the first round of the simulation. The dynamic is determined by a latency function ℓ. This function ℓ can be chosen arbitrarily among all L-bounded nice functions.*

▶ **Definition 7** (Computation of a Boolean Function in the L-bounded Edge-Delay Setting)**.** *Let $f : \{0, 1\}^n \to \{0, 1\}^k$ be a Boolean function. A network $\mathcal{N}$ with n input neurons $x_1, \ldots, x_n$ and k output neurons $z_1, \ldots, z_k$* computes *f in this setting if for every nice L-bounded function ℓ and for every fixed possible assignment to the input neurons $b_1, \ldots, b_n$ the following holds: (i) If $f_i(b_1, \ldots, b_n) = 1$, then there exists a round in which z_i fires, where $f_i(\cdot)$ is the i^{th} bit in the output of f. (ii) If $f_i(b_1, \ldots, b_n) = 0$ then z_i does not fire throughout the entire execution. Furthermore, the network $\mathcal{N}$ computes the function f* in r rounds *if $\mathcal{N}$ computes f, and for every nice L-bounded function ℓ, input bits $b_1, \ldots, b_n$ and index i such that $f_i(b_1, \ldots, b_n) = 1$, z_i fires in some round $\tau \leq r$.*

Note that by this definition, for a network $\mathcal{N}$ that computes a Boolean function f within r rounds, to evaluate the output of the function it is sufficient to inspect the state of the output bits over the first r rounds of the network's simulation. Furthermore, as edge delays are allowed to be chosen in an adversarial manner, one cannot hope for having all output neurons to fire in the exact same around. One mechanism that we use to keep the output neurons fire simultaneously is by using self-loop edges whose latency values is fixed to be 1.

Synchronizers. A synchronizer ν is an algorithm that gets as input a network $\mathcal{N}$ and outputs a network $\mathcal{N}' = \mathsf{sync}(\mathcal{N})$ that contains all the neurons of $\mathcal{N}$, plus additional auxiliary neurons. One of the auxiliary neurons in $\mathcal{N}'$ is a *starter* neuron that fires in the *first* round of the simulation. The network $\mathcal{N}'$ works in the asynchronous setting and should have *similar execution* to $\mathcal{N}$ in the sense that for every neuron $v \in V(\mathcal{N})$, the firing pattern of v in the asynchronous network should be similar to the one in the synchronous network. The output network $\mathcal{N}'$ simulates each round of the network $\mathcal{N}$ by a *phase*.

▶ **Definition 8** (Phases). *We partition the execution of $\mathcal{N}'$ into phases $1, 2, \ldots$, using a function $r : V(\mathcal{N}) \times \mathbb{N} \to \mathbb{N}$ that defines the beginning of phase p, i.e. the p^{th} phase is the round interval $[r(v,p), r(v,p+1))$.*

▶ **Definition 9** (Similar Executions (Deterministic Networks)). *The* synchronous *execution Π of a deterministic network $\mathcal{N}$ is specified by a list of states $\Pi = \{\sigma_1, \ldots, \}$ where each σ_i is a binary vector describing the firing status of the neurons in round i. The* asynchronous *execution of the network $\mathcal{N}' = \mathsf{sync}_E(\mathcal{N}, L)$ with a latency function ℓ denoted by $\Pi'(\ell)$ is defined analogously only when applying the asynchronous dynamic of Eq. (1). The execution $\Pi'(\ell)$ is divided into phases according the a function $r : V(\mathcal{N}) \times \mathbb{N} \to \mathbb{N}$.*

*The network $\mathcal{N}$ and the pair $\langle \mathcal{N}', \ell \rangle$ have a **similar execution** if $V(\mathcal{N}) \subseteq V(\mathcal{N}')$, and in addition, a neuron $v \in V(\mathcal{N})$ fires in round p in the execution Π iff v fires during phase p in $\Pi'(\ell)$. The networks $\mathcal{N}$ and $\mathcal{N}'$ are **similar** if $\mathcal{N}$ and $\langle \mathcal{N}', \ell \rangle$ have a similar execution for every nice latency function ℓ.*

Note that specifically, if a synchronous network $\mathcal{N}$ computes a Boolean function f by round r and $\mathcal{N}$ and $\mathcal{N}'$ are similar, then $\mathcal{N}'$ computes f by phase r. Therefore, if we know that each phase is of at most q rounds, we get that $\mathcal{N}'$ computes f in $r \cdot q$ rounds.

Finally, we note that the extension for randomized networks with probabilistic gates is quite straightforward if one simply fixed the random coins used by the neurons over the simulation. That is, to be able to faithfully compare the simulation of two random networks, one has to fix the random coins of both of the simulations to be the same. For this reason, given an input randomized network $\mathcal{N}$ in the synchronized model, we maintain all the random coins generated by the neurons of the network over the simulation. These random coins are then fed to the network $\mathcal{N}'$ (i.e., obtained by applying our synchronizers). Since we compare two randomized networks that use the same set of random coins, we can treat these networks as deterministic. In Appendix C we provide the analogous definitions for the T-bounded node-delay model. Throughout the main paper, we consider only the edge-delay model and to avoid cumbersome notation that synchronized network solutions for this model are denoted by $\mathsf{sync}(\mathcal{N})$ (rather than $\mathsf{sync}_E(\mathcal{N}, L)$).

3 Negative Results

Impossibility Result for Arbitrary Latency Functions. We start by considering Theorem 1, and show that if the latency values are allowed to be set in an adversarial manner in $\{1, 2\}$, then there exists no network that computes the AND of two Boolean inputs. In Appendix A, we show:

▶ **Lemma 10.** *Given input neurons x, y and an output neuron z, there is no network computing $AND(x, y)$ under every latency function $\ell : V \times V \to \{1, 2\}$.*

In the high level, we show that one can set the latency values such that all the spikes that *depend* on the value of x (resp., y) arrive at odd (resp., even) rounds. Therefore, at any round, there is no neuron that fires as a function of *both* x and y.

Size and Time Lower Bound

In this section we show the proof for Lemma 3. Here we focus on the size lower bound although the high level proof strategy for the time lower bound is quite similar. The time lower bound is presented in Appendix A.1. Our proof strategy is as follows. First we reduce any network $\mathcal{N}$ that computes $NOT(x)$ in the asynchronous setting, to a network $\mathcal{N}_{simple}$ with a simpler structure that makes it easier to make arguments on it. The second part of the argument shows the lower bound for simple networks. All missing proofs of this section are in Appendix A.

▶ **Definition 11** (Strong Neurons and Simple Networks)**.** *A neuron u is* strong *in a given network if $w(u, u) \geq b(u)$, and otherwise it is* weak*. Note that specifically, an excitatory neuron u with $b(u) \leq 0$ is strong. Given a single input neuron x, we say that a network $\mathcal{N}$ is* simple *if the following hold: (i) x is a strong neuron and has an outgoing edge of infinite* negative *weights to all other neurons in the network; and (ii) all other neurons are excitatory.*

We note that the simple network is not a *legally defined* neural network: the input neuron has an incoming edge (self-loop), and it is an inhibitor with a positive self-loop. However, this network definition is only for the sake of the analysis and as such, it is not restricted to follow any rule.

Reduction to Simple Networks. Given a network $\mathcal{N}$ with an input neuron x, define $\mathcal{N}_{simple}$ as follows. Exclude all the inhibitory neurons from $\mathcal{N}_{simple}$ and take all edges between excitatory neurons to be as in $\mathcal{N}$. Then, add a self-loop of infinite weight to the input neuron x, and connect it to every neuron with infinite[5] negative weight.

▶ **Lemma 12.** *If $\mathcal{N}$ computes $NOT(x)$ within r rounds starting with the initial state $\bar{\sigma}$, then also $\mathcal{N}_{simple}$ computes it within r rounds, when starting with the initial states as in $\bar{\sigma}$ restricted to the vertices of $\mathcal{N}_{simple}$.*

The proof goes by claiming that for any latency function ℓ_{simple} for $\mathcal{N}_{simple}$, we can show the existence of a latency function ℓ for $\mathcal{N}$ whose performance is only *worse* than that of $\mathcal{N}_{simple}$ with ℓ_{simple}. That is, when $x = 0$ (resp., $x = 1$) then the potential of all neurons in $\mathcal{N}_{simple}, \ell_{simple}$ is not decreased (resp. increased) when compared to $\mathcal{N}, \ell$. Since the network $\mathcal{N}$ computes $NOT(x)$ with the latency function ℓ within r rounds, we conclude that also $\mathcal{N}_{simple}$ computes it with the latency function ℓ_{simple} within at most r rounds.

Fix a $NOT(x)$ network $\mathcal{N}$. For an integer r, a latency function ℓ for $\mathcal{N}$ is *r-good* with the initial configuration $\bar{\sigma}$, if the network computes $NOT(x)$ within r rounds. I.e., when $x = 0$, the output of $\mathcal{N}$ fires in some round $\tau \leq r$, and when $x = 1$ it never fires when all latencies are given based on ℓ. If ℓ is r-good for some integer r we say it is *good*, and otherwise the

[5] By infinite we mean large enough so that when the spike by x arrives at some neuron v, v would not fire.

latency function is *bad* (the network fails to compute $NOT(x)$). Note that in order for a network to compute $NOT(x)$ within r rounds, it is required that any latency function is r-good for a fixed initial configuration.

Lower Bound for Simple Networks. Assume towards contradiction that there exists a *simple* network $\mathcal{N} = \mathcal{N}_{simple}$ with maximum in-degree $\Delta_{in} < L - 2$ that computes $NOT(x)$. I.e., there exists an initial configuration $\bar{\sigma}$ for all neurons but x such that every latency function ℓ is good for $\langle \mathcal{N}, \bar{\sigma} \rangle$. In what follows, we define two *conflicting* latency functions ℓ_0 and ℓ_1, such that if ℓ_0 is good when the initial state of x is 0, then it implies that ℓ_1 is bad when the initial state of x is 1.

Defining the Latency Functions ℓ_0 and ℓ_1. Recall that for every $b \in \{0,1\}$, $\bar{\sigma}_b = [b, \bar{\sigma}]$ is the initial state vector where x has the initial state b and the initial states of all other neurons is specified by the vector $\bar{\sigma}$. The construction of ℓ_0, ℓ_1 is inductive. To avoid cumbersome notation, we start the simulation in round -1 rather than in round 0. For this first round -1, let $\ell_b(v, u, -1) = 1$ for $v \neq x$, and $\ell_b(x, u, -1) = L$ for every u and $b \in \{0,1\}$. Thus, the positive spikes (by any $v \neq x$) fired in round -1 arrive in round 0, and the negative spikes of x arrive in round $L - 1$.

To define the latency of the edges in the remaining rounds $\tau \geq 0$, we partition them into blocks, each of size L rounds where the i^{th} block is $T_i = [iL, iL + (L-1)]$ for every $i \geq 0$. We continue in steps $i = 1, \ldots$ where in step i, the latency values of $\ell_0(e, \tau), \ell_1(e, \tau)$ are defined for every edge e in the network $\mathcal{N}$, and for every round $\tau \in T_i$. For every $b \in \{0,1\}$ and a block T_i, define $A_{i,b}$ as the set of neurons that fire (hence *active*) in the first round of T_i when executing $\mathcal{N}$ with the initial configuration $\bar{\sigma}_b$, and the latency function ℓ_b. Throughout the process of defining the latency functions, we maintain these invariants at the beginning of step i:

- (I1) All the positive spikes generated at any round before the interval T_i arrive to their destination by the first round of T_i. Furthermore, all negative spikes generated at any round before the interval T_i arrive to their destination either by the first round of T_i or on the last round of T_i, namely, round $iL + (L-1)$.
- (I2) $A_{i,0} \setminus \bigcup_{i' \leq i} A_{i',1} = \emptyset$.

We define the latency for the rounds in T_i, and then show that the invariants are maintained.

Defining the latency function ℓ_1 for T_i. For every self-loop edge e and every $\tau \in T_i$, let $\ell_1(e, \tau) = 1$. For every edge $e = (x, u)$ where $u \neq x$, and $\tau \in T_i \setminus \{iL + (L-1)\}$, let $\ell_1(e, \tau) = (iL + (L-1)) - \tau$, i.e., the spike of x arrives u in the last round of the interval T_i. For $e = (x, u)$ and $\tau = iL + (L-1)$, let $\ell_1(e, \tau) = L$ so that the spike arrives in the last round of the next block, i.e., round $(i+1)L + (L-1)$. For every other edge $e = (v, u)$ with $v \neq x$, let $\ell_1(e, \tau) = (i+1)L - \tau$, i.e., the spike arrives at the first *first* round of the next block T_{i+1}.

Defining the latency function ℓ_0 for T_i. As for ℓ_1, for a self-loop edge e, we set $\ell_0(e, \tau) = 1$. For an edge $e = (x, u)$ we set $\ell_0(e, \tau)$ arbitrarily (since $x = 0$, those values are meaningless). We now fix a neuron u, and set the latency values of all its incoming edges (v, u). Since we have already defined the latency values of all edges up to block T_i, at the beginning of step i, the sets $A_{i,0}, A_{i,1}$ can be computed. Let $g_1, \ldots, g_\omega$ be the weak incoming neighbors of u in $A_{i,0}$, and $h_1, \ldots, h_s$ be the strong incoming neighbors of u in $A_{i,0}$. We Consider two cases. The neuron u is said to have a *dominant* neighbor if it has a neighbor with a *sufficiently*

large incoming weight, where the precise weight threshold depend on whether the incoming neighbor is weak or strong. Specifically, it has a dominant neighbor if it has either a weak neighbor g_j with $w(g_j, u) \geq b(u)$, or a strong neighbor h_j with $w(h_j, u) \geq b(u)/(L-1)$.

- **Case 1: u has a dominant neighbor.** Let $\ell_0(e, \tau) = (i+1)L - \tau$ for every incoming edge $e = (v, u)$. That is, we schedule all the incoming spikes of u in this block to arrive at u in the *first* round of the next block T_{i+1}.
- **Case 2: u has no dominant neighbor.** Since $\deg(u) < L-2$, we have that $\omega + s < L-2$, and in particular $\omega \leq L-2$. For each weak neuron g_j, set $\ell_0(g_j, u, iL) = j+1$. That is, the spike from g_j in round iL is scheduled to arrive at u in round $iL + (j+1)$. For each strong neighbor h_j, we split all the spikes generated by h_j during the $\omega+1$ rounds $iL, \ldots, iL+\omega$ in a balanced manner over $L-(\omega+1)$ rounds. Specifically, we set the latency values of the at most $\omega+1$ spikes by h_j during the rounds $iL, \ldots, iL+\omega$ such that in each round $\tau \in [iL+(\omega+2), (i+1)L]$, u receives at most $(\omega+1)/(L-(\omega+1))$ spikes from h_j[6]. For every $\tau \in [iL+(\omega+1), iL+(L-1)]$, let $\ell_0(h_j, u, \tau) = 1$, i.e., the spike arrives one round later. The latency of all the remaining edges e and rounds τ in T_i is set to $\ell_0(e, \tau) = (i+1)L - \tau$, so that it arrives in round $(i+1)L$.

In AppendixA.1.2, we prove that the invariants hold by induction on the number of rounds. Since the output z is required to fire when $x = 0$ but must not fire when $x = 1$, we get the desired contradiction. In Appendix A.1, we show the time lower bound of $\Omega(L^3)$ rounds. This bound is tight, and the construction while having a similar high-level ideas is slightly more involved than the size lower bound.

4 Upper Bounds

4.1 Synchronization of Logic Gates and Boolean Circuits

First observe that the simple implementation of an OR-gate works also in the asynchronous setting.

▶ **Observation 13** (OR gate). *Given input neurons $x_1, \ldots, x_n$ and output neuron z, there exists a deterministic network* $\mathsf{OR}_{\mathsf{sync}}$ *with* no *auxiliary neurons, that computes the OR gate of $x_1, \ldots, x_n$ using L rounds. I.e, it holds that: (i) If $\sigma_0(x_1) \vee \ldots \vee \sigma_0(x_n) = 0$, then $\sigma_t(z) = 0$ for every t, and (ii) If $\sigma_0(x_1) \vee \ldots \vee \sigma_0(x_n) = 1$, then there exists a round $t \in [1, L]$ such that $\sigma_t(z) = 1$. Moreover, if an input neuron fires in round τ, the output neuron z fires in some round $t \in [\tau+1, \tau+L]$.*

We next consider the more technically involved setting of synchronizing a NOT gate.

▶ **Lemma 14** (NOT gate). *There is a network* $\mathsf{NOT}_{\mathsf{sync}}$ *of size $O(L^2)$ with input neuron x and output z, that computes $NOT(x)$ within $O(L^3)$ rounds. I.e, it holds that: (i) If $\sigma_0(x) = 1$, then $\sigma_t(z) = 0$ for every t, and (ii) If $\sigma_0(x) = 0$, then there exists a round $t \in [L, \Theta(L^3)]$ such that $\sigma_t(z) = 1$.*

The following synchronous implementation assumes that the network contains a special starter neuron v^* that fires at the beginning of the simulation, regardless of the input value of x. Later on in Section 4.3, when presenting the complete synchronization scheme, this neuron v^* will receive the starting firing signal from the *global* pulse generator.

[6] For simplicity, we assume that $(\omega+1)$ divides $(L-(\omega+1))$

Network Description. The network consists of the following components, see Figure 2.

1. A *chain* $C = [c_0 = v^*, \ldots, c_{5L^2}]$ containing $5L^2 + 1$ neurons. The head of the chain is the starter neuron that fires in the first round. For every $i \geq 0$, the neuron c_i has bias $b(c_i) = 1$. Moreover, for every $i \geq 1$ the neuron c_i has an incoming edge from c_{i-1} with weight 1.
2. A *memory neuron* m that remembers the initial state of x. The memory neuron has a positive incoming edge from x, as well as a self-loop both with weight 1 and bias $b(m) = 1$.
3. A *reset* inhibitory neuron r with an edge from m of weight $w(m, r) = 1$, and bias $b(r) = 1$.
4. A collection of $L + 1$ intermediate neurons $v_0, \ldots, v_L$ that are connected to the output neuron z, where each v_i has an incoming edge from the neuron $c_{5 \cdot iL} \in C$ with weight $w(c_{i \cdot 5L}, v_i) = 1$, a self-loop of weight 1 and bias $b(v_i) = 1$. In addition, each v_i has a negative incoming edge from the reset neuron r with weight $w(r, v_i) = -\infty$. Finally, each v_i has an edge to z with weight $w(v_i, z) = 1$ and bias $b(z) = L + 1$.

The correctness of the construction and the proof of Lemma 14 are deferred to Appendix B.1.

Synchronization of a Boolean Circuit. Given the synchronized sub-networks of Observation 13 and Lemma 14, we now show how to synchronize a Boolean circuit that contains OR and NOT gates.

▶ **Lemma 15.** *Given a Boolean circuit $\mathcal{A}$ of OR and NOT gates with n inputs, k outputs, m gates and depth d, there exists a deterministic network $\mathcal{N} = \mathsf{sync}(\mathcal{A})$ with input neurons $x_1, \ldots, x_n$, output neurons $z_1, \ldots, z_k$ and $O(dL^3 + mL^2)$ auxiliary neurons, that computes $\mathcal{A}$ in $O(dL^4)$ rounds. I.e., it holds that (i) If $[\mathcal{A}(\sigma_0(x_1), \ldots, \sigma_0(x_n))]_i = 0$ then $\sigma_t(z_i, \mathcal{N}) = 0$ for every t; and (ii) If $[\mathcal{A}(\sigma_0(x_1), \ldots, \sigma_0(x_n))]_i = 1$, then[7] there exists $t \in [1, O(dL^4)]$ such that $\sigma_t(z_i, \mathcal{N}) = 1$.*

In the high-level, the network $\mathcal{N} = \mathsf{sync}(\mathcal{A})$ is obtained by replacing each gate g_i with its synchronized module $\mathsf{Sync}(g_i)$. The input neurons to the gate modules in layer j of $\mathcal{A}$ are the output neurons of the gate modules of layer $j - 1$ in $\mathcal{A}$. The network then contains a chain of length $O(d \cdot L^3)$ to control the synchronization between layers: the modules of layer j are activated only after the modules of the previous layer have completed their computation. See Appendix B.2.

4.2 Synchronization of a Single Threshold Gate

Deterministic Threshold Gate. Given a deterministic threshold gate g with Δ inputs, one can implement g using a Boolean Circuit with $\mathrm{poly}(\Delta)$ gates and depth $O(\log \Delta)$ (see Appendix B.3). Combining with the construction described in Lemma 15 we show the following:

▶ **Lemma 16.** *Given a weighted threshold gate $g = f(x_1, \ldots, x_\Delta)$, there exists a network $\mathcal{N} = \mathsf{Sync}(g)$ with Δ input neurons $x_1, \ldots, x_\Delta$, an output neuron z, and $O(\log \Delta \cdot L^3 + \mathrm{poly}(\Delta) \cdot L^2)$ auxiliary neurons that computes f within $O(\log \Delta \cdot L^4)$ rounds. I.e. the output z fires in round $\tau \in [2, O(\log \Delta \cdot L^4)]$ if and only if $f(\sigma_0(x_1), \ldots, \sigma_0(x_\Delta)) = 1$.*

[7] For a vector of n bits $x \in \{0,1\}^n$, let $[x]_i$ denote the i^{th} bit of x. I.e., if $x = (x_1, \ldots, x_n)$, then $[x]_i = x_i$.

Probabilistic Threshold Gate. We next turn to consider the more challenging setting of probabilistic threshold gates. To synchronize such gates, we first describe how to implement them by using a Boolean *circuit* $\mathcal{A}$ that contains two types of gates: deterministic threshold gates, and input-less gates which outputs 1 with probability 1/2. We hereafter denote the latter gates by uniformly random gates[8]. The output distributions of the probabilistic threshold gate and the output gate of $\mathcal{A}$ will be very close up to a small additive error of $\epsilon \in (0,1)$. The synchronized probabilistic gate will be obtained by applying the synchronization scheme of Lemma 15 on the circuit $\mathcal{A}$.

Our key result might be of independent interest in the context of Boolean circuits:

▶ **Lemma 17.** *Given a* probabilistic *threshold gate g with Δ inputs, and an error parameter $\epsilon \in (0,1)$, there exists a Boolean circuit with depth* $\text{poly}(\log\Delta, \log(1/\epsilon))$ *and a total* $\text{poly}(\Delta, \log(1/\epsilon))$ deterministic *gates. In addition, there is a collection of $O(\log(1/\epsilon))$ uniformly random gates (each outputs 1 independently w.p. 1/2), and an output gate g' that approximates g in the following sense. Letting $p(\bar{x}), p'(\bar{x})$ be the probability that g, g' output 1 given input $\bar{x}$, it holds that $|p(\bar{x}) - p'(\bar{x})| \leq \theta(\epsilon)$ for any fixed assignment of input $\bar{x}$.*

Our starting point is the following useful fact from [20]:

▶ **Observation 18.** *Let g_1 be a* probabilistic *gate with an incoming weighted sum W and bias b_1. Let g_2 be a* deterministic *threshold gate with incoming weighted sum W and bias b_2, where b_2 is sampled from the Logistic distribution with mean b_1 and scale 1. Then* $\Pr[g_1 = 1] = \Pr[g_2 = 1] = 1/(1 + e^{-(W - b_1)})$.

The observation holds as the cumulative density function of the Logistic distribution is a Sigmoidal function. Since we already know how to implement a deterministic threshold gate using a Boolean circuit, the key challenge is in sampling a value from the Logistic distribution using a small number of uniformly random gates (i.e., fair coins). This is done in two key steps. First, using $O(\log 1/\epsilon)$ uniformly random gates, we sample a value from an ϵ^4-discretization of the uniform distribution [9]. Then, we use the method of inverse transform sampling to sample from a distribution that is $\Theta(\epsilon)$-close (in L_1 norm) to the Sigmoidal distribution. For a value r sampled u.a.r in $[0,1]$, a sample from the Logistic distribution with mean b and scale 1 is given by $b + \ln(r/(1-r))$. To compute the expression $b + \ln(r/(1-r))$ using a Boolean circuit, we approximate the $\ln(x)$ function using the first $O(\log 1/\epsilon)$ terms of the Taylor expansion. The almost-Logistic sample will serve as the bias of a deterministic threshold gate and will be fed to the Boolean circuit of Lemma 16. The full description is given in Appendix B.4.

We can then synchronize the Boolean Circuit as described in Lemma 17.

▶ **Corollary 19.** *Given a probabilistic threshold gate g with Δ inputs, and an error parameter $\epsilon \in (0,1)$, there exists a network $\mathcal{N} = \mathsf{Sync}(g)$ with Δ input neurons $x_1, \ldots, x_\Delta$, an output neuron z, and* $\text{poly}(\Delta, \log 1/\epsilon) \cdot L^3$ *auxiliary neurons such that z* approximates *the gate g within* $\text{poly}(\log\Delta, \log 1/\epsilon) \cdot L^4$ *rounds in the following sense. For any fixed input $\bar{x}$, with probability at least $1 - \Theta(\epsilon)$, it holds that g outputs 1 iff z fires in some round in* $[1, \text{poly}(\log\Delta, \log 1/\epsilon) \cdot L^4]$.

[8] A uniformly random gate is a fair coin, in contrast to probabilistic threshold gate that outputs 1 based on a Sigmoidal distribution.

[9] Our sample is equivalent to sampling a value from the uniform distribution and then rounding it to the closest value of the form $i \cdot \epsilon^4$ for some integer i.

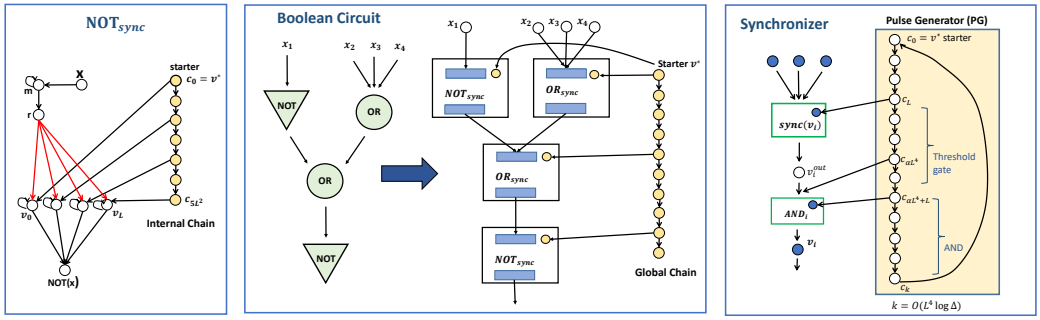

Figure 2 Left: synchronized network of a single NOT gate. Middle: A synchronized network for a Boolean circuit. Right: The transformation of a single neuron v_i in the synchronized network for the given SNN.

4.3 The Complete Synchronization Scheme

The complete synchronization scheme and the proof of Theorem 4 are given in Appendix B.5. In the high level, the construction has two parts: a global pulse generator, and a specific adaptation of the given network $\mathcal{N}$ into a network $\mathsf{sync}(\mathcal{N})$, see Figure 2.

The *pulse generator* is implemented by a directed cycle of length $k = \widetilde{O}(L^4 \log \Delta)$. The input layer and output layer in $\mathsf{sync}(\mathcal{N})$ are *exactly* as in $\mathcal{N}$. Let V be the neurons of $\mathcal{N}$. For each auxiliary neuron $v_i \in V$, we add its synchronized sub-network $\mathsf{Sync}(v_i)$ from Lemma 16 and Cor. 19. Recall that each neuron in $\mathcal{N}$ implements either a threshold gate or a probabilistic threshold gate. For each such $v_i \in V$, we also add an AND module AND_i, which receives input from the sub-network $\mathsf{Sync}(v_i)$ and the pulse generator. The neuron v_i is set to be the output neuron of this AND_i module.

A Missing Proofs for the Negative Results

Impossibility Result, Proof of Lemma 10. Assume towards contradiction there exists a network $\mathcal{N} = (V, \{x, y\}, \{z\}, w, b)$ that computes the AND gate of the initial states x_0, y_0 of the inputs x and y. It is then required that if $x_0 \wedge y_0 = 1$, then there exists a round in which z fires, and if $x_0 \wedge y_0 = 0$ then z is idle throughout the execution. Our goal is to show the existence of a bad assignment of latency values to the edges of $\mathcal{N}$. Such bad assignment exists even if we fix the latency of each edge to the same value throughout the entire execution. We begin with some quick observations.

- The state of a neuron v in round τ, namely, $\sigma_\tau(v)$, is fully determined by the network, the latency function, the input and the initial state σ_0, that is $\sigma_\tau(v) = H(\mathcal{N}, \ell, \sigma_0, x_0, y_0, v, \tau)$ for some function H.
- Given the network $\mathcal{N}$ and a latency function ℓ, the state of a neuron v in round τ is a function of the *previous* states of its incoming neighbors denoted as $u_1 \dots u_k$:

$$\sigma_\tau(v) = F_v(\sigma_{\tau-\ell(u_1,v)}(u_1), \dots, \sigma_{\tau-\ell(u_k,v)}(u_k)).$$

▶ **Definition 20.** *For a neuron v and round τ, we say that the state $\sigma_\tau(v)$ is* x-independent *(equivalently y-independent) if its value does not depend on the initial state of x, i.e if*

$$H(\mathcal{N}, \ell, \sigma_0, x_0 = 0, y_0, v, \tau) = H(\mathcal{N}, \ell, \sigma_0, x_0 = 1, y_0, v, \tau) \ .$$

▶ **Observation 21.** *A concatenation of x-independent functions is also x-independent. Specifically, for round τ and neuron v with incoming neighbors $u_1, \dots u_k$, it holds that if $\sigma_{\tau-\ell(u_1,v)}(u_1), \dots, \sigma_{\tau-\ell(u_k,v)}(u_k)$ are x-independent then $\sigma_\tau(v)$ is also x-independent.*

Given the network $\mathcal{N}$ we set the edge latencies as follows:

$$\ell(u, v) = \begin{cases} 1 & \text{if either } u = x \text{ or } v = x, \text{ but not both.} \\ 2 & \text{otherwise.} \end{cases}$$

We next show that for every neuron $v \in V$, its firing state in each round if either x-independent or y-independent. Specifically, the firing state of z in each round does not depend on both x_0 and y_0. This will contradict the assumption that z computes an AND gate of x_0 and y_0.

▷ Claim 22. For every round $\tau \geq 1$ it holds that: (1) For every $v \in V \setminus \{x\}$, the firing state $\sigma_\tau(v)$ is x-independent if τ is even and y-independent if τ is odd. (2) $\sigma_\tau(x)$ is x-independent if τ is odd and y-independent if τ is even.

Proof. By induction on the round τ. For $\tau = 1$, since all outgoing edges from y have latency 2 (except for the edge (y, x), if exists), in round 1 no neuron $v \in V \setminus \{x\}$ received a spike from y and therefore $\sigma_1(v)$ is y-independent. Because the edge from x to itself has latency 2, and the edge from y to x has latency 1, in round 1 the neuron x can receive a signal from y but not from x and therefore also $\sigma_1(x)$ is x-independent. For $\tau = 2$ and $v \neq x$, since the edges from x have latencies 1, and all other edges have latency 2, it holds that

$$\sigma_2(v) = F_v(\sigma_1(x), \sigma_0(y), \sigma_0(u_1), \ldots, \sigma_0(u_k)),$$

where $u_1, \ldots, u_k$ are the neighbors of v in $V \setminus \{x\}$. Because $\sigma_1(x)$ is x-independent, and $\sigma_0(u_i)$ are the initial states, by Observation 21 we can conclude that $\sigma_2(v)$ is x-independent. Next, for the input neuron x, since all its incoming edges (except for the self-loop) have latency 1 it holds that

$$\sigma_2(x) = F_x(\sigma_0(x), \sigma_1(u_1), \ldots, \sigma_1(u_k)).$$

Because $\sigma_1(v)$ is y-independent for all $v \neq x$, we conclude that $\sigma_2(x)$ is y-independent as well.

Assume the claim holds for every round $\tau' < \tau$ and we will show the claim holds for round τ as well. For $v \neq x$ with incoming neighbors $u_1, \ldots u_k$ in $V \setminus \{x\}$, by the definition of the latencies it holds that

$$\sigma_\tau(v) = F_v(\sigma_{\tau-1}(x), \sigma_{\tau-2}(u_1), \ldots, \sigma_{\tau-2}(u_k)).$$

If τ is even, so is $\tau - 2$ and by the induction assumption $\sigma_{\tau-2}(u_i)$ are x-independent. Because $\tau - 1$ is odd, $\sigma_{\tau-1}(x)$ is x-independent. Hence, by Observation 21 we conclude that $\sigma_\tau(v)$ is also x-independent. Similarly, if τ is odd, then by the induction assumption $\sigma_{\tau-2}(u_i)$ and $\sigma_{\tau-1}(x)$ are y-independent, and therefore $\sigma_\tau(v)$ is also y-independent. Then, for the neuron x, it holds that

$$\sigma_\tau(x) = F_x(\sigma_{\tau-2}(x), \sigma_{\tau-1}(u_1), \ldots, \sigma_{\tau-1}(u_k)).$$

If τ is odd, by the induction assumption $\sigma_{\tau-2}(x)$ as well as $\sigma_{\tau-1}(u_1), \ldots, \sigma_{\tau-1}(u_k)$ are x-independent and therefore $\sigma_\tau(x)$ is x-independent. On the other hand, if x is even, then by the induction assumption $\sigma_{\tau-2}(x)$ and $\sigma_{\tau-1}(u_1), \ldots, \sigma_{\tau-1}(u_k)$ are y-independent and therefore $\sigma_\tau(x)$ is also y-independent. ◁

Since in each round the output neuron z is either x-independent or y-independent, this contradicts the assumption and Lemma 10 follows.

A.1 Size Lower Bound for Computing $NOT(x)$

A.1.1 Reduction to Simple Networks, Proof of Lemma 12

The reduction is based on the following notion of domination between two configurations.

Domination. Given a network $\mathcal{N}$, a latency function ℓ, and a vector of starting states $\bar{\sigma}$ for all neurons but the input x, for $b \in \{0,1\}$ define $\text{pot}_b(u,\tau,\mathcal{N},\ell,\bar{\sigma})$ as the potential of neuron u in round τ in the simulation of $\mathcal{N}$ with the initial vector state $[b,\bar{\sigma}]$, i.e., with the initial state of x is being b and all other initial states are as in $\bar{\sigma}$. When $\bar{\sigma}$ is clear from the context, we may omit it, and simply write $\text{pot}_b(u,\tau,\mathcal{N},\ell)$. Given networks $\mathcal{N}_1,\mathcal{N}_2$ with vertices V_1,V_2 and latency functions ℓ_1,ℓ_2 respectively, we say that $\langle\mathcal{N}_1,\bar{\sigma}_1\rangle$ and $\langle\mathcal{N}_2,\bar{\sigma}_2\rangle$ are *compatible* if $V_1 \subseteq V_2$ and σ_1 and σ_2 agree on the mutual vertices of V_1, i.e., $\sigma_1(u) = \sigma_2(u)$ for every $u \in V_1$.

In our arguments, we consider a pair of compatible configurations $\langle\mathcal{N}_1,\bar{\sigma}_1\rangle$ and $\langle\mathcal{N}_2,\bar{\sigma}_2\rangle$ along with latency functions ℓ_1,ℓ_2 for these configurations. We say that $\langle\mathcal{N}_1,\bar{\sigma}_1,\ell_1\rangle$ *dominates* $\langle\mathcal{N}_2,\bar{\sigma}_2,\ell_2\rangle$ if $\langle\mathcal{N}_1,\bar{\sigma}_1\rangle$ and $\langle\mathcal{N}_2,\bar{\sigma}_2\rangle$ are compatible and in addition:

- $\text{pot}_1(u,\tau,\mathcal{N}_1,\ell_1,\bar{\sigma}_1) \leq \text{pot}_1(u,\tau,\mathcal{N}_2,\ell_2,\bar{\sigma}_2)$ for every $u \in V_1 \setminus \{x\}$ and $\tau \geq 0$.
- $\text{pot}_0(u,\tau,\mathcal{N}_1,\ell_1,\bar{\sigma}_1) \geq \text{pot}_0(u,\tau,\mathcal{N}_2,\ell_2,\bar{\sigma}_2)$ for every $u \in V_1 \setminus \{x\}$ and $\tau \geq 0$.

Let V, V_{simple} be the vertex sets of $\mathcal{N}$ and $\mathcal{N}_{simple}$ respectively. Let $\bar{\sigma}_{simple}$ be the initial state vector that agrees with $\bar{\sigma}$ on all vertices in V_{simple}. Thus, $\langle\mathcal{N}_{simple},\bar{\sigma}_{simple}\rangle$ and $\langle\mathcal{N},\bar{\sigma}\rangle$ are compatible. For a number of rounds r, a latency function ℓ is *r-good* for $\langle\mathcal{N},\bar{\sigma}\rangle$ if $\mathcal{N}$ computes $NOT(x)$ within r rounds under ℓ when starting from the initial state vector $\bar{\sigma}$. Our proof strategy is as follows. We will show that every latency function ℓ_{simple} is r-good for $\langle\mathcal{N}_{simple},\bar{\sigma}_{simple}\rangle$, by showing that there exists a function ℓ such that

$$\langle\mathcal{N}_{simple},\bar{\sigma}_{simple},\ell_{simple}\rangle \text{ dominates } \langle\mathcal{N},\bar{\sigma},\ell\rangle.$$

Given a latency function ℓ_{simple} for the network $\mathcal{N}_{simple}$, let ℓ be a latency function for $\mathcal{N}$ which is similar on excitatory neurons and gives inhibitory neurons the latency value of the neuron x. I.e., $\ell(v,u,\tau) = \ell_{simple}(v,u,\tau)$ for every pair of excitatory neurons. In addition, $\ell(v',u,\tau) = \ell_{simple}(x,u,\tau)$ for every inhibitory neuron v', and a neuron $u \in V_{simple}$. All remaining latency values (i.e., the incoming edges to the inhibitors of $\mathcal{N}$) can be chosen arbitrarily.

We show by induction on the round τ, that (i) $\text{pot}_1(u,\tau,\mathcal{N}_{simple},\ell_{simple}) \leq \text{pot}_1(u,\tau,\mathcal{N},\ell)$ for every $u \in V_{simple} \setminus \{x\}$, $\tau \geq 0$, and (ii) $\text{pot}_0(u,\tau,\mathcal{N}_{simple},\ell_{simple}) \geq \text{pot}_0(u,\tau,\mathcal{N},\ell)$ for every $u \in V_{simple} \setminus \{x\}$ and $\tau \geq 0$. For $\tau = 0$, this is true as the potential values in $\tau = 0$ are simply the initial states, and the vector of initial states of $\bar{\sigma}$ and $\bar{\sigma}_{simple}$ are compatible. For the induction step, let $\tau \geq 1$, and assume correctness for all $\tau' \leq \tau - 1$. We will prove the claims for round τ. Let u be a neuron in $V_{simple} \setminus \{x\}$, and let $v_1,\ldots,v_k$ be its incoming excitatory neighbors.

The initial state of x is 0. By the induction assumption, it holds that $\text{pot}_0(u,\tau',\mathcal{N}_{simple},\ell_{simple}) \geq \text{pot}_0(u,\tau',\mathcal{N},\ell)$ for every round $\tau' \leq \tau - 1$ and every neuron $v \in \{v_1,\ldots,v_k\}$. Thus every excitatory neuron v_i that fires in round τ' in the simulation of $\mathcal{N}$, also fires in round τ' in the simulation of $\mathcal{N}_{simple}$ for every $\tau' \leq \tau - 1$. Combining with the definition of the latency function ℓ, we get that each spike from v_i that arrives to u at round τ of the simulation of $\mathcal{N}$ also arrives u in round τ in the simulation of $\mathcal{N}_{simple}$. Let ω be an inhibitory incoming neighbor of u in $\mathcal{N}$, then ω does not exist in $\mathcal{N}_{simple}$. Also note that since $\sigma_0(x) = 0$, a negative spike from x never arrives at u in the simulation of network

$\mathcal{N}_{simple}$. Therefore, no negative spikes arrive at u in $\mathcal{N}_{simple}$. Summing over the positive and negative spike weights, we get that $\text{pot}_0(u, \tau, \mathcal{N}_{simple}, \ell_{simple}) \geq \text{pot}_0(u, \tau, \mathcal{N}, \ell)$ for every $u \in V_1 \setminus \{x\}$.

The initial state of x is 1. The initial state of x is 1: By the induction assumption it holds that $\text{pot}_1(u, \tau', \mathcal{N}_{simple}, \ell_{simple}) \leq \text{pot}_1(u, \tau', \mathcal{N}, \ell)$ for every round $\tau' \leq \tau - 1$ and every $u \in \{v_1, \ldots, v_k\}$. Thus every v_i that fires in round τ' in the simulation of $\mathcal{N}_{simple}$, also fires in round τ' in the simulation of $\mathcal{N}$. Combining with the definition of the latency function ℓ, we get that each spike from v_i that arrives at u in round τ of the simulation of $\mathcal{N}_{simple}$ also arrives at u in round τ in the simulation of $\mathcal{N}$.

Let ω be an inhibitory incoming neighbor of u in $\mathcal{N}$. By the definition of the latency function ℓ, and the fact that x fires in every round, for each spike that ω fires and arrives at u in round τ in $\mathcal{N}$, there is a spike from x that arrives at u in round τ in $\mathcal{N}_{simple}$. Since the edges from x have weight $-\infty$, we get that the negative spikes weight arriving at u in round τ in $\mathcal{N}_{simple}$ are larger (in absolute value) than the negative spikes in $\mathcal{N}$. Thus, summing up the both positive and negative spike weights, we get that $\text{pot}_1(u, \tau, \mathcal{N}_{simple}, \ell_{simple}) \leq \text{pot}_1(u, \tau, \mathcal{N}, \ell)$ for every $u \in V_{simple} \setminus \{x\}$. This proves the induction step for round τ. We get that $\langle \mathcal{N}_{simple}, \bar{\sigma}_{simple}, \ell_{simple} \rangle$ dominates $\langle \mathcal{N}, \bar{\sigma}, \ell \rangle$.

Finally, we show that if $\langle \mathcal{N}_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle \mathcal{N}_2, \bar{\sigma}_2, \ell_2 \rangle$ and ℓ_2 is r-good for $\langle \mathcal{N}_2, \bar{\sigma}_2 \rangle$, then also ℓ_1 is r-good for $\langle \mathcal{N}_1, \bar{\sigma}_1 \rangle$.

Consider the simulation of $\langle \mathcal{N}_2, \bar{\sigma}_2, \ell_2 \rangle$, and assume that the initial state of x is 0. Since ℓ_2 is r-good for $\mathcal{N}_2$, there is a round $\tau \leq r$ in which z fires in $\mathcal{N}_2$. Since $\langle \mathcal{N}_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle \mathcal{N}_2, \bar{\sigma}_2, \ell_2 \rangle$, we can apply the condition of domination for z, τ and get that z also fires in round τ in $\mathcal{N}_1$. Now, assume that the initial state of x is 1. Since ℓ_2 is r-good for $\mathcal{N}_2$, there is *no* round τ in which z fires in $\mathcal{N}_2$. Since $\langle \mathcal{N}_1, \bar{\sigma}_1, \ell_1 \rangle$ dominates $\langle \mathcal{N}_2, \bar{\sigma}_2, \ell_2 \rangle$, we can apply the condition of domination for z and every τ, and get that z also never fires in $\mathcal{N}_1$. Hence, ℓ_1 is r-good for $\mathcal{N}_1$. This completes the proof of the lemma.

A.1.2 Size Lower Bound for Simple Networks

We show that the latency values defined in the step i satisfy the invariant in the beginning of step $i + 1$.

Proving that the Invariants Hold. For round $i = 0$, the correctness of invariant (I1) hold since in the first round $\tau = -1$ all positive spikes are set to arrive in round 0 in both ℓ_0, ℓ_1, while a spike from x arrives at round $\tau = L - 1$. As for the correctness of invariant (I2), note that both simulations are similar for all neurons $V \setminus \{x\}$, and, again, a spike from x arrives only in round $L - 1$. Therefore the same neurons are active in round $\tau = 0$. Hence $A_{0,0} = A_{0,1}$ and we get correctness for (I2). We now show that the invariants are preserved after each step. Assume that the correctness holds at the beginning of each step $j \leq i$, and consider now the beginning of step $i + 1$.

- (I1) By the construction, in all of the cases, the values we set for ℓ_0, ℓ_1 in step i are such that all spikes except the spike from x generated at round $iL + (L - 1)$ which are generated in T_i arrive at some round $\tau \leq (i + 1)L$, i.e. by the first round of T_{i+1}. Furthermore, spikes from x generated at round $iL + (L - 1)$ is set to arrive in round $(i + 1)L + (L - 1)$. The invariant holds by combining with the correctness for all steps $i' \leq i$.
- (I2) We start by proving the following auxiliary claim.

▷ Claim 23. Consider the simulation of $\mathcal{N}$ with initial state $\bar{\sigma}_b$ and latency function ℓ_b, and let τ be round in T_i. Then:

1. For a strong neuron $u \in A_{i,1}$, u fires iff $\tau \in [iL, iL+(L-2)] \subseteq T_i$. For a strong neuron $u \in A_{i,0}$, u fires for every $\tau \in T_i$.
2. For a weak neuron $u \in A_{i,b}$, u fires iff $\tau = iL$.
3. For $u \notin A_{i,b}$, u is not active in round τ.

Proof.

Case $b = 1$: We start by showing that all three claims hold for $b = 1$. By the definition of ℓ_1, the only positive spikes received by any neuron in some round $\tau \in [iL+1, iL+(L-1)]$ are self-loop spikes. Since a strong active neuron $u \in A_{i,1}$ receives an inhibiting spike from x in round $iL + (L-1)$, it is not active in this last round. For a weak neuron u', its spike from the self-loop is not strong enough to make it active. Lastly, for $u \notin A_{i,1}$ since no negative spikes arrive at u in round iL we have that $b(u) > 0$. Due to the fact that no spikes arrive at u in round τ, we get that u stays inactive.

Case $b = 0$: claim (1) holds since a strong $u \in A_{i,0}$ never gets inhibited as x never fires. We will now consider claim (2) and (3) for a neuron u that is either a *weak* neuron, or a strong neuron that is *not* in $A_{i,0}$. By Invariant (I1), all the positive spikes from the previous blocks arrived by the first round of T_i. Thus if u fires in any round $\tau \in [iL+1, iL+(L-1)]$ (i.e., any round which is not the first one in T_i), this must be due to the incoming spikes generated in the first round of T_i. We will know prove by induction on the round τ that u does not fire in any round in $[iL+1, iL+(L-1)]$.

Induction Base, Round $\tau = iL + 1$: By the definition of the latency function ℓ_0, no spike arrives at u from an incoming neighbor in that round. Therefore, if u is weak, then a spike from itself will not make it active in round τ. In addition, if $u \notin A_{i,0}$ then u did not fire in round iL, and thus receives no self-spike in round τ. Since no negative spikes arrive at u in round iL, for every $u \notin A_{i,0}$, it must hold that $b(u) > 0$.

Induction Step $\tau \geq iL + 2$. Assume that the claims (2,3) hold up to round $\tau - 1$ and consider round $\tau \geq iL + 2$. Consider first the case that u has either a weak neighbor g_j with $w(g_j, u) \geq b(u)$, or alternatively a strong neighbor h_j with $w(h_j, u) \geq b(u)/(L-1)$. Then by the definition of ℓ_0 (Case I in our definition), all the spikes fired by the incoming neighbors of u are scheduled to arrive in the first round of T_{i+1}. Therefore, u does not receive any spike in round τ, and remains inactive.

Next, consider the complimentary case where all the weak neighbors g_j satisfy that $w(g_j, u) < b(u)$, and all the strong neighbors h_j satisfy $w(h_j, u) < b(u)/(L-1)$.

Case (1): $\tau \in [iL + 2, iL + \omega + 1]$. By the induction assumption on $\tau - 1$, u did not fire in round $\tau - 1$. By the definition of ℓ_0, u receives a spike from at most one weak neighbor g_j in round τ, and since $w(g_j, u) < b(u)$, it does not fire in this round.

Case (2): $\tau \in [iL + (\omega + 2), iL + (L-1)]$. Let h_j be a strong active neighbor of u. By the definition of ℓ_0, in round τ, u receives at most $(\omega+1)/(L-(\omega+1))$ of the spikes that fired by h_j during the interval $[iL, iL + \omega]$. Furthermore, there is one additional spike that h_j fired at round $\tau - 1$, that arrives at u in round τ. Note that u does not receive spikes from weak neighbors in round τ since all spikes from weak neighbors arrive in an earlier round $\tau'' \in [iL + 2, iL + (\omega + 1)]$. In addition, since u did not fire in round $\tau - 1$, it also does not get any self spikes in round τ. Overall, u receives at most $((\omega+1)/(L-(\omega+1))) + 1$ spikes by strong neighbors in round τ, and no other spikes (by a weak neighbor or by u). Since the spikes from the strong

neighbors have weight of at most $b(u)/(L-1)$, and there are s strong active neighbors, the overall weighted sum of the received spikes at round τ is at most

$$s \cdot ((\omega+1)/(L-(\omega+1))+1) \cdot \frac{b(u)}{L-1} <$$

$$s \cdot ((\omega+1)/s+1)\frac{b(u)}{L-1} = (s+\omega+1)\frac{b(u)}{L-1} < \quad b(u) \ , \tag{2}$$

where both inequalities follow as $s+\omega < L-2$. Therefore, u does not get activated at round τ, claims (2)+(3) follow. ◁

We are now ready to prove the induction step for (I2). Assume towards contradiction that there exists a neuron $u \in A_{i+1,0} \setminus \bigcup_{i' \leq i+1} A_{i',1}$. Since u is active in the first round of T_{i+1}, using Claim 23(3), it must have an incoming neighbor that fires in the *first round* of the previous block. Let $A_{i,0}(u) = \Gamma_{in}(u) \cap A_{i,0}$ be those neighbors.

▷ Claim 24. For every strong neuron $v \in A_{i,0}(u)$, it holds that $w(v,u) < b(u)/(L-1)$.

Proof. Consider such strong $v \in A_{i,0}(u)$. By Invariant (I2) for the beginning of step i, there exists a round $j \leq i$ such that $v \in A_{j,1}$. When running $\mathcal{N}$ with initial state $\bar{\sigma}_1$ and the latency function ℓ_1, by Claim 23(1), v fires in all of the $L-1$ rounds of $[jL, jL+(L-2)]$. By the construction of ℓ_1, all these $L-1$ spikes arrive in round $(j+1)L$. Therefore, if $(L-1) \cdot w(v,u) \geq b(u)$, then u is activated in round $(j+1)L$, i.e., $u \in A_{j+1,1}$, in contradiction to the definition of u. Therefore $(L-1) \cdot w(v,u) < b(u)$ for every strong neuron v. ◁

▷ Claim 25. For every weak neuron $v \in A_{i,0}(u)$, it holds that $w(v,u) < b(u)$.

Proof. Consider such weak neuron $v \in A_{i,0}(u)$. When running $\mathcal{N}$ with initial state $\bar{\sigma}_1$ and latency function ℓ_1, by Claim 23(2), v fires once in the interval T_j, i.e., in the first round jL. By the construction of ℓ_1 this spike arrives in round $(j+1)L$. Therefore, if $w(v,u) \geq b(u)$, then u is activated in round $(j+1)L$, implying that $u \in A_{j+1,1}$, contradiction to the definition of u. We therefore conclude that $w(v,u) < b(u)$ for every weak neuron $v \in A_{i,0}(u)$. ◁

Let ω, s be the number of weak (resp., strong) neurons in $A_{i,0}(u)$. By Claims 25 and 23(2), all active weak neurons in T_i fire only in the first round of that block. By the definition of the latency function, all these spikes are scheduled to the first ω rounds in T_i, and therefore none of them is scheduled to arrive on the first round of T_{i+1}. This implies that u fires in that round due to the spikes generated by its strong neighbors. By Claim 24, $w(v,u) < b(u)/(L-1)$ for each such strong neighbor v of u. This in particular implies that u is a weak neuron, and by Claim. 23 it did not fire in the last round of T_i. By the definition of the latency function, the spikes generated by such strong neighbors are divided almost evenly among $L-\omega$ rounds, up to the first round of T_{i+1}. Each round gets at most $s \cdot (\omega/(L-\omega)+1)$, which is strictly less than $b(u)$ by Eq. (2). Leading to contradiction for the assumption that $u \in A_{i+1,0}$.

Since ℓ_1 is a good latency function when starting with $x=1$, we have that z never fires and thus $z \notin \bigcup A_{i,1}$. By applying invariant (I2) on the output neuron z for every round $\tau \geq 0$, we get that $z \notin \bigcup A_{i,0}$. By using Claim 23, we get that z never fires with ℓ_0 and $x=0$. Contradiction to the fact that $\mathcal{N}$ solves $NOT(x)$.

A.2 Time Lower Bound for Computing $NOT(x)$

In this section we show the following.

▶ **Lemma 26.** *Every network $\mathcal{N}$ that computes $NOT(x)$ in the L-bounded asynchronous setting requires $\Omega(L^3)$ rounds.*

By Lemma 12, we restrict attention to a simple network $\mathcal{N} = \mathcal{N}_{simple}$ with one input neuron x that computes $NOT(x)$. Similarly to the size lower bound, we define two *conflicting* latency functions ℓ_0 and ℓ_1, such that if ℓ_1 is good when $x_0 = 1$, then the output neuron z of $\mathcal{N}$ fires after $\Omega(L^3)$ rounds in the simulation with the latency function ℓ_0 and $x_0 = 0$.

- The simulation with the latency function ℓ_0 is partitioned into consecutive blocks of L rounds, $T_i = [iL, iL + (L-1)]$ for every $i \in \mathbb{N}$.
- The simulation with the latency function ℓ_1 is based on the notion of *important* and *unimportant* rounds. Consider the L-round interval $T_k = [k \cdot L, k \cdot L + (L-1)]$ for $k \in \mathbb{N}$. Among the first $L/2$ rounds, there is an important round once every 16 rounds, and the rest are unimportant. Furthermore, each of the last $L/2$ rounds of the interval are unimportant. I.e., the important rounds in the interval are $\{kL + 16j \mid 16j < L/2, j \in \mathbb{N}\}$. Denote by τ_i the i^{th} important round in the simulation. Note that by definition $\tau_{i+1} - \tau_i \leq L/2$. In our arguments, the configuration of the network in the i^{th} important round τ_i of the simulation with ℓ_1 and $x_0 = 1$ will be compared against the configuration in round iL (i.e., the first round of the block T_i) in the simulation with ℓ_0 and $x_0 = 0$.
- Active subsets of neurons: For every $i \in \mathbb{N}$, let $A_{0,i}$ be the firing neurons (hence *active*) of round $i \cdot L$ (the first round of the block T_i) in the simulation of $\langle \mathcal{N}, \sigma_0, \ell_0 \rangle$. Similarly, let $A_{1,i}$ be the firing neurons in round τ_i of the simulation of $\langle \mathcal{N}, \sigma_1, \ell_1 \rangle$. Also define $A'_{b,i} = A_{b,i} \setminus \bigcup_{j \leq i-1} A_{b,j}$, the neurons that fire for the first time in "round" i.
- For every neuron u, $b \in \{0,1\}$ and $i \in \mathbb{N}$, let $A_{b,i}(u) = A_{b,i} \cap N_{in}(u)$, $A'_{b,i}(u) = A'_{b,i} \cap N_{in}(u)$ where $N_{in}(u)$ is the set of incoming neighbors of u.
- For a subset of neurons $V' \subseteq V$ and a neuron u, let $w(V', u) = \sum_{v \in V'} w(v, u)$. Moreover, let $\mathbf{S}(V')$ and $\mathbf{W}(V')$ be the strong[10] and weak (respectively) neurons subsets of V'.

A.2.1 Defining the latency functions ℓ_0 and ℓ_1

Throughout, a spike event is represented by a triplet $\langle v, u, \tau \rangle$ where $v \in N_{in}(u)$ fires in round τ. Since the functions are nice, the latency values for the self spikes $\langle u, u, \tau \rangle$ for every u and τ are set to 1. For technical reasons, it is more convenient to start the simulations in round -1, rather than in round 0. For this first round -1, let $\ell_b((v,u), -1) = 1$ for every u and every $v \neq x$, and $\ell_b((x,u), -1) = L$ for every u and $b \in \{0,1\}$. As a result, the positive spikes (by any $v \neq x$) fired in round -1 arrive to their destination in round 0, and the negative spikes of x arrive in round $L-1$. We now define the latency values for the remaining spikes.

Defining the function ℓ_0. Note that when $x_0 = 0$, x never fires and thus there is no need to define ℓ_0 values for the spikes of x. We define ℓ_0 iteratively in a block by block manner. Here we do not accumulate spikes and spikes generated in the i^{th} block T_i will arrive by the first round of the $(i+1)^{th}$ block T_{i+1}. Fix a block $T_i = [iL, iL + (L-1)]$ for $i \geq 0$ and assume that the latency values ℓ_0 for all prior spikes in rounds $\tau < iL$ have already been

[10] Recall that a neuron u is strong if $w(u,u) \geq b(u)$ and it is weak otherwise.

fixed. Thus the active set $A_{0,i}$ can be determined. First, the algorithm checks if there is a way to spread all the spikes generated in rounds of T_i among the interval $[iL+2,(i+1)L]$, in a way that guarantees that u will not fire in *any* of the rounds this interval. In particular, *no* spike is scheduled to arrive in round $iL+1$. Otherwise, all spikes generated in this block are scheduled to arrive in round $(i+1)L$ (the first round of the $(i+1)^{th}$ block).

Defining the function ℓ_1. The definition of the function ℓ_1 is more involved. Unlike the function ℓ_0 in which all spikes generated in block T_i are scheduled by round $(i+1)L$, here the setting is slightly more sensitive. Specifically, the scheduling algorithm of ℓ_1 will make sure that non-self spikes arrive to their destination only in important rounds.

Spikes by the input (inhibitory neuron) x: All spikes from x are scheduled to arrive in the last round of the blocks T_i, namely, in rounds of the form $i \cdot L + (L-1)$. Formally, for every spike $\langle x,u,\tau\rangle$ where $\tau = i\cdot L+(L-1)$ for some $i\in\mathbb{N}$, let $\ell_1((x,u),\tau) = L$ thus arriving in round $\tau + L = (i+1)L + L - 1$. For every $\tau \in [iL, iL+(L-2)]$, let $\ell_1((x,u),\tau) = (iL+(L-1)) - \tau$, thus arriving in round $iL+(L-1)$ as desired.

Spikes by $v \neq x$: The latency values are defined in a round by round fashion, such that for every important round τ_i, every neuron u gets activated if possible. Otherwise the arrival of the spikes towards u are postponed (when possible) to the next important round τ_{i+1}. The spikes generated at non-important rounds will be always delayed to the next important round. This is always possible as the distance to the next important round is at most $L/2$. For a subset of spikes S, let $w(S) = \sum_{\langle v,u,\tau\rangle\in S} w(v,u)$ be the total weight of the spikes in S. For every important round τ_i, we will maintain a list of pending spikes $\mathcal{R}_{\tau_i}(u)$ towards u that were not yet scheduled. In every step $\tau \geq 0$, the algorithm will schedule the spikes generated in this round. If the round τ is important, then the algorithm will also make decisions regarding the set of pending spikes $\mathcal{R}_{\tau_i}(u)$.

We will keep the invariant that at the beginning of step τ, the latency value of all spikes scheduled to arrive by round τ has already been determined. As we will see, the non-self spikes will always be scheduled to arrive in important rounds. As a result, a neuron u fires in an unimportant round τ iff u is strong and it fired in round $\tau-1$. Initially, for every neuron u, the algorithm adds every non-self spike $\langle v,u,-1\rangle$ to $\mathcal{R}_{\tau_i}(u)$. For every $\tau \geq 0$, we consider the following algorithm.

- All self-spikes $\langle u,u,\tau'\rangle$ are given a latency value of $\ell(u,u,\tau') = 1$.
- **Handling important rounds τ_i.** Consider a neuron u. If u fired in round $\tau_i - 1$, add the self-spike $\langle u,u,\tau_i-1\rangle$ to the pending spike set $\mathcal{R}_{\tau_i}(u)$. If the total weight of its pending spikes (towards u) is sufficiently large to make u fire, all the non-self spikes are scheduled to arrive in τ_i. Formally, if $w(\mathcal{R}_{\tau_i}(u)) \geq b(u)$, schedule all these spikes to round τ_i by setting $\ell(v,u,\tau') = \tau_i - \tau'$ for every spike $\langle v,u,\tau'\rangle \in \mathcal{R}_{\tau_i}(u)$.
  Otherwise, if the total weight of pending spikes is small, i.e., $w(\mathcal{R}_{\tau_i}(u)) < b(u)$, the non-self spikes are deferred to the next important round τ_{i+1} if possible (i.e., if the latency does not exceed its upper bound L). Formally, for every non-self pending spike $\langle v,u,\tau'\rangle \in \mathcal{R}_{\tau_i}(u)$, if $\tau_{i+1} - \tau' > L$ then let $\ell((v,u),\tau') = L$ (i.e., $\langle v,u,\tau'\rangle$ cannot be further deferred). Otherwise, add $\langle v,u,\tau'\rangle$ to the pending spike set $\mathcal{R}_{\tau_{i+1}}(u)$ of the next important round τ_{i+1}.
  Finally, all spikes generated in round τ_i are also (safely) added to the pending list $\mathcal{R}_{\tau_{i+1}}(u)$.
- **Handling unimportant rounds.** The non-self spikes towards u generated in round τ are added to the pending spike set $\mathcal{R}_{\tau_{i+1}}(u)$ of the next important round τ_{i+1} (after round τ).

First observe that the function ℓ_1 is valid: All self-spikes have a latency value of 1. Moreover, the non-self spikes have a latency value in $[1, L]$. To see this observe that for unimportant round τ, a non-self spike $\langle v, u, \tau \rangle$ is added to the pending list $\mathcal{R}_{\tau_{i+1}}(u)$ where τ_{i+1} is the next important round after τ. Due to the fact that $\tau_{i+1} - \tau_i \leq L/2$, this assignment is valid. In addition, the pending spikes $\langle v, u, \tau \rangle \in \mathcal{R}_{\tau_i}(u)$ are deferred to τ_{i+1} only if $\tau_{i+1} - \tau \leq L$.

A.2.2 Proof of Lemma 26

The key lemma that establishes Lemma 26 is the following:

▶ **Lemma 27.** *For every neuron $u \neq x$ with $u \in A'_{0,i}$ for $i < L^2/1024$, there exists some $i' \leq i$ such that $u \in A'_{1,i'}$.*

By the correctness of the simple network $\mathcal{N}$, the output neuron z should not fire when $x_0 = 1$ and with the latency function ℓ_1. In other words, $z \notin A_{1,i'}$ for any i'. By Lemma 27, we get that z can only be in $A'_{0,j}$ for some $j \geq L^2/1024$, hence firing when $x_0 = 0$ only after $\Omega(L^3)$ rounds. We start with the following simple observation.

▶ **Observation 28.** *In the simulation of $\langle \mathcal{N}, \bar{\sigma}_0 \rangle$ with ℓ_0, it holds for every i that: (i) each strong neuron $s \in A_{0,i}$ fires in every round of block T_i; (ii) each weak neuron $\omega \in A_{0,i}$ which is not x fires only in the first round of block T_i; and (iii) every neuron $v \notin A_{0,i}$ does not fire in any round of block T_i.*

Proof. (i). In the simulation with ℓ_0 with $x_0 = 0$ there are no inhibiting spikes, and if a strong neuron s fires in some round, it will keep on firing for the rest of the simulation.

(ii). By the definition of the latency function ℓ_0, no spikes from incoming neighbors of the weak neuron ω arrive in round $iL + 1$, the second round of block T_i. We will prove by induction on $\tau \in [iL + 1, iL + (L - 1)]$ that ω does not fire in round τ. For the base of the induction, since $\omega \neq x$ is excitatory and weak, it holds that $0 \leq w(\omega, \omega) < b(\omega)$, thus ω does not fire in round $iL + 1$. Assume that the claim holds up to round $\tau \geq iL + 1$ and consider round $\tau + 1$. Since ω did not fire in round τ by the induction assumption, it does not receive a self spike in round $\tau + 1$. By the definition of the function ℓ_0, the non-self spikes that arrive in round $\tau + 1 < (i + 1)L$ cannot make ω fire. Thus ω does not fire in $\tau + 1$ and (ii) holds.

(iii). Let $v \notin A_{0,i}$, i.e., v did not fire in round iL. Since v does not receive negative spikes in round iL (as the spikes of x are always scheduled to the last round of the blocks). We can then conclude that $b(v) > 0$. Since in round $iL + 1$, it receives no self-spike and no other spike, it also did not fire in round $iL + 1$. The argument then follows inductively in the same manner as in (ii). ◀

We next state the following claim which is crucial to complete the key lemma.

▷ Claim 29. Fix a neuron $u \in A'_{0,i}$ such that for every $v \in A_{0,i-1}$ it holds that $w(v, u) < b(u)$. Then the total weight of spikes fired towards u in block T_{i-1} is at least $L \cdot b(u)/8$.

We first complete the proof of Lemma 27 and only then prove Claim 29.

Proof of Lemma 27. The proof is shown by induction on the block i. For the base case of $i = 0$, note that the initial states and the latency functions for the neurons $V \setminus \{x\}$ in both simulations are the same, and that spikes from x (that exist only in the simulation with ℓ_1) arrive only in round $L - 1$. This implies that in both simulations the same neurons (except for x) are active in round $\tau = 0$, hence $A_{0,0} = A_{1,0} \setminus \{x\}$. Now consider the block T_i for $1 \leq i < L^2/1024$. Let $u \in A'_{0,i}$, i.e. u fires for the first time in round iL in the simulation with ℓ_0 and $x_0 = 0$.

Case 1: There exists a previously firing dominant incoming neighbor: First assume that u has some incoming neighbor $v \in A_{0,i-1}$ with $w(v,u) \geq b(u)$. By definition $v \in A'_{0,j}(u)$ for some $j \leq i-1$, and then by the induction assumption $v \in A'_{1,i'}$ for some $i' \leq j \leq i-1$. By definition of the latency function ℓ_1, since $w(v,u) \geq b(u)$, the total weight of spikes from incoming neighbors will be sufficient to activate u in the next important round, $\tau_{i'+1}$. Therefore, $u \in A_{1,i'+1}$, which implies $u \in A'_{1,i''+1}$ for some $i'' \leq i'+1$. Since $i'' \leq i'+1 \leq i$ the condition holds.

Case 2: All previously firing incoming neighbors are not dominant: By applying Claim 29 on u and block T_i, we get that the total weight of spikes fired towards u in block T_{i-1} is at least $L \cdot b(u)/8$. Due to Observation 28, we get

$$L \cdot w(\mathbf{S}(A_{0,i-1}(u)),u) + w(\mathbf{W}(A_{0,i-1}(u)),u) \geq \frac{L}{8} \cdot b(u).$$

By the definition of $A'_{0,j}$ and the induction assumption, it holds that

$$A_{0,i-1} \subseteq \bigcup_{j \leq i-1} A'_{0,j} \subseteq \bigcup_{i' \leq i-1} A'_{1,i'}.$$

We now consider the simulation with $x_0 = 1$ and the latency function ℓ_1, and partition all the rounds until τ_i into k blocks of L rounds (expect perhaps the last one). Formally, for every $j \leq k-2$, let $B_j = [jL, jL+(L-1)]$ and let $B_{k-1} = [(k-1)L, \tau_{i-1}+15]$. Denote by $\mathbf{S}(B_j)$ and $\mathbf{W}(B_j)$ the strong and weak (respectively) incoming neighbors of u that fire in some round of B_j. Using these notations, we can write

$$\sum_{j=0}^{k-1} L \cdot w(\mathbf{S}(B_j),u) + w(\mathbf{W}(B_j),u) \geq \frac{L}{8} \cdot b(u).$$

Case 2.1: Most of the weight is in the last block. We first assume that

$$L \cdot w(\mathbf{S}(B_{k-1}),u) + w(\mathbf{W}(B_{k-1}),u) \geq \frac{L}{16} \cdot b(u).$$

Consider the algorithm that defines ℓ_1, and recall that $\mathcal{R}_{\tau_{i'}}(u)$ is the set of pending spikes that were not yet scheduled when the algorithm considered the important round τ_i. The interesting case is when u did not fire in any round of B_{k-1}. In such a case, all the spikes generated towards u in the rounds of B_{k-1} were added to the pending list of $\mathcal{R}_{\tau_i}(u)$. Note that each strong neuron $v \in \mathbf{S}(B_{k-1})$ fires at least 16 spikes in B_{k-1}, since $\tau_i - \tau_{i-1} = 16$. Furthermore, each $v \in \mathbf{W}(B_{k-1})$ fires at least one spike in B_{k-1}. Moreover, the gap between any $\tau_{i'} \in B_{k-1}$ and τ_i is at most L rounds, so they do not exceed the maximal latency in τ_i. Altogether, we get that

$$\begin{aligned} &w(\mathcal{R}_{\tau_i}(u)) \geq 16 \cdot w(\mathbf{S}(B_{k-1}),u) + w(\mathbf{W}(B_{k-1}),u) \geq \\ &\frac{16}{L} \cdot (L \cdot w(\mathbf{S}(B_{k-1}),u) + w(\mathbf{W}(B_{k-1}),u)) \geq b(u)\ . \end{aligned} \tag{3}$$

Therefore u fires in τ_i and $u \in A_{1,i'}$ for some $i' \leq i$ as desired.

Case 2.2: Most of the weight is in the first $k-1$ blocks. It remains to consider the complementary case where

$$\sum_{j=0}^{k-2} L \cdot w(\mathbf{S}(B_j),u) + w(\mathbf{W}(B_j),u) \geq \frac{L}{16} \cdot b(u).$$

Since $i < L^2/1024$ and each block B_j for $j \leq k-2$ consists of $L/32$ important rounds, we have $k \leq \frac{L^2/1024}{L/32} = \frac{L}{32}$. Therefore, by an averaging argument there exists B_j for $j \leq k-2$ satisfying that:

$$L \cdot w(\mathbf{S}(B_j), u) + w(\mathbf{W}(B_j), u) \geq 2 \cdot b(u). \tag{4}$$

First observe that every strong neuron $s \in \mathbf{S}(B_j)$ fires for at least $L/2$ rounds in this block. The reason is that there is a gap of $L/2$ rounds between the last important rounds of B_j and the round where the inhibiting spike from x arrives. During this time interval every strong neuron in $\mathbf{S}(B_j)$ keeps on firing. Now, assume that u does not fire in any round of B_j, and denote the first important round of B_{j+1} by $\tau_{i'}$. Again, consider the algorithm that defines ℓ_1. Since u did not fire in any round of the block B_j, all the spikes that are fired towards u in B_j are in the residual set $\mathcal{R}_{\tau_{i'}}(u)$. Therefore by Eq. (4), we get that $w(\mathcal{R}_{\tau_{i'}}(u)) \geq (L/2) \cdot w(\mathbf{S}(B_j), u) + w(\mathbf{W}(B_j), u) \geq b(u)$, and u fires in $\tau_{i'}$. Therefore, we get that u fires either in some important round of B_j or in $\tau_{i'}$. In both cases there is a round $\tau_{i''}$ with $i'' \leq i$ such that $u \in A_{1,i''}$. This implies $u \in A'_{1,i''}$ for $i'' \leq i$, and the condition holds. ◀

Finally, it remains to prove Claim 29.

Proof of Claim 29. Recall that $\mathbf{S}(A_{0,i-1}(u))$ and $\mathbf{W}(A_{0,i-1}(u))$ are the strong and weak (respectively) incoming neighbors of u that fire in block T_{i-1}. If $w(\mathbf{S}(A_{0,i-1}), u) \geq b(u)/8$, then by Observation 28 the total spike weight fired in block $i-1$ is at least $L \cdot b(u)/8$, and we are done. Therefore, it remains to consider the case where $w(\mathbf{S}(A_{0,i-1}), u) < b(u)/8$ and $w(\mathbf{W}(A_{0,i-1})) < L \cdot b(u)/8$. We will show that in this case, there is a way to schedule all spikes fired towards u in block T_{i-1} to arrive in rounds $[(i-1)L+2, iL]$, such that u does not get activate in any of these rounds. By the definition of ℓ_0, we get that u does not get activated in any of the rounds $[(i-1)L+2, iL]$, and in particular $u \notin A'_{0,i}$, thus a contradiction.

First observe that $b(u) > 0$ since u did not fire in round $(i-1)L$ (as $u \notin A_{0,i-1}$) and it did not receive any negative spike in that round (as all negative spikes arrive in the last rounds of the blocks). We next show that all the spikes generated in block T_{i-1} can be scheduled in rounds $[(i-1)L+2, iL]$ without making u fire in any of these rounds. Since the scheduling algorithm of ℓ_0 works in this manner, we will get a contradiction to the fact that $u \in A_{0,i}$.

Scheduling spikes from weak neighbors. Let $F_{\mathbf{W}} = \{\langle v, u, (i-1)L\rangle \mid v \in \mathbf{W}(A_{0,i-1})\}$ be the spikes of weak neighbors fired in the block T_{i-1}. Recall that by Observation 28, these weak neurons fire only in the first round. Since these spikes are fired in round $(i-1)L$, they can arrive in any of the rounds $[(i-1)L+2, iL]$. As the total weight of the weak spikes is at most $Lb(u)/8$, we show that we can schedule them in a greedy manner into at most $L/2-2$ rounds while keeping the total weight in each such round to strictly less than $b(u)$. We traverse the weak spikes one by one, and start throwing them into rounds in $[(i-1)L+2, iL-1]$. We add a spike to round τ as long as the total weight of weak spikes scheduled to it is at most $b(u)/2$. If the addition of the next weak spike raises the weight to above $b(u)$ it is deferred to the next round $\tau+1$. Let τ' be the last round to which the weak spikes are schedules. Since in each $\tau \in [(i-1)L+2, \tau'-1]$ the total weight of weak spikes is at least $b(u)/2$, we get that $\tau' \leq (i-1)L + L/4 + 3 \leq (i-1)L + L/2$ as desired.

Scheduling spikes from strong neighbors. We next turn to show that also the strong spikes can be scheduled in a balanced manner in the remaining $L/2$ slots of the block T_i without activating the neuron u. Let $F_{\mathbf{S}} = \{\langle v, u, \tau\rangle \mid v \in \mathbf{S}(A_{0,i-1}), \tau \in T_{0,i-1})\}$ be the spikes of

strong neighbors fired in block T_{i-1}. For a spike $\langle v, u, \tau \rangle \in F_{\mathbf{S}}$ with $\tau \leq (i-1)L+(L/2-1)$, schedule $\langle v, u, \tau \rangle$ to arrive in round $\tau+L/2+1$. For $\langle v, u, \tau \rangle \in F_{\mathbf{S}}$ with $\tau \geq (i-1)L+L/2$, schedule $\langle v, u, \tau \rangle$ to arrive in round $\tau+1$. In this way, due to Observation 28, u receive two spikes from each $v \in \mathbf{W}(A_{0,i-1})$ in each round $\tau \in [(i-1)L + L/2 + 1, iL]$. Since $w(\mathbf{S}(A_{0,i-1})) < b(u)/8$, we get that the total weight of spikes that u receives in each of these rounds is less than $b(u)/4$, and therefore u does not get activated. Overall, all spikes generated in the block T_{i-1} are scheduled by ℓ_0 without activating the neuron u in any of the rounds $[(i-1)L+2, iL]$, contradiction to the fact that $u \in A_{i,0}$. The claim follows. ◁

B Missing Proofs for the Positive Results

B.1 Synchronization of Boolean Gates

Proof of Observation 13. The network is as follows: connect each input neuron x_i to the output neuron z by an edge of weight $w(x_i, z) = 1$, and let the bias of z be $b(z) = 1$. First note that if all input neurons x_i did not fire in round 0, then $\text{pot}(z, \tau) = -1$ for all τ, and z will not fire. If a neuron x_i fires in round τ, since the latency of each edge is at most L, there is a round $\tau' \in [\tau+1, \tau+L]$ in which the spike from x_i arrives to z. Thus, in round τ', the weighted incoming sum to z is at least 1, therefore $\text{pot}(z, \tau') \geq 0$ and z fires in round τ'. ◀

The Complete Proof of Lemma 14. We analyze the correctness of the network $\mathsf{NOT}_{\mathsf{sync}}$. We begin by proving the following auxiliary claim.

▷ Claim 30. If all the intermediate neurons $v_0, \ldots v_L$ fire starting round τ for at least $L(L+1)$ rounds, then there exists a round $\tau' \in [\tau+1, \tau+L(L+1)]$ in which the output neuron z fires (i.e., regardless of the latencies of the edges).

Proof. For every $i \in \{0, 1 \ldots, L(L+1)\}$, denote the L-length interval $T_i = [\tau + i \cdot L, \tau + (i+1)L - 1]$. In addition, define $\widetilde{T} = T_0 \cup \ldots \cup T_{L+1}$. Let q_i be the number of spikes that were fired in the interval of T_i but received by z in the next interval T_{i+1}. Note that since the maximum edge latency is L, in the worst case the spikes of interval T_i must arrive to z by the end of the next interval T_{i+1}. We next prove by induction on i that either z fires by the end of the interval T_i, or $q_{i+1} \geq i \cdot L$. For the base of the induction, consider $i = 0$. If z did not fire in some round during T_0, we claim that $q_1 \geq L$. Since all the $L+1$ neurons fire in every round during the interval, overall $L(L+1)$ many spikes where fired. By the fact that z did not fire during T_0, we have that in each of these rounds, it received at most L spikes. This implies that z received at most L^2 many spikes during T_0, and therefore at least $q_1 \geq L$ many spikes will be received by z in the interval T_1. Assume that the claim holds up to $i-1$ and consider the i^{th} interval. If z fired by the end of the i^{th} interval T_i, we are done. Otherwise, by induction assumption for $i-1$, we have that $q_i \geq i \cdot L$. In addition, all these q_i spikes must be received at z during the interval T_i. Then, in interval T_i we again have a total of $L(L+1)$ fresh spikes by the neurons $v_0, \ldots v_L$. This creates a total of $L(L+1) + i \cdot L$ spikes. As z did not fire in T_i, it received at most L^2 many spikes, leaving at least $q_{i+1} \geq L(L+1) + i \cdot L - L^2 \geq (i+1)L$ spikes for the next interval. This completes the proof of the induction step.

Overall, for $i = L$, we have that either z fired by the end of the interval T_L, or that $q_{L+1} \geq L(L+1)$. In the latter case, since all these spikes must arrive during the last interval T_{L+1}, by the pigeonhole principle there must be a round in this interval in which z received at least $L+1$ spikes and fire. This completes the proof of the claim. ◁

Proof of Lemma 14. Due to Claim 30, it remains to show that if x did not fire in round 0, then there must be a starting round τ, in which all the neuron $v_0, \dots v_L$ fire for at least $L(L+1)$ rounds.

If x did not fire, then neither the memory neuron m nor the reset neuron r fire during the execution. Since we assume that v^* fires in round 0, it must hold that all these neurons fire starting some round $\tau \in [5L^2, 5L^3 + 2L]$. This holds due to the self-loops on the neurons $v_0, \dots v_L$, and the chain of length $5L^2$. By Claim 30, there exists a round $\tau' \in [\tau + 1, \tau + L(L+1)]$ in which z fires.

We next show that if x fired in round 0, then z would not fire in any round. The key observation is as follows:

▶ **Observation 31.** *In order for z to fire in some round τ, it must receive spikes from* at least *two different v_i neurons.*

Proof. To see this, note that since the maximum edge latency is L, in round τ, z can receive spikes only from the L previous rounds $\tau - L, \dots, \tau - 1$. In particular, a single neuron can be accounted for at most L many spikes received by z in a given round. Finally, since the bias of z is $L + 1$, and all edge weights are 1, we conclude that z must receive spikes from at least two neurons in order to fire. ◀

When x fires in round 0, the memory neuron m fires from round $\tau_m \in [1, L+1]$ ahead, due to its self-loop. Hence, starting round $\tau_r \in [2, 2L+2]$, the reset neuron r starts firing at least *once* in every interval of $2L$ rounds. Recall that each v_i gets a negative spike from the inhibitor r and positive spike from the neuron $c_{5iL} \in C$. We next show that each neuron v_i gets inhibited at least L rounds *before* the activation of the neurons v_{i+1}. As a result, at any point of time, there will be no two neurons v_i and v_j such that z received both of their spikes in the same round. By induction on i, the first intermediate neuron v_0 has an incoming edge from $c_0 = v^*$, and thus it begins to fire in some round $\tau' \in [0, L]$. Due to the negative edge from the reset neuron r, it stops firing before round $3L + 2$. Since v_1 has an incoming edge from c_{5L}, it starts firing only after round $5L + 1$, and therefore z starts receiving spikes from v_1 only starting round $5L + 2$. Assume the claim is correct for neurons $v_0, \dots, v_{i-1}$ and consider neuron v_i. If the neuron v_i starts firing in round τ_i, by round $\tau_i + 2L$ it is inhibited by r. Because v_i starts to fire after receiving a spike from $c_{5 \cdot i \cdot L}$ and v_{i+1} starts firing after receiving a spike from $c_{5(i+1)L}$, neuron v_{i+1} begins to fire only after round $\tau_i + 4L$, at least L rounds after v_i is inhibited.

Hence, z cannot receive input from two different neurons v_i, v_j at the same round, and the claim follows by combining Observation 31. Finally, the next observation plays a rule in the subsequent constructions.

▶ **Observation 32.** *The correctness still holds even if the chain starts to fire at some round $\tau > 0$. In this case the output neuron z fires in some round $t \in [\tau + 1, \tau + \Theta(L^3)]$.*

Proof of Observation 32. The correctness of the observation follows from the fact that the input neuron x activates the memory neuron m, that keeps on firing (i.e., presenting the state of x) due to its self-loop. Thus all arguments in Lemma 14 still hold in case the chain starts to fire in any later round. ◀

B.2 Synchronization of a Boolean Circuit, Proof of Lemma 15

The Construction. Given a Boolean circuit $\mathcal{A}$ of OR / NOT gates $g_1, \ldots, g_m$ of depth d, we describe a construction of an analogous neural network $\mathcal{N}$ with a similar execution. For every g_i, let $\mathsf{Sync}(g_i)$ be the synchronized sub-network of the gate g_i. Specifically, for a NOT gate (resp., OR) g_i, the sub-network $\mathsf{Sync}(g_i)$ is taken from Lemma 14 (resp., Observation 13). Recall, that for a NOT gate g_i, its syncronized sub-network $\mathsf{Sync}(g_i)$ contains a chain of neurons where the head of the chain c_0 will be denoted hereafter by v_i^*. The network $\mathcal{N}$ consists the following components:

1. Input neurons $x_1, \ldots, x_n$, and output neurons $z_1, \ldots, z_k$, that serve as the input and the output for the network $\mathcal{N}$.
2. A chain $C = [c_0, \ldots, c_q]$ containing $q + 1 = \alpha d L^3 + 1$ neurons, where α is a constant satisfying that $\alpha L^3 \geq 5L^3 + L$. For every $i \geq 0$, the neuron c_i has bias $b(c_i) = 1$. Moreover, for every $i \geq$ the neuron c_i has a positive incoming edge from c_{i-1} with weight $w(c_{i-1}, c_i) = 1$. Our simulation starts with neuron c_0 firing.
3. A $\mathsf{Sync}(g_i)$ network (using Lemma 14 and Observation 13 respectively) for every gate g_i.

The connections between these components are as follows:

1. For every gate g_i in the first layer, the input for its synchronized sub-network $\mathsf{Sync}(g_i)$ is given by $x_{i,1}, \ldots, x_{i,k_i}$, namely, the input bits of the gate g_i in the circuit $\mathcal{A}$.
2. For every gate g_i in layer $j \geq 2$, denote by $g_{i,1}, \ldots, g_{i,k_i}$ the input of the gate g_i in the circuit $\mathcal{A}$. In the network $\mathcal{N}$, the input to the sub-network $\mathsf{Sync}(g_i)$ are the output neurons of the sub-networks $\mathsf{Sync}(g_i)$, $\mathsf{Sync}(g_{i_1}), \ldots, \mathsf{Sync}(g_{i_k})$.
3. The output gates of the network $\mathcal{N}$ are the output neurons of the sub-networks $\mathsf{Sync}(o_1), \ldots, \mathsf{Sync}(o_k)$, where $o_1, \ldots, o_k$ are the output gates of the circuit $\mathcal{A}$.
4. Finally, the synchronized sub-networks of the NOT gates are connected to the chain C as follows. For each NOT gate g_i in every layer j, the $(j\alpha L^3)^{th}$ neuron $c_{j\alpha L^3}$ in the chain has an outgoing edge to v_i^* with weight 1 (where v_i^* is the head of the internal chain in $\mathsf{Sync}(g_i)$), since the bias of v_i^* is 1, a spike from $c_{j\alpha L^3}$ makes v_i^* fire.

Figure 3 illustrates the construction for a circuit with 4 NOT and OR gates of depth 3. We note that one can shave an L-factor in the size and time overhead of lemma 15, by reusing the synchronization chain for all the Boolean gates in the network.

Correctness. Let V be the total set of neurons in $\mathcal{N}$, and let $\ell : V \times V \times \mathbb{N} \to [1, L]$ be a fixed (arbitrary) nice latency function. First note that in the global chain C, each of the neurons fires once, in a sequential manner. Recall, that we assume that the starter c_0 fires in round $\tau_0 = 0$. For every $j \in \{1, \ldots, d\}$, let τ_j be the round in which $c_{j\alpha L^3}$ fires (i.e., the spike from $c_{j\alpha L^3 - 1}$ is received at $c_{j\alpha L^3}$ in round $\tau_j - 1$).

For every gate g_i in the circuit $\mathcal{A}$ in layer $j \geq 1$, denote by $out(g_i, \mathcal{A})$ the final state of g_i after receiving its inputs in the circuit $\mathcal{A}$. In addition, let q_i be the output neuron in the sub-network $\mathsf{Sync}(g_i)$, and let $\sigma_t(q_i, \mathcal{N})$ be the state of the neuron in round t when simulating the network $\mathcal{N}$. Our goal is to show that for every g_i, its corresponding output q_i in the network $\mathcal{N}$, has the same "output" as g_i in the circuit $\mathcal{A}$.

▷ Claim 33. For every layer $j \in \{1, \ldots, d\}$ and every gate g_i in layer j of circuit $\mathcal{A}$, its holds that: (i) If $out(g_i, \mathcal{A}) = 0$, then $\sigma_t(q_i, \mathcal{N}) = 0$ for every t, and (ii) If $out(g_i, \mathcal{A}) = 1$, then there exists $t \in [\tau_{j-1} + 1, \tau_j]$ such that $\sigma_t(q_i, \mathcal{N}) = 1$.

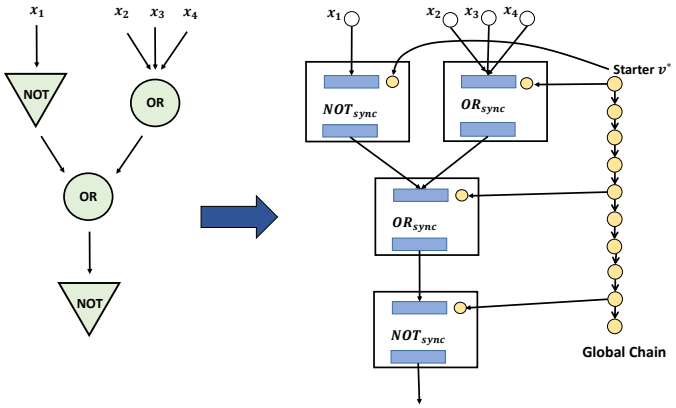

Figure 3 The transformation of the circuit on the left with 4 inputs and 3 layers. For each gate we add the corresponding synchronized sub-network, where we connect the input and output neurons of the sub-network according to the original circuit. In addition we introduce a global chain that activates the sub-networks in each layer after the previous layers have already finished the computation. The first neuron in the global chain is set to be the starter neuron which fires in the beginning of the simulation.

Proof. We prove by induction on the layer j. For $j = 1$, recall that the input neurons $x_{i,1}, \ldots, x_{i,k_i}$ of the sub-network $\mathsf{Sync}(g_i)$ are the input neurons of the network $\mathcal{N}$. Therefore, in round 0 in the simulation of $\mathcal{N}$, the sub-network $\mathsf{Sync}(g_i)$ has the same input as gate g_i in the circuit $\mathcal{A}$. Assume first that g_i is a NOT gate. Then the spike of the starter neuron c_0 arrived at the head chain v_i^* by round L. Combining with Observation 32 we get that if $out(g_i, \mathcal{A}) = 1$ then $\sigma_t(q_i, \mathcal{N}) = 1$ for some $t \in [L, L + 5L^3] \subseteq [1, \alpha L^3]$. In addition, if $out(g_i, \mathcal{A}) = 0$ then $\sigma_t(q_i, \mathcal{N}) = 0$ for every t. The case where g_i is an OR gate is even simpler and follows by Observation 13. Since the path from c_0 to $c_{\alpha L^3}$ in the chain C is of length αL^3, we have that $\tau_1 \geq \alpha L^3$. Therefore $[1, \alpha L^3] \subseteq [\tau_0 + 1, \tau_1]$, and the claim holds for $j = 1$.

For the induction step, let $j \geq 2$, and assume correctness up to layer $j - 1$. We now prove the claim for layer j. Let g_i be a gate in layer j. By Observation 32, the important thing to take care of regarding a NOT gate g is to make sure that its inputs have the correct states (i.e., as the corresponding states in $\mathcal{A}$) by the time that the head of the chain v_i^* in $\mathsf{Sync}(g)$ has received the spike from $c_{(j-1)\alpha L^3}$. Denote by $q_{i,1}, \ldots, q_{i,k_i}$ the output neurons of the sub-networks $\mathsf{Sync}(g_{i,1}), \ldots, \mathsf{Sync}(g_{i,k_i})$. By the induction assumption, for each $g_{i,h}$, if $out(g_{i,h}, \mathcal{A}) = 0$ then $\sigma_t(q_{i,h}) = 0$ for every t, and otherwise $\sigma_t(q_{i,h}) = 1$ for some $t \leq \tau_{j-1}$. Since the neurons $q_{i,1}, \ldots, q_{i,k_i}$ are the input neurons of g, it holds that the sub-network $\mathsf{Sync}(g)$ gets the same input as the input of g in $\mathcal{A}$, by round τ_{j-1} of the simulation of $\mathcal{N}$.

Now, assume that g_i is a NOT gate. Then, by round $\tau_{j-1} + L$, the head of the chain v_i^* has recieved the spike from $c_{(j-1)\cdot\alpha\cdot L^3}$. Combining with Observation 32, when $out(q_i, \mathcal{N}) = 1$, it holds that $\sigma_t(q_i, \mathcal{N}) = 1$ for some $t \in [\tau_{j-1} + 1, \tau_{j-1} + L + 5L^3]$. In addition, when $out(q_i, \mathcal{N}) = 0$ then $\sigma_t(q_i, \mathcal{N}) = 0$ for every t. Again, since the path from $c_{(j-1)\alpha L^3}$ to $c_{j\alpha L^3}$ in the chain C is of length αL^3, we have that $\tau_j \geq \tau_{j-1} + L + 5L^3$, and the claim follows. The case where g_i is an OR gate follows in a similar way by Observation 13. ◁

Lemma 15 follows by using Claim 33 with $j = d$, and noting that each output neuron z_i in $\mathcal{N}$ is the output neuron $q_{i'}$ for some sub-network $\mathsf{Sync}(g_{i'})$ where $g_{i'}$ is a gate in layer d of $\mathcal{A}$. This completes the correctness and the bound on the time overhead. We finally bound the

size of the network. The network $\mathcal{N}$ consists of a chain of $O(dL^3)$ neurons, and a $\mathsf{Sync}(g_i)$ sub-network of size $O(L^2)$ for each gate g_i in $\mathcal{A}$. Therefore, there are overall $O(dL^3 + mL^2)$ auxiliary neurons.

B.3 Synchronization of a Single Deterministic Threshold Gate

We now turn to consider the synchronized implementation of a single deterministic threshold gate and prove Lemma 16.

Thanks to a result of [30], we can assume without loss of generality that the weights and bias values can be represented using binary vectors of length $\lceil \Delta \log \Delta \rceil$. Hastad [10] also showed that this bound is tight. In addition, we can also assume without loss of generality that $b(z) \geq 0$. The key part is to implement the single threshold gate by a Boolean circuit. This requires small adaptations from existing results in the area, specifically we will use the following known facts.

▶ **Fact 34** (Iterated Addition [31, 38]). *Given two input binary vectors $\bar{x} = [x_1, \ldots, x_\Delta]$ and $\bar{y} = [y_1, \ldots, y_\Delta]$, there exists a Boolean circuit with $\mathrm{poly}(\Delta)$ gates and $O(1)$ depth that outputs the binary representation of $\mathrm{dec}(\bar{x}) + \mathrm{dec}(\bar{y})$.*

▶ **Corollary 35** (Multiple Iterated Addition). *Given Δ input binary vectors $\bar{x}_1, \ldots, \bar{x}_\Delta$ where $\bar{x}_i \in \{0,1\}^m$ for some integer $m \geq 1$, there exists a Boolean circuit with $\mathrm{poly}(\Delta, m)$ gates and $O(\log \Delta)$ depth that outputs the binary representation of $\sum_i \mathrm{dec}(\bar{x}_i)$.*

▶ **Observation 36** (Comparison). *Given two input binary vectors $\bar{x} = [x_1, \ldots, x_\Delta]$ and $\bar{y} = [y_1, \ldots, y_\Delta]$, there exists a Boolean circuit with $\mathrm{poly}(\Delta)$ gates and $O(1)$ depth that outputs 1 iff $\mathrm{dec}(\bar{x}) \geq \mathrm{dec}(\bar{y})$.*

We are now ready to implement a threshold gate by a small depth Boolean circuit of polynomial size. This lemma explains the dependency in the largest in-degree Δ of the final synchronized solution.

▶ **Lemma 37.** *Given a threshold gate g with Boolean inputs $x_1, \ldots, x_\Delta$ with weights $w_1, \ldots, w_\Delta$, and an output neuron z with bias $b(z)$, there exists a Boolean circuit that computes g (i.e., outputs 1 iff $\sum w_i \cdot x_i \geq b(z)$) using $\mathrm{poly}(\Delta)$ gates and depth $O(\log \Delta)$.*

Proof. Each input x_i is connected to $\ell = \lceil \Delta \cdot \log \Delta \rceil$ neurons $w_{i,1}, \ldots, w_{i,\ell}$, where the edge weight $w(x_i, w_{i,j})$ is 1 if the j^{th}-bit in w_i is 1 and 0 otherwise. We set the bias values to be $b(w_{i,j}) = 1$. Thus, the outgoing edge weights of x_i encode the binary representation of the weight w_i. As a result, once x_i fires in round τ, after at most L rounds, $w_{i,j}$ fires iff the j^{th} bit in the representation of w_i is 1. As we will see, those $\Delta^2 \cdot \log \Delta$ neurons $w_{1,1}, \ldots, w_{\Delta,\ell}$ will serve as the input layer to the circuit. In addition, we also represent the bias of z using ℓ neurons $b_1, \ldots, b_\ell$ that encode the binary representation of $b(z)$: the bias of $b_j = 1$ if the j^{th} bit in $b(z)$ is 0, and $b_j = -1$ otherwise. Let $\bar{x}_{pos} = \{x_i \mid w_i \geq 0\}$ and $\bar{x}_{neg} = \{x_i \mid w_i < 0\}$. In the same manner, let $W_{pos} = \sum\{w_i \mid w_i \geq 0\}$ and $W_{neg} = \sum\{|w_i| \mid w_i < 0\}$. We will use the Multiple Iterated Addition circuit of Corollary 35 to compute the binary representation of W_{pos} and $W_{neg} + b(z)$. Finally, we use the Comparison circuit of Observation 36 to compare those values, such that the output will be 1 iff $W_{pos} \geq W_{neg} + b(z)$, hence computing the function of the threshold gate. ◀

The final synchronous implementation of g is obtained by applying Lemma 15 on $\mathcal{C}$, i.e., $\mathsf{Sync}(g) \leftarrow \mathsf{Sync}(\mathcal{C})$. The construction uses a total $O(\log \Delta \cdot L^3 + \mathrm{poly}(\Delta) \cdot L^2)$ auxiliary neurons, and computation time of $O(L^4 \cdot \log \Delta)$ rounds. This completes the proof of Lemma 16.

B.4 Probabilistic Threshold Gate

B.4.1 Description of the Boolean Circuit

The construction of the boolean circuit $\mathcal{A}$ approximating a probabilistic threshold gate is achieved using two main steps. First we sample an almost uniform random variable, then we use the sampled value in order to approximate a sample from the Logistic distribution.

Step 1: Sampling from the Almost Uniform Distribution. We introduce $k = 4\log(1/\epsilon)$ uniformly random gates, denoted as $r_1, \dots r_k$. Hence, $\mathrm{dec}(\bar{r})$ encodes an integer number that is uniformly sampled between 0 and $\lceil (1/\epsilon)^4 \rceil$. In addition, we introduce k input bits (with fixed value) $a_1, \dots a_k$ such that $\mathrm{dec}(\bar{a}) = \lceil (1/\epsilon)^4 \rceil$. Thus, the value $r' = \mathrm{dec}(\bar{r})/\mathrm{dec}(\bar{a})$ is sampled uniformly at random from the set $\{0, \epsilon^4, 2\epsilon^4, 3\epsilon^4, \dots 1\}$.

Step 2: Sampling from the Almost Logistic Distribution. Next, we transform the sample r' from Step 1 into a sample from an almost Logistic distribution. This is done by using the method of inverse transform sampling. In our context, for a sample r u.a.r in $[0, 1]$, the value $b + \ln(r/(1-r))$ is a sample from the Logistic distribution with mean b and scale 1. To compute the expression $b + \ln(r'/(1-r'))$ using a Boolean circuit, we approximate the $\ln(x)$ function (up to $\pm\,\mathrm{poly}(\epsilon)$) using the first $O(\log 1/\epsilon)$ terms of the Taylor expansion around a point x_0 where $0 \le x_0 - x \le 1/2$.

▶ **Definition 38** (ϵ-Approximation of the $\ln(x)$ Function). *Given $x > 0$ and a positive integer k, let $\widehat{\ln}_k(x)$ be the* ln*-approximation of x obtained by computing the first k terms of the Taylor expansion around a point x_0, where $0 \le x_0 - x \le 1/2$. When k is clear from the content we may omit it and simply write $\widehat{\ln}(x)$.*

The task of sampling from the (almost) Logistic distribution then boils into computing $f(r') = \widehat{\ln}_k(r'/(1-r'))$ with $k = \lceil 4\log 1/\epsilon \rceil$. We first use a Boolean circuit to distinguish between the case where $r' \le 1 - r'$, and the complementary case. Using the vectors $\bar{r}$ and $\bar{a}$, this can be done using integer operations and comparison as $r'/(1-r') = \mathrm{dec}(\bar{r})/(\mathrm{dec}(\bar{a}) - \mathrm{dec}(\bar{r}))$. When $r' > 1 - r'$, we calculate $f(-r')$, and then either add or subtracts it from the bias b respectively.

In what follows, assume that $r' \le 1 - r'$, and therefore $r'/(1-r') \in [0, 1]$. To pick the point x_0 around which the Taylor approximation is expended, we let $x_0 = 1/2$ when $r'/(1-r') \le 1/2$, and $x_0 = 1$ otherwise. This latter condition can also be easily checked with a Boolean circuit.

To finally be able to compute the function $\widehat{\ln}_k(x)$ using a Boolean circuit, we must ensure that all our operations are applied on *integers*. Therefore, instead of computing $f(r')$, we will be actually computing $q \cdot f(r')$ for some large enough constant q that guarantees that $q \cdot f(r')$ is an integer. Specifically, letting $q = (\mathrm{dec}(\bar{a}) - \mathrm{dec}(\bar{r}))^k$ does the job as the function $\widehat{\ln}_k(x)$ is a polynomial of degree k. This factor of q would not affect the correctness of the computation as it will be canceled out later on. Using the circuit for iterated addition [38, 31] and fast multipliers [9], we can compute $q \cdot f(r')$ using only integer addition and multiplication. The output of the final Boolean circuit is $\bar{y}$ where $\mathrm{dec}(\bar{y}) = q \cdot b + q \cdot f(r')$. In the analysis section, we show that $\mathrm{dec}(\bar{y})/q$ is sampled from a distribution that is $\mathrm{poly}(\epsilon)$-close to the Logistic distribution with mean b.

Putting all Together: The Output Circuit. Let $w_1, \ldots, w_\Delta$ be the weights of the probabilistic threshold gate g. To cancel out the multiplication of q in the output bias value from the previous step, we multiply all the incoming weights by q as well. We can then use the construction of Lemma 16 for a deterministic threshold gate with weights $w'_1 = q \cdot w_1, \ldots, w'_\Delta = q \cdot w_\Delta$ and bias $b'' = \mathrm{dec}(\bar{y})$. This completes the description of the construction.

B.4.2 Analysis and Proof of Lemma 17

We now turn to prove Lemma 17 and start with several auxiliary claims.

▷ Claim 39. Let $r_1, r_2 \in [0,1]$ such that $|r_1 - r_2| \leq \epsilon^2$ and $\epsilon \leq r_1 \leq 1 - \epsilon$, then

$$|\ln(r_1/(1-r_1)) - \ln(r_2/(1-r_2))| \leq 2\epsilon \ .$$

Proof. By the definition of r_1 and r_2 we get the following inequalities:

$$\begin{aligned} |\ln(r_1/(1-r_1)) - \ln(r_2/(1-r_2))| &= |\ln(r_1) - \ln(1-r_1) - \ln(r_2) + \ln(1-r_2)| \\ &\leq |\ln(\frac{r_1+\epsilon^2}{r_1})| + |\ln(\frac{1-r_1+\epsilon^2}{1-r_1})| \\ &\leq |\ln(1+\epsilon^2/r_1)| + |\ln(1+\epsilon^2/(1-r_1))| \\ &\leq 2\ln(1+\epsilon) \leq 2\cdot\epsilon \ , \end{aligned}$$

where the last inequality is due to the Taylor expansion of $\ln(1+x)$ around 0. ◁

Recall that given $x > 0$ and an integer $k > 0$, $\widehat{\ln}_k(x)$ is the ln-approximation of x obtained by computing the first k terms of the Taylor expansion around a point x_0 where $0 \leq x_0 - x \leq 1/2$.

▷ Claim 40. Fix $r_1, r_2 \in [0,1]$ such that $|r_1 - r_2| \leq \epsilon^2$ and $\epsilon \leq r_1 \leq 1 - \epsilon$, denote $\widehat{b}_1 = b + \ln(r_1/(1-r_1))$ and $\widehat{b}_2 = b + \widehat{\ln}(r_2/(1-r_2))$. Then, $|\widehat{b}_1 - \widehat{b}_2| \leq 3\epsilon$.

Proof. Fix $x \in (0,1)$. Since $\widehat{\ln}(x)$ is obtained by using the first k terms in the Taylor expansion of $\ln(x)$ around x_0, we have that $|\ln(x) - \widehat{\ln}(x)| = \frac{1}{x_0^k} \cdot \frac{(x-x_0)^k}{k} \cdot \eta^k$, where $\eta \in [x, x_0]$. Since $x_0 \geq x$, also $x_0 \geq \eta$. As $|x - x_0| \leq 1/2$, we get that $|\ln(x) - \widehat{\ln}(x)| \leq (1/2)^k$. By plugging $k = \Theta(\log 1/\epsilon)$, we have that $|\ln(x) - \widehat{\ln}(x)| \leq \epsilon$ for every x.

Thus, combining with Claim 39 we conclude the following:

$$\begin{aligned} |\widehat{b}_1 - \widehat{b}_2| &= |b + \ln(r_1/(1-r_1)) - b - \widehat{\ln}(r_2/(1-r_2))| \\ &\leq |\ln(r_1/(1-r_1)) - \ln(r_2/(1-r_2)) + \epsilon| \\ &\leq \epsilon + |\ln(r_1/(1-r_1)) - \ln(r_2/(1-r_2))| \leq 3\cdot\epsilon \ . \end{aligned} \tag{5}$$

◁

▷ Claim 41. Consider two threshold gates g_1, g_2 with the same weighted sum and bias values $b_1 \leq b_2$ such that $b_2 - b_1 \leq \epsilon$. Then $|\Pr[g_1 = 1] - \Pr[g_2 = 1]| \leq \sqrt{\epsilon}$.

Proof. Let W be the weighted incoming sum to both g_1 and g_2. The probability that g_1 outputs 1 is $1/(1+e^{-(W-b_1)})$, and the probability that g_2 outputs 1 is $1/(1+e^{-(W-b_2)})$. The following holds:

$$\begin{aligned} \Pr[g_2 = 1] &= 1/(1+e^{-(W-b_2)}) \geq 1/(1+e^{-(W-b_1-\epsilon)}) = 1/(1+e^{\epsilon}e^{-(W-b_1)}) \\ &\geq \frac{1}{e^{\epsilon}\cdot(1+e^{-(W-b_1)})} \geq \frac{1}{(1+\sqrt{\epsilon})\cdot(1+e^{-(W-b_1)})} \\ &= (1-\sqrt{\epsilon})(1/(1+e^{-(W-b_1)})) \geq 1/(1+e^{-(W-b_1)}) - \sqrt{\epsilon} = \Pr[g_1 = 1] - \sqrt{\epsilon} \ . \end{aligned}$$

In the third inequality we use the fact that $e < (1+\sqrt{\epsilon})^{\frac{1}{\epsilon}}$ and thus $e^{\epsilon} < 1+\sqrt{\epsilon}$. On the other hand, since $b_2 \geq b_1$ it holds that

$$\Pr[g_2 = 1] = 1/(1+e^{-(W-b_2)}) \leq 1/(1+e^{-(W-b_1)}) = \Pr[g_1 = 1] \ .$$

Hence, we conclude that $|\Pr[g_2 = 1] - \Pr[g_1 = 1]| \leq \sqrt{\epsilon}$ as required. ◁

Analysis of Step 1. In the first step of the construction, since each uniformly random gate r_i is 1 with probability 1/2, the value $\mathrm{dec}(\bar{r})$ is a uniform sample in $\{0, 1 \ldots, (1/\epsilon)^4\}$. Therefore, $r' = \mathrm{dec}(\bar{r})/\mathrm{dec}(\bar{a}) = \epsilon^4 \cdot \mathrm{dec}(\bar{r})$ is sampled uniformly at random from $\{0, \epsilon^4, 2\epsilon^4, 3\epsilon^4, \ldots 1\}$. By a simple coupling argument, sampling r' is equivalent to the process of sampling a uniform random variable $r_1 \in [0,1]$ and rounding it to the closest value of the form $i \cdot \epsilon^4$ for some integer i. In this manner, these two samples have an additive distance of at most ϵ^4.

Analysis of Step 2. Denote the probability z outputs 1 by q, and the probability u outputs 1 by p. Recall that g is the probabilistic gate and g' is the output gate of the Boolean circuit that approximates g.

In the second step, we compute $\mathrm{dec}(\bar{y}) = q \cdot (b + f(r'))$ where $q = (\mathrm{dec}(\bar{a}) - \mathrm{dec}(\bar{r}))^k$ and $f(r') = \widehat{\ln}(r'/(1-r'))$. Then g' outputs 1 iff $\mathrm{dec}(\bar{y}) \leq W \cdot q$, or simply iff $b + f(r') \leq W$. Given that $r' \in [2\epsilon^2, 1-2\epsilon^2]$ by Claim 40, $b' = b + f(r')$ satisfies that $|b^* - b'| \leq 3\epsilon^2$ where b^* is a true sample from the Logistic distribution with mean b. Therefore, the following holds.

$$\begin{aligned}
\Pr[g' = 1 \ \mid \ r' \in [2\epsilon^2, 1-2\epsilon^2]] &= \Pr[W \geq b' \mid r' \in [2\epsilon^2, 1-2\epsilon^2]] \\
&\leq \Pr[W + 3\epsilon^2 \geq b^* \mid r' \in [2\epsilon^2, 1-2\epsilon^2]] \\
&= 1/(1+e^{-(W-b+3\epsilon^2)}),
\end{aligned}$$

and in addition

$$\Pr[g' = 1] \geq \Pr[W - 3\epsilon^2 \geq b^* \mid r' \in [2\epsilon^2, 1-2\epsilon^2]] = 1/(1+e^{-(W-b-3\epsilon^2)}).$$

Recall that $\Pr[g=1] = \frac{1}{1+e^{-(W-b)}}$. By claim 41 we conclude that $|\Pr[g'=1] - \Pr[g=1]| \leq 3\epsilon$.

We note that $r' \in [2\epsilon^2, 1-2\epsilon^2]$ with probability at least $1-4\epsilon^2$. Hence, we conclude that:

$$\Pr[g' = 1] \leq \Pr[g' = 1 \ \mid \ r' \in [2\epsilon^2, 1-2\epsilon^2]] + 4\epsilon^2 \leq \Pr[g=1] + 3\epsilon + 4\epsilon^2 = p + \Theta(\epsilon) \ ,$$

and on the other hand:

$$\begin{aligned}
\Pr[g' = 1] &\geq (1-4\epsilon^2)\Pr[g' = 1 \ \mid \ r' \in [2\epsilon^2, 1-2\epsilon^2]] \\
&\geq (1-4\epsilon^2)(\Pr[g=1] - 3\epsilon) \geq \Pr[g=1] - \Theta(\epsilon) \ .
\end{aligned}$$

Thus, $|\Pr[g=1] - \Pr[g'=1]| = O(\epsilon)$ as required.

Complexity. We assume that the bias and weights of the given probabilistic threshold gate g are polynomial in $1/\epsilon$. We first claim that with high probability of $1 - \Theta(\epsilon)$, the approximate bias sampled from the almost Logistic distribution in also bounded by $\mathrm{poly}(1/\epsilon)$.

▷ Claim 42. Given that $|\mu| = \mathrm{poly}(1/\epsilon)$, for a random variable x drown from the logistic distribution with mean μ it holds that $|x| = \mathrm{poly}(1/\epsilon)$ with probability greater than $1-\epsilon$.

Proof. By the definition of the Logistic CNF function it holds that

$$\Pr[x > 2\ln(1/\epsilon) + \mu] = 1 - \frac{1}{1+e^{-2\ln(1/\epsilon)-\mu+\mu}} = \frac{\epsilon^2}{1+\epsilon^2} < \epsilon^2 \ .$$

On the other hand

$$\Pr[x \leq -2\ln(1/\epsilon) + \mu] = \frac{1}{1 + e^{2\ln(1/\epsilon) - \mu + \mu}} = \frac{1}{1 + 1/\epsilon^2} < \epsilon^2 \ . \qquad \lhd$$

Thus we can assume from now on that all integer numbers can be representing using $O(\text{poly}(1/\epsilon))$ bits. Using circuits for fast integers multiplication as described in [9] and iterated addition [38, 31], there exists a Boolean circuit computing $W \cdot q$ as well as $b \cdot q$ using $\text{poly}(\Delta, \log(1/\epsilon))$ gates and $\text{poly}(\log \Delta, \log(1/\epsilon))$ depth. When computing the polynomial $q \cdot \widehat{\ln}(\frac{r'}{1-r'})$ (of total degree $2k$), calculating each term requires $O(\log k)$ multiplicity operations. Since we have k summands, in total we use $k \cdot \log k$ multiplicity operations, each requires $O(k \cdot \log k \cdot 2^{O(\log^* k)})$ gates (and depth), and $\log k$ addition operations. The comparison circuits uses $\text{poly}(\log 1/\epsilon)$ gates and depth, and the final threshold gate circuit requires $\text{poly}(\Delta, \log 1/\epsilon)$ gates and depth $\text{poly}(\log \Delta, \log 1/\epsilon)$. We conclude that the Boolean circuit has $\text{poly}(\Delta, \log(1/\epsilon))$ gates and depth of $\text{poly}(\log \Delta, \log(1/\epsilon))$.

B.4.3 Synchronizing a Probabilistic Threshold Gate

In order to construct a synchronized neural network computing the Boolean Circuit described in Lemma 17, we use the construction for synchronized Boolean circuits as described in Lemma 15. We are left with describing the implementation of the random bits $\bar{r}$ and the constant bits $\bar{a}$.

- In order to represent $\bar{a}$, we introduce k neurons $a_1, \ldots, a_k$. If the i^{th} bit in the binary representation of $\text{dec}(\bar{a}) = (1/\epsilon)^4$ equals 1 we set the bias of a_i to be $b(a_i) = -1$ and otherwise we set the bias to be $b(a_i) = 1$. As a result, the neurons that represent the bits that are 1 in the binary representation fire on every round, and the other neurons idle thought the execution.
- In order to represent $\bar{r}$ we introduce k *spiking* neurons $r_1, \ldots, r_k$. For the computation to succeed, we need to sample each random variable r_i only once. Therefore, each neuron r_i has a very large bias $b(r_i) = \text{poly}(1/\epsilon)$ and an incoming edge from the starter neuron s with weight $w(s, r_i) = b(r_i)$. As a result, as long as r_i did not receive a spike from s, with high probability it does not fire. On the other hand, when neuron r_i receives a spike from the starter neuron v^* it fires with probability $1/2$.

B.5 The Complete Synchronization Scheme

Finally, we describe the synchronizer for a given neural network and prove Theorem 4. We start by describing the construction for a network of deterministic threshold gates. The adaptation to a network of spiking neurons is quite straightforward as discussed in the end of the section. The construction has two parts: a global pulse generator that can be used to synchronize many networks, and an adaptation of the given network $\mathcal{N}$ into a network $\mathsf{Sync}(\mathcal{N})$, see Figure 2. The *pulse generator* is implemented by a directed cycle $PG = [c_0, \ldots, c_k]$ of length $k = O(L^4 \log \Delta)$. All neurons in PG have bias $b(c_i) = 1$. In addition, for every $i \geq 1$ neuron c_i has an incoming edge from neuron c_{i-1} with weight $w(c_{i-1}, c_i) = 1$, and the first neuron c_0 has an incoming edge from the last neuron c_k with weight $w(c_0, c_k) = 1$. The last neuron of the chain c_k will declare the end of each phase. We assume throughout that the simulation starts by a spike of the starter $v^* = c_0$.

Modifications to the Network $\mathsf{Sync}(\mathcal{N})$. The input layer and output layer in $\mathsf{Sync}(\mathcal{N})$ are *exactly* as in $\mathcal{N}$. We will now focus on the set of *auxiliary* neurons V in $\mathcal{N}$. The network $\mathsf{Sync}(\mathcal{N})$ contains the vertices V of the original network $\mathcal{N}$, and in addition, for each neuron $v_i \in V$ we add the following components to the network:

- A synchronized sub-network $\mathsf{Sync}(v_i)$ using Lemma 16 implementing the threshold gate defined by neuron v_i. The input neurons to the sub-network $\mathsf{Sync}(v_i)$ are the incoming neighbors of v_i in $\mathcal{N}$. The first neuron v_i^* in the internal chain of the sub-network $\mathsf{Sync}(v_i)$ has an incoming edge from the L^{th} neuron of PG cycle, namely c_L with weight 1 and bias $b(v_i^*) = 1$. Denote the output of the sub-network $\mathsf{Sync}(v_i)$ by v_i^{out}.
- An AND module AND_i whose output neuron is v_i. This module is implemented by a circuit of $\mathsf{OR}_{\mathsf{sync}}$ and $\mathsf{NOT}_{\mathsf{sync}}$ gates with three layers (using simple De-morgan rule). The AND_i module receives input from the neuron v_i^{out} and from the $(\alpha L^4)^{th}$ neuron in PG, $c_{\alpha L^4}$ where α is a large enough constant. The internal chains of the AND_i circuit receive input from neuron c_β in PG where $\beta = \alpha L^4 + L$, making sure the circuit begins the execution *after* receiving all its inputs[11].

Modifications to the Circuit Synchronization of Sec. 4.1. So far, we handled the synchronization of circuits. In order to handle general networks (e.g., that contains self-loops and recurrent edges), we need to apply small adaptations to the synchronized sub-networks of Sec. 4.1. Specifically, unlike circuits, in the execution of a network, certain neurons (or gates) might be activated several times. To be able to re-use the sync. sub-networks throughout the execution, we need to reset the states kept by their self-loops.

We therefore adapt the construction of the sync. sub-network presented in Section 4.1 to reset themselves at the end of their computation. For each $\mathsf{NOT}_{\mathsf{sync}}$ gate, we augment its internal chain by $3 \cdot L^2$ neurons, and the last neuron of this chain is connected to an inhibitor neuron v_r. The inhibitor v_r has outgoing edges of weight $-\infty$ to all neurons in the sub-network. Due to Claim 30, it holds that the inhibition by v_r (i.e., the round in which v_r fires) occurs *after* the output neuron has already fired. Observe that the timing of the inhibition by v_r is set in a way that guarantees that all gates in the sub-network will be idle from that point on (i.e., there will be no delayed spikes that arrive after this inhibition). For the sub-network $\mathsf{OR}_{\mathsf{sync}}$ which do not contain self-loops, no adaptation is needed.

B.6 Correctness

Throughout, we fix a synchronous execution Π_{sync} and an asynchronous execution Π_{async}. For every neuron v and phase p, define the beginning of phase p of v in the asynchronous execution $(r(v,p))$ as the round in which the p^{th} spike of c_0 is fired. I.e., the p^{th} phase of v is the time interval $[r(v,p), r(v,p+1))$. For every round p, let $V^+_{\mathsf{sync}}(p)$ be the set of neurons that fire in round p in Π_{sync} (i.e., the neurons with positive entries in σ_p). Similarly, let $V^+_{\mathsf{async}}(p)$ be the set of neurons that fire during phase p.

▶ **Lemma 43.** *The networks* $\mathsf{Sync}(\mathcal{N})$ *and* $\mathcal{N}$ *have similar executions.*

In order to show the networks $\mathsf{Sync}(\mathcal{N})$ and $\mathcal{N}$ have similar executions, we show by induction on round (resp., phase) p that $V^+_{\mathsf{sync}}(p) = V^+_{\mathsf{async}}(p)$. For $p = 1$, let $V^+_{\mathsf{sync}}(0)$ be the neurons that fired at the beginning of the simulation in round 0. We will show that every neuron $v_i \in V$ fires in phase 1 iff $v_i \in V^+_{\mathsf{sync}}(1)$. For $v_i \in V$, the spikes from its incoming neighbors in $V^+_{\mathsf{sync}}(0)$ reach the sub-network $\mathsf{Sync}(v_i)$ by round L. The global chain in $\mathsf{Sync}(v_i)$ is then activated by the neuron c_L in some round $\tau \in [L, L^2]$. Therefore, by Lemma 16 there exists a constant γ such that v_i^{out} fires in some round $\tau_i \in [2, \tau + \gamma \cdot \log \Delta \cdot L^4]$ iff the output of the

[11] We say that the circuit receives its input, if every gate in the first layer has received the signals from its incoming input.

threshold function corresponding to v_i is 1, meaning that $v_i \in V^+_{\mathsf{sync}}(1)$. We next note that the first layer of the sub-network AND_i consists of two $\mathsf{NOT}_{\mathsf{sync}}$ sub-networks with input from $c_{\alpha \cdot L^4}$ and v_i^{out}. Hence, by Observation 32 as long as AND_i receives the information from $c_{\alpha \cdot L^4}$ and v_i^{out} before the activation of the global chain of the network AND_i in some round τ^* its output neuron fires by round $\tau^* + O(L^4)$ iff both v_i^{out} and $c_{\alpha \cdot L^4}$ fired.

The global chain of AND_i is activated by neuron c_β for $\beta = \alpha \cdot L^4 + L$ and therefore is indeed activated *after* AND_i receives the spike from $c_{\alpha L^4}$. In addition, we choose α such that $\alpha L^4 > L^2 + \gamma \cdot \log \Delta \cdot L^4$. Therefore the neuron c_β fires *after* round $\tau_i + L$, i.e. after AND_i received the spike from v_i^{out} as well. We conclude that v_i fires in some round $\tau'' \in [\beta, O(L^4)]$ iff v_i^{out} fires in round τ_i. We choose k to be large enough to make sure that c_k fires after round τ'' and therefore all neurons in $V^+(1)$ fired during the first phase.

Next, we assume that $V^+_{\mathsf{sync}}(p) = V^+_{\mathsf{async}}(p)$ and consider phase $p+1$. Let τ_p be the round that c_0 fired at the beginning of phase p and let τ_{p+1} be the round in which c_0 fired at the beginning of phase $p+1$. In addition, we denote the round in which $c_{\alpha L^4}$ fired during phase p by τ_α. By the induction assumption, neuron v_i fires between round τ_p and round τ_{p+1} iff $v_i \in V^+_{\mathsf{sync}}(p)$. Moreover, since the activation of the sub-network AND_i is performed by neuron c_β, every $v_i \in V^+_{\mathsf{sync}}(p)$ fires after round τ_α. We choose α to be large enough such that by round τ_α, all sub-networks $\mathsf{Sync}(v_i)$ have been reset due to the modification in the circuit synchronization. Hence, for neuron $v_i \in V$, the spikes from its incoming neighbors in $V^+_{\mathsf{async}}(p)$ reach $\mathsf{Sync}(v_i)$ after the sub-network has already been reset. Thus, when the global chain of the sub-network $\mathsf{Sync}(v_i)$ is activated by the neuron c_L in round $\tau_L \in [\tau_{p+1} + L, \tau_{p+1} + L^2]$, the sub-network $\mathsf{Sync}(v_i)$ received spikes from the incoming neighbors of v_i in $V^+_{\mathsf{async}}(p)$. Combining with Lemma 16 we conclude that v_i^{out} fires in round $\tau_i \in [\tau_{p+1} + L, \tau_{p+1} + L^2 + \gamma \cdot \log \Delta \cdot L^4]$ iff $v_i \in V^+_{\mathsf{sync}}(p+1)$. Thus, when neuron c_β fires in phase $p+1$, the sub-network AND_i has received the spikes from both v_i^{out} and $c_{\alpha L^4}$. Since the global chain of AND_i is activated by the neuron c_β, we conclude that v_i fires in some round $\tau^* \in [\tau_{p+1} + \beta, \tau_{p+1} + \Theta(L^4)]$, iff $v_i \in V^+_{\mathsf{sync}}(p+1)$. Choosing k to be large enough, τ^* occurs before c_k fires and ends the phase.

Synchronization of a Spiking Neural Network. We next explain the adaptation of the construction given a network of spiking neurons $\mathcal{N}$. Let n be the number of auxiliary neurons in $\mathcal{N}$ and let t be the number of rounds. Each spiking neuron implemented by a probabilistic threshold gate can be made synchronized using Cor. 19 where we use an error parameter of $\epsilon = 1/\operatorname{poly}(n,t)$. Thus, The network $\mathsf{Sync}(\mathcal{N})$ consists of $\operatorname{poly}(\Delta, \log n \cdot t) \cdot L^4 \cdot n$ auxiliary neurons and uses $\operatorname{poly}(\log \Delta, \log n \cdot t) \cdot L^5$ rounds.

To compare the simulation of the given spiking neural network $\mathcal{N}$ and the synchronized network $\mathsf{Sync}(\mathcal{N})$, we fix the randomness used by $\mathcal{N}$ throughout the simulation and use these coins when simulated the network $\mathsf{Sync}(\mathcal{N})$. For neuron $v \in V$ and round $\tau \geq 1$, by Cor. 19, with probability at least $1 - 1/\operatorname{poly}(n \cdot t)$ it holds that $v \in V^+_{\mathsf{sync}}(\tau)$ iff $v \in V^+_{\mathsf{async}}(\tau)$. By applying the union bound over all n neurons and t rounds of the simulation, we conclude that with high probability $\mathcal{N}$ and $\mathsf{Sync}(\mathcal{N})$ have similar executions.

C Synchronization in the Node-Delay Model

C.1 Network Dynamics in the Node Delay Setting

Network evolution proceeds in *seconds*, namely, a sufficiently small time unit. For a given integer $T \geq 1$, the dynamics is specified by a node-delay function $t : V \to \mathbb{N}_{\leq T}$ interpreted as follows: the round duration on each neuron v consists of $t(v)$ seconds. Specifically, the i^{th}

round of v is defined by the time interval $R_i(v) = [(i-1)t(v)+1, i \cdot t(v)]$ for every $i \geq 1$. All spikes are assumed to arrive with a delay of a single second[12]. For the neuron v and integer i, the set of spikes received at v during its i^{th} round is given by

$$A(v,i) = \{(u, j \cdot t(u)) \mid j \cdot t(u) + 1 \in R_i(v)\}.$$

The state of v in its i-round (i.e., at the second $i \cdot t(v)$) is given by:

$$\text{pot}(v,i) = \sum_{(u,j\cdot t(u)) \in A(v,i)} w(u,v) \cdot \sigma_j(v) \; - \; b(v) \;\text{ and }\; \sigma_i(v) = 1 \text{ iff } \text{pot}(v,i) \geq 0 \; . \tag{6}$$

If v is a probabilistic threshold gate then it fires in second $i \cdot t(v)$ with probability $p(v,i) = \frac{1}{1+e^{-\text{pot}(v,i)}}$.

▶ **Definition 44** (The T-bounded Node-Delay Setting). *We are given a network $\mathcal{N}$ and an integer T. It is assumed the network contains a special neuron, the* starter*, that fires in the first round of the simulation. The dynamic is determined by a node-delay function $t : V \to \mathbb{N}_{\leq T}$. This function t can be chosen arbitrarily.*

▶ **Definition 45** (Computation of a Boolean Function in the T-bounded Node-Delay Setting). *Let $f : \{0,1\}^n \to \{0,1\}^k$ be a Boolean function. A network $\mathcal{N}$ with n input neurons $x_1, \ldots, x_n$ and k output neurons $z_1, \ldots, z_k$* computes *f in this setting if for every T-bounded function $t : V \to \mathbb{N}_{\leq T}$ and for every fixed possible assignment to the input neurons $b_1, \ldots, b_n$ the following holds: (i) If $f_i(b_1, \ldots, b_n) = 1$, then there exists a round in which z_i fires, where $f_i(\cdot)$ is the i^{th} bit in the output of f. (ii) If $f_i(b_1, \ldots, b_n) = 0$ then z_i does not fire throughout the entire execution.*

Synchronizers for the Node-Delay. A synchronizer ν is an algorithm that gets as input a network $\mathcal{N}$ and integer T, and outputs a network $\mathcal{N}' = \mathsf{sync}_V(\mathcal{N}, T)$ that contains all the neurons of $\mathcal{N}$, plus additional auxiliary neurons. One of the auxiliary neurons in $\mathcal{N}'$ is a *starter* neuron that fires in the *first* round of the simulation. The network $\mathcal{N}'$ works in the asynchronous setting and should have *similar execution* to $\mathcal{N}$ in the sense that for every neuron $v \in V(\mathcal{N})$, the firing pattern of v in the asynchronous network should be similar to the one in the synchronous network. The output network $\mathcal{N}'$ simulates each round of the network $\mathcal{N}$ by a phase.

▶ **Definition 46** (Phases). *We partition the execution of $\mathcal{N}'$ into phases $1, 2, \ldots$, using a function $r : V(\mathcal{N}) \times \mathbb{N} \to \mathbb{N}$ that defines the beginning of phase p. Hence, the p^{th} phase is the round interval $[r(v,p), r(v,p+1))$.*

▶ **Definition 47** (Similar Executions (Deterministic Networks)). *The* synchronous *execution Π of a deterministic network $\mathcal{N}$ is specified by a list of states $\Pi = \{\sigma_1, \ldots, \}$ where each σ_i is a binary vector describing the firing status of the neurons in round i. The* asynchronous *execution of the network $\mathcal{N}' = \mathsf{sync}_V(\mathcal{N}, T)$ with a node-delay function $t : V \to \mathbb{N}_{\leq T}$ denoted by $\Pi'(t)$ is defined analogously only when applying the asynchronous dynamic. The execution $\Pi'(t)$ is divided into phases according the a function $r : V(\mathcal{N}) \times \mathbb{N} \to \mathbb{N}$.*

*The network $\mathcal{N}$ and the pair $\langle \mathcal{N}', t \rangle$ have a **similar execution** if $V(\mathcal{N}) \subseteq V(\mathcal{N}')$, and in addition, a neuron $v \in V(\mathcal{N})$ fires in round p in the execution Π iff v fires during phase p in $\Pi'(t)$.*

[12] As discussed in the introduction, this model can be generalized to support both edge-delays and node-delays, to isolate the node-delay effect we assume that all edges have latency of 1.

The networks $\mathcal{N}$ and $\mathcal{N}'$ are ***similar*** *if $\mathcal{N}$ and $\langle \mathcal{N}', t\rangle$ have a similar execution for every node-delay function t.*

As for the edge-delay model, the extension for randomized networks is made by fixing the random bits in the simulation of the input network.

C.2 Reduction to the Edge-Delay Model: A Simulation Result

Given a neural network $\mathcal{N}$ and an integer parameter T, our goal is to construct a network $\mathcal{N}_R = \mathsf{sync}_V(\mathcal{N}, T)$ in the T-bounded node-delay model that behaves similarly to $\mathcal{N}$, i.e., that $\mathcal{N}$ and $\mathcal{N}_R$ are similar according to Definition 47.

Given the network $\mathcal{N}$ and the delay bound T, we start by computing the network $\mathcal{N}_\mathcal{L} = \mathsf{sync}_E(\mathcal{N}, L)$ with $L = 5T^2$. The desired $\mathcal{N}_R = \mathsf{sync}_V(\mathcal{N}_T)$ is obtain by changing some of the edge weights in $\mathcal{N}_\mathcal{L}$. Our proof of correctness is based on similarity between a network in the node-delay model and a network in the edge-delay model.

Similarity between the networks $\mathcal{N}_R$ and $\mathcal{N}_\mathcal{L}$. Fix integer parameters T, L. Given an edge-delay network $\mathcal{N}_\mathcal{L}$, a latency function $\ell : E(\mathcal{N}_\mathcal{L}) \times \mathbb{N} \to \mathbb{N}_{\leq L}$, a node-delay network $\mathcal{N}_R$ on the same neuron set and a node-delay function $t : V(\mathcal{N}_R) \to \mathbb{N}_{\leq T}$, we want to define similarity between the simulations $\langle \mathcal{N}_\mathcal{L}, \ell\rangle$ and $\langle \mathcal{N}_R, t\rangle$, where both simulations use the same initial configuration.

This notion of similarity is based on defining different time scales in each of the simulations. Specifically, for every $i \geq 1$ and neuron $u \in V$ the time window $R_i(u)$ will be the time that u collects spikes for its round i in the simulation of $\langle \mathcal{N}_R, t\rangle$. Moreover, for every $i \geq 0$ the time window $L_i(u)$ correspond to the firing period of round i of u in the simulation of $\langle \mathcal{N}_R, t\rangle$, where

$$R_i(u) = [(i-1)\cdot t(u) + 1, i \cdot t(u)] \text{ and } L_i(u) = [i \cdot T \cdot t(u), i \cdot T \cdot t(u) + (T \cdot t(u) - 1)].$$

Furthermore, for every second τ_R in the simulation of $\langle \mathcal{N}_R, t\rangle$ we will have the corresponding block $B_{\tau_R} = [\tau_R \cdot T, \tau_R \cdot T + (T-1)]$ in the simulation of $\langle \mathcal{N}_\mathcal{L}, \ell\rangle$. For the simulation of $\langle \mathcal{N}_\mathcal{L}, \ell\rangle$ define for every neuron u and $i \geq 0$:

$$\sigma_i(u, \mathcal{N}_\mathcal{L}) = \begin{cases} 1 & u \text{ is strong and } u \text{ fires in every } \tau_\mathcal{L} \in L_i(u) \\ 1 & u \text{ is weak and } u \text{ fires in } \tau_\mathcal{L} \in L_i(u) \text{ only for } \tau_\mathcal{L} = i \cdot T \cdot t(u) \\ 0 & u \text{ never fires in } L_i(u) \\ \emptyset & \text{Otherwise.} \end{cases}$$

For the simulation of $\langle \mathcal{N}_R, t\rangle$ define for every neuron u and $i \geq 0$:

$$\sigma_i(u, \mathcal{N}_R) = \begin{cases} 1 & u \text{ fires in round } i \text{ of } u \text{ (i.e. in the second } i \cdot t(u)) \\ 0 & \text{Otherwise.} \end{cases}$$

▶ **Definition 48.** *The simulations $\langle \mathcal{N}_R, t\rangle, \langle \mathcal{N}_\mathcal{L}, \ell\rangle$ are* similar*, denoted as $\langle \mathcal{N}_R, t\rangle \sim \langle \mathcal{N}_\mathcal{L}, \ell\rangle$, if for every neuron u and $i \geq 0$ it holds that $\sigma_i(u, \mathcal{N}_\mathcal{L}) = \sigma_i(u, \mathcal{N}_R)$.*

A network $\mathcal{N}_\mathcal{L}$ in the L-bounded edge-delay model and a network $\mathcal{N}_R$ in the T-bounded node-delay model are similar*, denoted by $\mathcal{N}_\mathcal{L} \sim \mathcal{N}_R$, if for every node-delay function $t : V(\mathcal{N}_R) \to \mathbb{N}_{\leq T}$ there exists a latency function $\ell : E(\mathcal{N}_\mathcal{L}) \times \mathbb{N} \to \mathbb{N}_{\leq L}$ such that $\langle \mathcal{N}_R, t\rangle \sim \langle \mathcal{N}_\mathcal{L}, \ell\rangle$.*

The key simulation lemma used in the synchronization scheme is as follow:

▶ **Lemma 49.** *Given a network $\mathcal{N}_\mathcal{L}$ in the L-bounded edge delay model such that:*

1. *$b(u) > 0$ for every neuron u.*
2. *Every weak neuron v has no self-loop.*
3. *There is no edge from a strong neuron to a strong neuron.*
4. *Every negative edge has weight $-\infty$.*
5. *For every neuron u, either any excitatory incoming neighbor of u is weak, or any excitatory incoming neighbor of u is strong.*
6. *Let v be a strong incoming neighbor of a neuron u, and let f be an inhibitor. Then if f has an edge to v, it also has an edge to u.*

Then there exists a network $\mathcal{N}_R$ in the T-bounded node-delay model with $T \leq \sqrt{L/5}$ with $V(\mathcal{N}_R) = V(\mathcal{N}_\mathcal{L})$ such that $\mathcal{N}_R$ and $\mathcal{N}_\mathcal{L}$ are similar.

Defining the node-delay network $\mathcal{N}_R$. The network $\mathcal{N}_R$ is exactly as $\mathcal{N}_\mathcal{L}$, up to small adaption of the weights. Denote by $w_\mathcal{L} : V \to \mathbb{R}$ the weight function of the network $\mathcal{N}_\mathcal{L}$. Define the weight function w_R of $\mathcal{N}_R$ as

$$w_R(v,u) = \begin{cases} T \cdot w_\mathcal{L}(v,u) & v \neq u,\ v \text{ is strong,} \\ w_\mathcal{L}(v,u) & \text{Otherwise.} \end{cases}$$

Correctness. We will show that $\mathcal{N}_\mathcal{L}$ and $\mathcal{N}_R$ are similar. Fix a node-delay function $t : V \to \mathbb{N}_{\leq T}$. First, we define the corresponding latency function ℓ and prove it is valid, i.e. that ℓ is nice and $\ell(v,u,\tau) \in [1,L]$ for every neurons v,u and round τ. Then, we restate Lemma 49 in order to prove its correctness by induction on the round.

Definition of the latency function ℓ. First, set the latency of self-spikes to be of value 1. For a neuron u, we say that u is *weak-incoming* if any excitatory incoming neighbor of u is weak, and we say that u is *strong-incoming* if any excitatory incoming neighbor of u is strong. Note that by property 5, every neuron u is either weak-incoming or strong-incoming. For a strong-incoming neuron u, an inhibitor v and $\tau_\mathcal{L} \geq 0$, set $\ell(v,u,\tau_\mathcal{L}) = 2T^2 + 1$. Now consider the remaining spikes, which are either positive spikes, or spikes to a weak-incoming neuron u.

For every $\tau_\mathcal{L} \geq 0$ define the latency value for the spike event $\langle v,u,\tau_\mathcal{L}\rangle$ as follows. Let j be an integer satisfying that $\tau_\mathcal{L} \in L_j(v)$, and let i be such that $j \cdot t(v) + 1 \in R_i(u)$, hence $(v, j \cdot t(v)) \in A(u,i)$.

If v is weak, then for $\tau_\mathcal{L} = j \cdot T \cdot t(v)$ set $\ell(v,u,\tau_\mathcal{L}) = i \cdot T \cdot t(u) - \tau_\mathcal{L}$. That is, the spike $\langle v,u,\tau_\mathcal{L}\rangle$ is scheduled to arrive in the first round of $L_i(u)$. For $\tau_\mathcal{L} > j \cdot T \cdot t(v)$, set $\ell(v,u,\tau_\mathcal{L}) = 1$. Otherwise, if v is strong, consider the following argument. For every second $\tau_\mathcal{L}$ in the edge-latency simulation, let τ_R be the second in the node-delay simulation such that $\tau_\mathcal{L} \in B_{\tau_R}$.

- **Case (I):** there exists a second in $[\tau_R + 1, \tau_R + 2T]$ such that u fires in the node-delay simulation, let τ'_R be the first such second. Set $\ell(v,u,\tau_\mathcal{L}) = \tau'_R \cdot T - \tau_\mathcal{L}$, that is schedule $\langle v,u,\tau_\mathcal{L}\rangle$ to arrive in round $\tau'_R \cdot T$.
- **Case (II):** case I does not apply, and there is an inhibitor f which is an incoming neighbor of u, and a second $\tau'_R \in [\tau_R - T, \tau_\mathcal{L} + 2T]$ such that f fires in τ'_R in the node-delay simulation. Then for such τ'_R, set $\ell(v,u,\tau_\mathcal{L}) = \tau'_R \cdot T + (2T^2 + 1) - \tau_R$, that is schedule $\langle v,u,\tau_\mathcal{L}\rangle$ to arrive in round $\tau'_R \cdot T + (2T^2 + 1)$.
- **Case (III):** neither case (I) nor case (II) apply. Set $\ell(v,u,\tau_\mathcal{L}) = 1$.

The intuition is that for a positive spike in the edge-delay simulation, we look for a round such that u is supposed to fire in the next $2T^2$ rounds. If we cannot find one, we want to send the spike to a round that we know it will not activate u. This is a round in which u receives a negative spike (since negative spikes are of weight $-\infty$). If such round also does not exist, it implies that the total weight of positive incoming neighbors of u that fired in round $\tau_{\mathcal{L}}$ is low, and we can schedule all these spikes to arrive together in $\tau_{\mathcal{L}}+1$ without activating u. We next show that ℓ is valid.

▷ Claim 50. ℓ is a valid latency function for $\mathcal{N}_{\mathcal{L}}$.

Proof. First, since all self-spikes have latency value 1, ℓ is nice. For a negative spike $\langle v,u,\tau_{\mathcal{L}}\rangle$ such that u is strong-incoming, it holds that $\ell(v,u,\tau)=2T^2+1<L$. Therefore we are left to show validity for positive spikes, and for negative spikes that are fired towards a weak-incoming neuron. Consider a spike $\langle v,u,\tau_{\mathcal{L}}\rangle$, and let j be an integer satisfying that $\tau_{\mathcal{L}}\in L_j(v)$. Furthermore, let i be an integer such that $j\cdot t(v)+1\in R_i(u)$.

Next, assume that v is weak. We distinguish between two cases depending whether $\tau_{\mathcal{L}}$ is the first round in the block or not. For $\tau_{\mathcal{L}}=i\cdot T\cdot t(v)$ we have $\ell(v,u,\tau_{\mathcal{L}})=i\cdot T\cdot t(u)-\tau_{\mathcal{L}}$. Recall that $R_i(u)=[(i-1)\cdot t(u)+1, i\cdot t(u)]$, thus $j\cdot t(v)+1\leq i\cdot t(u)$, and $\ell(v,u,\tau_{\mathcal{L}})=T\cdot(i\cdot t(u)-j\cdot t(v))\geq T\geq 1$. Furthermore $j\cdot t(v)+1\geq (i-1)\cdot t(u)+1$, hence $i\cdot t(u)-j\cdot t(v)\leq t(u)\leq T$, and $\ell(v,u,\tau_{\mathcal{L}})\leq T\cdot(i\cdot t(u)-j\cdot t(v))\leq L$. Otherwise, i.e. for $\tau_{\mathcal{L}}\geq i\cdot T\cdot t(v)$, it holds that $\ell(v,u,\tau_{\mathcal{L}})=1$, and thus $\ell(v,u,\tau_{\mathcal{L}})\in[1,L]$.

It remains to consider the case where v is strong. Let τ_R be the second in the node-delay simulation such that $\tau_{\mathcal{L}}\in B_{\tau_R}$. Consider the definition of ℓ for a spike $\langle v,u,\tau_{\mathcal{L}}\rangle$. In case (I), we have $\ell(v,u,\tau_{\mathcal{L}})=\tau'_R\cdot T-\tau_{\mathcal{L}}$, and since $\tau'_R\in[\tau_R+1,\tau_R+2T]$ it holds that $1\leq\tau'_R\cdot T-\tau_{\mathcal{L}}\leq 2T^2<L$. In case (II), since $\tau'_R\in[\tau_R-T,\tau_R+2T]$, we have that $\ell(v,u,\tau_{\mathcal{L}})=\tau'_R\cdot T+(2T^2+1)-\tau_{\mathcal{L}}\in[1,5T^2]$. Finally, in case (III) we simply have $\ell(v,u,\tau_{\mathcal{L}})=1$. Hence, in all cases it holds that $\ell(v,u,\tau_{\mathcal{L}})\in[1,L]$. ◁

In order to show that $\langle\mathcal{N}_R,t\rangle\sim\langle\mathcal{N}_{\mathcal{L}},\ell\rangle$, we restate the condition for similarity in the following lemma. We then prove the lemma by induction on the round $\tau_{\mathcal{L}}$.

▶ **Lemma 51** (Restating Lemma 49). *For every round $\tau_{\mathcal{L}}\geq 0$ of the simulation $\langle\mathcal{N}_{\mathcal{L}},\ell\rangle$ and for every neuron u, let i be such that $\tau_{\mathcal{L}}\in L_i(u)$. Then:*

1. *If $\sigma_i(u,\mathcal{N}_R)=1$:*
   - *If $\tau_{\mathcal{L}}=i\cdot T\cdot t(u)$ then u fires in $\tau_{\mathcal{L}}$.*
   - *If $\tau_{\mathcal{L}}>i\cdot T\cdot t(u)$ then u fires iff u is strong.*
2. *If $\sigma_i(u,\mathcal{N}_R)=0$ then u does not fire in $\tau_{\mathcal{L}}$.*

For the base case $\tau_{\mathcal{L}}=0$, the correctness follows the fact that both simulations have the same starting configuration. Now, let $\tau_{\mathcal{L}}\geq 1$ and assume correctness for every $\tau'_{\mathcal{L}}\leq\tau_{\mathcal{L}}-1$. Fix a neuron u and let i be an integer such that $\tau_{\mathcal{L}}\in L_i(u)$. We start with a useful auxiliary claim.

▷ Claim 52. Let u be a weak-incoming neuron, v an incoming neighbor of u, and $\tau'_{\mathcal{L}}\geq 0$. Furthermore, let j be such that $\tau'_{\mathcal{L}}\in L_j(v)$, and i such that $j\cdot t(v)+1\in R_i(u)$. Then the spike $\langle v,u,\tau'_{\mathcal{L}}\rangle$ occurs and arrives to u in round $\tau_{\mathcal{L}}=i\cdot T\cdot t(u)$ in the simulation $\langle\mathcal{N}_{\mathcal{L}},\ell\rangle$ iff $\tau'_{\mathcal{L}}=j\cdot t(v)$ and the spike $\langle v,u,j\cdot t(v)\rangle$ occurs and arrives to u in $R_i(u)$ in the simulation $\langle\mathcal{N}_R,t\rangle$.

Proof of Claim 52. Since u is weak-incoming v is weak, then by the induction assumption for $\tau'_{\mathcal{L}}$ and the definition of ℓ, the spike event $\langle v,u,\tau'\rangle$ occurs and arrives in round $\tau_{\mathcal{L}}$ iff there exists j such that $\tau'_{\mathcal{L}}=j\cdot T\cdot t(v)$ and $\sigma_j(v,\mathcal{N}_R)=1$. This happens iff in the simulation of $\langle\mathcal{N}_R,t\rangle$ the spike event $\langle v,u,j\cdot t(v)\rangle$ occurs and arrives to u in $R_i(u)$. ◁

We split the proof of Lemma 51 into two cases.

Case 1: u is weak-incoming. Assume $\tau_{\mathcal{L}} = i \cdot T \cdot t(u)$, we want to show that u fires in round $\tau_{\mathcal{L}}$ iff $\sigma_i(u, \mathcal{N}_R) = 1$. By Claim 52, we get that the mapping $\langle v, u, j \cdot T \cdot t(v) \rangle \mapsto \langle v, u, j \cdot t(v) \rangle$ is a bijection between the set of non self-spikes that u receives in $\tau_{\mathcal{L}}$ in the simulation $\langle \mathcal{N}_{\mathcal{L}}, \ell \rangle$ and the set of non-self spikes that u receives in $R_i(u)$ in the simulation $\langle \mathcal{N}_R, t \rangle$. As for self-spikes, note that if u is weak it has no self-loop. If u is strong, then by the induction assumption u fires in $\tau_{\mathcal{L}} - 1$ iff $\sigma_{i-1}(u, \mathcal{N}_R)$. Thus, u receives the self-spike $\langle u, u, \tau_{\mathcal{L}} - 1 \rangle$ in $\tau_{\mathcal{L}}$ iff it receives the self-spike $\langle u, u, (i-1) \cdot T \cdot t(u) \rangle$ in $R_i(u)$. Since $w_{\mathcal{L}}(v, u) = w_R(v, u)$ for every weak neuron v and for $v = u$, we get that the total spike weight that u receives in $\tau_{\mathcal{L}}$ equals to the total spike weight it receives in $R_i(u)$. Thus, u fires in round $\tau_{\mathcal{L}}$ iff $\sigma_i(u, \mathcal{N}_R) = 1$.

Now, assume $\tau_{\mathcal{L}} > i \cdot T \cdot t(u)$ and that either v is weak, or v is strong and $\sigma_i(u, \mathcal{N}_R) = 0$. We want to show that u does not fire. Note that if v is weak then it has no self-loop, and if v is strong and $\sigma_i(u, \mathcal{N}_R) = 0$ then by the induction assumption for $\tau_{\mathcal{L}} - 1$, u does not fire in $\tau_{\mathcal{L}} - 1$. Thus, in both cases u does not receive a self-spike in $\tau_{\mathcal{L}}$. Furthermore, u has no strong neighbors, therefore by Claim 52 u does not receive any positive spikes from incoming neighbors. Since $b(u) > 0$, u does not fire in $\tau_{\mathcal{L}}$.

Finally, assume $\tau_{\mathcal{L}} > i \cdot T \cdot t(u)$, and assume u is strong and $\sigma_i(u, \mathcal{N}_R) = 1$. We want to show that u fires. Note that by Claim 52, u does not receive a negative spike in $\tau_{\mathcal{L}}$. Furthermore, since $\sigma_i(u, \mathcal{N}_R) = 1$ by the induction assumption for $\tau_{\mathcal{L}} - 1$, u fires in $\tau_{\mathcal{L}} - 1$ and therefore u receives a self-spike in $\tau_{\mathcal{L}}$. Since $w_{\mathcal{L}}(u, u) \geq b(u)$, u fires in $\tau_{\mathcal{L}}$.

Case 2: u is strong-incoming. By the properties of $\mathcal{N}_{\mathcal{L}}$ there is no edge between strong neurons, and weak neurons have no self-loop. Hence u is weak and has no self-loop. We handle separately the following sub-cases:

Case 2.1: $\sigma_i(u, \mathcal{N}_R) = 1$ and $\tau_{\mathcal{L}} = i \cdot T \cdot t(u)$. We want to show that u fires in $\tau_{\mathcal{L}}$. Let $\langle v, u, j \cdot t(v) \rangle$ be a positive spike in the simulation $\langle \mathcal{N}_R, t \rangle$ that arrives to u in $R_i(u)$, and let $\tau'_{\mathcal{L}}$ be one of the T rounds $[j \cdot T \cdot t(v), j \cdot T \cdot t(v) + (T-1)]$. Since v is strong then by the induction assumption for $\tau'_{\mathcal{L}}$ v fires in $\tau'_{\mathcal{L}}$, and therefore the spike event $\langle v, u, \tau'_{\mathcal{L}} \rangle$ occurs in the simulation $\langle \mathcal{N}_{\mathcal{L}}, \ell \rangle$. We now show that $\langle v, u, \tau'_{\mathcal{L}} \rangle$ arrives to u in $\tau_{\mathcal{L}}$, according to the definition of ℓ for spikes from strong neurons.

Since $\sigma_i(u, \mathcal{N}_R) = 1$, u fires in the second $r_R = i \cdot t(u)$ in the simulation $\langle \mathcal{N}_R, t \rangle$. Note that $j \cdot t(v) + 1 \in R_i(u)$ implies that $i \cdot t(u) - j \cdot t(v) \leq T$. Hence in particular $i \cdot t(u) \in [j \cdot t(v) + 1, j \cdot t(v) + 2T]$. Let $r'_R \in [j \cdot t(v) + 1, j \cdot t(v) + 2T]$ with $r'_R < i \cdot t(u)$. Note that $r'_R \in R_i(u)$, therefore r'_R is not an end of a round of u. Hence u does not fire in r'_R. Therefore the second $r_R = i \cdot t(u)$ is the first second in $[j \cdot t(v) + 1, j \cdot t(v) + 2T]$ that u fires, and due to the definition of ℓ the spike $\langle v, u, \tau'_{\mathcal{L}} \rangle$ arrives in round $\tau_{\mathcal{L}}$.

Now, let f be an inhibitory incoming neighbor of u. By the definition of ℓ, a spike from f to u can arrive only in a round of the form $\tau'_R \cdot T + T^2 + 1$ for some second τ'_R, which is not a multiplicity of T. Note that $\tau_{\mathcal{L}} = i \cdot T \cdot t(u)$ is a multiplicity of T. Thus u does not receive a negative spike in $\tau_{\mathcal{L}}$.

We get that in round $\tau_{\mathcal{L}}$, u receives only positive spikes in $\tau_{\mathcal{L}}$, and for every positive spike $\langle v, u, j \cdot t(v) \rangle$ that arrives to u in $R_i(u)$ and every $\tau'_{\mathcal{L}} \in [j \cdot T \cdot t(v), j \cdot T \cdot t(v) + (T-1)]$, u receives a spike $\langle v, u, \tau'_{\mathcal{L}} \rangle$. Since $w_R(v, u) = T \cdot w_{\mathcal{L}}(v, u)$ for every strong v and $[j \cdot T \cdot t(v), j \cdot T \cdot t(v) + (T-1)]$ contains T rounds, we get that the total spike weight that u receives in $\tau_{\mathcal{L}}$ is at least the total spike weight it receives in $R_i(u)$ in the node-delay simulation. Since $\sigma_i(u, \mathcal{N}_R) = 1$, u receives in $R_i(u)$ a spike weight of at least $b(u)$, which implies the same for round $\tau_{\mathcal{L}}$ in the edge-delay simulation. Thus u fires in round $\tau_{\mathcal{L}}$.

Case 2.2: $\sigma_i(u, \mathcal{N}_R) = 0$ or $\tau_{\mathcal{L}} > i \cdot T \cdot t(u)$. We want to show that u does not fire in $\tau_{\mathcal{L}}$. Towards contradiction, assume that it does. First note that if u receives no positive spikes in $\tau_{\mathcal{L}}$, then since $b(u) > 0$ u does not fire in $\tau_{\mathcal{L}}$. Otherwise, let $\langle v, u, \tau'_{\mathcal{L}} \rangle$ be a positive spike that arrives to u in round $\tau_{\mathcal{L}}$. Recall that since v is strong, there are three cases for defining the latency value of $\langle v, u, \tau'_{\mathcal{L}} \rangle$.

We will now show that $\langle v, u, \tau'_{\mathcal{L}} \rangle$ belongs to case (II). It does not belong to case (I), since it does not hold that $\sigma_i(u) = 1$ and $\tau_{\mathcal{L}} = i \cdot T$ If we are in case (II), then there exists an inhibitor f which is connected to u that fired in second τ'_R in the node-delay simulation that arrived in $\tau_{\mathcal{L}}$, i.e. such that $\tau_{\mathcal{L}} = \tau'_R \cdot T + (T^2 + 1)$. By the induction assumption for $\tau'_R \cdot T$, u fires in round $\tau'_R \cdot T$ in the edge-delay simulation, and since u is strong-incoming then by the definition of ℓ the spike $\langle f, u, \tau'_R \cdot T \rangle$ arrives to u in round $\tau'_R \cdot T + (T^2 + 1) = \tau_{\mathcal{L}}$. Since negative spikes are of weight $-\infty$, u does not fire in $\tau_{\mathcal{L}}$. Therefore, $\langle v, u, \tau'_{\mathcal{L}} \rangle$ belongs to case (III).

By the definition of case (III), $\langle v, u, \tau'_{\mathcal{L}} \rangle$ was generated in round $\tau'_{\mathcal{L}} = \tau_{\mathcal{L}} - 1$. Let j be such that $\tau_{\mathcal{L}} - 1 \in L_j(v)$, and let τ_R such that $\tau_{\mathcal{L}} - 1 \in B_{\tau_R}$. Furthermore, let v be an excitatory incoming neighbor that fires in $\tau_{\mathcal{L}} - 1$, let j be such that $\tau_{\mathcal{L}} - 1 \in L_j(v)$, and let τ_R such that $\tau_{\mathcal{L}} - 1 \in B_{\tau_R}$. Our goal is to show that v fires in $[\tau_R + 1, \tau_R + T]$ in the node-delay simulation, by showing that it receives enough positive spikes from its neighbors in this interval.

Let f be an inhibitor that has an edge to v. By the network properties f also has an edge to u, and since we are not in case (II) in the definition of ℓ, f does not fire in the interval $[\tau_R - T, \tau_{\mathcal{L}} + 2T]$ in the node-delay simulation. This implies that v does not receive a negative spike in $[\tau_R - T + 1, \tau_R + 2T + 1]$. Notice that $\tau_R \in [j \cdot t(v), (j+1) \cdot t(v) - 1]$, and since $t(v) \leq T$ we get

$$R_{j+1}(v) = [j \cdot t(v) + 1, (j+1) \cdot t(v)] \subseteq [\tau_R - T + 1, \tau_R + 2T + 1].$$

Therefore, v does not receive a negative spike in $R_{j+1}(v)$.

By the induction assumption for $\tau_{\mathcal{L}} - 1$ we have $\sigma_j(v, \mathcal{N}_R) = 1$. Together with the fact that v is strong and receives no negative spikes in $R_{j+1}(v)$, we get that $\sigma_{j+1}(v, \mathcal{N}_R) = 1$, i.e. v fires in the node-delay simulation in the second $(j+1) \cdot t(v)$. This implies that u receives a spike from v in $(j+1) \cdot t(v) + 1$, which is inside the interval $[\tau_R + 1, \tau_R + T]$. If so, let W the total weight of the incoming neighbors of u that fired in round $\tau_{\mathcal{L}} - 1$. Since u fires in round $\tau_{\mathcal{L}}$, it holds that $W \geq b(u)$. We will show this implies that u fires in some round in $[\tau_R + 1, \tau_R + 2T]$, which contradicts the fact that none of the arriving spikes belong to case I.

We showed that for every neuron v that fires in $\tau_{\mathcal{L}} - 1$ in the edge-latency simulation, u receive a spike from v in some round $\tau'_R \in [\tau_R + 1, \tau_R + T]$ in the node-delay simulation. By the definition of w_R it holds that $w_R(v, u) = T \cdot w_{\mathcal{L}}(v, u)$, and therefore we get

$$\sum_{\tau'_R = \tau_R + 1}^{\tau_R + T} W_{\tau'_R} \geq T \cdot W.$$

By an averaging argument there is a second $\tau'_R \in [\tau_R + 1, \tau_R + T]$ with $W_{\tau'_R} \geq (T \cdot W)/T = W$.

Let i' be an integer such that $\tau'_R \in R_{i'}(u)$. Therefore u receive in $R_{i'}(u)$ a total positive spike weight of at least $W \geq b(u)$. Furthermore, since no spike belongs to case C.2, u do not receive a negative spike in $R_{i'}(u) \subseteq [\tau_R + 1, \tau_R + 2T]$. Thus, u fires in the second $i' \cdot t(u) \in [\tau_R + 1, \tau_R + 2T]$, a contradiction.

C.3 The Complete Synchronization Scheme

We are now ready to complete the proof of Theorem 5. We consider a neural network $\mathcal{N}$ and an integer parameter T. Set $L = 5T^2$ and let $\mathcal{N}_\mathcal{L} = \mathsf{sync}_E(\mathcal{N}, L)$ be the synchronized network of $\mathcal{N}$ in the L-bounded node-delay model. We will now show that $\mathcal{N}_\mathcal{L}$ satisfies the properties in the conditions of Lemma 49.

Showing that $\mathcal{N}_\mathcal{L}$ satisfies the properties of Lemma 49. Note that by the definition of the edge-delay synchronization scheme given in Section 4.3, every neuron $u \in \mathcal{N}_\mathcal{L}$ is contained in one of the following modules: (1) an $\mathsf{OR}_{\mathsf{sync}}$ or $\mathsf{NOT}_{\mathsf{sync}}$ subnetwork (Section 4.1), (2) a chain of a threshold gate which is a implemented as a boolean circuit subnetwork (Section B.3), or (3) the chain of the global pulse generator (Section 4.3). By the definitions of these modules, properties 1 and 2 hold. Moreover, together with the fact that edges between the modules connect only weak excitatory neurons, we also get property 3. Furthermore, note that the only inhibitors in the network are r and v_r neurons (which is later added in 4.3) in the $\mathsf{NOT}_{\mathsf{sync}}$ module, and all their edges have weight $-\infty$. Therefore, property 4 is satisfied.

The remaining properties 5 and 6 are relevant only for strong neurons. Therefore, consider the $\mathsf{NOT}_{\mathsf{sync}}$ module (Lemma 14), which is the only module that contains strong neurons. By the module definition, there are two possible types of strong neurons: (i) the memory neuron m, that is only connected to the reset neuron r; and (ii) intermediate neuron v_i, that is only connected to the output neuron z. In case (i), v has only one incoming inhibitor, which is the neuron v_r that resets the whole network after it finishes. Thus v_r also has an edge to r. In case (ii), v has two incoming inhibitors, v_r and r, which both have an edge to z. Therefore property 6 holds. Furthermore, both r and z have no edges from weak neurons. Hence, property 5 holds.

Indeed, $\mathcal{N}_\mathcal{L}$ satisfies the conditions of Lemma 49, and therefore there exists a network $\mathcal{N}_R$ in the T-bounded node delay model which is similar to $\mathcal{N}_\mathcal{L}$. We are left to show the transitivity of similarity, i.e. that if $\mathcal{N} \sim \mathcal{N}_\mathcal{L}$ and $\mathcal{N}_\mathcal{L} \sim \mathcal{N}_R$, also $\mathcal{N} \sim \mathcal{N}_R$.

Showing transitivity of similarity. Let t be a node-delay function for $\mathcal{N}_R$. First, by the similarities of the networkss we get $V(\mathcal{N}) = V(\mathcal{N}_\mathcal{L}) = V(\mathcal{N}_R)$. Moreover, by the definition of $\mathcal{N}_\mathcal{L} \sim \mathcal{N}_R$ there exists a latency function ℓ for $\mathcal{N}_\mathcal{L}$ such that $\langle \mathcal{N}_\mathcal{L}, \ell \rangle \sim \langle \mathcal{N}_R, t \rangle$. Let Π be the execution of $\mathcal{N}$, $\Pi_\mathcal{L}$ be the execution of $\langle \mathcal{N}, \ell \rangle$, and Π_R be the execution of $\langle \mathcal{N}, t \rangle$. Let the interval $[r_\mathcal{L}(v,p), r_\mathcal{L}(v,p+1))$ be the p^{th} phase of $\Pi_\mathcal{L}$, and define $[r_R(v,p), r_R(v,p+1))$ as the p^{th} phase of Π_R, where the definition of $r_R(v,p)$ is as follows. Let $L_p^*(v)$ be the earliest block $L_i(v)$ whose first round τ_p^* is contained in phase p of $\Pi_\mathcal{L}$, then $r_R(v,p) = \tau_p^*/T$. We wish to prove the following claim.

▷ Claim 53. For every neuron v and $p \geq 0$, v fires in round p of Π iff v fires in phase p of Π_R.

First, note that by the construction of $\mathcal{N}_\mathcal{L} = \mathsf{sync}_(\mathcal{N}, \mathcal{L})$, every neuron $v \in V(\mathcal{N})$ can fire only after the chain neuron $c_{\alpha L^4 + L}$ fires. Since $\alpha L^4 > t(v) \cdot T$ this implies that v does not fire in the first $t(v) \cdot T$ rounds of each phase in $\Pi_\mathcal{L}$. We prove the two directions of the claim.

- Assume neuron v fires in round p in Π. Because $\mathcal{N} \sim \langle \mathcal{N}_\mathcal{L}, \ell \rangle$ there is a round $\tau_\mathcal{L}$ in phase p of $\Pi_\mathcal{L}$ where v fires. Since v does not fire in the first $t(v) \cdot T$ rounds of each phase we have $\tau_\mathcal{L} \geq r_\mathcal{L}(v,p) + t(v) \cdot T$. Since $L_j(v)$ consists of $t(v) \cdot T$ rounds, the first round of $L_j(v)$ is in phase p. Therefore, $j \cdot t(v) \cdot T \geq \tau^*$, and therefore $j \cdot t(v) \geq r_R(v,p)$.

Furthermore we have that $j \cdot t(v)$ is not in phase $p+1$. Hence also $j \cdot (v) < r_R(v, p+1)$, i.e. $j \cdot t(v)$ is in phase p of Π. Due to the similarity $\langle \mathcal{N}_{\mathcal{L}}, \ell \rangle \sim \langle \mathcal{N}_R, t \rangle$, since v fires in $L_j(v)$ it also fires in $j \cdot t(v)$. Hence v fires in phase p of Π_R.

- Assume that v fires in phase p in Π_R. Assume this happens in round τ_R, then $\tau_R \geq \tau_p^*/T$. Thus $j \cdot T \cdot t(v) \geq \tau_p^* \geq r_{\mathcal{L}}(v, i)$. Furthermore, $j \cdot t(v) < \tau_p^*/T$ implies that round $j \cdot T \cdot t(v)$ was before phase $p+1$ of $\Pi_{\mathcal{L}}$. Therefore $j \cdot T \cdot t(v)$ is in phase p of $\Pi_{\mathcal{L}}$. By the similaritiy $\langle \mathcal{N}_{\mathcal{L}}, \ell \rangle \sim \langle \mathcal{N}_R, t \rangle$ we have that v fires in round $j \cdot T \cdot t(v)$ in $\Pi_{\mathcal{L}}$. Hence v fires in phase p of $\Pi_{\mathcal{L}}$. By the similarity $\mathcal{N} \sim \langle \mathcal{N}_{\mathcal{L}}, \ell \rangle$ we get that v fires in round p of Π.

Certified Algorithms: Worst-Case Analysis and Beyond

Abstract

In this paper, we introduce the notion of a *certified algorithm*. Certified algorithms provide worst-case and beyond-worst-case performance guarantees. First, a γ-certified algorithm is also a γ-approximation algorithm – it finds a γ-approximation no matter what the input is. Second, it exactly solves γ-perturbation-resilient instances (γ-perturbation-resilient instances model real-life instances). Additionally, certified algorithms have a number of other desirable properties: they solve both maximization and minimization versions of a problem (e.g. Max Cut and Min Uncut), solve weakly perturbation-resilient instances, and solve optimization problems with hard constraints.

In the paper, we define certified algorithms, describe their properties, present a framework for designing certified algorithms, provide examples of certified algorithms for Max Cut/Min Uncut, Minimum Multiway Cut, k-medians and k-means. We also present some negative results.

1 Introduction

In this paper, we introduce and study certified algorithm, describe their properties, present a framework for designing certified algorithms, provide examples of certified algorithms for Max Cut/Min Uncut, Minimum Multiway Cut, k-medians and k-means. Recall the definition of an instance perturbation, which was given by Bilu and Linial [10].

▶ **Definition 1.** *Consider a combinatorial optimization or clustering problem. Suppose that every instance has a number of parameters $p_1, \dots, p_m > 0$; for example, if the problem is a graph partitioning problem, the parameters are edge weights; if it is a constraint satisfaction problem, the parameters are constraint weights; if it is a clustering problem, the parameters are distances between points.*

Let $\gamma \geq 1$. An instance $\mathcal{I}'$ is a γ-perturbation of $\mathcal{I}$ if it differs from $\mathcal{I}$ only by the values of the parameters, and the parameters $p'_1, \dots, p'_m$ of $\mathcal{I}'$ satisfy the following inequality

$$p_i \leq p'_i \leq \gamma p_i \quad \text{for every } i \tag{1}$$

alternatively, we may require that

$$p_i/\gamma \leq p'_i \leq p_i \quad \text{for every } i. \tag{2}$$

Note that if $\gamma = 1$, then $\mathcal{I}' = \mathcal{I}$. Loosely speaking, the closer γ to 1 is, the closer $\mathcal{I}'$ to $\mathcal{I}$ is. All problems we consider are scale invariant, so it will not matter whether we use formula (1) or (2). It will be convenient to use (1) for combinatorial optimization problems and (2) for clustering problems. The central definition of this paper is that of a certified algorithm.

▶ **Definition 2.** *A γ-certified solution for instance $\mathcal{I}$ is a pair $(\mathcal{I}', s^*)$, where $\mathcal{I}'$ is a γ-perturbation of $\mathcal{I}$ and s^* is an optimal solution for $\mathcal{I}'$. A γ-certified algorithm (or a γ-certified approximation algorithm) is an algorithm that finds a γ-certified solution.*[1]

The definition of a certified algorithm is inspired by the notions of smoothed analysis [18] and perturbation-resilience (also known as Bilu-Linial stability) [10]. Recall that in the smoothed analysis framework, we analyze the performance of an algorithm on a small random perturbation of the input instance. That is, we show that, after we randomly perturb the input, the algorithm can solve it with the desired accuracy in the desired time. A certified approximation algorithm perturbs the input instance *on its own* and then solves the obtained instance exactly. Importantly, the perturbation does not have to be random or small. Now, let us talk about perturbation resilience.

▶ **Definition 3** ([10])**.** *An instance $\mathcal{I}$ is γ-perturbation-resilient*[2] *if every γ-perturbation of $\mathcal{I}$ has the same optimal solution as $\mathcal{I}$ (we require that $\mathcal{I}$ have a unique optimal solution).*

Bilu and Linial [10] initiated the study of perturbation resilience in 2010. Perturbation-resilient instances model practical instances, and the model is particularly well-suited for capturing problems arising in machine learning. As Bilu-Linial (as well as other authors, see [6, 9]) argued most practically relevant instances should be perturbation-resilient. Since the seminal paper by Bilu and Linial, there has been a lot of research on algorithms for perturbation-resilient instances (see e.g., [10, 9, 6, 16, 7, 3, 11, 8], see also [15] for a survey of known results) and by now there are a number of algorithms for perturbation-resilient instances of various graph partitioning, clustering, and other problems. A closely related notion to perturbation resilience is that of weak perturbation resilience.

▶ **Definition 4** ([16])**.** *Consider an instance $\mathcal{I}$. Let s^* be an optimal solution and N be a set of solutions, which includes all optimal solutions. Assume that for every γ-perturbation $\mathcal{I}'$ of $\mathcal{I}$, solution s^* is better than every $s \notin N$ with respect to the $\mathcal{I}'$ objective. Then $\mathcal{I}$ is (γ, N)-weakly perturbation-resilient. We say that an algorithm solves a weakly perturbation-resilient instance $\mathcal{I}$, if given a (γ, N)-weakly perturbation-resilient instance, it finds a solution $s \in N$ (crucially, the algorithm does not know N.)*

Intuitively, N is the set of solutions that are close to s^* in some sense. Say, N might be the set of solutions that are at most ε far from s^* in some metric or have similar structural properties to s^*. Note that $(\gamma, \{s^*\})$-weak perturbation resilience is equivalent to γ-perturbation resilience. In general, the requirement that an instance $\mathcal{I}$ be weakly perturbation-resilient is somewhat less restrictive than the one that $\mathcal{I}$ be perturbation-resilient.

---

[1] We call the solution "certified", because, as we will see later, $\mathcal{I}'$ "certifies" that s^* is a γ-approximation.
[2] Perturbation-resilient instances are also known as Bilu–Linial stable instances.

1.1 Overview: Properties of Certified Algorithms

Consider a γ-certified algorithm $\mathcal{A}$ for a constraint satisfaction or graph partitioning problem (or any problem whose objective is homogeneous of degree 1)[3]. First of all, $\mathcal{A}$ is also a γ-approximation algorithm, it *always* finds a γ-approximate solution. Then it exactly solves γ-perturbation-resilient instances and solves (γ, N)-weakly perturbation-resilient instances. Thus, we have both worst-case and beyond-worst-case guarantees for $\mathcal{A}$. We believe that this property is very desirable in practice. In particular, if our instance is indeed perturbation-resilient, we will find an exact solution; if it is not, we will find a reasonably good approximate solution. Note that other algorithms do not satisfy this property: state-of-the-art approximation algorithms do not solve perturbation-resilient instances and state-of-the-art algorithms for perturbation-resilient instances do not provide a good approximation if the instance is not perturbation-resilient. Additionally, $\mathcal{A}$ also satisfies some other properties; we prove in Theorems 10, 11, and 13 that:

- **Worst-Case Guarantees.** Algorithm $\mathcal{A}$ finds a γ-approximate solution for any instance $\mathcal{I}$; further, it finds a γ-approximate solution for the complimentary objective. For example, if the problem is a constraint satisfaction problem (CSP), then $\mathcal{A}$ finds a solution that is a γ-approximation for the problems of (1) maximizing the weight of the satisfied constraints and (2) minimizing the weight of the unsatisfied constraints. Additionally, if the problem is a CSP, $\mathcal{A}$ is also a γ-approximation algorithm for the variant of the problem with hard constraints.
- **Beyond-Worst-Case Guarantees.** Algorithm $\mathcal{A}$ exactly solves γ-perturbation-resilient instances and solves (γ, N)-weakly perturbation-resilient instances.

▶ Remark 5. The running time of most algorithms that we consider will depend not only on the size of the instance but also on the magnitude of the parameters. In a sense, we will assume that all parameters are given in the unary. More precisely, let ρ be the ratio between the largest and smallest parameters (for constraint satisfaction and graph partitioning problems, ρ is the ratio between the largest and smallest constraint/edge/node weights; for clustering problems, ρ is the aspect ratio of the given metric space, the ratio between the largest and smallest distances). Then the running time will depend polynomially on the input size and ρ. Thus we will call our algorithms *pseudo-polynomial-time algorithms*.

▶ **Definition 6.** *We say that a certified algorithm runs in pseudo-polynomial time if its running time is polynomial in the size of the input n and $\rho = \frac{\max_i p_i}{\min_i p_i}$.*

1.2 Our Results

The main contribution of this paper is conceptual rather than technical. We introduce the notion of a certified algorithm and prove that certified algorithms satisfy the properties listed above. We believe that certified algorithms will prove useful in developing new algorithms for solving worst-case and beyond-worst-case instances. We also believe that even if one is primarily interested in designing an algorithm for solving perturbation-resilient instances, it is often more convenient to design a certified algorithm (as it is guaranteed to solve perturbation-resilient instances).

[3] That is, the value of the objective multiplies by α when we multiply all the parameters (exactly) by α.

We provide a general framework for designing polynomial-time certified algorithms for combinatorial optimization problems and give examples of algorithms for combinatorial optimization and clustering problems. We also present some negative results. In establishing these results, we heavily use techniques from papers on perturbation resilience [16, 3, 11, 8, 12]. Specifically, we give pseudo-polynomial-time γ-certified algorithms for

- Min Uncut and Max Cut with $\gamma = O(\sqrt{\log n}\log\log n)$ (*cf.* the state-of-the-art approximation algorithm for Min Uncut gives an $O(\sqrt{\log n})$ approximation [1]),
- Minimum Multiway Cut with $\gamma = 2 - 2/k + \varepsilon_n$ for every ε_n such that $\varepsilon_n > 1/\operatorname{poly}(n)$ (*cf.* the state-of-the-art approximation algorithm gives a ≈ 1.296 approximation [17])
- k-medians with $\gamma = 3 + \varepsilon$ for every fixed $\varepsilon > 0$ (*cf.* the state-of-the-art algorithm gives a ≈ 2.732 approximation [14]).

We also observe that the algorithm for $(1+\varepsilon)$ -perturbation resilient instances of Euclidean k-means and k-medians by Friggstad, Khodamoradi, and Salavatipour [12] is $(1+\varepsilon)$-certified (see Theorem 24). Additionally, we show that there are no polynomial-time or pseudo-polynomial-time $O(n^{1-\delta})$-certified algorithms for Minimum Vertex Cover, Set Cover, and Min 2-Horn Deletion if $\mathcal{P} \neq \mathcal{NP}$ (for every fixed $\delta > 0$).

▶ Note (Follow-up work). In a follow-up paper [2], Angelidakis, Awasthi, Blum, Chatziafratis, and Dan use our framework to design a number of new certified algorithms for such problems as Euclidean Maximum Independent Set and Node Multiway Cut.

2 Preliminaries

We start with formally defining what an instance of a combinatorial optimization problem is.

▶ **Definition 7.** *An instance of a combinatorial optimization problem is specified by a set of feasible solutions $\mathcal{S}$ (the solution space), a set of constraints $\mathcal{C}$, and constraint weights $w_c > 0$ for $c \in \mathcal{C}$. Typically, the solution space $\mathcal{S}$ is of exponential size and is not provided explicitly. Each constraint is a map from $\mathcal{S}$ to $\{0,1\}$. We say that a feasible solution $s \in \mathcal{S}$ satisfies a constraint c in $\mathcal{C}$ if $c(s) = 1$.*

We consider maximization and minimization objectives.

- *The maximization objective is to maximize the total weight of the satisfied constraints: find $s \in \mathcal{S}$ that maximizes $\operatorname{val}_{\mathcal{I}}(s) \equiv \sum_{c\in\mathcal{C}} w_c c(s)$.*
- *The minimization objective is to minimize the total weight of the unsatisfied constraints: find $s \in \mathcal{S}$ that minimizes $\sum_{c\in\mathcal{C}} w_c(1-c(s)) = w(\mathcal{C}) - \operatorname{val}_{\mathcal{I}}(s)$ (where $w(\mathcal{C}) = \sum_{c\in\mathcal{C}} w(c)$ is the total weight of all the constraints).*

We say that maximization and minimization are complementary objectives. Weights $\{w_c\}_{c\in\mathcal{C}}$ are the parameters of the instance in the sense of Definition 1.

Note that s^* is an optimal solution for $\mathcal{I}$ with the maximization objective if and only if it is an optimal solution for $\mathcal{I}$ with the minimization objective. Accordingly, $(\mathcal{I}', s)$ is a γ-certified solution for $\mathcal{I}$ with the maximization objective if and only if it is a γ-certified solution for $\mathcal{I}$ with the minimization objective.

▶ **Definition 8.** *An optimization problem $\mathcal{P}$ is a family $\mathcal{F}$ of instances. All instances in $\mathcal{F}$ have a fixed objective; either all of them have a maximization or all have a minimization objective. We assume that if instance $(\mathcal{S}, \mathcal{C}, w)$ is in $\mathcal{F}$, then so is $(\mathcal{S}, \mathcal{C}, w')$ for any choice of weights $w_c > 0$.*

This definition captures various constraint satisfaction, graph partitioning, and covering problems. Consider for example Min Uncut. In Min Uncut, the goal is to find a cut $(S, \bar{S})$ in a given graph $G = (V, E, w)$ that minimizes the total weight of the uncut edges (edges that

connect vertices within S or within $\bar{S}$). For Min Uncut, $\mathcal{S}$ is the set of all cuts in G. There is a constraint c_e for every edge $e \in E$; a cut satisfies constraint c_e if and only if it cuts edge e. The objective is to minimize $\sum_{c\in\mathcal{C}} w_c(1 - c((S, \bar{S})))$. The objective for the complementary problem, Max Cut, is $\sum_{c\in\mathcal{C}} w_c c((S, \bar{S}))$.

There are also certified algorithms for clustering problems. In this paper, we describe a $(3 + \varepsilon)$-certified algorithm for k-medians and note that algorithms for Euclidean k-means and k-medians from [12] are $(1 + \varepsilon)$-certified. Recall the definition of k-medians.

▶ **Definition 9.** *In k-medians, we are a given a set of points X, metric d on X, which satisfies triangle inequalities, and a parameter $k \geq 1$. The cost of a cluster $C \subset X$ is*

$$\operatorname{cost} C = \min_{c\in X} \sum_{u\in C} d(u, c).$$

The goal is to partition X into k clusters $C_1, \dots, C_k$ so as to minimize their total cost $\sum_{i=1}^{k} \operatorname{cost} C_i$. The parameters of the problem (in the sense of Definition 1) are the pairwise distances $d(u, v)$.

We say that c is an optimal center for C, if $c \in \arg\min_{c\in X} \sum d(u, c)$. Note that a set of centers $c_1, \dots, c_k$ defines a clustering $C_1, \dots, C_k$ of X; namely, $C_1, \dots, C_k$ is the Voronoi partition for $c_1, \dots, c_k$ (if there are ties, several partitions may correspond to the same set of centers).

A γ-perturbation of an instance (X, d) is an instance (X, d'), such that $\frac{1}{\gamma} d(u, v) \leq d'(u, v) \leq d(u, v)$ for every $u, v \in X$. Note that we do not require that d' satisfy triangle inequalities (if we did, we would get the definition of a metric perturbation; see [3] for details).

3 Properties of Certified Algorithms

In this section, we prove that certified algorithms satisfy the properties we described in Section 1.

▶ **Theorem 10.** *Consider a γ-certified algorithm $\mathcal{A}$ for a combinatorial optimization problem.*

- *$\mathcal{A}$ finds a solution that is a γ-approximate solution w.r.t. both the maximization and minimization objectives.*
- *If the instance is γ-perturbation-resilient, $\mathcal{A}$ finds the optimal solution. If it is (γ, N)-weakly perturbation-resilient, $\mathcal{A}$ finds a solution in N.*

Proof. Consider an instance $\mathcal{I}$. Denote its optimal solution by s^*. Denote the certified solution found by $\mathcal{A}$ by $(\mathcal{I}', s')$. For each $c \in \mathcal{C}$, let w_c and w'_c be its weights in $\mathcal{I}$ and $\mathcal{I}'$, respectively.

I. First, we prove that the algorithm always gives a γ-approximation for both objectives. Consider the maximization objective. We have,

$$\operatorname{val}_{\mathcal{I}}(s') = \sum_{c\in\mathcal{C}} w_c c(s') \geq \sum_{c\in\mathcal{C}} \frac{w'_c}{\gamma} c(s') = \frac{1}{\gamma} \sum_{c\in\mathcal{C}} w'_c c(s')$$
$$\overset{(\star)}{\geq} \frac{1}{\gamma} \sum_{c\in\mathcal{C}} w'_c c(s^*) \geq \frac{1}{\gamma} \sum_{c\in\mathcal{C}} w_c c(s^*) = \frac{\operatorname{val}_{\mathcal{I}}(s^*)}{\gamma}$$

where $(\star)$ holds since s' is an optimal solution for $\mathcal{I}'$. We conclude that s' is a γ-approximate solution for the maximization objective. Similarly, we analyze the minimization objective.

$$\sum_{c\in\mathcal{C}} w_c(1 - c(s')) \leq \sum_{c\in\mathcal{C}} w'_c(1 - c(s')) \leq \sum_{c\in\mathcal{C}} w'_c(1 - c(s^*)) \leq \gamma \sum_{c} w_c(1 - c(s^*)).$$

	problem $\mathcal{P}_{hard}$	problem $\mathcal{P}$
unperturbed instance	$\mathcal{I}$	$\mathcal{J}$
perturbed instance	$\mathcal{I}'$	$\mathcal{J}'$

Figure 1 Instances $\mathcal{I}$, $\mathcal{J}$, $\mathcal{I}'$, and $\mathcal{J}'$. If s is a feasible solution for $\mathcal{I}'$, $\mathrm{val}_{\mathcal{I}'}(s) = \mathrm{val}_{\mathcal{J}'}(s) - W_H$.

II. Now, assume that $\mathcal{I}$ is γ-perturbation-resilient. By the definition of perturbation resilience, $\mathcal{I}$ and $\mathcal{I}'$ have the same optimal solution. Thus, s^* is an optimal solution not only for $\mathcal{I}'$ but also for $\mathcal{I}$. Finally, assume that $\mathcal{I}$ is (γ, N)-weakly perturbation-resilient. Since $\mathcal{I}$ is (γ, N)-weakly perturbation-resilient and $\mathcal{I}'$ is a γ-perturbation of $\mathcal{I}$, we get form Definition 4 that either $s' \in N$ or s^* is better than s' w.r.t. to the $\mathcal{I}'$ objective. The latter is not possible, since s' is an optimal solution for $\mathcal{I}'$. We conclude that $s' \in N$. ◀

Consider an instance of an optimization problem. We may choose a subset of constraints $H \subset \mathcal{C}$ and require that all of them are satisfied. We call them *hard constraints* and the obtained instance an instance with hard constraints. Formally, given an instance $(\mathcal{S}, \mathcal{C}, w)$ and a subset of constraints H, we define the correspondent instance $(\mathcal{S}', \mathcal{C}', w)$ with hard constraints as follows: $\mathcal{S}' = \{a \in \mathcal{S} : c(s) = 1 \text{ for every } c \in H\}$; $\mathcal{C}' = \mathcal{C} \setminus H$; $w'(c) = w(c)$ for $c \in \mathcal{C}'$.

▶ **Theorem 11.** *Assume that $\gamma = \gamma_n$ is at most polynomial in n. If there is a pseudo-polynomial-time γ-certified algorithm for a problem $\mathcal{P}$, then there is also a pseudo-polynomial-time γ-certified algorithm for a variant $\mathcal{P}_{hard}$ of $\mathcal{P}$ with hard constraints.*

Proof. Consider an instance $\mathcal{I}$ of $\mathcal{P}_{hard}$. Let H be the set of hard constraints and S be the set of soft constraints. We transform $\mathcal{I}$ to an instance $\mathcal{J}$ of $\mathcal{P}$ by setting the weight of every hard constraint $c \in H$ to $(\gamma+1)W$ where $W = \sum_{c \in S} w_c$ is the total weight of the soft constraints (see Figure 1). Note that the parameter $\rho_{\mathcal{J}}$ for $\mathcal{J}$ (the ratio between the largest and smallest constraint weights in $\mathcal{J}$; see Definition 6) is polynomial in $\rho_{\mathcal{I}}$ and the input size:

$$\rho_{\mathcal{J}} = \frac{(\gamma+1)W}{\min_{c \in \mathcal{C}} w_c} \leq \frac{|S|(\gamma+1)\max_{c \in \mathcal{C}} w_c}{\min_{c \in \mathcal{C}} w_c} \leq |S|(\gamma+1)\rho_{\mathcal{I}}.$$

We run the algorithm for $\mathcal{P}$ on input $\mathcal{J}$ and get a certified solution $(\mathcal{J}', s^*)$. Let $W_H = \sum_{c \in H} w_c^{\mathcal{J}'}$, where $w_c^{\mathcal{J}'}$ is the weight of c in $w_c^{\mathcal{J}'}$. Every feasible solution s for $\mathcal{I}$ satisfies all the constraints in H and thus $\mathrm{val}_{\mathcal{J}'}(s) \geq W_H$. In particular, if $\mathcal{I}$ has a feasible solution s, then $\mathrm{val}_{\mathcal{J}'}(s^*) \geq \mathrm{val}_{\mathcal{J}'}(s) \geq W_H$. Conversely, every solution s for $\mathcal{J}'$ with $\mathrm{val}_{\mathcal{J}'}(s) \geq W_H$ satisfies all the hard constraints (since the total weight of the soft constraints is less than the weight of any hard constraint in $\mathcal{J}'$) and thus is a feasible solution for $\mathcal{I}$.

If $\mathrm{val}_{\mathcal{J}'}(s^*) < W_H$, we report that $\mathcal{I}$ has no feasible solution. Otherwise, s^* is a feasible solution for $\mathcal{I}$. We let $\mathcal{I}'$ be a perturbation of $\mathcal{I}$, in which all the soft constraints have the same weights as in $\mathcal{J}'$. Observe that for every feasible solution s of $\mathcal{I}'$, $\mathrm{val}_{\mathcal{I}'}(s) = \mathrm{val}_{\mathcal{J}'}(s) - W_H$. It follows that s^* is an optimal solution for $\mathcal{I}'$. We output $(\mathcal{I}', s^*)$. ◀

▶ **Corollary 12.** *Consider a problem $\mathcal{P}$ and its variant with hard constraints $\mathcal{P}_{hard}$. Let γ_n be at most polynomial in n (the instance size). If there is a pseudo-polynomial-time γ_n-certified algorithm for $\mathcal{P}$, then there are pseudo-polynomial-time γ_n-approximation algorithms for maximization and minimization variants of $\mathcal{P}_{hard}$.*

We prove an analog of Theorem 10 for k-medians and k-means in Appendix (its proof is very similar to that of Theorem 10).

▶ **Theorem 13.** *Consider a γ-certified algorithm $\mathcal{A}$ for k-medians or k-means. If $\mathcal{A}$ is for k-medians, then $\mathcal{A}$ is a γ-approximation algorithm; if $\mathcal{A}$ is for k-means, then $\mathcal{A}$ is a γ^2-approximation algorithm. If the instance is γ-perturbation-resilient, $\mathcal{A}$ finds the optimal solution. If it is (γ, N)-weakly perturbation-resilient, $\mathcal{A}$ finds a solution in N.*

4 Designing Certified Algorithms

4.1 Iterative Improvement Algorithms

We use an iterative approach to design certified algorithms: our certified algorithms start with an arbitrary solution and then iteratively improve it. The approach resembles that of local search, except that improvements will not necessarily be local. In this approach, the key component of a certified algorithm is a procedure for improving the current solution; namely, a procedure for solving the following task.

▶ **Task 14.** *Given an instance $\mathcal{I}$ and the current solution s,*
- *either find a new solution s', which is better than s (w.r.t. to the $\mathcal{I}$ objective), or*
- *find a γ certified solution $(\mathcal{I}', s)$.*

▷ Claim 15. Consider a combinatorial optimization or clustering problem. Let $\varepsilon = \varepsilon_n > 1/\operatorname{poly}(n)$. Assume the following.
1. There is a polynomial-time algorithm for Task 14 with $\gamma = \gamma_n$.
2. There is polynomial-time algorithm that finds a feasible solution.

Then there is a pseudo-polynomial-time $(1+\varepsilon_n)\gamma_n$-certified algorithm for the problem.

Proof. Let $p_{min} = \min_i p_i$ be the smallest parameter and $\varepsilon' = \varepsilon/2$. First, we apply a preprocessing step, where we round all parameters p_i to multiples of $q = \varepsilon' p_{min}$ as follows:

$$p'_i = (\lceil p_i/q \rceil + 1)q.$$

It is easy to see that $q \le p'_i - p_i \le 2q$. Thus, instance $\mathcal{I}'$ with parameters p'_i is a $(1+\varepsilon)$ perturbation of $\mathcal{I}$.

If the problem is k-medians (or for that matter another clustering problem), then parameters p_i are distances $d(u,v)$, satisfying triangle inequalities. Then the new distances $d'(u,v)$ also satisfy triangle inequalities:

$$d'(u,v) + d'(v,w) \ge (d(u,v)+q) + (d(v,w)+q) \ge d(u,w) + 2q \ge d'(u,w).$$

Now we proceed as follows. We find a feasible solution for $\mathcal{I}'$ and then iteratively improve it using the procedure for Task 14, until the procedure finds a γ-certified solution $(\mathcal{I}'', s)$ for $\mathcal{I}'$. Clearly, $\mathcal{I}''$ is a $(1+\varepsilon)\gamma$-perturbation of $\mathcal{I}$. Thus, $(\mathcal{I}'', s)$ is a $(1+\varepsilon)\gamma$-certified solution for $\mathcal{I}$.

It remains to prove that the algorithm runs in pseudo-polynomial time. To do so, we need to upper bound the number of iterations. Assume that the problem is a combinatorial optimization problem. Consider the maximization objective. Initially the value of the problem is non-negative. It increases by at least q in every iteration. When the program terminates, it is at most $\sum_{c\in\mathcal{C}} w'_c \le (\rho w_{\min} + 2q)|\mathcal{C}|$ (where ρ as in Definition 6). Thus the algorithm performs at most $\frac{(\rho w_{\min}+2q)|\mathcal{C}|}{q} \le 2(\rho/\varepsilon+1)|\mathcal{C}|$ iterations, which is polynomial in $|\mathcal{C}|$, ρ, and $1/\varepsilon$.

If the problem is k-medians, the cost of the initial clustering is at most $n \max_{u,v\in X} d'(u,v)$. It decreases by at least q in every iteration. The cost of the obtained clustering is non-negative. It is easy to see that the number of iterations is polynomial in n, ρ, and $1/\varepsilon$.

We conclude that the algorithm runs in pseudo-polynomial time. ◁

4.2 Designing Certified Algorithms for Combinatorial Optimization Problems

Consider a combinatorial optimization problem. We show that in order to solve Task 14, it suffices to solve the following task.

▶ **Task 16.** *Assume that we are given an instance $\mathcal{I} = (\mathcal{S}, \mathcal{C}, w)$, a partition of its constraints $\mathcal{C} = C_1 \cup C_2$, and a parameter $\gamma \geq 1$. We need to either*
- *find $s \in \mathcal{S}$ such that $\gamma \sum_{c \in C_1} w_c c(s) > \sum_{c \in C_2} w_c (1 - c(s))$, or*
- *report that for every $s \in \mathcal{S}$: $\sum_{c \in C_1} w_c c(s) \leq \sum_{c \in C_2} w_c (1 - c(s))$.*

(Note that the above options are not mutually exclusive.)

▶ **Theorem 17.** *Assume that (1) there is a polynomial-time procedure for Task 16 with $\gamma = \gamma_n$ and (2) there is a polynomial-time algorithm that finds some $s \in \mathcal{S}$. Then there exists a pseudo-polynomial-time $(\gamma_n + \varepsilon_n)$-certified algorithm for the problem (for every $\varepsilon_n > 1/\operatorname{poly}(n)$).*

Proof. By Claim 15, it suffices to design an algorithm for Task 14. Given a solution s, we will either find a better solution s' or return a certified solution $(\mathcal{I}', s)$. Let $C_1 = \{c \in \mathcal{C} : c(s) = 0\}$ and $C_2 = \{c \in \mathcal{C} : c(s) = 1\}$ be the sets of unsatisfied and satisfied constraints, respectively. Define weights w' as follows:

$$w'_c = \begin{cases} w_c, & \text{if } c \in C_1 \\ \gamma w_c, & \text{if } c \in C_2 \end{cases}$$

We run the procedure for Task 16 on instance $\mathcal{I}' = (\mathcal{S}, \mathcal{C}, w')$. Consider two cases. Assume first that the procedure returns a solution s' such that $\gamma \sum_{c \in C_1} w'_c c(s') > \sum_{c \in C_2} w'_c (1 - c(s'))$. We get that

$$\sum_{c \in C_1} w_c c(s') > \sum_{c \in C_2} w_c (1 - c(s'))$$

and thus

$$\operatorname{val}_{\mathcal{I}}(s') = \sum_{c \in C_1 \cup C_2} w_c c(s') > \sum_{c \in C_2} w_c = \operatorname{val}_{\mathcal{I}}(s).$$

In this case, we return s'. Assume now that the procedure reports that for every solution s':

$$\sum_{c \in C_1} w'_c c(s') \leq \sum_{c \in C_2} w'_c (1 - c(s'))$$

or, equivalently,

$$\operatorname{val}_{\mathcal{I}'}(s') = \sum_{c \in C_1 \cup C_2} w'_c c(s') \leq \sum_{c \in C_2} w'_c = \operatorname{val}_{\mathcal{I}'}(s).$$

Then s is an optimal solution for $\mathcal{I}'$. We return a γ-certified solution $(\mathcal{I}', s)$. ◀

4.3 Certified Algorithm via Convex Relaxations

We describe how to design certified algorithms for combinatorial optimization problems using convex relaxations. Consider a problem and a convex relaxation for it. We refer to problem solutions $s \in \mathcal{S}$ as *combinatorial* solutions and relaxation solutions x as *fractional* solutions;

we say that x is *integral* if it corresponds to a combinatorial solution $s \in \mathcal{S}$. We assume that in the relaxation we have a variable x_c for each constraint c so that $x_c = c(s)$ for every integral solution x and corresponding combinatorial solution s. The relaxations objective is to maximize $\mathrm{fval}(x) = \sum_{c\in\mathcal{C}} w_c x_c$ or (equivalently) minimize $\sum_{c\in\mathcal{C}} w_c(1-x_c)$.

Consider a *randomized* rounding scheme $\mathcal{R}$ that given a fractional solution x outputs a combinatorial solution $\mathcal{R}(x)$. Rounding schemes are widely used for designing approximation algorithms. When designing an algorithm for a *maximization* objective, one typically wants the rounding scheme to satisfy the following approximation condition.

- **Approximation Condition.** The probability that each constraint $c \in \mathcal{C}$ is satisfied by $\mathcal{R}(x)$ is at least x_c/α (the probability is over the random choices made by $\mathcal{R}$).

If $\mathcal{R}$ satisfies this condition, it gives an α approximation for the maximization objective (in expectation). On the other hand, when designing an algorithm for a *minimization* objective, one wants the rounding scheme to satisfy the co-approximation condition.

- **Co-approximation Condition.** The probability that each constraint $c \in \mathcal{C}$ is unsatisfied by $\mathcal{R}(x)$ is at most $\beta(1-x_c)$.

If $\mathcal{R}$ satisfies this condition, it gives a β approximation for the minimization objective (in expectation). Following [16, 3], we consider rounding schemes that simultaneously satisfy the approximation and co-approximation conditions.

▶ **Definition 18.** *We say that a rounding scheme $\mathcal{R}$ is an (α,β)-rounding if it simultaneously satisfies the approximation and co-approximation conditions with parameters α and β.*

We note that (α,β)-rounding schemes have been shown to be very useful for solving perturbation-resilient and weakly perturbation-resilient instances [16, 3]. In particular, if there is an (α,β)-rounding scheme, then the relaxation is integral for $(\alpha\beta)$-perturbation-resilient instances [16]. We now show that (α,β)-rounding schemes can be used for designing certified algorithms.

▶ **Theorem 19.** *Assume that there exists an (α,β)-rounding scheme $\mathcal{R}$. Additionally, assume that the support of $\mathcal{R}$ is of polynomial size and can be found in polynomial time.*

Then there exists a pseudo-polynomial-time certified $(\gamma+\varepsilon_n)$-approximation algorithm for the problem where $\gamma = \alpha\beta$ (for any $\varepsilon > 1/\operatorname{poly}(n)$). Further, the algorithm outputs a certified solution $(\mathcal{I}', s^*)$ such that s^* is an optimal solution not only for $\mathcal{I}'$ but also for the relaxation for $\mathcal{I}'$.

Proof. By Theorem 17, it suffices to design a polynomial-time procedure for solving Task 16. First, we solve the convex relaxation for the problem and obtain an optimal fractional solution $x = x^*$. If $\sum_{c\in C_1} w_c x_c \le \sum_{c\in C_2} w_c(1-x_c)$, then for every $s \in \mathcal{S}$

$$\sum_{c\in C_1} w_c c(s) + \sum_{c\in C_2} w_c c(s) \le \sum_{c\in C_1} w_c x_c + \sum_{c\in C_2} w_c x_c \le \sum_{c\in C_2} w_c(1-x_c) + \sum_{c\in C_2} w_c x_c = \sum_{c\in C_2} w_c. \quad (3)$$

So we report that $\sum_{c\in C_1} w_c c(s) \le \sum_{c\in C_2} w_c(1-c(s))$ for every s (option 2). Note that in this case, the certified algorithm from Theorem 17 returns a certified solution $(\mathcal{I}, s^*)$ of value $\mathrm{val}_{\mathcal{I}'}(s^*) = w(C_2) \equiv \sum_{c\in C_2} w_c$. Eq. (3) shows that the value of every fractional solution (let alone integral) is at most $w(C_2)$. Thus s^* is an optimal solution not only for $\mathcal{I}'$ but also for the relaxation for $\mathcal{I}'$.

Assume now that $\sum_{c\in C_1} w_c x_c > \sum_{c\in C_2} w_c(1-x_c)$. We apply rounding scheme $\mathcal{R}$ and obtain a solution $\mathcal{R}(x)$. From the approximation and co-approximation conditions, we get

$$\mathbf{E}\left[\gamma \sum_{c\in C_1} w_c c(\mathcal{R}(x)) - \sum_{c\in C_2} w_c(1-c(\mathcal{R}(x)))\right] \ge \frac{\gamma}{\alpha}\sum_{c\in C_1} w_c x_c - \beta \sum_{c\in C_2} w_c(1-x_c) > 0.$$

Here, we used that $\gamma = \alpha\beta$. Thus for some solution s in the support of $\mathcal{R}(x)$, we have $\gamma\sum_{c\in C_1} w_c c(s) > \sum_{c\in C_2} w_c(1-c(s))$. We find and return such a solution s. ◀

We note that it is sufficient to design a rounding procedure only for solutions that are close to integral solutions.

▶ **Definition 20.** *Let us say that a fractional solution x is δ-close to an integral if $x = (1-\delta)x^{int} + \delta x^{frac}$ for some integral solution x^{int} and fractional solution x^{frac}. Rounding scheme $\mathcal{R}$ is a δ-local (α, β)-rounding if it is defined and satisfies the approximation and co-approximation conditions for fractional solutions x that are δ-close to an integral solution.*

It turns out that it is sufficient to have a δ-local rounding scheme (for any $\delta > 0$) in Theorem 19. To see that, we slightly change the proof of Theorem 19. We first find an optimal fractional solution x^* and then apply the rest of the argument to solution $x = \delta x^* + (1-\delta)x^s$ (where x^s is the fractional solution corresponding to s).

Finally, we note that if the support of $\mathcal{R}$ is not of a polynomial size, we can get a *randomized* certified algorithm. To do so, instead of trying out all solutions s in the support of $\mathcal{R}(x)$, we apply $\mathcal{R}$ to x sufficiently many times and let s be the best of the obtained solutions (if we use a δ-local rounding scheme, we need that $\delta > 1/\operatorname{poly}(n)$).

5 Examples of Certified Algorithms for Optimization Problems

▶ **Theorem 21.**

I. *There exists a pseudo-polynomial-time $(1+\varepsilon_n)\alpha_n$-certified algorithm for Min Uncut and Max Cut (these problems are complementary), where $\alpha_n = O(\sqrt{\log n}\log\log n)$ is the approximation factor for Sparsest Cut with Non-uniform Demands from [4] and $\varepsilon_n > 1/\operatorname{poly}(n)$.*

II. *There exists a pseudo-polynomial-time $(2 - 2/k + \varepsilon_n)$-certified algorithm for Minimum Multiway Cut.*

Proof.

I. We show how to solve Task 16 in polynomial time. Recall that in our formulation of Min Uncut, $c_e((S,\bar{S})) = 1$ if edge e is cut. Let $E_1 = \{e \in E : c_e \in C_1\}$ and $E_2 = \{e \in E : c_e \in C_2\}$; denote the weight of the edges in E_i cut by $(S,\bar{S})$ by $w(E_i(S,\bar{S}))$. Let $\phi(S) = \frac{w(E_2(S,\bar{S}))}{w(E_1(S,\bar{S}))}$. Then our goal is to either find a cut $(S,\bar{S})$ such that $\phi(S) < \gamma$ or report that $\phi(S) \geq 1$ for every $(S,\bar{S})$. Now the problem of minimizing $\phi(S)$ over all cuts $(S,\bar{S})$ is the same as finding the sparsest cut with non-uniform demands in graph (V, E_2) with edge capacities w, demand pairs E_1, and demand weights w. We run the approximation algorithm for Sparsest Cut and get a cut $(S,\bar{S})$ that approximately – within a factor of γ – minimizes $\phi(S)$. If $\phi(S) < \gamma$, we report cut $(S,\bar{S})$; otherwise, we report that $\phi(S') \geq 1$ for every cut $(S',\bar{S}')$.

II. Consider the LP relaxation for Minimum Multiway Cut by Călinescu, Karloff, and Rabani. It is shown in [3] that there exists a δ-local (α,β)-rounding procedure for it with $\alpha\beta = 2 - 2/k$. It follows from Theorem 19, that there is a $(2 - 2/k + \varepsilon_n)$-certified algorithm. ◀

6 $(3+\varepsilon)$-Certified Local Search Algorithm for k-medians

In this section, we consider k-medians. We show that a local search algorithm is $(3+\varepsilon)$-certified. We note that our analysis is very similar to that in [11, 8].

We first apply the preprocessing step form Theorem 17 (where we round all distances to multiples of some q). Then, we consider an arbitrary set of centers $c_1, \ldots, c_k$ and the corresponding clustering $C_1, \ldots, C_k$. Then, at each iteration, we go over all possible swaps

of size r: we swap r centers among $c_1, \dots, c_k$ with r points outside of $c_1, \dots, c_k$. We choose a swap that decreases the cost of the clustering, if there is one, and recompute $C_1, \dots, C_k$. If there is no such swap, we terminate and output a certified solution $((X, d'), (C_1, \dots, C_k))$, where $d'(u, v) = \frac{1}{\gamma} d(u, v)$ if $u = c_i$ and $v \in C_i$ for some i (or the other way around), and $d'(u, v) = d(u, v)$, otherwise.

▶ **Theorem 22.** *The ρ-local search algorithm for k-medians (described above) is a pseudo-polynomial-time $(3 + O(1/\rho))$-certified algorithm.*

Proof. We use Theorem 14. It guarantees that the algorithm runs in pseudo-polynomial time. We need to show that when the algorithm terminates it indeed outputs a certified solution. Suppose that the algorithm outputs a clustering with centers $L = \{l_1, \dots, l_k\}$.

Consider an arbitrary set of centers $S = \{s_1, \dots, s_k\}$. We need to show that the cost of the k-median clustering with centers in L is at most the cost of the k-median clustering with centers in S with respect to the perturbed distance function d'. Let $l(u)$ and $s(u)$ be the closest centers to point u in L and S respectively with respect to d; and let $l'(u)$ and $s'(u)$ be the closest centers to point u in L and S respectively with respect to d'. Our goal is to prove that

$$\sum_{u \in X} d'(u, l'(u)) \le \sum_{u \in X} d'(u, s'(u)). \tag{4}$$

Observe that for every point $u \in X$, we have $d(u, v) = d'(u, v)$ for all v but $v = l(u)$. Thus, $l'(u) = l(u)$ and $d'(u, l'(u)) = d(u, l(u))/\gamma$. Consequently, the left hand side of (4) equals $\sum_{u \in X} d(u, l(u))/\gamma$. Similarly, $s'(u) = s(u)$ and $d'(u, s'(u)) = d(u, s(u))$ if $l(u) \notin S$. However, if $l(u) \in S$, then $d'(u, s'(u)) = \min\big(d(u, s(u)), d(u, l(u))/\gamma\big)$ as, in this case, the optimal center for u in S w.r.t. d' can be $l(u)$.

Let us split all vertices in X into two groups $A = \{u : l(u) \in S\}$ and $B = \{u : l(u) \notin S\}$. Then, for $u \in A$, we have $d'(u, s'(u)) = \min\big(d(u, s(u)), d(u, l(u))/\gamma\big)$; and for for $u \in B$, we have $d'(u, s'(u)) = d(u, s(u))$. Thus, inequality (4) is equivalent to

$$\sum_{u \in X} \frac{d(u, l(u))}{\gamma} \le \sum_{u \in A} \min\left(d(u, s(u)), \frac{d(u, l(u))}{\gamma}\right) + \sum_{u \in B} d(u, s(u)),$$

which after multiplying both parts by γ can be written as

$$\sum_{u \in X} d(u, l(u)) \le \sum_{u \in A} \min\Big(\gamma d(u, s(u)), d(u, l(u))\Big) + \sum_{u \in B} \gamma d(u, s(u)). \tag{5}$$

For $u \in A$, we have $d(u, s(u)) \le d(u, l(u))$ since both $s(u)$ and $l(u)$ are in S and $s(u) = \arg\min_{v \in S} d(u, v)$. Thus, $\min\big(\gamma d(u, s(u)), d(u, l(u))\big) \ge d(u, s(u))$. Consequently, inequality (5) follows from the following theorem from [11] (see also [5] and [13]).

▶ **Theorem 23** (Local Approximation; [11])**.** *Let L be a r-locally optimal set of centers with respect to a metric d and S be an arbitrary set of k centers. Define sets A and B as above. Then,*

$$\sum_{u \in X} d(u, l(u)) \le \sum_{u \in A} d(u, s(u)) + \gamma \sum_{u \in B} d(u, s(u)),$$

for some $\gamma = 3 + O(1/r)$. ◀

7 Euclidean k-means and k-medians

We note that the algorithm for $(1+\varepsilon)$-perturbation-resilient instances of Euclidean k-means and k-medians (in a fixed dimensional space) by Friggstad, Khodamoradi, and Salavatipour [12] is $(1+\varepsilon)$-certified. The algorithm finds a solution $\mathcal{S}$ and perturbed metric δ' on $X \cup \mathcal{S}$ such that (see Lemma 2.2 in [12])

$$\text{cost}'(\mathcal{S}) \leq \text{cost}'(\mathcal{O}),$$

where cost$'$ is the cost of the clustering w.r.t the perturbed metric δ'. In [12], $\mathcal{O}$ is the optimal solution for the non-perturbed instance; however, the proof does not use that $\mathcal{O}$ is an optimal solution and goes through if $\mathcal{O}$ is an arbitrary solution. Thus, Friggstad, Khodamoradi, and Salavatipour proved that their algorithm finds a solution $\mathcal{S}$ (specified by the list of centers), which is optimal w.r.t. the perturbed distances δ'. We get the following theorem.

▶ **Theorem 24.** *For every fixed $\varepsilon > 0$ and $d \geq 1$, there exist $(1+\varepsilon)$-certified algorithms for Euclidean instances of k-means and k-medians in $\mathbb{R}^d$ (namely, the local search algorithms from [12]). The algorithms run in time polynomial in the bit complexity of the input.*

8 Negative Results

In this section, we present several negative results for certified algorithms. They immediately follow from the properties of certified algorithm we saw in Section 3. We note that similar negative results were shown in [3] for robust algorithms for perturbation-resilient instances.

▶ **Theorem 25.** *There are no pseudo-polynomial-time $O(n^{1-\delta})$-certified algorithms for Minimum Vertex Cover, Set Cover, and Min 2-Horn Deletion if $\mathcal{P} \neq \mathcal{NP}$ (for every fixed $\delta > 0$).*

Proof. Let $\gamma = cn^{1-\delta}$ be the hardness of Maximum Independent Set (MIS) [19].

I. According o Theorem 10, if there were a pseudo-polynomial-time or polynomial-time γ-certified algorithm for Vertex Cover, then there would be a polynomial-time γ-approximation algorithm for Maximum Independent Set (the problem complementary to Minimum Vertex Cover).

II. Since each Vertex Cover instance is also a Set Cover instance, a certified algorithm for Set Cover would also be a certified algorithm for Vertex Cover.

III. Observe that Max 2-Horn SAT with hard constraints is more difficult than MIS. An instance (G, V, E) of MIS is equivalent to the following instance of Max 2-Horn SAT with hard constraints: there is a variable x_u for every $u \in V$, a hard constraint $x_u \vee x_v$ for every $(u, v) \in E$, and a soft constraint x_u. By Corollary 12, since there is no γ-approximation for MIS, there is no polynomial-time algorithm for γ-perturbation-resilient instances of Min 2-Horn Deletion. ◀

A Proof of Theorem 13

Proof.

I. Denote the certified solution returned by the algorithm by $((X, d'), (C_1, \dots, C_k))$. Let $C_1^*, \dots, C_k^*$ be an optimal clustering. Let c_i and c_i^* be optimal centers of C_i and C_i^* (respectively). Consider the case of k-medians first. We upper bound the cost of $(C_1, \dots, C_k)$ w.r.t d as follows:

$$\sum_{i=1}^{k}\sum_{u\in C_i} d(u,c_i) \le \gamma\sum_{i=1}^{k}\sum_{u\in C_i} d'(u,c_i) \le \gamma\sum_{i=1}^{k}\sum_{u\in C_i^*} d'(u,c_i^*) \le \gamma\sum_{i=1}^{k}\sum_{u\in C_i^*} d(u,c_i^*).$$

Now, consider the case of k-means.

$$\sum_{i=1}^{k}\sum_{u\in C_i} d(u,c_i)^2 \le \sum_{i=1}^{k}\sum_{u\in C_i} (\gamma d'(u,c_i))^2 \le \gamma^2\sum_{i=1}^{k}\sum_{u\in C_i^*} d'(u,c_i^*) \le \gamma^2\sum_{i=1}^{k}\sum_{u\in C_i^*} d(u,c_i^*).$$

II. The proof is identical to that of Theorem 10. ◀

Low Diameter Graph Decompositions by Approximate Distance Computation

Abstract

In many models for large-scale computation, decomposition of the problem is key to efficient algorithms. For distance-related graph problems, it is often crucial that such a decomposition results in clusters of small diameter, while the probability that an edge is cut by the decomposition scales linearly with the length of the edge. There is a large body of literature on low diameter graph decomposition with small edge cutting probabilities, with all existing techniques heavily building on *single source shortest paths (SSSP)* computations. Unfortunately, in many theoretical models for large-scale computations, the SSSP task constitutes a complexity bottleneck. Therefore, it is desirable to replace exact SSSP computations with approximate ones. However this imposes a fundamental challenge since the existing constructions of low diameter graph decomposition with small edge cutting probabilities inherently rely on the subtractive form of the triangle inequality, which fails to hold under distance approximation.

The current paper overcomes this obstacle by developing a technique termed *blurry ball growing*. By combining this technique with a clever algorithmic idea of Miller et al. (SPAA 2013), we obtain a construction of low diameter decompositions with small edge cutting probabilities which replaces exact SSSP computations by (a small number of) approximate ones. The utility of our approach is showcased by deriving efficient algorithms that work in the CONGEST, PRAM, and semi-streaming models of computation. As an application, we obtain metric tree embedding algorithms in the vein of Bartal (FOCS 1996) whose computational complexities in these models are optimal up to polylogarithmic factors. Our embeddings have the additional useful property that the tree can be mapped back to the original graph such that each edge is "used" only logaritmically many times, which is of interest for capacitated problems and simulating CONGEST algorithms on the tree into which the graph is embedded.

1 Introduction

Consider an n-vertex graph $G = (V, E, \ell)$, where $\ell : E \to \mathbb{Z}_{>0}$ is an edge *length* function.[1] The *distance* between two vertices u and v in G, denoted by $\mathrm{d}_G(u, v)$, is defined to be the length with respect to ℓ of a shortest (u, v)-path in G. The *diameter* of G is the maximum distance between any two vertices, denoted by $\mathrm{diam}(G) = \max_{u,v \in V}\{\mathrm{d}_G(u, v)\}$.

A *decomposition* D of G is a partition of the vertex set V into pairwise disjoint *clusters*. Such a decomposition induces a (multiway) *cut* on G and we use $E^{\mathrm{cut}}(D)$ to denote the subset of edges that cross this cut, namely, edges whose endpoints belong to different clusters of D. The *weight* of the decomposition D is defined to be the sum $\sum_{e \in E^{\mathrm{cut}}(D)} \frac{1}{\ell_e}$ of the reciprocal lengths of the edges crossing its cut. Our focus in this paper is on the construction of decompositions whose clusters' diameter is bounded by some specified parameter r (the notion of a cluster's diameter will be made clear soon), referred to hereafter as *low diameter decompositions*. The challenging part is to keep the weight of D small.

Low diameter decompositions with small weight were first studied by Awerbuch [5] (see also [6, 4]). Bartal [7] introduced their (combinatorially equivalent) probabilistic counterpart: An (r, λ)-*decomposition* of the graph $G = (V, E, \ell)$ is a random decomposition D of G such that (1) the diameter of each cluster in D is at most r; and (2) $\Pr[e \in E^{\mathrm{cut}}(D)] \leq \frac{\lambda \ell_e}{r}$ for every edge $e \in E$. Bartal presented a method that, for a given parameter r, constructs an $(r, O(\log n))$-decomposition and proved the resulting bound on the edge cutting probabilities to be asymptotically tight.

Low diameter decompositions with small edge cutting probabilities have proven to be very useful in the algorithmic arena (see Section 7) and several different techniques have been developed over the years for constructing them [3, 7, 18, 22, 43, 24]. A common thread of all the existing techniques is that they rely heavily on making calls to a single source shortest paths (SSSP) subroutine. While we know how to solve the SSSP problem efficiently in the sequential (centralized) model of computation, the situation is much more challenging in restricted models of computation such as the CONGEST model of distributed computing, the parallel random access memory (PRAM) model, or the semi-streaming graph algorithms model. As it stands, SSSP computations are the main obstruction to designing efficient constructions of low diameter decompositions with small edge cutting probabilities in the aforementioned computational models (and related ones).

1.1 Our Contribution

In this paper, we introduce a new technique that, given a graph $G = (V, E, \ell)$ and a parameter r, constructs an $(r, O(\log n))$-decomposition of G. The crux of our construction is that it does not rely on any *exact* SSSP computations. Rather, it efficiently reduces the task to a small number of calls to an approximate SSSP subroutine. The technical challenge in this regard stems from the fact that the existing constructions of low diameter decompositions with small edge cutting probabilities crucially rely on the subtractive form of the triangle inequality, stating that $\mathrm{d}_G(u, v) \geq \mathrm{d}_G(u, w) - \mathrm{d}_G(v, w)$ for every three vertices $u, v, w \in V$. Due to the subtraction on the right hand side, the inequality fails if one replaces exact distances with approximate ones. The main technical contribution of this paper lies in overcoming this difficulty.

[1] We sometimes use the shorthand ℓ_e for $\ell(e)$.

The approximate SSSP problem can be solved efficiently in the CONGEST [12], PRAM [14], and semi-streaming [12] models, hence we obtain efficient algorithms for constructing $(r, O(\log n))$-decompositions for the three computation models. These in turn can be invoked recursively to yield efficient CONGEST, PRAM, and semi-streaming constructions of path embeddable trees [16, 15] and hierarchically well-separated trees [7, 8, 9, 22] with low *stretch* – important combinatorial objects in their own right. In fact, our low diameter decompositions (and the resulting tree embeddings) admit an even stronger property.

Tree-Supported Decompositions

The notion of graph diameter naturally extends from the entire graph $G = (V, E, \ell)$ to a vertex subset $U \subseteq V$ by considering the maximum distance between any two vertices in U. This yields the following distinction: the *weak diameter* of U in G considers the distances in the underlying graph G, formally defined as $\max_{u,v\in U}\{\mathrm{d}_G(u, v)\}$; the *strong diameter* of U in G considers the distances in the subgraph $G(U)$ induced by G on U, formally defined as $\mathrm{diam}(G(U))$.[2] In the context of low diameter graph decompositions with small edge cutting probabilities, both the weak and strong notions of the cluster diameter have been considered in the literature. As we now explain, the current paper adopts a diameter notion that falls somewhere in between the two.

For a decomposition D of the graph $G = (V, E, \ell)$, we require that each cluster $C \in D$ is associated with a tree $T_C = (U_C, F_C)$, referred to as the *supporting tree* of C, that is a subgraph of G and spans C, i.e., $C \subseteq U_C \subseteq V$ and $F_C \subseteq E$. To emphasize this requirement, we refer to the decomposition D as a *tree-supported decomposition (TSD)*. The *diameter* of a TSD D of G is then defined to be the maximum diameter of any of its supporting trees, denoted by $\mathrm{diam}(D) = \max_{C\in D}\{\mathrm{diam}(T_C)\}$.

Notice that if the supporting tree T_C of each cluster $C \in D$ is required to be a spanning tree of $G(C)$, then $\mathrm{diam}(D)$ bounds the strong diameter of D's clusters. This requirement is not imposed in the current paper, allowing T_C to use edges (and vertices) outside of $G(C)$, meaning that $\mathrm{diam}(D)$ merely bounds the weak diameter of the clusters. However, we do require that the maximum edge *load* is kept small, where the load of edge $e \in E$ in D is defined to be the number of clusters $C \in D$ such that e is included in the supporting tree of C, denoted by $\mathrm{load}_D(e) = |\{C \in D : e \in F_C\}|$. The properties of our graph decomposition construction can now be formally stated.

▶ **Theorem 1.** *There exists a (randomized) algorithm that given a graph $G = (V, E, \ell)$ and a real parameter $r > 0$, constructs a random TSD D of G with the following guarantees: (1)* $\mathrm{diam}(D) \leq r$ *w.h.p.;*[3] *(2)* $\max_{e\in E}\{\mathrm{load}_D(e)\} \leq O(\log n)$ *w.h.p.; and (3)* $\Pr\left[e \in E^{\mathrm{cut}}(D)\right] \leq O\left(\frac{\ell_e \cdot \log n}{r}\right)$ *for every edge $e \in E$. The algorithm is based on an approximate SSSP subroutine without any exact SSSP computations.*

The algorithm promised in Theorem 1 is designed by combining a novel technique termed *blurry ball growing* with the algorithmic ideas of Miller et al. [43]. As discussed earlier, this combination allows us to bypass the need for exact SSSP computations, implementing our algorithm based solely on approximate SSSP. By example of the CONGEST, PRAM, and semi-streaming models, we show that this leads to efficient implementations. We stress that

[2] Unless stated otherwise, the edge length function of a subgraph H of G is the restriction of ℓ to H's edge set.

[3] We say that event A occurs *with high probability*, abbreviated *w.h.p.*, if $\Pr[A] \geq 1 - n^{-c}$, where c is an arbitrarily large constant chosen upfront.

what little computation is performed beyond approximate SSSP computations is very easy, if not trivial, to implement. Accordingly, we expect the technique to carry over to further computational models.

We emphasize that our decomposition maintains a small load of $O(\log n)$ on the edges. Consequently, in many situations, our decomposition can be used in an identical way as a strong diameter decomposition with only polylogarithmic overheads. For example, although we cannot construct low average stretch spanning trees as these are required to be subgraphs of the original graph, we can construct *projected trees* (see Section 5.2), a special case of path-embeddable trees [15, 16]. Projected trees have a mapping of their edges to the original graph such that, e.g., a CONGEST algorithm on the projected tree can be simulated on the original graph with a round complexity overhead proportional to the maximum edge load. Our result is related to the low-congestion shortcuts of Ghaffari and Haeupler [28] with the following differences. In Ghaffari and Haeupler's work, the partition is chosen by an adversary and the input is restricted to unweighted graphs. In contrast, our technique constructs the partition, but weighted graphs can be treated as well. A further possible application of our projected trees is in the field of solvers for symmetric diagonally dominant linear systems, utilizing them in a similar way as low average stretch spanning trees (cf. [16, 15]). Prior algorithms for metric tree embeddings lack this property and, accordingly, cannot take this role.

1.2 Structure of this Paper

We first fix some notation and state basic facts in the preliminaries in Section 2. In Section 3, we present the blurry ball growing technique that we use in Section 4 in order to obtain the routine for computing a random TSD of low diameter, load, and edge cutting probability, as promised in Theorem 1. In Section 5, we highlight some applications of this routine: We first explain how to obtain a hierarchical decompositions by applying the method recursively (Section 5.1) and then show how to obtain random projected trees (Section 5.2) and hierarchically well-separated trees (Section 5.3) with $O(\log^2 n)$ bound on the expected stretch. We also show that this bound can be improved to $O(\log n)$ by considering the relaxed notion of p-stretch [15, 16] (Section 5.4). In Section 6, we explain how to implement our algorithms in the CONGEST, PRAM, and semi-streaming models. Further related work is reviewed in Section 7.

2 Preliminaries

We start with basic notation. We consider a weighted, undirected, connected n-vertex graph $G = (V, E, \ell)$, where $\ell : E \to \mathbb{Z}_{\geq 0}$ is an edge length function. Notice that while some of our subroutines introduce edges $e \in E$ with zero length $\ell_e = 0$, it is assumed that all edges in the original graph input to the $(r, O(\log n))$-decomposition algorithm (as well as the algorithms built on top of it) admit positive lengths. We denote the set of positive length edges by $E_{>0} = \{e \in E \mid \ell_e > 0\}$ and let $\ell_{\min} = \min\{\ell_e \mid e \in E_{>0}\}$ and $\ell_{\max} = \max\{\ell_e \mid e \in E_{>0}\}$. The ratio of $\ell_{\max}$ to $\ell_{\min}$, denoted by $\sigma = \frac{\ell_{\max}}{\ell_{\min}}$ is referred to as the *aspect ratio* of G.

For a subgraph H of G, we denote by $\mathrm{d}_H(u, v)$ the length of the shortest path between two nodes u and v in H. If $H = G$, we may omit the subscript. For a set $B \subseteq V$ and a node $v \in V$, we use $\mathrm{d}(B, v) := \min_{u \in B}\{\mathrm{d}(u, v)\}$ to denote the distance of the node v to the set B. For a set of vertices $U \subseteq V$, we denote by $E^{\mathrm{cut}}(U) := \{e = \{u, v\} \in E \colon u \in U, v \in V \setminus U\}$ the set of edges that are "cut" by U.

Approximate Single Source Shortest Paths

The main subroutine we use in our algorithm computes $(1+\varepsilon)$-*approximate* SSSP in undirected graphs. A $(1+\varepsilon)$-*approximate SSSP algorithm* is an algorithm that takes as input a weighted undirected graph $G = (V, E, \ell)$ and a source node $s \in V$ and returns a spanning tree T of G such that, for every node $v \in V$, the length of the path from s to v in T is at most $(1+\varepsilon) \cdot \mathrm{d}(s, v)$, i.e., $\mathrm{d}(s, v) \leq \mathrm{d}_T(s, v) \leq (1+\varepsilon) \cdot \mathrm{d}(s, v)$.

Super-Source Graphs

Our approach requires $(1+\varepsilon)$-approximate SSSP computations in graphs G_s that result from subgraphs of G by adding a (virtual) *super-source node* $s \notin V$:

▶ **Definition 2** (Super-source graphs). *Fix a subgraph $H = (V_H, E_H, \ell|_H)$ of G. Construct $G_s = (V_H \dot\cup \{s\}, E_H \cup E_s, \ell^{G_s})$ by choosing $E_s \subseteq V_H \times \{s\}$, picking $\ell_e^{G_s} \in \{1, \ldots, n^c\}$ for $e \in E_s$, and setting $\ell_e^{G_s} = \ell_e$ for all $e \in E_H$. We refer to G_s as a* super-source graph *(of G) and to s as its* super-source.

We note that one way of obtaining a super-source graph of a graph G is to contract a subset of nodes, say B, into a super-source s. In this case $V_H = V \setminus B$ and the edges E_s and their lengths result from the contraction of B into s.

Exponential Distribution

We denote the exponential distribution with mean $\frac{1}{\beta}$ by Exp_β. Using the Heaviside step function that is defined as $H(x) = 0$ if $x < 0$ and $H(x) = 1$ otherwise, the density function of the exponential distribution is given by $f_{\mathrm{Exp}_\beta}(x) = \beta \exp(-\beta x) \cdot H(x)$. Its cumulative density function is $F_{\mathrm{Exp}_\beta}(x) = (1 - \exp(-\beta x)) \cdot H(x)$. A standard result is that drawing from this distribution results in values of $O(\beta \log n)$ w.h.p.:

▶ **Lemma 3.** *For parameters $0 < \varepsilon < 1$, $\beta > 0$, and a sufficiently large constant $c > 0$, let $t := \frac{c \log n}{4(1+\varepsilon)\beta}$ and $X \sim \mathrm{Exp}_\beta$. Then $P[X \geq t] = n^{-\Omega(c)}$, i.e., $X < t$ w.h.p.*

Proof. Using the form of the density function, we get

$$P[X \geq t] = \frac{\int_t^\infty \exp(-\beta x)\, dx}{\int_0^\infty \exp(-\beta x)\, dx} = \frac{\exp(-\beta t) \int_0^\infty \exp(-\beta x)\, dx}{\int_0^\infty \exp(-\beta x)\, dx} = \exp(-\Omega(c \log n)) = n^{-\Omega(c)}. \blacktriangleleft$$

We will make heavy use of the following lemma, see the paper by Miller et al. [43] for the proof. Note that in their paper they state the lemma with an upper bound of $O(\beta c)$ on the probability, although their proof in fact bounds the probability by exactly βc.

▶ **Lemma 4** (Lemma 4.4 in [43]). *Let $d_1 \leq \ldots \leq d_s$ be arbitrary values and $\delta_1, \ldots, \delta_s$ be independent random variables picked from Exp_β. Then the probability that the smallest and the second smallest values of $d_i - \delta_i$ are within c of each other is at most βc.*

Miller et al. [43] used this lemma to analyze the following ball growing technique that proceeds in time steps. Every node u in the graph grows a ball B_u independently and in parallel, but with a delay of δ_u time steps, where $\delta_u \sim \mathrm{Exp}_\beta$. Every ball increases its radius by 1 in each time step and we say that the ball B_v "arrives" at node u, if node v minimizes $\mathrm{d}(u, v) - \delta_v$ over all nodes. In this case u "gets absorbed" by v's ball B_v. The process stops when every node u is absorbed by some ball. Notice that u gets absorbed by its own ball B_u, if and only if no other ball arrives at u during the first δ_u time steps.

Now consider an arbitrary edge e in the graph and imagine it to be split into two equal length edges by a node v_e. If we let $d_1 \leq \ldots \leq d_n$ denote the n values $\mathrm{d}(u, v_e) - \delta_u$ for every $u \in V$, the above lemma shows that the arrival times of the first and second ball at node v_e differ by at least $2\ell_e$ with probability $1 - O(\beta\ell_e) = 1 - O(\frac{\ell_e \log n}{\varepsilon r})$, when choosing $\beta = \Theta(\frac{\log n}{\varepsilon r})$. Hence the lemma allows for bounding the probability of an edge being cut by such ball growing process with exponentially distributed delays.

We remark that the implementations in Section 6 draw from discrete distributions. Rounding continuous distributions to multiples of n^{-c} for sufficiently large $c \in O(1)$ yields w.h.p. the same results, but limits the number of random bits required to draw and store a random value to $O(\log n)$.

3 Blurry Ball Growing

In this section, we describe a subroutine called `blur` that takes as input a graph $G = (V, E, \ell)$ with aspect ratio $\sigma = \frac{\ell_{\max}}{\ell_{\min}} \leq \mathrm{poly}(n)$, a node set $B \subseteq V$, and a real $0 < \rho < \ell_{\max}$, and outputs a superset U of B. It guarantees that nodes in U are not too far from B, yet the probability to cut edges is small. More precisely, we establish the following theorem.

▶ **Theorem 5.** *Let $n \geq 2$. There is a routine $\texttt{blur}(G, \rho, B)$ that outputs a superset U of B such that:*

1. *For every edge $e \in E$, the probability that $e \in E^{\mathrm{cut}}(U)$ is bounded by $O(\frac{\ell_e}{\rho})$.*
2. *For every $v \in U$, it holds that $\mathrm{d}(B, v) \leq \frac{\rho}{1-\alpha}$, where $\alpha = \frac{1}{2 \log n}$.*

The routine `blur`, see Algorithm 1, is based on $(1+\varepsilon)$-approximate SSSP computations and contractions of node sets and thus can be readily parallelized. The basic idea is to grow a ball of uniformly random radius around B, where contraction of B yields the super-source of the SSSP computation. However, as approximating distances may imply that the "noise" due to the relative ε-error may cut a short edge with a comparatively large probability, the procedure is repeated with random radii drawn from uniform distributions with width that decrease by factor $\alpha = \frac{1}{2 \log n}$ in each step. To make this work, the approximation error of the SSSP algorithm must satisfy $\varepsilon \leq \alpha^2$. Accordingly, it would be desirable to chose α large for the sake of small computational costs in the approximate SSSP routine. However, it turns out that, in order to achieve Property 1 in Theorem 5, we have to set α such that $\alpha = O\big(\frac{\log \log n}{\log n}\big)$. In addition, the approximate SSSP computations must respect the 0-length edges in the sense that none of the balls we grow cuts these edges. This is ensured by updating the approximate distances so that all nodes in the same connected component of the graph induced by the 0-length edges hold the same value.

Analysis

We begin with two important properties of the distance approximations $\widetilde{\mathrm{d}}^i(\cdot)$ computed in line 9.

▶ **Lemma 6.** *For every iteration i and vertex v in $G^{[i]}$, the distance approximation $\widetilde{\mathrm{d}}^i(v)$ satisfies (I) $\mathrm{d}_{G^{[i]}}(s^{[i]}, v) \leq \widetilde{\mathrm{d}}^i(v) \leq (1+\alpha^2)\,\mathrm{d}_{G^{[i]}}(s^{[i]}, v)$; and (II) if $\{u, v\}$ is a 0-length edge in $G^{[i]}$, then $\widetilde{\mathrm{d}}^i(u) = \widetilde{\mathrm{d}}^i(v)$.*

Proof. Property (II) follows immediately from the definition of $\widetilde{\mathrm{d}}^i(v)$ (see line 9). To see that property (I) holds, notice that $\widetilde{\mathrm{d}}^i(v)$ captures the distance from $s^{[i]}$ to v in the subgraph of $G^{[i]}$ induced by the union of the edge set of $T^{[i]}$ and the 0-length edges. The assertion follows since $T^{[i]}$ is a $(1+\alpha^2)$-approximate SSSP tree of $G^{[i]}$. ◀

Algorithm 1 `blur`(G, ρ, B).

Input : graph $G = (V, E, \ell)$, real $0 < \rho < \ell_{\max}$, set $B \subset V$
Output : set $U \subseteq V$

1 $i := 0$, $B^{[0]} := B$, $\alpha := \frac{1}{2 \log n}$
2 **while** $\alpha^i \rho \geq \ell_{\min}$ **do**
3 $i := i + 1$, $r^{[i]} \in \mathcal{U}[0, \alpha^{i-1}\rho]$.
4 Obtain super-source graph $G^{[i]}$ from G by contracting $B^{[i-1]}$ into a super-source node $s^{[i]}$
5 Compute $(1 + \alpha^2)$-approximate SSSP tree $T^{[i]}$ of $G^{[i]}$
6 Let $G_0^{[i]}$ be the restriction of the graph $G^{[i]}$ to its 0-length edges
7 **for** *each* $v \in G^{[i]}$ **do**
8 Let $W(v)$ be the connected component of v in $G_0^{[i]}$
9 $\widetilde{\mathrm{d}}^{[i]}(v) := \min\{\mathrm{d}_{T^{[i]}}(s^{[i]}, u) \mid u \in W(v)\}$
10 $B^{[i]} := B^{[i-1]} \cup \{v \in G^{[i]} \mid \widetilde{\mathrm{d}}^{[i]}(v) \leq r^{[i]}\} \setminus \{s^{[i]}\}$
11 **return** $\bigcup_{j=0}^{i} B^{[i]}$

Next, we establish Property 2 of Theorem 5, which readily follows from the manner in which we sample $r^{[i]}$ from $\mathcal{U}[0, \alpha^{i-1}\rho]$.

▶ **Lemma 7.** *If* $\mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, u) = \mathrm{d}(B^{[i]}, u) \geq \frac{\alpha^i \rho}{1-\alpha}$ *for some* i*, then* $u \notin U$*. In particular, it holds that* $\mathrm{d}_G(B, v) \leq \frac{\rho}{1-\alpha}$ *for every* $v \in U$*.*

Proof. Any $u \in B^{[k]}$ for $k > i$ has distance to $B^{[i]}$ at most $\sum_{j \geq i+1} r^{[j]} \leq \sum_{j \geq i+1} \alpha^{j-1}\rho < \alpha^i \rho \sum_{j=0}^{\infty} \alpha^j = \frac{\alpha^i \rho}{1-\alpha}$, showing the first claim. Setting $i = 0$ yields the second claim. ◀

It remains to verify Property 1 of Theorem 5, i.e., that the probability of cutting edge $e = \{u, v\} \in E$ is bounded from above by $O(\frac{\ell_e}{\rho})$. Property (II) of Lemma 6 ensures that this bound holds if $\ell_e = 0$ as in this case, in each iteration i, either both u and v join $B^{[i]}$ in line 10 or none of them does. In the remainder of this section, we therefore focus on the edges in $E_{>0} = \{e \in E \mid \ell_e > 0\}$, starting with the following definition.

▶ **Definition 8.** *We say that edge* $\{u, v\} \in E_{>0}$ *is* safe *after step* i *of* `blur`(G, ρ, B) *if either* $u, v \in B^{[i]}$ *or* $\min\{\mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, u), \mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, v)\} \geq \frac{\alpha^i \rho}{1-\alpha}$.

Clearly, if $\{u, v\} \in E$ is safe after step i of `blur`(G, ρ, B), then $e \notin E^{\mathrm{cut}}(U)$: if $u, v \in B^{[i]}$, then $u, v \in U$ by construction; if $\min\{\mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, u), \mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, v)\} \geq \frac{\alpha^i \rho}{1-\alpha}$, then $u, v \notin U$ by Lemma 7. See Figure 1 for an illustration of these two cases. Thus, in order to bound the probability of an edge being cut, it suffices to bound the probability that an edge never becomes safe. Accordingly, we define $X_{i,e}$ to be the event that e is not safe after step i of the algorithm conditioned on the event that e was not safe after step $i - 1$ and bound $P[X_{i,e}]$.

▶ **Lemma 9.** *For each iteration* i *and* $e \in E_{>0}$*, it holds that* $\Pr[X_{i,e}] \leq \frac{5}{4} \cdot \frac{\ell_e}{\alpha^{i-1}\rho} + \alpha \cdot (1 + 4\alpha)$.

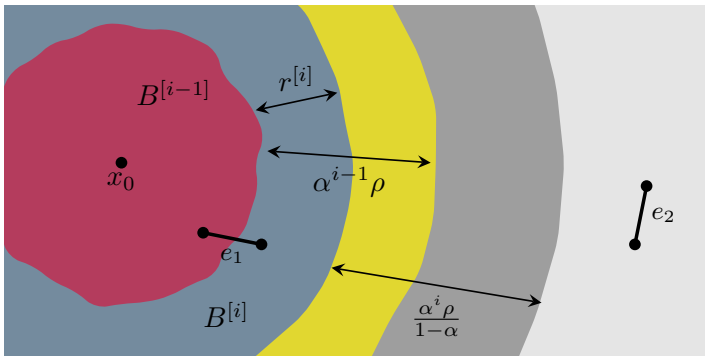

Figure 1 An illustration of the blurry ball growing procedure $\texttt{blur}(G, \rho, B)$ in iteration i. The radius $r^{[i]}$ is sampled uniformly from $[0, \alpha^{i-1}\rho]$ and $B^{[i]}$ is defined as all nodes whose $(1+\alpha^2)$-approximate distance to $B^{[i-1]}$ is at most $r^{[i]}$. Both edges e_1 and e_2 are safe from being cut after iteration i: e_1 has both endpoints in $B^{[i]} \subseteq U$ and both endpoints of e_2 are farther away from $B^{[i]}$ than $\frac{\alpha^i\rho}{1-\alpha}$, meaning that neither of them will lie in U after termination.

Proof. By Definition 8, it holds that if $e = \{u, v\} \in E_{>0}$ is not safe after step i, we must, w.l.o.g. over the choice of u, v, have $\mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, u) < \frac{\alpha^i\rho}{1-\alpha}$ and $\{u, v\} \not\subseteq B^{[i]}$. By the approximation guarantee of the SSSP algorithm and the triangle inequality, we get

$$\begin{aligned} r^{[i]} < \max\{\widetilde{\mathrm{d}}^{[i]}(u), \widetilde{\mathrm{d}}^{[i]}(v)\} &\leq (1+\alpha^2)\max\{\mathrm{d}_{G^{[i]}}(s^{[i]}, u), \mathrm{d}_{G^{[i]}}(s^{[i]}, v)\} \\ &\leq (1+\alpha^2)(\mathrm{d}_{G^{[i]}}(s^{[i]}, u) + \ell_e)\,, \end{aligned}$$

where the first transition follows from property (I) in Lemma 6. From the former inequality, we get that

$$\mathrm{d}_{G^{[i]}}(s^{[i]}, u) \leq \mathrm{d}_{G^{[i+1]}}(s^{[i+1]}, u) + r^{[i]} < \frac{\alpha^i\rho}{1-\alpha} + r^{[i]}, \tag{1}$$

which yields $r^{[i]} \geq \mathrm{d}_{G^{[i]}}(s^{[i]}, u) - \frac{\alpha^i\rho}{1-\alpha}$. As $r^{[i]}$ is drawn uniformly from an interval of length $\alpha^{i-1}\rho$, these lower and upper bounds on $r^{[i]}$ readily imply a bound on the probability of $X_{i,e}$:

$$\begin{aligned} \Pr[X_{i,e}] &\leq \Pr\left[r^{[i]} \in \left(\mathrm{d}_{G^{[i]}}(s^{[i]}, u) - \frac{\alpha^i\rho}{1-\alpha}, (1+\alpha^2)\cdot(\mathrm{d}_{G^{[i]}}(s^{[i]}, u) + \ell_e)\right)\right] \\ &\leq \frac{(1+\alpha^2)\ell_e}{\alpha^{i-1}\rho} + \frac{\alpha^2\,\mathrm{d}_{G^{[i]}}(s^{[i]}, u)}{\alpha^{i-1}\rho} + \frac{\alpha}{1-\alpha}. \end{aligned} \tag{2}$$

Moreover, from (1) and $r^{[i]} \leq \alpha^{i-1}\rho$, we conclude that $\mathrm{d}_{G^{[i]}}(s^{[i]}, u) < \alpha^{i-1}\rho\cdot(1+\frac{\alpha}{1-\alpha}) = \frac{\alpha^{i-1}\rho}{1-\alpha}$. Plugging into (2), with $\alpha \leq \frac{1}{2}$ we get that $\Pr[X_{i,e}] \leq \frac{5}{4}\cdot\frac{\ell_e}{\alpha^{i-1}\rho} + \frac{\alpha^2}{1-\alpha} + \frac{\alpha}{1-\alpha} \leq \frac{5}{4}\cdot\frac{\ell_e}{\alpha^{i-1}\rho} + \alpha(1+4\alpha)$. ◀

Applying this lemma to all iterations in which e has a significant probability to become safe (i.e., all iterations i for which $\alpha^{i-1}\rho \geq \ell_e$), we obtain the desired bound on the probability that e is cut.

▶ **Lemma 10.** *For every edge $e \in E$, it holds that* $\Pr[e \in E^{\mathrm{cut}}(U)] = O\left(\frac{\ell_e}{\rho}\right)$.

Proof. The case where $\ell_e = 0$ has already been treated, so assume hereafter that $e \in E_{>0}$. If $\ell_e > \rho$, then trivially $\Pr[e \in E^{\text{cut}}(U)] \leq 1 < \frac{\ell_e}{\rho}$. Otherwise, we let $i_e \geq 1$ be the largest index such that $\ell_e \leq \alpha^{i_e-1}\rho$. By Lemma 9, for all i, the probability that an edge that is not safe after $i-1$ steps is still not safe after step i is bounded by $\Pr[X_{i,e}] \leq \frac{5}{4} \cdot \frac{\ell_e}{\alpha^{i-1}\rho} + \alpha \cdot (1+4\alpha)$. Depending on the index i, we differentiate this upper bound further:

- Case $i = i_e$: As $\alpha^{i_e}\rho < \ell_e$, we get that $\alpha < \frac{\ell_e}{\alpha^{i_e-1}\rho}$. With $\alpha \leq \frac{1}{2}$, $\Pr[X_{i_e,e}] < \frac{5\ell_e}{\alpha^{i_e-1}\rho}$ follows.
- Case $i = i_e - 1$: As $\ell_e \leq \alpha^{i_e-1}\rho$, we conclude that $\frac{\ell_e}{\alpha^{i-1}\rho} \leq \frac{\alpha^{i_e-1}}{\alpha^{i_e-2}} = \alpha$, yielding with $\alpha \leq \frac{1}{2}$ that $\Pr[X_{i_e-1,e}] < 5\alpha$.
- Case $i \leq i_e - 2$: This entails that $\frac{\ell_e}{\alpha^{i-1}\rho} \leq \alpha^2$ and thus $\Pr[X_{i,e}] < 2\alpha^2 + \alpha \cdot (1+4\alpha) = \alpha \cdot (1+6\alpha)$.

Using these bounds and distinguishing cases based on i_e, we can bound the overall probability that the edge is cut.

- Case $i_e = 1$: $\Pr[e \in E^{\text{cut}}(U)] \leq \Pr[X_{1,e}] = \Pr[X_{i_e,e}] < \frac{5\ell_e}{\rho}$.
- Case $i_e = 2$: $\Pr[e \in E^{\text{cut}}(U)] \leq \Pr[X_{2,e}] \cdot \Pr[X_{1,e}] = \Pr[X_{i_e,e}] \cdot \Pr[X_{i_e-1,e}] < \frac{5\ell_e}{\alpha\rho} \cdot 5\alpha = \frac{25\ell_e}{\rho}$.
- Case $i_e \geq 3$: $\Pr[e \in E^{\text{cut}}(U)] \leq \frac{25\ell_e}{\alpha^{i_e-2}\rho} \cdot \prod_{i \leq i_e-2} \Pr[X_{i,e}] \leq \frac{25\ell_e}{\alpha^{i_e-2}\rho} \cdot (\alpha(1+6\alpha))^{i_e-2} < \frac{25\ell_e}{\rho} \cdot (1+6\alpha)^{i_e}$.

Hence, it remains to bound $(1+6\alpha)^{i_e} = O(1)$. Since $\rho < \ell_{\max}$, it follows that

$$\ell_{\min} \leq \ell_e \leq \alpha^{ie-1}\rho < \alpha^{ie-1}\ell_{\max}\,.$$

Recalling that $\sigma = \frac{\ell_{\min}}{\ell_{\max}} \leq n^{O(1)}$, we conclude that $i_e = O\left(\frac{\log n}{\log(1/\alpha)}\right)$. Therefore,

$$(1+6\alpha)^{i_e} = (1+6\alpha)^{O(\log n/\log(1/\alpha))} = \left((1+6\alpha)^{1/(6\alpha)}\right)^{O(\alpha \log n/\log(1/\alpha))} = e^{O(\alpha \log n/\log(1/\alpha))}\,.$$

The assertion follows by the choice of $\alpha = \frac{1}{2\log n}$. ◀

Theorem 5 now follows from Lemmas 7 and 10.

4 Tree-Supported Decomposition

In this section, we present the construction of TSDs that admit low diameter, low load, and low edge cutting probability, establishing Theorem 1. Our method is inspired by the partition technique from [43] that allows for efficient parallel and distributed implementations. However, we seek to rely on approximate rather than on exact distance computations.

To motivate our approach, consider a naive application of the decomposition technique from [43] using approximate rather than exact distance computations. This would look as follows: One would add a super-source s to the graph, assign exponentially sampled lengths to the edges adjacent to s, compute a $(1+\varepsilon)$-approximate SSSP tree T rooted at s for some small enough ε, and partition the node set V according to the subtrees of T rooted at the children of s. This approach certainly leads to a decomposition of G. However, a consequence of the approximate distance computation is that the probability to cut a short edge is dominated by the approximation error, which is ε times the distance to the source – an expression that may be very large compared to the length of the edge.

In order to still ensure the desired bound, we seek to employ the blurring technique from the previous section to clusters obtained as described above. This introduces the new obstacle that the clusters need to be separated from each other first, as the blurring procedure grows the clusters by a random radius. We enforce this separation by removing from each cluster every node that is too close to its boundary; Property 2 of Theorem 5, stating that

the distance of any node in the blurred cluster from the original cluster is at at most $\frac{\rho}{1-\alpha}$, determines what precisely is "too close." While this may result in a large portion of the graph not being contained in any cluster even after blurring all clusters, we can ensure that each edge is contained in some cluster with probability at least $p = \Omega(1)$ (or is very long and can be safely deleted). Hence, repeating the procedure $O(\log n)$ times completes the decomposition w.h.p.

The blurring procedure presented in Section 3 requires that the aspect ratio $\sigma = \frac{\ell_{\max}}{\ell_{\min}}$ of its input graph is bounded by $\text{poly}(n)$ and that the parameter ρ is smaller than $\ell_{\max}$. Therefore, we have to slightly modify the graph so that it satisfies these two conditions before invoking the blurring procedure. The latter requirement is readily satisfied by deleting all edges that are sufficiently long for the edge cutting probability bound to be greater than 1 (clearly, these edges can be safely deleted). For the former requirement, we reset the length of all edges $e \in E$ that are significantly shorter than the cluster diameter bound, thus ensuring that the aspect ratio of the graph is $n^{O(1)}$. The original length of all 0-length edges is then recovered after the decomposition is constructed. Since any simple path in the graph contains at most $n-1$ short edges, it follows that the length recovery operation does not increase the diameter of any cluster in the decomposition by "too much".

Algorithm 2 `ts_decompose` (G, Δ).

Input : graph $G = (V, E, \ell)$ and $\Delta \in \mathbb{N}$
Output : decomposition $D = (C_1, \dots, C_k)$ of G, trees $\mathcal{T} = (T_1, \dots, T_k)$ of depth $\leq \frac{\Delta}{2}$ s.t. T_i spans a superset of C_i

$\beta := \frac{3c \log n}{\Delta}$, $\varepsilon := \frac{1}{c \log^2 n}$, $D := \emptyset$, $\mathcal{T} := \emptyset$ *// c sufficiently large constant*
delete all edges $e \in E$ of length $\ell_e > \frac{1}{40\beta}$ *// long edges*
reset the length of each edge $e \in E$ with $\ell_e < \frac{\Delta}{6n}$ by setting $\ell_e = 0$ *// short edges*
while $E(G) \neq \emptyset$ **do**
  *// * initial decomposition by exponential shifts **
  pick $\delta_u \sim \text{Exp}_\beta$ for each $u \in V$ independently
  $G_s :=$ super-source graph of G with edges $\{u, s\}$ of length $\ell_{us} = 1 + \max_{v \in V}\{\delta_v\} - \delta_u$ for $u \in V$
  $T :=$ $(1+\varepsilon)$-approximate SSSP tree for G_s with source s

    $G := G \setminus C_u$
recover the original length of each edge $e \in E$ with $\ell_e = 0$
return $(D, \mathcal{T})$

▶ Remark. The operations of resetting the lengths of the short edges (line 3) and recovering their original lengths (line 17) are necessary only if the aspect ratio of G is large and can be ignored if the aspect ratio is guaranteed to be bounded by $n^{O(1)}$. In this case, the graphs handed to the blurring procedure (line 14) have no zero length edges.

Algorithm

The pseudocode of our procedure `ts_decompose` is given in Algorithm 2. The value β chosen in Line 1 is the parameter chosen for the exponential distributions: up to normalization, the density of the distribution is $\exp(-\beta x)$. The diameter of each (initial) cluster is bounded by $\max_{v\in V}\{\delta_v\}$, which we need to be smaller than $\frac{\Delta}{2}$ w.h.p. However, the probability to cut edges increases as we make the distributions "narrower," i.e., β larger. Accordingly, we choose $\beta = \Theta\left(\frac{\log n}{\Delta}\right)$, just small enough to ensure $\delta_v \leq \frac{\Delta}{2}$ w.h.p. for all $v \in V$.

The partition from [43] can be interpreted as a Voronoi decomposition in which each cell center x_v is a virtual copy of its corresponding node $v \in V$ that is attached to v by an edge of length $\max_{w\in V}\{\delta_w\} - \delta_v$. Note that the children of the virtual node s in the (approximate) shortest path tree T are exactly the nodes which have not been "absorbed" into another node's Voronoi cell before they started to grow their own. Lines 9 to 13 remove from each cluster nodes that are in distance (roughly) $\frac{1}{4\beta}$ from the boundary of the Voronoi cell containing them. Choosing a distance of $O\left(\frac{1}{\beta}\right)$ here ensures a constant probability that edges of this length remain in a shrunk cluster; longer edges can safely be cut, as the required bound on the probability for cutting them is trivial (i.e., 1), which is why they are removed at the start of the routine. We then proceed to applying the blurring subroutine to each (remaining) shrunk cluster. Note that, as the clusters remain separated due to the choice of parameters, we can realize this step concurrently for all clusters. The algorithm iterates until all nodes are assigned to clusters, which requires $O(\log n)$ loop iterations w.h.p.

The remainder of this section is dedicated to proving Theorem 1.

Number of Iterations

We first prove the key statement that, with at least constant probability, for any node w, a ball of radius $\Theta(\frac{1}{\beta})$ around it is contained within the interior of a cell.

▶ **Lemma 11.** *Consider an iteration of the while loop of Algorithm 2 and (by slight abuse of notation) denote by $G = (V, E)$ the subgraph that remains at the beginning of the iteration. For any $w \in V$, with at least constant probability a ball of radius $\frac{1}{40\beta}$ around it is contained in the interior of a cell computed in Line 13.*

Proof. For $x \in V$, set $\mathrm{d}_x := \mathrm{d}_{G_s}(x, w) + 1 + \max_{y\in V}\{\delta_y\}$. Moreover, set $X_x := \mathrm{d}_x - \delta_x = \ell_{sx} + d_{G_s}(x, w)$ for $x \in V$ and let $X^{(i)}$ be the i'th order statistic of the variables X_v (i.e., the i'th smallest element). Denote by $x_{\min} \in V$ the node for which $X_{x_{\min}} = X^{(1)}$. By Lemma 4, with constant probability $X^{(2)} - X^{(1)} \geq \frac{7}{8\beta}$. Condition on this event. Accordingly, we have for all $x \in V \setminus \{x_{\min}\}$ that $X_x - X_{x_{\min}} \geq X^{(2)} - X^{(1)} \geq \frac{7}{8\beta}$.

Denote for each $v \in V$ by x_v the child of s in T in whose subtree v is situated. Then the assumption that $x_v \neq x_{\min}$ implies by copious use of the triangle inequality that

$$\begin{aligned}
\mathrm{d}_T(s,v) - \mathrm{d}_{G_s}(s,v) &= \ell_{x_v s} + \mathrm{d}_T(x_v,v) - \mathrm{d}_{G_s}(s,v) \\
&\geq \ell_{x_v s} + \mathrm{d}_{G_s}(x_v,v) - \mathrm{d}_{G_s}(s,v) \\
&\geq \ell_{x_v s} + \mathrm{d}_{G_s}(x_v,w) - \mathrm{d}_{G_s}(v,w) - (\mathrm{d}_{G_s}(s,w) + \mathrm{d}_{G_s}(v,w)) \\
&\geq \ell_{x_v s} + \mathrm{d}_{G_s}(x_v,w) - (\ell_{x_{\min} s} + \mathrm{d}_{G_s}(x_{\min},w)) - 2\,\mathrm{d}_{G_s}(v,w) \\
&= X_{x_v} - X_{x_{\min}} - 2\,\mathrm{d}_{G_s}(v,w) \geq \frac{7}{8\beta} - 2\,\mathrm{d}_{G_s}(v,w).
\end{aligned}$$

On the other hand, the approximation guarantee of the SSSP algorithm yields that

$$\mathrm{d}_T(s,v) - \mathrm{d}_{G_s}(s,v) \leq \varepsilon\,\mathrm{d}_{G_s}(s,v) \leq \varepsilon \ell_{vs} \leq \varepsilon \max_{x \in V}\{1+\delta_x\}.$$

By Lemma 3, w.h.p. $\max_{x\in V}\{\delta_x\} \leq t = \frac{c\log n}{4(1+\varepsilon)\beta}$ after sampling the δ-values in Line 5 of this iteration. Condition on this event as well. Using that $\varepsilon = \frac{1}{c\log^2 n}$ and c is sufficiently large, we get that $\mathrm{d}_T(s,v) - \mathrm{d}_{G_s}(s,v) \leq \varepsilon(1+t) < \frac{1}{4\beta}$.

In summary, if both events on which we conditioned occur, $x_v \neq x_{\min}$ entails that

$$\mathrm{d}_{G_s}(v,w) > \frac{5}{16\beta}. \tag{3}$$

In particular, choosing $v = w$ yields the contradiction $0 = \mathrm{d}_{G_s}(w,w) > \frac{5}{16\beta}$, i.e., $x_w = x_{\min}$.

We proceed to show that $\mathrm{d}_G(v,w) \leq \frac{1}{40\beta}$ implies that also $v \in V^\circ_{x_{\min}}$. By a union bound over the two events on which we conditioned, this will complete the proof. To this end, observe that Inequality (3) shows that a ball of radius $\frac{5}{16\beta}$ around w in G_s is contained within $V_{x_{\min}}$. Because longer edges have been deleted, nodes in $\partial\mathcal{V}$ are connected to neighbors outside their cell by edges of length at most $\frac{1}{40\beta}$. Together with the approximation guarantee of the second SSSP computation used to compute T', it follows that nodes $v \in V$ for which $\mathrm{d}_{G_s}(v,w) \leq \frac{1/16 - 1/40 - \varepsilon}{\beta} < \frac{5}{16\beta} - \frac{(1+\varepsilon)^2}{4\beta} - \frac{1}{40\beta}$ end up in $V^\circ_{x_{\min}}$. In particular, as trivially $\mathrm{d}_{G_s}(v,w) \leq \mathrm{d}_G(v,w)$ and ε is sufficiently small, we conclude that $\mathrm{d}_G(v,w) \leq \frac{1}{40\beta}$ implies that $v \in V^\circ_{x_{\min}}$. ◀

▶ **Corollary 12.** *Algorithm 2 terminates after $O(\log n)$ iterations of the while loop w.h.p.*

Proof. Consider any edge $e \in E$ that is not deleted right away, i.e., $\ell_e \leq \frac{1}{40\beta}$. By Lemma 11, in each iteration in which e is present in the remaining subgraph of G, there is a constant probability that it is contained in V°_u for some node u. Thus, the probability that the edge remains for $c\log n$ iterations is bounded by $2^{-\Omega(c\log n)} = n^{-\Omega(c)}$. By a union bound, this implies that all edges are either cut or included in a part within $O(\log n)$ iterations w.h.p., i.e., the termination condition that $E(G)$ is empty becomes satisfied. ◀

The Diameter Bound

In order to prove that the diameter bound holds, we first show that for each iteration of the while loop of Algorithm 2 and each $u \in R$, we have that $C_u \subseteq V_u$.

▶ **Lemma 13.** *Fix any iteration of the while loop of Algorithm 2 and $u \in R$. It holds that $C_u \subseteq V_u$.*

Proof. Again, denote for simplicity the remaining subgraph at the beginning of the loop iteration by $G = (V,E)$. By the approximation guarantee of the second call to the SSSP algorithm, $v \in V^\circ_u$ implies that $\mathrm{d}(v,\partial\mathcal{V}) \geq \frac{1}{4\beta}$. By Theorem 5, $w \in C_u$ implies that

$\mathrm{d}_G(w, V_u^\circ) \leq \frac{\rho}{1-1/(2\log n)} = \frac{1}{4\beta}$. Consider the node $v \in V_u^\circ$ that is closest to w and fix a shortest path from v to w. By the second bound, the path is no longer than $\frac{1}{4\beta}$, which by the first bound implies that it cannot leave V_u. Hence, $w \in V_u$, showing the claim of the lemma. ◀

We observe that the above lemma yields that the algorithm indeed outputs a partition of V, and each set in the partition is spanned by the corresponding tree in $\mathcal{T}$. We now apply the tail bound on Exp_β given in Lemma 3 to infer that the diameter of the computed parts is appropriately bounded w.h.p.

▶ **Lemma 14.** *W.h.p., each cluster in the decomposition D returned by* `ts_decompose`(G, Δ) *has weak diameter at most $\frac{\Delta}{2}$. This is witnessed by the corresponding tree in $\mathcal{T}$.*

Proof. We prove that each tree $T \in \mathcal{T}$ has diameter at most $\frac{\Delta}{3}$ assuming that the lengths of the short edges e are reset to $\ell_e = 0$ (see line 3 of `ts_decompose`(G, Δ)). This implies the desired $\frac{\Delta}{2}$-bound on the diameter of T in the original graph since each path P in T includes less than n short edges and each such short edge adds at most a $\frac{\Delta}{6n}$-term to the total length of P when recovering its original length (line 17 of `ts_decompose`(G, Δ)).

By Lemma 3 and a union bound over all nodes, w.h.p. always $\max_{v\in V}\{\delta_v\} \leq 1 + t$ for $t = \frac{c\log n}{4(1+\varepsilon)\beta}$ in Line 5 of `ts_decompose`(G, Δ). Assume that v ends up in the subtree of T rooted at the child x_v of s in G_s. From the above bound, it follows that, w.h.p.,

$$\begin{aligned}\mathrm{d}_T(x_v, v) &= \mathrm{d}_T(s, v) - \ell_{x_v s} \leq (1+\varepsilon)\cdot \mathrm{d}_{G_s}(s, v) - \ell_{x_v s} \leq (1+\varepsilon)\cdot \ell_{vs} - \ell_{x_v s}\\ &= \varepsilon\cdot(1 + \max_{x\in V}\{\delta_x\} - \delta_v) + \delta_{x_v} - \delta_v \leq \varepsilon\cdot(1+t) + t = (1+\varepsilon)\cdot t + \varepsilon.\end{aligned}$$

Recalling that R denotes the children of the root node in T, it follows that for each $x \in R$, we have that T_x has (weighted) depth at most $(1+\varepsilon)t+\varepsilon$ w.h.p. in Line 8 of `ts_decompose`(G, Δ). We conclude that w.h.p., for all $u \in R$, it holds that the subgraph induced by V_u has diameter at most $2[(1+\varepsilon)t + \varepsilon] \leq \frac{c\log n}{2\beta} + 2\varepsilon \leq \frac{\Delta}{3}$, using that $\varepsilon = \frac{1}{c\log^2 n} \leq \frac{1}{12}$ for sufficiently large c. Using Lemma 13 concludes the proof. ◀

The Edge Cutting Probability Bound

We proceed to showing that the probability to cut an edge is sufficiently small. This follows from the analysis of Algorithm 1 and the probabilistic progress guarantee from Lemma 11.

▶ **Corollary 15.** *The probability that edge $e \in E$ is cut by* `ts_decompose`(G, Δ) is $O\left(\frac{\ell_e \log n}{\Delta}\right)$.

Proof. Consider edge $e = \{v, w\} \in E$. If e is deleted right away, then $\ell_e > \frac{1}{40\beta} = \Omega\left(\frac{\Delta}{\log n}\right)$ and the claim trivially holds. Accordingly, assume that $\ell_e \leq \frac{1}{40\beta}$ in the following.

As shown in Lemma 13, in each iteration the parts $(V_u^\circ)_{u\in C}$ satisfy that $V_u^\circ \subseteq V_u$. Thus, if $v \in V_x$ and $w \in V_y$ for some $x, y \in C$ after Line 8, e can be only cut by v ending up in C_x, while w does not, or w ending up in C_y, while v does not. Lemma 10 shows that the probability for either event is bounded by $O\left(\frac{\ell_e \log n}{\Delta}\right)$, independently of the subgraph the calls to Algorithm 1 are executed on.

Combining this observation with the fact that, in each iteration in which e is still present by Lemma 11 it ends up in some part with probability at least $p \in \Omega(1)$, we can bound the probability that e is cut by

$$\sum_{i=1}^{\infty}(1-p)^{i-1} O\left(\frac{\ell_e \log n}{\Delta}\right) = O\left(\frac{\ell_e \log n}{p\Delta}\right) = O\left(\frac{\ell_e \log n}{\Delta}\right).$$ ◀

The Load Bound

As the trees added to the output in a single iteration are subtrees of the same shortest path tree, these trees are disjoint. Hence, the bound on the number of iterations also bounds the number of trees in which an edge may participate and thus the load of that edge in the output decomposition D. This concludes the proof of Theorem 1.

5 Sampling from Low Stretch Tree Embeddings

Consider some graph $G = (V, E, \ell)$ with positive edge lengths. We say that graph $G' = (V', E', \ell')$ with $V' \supseteq V$ *dominates* G if $\mathrm{d}_{G'}(u, v) \geq \mathrm{d}_G(u, v)$ for every two vertices $u, v \in V$. In that case, we define the stretch of edge $e = \{u, v\} \in E$ in G' to be

$$\mathrm{str}_{G'}(e) = \frac{\mathrm{d}_{G'}(u, v)}{\ell_e}.$$

Our goal in this section is to construct random dominating trees of a given graph $G = (V, E, \ell)$ that guarantee low expected stretch for each edge in E. The dominating trees we construct, referred to hereafter as *virtual trees*, are not spanning trees of G, because they may include vertices and edges that do not belong to V and E, respectively. Nevertheless, they admit some useful characteristics. Specifically, we consider two types of virtual (dominating) trees: *projected trees* (a special case of the path embeddable trees of [15, 16]) addressed in Section 5.2 and *hierarchically well separated trees (HSTs)* addressed in Section 5.3. In both cases, the respective constructions are based on recursive applications of the graph decomposition technique presented in Section 4, generating a *hierarchical* version of TSDs as presented in Section 5.1.

5.1 Hierarchical Decompositions

A *hierarchical tree-supported decomposition (HTSD)* $\mathbf{D}$ of a graph G is a sequence $\mathbf{D} = (D_0, D_1, \ldots, D_k)$ of TSDs that satisfies (i) $D_0 = \{V\}$; (ii) $D_k = \{\{v\} \mid v \in V\}$; and (iii) for every $1 \leq i \leq k$ and $C \in D_i$, there exists some $C' \in D_{i-1}$ such that $C \subseteq C'$. The TSDs $D_0, D_1, \ldots, D_k$ are referred to as the *levels* of $\mathbf{D}$ and the parameter k is referred to as its *depth*. The *load* of edge $e \in E$ in $\mathbf{D}$ is defined to be $\mathrm{load}_{\mathbf{D}}(e) = \sum_{i=0}^{k} \mathrm{load}_{D_i}(e)$.

The real sequence $\mathbf{d} = (d_0, d_1, \ldots, d_k)$ is said to be *diameter bounding* for the HTSD $\mathbf{D}$ if $\mathrm{diam}(D_i) \leq d_i$ for every $0 \leq i \leq k$. Of particular interest are HTSDs that admit a *geometrically decreasing* diameter bounding sequence, namely a sequence $\mathbf{d} = (d_0, d_1, \ldots, d_k)$ that satisfies $d_i \leq \alpha \cdot d_{i-1}$, $1 \leq i \leq k$, for some constant $\alpha > 1$.

Consider some HTSD $\mathbf{D} = (D_0, D_1, \ldots, D_k)$ of G with a geometrically decreasing diameter bounding sequence $\mathbf{d} = (d_0, d_1, \ldots, d_k)$. Edge $e = \{u, v\} \in E$ is said to be *decoupled* on level $0 \leq i \leq k-1$ if u and v belong to the same cluster in level i and to different clusters in level $i+1$, that is $e \in E^{\mathrm{cut}}(D_{i+1}) - E^{\mathrm{cut}}(D_i)$. In that case, we define the *stretch* of e in $\mathbf{D}$ with respect to $\mathbf{d}$ to be

$$\mathrm{str}_{\mathbf{D},\mathbf{d}}(e) = \frac{d_i}{\ell_e}.$$

▶ **Theorem 16.** *There exists a (randomized) algorithm that, given a graph $G = (V, E, \ell)$ with positive integral edge lengths and aspect ratio $\sigma = \frac{\ell_{\max}}{\ell_{\min}}$, constructs a random HTSD $\mathbf{D}$ of G with the following guarantees: (1) the depth of $\mathbf{D}$ is $n^{O(1)}$ w.h.p.; (2) $\mathbf{D}$ admits a geometrically decreasing diameter bounding sequence $\mathbf{d} = (d_0, d_1, \ldots, d_k)$ w.h.p.; (3) $\mathrm{load}_{\mathbf{D}}(e) = O(\log \sigma)$ for every edge $e \in E$ w.h.p.; and (4) $\mathbb{E}_{\mathbf{D}}[\mathrm{str}_{\mathbf{D},\mathbf{d}}(e)] = O(\log^2 n)$ for every edge $e \in E$.*

Proof. We first present the construction of the (random) HTSD $\mathbf{D} = (D_0, D_1, \ldots, D_k)$ and its geometrically decreasing diameter bounding sequence $\mathbf{d} = (d_0, d_1, \ldots, d_k)$ and then establish their desired properties.

Let $D_0 = \{V\}$. Construct a 2-approximate SSSP tree T_0 of G and set $d_0 = \mathrm{diam}(T_0)$. Assume by induction that we have already constructed the TSD D_i, $i \geq 0$, with clusters $C_i^1, \ldots, C_i^q$ and corresponding supporting trees $T_i^1, \ldots, T_i^q$. Set

$$d_i \;=\; \max\left\{\mathrm{diam}(T_i^j) \mid j = 1, \ldots, q\right\}$$

to be the maximum diameter of the trees supporting D_i's clusters. If $d_i = 0$, i.e., all clusters in D_i are singletons, then we set $k = i$ and the construction of $\mathbf{D}$ and $\mathbf{d}$ is completed. Otherwise, we call

$$\texttt{ts\_decompose}\left(G(C_i^j), \Delta_{i+1}\right), \quad j = 1, \ldots, q,$$

where $\Delta_{i+1} = \frac{d_i}{2}$, and take D_{i+1} to be the union of the clusters returned by these q calls.

To analyze this construction, we first observe that since $d_{i+1} \leq \Delta_{i+1} \leq d_i/2$ for every $0 \leq i \leq k-1$, it follows that

$$k \;\leq\; O(\log \sigma)\,.$$

Moreover, each d_i corresponds to the diameter of some approximate SSSP tree w.h.p., thus it provides a constant approximation for the actual distance in G between some pair of nodes. As there are $\binom{n}{2} < n^2$ such node pairs, we conclude that the depth of $\mathbf{d} = (d_0, d_1, \ldots, d_k)$ satisfies

$$k \;\leq\; O\left(n^2\right)$$

w.h.p.

For the expected stretch bound, consider some edge $e \in E$ of length $\ell_e \in \mathbb{Z}_{>0}$. As long as `ts_decompose` is invoked with diameter bound $\Delta_i > 6n\ell_e$, the length of e is reset (see line 3 in Algorithm 2), ensuring that e is not decoupled on that level. For each level i such that $\Delta_i \leq 6n\ell_e$, Corollary 15 guarantees that the probability that e is decoupled on level i is at most

$$O\left(\frac{\ell_e \cdot \log(n)}{\Delta_i}\right) \leq O\left(\frac{\ell_e \cdot \log(n)}{d_i}\right).$$

Taking i_e to be the smallest $i \geq 0$ such that $\Delta_i \leq 6n\ell_e$ and i'_e to be the smallest i such that $\Delta_i \leq \ell_e \log n$, we can bound the expected stretch of e in $\mathbf{D}$ with respect to $\mathbf{d}$ as

$$\begin{aligned}
\mathbb{E}_{\mathbf{D}}[\mathrm{str}_{\mathbf{D},\mathbf{d}}(e)] &\leq \sum_{i=0}^{k-1} \Pr(e \text{ is decoupled on level } i) \cdot \frac{d_i}{\ell_e} \\
&\leq \sum_{i=i_e}^{i'_e-1} O\left(\frac{\ell_e \cdot \log(n)}{d_i}\right) \cdot \frac{d_i}{\ell_e} + \sum_{i=i'_e}^{k-1} O(1) \cdot \frac{d_i}{\ell_e} \\
&\leq (i'_e - i_e) \cdot O(\log n) + O(1)\,,
\end{aligned}$$

where the last transition holds as the sequence $\mathbf{d}$ is geometrically decreasing. Since $\Delta_{i+1} \leq d_i/2 \leq \Delta_i/2$ for every i, it follows, by the definitions of i_e and i'_e, that $i'_e - i_e \leq O(\log n)$, thus yielding the desired bound $\mathbb{E}_{\mathbf{D}}[\mathrm{str}_{\mathbf{D},\mathbf{d}}(e)] \leq O(\log^2 n)$.

It remains to show that the load of every edge $e \in E$ in $\mathbf{D}$ is $O(\log \sigma)$ w.h.p. To that end, recall that in Section 4 we proved that the load on edge e in the TSD D_i is stochastically dominated by a geometric random variable with parameter $\Omega(1)$. The claim follows recalling that the depth $k \leq O(\log \sigma)$ as the sum of k such random variables is $O(k)$ w.h.p. ◀

We note that a crucial point is, of course, that the algorithm can be implemented efficiently due to relying on approximate SSSP computations only. However, as the resulting complexities are model-specific, the respective discussion is postponed to Section 6.

5.2 Embedding into a Random Projected Tree

Consider some graph $G = (V, E, \ell)$. Graph $G' = (V', E', \ell')$ with $V' \supseteq V$ is said to be a *projected* graph of G if there exists a mapping $\pi : V' \to V$ so that
(a) $\pi(v) = v$ for every $v \in V$;
(b) if $e' = \{u', v'\} \in E'$, then $\pi(e') := \{\pi(u'), \pi(v')\} \in E$; and
(c) $\ell'(e') = \ell(e)$ for every $e \in E$ and $e' \in E'$ such that $\pi(e') = e$.
The *load* of edge $e \in E$ under the projected graph G' of G (with respect to π) is defined to be the size of its preimage under π, denoted by $\mathrm{load}_{G'}(e) = |\{e' \in E' \mid \pi(e') = e\}|$. Notice that, by definition, every projected graph of G dominates G. Observe also that ℓ' is fully determined by π and ℓ, hence we may omit it from the notation in the following. Our goal in this section is to prove the following theorem.

▶ **Theorem 17.** *There exists a (randomized) algorithm that, given a graph $G = (V, E, \ell)$ with $\mathrm{poly}(n)$-bounded edge lengths, constructs a random projected tree T of G that satisfies the following guarantees for every edge $e \in E$: (1) $\mathrm{load}_T(e) = O(\log \sigma)$ w.h.p.; and (2) $\mathbb{E}_T[\mathrm{str}_T(e)] = O(\log^2 n)$.*

Theorem 17 is established by combining Theorem 16 with the following lemma.

▶ **Lemma 18.** *There exists an algorithm that given a graph $G = (V, E, \ell)$, a HTSD $\mathbf{D}$ of G, and a geometrically decreasing diameter bounding sequence $\mathbf{d}$ for $\mathbf{D}$, constructs a projected tree $T = (V_T, E_T, \ell_T)$ of G such that $\mathrm{load}_T(e) = \mathrm{load}_{\mathbf{D}}(e)$ and $\mathrm{str}_T(e) = O(\mathrm{str}_{\mathbf{D},\mathbf{d}}(e))$ for each $e \in E$.*

The rest of Section 5.2 is dedicated to proving Lemma 18. This is done by a series of graph transformations that results in the desired projected tree T. Let k be the depth of $\mathbf{D} = (D_0, D_1, \ldots, D_k)$. For $0 \leq i \leq k$, let $H_i = (V_i^H, E_i^H)$ be the forest obtained by taking the (graph) union over all level i supporting trees of $\mathbf{D}$, where each level i supporting tree $T_C = (U_C, F_C)$ contributes its own (distinct) copies of the vertices in U_C and edges in F_C (this means, in particular, that $|V_i^H| = \sum_{C \in D_i} |U_C|$ and $|E_i^H| = \sum_{C \in D_i} |F_C|$). Define the function $\pi_i^H : V_i^H \to V$ by mapping each vertex $v \in V_i^H$ to the vertex $\pi_i^H(v) \in V$ from which it originates, recalling that T_C is a subgraph of G. Although the preimage of vertex $u \in V$ under π_i^H may consist of several vertices, it includes exactly one vertex $v_i \in U_C$, where C is the (unique) level i cluster that contains v. We hereafter refer to this vertex v_i as the level i *clone* of v.

Recalling that the level k clusters of $\mathbf{D}$ are singletons, we identify the vertices in V_k^H with their images under (the bijection) π_k^H so that $V_k^H = V$. Let $H = (V^H, E^H)$ be the forest obtained by taking the (graph) union over $H_0, H_1, \ldots, H_k$ and let $\pi^H : V^H \to V$ be the function defined by mapping each vertex $v \in V_i^H$, $0 \leq i \leq k$, to $\pi^H(v) = \pi_i^H(v)$. Notice that H is a projected graph of G realized by π^H and that $\mathrm{load}_H(e) = \mathrm{load}_{\mathbf{D}}(e)$ for every edge $e \in E$. It remains to show that we can turn H into a projected tree $T = (V_T, E_T)$ by

connecting its connected components without increasing the load on the edges while ensuring that the stretch of every edge $e \in E$ in T is at most $O(1)$ times larger than its stretch in $\mathbf{D}$ with respect to $\mathbf{d}$.

Given a level $0 \leq i \leq k$ and a level i cluster C, we refer to the vertex with smallest ID in C as the *leader* of cluster C, denoted by $\lambda(C)$. Notice that every vertex $v \in V$ is a leader of its level k cluster and that if v is the leader of its level i cluster, then it is also the leader of its level j cluster for all $i \leq j \leq k$.

We now construct a projected tree $T = (V^T, E^T)$ of G from H in two additional steps. First, we connect each connected component T_C of H_i, $1 \leq i \leq k$, to the unique connected component $T_{C'}$ of H_{i-1} that satisfies $C' \supseteq C$. Assuming that the leader of cluster C is $v = \lambda(C)$, this connection is realized by augmenting H with a 0-length edge that connects v_i with v_{i-1}, i.e., the level i and level $i-1$ clones of v. (Note that v_{i-1} is not necessarily the leader of cluster C'.) We call this new edge connecting v_i and v_{i-1} a *vertical* edge and denote the set of all vertical edges added to H during this step of the construction by $E_\uparrow$. Observe that the graph obtained from H by augmenting it with the vertical edges is a tree denoted hereafter by $T^\uparrow = (V^H, E^H \cup E_\uparrow)$. This holds since starting from the forest H, we connected each connected component in level $1 \leq i \leq k$ to a connected component in level $i-1$ using a single vertical edge and since H_0 is a tree.

The next and final step simply contracts all vertical edges in $T^\uparrow$, resulting in the tree $T = (V^T, E^T)$. Since the vertical edge $\{v_i, v_{i-1}\} \in E^\uparrow$ connects the clones v_i and v_{i-1} of the same vertex $v \in V$, it follows that both endpoints of the vertical edge are mapped to v under π^H. Accordingly, we readily obtain a projection $\pi^T \colon V^T \to V$ from π^H by mapping each vertex $v^T \in V^T$ to $\pi^H(v')$, where $v' \in V^H$ is any node that participated in the contraction that created v^T. Finally, note that there is a natural bijection $b \colon E^H \to E^T$ between edges in H and T, as T is obtained by first augmenting H with $E^\uparrow$ of vertical edges and then contracting these edges. By construction, we have $\pi^T(b(e)) = \pi^H(e)$ for all $e \in E^H$. In particular, T is indeed a projected tree of G and $\mathrm{load}_T(e) = \mathrm{load}_H(e) = \mathrm{load}_{\mathbf{D}}(e)$ for all $e \in E$.

It remains to prove that $\mathrm{str}_T(e) = O(\mathrm{str}_{\mathbf{D},\mathbf{d}}(e))$ for every edge $e = \{x, y\} \in E$. Since T is obtained from $T^\uparrow$ by contracting 0-length edges, it follows that $\mathrm{d}_{T^\uparrow}(x, y) = \mathrm{d}_T(x, y)$, hence it suffices to prove that $\mathrm{str}_{T^\uparrow}(e) = O(\mathrm{str}_{\mathbf{D},\mathbf{d}}(e))$. To this end, fix some node $v \in V$ and let $C_i \in D_i$, $0 \leq i \leq k$, be the (unique) level i cluster that contains v. Let $\lambda(i) = \lambda(C_i)$ be the leader of C_i and denote the level j clone of $\lambda(i)$ by $\lambda_j(i)$.

▶ Remark 19. For every $0 \leq i \leq k$, we have $\mathrm{d}_{T^\uparrow}(v, \lambda_i(i)) \leq \sum_{j=i}^{k-1} d_j$.

Proof. By induction on i. The base case $i = k$ holds since every vertex is the leader of its (singleton) level k cluster, hence $\lambda_i(i) = v$. For the inductive step from $i+1$ to $0 \leq i \leq k-1$, we notice that

$$\mathrm{d}_{T^\uparrow}(v, \lambda_i(i)) = \mathrm{d}_{T^\uparrow}(v, \lambda_{i+1}(i+1)) + \mathrm{d}_{T^\uparrow}(\lambda_{i+1}(i+1), \lambda_i(i+1)) + \mathrm{d}_{T^\uparrow}(\lambda_i(i+1), \lambda_i(i)) .$$

Recalling that $\lambda_{i+1}(i+1)$ and $\lambda_i(i+1)$ are connected in $T^\uparrow$ by a vertical edge, we conclude that $\mathrm{d}_{T^\uparrow}(\lambda_{i+1}(i+1), \lambda_i(i+1)) = 0$. Moreover, since $\lambda_i(i+1)$ and $\lambda_i(i)$ belong to the same level i cluster $C_i \in D_i$, their distance in $T^\uparrow$ is equal to their distance in the supporting tree of C_i whose diameter is bounded by d_i, hence $\mathrm{d}_{T^\uparrow}(\lambda_i(i+1), \lambda_i(i)) \leq d_i$. The assertion follows by the inductive hypothesis ensuring that $\mathrm{d}_{T^\uparrow}(v, \lambda_{i+1}(i+1)) \leq \sum_{j=i+1}^{k-1} d_j$. ◀

Now, consider some edge $e = \{u, v\} \in E$ and let $0 \leq i \leq k-1$ be the level on which e is decoupled. Let $C \in D_i$ to be the level i cluster that contains u and v and let w be the level i clone of the leader $\lambda(C)$ of C. Remark 19 guarantees that $\mathrm{d}_{T^\uparrow}(u, w) \leq \sum_{j=i}^{k-1} d_j$ and

$\mathrm{d}_{T^\uparrow}(v,w) \leq \sum_{j=i}^{k-1} d_j$, hence

$$\mathrm{d}_{T^\uparrow}(u,v) \;\leq\; 2\sum_{j=i}^{k-1} d_j \;=\; O(d_i)\,,$$

where the last transition holds since $\mathbf{d} = (d_0, d_1, \ldots, d_k)$ is geometrically decreasing. The proof of Lemma 18 is completed by the definitions of $\mathrm{str}_{\mathbf{D},\mathbf{d}}(e) = \frac{d_i}{\ell_e}$ and $\mathrm{str}_{T^\uparrow}(e) = \frac{\mathrm{d}_{T^\uparrow}(u,v)}{\ell_e}$.

5.3 Embedding into a Random HST

In this section we show how to construct an embedding into a random *hierarchically* 2-*separated* dominating tree (HST) with small expected stretch from the projected trees constructed in the previous section.

▶ **Definition 20** (Hierarchically Separated Trees)**.** *An* embedding *of a weighted graph $G = (V, E, \ell)$ into a (rooted) tree $T = (V^T, E^T, \ell^T)$ is given by a one-to-one mapping $\iota\colon V \to V^T$. For $k > 1$, the tree is* hierarchically k-separated*, if for each internal non-root node, the weight of edges connecting it to its children is exactly by factor k smaller than the weight of the edge connecting it to its parent. The stretch of edge $e = \{u, v\} \in E$ w.r.t. T is defined as* $\mathrm{str}_T(e) := \frac{\mathrm{d}_T(\iota(u),\iota(v))}{\ell_e}$.

We note that our definition of hierarchical well-separation is (formally) weaker than that of hierarchically well-separated trees from the literature [7], as we dropped the requirement that the tree is balanced, i.e., all leaves are in the same depth. However, this can be easily achieved, and our construction does so without modification.

Construction

We construct our HST from a projected tree (see Section 5.2). The construction of $T = (V^T, E^T, \ell^T)$ is straightforward. Let $\mathbf{D} = (D_0, \ldots, D_k)$ be the HTSD from which the projected tree was constructed. We recall that we had assigned a leader $\lambda(C)$ to each cluster C, namely the smallest ID vertex in C. We construct V^T simply as the multiset[4] of leaders of all clusters in $\mathbf{D}$. Note that the nodes constructed for level k clusters, correspond, one-to-one, to the original nodes V of the graph. This enables us to define an embedding $\iota : V \to V^T$ as required in Definition 20. We construct the set of edges E^T as follows: Let $\lambda \in V^T$ be a node corresponding to an arbitrary level i cluster C with $i < k$. We introduce an edge $e := \{\lambda(C), \lambda(C')\}$, for every level $i+1$ cluster C' that cluster C decomposes into, i.e., $C' \subseteq C$. We assign length $\ell^T_e := d_i$ to such an edge e between nodes corresponding to level i and level $i+1$ clusters. Rooting the tree at the node in V^T corresponding to the leader of the (unique) level 0 cluster V, it is clear that the resulting tree $T = (V^T, E^T, \ell^T)$ is a hierarchically 2-separated tree of depth k.

Regarding distances, we get essentially the same result as for the projected tree we could have constructed. Denote for $v \in V$ by $\lambda(i)$ the leader of the unique level i cluster $C_i \in D_i$ such that $v \in C_i$ and denote by $\lambda^T(i) \in V^T$ its copy in T corresponding to C_i.

▶ Remark 21. For every $0 \leq i \leq k$, we have $\mathrm{d}_T(v, \lambda^T(i)) = \sum_{j=i}^{k-1} d_j$.

Proof. $\mathrm{d}_T(v, \lambda^T(i)) = \sum_{j=i}^{k-1} \ell^T_{\{\lambda^T(j),\lambda^T(j+1)\}} = \sum_{j=i}^{k-1} d_j$. ◀

[4] For each cluster C a node $v \in V$ is leader of, there is a separate copy of v.

▶ **Corollary 22.** *T is a dominating hierarchically 2-separated tree with $\mathrm{E}_T[\mathrm{str}_T(e)] = O(\log^2 n)$ for each edge $e \in E$.*

Proof. As discussed, T is hierarchically 2-separated by construction and we have the desired embedding $\iota\colon V \to V^T$. By Remarks 19 and 21, distances between leaves of T are at least as large as in the projected tree constructed in Section 5.2, which dominates G. The stretch bound follows analogous to Section 5.2, where Remark 19 takes the place of Remark 21. ◀

We remark that this establishes a straightforward relation between our projected trees and the HSTs constructed here. The HST edges are realized by the corresponding paths in the projected tree. In particular, while the HST may incur large loads on some graph edges, the "more fine-grained" view provided by the projected tree shows that a low-load mapping of paths in the HST to the original graph is feasible. On the other hand, this relation also demonstrates that a projected tree "behaves" like an HST due to the geometrically decreasing diameter bounding sequence of the underlying HTSD.

5.4 Bounding the p-Stretch

Cohen et al. [16] introduced the notion of p-stretch.

▶ **Definition 23** (p-Stretch)**.** *For a graph G, an embedding of G into T, and a real $p \in (0,1]$, the* p-stretch *of an edge $e = \{u,v\} \in E$ is given by $\left(\frac{\mathrm{d}_T(u,v)}{\ell_e}\right)^p$. Analogously, we define the p-stretch of an HTSD for edge e as $\left(\frac{d_i}{\ell_e}\right)^p$, where i is the level on which e is decoupled.*

Note that the 1-stretch coincides with the definition of the standard stretch defined at the beginning of this section. Our constructions meet a stronger bound of $O(\log n)$ on the p-stretch for $p < 1$, owed to the fact that for $p < 1$ larger stretch is weighed less.

▶ **Lemma 24.** *For $p \in (0,1)$, the tree embeddings presented in Sections 5.2 and 5.3 satisfy that for each edge $e \in E$ the expected p-stretch is $O(\log n)$.*

Proof. When bounding the stretch in the proof of Theorem 16, we summed over all levels of the decomposition. Recall that the probability to decouple edge e on level i is, by Corollary 15, $O\left(\frac{\ell_e \cdot \log n}{d_i}\right)$. Denote by i_e the level such that $d_{i_e} \leq \ell_e < 2d_{i_e}$. If $i > i_e$, then the stretch of e w.r.t. the HTSD is smaller than 1. For $p < 1$, the sum now can thus be bounded as

$$\begin{aligned}\sum_{i=1}^{k} O\left(\frac{\ell_e \cdot \log n}{d_i}\right) \cdot \left(\frac{d_i}{\ell_e}\right)^p &= O\left(1 + \log n \cdot \left(\frac{\ell_e}{d_{i_e}}\right)^{1-p} \cdot \sum_{i=1}^{i_e} \left(\frac{d_{i_e}}{d_i}\right)^{1-p}\right)\\ &= O\left(1 + \log n \cdot \sum_{i=1}^{i_e} \left(\frac{1}{2}\right)^{(1-p)(i_e-i)}\right)\\ &= O(\log n),\end{aligned}$$

where the final step exploits that the sum is a geometric series due to $1 - p > 0$. ◀

6 Implementation in Different Models

In this section, we describe how to implement the above techniques in the CONGEST, PRAM, and multipass streaming models. These should be considered as exemplary computational models and it seems likely that our techniques transfer to other models in which a discrepancy between exact and approximate SSSP computations exist. Under the CONGEST model, some

effort is needed in order to transfer the $(1+\varepsilon)$-approximate SSSP result to $(1+\varepsilon)$-approximate SSSP in super-source graphs (see Definition 2); this transformation is immediate under the PRAM and multipass streaming models.

For simplicity, we assume throughout this section that the edge lengths in the input graph $G = (V, E, \ell)$ are integers in the range $[1, n^{O(1)}]$. This means, in particular, that we do not have to worry about 0-length edges in the blurring procedure (Algorithm 1).

6.1 CONGEST Model

In the CONGEST model of computation [44], every node is a computing unit (of unlimited computational power) and is labeled by a unique $O(\log n)$-bit identifier. Computation proceeds in synchronous rounds, in each of which a node (1) performs local computations, (2) sends $O(\log n)$-bit messages to its neighbors, and (3) receives the messages that its neighbors sent. Initially, every node in the input graph $G = (V, E, \ell)$ knows its identifier and its incident edges together with their length. We note that the restriction to polynomially bounded edge lengths implies that distances can be encoded using $O(\log n)$ bits.

At termination every node needs to know its part of the output. For the task of constructing the random TSD, this means that every node $v \in V$ knows (1) the ID of its own cluster's leader (i.e., the vertex with minimum ID, see Section 5.2); (2) the ID of the leader of cluster C if $v \in U_C$, that is, if v participates in the supporting tree T_C of cluster C; and (3) its incident edges in T_C for each supporting tree T_C in which v participates. For the task of constructing the random HTSD, v should hold that knowledge for every level of the hierarchy. As discussed in Section 5, this also provides the nodes with all what they need in order to reconstruct the resulting projected tree or HST.

In order to avoid confusion with the weighted diameter $\mathrm{diam}(G)$, in what follows, we use $\mathrm{hop}(G)$ to denote the "unweighted" diameter of G, also called the *hop diameter*.

The following corollary discusses how to compute $(1+\varepsilon)$-approximate SSSP in a super-source graph H of a graph G in the CONGEST model. We assume that each node $v \in V$ initially knows which of its incident edges in G are in H, whether it is connected to s, and, if so, the length $\ell(\{s, v\})$.

▶ **Corollary 25** (of [12]). *Let $\varepsilon = \frac{1}{\mathrm{polylog}\, n}$. Then $(1+\varepsilon)$-approximate SSSP in super-source graphs can be solved in $\tilde{O}(\sqrt{n} + \mathrm{hop}(G))$ rounds w.h.p. in the* CONGEST *model.*

Proof. The algorithm from [12] consists of three main steps:

1. Let S be a set composed of s and $\tilde{\Theta}(\sqrt{n})$ nodes sampled uniformly at random. Let each node $v \in S$ learn a $(1+\frac{\varepsilon}{3})$-approximation to the minimum length of $\tilde{O}(\sqrt{n})$-hop paths to each sampled node $w \in S$ (if no such node exists, any result of at least $d(v, w)$ is fine, including ∞). For each finite value, nodes on a (unique) path in G learn about them being part of this path and the next node on it.
2. Simulate a broadcast congested clique[5] $(1+\varepsilon/3)$-approximate SSSP algorithm on the (virtual) graph on S with edge lengths given by the result from the previous step (∞ means no edge).
3. Run $\tilde{O}(\sqrt{n})$ iterations of single source Bellman-Ford on G, where the distance values of nodes in S are initialized to the distances obtained from the previous step.

[5] The broadcast congested clique is the special case of the Congest model restricted to complete graphs and, for each round, nodes sending the same message to each of their neighbors.

Assuming w.l.o.g. that $\varepsilon \leq 1$, this yields $(1+\varepsilon)$-approximate distances to s. As the first step yields suitable routing information and the result of the second (i.e., an approximate SSSP-tree on the virtual graph) is global knowledge, nodes can locally determine their parent in the output tree T.

We adapt the algorithm to super-source graphs as follows.

1. The first step is based on a pipelined version of the (multi-source) Bellman-Ford algorithm that also works on directed graphs [39, Corollary 5.8]. Formally, we orient all edges of s towards it (no other change is made). Then we can easily simulate the procedure on the resulting graph, as all communication by s over one of its edges can be inferred from its length (which is known to the recipient).
   Note that the result is not exactly the same as that of the first step above: all paths containing s as non-starting node have been removed. However, the decisive property of the constructed graph is that it preserves G-distances to s up to a factor of $1+\varepsilon$. The virtual graph also needs to be undirected, which is achieved by dropping the directionality of the computed distances.
2. The simulation of the broadcast congested clique algorithm in the Congest model is based on making all communication global knowledge. Using pipelining over a BFS tree, the input of s in the virtual graph (i.e., its incident edges and their lengths) can be made global knowledge in $\tilde{O}(\sqrt{n}+\mathrm{hop}(G))$ rounds. Together, this implies that all nodes can locally simulate s.
3. Simulating the communication by s in the third step of the algorithm, which is a standard Bellman-Ford computation, is straightforward.

As all steps can be adjusted preserving the guarantees of the algorithm and the asymptotic running time is increased by additive $\tilde{O}(\sqrt{n}+\mathrm{hop}(G))$ only, the result now follows from [12]. ◀

This leads to the following result for Algorithm 1 from Section 3. As it is basically a sequence of approximate SSSP computations, a running time bound is immediate from Corollary 25.

▶ **Corollary 26.** *Suppose* $\alpha = \frac{1}{\mathrm{polylog}\, n}$ *and* $\rho = n^{O(1)}$. *Then Algorithm 1 can be executed in the* CONGEST *model in* $\tilde{O}(\sqrt{n}+\mathrm{hop}(G))$ *rounds w.h.p.*

Proof. The while loop terminates after at most $\lceil \log_{1/\alpha} \rho = O(\log n) \rceil$ iterations. In each iteration, $r^{[i]}$ can be chosen by an arbitrary node (e.g. the one with lowest identifier) and broadcasted via a BFS tree in $O(\mathrm{hop}(G))$ rounds. Each node then can infer from the result from the previous iteration (or the input if $i=1$) whether it is part of $B^{[i-1]}$. Nodes adjacent to $B^{[i-1]}$ can learn about this in one communication round and infer the length of the edge connecting them to $s^{[i]}$ in $G^{[i]}$. Thus, all that remains is the approximate SSSP computation, which can be performed in the stated running time by Corollary 25 w.h.p. The $\tilde{O}$-notation absorbs the $O(\log n)$-factor from the number of loop iterations. ◀

We turn to Algorithm 2 from Section 4. As each iteration can be performed within $\tilde{O}(\sqrt{n}+\mathrm{hop}(G))$ rounds w.h.p., this implies a bound on the running time of the overall algorithm.

▶ **Corollary 27.** *There exists a (randomized)* CONGEST *algorithm that given a graph* $G=(V,E,\ell)$ *with* $\mathrm{poly}(n)$*-bounded edge lengths and a real parameter* $\Delta > 0$*, constructs a random TSD* D *of* G *with the following guarantees in* $\tilde{O}(\sqrt{n}+\mathrm{hop}(G))$ *rounds w.h.p.: (1)* $\mathrm{diam}(D) \leq \Delta$ *w.h.p.; (2)* $\max_{e\in E}\{\mathrm{load}_D(e)\} \leq O(\log n)$ *w.h.p.; and (3)* $\Pr\left[e \in E^{\mathrm{cut}}(D)\right] \leq O\left(\frac{\ell_e \cdot \log n}{\Delta}\right)$ *for every edge* $e \in E$.

Proof. All computations in Algorithm 2 with the exception of the approximate SSSP computations and the call to `blur` are local. By Corollary 26, the stated running time bound follows for a single iteration of the while loop. Here we use that the instances of `blur` can be run in parallel by Lemma 13: As $C_u \subseteq V_u$, we can delete all edges which are not connecting two nodes within the same V_u for some u and then run a single $(1+\varepsilon)$-approximate SSSP instance, where we identify the super-sources of all calls to `blur`. Therefore, Corollary 12 and a union time bound yield the claim. ◀

We now turn to the techniques from Section 5. As the recursive calls for each level of the decomposition hierarchy when computing an HTSD can be executed concurrently with a single call to the approximate SSSP subroutine, we obtain the following result.

▶ **Corollary 28.** *There exists a (randomized)* CONGEST *algorithm that, given a graph $G = (V, E, \ell)$ with $\mathrm{poly}(n)$-bounded edge lengths, constructs a random HTSD $\mathbf{D}$ of G with the following guarantees in $\tilde{O}(\sqrt{n} + \mathrm{hop}(G))$ rounds w.h.p.: (1) the depth of $\mathbf{D}$ is $O(\log n)$; (2) $\mathbf{D}$ admits a (deterministic) geometrically decreasing diameter bounding sequence $\mathbf{d}$ w.h.p.; (3) $\mathrm{load}_{\mathbf{D}}(e) = O(\log n)$ for every edge $e \in E$ w.h.p.; and (4) $\mathbb{E}_{\mathbf{D}}[\mathrm{str}_{\mathbf{D},\mathbf{d}}(e)] = O(\log^2 n)$ for every edge $e \in E$.*

Proof. For each of the $O(\log n)$ levels of the decomposition, the recursive SSSP calls for each of the clusters can be merged into a single one by identifying their super-sources. The claim hence follows from Theorem 16 and Corollary 27. ◀

From the hierarchical decomposition, we obtain embeddings into projected trees and hierarchically 2-separated trees as described in Sections 5.2 and 5.3.

▶ **Corollary 29.** *There exists a (randomized)* CONGEST *algorithm that, given a graph $G = (V, E, \ell)$ with $\mathrm{poly}(n)$-bounded edge lengths, constructs a random projected tree T of G in $\tilde{O}(\sqrt{n} + \mathrm{hop}(G))$ rounds that satisfies the following guarantees for every edge $e \in E$: (1) $\mathrm{load}_T(e) = O(\log n)$ w.h.p.; and (2) $\mathbb{E}_T[\mathrm{str}_T(e)] = O(\log^2 n)$.*

Proof. We obtain an HTSD using Corollary 28. Inspection of the construction in Section 5.2 reveals that all operations are local once we identify the leaders of clusters. This is, e.g., achieved by rooting all supporting trees at the respective cluster's leader, which can be done by using the Garay-Kutten-Peleg minimum spanning tree algorithm [27, 38] to compute a spanning forest of H. As the load of each edge is $O(\log n)$, the algorithm on H can be simulated at a multiplicative overhead of $O(\log n)$, resulting in running time $\tilde{O}(\sqrt{n} + \mathrm{hop}(G))$. ◀

▶ **Corollary 30.** *There exists a (randomized)* CONGEST *algorithm that, given a graph $G = (V, E, \ell)$ with $\mathrm{poly}(n)$-bounded edge lengths, constructs an embedding into a random dominating hierarchically 2-separated tree T of G in $\tilde{O}(\sqrt{n} + \mathrm{hop}(G))$ rounds with expected stretch $\mathbb{E}_T[\mathrm{str}_T(e)] = O(\log^2 n)$ for each edge $e \in E$.*

Proof. Analogous to Corollary 29. ◀

6.2 PRAM Model

In the PRAM model, multiple processors share a random access memory to jointly solve a computational problem. Various contention models exist for concurrent access to the same memory cell by multiple processors, but are equivalent up to small (sub-logarithmic) factors in complexity, so we assume that there is no contention. Then we can view the computation as a DAG whose nodes represent elementary computational steps and edges

dependencies. The input is represented by the sources of the DAG. The crucial complexity measures are *work*, the total size of the DAG (or, equivalently, the sequential complexity of the computation) and *depth*, the maximum length of a path in the DAG (or, equivalently, the time to complete the computation with an unbounded number of processors executing steps at unit speed).

We use a result on approximate SSSP computations due to Cohen, who introduced hop sets for this purpose. Following standard notation, we use $m := |E|$, where $G = (V, E, \ell)$ is the input graph.

▶ **Corollary 31** (of [14, 20]). *Let $\varepsilon_0 > 0$ be a constant and $\varepsilon = \frac{1}{\operatorname{polylog} n}$. Then $(1+\varepsilon)$-approximate SSSP in super-source graphs can be solved in $O(m^{1+\varepsilon_0})$ work and $\operatorname{polylog} n$ time w.h.p.*

We remark that the assumption that the graph G is connected implies $m^{\varepsilon_0} \geq \Omega(n^{\varepsilon_0})$ and thus the term m^{ε_0} can absorb $\operatorname{polylog} n$ factors.

Following the same route as for the CONGEST model, we obtain a string of corollaries. As coordination between processes is easier in the PRAM model, in most cases the results are immediate.

▶ **Corollary 32.** *Suppose $\alpha = \frac{1}{\operatorname{polylog} n}$, $\rho = n^{O(1)}$, and ε_0 is a constant. Then Algorithm 1 can be executed in the PRAM model with depth $\operatorname{polylog} n$ and work $O(m^{1+\varepsilon_0})$ w.h.p.*

▶ **Corollary 33.** *Fix any constant $\varepsilon_0 > 0$. There exists a (randomized) PRAM algorithm of depth $\operatorname{polylog} n$ and work $O(m^{1+\varepsilon_0})$ that, for a graph $G = (V, E, \ell)$ with $\operatorname{poly}(n)$-bounded edge lengths and a real parameter $\Delta > 0$, constructs a random TSD D of G with the following guarantees: (1) $\operatorname{diam}(D) \leq \Delta$ w.h.p.; (2) $\max_{e \in E}\{\operatorname{load}_D(e)\} \leq O(\log n)$ w.h.p.; and (3) $\Pr[e \in E^{\mathrm{cut}}(D)] \leq O\left(\frac{\ell_e \cdot \log n}{\Delta}\right)$ for every edge $e \in E$.*

Combining this corollary with Theorem 16, we obtain the following result.

▶ **Corollary 34.** *Fix any constant $\varepsilon_0 > 0$. There exists a (randomized) PRAM algorithm of depth $\operatorname{polylog} n$ and work $O(m^{1+\varepsilon_0})$ that, for a graph $G = (V, E, \ell)$ with $\operatorname{poly}(n)$-bounded edge lengths, constructs a random HTSD $\mathbf{D}$ of G with the following guarantees w.h.p.: (1) the depth of $\mathbf{D}$ is $O(\log n)$; (2) $\mathbf{D}$ admits a (deterministic) geometrically decreasing diameter bounding sequence $\mathbf{d}$ w.h.p.; (3) $\operatorname{load}_{\mathbf{D}}(e) = O(\log n)$ for every edge $e \in E$ w.h.p.; and (4) $\mathbb{E}_{\mathbf{D}}[\operatorname{str}_{\mathbf{D},\mathbf{d}}(e)] = O(\log^2 n)$ for every edge $e \in E$.*

▶ **Corollary 35.** *Fix any constant $\varepsilon_0 > 0$. There exists a (randomized) PRAM algorithm of depth $\operatorname{polylog} n$ and work $O(m^{1+\varepsilon_0})$ that, given a graph $G = (V, E, \ell)$ with $\operatorname{poly}(n)$-bounded edge lengths, constructs a random projected tree T of G that satisfies the following guarantees for every edge $e \in E$: (1) $\operatorname{load}_T(e) = O(\log n)$ w.h.p.; and (2) $\mathbb{E}_T[\operatorname{str}_T(e)] = O(\log^2 n)$.*

Proof. Again, the main step after obtaining an HTSD is to identify cluster leaders. This can be easily done by pointer jumping within the stated complexity bounds. ◀

▶ **Corollary 36.** *Fix any constant $\varepsilon_0 > 0$. There exists a (randomized) PRAM algorithm of depth $\operatorname{polylog} n$ and work $O(m^{1+\varepsilon_0})$ that, given a graph $G = (V, E, \ell)$ with $\operatorname{poly}(n)$-bounded edge lengths, constructs an embedding into a random dominating hierarchically 2-separated tree T of G with expected stretch $\mathbb{E}_T[\operatorname{str}_T(e)] = O(\log^2 n)$ for each edge $e \in E$.*

6.3 Semi-Streaming Model

In the *streaming model* [32, 41], the input graph is given as a stream of edges without repetitions. The performance of an algorithm is measured by the space it uses, whereby space is organized in memory words of $O(\log n)$ bits. In the *multipass streaming model*, the input is presented to the algorithm in several such passes, and the goal is to keep both the number of required passes and the space consumption small. For algorithms for graph problems, it is usual to assume arbitrary arrival order of the edges. The special case where the computational problem takes an n-vertex graph as input and the amount of memory is $\tilde{O}(n)$ is also known as the *semi-streaming model* [23]. All our results in this subsection are for this setting.

▶ **Corollary 37** (of [12]). *In the semi-streaming model, $(1+\varepsilon)$-approximate SSSP in super-source graphs can be solved in* $\operatorname{polylog} n$ *passes w.h.p. for any* $\varepsilon = \frac{1}{\operatorname{polylog} n}$.

All computational steps that are not SSSP computations can be either directly executed in memory (because only graphs of size $\tilde{O}(n)$ are involved) or easily performed by storing $\operatorname{polylog} n$ words for each node and streaming once (e.g., finding cluster leaders). Thus, corollaries analogous to the CONGEST and PRAM models are immediate.

▶ **Corollary 38.** *Suppose* $\alpha = \frac{1}{\operatorname{polylog} n}$, $\rho = n^{O(1)}$. *Then Algorithm 1 can be executed in the semi-streaming model with* $\operatorname{polylog} n$ *passes w.h.p.*

▶ **Corollary 39.** *There exists a (randomized) semi-streaming algorithm that given a graph $G = (V, E, \ell)$ with* $\operatorname{poly}(n)$*-bounded edge lengths and a real parameter $\Delta > 0$, constructs a random TSD D of G with the following guarantees in* $\operatorname{polylog} n$ *passes w.h.p.: (1)* $\operatorname{diam}(D) \leq \Delta$ *w.h.p.; (2)* $\max_{e \in E}\{\operatorname{load}_D(e)\} \leq O(\log n)$ *w.h.p.; and (3)* $\Pr[e \in E^{\text{cut}}(D)] \leq O\left(\frac{\ell_e \cdot \log n}{\Delta}\right)$ *for every edge $e \in E$.*

▶ **Corollary 40.** *There exists a (randomized) semi-streaming algorithm that given a graph $G = (V, E, \ell)$ with* $\operatorname{poly}(n)$*-bounded edge lengths, constructs a random HTSD $\mathbf{D}$ of G with the following guarantees in* $\operatorname{polylog} n$ *passes w.h.p.: (1) the depth of $\mathbf{D}$ is $O(\log n)$; (2) $\mathbf{D}$ admits a (deterministic) geometrically decreasing diameter bounding sequence $\mathbf{d}$ w.h.p.; (3)* $\operatorname{load}_{\mathbf{D}}(e) = O(\log n)$ *for every edge $e \in E$ w.h.p.; and (4)* $\mathbb{E}_{\mathbf{D}}[\operatorname{str}_{\mathbf{D},\mathbf{d}}(e)] = O(\log^2 n)$ *for every edge $e \in E$.*

Corollary 40 readily implies semi-streaming algorithms that construct low stretch projected trees and dominating hierarchically 2-separated trees in $\operatorname{polylog} n$ passes w.h.p. However, one can, in fact, obtain such constructions in a single pass by (i) partitioning the edges to ($O(\log n)$ many) length classes; (ii) using known techniques to construct a spanner with $O(n)$ edges and $O(\log n)$ stretch for each length class; and (iii) construct the desired low stretch trees for the graph obtained from the union of these spanners in an offline fashion, observing that this graph has $O(n \log n)$ edges.[6]

7 Related Work

Low diameter graph decompositions with small edge cutting probabilities (or with small weight) play a major role in many algorithmic applications. These include the construction of low stretch spanning trees [2, 3, 4, 11, 18] and low distortion probabilistic embeddings of

[6] We thank an anonymous ITCS 2020 reviewer for pointing out this simple alternative construction.

metric spaces into hierarchically well-separated trees [7, 8, 9, 22], fast approximate solvers of symmetric diagonally dominant linear systems [15, 36, 37, 47], constructing graph spanners [42, 45], and spectral sparsification [33, 35]. The literature in this field being vast, we can only give an incomplete review of it. We first focus on related work in distributed and parallel models of computation, as these results are closest to ours, and then turn to the related work in the streaming model. Our discussion of the related work in the former models starts with reviewing the literature on low diameter graph decompositions, and then it turns to their applications, focusing on low average stretch spanning trees and tree embeddings.

Low Diameter Graph Decompositions

In the LOCAL and CONGEST models of distributed computation[7] low diameter graph decompositions for unweighted graphs, i.e., $G = (V, E, \mathbb{1})$, play a special role as they can be leveraged to design fast algorithms for a large class of problems. More precisely, the decomposition task is complete for a certain class of local problems [30], where a problem is called local if it does not require $\Omega(\mathrm{hop}(G))$ rounds of communication (recall the definition of the hop diameter $\mathrm{hop}(G)$ from Section 6.1). Here, $\mathrm{hop}(G)$ is of relevance even in problems where the input graph is weighted, as communication over large hop distances is an inherent obstacle to small running times in distributed algorithms.

Several distributed decomposition algorithms with round complexities of $\mathrm{polylog}\, n$ and small edge cut probabilities are known for the unweighted case [19, 40, 43].[8] However, the weighted setting considered in this work is fundamentally different. A lower bound of $\mathrm{hop}(G)$ is trivial, i.e., the task is not local: intuitively, decoupling hop distance from graph distance implies that finding close-by nodes may require communication over $\mathrm{hop}(G)$ hops. In the LOCAL model, this bound is trivially tight, as nodes can learn about the entire graph in $\mathrm{hop}(G)$ rounds. In the CONGEST model, a reduction from 2-party communication complexity shows a lower bound of $\Omega\left(\frac{\sqrt{n}}{\log n}\right)$ rounds for computing an (r, λ)-decomposition for any non-trivial values of r and λ. This lower bound even holds if $\mathrm{hop}(G) = O(\log n)$ [46].[9]

Miller et al. [43] show how to compute low diameter graph decomposition with small edge cutting probabilities in unweighted graphs in the PRAM model. Their approach relies on exact SSSP computations. Given the current discrepancy in the state of the art of exact and approximate SSSP in the PRAM model, it thus cannot lead to satisfying bounds in the weighted setting.

Low Stretch Spanning Trees

Nevertheless, there has been some work applying decompositions in the vein of Miller et al. in order to obtain low average stretch[10] spanning trees for weighted graphs. A construction by Alon et al. [4] reduces weighted graphs to unweighted (multi)graphs. As a result Blelloch et al. [13] were able to give an efficient PRAM construction of low stretch spanning trees based on the decomposition technique by Miller et al. As shown by Blelloch et al., computation

[7] See Section 6.1 for the formal definition of CONGEST. The LOCAL model is identical, except that it does not restrict message sizes to $O(\log n)$.

[8] Some works only care about the chromatic number of the graph resulting from contracting clusters. However, the cited works achieve this by cutting few edges only.

[9] A low-diameter decomposition can be used to determine whether or not there is a light s-t cut in the family of lower bound graphs from [46]; s and t end up in the same cluster if and only if there is no light cut between them, as otherwise their distance is large.

[10] The ratio of distance in the tree to edge length, averaged over all edges.

of such trees is of use for efficient PRAM solvers for symmetric diagonally dominant linear systems. A similar connection was exploited by Ghaffari et al. [29], who transferred the approach of Blelloch et al. to the CONGEST model, obtaining a low average stretch tree construction that they leveraged for approximate maximum flow computations. A downside of the aforementioned approaches is that the construction by Alon et al. suffers from a poor average stretch of $2^{\Theta(\sqrt{\log n \log\log n})}$, resulting in respective overheads in work and depth resp. round complexity in the two models when applying the computed trees in further computations.

For the CONGEST model, Becker et al. [11] gave a construction of low-average stretch spanning trees that combines the decomposition technique of Miller et al. with the star decomposition technique of Elkin et al. [18]. This approach achieves polylog n average stretch. Again, the complexity of their approach is essentially determined by an exact SSSP computation. Thus, the resulting algorithm is round-optimal up to polylogarithmic factors in the unweighted case (i.e., the running time is $\mathrm{hop}(G)\,\mathrm{polylog}\, n$), while essentially matching the round complexity of exact SSSP in the weighted case. Exact SSSP computation in the CONGEST model is still not too well understood, with the best upper bound of $\tilde{O}(\min\{\sqrt{n\,\mathrm{hop}(G)}, \sqrt{n}\,\mathrm{hop}(G)^{1/4} + n^{3/5} + \mathrm{hop}(G)\})$ [25] still being polynomially far from the $\tilde{\Omega}(\sqrt{n} + \mathrm{hop}(G))$ lower bound.

Tree Embeddings

We apply our decomposition technique in order to obtain a metric tree embedding, following the same route as Bartal [7], obtaining the same $O(\log^2 n)$ bound on the expected stretch (note that the bound in [7] holds for any edge lengths whereas in the current paper, we make the simplifying assumption that the ratio of the maximum to minimum edge length is $\mathrm{poly}(n)$). Bartal later improved this bound to $O(\log n \log\log n)$ [8] and subsequently to asymptotically optimal $O(\log n)$ [9]. Although we cannot readily apply the same techniques, Bartal's work suggests that future improvements to our stretch bound are feasible.

Fakcharoenphol et al. [22] achieved the $O(\log n)$ stretch bound earlier, following a different approach in which the graph is not (explicitly) decomposed. However, at its core the main idea is very similar: randomization is leveraged to keep the probability of "cutting" edges proportional to their length based on the subtractive form of the triangle inequality. Also here, PRAM and CONGEST algorithms have been developed that try to mitigate the bottleneck imposed by exact SSSP computations. In the CONGEST model, it is straightforward to implement the algorithm from [22] with a round complexity that is (up to a factor of $O(\log n)$) equal to the running time of the Bellman-Ford algorithm [34]. However, shortest paths may have hop length up to $n-1$, resulting in a running time far from the $\tilde{\Omega}(\sqrt{n} + \mathrm{hop}(G))$ lower bound. Ghaffari and Lenzen broke down shortest paths by sampling a "skeleton" of $\tilde{\Theta}(\sqrt{n})$ nodes uniformly, computing a spanner (refer to the sequel of this section for the definition of a spanner) of a graph representing the induced metric, computing a tree embedding of this spanner, and finally extending this embedding to one of the original graph with modified weights via a Bellman-Ford computation. This can be seen as distorting the original distance metric such that it becomes sufficiently simple to solve exact SSSP fast, resulting in a round complexity of $\tilde{O}(n^{0.5+\varepsilon} + \mathrm{hop}(G))$ for stretch $O(\varepsilon^{-1}\log n)$. In particular, by setting $\varepsilon = \frac{1}{\log n}$, the stretch and running time bounds match our results. However, Ghaffari and Lenzen do not guarantee bounded load. We also note that their approach is inherently limited to stretch $\Omega(\log^2 n)$ when requiring a running time bound within polylog n of the lower bound, as both spanners with a near-linear number of edges and metric tree embedding must incur $\Omega(\log n)$ stretch each.

Friedrichs and Lenzen [26] provide fast PRAM and CONGEST algorithms for tree embeddings with stretch $O(\log n)$. The main difference to [31] is the use of hop sets [14] to provide "shortcuts" for distance computation that are not present in the original graph. Again, distances are then distorted by metric embeddings such that exact distance computation by a Bellman-Ford style computation becomes efficient. This leads to a $2^{O(\sqrt{\log n})}(\sqrt{n} + \mathrm{hop}(G))$-round algorithm in CONGEST and a PRAM algorithm of depth $\mathrm{polylog}\, n$ and work $O(m^{1+\varepsilon})$ (for any fixed constant $\varepsilon > 0$), where m is the number of edges and $\Omega(m)$ a trivial lower bound on the work. While the stretch guarantee is better than in our case, it should be noted that also here fundamental barriers limit this technique: lower bounds on the size of hop sets due to Abboud et al. [1] imply that any hop-set based approach must incur running time resp. work overheads of $2^{\Omega(\sqrt{\log n})}$. Although in the PRAM model we suffer the same work overhead by relying on hop-sets for the currently best known approximate SSSP algorithms [14, 20], our result shows that one can trade the additional log-factor in stretch for a logarithmic load bound that the method of Friedrichs and Lenzen cannot guarantee.

Streaming Algorithms

To the best of our knowledge, constructions of low diameter decompositions with small edge cutting probabilities have not been addressed so far in the semi-streaming literature. A related graph theoretic object whose construction has been studied in the context of streaming algorithms is *spanners*. Similarly to low (average) spanning trees, spanners also provide a sparse distance preserving representation of the graph, only that they are not required to be trees. On the other hand, their notion of distance preservation is stronger in the sense that it is required to hold in the worst case, rather than on average. Specifically, a κ-spanner of graph $G = (V, E, \ell)$ is a spanning subgraph of G that guarantees a stretch bound of at most κ for every edge in E. One is typically interested in constructing κ-spanners with a small number of edges, where $O(n^{1+2/(\kappa+1)})$ edges is the asymptotically tight bound. Streaming constructions of sparse spanners exist only for unweighted graphs [10, 17, 23], as there, the distance computations are typically restricted to the sparse subgraph maintained by the algorithm. A related notion in unweighted graphs, which has also been studied in the streaming literature [21], is an (α, β)-spanner, where the distance between vertices $u, v \in V$ in the spanner is required to be at most $\alpha \cdot \mathrm{d}_G(u, v) + \beta$ for every $u, v \in V$.

Abstract

This paper concerns itself with the question of list decoding for *general adversarial channels*, e.g., bit-flip (XOR) channels, erasure channels, AND (Z-) channels, OR (Σ-) channels, real adder channels, noisy typewriter channels, etc. We precisely *characterize* when exponential-sized (or positive *rate*) $(L-1)$-*list decodable* codes (where the *list size* L is a universal constant) exist for such channels. Our criterion essentially asserts that:

> For any given general adversarial channel, it is possible to construct positive rate $(L-1)$-list decodable codes *if and only if* the set of *completely positive tensors* of order-L with admissible marginals is not entirely contained in the order-L *confusability set* associated to the channel.

The sufficiency is shown via random code construction (combined with expurgation or time-sharing). The necessity is shown by

1. extracting approximately equicoupled subcodes (generalization of equidistant codes) from *any* sequence of "large" codes using hypergraph Ramsey's theorem, and
2. significantly extending the classic *Plotkin bound* in coding theory to list decoding for general channels using duality between the completely positive tensor cone and the *copositive* tensor cone.

In the proof, we also obtain a new fact regarding asymmetry of joint distributions, which may be of independent interest.

Other results include

1. List decoding capacity with asymptotically large L for general adversarial channels;
2. A *tight* list size bound for *most constant composition* codes (generalization of constant weight codes);
3. Rederivation and demystification of Blinovsky's [9] characterization of the list decoding *Plotkin points* (threshold at which large codes are impossible) for bit-flip channels;
4. Evaluation of general bounds ([43]) for *unique decoding* in the error correction code setting.

1 Warmup

In favour of motivating general problems, introducing general notions and stating our general theorems, we first go through concrete numerical examples that are special cases of our results.

Suppose Alice can transmit a length-n bit string (*codeword*) to Bob and an adversary James can flip np $(0 \leqslant p \leqslant 1)$ of these bits. Consider first the classic coding theory question.

1. **Error correction.** For what values of p, can one construct a *code* (collection of codewords) of *positive rate* (i.e., codebook size at least 2^{Rn} for some constant $1 \geqslant R > 0$) such that Bob can uniquely decode? The classic Plotkin bound [33] tells us that this is impossible for $p > 1/4$,[1] and the classic Gilbert–Varshamov (GV) bound [22, 42] tells us that this is possible for $p < 1/4$.
2. **List decoding.** For what values of p, can one construct a code of positive rate such that it is *3-list decodable* (i.e., regardless of which np bits James flips, Bob can always decode the received word to a *list* of at most 3 codewords, one of which is the codeword transmitted by Alice)?[2] Due to work by Blinovsky, it is known that this is possible if and only if $p \leqslant 5/16$.[3]

In this work, not only are we are able to rederive all the above thresholds, but are also able to derive the corresponding thresholds for a vast variety of *general adversarial channels* such as bit-flip channels, erasure channels, AND (Z-) channels, OR (Σ-) channels, adder channels, noisy typewriter channels, etc..

In this section, let us revisit the answers to questions 1 and 2 in the technical language we develop in this paper.

1. **Error correction.** Consider any pair of codewords $\underline{x}_1, \underline{x}_2$ that are resilient to np bit-flips. They must therefore be at a Hamming distance larger than $2np$. Said differently, the *joint type* (i.e., the 2×2 matrix whose (x_1, x_2)-th, $x_1, x_2 \in \{0, 1\}$, entry is the fraction of locations i of $(\underline{x}_1, \underline{x}_2)$ such that $\underline{x}_1(i) = x_1$ and $\underline{x}_2(i) = x_2$) $\tau_{\underline{x}_1, \underline{x}_2} = \begin{bmatrix} t(0,0) & t(0,1) \\ t(1,0) & t(1,1) \end{bmatrix}$ of these two codewords must satisfy the condition that

   C1 $t(0,1) + t(1,0) \geqslant 2p$.

[1] Actually for $p = 1/4$ this is still impossible.
[2] Note that a 1-list decodable code is exactly a uniquely decodable code (or more commonly called an *error correction code*).
[3] In fact Blinovsky identified the threshold p up to which positive rate $(p, L-1)$-list decodable codes exist for *any* integer $L \geqslant 2$. This, in particular, recovers the Plotkin bound.

a. In [9, 34, 2][4] and [43], it was shown that: if a code $\mathcal{C}$ of size 2^{Rn} exists, then there must exist a *positive rate* subcode $\mathcal{C}' \subset \mathcal{C}$ such that for *every* pair of codewords $\underline{x}_1, \underline{x}_2$ in $\mathcal{C}'$, their joint type is approximately the same (as, say, $P_{\mathbf{x}_1,\mathbf{x}_2}$).

b. In [43], it was shown that: it is possible to construct positive rate codes with joint types (close to) $P_{\mathbf{x}_1,\mathbf{x}_2}$ if and only if $P_{\mathbf{x}_1,\mathbf{x}_2}$ is a *completely positive (*CP*)* distribution, i.e., $P_{\mathbf{x}_1,\mathbf{x}_2}$ can be written as a convex combination of products of independent and identical distributions,

$$P_{\mathbf{x}_1,\mathbf{x}_2} = \sum_{i=1}^{k} \lambda_i P_{\mathbf{x}_i} P_{\mathbf{x}_i}^{\top},$$

for some positive integer k, convex combination coefficients $\{\lambda_i\}_{1\leqslant i\leqslant k}$ and probability vectors $\{P_{\mathbf{x}_i}\}_{1\leqslant i\leqslant k}$. For example,

$$\lambda \begin{bmatrix} 1/2 & 0 \\ 0 & 1/2 \end{bmatrix} + (1-\lambda) \begin{bmatrix} 1/4 & 1/4 \\ 1/4 & 1/4 \end{bmatrix} \tag{1}$$

is CP for $\lambda \in [0,1]$ since it can be written as $\frac{\lambda}{2}\begin{bmatrix}1\\0\end{bmatrix}\begin{bmatrix}1 & 0\end{bmatrix} + \frac{\lambda}{2}\begin{bmatrix}0\\1\end{bmatrix}\begin{bmatrix}0 & 1\end{bmatrix} + (1-\lambda)\begin{bmatrix}1/2\\1/2\end{bmatrix}\begin{bmatrix}1/2 & 1/2\end{bmatrix}$. One can check that for $\lambda < 0$, matrix (1) is not CP. For condition **C1** to be satisfied by some CP distribution, it must be the case that $2p \leqslant 2\cdot(1-\lambda)\cdot(1/4)$ for some $\lambda \in [0,1]$. This is impossible if $p > 1/4$. As a consequence, the classic Plotkin bound is recovered in this convex geometry language, since the non-CP matrices of the form (1) with *negative* λ correspond to codes with minimum pairwise fractional distance $\frac{1+|\lambda|}{2}$ (hence correspond to $p = \frac{1+|\lambda|}{4} > 1/4$), which, by the Plotkin bound, cannot have positive rate.

2. **List decoding.** Now let us move to the list decoding question in hands. For a code to be 3-list decodable, it must be the case that for any quadruple $\underline{x}_1, \underline{x}_2, \underline{x}_3, \underline{x}_4$, there is no $\underline{y}$ such that the Hamming distance from $\underline{x}_i$ to $\underline{y}$ is at most np for *every* $i \in \{1,2,3,4\}$. In this case, the appropriate object is therefore a $2\times2\times2\times2$ tensor (or a joint distribution of $(\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4)$) $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4}$ such that

C2 any of its *extension* $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4,\mathbf{y}}$ (i.e., a coupling of $(\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4)$ and $\mathbf{y}$, or a $2\times2\times2\times2\times2$ tensor such that $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4} = P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4,\mathbf{y}=0} + P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4,\mathbf{y}=1}$) satisfies the condition that $P_{\mathbf{x}_i,\mathbf{y}}(0,1) + P_{\mathbf{x}_i,\mathbf{y}}(1,0) > p$ for at least one $i \in \{1,2,3,4\}$.

a. Again, by [9, 34, 2] and our work, we can restrict our attention to codes in which every 4-tuple of codewords has joint type close to some $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4}$, since we can find such a subcode which is sufficiently large in *any* positive rate code.

b. Generalizing [43], we show that codes with order-4 joint types (close to) $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4}$ exist if and only if $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4}$ is a *completely positive tensor* of order-4, i.e., $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4}$ can be written as a convex combination of products of independent and identical distributions,

$$P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4} = \sum_{i=1}^{k} \lambda_i P_{\mathbf{x}_i}^{\otimes 4}.$$

[4] Their and our work showed that it is also possible to find a positive rate subcode such that every L-tuple of codewords has joint type close to some $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. This, as we shall see momentarily, is useful for list decoding.

One can check that distributions of the form

$$\lambda \operatorname{diag}(1/2) + (1-\lambda)\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes 4} = \frac{\lambda}{2}\begin{bmatrix}1\\0\end{bmatrix}^{\otimes 4} + \frac{\lambda}{2}\begin{bmatrix}0\\1\end{bmatrix}^{\otimes 4} + (1-\lambda)\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes 4}$$

is CP if and only if $\lambda \in [0,1]$. On the other hand, for condition **C2** to be satisfied by some tensor like that, it turns out, as shown by Blinovsky [9] and us, that p has to be no larger than 5/16.

Of course, bit-flips are just one of the simplest models of corruption that may occur in real-world communication/storage systems. Perhaps, under certain circumstances, in the system of interest, we are allowed to transmit length-n codewords taking values from $\{0,1,2,3,4,5\}$, but each legitimate codeword $\underline{x}$ has to satisfy the following constraints inherently associated to this communication system

$$\begin{cases} \tau_{\underline{x}}(1) + 3\tau_{\underline{x}}(3) \leqslant 1.2 \\ \tau_{\underline{x}}(2) - \tau_{\underline{x}}(3) \geqslant 0.05 \\ \tau_{\underline{x}}(0) - \tau_{\underline{x}}(4) - 0.2\tau_{\underline{x}}(5) \leqslant 0.7 \end{cases},$$

where $\tau_{\underline{x}}(x)$ denotes the fraction of $x \in \{0,1,\cdots,5\}$ in $\underline{x} \in \{0,1,\cdots,5\}^n$. An adversary is allowed to change symbols in the transmitted codeword only from small values to large values; the cost he pays by changing every i to j $(0 \leqslant i < j \leqslant 5)$ is $j-i$ dollars, and he has a budget of $2.3n$ dollars in total. Among others, one of the fundamental questions we are able to answer in this paper is the following: is it possible for us to design exponentially large codes such that no matter which codeword is transmitted and no matter how an adversary corrupts it via a legitimate action, the decoder is always able to output a list of at most (say) 10 codewords which contains the correct one?

The answer to the above question is affirmative and can be stated in a similar manner: it is possible if and only if there is a CP tensor of order 11 and dimension 6 which does not lie inside the *confusability set* determined by the channel. In particular, the confusability set is the set of joint distributions which fail to meet the conditions similar to **C1** or **C2** that are determined by the channel.

Our results tell us that if one only aims to search for exponentially large $(L-1)$-list decodable codes (instead of optimizing its size) for a given general adversarial channel, then it is *sufficient* (and obviously necessary) to restrict our attention to codes that are *chunk-wise random-like*. Such codes correspond to some CP distribution $\sum_{i=1}^{k}\lambda_i P_{\mathbf{x}_i}^{\otimes L}$. If a random code of positive rate, where the $\lambda_i n$ $(1 \leqslant i \leqslant k)$ components in the i-th chunk of each codeword are sampled from distribution $P_{\mathbf{x}_i}$, does not "work" with high probability (w.h.p.), then we can never find positive rate codes of any other form that "work" for the underlying channel.

By setting the *list size* $L-1=1$, results in [43] are recovered by our work.

2 Introduction

While the main contribution of this work is to strictly generalize notions that have been primarily studied for "Hamming metric" channels, before we precisely define general channels, let us reprise what is known for Hamming metric channels in this section.

2.1 Error correction and the Plotkin bound

The theory of error correction codes is about protecting data from errors. In classic coding theory, a code, say $\mathcal{C}$, is just a collection of binary *codewords* (which are usually just binary length-n sequences, where n is called the *blocklength*). The most well-studied error model is *bit-flip*. When a certain codeword is transmitted, an adversary can arbitrarily flip at most np $(0 \leqslant p \leqslant 1)$ bits. It is easy to see that two codewords are not *confusable* if and only if their Hamming distance (number of locations where they differ, denoted $d_{\mathrm{H}}(\cdot,\cdot)$) is at least $2np+1$. Let

$$d_{\min}(\mathcal{C}) := \min_{\substack{\underline{x},\underline{x}'\in\mathcal{C}\\ \underline{x}\neq\underline{x}'}} d_{\mathrm{H}}\left(\underline{x},\underline{x}'\right)$$

denote the minimum pairwise distance of codewords in $\mathcal{C}$. The goal is to *pack* as many codewords as possible in the Hamming space $\mathbb{F}_2^n$ while ensuring that the minimum distance is at least $2np+1$. By a simple volume argument (Gilbert–Varshamov (GV) bound [22, 42]), it is known that *exponentially many* such vectors can be packed when $p < 1/4$. The fundamental quantity that coding theorists are seeking when faced with any communication model is the largest *achievable* rate, i.e., *capacity*. The *rate* $R(\mathcal{C})$ of a code $\mathcal{C}$ is its normalized cardinality, i.e., $R(\mathcal{C}) := \frac{\log|\mathcal{C}|}{n}$. The capacity C measures, asymptotically as the blocklength grows, the largest fraction of bits (out of n) that can be reliably transmitted despite np adversarial bit-flips. C is formally defined as[5]

$$C := \limsup_{n\to\infty} \max_{\mathcal{C}\subset\mathbb{F}_2^n:\, d_{\min}(\mathcal{C})>2np} R(\mathcal{C}).$$

For the aforementioned bit-flip model, as said, the problem of finding the capacity can be also cast as determining the *sphere packing density*. This problem is notoriously difficult and is still open to date. However, we do know that $p = 1/4$ is the threshold below which exponential-sized packing exists (as suggested by the GV bound) and above which it is impossible. The latter fact is the famous Plotkin bound. More formally,

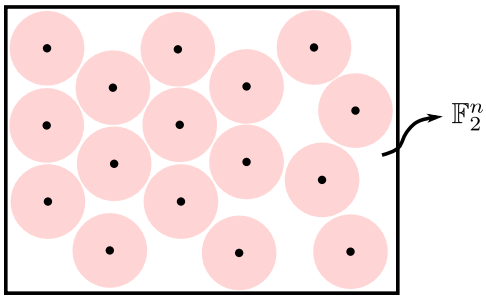
▶ **Theorem 1** (Plotkin bound [33]). *If $p = 1/4 + \epsilon$, $\epsilon > 0$, then any code $\mathcal{C}$ of distance larger than $2np$ has cardinality at most $1 + \frac{1}{4\epsilon}$ (and hence has zero rate).*

We will call the value of p at which the capacity hits zero, the *Plotkin point*. Note that the Plotkin bound actually tells us that above the Plotkin point, not only does every code/packing have a size $2^{o(n)}$ (and hence, rate zero), but also that its size should be at most a *constant* (independent of the blocklength n). Coupled with the achievability result given by the GV bound, the phase transition threshold for exponential-sized packing is thereby identified precisely.

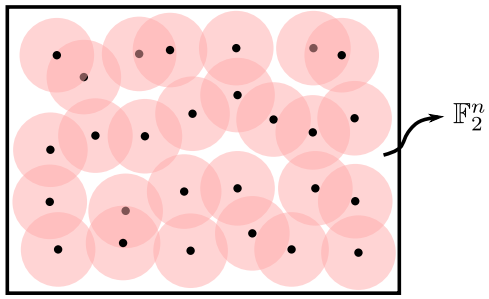
2.2 List decoding and the list decoding Plotkin bound

We now introduce another important notion: *list decoding*. List decodability still requires codewords to be separated out, but in a more relaxed sense; only a few codewords (instead of exactly one under unique decoding discussed earlier) can be captured by a ball of certain radius, no matter where it is located.

[5] It turns out that allowing vanishing probability of decoding error does not change the problem.



(a) An $(L-1)$-packing for $L=2$, i.e., disjoint packing.



(b) An $(L-1)$-packing for $L=3$, i.e., packing with multiplicity 2.

Figure 1 Packing (uniquely decodable codes) vs. multiple packing (list decodable codes). The geometry depicted in the above figures may be misleading compared with the truth in binary Hamming space.

▶ **Definition 2** (List decodability [21, 46]). *A code $\mathcal{C}$ is $(p, L-1)$-list decodable (or $(p, <L)$-list decodable) if for all $\underline{y} \in \mathbb{F}_2^n$, $\left|\mathcal{C} \cap \mathcal{B}_H\left(\underline{y}, np\right)\right| < L$, where $\mathcal{B}_H(\underline{y}, np)$ denotes a Hamming ball centered at $\underline{y}$ of radius np.*

Of course we want the *list size* L to be as small as possible. In particular, the problem is trivial when $L = |\mathcal{C}|$. (The decoder ignores the received word and outputs the whole code.) When $L = 2$, the problem precisely becomes packing. As the admissible L grows, the problem is expected to become easier.

Introduced by Elias [21], list decoding is an important and well-studied subject in coding theory. It is a natural mathematical question to pose towards understanding high-dimensional geometry in discrete spaces. It also serves as a primitive that is useful within and beyond the scope of coding theory. For instance, in many communication problems (e.g., [1, 13]), one proof technique is to let the decoder list decode to a short list (usually $\text{poly}(n)$-sized suffices) of candidate messages, then use other information to disambiguate the list and get a unique message. List decoding also finds applications in complexity theory, cryptography, etc. [25]. For instance, it is used for amplifying hardness and constructing extractors, pseudorandom generators and other pseudorandom objects [20]. The idea of relaxing the problem by asking the solver to just output a list (ideally as small as possible) of solutions that is guaranteed to contain the correct one, instead of insisting on a unique answer, is also adopted in many other fields in computer science [19, 35, 28]. In the context of high-dimensional geometry over finite fields, list decoding is equivalent to multiple packing, just like error correction codes are equivalent to sphere packing. Multiple packing is a natural generalization of the famous sphere packing problem in which, instead of insisting on disjoint alignment, overlap with bounded multiplicity is allowed.

▶ **Definition 3** (Multiple packing). *A subset $\mathcal{C} \subset \mathbb{F}_2^n$ is a $(p, L-1)$-multiple packing if when we put Hamming balls of radii np around each vector in $\mathcal{C}$, no point in the space simultaneously lies in the intersection of at least L balls.*

See Fig. 1 for examples of packing and multiple packing in the Hamming space.

Surprisingly, list decoding capacity is known if we allow L to be asymptotically large. In some sense, list decoding makes us information-theoretic since in many (though not all) cases the list decoding capacity coincides with the capacity of the corresponding Shannon channels in which the noise is random with the same "power" (e.g., in the bit-flip/bit-erasure case, each component of the random noise is independently and identically distributed (i.i.d.) according to a Bernoulli distribution with mean p).

▶ **Theorem 4** (List decoding capacity (folklore) [47]). *Given any $\delta > 0$, there exists an infinite sequence of $(p, \mathcal{O}(1/\delta))$-list decodable codes $\{\mathcal{C}_n\}_n$, each of rate $1 - H(p) - \delta$. Indeed, for any sufficiently large n, a random code (each codeword sampled uniformly at random from $\mathbb{F}_2^n$) of rate $1 - H(p) - \delta$ is $(p, \mathcal{O}(1/\delta))$-list decodable w.h.p..*

On the other hand, any infinite sequence of codes of rate $1 - H(p) + \delta$ is $\left(p, 2^{\Omega(n\delta)}\right)$-list decodable.

*We call $1 - H(p)$ the p-*list decoding capacity *(without specifying a specific L). In particular, the Plotkin point for p-list decoding when L is sufficiently large is $1/2$.*

Though the fundamental limit for the relaxed problem for large constant L is essentially understood, $(p, L-1)$-list decodability for small L (e.g., absolute constant, say $3, 8, 100$, etc.; or sublinear in $1/\delta$, say $(1/\delta)^{1/2}$, $(1/\delta)^{1/3}\log(1/\delta)$, $\log\log(1/\delta)$) is far from being understood. Indeed, it is believed (at least for absolute constant L) to be equivalently hard as the sphere packing problem. Formally, the question of understanding the role of L can be cast as follows. Note first that when $L = 2$, the (unknown) capacity lies somewhere between the Gilbert–Varshamov bound and the Linear Programming bound ([18, 30, 44, 31, 32]). When $L = \mathcal{O}(1/\delta)$, the list decoding capacity $1 - H(p)$ is much larger than the unique decoding capacity. As we increase L, the $(p, L-1)$-list decoding capacity should be gradually "lifted" and the corresponding Plotkin point (the value of p where the capacity is zero) should somehow move rightwards from $1/4$ to $1/2$. The principal goal is to completely understand the dynamics of this evolution.

▶ Remark 5. In this paper, we explicitly distinguish the list decoding capacity for large L and for small L. When we say that L is asymptotically large, we refer to $L = \Omega(1/\delta)$ which suffices to approach the p-list decoding capacity within gap δ. When we say that L is small without further specification, we refer to absolute constant L. For large L, the p-list decoding capacity, denoted by C (recall that we do not explicitly specify L for this regime, see Theorem 4), is fully characterized; however, the $(p, L-1)$-list decoding capacity for small L, denoted by C_{L-1}, is widely open.

Again, for any absolute constant L, the $(p, L-1)$-list decoding capacity is poorly understood. We only have non-matching lower and upper bounds. To our knowledge, the current best bounds are due to Blinovsky from the 80s [9, 10, 11], except for sporadic values of L in some regimes of p. Specifically, for $L = 3$, Ashikhmin–Barg–Litsyn [3] can uniformly improve Blinovsky's upper bound for all values of p. For *even* L's that are at least 4, Polyanskiy [34] can partially beat Blinovsky's upper bounds in the low rate regime.

Though how C_{L-1} approaches C as L increases is not exactly known, Blinovsky's bounds *do* resolve the dynamics of the Plotkin point evolution! Let P_{L-1} denote the Plotkin point for $(p, L-1)$-list decoding. Let $L = 2k$ or $2k+1$ ($k \geqslant 1$). Then Blinovsky's results imply that P_{L-1} is precisely given by the following formula

$$P_{L-1} = \sum_{i=1}^{k} \frac{\binom{2(i-1)}{i-1}}{i} 2^{-2i}.$$

Later, Alon–Bukh–Polyanskiy [2] recovered this result with a simpler-looking formula

$$P_{L-1} = \frac{1}{2} - 2^{-2k-1}\binom{2k}{k},$$

For instance, $P_1 = P_2 = 1/4$, $P_3 = P_4 = 5/16$, etc. As can be noted, the Plotkin point moves *periodically*! The fact that the above two formulas always evaluate to the same value is implicit in [2] and is formally established in Appendix D.

3 Our contributions

Our motivation comes from a well-known connection between list decodability and reliability of communication over adversarial channels. A binary code is $(p, L-1)$-list decodable if and only if it has zero error when used over the following *adversarial bit-flip channel* (Fig. 2).

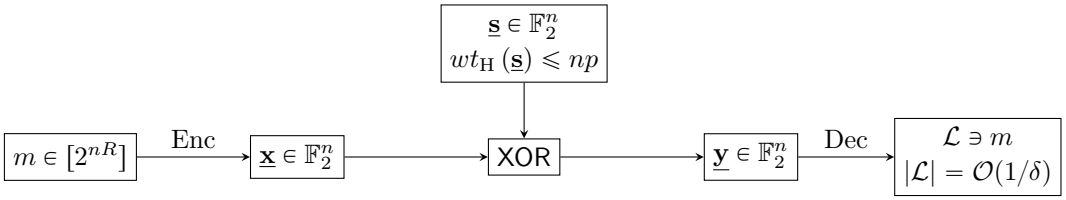


Figure 2 Adversarial bit-flip channels.

The above system depicts a one-way point-to-point communication scenario in which the encoder (Alice) randomly picks a message m from 2^{nR} of them and encodes it into an n-bit string. The adversary (James) stares at this entire codeword and maliciously flips at most np bits of it. Then, the decoder (Bob) receives the corrupted word and is required to output a short list of messages which is guaranteed to contain m with probability 1.

In the above model, the adversary is power constrained in the sense that he only has a budget of np bit-flips. But the encoder is not constrained – she can encode the message into any vector in $\mathbb{F}_2^n$. In some scenarios, codewords are also weight constrained. It makes sense to pose the same question (understanding the list decoding capacity) for input constrained channels. Indeed, this question was also studied in the literature [26].

Motivated by this connection, we significantly generalize the bit-flip model and define list decodability for *general adversarial channels*. We consider a large family of channels in which the encoder is allowed to encode the message into a length-n sequence $\underline{x}$ over *any* alphabet $\mathcal{X}$ of constant size, the adversary is allowed to design an adversarial noise pattern $\underline{s}$ over *any* alphabet $\mathcal{S}$ and the channel can be any *deterministic component-wise* function taking as input a pair of strings from $\mathcal{X}^n \times \mathcal{S}^n$, outputting a sequence $\underline{y}$ over *any* alphabet $\mathcal{Y}$ of the same length. The system designer can incorporate a large family of constraints on $\underline{x}$ and $\underline{s}$ in terms of their *types* (i.e., empirical distributions). The above family of adversarial channels we consider includes but is not limited to

1. The standard adversarial bit-flip channels and adversarial erasure channels;
2. Z-channels in which the adversary can only flip 1 to 0 but not the other way around;
3. Adder channels in which the output is the sum of inputs over the reals rather than modulo the input alphabet size;
4. Channels equipped with Lee distance instead of the Hamming metric.

Indeed, our framework covers most well-studied error models and more that potentially have not been studied in the literature.

However, since we require the channel transition function to act on each component of the inputs independently, a well-studied family of channels is excluded: the *adversarial deletion channels* (cf. [12]). In this model, the adversary can *delete* at most np entries of the transmitted codeword and the decoder receives a vector of smaller length (but at least $(1-p)n$) without knowing the original locations of the symbols he got[6]. Determining the

[6] We want to emphasize the difference between deletions and erasures. When symbols in the codeword are deleted, the rest of the symbols are concatenated and the receiver has no idea which symbols were

Plotkin point for this channel is a long standing open problem. It is known [12] that for binary channels the Plotkin point lies between $\sqrt{2}-1 \approx 0.414$ and 0.5; for q-ary channels, it lies between $1-\frac{2}{q+\sqrt{q}}$ and $1-\frac{1}{q}$. The capacity of this channel is even less understood.

For technical simplicity, we also assume that the channel transition function is *deterministic*, i.e., the output symbol y is a deterministic function of the codeword symbol x and the error symbol s.[7]

We can assume, without any loss of generality, that none of the encoder, decoder and adversary has private randomness to randomize their strategy. This is because there are reductions showing that, given stochastic encoder/decoder, we can construct a deterministic coding scheme with essentially the same rate. Similarly, given a stochastic adversarial error function, we can turn it into a deterministic one which is equivalently malicious in terms of rate. Therefore, for the encoder, it suffices to only consider deterministic codes where each message is mapped to a unique codeword with probability 1. For the adversary, we can assume the error pattern is a deterministic function of the transmitted codeword. Nevertheless, note that the error function does *not* have to be component-wise independent. The i-th component $\underline{s}(i)$ of the noise pattern $\underline{s}$ can depend on *every* entry of $\underline{x}$, not only on the corresponding $\underline{x}(i)$. Moreover, the decoder's decision on the estimated message given the received word can also be assumed to be deterministic. That is, we can require the decoder to output the correct message with *zero* error probability. Hence, the problem is purely combinatorial and all desirable events should happen with probability one.

In this work, we precisely *characterize* the Plotkin point for list decoding over any channel from the above family of general adversarial channels. That is, we essentially provide a criterion (sufficient and necessary condition) for the existence of positive rate $(L-1)$-list decodable codes for such channels.

In the context of high-dimensional geometry over finite fields, the result can be also cast as pinning down the location of the phase transition threshold for the optimal density of $(L-1)$-multiple packing using *general shapes* (not necessarily Hamming balls) corresponding to the defining constraints on codewords and errors of the channel. Above the threshold, exponential-sized multiple packing exists while below that, it is impossible to have such exponential-sized multiple packings.

This criterion can be summarized in one sentence:

> exponential-sized $(L-1)$-list decodable codes for general adversarial channels (or $(L-1)$-multiple packings using general shapes) essentially exist if and only if the *completely positive tensor cone* of order-L is not entirely contained in the *confusability set* of the channel for $(L-1)$-list decoding.

Jargon in the above informal statement will become understandable once we formalize the problem setup and present rigorous claims. The proof consists of the sufficiency part and the necessity part. At a very high level, the sufficiency part follows from a random coding argument and its generalization inspired by the time-sharing argument frequently used in Network Information Theory. The necessity part builds upon and significantly generalizes the classic Plotkin bound, which goes by first extracting an *equicoupled* subcode using Ramsey theory and then applying a generalized *double counting* trick.

---

deleted. However, when symbols are erased, they are replaced by erasure symbols erasure at the same locations and the receiver seeing them knows exactly which symbols were erased. Hence the erasure case is much simpler than the deletion case.

[7] The general case in which the channel law is given by a conditional distribution $W_{\mathbf{y}|\mathbf{x},\mathbf{s}}$ (with not necessarily only singleton atoms) is more technical and is left as one of our future directions.

Our other results include the following:

1. For any given general adversarial channel, we pin down the list decoding capacity for asymptotically large L. This generalizes the classic list decoding capacity in the bit-flip case. The lower bound is achieved by a purely random code. The upper bound follows from a volume packing argument.
2. For any given general adversarial channel, we determine the *exact* order (in terms of δ) of the list sizes of a large fraction (exponentially close to one) of constant composition codes (in which all codewords have the same type) achieving the list decoding capacity within gap δ. It turns out that if we pick a constant composition code from the set of all such codes uniformly at random, with high probability, it is exactly $\Theta(1/\delta)$-list decodable.
3. For any given general adversarial channel and any $L \geqslant 2$, we give a lower bound on the $(L-1)$-list decoding capacity. It coincides with the generalized Gilbert–Varshamov bound obtained by [43] when $L-1$ is equal to 1. Our bound follows from a random code construction assisted by expurgation, generalizing a classic construction for $(p, L-1)$-list decoding in the bit-flip case [24]. Note that this construction differs from [43]'s construction for unique decoding using greedy packing.
4. In the special case where $L = 2$, i.e., the unique decoding setting and under the bit-flip model, we evaluate the Gilbert–Varshamov-type bound and an achievable rate expression of cloud codes (codes constructed from CP distributions) obtained by [43]. In particular, we show that the Gilbert–Varshamov-type bound for general adversarial channels matches the classic GV bound in coding theory. We also provide an explicit convex program for evaluating achievable rates of cloud codes.
5. By evaluating our general criterion under the bit-flip model, we *numerically* recover Blinovsky's [9] characterization of the Plotkin points for $(p, L-1)$-list decoding. This boils down to checking the feasibility of an explicit linear program with structured coefficient matrix. Though the LP has size exponential in L, its feasibility can be checked in constant time since our results are tailored for constant L independent of the blocklength n (which needs to approach infinity for many of our results to hold).
6. By utilizing facts discovered in this paper, we *rigorously* recover Blinovsky's [9] characterization of the Plotkin points for $(p, L-1)$-list decoding. Our proof avoids the complicated calculations Blinovsky did and demystifies the formula by Blinovsky[8]. In particular, our lower bound on the Plotkin point explains why, in the low rate regime, *average-radius*[9] list decoding is equivalent to the classic notion of list decoding. We believe that this fact was first observed and rigorously justified by Blinovsky. It was later rediscovered many times and became one of the basic starting points of many papers, especially those regarding list decoding random q-ary linear codes. Our upper bound relates the Plotkin point P_{L-1} to the expected translation distance of a one-dimensional unbiased random walk after L steps. In summary, using connections between codes and random variables, we are able to re-interpret the results by Blinvosky [9] and Alon–Bukh–Polyanskiy [2] within the framework we established by providing a more intuitive formula which matches known results.

[8] In fact, he provided upper and lower bounds on the $(p, L-1)$-list decoding capacity which happen to vanish at the same value of p.

[9] $(p, L-1)$-average-radius list decodability requires that the *average* distance (instead of maximum distance required by the classic notion of $(p, L-1)$-list decodability) from any L-tuple of codewords to their centroid is larger than np. Average-radius list decodability is a more stringent requirement since it implies the classic list-decodability. However, it is easier to analyze since the problem is *linearized* from infinity norm to one norm. Indeed it plays a useful role in a long line of work towards understanding the list decodability of random linear codes [26, 45, 36, 37, 38].

4 Overview of techniques

Our paper is highly correlated to a sister paper [43] which a subset of the authors are involved in. That paper provides generalized Plotkin bound for *unique* decoding over general adversarial channels. The authors showed that exponential-sized *uniquely* decodable codes or hard packings exist if and only if the set of completely positive *matrices* is not entirely contained in the *confusability set* associated to the given channel. This answers the question we posed in the beginning of the paper for the $L = 2$ case. We generalize their results to *any universal constant* L. Almost all results in [43] can be recovered by setting $L = 2$ in our paper.

We give an overview of the techniques used in this paper and highlight the similarities and differences between [43][10] and our work.

1. The general adversarial channel models that both papers are concerned with belong to a larger family of channels known as *Arbitrarily Varying Channels (AVC)* in Information Theory community; these were first studied by Blackwell et al. [8] (see [29] for a detailed survey). We want to emphasize that the bulk of the literature on AVCs deals with *oblivious* adversary channels in which the adversary has to pick his malicious noise pattern *before* the codeword is chosen from the codebook (and hence, *oblivious* of the transmitted codeword) by the encoder. This makes the problem significantly easier and the capacity of such channels is precisely known (cf. [17]). The channels that [43] and we are considering are such that the adversary gets to design the error pattern with the complete knowledge of the transmitted codeword; these are called *omniscient* adversaries in [43]. This problem is much more difficult and the capacity is, again, widely open even for simple models such as the bit-flip channels. Indeed, the subclass of AVCs that [43] and we defined is motivated by the bit-flip channels and its various variants, e.g., q-ary channels, weight constrained channels, asymmetric channels, etc..
2. The connection between codes and random variables/distributions is classic in Theoretical Computer Science. The idea of realizing binary error correction codes using $\{-1, 1\}$-valued random variables or functions supported on the Boolean hypercube $\{-1, 1\}^n$ is spread out in the literature explicitly or in disguise. Such a trick allows one to borrow tools from other fields of Theoretical Computer Science, e.g., the theory of expander graphs, randomness extractors, small-bias distributions, discrete Fourier analysis, etc., (cf. [40, 5, 41, 7]) to understand, construct and analyze codes.
3. With respect to (w.r.t.) codes for general adversarial channels, the specific idea of collecting admissible types of good codes and studying the set of corresponding distributions was used in [43]. In particular, they defined similar notions of self-couplings and confusability sets which are submanifolds of *matrices* corresponding to joint distributions. Such objects only take care of *pairwise* interaction of codewords, which is insufficient for understanding list decoding. We generalize their notions to *tensors* which capture the (empirical) joint distributions of *lists* of codewords. While some properties in [43] continue to hold when objects in the matrix case are extended to their tensor versions, others fail to hold, as we will see in the rest of the paper. We also encounter issues which do not arise in the unique decoding setting. As is well-known, tensors are much more delicate [27] to handle compared to matrices.

[10] Though the work by Wang–Budkuley–Bogdanov–Jaggi [43] has been accepted to ISIT 2019, the conference version is limited to 5 pages and contains essentially no proof. At the time this paper is written, we do not have a publicly available *full* version of [43] and the following comparison is w.r.t. the current status of a draft of [43] that the authors kindly shared with us.

4. To prove *upper* bounds on capacity, it is also an old idea to extract structured subcodes from *any* infinite sequence of good codes. Depending on the applications, the nature of *structures* and techniques used to extract them may vary. To the best of our knowledge, in coding theory, the use of Ramsey theory for obtaining symmetric subcodes dates back to as least as early as Blinovsky [9]. His techniques were applied in a similar manner in followup works by Polyanskiy [34] and Alon–Bukh–Polyanskiy [2]. The work in [43] generalized this idea and managed to extract structured subcodes from arbitrary codes for *general* adversarial channels. Since they dealt with unique decoding, *pairwise* equicoupledness suffices. In our setup, we would like a sequence of subcodes which are *L-wise equicoupled* in the sense that the (empirical) joint distribution of any L-tuple of codewords from the extracted subcode is approximately the same and is close to some $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. This resembles but generalizes Polyanskiy's [34] techniques. One of the downsides of invoking Ramsey theory is that the reduction usually causes terrible detriment to the rate of the code, since the smallest size for a combinatorial object to contain abundant structures is generally poorly understood in combinatorics. However, we are fine to tolerate such a rate loss since we only care about the *positivity* of the $(L-1)$-list decoding capacity.
5. To show *lower* bounds on capacity, we use the random coding argument aided by *expurgation*. In the prior work [43], the achievability result is obtained by greedy packing. This is reminiscent of a classic technique in coding theory for proving the existence of good codes of certain size. Since in the unique decoding (hard packing) setting, goodness of a code relies merely on pairwise statistics, the size of a greedy packing can be lower bounded using a standard volume counting argument. Indeed, this idea can be implemented in the general setting by counting the volume of the "forbidden region" of any codeword [43]. However, in list decoding setting, the notion of *confusability* is defined for *tuples* of codewords and translates to bounded multiplicity of intersection of forbidden regions of codewords. It is thus not clear how to pack codewords in a greedy manner while ensuring non-existence of local dense clusters. Instead, our code construction is more information-theoretic. We apply ideas of random coding with expurgation which is commonly used in the study of error exponent in Information Theory. A random code may be mildly locally clustered, but this only occurs at rare locations in the space of all length-n input sequences. Indeed, we are able to show that, with high probability, a random code carefully massaged by shoveling off a small number of codewords attains a GV-type bound for general channels.
6. The most difficult part of our work is the converse.
   a. First assume that the distribution $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ associated to the subcode obtained by Ramsey reduction is *symmetric*. To show that no large $(L-1)$-list decodable code exists for general adversarial channels when $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is not completely positive, we provide upper and lower bounds on the average (over all L-tuples in the equicoupled subcode) inner product between the empirical distribution of an L-tuple and a copositive witness of non-complete positivity of $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. The bounds contradict each other if the code size exceeds certain constant (independent of the blocklength). We review this *double counting trick* (for unique and list decoding under special settings that appeared in prior work) in Section 5. The $L = 2$ case is proved in [43]. The existence of the witness of non-complete positivity is guaranteed by the duality of certain matrix cones. We generalize calculations in [43] to joint distributions of > 2 random variables. Similar notions of complete positivity and copositivity for tensors exist in the literature and the duality continues to hold.

b. If $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is *asymmetric*, we use a completely different argument. We reduce the claim, in a nontrivial way, to the $L = 2$ case which is known to be true [43]. The $L = 2$ case itself is proved [43] by viewing the task of constructing a long sequence of random variables with prescribed asymmetric pairwise marginals as a zero sum game and using discrete Fourier analysis to provide conflicting bounds on the value of the game, if the sequence is longer than certain constant (again independent of the blocklength).

5 Prior work

Among various ideas, our results are built upon prior work which applies a *double counting trick* to obtain upper bounds on code sizes. We first review this technique which can be found in the proof of the classic Plotkin bound and its generalizations.

5.1 Plotkin [33]

One way to prove Theorem 1 is by lower and upper bounding the expected pairwise distance of any given code $\mathcal{C}$ with minimum distance larger than $2np$ ($p = 1/4 + \epsilon$)

$$\mathop{\mathbb{E}}_{(\underline{x},\underline{x}')\sim\mathcal{C}\times\mathcal{C}}\left[d_{\mathrm{H}}\left(\underline{x},\underline{x}'\right)\right], \tag{2}$$

where $\underline{x}, \underline{x}'$ are uniformly and independently picked from $\mathcal{C}$. First note that pairs $\underline{x} = \underline{x}'$ do not contribute to the expectation. On the one hand, the expectation is clearly at least

$$\frac{|\mathcal{C}|(|\mathcal{C}|-1)}{|\mathcal{C}|^2} d_{\min} > |\mathcal{C}|^{-1}(|\mathcal{C}|-1)2np = |\mathcal{C}|^{-1}(|\mathcal{C}|-1)2n(1/4+\epsilon).$$

On the other hand, if we stack codewords into a $2^{nR} \times n$ matrix and let S_j denote the number of 1's in the j-th column, then from the column's perspective, the above expectation is at most

$$\frac{1}{|\mathcal{C}|^2}\sum_{j=1}^{n} 2S_j(|\mathcal{C}| - S_j).$$

The coefficient 2 is because we need to count $(\underline{x}, \underline{x}')$ and $(\underline{x}', \underline{x})$ separately. This bound is at most $n/2$ by concavity of the summands in S_j. Comparing the upper and lower bounds we have that $|\mathcal{C}| \leqslant 1 + \frac{1}{4\epsilon}$, as claimed in Theorem 1.

5.2 Blinovsky [9]

The above double counting argument can be generalized to the setting of list decoding. For the $(p, L-1)$-list decoding setup we introduced in Definition 2, the earliest work we are aware of following this idea is the one by Blinovsky [9].

Unlike Theorem 1, not only did Blinovsky show that any $(p, L-1)$-list decodable code has to be small as long as $p > P_{L-1}$, he even gave an upper bound (it is still essentially the best as far as we know) on the $(p, L-1)$-list decoding capacity for *any* L. We sketch his idea below but omit the complicated calculations.

First note that proving upper bounds on C_{L-1} for fixed p is equivalent to proving upper bounds on p for fixed rate R. We then define the following three quantities

$$r_{\mathrm{LD}} = \min_{\mathcal{L}\in\binom{\mathcal{C}}{L}} \min_{\underline{y}\in\mathbb{F}_2^n} \max_{\underline{x}\in\mathcal{L}} d_{\mathrm{H}}\left(\underline{y},\underline{x}\right), \tag{3}$$

$$r_{\mathrm{avg}} = \min_{\mathcal{L}\in\binom{\mathcal{C}}{L}} \min_{\underline{y}\in\mathbb{F}_2^n} \mathop{\mathbb{E}}_{\underline{x}\sim\mathcal{L}} \left[d_{\mathrm{H}}\left(\underline{y},\underline{x}\right)\right], \tag{4}$$

$$r_{\mathrm{DC}} = \mathop{\mathbb{E}}_{\mathcal{L}\sim\binom{\mathcal{C}}{L}} \min_{\underline{y}\in\mathbb{F}_2^n} \mathop{\mathbb{E}}_{\underline{x}\sim\mathcal{L}} \left[d_{\mathrm{H}}\left(\underline{y},\underline{x}\right)\right]. \tag{5}$$

All expectations are over uniform selections from the corresponding sets. Namely,

$$\mathop{\mathbb{E}}_{\mathcal{L}\sim\binom{\mathcal{C}}{L}}[\cdot] = \frac{1}{\binom{|\mathcal{C}|}{L}} \sum_{\mathcal{L}\in\binom{\mathcal{C}}{L}} [\cdot], \quad \mathop{\mathbb{E}}_{\underline{x}\sim\mathcal{L}}[\cdot] = \frac{1}{L}\sum_{\underline{x}\in\mathcal{L}}[\cdot].$$

Let us parse what these quantities are measuring.

1. r_{LD} is known as the *list decoding radius* of a given code $\mathcal{C}$. The minimax expression associated to a set $\mathcal{L}$ of vectors

   $$r_{\mathrm{Cheb}} \coloneqq \min_{\underline{y}\in\mathbb{F}_2^n} \max_{\underline{x}\in\mathcal{L}} d_{\mathrm{H}}\left(\underline{y},\underline{x}\right)$$

   is known as the *Chebyshev radius* of $\mathcal{L}$. It is the radius of the smallest circumscribed ball of $\mathcal{L}$. And

   $$p^*(R) \coloneqq \limsup_{n\to\infty} \max_{\mathcal{C}\subset\mathbb{F}_2^n\colon |\mathcal{C}|\geqslant 2^{nR}} r_{\mathrm{LD}}(\mathcal{C})$$

   is precisely the largest allowable p for $(p, L-1)$-list decodable codes of a fixed rate R to exist. Note that $p^*(0) = P_{L-1}$.
2. r_{avg} is known as the *average list decoding radius* and the min-average expression

   $$\min_{\underline{y}\in\mathbb{F}_2^n} \mathop{\mathbb{E}}_{\underline{x}\sim\mathcal{L}} \left[d_{\mathrm{H}}\left(\underline{y},\underline{x}\right)\right]$$

   is the *average radius* of a list. It is not hard to see that the average radius center of $\mathcal{L}$ is the component-wise majority of vectors in $\mathcal{L}$, i.e., the minimizer $\underline{y}^*$ has $\mathsf{MAJ}\left(\underline{x}(i)\colon \underline{x}\in\mathcal{L}\right)$ as its i-th component. Define *plurality* as

   $$\begin{array}{rccl} \mathsf{PLUR}\colon & \mathbb{F}_2^L & \to & [0,1] \\ & (x_1,\cdots,x_L) & \mapsto & \frac{1}{L}\left|\{i\in[L]\colon x_i = \mathsf{MAJ}(x_1,\cdots,x_L)\}\right|, \end{array}$$

   which is the fraction of the most frequent symbol. Then the average radius of $\mathcal{L}$ can be explicitly written as

   $$\min_{\underline{y}\in\mathbb{F}_2^n} \mathop{\mathbb{E}}_{\underline{x}\sim\mathcal{L}} \left[d_{\mathrm{H}}\left(\underline{y},\underline{x}\right)\right] = \sum_{j=1}^{n} \left(1 - \mathsf{PLUR}\left(\underline{x}(j)\colon \underline{x}\in\mathcal{L}\right)\right).$$

3. r_{DC} is a further variant of r_{LD} – the ultimate quantity we are looking for. It is the object that Blinovsky was really dealing with. Note that it is in the same spirit as the quantity (2) considered in the double counting argument in the proof of the classic Plotkin bound. Blinovsky used r_{DC} as a proxy to finally bound r_{LD}.

By extracting a constant weight subcode and applying the double counting trick (and using the convexity of a certain function), Blinovsky showed the following

▶ **Lemma 6.** *Let $\lambda\in[0,1/2]$ and fix $R = 1 - H(\lambda)$. Then*

$$r_{\mathrm{DC}} \leqslant \sum_{i=1}^{\lceil L/2\rceil} \frac{\binom{2i-2}{i-1}}{i} (\lambda(1-\lambda))^i.$$

Apparently, by definition, we have

$$r_{\mathrm{LD}} \geqslant r_{\mathrm{avg}}, \quad r_{\mathrm{DC}} \geqslant r_{\mathrm{avg}}.$$

So Lemma 6 automatically holds for r_{avg}. However, a priori the relation between r_{LD} and r_{DC} is unclear. Surprisingly, Blinovsky showed that it is "okay" to replace the first and third optimization in r_{LD} with averaging in the sense that the following holds.

▶ **Lemma 7.** *For any infinite sequence of codes $\{\mathcal{C}_n\}_n$, there exists an infinite sequence of subcodes $\mathcal{C}'_n \subseteq \mathcal{C}_n$ such that $r_{\mathrm{LD}}(\mathcal{C}') = r_{\mathrm{avg}}(\mathcal{C}') + o(n)$.*

The proof involves an *equidistant* subcode extraction step using Ramsey theory. Lemma 7 implies that the same bound in Lemma 6 holds for r_{LD} as well!

5.3 Cohen–Litsyn–Zémor [15]

Similar ideas were used to provide upper bounds on the erasure list decoding capacity. A binary code is said to be $(p, L-1)$-*erasure list decodable* if for any $\mathcal{T} \in \binom{[n]}{n(1-p)}$ and any $\underline{y} \in \mathbb{F}_2^{(1-p)n}$, $\left|\{\underline{x} \in \mathcal{C} \colon \underline{x}|_{\mathcal{T}} = \underline{y}\}\right| \leqslant L-1$, where $\underline{x}|_{\mathcal{T}}$ denotes the restriction of $\underline{x}$ to $\mathcal{T}$, i.e., a vector of length $|\mathcal{T}|$ only consisting of components from $\underline{x}$ indexed by elements in $\mathcal{T}$. The erasure list decoding radius $r_{\mathrm{LD,eras}}$ and the $(p, L-1)$-erasure list decoding capacity $C_{L-1,\mathrm{eras}}$ are defined in the same manner. Cohen–Litsyn–Zémor [15] showed that

▶ **Theorem 8** ([15])**.** *$C_{L,\mathrm{eras}} \leqslant 1 - H(\lambda)$, where λ is the unique root of the equation $\lambda^{L+1} + (1-\lambda)^{L+1} = 1 - p$ in $[0, 1/2]$.*

The idea is essentially still double counting. Here, it turns out that the right object to be counted is the *erasure radius* of a list $\mathcal{L}$,

$$r_{\mathrm{eras}} := \left|\{i \in [n] \colon \underline{x}(i) \text{ are the same } \forall \underline{x} \in \mathcal{L}\}\right|.$$

Extracting a subcode living on a sphere (followed by shifting out the center to get a constant weight subcode $\mathcal{C}'$) and conducting similar calculations on

$$\mathop{\mathbb{E}}_{\mathcal{L} \sim \binom{\mathcal{C}'}{L}} \left[r_{\mathrm{eras}}(\mathcal{L})\right],$$

allow the authors to conclude Theorem 8.

▶ Remark 9. The original paper [15] was stated for *generalized distance* which is equivalent to erasure list decoding radius via a well-known connection. The above version was presented in Guruswami's PhD thesis [24].

5.4 Wang–Budkuley–Bogdanov–Jaggi [43]

As mentioned, our work is a continuation of the prior work [43] which a subset of the authors were involved in. We refer the readers to the corresponding paragraphs in Sec. 1 and Sec. 3 for a review of their work along with a comparison with this work.

6 Organization of the paper

In Sec. 1 we have seen numeric examples that illustrate our results. In Sec. 2 we properly motivated the problem and introduced relevant background in coding theory. Our contributions in this paper were listed in details in Sec. 3. In Sec. 4 we reviewed various techniques used in this paper and highlighted our innovations. Prior works that our results build up on and push forward were surveyed in Sec. 5.

The rest of the paper is organized as follows. We fix our notational conventions in Sec. 7 and provide necessary preliminaries, especially *the method of types* in Information Theory, in Sec. 8. We develop basic notions that will be used throughout the paper in Sec. 9. In particular, *general adversarial channels* and objects associated to them will be introduced in this section. In Sec. 10 we prove the list decoding capacity theorem for general adversarial channels when L is asymptotically large. Furthermore, we obtain *tight* list size bounds for *most* capacity-achieving constant composition codes in Sec. 11. In Sec. 12 and Sec. 13 we show sufficiency and necessity, respectively, of the criterion for the existence of exponential-sized $(L-1)$-list decodable codes (where L is an arbitrary universal constant) for general adversarial channels. In Sec. 14 we make two remarks on the converse, which is technically the most challenging piece of our work. In Sec. 15 we verify the correctness of our characterization obtained in Sec. 12 and Sec. 13 by running it on the problem specialized to the bit-flip model which has been understood in prior works [9, 2]. In Sec. 16, utilizing tools developed and facts proved in this paper, we rigorously rederive Blinovsky's [9] results. We obtain more intuitive expressions and demystify his calculations. In Sec. 17 we evaluate bounds on the unique decoding capacity ($L = 2$) in [43] under the bit-flip model. We conclude the paper and list several open questions and future directions in Sec. 18. Some calculations and background knowledge are deferred to Appendices A, B, C and D.

7 Notation

Conventions. Sets are denoted by capital letters in calligraphic typeface, e.g., $\mathcal{C}, \mathcal{I}$, etc.. Random variables are denoted by lower case letters in boldface or capital letters in plain typeface, e.g., $\mathbf{m}, \mathbf{x}, \mathbf{s}, U, W$, etc.. Their realizations are denoted by corresponding lower case letters in plain typeface, e.g., m, x, s, u, w, etc.. Vectors (random or fixed) of length n, where n is the blocklength without further specification, are denoted by lower case letters with underlines, e.g., $\underline{\mathbf{x}}, \underline{\mathbf{s}}, \underline{x}, \underline{s}$, etc.. The i-th entry of a vector $\underline{x} \in \mathcal{X}^n$ is denoted by $\underline{x}(i)$ since we can alternatively think of $\underline{x}$ as a function from $[n]$ to $\mathcal{X}$. Same for a random vector $\underline{\mathbf{x}}$. Matrices are denoted by capital letters in boldface, e.g., $\mathbf{P}, \mathbf{\Sigma}$, etc.. Similarly, the (i,j)-th entry of a matrix $\mathbf{G} \in \mathbb{F}^{n\times m}$ is denoted by $\mathbf{G}(i,j)$. We sometimes write $\mathbf{G}_{n\times m}$ to explicitly specify its dimension. For square matrices, we write $\mathbf{G}_n$ for short. Letter $\mathbf{I}$ is reserved for identity matrix. Tensors are denoted by capital letters in plain typeface, e.g., T, P, etc..

Functions. We use the standard Bachmann–Landau (Big-Oh) notation for asymptotics of real-valued functions in positive integers.

For $x \in \mathbb{R}$, let $[x]^+ \coloneqq \max\{x, 0\}$.

For two real-valued functions f, g on the same domain Ω, let fg and f/g denote the functions obtained by multiplying and taking the ratio of the images of f and g point-wise, respectively. That is, for $\omega \in \Omega$,

$$(fg)(\omega) \coloneqq f(\omega)g(\omega), \quad (f/g)(\omega) \coloneqq f(\omega)/g(\omega).$$

In particular, for types or distributions, we can write $\tau_{\mathbf{x},\mathbf{y}} = \tau_{\mathbf{x}}\tau_{\mathbf{y}|\mathbf{x}}, \tau_{\mathbf{y}|\mathbf{x}} = \tau_{\mathbf{x},\mathbf{y}}/\tau_{\mathbf{x}}$, or $P_{\mathbf{x},\mathbf{y}} = P_{\mathbf{x}}P_{\mathbf{y}|\mathbf{x}}, P_{\mathbf{y}|\mathbf{x}} = P_{\mathbf{x},\mathbf{y}}/P_{\mathbf{x}}$ and so on.

For two real-valued functions $f(n), g(n)$ in positive integers, we say that $f(n)$ *asymptotically equals* $g(n)$, denoted $f(n) \asymp g(n)$, if

$$\lim_{n\to\infty} \frac{f(n)}{g(n)} = 1.$$

For instance, $2^{n+\log n} \asymp 2^{n+\log n} + 2^n$, $2^{n+\log n} \not\asymp 2^n$. We write $f(n) \doteq g(n)$ (read $f(n)$ dot equals $g(n)$) if the coefficients of the dominant terms in the exponents of $f(n)$ and $g(n)$ match,

$$\lim_{n\to\infty} \frac{\log f(n)}{\log g(n)} = 1.$$

For instance, $2^{3n} \doteq 2^{3n+n^{1/4}}$, $2^{2^n} \neq 2^{2^{n+\log n}}$. Note that $f(n) \asymp g(n)$ implies $f(n) \doteq g(n)$, but the converse is not true.

For any $q \in \mathbb{R}_{>0}$, we write $\log_q(\cdot)$ for the logarithm to the base q. In particular, let $\log(\cdot)$ and $\ln(\cdot)$ denote logarithms to the base two and e, respectively.

Sets. For any two sets $\mathcal{A}$ and $\mathcal{B}$ with additive and multiplicative structures, let $\mathcal{A}+\mathcal{B}$ and $\mathcal{A}\cdot\mathcal{B}$ denote the Minkowski sum and Minkowski product of them which are defined as

$$\mathcal{A}+\mathcal{B} \coloneqq \{a+b\colon a\in\mathcal{A}, b\in\mathcal{B}\}, \quad \mathcal{A}\cdot\mathcal{B} \coloneqq \{a\cdot b\colon a\in\mathcal{A}, b\in\mathcal{B}\},$$

respectively. If $\mathcal{A}=\{x\}$ is a singleton set, we write $x+\mathcal{B}$ and $x\cdot\mathcal{B}$ for $\{x\}+\mathcal{B}$ and $\{x\}\cdot\mathcal{B}$.

For any finite set $\mathcal{X}$ and any integer $0 \leqslant k \leqslant |\mathcal{X}|$, we use $\binom{\mathcal{X}}{k}$ to denote the collection of all subsets of $\mathcal{X}$ of size k.

$$\binom{\mathcal{X}}{k} \coloneqq \{\mathcal{Y}\subseteq\mathcal{X}\colon\ |\mathcal{Y}|=k\}.$$

For $M\in\mathbb{Z}_{>0}$, we let $[M]$ denote the set of first M positive integers $\{1,2,\cdots,M\}$.

For any $\mathcal{A}\subseteq\Omega$, the indicator function of $\mathcal{A}$ is defined as, for any $x\in\Omega$,

$$\mathbb{1}_{\mathcal{A}}(x) \coloneqq \begin{cases} 1, & x\in\mathcal{A} \\ 0, & x\notin\mathcal{A} \end{cases}.$$

At times, we will slightly abuse notation by saying that $\mathbb{1}_{\mathsf{A}}$ is 1 when event A happens and 0 otherwise. Note that $\mathbb{1}_{\mathcal{A}}(\cdot) = \mathbb{1}_{\{\cdot\in\mathcal{A}\}}$.

Geometry. For any $\underline{x}\in\mathbb{F}_q^n$, let $wt_{\mathrm{H}}(\underline{x})$ denote the Hamming weight of $\underline{x}$, i.e., the number of nonzero entries of $\underline{x}$.

$$wt_{\mathrm{H}}(\underline{x}) \coloneqq |\{i\in[n]\colon \underline{x}(i)\neq 0\}|.$$

For any $\underline{x},\underline{y}\in\mathbb{F}_q^n$, let $d_{\mathrm{H}}(\underline{x},\underline{y})$ denote the Hamming distance between $\underline{x}$ and $\underline{y}$, i.e., the number of locations where they differ.

$$d_{\mathrm{H}}(\underline{x},\underline{y}) \coloneqq wt_{\mathrm{H}}(\underline{x}-\underline{y}) = \left|\left\{i\in[n]\colon \underline{x}(i)\neq\underline{y}(i)\right\}\right|.$$

Balls and spheres in $\mathbb{F}_q^n$ centered around some point $\underline{x}\in\mathbb{F}_q^n$ of certain radius $r\in\{0,1,\cdots,n\}$ w.r.t. the Hamming metric are defined as follows.

$$\mathcal{B}_{\mathrm{H}}^n(\underline{x},r) \coloneqq \left\{\underline{y}\in\mathbb{F}_q^n\colon d_{\mathrm{H}}(\underline{x},\underline{y})\leqslant r\right\}, \quad \mathcal{S}_{\mathrm{H}}^n(\underline{x},r) \coloneqq \left\{\underline{y}\in\mathbb{F}_q^n\colon d_{\mathrm{H}}(\underline{x},\underline{y})= r\right\}.$$

We will drop the subscript and superscript for the associated metric and dimension when they are clear from the context.

Probability. The probability mass function (p.m.f.) of a discrete random variable $\mathbf{x}$ or a random vector $\underline{\mathbf{x}}$ is denoted by $P_{\mathbf{x}}$ or $P_{\underline{\mathbf{x}}}$. Here we use the following shorthand notation to denote the probability that $\mathbf{x}$ or $\underline{\mathbf{x}}$ distributed according to $P_{\mathbf{x}}$ or $P_{\underline{\mathbf{x}}}$ takes a particular value.

$$P_{\mathbf{x}}(x) \coloneqq \Pr_{\mathbf{x}\sim P_{\mathbf{x}}}[\mathbf{x} = x], \quad P_{\underline{\mathbf{x}}}(\underline{x}) = \Pr_{\underline{\mathbf{x}}\sim P_{\underline{\mathbf{x}}}}[\underline{\mathbf{x}} = \underline{x}],$$

for any $x \in \mathcal{X}$ or $\underline{x} \in \mathcal{X}^n$. If every entry of $\underline{\mathbf{x}}$ is independently and identically distributed (i.i.d.) according to $P_{\mathbf{x}}$, then we write $\underline{\mathbf{x}} \sim P_{\mathbf{x}}^{\otimes n}$, where $P_{\mathbf{x}}^{\otimes n}$ is a product distribution defined as

$$P_{\underline{\mathbf{x}}}(\underline{x}) = P_{\mathbf{x}}^{\otimes n}(\underline{x}) \coloneqq \prod_{i=1}^{n} P_{\mathbf{x}}(\underline{x}(i)).$$

For a finite set $\mathcal{X}$, $\Delta(\mathcal{X})$ denotes the probability simplex on $\mathcal{X}$, i.e., the set of all probability distributions supported on $\mathcal{X}$,

$$\Delta(\mathcal{X}) \coloneqq \left\{ P_{\mathbf{x}} \in [0,1]^{|\mathcal{X}|} \colon \sum_{x\in\mathcal{X}} P_{\mathbf{x}}(x) = 1 \right\}.$$

Similarly, $\Delta(\mathcal{X}\times\mathcal{Y})$ denotes the probability simplex on $\mathcal{X}\times\mathcal{Y}$,

$$\Delta(\mathcal{X}\times\mathcal{Y}) \coloneqq \left\{ P_{\mathbf{x},\mathbf{y}} \in [0,1]^{|\mathcal{X}|\times|\mathcal{Y}|} \colon \sum_{x\in\mathcal{X}}\sum_{y\in\mathcal{Y}} P_{\mathbf{x},\mathbf{y}}(x,y) = 1 \right\}.$$

Let $\Delta(\mathcal{Y}|\mathcal{X})$ denote the set of all conditional distributions,

$$\Delta(\mathcal{Y}|\mathcal{X}) \coloneqq \left\{ P_{\mathbf{y}|\mathbf{x}} \in \mathbb{R}^{|\mathcal{X}|\times|\mathcal{Y}|} \colon P_{\mathbf{y}|\mathbf{x}}(\cdot|x) \in \Delta(\mathcal{Y}),\ \forall x \in \mathcal{X} \right\}.$$

The general notion for multiple spaces is defined in the same manner.

Let $\mathrm{Unif}(\Omega)$ denote the uniform distribution on some probability space Ω.

For a joint distribution $P_{\mathbf{x},\mathbf{y}} \in \Delta(\mathcal{X}\times\mathcal{Y})$, let $[P_{\mathbf{x},\mathbf{y}}]_{\mathbf{x}} \in \Delta(\mathcal{X})$ denote the *marginalization* onto the variable $\mathbf{x}$, i.e., for $x \in \mathcal{X}$,

$$[P_{\mathbf{x},\mathbf{y}}]_{\mathbf{x}}(x) \coloneqq \sum_{y\in\mathcal{Y}} P_{\mathbf{x},\mathbf{y}}(x,y).$$

Sometimes we simply write it as $P_{\mathbf{x}}$ when the notation is not overloaded.

Algebra. Let $\|\cdot\|_p$ denote the standard ℓ^p-norm. Specifically, for any $\underline{x} \in \mathbb{R}^n$,

$$\|\underline{x}\|_p \coloneqq \left(\sum_{i=1}^{n} |\underline{x}(i)|^p \right)^{1/p}.$$

For brevity, we also write $\|\cdot\|$ for the ℓ^2-norm.

An order-k dimension-$(n_1,\cdots,n_k)$ tensor T is a multidimensional array. It can be thought as a function on the product space $[n_1]\times\cdots\times[n_k]$ which identifies the value of each of its entries.

$$\begin{array}{rccl} T\colon & [n_1]\times\cdots\times[n_k] & \to & \mathbb{R} \\ & (i_1,\cdots,i_k) & \mapsto & T(i_1,\cdots,i_k), \end{array}$$

where, as usual, we use $T(i_1,\cdots,i_k)$ to denote its $(i_1,\cdots,i_k)$-th entry.

Without specification, all matrices and tensors are over the real number field. The space of $n \times m$ matrices is denoted by

$$\mathsf{Mat}_{n\times m} := \left\{\mathbf{M} \in \mathbb{R}^{n\times m}\right\} \cong \mathbb{R}^{n\cdot m}.$$

When $n = m$, we write Mat_n for the space of square matrices of dimension n. The space of order-k dimension-$(n_1, \cdots, n_k)$ tensors is denoted by

$$\mathsf{Ten}^{\otimes k}_{n_1,\cdots,n_k} := \left\{T \in \mathbb{R}^{n_1\times\cdots\times n_k}\right\} \cong \mathbb{R}^{n_1\cdots n_k}.$$

If every dimension of T is the same, $n_1 = \cdots = n_k = n$, then we write $\mathsf{Ten}^{\otimes k}_n$ for the space of equilateral tensors of order k and dimension n. Definitions of the sets of *symmetric* (Sym), *non-negative* (NN), *doubly non-negative* (DNN), *positive semidefinite* (PSD), *completely positive* (CP), *copositive* (coP), etc., matrices and tensors are deferred to the corresponding sections where we need them. Note that $\mathsf{Mat}_{n,m} = \mathsf{Ten}^{\otimes 2}_{n,m}$. When the order of the tensors is $k = 2$, namely matrices, we drop the superscript $\otimes 2$.

For a tensor $T \in \mathsf{Ten}^{\otimes k}_{n_1,\cdots,n_k}$, we use $\|T\|_{\mathrm{F}}$ to denote the *Frobenius norm* of T, which is the ℓ^2 norm when T is vectorized into a length-$n_1\cdots n_k$ vector.

$$\|T\|_{\mathrm{F}} := \left(\sum_{(i_1,\cdots,i_k)\in[n_1]\times\cdots\times[n_k]} T(i_1,\cdots,i_k)^2\right)^{1/2}.$$

We use $\|T\|_{\mathrm{sav}}$ to denote the *sum-absolute-value norm* of T which is the ℓ^1 norm after vectorization.

$$\|T\|_{\mathrm{sav}} := \sum_{(i_1,\cdots,i_k)\in[n_1]\times\cdots\times[n_k]} |T(i_1,\cdots,i_k)|.$$

Similarly, define

$$\|T\|_{\mathrm{mav}} := \max_{(i_1,\cdots,i_k)\in[n_1]\times\cdots\times[n_k]} |T(i_1,\cdots,i_k)|$$

to be the *max-absolute-value* norm of T, which is the ℓ^∞ norm when viewed as a vector.

Note that the Frobenius norm, sum-absolute-value norm and max-absolute-value are different from the matrix/tensor 2-norm, 1-norm and ∞-norm. Though they do trivially coincide with the corresponding vector norm when the order of the tensor is one.

We endow the matrix/tensor space with an inner product. For tensors T_1 and T_2 both in $\mathsf{Ten}^{\otimes k}_{n_1,\cdots,n_k}$,

$$\langle T_1, T_2\rangle := \sum_{(i_1,\cdots,i_k)\in[n_1]\times\cdots\times[n_k]} T_1(i_1,\cdots,i_k)T_2(i_1,\cdots,i_k).$$

When T_1, T_2 are matrices, the above definition agrees with the *Frobenius inner product*, which is alternatively defined as $\mathrm{Tr}\left(T_1^\top T_2\right)$. When T_1, T_2 are vectors, this inner product becomes the standard inner product associated to $\mathbb{R}^n$ as a Hilbert space, which is denoted by the same notation without confusion.

Let S_n denote the *symmetric group* of degree n consisting of $n!$ permutations on $[n]$. Permutations are typically denoted by lower case Greek letters.

Information theory. We use $H(\cdot)$ to interchangeably denote the binary entropy function and the Shannon entropy; the exact meaning will be clear from the context. In particular, for any $p \in [0,1]$, $H(p)$ denotes the binary entropy

$$H(p) = p \log \frac{1}{p} + (1-p) \log \frac{1}{1-p}.$$

For a distribution $P \in \Delta(\mathcal{X})$ on a finite alphabet $\mathcal{X}$ or a random variable $\mathbf{x} \sim P$ distributed according to P, the Shannon entropy of P or $\mathbf{x}$ is defined similarly as

$$H(P) = H(\mathbf{x}) \coloneqq \sum_{x \in \mathcal{X}} P(x) \log \frac{1}{P(x)}.$$

For two distributions $P, Q \in \Delta(\mathcal{X})$ on the same alphabet $\mathcal{X}$, the *Kullback–Leibler (KL) divergence* between them is defined as

$$D(P \| Q) \coloneqq \sum_{x \in \mathcal{X}} P(x) \log \frac{P(x)}{Q(x)}.$$

If $\mathbf{x}, \mathbf{y}$ are jointly distributed according to $P_{\mathbf{x},\mathbf{y}} \in \Delta(\mathcal{X} \times \mathcal{Y})$, then their *joint entropy* is defined as

$$H(\mathbf{x}, \mathbf{y}) = H(P_{\mathbf{x},\mathbf{y}}) \coloneqq \sum_{x \in \mathcal{X}} \sum_{y \in \mathcal{Y}} P_{\mathbf{x},\mathbf{y}}(x,y) \log \frac{1}{P_{\mathbf{x},\mathbf{y}}(x,y)};$$

their *mutual information* is defined as

$$\begin{aligned} I(\mathbf{x}; \mathbf{y}) \coloneqq & D\left(P_{\mathbf{x},\mathbf{y}} \| P_{\mathbf{x}} P_{\mathbf{y}}\right) \\ = & \sum_{x \in \mathcal{X}} \sum_{y \in \mathcal{Y}} P_{\mathbf{x},\mathbf{y}}(x,y) \log \frac{P_{\mathbf{x},\mathbf{y}}(x,y)}{P_{\mathbf{x}}(x) P_{\mathbf{y}}(y)} \\ = & \sum_{y \in \mathcal{Y}} P_{\mathbf{y}}(y) \sum_{x \in \mathcal{X}} P_{\mathbf{x}|\mathbf{y}}(x|y) \log \frac{P_{\mathbf{x}|\mathbf{y}}(x|y)}{P_{\mathbf{x}}(x)}. \end{aligned}$$

If the conditional distribution of $\mathbf{y}$ given $\mathbf{x}$ is $P_{\mathbf{y}|\mathbf{x}} \in \Delta(\mathcal{Y}|\mathcal{X})$, then the *conditional entropy* of $\mathbf{y}$ given $\mathbf{x}$ is defined as

$$\begin{aligned} H(\mathbf{y}|\mathbf{x}) \coloneqq & \sum_{x \in \mathcal{X}} P_{\mathbf{x}}(x) H(\mathbf{y}|\mathbf{x} = x) \\ = & \sum_{x \in \mathcal{X}} \sum_{y \in \mathcal{X}} P_{\mathbf{x},\mathbf{y}}(x,y) \log \frac{P_{\mathbf{x}}(x)}{P_{\mathbf{x},\mathbf{y}}(x,y)}. \end{aligned}$$

It is easy to check that different definitions above for the same quantities are consisted with each other.

8 Preliminaries

▶ **Lemma 10** (Stirling's approximation). *For any $n \in \mathbb{Z}_{>0}$, $n! \asymp \sqrt{2\pi n}\,(n/e)^n$.*

▶ **Corollary 11** (Asymptotics of multinomials). *For any positive integers $n \geqslant q$ and any q-partition $(n_1, \cdots, n_q)$ of n ($n_1 + \cdots + n_q = n$, $n_i \geqslant 0$ for every i), $\binom{n}{n_1, \cdots, n_q} \doteq 2^{nH(P)}$, where $P \in \Delta([q])$ is an empirical distribution such that for $i \in [q]$, $P(i) = n_i/n$. More precisely, we have $\binom{n}{n_1, \cdots, n_q} \asymp \nu(n)^{-1} 2^{nH(P)}$, where $\nu(n)$ is a polynomial defined as*

$$\nu(n) \coloneqq (2\pi n)^{\frac{q-1}{2}} \left(\prod_{i=1}^{q} P(i) \right)^{\frac{1}{2}}.$$

▶ **Fact 12** (Approximation of binomials). *For any positive integers $n \geqslant k$,*

$$\left(\frac{n}{k}\right)^k \leqslant \binom{n}{k} \leqslant \left(\frac{en}{k}\right)^k, \tag{6}$$

$$(n-k)^k \leqslant (n-k+1)^k \leqslant \binom{n}{k} \leqslant n^k. \tag{7}$$

Without loss of generality, we write $\mathcal{X} = \{1, \cdots, |\mathcal{X}|\}$. For $\underline{x} \in \mathcal{X}^n$ and $x \in \mathcal{X}$, let

$$N_x(\underline{x}) := \left|\{i \in [n] \colon \underline{x}(i) = x\}\right|,$$

which counts the number of occurrences of a symbol x in a vector $\underline{x}$. Similarly, define

$$N_{x,y}\left(\underline{x}, \underline{y}\right) := \left|\left\{i \in [n] \colon \underline{x}(i) = x,\ \underline{y}(i) = y\right\}\right|.$$

▶ **Definition 13** (Types). *For a length-n vector $\underline{x}$ over a finite alphabet $\mathcal{X}$, the type $\tau_{\underline{x}}$ of $\underline{x}$ is a length-$|\mathcal{X}|$ (empirical) probability vector (or the histogram of $\underline{x}$), i.e., $\tau_{\underline{x}} \in [0,1]^{|\mathcal{X}|}$ has entries $\tau_{\underline{x}}(x) := N_x(\underline{x})/n$ for all $x \in \mathcal{X}$.*

▶ **Definition 14** (Joint types and conditional types). *The* joint type $\tau_{\underline{x},\underline{y}} \in [0,1]^{|\mathcal{X}|\times|\mathcal{Y}|}$ *of two vectors $\underline{x} \in \mathcal{X}^n$ and $\underline{y} \in \mathcal{Y}^n$ is defined as $\tau_{\underline{x},\underline{y}}(x,y) = N_{x,y}(\underline{x},\underline{y})/n$ for $x \in \mathcal{X}$ and $y \in \mathcal{Y}$.*

The conditional type $\tau_{\underline{y}|\underline{x}} \in [0,1]^{|\mathcal{X}|\times|\mathcal{Y}|}$ of a vector $\underline{y} \in \mathcal{Y}^n$ given another vector $\underline{x} \in \mathcal{X}^n$ is defined as $\tau_{\underline{y}|\underline{x}}(y|x) = N_{x,y}\left(\underline{x},\underline{y}\right)/N_x\left(\underline{x}\right)$.

▶ Remark 15 (Types vs. distributions). Types are empirical distributions of length-n vectors. They can only take rational values, in particular, a/n for $a \in \{0,1,\cdots,n\}$. For finite alphabets and a fixed n, there are only poly(n) many types. However, there are uncountably infinitely many distributions on any finite alphabets and they form a probability simplex.

▶ Remark 16. We will also write $\tau_{\mathbf{x}}, \tau_{\mathbf{x},\mathbf{y}}, \tau_{\mathbf{y}|\underline{x}}, \tau_{\mathbf{y}|\mathbf{x}}$, etc., for generic types that are taken from the corresponding sets of types even if they do not come from instantiated vectors. For instance, $\tau_{\mathbf{x}}$ is a type in $\mathcal{P}^{(n)}(\mathcal{X})$ corresponding to any $\underline{x} \in \mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}})$. The particular choice of $\underline{x}$ is not important and will not be specified. These notations are for explicitly distinguishing types from distributions.

▶ **Definition 17** (Set of types). *We use $\mathcal{P}^{(n)}(\mathcal{X})$ to denote the set of types of all length-n vectors over $\mathcal{X}$.*

$$\mathcal{P}^{(n)}(\mathcal{X}) = \left\{\tau_{\underline{x}} \colon \underline{x} \in \mathcal{X}^n\right\}.$$

Similarly, define

$$\mathcal{P}^{(n)}(\mathcal{X},\mathcal{Y}) = \left\{\tau_{\underline{x},\underline{y}} \colon \underline{x} \in \mathcal{X}^n,\ \underline{y} \in \mathcal{Y}^n\right\},$$
$$\mathcal{P}^{(n)}(\mathcal{Y}|\underline{x}) = \left\{\tau_{\underline{y}|\underline{x}} \colon \underline{y} \in \mathcal{Y}^n\right\},$$
$$\mathcal{P}^{(n)}(\mathcal{Y}|\mathcal{X}) = \left\{\tau_{\underline{y}|\underline{x}} \colon \underline{x} \in \mathcal{X}^n,\ \underline{y} \in \mathcal{Y}^n\right\}$$

to be

1. *the set of all joint types;*
2. *the set of all conditional types of $\underline{y}$ given a particular $\underline{x}$;*
3. *the set of all conditional types of $\underline{y}$ given some $\underline{x}$,*

respectively.

▶ **Lemma 18** (Types are dense in distributions). *The union of the sets of types of all possible blocklengths is dense in the set of distributions, i.e.,*

$$\bigcup_{n=1}^{\infty} \mathcal{P}^{(n)}(\mathcal{X})$$

is dense in $\Delta(\mathcal{X})$. This holds true for joint types and conditional types as well.

▶ **Lemma 19** (Number of types). *When alphabet sizes are constants, the number of types of length-n vectors is polynomial in n. To be precise, the number of types of length-n vectors over $\mathcal{X}$ is*

$$\left|\mathcal{P}^{(n)}(\mathcal{X})\right| = \binom{n+|\mathcal{X}|-1}{|\mathcal{X}|-1}. \tag{8}$$

For a vector $\underline{x} \in \mathcal{X}^n$ of type $\tau_{\underline{x}}$, the number of conditional types of length-n vectors over $\mathcal{Y}$ given $\underline{x}$ is

$$\left|\mathcal{P}^{(n)}(\mathcal{Y}|\underline{x})\right| = \prod_{x\in\mathcal{X}} \binom{\tau_{\underline{x}}(x)n+|\mathcal{Y}|-1}{|\mathcal{Y}|-1}. \tag{9}$$

The number of conditional types of $\mathcal{Y}$-valued vectors given some $\mathcal{X}$-valued vector is

$$\mathcal{P}^{(n)}(\mathcal{Y}|\mathcal{X}) = \sum_{\tau_{\mathbf{x}}\in\mathcal{P}^{(n)}(\mathcal{X})} \prod_{x\in\mathcal{X}} \binom{\tau_{\mathbf{x}}(x)n+|\mathcal{Y}|-1}{|\mathcal{Y}|-1}. \tag{10}$$

The following elementary bounds from [16] are sufficient for the purposes of this paper.

$$\left|\mathcal{P}^{(n)}(\mathcal{X})\right| \leqslant (n+1)^{|\mathcal{X}|},$$
$$\left|\mathcal{P}^{(n)}(\mathcal{Y}|\underline{x})\right| \leqslant \left|\mathcal{P}^{(n)}(\mathcal{Y}|\mathcal{X})\right| \leqslant (n+1)^{|\mathcal{X}|\cdot|\mathcal{Y}|}.$$

▶ **Definition 20** (Type classes). *Define type class $\mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}})$ w.r.t. a type $\tau_{\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{X})$ as*

$$\mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}}) \coloneqq \left\{\underline{x} \in \mathcal{X}^n \colon \tau_{\underline{x}} = \tau_{\mathbf{x}}\right\}.$$

Similarly, the joint type class $\mathcal{T}_{\underline{\mathbf{x}},\underline{\mathbf{y}}}(\tau_{\mathbf{x},\mathbf{y}})$ w.r.t. a joint type $\tau_{\mathbf{x},\mathbf{y}} \in \mathcal{P}^{(n)}(\mathcal{X}\times\mathcal{Y})$ is defined as

$$\mathcal{T}_{\underline{\mathbf{x}},\underline{\mathbf{y}}}(\tau_{\mathbf{x},\mathbf{y}}) \coloneqq \left\{(\underline{x},\underline{y}) \in \mathcal{X}^n \times \mathcal{Y}^n \colon \tau_{\underline{x},\underline{y}} = \tau_{\mathbf{x},\mathbf{y}}\right\}.$$

The conditional type class $\mathcal{T}_{\underline{\mathbf{y}}|\underline{x}}(\tau_{\mathbf{y}|\underline{x}})$ w.r.t. a conditional type $\tau_{\mathbf{y}|\underline{x}} \in \mathcal{P}^{(n)}(\mathcal{Y}|\underline{x})$ given a vector $\underline{x} \in \mathcal{X}^n$ is defined as

$$\mathcal{T}_{\underline{\mathbf{y}}|\underline{x}}(\tau_{\mathbf{y}|\underline{x}}) \coloneqq \left\{\underline{y} \in \mathcal{Y}^n \colon \tau_{\underline{y}|\underline{x}} = \tau_{\mathbf{y}|\underline{x}}\right\}.$$

The conditional type class $\mathcal{T}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}}(\tau_{\mathbf{y}|\mathbf{x}})$ w.r.t. a conditional type $\tau_{\mathbf{y}|\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{Y}|\mathcal{X})$ is defined as

$$\mathcal{T}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}}(\tau_{\mathbf{y}|\mathbf{x}}) \coloneqq \bigcup_{\tau_{\mathbf{x}}\in\mathcal{P}^{(n)}(\mathcal{X})} \mathcal{T}_{\underline{\mathbf{y}}|\underline{x}'}(\tau_{\mathbf{y}|\mathbf{x}}) \tag{11}$$

$$= \left\{\underline{y} \in \mathcal{Y}^n \colon \exists \underline{x}' \in \mathcal{X}^n,\ \tau_{\underline{y}|\underline{x}'} = \tau_{\mathbf{y}|\mathbf{x}}\right\}, \tag{12}$$

where in Eqn. (11) $\underline{x}'$ can be chosen arbitrarily from $\mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}})$.

▶ **Lemma 21** (Size of type classes)**.**

1. *For any type* $\tau_{\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{X})$, $\left|\mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}})\right| \doteq 2^{nH(P_{\mathbf{x}})}$.
2. *For any vector* $\underline{x} \in \mathcal{X}^n$ *and any conditional type* $\tau_{\mathbf{y}|\underline{x}} \in \mathcal{P}^{(n)}(\mathcal{Y}|\underline{x})$, $\left|\mathcal{T}_{\underline{\mathbf{y}}|\underline{x}}\left(\tau_{\mathbf{y}|\underline{x}}\right)\right| \doteq 2^{nH(\mathbf{y}|\mathbf{x})}$, *where the conditional entropy is evaluated w.r.t. the joint type* $\tau_{\underline{x}}\tau_{\mathbf{y}|\underline{x}}$.
3. *For any conditional type* $\tau_{\mathbf{y}|\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{Y}|\mathcal{X})$,

$$\left|\mathcal{T}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}}\left(\tau_{\mathbf{y}|\mathbf{x}}\right)\right| \doteq 2^{n \max_{\tau_{\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{X})} H(\mathbf{y}|\mathbf{x})},$$

where the conditional entropy is evaluated w.r.t. the joint type $\tau_{\mathbf{x}}\tau_{\mathbf{y}|\mathbf{x}}$.

Proof.

1. The number of sequences $\underline{x} \in \mathcal{X}^n$ of type $\tau_{\mathbf{x}}$ is precisely

$$\binom{n}{n\tau_{\mathbf{x}}(1), \cdots, n\tau_{\mathbf{x}}(|\mathcal{X}|)}$$

and the claim follows from Lemma 10.

2. Given $\underline{x} \in \mathcal{X}^n$, the number of sequences $\underline{y} \in \mathcal{Y}^n$ of conditional type $\tau_{\mathbf{y}|\underline{x}}$ is precisely

$$\prod_{x \in \mathcal{X}} \binom{n\tau_{\underline{x}}(x)}{n\tau_{\mathbf{y}|\underline{x}}(1|x), \cdots, n\tau_{\mathbf{y}|\underline{x}}(|\mathcal{Y}|\,|x)},$$

and the lemma follows from 10.

3. Note that

$$\mathcal{T}_{\underline{\mathbf{y}}|\underline{x}^*}\left(\tau_{\mathbf{y}|\underline{x}^*}\right) \leqslant \left|\mathcal{T}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}}\left(\tau_{\mathbf{y}|\mathbf{x}}\right)\right| \leqslant \left|\mathcal{P}^{(n)}(\mathcal{X})\right| \mathcal{T}_{\underline{\mathbf{y}}|\underline{x}^*}\left(\tau_{\mathbf{y}|\underline{x}^*}\right),$$

where $\underline{x}^*$ is chosen arbitrarily from $\mathcal{T}_{\underline{\mathbf{x}}}\left(\tau^*_{\mathbf{x}}\right)$ and[11]

$$\tau^*_{\mathbf{x}} = \operatorname*{argmax}_{\tau_{\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{X})} \left|\mathcal{T}_{\underline{\mathbf{y}}|\underline{x}}\left(\tau_{\underline{\mathbf{y}}|\underline{x}}\right)\right|.$$

The claim follows from Eqn. (8) and the previous claim.

◀

▶ **Lemma 22.** *If* $\underline{\mathbf{x}}$ *is generated using the product distribution* $P_{\mathbf{x}}^{\otimes n}$*, then for any* $\underline{x} \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}})$,

$$\Pr\left[\underline{\mathbf{x}} = \underline{x}\right] = 2^{-nH(P_{\mathbf{x}})}.$$

Moreover,

$$\Pr\left[\underline{\mathbf{x}} \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}})\right] \asymp \nu(n)^{-1}.$$

Proof. Both claims follow from elementary calculations. For the first one,

$$\begin{aligned}\Pr\left[\underline{\mathbf{x}} = \underline{x}\right] &= \prod_{x \in \mathcal{X}} P_{\mathbf{x}}(x)^{N_x(\underline{x})} \\ &= 2^{\sum_{x \in \mathcal{X}} N_x(\underline{x}) \log P_{\mathbf{x}}(x)} \\ &= 2^{n \sum_{x \in \mathcal{X}} P_{\mathbf{x}}(x) \log P_{\mathbf{x}}(x)} \qquad (13) \\ &= 2^{-nH(P_{\mathbf{x}})},\end{aligned}$$

where Eqn. (13) is because $\tau_{\underline{x}} = P_{\mathbf{x}}$ and hence $N_x(\underline{x})/n = P_{\mathbf{x}}(x)$ for any $x \in \mathcal{X}$.

[11] In the argmax, $\underline{x} \in \mathcal{T}_{\underline{\mathbf{x}}}\left(\tau_{\mathbf{x}}\right)$ is arbitrary as well.

For the second one,

$$\begin{aligned}\Pr\left[\underline{\mathbf{x}} \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}})\right] =& \Pr\left[\tau_{\underline{\mathbf{x}}} = P_{\mathbf{x}}\right] \\ =& \binom{n}{nP_{\mathbf{x}}(1), \cdots, nP_{\mathbf{x}}(|\mathcal{X}|)} \prod_{x\in\mathcal{X}} P_{\mathbf{x}}(x)^{nP_{\mathbf{x}}(x)} \\ \asymp& \nu(n)^{-1} 2^{nH(P)} 2^{-nH(P)} \qquad (14) \\ =& \nu(n)^{-1},\end{aligned}$$

where Eqn. (14) is by Corollary 11. ◀

▶ **Lemma 23** (Markov). *For any non-negative random variable X and any positive number x,*

$$\Pr[X \geqslant x] \leqslant \frac{\mathbb{E}[X]}{x}.$$

▶ **Lemma 24** (Chernoff). *Let $X_1, \cdots, X_n$ be independent (not necessarily identically distributed) $\{0,1\}$-valued random variables. Let*

$$X := \sum_{i=1}^{n} X_i.$$

Then

$$\begin{aligned}\Pr[X \geqslant (1+\epsilon)\mathbb{E}[X]] \leqslant& e^{-\frac{\epsilon^2}{3}\mathbb{E}[X]}, \\ \Pr[X \leqslant (1-\epsilon)\mathbb{E}[X]] \leqslant& e^{-\frac{\epsilon^2}{2}\mathbb{E}[X]}, \\ \Pr[X \notin (1\pm\epsilon)\mathbb{E}[X]] \leqslant& 2e^{-\frac{\epsilon^2}{3}\mathbb{E}[X]}.\end{aligned}$$

▶ **Lemma 25** (Sanov). *Let $\mathcal{Q} \subset \Delta(\mathcal{X})$ be a subset of distributions such that it is equal to the closure of its interior. Let $\underline{\mathbf{x}} \sim P_{\mathbf{x}}^{\otimes n}$ be a random vector whose components are i.i.d. according to $P_{\mathbf{x}}$. Clearly $\underline{\mathbf{x}}$ is expected to have type $\mathbb{E}\left[\tau_{\underline{\mathbf{x}}}\right] = P_{\mathbf{x}}$. Sanov's theorem determines the first-order exponent of the probability that the vector empirically looks like coming from some distribution $Q \in \mathcal{Q}$.*

$$\Pr\left[\tau_{\underline{\mathbf{x}}} \in \mathcal{Q}\right] \doteq 2^{-n \inf_{Q\in\mathcal{Q}} D(Q\|P_{\mathbf{x}})}.$$

▶ Remark 26. One can view Sanov's theorem as a particular form of the Chernoff bound. Since $\underline{\mathbf{x}}(i)$'s are independent, it gives the *correct* exponent of $\Pr\left[\tau_{\underline{\mathbf{x}}} \in \mathcal{Q}\right]$ (up to lower order terms) rather than being merely a bound.

▶ **Lemma 27** (Anti-concentration). *Let X be a non-negative random variable. Then*

$$\Pr[X = 0] \leqslant \frac{Var[X]}{\mathbb{E}[X]^2}.$$

▶ **Fact 28** (Binomial identities). *For any non-negative integers n, K and $0 \leqslant k \leqslant n$, we have*

$$\binom{n}{k} = \binom{n}{n-k}, \qquad (15)$$

$$\binom{n}{k} = \frac{n}{k}\binom{n-1}{k-1}, \qquad (16)$$

$$\binom{n}{k} + \binom{n}{k+1} = \binom{n+1}{k+1}, \tag{17}$$

$$2^K = \sum_{i=0}^{K} \binom{n}{i}. \tag{18}$$

We list several basic (in)equalities concerning information measures that we will frequently refer to.

▶ **Fact 29** (Information (in)equalities). *The following inequalities hold for any random variables/distributions over finite sets.*

$$\begin{aligned} H(\mathbf{x},\mathbf{y}) =& H(\mathbf{x}) + H(\mathbf{y}|\mathbf{x}) \\ =& H(\mathbf{y}) + H(\mathbf{x}|\mathbf{y}) \\ =& H(\mathbf{x}|\mathbf{y}) + H(\mathbf{y}|\mathbf{x}) + I(\mathbf{x};\mathbf{y}) \\ =& H(\mathbf{x}) + H(\mathbf{y}) - I(\mathbf{x};\mathbf{y}), \\ I(\mathbf{x};\mathbf{y}) =& H(\mathbf{x}) - H(\mathbf{x}|\mathbf{y}) \\ =& H(\mathbf{y}) - H(\mathbf{y}|\mathbf{x}) \\ =& D\left(P_{\mathbf{x},\mathbf{y}} \| P_{\mathbf{x}} P_{\mathbf{y}}\right). \end{aligned}$$

9 Basic definitions

▶ **Definition 30** (Adversarial channels). *An adversarial channel* $\mathcal{A} = (\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}})$ *(Fig. 3) is a sextuple consisting of*

1. *an input alphabet* $\mathcal{X}$*;*
2. *a set of input constraints* $\lambda_{\mathbf{x}} \subseteq \mathcal{P}^{(n)}(\mathcal{X})$*;*
3. *a noise alphabet* $\mathcal{S}$*;*
4. *a set of noise constraints* $\lambda_{\mathbf{s}} \subseteq \mathcal{P}^{(n)}(\mathcal{S})$*;*
5. *an output alphabet* $\mathcal{Y}$*;*
6. *a channel law given by a transition probability* $W_{\mathbf{y}|\mathbf{x},\mathbf{s}} \in \Delta(\mathcal{Y}|\mathcal{X} \times \mathcal{S})$.

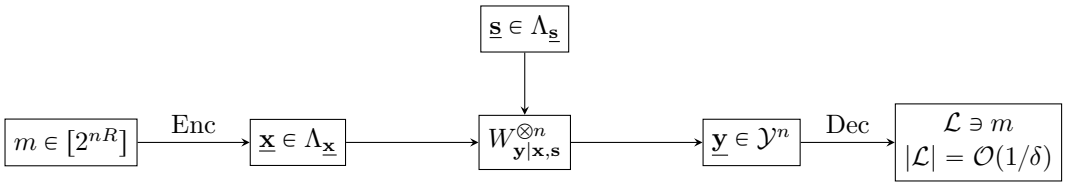

Figure 3 General adversarial channels.

▶ Remark 31. In this paper, we are only concerned with finite alphabets of constant size independent of the blocklength n.

Specifically,

- Though the alphabets $\mathcal{X}, \mathcal{S}$ and $\mathcal{Y}$ can be arbitrary finite sets, it is without loss of generality to realize them using the first $|\mathcal{X}|, |\mathcal{S}|$ and $|\mathcal{Y}|$ positive integers, i.e., $\mathcal{X} = [|\mathcal{X}|], \mathcal{S} = [|\mathcal{S}|]$ and $\mathcal{Y} = [|\mathcal{Y}|]$.[12]

[12] Under such realizations, these sets are *not* necessarily equipped with real arithmetic or modular arithmetic. The metric, if one cares, would be specified by the channel function.

- The input and noise constraint sets $\lambda_{\mathbf{x}}$ and $\lambda_{\mathbf{s}}$ are subsets of types $\mathcal{P}^{(n)}(\mathcal{X})$ and $\mathcal{P}^{(n)}(\mathcal{S})$ respectively. In this paper we assume they are *convex* sets. Since there are polynomially many types in total, we can also think of these collections of types as defined by intersections of hyperplanes or halfspaces, that is, types satisfying a certain finite number of linear (in the entries of the types) (in)equality constraints.
- In this paper, for technical simplicity, we assume that the channel transition function has only *singleton* mass. That is, for each $x \in \mathcal{X}, s \in \mathcal{S}$, $W_{\mathbf{y}|\mathbf{x},\mathbf{s}}(y|x,s) = 1$ only for one $y \in \mathcal{Y}$ and is zero for all other outputs. Equivalently, such degenerate distributions can be alternatively thought of as *deterministic* functions

$$\begin{array}{rccc} W\colon & \mathcal{X}\times\mathcal{S} & \to & \mathcal{Y} \\ & (x,s) & \mapsto & y, \end{array}$$

  where y is the *unique* output which is assigned the full probability, $W_{\mathbf{y}|\mathbf{x},\mathbf{s}}(y|x,s) = 1$. Here we slightly abuse the notation and use the same letter for the channel transition distribution and the channel transition function (when the distribution is degenerate). Moreover, we use $\underline{y} = W(\underline{x},\underline{s})$ (with the superscript $\otimes n$ being dropped) to denote the output of n uses of the channel, or equivalently, the n-letter output of the function which acts on $(\underline{x},\underline{s})$ component by component.
  It seems this is a severe restriction (and turns out indeed to be so). Nevertheless, it is still a very first and significant step towards understanding general adversarial channels in full generality. The case where $W_{\mathbf{y}|\mathbf{x},\mathbf{s}}$ is an arbitrary conditional distribution, or equivalently, the function W is *non-deterministic*, is interesting as well and is left as a future direction.
- For notational convenience, let

$$\begin{aligned} \Lambda_{\underline{\mathbf{x}}} &:= \left\{\underline{x} \in \mathcal{X}^n \colon \tau_{\underline{x}} \in \lambda_{\mathbf{x}}\right\} \\ &= \bigcup_{\tau_{\mathbf{x}} \in \lambda_{\mathbf{x}}} \mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}}), \\ \Lambda_{\underline{\mathbf{s}}} &:= \left\{\underline{s} \in \mathcal{S}^n \colon \tau_{\underline{s}} \in \lambda_{\mathbf{s}}\right\} \\ &= \bigcup_{\tau_{\mathbf{s}} \in \lambda_{\mathbf{s}}} \mathcal{T}_{\underline{\mathbf{s}}}(\tau_{\mathbf{s}}), \end{aligned}$$

  be sets of codewords and error patterns of admissible types.

▶ **Example 32.** Our framework covers a large family of channel models, including most of the popular and well-studied ones.

1. The standard bit-flip channels. $\mathcal{X} = \mathbb{F}_2, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{F}_2), \mathcal{S} = \mathbb{F}_2$,

$$\lambda_{\mathbf{s}} = \left\{\tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathbb{F}_2) \colon \tau_{\mathbf{s}}(1) \leqslant p\right\},$$

   $\mathcal{Y} = \mathbb{F}_2, y = W(x,s) = x \,\mathsf{XOR}\, s$.
2. The standard q-ary channels. $\mathcal{X} = \mathbb{Z}_q$, $\lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{Z}_q)$, $\mathcal{S} = \mathbb{Z}_q$,

$$\lambda_{\mathbf{s}} = \left\{\tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathbb{Z}_q) \colon \tau_{\mathbf{s}}(1) + \cdots + \tau_{\mathbf{s}}(q-1) \leqslant p\right\},$$

   $\mathcal{Y} = \mathbb{Z}_q, y = W(x,s) = x + s \mod q$.
3. The standard erasure channels. $\mathcal{S} = \mathbb{Z}_q, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{Z}_q), \mathcal{S} = \mathbb{F}_2$,

$$\lambda_{\mathbf{s}} = \left\{\tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathbb{F}_2) \colon \tau_{\mathbf{s}}(1) \leqslant p\right\},$$

$\mathcal{Y} = \mathbb{Z}_q \cup \{\mathsf{erasure}\}$,

$$y = W(x,s) = \begin{cases} x, & s = 0 \\ \mathsf{erasure}, & s = 1 \end{cases}.$$

4. Weight constrained channels. Any of the above channels with

$$\lambda_{\mathbf{x}} = \left\{ \tau_{\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{X}) \colon 1 - \tau_{\mathbf{x}}(0) \leqslant w \right\}.$$

5. Z-channels (or multiplier/AND channels). $\mathcal{X} = \mathbb{F}_2, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{F}_2), \mathcal{S} = \mathbb{F}_2$,

$$\lambda_{\mathbf{s}} = \left\{ \tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathbb{F}_2) \colon \tau_{\mathbf{s}}(1) \leqslant p \right\},$$

$\mathcal{Y} = \mathbb{F}_2$,

$$y = W(x,s) = \begin{cases} 0, & s = 0 \text{ or } x = 0 \\ x, & s = 1 \text{ and } x = 1 \end{cases},$$

or equivalently $y = W(x,s) = x \,\mathsf{AND}\, s$.

6. Adder channels. $\mathcal{X} = \{0, 1, \cdots, q-1\}, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathcal{X}), \mathcal{S} = \{0, 1, \cdots, q-1\}$,

$$\lambda_{\mathbf{s}} = \left\{ \tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathcal{S}) \colon \tau_{\mathbf{s}}(1) + \cdots + \tau_{\mathbf{s}}(q-1) \leqslant p \right\},$$

$\mathcal{Y} = \{0, 1, \cdots, 2(q-1)\}, y = W(x,s) = x + s$, where the addition is over $\mathbb{R}$.

7. Noisy typewriter channels. $\mathcal{X} = \mathbb{Z}_q, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{Z}_q), \mathcal{S} = \mathbb{F}_2, \lambda_{\mathbf{s}} = \mathcal{P}^{(n)}(\mathbb{F}_2), \mathcal{Y} = \mathbb{Z}_q, y = W(x,s) = x + s \mod q$.
8. OR channels (or $\mathfrak{T}$-channels). $\mathcal{X} = \mathbb{F}_2, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{F}_2), \mathcal{S} = \mathbb{F}_2$,

$$\lambda_{\mathbf{s}} = \left\{ \tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathbb{F}_2) \colon \tau_{\mathbf{s}}(1) \leqslant p \right\},$$

$\mathcal{Y} = \mathbb{F}_2, y = W(x,s) = x \,\mathsf{OR}\, s$,

9. Channels under Lee distance. $\mathcal{X} = \mathbb{Z}_q, \lambda_{\mathbf{x}} = \mathcal{P}^{(n)}(\mathbb{Z}_q)$, $\mathcal{S} = \{-\lfloor \frac{q}{2} \rfloor, -\lfloor \frac{q}{2} \rfloor + 1, \cdots, \lfloor \frac{q}{2} \rfloor - 1, \lfloor \frac{q}{2} \rfloor\}$,

$$\lambda_{\mathbf{s}} = \left\{ \tau_{\mathbf{s}} \in \mathcal{P}^{(n)}(\mathcal{S}) \colon \sum_{s=1}^{\lfloor q/2 \rfloor} (\tau_{\mathbf{s}}(s) - \tau_{\mathbf{s}}(-s)) \cdot s \leqslant p \right\},$$

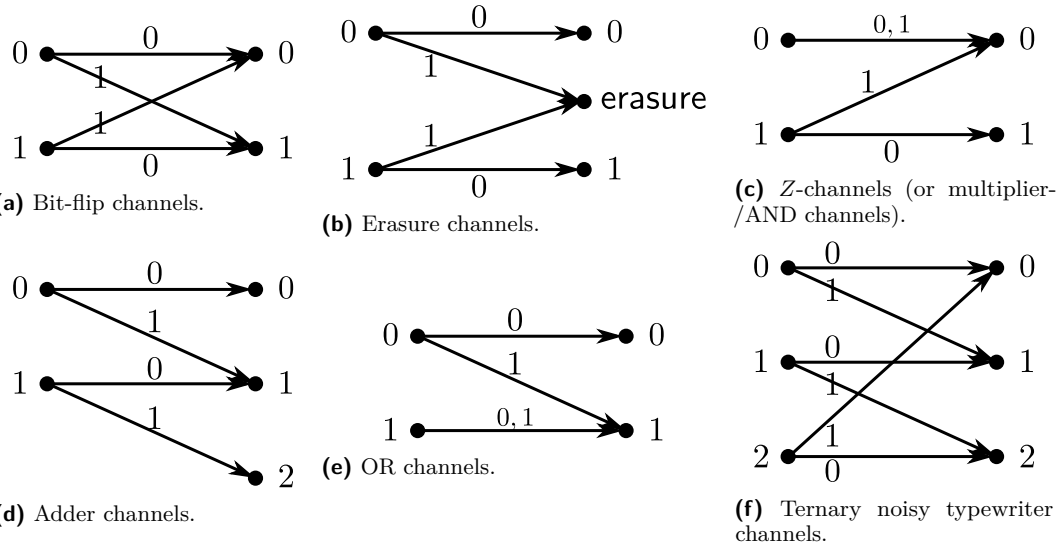
$\mathcal{Y} = \mathbb{Z}_q, y = W(x,s) = x + s$ over the reals.

10. Other more complicated channels, e.g., the one we defined in Sec. 1.

▶ **Definition 33** (Self-couplings). *A joint distribution $P_{\mathbf{x}_1, \cdots, \mathbf{x}_L} \in \Delta(\mathcal{X}^L)$ is said to be a* $(P_{\mathbf{x}}, L)$-self-coupling *for some $P_{\mathbf{x}} \in \Delta(\mathcal{X})$ if all of its marginals equal $P_{\mathbf{x}}$, i.e., $\left[P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}\right]_{\mathbf{x}_i} = P_{\mathbf{x}}$ for all $i \in [L]$. The set of all $(P_{\mathbf{x}}, L)$-self-couplings is denoted by $\mathcal{J}^{\otimes L}(P_{\mathbf{x}})$.*

▶ **Definition 34** (Codes). *In general, a code $\mathcal{C}$ is a subset of $\mathcal{X}^n$. A code $\mathcal{C}$ for an adversarial channel $\mathcal{A} = (\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}})$ is a subset of $\Lambda_{\underline{\mathbf{x}}}$; n is called the blocklength. Elements in $\mathcal{C}$ are called codewords. The rate $R(\mathcal{C})$ of $\mathcal{C}$ is defined as $R(\mathcal{C}) := (\log |\mathcal{C}|)/n$.*

▶ **Definition 35** (Constant composition codes). *A code $\mathcal{C} \subset \mathcal{X}^n$ is said to be $P_{\mathbf{x}}$-constant composition for some $P_{\mathbf{x}} \in \Delta(\mathcal{X})$ if the type of each codeword is $P_{\mathbf{x}}$, i.e., $\tau_{\underline{x}} = P_{\mathbf{x}}$ for every $\underline{x} \in \mathcal{C}$.*



(a) Bit-flip channels.

(b) Erasure channels.

(c) Z-channels (or multiplier-/AND channels).

(d) Adder channels.

(e) OR channels.

(f) Ternary noisy typewriter channels.

Figure 4 Examples of various well-studied channel models.

▶ **Lemma 36.** *For any code $\mathcal{C} \subset \mathcal{X}^n$ of rate R, there is a constant composition subcode $\mathcal{C}' \subseteq \mathcal{C}$ of asymptotically the same rate.*

Proof. Let $\mathcal{C}' = \mathcal{C} \cap \mathcal{T}_{\underline{\mathbf{x}}}(\tau^*_{\mathbf{x}})$, where

$$\tau^*_{\mathbf{x}} = \operatorname*{argmax}_{\tau_{\mathbf{x}} \in \mathcal{P}^{(n)}(\mathcal{X})} \left|\mathcal{C} \cap \mathcal{T}_{\underline{\mathbf{x}}}(\tau_{\mathbf{x}})\right|$$

is the most common type in $\mathcal{C}$. By Lemma 8 and Lemma 23,

$$\left|\mathcal{C}'\right| \geqslant \frac{|\mathcal{C}|}{(n+1)^{|\mathcal{X}|}} = 2^{nR + |\mathcal{X}| \log(n+1)},$$

which implies that $R(\mathcal{C}') \asymp R(\mathcal{C})$ as n grows. ◀

▶ **Definition 37** (Confusability of tuples of vectors)**.** *A list of L distinct codewords $\underline{x}_1, \cdots, \underline{x}_L \in \mathcal{X}^n$ is said to be* L-confusable *if there are $\underline{y} \in \mathcal{Y}^n$ and $\underline{s}_1, \cdots, \underline{s}_L \in \Lambda_{\underline{\mathbf{s}}}$ such that $W(\underline{x}_i, \underline{s}_i) = \underline{y}$ for all $i \in [L]$.*

▶ **Definition 38** (Confusability of joint distributions)**.** *A $(P_{\mathbf{x}}, L)$-self-coupling $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}})$ is said to be* L-confusable *if it has some extension given by $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L,\mathbf{s}_1,\cdots,\mathbf{s}_L,\mathbf{y}} \in \Delta\left(\mathcal{X}^L \times \mathcal{S}^L \times \mathcal{Y}\right)$ such that*

1. $[P_{\mathbf{x},\cdots,\mathbf{x}_L,\mathbf{s}_1,\cdots,\mathbf{s}_L,\mathbf{y}}]_{\mathbf{x}_1,\cdots,\mathbf{x}_L} = P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$;
2. $P_{\mathbf{s}_i} \in \lambda_{\mathbf{s}}$ *for all* $i \in [L]$;
3. $P_{\mathbf{x}_i,\mathbf{s}_i,\mathbf{y}} = P_{\mathbf{x}} P_{\mathbf{s}_i|\mathbf{x}_i} W_{\mathbf{y}|\mathbf{x}_i,\mathbf{s}_i}$ *for all* $i \in [L]$.

▶ **Definition 39** (Confusability set)**.** *The $(P_{\mathbf{x}}, L)$-confusability set $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$ of a channel $\mathcal{A} = \left(\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right)$ is defined as*

$$\mathcal{K}^{\otimes L}(P_{\mathbf{x}}) \coloneqq \left\{P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \colon P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \text{ is } L\text{-confusable}\right\}.$$

▶ Remark 40. In the above definitions, we overload the notion of confusability for types and distributions.

$$\mathcal{K}^{\otimes L}(P_{\mathbf{x}}) = \bigcup_{n=1}^{\infty} \left\{\tau_{\underline{x}_1,\cdots,\underline{x}_L} \colon (\underline{x}_1, \cdots, \underline{x}_L) \text{ is } L\text{-confusable};\ \underline{x}_i \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}}),\ \forall i \in [L]\right\}.$$

▶ **Definition 41** (List decodable codes). *A code $\mathcal{C} \subset \mathcal{X}^n$ is said to be $(L-1)$-*list decodable *if no size-L list is confusable, i.e., for any $\mathcal{L} \in \binom{\mathcal{C}}{L}$, $\mathcal{L}$ is non-L-confusable.*

▶ **Definition 42** (Achievable rate and list decoding capacity). *A rate R is said to be achievable under $(L-1)$-list decoding if there is an infinite sequence of $(L-1)$-list decodable codes $\{\mathcal{C}_i\}_{i\geqslant 1}$ of blocklength $n_i \in \mathbb{Z}_{>0}$ (such that $\{n_i\}$ is a non-vanishing sequence) and rate $R(\mathcal{C}) \geqslant R$.*

The $(L-1)$-list decoding capacity is defined as the maximal achievable rate.

$$C := \limsup_{n\to\infty} \max_{\substack{\mathcal{C}\subseteq\Lambda_{\underline{\mathbf{x}}} \\ (L-1)\text{-list decodable}}} R(\mathcal{C}).$$

10 List decoding capacity

▶ **Theorem 43** (List decoding capacity). *For any adversarial channel $\mathcal{A} = (\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W)$, let*[13]

$$C := \max_{P_{\mathbf{x}}\in\lambda_{\mathbf{x}}} \min_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} I(\mathbf{x};\mathbf{y}), \tag{19}$$

which can be viewed as a generalized sphere-packing bound. The mutual information is evaluated w.r.t.

$$P_{\mathbf{x},\mathbf{y}} = \left[P_{\mathbf{x}} P_{\mathbf{s}|\mathbf{x}} W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{x},\mathbf{y}}.$$

Then

1. *(Achievability) For any $\delta > 0$ and sufficiently large n, there exists $\mathcal{C}$ of rate $C - \delta$ such that it can be $\mathcal{O}(1/\delta)$ list decoded.*
2. *(Converse) For any $\mathcal{C}$ of rate $C + \delta$, $\mathcal{C}$ is $2^{\Omega(n\delta)}$-list decodable.*

Proof. We follow the idea used in the proof of list decoding theorem 4 under the standard bit-flip model but conduct the calculations under our generalized setting [39].

1. (Achievability) Let $R = C - \delta$. Fix $P_{\mathbf{x}}^* \in \lambda_{\mathbf{x}}$ to be a maximizer of expression (19). Generate a random code by sampling 2^{nR} codewords independently and uniformly from $\mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}}^*)$. We will actually show that

   ▶ **Lemma 44.** *For any $\delta > 0$ and sufficiently large n, a random $P_{\mathbf{x}}^*$-constant composition code of rate $R = C - \delta$ as defined above is $\left(\frac{1+\log|\mathcal{Y}|}{\delta} - 1\right)$-list decodable with probability at least $1 - 2^{-n(1-R)}$.*

   For every $\underline{y} \in \mathcal{Y}^n$, define *conditional typical set*

   $$\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} := \left\{\underline{x} \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}}^*) : \exists \underline{s} \in \Lambda_{\underline{\mathbf{s}}},\ \underline{y} = W(\underline{x},\underline{s})\right\}$$

   to be the set of all $\underline{x}$ of type $P_{\mathbf{x}}^*$ that can reach $\underline{y}$ via allowable $\underline{s} \in \Lambda_{\underline{\mathbf{s}}}$. Note that $\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}$ is precisely the list of codewords around $\underline{y}$ whose size we would like to bound. In favour of proceeding calculations, we write $\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}$ in terms of types and estimate its size. We say that a type $\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \in \mathcal{P}^{(n)}(\mathcal{X}\times\mathcal{S}\times\mathcal{Y})$ is *valid* if

   a. $[\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}]_{\mathbf{x}} = P_{\mathbf{x}}^*$;
   b. $[\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}]_{\mathbf{s}} \in \lambda_{\mathbf{s}}$;
   c. $\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} = P_{\mathbf{x}}^* \tau_{\mathbf{s}|\mathbf{x}} W_{\mathbf{y}|\mathbf{x},\mathbf{s}}$.

[13] It can be easily seen that the set $\lambda_{\mathbf{s}|\mathbf{x}}$ is immediately specified given $P_{\mathbf{x}}$, $\lambda_{\mathbf{x}}$ and $\lambda_{\mathbf{s}}$.

Then it is not hard to see that

$$\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} = \bigcup_{\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \text{ valid}} \mathcal{T}_{\underline{\mathbf{x}}|\underline{y}}\left(\tau_{\mathbf{x}|\underline{y}}\right),$$

where $\tau_{\mathbf{x}|\underline{y}}$ is obtained from $\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}$. Note that there is only a polynomial number of types and the volume of each $\mathcal{T}_{\underline{\mathbf{x}}|\underline{y}}\left(\tau_{\mathbf{x}|\underline{y}}\right)$ is dot equal to $2^{nH(\mathbf{x}|\mathbf{y})}$, where $H(\mathbf{x}|\mathbf{y})$ is evaluated w.r.t. $\left[\tau_{\mathbf{x},\mathbf{s},\underline{y}}\right]_{\mathbf{x},\underline{y}} = \tau_{\underline{y}}\tau_{\mathbf{x}|\underline{y}}$. Hence the volume of $\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}$ is

$$\begin{aligned}
\frac{1}{n}\log\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right| &\xrightarrow{n\to\infty} \max_{\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \text{ valid}} H(\mathbf{x}|\mathbf{y}) && (20)\\
&= \max_{\substack{P^*_{\mathbf{x}}\tau_{\mathbf{s}|\mathbf{x}}W_{\mathbf{y}|\mathbf{x},\mathbf{s}}:\\ \left[P^*_{\mathbf{x}}\tau_{\mathbf{s}|\mathbf{x}}W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{s}}\in\lambda_{\mathbf{s}}}} H(\mathbf{x}|\mathbf{y}) && (21)\\
&\to \max_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} H(\mathbf{x}|\mathbf{y}). && (22)
\end{aligned}$$

In Eqn. (20) and (21), the conditional entropy is evaluated w.r.t. $\left[\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}\right]_{\mathbf{x},\mathbf{y}}$ and $\left[P^*_{\mathbf{x}}\tau_{\mathbf{s}|\mathbf{x}}W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{x},\mathbf{y}}$, respectively. In Eqn. (22), the conditional entropy is evaluated w.r.t. $\left[P^*_{\mathbf{x}}P_{\mathbf{s}|\mathbf{x}}W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{x},\mathbf{y}}$. This equality holds in the limit as n approaches infinity since types are asymptotically dense in distributions. Note that $\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \subset \mathcal{T}_{\underline{\mathbf{x}}}(P^*_{\mathbf{x}})$. We have that the probability q that a random codeword $\underline{\mathbf{x}}$ is able to result in $\underline{y}$ via some admissible $\underline{s} \in \Lambda_{\mathbf{s}}$ is

$$\begin{aligned}
\frac{1}{n}\log q \coloneqq& \frac{1}{n}\log\Pr\left[\underline{\mathbf{x}} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right]\\
=& \frac{1}{n}\log\frac{\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right|}{\left|\mathcal{T}_{\underline{\mathbf{x}}}(P^*_{\mathbf{x}})\right|} && (23)\\
\xrightarrow{n\to\infty}& \max_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} H(\mathbf{x}|\mathbf{y}) - H(\mathbf{x}) && (24)\\
=& -\max_{P_{\mathbf{x}}\in\lambda_{\mathbf{x}}}\min_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} I(\mathbf{x};\mathbf{y}) && (25)\\
=& -C.
\end{aligned}$$

Eqn. (23) follows since codewords are picked uniformly from $\mathcal{T}_{\underline{\mathbf{x}}}(P^*_{\mathbf{x}})$. Eqn. (24) is by Eqn. (22) and Eqn. (21). Eqn. (25) is by the choice of $P^*_{\mathbf{x}}$. The probability that there is a large list clustered around $\underline{y}$ is given by

$$\Pr_{\mathcal{C}}\left[\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \cap \mathcal{C}\right| \geqslant L\right] \doteq \sum_{i=L}^{2^{nR}} \binom{2^{nR}}{i} q^i (1-q)^{2^{nR}-i}.$$

Let S_i denote the summand

$$S_i \coloneqq \binom{2^{nR}}{i} q^i (1-q)^{2^{nR}-i}.$$

Note that

$$\begin{aligned}
\frac{S_i}{S_{i+1}} =& \frac{i+1}{2^{nR}-i}\frac{1-q}{q}\\
\geqslant& \frac{2}{2^{n(C-\delta)}}\frac{1-2^{-nC}}{2^{-nC}} && (26)
\end{aligned}$$

$$
\begin{aligned}
&=2\cdot\frac{1}{2}\cdot 2^{n\delta} && (27)\\
&>1,
\end{aligned}
$$

where Eqn. (26) follows since $i \geqslant L \geqslant 1$ and Eqn. (27) follows since $1-2^{-nC} \geqslant \frac{1}{2}$ when $n \geqslant \frac{1}{C}$. The largest summand is the first term. Therefore we can bound the error probability by replacing each term with the first one.

$$
\begin{aligned}
\Pr_{\mathcal{C}}\left[\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\cap\mathcal{C}\right|\geqslant L\right] \leqslant& 2^{nR}\binom{2^{nR}}{L}q^{L}(1-q)^{2^{nR}-L}\\
\leqslant& 2^{nR}2^{nRL}2^{-nCL}\\
=& 2^{-n((L+1)\delta-C)}.
\end{aligned}
$$

Finally taking a union bound over all $\underline{y}\in\mathcal{Y}^n$, we know that the probability of list decoding error is at most

$$
\begin{aligned}
\Pr\left[\exists\underline{y}\in\mathcal{Y}^n,\ \left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\cap\mathcal{C}\right|\geqslant L\right] \leqslant& |\mathcal{Y}|^n\, 2^{-n((L+1)\delta-C)}\\
=& 2^{-n((L+1)\delta-C-\log|\mathcal{Y}|)},
\end{aligned}
$$

which is $2^{-\Omega(n)}$ if $L > \frac{1+\log|\mathcal{Y}|}{\delta}-1$. Specifically, taking $L=\frac{1+\log|\mathcal{Y}|}{\delta}$, we have that the list decoding error probability is at most $2^{-n(1+\delta-C)}=2^{-n(1-R)}$, as desired.

2. (Converse) Given any code $\mathcal{C}$ of rate $C+\delta$, choose the $\tau^*_{\mathbf{x}}\in\mathcal{P}^{(n)}(\mathcal{X})$ such that $|\mathcal{C}\cap\mathcal{T}_{\underline{\mathbf{x}}}(\tau^*_{\mathbf{x}})|$ is maximized. By Lemma 36, $R(\mathcal{C}')\asymp R(\mathcal{C})$. For this $\tau^*_{\mathbf{x}}$, choose legitimate $\tau^*_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}$ such that

$$
\tau^*_{\mathbf{s}|\mathbf{x}} := \operatorname*{argmin}_{\tau_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} I(\mathbf{x};\mathbf{y}),
$$

where $I(\mathbf{x};\mathbf{y})$ is evaluated according to $\left[\tau^*_{\mathbf{x}}\tau_{\mathbf{s}|\mathbf{x}}W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{x},\mathbf{y}}$. Now define $\tau^*_{\mathbf{x},\mathbf{s},\mathbf{y}}:=\tau^*_{\mathbf{x}}\tau^*_{\mathbf{s}|\mathbf{x}}W_{\mathbf{y}|\mathbf{x},\mathbf{s}}$, $\tau^*_{\mathbf{x},\mathbf{y}}:=\left[\tau^*_{\mathbf{x},\mathbf{s},\mathbf{y}}\right]_{\mathbf{x},\mathbf{y}}$ and $\tau^*_{\mathbf{y}}:=\left[\tau^*_{\mathbf{x},\mathbf{y}}\right]_{\mathbf{y}}$. Over the randomness of selecting $\underline{\mathbf{y}}$ uniformly from $\mathcal{T}_{\underline{\mathbf{y}}}\left(\tau^*_{\mathbf{y}}\right)$, the average number of codewords in $\mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}}$ is dot equal to

$$
\begin{aligned}
\mathop{\mathbb{E}}_{\underline{\mathbf{y}}}\left[\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}}\cap\mathcal{C}'\right|\right] &= \mathop{\mathbb{E}}_{\underline{\mathbf{y}}}\left[\sum_{\underline{x}\in\mathcal{C}'}\mathbb{1}_{\left\{\mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}}\ni\underline{x}\right\}}\right]\\
&= \sum_{\underline{x}\in\mathcal{C}'}\Pr_{\underline{\mathbf{y}}}\left[\mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}}\ni\underline{x}\right] && (28)\\
&= \sum_{\underline{x}\in\mathcal{C}'}\Pr_{\underline{\mathbf{y}}}\left[\mathcal{T}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}}\left(\tau^*_{\mathbf{x}|\mathbf{y}}\right)\ni\underline{x}\right] && (29)\\
&= \sum_{\underline{x}\in\mathcal{C}'}\Pr_{\underline{\mathbf{y}}}\left[\tau_{\underline{x}|\underline{\mathbf{y}}}=\tau^*_{\mathbf{x}|\mathbf{y}}\right] && (30)\\
&= \sum_{\underline{x}\in\mathcal{C}'}\frac{1}{\left|\mathcal{T}_{\underline{\mathbf{y}}}\left(\tau^*_{\mathbf{y}}\right)\right|}\prod_{x\in\mathcal{X}}\binom{\tau^*_{\mathbf{x}}(x)n}{\tau^*_{\mathbf{y}}(1)n\cdot\tau^*_{\mathbf{x}|\mathbf{y}}(x|1),\cdots,\tau^*_{\mathbf{y}}(|\mathcal{Y}|)n\cdot\tau^*_{\mathbf{x}|\mathbf{y}}(x||\mathcal{Y}|)}. && (31)
\end{aligned}
$$

Eqn. (28) is linearity of expectation. Note that by our choice of $\tau^*_{\mathbf{x}}$ and $\tau^*_{\mathbf{s}|\mathbf{x}}$ (hence $\tau^*_{\mathbf{x},\mathbf{s},\mathbf{y}}$ and $\tau^*_{\mathbf{x},\mathbf{y}}$), $\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}$ only contains one type class $\mathcal{T}_{\underline{\mathbf{x}}|\underline{y}}\left(\tau^*_{\mathbf{x}|\mathbf{y}}\right)$, where $\tau^*_{\mathbf{x}|\mathbf{y}}$ is computed from $\tau^*_{\mathbf{x},\mathbf{y}}$. Eqn. (29) then follows. Eqn. (30) follows from the definition of type classes

(Definition 20). Eqn. (31) is by analyzing the sampling procedure from the first principle. The product is exactly, given $\underline{x} \in \mathcal{C}'$, the number of ways to pick $\underline{y}$ from $\mathcal{T}_{\underline{\mathbf{x}}|\underline{y}}\left(\tau^*_{\mathbf{y}}\right)$ such that $\tau_{\underline{x}|\underline{y}} = \tau^*_{\mathbf{x}|\mathbf{y}}$. We compute the exponent of the above expectation.

$$\begin{aligned}
\frac{1}{n}\log \mathop{\mathbb{E}}_{\underline{\mathbf{y}}}\left[\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \cap \mathcal{C}'\right|\right] \xrightarrow{n\to\infty} & R' - H\left(\tau^*_{\mathbf{y}}\right) \\
& + \sum_{x\in\mathcal{X}} \tau^*_{\mathbf{x}}(x) \sum_{y\in\mathcal{Y}} \frac{\tau^*_{\mathbf{y}}(y)\tau^*_{\mathbf{x}|\mathbf{y}}(x|y)}{\tau^*_{\mathbf{x}}(x)} \log \frac{\tau^*_{\mathbf{x}}(x)}{\tau^*_{\mathbf{y}}(y)\tau^*_{\mathbf{x}|\mathbf{y}}(x|y)} && (32)\\
=& R - H\left(\tau^*_{\mathbf{y}}\right) + \sum_{x\in\mathcal{X}} \tau^*_{\mathbf{x}}(x) H(\mathbf{y}|\mathbf{x}=x) && (33)\\
=& R - H(\mathbf{y}) + H(\mathbf{y}|\mathbf{x}) && (34)\\
=& R - I(\mathbf{x};\mathbf{y}) \\
\geqslant& R - C && (35)\\
=& \delta.
\end{aligned}$$

Since codewords in the subcode $\mathcal{C}'$ are $\tau^*_{\mathbf{x}}$-constant composition, the summand in Eqn. (31) is independent of particular choices of $\underline{x}$. Eqn. (32) then follows from Stirling's approximation (Lemma 10). In Eqn. (33), $H(\mathbf{y}|\mathbf{x}=x)$ is drawn according to the conditional type

$$\tau^*_{\mathbf{y}|\mathbf{x}}(\cdot|x) = \frac{\tau^*_{\mathbf{y}}(\cdot)\tau^*_{\mathbf{x}|\mathbf{y}}(x|\cdot)}{\tau^*_{\mathbf{x}}(x)}.$$

In Eqn. (34), we pass types to distributions by the fact that types are dense in distributions asymptotically in n. $H(\mathbf{y})$ and $H(\mathbf{y}|\mathbf{x})$ are evaluated using distribution $\left[\tau^*_{\mathbf{x}} P^*_{\mathbf{s}|\mathbf{x}} W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{x},\mathbf{y}}$, where

$$P^*_{\mathbf{s}|\mathbf{x}} := \mathop{\operatorname{argmin}}_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} I(\mathbf{x};\mathbf{y}),$$

and the objective function $I(\mathbf{x};\mathbf{y})$ is evaluated using $\left[\tau^*_{\mathbf{x}} P_{\mathbf{s}|\mathbf{x}} W_{\mathbf{y}|\mathbf{x}}\right]_{\mathbf{x},\mathbf{y}}$. Eqn. (35) is by the definition of C (Eqn. (19)). $\tau^*_{\mathbf{x}}$ always gives rise to mutual information no larger than the maximizer in C.

Therefore, we have shown that there exists at least one $\underline{y} \in \mathcal{Y}^n$ such that the corresponding list around $\underline{y}$ has size at least $2^{n(\delta - o(1))}$. ◀

11 List sizes of random codes

In this section, we show that, if L has order lower than $1/\delta$, then the code used in the proof of achievability (part 1) of the list decoding capacity theorem (Theorem 43) is list decodable with vanishingly small probability. This coupled with Theorem 43 implies that, for the majority (an exponentially close to 1 fraction) of random constant composition capacity-achieving (within gap δ) codes, $\Theta(1/\delta)$ is actually the *correct* order of their list sizes.

▶ **Corollary 45.** *For $\delta > 0$ and sufficiently large n, at least a $1 - 2^{-n(1-R)} - 2^{-n\delta + \frac{2}{\delta}\log\frac{1}{\delta}}$ fraction of $P^*_{\mathbf{x}}$-constant composition codes ($P^*_{\mathbf{x}}$ as defined in Eqn. (36)) of rate $R = C - \delta$ is $(L-1)$-list decodable, where $L = \Theta(1/\delta)$ lies within the following range*

$$L \in \left[\frac{C}{\delta}, \frac{1+\log|\mathcal{Y}|}{\delta}\right].$$

▶ **Theorem 46.** *For an adversarial channel* $\mathcal{A} = \left(\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, , \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right)$*, take an optimizing input distribution* $P_{\mathbf{x}}$ *which attains the list decoding capacity* C*,*

$$P_{\mathbf{x}}^{*} := \underset{P_{\mathbf{x}} \in \lambda_{\mathbf{x}}}{\operatorname{argmax}} \min_{P_{\mathbf{s}|\mathbf{x}} \in \lambda_{\mathbf{s}|\mathbf{x}}} I(\mathbf{x}; \mathbf{y}). \tag{36}$$

For any $\delta > 0$*, for each sufficiently large blocklength* n*, sample a random code* $\mathcal{C}$ *of rate* $R = C - \delta$ *whose codewords are selected independently and uniformly from* $\mathcal{T}_{\underline{\mathbf{x}}}\left(P_{\mathbf{x}}^{*}\right)$*. Then* $\mathcal{C}$ *is* $< (C/\delta - 1)$*-list decodable with probability at most* $2^{-n\delta + \frac{2}{\delta}\log\frac{1}{\delta}}$*.*

The theorem follows from second moment calculations and generalizes similar theorems for list decodability of random error/erasure correction codes over $\mathbb{F}_q$ [26].

Proof. Let $M := 2^{nR}$. Define *typical set*

$$\mathcal{A}_{\underline{\mathbf{y}}} := \left\{W\left(\underline{x}, \underline{s}\right) \in \mathcal{Y}^n : \underline{x} \in \mathcal{T}_{\underline{\mathbf{x}}}\left(P_{\mathbf{x}}^{*}\right),\ \underline{s} \in \Lambda_{\underline{\mathbf{s}}}\right\}.$$

Put in the language of types, it can also be written as

$$\mathcal{A}_{\underline{\mathbf{y}}} = \bigcup_{\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \text{ valid}} \mathcal{T}_{\underline{\mathbf{y}}}\left(\tau_{\mathbf{y}}\right),$$

where $\tau_{\mathbf{y}} = \left[\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}\right]_{\mathbf{y}}$. Define random variable W as a witness for non-list decodability of $\mathcal{C}$

$$W := \sum_{\underline{y} \in \mathcal{A}_{\underline{\mathbf{y}}}} \sum_{\{m_1, \cdots, m_L\} \in \binom{[M]}{L}} \mathbb{1}_{\left\{\left\{\underline{\mathbf{x}}_{m_1}, \cdots, \underline{\mathbf{x}}_{m_L}\right\} \subset \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right\}}.$$

Then by Chebyshev's inequality,

$$\begin{aligned}
\Pr\left[\mathcal{C} \text{ is } (L-1)\text{-list decodable}\right] &= \Pr\left[\bigcap_{\underline{y} \in \mathcal{Y}^n} \left\{\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \cap \mathcal{C}\right| < L\right\}\right] \qquad (37)\\
&\leqslant \Pr\left[\bigcap_{\underline{y} \in \mathcal{A}_{\underline{\mathbf{y}}}(P_{\mathbf{y}})} \left\{\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \cap \mathcal{C}\right| < L\right\}\right]\\
&= \Pr\left[\left(\bigcup_{\underline{y} \in \mathcal{A}_{\underline{\mathbf{y}}}} \left\{\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \cap \mathcal{C}\right| \geqslant L\right\}\right)^{c}\right]\\
&= \Pr\left[W = 0\right] \qquad (38)\\
&\leqslant \frac{\operatorname{Var}\left[W\right]}{\mathbb{E}\left[W\right]^2},
\end{aligned}$$

where Eqn. (38) follows since $W = 0$ if and only if none of the events $\left\{\left|\mathcal{A}_{\underline{\mathbf{x}}|\underline{y}} \cap \mathcal{C}\right| \geqslant L\right\}$ $(\underline{y} \in \mathcal{A}_{\underline{\mathbf{y}}})$ happens. In what follows, we will obtain an upper bound on $\operatorname{Var}\left[W\right]$ and a lower bound on $\mathbb{E}\left[W\right]$, and hence an upper bound on the probability (37).

Lower bounding $\mathbb{E}\left[W\right]$. We can get a lower bound on the expected value of W from a straightforward calculation.

$$\begin{aligned}
\mathbb{E}\left[W\right] &= \sum_{\underline{y} \in \mathcal{A}_{\underline{\mathbf{y}}}} \sum_{\{m_1, \cdots, m_L\} \in \binom{[M]}{L}} \Pr\left[\left\{\underline{\mathbf{x}}_{m_1}, \cdots, \underline{\mathbf{x}}_{m_L}\right\} \subset \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right]\\
&= \sum_{\underline{y} \in \mathcal{A}_{\underline{\mathbf{y}}}} \sum_{\{m_1, \cdots, m_L\} \in \binom{[M]}{L}} \Pr\left[\underline{\mathbf{x}} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right]^{L} \qquad (39)
\end{aligned}$$

$$\begin{aligned}
&\doteq \left|\mathcal{A}_{\underline{\mathbf{y}}}\right| \binom{M}{L} 2^{-nCL} && (40)\\
&\geqslant \left|\mathcal{A}_{\underline{\mathbf{y}}}\right| \left(\frac{M}{L}\right)^{L} 2^{-nCL}\\
&= \left|\mathcal{A}_{\underline{\mathbf{y}}}\right| 2^{-n\delta L - L\log L}.
\end{aligned}$$

Eqn. (39) follows since codewords are independent. Eqn. (40) is by Eqn. (25).

Upper bounding Var $[W]$. Define, for any $\underline{y} \in \mathcal{Y}^n$ and $\mathcal{L} \in \binom{[M]}{L}$,

$$\begin{aligned}
\mathbb{I}\left(\underline{y}, \mathcal{L}\right) :=& \mathbb{1}_{\left\{\{\underline{\mathbf{x}}_m\}_{m\in\mathcal{L}} \subset \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right\}}\\
=& \prod_{m\in\mathcal{L}} \mathbb{1}_{\left\{\underline{\mathbf{x}}_m \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right\}},
\end{aligned}$$

as the indicator function of the event $\bigcap_{m\in\mathcal{L}} \left\{\underline{\mathbf{x}}_m \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{y}}\right\}$ that the list $\mathcal{L}$ is L-confusable w.r.t. $\underline{y}$.

Now the variance of W can be upper bounded as follows.

$$\begin{aligned}
\mathrm{Var}\left[W\right] =& \mathbb{E}\left[W^2\right] - \mathbb{E}\left[W\right]^2 && (41)\\
=& \sum_{\underline{y}_1,\underline{y}_2 \in \mathcal{A}_{\underline{\mathbf{y}}}} \sum_{\mathcal{L}_1,\mathcal{L}_2 \in \binom{[M]}{L}} \mathbb{E}\left[\mathbb{I}\left(\underline{y}_1, \mathcal{L}_1\right)\mathbb{I}\left(\underline{y}_2, \mathcal{L}_2\right)\right] - \mathbb{E}\left[\mathbb{I}\left(\underline{y}_1, \mathcal{L}_1\right)\right]\mathbb{E}\left[\mathbb{I}\left(\underline{y}_2, \mathcal{L}_2\right)\right] && (42)\\
\leqslant& \sum_{\substack{\mathcal{L}_1,\mathcal{L}_2 \in \binom{[M]}{L}\\ \mathcal{L}_1\cap\mathcal{L}_2 \neq \varnothing}} \sum_{\underline{y}_1,\underline{y}_2 \in \mathcal{A}_{\underline{\mathbf{y}}}} \mathbb{E}\left[\mathbb{I}\left(\underline{y}_1, \mathcal{L}_1\right)\mathbb{I}\left(\underline{y}_2, \mathcal{L}_2\right)\right] && (43)\\
=& \left|\mathcal{A}_{\underline{\mathbf{y}}}\right|^2 \sum_{\ell=1}^{L} \sum_{|\mathcal{L}_1\cap\mathcal{L}_2|=\ell} \Pr_{\underline{\mathbf{y}}_1,\underline{\mathbf{y}}_2,\mathcal{C}}\left[\mathcal{E}\right]. && (44)
\end{aligned}$$

Eqn. (41) follows from the definition of variance and Eqn. (42) follows from linearity of expectation. Note that $\mathbb{I}\left(\underline{y}_1, \mathcal{L}_1\right)$ and $\underline{I}\left(\underline{y}_2, \mathcal{L}_2\right)$ are independent if and only if $\mathcal{L}_1 \cap \mathcal{L}_2 = \varnothing$. When they are independent, the first expectation factors and the summand vanishes. The inequality (43) follows by dropping the negative term in the summand. In Eqn. (44), we rewrite the summation by randomizing the centers $\underline{y}_1, \underline{y}_2$ of the lists $\mathcal{L}_1, \mathcal{L}_2$. The probability is taken over $\underline{\mathbf{y}}_1$ and $\underline{\mathbf{y}}_2$ chosen uniformly at random from $\mathcal{A}_{\underline{\mathbf{y}}}$ and over the random code sampling procedure. We use $\mathcal{E}$ to denote the event that the lists $\mathcal{L}_1$ and $\mathcal{L}_2$ are simultaneously L-confusable w.r.t. $\underline{\mathbf{y}}_1$ and $\underline{\mathbf{y}}_2$, respectively,

$$\mathcal{E} := \bigcap_{m_1\in\mathcal{L}_1} \left\{\underline{\mathbf{x}}_{m_1} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}_1}\right\} \cap \bigcap_{m_2\in\mathcal{L}_2} \left\{\underline{\mathbf{x}}_{m_2} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}_2}\right\}.$$

It then suffices to bound $\Pr\left[\mathcal{E}\right]$. To this end, first define conditional typical set, for $\underline{x} \in \mathcal{X}^n$,

$$\begin{aligned}
\mathcal{A}_{\underline{\mathbf{y}}|\underline{x}} :=& \left\{W\left(\underline{x}, \underline{s}\right) \in \mathcal{Y}^n \colon \underline{s} \in \Lambda_{\underline{\mathbf{s}}}\right\}\\
=& \bigcup_{\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \text{ valid}} \mathcal{T}_{\underline{\mathbf{y}}}\left(\tau_{\mathbf{y}|\underline{x}}\right),
\end{aligned}$$

where $\tau_{\mathbf{y}|\underline{x}}$ is computed from $\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}$ and $\tau_{\underline{x}}$, $\tau_{\mathbf{y}|\underline{x}} = \left[\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}\right]_{\mathbf{x},\mathbf{y}} / \tau_{\underline{x}}$. Then define the following events in favour of bounding $\Pr\left[\mathcal{E}\right]$.

$$\mathcal{E}_1 := \left\{\underline{\mathbf{y}}_1 \in \mathcal{A}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}_m}\right\} \cap \left\{\underline{\mathbf{y}}_2 \in \mathcal{A}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}_m}\right\},$$

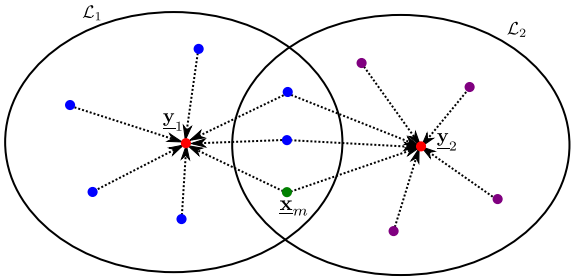


Figure 5 $\mathcal{E} \subset \mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3$. We upper bound $\Pr[\mathcal{E}]$ by neglecting the fact that codewords $\underline{\mathbf{x}}_i$ for $i \in (\mathcal{L}_1 \cap \mathcal{L}_2)\setminus\{m\}$ are simultaneously $\underline{\mathbf{y}}_1$-confusable and $\underline{\mathbf{y}}_2$-confusable, or equivalently, neglecting that $\underline{\mathbf{y}}_1, \underline{\mathbf{y}}_2$ should simultaneously belong to $\mathcal{A}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}_{m'}}$ for all $m' \in \mathcal{L}_1 \cap \mathcal{L}_2$, not only the particular m we have chosen.

$$\mathcal{E}_2 := \bigcap_{m_1 \in \mathcal{L}_1 \setminus \{m\}} \left\{ \underline{\mathbf{x}}_{m_1} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}_1} \right\},$$
$$\mathcal{E}_3 := \bigcap_{m_2 \in \mathcal{L}_2 \setminus \mathcal{L}_1} \left\{ \underline{\mathbf{x}}_{m_2} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}_2} \right\},$$

where $m \in \mathcal{L}_1 \cap \mathcal{L}_2$ is any message that appears in both $\mathcal{L}_1$ and $\mathcal{L}_2$. It is easy to verify that $\mathcal{E} \subset \mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3$ (see Fig. 5). Note that $\mathcal{E}_2$ and $\mathcal{E}_3$ are independent conditioned on $\mathcal{E}_1$ since $\mathcal{L}_1\setminus\{m\}$ and $\mathcal{L}_2\setminus\mathcal{L}_1$ are disjoint. The probabilities of the above events can be computed precisely.

$$\Pr[\mathcal{E}_1] = \Pr\left[\underline{\mathbf{y}} \in \mathcal{A}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}_m}\right]^2 \tag{45}$$
$$= \left(\frac{\left|\mathcal{A}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}_m}\right|}{\left|\mathcal{A}_{\underline{\mathbf{y}}}\right|}\right)^2, \tag{46}$$

where Eqn. (45) is because $\underline{\mathbf{y}}_1$ and $\underline{\mathbf{y}}_2$ are independent, and Eqn. (46) follows since $\underline{\mathbf{y}}$ is chosen uniformly from $\mathcal{A}_{\underline{\mathbf{y}}}$. We now compute the exponent of $\Pr[\mathcal{E}]$.

$$\frac{1}{n}\log\left|\mathcal{A}_{\underline{\mathbf{y}}}\right| \xrightarrow{n\to\infty} \max_{\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \text{ valid}} H(\mathbf{y}) \tag{47}$$
$$= \max_{P_{\mathbf{s}|\mathbf{x}} \in \lambda_{\mathbf{s}|\mathbf{x}}} H(\mathbf{y}), \tag{48}$$

where in Eqn. (47) the entropy is computed w.r.t. $\tau_{\mathbf{y}} = [\tau_{\mathbf{x},\mathbf{s},\mathbf{y}}]_{\mathbf{y}}$; Eqn. (48) follows from similar calculations as done for $\mathcal{A}_{\mathbf{x}|\underline{y}}$ (Eqn. (20)) and the entropy is evaluated using $\left[P^*_{\mathbf{x}} P_{\mathbf{s}|\mathbf{x}} W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{y}}$.

Similarly,

$$\frac{1}{n}\log\left|\mathcal{A}_{\underline{\mathbf{y}}|\underline{\mathbf{x}}_m}\right| \xrightarrow{n\to\infty} \max_{\tau_{\mathbf{x},\mathbf{s},\mathbf{y}} \text{ valid}} H(\mathbf{y}|\mathbf{x}) \tag{49}$$
$$= \max_{P_{\mathbf{s}|\mathbf{x}} \in \lambda_{\mathbf{s}|\mathbf{x}}} H(\mathbf{y}|\mathbf{x}), \tag{50}$$

where the conditional entropies in Eqn. (49) and (50) are evaluated w.r.t. $\tau_{\underline{x}}\tau_{\mathbf{y}|\underline{x}}$ and $\left[P^*_{\mathbf{x}} P_{\mathbf{s}|\mathbf{x}} W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right]_{\mathbf{x},\mathbf{y}}$ (since $\tau_{\underline{x}} \to P^*_{\mathbf{x}}$ as n approaches infinity), respectively. Continuing with

Eqn. (46), putting Eqn. (48) and Eqn. (50) together, we have

$$\begin{aligned}\Pr[\mathcal{E}_1] &\doteq \left(2^{n\max_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} H(\mathbf{y}|\mathbf{x})-H(\mathbf{y})}\right)^2 \\ &= 2^{-2n\min_{P_{\mathbf{s}|\mathbf{x}}\in\lambda_{\mathbf{s}|\mathbf{x}}} I(\mathbf{x};\mathbf{y})} \\ &= 2^{-2nC}, \end{aligned} \tag{51}$$

where Eqn. (51) is by the choice of $P^*_{\mathbf{x}}$ (Eqn. (36)).

We also have

$$\Pr[\mathcal{E}_2|\mathcal{E}_1] = \Pr\left[\underline{\mathbf{x}} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}_1} \middle| \mathcal{E}_1\right]^{L-1} \doteq 2^{-nC(L-1)}, \tag{52}$$

$$\Pr[\mathcal{E}_3|\mathcal{E}_1] = \Pr\left[\underline{\mathbf{x}} \in \mathcal{A}_{\underline{\mathbf{x}}|\underline{\mathbf{y}}_1} \middle| \mathcal{E}_1\right]^{L-\ell} \doteq 2^{-nC(L-\ell)}, \tag{53}$$

where Eqn. (52) and Eqn. (53) follow since $|\mathcal{L}_1| = |\mathcal{L}_2| = L$ and $|\mathcal{L}_1 \cap \mathcal{L}_2| = \ell$. We thus have, from Eqn. (51), (52) and (53), that

$$\begin{aligned}\Pr[\mathcal{E}] &\leqslant \Pr[\mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3] \\ &= \Pr[\mathcal{E}_1]\Pr[\mathcal{E}_2|\mathcal{E}_1]\Pr[\mathcal{E}_3|\mathcal{E}_1] \\ &\doteq 2^{-nC(2L-\ell+1)}. \end{aligned} \tag{54}$$

Note that the number of pairs of lists $\mathcal{L}_1$ and $\mathcal{L}_2$ with intersection size ℓ is

$$\begin{aligned}\binom{M}{\ell}\binom{M-\ell}{L-\ell}\binom{M-\ell}{L-\ell} &\leqslant M^\ell M^{L-\ell} M^{L-\ell} \\ &\leqslant M^{2L-\ell}. \end{aligned} \tag{55}$$

Therefore, the variance of W can be bounded as follows.

$$\mathrm{Var}[W] \leqslant \left|\mathcal{A}_{\underline{\mathbf{y}}}\right|^2 \sum_{1\leqslant\ell\leqslant L} M^{2L-\ell} 2^{-nC(2L-\ell+1)} \tag{56}$$

$$= \left|\mathcal{A}_{\underline{\mathbf{y}}}\right|^2 2^{-nC} \sum_{1\leqslant\ell\leqslant L} 2^{-n\delta(2L-\ell)} \tag{57}$$

$$\leqslant \left|\mathcal{A}_{\underline{\mathbf{y}}}\right|^2 2^{-nC} 2^{-n\delta(2L-\ell)+\log L}, \tag{58}$$

where Eqn. (56) is by Eqn. (44), (55) and (54); Eqn. (57) is by the definition of M and the choice of R; Eqn. (58) is by replacing each term with the largest one in the summation.

Putting them together.

$$\begin{aligned}\Pr[\mathcal{C} \text{ is } (L-1)\text{-list decodable}] &\leqslant \frac{\mathrm{Var}[W]}{\mathbb{E}[W]^2} \\ &\leqslant 2^{-nC+n\delta L+(2L+1)\log L}. \end{aligned}$$

The above probability vanishes in n if $L < C/\delta$. Say $L = C/\delta - 1$, then it is at most

$$2^{-n\delta+(2(C/\delta-1)+1)\log(C/\delta-1)} \leqslant 2^{-n\delta+\frac{2}{\delta}\log\frac{1}{\delta}}.$$

◀

12 Achievability

In this section, we are going to show, via concrete random code constructions, that as long as some completely positive $(P_{\mathbf{x}}, L)$-self-coupling of order L lies outside the order-L confusability set of the channel, the $(L-1)$-list decoding capacity is positive.

Let $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) := \mathsf{CP}^{\otimes L}_{|\mathcal{X}|} \cap \mathcal{J}^{\otimes L}(P_{\mathbf{x}})$.

▶ **Theorem 47** (Achievability). *For any given general adversarial channel $\mathcal{A} = (\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}})$, its $(L-1)$-list decoding capacity is positive if there is a completely positive $(P_{\mathbf{x}}, L)$-self-coupling $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}})$ outside $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$ for some $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$.*

We first state a lemma concerning the rate of a random constant composition code.

▶ **Lemma 48** (Constant composition codes). *Let $\mathcal{C} = \{\underline{\mathbf{x}}_i\}_{i=1}^{2^{nR}}$ be a random code of rate R in which each codeword is selected according to product distribution $P_{\mathbf{x}}^{\otimes n}$ independently. Let $\mathcal{C}'$ be the $P_{\mathbf{x}}$-constant composition subcode of $\mathcal{C}$, $\mathcal{C}' = \mathcal{C} \cap \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}})$. Then*

$$\Pr\left[\left|\mathcal{C}'\right| \notin (1 \pm 1/2)\frac{2^{nR}}{\nu(n)}\right] \leqslant 2\exp\left(-\frac{2^{nR}}{12\nu(n)}\right).$$

Proof. The lemma is a simple consequence of concentration of measure (Lemma 24).

$$\begin{aligned}\Pr\left[\left|\mathcal{C}'\right| \notin (1 \pm 1/2)\frac{2^{nR}}{\nu(n)}\right] &= \Pr\left[\sum_{i=1}^{2^{nR}} \mathbb{1}_{\{\tau_{\underline{\mathbf{x}}_i} = P_{\mathbf{x}}\}} \notin (1 \pm 1/2)\frac{2^{nR}}{\nu(n)}\right] \\ &\leqslant 2\exp\left(-\frac{(1/2)^2}{3}\mu\right) \qquad (59) \\ &= 2\exp\left(-\frac{2^{nR}}{12\nu(n)}\right).\end{aligned}$$

where in Eqn. (59), we note that

$$\begin{aligned}\mathbb{E}\left[\sum_{i=1}^{2^{nR}} \mathbb{1}_{\{\tau_{\underline{\mathbf{x}}_i} = P_{\mathbf{x}}\}}\right] &= 2^{nR}\Pr\left[\underline{\mathbf{x}} \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}})\right] \\ &= \frac{2^{nR}}{\nu(n)} \\ &=: \mu.\end{aligned}$$

◀

12.1 Low rate codes

Let us proceed gently. We first show that a purely random code with each entry i.i.d. w.r.t. some distribution $P_{\mathbf{x}}$ is $(L-1)$-list decodable w.h.p. as long as $P_{\mathbf{x}}^{\otimes L}$ is not L-confusable.

▶ **Lemma 49.** *For any general adversarial channel $\mathcal{A} = (\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}})$, if there exists a legitimate input distribution $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$ such that $P_{\mathbf{x}}^{\otimes L} \notin \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, then the $(L-1)$-list decoding capacity of $\mathcal{A}$ is positive.*

Proof. Let $M = 2^{nR}$ for some rate R to be specified momentarily. Sample a code $\mathcal{C} = \{\underline{\mathbf{x}}_1, \cdots, \underline{\mathbf{x}}_M\}$ where each $\underline{\mathbf{x}}_i \overset{\text{i.i.d.}}{\sim} P_{\mathbf{x}}^{\otimes n}$. The expected joint type $\tau_{\underline{\mathbf{x}}_{i_1},\cdots,\underline{\mathbf{x}}_{i_L}}$ $(1 \leqslant i_1 < \cdots < i_L \leqslant M)$ of any list $\underline{\mathbf{x}}_{i_1}, \cdots, \underline{\mathbf{x}}_{i_L}$ is $P_{\mathbf{x}}^{\otimes L}$. (See Fig. 6.)

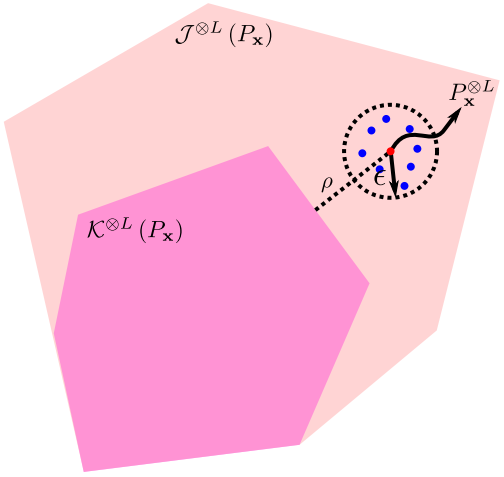

Figure 6 Low rate codes from product distribution. If the product distribution $P_{\mathbf{x}}^{\otimes L}$ is strictly separated away from $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, then we could hope for a positive rate achieved by a random code with each entry sampled from $P_{\mathbf{x}}$. This is because w.h.p. the joint types of all (ordered) lists are contained in a $\|\cdot\|_{\text{mav}}$-ball which is completely outside the confusability set.

Let $\mathcal{C}' = \mathcal{C} \cap \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}})$ be the $P_{\mathbf{x}}$-constant composition subcode of $\mathcal{C}$. Let

$$\rho \coloneqq \inf_{P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{K}^{\otimes L}(P_{\mathbf{x}})} \left\| P_{\mathbf{x}}^{\otimes L} - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \right\|_{\text{mav}}$$

be the max-absolute-value tensor distance from the product distribution to the confusability set. Let $R = \frac{\log e}{12}\frac{\rho^2}{L} - \delta$ for some small constant $\delta > 0$. We will show that

▶ **Lemma 50.** *The random $P_{\mathbf{x}}$-constant composition code $\mathcal{C}'$ as constructed above has rate $R = \frac{\log e}{12}\frac{\rho^2}{L} - \delta$ and is $(L-1)$-list decodable with probability at least $1 - 2\exp\left(-2^{nR}/\nu(n)\right) - 2^{-n\delta + L\log|\mathcal{X}|+1}$.*

Let $\epsilon \coloneqq \rho/2$. Define error events

$$\mathcal{E}_1 \coloneqq \left\{ \left|\mathcal{C}'\right| \notin (1 \pm 1/2)\frac{2^{nR}}{\nu(n)} \right\},$$
$$\mathcal{E}_2 \coloneqq \left\{ \mathcal{C}' \text{ is not } (L-1)\text{-list decodable} \right\}.$$

By Lemma 48,

$$\Pr\left[\mathcal{E}_1\right] \leqslant 2\exp\left(-\frac{2^{nR}}{\nu(n)}\right).$$

Hence the rate R' of $\mathcal{C}'$ is asymptotically equal to R w.h.p.

By Chernoff bound,

$$\begin{aligned}
&\Pr\left[\left\|\tau_{\underline{\mathbf{x}}_{i_1},\cdots,\underline{\mathbf{x}}_{i_L}} - P_{\mathbf{x}}^{\otimes L}\right\|_{\text{mav}} \geqslant \epsilon\right] \\
=&\Pr\left[\exists (x_1,\cdots,x_L) \in \mathcal{X}^L,\ \left|\tau_{\underline{\mathbf{x}}_{i_1},\cdots,\underline{\mathbf{x}}_{i_L}}(x_1,\cdots,x_L) - P_{\mathbf{x}}(x_1)\cdots P_{\mathbf{x}}(x_L)\right| \geqslant \epsilon\right] \qquad (60)\\
\leqslant&|\mathcal{X}|^L \Pr\left[\left|\sum_{j=1}^{n} \mathbb{1}_{\left\{\left(\underline{\mathbf{x}}_{i_1}(j),\cdots,\underline{\mathbf{x}}_{i_L}(j)\right)=(x_1,\cdots,x_L)\right\}} - nP_{\mathbf{x}}(x_1)\cdots P_{\mathbf{x}}(x_L)\right| \geqslant n\epsilon\right] \qquad (61)
\end{aligned}$$

$$
\begin{aligned}
&= |\mathcal{X}|^L \Pr\left[\sum_{j=1}^{n} \mathbb{1}_{\left\{\left(\underline{\mathbf{x}}_{i_1}(j),\cdots,\underline{\mathbf{x}}_{i_L}(j)\right)=(x_1,\cdots,x_L)\right\}} \notin \left(1 \pm \frac{n\epsilon}{\mu}\right)\mu\right] && (62)\\
&\leqslant |\mathcal{X}|^L \cdot 2\exp\left(-\frac{1}{3}\left(\frac{n\epsilon}{\mu}\right)^2 \mu\right) && (63)\\
&= |\mathcal{X}|^L \cdot 2\exp\left(-\frac{n\epsilon^2}{3P_{\mathbf{x}}^{\otimes L}(x_1,\cdots,x_L)}\right) && (64)\\
&\leqslant |\mathcal{X}|^L \cdot 2\exp\left(-\frac{n}{3}\left(\frac{\rho}{2}\right)^2\right) && (65)\\
&= 2\cdot|\mathcal{X}|^L \cdot \exp\left(-\frac{\rho^2}{12}n\right).
\end{aligned}
$$

Eqn. (60) follows from the definition of max-absolute-value norm. Eqn. (61) is obtained by taking a union bound and expanding the type using definition. In Eqn. (62), we define

$$\mu \coloneqq nP_{\mathbf{x}}^{\otimes L}(x_1,\cdots,x_L),$$

which equals

$$\mathbb{E}\left[\sum_{j=1}^{n} \mathbb{1}_{\left\{\left(\underline{\mathbf{x}}_{i_1}(j),\cdots,\underline{\mathbf{x}}_{i_L}(j)\right)=(x_1,\cdots,x_L)\right\}}\right].$$

Eqn. (63) is by Chernoff bound (Lemma 24). Eqn. (64) is by the definition of μ. Eqn. (65) is by the choice of ϵ and that $P_{\mathbf{x}}^{\otimes L}(x_1,\cdots,x_L) \leqslant 1$ for any $(x_1,\cdots,x_L) \in \mathcal{X}^L$. Taking a union bound over all lists $(i_1,\cdots,i_L) \in \binom{\mathcal{M}}{L}$,

$$
\begin{aligned}
&\Pr\left[\exists\,(i_1,\cdots,i_L) \in \binom{\mathcal{M}}{L},\ \left\|\tau_{\underline{\mathbf{x}}_{i_1},\cdots,\underline{\mathbf{x}}_{i_L}} - P_{\mathbf{x}}^{\otimes L}\right\|_\infty \geqslant \epsilon\right]\\
&\leqslant \binom{M}{L} 2\cdot|\mathcal{X}|^L \cdot \exp\left(-\frac{\rho^2}{12}n\right)\\
&\leqslant 2^{-n\left(\frac{\rho^2\log e}{12} - RL\right) + L\log|\mathcal{X}|+1}.
\end{aligned}
$$

We therefore get that $\mathcal{C}$ is $(L-1)$-list decodable with probability at least $1 - 2^{-n\delta + L\log|\mathcal{X}|+1}$ as long as

$$R = \frac{\log e}{12}\frac{\rho^2}{L} - \delta.$$

Overall, we have that

$$
\begin{aligned}
\Pr[\mathcal{E}_1 \cup \mathcal{E}_2] &\leqslant \Pr[\mathcal{E}_1] + \Pr[\mathcal{E}_2]\\
&\leqslant 2\exp\left(-\frac{2^{nR}}{\nu(n)}\right) + \Pr[\mathcal{C} \text{ is not } (L-1)\text{-list decodable}]\\
&\leqslant 2\exp\left(-\frac{2^{nR}}{\nu(n)}\right) + 2^{-n\delta + L\log|\mathcal{X}|+1}.
\end{aligned}
$$

◀

12.2 Random codes with expurgation

In the previous section, we only got an $(L-1)$-list decodable code of positive rate without making the effort to optimize the rate. In this section, we provide a lower bound on the $(L-1)$-list decoding capacity. It is achieved by a different code construction (random code with expurgation). However, we can only show the *existence* of such codes instead of showing that they attain the following bound w.h.p.

▶ **Lemma 51.** *The $(L-1)$-list decoding capacity of a channel $\mathcal{A}$ is at least*

$$C_{L-1} \geqslant \max_{P_{\mathbf{x}} \in \lambda_{\mathbf{x}}} \min_{P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{K}^{\otimes L}(P_{\mathbf{x}})} \frac{1}{L-1} D\left(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \| P_{\mathbf{x}}^{\otimes L}\right). \tag{66}$$

Proof. Fix any $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$ to be the maximizer of Eqn. (66). Let $M = 2^{nR}$ for some rate R to be determined. Generate a random code $\mathcal{C}$ of size $2M$ by sampling each entry of the codebook independently from $P_{\mathbf{x}}$.

For any $\underline{\mathbf{x}} \in \mathcal{C}$, by Lemma 22,

$$\Pr\left[\tau_{\underline{\mathbf{x}}} = P_{\mathbf{x}}\right] = 1/\nu(n).$$

Hence the expected number of codewords with type $P_{\mathbf{x}}$ is $2M/\nu(n)$.

For any $(\underline{\mathbf{x}}_1, \cdots, \underline{\mathbf{x}}_L) \in \binom{\mathcal{C}}{L}$,

$$\Pr\left[\tau_{\underline{\mathbf{x}}_1,\cdots,\underline{\mathbf{x}}_L} \in \mathcal{K}^{\otimes L}(P_{\mathbf{x}})\right] \doteq \sup_{P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{K}^{\otimes L}(P_{\mathbf{x}})} 2^{-nD\left(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \| P_{\mathbf{x}}^{\otimes L}\right)},$$

by Sanov's theorem 25. Let $P^* \in \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$ be the extremizer for the above supremum. Hence the expected number of confusable lists is at most

$$\binom{2M}{L} 2^{-nD\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)} \leqslant (2M)^L 2^{-nD\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)}.$$

Pick M such that

$$(2M)^L 2^{-nD\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)} \leqslant M/\nu(n),$$

i.e.,

$$L + nRL - nD\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right) \leqslant nR - \log \nu(n).$$

That is, R can be taken arbitrarily close to $\frac{1}{L-1} D\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)$.

$$\begin{aligned} R \leqslant & \frac{D\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)}{L-1} - \frac{\log \nu(n)}{(L-1)n} - \frac{L}{(L-1)n} \\ \overset{n\to\infty}{\to} & \frac{D\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)}{L-1}. \end{aligned}$$

Now, we remove all codewords of types different from $P_{\mathbf{x}}$. We also remove one codeword from each of the confusable lists. In expectation, this process reduces the size of the code by at most $2M - 2M/\nu(n)$ (due to the first expurgation) plus $(2M)^L 2^{-nD\left(P^* \| P_{\mathbf{x}}^{\otimes L}\right)} \leqslant M/\nu(n)$ (due to the second expurgation). After expurgation, we get an $(L-1)$-list decodable $P_{\mathbf{x}}$-constant composition code $\mathcal{C}'$ of size at least

$$2M - (2M/\nu(n) - 2M/\nu(n)) - M/\nu(n) = M/\nu(n).$$

The rate R' of $\mathcal{C}'$ is asymptotically the same as R.

$$\begin{aligned} R' = & R - \frac{\log \nu(n)}{n} \\ \overset{n\to\infty}{\to} & R. \end{aligned}$$

This finishes the proof. ◀

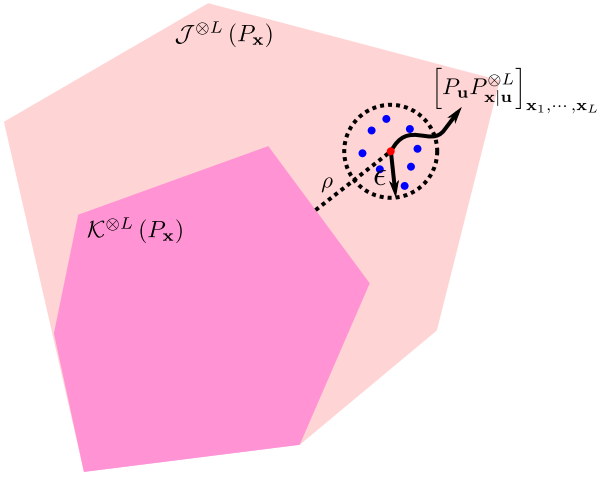

Figure 7 Low rate codes from CP distribution. If there is a CP distribution strictly outside $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, then we can get a positive rate from random code using time-sharing. The only variation is that we divide codebook into chunks according to $P_{\mathbf{u}}$ and construct random codes of shorter length for each chunk u using distribution $P_{\mathbf{x}|\mathbf{u}=u}$.

12.3 Cloud codes

▶ **Lemma 52.** *If there is a $(P_{\mathbf{x}}, L)$-self-coupling ($P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$) $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$ which can be decomposed into*

$$\begin{aligned} & P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(\underline{x}_1,\cdots,\underline{x}_L) \\ =& \sum_{u\in\mathcal{U}} P_{\mathbf{u}}(u)\, P_{\mathbf{x}|\mathbf{u}}^{\otimes L}(\underline{x}_1,\cdots,\underline{x}_L|u) \\ =& \sum_{u\in\mathcal{U}} P_{\mathbf{u}}(u) \prod_{i=1}^{L} P_{\mathbf{x}|\mathbf{u}}(\underline{x}_i|u)\,. \end{aligned}$$

for some distributions $P_{\mathbf{u}} \in \Delta(\mathcal{U})$ of finite support $|\mathcal{U}|$ and $P_{\mathbf{x}|\mathbf{u}} \in \Delta(\mathcal{X}|\mathcal{U})$ (see Fig. 7), then there exist positive rate $(L-1)$-list decodable codes.

Proof. The proof follows from a time-sharing argument combined with the previous low rate code construction (Lemma 49).

Fix R to be determined later. Sample 2^{nR} codewords in $\mathcal{C}$ independently from the following distribution. Divide each length-n codeword into $|\mathcal{U}|$ chunks $1,\cdots,|\mathcal{U}|$. For the u-th ($u \in \mathcal{U}$) chunk, sample $P_{\mathbf{u}}(u)n$ components in the chunk independently using distribution $P_{\mathbf{x}|\mathbf{u}=u}$. Let $P_{\mathbf{u},\mathbf{x}} = P_{\mathbf{u}}P_{\mathbf{x}|\mathbf{u}}$ and $P_{\mathbf{x}} = [P_{\mathbf{u},\mathbf{x}}]_{\mathbf{x}}$. Let $\mathcal{C}'$ be all codewords in $\mathcal{C}$ of type $P_{\mathbf{x}}$. (See Fig. 8.) Define

$$\rho := \inf_{P'_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{K}^{\otimes L}(P_{\mathbf{x}})} \left\| P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} - P'_{\mathbf{x},\cdots,\mathbf{x}_L} \right\|_{\text{mav}}.$$

Let

$$u^* := \operatorname*{argmin}_{u\in\mathcal{U}} P_{\mathbf{u}}(u).$$

Note that $P_{\mathbf{u}}(u^*) > 0$ since $|\mathcal{U}|$ is the *support* of $P_{\mathbf{u}}$. Let $R = \frac{P_{\mathbf{u}}(u^*)\log e}{12}\frac{\rho^2}{L} - \delta$. We will show that

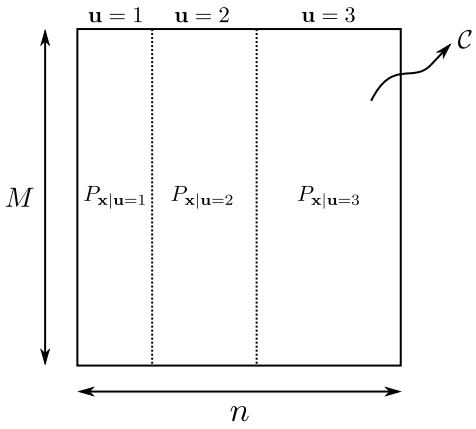

Figure 8 An example of cloud code construction in which $\mathcal{U} = \{1, 2, 3\}$. The codebook is divided into 3 chunks and symbols in the i-th chunk are sampled independently from $P_{\mathbf{x}|\mathbf{u}=i}$ $(i = 1, 2, 3)$.

▶ **Lemma 53.** *A random $P_{\mathbf{x}}$-constant composition cloud code as constructed above has rate $R = \frac{P_{\mathbf{u}}(u^*)\log e}{12}\frac{\rho^2}{L} - \delta$ and is $(L-1)$-list decodable with probability at least*

$$1 - 2\exp\left(-\frac{2^{nR}}{12\prod_{u\in\mathcal{U}}\nu(P_{\mathbf{u}}(u)n)}\right) - 2^{-n\delta + L\log|\mathcal{X}| + \log|\mathcal{U}| + 1}.$$

We write a length-n codeword as the concatenation of $|\mathcal{U}|$ chunks,

$$\underline{\mathbf{x}} = \left(\underline{\mathbf{x}}^{(1)}, \cdots, \underline{\mathbf{x}}^{(|\mathcal{U}|)}\right).$$

First we argue that w.h.p. the code $\mathcal{C}$ is almost $P_{\mathbf{x}}$-constant composition. The expected size of $\mathcal{C}'$ is

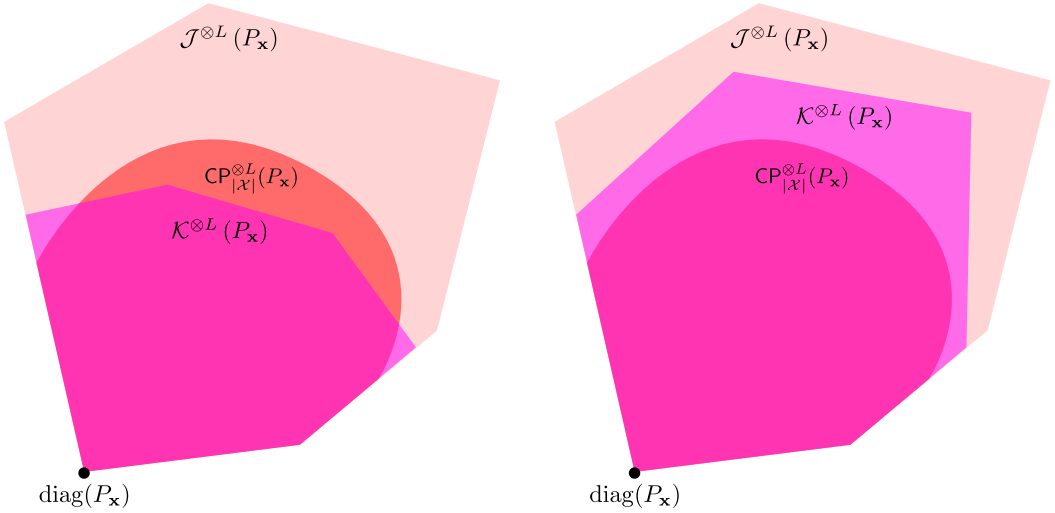
$$\begin{aligned}
\mathbb{E}\left[\left|\mathcal{C}'\right|\right] =& \mathbb{E}\left[\left|\mathcal{C} \cap \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}|\mathbf{u}})\right|\right] \\
=& \sum_{i\in[M]} \Pr\left[\underline{\mathbf{x}}_i \in \mathcal{T}_{\underline{\mathbf{x}}}(P_{\mathbf{x}|\mathbf{u}})\right] && (67)\\
=& \sum_{i\in[M]} \Pr\left[\bigcap_{u\in\mathcal{U}} \left\{\underline{\mathbf{x}}_i^{(u)} \in \mathcal{T}_{\underline{\mathbf{x}}^{(u)}}(P_{\mathbf{x}|\mathbf{u}=u})\right\}\right] \\
=& \sum_{i\in[M]} \prod_{u\in\mathcal{U}} \Pr\left[\underline{\mathbf{x}}^{(u)} \in \mathcal{T}_{\underline{\mathbf{x}}^{(u)}}(P_{\mathbf{x}|\mathbf{u}=u})\right] && (68)\\
\asymp& M\prod_{u\in\mathcal{U}} \nu(P_{\mathbf{u}}(u)n)^{-1}, && (69)
\end{aligned}$$

where Eqn. (67) is by linearity of expectation; Eqn. (68) follows since different chunks are independent; Eqn. (69) follows from Lemma 22. Then by Lemma 48

$$\Pr\left[\left|\mathcal{C}'\right| \notin (1 \pm 1/2)\mathbb{E}\left[\left|\mathcal{C}'\right|\right]\right] \leqslant 2\exp\left(-\frac{2^{nR}}{12\prod_{u\in\mathcal{U}}\nu(P_{\mathbf{u}}(u)n)}\right).$$

Secondly, for any list $1 \leqslant i_1 < \cdots < i_L \leqslant M$ of distinct ordered messages,

$$\begin{aligned}
\Pr\left[\exists u \in \mathcal{U},\ \left\|\tau_{\underline{\mathbf{x}}_{i_1}^{(u)},\cdots,\underline{\mathbf{x}}_{i_L}^{(u)}} - P_{\mathbf{x}|\mathbf{u}=u}^{\otimes L}\right\|_{\max} \geqslant \epsilon\right] &\leqslant \sum_{u\in\mathcal{U}} 2\cdot|\mathcal{X}|^L \cdot \exp\left(-\frac{\rho^2}{12}nP_{\mathbf{u}}(u)\right) && (70)\\
&\leqslant 2|\mathcal{U}||\mathcal{X}|^L \exp\left(-\frac{\rho^2}{12}nP_{\mathbf{u}}(u^*)\right), && (71)
\end{aligned}$$



(a) "Below Plotkin point", positive $(L-1)$-list decoding rate is possible. In this case, for some input distribution $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$, the slice of $P_{\mathbf{x}}$-self-coupling CP tensors is not entirely contained in the confusability set $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$.

(b) "Above Plotkin point", no positive rate for $(L-1)$-list decoding is achievable. In this case, for every input distribution $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$, the slice of $P_{\mathbf{x}}$-self-coupling CP tensors is entirely contained in the confusability set $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$.

Figure 9 A characterization of when positive rate generalized list decodable codes exist.

where the first inequality (70) follows from a union bound and same calculations as in Lemma 49. The second inequality (71) follows from the definition of u^*.

Finally, by taking another union bound over lists $\mathcal{L} \in \binom{[M]}{L}$, we get

$$\Pr\left[\exists (i_1,\cdots,i_L) \in \binom{\mathcal{M}}{L},\ \exists u \in \mathcal{U},\ \left\| \tau_{\underline{\mathbf{x}}^{(u)}_{i_1},\cdots,\underline{\mathbf{x}}^{(u)}_{i_L}} - P^{\otimes L}_{\mathbf{x}|\mathbf{u}=u} \right\|_{\mathrm{mav}} \geqslant \epsilon \right]$$
$$\leqslant 2^{-n\left(\frac{\rho^2 \log e P_{\mathbf{u}}(u^*)}{12} - RL\right) + L\log|\mathcal{X}| + \log|\mathcal{U}| + 1}.$$

Therefore, we have that the probability that the random $P_{\mathbf{x}}$-constant composition cloud code $\mathcal{C}'$ constructed above has rate $R = \frac{P_{\mathbf{u}}(u^*)\log e}{12}\frac{\rho^2}{L} - \delta$ and is $(L-1)$-list decodable with probability at least

$$1 - 2\exp\left(-\frac{2^{nR}}{12\prod_{u\in\mathcal{U}}\nu(P_{\mathbf{u}}(u)n)}\right) - 2^{-n\delta + L\log|\mathcal{X}| + \log|\mathcal{U}| + 1},$$

which completes the proof. ◀

The above lemma apparently implies Theorem 47.

13 Converse

Let $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) := \mathsf{CP}^{\otimes L}_{|\mathcal{X}|} \cap \mathcal{J}^{\otimes L}(P_{\mathbf{x}})$ and $\mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) := \mathsf{Sym}^{\otimes L}_{|\mathcal{X}|} \cap \mathcal{J}^{\otimes L}(P_{\mathbf{x}})$.

We have shown in the previous section that if $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) \cap \mathcal{K}^{\otimes L}(P_{\mathbf{x}})^c \neq \varnothing$, then the $(L-1)$-list decoding capacity is positive. In this section we are going to prove the converse. That is, such a condition is also necessary for positive rate being possible. Indeed, we will show that

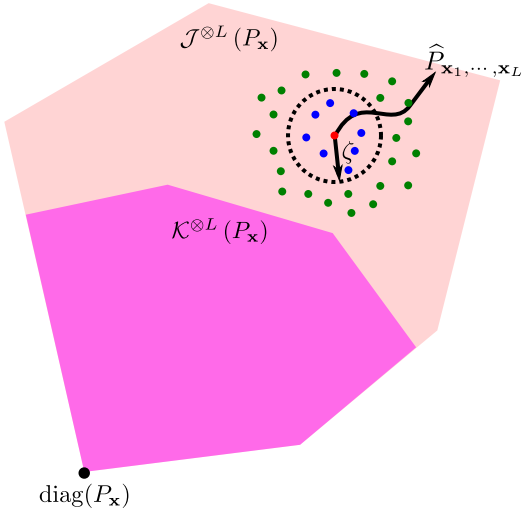


Figure 10 Equicoupled subcode extraction using hypergraph Ramsey's theorem. The union of green and blue dots represents the set of all joint types of ordered L-lists in $\mathcal{C}$. The blue dots correspond to joint types of its subcode $\mathcal{C}'$. (Note that they are all non-confusable.) They are clustered within a small ball (w.r.t. sum-absolute-value norm) centered at some distribution $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. Since the hypergraph Ramsey number is finite, there exists such $\mathcal{C}'$ which is suitably large.

▶ **Theorem 54** (Converse). *Given a general adversarial channel* $\mathcal{A} = \left(\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x}}\right)$, *if for every admissible input distribution* $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$, $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) \subseteq \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, *then the* $(L-1)$*-list decoding capacity of* $\mathcal{A}$ *is zero.*

13.1 Equicoupled subcode extraction

▶ **Definition 55** (Equicoupledness and ϵ-equicoupledness). *A code* $\mathcal{C}$ *is said to be* $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$-equicoupled *if for all* ordered *lists* $(\underline{x}_{i_1},\cdots,\underline{x}_{i_L}) \in \binom{\mathcal{C}}{L}$ *where* $1 \leqslant i_1 < \cdots < i_L \leqslant |\mathcal{C}|$, $\tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}} = P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. *A code* $\mathcal{C}$ *is said to be* $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$-equicoupled *if for all ordered lists* $(\underline{x}_{i_1},\cdots,\underline{x}_{i_L}) \in \binom{\mathcal{C}}{L}$, *where* $1 \leqslant i_1 < \cdots < i_L \leqslant |\mathcal{C}|$, $\left\|\tau_{\underline{x}_1,\cdots,\underline{x}_{i_L}} - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right\|_{\mathrm{sav}} \leqslant \epsilon$.

▶ Remark 56. The above definition can also be overloaded for sequences of random variables or their joint distributions. We say a sequence of random variables $\mathbf{w}_1,\cdots,\mathbf{w}_M$ or the joint distribution $P_{\mathbf{w}_1,\cdots,\mathbf{w}_M}$ is $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$-equicoupled (or $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$-equicoupled) if every order-L marginal $P_{\mathbf{w}_{i_1},\cdots,\mathbf{w}_{i_L}}$ $(1 \leqslant i_1 < \cdots < i_L \leqslant M)$ equals (or is ζ-close to in $\|\cdot\|_{\mathrm{sav}}$) $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$.

Using the hypergraph Ramsey's theorem, we first show that any infinite sequence of codes of positive rate has an infinite sequence of subcodes which are ζ-equicoupled.

▶ **Lemma 57** (Equicoupled subcode extraction). *For any infinite sequence of codes* $\{\mathcal{C}_i\}_{i\geqslant 1}$ *of blocklengths* n_i*'s and positive rate, where* $\{n_i\}_{i\geqslant 1}$ *is an infinite increasing integer sequence, for any* $\zeta > 0$ *and any* $M \in \mathbb{Z}_{>0}$, *there is an* $N \in \mathbb{Z}_{>0}$ *such that if* $|\mathcal{C}_i| \geqslant N$ *then* $\mathcal{C}'$ *contains a subcode* $\mathcal{C}'_i$ *satisfying that*

- $|\mathcal{C}'_i| \geqslant M$;
- $\mathcal{C}'_i$ *is* $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$*-equicoupled for some* $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$.

See Fig. 10.

Again, this lemma is a consequence of the hypergraph Ramsey's theorem. Let us denote by $R_c^{(m)}(n_1, \cdots, n_c)$ the smallest integer n such that the complete m-uniform hypergraph on n vertices with any c-colouring of hyperedges contains at least one of a clique of colour 1 and size n_1, ..., a clique of colour c and size n_c. It is known that $R_c^{(m)}(n_1, \cdots, n_c)$ is finite (Lemma 101), i.e., independent of the size n of the hypergraph.

Proof of Lemma 57. Recall that we assume $\mathsf{CP}_{|\mathcal{X}|}^{\otimes L}(P_{\mathbf{x}}) \cap \mathcal{K}^{\otimes L}(P_{\mathbf{x}})^c = \varnothing$. Let ρ be the gap between $\mathsf{CP}_{|\mathcal{X}|}^{\otimes L}(P_{\mathbf{x}})$ and $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$,

$$\rho := \inf_{\substack{P \in \mathsf{CP}_{|\mathcal{X}|}^{\otimes L}(P_{\mathbf{x}}) \\ P' \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})}} \left\| P - P' \right\|_{\mathrm{sav}}.$$

▶ **Definition 58** (ϵ-net)**.** *For a metric space $(\mathcal{X}, d)$, an ϵ-net $\mathcal{N} \subset \mathcal{X}$ is a subset which is a discrete ϵ-approximation of $\mathcal{X}$ in the sense that for any $x \in \mathcal{X}$, there is an $x' \in \mathcal{N}$ such that $d(x, x') \leqslant \epsilon$.*

We claim that

▶ **Lemma 59** (Bound on size of ϵ-net)**.** *There is an ϵ-net $\mathcal{N}$ of $\mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$ equipped with ℓ^1 metric of size at most $\left(\frac{|\mathcal{X}|^L}{2\epsilon} + 1\right)^{|\mathcal{X}|^L}$.*

Proof. The following construction is by no means optimal, but its size has a *finite* upper bound which is enough for our purposes. Indeed, it suffices to take $\mathcal{N}$ to be the coordinate-quantization net of $\mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$. Note that for any $P \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}})$, each entry of P lies in $[0, 1]$. Take $\delta := \frac{2\epsilon}{|\mathcal{X}|^L}$. Divide $[0, 1]$ into sub-intervals of length δ (possibly except the last sub-interval that may have length less than δ). For each entry of P, there are at most $\frac{1}{\delta} + 1$ sub-intervals. Quantize each component of P to the nearest middle point of these sub-intervals. The set of all representatives whose components take values from the set of middle points of the sub-intervals form a net $\mathcal{N}$. In total, there are at most $\left(\frac{1}{\delta} + 1\right)^{|\mathcal{X}|^L}$ such representatives. For any $P \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, let $Q_{\mathcal{N}}(P)$ denote the quantization of P using $\mathcal{N}$, i.e.,

$$Q_{\mathcal{N}}(P) := \operatorname*{argmin}_{P' \in \mathcal{N}} \left\| P - P' \right\|_{\mathrm{sav}}.$$

The quantization error is at most

$$\begin{aligned} \left\| P - Q_{\mathcal{N}}(P) \right\|_{\mathrm{sav}} &\leqslant \sum_{(x_1, \cdots, x_L) \in \mathcal{X}^L} \left| P(x_1, \cdots, x_L) - Q_{\mathcal{N}}(P)(x_1, \cdots, x_L) \right| \\ &\leqslant |\mathcal{X}|^L \frac{\delta}{2} \\ &\leqslant \epsilon. \end{aligned}$$

We thus have shown that $\mathcal{N}$ constructed as above is an ϵ-quantizer of small cardinality. ◀

Let

$$\lambda := - \sup_{\widehat{P} \in (\mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})) \cap \mathsf{Sym}_{|\mathcal{X}|}^{\otimes L}(P_{\mathbf{x}})} \inf_{Q \in \mathsf{coP}_{|\mathcal{X}|}^{\otimes L}} \left\langle \widehat{P}, Q \right\rangle. \tag{72}$$

We know that CP cone and coP cone are dual (Theorem 96) in the space of symmetric tensor cone. Thus, for any non-CP *symmetric* tensor $\widehat{P} \in \mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) \backslash \mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}})$, there must be a witness Q with strictly negative inner product with $\widehat{P}$. The infimum

$$\inf_{Q \in \mathsf{coP}^{\otimes L}_{|\mathcal{X}|}} \left\langle \widehat{P}, Q \right\rangle < 0.$$

λ is the absolute value of the smallest inner product among all symmetric non-CP tensors. We know that $\lambda > 0$, since $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}})$ is *strictly* contained in $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$.

Let

$$\zeta := \frac{1}{2} \min \left\{ \rho, \frac{\lambda}{|\mathcal{X}|^L} \right\}. \tag{73}$$

Take a ζ-net of $\left(\Delta\left(\mathcal{X}^L\right), \ell^1\right)$ as constructed in Lemma 59. Such a net has cardinality at most $K := \left(\frac{|\mathcal{X}|^L}{\rho} + 1\right)^{|\mathcal{X}|^L}$.

Build an L-uniform complete hypergraph $\mathcal{H} = (\mathcal{C}, \mathcal{E})$ on $\mathcal{C}$. The vertices of $\mathcal{H}$ are codewords in $\mathcal{C}$. For every tuple $\left(\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}\right) \in \binom{\mathcal{C}}{L}$ (where the indices $1 \leqslant i_1 < \cdots < i_L \leqslant |\mathcal{C}|$ are sorted in ascending order) of distinct codewords, there is a hyperedge connecting them. There are totally $\binom{|\mathcal{C}|}{L}$ hyperedges in $\mathcal{E}$. We now label hyperedges using distributions in $\mathcal{N}$. For each hyperedge $\left(\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}\right) \in \mathcal{E}$, label it using the unique element $Q_{\mathcal{N}}\left(\tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}}\right)$ from $\mathcal{N}$. This can be viewed as an edge colouring of $\mathcal{H}$ using at most K colours.

By hypergraph Ramsey's theorem (Theorem 101), there is a constant N such that if the size $|\mathcal{C}|$ of the hypergraph is at least N, then there is a monochromatic (each hyperedge in the sub-hypergraph has the same colour) clique $\mathcal{C}' \subset \mathcal{C}$ of size at least M. Indeed, we can take N to be the hypergraph Ramsey number $N = R^{(L)}_K(M, \cdots, M)$. By Theorem 102, there is a constant $c' > 0$ such that $N < t_L(c' \cdot K \log K)$, where $t_L(\cdot)$ is the tower function of height L. Put in another way, there exists a subcode $\mathcal{C}' \subset \mathcal{C}$ of size at least M such that for some distribution $\widehat{P}_{\mathbf{x}_1, \cdots, \mathbf{x}_L} \in \mathcal{N}$, the joint type of every ordered tuple of L distinct codewords in $\mathcal{C}'$ is ζ-close to $\widehat{P}_{\mathbf{x}_1, \cdots, \mathbf{x}_L}$. I.e., for every $\mathcal{L} = (\underline{x}_1, \cdots, \underline{x}_L) \in \binom{\mathcal{C}'}{L}$,

$$\left\| \tau_{\underline{x}_1, \cdots, \underline{x}_L} - \widehat{P}_{\mathbf{x}_1, \cdots, \mathbf{x}_L} \right\|_{\mathrm{sav}} \leqslant \zeta.$$

This completes the proof of Lemma 57. ◀

Before proceeding with the proof of converse, we first list several corollaries that directly follow from the above lemma. They are concerned with basic properties of $(\zeta, P_{\mathbf{x}_1, \cdots, \mathbf{x}_L})$-equicoupled codes.

▶ **Corollary 60.** *Any two lists of L (ordered) codewords from $\mathcal{C}'$ have joint types 2ζ close to each other in sum-absolute-value distance.*

Proof. For any $\mathcal{L}_1 = \left(\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}\right)$ and $\mathcal{L}_2 = \left(\underline{x}_{j_1}, \cdots, \underline{x}_{j_L}\right)$ in $\binom{\mathcal{C}'}{L}$,

$$\begin{aligned} \left\| \tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}} - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_L}} \right\|_{\mathrm{sav}} &\leqslant \left\| \tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}} - \widehat{P}_{\mathbf{x}_1, \cdots, \mathbf{x}_L} \right\|_{\mathrm{sav}} + \left\| \widehat{P}_{\mathbf{x}_1, \cdots, \mathbf{x}_L} - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_L}} \right\|_{\mathrm{sav}} \\ &\leqslant \zeta + \zeta \\ &= 2\zeta. \end{aligned} \tag{74}$$

◀

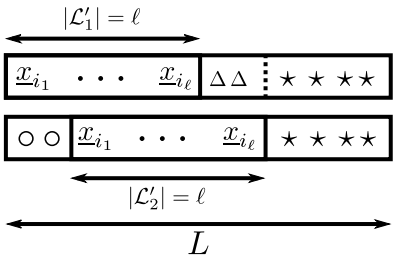

Figure 11 Two ways to complete the size-ℓ list $i_1, \cdots, i_\ell$ to size-L lists $\mathcal{L}_1, \mathcal{L}_2$, respectively. Triangles Δ, circles $\circ$ and stars $\star$ represent indices j's, k's and l's, respectively.

▶ **Corollary 61.** *Any two size-ℓ ($1 \leqslant \ell \leqslant L$) lists in $\mathcal{C}'$ have joint type 2ζ close to each other in sum-absolute-value distance, provided $|\mathcal{C}'| > 2L$.*

Proof. For any $\mathcal{L}'_1 = (\underline{x}_{i_1}, \cdots \underline{x}_{i_{L-1}})$ and $\mathcal{L}'_2 = (\underline{x}_{j_1}, \cdots, \underline{x}_{j_{L-1}})$ in $\binom{\mathcal{C}'}{L-1}$, take $\underline{x}_\iota \in \mathcal{C}' \backslash (\mathcal{L}'_1 \cup \mathcal{L}'_2)$. (This can be done as long as $|\mathcal{C}'| > 2L$.) Without loss of generality, assume $\iota > \max\{i_{L-1}, j_{L-1}\}$. Let $\mathcal{L}_1 := \mathcal{L}'_1 \cup \{\underline{x}_\iota\}, \mathcal{L}_2 := \mathcal{L}'_2 \cup \{\underline{x}_\iota\}$. We know that

$$
\begin{aligned}
2\zeta \geqslant & \left\| \tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_{L-1}}, \underline{x}_\iota} - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_{L-1}}, \underline{x}_\iota} \right\|_{\text{sav}} \\
= & \sum_{(x_1, \cdots, x_{L-1}, x) \in \mathcal{X}^L} \left| \tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_{L-1}}, \underline{x}_\iota}(x_1, \cdots, x_{L-1}, x) - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_{L-1}}, \underline{x}_\iota}(x_1, \cdots, x_{L-1}, x) \right| \\
\geqslant & \sum_{(x_1, \cdots, x_{L-1}) \in \mathcal{X}^{L-1}} \\
& \qquad \left| \sum_{x \in \mathcal{X}} \left(\tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_{L-1}}, \underline{x}_\iota}(x_1, \cdots, x_{L-1}, x) - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_{L-1}}, \underline{x}_\iota}(x_1, \cdots, x_{L-1}, x) \right) \right| \\
= & \sum_{(x_1, \cdots, x_{L-1}) \in \mathcal{X}^{L-1}} \left| \tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_{L-1}}}(x_1, \cdots, x_{L-1}) - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_{L-1}}}(x_1, \cdots, x_{L-1}) \right| \\
= & \left\| \tau_{\underline{x}_{i_1}, \cdots, \underline{x}_{i_{L-1}}} - \tau_{\underline{x}_{j_1}, \cdots, \underline{x}_{j_{L-1}}} \right\|_{\text{sav}}.
\end{aligned}
$$

Similarly we can see that Eqn. (74) holds also for size-ℓ ($\ell \leqslant L$) lists. ◀

For a subset $\mathcal{B} \subset [n]$, we let $P_{\mathbf{x}_\mathcal{B}}$ denote the marginalization of $P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}$ onto the random variables indexed by elements in $\mathcal{B}$, $[P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}]_{\{\mathbf{x}_i \,:\, i \in \mathcal{B}\}}$.

▶ **Corollary 62.** *For any $1 \leqslant \ell < L$ and any subsets $\mathcal{L}'_1, \mathcal{L}'_2 \in \binom{[n]}{\ell}$, $P_{\mathbf{x}_{\mathcal{L}'_1}}$ and $P_{\mathbf{x}_{\mathcal{L}'_2}}$ are 3ζ close to each other in sum-absolute-value distance, given $|\mathcal{C}'| > 2L$.*

Proof. Given two subsets $\mathcal{L}'_1, \mathcal{L}'_2 \subset [n]$ both of cardinality $\ell < L$, as long as the code size M is larger than $2L$, we can always find a tuple $1 \leqslant i_1 < \cdots < i_\ell \leqslant M$ such that it can be completed to L-tuples $\mathcal{L}_1, \mathcal{L}_2$ in two different ways

$$
\begin{aligned}
\mathcal{L}_1 = (&i_1, \cdots, i_{\ell-\ell'}, i_{\ell-\ell'+1}, \cdots, i_\ell, j_1, \cdots, j_{\ell-\ell'}, l_1, \cdots, l_{L-(2\ell-\ell')}), \\
\mathcal{L}_2 = (&k_1, \cdots, k_{\ell-\ell'}, i_1, \cdots, i'_\ell, i_{\ell'+1}, \cdots, i_\ell, l_1, \cdots, l_{L-(2\ell-\ell')}),
\end{aligned}
$$

for some $1 \leqslant k_1 < \cdots < k_{\ell-\ell'} < i_1 < \cdots < i_\ell < j_1 < \cdots < j_{\ell-\ell'} < l_1 < \cdots < l_{L-(2\ell-\ell')} \leqslant M$, where $\ell' = |\mathcal{L}'_1 \cap \mathcal{L}'_2|$. See Fig. 11. We know that

$$
\begin{aligned}
\|\tau_{\mathcal{L}_1} - P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}\|_{\text{sav}} \leqslant & \zeta, \\
\|\tau_{\mathcal{L}_2} - P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}\|_{\text{sav}} \leqslant & \zeta.
\end{aligned}
$$

Note that

$$\begin{aligned}
\zeta \geqslant & \left\| \tau_{\underline{x}_{\mathcal{L}_1}} - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \right\|_{\text{sav}} \\
= & \sum_{\mathcal{L}_1 \in \{0,1\}^L} \left| \tau_{\underline{x}_{\mathcal{L}_1}}(\mathcal{L}_1) - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(\mathcal{L}_1) \right| \\
\geqslant & \sum_{i_1,\cdots,i_\ell} \Bigg| \sum_{\mathcal{L}_1 \backslash \{i_1,\cdots,i_\ell\} \in \{0,1\}^{L-\ell}} \tau_{\underline{x}_{\mathcal{L}_1}}(i_1,\cdots,i_\ell,\mathcal{L}_1 \backslash \{i_1,\cdots,i_\ell\}) \\
& \qquad - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(i_1,\cdots,i_\ell,\mathcal{L}_1 \backslash \{i_1,\cdots,i_\ell\}) \Bigg| \\
\leqslant & \sum_{i_1,\cdots,i_\ell} \left| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}}(i_1,\cdots,i_\ell) - P_{\mathbf{x}_{\mathcal{L}'_1}}(i_1,\cdots,i_\ell) \right| \\
= & \left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} - P_{\mathbf{x}_{\mathcal{L}'_1}} \right\|_{\text{sav}}.
\end{aligned}$$

Similarly,

$$\left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} - P_{\mathbf{x}_{\mathcal{L}'_2}} \right\|_{\text{sav}} \leqslant \zeta.$$

By triangle inequality,

$$\begin{aligned}
\left\| P_{\mathbf{x}_{\mathcal{L}'_1}} - P_{\mathbf{x}_{\mathcal{L}'_2}} \right\|_{\text{sav}} \leqslant & \left\| P_{\mathbf{x}_{\mathcal{L}'_1}} - \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} \right\|_{\text{sav}} + \left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} - P_{\mathbf{x}_{\mathcal{L}'_2}} \right\|_{\text{sav}} \\
\leqslant & 2\zeta.
\end{aligned}$$

◀

▶ **Corollary 63.** *A $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$-equicoupled code $\mathcal{C}'$ is $(3\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_\ell})$-equicoupled for any $1 \leqslant \ell \leqslant L$, as long as $|\mathcal{C}'| > 2L$.*

Proof. For any list of codewords $\underline{x}_{i_1}, \cdots, \underline{x}_{i_\ell}$, we can always find a completion of $(i_1, \cdots, i_\ell)$ to an L-tuple. Let $\mathcal{T}$ denote the set of locations of $i_1, \cdots, i_\ell$ in the completion. We know that

$$\left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} - P_{\mathbf{x}_\mathcal{T}} \right\|_{\text{sav}} \leqslant \zeta.$$

By the previous corollary,

$$\begin{aligned}
\left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} - P_{\mathbf{x}_1,\cdots,\mathbf{x}_\ell} \right\|_{\text{sav}} \leqslant & \left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_\ell}} - P_{\mathbf{x}_\mathcal{T}} \right\|_{\text{sav}} + \left\| P_{\mathbf{x}_\mathcal{T}} - P_{\mathbf{x}_1,\cdots,\mathbf{x}_\ell} \right\|_{\text{sav}} \\
\leqslant & \zeta + 2\zeta \\
= & 3\zeta.
\end{aligned}$$

◀

Now we apply the double counting trick used in the Plotkin-type bound for list decoding. We want to show that if $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is not completely positive, then any $(L-1)$-list decodable code cannot be large.

▶ **Definition 64** (Symmetry of tensors). *A tensor $T \in \mathsf{Ten}_n^{\otimes m}$ is said to be* symmetric *if its components are invariant under permutation of indices, i.e., for any $\sigma \in S_m$ and any $(t_1, \cdots, t_m) \in [n]^m$,*

$$T(t_1, \cdots, t_m) = T\left(t_{\sigma(1)}, \cdots, t_{\sigma(m)}\right).$$

The set of dimension-n order-m symmetric tensors is denoted by $\mathsf{Sym}_n^{\otimes m}$.

13.2 Symmetric case

In this subsection, assume $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is symmetric as a dimension-$|\mathcal{X}|$ order-L tensor. We are going to show that

▶ **Lemma 65** (Converse, symmetric case). *For a general adversarial channel given by $\mathcal{A} = \left(\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\right)$ and an admissible input distribution $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$, if $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) \subseteq \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, the any $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$-equicoupled $(L-1)$-list decodable code $\mathcal{C}'$ has size at most*

$$|\mathcal{C}'| \leqslant \max\left\{2(L-1), \frac{2^{L+1}L!}{\lambda}\right\},$$

where $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) \backslash \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$ is a symmetric, non-confusable joint distribution.

Proof. Since $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}(P_{\mathbf{x}}) \backslash \mathsf{CP}^{\otimes L}_{|\mathcal{X}|}$, by duality (Theorem 96) between the CP tensor cone and coP tensor cone, there is a copositive tensor $Q \in \mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$ such that $\|Q\|_{\mathrm{F}} = 1$ (by normalization) and

$$\left\langle P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}, Q \right\rangle = -\eta \tag{75}$$

for some $\eta > 0$. Note that, by definition of λ, $\eta > \lambda$. We will bound

$$\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L} \left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q \right\rangle$$

from above and below and argue that if $|\mathcal{C}'|$ is larger than some constant[14], then we get a strictly negative upper bound and a non-negative lower bound. Such a contradiction implies that no positive rate is possible for $(L-1)$-list decoding if $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is a non-CP symmetric distribution.

Upper bound.

Case when $i_1,\cdots,i_L \in [|\mathcal{C}'|]$ are not all distinct. For $i_1 \leqslant \cdots \leqslant i_L \in [|\mathcal{C}'|]$ not all distinct,

$$\left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q \right\rangle \leqslant \left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}} \right\|_{\mathrm{F}} \|Q\|_{\mathrm{F}} \tag{76}$$

$$\leqslant \left\| \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}} \right\|_{\mathrm{sav}} \|Q\|_{\mathrm{F}} \tag{77}$$

$$\leqslant 1. \tag{78}$$

Eqn. (76) is by Cauchy–Schwarz inequality. Eqn. (77) is because q-norm of a vector is non-increasing in q. Eqn. (78) is because a probability/type vector has one-norm 1 and Q is normalized to have F-norm 1.

Thus

$$\sum_{\substack{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L \\ \text{not all distinct}}} \left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q \right\rangle \leqslant |\mathcal{C}'|^L - \binom{|\mathcal{C}'|}{L} L!.$$

[14] Note that we will actually show that the size of the code is upper bounded by a *constant* (independent of blocklength n), not just that the rate of the code is vanishing.

Case when $i_1, \cdots, i_L \in [|\mathcal{C}'|]$ are all distinct. By Lemma 57, for any $\underline{x}_{i_1}, \cdots, \underline{x}_{i_L} \in \mathcal{C}'$ distinct,

$$\begin{aligned}\left\|\tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}} - \widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right\|_{\mathrm{mav}} \leqslant& \left\|\tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}} - \widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right\|_{\mathrm{sav}}\\ \leqslant& \zeta.\end{aligned}$$

For any $(i_1, \cdots, i_L) \in \binom{|\mathcal{C}'|}{L}$ distinct, let $\Delta_{i_1,\cdots,i_L} \coloneqq \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}} - \widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. Immediately, $\|\Delta_{i_1,\cdots,i_L}\|_{\mathrm{mav}} \leqslant \zeta$.

Now,

$$\left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q\right\rangle = \langle \Delta_{i_1,\cdots,i_L}, Q\rangle + \left\langle \widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}, Q\right\rangle.$$

Note that

$$\begin{aligned}|\langle \Delta_{i_1,\cdots,i_L}, Q\rangle| =& \left|\sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L} \Delta_{i_1,\cdots,i_L}(x_1,\cdots,x_L)Q(x_1,\cdots,x_L)\right|\\ \leqslant& \sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L} |\Delta_{i_1,\cdots,i_L}(x_1,\cdots,x_L)| \qquad (79)\\ \leqslant& |\mathcal{X}|^L \cdot \zeta, \qquad (80)\end{aligned}$$

where Eqn. (79) follows from triangle inequality and $\|Q\|_{\mathrm{mav}} \leqslant \|Q\|_{\mathrm{sav}} \leqslant \|Q\|_{\mathrm{F}} = 1$.

Hence

$$\begin{aligned}\left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q\right\rangle \leqslant& -\eta + |\mathcal{X}|^L \zeta \qquad (81)\\ \leqslant& -\lambda + \frac{\lambda}{2} \qquad (82)\\ =& -\frac{\lambda}{2},\end{aligned}$$

where Eqn. (81) follows from Eqn. (75) and Eqn. (80), Eqn. (82) is by the definition of λ (Eqn. (72)) and the choice of ζ (Eqn. (73)).

Therefore,

$$\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L \text{ distinct}} \left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q\right\rangle \leqslant -\frac{\lambda}{2}\binom{|\mathcal{C}'|}{L} L!.$$

Overall,

$$\begin{aligned}\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L} \left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q\right\rangle \leqslant& |\mathcal{C}'|^L - \binom{|\mathcal{C}'|}{L} L! - \frac{\lambda}{2}\binom{|\mathcal{C}'|}{L} L!\\ <& 0 \qquad (83)\end{aligned}$$

if $|\mathcal{C}'|$ is sufficiently large. To see this, note that $p(|\mathcal{C}'|) \coloneqq |\mathcal{C}'|^L - \binom{|\mathcal{C}'|}{L} L!$ is a polynomial in $|\mathcal{C}'|$ of degree $L-1$, while $-\frac{\lambda}{2}\binom{|\mathcal{C}'|}{L} L!$ is a polynomial in $|\mathcal{C}'|$ of degree L. To give an explicit bound on $|\mathcal{C}'|$, note that the RHS of (83) equals

$$\begin{aligned}p\left(|\mathcal{C}'|\right) - \frac{\lambda}{2}|\mathcal{C}'|\left(|\mathcal{C}'|-1\right)\cdots\left(|\mathcal{C}'|-(L-1)\right) \leqslant& L\cdot(L-1)!\cdot|\mathcal{C}'|^{L-1} - \frac{\lambda}{2}\left(|\mathcal{C}'|-(L-1)\right)^L\\ =& L!\cdot|\mathcal{C}'|^{L-1} - \frac{\lambda}{2}\left(|\mathcal{C}'|-(L-1)\right)^L.\end{aligned}$$

In the above inequality, to upper bound $p\left(|\mathcal{C}'|\right)$, we replace each term of p with a monomial with the largest possible coefficient in absolute value and the largest possible degree. To make the RHS negative, we want

$$(L!)^{\frac{1}{L}}\left|\mathcal{C}'\right|^{1-\frac{1}{L}} < \left(\frac{\lambda}{2}\right)^{\frac{1}{L}}\left|\mathcal{C}'\right| - \left(\frac{\lambda}{2}\right)^{\frac{1}{L}}(L-1).$$

One can easily check that when $|\mathcal{C}'| > 2(L-1)$,

$$\frac{1}{2}\left(\frac{\lambda}{2}\right)^{\frac{1}{L}}\left|\mathcal{C}'\right| < \left(\frac{\lambda}{2}\right)^{\frac{1}{L}}\left|\mathcal{C}'\right| - \left(\frac{\lambda}{2}\right)^{\frac{1}{L}}(L-1).$$

Moreover, when $|\mathcal{C}'| > \frac{2^{L+1}L!}{\lambda}$,

$$(L!)\left|\mathcal{C}'\right|^{1-\frac{1}{L}} < \frac{1}{2}\left(\frac{\lambda}{2}\right)^{\frac{1}{L}}\left|\mathcal{C}'\right|$$

is satisfied, so is the original inequality (83).

Overall, we have that

$$\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L}\left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q\right\rangle < 0$$

as long as

$$\left|\mathcal{C}'\right| > \max\left\{2(L-1), \frac{2^{L+1}L!}{\lambda}\right\}. \tag{84}$$

Though the bound (84) is crude, it is a *constant* not depending on the blocklength n.

Lower bound.

$$\begin{aligned}
&\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L}\left\langle \tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}, Q\right\rangle\\
=&\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L}\sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L}\tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}(x_1,\cdots,x_L)Q(x_1,\cdots,x_L)\\
=&\sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L}\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L}\frac{1}{n}\sum_{j=1}^{n}\mathbb{1}_{\left\{\underline{x}_{i_1}(j)=x_1,\cdots,\underline{x}_{i_L}(j)=x_L\right\}}Q(x_1,\cdots,x_L)\\
=&\frac{1}{n}\sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L}\sum_{j=1}^{n}\sum_{(i_1,\cdots,i_L)\in[|\mathcal{C}'|]^L}\mathbb{1}_{\left\{\underline{x}_{i_1}(j)=x_1\right\}}\cdots\mathbb{1}_{\left\{\underline{x}_{i_L}(j)=x_L\right\}}Q(x_1,\cdots,x_L)\\
=&\frac{1}{n}\sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L}\sum_{j=1}^{n}\left(\sum_{i\in[|\mathcal{C}'|]}\mathbb{1}_{\left\{\underline{x}_i(j)=x_1\right\}}\right)\cdots\left(\sum_{i\in[|\mathcal{C}'|]}\mathbb{1}_{\left\{\underline{x}_i(j)=x_L\right\}}\right)Q(x_1,\cdots,x_L)\\
=&\frac{|\mathcal{C}'|^L}{n}\sum_{(x_1,\cdots,x_L)\in\mathcal{X}^L}\sum_{j=1}^{n}P_{\mathbf{x}}^{(j)}(x_1)\cdots P_{\mathbf{x}}^{(j)}(x_L)Q(x_1,\cdots,x_L) \qquad (85)\\
=&\frac{|\mathcal{C}'|^L}{n}\sum_{j=1}^{n}\left\langle\left(P_{\mathbf{x}}^{(j)}\right)^{\otimes L}, Q\right\rangle\\
\geqslant&0. \qquad (86)
\end{aligned}$$

To see equality (85), let $P_{\mathbf{x}}^{(j)}$ be the empirical distribution of the j-th *column* of $\mathcal{C}'$ as a $|\mathcal{C}'| \times n$ matrix, i.e., for $x \in \mathcal{X}$,

$$P_{\mathbf{x}}^{(j)}(x) \coloneqq \frac{1}{|\mathcal{C}'|} \sum_{i=1}^{|\mathcal{C}'|} \mathbb{1}_{\{\underline{x}_i(j)=x\}}.$$

The last inequality (86) follows since $\left(P_{\mathbf{x}}^{(j)}\right)^{\otimes L}$ is a completely positive tensor.

The lower bound and the upper bound are contradicting each other, which completes the proof. ◀

13.3 Asymmetric case

In this section, we handle the asymmetric case of the converse.

▶ **Definition 66** (Asymmetry of tensors). *For a joint distribution $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \Delta\left(\mathcal{X}^L\right)$, alternatively a tensor $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{Ten}_{|\mathcal{X}|}^{\otimes L}$, define its* asymmetry *as*

$$\operatorname{asymm}(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}) \coloneqq \max_{(x_1,\cdots,x_L)\in\mathcal{X}^L} \max_{\sigma\in S_L\setminus\{\mathrm{id}\}} \left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_{\sigma(1)},\cdots,x_{\sigma(L)})\right|.$$

▶ Remark 67. If $\operatorname{asymm}(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}) = 0$, then $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is symmetric in the sense of Definition 64.

We will show that

▶ **Lemma 68** (Converse, asymmetric case). *If $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{Ten}_{|\mathcal{X}|}^{\otimes L}(P_{\mathbf{x}})$ is asymmetric as a tensor in $\mathsf{Ten}_{|\mathcal{X}|}^{\otimes L}(P_{\mathbf{x}})$ and has asymmetry α, then for any $0 < \zeta < \alpha$, any $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$-equicoupled (w.r.t. max-absolute-value distance)*[15] *code $\mathcal{C}'$ has size at most*

$$|\mathcal{C}'| \leqslant \exp\left(\frac{c}{\alpha/\binom{L}{2} - \zeta}\right) + L - 2$$

for some absolute constant $c > 0$.

Lemma 68 is shown by reducing the problem, in a nontrivial way, from general values of L to $L = 2$ in which case it is known [43] that such codes cannot be large.

▶ **Lemma 69** (Reduction from general L to $L = 2$). *If $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{Ten}_{|\mathcal{X}|}^{\otimes L}$ has asymmetry $\operatorname{asymm}(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}) = \alpha$, then among the following distributions*

$$P_{\mathbf{y}_1,\mathbf{z}_1},\ P_{\mathbf{y}_2,\mathbf{z}_2},\cdots,P_{\mathbf{y}_{L-1},\mathbf{z}_{L-1}},$$

there is at least one distribution $P_{\mathbf{y}_{i^*},\mathbf{z}_{i^*}}$ ($i^* \in [L-1]$) with asymmetry at least

$$\operatorname{asymm}\left(P_{\mathbf{y}_{i^*},\mathbf{z}_{i^*}}\right) = \frac{\alpha}{\binom{L}{2}}.$$

[15] Note that ζ-equicoupledness w.r.t. sum-absolute-value distance implies ζ-equicoupledness w.r.t. max-absolute-value distance. Hence this lemma directly applies to the subcode we obtained in the previous section.

Here, for $i \in [L-1]$, $\mathbf{y}_i$ and $\mathbf{z}_i$ $(1 \leqslant i \leqslant L-1)$ are tuples of random variables defined as

$$\begin{aligned} \mathbf{y}_i &:= (\mathbf{x}_1, \cdots, \mathbf{x}_{i-1}, \mathbf{x}_i, \quad\quad \mathbf{x}_{i+2}, \cdots, \mathbf{x}_L), \\ \mathbf{z}_i &:= (\mathbf{x}_1, \cdots, \mathbf{x}_{i-1}, \quad\quad \mathbf{x}_{i+1}, \mathbf{x}_{i+2}, \cdots, \mathbf{x}_L), \end{aligned}$$

respectively.

Proof. The proof is by contradiction. We will show that if all of $\{P_{\mathbf{y}_i,\mathbf{z}_i}\}_{1\leqslant i\leqslant L-1}$ have small asymmetry, then they do not not suffice to back propagate their asymmetry using transpositions to result in the asymmetry α of $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. To make this intuition clear, assume, towards a contradiction, that all of the distributions $\{P_{\mathbf{y}_i,\mathbf{z}_i}\}_{1\leqslant i\leqslant L-1}$ have asymmetry strictly less than $\alpha' = \frac{\alpha}{\binom{L}{2}}$,

$$\operatorname{asymm}(P_{\mathbf{y}_i,\mathbf{z}_i}) < \frac{\alpha}{\binom{L}{2}}, \ \forall i \in [L-1]. \tag{87}$$

Assume the asymmetry of $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is witnessed by coordinates $(x_1,\cdots,x_L) \in \mathcal{X}^L$ and permutation $\pi \in S_L$, i.e.,

$$\begin{aligned} \alpha &= \left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_{\pi(1)},\cdots,x_{\pi(L)})\right| \\ &= \left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right|. \end{aligned} \tag{88}$$

Note that the set of transpositions $\{\sigma_1,\cdots,\sigma_{L-1}\}$ forms a generator set of S_L, where

$$\sigma_i := \begin{pmatrix} 1 & \cdots & i-1 & i & i+1 & i+2 & \cdots & L \\ 1 & \cdots & i-1 & i+1 & i & i+2 & \cdots & L \end{pmatrix}.$$

Any permutation $\sigma \in S_L$ can be written as a product of σ_i's, $\sigma = \sigma_{i_\ell}\cdots\sigma_{i_1}$ for some positive integer ℓ and a subset of transpositions, $i_j \in [L-1]$ for each $j \in [\ell]$. Such a representation, in particular the value of ℓ, is not necessarily unique. Let

$$\ell(\sigma) := \min\{\ell \in \mathbb{Z}_{\geqslant 0} \colon \sigma = \sigma_{i_\ell}\cdots\sigma_{i_1} \text{ transposition representation}\}$$

be the *transposition length* of σ, i.e., the length of the shortest representation using product of transpositions. Let

$$\ell^* := \max_{\sigma\in S_L} \ell(\sigma).$$

We claim that $\ell^* \leqslant \binom{L}{2}$. To see this, it suffices to bound $\ell(\sigma)$ for the worst case permutation

$$\sigma = \begin{pmatrix} 1 & 2 & \cdots & L \\ L & L-1 & \cdots & 1 \end{pmatrix}.$$

The claim follows by noting that σ can be written as

$$\sigma = \prod_{j=1}^{L-1} \prod_{i=j,j-1,\cdots,1} \sigma_i, \tag{89}$$

which contains $\binom{L}{2}$ transpositions.

▶ Remark 70. A potential confusion may arise from two conflicting conventions that

1. a product is usually written from left to right, i.e.,

$$\prod_{i=1}^{\ell} \sigma_i = \sigma_1\cdots\sigma_\ell;$$

2. a composition of permutations acts like functions on an element from right to left, i.e., for $\sigma, \pi \in S_L$ and $i \in [L]$,

$$(\sigma\pi)(i) = \sigma(\pi(i)).$$

With this kept in mind, the representation in Eqn. (89) should be understood as

$$\sigma = (\sigma_1)(\sigma_2\sigma_1)\cdots(\sigma_{L-2}\cdots\sigma_2\sigma_1)(\sigma_{L-1}\cdots\sigma_2\sigma_1).$$

The product in the $(L-1)$-st parenthesis (from left to right) moves L in the initial sequence $(L, L-1, \cdots, 1)$ to the L-th position; the product in the $(L-2)$-nd parenthesis moves $L-1$ to the $(L-1)$-st position; ...; the permutation σ_1 in the 1-st parenthesis moves 2 to the 2-st position, and automatically 1 is in the 1-st position. We get the target sequence $(1, 2, \cdots, L)$. We can write

$$\pi = \prod_{j=\ell,\ell-1,\cdots,1} \sigma_{i_j}, \tag{90}$$

for some $\ell \leqslant \ell^* \leqslant \binom{L}{2}$.

Our assumption Eqn. (87) implies that, for any $(x_1, \cdots, x_L) \in \mathcal{X}^L$ and any transposition σ_i,

$$\begin{aligned}
&\left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\sigma_i(1)},\cdots,\mathbf{x}_{\sigma_i(L)}}(x_1,\cdots,x_L)\right| \\
=&\left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_{i-1},\mathbf{x}_i,\mathbf{x}_{i+1},\mathbf{x}_{i+2},\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_1,\cdots,\mathbf{x}_{i-1},\mathbf{x}_{i+1},\mathbf{x}_i,\mathbf{x}_{i+2},\cdots,\mathbf{x}_L}(x_1,\cdots,x_L)\right| \\
=&\left|P_{(\mathbf{x}_1,\cdots,\mathbf{x}_{i-1},\mathbf{x}_i,\mathbf{x}_{i+2},\cdots,\mathbf{x}_L),(\mathbf{x}_1,\cdots,\mathbf{x}_{i-1},\mathbf{x}_{i+1},\mathbf{x}_{i+2},\cdots,\mathbf{x}_L)}\begin{pmatrix}(x_1,\cdots,x_{i-1},x_i,x_{i+2},\cdots,x_L),\\(x_1,\cdots,x_{i-1},x_{i+1},x_{i+2},\cdots,x_L)\end{pmatrix}\right. \\
&\quad\left. - P_{(\mathbf{x}_1,\cdots,\mathbf{x}_{i-1},\mathbf{x}_{i+1},\mathbf{x}_{i+2},\cdots,\mathbf{x}_L),(\mathbf{x}_1,\cdots,\mathbf{x}_{i-1},\mathbf{x}_i,\mathbf{x}_{i+2},\cdots,\mathbf{x}_L)}\begin{pmatrix}(x_1,\cdots,x_{i-1},x_i,x_{i+2},\cdots,x_L),\\(x_1,\cdots,x_{i-1},x_{i+1},x_{i+2},\cdots,x_L)\end{pmatrix}\right| \\
=&\left|P_{\mathbf{y}_i,\mathbf{z}_i}(y,z) - P_{\mathbf{z}_i,\mathbf{y}_i}(y,z)\right| \\
=&\left|P_{\mathbf{y}_i,\mathbf{z}_i}(y,z) - P_{\mathbf{y}_i,\mathbf{z}_i}(z,y)\right| \\
<&\alpha',
\end{aligned} \tag{91}$$

where

$$\begin{aligned}
y &:= (x_1, \cdots, x_{i-1}, x_i, x_{i+2}, \cdots, x_L), \\
z &:= (x_1, \cdots, x_{i-1}, x_{i+1}, x_{i+2}, \cdots, x_L).
\end{aligned}$$

Now

$$\begin{aligned}
\alpha =& \left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right| && (92)\\
\leqslant& \left|P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_1}(L)}}(x_1,\cdots,x_L)\right| \\
&+ \left|P_{\mathbf{x}_{\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right| && (93)\\
<&\alpha' + \left|P_{\mathbf{x}_{\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right| && (94)\\
\leqslant&\alpha' + \left|P_{\mathbf{x}_{\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\sigma_{i_2}\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_2}\sigma_{i_1}(L)}}(x_1,\cdots,x_L)\right| \\
&+ \left|P_{\mathbf{x}_{\sigma_{i_2}\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_2}\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right| && (95)\\
<&2\alpha' + \left|P_{\mathbf{x}_{\sigma_{i_2}\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_2}\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right| && (96)
\end{aligned}$$

$$\cdots$$

$$\leqslant(\ell-1)\alpha' + \left|P_{\mathbf{x}_{\sigma_{i_{\ell-1}}\cdots\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_{\ell-1}}\cdots\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\pi(1)},\cdots,\mathbf{x}_{\pi(L)}}(x_1,\cdots,x_L)\right| \tag{97}$$

$$=(\ell-1)\alpha' + \Big|P_{\mathbf{x}_{\sigma_{i_{\ell-1}}\cdots\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_{\ell-1}}\cdots\sigma_{i_1}(L)}}(x_1,\cdots,x_L) - P_{\mathbf{x}_{\sigma_{i_\ell}\sigma_{i_{\ell-1}}\cdots\sigma_{i_1}(1)},\cdots,\mathbf{x}_{\sigma_{i_\ell}\sigma_{i_{\ell-1}}\cdots\sigma_{i_1}(L)}}(x_1,\cdots,x_L)\Big| \tag{98}$$

$$<\ell\alpha' \tag{99}$$

$$\leqslant\binom{L}{2}\alpha'$$

$$=\alpha. \tag{100}$$

1. Eqn. (92) follows from Eqn. (88).
2. Eqn. (93), (95), etc., are by triangle inequality.
3. Eqn. (94), (96), (99), etc. , are by Eqn. (91).
4. Eqn. (97) is by recursively applying the previous calculations.
5. Eqn. (98) is by the transposition representation of π (Eqn. (90)).
6. Eqn. (100) is by the choice of α'.

We reach a contradiction that α is strictly less than itself. This finishes the proof. ◀

Next, we show the key lemma 68 in this section. Note that, according to the statement, Lemma 68 is independent of the channel that the code $\mathcal{C}'$ is used for. Hence we will directly prove the random variable version of this lemma which is concerned with fundamental properties of joint distributions. If the joint distribution of a sequence of random variables has all of its size-L marginals being ζ-close to some *asymmetric* distribution, then such a sequence cannot be infinitely long. We will prove a finite upper bound on the length of the sequence by reducing this problem from the general $L > 2$ case to the $L = 2$ case. In the $L = 2$ case, prior work [43] shows that this is indeed the case.

▶ **Lemma 71** (Converse, asymmetric case, $L = 2$ [43]). *Assume $P_{\mathbf{x}_1,\mathbf{x}_2} \in \Delta(\mathcal{X}^2)$ has asymmetry* $\operatorname{asymm}(P_{\mathbf{x}_1,\mathbf{x}_2}) = \alpha$. *Let $\mathbf{w}_1,\cdots,\mathbf{w}_M$ be a sequence of M random variables supported on $\mathcal{X}$ such that for every $1 \leqslant j_1 < j_2 \leqslant M$,*

$$\left\|P_{\mathbf{w}_{j_1},\mathbf{w}_{j_2}} - P_{\mathbf{x}_1,\mathbf{x}_2}\right\|_{\text{mav}} \leqslant \zeta.$$

for some $0 < \zeta < \alpha$. Then

$$M \leqslant \exp\left(\frac{c}{\alpha-\zeta}\right)$$

for some universal constant $c > 0$.

We are now ready to prove the restated version of Lemma 68.

▶ **Lemma 72** (Converse, asymmetric case, general L). *If a joint distribution $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \Delta\left(\mathcal{X}^L\right)$ has asymmetry* $\operatorname{asymm}(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}) = \alpha$, *and a sequence of M random variables $\mathbf{w}_1,\cdots,\mathbf{w}_M$ supported on $\mathcal{X}$ satisfies that for any $1 \leqslant j_1 < \cdots < j_L \leqslant M$,*

$$\left\|P_{\mathbf{w}_{j_1},\cdots,\mathbf{w}_{j_L}} - P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right\|_{\text{mav}} \leqslant \zeta. \tag{101}$$

Then

$$M \leqslant \exp\left(\frac{c}{\alpha/\binom{L}{2} - \zeta}\right) + L - 2$$

for some universal constant $c > 0$*.*

Proof. Construct the following $L-1$ sequences $\left\{\mathbf{v}^{(i)}\right\}_{1\leqslant i\leqslant L-1}$ of random variables, each of which has length $M-L+2$,

$$\begin{array}{lclllll}
\mathbf{v}^{(1)} & = & (\mathbf{v}_1^{(1)}, & \mathbf{v}_2^{(1)}, & \cdots, & \mathbf{v}_{M-L+2}^{(1)}), \\
\mathbf{v}^{(2)} & = & (\mathbf{v}_2^{(2)}, & \mathbf{v}_2^{(2)}, & \cdots, & \mathbf{v}_{M-L+3}^{(2)}), \\
\cdots & & & & & \\
\mathbf{v}^{(L-1)} & = & (\mathbf{v}_{L-1}^{(L-1)}, & \mathbf{v}_2^{(1)}, & \cdots, & \mathbf{v}_M^{(L-1)}).
\end{array}$$

For $1 \leqslant i \leqslant L-1$ and $i \leqslant j \leqslant M-L+i+1$, $\mathbf{v}_j^{(i)}$ is defined as atuple

$$\mathbf{v}_j^{(i)} := \left(\mathbf{w}_1, \cdots, \mathbf{w}_{i-1}, \mathbf{w}_j, \mathbf{w}_{M-L+i+2}, \cdots, \mathbf{w}_M\right).$$

Then, for any

$$\begin{array}{lclllllll}
v_1 & := & (x_1, & \cdots, & x_{i-1}, & x_i, & & x_{i+2}, & \cdots, & x_L) \in \mathcal{X}^{L-1}, \\
v_2 & := & (x_1, & \cdots, & x_{i-1}, & & x_{i+1}, & x_{i+2}, & \cdots, & x_L) \in \mathcal{X}^{L-1},
\end{array}$$

and $i \leqslant j_1 < j_2 \leqslant M-L+i+1$, we have

$$\begin{aligned}
&\left|P_{\mathbf{v}_{j_1}^{(i)}, \mathbf{v}_{j_2}^{(i)}}(v_1, v_2) - P_{\mathbf{y}_i, \mathbf{z}_i}(v_1, v_2)\right| \\
=&\Bigg|P_{(\mathbf{w}_1, \cdots, \mathbf{w}_{i-1}, \mathbf{w}_{j_1}, \mathbf{w}_{M-L+i+2}, \cdots, \mathbf{w}_M), (\mathbf{w}_1, \cdots, \mathbf{w}_{i-1}, \mathbf{w}_{j_2}, \mathbf{w}_{M-L+i+2}, \cdots, \mathbf{w}_M)} \\
&\qquad\qquad\begin{pmatrix} (x_1, \cdots, x_{i-1}, x_i, x_{i+2}, \cdots, x_L), \\ (x_1, \cdots, x_{i-1}, x_{i+1}, x_{i+2}, \cdots, x_L) \end{pmatrix} \\
&\quad - P_{(\mathbf{x}_1, \cdots, \mathbf{x}_{i-1}, \mathbf{x}_i, \mathbf{x}_{i+2}, \cdots, \mathbf{x}_L), (\mathbf{x}_1, \cdots, \mathbf{x}_{i-1}, \mathbf{x}_{i+1}, \mathbf{x}_{i+2}, \cdots, \mathbf{x}_L)}\begin{pmatrix} (x_1, \cdots, x_{i-1}, x_i, x_{i+2}, \cdots, x_L), \\ (x_1, \cdots, x_{i-1}, x_{i+1}, x_{i+2}, \cdots, x_L) \end{pmatrix}\Bigg| \\
=&\Big|P_{\mathbf{w}_1, \cdots, \mathbf{w}_{i-1}, \mathbf{w}_{j_1}, \mathbf{w}_{j_2}, \mathbf{w}_{M-L+i+2}, \cdots, \mathbf{w}_M}(x_1, \cdots, x_{i-1}, x_i, x_{i+1}, x_{i+2}, \cdots, x_L) \\
&\qquad\qquad - P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}(x_1, \cdots, x_L)\Big| \\
\leqslant&\zeta,
\end{aligned}$$

by the assumption Eqn. (101). Therefore, all sequences $\mathbf{v}^{(i)}$'s are $(\zeta, P_{\mathbf{y}_i, \mathbf{z}_i})$-equicoupled, $1 \leqslant i \leqslant L-1$.

Since $P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}$ is α-asymmetric, by Lemma 69, at least one of the distributions $P_{\mathbf{y}_i, \mathbf{z}_i}$'s ($1 \leqslant i \leqslant L-1$) is at least α'-asymmetric ($\alpha' = \alpha/\binom{L}{2}$). Without loss of generality, assume $P_{\mathbf{y}_{i_0}, \mathbf{z}_{i_0}}$ is $\geqslant \alpha'$-asymmetric. Then the i_0-th sequence $\mathbf{v}^{(i_0)}$ is short by Lemma 71,

$$M - L + 2 \leqslant \exp\left(\frac{c}{\alpha' - \zeta}\right),$$

for some universal constant $c > 0$. Hence

$$M \leqslant \exp\left(\frac{c}{\alpha/\binom{L}{2} - \zeta}\right) + L - 2,$$

which finishes the proof. ◀

▶ Remark 73 (Asymmetric but projectively symmetric tensors). Lemma 69 does not follow from naïvely marginalizing an asymmetric distribution $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ and hoping that $P_{\mathbf{x}_i,\mathbf{x}_j}$ is asymmetric for some $1 \leqslant i < j \leqslant L$. Just like there exist asymmetric matrices (self-couplings) with the same column sum and row sum, we should not expect that the asymmetry of a tensor is preserved under projections.

We say that a tensor $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathsf{Ten}_{|\mathcal{X}|}^{\otimes L}$ is *ℓ-projectively symmetric* ($1 \leqslant \ell < L$) if all of its order-ℓ projections are symmetric, i.e., for any $1 \leqslant i_1 < \cdots < i_\ell \leqslant L$,

$$P_{\mathbf{x}_{i_1},\cdots,\mathbf{x}_{i_\ell}} \coloneqq [P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}]_{\mathbf{x}_{i_1},\cdots,\mathbf{x}_{i_\ell}} \in \mathsf{Ten}_{|\mathcal{X}|}^{\otimes \ell}$$

is symmetric.

One can easily verify the following facts.

▶ **Lemma 74.** *Let $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ be a tensor of dimension $|\mathcal{X}|$ and order L.*

1. *If $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is ℓ-projectively symmetric ($1 \leqslant \ell < L$), then all of its order-ℓ' ($1 \leqslant \ell' < \ell$) marginals are the same.*
2. *If $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is ℓ-projectively symmetric ($1 \leqslant \ell < L$), then it is also ℓ'-projectively symmetric for any $1 \leqslant \ell' < \ell$.*
3. *A symmetric tensor $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is also ℓ-projectively symmetric for all $1 \leqslant \ell < L$. In particular, it is a self-coupling, i.e., $P_{\mathbf{x}_i}$ is the same for all $i \in [L]$.*

We provide an example showing that the asymmetry of a tensor cannot be recovered from all of its lower order projections. That is, there is an asymmetric tensor with every projection of one less order being symmetric.

We now construct a concrete example. In order for a dimension-2 order-3 tensor $T\colon [2]^3 \to \mathbb{R}$ to be symmetric, it has to satisfy the following system $\mathcal{E}_1$ of linear equations,

$$t_{112} = t_{121}, \quad t_{121} = t_{211}, \quad t_{212} = t_{122}, \quad t_{122} = t_{221}.$$

where $t_{ijk} \coloneqq T(i,j,k)$ for $i,j,k \in [2]$. On the other hand, for it to be projectively symmetric, it has to satisfy the following system $\mathcal{E}_2$ of linear equations,

$$\begin{aligned} t_{122} + t_{121} &= t_{212} + t_{211}, \\ t_{112} + t_{122} &= t_{211} + t_{221}, \\ t_{121} + t_{221} &= t_{112} + t_{212}. \end{aligned}$$

Additionally, for T to represent a joint distribution, all entries should be non-negative and sum up to one. Note that $\mathcal{E}_2$ is a *less determined* system than $\mathcal{E}_1$, which means that we should be able to find a solution to $\mathcal{E}_2$ which does not satisfy $\mathcal{E}_1$.

Indeed, consider the following explicit example of $T \in \mathsf{Ten}_2^{\otimes 3}$. (See Fig. 12.)

$$\begin{aligned} t_{111} &= \frac{1}{60}, \quad t_{121} = \frac{1}{4}, \quad t_{112} = \frac{1}{6}, \quad t_{122} = \frac{1}{20}, \\ t_{211} &= \frac{1}{60}, \quad t_{221} = \frac{1}{5}, \quad t_{212} = \frac{17}{60}, \quad t_{222} = \frac{1}{60}. \end{aligned}$$

It is asymmetric but projectively symmetric. Note that T is forced to have multiple witnesses of asymmetry due to its projective symmetry. Indeed,

$$\begin{aligned} t_{121} - t_{112} &= t_{212} - t_{221} = \frac{5}{60}, \\ t_{121} - t_{211} &= t_{212} - t_{122} = \frac{14}{60}, \\ t_{112} - t_{211} &= t_{221} - t_{122} = \frac{9}{60}. \end{aligned}$$

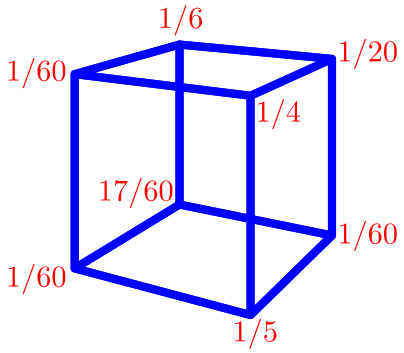

Figure 12 An asymmetric tensor $T \in \mathsf{Ten}_2^{\otimes 3}$ that is 2-projectively symmetric.

Therefore $\operatorname{asymm}(T) = \frac{14}{60} = \frac{7}{30}$, given by $t_{121} - t_{211}$ and $t_{212} - t_{122}$. All of its order-2 projections are given by

$$\begin{bmatrix} \frac{11}{60} & \frac{3}{10} \\ \frac{3}{10} & \frac{13}{60} \end{bmatrix}, \quad \begin{bmatrix} \frac{4}{15} & \frac{13}{60} \\ \frac{13}{60} & \frac{3}{10} \end{bmatrix}, \quad \begin{bmatrix} \frac{1}{30} & \frac{9}{20} \\ \frac{9}{20} & \frac{1}{15} \end{bmatrix}.$$

All of their margins are equal to $\begin{bmatrix} \frac{29}{60} \\ \frac{31}{60} \end{bmatrix}$.

In general, for any dimension-d order-L tensor, such examples can always be constructed due to the gap of degrees of freedom between the homogeneous linear systems $\mathcal{E}_1$ and $\mathcal{E}_2$.

14 Rethinking the converse

14.1 A cheap converse

If for a general $\mathcal{A} = (\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}})$, for every $P_{\mathbf{x}} \in \lambda_{\mathbf{x}}$, the confusability set is a halfspace defined by a single linear constraint

$$\mathcal{K}^{\otimes L}(P_{\mathbf{x}}) \coloneqq \left\{ P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}}) \colon \langle P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}, C \rangle \leqslant b \right\},$$

for some tensor $C \in \mathsf{Ten}_{|\mathcal{X}|}^{\otimes L}$ and constant b, then the converse can be significantly simplified. In particular, we do not have to handle symmetric and asymmetric cases separately. We describe the proof idea below.

Proof. The proof essentially follow from the following observation. For any asymmetric $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$, given any $P_{\mathbf{x}}$-constant composition $(\zeta, P_{\mathbf{x}_1,\cdots,\mathbf{x}_L})$-equicoupled code $\mathcal{C} = \{\underline{x}_i\}_{i=1}^M$ in $\mathcal{X}^n$ of size M, we can construct a code $\mathcal{C}' = \{\underline{x}'_i\}_{i=1}^M$ in $\mathcal{X}^{n \cdot M!}$ of the same size which is *symmetric*. Indeed, we can permute the rows of $\mathcal{C}$ using $\sigma \in S_M$ and juxtapose all possible ($M!$ of them in total) such row-permuted codes $\sigma(\mathcal{C})$. (See Fig. 13.) The resulting code $\mathcal{C}'$ is actually not only L-wise approximately equicoupled, but M-wise exactly equicoupled! For *any* $L \in [M]$ and any L-sized (not necessarily ordered) subset $\{i_1, \cdots, i_L\}$ of $[M]$, the joint type of $\underline{x}'_{i_1}, \cdots, \underline{x}'_{i_L}$ is *exactly* equal to

$$\tau_{\underline{x}'_{i_1},\cdots,\underline{x}'_{i_L}} = \frac{1}{\binom{M}{L}} \sum_{\{i_1,\cdots,i_L\} \in \binom{[M]}{L}} \frac{1}{L!} \sum_{\sigma \in S_L} \tau_{\underline{x}_{\sigma(i_1)},\cdots,\underline{x}_{\sigma(i_L)}},$$

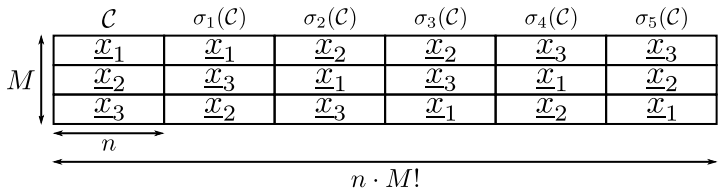

Figure 13 Construction of $\mathcal{C}'$ by permuting rows of $\mathcal{C} = \{\underline{x}_1, \underline{x}_2, \underline{x}_3\}$ using $\sigma \in S_3$ (where $S_3 = \{\mathrm{id}, \sigma_1, \cdots, \sigma_5\}$) and juxtaposing all $\sigma(\mathcal{C})$ (6 of them in total) together.

which is *symmetric* and independent of the choice of the list $(i_1, \cdots, i_L)$ (hence let us denote it by $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$). In particular, letting $L = M$, we get that

$$\tau_{\underline{x}'_1,\cdots,\underline{x}'_M} = \frac{1}{M!} \sum_{\sigma \in S_M} \tau_{\underline{x}_{\sigma(1)},\cdots,\underline{x}_{\sigma(M)}}.$$

To see the above claims, note that if we juxtapose two pairs of codewords $(\underline{x}_1, \underline{x}_2)$ and $(\underline{x}'_1, \underline{x}'_2)$, we get a pair of longer codewords $(\widetilde{\underline{x}}_1, \widetilde{\underline{x}}_2) \coloneqq (\underline{x}_1 \circ \underline{x}'_1, \underline{x}_2 \circ \underline{x}'_2)$ (where $\circ$ denotes concatenation) with joint type

$$\tau_{\widetilde{\underline{x}}_1,\widetilde{\underline{x}}_2} = \frac{1}{2}(\tau_{\underline{x}_1,\underline{x}_2} + \tau_{\underline{x}'_1,\underline{x}'_2}).$$

This still holds if two pairs of codewords of different blocklengths are juxtaposed. Say, $(\underline{x}_1, \underline{x}_2)$ has blocklength n while $(\underline{x}'_1, \underline{x}'_2)$ has blocklength n'. Then

$$\tau_{\widetilde{\underline{x}}_1,\widetilde{\underline{x}}_2} = \frac{n}{n+n'}\tau_{\underline{x}_1,\underline{x}_2} + \frac{n'}{n+n'}\tau_{\underline{x}'_1,\underline{x}'_2}.$$

Back to the proof of the converse in such a spacial case, since the confusability set is defined by a single linear constraint, any convex combinations of non-confusable joint types is still outside the confusability set, in particular, $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$. We hence reduce the problem to the symmetric case and the rest of the proof is handled by Theorem 65. ◀

14.2 Towards a unifying converse

We feel it unusual that we have to use drastically different techniques to prove the symmetric and the asymmetric parts of the converse. We suspect that it can be proved in a unifying way using the duality between CP and coP tensors which is the source of contradiction in our current proof of the symmetric case.

Note that the duality holds only in the space of *symmetric* tensors. To be specific, traditionally, CP and coP tensors are defined to be symmetric. And they are dual cones living in the ambient space $\mathsf{Sym}_n^{\otimes}$. If we extend the definitions of CP and coP tensors to the set of *all* (including asymmetric) tensors, then it is unclear whether duality still holds. Indeed, there are pairs of cones which are dual to each other in a certain ambient space but are no long dual in a larger ambient space. In a word, the ambient space that the dual cone is computed with respect to matters much.

We provide evidence showing that the symmetric and asymmetric parts of the converse can be potentially unified by the Plotkin-type bound since duality between CP and coP tensors–the core of the double counting argument–fortunately holds in larger generality.

Duality. We know that $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}$ and $\mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$ are dual cones in the space $\mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}$ of *symmetric* tensors. However, $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ (associated to the equicoupled subcode extracted using hypergraph Ramsey's theorem) is not guaranteed to be symmetric. We claim that duality still holds in the space $\mathsf{Ten}^{\otimes L}_{|\mathcal{X}|}$ of *all* tensors. Hence, copositive witness Q of a non-CP $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ exists even when $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is asymmetric.

▷ Claim 75. $\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}$ and $\mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$ are dual cones in $\mathsf{Ten}^{\otimes L}_{|\mathcal{X}|}$.

Proof. By definition,

$$\left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^* := \left\{B \in \mathsf{Ten}^{\otimes L}_{|\mathcal{X}|} \colon \forall A \in \mathsf{CP}^{\otimes L}_{|\mathcal{X}|},\, \langle A, B\rangle \geqslant 0\right\}.$$

Note that it is important that B is now taken from $\mathsf{Ten}^{\otimes L}_{|\mathcal{X}|}$ rather than $\mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}$. Also recall that

$$\mathsf{coP}^{\otimes L}_{|\mathcal{X}|} := \left\{B \in \mathsf{Ten}^{\otimes L}_{|\mathcal{X}|} \colon \forall \underline{x} \in \mathbb{R}^{|\mathcal{X}|}_{\geqslant 0},\, \left\langle B, \underline{x}^{\otimes L}\right\rangle \geqslant 0\right\}.$$

Note that this definition *differs* from the standard one 95 and this cone is potentially larger.[16] The goal is to show $\left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^* = \mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$.

The direction $\mathsf{coP}_{|\mathcal{X}|} \subseteq \left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^*$ is trivial, since the definitions of CP and coP tensors remain the same but the dual cone is computed w.r.t. a larger space. The new dual cone we are considering is no smaller than the old one. The inclusion that used to hold in the traditional setting should continue to hold now. Indeed, take any $B \in \mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$, for any $A = \sum_i \underline{x}_i^{\otimes L} \in \mathsf{CP}^{\otimes L}_{|\mathcal{X}|}$, where $\underline{x}_i \in \mathbb{R}^{|\mathcal{X}|}_{\geqslant 0}$,

$$\langle A, B\rangle = \left\langle \sum_i \underline{x}_i^{\otimes L}, B \right\rangle = \sum_i \left\langle B, \underline{x}_i^{\otimes L}\right\rangle.$$

Since $B \in \mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$, by definition, all $\left\langle B, \underline{x}_i^{\otimes L}\right\rangle$'s are non-negative, hence so is $\langle A, B\rangle$. Therefore $B \in \left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^*$.

Now we show $\left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^* \subseteq \mathsf{coP}^{\otimes L}_{|\mathcal{X}|}$. Take any $B \in \left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^*$ and any $\underline{x} \in \mathbb{R}^{|\mathcal{X}|}_{\geqslant 0}$. Then $\left\langle B, \underline{x}^{\otimes L}\right\rangle \geqslant 0$, since $\underline{x}^{\otimes L} \in \mathsf{CP}^{\otimes L}_{|\mathcal{X}|}$ and $B \in \left(\mathsf{CP}^{\otimes L}_{|\mathcal{X}|}\right)^*$. This finishes the whole proof. ◁

▶ Remark 76. In general, duality does not necessarily hold in a larger ambient space. Namely, computing dual cone w.r.t. a larger space may result in a larger cone. For instance, $\mathsf{PSD}_{|\mathcal{X}|}$ cone is known to be self dual in $\mathsf{Sym}_{|\mathcal{X}|}$, i.e., $\mathsf{PSD}^*_{|\mathcal{X}|} = \mathsf{PSD}_{|\mathcal{X}|}$. However, in $\mathsf{Mat}_{|\mathcal{X}|}$, $\mathsf{PSD}^*_{|\mathcal{X}|}$ is strictly containing $\mathsf{PSD}_{|\mathcal{X}|}$. To see this, note that any skew symmetric matrix B is in $\mathsf{PSD}^*_{|\mathcal{X}|}$ since for any PSD (hence symmetric) matrix A, $\langle A, B\rangle = 0 \geqslant 0$; while B is not necessarily PSD.

Define, for $\sigma \in S_L$, $\sigma\left(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right) := P_{\mathbf{x}_{\sigma(1)},\cdots,\mathbf{x}_{\sigma(L)}}$. Though duality holds for all symmetric and asymmetric tensors, we do not have a full proof of the converse using duality, since we have trouble bounding the term

$$\left\langle \sigma\left(P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right), Q\right\rangle = \left\langle P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}, \sigma(Q)\right\rangle$$

which does not necessarily equal $\langle P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}, Q\rangle$ for *asymmetric* Q.

We next show that such asymmetric witness Q does exist and is sometimes necessary in the sense that, some asymmetric (hence non-CP) tensors have *no* symmetric witness. This means that the dual cone of coP w.r.t. $\mathsf{Ten}^{\otimes L}_{|\mathcal{X}|}$ (instead of $\mathsf{Sym}^{\otimes L}_{|\mathcal{X}|}$) is strictly larger.

[16] Indeed, we will see shortly that it is strictly larger.

Asymmetric distributions without symmetric coP witness. Let $L = 2$. We construct an asymmetric self-coupling $P_{\mathbf{x}_1,\mathbf{x}_2} \in \Delta\left([3]^2\right)$ without symmetric coP witness Q such that $\langle P_{\mathbf{x}_1,\mathbf{x}_2}, Q\rangle < 0$. Indeed, let

$$P_{\mathbf{x}_1,\mathbf{x}_2} = \begin{bmatrix} \frac{4}{9} & \frac{7}{48} & \frac{11}{144} \\ \frac{3}{16} & \frac{1}{16} & 0 \\ \frac{5}{144} & \frac{1}{24} & \frac{1}{144} \end{bmatrix}.$$

Note that

$$P_{\mathbf{x}_1} = P_{\mathbf{x}_2} = \begin{bmatrix} \frac{2}{3} \\ \frac{1}{4} \\ \frac{1}{12} \end{bmatrix} =: P_{\mathbf{x}}.$$

Then

$$\frac{P_{\mathbf{x}_1,\mathbf{x}_2} + P_{\mathbf{x}_1,\mathbf{x}_2}^\top}{2} = \begin{bmatrix} \frac{4}{9} & \frac{1}{6} & \frac{1}{18} \\ \frac{1}{6} & \frac{1}{16} & \frac{1}{48} \\ \frac{1}{18} & \frac{1}{48} & \frac{1}{144} \end{bmatrix} = \begin{bmatrix} \frac{2}{3} \\ \frac{1}{4} \\ \frac{1}{12} \end{bmatrix} \begin{bmatrix} \frac{2}{3} & \frac{1}{4} & \frac{1}{12} \end{bmatrix} = P_{\mathbf{x}} P_{\mathbf{x}}^\top.$$

If there was a symmetric coP Q such that $\langle P_{\mathbf{x}_1,\mathbf{x}_2}, Q\rangle < 0$, then

$$\begin{aligned} \left\langle P_{\mathbf{x}} P_{\mathbf{x}}^\top, Q\right\rangle &= \frac{1}{2}\left(\langle P_{\mathbf{x}_1,\mathbf{x}_2}, Q\rangle + \left\langle P_{\mathbf{x}_1,\mathbf{x}_2}^\top, Q\right\rangle\right) \\ &= \frac{1}{2}\left(\langle P_{\mathbf{x}_1,\mathbf{x}_2}, Q\rangle + \left\langle P_{\mathbf{x}_1,\mathbf{x}_2}, Q^\top\right\rangle\right) \\ &= \langle P_{\mathbf{x}_1,\mathbf{x}_2}, Q\rangle < 0. \end{aligned}$$

However, $P_{\mathbf{x}} P_{\mathbf{x}}^\top$ is CP, so $\left\langle P_{\mathbf{x}} P_{\mathbf{x}}^\top, Q\right\rangle \geqslant 0$, which is a contradiction.

15 Sanity checks

Consider the bit-flip model.

In this section, we are going to verify the correctness of our characterization of the generalized Plotkin point using the bit-flip model as a running example. For $L = 3, 4$,[17] we will numerically recover Blinovsky's [9] characterization of the Plotkin point P_{L-1} for $(p, L-1)$-list decoding. In particular, $P_2 = 1/4$ and $P_3 = 5/16$.

15.1 $L = 3$

We first consider $(L-1)$-list decoding for $L - 1 = 2$, i.e., $L = 3$. It is known that the Plotkin point at $L - 1 = 2$ is $P_2 = 1/4$.

Fix any input distribution $P_{\mathbf{x}} := \mathrm{Bern}(w) = \begin{bmatrix} 1-w \\ w \end{bmatrix}$ for $0 < w < 1$. We first compute $\mathcal{J}^{\otimes 3}(P_{\mathbf{x}})$, $\mathcal{K}^{\otimes 3}(P_{\mathbf{x}})$. Let $p_{i,j,k,\ell} := P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}}(i,j,k,\ell)$ where $i,j,k,\ell \in \{0,1\}$.

$$\mathcal{J}^{\otimes 3}(P_{\mathbf{x}}) = \left\{P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} \in \Delta\left(\{0,1\}^3\right) : P_{\mathbf{x}_i} = P_{\mathbf{x}},\ i = 1,2,3\right\}$$

[17] For $L = 2$, i.e., the unique decoding case, the work [43] already recovers the classic Plotkin bound $P_1 = 1/4$.

$$= \left\{ P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} : \begin{array}{rl} p_{i,j,k} \geqslant & 0,\ i,j,k \in \{0,1\} \\ \sum_{i,j,k} p_{i,j,k} = & 1 \\ \sum_{i,j} p_{i,j,1} = & w \\ \sum_{i,k} p_{i,1,k} = & w \\ \sum_{j,k} p_{1,j,k} = & w \end{array} \right\}.$$

$$\begin{aligned} &\mathcal{K}^{\otimes 3}(P_{\mathbf{x}}) \\ &= \left\{ P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} = [P_{\mathbf{x}_2,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}}]_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} \in \mathcal{J}^{\otimes 3}(P_{\mathbf{x}}) : \begin{array}{rl} P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}} \in & \Delta\left(\{0,1\}^4\right) \\ P_{\mathbf{x}_i,\mathbf{y}}(0,1) + P_{\mathbf{x}_i,\mathbf{y}}(1,0) \leqslant & p,\ i = 1,2,3 \end{array} \right\} \\ &= \left\{ [P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}}]_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} \in \mathcal{J}^{\otimes 3}(P_{\mathbf{x}}) : \begin{array}{rl} p_{i,j,k,\ell} \geqslant & 0,\ i,j,k,\ell \in \{0,1\} \\ \sum_{i,j,k,\ell} p_{i,j,k,\ell} = & 1 \\ \sum_{j,k} p_{0,j,k,1} + p_{1,j,k,0} \leqslant & p \\ \sum_{i,k} p_{i,0,k,1} + p_{i,1,k,0} \leqslant & p \\ \sum_{i,j} p_{i,j,0,1} + p_{i,j,1,0} \leqslant & p \end{array} \right\}. \end{aligned}$$

$\widehat{\mathcal{J}}^{\otimes(L+1)}(P_{\mathbf{x}})$ and $\widehat{\mathcal{K}}^{\otimes(L+1)}(P_{\mathbf{x}})$ are extended formulations of $\mathcal{J}^{\otimes L}(P_{\mathbf{x}})$ and $\mathcal{K}^{\otimes L}(P_{\mathbf{x}})$, respectively.

$$\widehat{\mathcal{J}}^{\otimes 4}(P_{\mathbf{x}}) = \left\{ P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}} : \begin{array}{rl} p_{i,j,k,\ell} \geqslant & 0,\ i,j,k,\ell \in \{0,1\} \\ \sum_{i,j,k,\ell \in \{0,1\}} p_{i,j,k,\ell} = & 1 \\ \sum_{i,j} p_{i,j,1} = & w \\ \sum_{i,k} p_{i,1,k} = & w \\ \sum_{j,k} p_{1,j,k} = & w \end{array} \right\}.$$

$$\widehat{\mathcal{K}}^{\otimes 4}(P_{\mathbf{x}}) = \left\{ P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}} \in \widehat{\mathcal{J}}^{\otimes 4}(P_{\mathbf{x}}) : \begin{array}{rl} \sum_{j,k \in \{0,1\}} p_{0,j,k,1} + p_{1,j,k,0} \leqslant & p \\ \sum_{i,k \in \{0,1\}} p_{i,0,k,1} + p_{i,1,k,0} \leqslant & p \\ \sum_{i,j \in \{0,1\}} p_{i,j,0,1} + p_{i,j,1,0} \leqslant & p \end{array} \right\}.$$

To verify the value of Plotkin point P_{L-1} at $L = 3$, it suffices to verify that, if $w = 1/2$, then $P_{\mathbf{x}}^{\otimes 3} \notin \mathcal{K}^{\otimes 3}(P_{\mathbf{x}})$ iff $p < 1/4$, since we know that the optimizing input distribution when codewords are weight unconstrained is uniform. To this end, define a hyperplane

$$\mathcal{H}\left(P_{\mathbf{x}}^{\otimes 3}\right) := \left\{ P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}} \in \widehat{\mathcal{J}}^{\otimes 4}(P_{\mathbf{x}}) : [P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}}]_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} = P_{\mathbf{x}}^{\otimes 3} \right\}.$$

Note that $P_{\mathbf{x}}^{\otimes 3} \notin \mathcal{K}^{\otimes 3}(P_{\mathbf{x}})$ is equivalent to $\mathcal{H}\left(P_{\mathbf{x}}^{\otimes 3}\right) \cap \widehat{\mathcal{K}}^{\otimes 4}(P_{\mathbf{x}}) = \varnothing$. Since $\mathcal{H}\left(P_{\mathbf{x}}^{\otimes 3}\right)$ depends on w and $\widehat{\mathcal{K}}^{\otimes 4}(P_{\mathbf{x}})$ depends on w, p, we write them as $\mathcal{H}(w)$ and $\widehat{\mathcal{K}}^{\otimes 4}(w,p)$, respectively, for simplicity.

We claim that the Plotkin point P_{L-1} is precisely the optimal value of the following LP, i.e., the smallest p^* such that the hyperplane $\mathcal{H}(1/2)$ has no intersection with the corresponding high-dimensional polytope $\widehat{\mathcal{K}}^{\otimes 4}(1/2, p^*)$.

$$\begin{array}{rl} \min & p \\ \text{subject to} & \mathcal{H}(1/2) \cap \widehat{\mathcal{K}}^{\otimes 4}(1/2,p) \neq \varnothing. \end{array}$$

Equivalently, collecting all constraints together, we want to find the minimal p so that the polytope (the feasible region of the LP) defined by the following constraints is nonempty.

$$P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}} \in \widehat{\mathcal{J}}^{\otimes 4}(P_{\mathbf{x}})$$

$$
\begin{aligned}
[P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}}]_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} =& P_{\mathbf{x}}^{\otimes 3}\\
\sum_{j,k\in\{0,1\}} p_{0,j,k,1} + p_{1,j,k,0} \leqslant& p\\
\sum_{i,k\in\{0,1\}} p_{i,0,k,1} + p_{i,1,k,0} \leqslant& p\\
\sum_{i,j\in\{0,1\}} p_{i,j,0,1} + p_{i,j,1,0} \leqslant& p.
\end{aligned}
$$

Expanding everything out and noting that the first constraint regarding constant composition $P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}\in\hat{\mathcal{J}}^{\otimes 4}(P_{\mathbf{x}})}$ is redundant since it is the same as the constraint $[P_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\mathbf{y}}]_{\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3} = P_{\mathbf{x}}^{\otimes 3} \in \mathcal{J}^{\otimes 3}(P_{\mathbf{x}})$, we simplify the defining (in)equalities of the polytope as follows,

$$
\begin{aligned}
p_{i,j,k,\ell} \geqslant& 0,\ i,j,k,\ell \in \{0,1\}\\
\sum_{i,j,k,\ell\in\{0,1\}} p_{i,j,k,\ell} =& 1\\
p_{i,j,k,0} + p_{i,j,k,1} =& 1/8,\ i,j,k \in \{0,1\}\\
\sum_{j,k\in\{0,1\}} p_{0,j,k,1} + p_{1,j,k,0} \leqslant& p\\
\sum_{i,k\in\{0,1\}} p_{i,0,k,1} + p_{i,1,k,0} \leqslant& p\\
\sum_{i,j\in\{0,1\}} p_{i,j,0,1} + p_{i,j,1,0} \leqslant& p,
\end{aligned}
$$

since $P_{\mathbf{x}}^{\otimes 3}(i,j,k) = P_{\mathbf{x}}(i)P_{\mathbf{x}}(j)P_{\mathbf{x}}(k) = 1/8$ for all $i,j,k \in \{0,1\}$.

Let

$$\underline{p} \coloneqq \begin{bmatrix} p_{0,0,0,0} & \cdots & p_{1,1,1,1} \end{bmatrix}^\top.$$

The LP can be written in a compact form as

$$
\begin{bmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1\\
1 & 1 & & & & & & & & & & & & & & \\
 & & 1 & 1 & & & & & & & & & & & & \\
 & & & & 1 & 1 & & & & & & & & & & \\
 & & & & & & 1 & 1 & & & & & & & & \\
 & & & & & & & & 1 & 1 & & & & & & \\
 & & & & & & & & & & 1 & 1 & & & & \\
 & & & & & & & & & & & & 1 & 1 & & \\
 & & & & & & & & & & & & & & 1 & 1
\end{bmatrix}
\underline{p} =
\begin{bmatrix} 1\\1/8\\1/8\\1/8\\1/8\\1/8\\1/8\\1/8\\1/8 \end{bmatrix},
$$

$$
\begin{bmatrix}
1 & & 1 & & 1 & & 1 & 1 & & 1 & & 1 & & 1 & \\
1 & & 1 & 1 & & 1 & & & 1 & & 1 & 1 & & 1 & \\
1 & 1 & & & 1 & 1 & & & 1 & 1 & & & 1 & 1 &
\end{bmatrix}
\underline{p} \leqslant
\begin{bmatrix} p\\p\\p \end{bmatrix}
$$

$$\underline{p} \geqslant \underline{0}.$$

Observe that as p increases, the linear system becomes monotonically easier to be satisfied. Checked by `Mathematica`, the above LP is feasible if $p > 1/4$ (and hence the distribution $\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes 3}$ is confusable) and is infeasible if $p < 1/4$ (and hence $\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes 3}$ is not confusable). Therefore, the $(p, L-1)$-list decoding capacity hits 0 precisely at $p = 1/4$.

15.2 $L = 4$

For $L = 4$, one can obtain a similar LP whose infeasibility is equivalent to $\mathcal{H}\left(\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes 4}\right)$ and $\widehat{\mathcal{K}}^{\otimes 5}\left(\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes 4}, p\right)$ being disjoint.

$$\begin{bmatrix}
1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1\\
1&1&&&&&&&&&&&&&&&&&&&&&&&&&&&&\\
&&1&1&&&&&&&&&&&&&&&&&&&&&&&&&&\\
&&&&1&1&&&&&&&&&&&&&&&&&&&&&&&&\\
&&&&&&1&1&&&&&&&&&&&&&&&&&&&&&&\\
&&&&&&&&1&1&&&&&&&&&&&&&&&&&&&&\\
&&&&&&&&&&1&1&&&&&&&&&&&&&&&&&&\\
&&&&&&&&&&&&1&1&&&&&&&&&&&&&&&&\\
&&&&&&&&&&&&&&1&1&&&&&&&&&&&&&&\\
&&&&&&&&&&&&&&&&1&1&&&&&&&&&&&&\\
&&&&&&&&&&&&&&&&&&1&1&&&&&&&&&&\\
&&&&&&&&&&&&&&&&&&&&1&1&&&&&&&&\\
&&&&&&&&&&&&&&&&&&&&&&1&1&&&&&&\\
&&&&&&&&&&&&&&&&&&&&&&&&1&1&&&&\\
&&&&&&&&&&&&&&&&&&&&&&&&&&1&1&&\\
&&&&&&&&&&&&&&&&&&&&&&&&&&&&1&1
\end{bmatrix}\underline{p} = \begin{bmatrix}1\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\\1/16\end{bmatrix},$$

$$\begin{bmatrix}
1&1&1&1&1&1&1&1&1&1&1&1&1&1&1&1\\
1&1&1&1&1&1&1&1&&&&&&&&\\
1&1&1&1&&&&&1&1&1&1&&&&\\
1&1&&&1&1&&&1&1&&&1&1&&\\
&&1&1&&&1&1&&&1&1&&&1&1
\end{bmatrix}\underline{p} \leqslant \begin{bmatrix}p\\p\\p\\p\end{bmatrix},$$

$$\underline{p} \geqslant \underline{0},$$

where

$$\underline{p} = \begin{bmatrix}p_{0,0,0,0,0} & \cdots & p_{1,1,1,1,1}\end{bmatrix}^{\top}.$$

One can numerically check that the above LP is feasible if $p > 5/16$ and infeasible otherwise.

In general, to check whether

$$\mathcal{H}\left(\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes L}\right) \cap \widehat{\mathcal{K}}^{\otimes(L+1)}\left(\begin{bmatrix}1/2\\1/2\end{bmatrix}^{\otimes L}, p\right)$$

is empty, it boils down to checking the infeasibility of a linear program with 2^{L+1} variables and $2^{L+1} + 1 + 2^L + L$ constraints, 2^{L+1} of them for non-negativity of probability mass, 1 of them for probability mass summing up to one, 2^L of them for ensuring that $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \mathcal{J}^{\otimes L}(P_{\mathbf{x}})$ is a $(P_{\mathbf{x}}, L)$-self-coupling, L of them for the non-confusability guarantee: $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \notin \mathcal{K}^{\otimes L}(P_{\mathbf{x}})$. The size of the program (or the number of defining constraints of the corresponding polytope) grows exponentially in L. However, since we are concerned with absolute constant L in this paper, for any given L, the feasibility can be certified in constant time. Observe that, since the LP in the bit-flip setting is so structured, one can write it down explicitly by hand for any given L.

16 Blinovsky [9] revisited

In this section, we *fully* recover Blinovsky's [9] results on characterization of the Plotkin points P_{L-1} for $(p, L-1)$-list decoding under the bit-flip model.

Let ϕ be the standard bijection between $\{0,1\}$ and $\{-1,1\}$,

$$\begin{array}{rccc}
\phi\colon & \mathbb{F}_2 & \to & \{-1,1\}\\
& 0 & \mapsto & 1\\
& 1 & \mapsto & -1.
\end{array}$$

We identify the type $\tau_{\underline{x}} \in \mathcal{P}^{(n)}(\mathbb{F}_2)$ of a binary length-n vector $\underline{x} \in \mathbb{F}_2^n$ using a $\{-1,1\}$-valued random variable $\mathbf{x}$ defined as

$$\Pr[\mathbf{x}=-1] = \frac{wt_{\mathrm{H}}(\underline{x})}{n}, \quad \Pr[\mathbf{x}=1] = 1 - \frac{wt_{\mathrm{H}}(\underline{x})}{n}.$$

Indeed the distribution $P_{\mathbf{x}} \in \mathcal{P}^{(n)}(\{-1,1\})$ of $\mathbf{x}$ is the type of the image $\phi(\underline{x})$ of $\underline{x}$ under ϕ.

$$P_{\mathbf{x}}(\phi(0)) = \tau_{\underline{x}}(0), \quad P_{\mathbf{x}}(\phi(1)) = \tau_{\mathbf{x}}(1).$$

For a collection of vectors $\underline{x}_1, \cdots, \underline{x}_k \in \mathbb{F}_2^n$, their joint type is now represented by a sequence of random variables $\mathbf{x}_1, \cdots, \mathbf{x}_k$ with joint distribution $P_{\mathbf{x}_1,\cdots,\mathbf{x}_k}$, for any $x_1, \cdots, x_k \in \{-1,1\}$,

$$\begin{aligned} P_{\mathbf{x}_1,\cdots,\mathbf{x}_k}(x_1,\cdots,x_k) =& \Pr[\mathbf{x}_1 = x_1, \cdots, \mathbf{x}_k = x_k] \\ =& \tau_{\underline{x}_1,\cdots,\underline{x}_k}(\phi^{-1}(x_1), \cdots, \phi^{-1}(x_k)). \end{aligned}$$

It is easy to check that, for $\underline{x}_1, \underline{x}_2 \in \mathbb{F}_2^n$,

$$\frac{d_{\mathrm{H}}(\underline{x}_1, \underline{x}_2)}{n} = \frac{1}{2}\left(1 - \mathop{\mathbb{E}}_{(\mathbf{x}_1,\mathbf{x}_2)\sim P_{\mathbf{x}_1,\mathbf{x}_2}}[\mathbf{x}_1\mathbf{x}_2]\right). \tag{102}$$

Indeed

$$\begin{aligned} \text{RHS} =& \frac{1}{2}\left(1 - \tau_{\underline{x}_1,\underline{x}_2}(0,1)\cdot(-1) - \tau_{\underline{x}_1,\underline{x}_2}(1,0)\cdot(-1) - \tau_{\underline{x}_1,\underline{x}_2}(0,0)\cdot 1 - \tau_{\underline{x}_1,\underline{x}_2}(1,1)\cdot 1\right) \\ =& \frac{1}{2}\left(1 + \frac{d_{\mathrm{H}}(\underline{x}_1,\underline{x}_2)}{n} - \left(1 - \frac{d_{\mathrm{H}}(\underline{x}_1,\underline{x}_2)}{n}\right)\right) \\ =& \text{LHS}. \end{aligned}$$

Let

$$r := \mathop{\mathbb{E}}_{(\mathbf{x}_1,\cdots,\mathbf{x}_L)\sim\{-1,1\}^L}\left[|\mathbf{x}_1 + \cdots + \mathbf{x}_L|\right], \tag{103}$$

be the expected translation distance of a 1-dimensional unbiased random walk after L steps. Each $\mathbf{x}_i$ $(1 \leqslant i \leqslant L)$ is independent and uniformly distributed on $\{-1,1\}$.

▶ **Theorem 77.** *The Plotkin point P_{L-1} for $(p, L-1)$-list decoding is given by*

$$P_{L-1} = \frac{1 - r/L}{2}.$$

▶ Remark 78. Note that the formula in Theorem 77 agrees with the one by Blinovsky. To see this, we first compute r. For odd $L = 2k+1$, where $k \in \mathbb{Z}_{>0}$ is some strictly positive integer, it is easy to see that

$$\begin{aligned} r =& \mathbb{E}\left[|\mathbf{x}_1 + \cdots + \mathbf{x}_L|\right] \\ =& \sum_{i=0}^{k} \frac{2\binom{L}{i}}{2^L}(L-2i). \end{aligned}$$

Recall that, by binomial theorem (Fact (18)),

$$2^L = \sum_{i=0}^{L}\binom{L}{i} = \sum_{i=0}^{k} 2\binom{L}{i}.$$

Now we simplify the formula in Theorem 77.

$$\begin{aligned}
P_{L-1} =& \frac{1}{2} - \frac{r}{2L} \\
=& \sum_{i=0}^{k} \frac{\binom{L}{i}}{2^L} - \sum_{i=0}^{k} \left(1 - \frac{2i}{L}\right) \frac{\binom{L}{i}}{2^L} \\
=& \sum_{i=0}^{k} \frac{2i}{L} \frac{\binom{L}{i}}{2^L} \\
=& \sum_{i=1}^{k} \frac{i}{L} \frac{\frac{L}{i}\binom{L-1}{i-1}}{2^{L-1}} && (104) \\
=& \frac{1}{2^{L-1}} \sum_{i=0}^{k-1} \binom{L-1}{i} \\
=& \frac{1}{2^{L-1}} \frac{1}{2} \left(2^{L-1} - \binom{L-1}{k}\right) && (105) \\
=& \frac{1}{2} - 2^{-L} \binom{2k}{k},
\end{aligned}$$

where Eqn. (104) is by Fact (16); Eqn. (105) follows from binomial theorem (Fact (18)) again,

$$2^{L-1} = \binom{2k}{k} + 2 \sum_{i=0}^{k-1} \binom{2k}{i}.$$

▶ **Lemma 79** (Lower bound). *The Plotkin point P_{L-1} for $(p, L-1)$-list decoding is lower bounded by*

$$P_{L-1} \geqslant \frac{1 - r/L}{2}.$$

That is, if $p < P_{L-1}$, then the $(p, L-1)$-list decoding capacity is positive, i.e., there is an infinite sequence of $(p, L-1)$-list decodable codes of positive rate.

Proof. We will show that if $p = \frac{1 - \frac{r+\eta}{L}}{2} < \frac{1-r/L}{2}$ for any $\eta > 0$, then the product distribution $\mathrm{Bern}^{\otimes L}(1/2)$ lies outside the corresponding confusability set $\mathcal{K}^{\otimes L}(\mathrm{Bern}(1/2))$. Using the framework developed in this paper, a random code of a suitable positive rate in which each codeword is sampled independently and uniformly from $\mathcal{T}_{\underline{\mathbf{x}}}(\mathrm{Bern}(1/2))$ is $(p, L-1)$-list decodable w.h.p.

The proof is by contradiction. If $P_{\mathbf{x}_1,\cdots,\mathbf{x}_L} := \mathrm{Bern}^{\otimes L}(1/2)$ is confusable, then, by the definition 37 of confusability of tuples, an L-tuple of distinct codewords $\underline{x}_1, \cdots, \underline{x}_L$ of joint type $\tau_{\underline{x}_1,\cdots,\underline{x}_L} = P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ can be covered by a ball of radius np centered around some $\underline{y} \in \mathbb{F}_2^n$. Equivalently, by the definition 38 of confusability of distributions, there is a refinement $P_{\mathbf{x}_1,\cdots,\mathbf{x},\mathbf{y}} \in \Delta\left(\{-1,1\}^{L+1}\right)$ such that $[P_{\mathbf{x}_1,\cdots,\mathbf{x}_L,\mathbf{y}}]_{\mathbf{x}_1,\cdots,\mathbf{x}_L} = P_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$, and for every $i \in [L]$,

$$P_{\mathbf{x}_i,\mathbf{y}}(0,1) + P_{\mathbf{x}_i,\mathbf{y}}(1,0) \leqslant p.$$

This means that for every $i \in [L]$,

$$\mathbb{E}[\mathbf{x}_i \mathbf{y}] \geqslant \frac{r+\eta}{L},$$

by the relation (Eqn. (102)) between Hamming distance between vectors and correlation of their random variable representations. Hence

$$\mathbb{E}\left[(\mathbf{x}_1 + \cdots + \mathbf{x}_L)\,\mathbf{y}\right] \geqslant r + \eta. \tag{106}$$

The $\{-1,1\}$-valued random variable $\mathbf{y}$ that has the largest correlation with $\mathbf{x}_1 + \cdots + \mathbf{x}_L$ is $\mathbf{y} = \mathsf{MAJ}\left(\mathbf{x}_1, \cdots, \mathbf{x}_L\right)$, where

$$\begin{array}{rccc} \mathsf{MAJ}: & \{-1,1\}^L & \to & \{-1,1\} \\ & (x_1, \cdots, x_L) & \mapsto & \operatorname{sgn}\left(x_1 + \cdots + x_L\right). \end{array}$$

is the majority function. To see this, just expand the above expectation,

$$\begin{aligned} \mathbb{E}\left[(\mathbf{x}_1 + \cdots + \mathbf{x}_L)\,\mathbf{y}\right] &= \sum_{x_1, \cdots, x_L, y \in \{-1,1\}} P_{\mathbf{x}_1, \cdots, \mathbf{x}_L, \mathbf{y}}(x_1, \cdots, x_L, y)(x_1 + \cdots + x_L)y \\ &= \sum_{x_1, \cdots, x_L \in \{-1,1\}} P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}(x_1, \cdots, x_L) \\ &\qquad \sum_{y \in \{-1,1\}} P_{\mathbf{y}|\mathbf{x}_1, \cdots, \mathbf{x}_L}(y|x_1, \cdots, x_L)(x_1 + \cdots + x_L)y. \end{aligned}$$

Note that, each summand

$$P_{\mathbf{y}|\mathbf{x}_1, \cdots, \mathbf{x}_L}(1|x_1, \cdots, x_L)(x_1 + \cdots + x_L) - P_{\mathbf{y}|\mathbf{x}_1, \cdots, \mathbf{x}_L}(-1|x_1, \cdots, x_L)(x_1 + \cdots + x_L)$$

is maximized when the conditional probability mass of $\mathbf{y}$ is concentrated on the singleton $\operatorname{sgn}(x_1 + \cdots + x_L)$,

$$P_{\mathbf{y}|\mathbf{x}_1, \cdots, \mathbf{x}_L}(\operatorname{sgn}(x_1 + \cdots + x_L)|x_1, \cdots, x_L) = 1, P_{\mathbf{y}|\mathbf{x}_1, \cdots, \mathbf{x}_L}(-\operatorname{sgn}(x_1 + \cdots + x_L)|x_1, \cdots, x_L) = 0.$$

In this case, each summand attains its maxima

$$\operatorname{sgn}(x_1 + \cdots + x_L)(x_1 + \cdots + x_L) = |x_1 + \cdots + x_L|.$$

Overall, the corresponding maximal correlation is precisely

$$\begin{aligned} &\mathbb{E}(\mathbf{x}_1 + \cdots + \mathbf{x}_L)\mathsf{MAJ}(\mathbf{x}_1, \cdots, \mathbf{x}_L) \\ &= \sum_{x_1, \cdots, x_L \in \{-1,1\}} P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}(x_1, \cdots, x_L)\,|x_1 + \cdots + x_L| \\ &= \mathop{\mathbb{E}}_{(\mathbf{x}_1, \cdots, \mathbf{x}_L) \sim P_{\mathbf{x}_1, \cdots, \mathbf{x}_L}} \left[|\mathbf{x}_1 + \cdots + \mathbf{x}_L|\right]. \end{aligned} \tag{107}$$

Using the above observation, we get

$$\begin{aligned} r &= \mathop{\mathbb{E}}_{(\mathbf{x}_1, \cdots, \mathbf{x}_L) \sim \{-1,1\}^L} \left[|\mathbf{x}_1 + \cdots + \mathbf{x}_L|\right] && (108) \\ &= \mathbb{E}\left[(\mathbf{x}_1 + \cdots + \mathbf{x}_L)\,\mathsf{MAJ}\left(\mathbf{x}_1, \cdots, \mathbf{x}_L\right)\right] && (109) \\ &\geqslant r + \eta, && (110) \end{aligned}$$

Eqn. (108) is by the definition of r (Eqn. (103)). Eqn. (109) follows from Eqn. (107). Eqn. (110) is by Eqn. (110). We hence reach a contradiction which finishes the proof. ◀

▶ **Lemma 80** (Upper bound). *The Plotkin point P_{L-1} for $(p, L-1)$-list decoding is upper bounded by*

$$P_{L-1} \leqslant \frac{1 - r/L}{2}.$$

That is, if $p > P_{L-1}$, then no positive rate is possible, i.e, there is no infinite sequence of $(p, L-1)$-list decodable codes of positive rate.

Proof. Our goal is to show that if $p > P_{L-1}$, then $C_{L-1} = 0$. Suppose $p = \frac{1-\frac{r-\eta}{L}}{2}$ for a constant $\eta > 0$.

We are going to show that any infinite sequence of codes $\mathcal{C}_n$ each of positive rate is not $(p, L-1)$-list decodable. First, by the previous argument in last section, we can extract a sequence of subcodes $\mathcal{C}'_n \subseteq \mathcal{C}_n$ of positive rate satisfying that, for every tuple of *distinct* codewords $\underline{x}_1, \cdots, \underline{x}_L \in \mathcal{C}'$ and $x_1, \cdots, x_L \in \mathbb{F}_2$,

$$\left|\tau_{\underline{x}_1,\cdots,\underline{x}_L}(x_1,\cdots,x_L) - \widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(x_1,\cdots,x_L)\right| \leqslant \zeta$$

for some *symmetric* distribution $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L} \in \Delta\left(\mathcal{X}^L\right)$ and some positive constant $\zeta > 0$. In favour of the proceeding calculations, it suffices to take

$$\zeta = \frac{L}{(L-1)r2^{L+2}}\eta. \tag{111}$$

To show non-list decodability of $\mathcal{C}'$ (and hence $\mathcal{C}$), we will argue that there is a list $(\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}) \in \binom{\mathcal{C}'}{L}$ that can be covered by a ball of radius np centered around the point $\mathsf{MAJ}\left(\underline{x}_{i_1}, \cdots, \underline{x}_{i_L}\right)$. The proof is by contradiction. Suppose this is not the case, i.e., no list can be covered by the ball centered at its majority. Define, for $(i_1, \cdots, i_L) \in \left[2^{nR}\right]^L$,

$$Q_{i_1,\cdots,i_L} = (\mathbf{x}_{i_1} + \cdots + \mathbf{x}_{i_L}) \cdot \mathsf{MAJ}\left(\mathbf{x}_{i_1}, \cdots, \mathbf{x}_{i_L}\right) - r.$$

We will provide a *strictly negative* upper bound and a *non-negative* lower bound on

$$Q \coloneqq \mathop{\mathbb{E}}_{(\mathbf{i}_1,\cdots,\mathbf{i}_L)\sim[2^{nR}]^L} \mathop{\mathbb{E}}_{(\mathbf{x}_{\mathbf{i}_1},\cdots,\mathbf{x}_{\mathbf{i}_L})\sim P_{\mathbf{x}_{\mathbf{i}_1},\cdots,\mathbf{x}_{\mathbf{i}_L}}} [Q_{\mathbf{i}_1,\cdots,\mathbf{i}_L}],$$

which is a contradiction and finishes the proof.

Upper bound on Q. By the assumption of list decodability, for every L-tuple of distinct codewords $\underline{x}_1, \cdots, \underline{x}_L \in \mathcal{C}'$, there is a codeword $\underline{x}_i$ ($i \in [L]$) among them such that

$$d_{\mathrm{H}}\left(\underline{x}_i, \mathsf{MAJ}\left(\underline{x}_1, \cdots, \underline{x}_L\right)\right) \geqslant np.$$

Equivalently,

$$\mathbb{E}\left[\mathbf{x}_i \mathsf{MAJ}\left(\mathbf{x}_1, \cdots, \mathbf{x}_L\right)\right] \leqslant \frac{r-\eta}{L}.$$

Since $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$ is symmetric and $\mathcal{C}'$ is $\left(\zeta, \widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}\right)$-equicoupled, we expect that the term $\mathbb{E}\left[\mathbf{x}_j \mathsf{MAJ}\left(\mathbf{x}_1, \cdots, \mathbf{x}_L\right)\right] \lesssim \frac{r-\eta}{L}$ for all $j \in [L]$, potentially with some slack depending on ζ. Indeed, for any $j \in [L] \backslash \{i\}$ (without loss of generality, assume $j > i$),

$$\begin{aligned}
&\left|\mathbb{E}\left[\mathbf{x}_i \mathsf{MAJ}\left(\mathbf{x}_1, \cdots, \mathbf{x}_L\right)\right] - \mathbb{E}\left[\mathbf{x}_j \mathsf{MAJ}\left(\mathbf{x}_1, \cdots, \mathbf{x}_L\right)\right]\right| \\
=&\left| \sum_{x_1,\cdots,x_L \in \{-1,1\}} \tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_1), \cdots, \phi^{-1}(x_L)) x_i \mathsf{MAJ}\left(x_1, \cdots, x_L\right) \right. \\
&\left. - \sum_{x_1,\cdots,x_L \in \{-1,1\}} \tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_1), \cdots, \phi^{-1}(x_L)) x_j \mathsf{MAJ}\left(x_1, \cdots, x_L\right) \right| \\
=&\left| \sum_{x_1,\cdots,x_L \in \{-1,1\}} \tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_1), \cdots, \phi^{-1}(x_L)) x_i \mathsf{MAJ}\left(x_1, \cdots, x_L\right) \right.
\end{aligned} \tag{112}$$

$$
\begin{aligned}
&- \sum_{x_{\sigma(1)},\cdots,x_{\sigma(L)}\in\{-1,1\}} \tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_{\sigma(1)}),\cdots,\phi^{-1}(x_{\sigma(L)}))x_{\sigma(j)}\mathsf{MAJ}\left(x_{\sigma(1)},\cdots,x_{\sigma(L)}\right)\Bigg| \qquad (113)\\
=&\Bigg|\sum_{x_1,\cdots,x_L\in\{-1,1\}} \tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_1),\cdots,\phi^{-1}(x_L))x_i\mathsf{MAJ}\left(x_1,\cdots,x_L\right)\\
&- \sum_{x_1,\cdots,x_L\in\{-1,1\}} \tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_{\sigma(1)}),\cdots,\phi^{-1}(x_{\sigma(L)}))x_i\mathsf{MAJ}\left(x_1,\cdots,x_L\right)\Bigg|\\
=&\left|\sum_{x_1,\cdots,x_L\in\{-1,1\}}\left[\begin{array}{c}\left(\begin{array}{c}\tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_1),\cdots,\phi^{-1}(x_L))\\ -\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(\phi^{-1}(x_1),\cdots,\phi^{-1}(x_L))\end{array}\right)\\ +\left(\begin{array}{c}\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(\phi^{-1}(x_{\sigma(1)}),\cdots,\phi^{-1}(x_{\sigma(L)}))\\ -\tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_{\sigma(1)}),\cdots,\phi^{-1}(x_\sigma(L)))\end{array}\right)\end{array}\right]x_i\mathsf{MAJ}\left(x_1,\cdots,x_L\right)\right| \qquad (114)\\
\leqslant&\left(\begin{array}{c}\left|\begin{array}{c}\tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_1),\cdots,\phi^{-1}(x_L))\\ -\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(\phi^{-1}(x_1),\cdots,\phi^{-1}(x_L))\end{array}\right|\\ +\left|\begin{array}{c}\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}(\phi^{-1}(x_{\sigma(1)}),\cdots,\phi^{-1}(x_{\sigma(L)}))\\ -\tau_{\underline{x}_1,\cdots,\underline{x}_L}(\phi^{-1}(x_{\sigma(1)}),\cdots,\phi^{-1}(x_\sigma(L)))\end{array}\right|\end{array}\right)\left|\sum_{x_1,\cdots,x_L\in\{-1,1\}} x_i\mathsf{MAJ}\left(x_1,\cdots,x_L\right)\right| \qquad (115)\\
\leqslant&2\zeta\cdot\frac{2^L}{L}\mathop{\mathbb{E}}_{(\mathbf{x}_1,\cdots,\mathbf{x}_L)\sim\{-1,1\}^L}\left[(\mathbf{x}_1+\cdots+\mathbf{x}_L)\,\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)\right] \qquad (116)\\
=&\frac{2^{L+1}}{L}\zeta\mathop{\mathbb{E}}_{(\mathbf{x}_1,\cdots,\mathbf{x}_L)\sim\{-1,1\}^L}\left[|\mathbf{x}_1+\cdots+\mathbf{x}_L|\right]\\
=&\frac{2^{L+1}r}{L}\zeta. \qquad (117)
\end{aligned}
$$

In the above chain of equalities and inequalities, we used the following facts.

1. In Eqn. (113), $\sigma\in S_L$ denotes the transposition which swaps the i-th and j-th element,
$$\sigma=\begin{pmatrix}1&\cdots&i-1&i&i+1&\cdots&j-1&j&j+1&\cdots&L\\1&\cdots&i-1&j&i+1&\cdots&j-1&i&j+1&\cdots&L\end{pmatrix}.$$
2. Eqn. (114) is due to symmetry of $\widehat{P}_{\mathbf{x}_1,\cdots,\mathbf{x}_L}$.
3. Inequality (115) is by triangle inequality of absolute value.
4. Eqn. (116) follows since
$$\left|\sum_{x_1,\cdots,x_L\in\{-1,1\}} x_i\mathsf{MAJ}\left(x_1,\cdots,x_L\right)\right|=2^L\left|\frac{1}{L}\sum_{i=1}^{L}\sum_{x_1,\cdots,x_L\in\{-1,1\}}\frac{1}{2^L}x_i\mathsf{MAJ}\left(x_1,\cdots,x_L\right)\right|,$$
and the expectation is over $\mathbf{x}_i$'s which are independent and uniformly distributed on $\{-1,1\}$.

Now, for any $j\in[L]\backslash\{i\}$,

$$
\begin{aligned}
\mathbb{E}\left[\mathbf{x}_j\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)\right]=&\mathbb{E}\left[\mathbf{x}_i\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)\right]+\left(\mathbb{E}\left[\mathbf{x}_j\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)\right]\right.\\
&\left.-\mathbb{E}\left[\mathbf{x}_i\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)\right]\right)\\
\leqslant&\frac{r-\eta}{L}+\frac{2^{L+1}r}{L}\zeta.
\end{aligned}
$$

Thus we have

$$\mathbb{E}\left[(\mathbf{x}_1+\cdots+\mathbf{x}_L)\,\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)\right]\leqslant r-\eta+\frac{2^{L+1}r(L-1)}{L}\zeta.$$

That is,

$$\begin{aligned}\mathbb{E}\left[Q_{1,\cdots,L}\right] =& \mathbb{E}\left[\left(\mathbf{x}_1+\cdots+\mathbf{x}_L\right)\mathsf{MAJ}\left(\mathbf{x}_1,\cdots,\mathbf{x}_L\right)-r\right]\\ \leqslant& -\eta+\frac{2^{L+1}r(L-1)}{L}\zeta\\ =& -\frac{\eta}{2},\end{aligned} \tag{118}$$

where the last Eqn. (118) follows by the choice of ζ (Eqn. (111)). Since the above calculations work for any list $\underline{x}_1,\cdots,\underline{x}_L\in\mathcal{C}'$ of *distinct* codewords, we have that for $(i_1,\cdots,i_L)\in\binom{[M']}{L}$, the same bound holds,

$$\mathbb{E}\left[Q_{i_1,\cdots,i_L}\right]\leqslant-\frac{\eta}{2}.$$

For lists $(i_1,\cdots,i_L)\in[M']^L$ that are not all distinct, we use the trivial bound,

$$\begin{aligned}\mathbb{E}\left[Q_{i_1,\cdots,i_L}\right] =& \mathbb{E}\left[\left|\mathbf{x}_{i_1}+\cdots+\mathbf{x}_{i_L}\right|-r\right]\\ \leqslant& L-r.\end{aligned}$$

Overall we have

$$\begin{aligned}Q=& \mathop{\mathbb{E}}_{(\mathbf{i}_1,\cdots,\mathbf{i}_L)\sim[2^{nR}]^L}\mathbb{E}\left[Q_{\mathbf{i}_1,\cdots,\mathbf{i}_L}\right]\\ =&\frac{1}{2^{nRL}}\left(\sum_{i_1,\cdots,i_L\in[2^{nR}]\text{ distinct}}Q_{i_1,\cdots,i_L}+\sum_{i_1,\cdots,i_L\in[2^{nR}]\text{ not distinct}}Q_{i_1,\cdots,i_L}\right)\\ \leqslant&\frac{1}{2^{nRL}}\Bigg[2^{nR}\left(2^{nR}-1\right)\cdots\left(2^{nR}-L+1\right)\left(-\frac{\eta}{2}\right)\\ &+\left(2^{nRL}-2^{nR}\left(2^{nR}-1\right)\cdots\left(2^{nR}-L+1\right)\right)(L-r)\Bigg]\\ <&0.\end{aligned} \tag{119}$$

The last inequality (119) holds if

$$\left|\mathcal{C}'\right|>\max\left\{2(L-1),\frac{2^{L+1}L!(L+r)}{\eta}\right\},$$

by similar calculations to Sec. 13.2.

Lower bound on Q. Following the calculations in the proof of generalized Plotkin bound for list decoding, we have

$$\begin{aligned}&Q+r\\ =&\mathop{\mathbb{E}}_{(\mathbf{i}_1,\cdots,\mathbf{i}_L)\sim[2^{nR}]^L}\mathbb{E}\left[\left|\mathbf{x}_{\mathbf{i}_1}+\cdots+\mathbf{x}_{\mathbf{i}_L}\right|\right]\\ =&\frac{1}{2^{nRL}}\sum_{i_1,\cdots,i_L\in[2^{nR}]}\sum_{x_1,\cdots,x_L\in\{-1,1\}}\tau_{\underline{x}_{i_1},\cdots,\underline{x}_{i_L}}\left(\phi^{-1}(x_1),\cdots,\phi^{-1}(x_L)\right)\left|x_1+\cdots+x_L\right|\\ =&\frac{1}{2^{nRL}}\sum_{\substack{i_1,\cdots,i_L\in\left[2^{nR}\right]\\ x_1,\cdots,x_L\in\{-1,1\}}}\frac{1}{n}\sum_{j=1}^{n}\mathbb{1}_{\left\{\underline{x}_{i_1}(j)=\phi^{-1}(x_1)\right\}}\cdots\mathbb{1}_{\left\{\underline{x}_{i_L}(j)=\phi^{-1}(x_L)\right\}}\left|x_1+\cdots+x_L\right|\end{aligned} \tag{120}$$

$$= \frac{1}{n}\sum_{j=1}^{n}\sum_{x_1,\cdots,x_L\in\{-1,1\}}\prod_{\ell=1}^{L}\left(\frac{1}{2^{nR}}\sum_{i\in[2^{nR}]}\mathbb{1}_{\{\underline{x}_i(j)=\phi^{-1}(x_\ell)\}}\right)|x_1+\cdots+x_L| \tag{121}$$

$$= \frac{1}{n}\sum_{j=1}^{n}\sum_{x_1,\cdots,x_L\in\{-1,1\}}\prod_{\ell=1}^{L}P_{\mathbf{x}}^{(j)}(\phi^{-1}(x_\ell))\,|x_1+\cdots+x_L| \tag{122}$$

$$= \mathop{\mathbb{E}}_{\mathbf{j}\sim[n]}\left[\mathop{\mathbb{E}}_{\left(\mathbf{x}_1^{(\mathbf{j})},\cdots,\mathbf{x}_L^{(\mathbf{j})}\right)\sim\left(P_{\mathbf{x}}^{(\mathbf{j})}\right)^{\otimes L}}\left[\left|\mathbf{x}_1^{(\mathbf{j})}+\cdots+\mathbf{x}_L^{(\mathbf{j})}\right|\right]\right]. \tag{123}$$

In the above calculations, we used the following definitions and facts.

1. Eqn. (120) follows from the definition of joint types.
2. Eqn. (121) is obtained by rearranging terms.
3. In Eqn. (122), as before, we let, for $j\in[n]$, $x\in\mathbb{F}_2$,

$$P_{\mathbf{x}}^{(j)}(x)=\frac{1}{2^{nR}}\sum_{i\in[2^{nR}]}\mathbb{1}_{\{\underline{x}_i(j)=x\}}$$

denote the empirical distribution of the j-th *column* of $\mathcal{C}'$ when viewed as an $M'\times n$ matrix.

In expression (123), the j-th summand can be viewed as the translation distance of a non-lazy one-dimensional random walk after L steps. The walker moves left ($x=1$) with probability $P_{\mathbf{x}}^{(j)}(1)$ and moves right ($x=0$) with probability $P_{\mathbf{x}}^{(j)}(0)$. It is not hard to check that the expected translation distance is minimized when the walker is unbiased, i.e., when $P_{\mathbf{x}}^{(j)}(1)=P_{\mathbf{x}}^{(j)}(0)=1/2$. This is formally justified in Appendix C. Hence, for every $j\in[n]$,

$$\mathop{\mathbb{E}}_{\left(\mathbf{x}_1^{(j)},\cdots,\mathbf{x}_L^{(j)}\right)\sim\left(P_{\mathbf{x}}^{(j)}\right)^{\otimes L}}\left[\left|\mathbf{x}_1^{(j)}+\cdots+\mathbf{x}_L^{(j)}\right|\right]-r\geqslant 0.$$

Since the above bound is valid for every $j\in[n]$, it is still valid averaged over $\mathbf{j}\sim[n]$. Hence we have $Q\geqslant 0$. ◀

17 GV rate vs. cloud rate

In this section, we are concerned with the question of unique decoding (special case where $L-1=1$) under the bit-flip model.

In [43], bounds on achievable rates of codes for general adversarial channels are provided. A Gilbert–Varshamov-type expression was obtained using a purely random code construction, and a rate lower bound (we call *cloud rate*) that generalizes the GV-type expression was given by a cloud code construction. We evaluate both bounds under the bit-flip model. We show that the Gilbert–Varshamov-type bound for general adversarial channels indeed coincide with the classic GV bound in this particular setting. We also provide a convex program for evaluating the cloud rate.

We use the probability vector $\begin{bmatrix}P_{\mathbf{x}}(1) & \cdots & P_{\mathbf{x}}(|\mathcal{X}|)\end{bmatrix}^\top$ to denote a distribution $P_{\mathbf{x}}\in\Delta(\mathcal{X})$. Take any input distribution

$$P_{\mathbf{x}}=\mathrm{Bern}(w)=\begin{bmatrix}1-w\\ w\end{bmatrix},$$

from $\Delta(\{0,1\})$, we first explicitly compute the basic objects we are concerned with in this paper.

$$
\begin{aligned}
\Delta :=& \Delta(\{0,1\}) \\
=& \left\{ P_{\mathbf{x}_1,\mathbf{x}_2} \in \mathbb{R}^{2\times 2} \colon \begin{array}{rl} P_{\mathbf{x}_1,\mathbf{x}_2}(x_1,x_2) & \geqslant 0,\ \forall x_1,x_2 \\ \sum_{x_1,x_2} P_{\mathbf{x}_1,\mathbf{x}_2}(x_1,x_2) & = 1 \end{array} \right\} \\
=& \left\{ \begin{bmatrix} a & c \\ d & b \end{bmatrix} \in \mathbb{R}^{2\times 2} \colon \begin{array}{rl} a,b,c,d & \geqslant 0 \\ a+b+c+d & = 1 \end{array} \right\} \\
=& \left\{ \begin{bmatrix} a & c \\ 1-a-b-c & b \end{bmatrix} \in \mathbb{R}^{2\times 2} \colon \begin{array}{rl} a,b,c & \geqslant 0 \\ a+b+c & \leqslant 1 \end{array} \right\}.
\end{aligned}
$$

$$
\begin{aligned}
\mathcal{J}(w) :=& \mathcal{J}\left(\begin{bmatrix} 1-w \\ w \end{bmatrix} \right) \\
=& \{ P_{\mathbf{x}_1,\mathbf{x}_2} \in \Delta \colon P_{\mathbf{x}_1} = P_{\mathbf{x}_2} = P_{\mathbf{x}} \} \\
=& \left\{ \begin{bmatrix} a & c \\ d & b \end{bmatrix} \in \mathbb{R}^{2\times 2} \colon \begin{array}{l} a,b,c,d \geqslant 0 \\ a+b+c+d = 1 \\ d+b = w \\ c+b = w \end{array} \right\} \\
=& \left\{ \begin{bmatrix} 1-w-d & d \\ d & w-d \end{bmatrix} \in \mathbb{R}^{2\times 2} \colon 0 \leqslant d \leqslant \min\{w, 1-w\} \right\}.
\end{aligned}
$$

$$
\begin{aligned}
\mathcal{K}(w,p) :=& \mathcal{K}\left(\begin{bmatrix} 1-w \\ w \end{bmatrix} \right) \\
=& \{ P_{\mathbf{x}_1,\mathbf{x}_2} \in \mathcal{J}(w) : P_{\mathbf{x}_1,\mathbf{x}_2}(0,1) + P_{\mathbf{x}_1,\mathbf{x}_2}(1,0) \leqslant 2p \} \\
=& \left\{ \begin{bmatrix} 1-w-d & d \\ d & w-d \end{bmatrix} \in \mathbb{R}^{2\times 2} \colon 0 \leqslant d \leqslant \min\{w, 1-w, p\} \right\}.
\end{aligned}
$$

Since $\mathsf{CP}_2 = \mathsf{DNN}_2$, we have

$$
\begin{aligned}
&\mathsf{CP}_2(w) \\
=& \mathsf{CP}_2 \cap \mathcal{J}(w) \\
=& \left\{ \begin{bmatrix} w-d & d \\ d & 1-w-d \end{bmatrix} : 0 \leqslant d \leqslant \min\{w, 1-w\},\ (w-d)(1-w-d) - d^2 \geqslant 0 \right\} \\
=& \left\{ \begin{bmatrix} w-d & d \\ d & 1-w-d \end{bmatrix} : 0 \leqslant d \leqslant w - w^2 \right\}.
\end{aligned}
$$

Note that to ensure $\mathsf{CP}_2(w) \backslash \mathcal{K}(w,p) \neq \varnothing$, we need

$$
0 < p < 1/4,\ w \in \left(\tfrac{1-\sqrt{1-4p}}{2}, \tfrac{1+\sqrt{1-4p}}{2} \right).
$$

In other words, $0 < w < 1$ and $0 < p < w - w^2$. In this case,

$$
\mathcal{K}(w,p) = \left\{ \begin{bmatrix} 1-w-d & d \\ d & w-d \end{bmatrix} \in \mathbb{R}^{2\times 2} \colon 0 \leqslant d \leqslant p \right\}.
$$

Actually, if the above conditions hold, then when $1/3 \leqslant w < 1$, the boundary of $\mathcal{K}(w,p)$ is p and the boundary of $\mathsf{CP}_2(w)$ is $w - w^2$. Note that the right boundary $\begin{bmatrix} (1-w)^2 & w-w^2 \\ w-w^2 & w^2 \end{bmatrix} = \begin{bmatrix} 1-w \\ w \end{bmatrix}^{\otimes 2}$ of $\mathsf{CP}_2(w)$ is the *only* distribution in $\mathsf{CP}_2(w)$ of CP-rank-1.

GV rate. We first state the GV-type expression given by in [43].

▶ **Lemma 81** (Gilbert–Varshamov rate). *For a general adversarial channel given by* $\mathcal{A} = \{\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\}$*, its unique decoding capacity is at least*

$$R_{\mathrm{GV}} = \max_{P_{\mathbf{x}} \in \lambda_{\mathbf{x}}} \min_{P_{\mathbf{x}_1,\mathbf{x}_2} \in \mathcal{K}(P_{\mathbf{x}})} I(\mathbf{x};\mathbf{x}'),$$

where the mutual information is calculated using $P_{\mathbf{x}_1,\mathbf{x}_2}$*.*

We now evaluate the above expression under the bit-flip model.

$$\begin{aligned}
R_{\mathrm{GV}} &= \max_{P_{\mathbf{x}} \in \lambda_{\mathbf{x}}} \min_{P_{\mathbf{x}_1,\mathbf{x}_2} \in \mathcal{K}(P_{\mathbf{x}})} I(\mathbf{x};\mathbf{x}') \\
&= \max_{\begin{bmatrix} 1-w \\ w \end{bmatrix} \in \Delta} \min_{\begin{bmatrix} 1-w-d & d \\ d & w-d \end{bmatrix} \in \mathcal{K}(w,p)} D\left(\begin{bmatrix} 1-w-d & d \\ d & w-d \end{bmatrix} \middle\| \begin{bmatrix} 1-w \\ w \end{bmatrix}^{\otimes 2} \right) \\
&= \max_{0<w<1} \min_{0 \leqslant d \leqslant p} (w-d) \log \frac{w-d}{w^2} + 2d \log \frac{d}{w(1-w)} + (1-w-d) \log \frac{1-w-d}{(1-w)^2} \\
&= \max_{0<w<1} (w-p) \log \frac{w-p}{w^2} + 2p \log \frac{p}{w(1-w)} + (1-w-p) \log \frac{1-w-p}{(1-w)^2} \\
&= (1/2-p) \log \frac{1/2-p}{(1/2)^2} + 2p \log \frac{p}{(1/2)(1-1/2)} + (1-1/2-p) \log \frac{1-1/2-p}{(1-1/2)^2} \\
&= 1 - H(2p).
\end{aligned}$$

This matches the classic GV bound given a greedy volume packing argument.

Cloud rate. We now state the cloud rate expression given by [43].

▶ **Lemma 82** (Cloud rate).

For a general adversarial channel $\mathcal{A} = \{\mathcal{X}, \lambda_{\mathbf{x}}, \mathcal{S}, \lambda_{\mathbf{s}}, \mathcal{Y}, W_{\mathbf{y}|\mathbf{x},\mathbf{s}}\}$, its unique decoding capacity is at least

$$R_{\mathrm{cloud}} = \max_{P_{\mathbf{x}} \in \lambda_{\mathbf{x}}} \max_{P_{\mathbf{x}_1,\mathbf{x}_2} \in \mathsf{CP}_2(P_{\mathbf{x}}) \setminus \mathcal{K}(P_{\mathbf{x}})} \max_{\substack{P_{\mathbf{u}}, P_{\mathbf{x}|\mathbf{u}}: \\ \left[P_{\mathbf{u}} P_{\mathbf{x}|\mathbf{u}}^{\otimes 2}\right]_{\mathbf{x}_1,\mathbf{x}_2} = P_{\mathbf{x}_1,\mathbf{x}_2}}} \min_{P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_1} \in \mathcal{K}_{\mathrm{cloud}}(P_{\mathbf{u},\mathbf{x}})} D\left(P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2} \middle\| P_{\mathbf{u}} P_{\mathbf{x}|\mathbf{u}}^{\otimes 2}\right),$$

where

$$\mathcal{K}_{\mathrm{cloud}}(P_{\mathbf{u},\mathbf{x}}) := \left\{ [P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2,\mathbf{s}_1,\mathbf{s}_2,\mathbf{y}}]_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2} \in \Delta\left(\mathcal{U} \times \mathcal{X}^2\right) : \begin{array}{rl} P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2,\mathbf{s}_1,\mathbf{s}_2,\mathbf{y}} \in & \Delta\left(\mathcal{U} \times \mathcal{X}^2 \times \mathcal{S}^2 \times \mathcal{Y}\right) \\ P_{\mathbf{s}_1}, P_{\mathbf{s}_2} \in & \lambda_{\mathbf{s}} \\ P_{\mathbf{u},\mathbf{x}_1,\mathbf{s}_1,\mathbf{y}} = & P_{\mathbf{u},\mathbf{x}} P_{\mathbf{s}_1|\mathbf{u},\mathbf{x}_1} W_{\mathbf{y}|\mathbf{x}_1,\mathbf{s}_1} \\ P_{\mathbf{u},\mathbf{x}_2,\mathbf{s}_2,\mathbf{y}} = & P_{\mathbf{u},\mathbf{x}} P_{\mathbf{s}_2|\mathbf{u},\mathbf{x}_2} W_{\mathbf{y}|\mathbf{x}_2,\mathbf{s}_2} \end{array} \right\}.$$

▶ Remark 83. The reason that [43] has to define a different confusability set $\mathcal{K}_{\mathrm{cloud}}$ when cloud code is using is that as a part of the code design, the distributions $P_{\mathbf{u}}, P_{\mathbf{u}|\mathbf{x}}$ are revealed to every party, including the adversary, hence he may be able to inject noise patterns that are potentially more malicious compared with the case where he does not have such knowledge. We refer the readers to the proof in [43].

In the bit-flip setting, it is easy to verify that

$$\begin{aligned}\mathcal{K}_{\text{cloud}}(P_{\mathbf{u},\mathbf{x}}) &= \left\{ P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2} \in \Delta\left(\mathcal{U}\times\mathcal{X}^2\right) : \begin{array}{rl} P_{\mathbf{u},\mathbf{x}_1} = P_{\mathbf{u},\mathbf{x}_2} = & P_{\mathbf{u},\mathbf{x}} \\ P_{\mathbf{x}_1,\mathbf{x}_2}(0,1) + P_{\mathbf{x}_1,\mathbf{x}_2}(1,0) \leqslant & 2p \end{array} \right\} \\ &= \left\{ p \in \mathbb{R}^{|\mathcal{U}|\times 2\times 2} : \begin{array}{rl} p_{u,x_1,x_2} \geqslant & 0,\ \forall u,x_1,x_2 \\ \sum_{u,x_1,x_2} p_{u,x_1,x_2} = & 1 \\ \sum_{x_2} p_{u,x_1,x_2} = & p_{u,x_1},\ \forall u,x_1 \\ \sum_{x_1} p_{u,x_1,x_2} = & p_{u,x_2},\ \forall u,x_2 \\ \sum_u p_{u,0,1} + p_{u,1,0} \leqslant & 2p \end{array} \right\}.\end{aligned}$$

We use the notation $p_{u,x_1,x_2} \coloneqq P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2}(u,x_1,x_2)$ and $p_{u,x} \coloneqq P_{\mathbf{u},\mathbf{x}}(u,x)$ for all $u \in \mathcal{U}, x_1, x_2 \in \{0,1\}$. The third maximization is over all extensions which correspond to CP decompositions of $P_{\mathbf{x}_1,\mathbf{x}_2}$. Note that for a CP matrix, its CP decomposition is not necessarily unique, even if we require the decomposition to meet the CP-rank [23]. A CP decomposition of a CP distribution can contain an arbitrarily large number of terms. Here we focus on decompositions which *meet* the CP-rank of $P_{\mathbf{x}_1,\mathbf{x}_2}$. That is, $|\mathcal{U}| = \text{CP-rank}(P_{\mathbf{x}_1,\mathbf{x}_2})$.

Note that the objective function KL-divergence also equals

$$D\left(P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2} \middle\| P_{\mathbf{u}} P_{\mathbf{x}|\mathbf{u}}^{\otimes 2}\right) = I\left(\mathbf{x}_1;\mathbf{x}_2|\mathbf{u}\right),$$

where the mutual information is w.r.t. $P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2}$.

Note that even if we could show $R_{\text{cloud}} \leqslant R_{\text{GV}}$, this does *not* mean cloud codes will never attain a rate larger than the GV bound. It only means that the cloud rate expression we have cannot take values larger than the GV bound. This is because our bounds are only achievable, but we do not have matching upper bounds. Indeed, this is an extremely difficult question even under simple models.

Actually *all* CP decompositions meeting the CP-rank of a CP distribution can be computed. For a CP-rank-2 distribution $\begin{bmatrix} 1-w-b & b \\ b & w-b \end{bmatrix} \in \mathsf{CP}_2(w) \backslash \mathcal{K}(w,p)$ where $b \neq w - w^2$, we write its CP decomposition as

$$\begin{aligned}\begin{bmatrix} 1-w-b & b \\ b & w-b \end{bmatrix} =& \alpha \begin{bmatrix} 1-u \\ u \end{bmatrix}^{\otimes 2} + \beta \begin{bmatrix} 1-v \\ v \end{bmatrix}^{\otimes 2} \\ =& \begin{bmatrix} \alpha(1-u)^2 + \beta(1-v)^2 & \alpha u(1-u) + \beta v(1-v) \\ \alpha u(1-u) + \beta v(1-v) & \alpha u^2 + \beta v^2 \end{bmatrix}.\end{aligned}$$

Solving the equation in terms of b and u, we have

$$\begin{aligned}\alpha \coloneqq& \alpha(w,b,u) = \frac{w-b-w^2}{u^2+w-2uw-b}, \\ \beta \coloneqq& \beta(w,b,u) = 1-\alpha = \frac{(u-w)^2}{u^2+w-2uw-b}, \\ v \coloneqq& v(w,b,u) = \frac{b-w+uw}{w-u},\end{aligned}$$

where $u \in \left[0, \frac{b}{1-w}\right] \cup \left[\frac{w-b}{w}, 1\right]$.

Any such decomposition gives rise to a joint distribution $P_{\mathbf{u}} P_{\mathbf{x}|\mathbf{u}}^{\otimes 2}$ which is a $2\times 2\times 2$ tensor.

$$P_{\mathbf{u}=0} P_{\mathbf{x}|\mathbf{u}=0}^{\otimes 2} = \begin{bmatrix} \alpha(1-u)^2 & \alpha u(1-u) \\ \alpha u(1-u) & \alpha(1-u)^2 \end{bmatrix}, \quad P_{\mathbf{u}=1} P_{\mathbf{x}|\mathbf{u}=1}^{\otimes 2} = \begin{bmatrix} \beta v^2 & \beta v(1-v) \\ \beta v(1-v) & \beta(1-v)^2 \end{bmatrix}.$$

It also induces a distribution $P_{\mathbf{u},\mathbf{x}}$.

$$P_{\mathbf{u},\mathbf{x}} = \begin{bmatrix} \alpha(1-u) & \alpha u \\ \beta(1-v) & \beta v \end{bmatrix}.$$

Now for any CP decomposition $P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2}$ of a CP distribution $P_{\mathbf{x}_1,\mathbf{x}_2} = \begin{bmatrix} w-b & b \\ b & 1-w-b \end{bmatrix}$, the inner minimization can be written as minimizing a convex function over a polytope.

$$\begin{array}{rl} \min_p & D(p\|P_{\mathbf{u}}P_{\mathbf{x}|\mathbf{u}}^{\otimes 2}) \\ \text{subject to} & p \in \mathcal{K}_{\text{cloud}}(P_{\mathbf{u},\mathbf{x}}) \end{array}.$$

It can be expanded in the following explicit form.

$$\begin{array}{rl} \min_p & p_{0,0,0}\log\frac{p_{0,0,0}}{\alpha(1-u)^2} + p_{0,0,1}\log\frac{p_{0,0,1}}{\alpha u(1-u)} + p_{0,1,0}\log\frac{p_{0,1,0}}{\alpha u(1-u)} + p_{0,1,1}\log\frac{p_{0,1,1}}{\alpha u^2} \\ & + p_{1,0,0}\log\frac{p_{1,0,0}}{\beta(1-v)^2} + p_{1,0,1}\log\frac{p_{1,0,1}}{\beta v(1-v)} + p_{1,1,0}\log\frac{p_{1,0,0}}{\beta v(1-v)} + p_{1,1,1}\log\frac{p_{1,1,1}}{\beta v^2} \\ \text{subject to} & \left.\begin{array}{l} p_{i,j,k} \geqslant 0,\ \forall i,j,k \\ \sum_{i,j,k} p_{i,j,k} = 1 \end{array}\right\} p \in \Delta\left(\{0,1\}^3\right) \\ & \left.\begin{array}{l} p_{0,0,0} + p_{0,0,1} = \alpha(1-u) \\ p_{0,1,0} + p_{0,1,1} = \alpha u \\ p_{1,0,0} + p_{1,0,1} = \beta(1-v) \\ p_{1,1,0} + p_{1,1,1} = \beta v \end{array}\right\} [P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2}]_{\mathbf{u},\mathbf{x}_1} = P_{\mathbf{u},\mathbf{x}} \\ & \left.\begin{array}{l} p_{0,0,0} + p_{0,1,0} = \alpha(1-u) \\ p_{0,0,1} + p_{0,1,1} = \alpha u \\ p_{1,0,0} + p_{1,1,0} = \beta(1-v) \\ p_{1,0,1} + p_{1,1,1} = \beta v \end{array}\right\} [P_{\mathbf{u},\mathbf{x}_1,\mathbf{x}_2}]_{\mathbf{u},\mathbf{x}_2} = P_{\mathbf{u},\mathbf{x}} \\ & p_{0,0,1} + p_{0,1,0} + p_{1,0,1} + p_{1,1,0} \leqslant 2p. \end{array}$$

Note that it is implied by the given constraints that $p_{u,x_1,x_2} = p_{u,x_2,x_1}$. Also, the p.m.f. constraint $\sum_{u,x_1,x_2} p_{u,x_1,x_2} = 1$ is actually redundant. Hence the problem can be simplified as follows.

$$\begin{array}{rl} \min_{\underline{p}} & p_{0,0,0}\log\frac{p_{0,0,0}}{\alpha(1-u)^2} + 2p_{0,0,1}\log\frac{p_{0,0,1}}{\alpha u(1-u)} + p_{0,1,1}\log\frac{p_{0,1,1}}{\alpha u^2} \\ & + p_{1,0,0}\log\frac{p_{1,0,0}}{\beta(1-v)^2} + 2p_{1,0,1}\log\frac{p_{1,0,1}}{\beta v(1-v)} + p_{1,1,1}\log\frac{p_{1,1,1}}{\beta v^2} \\ \text{subject to} & -p_{i,j,k} \leqslant 0,\ \forall i,j,k \\ & p_{0,0,0} + p_{0,0,1} = \alpha u \\ & p_{0,0,1} + p_{0,1,1} = \alpha(1-u) \\ & p_{1,0,0} + p_{1,0,1} = \beta v \\ & p_{1,0,1} + p_{1,1,1} = \beta(1-v) \\ & p_{0,0,1} + p_{1,0,1} \leqslant p. \end{array}$$

Let $D^*(w,b,u)$ denote the optimal value of the above minimization. The final cloud rate is given by

$$\max_{0<w<1} \max_{p<b\leqslant w-w^2} \max_{u\in\left[0,\frac{b}{1-w}\right]\cup\left[\frac{w-b}{w},1\right]} D^*(w,b,u),$$

where the first maximization corresponds to finding the optimal input distribution $\begin{bmatrix} 1-w \\ w \end{bmatrix}$, second maximization corresponds to finding the optimal CP distribution $\begin{bmatrix} 1-w-b & b \\ b & w-b \end{bmatrix}$ outside $\mathcal{K}(w)$, and the third optimization corresponds to finding the optimal CP-decomposition $\alpha\begin{bmatrix} 1-u \\ u \end{bmatrix}^{\otimes 2} + \beta\begin{bmatrix} 1-v \\ v \end{bmatrix}^{\otimes 2}$ of the optimal CP distribution.

18 Concluding remarks and open problems

In this paper, we study the list decoding problem on general adversarial channels for both large and small list sizes. Given any channel, for large (yet constant) list sizes, we prove the list decoding theorem which identifies the fundamental limit of list decoding. For small (yet arbitrary universal constant) list sizes, we characterize when positive rate list decodable codes are possible.

Many open questions are left after this work is done. We list some of them for future study.

1. In this paper, we made no attempt towards understanding channels with arbitrary transition distributions $W_{\mathbf{y}|\mathbf{x},\mathbf{s}}$ (instead of only those corresponding to deterministic bivariate functions). Pushing our results to such a general setting remains an intriguing open question.
2. Other adversarial channels under further assumptions, e.g., online (causal) channels, channels with feedback, channels with bounded memory, etc., are less understood. There are results regarding each of these topics under very restricted models, e.g., bit-flips [13, 6], deletions [12], etc..
3. We do not have any nontrivial *upper* bound on $(L-1)$-list decoding capacity for general adversarial channels. Existing upper bounds for error correction codes seem tricky to generalize. A reasonable starting point might be to extend the classic Elias–Bassalygo bound [4] whose proof has a similar spirit as the Plotkin bound.
4. Given any adversarial channel, when we are "below the Plotkin point" (i.e., there are non-confusable CP distributions), can we construct *explicit* codes of positive rate? We know that random codes are list decodable w.h.p..

A CP tensors and coP tensors

A.1 Tensor products

▶ **Definition 84** (Tensor product). *For two tensors* $A \in \mathsf{Ten}_n^{\otimes m}, B \in \mathsf{Ten}_n^{\otimes \ell}$, *Their* tensor product *is defined as*

$$A \otimes B := [A\,(i_1, \cdots, i_m)\,B\,(j_1, \cdots, j_\ell)] \in \mathsf{Ten}_n^{\otimes (m+\ell)}.$$

▶ **Definition 85** (Frobenius inner product, Frobenius norm). *For two tensors* $A, B \in \mathsf{Ten}_n^{\otimes m}$, *Their* inner product *is defined as*

$$\langle A, B\rangle := \sum_{i_1,\cdots,i_m \in [n]} A(i_1, \cdots, i_m) B(i_1, \cdots, i_m).$$

The Frobenius norm *is defined as* $\|A\|_F := \sqrt{\langle A, A\rangle}$.

▶ **Definition 86** (Hadamard product). *For two tensors* $A, B \in \mathsf{Ten}_n^{\otimes m}$, *Their* Hadamard product *is defined as*

$$A \circ B := [A(i_1, \cdots, i_m) B(i_1, \cdots, i_m)] \in \mathsf{Ten}_n^{\otimes m}.$$

A.2 Tensor decomposition

▶ **Definition 87** (Canonical decomposition). *For a tensor* $A \in \mathsf{Ten}_n^{\otimes m}$*, its* canonical decomposition *has form*

$$A = \sum_{j=1}^{r} \alpha_j \bigotimes_{i=1}^{m} \underline{x}_{j,i},$$

where each $\underline{x}_{j,i} \in \mathbb{S}_2^{n-1}$*. The smallest* r *for* A *to admit such a decomposition is called the* rank *of* A*. If* A *is symmetric, then*

$$A = \sum_{j=1}^{r} \alpha_j \underline{x}_j^{\otimes m}$$

is an analog of the eigendecomposition of symmetric matrices. The smallest r *is called the* symmetric rank *of* A*.*

▶ **Conjecture 88.** *For* $A \in \mathsf{Sym}_n^{\otimes m}$*,* $\mathrm{rank}(A) = \text{sym-rank}(A)$*.*

▶ Remark 89. It is known to be true if $\mathrm{rank}(A) \leqslant m$.

▶ **Definition 90** (Tucker decomposition). *For a tensor* $A \in \mathsf{Ten}_n^{\otimes m}$*, the* Tucker decomposition *has form*

$$A = \sum_{j_1=1}^{r_1} \cdots \sum_{j_m=1}^{r_m} \alpha_{j_1,\cdots,j_m} \bigotimes_{i=1}^{m} \underline{x}_{j_i,j}.$$

It is an analogy of the singular value decomposition of matrices.

A tensor $A \in \mathsf{Ten}_n^{\otimes m}$ has $n(m-1)^{n-1}$ eigenvalues. A may have non-real eigenvalues even if A is symmetric. If an eigenvector is real, then the corresponding eigenvalue is also real. Such eigenvalues are called *H-eigenvalues*. They always exist for even-order tensors.

A.3 Special tensors

▶ **Definition 91** (NN tensors). *A tensor is said to be* non-negative *if each of its entry is non-negative. The set of order-m dimension-n non-negative tensors is denoted by* $\mathsf{NN}_n^{\otimes m}$

▶ **Definition 92** (PSD tensors, PD Tensors). *For even* m*,* $A \in \mathsf{Ten}_n^{\otimes m}$ *is* positive semidefinite (PSD) *if* $\langle A, \underline{x}^{\otimes m} \rangle \geqslant 0$ *for any* $\underline{x} \in \mathbb{R}^n$*.* A *is* positive definite (PD) *if the above inequality is strict for all* $\underline{x} \neq 0$*.*

The sets of PSD *and* PD *tensors is denoted by* $\mathsf{PSD}_n^{\otimes m}$ *and* $\mathsf{PD}_n^{\otimes m}$*, respectively.*

▶ **Definition 93** (CP tensors, CP tensor rank). *A tensor* $P \in \mathsf{Ten}_n^{\otimes m}$ *is said to be* completely positive *if for some* $r \geqslant 1$*, there are component-wise non-negative vectors* $\underline{p}_1, \cdots, \underline{p}_r \in \mathbb{R}^n_{\geqslant 0}$ *such that*

$$P = \sum_{j=1}^{r} \underline{p}_j^{\otimes m}.$$

The set of CP *tensors is denoted by* $\mathsf{CP}_n^{\otimes m}$*. The least* r *such that* P *has a completely positive decomposition is called the* CP-rank *of* P*. If* $\mathrm{span}\{P_1, \cdots, P_r\} = \mathbb{R}^n$ *then* P *is said to be* strongly CP*.*

▶ **Fact 94.** *Verifying if a symmetric non-negative tensor is* CP *is* NP*-hard.*

▶ **Definition 95** (coP tensors). *$A \in \mathsf{Sym}_n^{\otimes m}$ is* copositive *if $\langle A, \underline{x}^{\otimes}\rangle \geqslant 0$ for all $\underline{x} \in \mathbb{R}^n_{\geqslant 0}$. The set of copositive tensors is denoted by $\mathsf{coP}_n^{\otimes m}$.*

▶ **Theorem 96** (Duality). *$\mathsf{CP}_n^{\otimes m}$ and $\mathsf{coP}_n^{\otimes m}$ are closed convex pointed cones with nonempty interior in $\mathsf{Sym}_n^{\otimes m}$. For $m \geqslant 2$, $n \geqslant 1$, they are dual to each other.*

▶ **Definition 97** (DNN tensors). *For even m, $A \in \mathsf{Sym}_n^{\otimes m}$ is* doubly non-negative (DNN) *if A is entry-wise non-negative and $\langle A, \underline{x}^{\otimes m}\rangle$ is a sum-of-square as a polynomial in the components of $\underline{x}$.*

▶ **Fact 98.** *The double non-negativity of a tensor can be verified in polynomial time using SDP.*

▶ **Fact 99.** *The following inclusion relations between different sets of special tensors hold.*
1. $\mathsf{PSD}_n^{\otimes m} \subseteq \mathsf{coP}_n^{\otimes m}$.
2. $\mathsf{CP}_n^{\otimes m} \subseteq \mathsf{DNN}_n^{\otimes m} \subseteq \mathsf{NN}_n^{\otimes m} \subseteq \mathsf{coP}_n^{\otimes m} \subseteq \mathsf{Sym}_n^{\otimes m}$.

B Hypergraph Ramsey numbers

Let $R_k^{(r)}(s_1, \cdots, s_k)$ denote the smallest size of an r-uniform hypergraph such that for any k-colouring, there must be a monochromatic clique of size s_i for some $i \in [k]$.

Define tower function $t_1(x) = x$ and $t_{i+1}(x) = 2^{t_i(x)}$.

▶ **Lemma 100** (Properties of hypergraph Ramsey numbers). 1. *For any $i \in [k]$, and $s_j \geqslant r$ $(j \neq i)$,*

$$R_k^{(r)}(s_1, \cdots, s_{i-1}, r, s_{i+1}, \cdots, s_k) = R_{k-1}^{(r)}(s_1, \cdots, s_{i-1}, s_{i+1}, \cdots, s_k).$$

2. *For any $\sigma \in S_k$,*

$$R_k^{(r)}(s_1, \cdots, s_k) = R_k^{(r)}(s_{\sigma(1)}, \cdots, s_{\sigma(k)}).$$

▶ **Lemma 101** (Finiteness of hypergraph Ramsey numbers). *For any positive integers r, k, s_1, $\cdots$, s_k, the hypergraph Ramsey number $R_k^{(r)}(s_1, \cdots, s_k)$ is finite. In particular, it satisfies the following recursive inequalities.*

$$R_k^{(r)}(s_1, \cdots, s_k) \leqslant 1 + R_k^{(r-1)}\Big(R_k^{(r)}(s_1 - 1, s_2, \cdots, s_k), R_k^{(r)}(s_1, s_2 - 1, \cdots, s_k), \cdots, \cdots, R_k^{(r)}(s_1, s_2, \cdots, s_k - 1)\Big),$$

$$R_k^{(r)}(s_1, \cdots, s_k) \leqslant 1 + \sum_{i=1}^{k} R_k^{(r-1)}\Big(R_k^{(r)}(s_1, \cdots, s_{i-1}, s_i - 1, s_{i+1}, \cdots, s_k), \cdots, \cdots, R_k^{(r)}(s_1, \cdots, s_{i-1}, s_i - 1, s_{i+1}, \cdots, s_k)\Big),$$

$$R_k^{(r)}(s_1, \cdots, s_k) \leqslant R_{k-1}^{(r)}\left(s_1, \cdots, s_{k-2}, R_2^{(r)}(s_{k-1}, s_k)\right),$$

▶ **Lemma 102** (Bounds on hypergraph Ramsey numbers)**.**

1. *For any* s, t*,*

$$R_2^{(r)}(s,t) \leqslant 2^{\binom{R_2^{(r-1)}(s-1,t-1)}{r-1}}.$$

2. *For* $r \geqslant 3$*, there are constants* $c, c' > 0$ *such that*

$$t_{r-1}(c \cdot s^2) \leqslant R_2^{(r)}(s,s) \leqslant t_r(c' \cdot s).$$

3. *For* $s > k \geqslant 2$*, there are constants* $c, c' > 0$ *such that*

$$t_r(c \cdot k) < R_k^{(r)}(s, \cdots, s) < t_r(c' \cdot k \log k).$$

C Expected translation distance of a one-dimensional random walk

▶ **Lemma 103.** *Consider a random walk* $\mathbf{x}_1, \cdots, \mathbf{x}_L$ *of length* L*. Each* $\mathbf{x}_i$ $(1 \leqslant i \leqslant L)$ *is an independent and identically distributed* $\{-1, 1\}$*-valued random variable satisfying*

$$\Pr[\mathbf{x}_i = 1] = p, \quad \Pr[\mathbf{x}_i = -1] = 1 - p.$$

Without loss of generality, assume $p \geqslant 1/2$*. Then, we have that the expected translation distance* $\mathbb{E}[|\mathbf{x}_1 + \cdots + \mathbf{x}_L|]$ *of this random walk after* L *steps is minimized when* $p = 1/2$*.*

Proof. Create another walk $\mathbf{x}'_1, \cdots, \mathbf{x}'_L$ with $p = 1/2$ that is coupled with $\mathbf{x}_1, \cdots, \mathbf{x}_L$ in the following way.

$$\Pr\left[\mathbf{x}_i = 1 | \mathbf{x}'_i = 1\right] = 1, \quad \Pr\left[\mathbf{x}_i = 1 | \mathbf{x}'_i = -1\right] = 2p - 1.$$

It is easy to see that the distribution of $\mathbf{x}_1, \cdots, \mathbf{x}_L$ is preserved under this coupling.

$$\begin{aligned}\Pr[\mathbf{x}_i = 1] =& \Pr\left[\mathbf{x}'_i = 1\right] \Pr\left[\mathbf{x}_i = 1 | \mathbf{x}'_i = 1\right] + \Pr\left[\mathbf{x}'_i = -1\right] \Pr\left[\mathbf{x}_i = 1 | \mathbf{x}'_i = -1\right] \\ =& \frac{1}{2} \cdot 1 + \frac{1}{2} \cdot (2p - 1) \\ =& p.\end{aligned}$$

Now,

$$\begin{aligned}&\mathbb{E}[|\mathbf{x}_1 + \cdots + \mathbf{x}_L|] - \mathbb{E}\left[|\mathbf{x}'_1 + \cdots + \mathbf{x}'_L|\right] \\ =& \sum_{d \in \{-L, -L+2, \cdots, L-2, L\}} \\ & \qquad \sum_{\substack{x_1, \cdots, x_L \in \{-1,1\} \\ \sum_{i=1}^L x_i = d}} \Pr\left[\mathbf{x}'_1 = x_1, \cdots, \mathbf{x}'_L = x_L\right] \mathbb{E}\left[\left|\sum_{i=1}^L \mathbf{x}_i\right| - |d| \,\middle|\, \mathbf{x}'_1 = x_1, \cdots, \mathbf{x}'_L = x_L\right].\end{aligned}$$

For each translation distance $d \in \{-L, -L+2, \cdots, L-2, L\}$ and trajectory $x_1, \cdots, x_L \in \{-1, 1\}$ such that $\sum_{i=1}^L x_i = d$, let $\ell := \{i \in [L] \colon x_i = -1\}$. Note $2(d + \ell) = L$. We have

$$\begin{aligned}\mathbb{E}\left[\left|\sum_{i=1}^L \mathbf{x}_i\right| - |d| \,\middle|\, \mathbf{x}'_1 = x_1, \cdots, \mathbf{x}'_L = x_L\right] =& ((2p-1) \cdot 1 + (1 - (2p-1)) \cdot (-1))\ell - (-\ell) \\ =& 2(2p-1)\ell,\end{aligned}$$

which is non-negative and attains its minima 0 when $p = 1/2$. This finishes the proof. ◀

D Blinovsky [9] vs. Alon–Bukh–Polyanskiy [2]

In this section we show that, though differing ostensibly, the formulas of the Plotkin points for $(p, L-1)$-list decoding given by Blinovsky and Alon–Bukh–Polyanskiy actually agree with each other. The proof is essentially due to the user `Sean Clark` on `Mathematics Stack Exchange` [14].

For $L = 2k$ or $2k+1$ for some positive integer $k \in \mathbb{Z}_{>0}$, Blinovsky's formula is

$$P_{L-1} = \sum_{i=1}^{k} \frac{\binom{2(i-1)}{i-1}}{i} 2^{-2i};$$

while Alon–Bukh–Polyanskiy wrote it as

$$P_{L-1} = \frac{1}{2} - 2^{-2k-1}\binom{2k}{k}.$$

We are going to show that

▶ **Lemma 104.** *For any $k \geqslant 1$,*

$$\sum_{i=1}^{k} \frac{\binom{2(i-1)}{i-1}}{i} 2^{-2i} = \frac{1}{2} - 2^{-2k-1}\binom{2k}{k}.$$

Proof. To see the above two expressions are always evaluated to the same value, we first massage the above equation. Multiplying 2^{2k+2} on both sides, shifting the summation index and rearranging terms, we have

$$\sum_{i=0}^{k-1} \frac{\binom{2i}{i}}{i+1} 2^{2(k-i)} = 2^{2k+1} - 2\binom{2k}{k}.$$

Adding $\frac{\binom{2k}{k}}{k+1}$ on both sides, we get

$$\begin{aligned}
\sum_{i=0}^{k} \frac{\binom{2i}{i}}{i+1} 2^{2(k-i)} =& 2^{2k+1} - \left(2 - \frac{1}{k+1}\right)\binom{2k}{k} \\
=& 2^{2k+1} - \frac{2k+1}{k+1}\binom{2k}{k} \\
=& 2^{2k+1} - \binom{2k+1}{k+1} && (124) \\
=& 2^{2k+1} - \binom{2k+1}{k}, && (125)
\end{aligned}$$

where Eqn. (124) is by Fact (16) and Eqn. (125) is by Fact (15).

To show

$$\sum_{i=0}^{k} \frac{\binom{2i}{i}}{i+1} 2^{2(k-i)} = 2^{2k+1} - \binom{2k+1}{k}, \tag{126}$$

we conduct induction on k.

1. When $k = 0$, LHS $= 1 =$ RHS.
2. Assume (126) holds for certain $k \geqslant 1$. We want to show it also holds for $k+1$.

$$\begin{aligned}
\sum_{i=0}^{k+1} \frac{\binom{2i}{i}}{i+1} 2^{2(k+1-i)} =& 2^2 \sum_{i=0}^{k} \frac{\binom{2i}{i}}{i+1} 2^{2(k-i)} + \frac{\binom{2(k+1)}{k+1}}{k+2} \\
=& 2^2 \left(2^{2k+1} - \binom{2k+1}{k} \right) + \frac{\binom{2k+2}{k+1}}{k+2} && (127) \\
=& 2^{2(k+1)+1} - 2 \left(\binom{2k+1}{k} + \binom{2k+1}{k+1} \right) + \frac{\binom{2k+2}{k+1}}{k+2} && (128) \\
=& 2^{2(k+1)+1} - \left(2 - \frac{1}{k+2} \right) \binom{2k+2}{k+1} && (129) \\
=& 2^{2(k+1)+1} - \frac{2k+3}{k+2} \binom{2k+2}{k+1} \\
=& 2^{2(k+1)+1} - \binom{2(k+1)+1}{(k+1)+1}. && (130)
\end{aligned}$$

Eqn. (127), (128), (129) and (130) follow from induction hypothesis, Fact (15), Fact (17) and Fact (16), respectively. Hence Eqn. (126) holds for $k+1$ as well. ◀

Abstract

The advice model of online computation captures the setting in which the online algorithm is given some partial information concerning the request sequence. This paradigm allows to establish tradeoffs between the amount of this additional information and the performance of the online algorithm. However, unlike real life in which advice is a recommendation that we can choose to follow or to ignore based on trustworthiness, in the current advice model, the online algorithm treats it as infallible. This means that if the advice is corrupt or, worse, if it comes from a malicious source, the algorithm may perform poorly. In this work, we study online computation in a setting in which the advice is provided by an untrusted source. Our objective is to quantify the impact of untrusted advice so as to design and analyze online algorithms that are robust and perform well even when the advice is generated in a malicious, adversarial manner. To this end, we focus on well- studied online problems such as ski rental, online bidding, bin packing, and list update. For ski-rental and online bidding, we show how to obtain algorithms that are Pareto-optimal with respect to the competitive ratios achieved; this improves upon the framework of Purohit et al. [NeurIPS 2018] in which Pareto-optimality is not necessarily guaranteed. For bin packing and list update, we give online algorithms with worst-case tradeoffs in their competitiveness, depending on whether the advice is trusted or not; this is motivated by work of Lykouris and Vassilvitskii [ICML 2018] on the paging problem, but in which the competitiveness depends on the reliability of the advice. Furthermore, we demonstrate how to prove lower bounds, within this model, on the tradeoff between the number of advice bits and the competitiveness of any online algorithm. Last, we study the effect of randomization: here we show that for ski-rental there is a randomized algorithm that Pareto-dominates any deterministic algorithm with advice of any size. We also show that a single random bit is not always inferior to a single advice bit, as it happens in the standard model.

1 Introduction

Suppose that you have an investment account with a significant amount in it, and that your financial institution advises you periodically on investments. One day, your banker informs you that company X will soon receive a big boost, and advises to use the entire account to buy stocks. If you were to completely trust the banker's advice, there are naturally two possibilities: either the advice will prove correct (which would be great) or it will prove wrong (which would be catastrophic). A prudent customer would take this advice with a grain of salt, and would not be willing to risk everything. In general, our understanding of advice is that it entails *knowledge that is not foolproof*.

In this work we focus on the online computation with advice. Our motivation stems from observing that, unlike the real world, the advice under the known models is often closer to "fiat" than "recommendation". Our objective is to propose a model which allows the possibility of incorrect advice, with the objective of obtaining more realistic and robust online algorithms.

1.1 Online computation and advice complexity

In the standard model of online computation that goes back to the seminal work of Sleator and Tarjan [26], an online algorithm receives as input a sequence of *requests*. For each request in this sequence, the algorithm must make an irrevocable decision concerning the item, without any knowledge of future requests. The performance of an online algorithm is usually evaluated by means of the competitive ratio, which is the worst-case ratio of the cost incurred by the algorithm (assuming a minimization problem) to the cost of an ideal solution that knows the entire sequence in advance.

In practice, however, online algorithms are often provided with some (limited) knowledge of the input, such as lookahead on some of the upcoming requests, or knowledge of the input size. While competitive analysis is still applicable, especially from the point of view of the analysis of a known, given algorithm, a new model was required to formally quantify the power and limitations of offline information. The term *advice complexity* was first coined by Dobrev et al. [12], and subsequent formal models were presented by Böckenhauer et al. [6] and Emek et al. [13], with this goal in mind. More precisely, in the advice setting, the online algorithm receives some bits that encode information concerning the sequence of input items. As expected, this additional information can boost the performance of the algorithm, which is often reflected in better competitive ratios.

Under the current models, the advice bits can encode any information about the input sequence; indeed, defining the "right" information to be conveyed to the algorithm plays an important role in obtaining better online algorithms. Clearly, the performance of the online algorithm can only improve with larger number of advice bits. The objective is thus to identify the exact trade-offs between the size of the advice and the performance of the algorithm. This is meant to provide a smooth transition between the purely online world (nothing is known about the input) and the purely "offline" world (everything is known about the input). In the last decade, a substantial number of online optimization problems have been studied in the advice model; we refer the reader to the survey of Boyar et al. [7] for an in-depth discussion of developments in this field.

As argued in detail in [7], there are compelling reasons to study the advice complexity of online computation. Lower bounds establish strict limitations on the power of any online algorithm; there are strong connections between randomized online algorithms and online algorithms with advice (see, e.g., [16]); online algorithms with advice can be of practical

interest in settings in which it is feasible to run multiple algorithms and output the best solution (see [17] about obtaining improved data compression algorithms by means of list update algorithms with advice); and the first complexity classes for online computation have been based on advice complexity [8].

Notwithstanding such interesting attributes, the known advice model has certain drawbacks. The advice is always assumed to be some error-free information that may be used to encode some property often explicitly connected to the optimal solution. In many settings, one can argue that such information cannot be readily available, which implies that the resulting algorithms are often impractical.

1.2 Online computation with untrusted advice

In this work, we address what is a significant drawback in the online advice model. Namely, all previous works assume that advice is, in all circumstances, completely trustworthy, and precisely as defined by the algorithm. Since the advice is infallible, no reasonable online algorithm with advice would choose to ignore the advice.

It should be fairly clear that such assumptions are very unrealistic or undesirable. Advice bits, as all information, are prone to transmission errors. In addition, the known advice models often require that the information encodes some information about the input, which, realistically, cannot be known exactly (e.g., some bits of the optimal, offline solution). Last, and perhaps more significantly, a malicious entity that takes control of the advice oracle can have a catastrophic impact. For a very simple example, consider the well-known ski rental problem: this is a simple, yet fundamental resource allocation, in which we have to decide ahead of time whether to rent or buy equipment without knowing the time horizon in advance. In the traditional advice model, one bit suffices to be optimal: 0 for renting throughout the horizon, 1 for buying right away. However, if this bit is wrong, then the online algorithm has unbounded competitive ratio, i.e., can perform extremely badly. In contrast, an online algorithm that does not use advice at all has competitive ratio at most 2, i.e., its output can be at most twice as costly as the optimal one.

The above observations were recently made in the context of online algorithms with machine-learned predictions. Lykouris and Vassilvitskii [21] and Purohit et al. [23] show how to use predictors to design and analyze algorithms with two properties: (i) if the predictor is good, then the online algorithm should perform close to the best offline algorithm (what is called *consistency*); and (ii) if the predictor is bad, then the online algorithm should gracefully degrade, i.e., its performance should be close to that of the online algorithm without predictions (what is called *robustness*).

Motivated by these definitions from machine learning, in this work we analyze online algorithms based on their performance in both settings of trusted and untrusted advice. In particular, we will characterize the performance of an online algorithm A by a pair of competitive ratios, denoted by (r_A, w_A), respectively. Here, r_A is the competitive ratio achieved assuming that the advice encodes precisely what it is meant to capture; we call this ratio the competitive ratio with *trusted* (thus, always correct) advice. In contrast, w_A is the competitive ratio of A when the advice is untrusted (thus, potentially wrong). More precisely, in accordance with the worst-case nature of competitive analysis, we allow the incorrect advice to be chosen *adversarially*. Namely, assuming a deterministic online algorithm A, the incorrect advice string is generated by a malicious, adversarial entity.

To formalize the above concept, assume the standard advice model, in which a deterministic online algorithm A processes a sequence of requests $\sigma = (\sigma[i])_{i\in[1,n]}$ using an advice tape. At each time t, A serves request $\sigma[t]$, and its output is a function of $\sigma[1..\ldots t-1]$ and

$\phi \in \{0,1\}^*$. Let $A(\sigma,\phi)$ denote the cost incurred by A on input σ, using an advice string ϕ. Denote by r_A, w_A as

$$r_A = \sup_{\sigma} \inf_{\phi} \frac{A(\sigma,\phi)}{\textsc{Opt}(\sigma)}, \quad \text{and} \quad w_A = \sup_{\sigma} \sup_{\phi} \frac{A(\sigma,\phi)}{\textsc{Opt}(\sigma)}, \tag{1}$$

where $\textsc{Opt}(\sigma)$ denotes the optimal offline cost for σ. Then we say that algorithm A is (r,w)-competitive for every $r \geq r_A$ and $w \geq w_A$. In addition, we say that A has advice complexity $s(n)$ if for every request sequence σ of length n, the algorithm A depends only on the first $s(n)$ bits of the advice string ϕ. To illustrate this definition, the opportunistic 1-bit advice algorithm for ski rental that was described above is $(1,\infty)$-competitive, whereas the standard competitively optimal algorithm without advice is $(2,2)$-competitive. In general, every online algorithm A without advice or ignoring its advice is trivially (w,w)-competitive, where w is the competitive ratio of A.

Hence, we can associate every algorithm A to a point in the 2-dimensional space with coordinates (r_A, w_A). These points are in general incomparable, e.g., it is difficult to argue that a $(2,10)$-competitive algorithm is better than a $(4,8)$-competitive algorithm. However, one can appeal to the notion of *dominance*, by saying that algorithm A dominates algorithm B if $r_A \leq r_B$ and $w_A \leq w_B$. More precisely, we are interested in finding the Pareto frontier in this representation of all online algorithms. For the ski rental example, the two above mentioned algorithms belong to the Pareto set.

A natural goal is to describe this Pareto frontier, which in general, may be comprised of several algorithms with vastly different statements. Ideally, however, one would like to characterize it by a single *family* $\mathcal{A}$ of algorithms, with similar statements (e.g., algorithms in $\mathcal{A}$ are obtained by appropriately selecting a parameter). We say that $\mathcal{A}$ is *Pareto-optimal* if it consists of pairwise incomparable algorithms, and for every algorithm B, there exists $A \in \mathcal{A}$ such that A dominates B. Regardless of optimality, given $\mathcal{A}$, we will describe its competitiveness by means of a function $f : \mathbb{R}_{\geq 1} \to \mathbb{R}_{\geq 1}$ such that for every ratio r there is an $(r, f(r))$-competitive algorithm in $\mathcal{A}$. This function will in general depend on parameters of the problem, such as, for example, the buying cost B in the ski rental problem.

1.3 Contribution

We study various online problems in the setting of untrusted advice. We also demonstrate that it is possible to establish both upper and lower bounds on the tradeoff between the size of the advice and the competitiveness in this new advice model. We begin in Section 2 with a simple, yet illustrative online problem as a case study, namely the *ski-rental* problem. Here, we give a Pareto-optimal algorithm with only one bit of advice. We also show that this algorithm is Pareto-optimal even in the space of all (deterministic) algorithms with advice of *any* size.

In Section 3 we study the *online bidding* problem, in which the objective is to guess an unknown, hidden value, using a sequence of bids. This problem was introduced in [11] as a vehicle for formalizing efficient doubling, and has applications in several important online and offline optimization problems. As with ski rental, this is another problem for which a trivial online algorithm is $(1,\infty)$-competitive. We first show how to find a Pareto-optimal strategy, when the advice encodes the hidden value, and thus can have unbounded size. Moreover, we study the competitiveness of the problem with only k bits of advice, for some fixed k, and show both upper and lower bounds on the achieved competitive ratios. The results illustrate that is is possible to obtain non-trivial lower bounds on the competitive ratios, in terms of the advice size. In particular, the lower bound implies that, unlike the ski rental problem, Pareto-optimality is not possible with a bounded number of advice bits.

In Sections 4 and 5, we study the *bin packing* and *list update* problems; these problems are central in the analysis of online problems and competitiveness, and have numerous applications in practice. For these problems, an efficient advice scheme should address the issues of "what constitutes good advice" as well as "how the advice should be used by the algorithm". We observe that the existing algorithms with advice perform poorly in the case the advice is untrusted. To address this, we give algorithms that can be "tuned" based on how much we are willing to trust the advice. This enables us to show guarantees in the form $(r, f(r))$-competitiveness, where r is strictly better than the competitive ratio of all deterministic online algorithms and $f(r)$ smoothly decreases as r grows, while still being close to the worst-case competitive ratio. To illustrate this, consider the bin packing problem. Our $(r, f(r))$-competitive algorithm has $f(r) = \max\{33 - 18r, 7/4\}$ for any $r \geq 1.5$. If $r = 1.5$, our algorithm is $(1.5, 6)$-competitive, and matches the performance of a known algorithm [10]. However, with a slight increase of r, one can improve competitiveness in the event the advice is untrusted. For instance, choosing $r = 1.55$, we obtain $f(r) = 5.1$. In other words, the algorithm designer can hedge against untrusted advice, by a small sacrifice in the trusted performance. Thus we can interpret r as the "risk" for trusting the advice: the smaller the r, the bigger the risk. Likewise, for the list update problem, our $(r, f(r))$-competitive algorithm has $f(r) = 2 + \frac{10-3r}{9r-5}$ for $r \in [5/3, 2]$. If the algorithm takes maximum risk, i.e., if r is smallest, the algorithm is equivalent to an existing $(5/3, 5/2)$-competitive algorithm [9]. Again, by increasing r, we better safeguard against the event of untrusted advice.

All the above results pertain to deterministic online algorithms. In Section 6, we study the power of randomization in online computation with untrusted advice. First, we show that the randomized algorithm of Purohit et al. [23] for the ski rental problem Pareto-dominates any deterministic algorithm, even when the latter is allowed unbounded advice. Furthermore, we show an interesting difference between the standard advice model and the model we introduce: in the former, an advice bit can be at least as powerful as a random bit, since an advice bit can effectively simulate any efficient choice of a random bit. In contrast, we show that in our model, there are situations in which a randomized algorithm with L advice bits and one random bit is Pareto-incomparable to the Pareto-optimal deterministic algorithm with $L + 1$ advice bits. This confirms the intuition that a random bit is considered trusted, and thus not obviously inferior to an advice bit.

While our work addresses issues similar to [21] and [23], in that trusted advice is related to consistency whereas untrusted advice is related to robustness, it differs in two significant aspects: First, our ideal objective is to identify an optimal family of algorithms, and we show that in some cases (ski rental, online bidding), this is indeed possible; when this is not easy or possible, we can still provide approximations. Note that finding a Pareto-optimal family of algorithms presupposes that the exact competitiveness of the online problem with no advice is known. For problems such as bin packing, the exact optimal competitive ratios are not known. Hence, a certain degree of approximation is unavoidable in such cases. In contrast, [21, 23] focus on "smooth" tradeoffs between the trusted and untrusted competitive ratios, but do not address the issues related to optimality and approximability of these tradeoffs.

Second, our model considers the size of advice and its impact on the algorithm's performance, which is the main focus of the advice complexity field. For all problems we study, we parameterize advice by its size, i.e., we allow advice of a certain size k. Specifically, the advice need not necessarily encode the optimal solution or the request sequence itself. This opens up more possibilities to the algorithm designer in regards to the choice of an appropriate advice oracle, which may have further practical applications in machine learning.

2 A warm-up: the ski rental problem

2.1 Background

The ski rental problem is a canonical example in online rent-or-buy problems. Here, the request sequence can be seen as vacation days, and on each day the vacationer (that is, the algorithm) must decide whether to continue renting skis, or buy them. Without loss of generality we assume that renting costs a unit per day, and buying costs $B \in \mathbb{N}^+$. The number of skiing days, which we denote by D, is unknown to the algorithm, and we observe that the optimal offline cost is $\min\{D, B\}$. Generalizations of ski rental have been applied in many settings, such as dynamic TCP acknowledgment [19], the parking permit problem [22], and snoopy caching [18].

Consider the single-bit advice setting. Suppose that the advice encodes whether to buy on day 1, or always rent. An algorithm that blindly follows the advice is optimal if the advice is trusted, but, if the advice is untrusted, the competitive ratio is as high as D/B, if $D > B$. Hence, this algorithm is $(1, \infty)$-competitive, for $D \to \infty$.

2.2 Ski rental with untrusted advice

We define the family of algorithms A_k, with parameter $0 < k \leq B$ as follows. There is a single bit of advice, which is the indicator of the event $D < B$. If the advice bit is 1, then A_k rents until until day $B - 1$ and buys on day B. Otherwise, the algorithms buys on day k.

▶ **Proposition 1.** *Algorithm A_k is $(1 + \frac{k-1}{B}, 1 + \frac{B-1}{k})$-competitive.*

Our algorithm A_k is slightly different from the one proposed in [23], which buys on day $\lceil B/k \rceil$ if the advice is 1 and is shown to be $(1+k/B, 1+B/k)$-competitive. More importantly, we show that A_k is Pareto-optimal in the space of all deterministic online algorithms with advice of *any size*. This implies that more than a single bit of advice will not improve the tradeoff between the trusted and untrusted competitive ratios.

▶ **Theorem 2.** *For any deterministic $(1 + \frac{k-1}{B}, w)$-competitive algorithm A, with $1 \leq k \leq B$, with advice of any size, it holds that $w \geq 1 + \frac{B-1}{k}$.*

Proof. Let A be an algorithm with trusted competitive ratio at most $1 + \frac{k-1}{B}$. First, note that if the advice is untrusted, the competitive ratio cannot be better than the competitive ratio of a purely online algorithm. For ski-rental, it is known that no online algorithm can achieve a competitive ratio better than $1 + (B-1)/B$ [18]. So, in the case $k = B$, the claim trivially holds. In the remainder of the proof, we assume $k < B$.

We use σ_D to denote the instance of the problem in which the number of skiing days is D, and use $A_t(\sigma_D)$ to denote the cost of A for σ_D in case of trusted advice.

Consider a situation in which the input is σ_{B+k} and the advice for A is trusted. Let j be the day the algorithm will buy under this advice. Since the advice is trusted and thus $\textsc{Opt}(\sigma_{B+k}) = B$, it must be that

$$A_t(\sigma_{B+k}) \leq \left(1 + \frac{k-1}{B}\right) \textsc{Opt}(\sigma_{B+k}),$$

which implies $j < B + k$. In other words, A indeed buys on day j. We conclude that $A_t(\sigma_{B+k}) = j - 1 + B$ which further implies $j \leq k$.

Let x be the trusted advice A receives on input σ_{B+k} and suppose A receives the same advice x on input σ_j. Note that x can be trusted or untrusted for σ_j. The important point is that A serves σ_j in the same way it serves σ_{B+k}, that is, it rents for $j - 1$ days and buys

on day j. The cost of A for σ_j is then $j-1+B$, while $\textsc{Opt}(\sigma_j)=j$. The ratio between the cost of the algorithm and Opt is therefore $1+\frac{B-1}{j}$, which is at least $1+\frac{B-1}{k}$ since $j\leq k$. Note that $1+\frac{B-1}{k}>1+\frac{k-1}{B}$ (since we assumed $k<B$) and therefore the advice in this situation has to be untrusted, by the assumption on the trusted competitive ratio of A. We conclude that the untrusted competitive ratio must be at least $1+(B-1)/k$. ◀

3 Online bidding

3.1 Background

In the *online bidding* problem, a player wants to guess a hidden, unknown real value $u\geq 1$. To this end, the player submits a sequence $X=(x_i)$ of increasing *bids*, until one of them is at least u. The strategy of the player is defined by this sequence of bids, and the cost of guessing the hidden value u is equal to $\sum_{i=1}^{j}x_i$, where j is such that $x_{j-1}<u\leq x_j$. Hence the following natural definition of the competitive ratio of the bidder's strategy.

$$w_X=\sup_u \frac{\sum_{i=1}^{j}x_i}{u},\ \text{where } j \text{ is such that } x_{j-1}<u\leq x_j.$$

The problem was introduced in [11] as a canonical problem for formalizing doubling-based strategies in online and offline optimization problems, such as searching for a target on the line, minimum latency, and hierarchical clustering. It is worth noting that online bidding is identical to the problem of minimizing the *acceleration ratio of interruptible algorithms* [25]; the latter and its generalizations are problems with many practical applications in AI (see, for instance [20]).

Without advice, the best competitive ratio is 4, and can be achieved using the doubling strategy $x_i=2^i$. If the advice encodes[1] the value u, and assuming trusted advice, bidding $x_1=u$ is a trivial optimal strategy. The above observations imply that there are simple strategies that are $(4,4)$-competitive and $(1,\infty)$-competitive, respectively.

3.2 Online bidding with untrusted advice

Suppose that $w\geq 4$ is a fixed, given parameter. We will show a Pareto-optimal bidding strategy X^*_u, assuming that the advice encodes u, which is $(\frac{w-\sqrt{w^2-4w}}{2},w)$-competitive (Theorem 5).

We begin with some definitions. Since the index of the bid which reveals the value will be important in the analysis, we define the class $S_{m,u}$, with $m\in\mathbb{N}^+$ as the set of bidding strategies with advice u which are w-competitive, and which, if the advice is trusted, succeed in finding the value with precisely the m-th bid. We say that a strategy $X\in S_{m,u}$ that is (r,w)-competitive dominates $S_{m,u}$ if for every $X'\in S_{m,u}$, such that X' is (r',w)-competitive, $r\leq r'$ holds.

The high-level idea is to identify, for any given m, a dominant strategy in $S_{m,u}$. Let $X^*_{m,u}$ denote such a strategy, and denote by $(r^*_{m,u},w)$ its competitiveness. Then $X^*_{m,u}$ and $r^*_{m,u}$ are the solutions to an infinite linear program which we denote by $P_{m,u}$, and which is shown below. For convenience, for any strategy X, we will always define x_0 to be equal to 1.

[1] We assume that the advice provides the exact value u to the algorithm. For practical considerations, it suffices to assume an oracle that provides an $(1+\epsilon)$-approximation of the hidden value, for sufficiently small $\epsilon>0$. This will only affect the competitive ratios by the same negligible factor.

$$
\begin{aligned}
\min \quad & r_{m,u} && (P_{m,u})\\
\text{s.t. } & x_i < x_{i+1}, \quad i \in \mathbb{N}^+\\
& x_{m-1} < u \le x_m\\
& \sum_{j=1}^{m} x_j \le r_{m,u} \cdot u\\
& \sum_{j=1}^{i} x_j \le w \cdot x_{i-1}, \quad i \in \mathbb{N}^+\\
& x_i \ge 0, \quad i \in \mathbb{N}^+.
\end{aligned}
\qquad
\begin{aligned}
\min \quad & \frac{1}{u} \cdot \sum_{i=1}^{m} x_i && (L_{m,u})\\
\text{s.t. } & x_i < x_{i+1}, \quad i \in \mathbb{N}^+\\
& x_m = u\\
& \sum_{j=1}^{i} x_i \le w \cdot x_{i-1}, \quad i \in \mathbb{N}^+ && (C_i)\\
& x_i \ge 0, \quad i \in \mathbb{N}^+.
\end{aligned}
$$

Note that in $P_{m,u}$ the constraints $\sum_{j=1}^{i} x_j \le w \cdot x_{i-1}$ guarantee that the untrusted competitive ratio of X is at most w, whereas the constraints $\sum_{j=1}^{m} x_j \le r_{m,u} \cdot u$ and $x_{m-1} < u \le x_m$ guarantee that if the advice is trusted, then X succeeds in finding u precisely with its m-th bid, and in this case the competitive ratio is $r_{m,u}$.

We also observe that an optimal solution $X^*_{m,u} = (x^*_i)_{i\ge 1}$ for $P_{m,u}$ must be such that $x_m = u$, otherwise one could define a strategy $X'_{m,u}$ in which $x'_i = x^*_i/\alpha$, for all $i \ge 1$, with $\alpha = u/x^*_m$, which is still feasible for $P_{m,u}$, is such that $x'_m = u$, and has better objective value than $X^*_{m,u}$, a contradiction. Furthermore, in an optimal solution, the constraint $\sum_{i=1}^{m} x_i \le r_{m,u} \cdot u$ must hold with equality. Therefore, $X^*_{m,u}$ and $r^*_{m,u}$ are also solutions to the linear program $L_{m,u}$.

Next, define $r^*_u = \inf_m r^*_{m,u}$, and $r^* = \sup_u r^*_u$. Informally, r^*_u, r^* are the optimal competitive ratios, assuming trusted advice. More precisely, the dominant strategy in the space of all w-competitive strategies is (r^*_u, w)-competitive, and r^* is an upper bound on r^*_u, assuming the worst-case choice of u.

We first argue how to compute $r^*_{m,u}$ and the corresponding strategy $X^*_{m,u}$, provided that $L_{m,u}$ is feasible. This is accomplished in Lemma 3. The main idea behind the technical proof is to show that in an optimal solution of $L_{m,u}$, all constraints C_i hold with equality. This allows us to describe the bids of the optimal strategy by means of a linear recurrence relation which we can solve so as to obtain an expression for the bids of $X^*_{m,u}$.

Define the sequences a_i and b_i as follows:

$$
a_i = \frac{a_{i-1}}{w - 1 - b_{i-1}}, \text{ with } a_0 = 1, \text{ and } \quad b_i = \frac{1 + b_{i-1}}{w - 1 - b_{i-1}}, \text{ with } b_0 = 0, \tag{2}
$$

Moreover, for $w > 4$, let $\rho_1 = \frac{w - \sqrt{w^2-4w}}{2}$ and $\rho_2 = \frac{w + \sqrt{w^2-4w}}{2}$ denote the two roots of $x^2 - wx + w$, the characteristic polynomial of the above linear recurrence.

▶ **Lemma 3.** *For every m define $X_{m,u}$ as follows:*

- *If $w > 4$, then $x_{m,u,i} = \alpha \cdot \rho_1^{i-1} + \beta \cdot \rho_2^{i-1}$, where $\alpha = \frac{a_{m-1}\rho_2^{m-1} - 1}{\rho_2^{m-1} - \rho_1^{m-1}} \cdot u$, and $\beta = \frac{a_{m-1}\rho_1^{m-1} - 1}{\rho_1^{m-1} - \rho_2^{m-1}} \cdot u$,*
- *If $w = 4$, then $x_{m,u,i} = (\alpha + \beta \cdot i) \cdot 2^i$, where $\alpha = \frac{2^{m-1} \cdot m \cdot a_{m-1} - 1}{2^m (m-1)} \cdot u$, and $\beta = \frac{1 - 2^{m-1} \cdot a_{m-1}}{2^m (m-1)} \cdot u$.*

Then, $X_{m,u}$ is an optimal feasible solution if and only if $a_{m-1} \cdot u \le w$.

We can now give the statement of the optimal strategy X^*_u. First, we can argue that the optimal objective value of $L_{m,u}$ is monotone increasing in m, thus it suffices to find the objective value of the smallest m^* for which $L_{m^*,u}$ is feasible; This can be accomplished with a binary search in the interval $[1, \lceil \log u \rceil]$, since we know that the doubling strategy in which

the i-th bid equals 2^i is w-competitive for all $w \geq 4$; hence $m^* \leq \lceil \log u \rceil$. Then X_u^* is derived as in the statement of Lemma 3. The time complexity of the algorithm is $O(\log \log u)$, since we can describe each a_i, b_i, and hence a_{m-1} in closed form, avoiding the recurrence which would add a $O(\log u)$ factor. The technical details can be found in the long version of this paper [2].

Last, the following lemma allows us to express r^* as a function of the values of the sequence b, which we can further exploit so as to obtain the exact value of r_u^*.

▶ **Lemma 4.** *It holds that* $r^* = 1 + \sum_{i=1}^{\infty} \prod_{j=1}^{i-1} b_j$. *Furthermore,* $r^* = \frac{w - \sqrt{w^2 - 4w}}{2}$.

Combining Lemmas 3 and 4 we obtain following result:

▶ **Theorem 5.** *Strategy* X_u^* *is Pareto-optimal and is* $(\frac{w - \sqrt{w^2 - 4w}}{2}, w)$*-competitive.*

Strategy X_u^* requires u as advice, which can be unbounded. A natural question is what competitiveness can one achieve with k advice bits, for some fixed k. We address this question both from the point of view of upper and lower bounds. Concerning upper bounds, we show the following:

▶ **Theorem 6.** *For every* $w \geq 4$*, there exists a bidding strategy with* k *bits of advice which is* (r, w)*-competitive, where*

$$r = \begin{cases} \frac{\left(w + \sqrt{w^2 - 4w}\right)^{1 + 1/K}}{2^{1/K}\left(w + \sqrt{w^2 - 4w} - 2\right)} & \text{if } w \leq (1+K)^2/K \\ \frac{(1+K)^{1+1/K}}{K} & \text{if } w \geq (1+K)^2/K. \end{cases}$$

and where $K = 2^k$.

In particular, for $w = 4$, the strategy of Theorem 6 is $(2^{1 + \frac{1}{2^k}}, 4)$-competitive, whereas X_u^* is $(2, 4)$-competitive. The following theorem gives a lower bound on the competitiveness of any bidding strategy with k bits. The result shows that one needs unbounded number of bids to achieve $(2, 4)$-competitiveness.

▶ **Theorem 7.** *For any bidding strategy with* k *advice bits that is* $(r, 4)$*-competitive it holds that* $r \geq 2 + \frac{1}{3 \cdot 2^k}$.

Proof sketch. We present only an outline. With k bits of advice, the online algorithm can differentiate only between $K = 2^k$ online bidding sequences, denoted by $X_1, \ldots, X_K$, each of which must have (untrusted) competitive ratio at least 4. Suppose, by way of contradiction, that the algorithm has trusted competitive ratio less than $2 + \frac{1}{3 \cdot 2^k}$. We reach a contradiction, by applying a game between the algorithm and the adversary, which proceeds in rounds. The adversary fixes a sufficiently large index $i \geq i_0$, for some i_0. In the first round, u is chosen by the adversary so as to be infinitesimally larger than $x_{K,i-1}$, namely the $(i-1)$-th bid of X_K. For the algorithm to guarantee the claimed r, we show that it will have to use the advice so as to "choose" one of the sequences $X_1, \ldots X_{K-1}$, say X_j. Then in the next round, the adversary will choose an appropriate u that is adversarial for X_j. The crux of the proof is to show that the algorithm's only response is to choose a sequence of index higher than j. Eventually, the only remaining choice for the algorithm is strategy X_K; moreover, we can show that throughout the execution of the algorithm the adversarial u is comparable to $x_{K,i-1}$, in particular, we show that $u \leq e^{1/3} x_{K,i-1}$. To conclude, the above argument shows that

$$r \geq \sup_{i \geq i_0} \frac{\sum_{j=1}^{i} x_{K,j}}{e^{\frac{1}{3}} x_{K,i-1}} = \frac{1}{e^{\frac{1}{3}}} \sup_{i=1} \frac{\sum_{j=1}^{i} x_{K,j}}{x_{K,i-1}} \geq \frac{4}{e^{\frac{1}{3}}} > 2 + \frac{1}{3K}.$$

where we used the fact that $\sup_{i=1} \frac{\sum_{j=1}^{i} x_{K,j}}{x_{K,i-1}} = 4$, since X_K is 4-competitive. ◀

4 Online bin packing

4.1 Background

An instance of the online bin packing problem consists of a sequence of items with different *sizes* in the range $(0, 1]$, and the objective is to pack these items into a minimum number of bins, each with a capacity of 1. For each arriving item, the algorithm must place it in one of the current bins or open a new bin for the item. We say that algorithm A has an asymptotic competitive ratio r if, on every sequence σ, the number of opened bins satisfies $A(\sigma) \leq r \cdot \textsc{Opt}(\sigma) + c$, where c is a constant. As standard in the analysis of bin packing problems, throughout this section, by "competitive ratio" we mean "asymptotic competitive ratio". The First Fit [15] algorithm maintains bins in the same order that they have been opened, and places an item into the first bin with enough free space; if no such bin exists, it opens a new bin. First Fit has a competitive ratio of 1.7 [15] while the best online algorithm has a competitive ratio of at least 1.54278 [5] and at most 1.57829 [4]. Online bin packing has also been studied in the advice setting [10, 24, 3]. In particular, it is possible to achieve a competitive ratio of 1.4702 with only a constant number of (trusted) advice bits [3].

In this section, we introduce an algorithm named Robust-Reserve-Critical (Rrc) which has a parameter $\alpha \in [0, 1]$, indicating how much the algorithm relies on the advice. Provided with $O(1)$ bits of advice, the algorithm is asymptotically $(r_{\text{Rrc}}, w_{\text{Rrc}})$-competitive for $r_{\text{Rrc}} = 1.5 + \frac{1-\alpha}{4-3\alpha}$ and $w_{\text{Rrc}} = 1.5 + \max\{\frac{1}{4}, \frac{9\alpha}{8-6\alpha}\}$. If the advice is reliable, we set $\alpha = 1$ and the algorithm is asymptotically $(1.5, 6)$-competitive; otherwise, we set α to a smaller value.

4.2 The Reserve-Critical algorithm

Our solution uses an algorithm introduced by Boyar et al. [10] which achieves a competitive ratio of 1.5 using $O(\log n)$ bits of advice [10]. We refer to this algorithm as Reserve-Critical in this paper and describe it briefly. The algorithm classifies items according to their size. Tiny items have their size in the range $(0, 1/3]$, small items in $(1/3, 1/2]$, critical items in $(1/2, 2/3]$, and large items in $(2/3, 1]$. In addition, the algorithm has four kinds of bins, called tiny, small, critical and large bins. Large items are placed alone in large bins, which are opened at each arrival. Small items are placed in pairs in small bins, which are opened every other arrival. Critical bins contain a single critical item, and tiny items up to a total size of $1/3$ per bin, while tiny bins contain only tiny items. The algorithm receives as advice the number of critical items, denoted by c, and opens c *critical bins* at the beginning. Inside each critical bin, a space of $2/3$ is reserved for a critical item, and tiny items are placed using First-Fit into the remaining space of these bins possibly opening new bins dedicated to tiny items. Each critical item is placed in one of the critical bins. Note that the algorithm is heavily dependent on the advice being trusted. Imagine that the encoded advice is strictly larger than the real number of critical items. This results in critical bins which contain only tiny items. The worst case is reached when all tiny items have size slightly more than $1/6$ while there is no critical item. In this case, all critical bins are filled up to a level slightly more than $1/6$. Hence, untrusted advice can result in a competitive ratio as bad as 6.

4.3 The Robust-Reserve-Critical (RRC) algorithm

Let t be the number of tiny bins opened by the Reserved-Critical algorithm. Recall that c is the number of critical bins. We call the fraction $c/(c+t)$ the *critical ratio*. The advice for Rrc is a fraction γ, integer multiple of $1/2^k$, that is encoded in k bits such that if the advice is trusted then $\gamma \leq c/(c+t) \leq \gamma + 1/2^k$. In case $c/(c+t)$ is a positive integer multiple of

$1/2^k$, we break the tie towards $\gamma < c/(c+t)$. Note that for sufficiently large, yet constant, number of bits, γ provides a good approximation of the critical ratio. Indeed having γ as advice is sufficient to achieve a competitive ratio that approaches 1.5 in the trusted advice model, as shown in [3].

The RRC algorithm has a parameter $0 \leq \alpha \leq 1$, which together with the advice γ can be used to define a fraction $\beta = \min\{\alpha, \gamma\}$. The algorithm maintains a proportion close to β of critical bins among critical and tiny bins. Formally, on the arrival of a critical item, the algorithm places it in a critical bin, opening a new one if necessary. Each arriving tiny item x is packed in the first critical bin which has enough space, with the restriction that the tiny items don't exceed a fraction $1/3$ in these bins. If this fails, the algorithm tries to pack x in a tiny bin using First-Fit strategy (this time on tiny bins). If this fails as well, a new bin B is opened for x. Now, B should be declared as a critical or a tiny bin. Let c' and t' denote the number of critical and tiny bins before opening B. If $c' + t' > 0$ and $\frac{c'}{c'+t'} < \beta$, then B is declared a critical bin; otherwise, B is declared a tiny bin. Large and small items are placed similarly to the Reserved-Critical algorithm (one large item in each large bin and two small items in each small bin).

4.4 Analysis

Intuitively, RRC works similarly to Reserved-Critical except that it might not open as many critical bins as suggested in the advice. The algorithm is more "conservative" in the sense that it does not keep two-third of many (critical) bins open for critical items that might never arrive. The smaller the value of α is, the more conservative the algorithm is. Our analysis is based on two possibilities in the final packing of the algorithm. In the first case (case I), all critical bins receive a critical item, while in the second case (case II) some of them have their reserved space empty. In case I, we show the number of bins in the packing of RRC is within a factor $1.5 + \frac{1-\beta}{4-3\beta}$ of the number of bins in the optimal packing. Note that this ratio decreases as the value of α (and β) grows. This implies a less conservative algorithm would be better packing in this case. Case II happens only if the advice is untrusted. In this case, the number of bins in the RRC packing is within a factor $1.5 + \frac{9\beta}{8-6\beta}$ of the number of bins in an optimal packing. This ratio increases with α (and β). This implies a more conservative algorithm would be better in this case as it would open less critical bins and, thus, would have fewer without critical items.

Assume the advice is trusted. Then either $\gamma \leq \alpha$ or $\gamma > \alpha$. In the former case, the algorithm maintains the same ratio as suggested by advice, and a result from [3] indicates that the competitive ratio is at most $1.5 + \frac{15}{2^{k/2+1}}$. In the former case, the algorithm maintains a smaller number of critical items than what the advice suggested; all these bins receive critical items and the final packing will be in Case I. Consequently, when the advice is trusted, the competitive ratio is at most $1.5 + \max\{\frac{1-\alpha}{4-3\alpha}, \frac{15}{2^{k/2+1}}\}$. If the advice is untrusted, both case I and case II can be realized for the final packing. The competitive ratio will be at most $1.5 + \max\{\frac{1}{4}, \frac{9\alpha}{8-6\alpha}\}$. We can conclude with the following theorem:

▶ **Theorem 8.** *Algorithm Robust-Reserve-Critical with parameter $\alpha \in [0, 1]$ and k bits of advice achieves a competitive ratio of $r_{\text{RRC}} \leq 1.5 + \max\{\frac{1-\alpha}{4-3\alpha}, \frac{15}{2^{k/2+1}}\}$ when the advice is trusted and a competitive ratio of $w_{\text{RRC}} \leq 1.5 + \max\{\frac{1}{4}, \frac{9\alpha}{8-6\alpha}\}$ when the advice is untrusted.*

Assuming the size k of the advice is a sufficiently large constant, we conclude the following.

▶ **Corollary 9.** *For bin packing with untrusted advice, there is a $(r, f(r))$-competitive algorithm where $r \geq 1.5$ and $f(r) = \max\{33 - 18r, 7/4\}$.*

5 List update

5.1 Background

The list update problem consists of a list of items of length m, and a sequence of n requests that should be served with minimum total cost. Every request corresponds to an "access" to an item in the list. If the item is at position i of the list then its access cost is i. After accessing the item, the algorithm can move it closer to the front of the list with no cost using a "free exchange". In addition, at any point, the algorithm can swap the position of any two consecutive items in the list using a "paid exchange" which has a cost of 1. Throughout this section, we adopt the standard assumption that m is a large integer but still a constant with respect to n.

Move-to-Front (MTF) is an algorithm that moves every accessed item to the front of the list using a free exchange. MTF has a competitive ratio of at most 2 [27], which is the best that a deterministic algorithm can achieve [14]. Timestamp [1] is another algorithm that achieves the optimal competitive ratio of 2. This algorithm uses a free exchange to move an accessed item x to the front of the first item that has been accessed at most once since the last access to x. Move-To-Front-Every-Other-Access (MTF2) is a class of algorithms which maintain a bit for each item in the list. Upon accessing an item x, the bit of x is flipped, and x is moved to front if its bit is 0 after the flip (otherwise the list is not updated). If all bits are 0 at the beginning, MTF2 is called called Move-To-Front-Even (MTFE), and if all bits are 1 at the beginning, MTF2 is called Move-To-Front-Odd (MTFO). Both MTFE and MTFO algorithms have a competitive ratio of 5/2 [9]. In [9] it is shown that, for any request sequence, at least one of Timestamp, MTFO, and MTFE has a competitive ratio of at most 5/3. For a given request sequence, the best option among the three algorithms can be indicated with two bits of advice, giving a 5/3-competitive algorithm. However, if the advice is untrusted, the competitive ratio can be as bad as 5/2.

To address this issue, we introduce an algorithm named Toggle (TOG) that has a parameter $\beta \in [0, 1/2]$, and uses 2 advice bits to select one of the algorithms Timestamp, MTFE or MTFO. This algorithm achieves a competitive ratio of $r_{\text{TOG}} = 5/3 + \frac{5\beta}{6+3\beta}$ when the advice is trusted and a competitive ratio of at most $w_{\text{TOG}} = 2 + 2/(4 + 5\beta)$ when the advice is untrusted. The parameter β can be tuned and should be smaller when the advice is more reliable. In particular, when $\beta = 0$, we get a $(5/3, 2.5)$-competitive algorithm.

5.2 The Toggle algorithm

Given the parameter β, the Toggle algorithm (TOG) works as follows. If the advice indicates Timestamp, the algorithm runs Timestamp. If the advice indicates either MTFO or MTFE, the algorithm will proceed in phases (the length of which partially depend on β) alternating ("toggling") between running MTFE or MTFO, and MTF. In what follows, we use MTF2 to represent the algorithm indicated by the advice. The algorithm TOG will initially begin with MTF2 until the cost of the accesses of the phase reaches a certain threshold, then a new phase begins and TOG switches to MTF. This new phase ends when the access cost of the phase reaches a certain threshold, and TOG switches back to MTF2. This alternating pattern continues as TOG serves the requests. As such, TOG will use MTF2 for the odd phases which we will call *trusting phases*, and MTF for the even phases which we will call *ignoring phases*. The actions during each phase are formally defined below.

Trusting phase: In a trusting phase, TOG will use MTF2 to serve the requests. Let σ_i be the first request of some trusting phase j for $1 \leq i \leq n$ and an odd $j \geq 1$. Before serving σ_i, TOG modifies the list with paid exchanges to match the list configuration that would result

from running MTF2 on the request sequence $\sigma_1, \ldots, \sigma_i$. The number of paid exchanges will be less than m^2. In addition, TOG will set the bits of items in the list to the same value as at the end of this hypothetical run. As such, during a trusting phase, TOG incurs the same access cost as MTF2. The trusting phase continues until the cost to access a request σ_ℓ, $i < \ell \leq n$, for TOG would cause the total access cost for the phase to become at least m^3 (or the request sequence ends). The next phase, which will be an ignoring phase, begins with request $\sigma_{\ell+1}$.

Ignoring phase: In an ignoring phase, TOG will use the MTF rule to serve the request. Unlike the trusting phase, TOG does not use paid exchanges to match another list configuration. Let σ_i be the first request of some ignoring phase j for $1 \leq i \leq n$ and an even $j \geq 1$. The ignoring phase continues until the cost to access a request σ_ℓ, $i < \ell \leq n$, for TOG would cause the total access cost for the phase to exceed $\beta \cdot m^3$ (or the request sequence ends). The next phase, which will be a trusting phase, begins with request $\sigma_{\ell+1}$.

5.3 Analysis

The access cost in each phase of TOG is $\Theta(m^3)$, while the cost that it might pay at the beginning of each phase is $O(m^2)$. Consequently, the cost of the algorithm in a trusting phase is roughly $m^3 + o(m^3)$ and $\beta m^3 + o(m^3)$ for an ignoring phase. Moreover, the optimal algorithm incurs a cost of at least $m^3/2.5 - m^2$ in a trusting phase and at least $\beta m^3/2 - m^2$ in an ignoring phase; these results follow from the upper bounds of respectively 2.5 and 2 for the competitive ratios of MTF and MTF2, and the fact that the discrepancy in the initial configuration of each phase changes the cost of OPT in that phase by at most m^2. We can extend these results to show that, for sufficiently long lists, the competitive ratio of TOG (regardless of the advice being trusted or not) converges to at most $2 + \frac{2}{4+5\beta}$. We conclude that, when the advice is untrusted, the competitive ratio of TOG is at most $2 + \frac{2}{4+5\beta}$.

Now, assume the advice is trusted. If the advice indicates Timestamp as the best algorithm among MTFE, MTFO, and Timestamp, the algorithm uses Timestamp to serve the entire sequence, and since the advice is right, the competitive ratio will be at most 5/3 [9]. If the advice indicates MTF2 (either MTFE or MTFO), we compare the cost of TOG with that of MTF2 in each phase. A careful phase analysis, similar to the one for the competitive ratio, shows that the ratio between the costs of the two algorithms converges to at most $2 + \frac{2}{4+5\beta}$. We conclude that, when the advice is trusted, the competitive ratio of the TOG algorithm converges to $5/3 + \frac{5\beta}{6+3\beta}$ for sufficiently long lists. We can state the following theorem:

▶ **Theorem 10.** *Algorithm* TOG *with parameter* $\beta \in [0, 1/2]$ *and* k *bits of advice achieves a competitive ratio of at most* $5/3 + \frac{5\beta}{6+3\beta}$ *when the advice is trusted and a competitive ratio of at most* $2 + \frac{2}{4+5\beta}$ *when the advice is untrusted.*

▶ **Corollary 11.** *For list update with untrusted advice, there is a* $(r, f(r))$*-competitive algorithm where* $r \in [5/3, 2]$ *and* $f(r) = 2 + \frac{10-3r}{9r-5}$.

6 Randomized online algorithms with untrusted advice

The discussion in all previous sections pertains to deterministic online algorithms. In this section we focus on randomization and its impact on online computation with untrusted advice. We will assume, as standard in the analysis of randomized algorithms, that the source of randomness is trusted (unlike the advice). Given a randomized algorithm A, its trusted and untrusted competitive ratios are defined as in (1), with the difference that the cost $A(\sigma, \phi)$ is now replaced by the expected cost $\mathbb{E}(A(\sigma, \phi))$.

First, we will argue that randomization can improve the competitiveness of the ski rental problem. For this, we note that [23] gave a randomized algorithm with a single advice bit for this problem which is $\left(\frac{\lambda}{1-e^{-\lambda}}, \frac{1}{1-e^{-(\lambda-1/B)}}\right)$-competitive, where $\lambda \in (1/B, 1)$ is a parameter of the algorithm. For simplicity, we may assume that B is large, hence this algorithm is $\left(\frac{\lambda}{1-e^{-\lambda}}, \frac{1}{1-e^{-\lambda}}\right)$-competitive, which we can write in the equivalent form $(w \ln \frac{w}{w-1}, w)$. In contrast, Theorem 2 shows that any deterministic Pareto-optimal algorithm with advice of any size is $(1+\lambda, 1+1/\lambda)$-competitive, or equivalently $(\frac{w}{w-1}, w)$-competitive. Standard calculus shows that $w \ln \frac{w}{w-1} < \frac{w}{w-1}$; therefore we conclude that the randomized algorithm Pareto-dominates any deterministic algorithm, even when the latter is allowed unbounded advice.

A second issue we address in this section is related to the comparison of random bits and advice bits as resource. More specifically, in the standard model in which advice is always trustworthy, an advice bit can be at least as powerful as a random bit since the former can simulate the efficient choice of the latter, and thus provide a "no-loss" derandomization. However, in the setting of untrusted advice, the interplay between advice and randomization is much more intricate. This is because random bits, unlike advice bits, are assumed to be trusted.

We show, using online bidding as an example, that there are situations in which a deterministic algorithm with $L+1$ advice bits is Pareto-incomparable to a randomized algorithm with 1 random bit and L advice bits. In particular we focus on the *bounded online bidding* problem, in which $u \leq B$, for some given B.

▶ **Theorem 12.** *For every $\epsilon > 0$ there exist sufficiently large B and L such that there is a randomized algorithm for bounded online bidding with L advice bits and 1 random bit, and which is $(\frac{1+\rho_1}{2}\rho_1 + \epsilon, \frac{1+\rho_1}{2\rho_1}w + \epsilon)$-competitive for all $w > 4$, where $\rho_1 = \frac{w-\sqrt{w^2-4w}}{2}$.*

Note that when $B, L \to \infty$, the competitiveness of the best deterministic algorithm with L advice bits approaches the one of X_u^*, as expressed in Theorem 5, namely (ρ_1, w). Thus, Theorem 12 shows that randomization improves upon the deterministic untrusted ratio w by a factor $\frac{1+\rho_1}{2\rho_1} > 1$, at the expense of a degradation of the trusted competitive ratio by a factor $\frac{1+\rho_1}{2} > 1$. For instance, if w is close to 4, then the randomized algorithm has untrusted competitive ratio less than 4, and thus better than any deterministic strategy.

Abstract

The most studied linear algebraic operation, matrix multiplication, has surprisingly fast $O(n^\omega)$ time algorithms for $\omega < 2.373$. On the other hand, the $(\min, +)$ matrix product which is at the heart of many fundamental graph problems such as All-Pairs Shortest Paths, has received only minor $n^{o(1)}$ improvements over its brute-force cubic running time and is widely conjectured to require $n^{3-o(1)}$ time. There is a plethora of matrix products and graph problems whose complexity seems to lie in the middle of these two problems. For instance, the Min-Max matrix product, the Minimum Witness matrix product, All-Pairs Shortest Paths in directed unweighted graphs and determining whether an edge-colored graph contains a monochromatic triangle, can all be solved in $\widetilde{O}(n^{(3+\omega)/2})$ time. While slight improvements are sometimes possible using rectangular matrix multiplication, if $\omega = 2$, the best runtimes for these "intermediate" problems are all $\widetilde{O}(n^{2.5})$.

A similar phenomenon occurs for convolution problems. Here, using the FFT, the usual $(+, \times)$-convolution of two n-length sequences can be solved in $O(n \log n)$ time, while the $(\min, +)$ convolution is conjectured to require $n^{2-o(1)}$ time, the brute force running time for convolution problems. There are analogous intermediate problems that can be solved in $O(n^{1.5})$ time, but seemingly not much faster: Min-Max convolution, Minimum Witness convolution, etc.

Can one improve upon the running times for these intermediate problems, in either the matrix product or the convolution world? Or, alternatively, can one relate these problems to each other and to other key problems in a meaningful way?

This paper makes progress on these questions by providing a network of fine-grained reductions. We show for instance that APSP in directed unweighted graphs and Minimum Witness product can be reduced to both the Min-Max product and a variant of the monochromatic triangle problem, so that a significant improvement over $n^{(3+\omega)/2}$ time for any of the latter problems would result in a similar improvement for both of the former problems. We also show that a natural convolution variant of monochromatic triangle is fine-grained equivalent to the famous 3SUM problem. As this variant is solvable in $O(n^{1.5})$ time and 3SUM is in $O(n^2)$ time (and is conjectured to require $n^{2-o(1)}$ time), our result gives the first fine-grained equivalence between natural problems of different running times. We also relate 3SUM to monochromatic triangle, and a coin change problem to monochromatic convolution, and thus to 3SUM.

1 Introduction

Matrix multiplication is arguably the most fundamental linear algebraic operation. It is an important primitive for an enormous variety of applications. Within algorithmic research it has a very special role since it is one of the few problems for which we have surprisingly fast and completely counter-intuitive algorithms. Starting with Strassen's breakthrough [36] in 1969, a long line of research culminated in the current bound $\omega < 2.373$ [42, 30], where ω is the smallest real number so that $n \times n$ matrix multiplication can be performed in $\mathcal{O}(n^{\omega+\varepsilon})$ time for all $\varepsilon > 0$.

In many applications, one needs to compute matrix products that are a bit different (often called funny [2]) from the usual definition of matrix multiplication over a ring such as the integers ($C_{ij} = \sum_k A_{ik} \cdot B_{kj}$). Such examples include matrix products over semirings such as the $(\min, +)$-product (often called distance product) which is over the tropical $((\min, +))$ semiring and the Max-Min product which is over the $(\max, \min)$-semiring. Both these products are equivalent to certain types of path optimization problems in graphs. The distance product of $n \times n$ matrices is equivalent to the All-Pairs Shortest Paths (APSP) problem in n-node graphs, so that a $T(n)$ time algorithm for one problem would imply an $\mathcal{O}(T(n))$ time algorithm for the other [21]. Similarly, the Max-Min product is equivalent to the so called All-Pairs Bottleneck Paths (APBP) in graphs (e.g. [35]).

There seems to be a distinct complexity difference between APSP and APBP (and hence the corresponding matrix products), however. The fastest algorithms for APSP and the distance product run in $n^3/\exp(\sqrt{\log n})$ time [46], which is only better by an $n^{o(1)}$ factor than the trivial cubic time algorithm for the distance product. Meanwhile, as was first shown by [38, 39], APBP and the Max-Min product admit a much faster than cubic time algorithm via a reduction to (normal) matrix multiplication; the fastest running time is $\mathcal{O}(n^{(3+\omega)/2})$ [19].

APSP is in fact conjectured to not admit any truly subcubic, $\mathcal{O}(n^{3-\varepsilon})$ time algorithms for $\varepsilon > 0$. Fine-grained complexity has strengthened this hypothesis by providing a large class of problems that are equivalent to APSP and the distance product, via fine-grained subcubic reductions. Thus the reason why distance product is seemingly so difficult is because there are many problems that are equivalent to it and researchers from different communities have all failed to solve these problems faster.

The best known running time for the $n \times n$ Max-Min product, $\widetilde{\mathcal{O}}(n^{(3+\omega)/2})$, while nontrivially subcubic, seems difficult to improve upon. In fact, $\widetilde{\mathcal{O}}(n^{(3+\omega)/2})$ is the best known running time for many other matrix and graph problems besides the Max-Min product: the Dominance product [32] and Equality product [47, 29], All-Pairs Nondecreasing Paths (APNP) and the $(\min, \leqslant)$-product [37, 41, 18]. For some of these problems [49, 24] one can obtain slightly improved running times using rectangular matrix multiplication [23]. However, the closer ω is to 2, the smaller the improvement, and when $\omega = 2$, the $\widetilde{\mathcal{O}}(n^{(3+\omega)/2}) = \widetilde{\mathcal{O}}(n^{2.5})$ running time is the best known for all of these problems. Since their running time exponent is essentially the average of the brute-force exponent 3 and the fast matrix multiplication exponent ω, we will call these problems "intermediate".

There are two additional problems that are intermediate if $\omega = 2$: the Minimum Witness product, which is equivalent to the problem of computing All-Pairs Least Common Ancestors in a DAG, and All-Pairs Shortest Paths (APSP) in unweighted directed graphs. For both problems we know algorithms running in $\widetilde{\mathcal{O}}(n^{(3+\omega)/2}) \leqslant \widetilde{\mathcal{O}}(n^{2.687})$ time [6, 2], and both algorithms can be improved upon, by using rectangular matrix multiplication [15, 50]. The improvement is already seen in a naive implementation, i.e. cutting rectangular matrices into square blocks, which gives an $\widetilde{\mathcal{O}}(n^{2+1/(4-\omega)}) \leqslant \widetilde{\mathcal{O}}(n^{2.615})$ time. Employing a specialized rectangular matrix multiplication algorithm [23], brings the runtime down to $\widetilde{\mathcal{O}}(n^{2.529})$. When $\omega = 2$, however, all the improvements vanish and those running times become $\widetilde{\mathcal{O}}(n^{2.5})$.

Is the 2.5 *running time exponent (for* $\omega = 2$*) for all of these problems a coincidence, or can we relate all of them via fine-grained reductions, and use plausible hypotheses to explain it?*

This is a question that many have asked, but unfortunately there are only two partial answers: First, it is known that Equality product and Dominance product are equivalent ([47, 29], also follows from Proposition 3.4 in [45]), and that they are equivalent to All-Pairs ℓ_{2p+1} Distances [29]. The second result is that the Max-Min product is equivalent to approximate APSP in weighted graphs without scaling [10]. The main question above remains *wide open*.

Parallel to the world of matrix products, there is a very similar landscape of *convolution* problems. While it is well-known that the $(+,\times)$-convolution[1] of two n-length vectors can be computed in $\mathcal{O}(n \log n)$ time using the Fast Fourier Transform (FFT), these techniques no longer work for the $(\min,+)$-convolution, and this problem is conjectured to require $n^{2-o(1)}$ time (see e.g. [14]). Similar to the "intermediate" matrix product problems, there are analogous "intermediate" convolution problems, all in $\widetilde{\mathcal{O}}(n^{3/2})$ time[2]: Max-Min convolution, Dominance convolution, Minimum Witness convolution, etc.

The convolution landscape is even somewhat cleaner than the matrix product one. As the normal convolution $((+,\times))$ is already in (near-)linear time, there are no analogues of rectangular matrix multiplication speedups, and all intermediate problems happen to have exactly the same running time (up to polylogarithmic factors). Still, there is no real formal explanation of why they have the same running time. The only reductions between these convolutions are analogous to the matrix product ones: Dominance convolution is equivalent to Equality convolution [29], and approximate $(\min,+)$-convolution is equivalent to exact Max-Min convolution [10].

1.1 Our contributions

In this paper we provide new fine-grained reductions between several intermediate matrix product and all-pairs graph problems, and between intermediate convolution problems, also relating these to other key problems from fine-grained complexity such as 3SUM. See Figure 1 for a pictorial representation of our results.

Reductions for Graph Problems and Matrix Products

Several of our reductions concern the All-Edges Monochromatic Triangle (AE-MonoΔ) problem: Given an n-node graph in which each edge has a color from 1 to n^2, decide for each edge whether it belongs to a *monochromatic* triangle, a triangle whose all three edges

[1] The $(+,\times)$-convolution of two vectors a and b is the vector c such that $c_i = \sum_j a_j b_{i-j}$.

[2] The exponent $(3+\omega)/2$ for intermediate matrix products is the average of the fast matrix multiplication exponent and the brute force matrix product exponent, and the exponent $3/2$ for intermediate convolution problems is the average of the fast convolution exponent 1 and the brute force exponent 2.

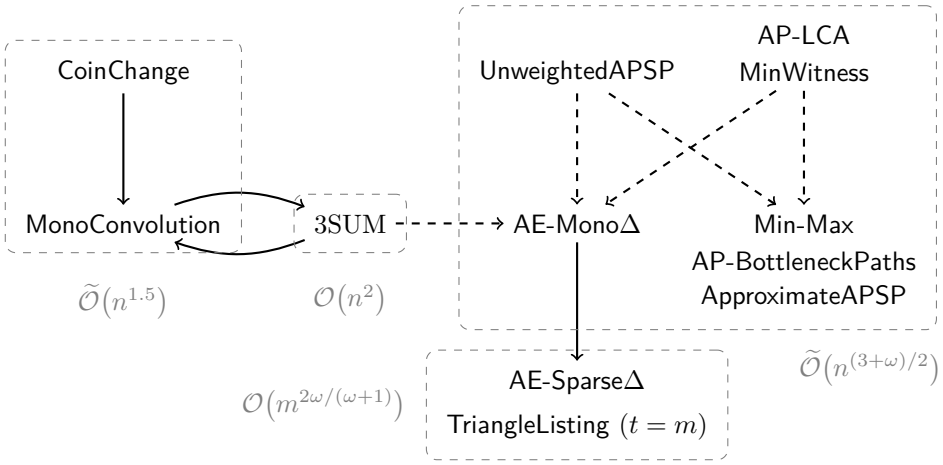

Figure 1 Our results. An arrow pointing from problem A to problem B means that problem A reduces to problem B in the fine-grained sense. Dashed arrows denote reductions which become tight when $\omega = 2$.

have the same color. Vassilevska, Williams and Yuster [40] studied the decision variant of AE-MonoΔ in which one asks whether the given graph contains a monochromatic triangle. They provided an $\mathcal{O}(n^{(3+\omega)/2})$ time algorithm for the decision problem, but that algorithm is in fact strong enough to also solve the all-edges variant AE-MonoΔ, making AE-MonoΔ one of the "intermediate" problems of interest.

To obtain their $\mathcal{O}(n^{(3+\omega)/2})$ time algorithm, Vassilevska, Williams and Yuster [40] implicitly reduce AE-MonoΔ (in a black-box way) to the AE-SparseΔ problem of deciding for every edge e in an m-edge graph whether e is in a triangle. The fastest known algorithm for AE-SparseΔ is by Alon, Yuster and Zwick [3], running in $\mathcal{O}(m^{2\omega/(\omega+1)})$ time, and the problem is known to be runtime equivalent to the problem of *listing* up to m triangles in an m-edge graph [20]. The black-box reduction of [40] from AE-MonoΔ to AE-SparseΔ implies that a significant improvement over the $\mathcal{O}(m^{2\omega/(\omega+1)})$ time for AE-SparseΔ would translate to an improvement over $\mathcal{O}(n^{(3+\omega)/2})$ for AE-MonoΔ.

▶ **Theorem 1** (implicit in [40]). *If* AE-SparseΔ *is in* $\mathcal{O}(m^{2\omega/(\omega+1)-\varepsilon})$ *time, for some* $\varepsilon > 0$, *then* AE-MonoΔ *is in* $\mathcal{O}(n^{(3+\omega)/2-\delta})$ *time, for some* $\delta > 0$.

Our first set of results shows that AE-MonoΔ is powerful enough to capture two well-studied intermediate problems: the Minimum Witness product of two Boolean matrices and the All-Pairs Shortest Paths problem in directed unweighted graphs.

The Minimum Witness product (MinWitness) C of two Boolean matrices A and B is defined as $C_{ij} = \min\{k \mid A_{ik} = B_{kj} = 1\}$ (where the minimum is defined to be ∞ if there is no witness k). It is well-known [15] that MinWitness is equivalent to determining for every pair u, v of vertices in a DAG, the least common ancestor of u and v, i.e. solving the All-Pairs Least Common Ancestors (AP-LCA) problem. The fastest known algorithm for MinWitness runs in $\mathcal{O}(n^{2.529})$ time using rectangular matrix multiplication, and in $\mathcal{O}(n^{2+1/(4-\omega)})$ time just using square matrix multiplication [15].

The All-Pairs Shortest Paths (APSP) problem in unweighted graphs is very well-studied. While in undirected graphs, the problem is known to be solvable in $\widetilde{\mathcal{O}}(n^\omega)$ time [34], the problem in directed graphs is one of our intermediate problems. Its fastest algorithm (similarly to MinWitness) runs in $\mathcal{O}(n^{2.529})$ time using rectangular matrix multiplication, and in $\widetilde{\mathcal{O}}(n^{2+1/(4-\omega)})$ time just using square matrix multiplication [50]. We will refer to the APSP problem in directed unweighted graphs as UnweightedAPSP.

We present reductions from MinWitness and UnweightedAPSP to AE-MonoΔ with only polylogarithmic overhead.

▶ **Theorem 2.** *If* AE-MonoΔ *is in* $T(n)$ *time, then* MinWitness *is in* $\mathcal{O}(T(n)\log n)$ *time.*

▶ **Theorem 3.** *If* AE-MonoΔ *is in* $T(n)$ *time, then* UnweightedAPSP *is in* $\mathcal{O}\big(T(n)\log^2 n\big)$ *time.*

The above reductions tightly relate MinWitness and UnweightedAPSP to AE-MonoΔ if $\omega = 2$, showing that any improvement over the 2.5 exponent for AE-MonoΔ, gives the same improvement for MinWitness and UnweightedAPSP. Due to the tight reduction (Theorem 1) from AE-MonoΔ to AE-SparseΔ, we also obtain that an $\mathcal{O}\big(m^{4/3-\varepsilon}\big)$ time algorithm, with $\varepsilon > 0$, for AE-SparseΔ would give $\mathcal{O}\big(n^{2.5-\delta}\big)$ time algorithms, for $\delta > 0$, for MinWitness and UnweightedAPSP, presenting another tight relationship for the case when $\omega = 2$.

Our next result is that improving over the exponent 2.5 for AE-MonoΔ is at least as hard as obtaining a truly subquadratic time algorithm for the 3SUM problem.

▶ **Theorem 4.** *If* AE-MonoΔ *is in* $\mathcal{O}\big(n^{5/2-\varepsilon}\big)$ *time, then* 3*SUM is in (randomized)* $\widetilde{\mathcal{O}}\Big(n^{2-\frac{4}{5}\varepsilon}\Big)$ *time.*

In 3SUM one is given n integers and is asked whether three of them sum to 0. The problem is easy to solve in $\mathcal{O}\big(n^2\big)$ time, and slightly subquadratic time algorithms exist [4, 11]. 3SUM is a central problem in fine-grained complexity [43]. It is hypothesized to require $n^{2-o(1)}$ time (on a word-RAM with $\mathcal{O}(\log n)$ bit words), and many fine-grained hardness results are conditioned on this hypothesis (see [22, 43]). Our reduction shows that, under the 3SUM Hypothesis, the exponent 2.5 for AE-MonoΔ cannot be beaten, and this is tight if $\omega = 2$. We note that before our work no intermediate matrix, graph, or convolution problem was known to be 3SUM-hard.

Next, we consider the Min-Max product (Min-Max) of two matrices A and B, defined as $C_{ij} = \min_k \max(A_{ik}, B_{kj})$. The Min-Max product is equivalent to the aforementioned Max-Min product (just negate the matrix entries) and the All-Pairs Bottleneck Paths problem, and is thus solvable in $\mathcal{O}\big(n^{(3+\omega)/2}\big)$ time [19].

A very simple folklore reduction shows that Min-Max on $n \times n$ integer matrices is at least as hard as MinWitness on $n \times n$ Boolean matrices, giving a tight relationship when $\omega = 2$.

▶ **Theorem 5** (folklore)**.** *If* Min-Max *is in* $T(n)$ *time, then* MinWitness *is in* $\mathcal{O}(T(n))$ *time.*

Our next result states that All-Pairs Shortest Paths in directed unweighted graphs (UnweightedAPSP) is also tightly reducible to Min-Max. This gives a second intermediate problem that is at least as hard as both MinWitness and UnweightedAPSP.

▶ **Theorem 6.** *If* Min-Max *is in* $T(n)$ *time, then* UnweightedAPSP *is in* $\mathcal{O}(T(n)\log n)$ *time.*

The above theorem also follows from a recent independent result by Barr, Kopelowitz, Porat and Roditty [5]. In particular, they reduce All-Pairs Shortest Paths in directed graphs with edge weights from $\{-1, 0, 1\}$ to Min-Max. Interestingly, they use a substantially different approach than ours. While their argument can be seen as inspired by Seidel's algorithm for unweighted APSP in undirected graphs [34], ours resembles Zwick's algorithm for directed graphs [50].

Reductions for Convolution Problems

Our main result for convolution problems regards the convolution version of AE-MonoΔ, which we call MonoConvolution: Given three integer sequences a, b, c, decide for each index i if there exists j such that $a_j = b_{i-j} = c_i$. We show that MonoConvolution is actually fine-grained equivalent to 3SUM.

▶ **Theorem 7.** *If* MonoConvolution *is in* $\mathcal{O}\left(n^{3/2-\varepsilon}\right)$ *time, then* 3SUM *is in (randomized)* $\widetilde{\mathcal{O}}\left(n^{2-\frac{4}{3}\varepsilon}\right)$ *time.*

▶ **Theorem 8.** *If* 3SUM *is in* $\mathcal{O}\left(n^{2-\varepsilon}\right)$ *time, then* MonoConvolution *is in* $\widetilde{\mathcal{O}}\left(n^{3/2-\varepsilon/4}\right)$ *time.*

This equivalence is arguably the first fine-grained equivalence between natural problems with *different* running time complexities: MonoConvolution is a problem in $\mathcal{O}\left(n^{3/2}\right)$ time, whereas 3SUM is in $\mathcal{O}\left(n^2\right)$ time, and a polynomial improvement on one of these running times would result in a polynomial improvement over the other. All previous fine-grained equivalences were between problems with the same running time exponent: the problems equivalent to APSP [44, 1] are all solvable in $\mathcal{O}\left(N^{1.5}\right)$ time where N is the size of their input, the problems equivalent to Orthogonal Vectors [12] or to $(\min, +)$-convolution [14] are all in quadratic time, the problems equivalent to CNF-SAT [13] are all in $\mathcal{O}(2^n)$ time, etc. While tight fine-grained reductions between problems with different running times are well-known, there was no such equivalence until our result, largely since it often seems difficult to reduce a problem with a smaller asymptotic running time to one with a larger running time, something our Theorem 8 overcomes. Note that the same apparent difficulty is overcome by the reduction from AE-MonoΔ to AE-SparseΔ in Theorem 1, as well as by the reductions from MinWitness and UnweightedAPSP to AE-SparseΔ, which follow from combining Theorems 2 and 3 with Theorem 1.

Theorem 8 together with Theorem 4 give a reduction from MonoConvolution to AE-MonoΔ. Previously reductions from a convolution to the corresponding graph/matrix problem were known only for problems with best known algorithms running in brute-force time, i.e. quadratic time for convolution and cubic time for product, e.g. $(\min, +)$-convolution and $(\min, +)$-product [7].

Finally, we relate MonoConvolution to an unweighted variant of a coin change problem [48, 28] that is related to the minimum word break problem [8]. Given a set of coin values from $\{1, 2, \ldots, n\}$, the CoinChange problem asks to determine for each integer value up to n what is the minimum number of coins (allowing repetitions) that sum to that value. We reduce CoinChange to MonoConvolution with only a polylogarithmic overhead. CoinChange is solvable in $\widetilde{\mathcal{O}}\left(n^{3/2}\right)$ time [9], and our reduction implies that any improvement over the known running times of MonoConvolution or 3SUM would also improve the running time for CoinChange.

▶ **Theorem 9.** *If* MonoConvolution *is in* $T(n)$ *time, then* CoinChange *is in* $\mathcal{O}\left(T(n)\log^2 n\right)$ *time.*

2 Preliminaries

In this section we recall formal definitions of all the problems involved in the reductions presented in the paper. We split these problems by their time complexity.

2.1 Problems in $\widetilde{\mathcal{O}}\left(n^{(3+\omega)/2}\right)$ time

▶ **Definition 10** (All-Edges Monochromatic Triangle, AE-MonoΔ). *Given an n-node graph G in which each edge has a color from 1 to n^2, decide for each edge whether it belongs to a* monochromatic *triangle, a triangle where all three edges have the same color.*

▶ **Definition 11** (Min-Max matrix product, Min-Max). *Given two $n \times n$ matrices A and B, compute matrix C such that*

$$C_{ij} = \min_k \max(A_{ik}, B_{kj}).$$

▶ **Definition 12** (Minimum Witness matrix product, MinWitness). *Given two $n \times n$ Boolean matrices A and B, compute matrix C such that*

$$C_{ij} = \min(\{k \mid A_{ik} = B_{kj} = 1\} \cup \{\infty\}).$$

▶ **Definition 13** (All-Pairs Shortest Paths in directed unweighted graphs, UnweightedAPSP). *Given an n-node unweighted directed graph $G = (V, E)$, compute for each pair of vertices $u, v \in V$ the length of a shortest path from u to v. Note that all path lengths will be in $\{0, 1, \ldots, n-1\} \cup \{\infty\}$.*

2.2 Problems in $\mathcal{O}\left(m^{2\omega/(\omega+1)}\right)$ time

▶ **Definition 14** (All-Edges Sparse Triangle, AE-SparseΔ). *Given an m-edge graph G decide for each edge whether it belongs to a triangle.*

2.3 Problems in $\mathcal{O}(n^2)$ time

▶ **Definition 15** (3SUM). *Given three lists, A, B and C, of n integers, determine if there exist $a \in A$, $b \in B$, and $c \in C$ such that $a + b = c$.*

Let us note that the 3SUM problem is defined in several different ways in literature. They differ as to whether the input is split into three list or all the numbers are in a single list, and whether one looks for $a + b = c$ or $a + b + c = 0$. All these variants are equivalent by simple folklore reductions.

2.4 Problems in $\widetilde{\mathcal{O}}(n^{1.5})$ time

▶ **Definition 16** (MonoConvolution). *Given three sequences a, b, c, all of length n, compute the sequence d such that*

$$d_i = \begin{cases} 1 & \text{if } \exists_j\ a_j = b_{i-j} = c_i, \\ 0 & \text{otherwise.} \end{cases}$$

▶ **Definition 17** (CoinChange). *Given a set of coin values $C \subseteq \{1, 2, \ldots, n\}$, assume you have for each $c \in C$ an infinite supply of coins of value c, and determine for each $v \in \{1, 2, \ldots, n\}$ the minimum number of coins that sums up to v.*

CoinChange can be solved in $\widetilde{\mathcal{O}}(n^{1.5})$ time [9]. The algorithm splits the coins into heavy coins, with weight at least $\sqrt{n}$, and light coins, with weight less than $\sqrt{n}$. The minimum sum for a value can use at most $\sqrt{n}$ heavy coins. By running FFT $\sqrt{n}$ times the algorithm produces a vector with the minimum number of heavy coins needed to sum to every value. That takes $\mathcal{O}(n^{1.5} \log n)$ time in total. Then a classical dynamic programming algorithm is run for the $\sqrt{n}$ light coins and n values, in $\mathcal{O}(n^{1.5})$ time.

2.5 Self-reducibility of 3SUM

In our proofs of Theorems 4 and 7 we use the following fact about 3SUM.

▶ **Lemma 18.** *For any $\alpha \in [0,1]$, a single instance of 3SUM of size n can be reduced to $\mathcal{O}(n^{2\alpha})$ instances of 3SUM of size $\mathcal{O}(n^{1-\alpha})$ each. The reduction runs in time linear in the total size of produced instances, and the original instance is a yes-instance if and only if at least one of the produced instances is a yes-instance.*

This fact appears in many 3SUM-related papers, e.g. [4, 26, 27, 31, 33]. In [4] it was proved using a randomized almost linear hashing scheme [17]. An alternative proof – using a domination argument to provide a deterministic reduction – appeared e.g. in [31, 25], and is based on ideas of [16].

3 Reductions for Graph and Matrix Problems

First, let us recall the algorithm of Vassilevska, Williams and Yuster [40] for AE-MonoΔ. We rephrase the argument so that it not only shows how to solve AE-MonoΔ in $\mathcal{O}(n^{(3+\omega)/2})$ time, but also proves that any polynomial improvement over the $\mathcal{O}(m^{2\omega/(\omega+1)})$ time algorithm of Alon, Yuster and Zwick [3] for AE-SparseΔ translates to a polynomial improvement for AE-MonoΔ.

▶ **Theorem 1** (implicit in [40])**.** *If* AE-SparseΔ *is in $\mathcal{O}(m^{2\omega/(\omega+1)-\varepsilon})$ time, for some $\varepsilon > 0$, then* AE-MonoΔ *is in $\mathcal{O}(n^{(3+\omega)/2-\delta})$ time, for some $\delta > 0$.*

Proof. Assume AE-SparseΔ is in $\mathcal{O}(m^\alpha)$ time. Take an AE-MonoΔ instance. For each color consider the subgraph composed of all the edges of that color. Each such subgraph constitutes an independent instance of AE-SparseΔ. However, simply using the $\mathcal{O}(m^\alpha)$ time algorithm on all of these instances is not efficient enough. Intuitively, some of the instances might be too dense.

Instead, for a parameter t to be determined later, take the t largest subgraphs (in terms of the number of edges). For each of them solve the problem by using fast matrix multiplication to compute the square of the adjacency matrix. This takes $\mathcal{O}(tn^\omega)$ time in total. Let m_i denote the number of edges in the i-th of the remaining subgraphs. Clearly, $\forall_i\ m_i \leqslant n^2/t$, and $\sum_i m_i \leqslant n^2$. On each of those subgraphs use the $\mathcal{O}(m^\alpha)$ time AE-SparseΔ algorithm. This takes an order of

$$\sum_i m_i^\alpha = \sum_i m_i \cdot m_i^{\alpha-1} \leqslant \sum_i m_i \cdot (n^2/t)^{\alpha-1} \leqslant n^2 \cdot (n^2/t)^{\alpha-1}$$

time. The total runtime is thus $\mathcal{O}(tn^\omega + n^{2\alpha}/t^{\alpha-1})$. Optimize by setting $t = n^{(2\alpha-\omega)/\alpha}$, and get an $\mathcal{O}(n^{\omega+2-(\omega/\alpha)})$ time.

Observe that for $\alpha = 2\omega/(\omega+1)$ the runtime is $\mathcal{O}(n^{(3+\omega)/2})$. Moreover, for $\alpha < 2\omega/(\omega+1)$ the exponent in the runtime becomes strictly smaller. ◀

Now, we proceed to show how to use AE-MonoΔ to solve two popular graph problems. We start with the problem of finding All-Pairs Least Common Ancestors in directed acyclic graphs, which is runtime-equivalent to MinWitness [15]. We reduce a single instance of MinWitness to $\log n$ instances of AE-MonoΔ.

▶ **Theorem 2.** *If* AE-MonoΔ *is in $T(n)$ time, then* MinWitness *is in $\mathcal{O}(T(n)\log n)$ time.*

Proof. The main idea is to use a parallel binary search. For each entry of the output matrix C we will keep an interval which that entry is guaranteed to lie in. With a single call to AE-MonoΔ we will be able to halve all the intervals.

W.l.o.g. assume the last column of A and last row of B are all ones, so that the output is always finite. For $\ell \in [\log n]$, let $C^{(\ell)}$ denote the matrix pointing to 2^ℓ-length intervals in which entries of C lie, that is $C^{(\ell)}_{ij}$ is the unique integer such that $C_{ij} \in \left[2^\ell \cdot C^{(\ell)}_{ij}, 2^\ell \cdot (C^{(\ell)}_{ij}+1)\right)$.

We will compute $C^{(\ell)}$ for $\ell = \lceil \log n \rceil, \ldots, 1, 0$. Observe that $C^{(\lceil \log n \rceil)}$ is the zero matrix. Knowing $C^{(\ell+1)}$, we compute $C^{(\ell)}$ as follows. We create a tripartite graph $G = (I \cup J \cup K, E)$, with each of I, J, K containing n vertices. We add edges between I and K according to the matrix A. Edges from the k-th column get the label $\lfloor k/2^\ell \rfloor$. We add edges between K and J according to the matrix B. Edges from the k-th row get the label $\lfloor k/2^\ell \rfloor$. Finally, we add the full bipartite clique between I and J. The edge between the i-th vertex of I and the j-th vertex of J gets the label $2 \cdot C^{(\ell+1)}$. That edge forms a monochromatic triangle if and only if $C_{ij} \in \left[2^\ell \cdot 2 \cdot C^{(\ell+1)}_{ij}, 2^\ell \cdot (2 \cdot C^{(\ell+1)}_{ij} + 1)\right)$, i.e. $C^{(\ell)}_{ij} = 2 \cdot C^{(\ell+1)}_{ij}$. Otherwise, it must be that $C_{ij} \in \left[2^\ell \cdot (2 \cdot C^{(\ell+1)}_{ij} + 1), 2^\ell \cdot (2 \cdot C^{(\ell+1)}_{ij} + 2)\right)$, i.e. $C^{(\ell)}_{ij} = 2 \cdot C^{(\ell+1)}_{ij} + 1$. Therefore, solving AE-MonoΔ on G suffices to compute $C^{(\ell)}$. Finally, observe that $C = C^{(0)}$. ◀

With a slightly more involved argument we show how to solve UnweightedAPSP with $\mathcal{O}(\log^2 n)$ calls to AE-MonoΔ.

▶ **Theorem 3.** *If* AE-MonoΔ *is in* $T(n)$ *time, then* UnweightedAPSP *is in* $\mathcal{O}(T(n) \log^2 n)$ *time.*

Proof. We solve UnweightedAPSP in $\log n$ rounds, in the i-th round we compute matrix $D^{\leqslant 2^i}$ of lengths of shortest paths of length up to 2^i (other entries equal to ∞). Each round will consist of a parallel binary search, similar to the one we use in our reduction from MinWitness to AE-MonoΔ (Theorem 2). The algorithm is based on the fact that in unweighted graphs every path can be split roughly in half, i.e. if the distance from u to v equals to k, then there must exist a vertex w such that the distances from u to w and from w to v equal to $\lfloor k/2 \rfloor + \{0, 1\}$.

To start, note that $D^{\leqslant 2^0}$ is a $\{0, 1, \infty\}$-matrix that can be easily obtained from the adjacency matrix of the input graph. Now, assume we already computed $D^{\leqslant 2^i}$ and let us proceed to compute $D^{\leqslant 2^{i+1}}$. To avoid excessive indexing, let A denote $D^{\leqslant 2^i}$, and B denote $D^{\leqslant 2^{i+1}}$. For each entry of the output matrix B we will keep an interval which that entry is guaranteed to lie in. With a single call to AE-MonoΔ we will be able to halve all the intervals.

For $\ell \in \{0, 1, \ldots, i+2\}$, let $B^{(\ell)}$ denote the matrix pointing to 2^ℓ-length intervals in which entries of B lie, that is $B^{(\ell)}_{uv}$ equals to the unique integer such that $B_{uv} \in \left[2^\ell \cdot B^{(\ell)}_{uv}, 2^\ell \cdot (B^{(\ell)}_{uv} + 1) - 1\right]$, or to infinity in case B_{uv} is infinite.

We will iterate over ℓ from $i+2$ down to 0. First, we need to compute $B^{(i+2)}$, whose entries are either zeros or infinities. Recall that we already know the matrix $A = D^{\leqslant 2^i}$. Consider a pair of nodes u and v that are at distance at most 2^{i+1}. There must exist a node w such that $A_{uw} \leqslant 2^i$ and $A_{wv} \leqslant 2^i$, that is, equivalently both A_{uw} and A_{wv} are finite. We obtain the matrix $B^{(i+2)}$ by squaring the $(0, 1)$ matrix obtained from A by putting ones at the finite entries and zeros elsewhere. That single matrix multiplication can be easily simulated by a single call to AE-MonoΔ, using just two colors.

Once we have the matrix $B^{(\ell+1)}$ we want to compute $B^{(\ell)}$. For this we first note that if $B^{(\ell+1)}_{uv} = j$ then $B^{(\ell)}_{uv}$ is either $2j$ or $2j+1$. If $B^{(\ell)}_{uv} = 2j$, then there must exist a vertex w such that

$$A_{uw} \in \big[2^{\ell-1}\cdot(2j), 2^{\ell-1}\cdot(2j+1)\big), \quad \text{and} \quad A_{wv} \in \big[2^{\ell-1}\cdot(2j), 2^{\ell-1}\cdot(2j+1)\big]. \tag{1}$$

Furthermore, if $B^{(\ell)}_{uv} > 2j$, then there is no w such that the above condition holds. This will allow us to distinguish between the $2j$ and $2j+1$ cases by coloring the matrix A based on which range the entries fall in. Note that the ranges in Condition (1) do not overlap with corresponding ranges for different integer values $j' \neq j$. Thus we will be able to use a single call to AE-MonoΔ to check in parallel for all values of $B^{(\ell)}_{uv}$ if they are the smaller even value $2\cdot B^{(\ell+1)}_{uv}$ or the larger odd value $2\cdot B^{(\ell+1)}_{uv}+1$.

We construct an AE-MonoΔ instance with a tripartite graph with the vertex set $U \sqcup V \sqcup W$ where U, V and W are disjoint copies of the original vertex set. The edges between U and V correspond to our desired output. If $B^{(\ell+1)}_{uv} = j$ then we color the edge $(u,v) \in U \times V$ with j. The edges between U and W correspond to the first part of Condition (1), i.e. if $A_{uw} \in \big[2^{\ell-1}\cdot(2j), 2^{\ell-1}\cdot(2j+1)\big)$, then we add the edge (u,w) to $U \times W$ with color j. The edges between W and V correspond to the second part of Condition (1), i.e. if $A_{wv} \in \big[2^{\ell-1}\cdot(2j), 2^{\ell-1}\cdot(2j+1)\big]$, then we add the edge (w,v) to $W \times V$ with color j. Any edge (u,v) in $U \times V$ that is in a monochromatic triangle implies $B^{(\ell)}_{uv} = 2\cdot B^{(\ell+1)}_{uv}$. Conversely, any edge (u,v) that is not a part of any monochromatic triangle implies $B^{(\ell)}_{uv} = 2\cdot B^{(\ell+1)}_{uv}+1$.

We iterate down until $B^{(0)}$, and observe that $B^{(0)} = B$. Thus, with $\mathcal{O}(\log n)$ calls we can compute $B = D^{\leqslant 2^{i+1}}$ from $A = D^{\leqslant 2^i}$. To solve UnweightedAPSP the total number of calls we need to make to AE-MonoΔ is $\mathcal{O}\big(\log^2(n)\big)$. Therefore, if AE-Mono$\Delta$ can be solved in $T(n)$ time then UnweightedAPSP can be solved in $\mathcal{O}\big(T(n)\log^2(n)\big)$ time. ◀

Now we show that AE-MonoΔ is 3SUM-hard. In our proof we use as a black-box the following reduction from 3SUM to AE-SparseΔ.

▶ **Lemma 19** (Kopelowitz, Pettie, Porat [27]). *A single instance of 3SUM of size n can be reduced to a single instance of* AE-SparseΔ *with $\Theta(n\log n)$ vertices and $\Theta\big(n^{3/2}\log n\big)$ edges.*

▶ **Theorem 4.** *If* AE-MonoΔ *is in $\mathcal{O}\big(n^{5/2-\varepsilon}\big)$ time, then 3SUM is in (randomized) $\widetilde{\mathcal{O}}\Big(n^{2-\frac{4}{5}\varepsilon}\Big)$ time.*

Proof. Given an instance of 3SUM of size N, we use the self-reduction (Lemma 18), and reduce it to $\mathcal{O}\big(N^{2/5}\big)$ instances of size $\mathcal{O}\big(N^{4/5}\big)$ each. Then, we reduce each of these instances to an AE-SparseΔ instance with $n = \Theta\big(N^{4/5}\log N\big)$ vertices and $m = \Theta\big(N^{6/5}\log N\big)$ edges, using Lemma 19. Now we will show how to combine these $\mathcal{O}\big(N^{2/5}\big)$ AE-SparseΔ instances to form polylogarithmically many AE-MonoΔ instances, each with $\mathcal{O}\big(N^{4/5}\log N\big)$ vertices, which will finish the proof.

Assume w.l.o.g. that all the created graphs are over the same vertex set $[n]$. If we were lucky enough and the edge sets of the created AE-SparseΔ instances were disjoint, the reduction would be essentially done. Indeed, we could simply union the edge sets to create a single graph, and use colors to track from which graph every edge originates. Solving that one AE-MonoΔ instance would provide answers to all AE-SparseΔ instances. Sadly, the chances of such a favorable collision-free scenario are very slim. The remaining part of the proof shows how to deal with multiple AE-SparseΔ instances containing the same edge.

We randomly permute the vertex sets, for each graph independently. For a fixed $(u,v) \in [n]^2$, the probability that a fixed graph contains the edge (u,v) equals to $p = m/\binom{n}{2} = \mathcal{O}\big((N^{2/5}\log N)^{-1}\big)$. The expected number of (u,v) edges across all graphs is $\mathcal{O}\big(N^{2/5}\cdot p\big) = \mathcal{O}(1/\log N)$. By a Chernoff bound, the probability that the number of (u,v) edges exceeds

$c \log n$ is less than $e^{\Theta(c \log n)}$. We take c large enough so that, by union bound, with probability at least $1/2$ no edge appears more than $c \log n$ times across all graphs. For each $(u, v) \in [n]^2$ we arbitrarily number all (u, v) edges with consecutive positive integers from 1 up to at most $c \log n$. We iterate over all triples $(i, j, k) \in [c \log n]^3$. For every triple we create a tripartite graph with the vertex set $V_1 \sqcup V_2 \sqcup V_3$, for $V_1 = V_2 = V_3 = [n]$. We create an edge (u, v) between V_1 and V_2 if there exists an edge (u, v) with number i assigned to it in any of the AE-SparseΔ instances. Note that there can be at most one such instance. We set the color of the newly created edge to the identifier of the instance it originates from. Similarly, we create edges between V_2 and V_3 using edges with number j assigned, and between V_3 and V_1 using number k. That gives us $(c \log n)^3$ instances of AE-MonoΔ. Note that every triangle present in any of the AE-SparseΔ instance corresponds to a single monochromatic in one of the AE-MonoΔ instances, and vice versa. We solve all AE-MonoΔ instances and combine the outputs in order to get the output for all AE-SparseΔ instances, and eventually for the 3SUM instance. ◀

The next two theorems use techniques similar to Theorems 2 and 3 to give reductions to Min-Max.

▶ **Theorem 5** (folklore). *If* Min-Max *is in* $T(n)$ *time, then* MinWitness *is in* $\mathcal{O}(T(n))$ *time.*

Proof. Given two $(0, 1)$ matrices A and B, we construct matrices A' and B' such that

$$A'_{ik} = \begin{cases} k & \text{if } A_{ik} = 1, \\ \infty & \text{if } A_{ik} = 0, \end{cases} \quad \text{and} \quad B'_{kj} = \begin{cases} k & \text{if } B_{kj} = 1, \\ \infty & \text{if } B_{kj} = 0. \end{cases}$$

Observe that the $(\min, \max)$-product of A' and B' equals to the minimum witness product of A and B. ◀

▶ **Theorem 6.** *If* Min-Max *is in* $T(n)$ *time, then* UnweightedAPSP *is in* $\mathcal{O}(T(n) \log n)$ *time.*

Proof. The reduction is similar to the reduction from UnweightedAPSP to AE-MonoΔ (Theorem 3) in that we also have $\log n$ rounds, and in the i-th round we compute matrix $D^{\leqslant 2^i}$ of lengths of shortest paths of length up to 2^i (other entries equal to ∞). The key difference is that, in each round, instead of performing a binary search and issuing $\log n$ calls to AE-MonoΔ, we issue just two calls to Min-Max.

As before, first note that $D^{\leqslant 2^0}$ is a $\{0, 1, \infty\}$-matrix that can be easily obtained from the adjacency matrix of the input graph. Now, assume we already computed $D^{\leqslant 2^i}$ and let us proceed to compute $D^{\leqslant 2^{i+1}}$. Let $\ell = 2^i$. Naturally, $D^{\leqslant 2\ell}$ is the $(\min, +)$-product of $D^{\leqslant \ell}$ with itself, but this sole observation is not enough for our purposes. We will exploit the fact that $D^{\leqslant \ell}$ is not an arbitrary matrix – but a (truncated) matrix of shortest paths in an unweighted graph – in order to compute that specific $(\min, +)$-product using a Min-Max algorithm. Let $A \mathbin{⍉} B$ denote the $(\min, \max)$-product of matrices A and B.

First, we handle even-length paths. We compute $E = 2 \cdot (D^{\leqslant \ell} \mathbin{⍉} D^{\leqslant \ell})$. Note that $D^{\leqslant 2\ell}_{uv} \leqslant E_{uv}$ for all $u, v \in V$, because for any two integers a, b we have $a + b \leqslant 2 \cdot \max(a, b)$. Moreover, if $D^{\leqslant 2\ell}_{uv} = 2k$, then there must exist $w \in V$ such that $D^{\leqslant \ell}_{uw} = D^{\leqslant \ell}_{wv} = k$, and thus $D^{\leqslant \ell}_{uw} + D^{\leqslant \ell}_{wv} = 2 \cdot \max(D^{\leqslant \ell}_{uw}, D^{\leqslant \ell}_{wv})$ and $D^{\leqslant 2\ell}_{uv} = E_{uv}$.

For odd-length paths we proceed in a similar manner, just the formulas become slightly more obscure. We compute $O = 2 \cdot (D^{\leqslant \ell} \mathbin{⍉} (D^{\leqslant \ell} - 1)) + 1$. Note that $D^{\leqslant 2\ell}_{uv} \leqslant O_{uv}$ for all $u, v \in V$, because for any two integers a, b we have $a + b \leqslant 2 \cdot \max(a, b - 1) + 1$. Moreover, if $D^{\leqslant 2\ell}_{uv} = 2k + 1$, then there must exist $w \in V$ such that $D^{\leqslant \ell}_{uw} = k$ and $D^{\leqslant \ell}_{wv} = k + 1$, and thus $D^{\leqslant \ell}_{uw} + D^{\leqslant \ell}_{wv} = 2 \cdot \max(D^{\leqslant \ell}_{uw}, D^{\leqslant \ell}_{wv} - 1) + 1$ and $D^{\leqslant 2\ell}_{uv} = O_{uv}$.

Consequently, we compute $D^{\leqslant 2\ell}_{uv} = \min(E_{uv}, O_{uv})$, for all $u, v \in V$. ◀

4 Reductions for Convolution Problems

In this section we provide two reductions which together show that MonoConvolution is fine-grained equivalent to 3SUM. Recall that the best known algorithms for MonoConvolution require time $n^{3/2-o(1)}$, and the best algorithms for 3SUM require time $n^{2-o(1)}$, so this is an equivalence between problems of different time complexity. At the end of the section we reduce CoinChange to MonoConvolution.

First, let us recall the All-Integers variant of 3SUM, which parallels the All-Edges variants of our graph problems. That variant is easier to work with than the original 3SUM problem for our purposes. Luckily if either variant has a subquadratic algorithm then they both do [44].

▶ **Definition 20** (All-Integers 3SUM). *Given three lists A, B, C of n integers each, output the list of all integers $c \in C$ such that there exist $a \in A$ and $b \in B$ such that $a + b = c$.*

▶ **Lemma 21** (Vassilevska Williams, Williams [44]). *If 3SUM is in $\mathcal{O}(n^{2-\varepsilon})$ time, then All-Integers 3SUM is in $\mathcal{O}(n^{2-\varepsilon/2})$ time.*

An important ingredient of our reduction from 3SUM to AE-MonoΔ (Theorem 7) is the following range reduction for 3SUM.

▶ **Lemma 22** (Baran, Demaine, Pătraşcu, rephrased, see Section 2.1 of [4]). *For every positive integer output size s, there exists a family of hash functions H such that:*

1. *Every hash function $h \in H$ hashes to the range $\{0, 1, \ldots, R-1\}$ for $R = 2^s$.*
2. *For all integers $a, b, c \in \mathbb{Z}$ and all hash functions $h \in H$, if $a + b = c$, then*

$$h(a) + h(b) \equiv h(c) + \{-1, 0, 1\} \mod R.$$

3. *Given an integer c and two lists of n integers A and B such that there are no $a \in A, b \in B$ with $a + b = c$, the probability, over hash functions h drawn uniformly at random from H, that there exist $a \in A, b \in B$ such that $h(a) + h(b) \equiv h(c) + \{-1, 0, 1\} \mod R$ is at most $\mathcal{O}(n^2/R)$.*

We are now ready to show that 3SUM can be solved efficiently with a MonoConvolution algorithm. Our reduction uses the fact that we can re-write a 3SUM instance with n integers in $\{-R, \ldots, R\}$ as a convolution of $\mathcal{O}(R)$-length $(0, 1)$ vectors, where a one in the i-th position corresponds to the number i in the original 3SUM instance. We will combine several such instances into one MonoConvolution instance by giving each instance its own number. A one in position i in a convolution instance labelled j will result in the MonoConvolution instance having j in position i.

▶ **Theorem 7.** *If MonoConvolution is in $\mathcal{O}(n^{3/2-\varepsilon})$ time, then 3SUM is in (randomized) $\widetilde{\mathcal{O}}\left(n^{2-\frac{4}{3}\varepsilon}\right)$ time.*

Proof. Given an instance of 3SUM of size n, we reduce it to $\mathcal{O}(n^{2/3})$ instances of size $\mathcal{O}(n^{2/3})$ each, using the self-reduction (Lemma 18). Although for the self-reduction itself it would be sufficient just to solve 3SUM on each of these instances – i.e. decide if there exist a, b, c with $a + b = c$ – we are going to solve the All-Integers 3SUM variant – i.e. decide for each c if there exist a and b with $a + b = c$.

To each created instance we apply a hashing scheme of Lemma 22 in order to reduce the universe size down to $R = n^{4/3}$. This introduces false positives for each element with probability $\mathcal{O}((n^{2/3})^2)/R = \mathcal{O}(1)$. Note that the hashing has one-sided error, i.e. if for some

element c there are no a and b such that $h(a)+h(b) \equiv h(c)+\{-1,0,1\} \mod R$, then with certainty there are no a and b such that $a+b=c$. To mitigate the effect of false positives we create $\mathcal{O}(\log n)$ copies of each instance, each copy with an independently drawn hash function. Note that for every fixed element c, if there are no a, b with $a+b=c$, then the probability that in each of the independent $\mathcal{O}(\log n)$ copies we detect that $h(a)+h(b) \equiv h(c)+\{-1,0,1\} \mod R$ for some $h(a), h(b)$ is $1/\text{poly}(n)$, and we can make the degree of the polynomial arbitrarily large by choosing an appropriate multiplicative constant for the number of copies. Therefore we can use the union bound to argue that with at least $2/3$ probability there are no false positives across all instances and all elements.

Suppose that for some subinstance A, B, C of size $n^{2/3}$ we obtained for every one of the $\mathcal{O}(\log n)$ hashed instance copies, for every $t \in [R]$ for which there is some c with $h(c)=t$, whether there are some $h(a), h(b)$ with $h(a)+h(b) \equiv h(c)+\{-1,0,1\} \mod R$. Then, we can go through every $c \in C$ and if for every copy the answer for $h(c)$ was YES, we can conclude that (whp) $\exists a \in A, b \in B$ with $a+b=c$, and if the answer was NO at least once, then we can conclude that there is no pair that sums to c.

Here an important point is that we need to solve *all* of the $\mathcal{O}\left(n^{2/3}\log n\right)$ instances of All-Integers 3SUM above on $n^{2/3}$ integers each over a range $[\mathcal{O}\left(n^{4/3}\right)]$. We will embed solving all instances simultaneously into solving a small number of MonoConvolution instances.

Each of the above $\mathcal{O}\left(n^{2/3}\log n\right)$ instances of All-Integers 3SUM easily reduces to an (OR, AND)-convolution of $(0,1)$ vectors of length $\mathcal{O}\left(n^{4/3}\right)$, each with only $\mathcal{O}\left(n^{2/3}\right)$ nonzero entries, and with only $\mathcal{O}\left(n^{2/3}\right)$ relevant output coordinates one needs to compute. If only we had no collisions – i.e. two instances with the same nonzero input coordinate or the same relevant output coordinate – we could easily combine all the convolution instances into a single instance of MonoConvolution, with $\mathcal{O}\left(n^{2/3}\log n\right)$ different colors/values. However, the collisions are unavoidable. In order to circumvent these collisions, we will add small random shifts, and use a similar analysis as in the 3SUM to AE-MonoΔ reduction of Theorem 4.

Specifically, for each instance we chose a shift s uniformly at random from a range of size $\mathcal{O}\left(n^{4/3}\right)$, we add s to all elements in A, add s to all elements in B, and add $-2s$ to all elements in C. Let the numbers after the shift lie in $\{-R', \ldots, R'\}$ where $R' = \mathcal{O}\left(n^{4/3}\right)$.

These shifts do not change whether for a given triplet a, b, c the condition $a+b=c$ holds or not. For a fixed value $v \in \{-R', \ldots, R'\}$ the expected number of instances containing v is $\mathcal{O}(\log n)$: for each particular instance, the probability that one of its numbers lands at v after the shift is $\mathcal{O}\left(n^{2/3}/R'\right) = \mathcal{O}\left(1/n^{2/3}\right)$; then summing over all the instances gives an expectation of $\mathcal{O}(\log n)$.

Since the shifts are independent, we can use a Chernoff bound to bound the probability that the number of instances containing v exceeds $c\log n$ by $\leqslant e^{\Theta(c\log n)}$. We take c large enough so that, by union bound, the probability that no value is contained in more than $c\log n$ instances is at least $2/3$.

Then, once again following the example of Theorem 4, we reduce the problem to $(c\log n)^3$ instances of MonoConvolution as follows.

For each value $r \in \{-R', \ldots, R'\}$, let the instances that contain r in their A sets be $in_A(r)[1], \ldots, in_A(r)[c\log n]$. Define $in_B(r)[1], \ldots, in_B(r)[c\log n]$ and $in_C(r)[1], \ldots, in_C(r)[c\log n]$ analogously.

We now create an instance of MonoConvolution for each choice of $(x,y,z) \in [c\log n]^3$. In instance (x,y,z) we create vectors a, b, c, where for each $r \in \{-R', \ldots, R'\}$, we set $a_r = in_A(r)[x]$, $b_r = in_B(r)[y]$ and $c_r = in_C(r)[z]$.

Then for any instance i that contains r in A, s in B and t in C, we would have $in_A(r)[x] = in_B(s)[y] = in_C(t)[z] = i$ for some x, y, z and so we will place i in a_r, b_s, and c_t for that choice of x, y, z. Thus all value collisions will be handled. ◀

This next reduction finishes the equivalence between MonoConvolution and 3SUM. It uses a high-frequency/low-frequency split. For elements that appear at a high frequency we use FFT. For elements of low frequency we make calls to All-Integers 3SUM. Recall that a subquadratic algorithm for 3SUM implies a subquadratic algorithm for All-Integers 3SUM.

▶ **Theorem 8.** *If 3SUM is in $\mathcal{O}(n^{2-\varepsilon})$ time, then* MonoConvolution *is in $\widetilde{\mathcal{O}}(n^{3/2-\varepsilon/4})$ time.*

Proof. For a parameter t to be determined later, consider the t most frequent values. For each of these values use FFT to calculate the standard $(+,\times)$-convolution of two $(0,1)$ vectors formed from vectors a and b by putting ones everywhere that value appears, and zeros everywhere else. Examine, where the outputs of these convolutions are nonzero, in order to determine the part of output to MonoConvolution corresponding to occurrences of the frequent values in vector c. This takes $\widetilde{\mathcal{O}}(tn)$ time in total.

Let n_i denote the number of occurrences of the i-th of the remaining values in all three sequences. Clearly, $\forall_i\ n_i \leqslant 3n/t$, and $\sum_i n_i \leqslant 3n$. For each value v out of those remaining values construct sets of indices at which it appears in vectors a, b, c, i.e. $A = \{j : a_j = v\}$, $B = \{j : b_j = v\}$, $C = \{j : c_j = v\}$, and solve All-Integers 3SUM on these sets. For each element j reported by the All-Integers 3SUM algorithm assign the corresponding output of MonoConvolution $d_j = 1$. By Lemma 21, solving these All-Integers 3SUM instances takes an order of

$$\sum_i n_i^{2-\varepsilon/2} = \sum_i n_i \cdot n_i^{1-\varepsilon/2} \leqslant \sum_i n_i \cdot (3n/t)^{1-\varepsilon/2} \leqslant 3n \cdot (3n/t)^{1-\varepsilon/2}$$

time. The total time is thus $\widetilde{\mathcal{O}}\big(tn + n \cdot (n/t)^{1-\varepsilon/2}\big)$. Optimize by setting $t = n^{1/2-\varepsilon/4}$, and get the desired runtime. ◀

The following theorem connects the CoinChange problem to our network of reduction. The proof uses the same structure and techniques as the reduction from UnweightedAPSP to AE-MonoΔ in Theorem 3.

▶ **Theorem 9.** *If* MonoConvolution *is in $T(n)$ time, then* CoinChange *is in $\mathcal{O}\big(T(n)\log^2 n\big)$ time.*

Proof. Let S denote the array of output values, i.e. $S[v]$ equals to the minimum number of coins that sum to v. Parallel to the proof of Theorem 3, let $S^{\leqslant 2^i}[v]$ be infinity if $S[v] > 2^i$, and otherwise equal to $S[v]$. We solve CoinChange in $\log n$ rounds, in the i-th round we compute $S^{\leqslant 2^i}$.

Note that $S^{\leqslant 2^0}[0] = 0$, and, for $v \geqslant 1$, $S^{\leqslant 2^0}[v] = 1$ if $v \in C$ and $S^{\leqslant 2^0}[v] = \infty$ otherwise. Further note that $S = S^{\leqslant 2^{\log n}}$. We will show how to compute $S^{\leqslant 2^{i+1}}$ given $S^{\leqslant 2^i}$. We will then iterate i from 0 up to $\log n$.

Following the style of Theorem 3, we avoid overparameterizing by setting $A = S^{\leqslant 2^i}$ and $B = S^{\leqslant 2^{i+1}}$. Let $B^{(\ell)}$ be an array pointing to 2^ℓ-length intervals in which entries of B lie, i.e. $B^{(\ell)}[v] = j$ if $B[v] \in [2^\ell j, 2^\ell(j+1) - 1]$. We will iterate ℓ from $i+2$ down to 0 to compute B from A.

First we show how to compute $B^{(i+2)}$ from A. If there is a way to sum to v with at most 2^{i+1} coins, then there must be a $u \in [0, n]$ such that both $A[u]$ and $A[v-u]$ are at most 2^i. Conversely, if there is no way to sum to v with at most 2^i coins, then there will be no u that meets the above criteria. Therefore we create a $(0,1)$ vector a with $a_v = 1$ if and only if $A[v]$ is finite. Then, we compute the $(+,\times)$-convolution of a with itself, in near-linear time using FFT. We set $B[v] = 0$ where the convolution output is non-zero and $B[v] = \infty$ everywhere else.

Now we show how to compute $B^{(\ell)}$ from A and $B^{(\ell+1)}$. Note that if $B^{(\ell+1)}[v] = j$ then $B^{(\ell)}[v] \in \{2j, 2j+1\}$. Next, note that if $B^{(\ell)}[v] = 2j$, then there must exist an integer $u \in [0, n]$ such that

$$A[u] \in \big[2^{\ell-1} \cdot (2j), 2^{\ell-1} \cdot (2j+1)\big), \quad \text{and} \quad A[v-u] \in \big[2^{\ell-1} \cdot (2j), 2^{\ell-1} \cdot (2j+1)\big]. \quad (2)$$

Furthermore, if $B^{(\ell)}[v] > 2j$, then there is no u such that the above condition holds. This will allow us to distinguish between the $2j$ and $2j+1$ cases. Note that the ranges in Condition (2) do not overlap with corresponding ranges for different integer values $j' \neq j$. Thus, we will be able to use a single call to MonoConvolution to check in parallel for all values v if $B^{(\ell)}[v]$ is the smaller even value $2B^{(\ell+1)}[v]$ or the larger odd value $2B^{(\ell+1)}[v] + 1$.

We construct a MonoConvolution instance with three input vectors a, b, c. The first input vector corresponds to the first part of Condition (2), i.e. if $A[v] \in \big[2^{\ell-1} \cdot (2j), 2^{\ell-1} \cdot (2j+1)\big)$, then $a_v = j$. Any entries a_v unset by this condition are given the special value $a_v = -1$. The second vector corresponds to the second part of Condition (2), i.e. if $A[v] \in \big[2^{\ell-1} \cdot (2j), 2^{\ell-1} \cdot (2j+1)\big]$, then $b_v = j$. Similarly, any entries b_v unset by this condition are given the special value $b_v = -1$. The last vector corresponds to our desired output, i.e. $c_v = B^{(\ell+1)}[v]$. Let d denote the vector output by this MonoConvolution call. Now, if $d_v = 1$ then $B^{(\ell)}[v] = 2B^{(\ell+1)}[v]$, else $B^{(\ell)}[v] = 2B^{(\ell+1)}[v] + 1$.

We iterate down until $B^{(0)}$, and observe that $B^{(0)} = B$. Thus, with $\mathcal{O}(\log n)$ calls to MonoConvolution we can compute $B = S^{\leqslant 2^{i+1}}$ from $A = S^{\leqslant 2^i}$. To solve CoinChange the total number of MonoConvolution calls is $\mathcal{O}\big(\log^2 n\big)$. Therefore if MonoConvolution can be solved in $T(n)$ time, then CoinChange can be solved in $\mathcal{O}\big(T(n) \log^2 n\big)$ time. ◀

Abstract

Is matching in NC, i.e., is there a deterministic fast parallel algorithm for it? This has been an outstanding open question in TCS for over three decades, ever since the discovery of randomized NC matching algorithms [17, 27]. Over the last five years, the theoretical computer science community has launched a relentless attack on this question, leading to the discovery of several powerful ideas. We give what appears to be the culmination of this line of work: An NC algorithm for finding a minimum-weight perfect matching in a general graph with polynomially bounded edge weights, provided it is given an oracle for the decision problem. Consequently, for settling the main open problem, it suffices to obtain an NC algorithm for the decision problem. We believe this new fact has qualitatively changed the nature of this open problem.

All known efficient matching algorithms for general graphs follow one of two approaches: given by [6] and [20]. Our oracle-based algorithm follows a new approach and uses many of ideas discovered in the last five years.

The difficulty of obtaining an NC perfect matching algorithm led researchers to study matching vis-a-vis clever relaxations of the class NC. In this vein, recently [10] gave a pseudo-deterministic RNC algorithm for finding a perfect matching in a bipartite graph, i.e., an RNC algorithm with the additional requirement that on the same graph, it should return the same (i.e., unique) perfect matching for almost all choices of random bits. A corollary of our reduction is an analogous algorithm for general graphs.

1 Introduction

Is matching in NC, i.e., is there a deterministic fast parallel[1] algorithm for finding a perfect or, more generally, a maximum matching in a general graph? This has been an outstanding open question in theoretical computer science for over three decades, ever since the discovery of RNC matching algorithms [17, 27]. Over the last five years, the TCS community has launched a relentless attack on this question, leading to the discovery of numerous powerful

[1] That runs in polylogarithmic time using polynomially many processors.

ideas [8, 32, 10, 1, 31]. We give what appears to be the culmination of this line of work: An NC algorithm for finding a minimum weight perfect matching in a general graph with polynomially bounded edge weights, provided it is given an oracle, say $\mathcal{O}$, for the decision problem. Consequently, for settling the main open problem, it suffices to obtain an NC algorithm for the decision problem. We believe this new fact has qualitatively changed the nature of this open problem. Henceforth, by *small weights* we will mean *polynomially bounded edge weights* and *acronym MWPM* will be short for *minimum weight perfect matching.*

The difficulty of obtaining an NC matching algorithm led researchers to study matching vis-a-vis certain clever relaxations of the class NC. One such relaxation is pseudo-deterministic RNC. This is an RNC algorithm with the additional property that on the same graph, it must return the same (i.e., unique) solution for almost all choices of random bits [9, 10]. Recently, [10] gave such an algorithm for perfect matching in bipartite graphs. A second relaxation of NC is quasi-NC, under which the algorithm must run in polylogarithmic time, though it can use $O(n^{\log^{O(1)} n})$ processors; see Section 1.1 for results obtained for this model.

A corollary of our result extends [10] to general graphs as follows: The precise decision problem for our result is: Given a graph G with small weights and a number W, is there a perfect matching of weight at most W in G. Clearly, this is NC equivalent to: Find the weight of a minimum weight perfect matching in G. This question is easy to answer in RNC with inverse-polynomial probability of error using the algorithm of [27]. Therefore, using this RNC algorithm in place of the oracle we get an RNC matching algorithm with the property that in a run, all queries to the decision problem will be answered correctly with overwhelming probability, i.e., this is a pseudo-deterministic RNC matching algorithm.

All known efficient matching algorithms for general graphs follow one of two approaches: given by [6] and [20]. Our oracle-based algorithm follows a new approach and uses many of ideas discovered in the last five years. In particular, it uses the overall structure of the recent NC algorithm of [1] for finding a perfect matching in planar graphs. Since oracle $\mathcal{O}$ can be implemented in NC for planar graphs, our current paper yields a simpler NC algorithm for finding a perfect matching in planar graphs. The second key ingredient which made our current result possible is an NC algorithm for finding a maximal laminar family of tight odd sets in a given face of the perfect matching polytope. This follows from the works of [4] and [31].

Our main result is:

▶ **Theorem 1.** *There is an* NC *algorithm for finding a minimum weight perfect matching in general graphs with small weights, provided the algorithm is given access to oracle $\mathcal{O}$ for the decision problem. The latter is: Given a graph G with small weights and a target weight W, is there a perfect matching of weight at most W in G?*

▶ **Corollary 2.** *There is an* NC *algorithm for finding a maximum matching in general graphs, provided the algorithm is given access to the oracle $\mathcal{O}$.*

▶ **Corollary 3.** *There is a pseudo-deterministic* RNC *algorithm for finding a minimum weight perfect matching in general graphs with small weights.*

We further show that our algorithms only need to call the decision oracle for minors of the input graph.

▶ **Theorem 4.** *Let $\mathcal{F}$ be a minor-closed family of graphs. If there is an* NC *algorithm for deciding whether a perfect matching of weight at most W exists in graphs from $\mathcal{F}$, weighted with polynomially small weights, then there is also an* NC *algorithm for* finding *a MWPM in such graphs.*

1.1 Related work and a brief history of parallel matching algorithms

The notion of a pseudo-deterministic algorithm with polynomial expected running time was given by [9]. Such an algorithm runs in expected polynomial time and is required to output the same (i.e., unique) solution on a given instance on each run with high probability. Hence, in this sense, it resembles a deterministic algorithm. [9] gave pseudo-deterministic polynomial expected running time algorithms for several number theoretic and cryptographic problems. The notion of pseudo-deterministic RNC algorithms was defined by [10].

An RNC algorithm for the decision problem, of determining if a graph has a perfect matching, was obtained by [20], using the Tutte matrix of the graph. The first RNC algorithm for the search problem, of actually finding a perfect matching, was obtained by [18]. This was followed by a simpler and more versatile algorithm due to [27]; besides perfect matching, it also yielded RNC algorithms for the problem of exact matching (see Section 8) and for finding a MWPM in a graph with small weights. The latter fact is crucially used for obtaining pseudo-deterministic RNC algorithms for bipartite graphs [10] and general graphs (current paper). The "philosophy" behind [27] will be useful for dealing with a difficulty that arises in the design of the current algorithm as well, so it is recalled below[2].

The matching problem occupies an especially distinguished position in the theory of algorithms: Some of the most central notions and powerful tools within this theory were discovered in the context of an algorithmic study of this problem, including the notion of polynomial time solvability [6], the counting class #P [33] and a polynomial time equivalence between random generation and approximate counting for self-reducible problems [15], which lies at the core of the Markov chain Monte Carlo method. The perspective of parallel algorithms has also led to such a gain, namely the Isolation Lemma [27], which has found several applications in complexity theory and algorithms. Considering the fundamental insights gained from an algorithmic study of perfect matchings, the problem of obtaining an NC algorithm for it has remained a premier open question ever since the 1980s.

The first substantial progress on this question was made for the case of planar bipartite graphs by [26] via a flow-based approach, followed by [24] using the fact that there is an NC algorithm for counting perfect matchings in planar graphs. The long-standing problem of extending this result to non-bipartite planar graphs was resolved by [1]. Subsequently, [31] also got the same result using different ideas. [1] also extended their algorithm to constant genus graphs. Subsequently, [7] gave an NC algorithm for perfect matching in one-crossing-minor-free graphs, which include K_5-free graphs and $K_{3,3}$-free graphs; the resolution of the latter class settles a thirty-year-old open problem asked in [34].

The quasi-NC algorithms for matching and its generalizations, mentioned above, work by achieving a partial derandomization of the Isolation Lemma. First, [8] gave a quasi-NC algorithm for perfect matching in bipartite graphs, which was followed by the algorithm of [32] for general graphs. Algorithms were also obtained for the generalization of bipartite matching to the linear matroid intersection problem by [11], and to a further generalization of isolating a vertex of a polytope with faces given by totally unimodular constraints, by [12].

[2] Under the NC model, any one processor does not even have enough time to read the entire input, and hence can perform only local computations. On the other hand, a perfect matching is a global object, unlike say, a maximal independent set. Further difficulties arise from the fact that the number of perfect matchings in a graph can vary widely, all the way from one to exponentially many (assuming it has at least one). If there were a unique perfect matching in the graph, the algorithm's task would become a lot simpler. [27] achieve uniqueness via a powerful probabilistic fact, the Isolating Lemma: under an assignment of randomly chosen small weights to the edges it claims that the MWPM will be unique with high probability.

1.2 What is the "right" decision problem?

Consider the following two decision problems for perfect matching:

- Given a graph G with small weights and a target W, is there a perfect matching of weight at most W in G?
- Does graph G have a perfect matching?

Clearly, the second can be reduced to the first and is therefore "easier". This leads to a legitimate question: why not attempt to reduce, in NC, the search problem to the second decision problem? Our experience suggests that the first problem is much more basic for the setting at hand. We next provide evidence to this effect.

Seeking a MWPM in a graph with small weights was the central problem in the work of [27]. The Isolating Lemma helped find small weights under which there was a unique MWPM. The second half of [27] gave an NC algorithm for finding this (unique) perfect matching, using the Tutte matrix of the graph and matrix inversion; the latter is known to be in NC [3]. Ever since then, perhaps the most popular avenue for obtaining an NC matching algorithm has been to derandomize the Isolating Lemma. This would deterministically yield small weights under which there is a unique MWPM, and it could be found using the second half of [27].

The question of MWPM in a graph with small weights plays a central role in NC-type approaches to all non-bipartite, and even some bipartite, perfect matching algorithms: partial derandomization leading to quasi-NC algorithms [8, 32], resolution of the open problem of non-bipartite planar graphs [1, 31], and quasi-deterministic RNC algorithms for bipartite [10] and general graphs (current paper).

In mathematics, sometimes solving the harder problem turns out to be easier than solving the easier one, if the former has a better "behavior". Our belief is that this is the case here.

1.3 Bipartite vs non-bipartite matching: An intriguing phenomenon

Decades of algorithmic work on the matching problem, from numerous perspectives, exhibits the following intriguing phenomenon: The bipartite case gets solved first. Then, using much more elaborate machinery, the general graph case also follows and yields the exact same result! This phenomenon is made all the more fascinating by the fact that the "elaborate machinery" consists not of one fact but numerous different structural properties and mathematical facts which happen to be just right for the problem at hand! We give a number of examples below.

The duality between maximum matching and minimum vertex cover for bipartite graphs extends to general graphs via the notion of an odd set cover, see [21]. The formulation of the perfect matching polytope for bipartite graphs extends by introducing constraints corresponding to odd sets [6]. Polynomial time algorithms for maximum matching and maximum weight matching in bipartite graphs generalize via the notion of blossoms [21]. The most efficient known algorithm for maximum matching in bipartite graphs [13, 19] obtained via an alternating breadth first search, extends via a much more elaborate algorithm with the same running time via the graph search procedure of double depth first search [25] and blossoms defined from the perspective of minimum length alternating paths [35]. The RNC matching algorithms [18, 27] use Tutte's theorem to extend to general graphs. The randomized matching algorithm of [30] uses Tutte's theorem and a theorem of Frobenius about ranks of sub-matrices of skew-symmetric matrices.

More recent work exhibits this phenomenon as well. The quasi-NC algorithm of [8] for bipartite graphs extends by handling tight odd cuts appropriately [32]. The NC algorithm of [24] for planar bipartite graphs was extended to non-bipartite graphs via Edmonds' formulation of the perfect matching polytope [6], an NC algorithm for max-flow in planar

graphs [16], and a result of [28] proving that the Gomory-Hu tree of a graph must contain a tight odd cut, and an elaborate NC algorithm for uncrossing tight odd cuts [1]. In the same vein, the current paper is extending the pseudo-deterministic RNC bipartite algorithm of [10] by giving a way of dealing with tight odd cuts in Edmonds' formulation of the perfect matching polytope [6] and using an NC procedure for finding a maximal laminar family of tight odd cuts [4, 31].

2 Overview and Technical Ideas

Most of this paper will concentrate on the problem of finding a perfect matching in a general graph in NC, given oracle $\mathcal{O}$. In Section 6.1 we will extend our ideas to finding a MWPM for small weights. Then, an algorithm for finding a maximum matching in a general graph in NC will easily follow. In this section, we will also give a number of key definitions which will be used throughout the paper.

2.1 The bipartite case

For ease of comprehension, we will first give an outline of a proof of Theorem 1 for the case of bipartite graphs. Such a proof can be gleaned from the paper of [10]; however, to the best of our knowledge, this important fact was not derived so far. Below, we build on the quasi-NC algorithm of [8] to obtain a somewhat simpler proof of this result.

The algorithm of [8] first starts with the perfect matching polytope and then iteratively moves to lower dimensional faces of this polytope, terminating when a vertex of the polytope is reached; this will be a perfect matching.

▶ **Definition 5.** *In a general graph $G = (V, E)$ with edge weight function w, an edge e is called an* allowed edge *if it participates in MWPM. Let $E[w]$ denote the set of all allowed edges. Edges in the complement of this set will be called* disallowed edges.

Assume w are small weights and let $\mathrm{PM}[w]$ denote the face of the polytope containing all fractional and integral MWPMs w.r.t. w. Since we are in the bipartite case, $\mathrm{PM}[w]$ has a simple description: It is defined by the set of disallowed edges, since they are set to zero, or equivalently its complement, i.e., the set of allowed edges, $E[w]$. The description of the algorithm given above can be refined to: Iteratively modify the weight vector w so that the dimension of face $\mathrm{PM}[w]$ keeps dropping, and equivalently $E[w]$ keeps getting sparser, until $E[w]$ is a perfect matching.

As argued earlier, using oracle $\mathcal{O}$, we can find the weight of a MWPM in G. Further, it is easy to see that for a given edge e, we can determine in NC if e participates in a MWPM, i.e., if $e \in E[w]$. Repeating for all edges in parallel, we can compute $E[w]$ in NC. The following is a fundamental notion in all recent NC-type matching algorithms:

▶ **Definition 6** ([5])**.** *Number the edges of an even cycle C in a general graph G with edge-weights w starting from an arbitrary edge. The* circulation of cycle C *is the absolute value of the difference of the sum of weights of odd-numbered and even-numbered edges and is denoted* $\mathrm{circ}_w(C)$.

It is easy to prove that if the MWPM in G is not unique, then any cycle in the symmetric difference of two such matchings must have zero circulation[3].

[3] Hence, if we find a weight vector w such that each cycle in G has nonzero circulation, then the MWPM must be unique and can be found in NC.

▶ **Proposition 7** ([8]). *In a bipartite graph, let cycle $C \subseteq E[w]$ have $\mathrm{circ}_w(C) = 0$. Let G denote the graph on edge set $E[w]$. Assign small weights w' to edges $E[w]$ so that $\mathrm{circ}'_w(C) > 0$. Then C will not be present in $E[w']$, i.e., at least one of its edges will be dropped in going from $E[w]$ to $E[w']$. We will say that C got* destroyed.

Hence, if we find a weight vector that destroys all cycles of G, we would be done. However, G may have exponentially many cycles, so this is non-trivial. One of the key ideas of [8] is a systematic way of destroying cycles: They iteratively destroy cycles of length $4, 8, 16, \ldots, n$; clearly, the number of iterations needed is $O(\log n)$. In the first round, G has at most $O(n^4)$ cycles of length 4. [8] show that if all cycles of length at most 2^i have already been destroyed, then there are at most $O(n^4)$ cycles of length at most 2^{i+1} left. Hence, in each iteration only $O(n^4)$ cycles need to be destroyed.

Suppose the current iteration starts with small weights w under which all cycles of length at most 2^i have already been destroyed. In this iteration, the algorithm finds a weight vector w' for the edges in $E[w]$ under which all cycles of length at most 2^{i+1} are destroyed. The following fact will play a central role in the current paper as well:

▶ **Proposition 8** ([8]). *In order to destroy any set of s cycles, it suffices to try certain well-chosen $O(n^2 s)$ integral weight vectors each of which uses numbers that are $O(n^2 s)$; one of these vectors is sure to work.*

Since in the current iteration $s = O(n^4)$, at most $O(n^6)$ weight vectors suffice. The algorithm for choosing a weight vector that works is as follows. In parallel, for each of the $O(n^6)$ weight vectors, y, compute $E[y]$ and find the girth of the resulting graph; this can easily be done in NC. Pick the lexicographically first weight vector, say w', such that $E[w']$ has girth $> 2^{i+1}$. Clearly, w' destroys all cycles of length at most 2^{i+1}.

2.2 Extension to general graphs

Matching algorithms for general graphs, in different computational models, are far harder because they need to handle odd cycles in special ways. The set of constraints capturing the perfect matching polytope is also more complex: it includes exponentially many odd set constraints. An odd set $S \subset V$ which satisfies this constraint with equality is called a *tight odd set*. The description of face $\mathrm{PM}[w]$ is also much more involved: in addition to edges $E[w]$, we need a maximal laminar family of tight odd sets, say $\mathcal{L}$; see Section 3.2.

The "engine" underlying our algorithm

Analogous to the bipartite case, there is an "engine" underlying our algorithm as well – it iteratively reduces the size of the graph. This engine can be thought of as composed of three components which draw on different domains to establish structural facts and algorithms.

2.2.1 Component based on the structure of the perfect matching polytope

Proposition 7, which yielded the "engine" for the bipartite case, does not hold in general graphs. Thus a non-bipartite graph may have an even cycle $C \subseteq E[w]$ with $\mathrm{circ}_w(C) > 0$. The reason for this is the presence of a tight odd set. As a result, Proposition 7 needs to be enhanced to the fact stated below. We will say that a cycle C *crosses* a tight odd set S if C has vertices in S as well as in $(V - S)$. Similarly, edge e *crosses* S if one of its endpoints is in S and the other is in $V - S$.

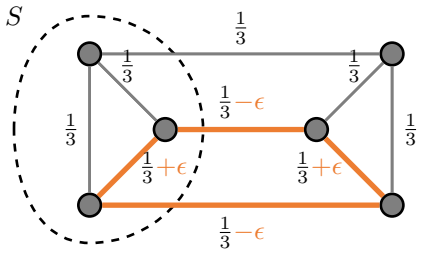

Figure 1 The orange even cycle crosses tight odd set S; example due to [8, 32].

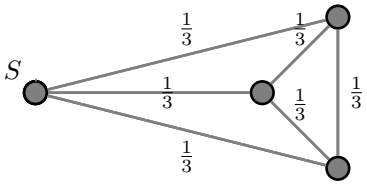

Figure 2 Resulting graph after shrinking tight odd set S.

▶ **Proposition 9** ([32]). *In a general graph G, suppose even cycle $C \subseteq E[w]$ has* $\text{circ}_w(C) > 0$. *Then, there must be a tight odd set S such that C* crosses *S.*

This is illustrated in Figure 1. In this graph, the three edges in $\delta(S)$ have weight 1 and the rest have weight 0. Observe that each edge participates in a MWPM and hence $E[w]$ consists of all edges. The cycle consisting of the four orange edges, say C, has positive circulation even though it is contained in $E[w]$. Cycle C crosses tight odd set S.

▶ **Definition 10.** *Assume that even cycle C* crosses *tight odd set S. Number the edges of C starting from an arbitrary edge. Let n_o and n_e denote the number of odd-numbered and even-numbered edges, respectively, that cross S. Then the* mismatch of C and S, *denoted* $\text{mismatch}(C, S)$, *is $|n_o - n_e|$.*

Note that in Figure 1, $\text{mismatch}(C, S) = 2$. Observe that if the MWPM is not unique and C is a cycle in the symmetric difference of two such perfect matchings then the following must hold:

- $\text{circ}_w(C) = 0$.
- If C crosses a tight odd set S, then $\text{mismatch}(C, S) = 0$; the reason is that each perfect matching crosses each tight set exactly once.

▶ **Proposition 11** (Lemma 25). *Consider a general graph G with weights w and even cycle $C \subseteq E[w]$ with* $\text{circ}_w(C) > 0$. *Let S be a tight odd set such that C crosses S. Then* $\text{mismatch}(C, S) > 0$ *and at least one edge of C has both its endpoints in S.*

Our strategy for dealing with cycle C having $\text{circ}_w(C) > 0$ is to *shrink* the tight odd set S it crosses; this is illustrated in Figure 2. By Proposition 11, this will shrink at least one edge of C, hence resulting in a smaller graph. Our overall strategy is as follow: Suppose w.r.t. weight vector w, $\text{circ}_w(C) = 0$. Let w' be a weight vector such that $\text{circ}_{w'}(C) > 0$. If so, [32] show that either C must lose an edge in going from $E[w]$ to $E[w']$ or a new odd set S goes tight w.r.t. w' such that C crosses S. In the latter case, we shrink S. In either case we will obtain a smaller graph and in both cases we will say that C is *destroyed*.

2.2.2 Component based on graph-theoretic facts

As stated in the Introduction, the overall structure of our algorithm is similar to that of [1]. Both algorithms require in each iteration a large enough number of edge-disjoint even cycles whose destruction will result in the removal of a corresponding number of edges. However, in both cases, the graph may have not such cycles. The recourse is to resort to even walks.

▶ **Definition 12** ([32]). *We call an ordered list of an even number of edges $C = (e_1, \ldots, e_{2k})$, not necessarily distinct, that start and end at the same vertex, an* even walk *if this list traverses either a simple even cycle or two odd cycles with a path joining them; in the latter case, the cycles are traversed once each and the path twice, once in each direction.*

The list C of edges of an even walk contains each edge either once or twice, and if it contains an edge e twice, then both copies will have the same parity. The notions of circulation and mismatch can be extended to even walks in a natural way by taking into consideration multiplicity of edges. Thus if e occurs twice in walk C, is odd-numbered and crosses tight odd set S, then it contributes 2 to n_o in the computation of mismatch(C, S) (see Definition 10) and it contributes $2w_e$ to the sum of odd-numbered edges in the computation of $\text{circ}_w(C)$ (see Definition 6). As shown in [32], all statements made above about destroying even cycles carry over to even walks as well.

[1] critically used Euler's formula and the planar dual of G for first finding a large number of edge-disjoint cycles in NC. If more than half were even, they sufficed. Otherwise, they paired up odd cycles and found paths connecting each pair to obtain even walks. This was done in a such a manner that the resulting even walks were edge-disjoint.

Finding edge-disjoint cycles in a general graph in NC appears to be quite difficult. Instead, we take a cue from the bipartite case, which finessed the issue of finding edge-disjoint cycles by using Proposition 7. As a result, showing the *existence* of cycles sufficed! However, there is a subtle difference: in the bipartite case, we needed to upper bound the number of cycles that needed to be destroyed in each iteration, whereas here we need to lower bound them; the latter is the case in [1] as well.

Using ideas from [2] we show that if the graph $G = (V, E)$ is not very sparse (see Definition 31), then it contains $\Omega\left(\frac{|E|}{\log^2|V|}\right)$ edge-disjoint even cycles. Then, using ideas from [1], we show how to pair up odd cycles to form walks. Unlike [1], the walks don't need to be found explicitly – establishing existence suffices.

If in an iteration the graph is very sparse, it will not have the required number of edge-disjoint cycles. For this case, we define the notion of a *triad* in Definition 21; this is a tight odd set consisting of three vertices. We show that the graph has sufficiently many disjoint triads, and a maximal independent set algorithm can find a large enough subset of these in NC. These can be shrunk simultaneously.

2.2.3 Component based on facts from matching theory

Suppose that in a certain iteration our algorithm is trying weight function w, as per Proposition 7. We will need to find in NC a description of face PM$[w]$, which involves, in addition to edges $E[w]$, a maximal laminar family of tight odd sets, say $\mathcal{L}$. Computing $E[w]$ using oracle $\mathcal{O}$ is straightforward. However, finding family $\mathcal{L}$ in NC is a difficult question. The difficulty is similar to that of finding a perfect matching in a graph, i.e., the presence of a plethora of solutions. Recall the "philosophy" of [27] given in Section 1.1, for dealing with this issue for perfect matching, namely attempt to narrow down the choices to one. Clearly unlike [27], randomization is not a resource we can use for this purpose. The solution involves imposing more and more restrictions on the family of tight odd sets until it becomes unique! These restrictions arise from deep structural facts from matching theory. Additional facts lead to an NC algorithm for computing $\mathcal{L}$ with the help of $\mathcal{O}$. These ideas are from [4] and [31] and are given in Section 3.2.

For the "correct" weight function, say w, among the set of even walks being handled in this iteration, some will be destroyed by losing an edge and some by crossing a tight odd set. By updating the edge set to $E[w]$, we can accrue the advantage from the first set of walks. For obtaining advantage from the second set of walks, for each such walk, say C, we need to shrink a tight odd set, say S, that it crosses. A major obstacle is that our algorithm does not "know" *any* of the walks! The way we finesse this difficulty is to shrink all outermost sets of L, which are clearly be disjoint, in the graph on edge set $E[w]$.

Finally, among all weight functions, we will pick the one, say w, that yields a graph with the smallest number of edges. There is no guarantee that w would have destroyed all s walks which we had established the existence of up-front. However, at least one of the weight functions must have done so and therefore led to a decrease of at least s edges. Hence, w must also decrease at least s edges, and that suffices for making progress. As shown in Lemma 42, the number of non-isolated edges gets reduced by a factor of $1 - \Omega(1/\log^2|V|)$ in each iteration.

2.3 The final idea: balanced viable set

Our current strategy is to iteratively reduce the number of edges until a perfect matching remains. After picking its edges, we need to recursively find a perfect matching in each of the shrunk sets (after removing its matched vertex). The resulting algorithm would have polylogarithmic depth; however, it does not run in polylogarithmic time because of the following inherent sequentiality: Perfect matchings in shrunk sets can be found only *after* finding a perfect matching in the shrunk graph, because the algorithm needs to know the vertex in S that is matched outside S. Moreover, perfect matchings in the shrunk graph and the shrunk sets need to be found via a recursive application of the full algorithm described so far.

The exact same issue arose in [1] as well. The solution proposed there was meant for general graphs and hence it works here as well. The solution is quite elaborate and hence is not repeated here; instead, we direct the reader to Section 4.2 in [1]. We note that the task is somewhat easier here because we have recourse to oracle $\mathcal{O}$; [1] had to resort to computing Pfaffians orientations, etc. We give a short, high-level summary below.

An odd set S is *viable* if there is at least one perfect matching in G which picks exactly one edge from $\delta(S)$. A set S is *balanced* if both S and its complement contain a constant fraction of the vertices. [1] show how to find in NC a balanced viable odd set. Let S be such a set. Clearly, using oracle $\mathcal{O}$, we can find an edge $e \in \delta(S)$ which is the unique edge in a perfect matching from this cut. Now we are done by a simple divide-and-conquer strategy: match e, remove its end-points and find perfect matchings in the two sides of the cut recursively, in parallel. Observe that even though perfect matchings in the two sides can be found only after finding the matched edge e, the latter can be done without any recursive calls, hence, leading to a polylogarithmic running time.

3 Preliminaries

We represent undirected graphs by $G = (V, E)$, where V is the set of vertices and E is the set of edges. Unless otherwise specified, we only work with graphs that have no loops, i.e., an edge from a vertex to itself. An edge between vertices u and v is represented as $\{u, v\}$. For a set $S \subseteq V$, we use $\delta(S)$ to denote the cut between S and its complement, i.e., $\delta(S) = \{\{u, v\} \in E \mid u \in S, v \notin S\}$. When S is a singleton, i.e., $\{v\}$ for some $v \in V$, we use the shorthand $\delta(v) = \delta(\{v\})$. A perfect matching is a subset of edges $M \subseteq E$ such that for all $v \in V$ we have $|M \cap \delta(v)| = 1$.

▶ **Definition 13.** *We call an edge* $e = \{u, v\}$ isolated *if* $\deg(u) = \deg(v) = 1$.

By this definition a graph is a perfect matching if it has no isolated vertices and all of its edges are isolated.

For a set $S \subseteq E$ of edges we use $\mathbb{1}_S \in \mathbb{R}^E$ to denote the indicator of S. We use the shorthand $\mathbb{1}_e$ to denote the e-th element of the standard basis for $\mathbb{R}^E$, where $e \in E$. We denote the standard inner product between vectors $w, x \in \mathbb{R}^E$ by $\langle w, x \rangle$.

Given a convex polytope $P \subseteq \mathbb{R}^E$, and a weight vector $w \in \mathbb{R}^E$, we use $P[w]$ to denote the set of points minimizing the weight function $x \mapsto \langle w, x \rangle$:

$$P[w] = \{x \in P \mid \forall y \in P : \langle w, x \rangle \leq \langle w, y \rangle\}.$$

Note that $P[w]$ is a face of P; all faces of P can be obtained as $P[w]$ for appropriately chosen w.

3.1 The perfect matching polytope

Given a graph $G = (V, E)$, we call a subset of edges $M \subseteq E$ a perfect matching if it contains exactly one edge in every degree cut, i.e., $|M \cap \delta(v)| = 1$ for all v. We call a graph matching-covered if any of its edges can be extended to a perfect matching.

▶ **Definition 14.** *A graph* $G = (V, E)$ *is* matching-covered *if for every edge* $e \in E$*, there exists a perfect matching* M *such that* $e \in M$*.*

The perfect matching polytope for $G = (V, E)$ is the convex hull of all perfect matchings of G in $\mathbb{R}^E$. Thus,

$$\mathrm{PM}_G = \mathrm{conv}\{\mathbb{1}_M \mid M \subseteq E \text{ is a perfect matching of } G\}.$$

Clearly the perfect matchings of G are in one-to-one correspondence with the vertices of this polytope.

When G is clear from context, we simply use PM to refer to this polytope. PM is alternatively described by the following set of linear equalities and inequalities [6]:

$$\mathrm{PM} = \left\{ x \in \mathbb{R}^E \;\middle|\; \begin{array}{ll} \langle \mathbb{1}_{\delta(v)}, x \rangle = 1 & \forall v \in V, \\ \langle \mathbb{1}_{\delta(S)}, x \rangle \geq 1 & \forall S \subseteq V, \text{ with } |S| \text{ odd}, \\ \langle \mathbb{1}_e, x \rangle \geq 0 & \forall e \in E. \end{array} \right\}. \tag{1}$$

Any face F of PM can be either described by a weight vector w, i.e., $F = \mathrm{PM}[w]$, or it can be alternatively described by the set of inequalities turned into equalities in Equation (1). These correspond to odd sets S and edges e. When face F is clear from context, we call odd sets whose inequalities have been turned into equalities, *tight* odd sets. We call an edge e *allowed* if $x_e > 0$ for some $x \in F$, i.e., if the inequality corresponding to e in Equation (1) has not been turned into equality. We use $E[w]$ or $E[F]$ to denote the set of allowed edges in the face $F = \mathrm{PM}[w]$. Putting it all together, to describe a face F it is enough to describe the set of allowed edges as well as tight odd sets.

3.2 Finding a description of a face

A key step in our oracle-based algorithm is: given small weights w, compute a description of the face $F = \mathrm{PM}[w]$. As stated before, using oracle $\mathcal{O}$, $E[w]$ can be computed in NC. However, as far as tight odd sets go, there are typically exponentially many choices of a

family of such sets that suffice. At this point, it will be useful to recall the "philosophy" of [27] given in Section 1.1, namely when designing an NC algorithm, faced with a plethora of solutions, one should attempt to narrow down the choices to one. Clearly unlike [27], randomization is not a resource we can use for this purpose. The solution to this puzzle is indeed one of the keys that enables our result and is described below. It involves imposing more and more structure on the family of tight odd sets we seek until it becomes unique! It turns out that the latter can be computed in NC with the help of $\mathcal{O}$.

Two tight odd sets $S_1, S_2 \subseteq V$ are said to *cross* if they are not disjoint and neither is a subset of the other. A family of these sets $\mathcal{L} \subseteq 2^V$ is said to be *laminar* if no pair of sets in it cross. It is well-known that each face F of the perfect matching polytope can be described by the set of allowed edges and a laminar family of tight odd sets $\mathcal{L}$:

$$F = \left\{ x \in \text{PM} \;\middle|\; \begin{array}{ll} \langle \mathbb{1}_{\delta(S)}, x \rangle = 1 & \forall S \in \mathcal{L}, \\ \langle 1_e, x \rangle = 0 & \forall e \notin E[F]. \end{array} \right\}.$$

In fact, $\mathcal{L}$ can be taken to be any *maximal* laminar family of tight odd sets for the given face F (see, e.g., [32, Lemma 2.2]). Note that we will always include all singletons $\{v\}$ in the laminar family $\mathcal{L}$ since the equalities $\langle \mathbb{1}_{\delta(v)}, x \rangle = 1$ are automatically satisfied over all of PM. However, there are still potentially many choices for the laminar family $\mathcal{L}$ describing face F, so we impose more conditions on $\mathcal{L}$.

▶ **Definition 15.** *Suppose we are given a face $F = \text{PM}[w]$. A* laminar optimal dual solution *is a laminar family $\mathcal{L}$ of tight odd sets, including all singletons, together with a function $\pi : \mathcal{L} \to \mathbb{R}$ such that for $S \in \mathcal{L}$, $\pi(S) > 0$ whenever $|S| > 1$ and for all edges e*

$$w_e \geq \sum_{S \in \mathcal{L} : e \in \delta(S)} \pi(S),$$

with equality for allowed edges.

This definition gives dual solutions for the linear program $\min\{\langle w, x \rangle \mid x \in \text{PM}\}$ that satisfy complimentary slackness and are in *laminar* form. By complimentary slackness, for any such solution, $\sum_{S \in \mathcal{L}} \pi(S)$ is equal to the weight of a MWPM. Laminar optimal dual solutions exist but are still not unique.

[4] showed that extra conditions can be imposed on laminar optimal dual solution to make it unique. They studied the notion of *balanaced critical dual solutions* and they showed how this unique $\mathcal{L}$ can be found by computing *primal* solutions to the MWPM problem. [31] used this procedure to design an alternative NC algorithm for planar graph perfect matching. We describe this procedure below. For more details see the work of [4]. Note that we will not use these rather complex and elaborate extra conditions in any other context, so we will not state them explicitly.

The following was shown by [4, Lemma 28].

▶ **Lemma 16** ([4])**.** *If $E[w]$ is connected, then a balanced critical dual is unique and Algorithm 1 finds its support, the laminar family $\mathcal{L}$.*

It was observed by [31] that all steps of Algorithm 1 can be performed in NC except for finding allowed edges $E[w]$ and the computation of $\mu(v)$'s. We note that using oracle $\mathcal{O}$, both these steps can be also be performed in NC.

▶ Remark 17. When $E[w]$ is not connected, Algorithm 1 still works but should be run in parallel for *each connected component* of $E[w]$.

Algorithm 1 Finding a balanced critical dual.

$\mathcal{L} \leftarrow \{\{v\} \mid v \in V\}$.
for $v \in V$ **in parallel do**
  $\mu(v) \leftarrow \min\{\langle w, \mathbb{1}_M \rangle \mid M \subseteq$
    $E[w]$ is a perfect matching on $V \setminus \{u, v\}$ for some vertex $u\}$.
end
Let $w'_e \leftarrow w_e + \mu(u) + \mu(v)$ for each $e \in E[w]$.
for $t \in \{w'_e \mid e \in E[w]\}$ **in parallel do**
  Find the connected components of the graph $(V, \{e \in E[w] \mid w'_e \leq t\})$.
  Add each nontrivial connected component to $\mathcal{L}$.
end
return $\mathcal{L}$.

3.3 Contraction of tight odd sets, matching minors, and triads

[6] observed that if a collection of tight odd sets are disjoint, one can shrink each one to a single node and obtain a smaller graph whose perfect matchings can be extended to perfect matchings in the original graph. For the sake of completeness we state and prove this fact here.

▶ **Proposition 18.** *Suppose that $F = \mathrm{PM}[w]$ is a face of the matching polytope for $G = (V, E)$ and $S_1, \ldots, S_k$ are disjoint tight odd sets w.r.t. F. Let H be obtained from G by removing disallowed edges and contracting each S_i to a single node. Then any perfect matching in H can be extended to a perfect matching in G.*

Proof. Suppose that M is a perfect matching in H. We can think of edges in M as edges in E as well; in fact $M \subseteq E[w]$, because we remove disallowed edges to obtain H. Because M is a perfect matching in H, for each S_i, there is a unique $e_i \in M \cap \delta_G(S_i)$. Now since e_i is an allowed edge, there must be some perfect matching M_i of G such that $e_i \in M_i$ and $\mathbb{1}_{M_i} \in F$. Since S_i is a tight odd set, M_i cannot have any other edge in $\delta(S_i)$, except for e_i. So if we look at $\{\{u, v\} \in M_i \mid u, v \in S_i\}$, we must have a matching covering all vertices of S_i except for the endpoint of e_i. Combining all of these matchings for $i = 1, \ldots, k$ together with M will give us a perfect matching in G as desired. ◀

Note that the graph H obtained above is a minor of the graph G. But it is not an arbitrary minor. It has the additional property that every perfect matching of it can be extended back to a perfect matching of the original graph. For convenience we name these minors, matching minors.

▶ **Definition 19.** *A matching minor H of a graph G, is a graph that can be obtained by a sequence of the following operations: Pick a face of the matching polytope and a collection of disjoint tight odd sets. Remove disallowed edges, and contract each tight odd set into a single node.*

The following statement follows directly from Proposition 18.

▶ **Lemma 20.** *If H is a matching minor of the graph G, then every perfect matching in H can be extended to a perfect matching in G.*

In our algorithms, we use the simple observation that a path of length 2 on vertices of degree 2 yields a tight odd set for the entire matching polytope. We call these paths triads.

▶ **Definition 21.** *A* triad *in graph $G = (V, E)$ is a set of three vertices $\{a, b, c\}$ such that* $\deg(a) = \deg(b) = \deg(c) = 2$*, and* $\{a, b\}, \{b, c\} \in E$*.*

▶ **Lemma 22.** *A triad $\{a, b, c\}$ is a tight odd set for the matching polytope and all of its faces.*

Proof. The only two neighbors of b are a, c. So in every perfect matching, b must be matched to one of them. The other vertex must have an edge to an outside vertex, and in fact that is the only possible edge in $\delta(\{a, b, c\})$. ◀

▶ Remark 23. Note that the proof of Lemma 22 does not use the assumptions $\deg(a) = \deg(c) = 2$ and only uses $\deg(b) = 2$. We will use these extra assumptions elsewhere, to prove that in certain situations, we can find many triads in our graph.

3.4 Even walks and weight vectors

Even walks were defined in Definition 12. For an even walk C, define the *signature* of C to be the vector:

$$\text{sign}(C) = \sum_{i=1}^{2k} (-1)^i \mathbb{1}_{e_i}.$$

The notions of circulation and mismatch can be stated in terms of signature:

$$\text{circ}_w(C) = |\langle w, \text{sign}(C)\rangle|$$

$$\text{mismatch}(C, S) = |\langle \mathbb{1}_{\delta(S)}, \text{sign}(C)\rangle|$$

Now, there cannot be two distinct points $x, y \in \text{PM}[w]$ whose difference $x - y$ is a multiple of $\text{sign}(C)$, since otherwise we would have $\langle w, x\rangle \neq \langle w, y\rangle$. Another way of stating this is that if $x \in \text{PM}[w]$, then $x + \epsilon\,\text{sign}(C) \notin \text{PM}[w]$ for any $\epsilon \neq 0$. So, some inequality or equality describing $\text{PM}[w]$ must be violated for this point. If we pick x to be in the relative interior of the face $\text{PM}[w]$ we will have some slack for non-tight inequalities describing $\text{PM}[w]$. So the violated constraint for $x + \epsilon\,\text{sign}(C)$ must be a constraint that is tight for the entire face $\text{PM}[w]$. This implies that:

▶ **Lemma 24.** *Let C be an even walk with* $\text{circ}_w(C) > 0$*. Then either there is an edge $e \in C$ that is disallowed, i.e., $e \notin E[w]$, or for any laminar dual $(\mathcal{L}, \pi)$ describing* $\text{PM}[w]$*, there is some set S such that* $\text{mismatch}(C, S) > 0$*.*

For a more detailed proof of this, see [1, 32]. Note that if $\text{mismatch}(C, S) > 0$, then C must have an edge with both endpoints inside S.

▶ **Lemma 25.** *If C is an even walk and S is a tight odd set such that* $\text{mismatch}(C, S) > 0$*, then there is an edge $e = \{u, v\} \in C$ such that $u, v \in S$.*

Proof. If this is not true, then every time C enters S it must immediately exit. So if we compute $\text{mismatch}(C, S)$ by looking at edges that cross S, we always get a $+1$ followed by a -1, and a -1 followed by a $+1$. So the entire sum would be 0 which is a contradiction. ◀

We also borrow from [8] the following important result, which is also stated in [32] and as Proposition 7 in this paper.

▶ **Lemma 26** ([8]). *There exists a polynomial sized family of polynomially bounded weight vectors $\mathcal{W}$, such that for any set of edge disjoint even walks $C_1, \ldots, C_k$, there is some $w \in \mathcal{W}$ which ensures*

$$\forall i : \mathrm{circ}_w(C) > 0.$$

Proof. This lemma is actually proved in [8, 32] for any collection of nonzero vectors, not just $\mathrm{sign}(C_i)$'s, as long as there is both a polynomial bound on the number of vectors and the absolute value of their coordinates. Edge-disjointness of even walks automatically puts a bound of $|E|$ on their number, and the coordinates of our even walks are always bounded in absolute value by 2. ◀

3.5 Maximal independent sets

Given a graph $G = (V, E)$, we call a subset $S \subseteq V$ independent if no edge $e \in E$ has both endpoints in S. We call an independent set maximal if no strict superset $T \supsetneq S$ is independent. We will crucially use the fact that maximal independent sets can be found in NC.

▶ **Theorem 27** ([22]). *There is a deterministic* NC *algorithm that on input graph $G = (V, E)$ returns a maximal independent set $S \subseteq V$.*

We usually want a large, rather than a maximal, independent set. We will use the fact that in bounded degree graphs, any maximal independent set is automatically large.

▶ **Proposition 28.** *If $G = (V, E)$ is a graph with $\deg(v) \leq \Delta$ for all $v \in V$, then any maximal independent set $S \subseteq V$ satisfies*

$$|S| \geq \frac{|V|}{\Delta + 1}.$$

4 The Decision Oracle

We will assume that our algorithm is equipped with an oracle $\mathcal{O}$ which answers the following type of queries: Given a graph $G = (V, E)$ and small weights $w \in \mathbb{Z}^E$, what is the weight of a MWPM in G? We denote the answer by

$$\mathcal{O}(G, w) = \min\{\langle w, x\rangle \mid x \in \mathrm{PM}_G\}.$$

We now list several deterministic NC primitives based on $\mathcal{O}$. Versions of these two lemmas appear implicitly, stated for planar graphs, in [31], but we prove them for the sake of completeness.

▶ **Lemma 29.** *Given access to $\mathcal{O}$, for polynomially bounded $w \in \mathbb{Z}^E$, one can find $E[w]$ in* NC.

Proof. An edge $e = \{u, v\}$ can be in a MWPM if and only if $\mathcal{O}(G, w) = w_e + \mathcal{O}(G - \{u\} - \{v\}, w)$, where $G - \{u\} - \{v\}$ is obtained from G by removing vertices u, v. This can be checked in parallel for all edges e. ◀

▶ **Lemma 30.** *Given access to $\mathcal{O}$, for polynomially bounded $w \in \mathbb{Z}^E$, one can run Algorithm 1 in* NC.

Proof. As was observed by [31], all steps of Algorithm 1 can be run in NC except for finding $E[w]$ and computing $\mu(v)$. Given access to $\mathcal{O}$, we can find $E[w]$ in NC by Lemma 29. Furthermore observe that for any $v \in V$

$$\mu(v) = \min\{\mathcal{O}(G - \{u\} - \{v\}, w) \mid u \in V - \{v\}\},$$

which can be computed by making all queries $\mathcal{O}(G - \{u\} - \{v\}, w)$ in parallel and then taking the minimum. ◀

An implementation for the oracle, in RNC with arbitrarily small inverse polynomial probability of error for general graphs, follows from [27], since they give an RNC algorithm for finding a MWPM for small weights. Since $\mathcal{O}$ is promised to be called at most polynomially many times, the probability of error over the entire run of the algorithm can be made inverse polynomially small.

5 Structural Facts

Our algorithm requires two structural facts, one for the case that the graph G is very sparse and the other for the complementary case. They are encapsulated in Lemmas 32 and 34.

▶ **Definition 31.** *A connected graph $G = (V, E)$ is said to be* very sparse *if $|E| < |V|/(1-\epsilon)$, for some constant $\epsilon < 1/9$.*

▶ **Lemma 32.** *If $G = (V, E)$ is a matching-covered, very sparse graph, then the number of triads in any maximal set of node-disjoint triads in G is at least $c_1|E|$, for some constant $c_1(\epsilon) > 0$.*

The proof of this lemma involves two steps: first, we prove that the total number of triads is large and second, that a maximal node-disjoint set of triads must also be large. The first step is accomplished in the following lemma.

▶ **Lemma 33.** *Suppose that $G = (V, E)$ is a graph with no vertices of degree 0 or 1. Then the number of triads in G is at least $9|V| - 8|E|$.*

Proof. Consider a charging scheme, where we allocate a budget of 1 to each edge, and the edge distributes its budget between its two endpoints. We then sum up the charge on all vertices and use the fact that this sum is exactly $|E|$.

Let $e = \{u, v\}$ be an edge. If neither u nor v is of degree 2, let the edge give $1/2$ to u, and $1/2$ to v. If both u and v are of degree 2, we allocate the budget the same way by splitting it equally between u and v. The only remaining case is when one of u and v has degree 2 and the other has degree at least 3; by symmetry let us assume that $\deg(u) = 2$ and $\deg(v) \geq 3$. Then we allocate $5/8$ to u and $3/8$ to v.

Now let us lower bound the charge that each vertex v receives. Note that the minimum amount v receives from any of its adjacent edges is $3/8$, so an obvious lower bound is $3\deg(v)/8$. If $\deg(v) \geq 3$, this is at least $9/8$. Now consider the case when $\deg(v) = 2$. Then v receives at least $1/2$ from each of its adjacent edges. If one of the neighbors of v is not of degree 2, then the charge that v receives will be at least $1/2 + 5/8 = 9/8$. The only possible case where v does not receive at least $9/8$ is when it is of degree 2, and both of its neighbors are also of degree 2 (the center of a triad), in which case it receives 1.

Now let k be the number of triads. Then, by the above argument the total charge on all the vertices is at least

$$\frac{9}{8}(|V| - k) + k \leq |E|.$$

Rearranging yields $k \geq 9|V| - 8|E|$. ◀

Proof of Lemma 32. We know that the number of triads is at least $9|V|-8|E| = (1-9\epsilon)|E|$. Now consider the conflict graph of triads, where nodes represent triads, and edges represent having an intersection. It is easy to see that any triad can only intersect at most 4 other triads. So the degrees in this conflict graph are bounded by 4. By Proposition 28, any maximal node-disjoint set of triads will contain at least $(1-9\epsilon)|E|/5$ many triads. So we can take $c_1(\epsilon) = (1-9\epsilon)/5$ which is positive for $\epsilon < 1/9$. ◀

▶ **Lemma 34.** *If $G = (V, E)$ is a matching-covered graph on $|V| > 2$ vertices that is not very sparse, then there exist $c_2|E|/\log^2|V|$ edge-disjoint even walks in G, for some constant $c_2(\epsilon) > 0$.*

We first show that there are many edge-disjoint cycles in a non-sparse graph. If at least half of them are even, we are done. Otherwise, we show how to pair up odd cycles and connect them via suitable paths to get sufficiently many edge-disjoint even walks. A proof of the next lemma can be found in [2]; however, for the sake of completeness we provide it here.

▶ **Lemma 35.** *In a graph $G = (V, E)$ there exists a collection of edge-disjoint cycles with at least the following number of cycles:*

$$\frac{|E| - |V|}{2\log_2|V|}.$$

Proof. We prove this by induction on $|V| + |E|$. We have several cases:

- **i)** If there are any loops in the graph, we extract that as one of our cycles, and remove the edge from the graph. The promised quantity goes down by $1/(2\log_2|V|)$ which is $\leq 1/2$. So from now on we assume that G has no loops.
- **ii)** If there are any two parallel edges e, e', we extract those as a cycle of length 2, and remove both from the graph. The promised number of edge-disjoint cycles goes down by $2/(2\log_2|V|) \leq 1$. So adding the cycle we extracted fulfills the promise. From now on we assume that G is simple.
- **iii)** If G has any vertices of degree 0: We can simply remove it and the promised quantity grows.
- **iv)** If G has a vertex of degree 1: We can also remove this vertex. This operation does not change the numerator but shrinks the denominator, which results in a larger promised quantity.
- **v)** If G has a vertex v of degree 2: Let e, e' be the two adjacent edges to v. Remove v, e, e' from the graph, and place a new edge e'' between the two former neighbors of v. By doing this, both $|V|$ and $|E|$ go down by 1. So now the promised number of edge-disjoint cycles becomes larger. By induction we find them, and now we replace the edge e'' if it is used at all in a cycle, by the path of length two consisting of e, e'. Since e'' appears in at most one cycle, this operation preserves edge-disjointness.
- **vi)** Finally if G is a simple graph with no vertices of degree ≤ 2, it must have a cycle of length at most $2\log_2|V|$. If we prove this, we are done by induction, because we can remove the edges of this cycle and the promised quantity goes down by at most 1. Now to prove the existence of this cycle, assume the contrary, that the length of the minimum cycle of the graph is at least $2\log_2|V| + 1$. Pick a vertex v and look at all simple paths of length at most $\log_2|V|$ going out of v. The number of paths of length i is at least twice the number of paths of length $i-1$. This is because every path of length $i-1$ ending at a vertex u can be extended in at least $\deg(u) - 1 \geq 2$ ways, and none of these extensions will intersect themselves, otherwise we would get a cycle of length $\log_2|V| + 1$.

So in the end, the total number of such paths will be $> 2^{\log_2|V|} = |V|$, which means that two of the paths must share an endpoint. But now from the union of these two paths, we can extract a cycle of length at most $\log_2|V| + \log_2|V| = 2\log_2|V|$. ◀

If at least half of the cycles guaranteed by Lemma 35 are odd, we need to pair them up and connect them with paths. We use a spanning tree to do this.

▶ **Proposition 36** ([1, Lemma 20]). *Consider a tree T with an even number of tokens placed on its vertices, with possibly multiple tokens on each vertex. There is a pairing, i.e., a partitioning of tokens into partitions of size two, such that the unique tree paths connecting each pair are all edge-disjoint.*

▶ **Lemma 37.** *Suppose that there are 2ℓ edge-disjoint cycles of odd length in a matching-covered connected graph $G = (V, E)$. Then G contains at least $\Omega(\ell^2/|E|)$ edge-disjoint even walks.*

Proof. We will pair up the odd cycles by paths connecting each pair. This will create ℓ even walks, but they might not be edge-disjoint. We will then show how to extract $\Omega(\ell^2/|E|)$ *edge-disjoint* even walks out of them.

Consider a spanning tree T of G. For each of the 2ℓ odd cycles, pick an arbitrary vertex, and put a token on that vertex. Now we have an even number of tokens on the vertices. We can pair up these tokens, so that the unique tree paths (of possibly length 0) connecting each pair are edge-disjoint, see Proposition 36.

Now for each pair of odd cycles C_1, C_2 whose tokens got paired up, we create an even walk. Let P be the tree path connecting tokens from C_1 and C_2. If P has no common edges with C_1, C_2 we can simply create our even walk, but this is not guaranteed to happen. So instead, traverse P from C_1's token to C_2's token and look at the last exit from C_1; afterwards look for the first time any vertex of C_2 is visited. This portion of P is a subpath connecting C_1 and C_2 having no common edged with either. We use C_1, C_2 and this subpath of P to create our even walk.

So far we have created ℓ even walks, but they might not be edge-disjoint. The odd cycles are edge-disjoint, as are the paths connecting them, but one of the paths might share an edge with an unrelated odd cycle. This also means that no edge e can be shared between more than two even walks; e can be used once as part of an odd cycle, and once as part of a path.

Now consider the number of edges in each even walk. If we sum this over all even walks, we get at most $2|E|$, since each edge can appear in at most two even walks. So the average number of edges in an even walk is $\leq 2|E|/\ell$. By Markov's inequality at least half of the even walks, $\ell/2$ of them, will have at most twice this average number of edges, $4|E|/\ell$. Now create a conflict graph where nodes represent these $\ell/2$ even walks, and an edge is placed when the two even walks share an edge. The degree of each node is at most $4|E|/\ell$. So if pick a maximal independent set in this conflict graph, it will consist of at least $\Omega(\ell^2/|E|)$ many even walks. ◀

We are finally ready to prove Lemma 34.

Proof of Lemma 34. First note that if our graph is not an isolated edge and is matching-covered it must contain at least one even cycle. This is so because there must be at least two perfect matchings in the graph, and in their symmetric difference, we can find one such cycle.

Because we are guaranteed to have at least 1 cycle, we can simply show that asymptotically we can extract $\Omega(|E|/\log^2|V|)$ edge-disjoint even walks. Then the asymptotic statement translates to the more concrete bound of $c_2|E|/\log^2|V|$.

If $(1-\epsilon)|E| \geq |V|$, by Lemma 35, we have at least $\epsilon|E|/2\log_2|V| = \Omega(|E|/\log|V|)$ cycles. If at least half of them are of even length, we are done. Otherwise we get $\Omega(|E|/\log|V|)$ odd cycles. Perhaps by throwing away one of them, we can assume the number of odd cycles we have is even. Then we can apply Lemma 37 to obtain $\Omega(|E|/\log^2|V|)$ edge-disjoint walks. This completes the proof. ◀

6 The Oracle-Based Algorithm

In this section we describe our oracle-based algorithm for finding a perfect matching. In Section 6.1, we will extend this to finding a *minimum weight* perfect matching for small weights.

On input $G = (V, E)$, our algorithm proceeds by finding smaller and smaller matching minors H of G, until H has a unique perfect matching, or in other words is a perfect matching. Then we pick the edges in H as a partial matching in G and extend this partial matching to a perfect matching independently and in parallel for the preimage of each node in H. That is for each node s in H, we take the set $S \subseteq V$ that got shrunk to s, remove the single endpoint of the partial matching from S, and recursively find a perfect matching in S. In the end we return the results of all these recursive calls along with the edges of H as the final answer.

We crucially make sure that the pre-image of nodes in H never contain more than a constant fraction of V. This makes sure that our recursive calls end in $O(\log|V|)$ steps.

In all of our algorithms, when we construct matching minors, we implicitly maintain the mapping from the resulting edges to the original edges, and the mapping from original vertices to the minor's vertices. These are trivial to maintain in NC, but for clarity we avoid explicitly mentioning them. We also keep node weights for matching minors, where the *weight of a node* is simply the number of original vertices that got shrunk to it.

Algorithm 2 Divide-and-conquer algorithm for finding a perfect matching.

```
PerfectMatching(G = (V, E))
if V = ∅ then
    return ∅.
else
    Call PartialMatching(G), and let H be the matching minor returned.
    Let M ⊆ E be the edges of H.
    for each node s of H in parallel do
        Let S ⊆ V be the nodes of G that are shrunk to s.
        Let v be the unique endpoint of the unique edge of M in δ(S).
        Let G_s be the induced graph on S − {v}.
        M ← M ∪ PerfectMatching(G_s).
    end
    return M.
end
```

The pseudocode for the main algorithm PerfectMatching can be seen in Algorithm 2. On input G, the algorithm calls PartialMatching to find a matching minor H of G which itself is a perfect matching. Then the edges of H, which form a partial matching in G, are extended to a perfect matching independently and in parallel in the preimage of each node from H. Since H is a matching minor, this extension can always be performed by Lemma 20.

The pseudocode for PartialMatching can be seen in Algorithm 3. This algorithm keeps a node-weighted matching minor of the input graph G. It tries several ways of obtaining a smaller matching minor, where *size of a matching minor* is measured in terms of the number

Algorithm 3 Find a matching minor of the input graph that is itself a perfect matching.

PartialMatching($G = (V, E)$)
Assign node weight 1 to each node $v \in V$.
while *G is not a perfect matching* **do**
  if *any node v of G has at least $1/6$ of the total node weight* **then**
    Remove disallowed edges $e \notin E[0]$ from G.
    Contract the complement of $\{v\}$ to a single node. If there are parallel edges, remove all except for an arbitrary one.
    return G.
  end
  Find a maximal set of node-disjoint triads in G.
  Let H be obtained from G by removing disallowed edges and contracting each triad into a single node.
  $U \leftarrow \{H\}$.
  for $w \in \mathcal{W}$ **in parallel do**
    Call Reduce(G, w) and let the result be H.
    $U \leftarrow U \cup \{H\}$.
  end
  Find the graph $H \in U$ with the minimum number of non-isolated edges.
  $G \leftarrow H$.
end
return G.

Algorithm 4 Remove disallowed edges and contract certain tight odd sets.

Reduce($G = (V, E)$, w) ; // The graph G has node weights.
Remove disallowed edges $e \notin E[w]$ from G.
Find all connected components of G.
for *each connected component C of G* **in parallel do**
  Run Algorithm 1 on C to find a laminar family of tight odd sets $\mathcal{L}$.
  for $S \in \mathcal{L}$ **in parallel do**
    if *node weight of S is more than half of the node weight of C* **then**
      Replace S in $\mathcal{L}$ with $C - S$.
    end
  end
  Find the inclusion-wise maximal sets in $\mathcal{L}$ and shrink each one to a single node.
end
return G.

of non-isolated edges, see Definition 13. One way of obtaining a smaller matching minor is by picking a maximal node-disjoint set of triads and shrinking them simultaneously. By Lemma 22, this produces a matching minor. Also note that the maximal set of node-disjoint triads can be found in NC by enumerating all triads and using Theorem 27.

Another way of obtaining smaller matching minors is by trying weights from the set of weight vectors $\mathcal{W}$ and calling Reduce to remove disallowed edges $e \notin E[w]$ and shrinking top-level sets of a laminar family of tight odd sets w.r.t. w.

Finally. the pseudocode for Reduce can be seen in Algorithm 4. This algorithm is simply fed a graph $G = (V, E)$ and a weight vector w. It removes disallowed edges $e \notin E[w]$ and shrinks the maximal sets of a laminar family of tight odd set. The laminar family is found using Algorithm 1, but is modified to make sure that no shrunk set becomes too large; to be more precise no shrunk vertex in the end will have node weight more than half of the total node weight.

6.1 Finding a minimum weight perfect matching

We extend our algorithm so it returns not just any perfect matching, but rather a minimum weight perfect matching, for small weights.

Given an input graph $G = (V, E)$ and a weight vector w, we can remove disallowed edges $e \notin E[w]$, and find a laminar family of tight odd sets $\mathcal{L}$ w.r.t. w, by calling Algorithm 1 on each connected component of G. By complementary slackness, any perfect matching that has only one edge in $\delta(S)$ for each $S \in \mathcal{L}$ will automatically be of minimum weight, see Definition 15. We can simply contract the top level sets in $\mathcal{L}$, use Algorithm 2 to find a perfect matching in the shrunk graph, and recursively extend this to a minimum weight perfect matching in each shrunk piece. Following an almost identical argument as in the proof of Proposition 18, the perfect matching in the shrunk graph can be extended to a minimum weight perfect matching.

The only problem with this method is that the recursion depth is not guaranteed to be polylogarithmic. However we can fix that by making sure that tight odd sets $S \in \mathcal{L}$ do not have more than half of the vertices in the graph; if they do, we replace them by their complements and we will see in Lemma 40 why this operation preserves laminarity.

6.2 Minor-closed families of graphs

Throughout our algorithm we only call the decision oracle on graphs obtained from the original through a sequence of edge and vertex removals and contractions. In this section we will prove that the decision oracle is only called on minors of the original graph, that is those graphs obtained by vertex and edge removals and contractions of *connected* subgraphs.

▶ **Lemma 38.** *Algorithms 2 to 4 call the decision oracle on minors of their input graph only.*

This lemma is all we need to prove Theorem 4. Note that there are several minor-closed families of graphs where the decision problem can be solved in NC by using a counting oracle. In particular we can count perfect matchings in graphs embedded on surfaces of genus at most $O(\log n)$, and therefore solve the decision problem, all in NC. This improves upon the genus bound of $O(\sqrt{\log n})$ given by [1].

▶ **Corollary 39.** *For graphs embedded on a surface of genus at most $O(\log n)$ and weighted with polynomially bounded edge weights, there is an NC algorithm to find a minimum weight perfect matching.*

Another consequence of Theorem 4 is an alternative algorithm for $K_{3,3}$-free graphs, which was resolved earlier by [7].

Now we prove Lemma 38.

Proof of Lemma 38. First we prove this for Algorithm 4. In this algorithm, we only remove edges from the input graph, and shrink tight odd sets in connected components. We just have to show that what we shrink is already connected. Consider a tight odd set S in a connected component C. If it is not internally connected, then one of its internal connected components must have odd size; let that be S'. Since $S \subseteq C$ and C is a connected component, there is an edge $e \in \delta(S - S')$. Since S' is not internally connected to $S - S'$, it must be that $e \in \delta(S)$ too. Now since the graph is matching-covered with minimum weight perfect matchings, there must be some minimum weight perfect matching $M \ni e$. But because S' is odd, there must also be an edge $f \in M \cap \delta(S')$. But note that $e \neq f$, and both $e, f \in \delta(S)$. This is a contradiction, since S cannot have more than one edge in a perfect matching. This shows that S must be connected and Algorithm 4 only produces minors of its input graph.

Next we prove the statement for Algorithm 3. This algorithm either calls Algorithm 4, or finds triads and contracts them. The former produces minors of the input graph, and the latter also produces minors of the input graph since triads are connected.

Note that the graph returned by Algorithm 3 may not be a proper minor of the input graph; that could happen if the node weight of some v goes above $1/6$ the total node weight. In this scenario, the complement of v might not be connected and yet we contract it. However the algorithm immediately returns and the decision oracle is not called on this returned graph. So this does not contradict the statement of the lemma.

Finally we prove the statement for Algorithm 2. The only graphs produced and passed onto Algorithm 3 are obtained from the input graph by vertex removals and edge removals. So they are all minors of the input graph. The output of Algorithm 3 might not be a proper minor, but this output is only used to decide which edges and vertices to remove from the original graph to get to induced graphs on $S - \{v\}$. ◀

7 Analysis of the algorithm

First we will prove that our oracle-based algorithm returns a correct answer. Next, we will bound the running time and prove that our algorithm runs in NC, modulo the calls to $\mathcal{O}$; this constitutes the most challenging part of the analysis.

7.1 Correctness

We will need the following lemma.

▶ **Lemma 40.** *Suppose that $\mathcal{L}$ is a laminar family of sets in a node-weighted graph $G = (V, E)$, and we replace every $S \in \mathcal{L}$ whose node weight is larger than half of the total node weight by the complement, i.e., $V - S$. Then the resulting family of sets $\mathcal{L}'$ is also laminar.*

Proof. Let S, S' be two sets in $\mathcal{L}$. They are either disjoint or one is contained in the other.

If $S \cap S' = \emptyset$: They cannot both have node weight more than $1/2$. So at most one of them gets replaced by its complement. Then it is easy to see that the resulting sets do not cross.

If $S \subseteq S'$: There are three possibilities. If none of them gets replaced by their complements, or both of them get replaced by their complements, they remain nested and therefore do not cross. If one of them gets replaced by its complement, it has to be the larger set S'. In that case the resulting sets become disjoint, and still do not cross. ◀

Using Lemma 40 and Lemma 20, we deduce that Reduce always returns a matching minor of its input graph. By definition, PartialMatching also returns a matching minor of its graph when it finishes (for the analysis of running time see Section 7.2).

This proves the correctness of the algorithm, since we always find a matching minor that has a unique perfect matching (itself), and by Lemma 20, we can extend it to a perfect matching, independently in the preimage of each node.

7.2 Running time

First we analyze PerfectMatching (Algorithm 2) assuming the calls to PartialMatching (Algorithm 3) are in NC.

▶ **Lemma 41.** *Assuming the calls to* PartialMatching *are in* NC*,* PerfectMatching *is in* NC*.*

Proof. We simply need to bound the number of levels in the recursion. We will prove that when PartialMatching returns a matching minor H, the node weight of every node is at most $5/6$ the total node weight. This proves that in each recursive call to PerfectMatching, the number of vertices gets reduced by a factor of $5/6$.

Note that the first time in Algorithm 3 that a node's weight goes above $1/6$ the total weight, the algorithm stops and returns a two-node minor. So we just need to prove that the weight of the node that just went above $1/6$ is not more than $5/6$. The current minor was obtained from the previous minor by either Reduce, or by shrinking triads. But Reduce never creates nodes with weight more than half the total weight. The weight of each node in a triad is also at most $1/6$ the total weight, so after shrinking the triad, the new weight can be at most $1/6 + 1/6 + 1/6 = 1/2$ the total weight. This finishes the proof. ◀

Finally, we need to prove that PartialMatching finishes in a polylogarithmic number of steps. Using the structural facts, Lemma 42 and Lemmas 32 and 34, we establish the following lemma.

▶ **Lemma 42.** *In each iteration of Algorithm 3, the number of non-isolated edges gets reduced by a factor of* $1 - \Omega(1/\log^2|V|)$*.*

Proof. First assume G is a connected graph. Then we can directly apply Lemmas 32 and 34 for some fixed $\epsilon < 1/9$ to show that we either find $c_1|E|$ triads or there exist $c_2|E|/\log^2|V|$ edge-disjoint even walks. In the former case, after contracting the triads, the number of edges gets reduced by a factor of $1 - c_1$. In the latter case, let $C_1, C_2, \ldots, C_k$ be the edge-disjoint even walks, and let $w \in \mathcal{W}$ be the weight vector such that $\langle w, \text{sign}(C_i)\rangle \neq 0$. Note that w is guaranteed to exist by Lemma 26. In the call to Reduce(G, w), every C_i loses at least edge by Lemmas 24 and 25, either because one of its edges becomes disallowed or it gets shrunk as a result of shrinking top-level tight odd sets. Therefore, one of the candidate graphs in U in Algorithm 3 will have a factor of $1 - c_3/\log^2|V|$ fewer edges, for some constant $c_3 > 0$.

Next assume G is not connected. If so, we apply the above-stated argument to each connected component that is not an isolated edge. We can further assume the same weight vector w works for all connected components. Now if H_1 is the graph obtained from shrinking triads, and H_2 is the result of Reduce(G, w), then we know that the average number of edges in H_1 and H_2 for each connected component is at most $1 - c_3/2\log^2|V|$ times the number of edges in the connected component. So one of H_1, H_2 must have at most $(1 - c_3/2\log^2|V|)$ times as many non-isolated edges as G. ◀

Note that Lemma 42 gives a polylogarithmic upper bound on the number of iterations in Algorithm 3, since if we track the number of non-isolated edges, after every $\Theta(\log^2|V|)$ steps we get a constant factor reduction, and therefore it takes at most $O(\log|E| \cdot \log^2|V|)$ iterations for it to reach 0.

8 Discussion

This paper has identified what appears to be the "core" of the difficult open problem of obtaining an NC matching algorithm, namely the decision problem. We must immediately mention that both decision problems stated in Section 1.2 have been the subject of numerous attacks over the past decades and hence resolution is not likely to be an easy matter. At the same time, we hope that since the "target" has been more precisely identified, the resolution of the open problem will gain added impetus.

An obvious open question is to build on the quasi-NC algorithm of [11] and related results of [12] to obtain the appropriate oracle-based NC algorithms and pseudo-deterministic RNC algorithms for linear matroid intersection and for finding a vertex of a polytope with faces given by totally unimodular constraints. An interesting problem defined by Papadimitriou and Yannakakis [29] , called Exact Matching, is the following: Given a graph G with a subset of the edges marked red and an integer k, find a perfect matching with exactly k red edges. This problem is known to be in RNC [27], even though it is not yet known to be in P. Is there a pseudo-deterministic RNC algorithm for it?

The phenomenon identified in Section 1.3 clearly deserves to be studied in depth. To the best of our knowledge, there are only two algorithmic results for bipartite matching that have not been extended to general graphs. The first is obtaining a fully polynomial randomized approximation scheme for counting the number of perfect matchings [14]; this is also among the outstanding open problems of theoretical computer science today. The second is obtaining an $O(m^{10/7})$ algorithm for maximum matching [23], which beats the earlier algorithms for sparse graphs.

Abstract

We study methods for improving fairness to subgroups in settings with overlapping populations and sequential predictions. Classical notions of fairness focus on the balance of some property across different populations. However, in many applications the goal of the different groups is not to be predicted equally but rather to be predicted well. We demonstrate that the task of satisfying this guarantee for multiple overlapping groups is not straightforward and show that for the simple objective of unweighted average of false negative and false positive rate, satisfying this for overlapping populations can be statistically impossible even when we are provided predictors that perform well separately on each subgroup. On the positive side, we show that when individuals are equally important to the different groups they belong to, this goal is achievable; to do so, we draw a connection to the sleeping experts literature in online learning. Motivated by the one-sided feedback in natural settings of interest, we extend our results to such a feedback model. We also provide a game-theoretic interpretation of our results, examining the incentives of participants to join the system and to provide the system full information about predictors they may possess. We end with several interesting open problems concerning the strength of guarantees that can be achieved in a computationally efficient manner.

1 Introduction

Concerns about ethical use of data in algorithmic decision-making have spawned an important conversation regarding machine learning techniques that are fair towards the affected populations. We focus here on binary decision-making: e.g., deciding whether to approve a loan, admit a student to an honors class, display a particular job advertisement, or prescribe a particular drug. While multiple fairness notions have been suggested to inform these decisions, most assume access to labeled data and that this data is drawn from i.i.d. distributions. In practice, data patterns are often dynamically evolving and the feedback received is biased by the decisions of the algorithms – such as only learning whether a student should have been

admitted to an honors class if the student is actually admitted – which induces additional misrepresentation of the actual data patterns. Despite the rich literature, approaching fairness considerations without these strong assumptions is rather underexplored.

Most fairness notions impose a requirement of balance across groups. For example, demographic parity [9] aims to ensure that the percentage of positive predictions is the same across different populations, and equality of opportunity [22] aims to ensure that the percentage of false negative predictions is the same across them. These notions are useful in identifying inequities between subpopulations, especially in settings such as criminal recividism [30] where there is a conflict between the incentives of the participants and the goal of accurate prediction. However, these notions may not be appropriate when the goal of each group is to be predicted as accurately as possible, and explicitly performing worse on one group in order to produce balance would be morally objectionable or absurd. For example, in a health application, a balance notion may lead to penalizing the majority population by willfully providing it worse treatment to make amends for the fact that a minority population is not classified correctly due to insufficient data. This would be clearly inappropriate.

More generally, there are many natural scenarios where the goal of each group is just to be predicted as accurately as possible. A student wishes to be admitted in an honors class only if they are qualified to succeed in it; otherwise their academic record may be jeopardized. A person requesting a microloan can be often significantly harmed by receiving it unless they return it (see [33] for an interesting discussion). A drug prescription is only beneficial if it helps enhance the health of the patient; otherwise it may cause adverse effects. In these settings what groups care about is not being treated *equally* but rather being treated *well*.

In this work, we consider a fairness notion for sequential non-i.i.d. settings where the subpopulations and the designer both strive for accurate predictions. We say that a prediction rule f is unfair to a subgroup g with respect to a family of rules $\mathcal{F}$ if there is some other rule $f_g \in \mathcal{F}$ that performs significantly better than f on g, in which case we say that f_g witnesses this unfairness. More generally, given a collection of rules, some of which may come from the designer, some from third-party entities, and some from the groups themselves, our goal is to achieve performance on each group comparable to that of the best of these rules for that group, even when groups overlap. Moreover, we aim to achieve this goal with as strong bounds as possible in a challenging "apple-tasting" feedback model where we only receive feedback on positive predictions (e.g., when a loan is given or a student is admitted). Interestingly, while our main results are positive, we show such guarantees are *not* possible if we replace the performance measure of accuracy (or error) with any fixed weighted average of false-positive and false-negative rates. Our positive results can also be thought of as a form of *individual rationality* with respect to the groups: no group has any incentive (up to low order terms) to pull out and, say, form its own lending agency just for members of that group. From this perspective, we also consider notions of *incentive compatibility* (could groups have any incentive to hide prediction rules from the system) and present a computationally-inefficient algorithm along with an open problem related to achieving this guarantee in a computationally-efficient manner.

1.1 Our contribution

We consider a decision-maker with some global decision function f_o that she would like to use (say to decide who gets a loan), and a collection of groups $\mathcal{G}$, where each group $g \in \mathcal{G}$ proposes some function f_g that *it* would like to be used instead on members of g.[1] The guarantee

[1] Both decision-maker and groups may have more functions; the guarantees are with respond to the best of them.

we aim to give is that our overall performance will be nearly as good (or better) than f_o on the entire population with respect to the objective function of the decision-maker, and for each group g our performance is nearly as good (or better) than the performance of f_g with respect to group g's objective. We would like to do this even when groups are overlapping and even when feedback on whether or not a decision was correct is only received when the decision made was "yes" (e.g., when the loan was given or the student was admitted).

Surprisingly, we show that when groups are overlapping and when the group objectives are to minimize the *unweighted* average of false-positive rate (FPR) and false-negative rate (FNR), there exist settings where *every* global prediction rule f must be unfair to one of the groups. In particular, we present a simple example with two overlapping groups having predictors f_1 and f_2 respectively, where performing nearly as well as f_1 on group 1 and nearly as well as f_2 on group 2 is fundamentally impossible when performance is measured as (FPR+FNR)/2 (or as max(FPR,FNR) or as any fixed non-degenerate weighting) even when the input does not arrive in an online manner. This shows that just having the fairness notions be the same across groups and aligned with the goals of the designer (who in this case does not have any additional goal other than to eliminate unfairness) is not by itself sufficient to be able to achieve our fairness criteria under objectives based on fixed combinations of FPR and FNR.

▶ **Informal theorem 1** (Theorem 10)**.** If subgroups are overlapping and their objectives are to minimize the unweighted average of false positive and false negative rates, there exist instances where no global function can simultaneously perform nearly as well on each group as the best function for that group. This holds even in the batch setting.

Instead we aim for low absolute error on each subgroup[2] and show a connection of this notion to an adversarial online learning setting, that of *sleeping experts* [6, 17]. In sleeping experts, each predictor (also referred to as an expert) can decide at each round to either make a prediction (fire) or abstain (sleep). Sleeping experts algorithms guarantee that, for any expert, the performance of the algorithm when the expert fires is nearly as good as the performance of this expert. Providing the functions f_o for the decision-maker and f_g for each group into existing sleeping-experts algorithms (viewing f_g as abstaining on any individual outside of group g) yields the following.

▶ **Informal theorem 2** (Theorem 1)**.** For the objective of minimizing absolute error, we can perform nearly as well as f_g for all groups g while performing nearly as well as f_o overall.

One particular complication that arises in many fairness-related settings, however, is that feedback received is one-sided: we only learn about the outcome if the loan is given, the student is admitted in the class, the advertisement is displayed, or the drug is prescribed; we do not learn about what would have happened when the action is not taken. In online learning, this is known as the *apple tasting* model [24]. We therefore initiate the study of sleeping experts in this apple tasting feedback model, aiming to achieve as strong regret guarantees as possible on a per-group basis. Combining apple tasting with sleeping experts poses interesting challenges as the exploration needs to be carefully coordinated among different subpopulations. In Section 3.2, we provide three different black-box reductions with different advantages in their performance guarantee.

[2] This is equivalent to FPR on a group weighted by the fraction of negative examples in that group plus FNR on a group is weighted by the fraction of positive examples in that group.

▶ **Informal theorem 3** (Theorems 3, 4, and 5)**.** Even if we only receive one-sided feedback, we can still perform nearly as well as f_g for all groups g while performing nearly as well as f_o overall.

Each of our guarantees is somewhat suboptimal. Theorem 3 is based on a construction that does not use sleeping experts, but has an exponential dependence on the number of groups which makes it computationally inefficient when there are many groups. Theorem 4 is a natural adaptation of sleeping experts to this setting but has an error bound with a (sublinear) dependence on the size of the total population instead of only depending on size of the subgroup, which makes the result less meaningful for small groups as this term may dominate their regret bound. Last, Theorem 5 has a more involved use of sleeping experts and does not suffer from the two previous issues, but has a suboptimal dependence on the size of the subgroup. Combining the advantages of these approaches without the resulting shortcomings is an intriguing open question.

The final contribution of our work (Section 4) is to provide a game-theoretic investigation of our setting in terms of incentives of the participating groups. In mechanism design, two important properties that a mechanism should satisfy are Individual Rationality (IR) and Incentive Compatibility (IC). The former asks that no player should prefer to opt out and seek service outside of the system instead. The latter refers to the mechanism creating no incentives for players to misreport their private information. Inspired by the kidney exchange literature [37, 3, 2], we consider each group as a player in our system. The IR property is satisfied when group g can get no benefit (asymptotically) from being predicted by their individual predictor f_g, say via their own loan agency. This is exactly what our above guarantees provide and therefore they can be interpreted as asymptotically IR. This observation brings up the question of whether incentive compatibility is also satisfied by sleeping experts algorithms. In this context, IC means that if a group g has a set of predictors $\{f_g\}$ then they get no benefit (asymptotically) from hiding some of those predictors from the decision-maker. Unfortunately, we show that current sleeping experts algorithms are *not* (even approximately) incentive compatible. On the other hand, we provide an algorithm that achieves both IR and IC guarantees, as well as operating in the apple tasting setting, at the expense of being computationally inefficient (enumerating over all exponentially-many group intersections). This leads to an interesting open question of finding a computationally efficient algorithm that satisfies both IR and IC properties.

▶ **Informal theorem 4** (Theorem 8)**.** Classical sleeping experts algorithms such as AdaNormalHedge do not satisfy the IC property.

▶ **Informal theorem 5** (Theorem 9)**.** Separate multiplicative weights algorithms for each intersection of groups satisfy the IC property at the expense of being computationally inefficient.

▶ **Open question 1** (Section 4.3)**.** Does there exist a computationally efficient algorithm satisfying both IR and IC properties?

1.2 Related work

There is a growing literature aiming to identify natural fairness notions and understand the limitations they impose; see [14, 22, 31, 12, 27, 1] for a non-exhaustive list. With respect to fairness among different demographic groups, notions such as disparate impact [9, 15] or equalized odds [22] aim to achieve some balance in performance across different populations. These make sense when there is an intrinsic conflict between the desires of the different groups

and those of the designer and can help identify undesirable inequities in the system that require remedies (that are often non-algorithmic and need policy changes). Unfortunately, aiming to satisfy these notions can also have undesired implications such as intentionally misclassifying some groups to make amends for the inability to classify other groups well enough. This has given rise to an important debate around alternative notions that do not suffer of these issues (see for example [13]). Our work aims to advance this direction.

When populations are overlapping, there are several recent works in the batch setting that tackle considerations similar to the ones we address. Kearns et al. [26] provide a simple example illustrating the issue that one can be non-discriminatory with respect to, say, gender and race in isolation but heavily discriminate against, say, black female participants; they also discuss how to audit whether a classifier exhibits such unfairness with respect to groups. In a similar motivation, Hebert-Johnson et al. [23] et al. suggest a fairness notion they term mutli-calibration that relates to accurate prediction of all populations that are *computationally identifiable*. Both these works show that their settings are equivalent to agnostic learning, which has strong computational hardness results but tends to have good heuristic guarantees.[3] Subgroup fairness is also discussed by Kim et al. [28, 29] for the related notion of multi-accuracy, with the aim of post-processing data to achieve this notion while maintaining overall accuracy [28] as well as metric subgroup fairness notions [29]. Our approach similarly considers overlapping demographic groups, but focuses on the more complex setting of online decision-making under limited feedback and addresses inherent conflicts between the incentives of different subgroups. In fact, even for the batch setting, our impossibility result of Section 5 with respect to the criterion of unweighted average of false positive and false negative rates is of a purely statistical flavor (has nothing to do with computational issues or arrivals being online). It therefore provides insights on complications that exist even when all the incentives seem well aligned. On the other hand, our connection to sleeping experts does not appear to directly have implications to multicalibration and multiaccuracy for similar reasons as the issues encountered regarding Incentive Compatibility; these notions tend to require a similar *no negative regret* property in order to be satisfied in an online context (similar to our results in Sections 4.1-4.2).

Fairness issues in online decision-making have also recently been considered. Joseph et al. [25] focus on a bandit learning approach and impose what they call *meritocratic fairness* against individuals with some stochastic but unknown quality. Celis et al. [10] discuss how to alleviate bias in settings like online advertising where bandit learning can lead to overexposure or underexpsure to particular actions. Blum et al. [7] focus on adversarial online learning and examine for different fairness notions whether non-discriminatory predictors can be combined efficiently in an online fashion while preserving non-discrimination. A recent line of work also focuses on online settings where decisions made today affect what is allowed tomorrow as they need to be connected via some metric-based notion of individual fairness [34, 19, 21]. Related to our work, Raghavan et al. [36] study externalities that arise in the exploration of classical stochastic bandit algorithms when applied across different subpopulations. Finally, Bechavod et al. [5] study a similar notion of one-sided feedback in online learning with fairness in mind. Unlike us, the latter work does not apply to overlapping populations but instead they take a contextual bandit approach, focus on stochastic and not adversarial losses, and aim for balance notions of fairness (where, as we discussed, there is conflict between incentives of designer and the groups).

[3] Their connection implies that for exact auditing, a linear dependence on the number of subpopulations is required but can be overcome if additional structure exists. Our work also has a linear dependence on the number of subgroups as it explicitly lists the subgroups. Understanding if this can be improved in our setting when the subgroups and predictors have additional structure is an interesting open direction.

Our work applies adversarial online learning which was initiated by the seminal works of Littlestone and Warmuth [32], and Freund and Schapire [16]. The classical experts guarantee we use in our first reduction can come from any of these or later developed algorithms. The apple tasting setting we consider to model the one-sided feedback was introduced by Helmbold et al. [24]; a related concept is that of label-efficient prediction that instead has an upper bound on the number of times the learner can explore [11]. Sleeping experts have been introduced by Blum [6] and Freund et al. [17]. Subsequently they were extended to a more general case of confidence-rated experts, and the results were better optimized [8, 18, 35]. The sleeping expert full feedback guarantee we use in our reductions is the one of AdaNormalHedge [35]. To the best of our knowledge, our work is the first to consider sleeping experts in the context of either apple tasting or label efficient prediction. We do so to enable our algorithms to deal with overlapping populations while only using realistic feedback (incorporating the one-sided nature of feedback).

2 Basic model

Online learning with group context

We consider an online learning setting with multiple overlapping demographic groups. The set of groups $\mathcal{G}$ can correspond to divisions based on gender, age, ethnicity, or other attributes. People (also referred to as examples) arrive sequentially, and the example at round $t = 1, 2, \ldots, T$ can be simultaneously a member of multiple groups (e.g., *female* and *hispanic*); the subset $\mathcal{G}_t \subseteq \mathcal{G}$ denotes all groups that person t belongs to.

At each round t, the system designer (or *learning algorithm* or *learner*) denoted by $\mathcal{A}$ aims to classify incoming examples by predicting a label $\hat{y}_t \in \hat{\mathcal{Y}}$. For example, in binary classication with deterministic predictors, the prediction space consists of positive and negative labels, i.e. $\hat{\mathcal{Y}} \in \{+, -\}$ (e.g. whether the corresponding person should be admitted to an honors class). To assist her goal, the designer has access to a set $\mathcal{F}_t$ of rules that suggest particular labels according to the features of the example; these are typically referred to as *experts* although they are not necessarily associated to any particular external knowledge. At every example, each expert $f \in \mathcal{F}_t$ makes a prediction $\hat{y}_{t,f} \in \hat{\mathcal{Y}}$ and the learner selects which expert's advice to follow in a (possibly randomized) manner; we use $p_{t,f}$ to denote the probability with which the learner follows the advice of expert f. Subsequently, the true label $y_t \in \mathcal{Y}$ is realized and each expert f is associated with a loss $\ell_{t,f} \in [0, 1]$. For example, if both the prediction and true label spaces are deterministic, i.e. $\hat{\mathcal{Y}} = \mathcal{Y} = \{+, -\}$, then a reasonable loss is whether the prediction was correct: $\ell_{t,f} = \mathbf{1}\{\hat{y}_{t,f} \neq y_t\}$. In order to not impose any i.i.d. assumption, we allow the losses to be adversarially selected. The learner then suffers expected loss $\hat{\ell}_t(\mathcal{A}) = \sum_{f \in \mathcal{F}_t} p_{t,f} \ell_{t,f}$ and observes some feedback (discussed below).

Feedback observed

In the first portion of this paper, we assume the learner receives *full feedback*, i.e. at the end of the round she observes the losses of all experts (this typically can be achieved by observing the label). In Section 3.2, we turn our attention to the apple tasting setting in which we only receive feedback about the losses when we select the positive outcome. To ease notation and streamline presentation, we present here the performance and fairness notions for full feedback and defer the apple tasting definitions to Section 3.2.

Overall regret guarantee

One natural goal for the designer in this setting is that it performs as well as the best among a class of experts $\mathcal{F}$ that are available every round, i.e. $\forall t : \mathcal{F} \subseteq \mathcal{F}_t$. Intuitively, when there exists a rule that consistently classifies examples more accurately, the learner should eventually realize this fact and trust it more often (or at least perform as well via combining other rules). This is formalized by the following notion of regret.

$$Reg = \sum_{t=1}^{T} \sum_{f \in \mathcal{F}_t} p_{t,f} \ell_{t,f} - \min_{f^\star \in \mathcal{F}} \sum_{t=1}^{T} \ell_{t,f^\star}. \tag{1}$$

In the classical expert setting, $\mathcal{F}_t = \mathcal{F}$ for all rounds t. Algorithms such as the celebrated multiplicative weights [16] incur regret that, on average, vanishes over time at a rate of $\sqrt{\log(|\mathcal{F}|)/T}$. Hence, despite the input not being i.i.d., the penalty we pay for not knowing in advance which expert is the best is very small and goes to 0 at a fast rate. We allow changes in the sets $\mathcal{F}_t$ to incorporate adaptive addition of rules as well as group-specific rules.

Subgroup regret guarantees

In order to not treat any group worse than what is inevitable, we are especially interested in group-based performance guarantees. In particular, for each group $g \in \mathcal{G}$, we want the performance on its members to be nearly as good as the best expert in a class $\mathcal{F}(g)$. This class can consist of all rules in $\mathcal{F}$, in which case this means we care not only about competing with the best rule in the class overall but also having the same guarantee for each group. It also allows each group to have rules specialized to it; for example, a third-party entity may observe a disparity in the performance of the group compared to what is achievable and recommend the use of a particular rule. To ease presentation we assume that the set $\mathcal{F}(g)$ is fixed in advance but most of our results extend to the case where new rules are added adaptively as potential unfairness is observed (see Remark 2). This notion of group-based regret is formalized below:

$$Reg(g) = \sum_{t:g \in \mathcal{G}_t} \sum_{f \in \mathcal{F}_t} p_{t,f} \ell_{t,f} - \min_{f^\star \in \mathcal{F}(g)} \sum_{t:g \in \mathcal{G}_t} \ell_{t,f^\star}. \tag{2}$$

In Section 3, we show that, via connecting to the literature of sleeping experts, we can have the average group-based regret vanish across time for all groups while still retaining the overall regret guarantee described above. In Section 5, we show that this is not in general possible for objectives based on fixed averages of false-positive and false-negative rates.

3 Sleeping experts and one-sided feedback

In this section, we focus on subgroup regret guarantees and conceptually connect the quest for these guarantees to the literature of sleeping experts and the incentives of the groups.

3.1 Subgroup regret guarantees via sleeping experts

Sleeping experts

Sleeping expert algorithms were originally developed to seamlessly combine task-specific rules so that their coexistence does not create negative externalities to other tasks. More formally, there is a set of experts $\mathcal{H}$ and, at each round t, any expert $h \in \mathcal{H}$ may decide

to either become active (fire) or abstain (sleep); the set of experts that fire at round t is denoted by $\mathcal{H}_t$. At any round, the algorithm can only select among active experts, i.e. puts non-zero probability $p_{t,h}$ only on experts $h \in \mathcal{H}_t$. The goal is that, for all experts $h^\star \in \mathcal{H}$, the performance of the algorithm in the rounds where the experts fire is at least as good as the one of $h^\star$. More formally the sleeping regret is:

$$\mathit{SleepReg}(h^\star) = \sum_{t:h^\star \in \mathcal{H}_t} \sum_{h \in \mathcal{H}} p_{t,h}\ell_{t,h} - \sum_{t:h^\star \in \mathcal{H}_t} \ell_{t,h^\star}. \tag{3}$$

The goal is to ensure that the average sleeping regret for any sleeping expert $h \in \mathcal{H}$ is vanishing with the number of times the expert fires, $T(h) = |t : h \in \mathcal{H}(t)|$, Multiple algorithms [6, 17, 8, 18, 35] achieve this goal. Probably the most effective among them is AdaNormalHedge by Luo and Schapire [35] with an average sleeping regret of $O\left(\sqrt{\log(|H|)/T(h)}\right)$. We elaborate on this algorithm in Section 4.1 in order to discuss its game-theoretic properties.

Subgroup regret formulated via sleeping experts

Looking closely at the definition of the desired subgroup regret from Eq. (2) and the one of sleeping regret from Eq. (3), there are clear similarities, which motivates formulating our problem as a sleeping experts problem and applying algorithms such as AdaNormalHedge. This leads to the following theorem.

▶ **Theorem 1.** *Let $\mathcal{A}$ be an algorithm with sleeping regret bounded by $\mathcal{O}\left(\sqrt{T(h) \cdot \log(|\mathcal{H}|)}\right)$ for any expert $h \in \mathcal{H}$ where $\mathcal{H}$ is any class. Let $\mathcal{G}$ be a set of overlapping groups and $N = |\mathcal{F}| + \sum_{g \in \mathcal{G}} |\mathcal{F}(g)|$. Then $\mathcal{A}$ can provide subgroup regret guarantee of $\mathcal{O}\left(\sqrt{T(g) \cdot \log(N)}\right)$ for any $g \in \mathcal{G}$ while ensuring overall regret guarantee of $\mathcal{O}(\sqrt{T \log(N)})$.*

Proof. The idea to bound subgroup regret as a sleeping experts problem is to have each expert $f \in \mathcal{F}(g)$ fire only for members of group g, guaranteeing that they experience performance at least as good as its own. One small issue is that we may want to use the same rule $f \in \mathcal{F}_t$ for multiple subgroups; to deal with that, we create different copies of this expert, each associated to one group.

More formally, we create a set of global sleeping experts $\mathcal{H}$ with one sleeping expert $h \in \mathcal{H}$ for every expert $f \in \mathcal{F}$. These sleeping experts fire every round and ensure the overall regret guarantee. Subsequently we create disjoint sets $\mathcal{H}(g)$ for each group $g \in \mathcal{G}$ where again we create a sleeping expert $h \in \mathcal{H}(g)$ for any expert $f \in \mathcal{F}(g)$. These sleeping experts fire only when the example is a member of group g and hence ensure the subgroup regret guarantee. The eventual sleeping expert set is $\bigcup_{g \in \mathcal{G}} \mathcal{H}(g) \cup \mathcal{H}$. The cardinality of this set is $N = |\mathcal{F}| + \sum_{g \in \mathcal{G}} |\mathcal{F}(g)|$. This formulation enables to automatically apply sleeping experts algorithms achieving subgroup regret of $\sqrt{T(g) \cdot \log(N)}$ for any group $g \in \mathcal{G}$ while also guaranteeing an overall regret of $\sqrt{T \cdot \log(N)}$. ◀

▶ Remark 2. In the above formulation, we assumed that all the experts exist in the beginning of the time-horizon. However, the sleeping experts algorithms allow for experts to be added dynamically over time (treating them as not firing in the initial rounds). Hence we can adaptively add new sleeping experts if a group or some third-party entity suggests it, guaranteeing that we do at least as well in the remainder of the game on the members of the group without affecting with the subgroup regret guarantees of other overlapping groups.

3.2 Subgroup regret with one-sided feedback

We now move our attention to the more realistic setting where we receive the label of the example (and therefore learn the losses of the experts) only if we select the positive outcome (e.g. admit the student to the honors class and observe her performance). This is captured by the so-called *apple tasting* setting which dates back to the work of Helmbold et al. [24].

Pay-for-feedback

Our algorithms opearate in a more challenging model where, at the beginning of each round, the learner needs to select whether to ask for the label. If she asks for it, she receives it at a cost of 1 instead of the loss of this outcome. Any guarantee for this setting is automatically an upper bound for the apple tasting setting. We can transform any such algorithm to an apple tasting one by selecting the positive outcomes at the rounds that we ask the label and ignoring any extra feedback. The loss of the positive outcome is upper bounded by 1; since we assume the losses to be bounded in $[0, 1]$, the loss in the pay-per feedback model is therefore only larger.

There are a few reasons why we want to work on this more stringent setting instead of the classical apple tasting setting. First, this feedback model makes it easy to create an estimator that is unbiased (since it does not condition on the prediction for the example and therefore our estimates do not suffer from selection bias). Second, in some applications, this model actually is more appropriate; for example, one may need to poll the participant to learn about their experience (which may be independent of whether they were classified as positive). Finally, this serves as an upper bound on the apple tasting setting; as we will see, arguing about lower bounds in this setting is significantly easier. Using the feedback in a more fine-grained way is an interesting open direction.

We now offer three guarantees for sleeping experts in the pay-per feedback setting, which are all achieved via black-box reductions to full-feedback algorithms (either sleeping experts or classical experts). Although the reductions become more involved as we proceed in the paper, no guarantee strictly dominates each other. Our algorithms select random points of exploration (when they ask for the labels to receive feedback). We denote by $\mathcal{E}$ the set of rounds that the algorithm ended up exploring (this is a random variable). For ease of presentation, we assume that we know the size of each demographic group and of all the intersections among groups; if these are not known, we can apply the so called doubling trick (similarly to the way described in Section 4.2).

First reduction: Independent classical experts algorithms per intersection

The first reduction we provide comes from treating all disjoint intersections between subgroups separately and running separate apple-tasting versions of classical (non-sleeping) experts algorithms on each intersection. Although this provides optimal dependence on the size of each subpopulation, the guarantee has an exponential dependence on the number of different groups.

For each disjoint intersection I between groups, let $T(I)$ be the size of this intersection and denote by $g \in I$ the case when intersection I includes g. Our algorithm splits the examples that lie in this intersection in $(T(I))^{2/3}$ phases, each of which consists of $(T(I))^{1/3}$ examples. At every phase, we select one random point of exploration. Whenever an example comes that belongs in I, our algorithm follows the advice of a classical experts algorithm (e.g. multiplicative weights) that is associated to I. This experts algorithm is updated at the end of the phase by the sample of the exploration round. This construction is in the spirit of Awerbuch and Mansour [4].

▶ **Theorem 3.** *Let $\mathcal{A}$ be an algorithm with regret bounded by $\mathcal{O}\sqrt{T \cdot \log(|\mathcal{H}|)}$ when compared to an expert class $\mathcal{H}$, run on T examples and split the examples in disjoint intersections, where each intersection corresponds to a distinct profile of subgroup memberships. For each intersection I, randomly selecting an exploration point every $(T(I))^{1/3}$ examples and running separate versions of $\mathcal{A}$ for each I provides subgroup regret on group $g \in \mathcal{G}$ of*

$$\mathcal{O}\left(\left(2^{|\mathcal{G}|}\right)^{1/3} \cdot (T(g))^{2/3} \cdot \sqrt{\log(N)}\right)$$

where $T(g) = |t : g \in \mathcal{G}(t)|$ is the size of the g-population and $N = |\mathcal{F}| + \sum_{g \in \mathcal{G}} |\mathcal{F}(g)|$.

Proof sketch. The guarantee follows from three observations formalized in Appendix A.

1. Among the exploration points, we run a classical experts algorithm so, on these examples, we have a regret guarantee that is square-root of the number of these examples.
2. For each phase, the exploration point is randomly selected and therefore the regret that we incur in the exploration point is an unbiased estimator of the average regret we incur in the whole phase (since the distribution of the algorithm in the phase is the same). As a result, the total regret in a phase is in expectation $(T(I))^{1/3}$ times the regret at the exploration point.
3. A particular group can have examples in at most $2^{|G|}$ intersections (as this is all the possible membership relationships with respect to the demographic groups). ◀

Second reduction: Sleeping experts with fixed exploration phases

Aiming to avoid the exponential dependence on the number of groups, we now apply a sleeping experts algorithm such as AdaNormalHedge as our base algorithm. The algorithm described in this part removes this exponential dependence but introduces a dependence on the time horizon and therefore the regret guarantee can be suboptimal for minority populations whose size is significantly smaller than the total population. On the other hand, when all populations are well represented (and are of the same order as the time-horizon) then the guarantee has the optimal dependence on the size of the population without suffering in the number of groups.

The algorithm splits the examples in $T^{2/3}$ phases and selects one random point in each of the phases. Each phase consists in total of $T^{1/3}$ examples but its examples can be distributed differently across it. At the end of the phase, we update a sleeping experts algorithm (e.g. AdaNormalHedge) based on the observations at the exploration point.

▶ **Theorem 4.** *Let $\mathcal{A}$ be an algorithm with sleeping regret bounded by $\mathcal{O}\left(\sqrt{T(h) \cdot \log(|\mathcal{H}|)}\right)$ for any expert h in class $\mathcal{H}$. Randomly selecting an exploration point every $T^{1/3}$ examples (irrespective of what groups they come from) and running $\mathcal{A}$ on these points provides subgroup regret on group $g \in \mathcal{G}$ of*

$$\mathcal{O}\left(T^{1/6} \cdot (T(g))^{1/2} \cdot \sqrt{\log(N)}\right)$$

where $T(g) = |t : g \in \mathcal{G}(t)|$ is the size of the group-g population and $N = |\mathcal{F}| + \sum_{g \in \mathcal{G}} |\mathcal{F}(g)|$.

Proof sketch. The guarantee follows from two observations formalized in Appendix B.

1. Given that we run a sleeping experts algorithm across the exploration points, if we just focused on those examples, we simultaneously satisfy regret on them that is square-root of their size.

2. Within any phase the exploration point is selected uniformly at random. As a result, it is an unbiased estimator of the average regret we incur in the whole phase. Note that this is now the average across all rounds and not only rounds where we have members of the particular group which results in the dependence on the time-horizon T. ◀

Third reduction: Sleeping experts with adaptive exploration phases

Our final reduction aims to remove the dependence on the time horizon while also avoiding an exponential dependence on the number of groups. Towards this end, we make the size of the phases adaptive based on the sizes of the populations. Our guarantee has both the aforementioned desired properties. On the negative side, the exponent on the group size is suboptimal (see discussion in the end of the section).

We again use a sleeping experts algorithm $\mathcal{A}$ across phases but phases are now designed adaptively. At the beginning of each phase r, we initialize a counter per group to capture the number of examples we have seen from it in phase r. When an example arrives, we increase the corresponding counters for all groups related to the example (possibly the example belongs in multiple groups; then we increase all the corresponding counters simultaneously). The phase ends when one of the groups $g \in \mathcal{G}$ has received $(T(g))^{1/4}$ examples in this phase.

At the beginning of a phase r, we draw for each group $g \in \mathcal{G}$ a uniform random number $X(g,r) \in \{1, 2, \ldots, T(g)\}$. This determines the exploration round for group g at phase r; let $t(r,g)$ be the random variable determining the time that the $X(g,r)$-th example (after time τ_r) from group g will arrive. If the phase ends before this example arrives, i.e. $t(r,g) > \tau_r$ then we associate this phase with 0 estimated losses for group g: $\tilde{\ell}_f(r,g) = 0$ for all $f \in \mathcal{F}(g)$. Otherwise, the estimated loss corresponding to the phase is the loss at the exploration point, i.e. $\tilde{\ell}_f(r,g) = \ell_{t(r,g),f}$. Since the phase ends once any group counter reaches the upper bound on examples for its phase, this means that we may not reach the exploration point for some other groups (this is the reason why we may have $t(r,g) > \tau_{r+1}$). Before proceeding to the next phase, we feed the estimated losses $\tilde{\ell}(r,g)$ to $\mathcal{A}$.

▶ **Theorem 5.** *Applying the above algorithm provides subgroup regret on group $g \in \mathcal{G}$ of*

$$\mathcal{O}\left(|\mathcal{G}| \cdot (T(g))^{3/4} \cdot \sqrt{\log(N)}\right)$$

where $T(g) = |t : g \in \mathcal{G}(t)|$ is the size of the g-population and $N = |\mathcal{F}| + \sum_{g \in \mathcal{G}} |\mathcal{F}(g)|$.

Proof sketch. There are three components to prove this guarantee, formalized in Appendix C.

1. The number for relevant phases of each group (phases where they have at least one example) is at most $T(g)$. This provides an upper bound on the number of phases that we need to consider with respect to group g.
2. Using a similar analysis as before, we can create a guarantee about the regret we are incurring in the exploration points and multiply it by the $(T(g))^{1/4}$ which is the size of the phase. This would have created a completely unbiased estimator if there was no overlap with other groups.
3. A final complication is that exploration may occur due to other groups so we need to understand how much we lose there. For that, we observe that smaller groups are explored with higher probability (the interaction with larger groups does not therefore significantly increase their probability of inspection). On the other hand, larger groups do not often collide with significantly smaller groups due to the latters' size. ◀

On the optimality of the bounds

In the pay-for-feedback model, even if we do not work in a sleeping experts setting, the best that one can hope for is a guarantee of $T^{2/3}$. If we explore T^a examples, we obtain a regret of $T^{a/2}$ on them. If the estimator is unbiased, we need to then multiply this with T^{1-a}, which gives a regret of $T^{1-a/2}$. Since we pay for feedback, we also lose T^a. The maximum of the two is minimized when $a = 2$. As a result, even if the groups were disjoint, we cannot hope for a better subgroup regret than $(T(g))^{2/3}$. Note that our results do not quite achieve this bound: having either a multiplicative term exponential in the number of groups (Theorem 3) or having a portion of the regret bound be in terms of the total time T rather than $T(g)$ (Theorem 4). Achieving a bound of $(T(g))^{2/3}$ without enumerating over all possible disjoint intersections across groups is therefore an interesting open direction.

4 A game-theoretic interpretation

In this section, we provide a game-theoretic interpretation of the above subgroup regret guarantee, connecting it to the notions of Individually Rationality (IR) and Incentive Compatibility (IC).

Individual Rationality

In game theory, a mechanism is considered Individually Rational when the participants prefer to stay and be served in the system rather than to leave and use their best outside option. Consider each subgroup as a player in a game and the cost experienced by this player as the total loss in all its members; e.g., imagine each group has a representative who looks out for their best interests. This representative has access to the rules in $\mathcal{F}(g)$ (private type) and can opt to defect from the global learning system and create its own predictor with only rules in $\mathcal{F}(g)$.

We say that a learning algorithm induces an IR mechanism if no group has significant incentive to opt out. (We cannot require zero incentive since the system needs some time to learn.)

The subgroup regret guarantee can be thought as an asymptotic version of the individual rationality property. The guarantee ensures that the average benefit from being served outside of the system vanishes as the group size grows as formalized below.

▶ **Definition 6.** *A learning algorithm induces an asympotically individual rational (IR) mechanism if no group gains (asymptotically) by getting served outside of the system.*

$$\forall g \in \mathcal{G} : \sum_{t:g\in\mathcal{G}_t} \sum_{f\in\mathcal{F}_t} p_{t,f}\ell_{t,f} - \min_{f^\star\in\mathcal{F}(g)} \sum_{t:g\in\mathcal{G}_t} \ell_{t,f^\star} = o(T(g)).$$

Incentive Compatibility

A second desired game-theoretic notion is that of Incentive Compatibility which states that the player has no incentive to misreport her true type. In our context, we define the type of a group to be the set $\mathcal{F}(g)$ of experts that it knows about, and IC means that group g could not achieve enhanced performance for the group by hiding a subset of $\mathcal{F}(g)$ and removing it from the global learning process. Recall that $\hat{\ell}_t(\mathcal{A}) = \sum_{f\in\mathcal{F}(t)} p_f^t \ell_f^t$ denote the expected loss of the algorithm $\mathcal{A}$ at round t.

We say that a learning algorithm induces an IC mechanism if removing a subset of group-based experts does not improve the performance of the group. More formally, let $\mathcal{A}(\emptyset)$ denote the algorithm running with all the experts and nothing removed and $\mathcal{A}(\{g, H\})$ denote the algorithm running with the subset $H \in \mathcal{F}(g)$ removed from the group-based experts and also from the overall set $\mathcal{F}$. Then:

▶ **Definition 7.** *A learning algorithm $\mathcal{A}$ induces an asympotically incentive compatible (IC) mechanism if no group gains (asymptotically) by hiding a subset of its experts.*

$$\forall g \in \mathcal{G}, \forall H \in \mathcal{F}(g) : \sum_{t:g\in\mathcal{G}(t)} \hat{\ell}_t(\mathcal{A}(\emptyset)) - \sum_{t:g\in\mathcal{G}(t)} \hat{\ell}_t(\mathcal{A}(\{g, H\})) = o(T(g)).$$

As before, we cannot hope to achieve the IC property exactly as extra experts will definitely delay the learning process, but we would like to satisfy an approximate version of this property where the average benefit from removing some experts vanishes as the group size grows. This is a desirable property as, when satisfied, it suggests that the groups should not overly think about potential adverse effects of suggesting particular predictors but instead provide all their proposed rules.

4.1 Roadblocks in applying sleeping experts for Incentive Compatibility

In this section, we show a strong negative result about classical sleeping experts algorithms with respect to the IC property. To make this formal, we present the result for the AdaNormalHedge algorithm of Luo and Schapire [35] but a similar intuition carries over to other sleeping experts algorithms (see Section 4.3).

AdaNormalHedge

AdaNormalHedge [35] is an algorithm with strong adaptive regret guarantees. Its sleeping experts version starts with a set of experts with cardinality N and a prior distribution q that is typically initialized uniformly: $q_i = 1/N$ for all $i \in [N]$. Every expert keeps two quantities $R_{t,i}$ capturing the total regret it has experienced so far in the rounds that it fired and $C_{t,i}$ capturing the desired regret guarantee. These parameters determine the weight of its expert which is expresssed using a potential function $\Phi(R, C) = \exp(\frac{\max(0,R)^2}{3C})$ giving rise to a weight function:

$$w(R, C) = \frac{1}{2}(\Phi(R + 1, C + 1) - \Phi(R - 1, C + 1).$$

More formally, both the expert quantities are initialized to 0, i.e. $R_{0,i} = C_{0,i} = 0$. At round $t = 1 \dots T$, a set $A(t)$ of experts is activated and the learner predicts with probability proportional to the weight of its firing expert: $p_{t,i} \propto q_i \cdot w(R_{t-1,i}, C_{t-1,i}) \cdot \mathbf{1}\{i \in F(t)\}$.[4] The adversary then reveals the loss vector ℓ_t and the learner suffers loss $\hat{\ell}_t = \sum_{i\in[N]} p_{t,i}\ell_{t,i}$. This gives rise to an instantaneous regret for each firing expert: $r_{t,i} = \left(\hat{\ell}_t - \ell_{t,i}\right) \cdot \mathbf{1}\{i \in A(t)\}$ which is used to update the expert parameters: $R_{t,i} = R_{t-1,i} + r_{t,i}$ and $C_{t,i} = C_{t-1,i} + |r_{t,i}|$, before proceeding to the next round.

The regret of this algorithm with respect to an expert $i \in [N]$ is roughly of order $\sqrt{C_{T,i}}$ which in the sleeping experts version gives a sleeping regret $\sqrt{|t : i \in A(t)| \log(N)}$. This is why using such an algorithm for subgroup regret guarantees provides a guarantee of $\sqrt{T(g) \log(N)}$, ignoring constants.

[4] Luo and Schapire [35] predict arbitrarily if all weights are 0; we commit on selecting uniformly at random then.

The IC lower bound

Although the subgroup regret guarantee that sleeping experts provide makes them satisfy an asymptotic version of the IR property, we now show that this is not the case for the IC property; we illustrate this for AdaNormalHedge and further discuss it in Section 4.3.

▶ **Theorem 8.** *AdaNormalHedge does not induce an asymptotically incentive compatible mechanism, i.e. there exists an instance where a group can asymptotically benefit from hiding one of its experts.*

Proof. Consider a setting with two groups where the bigger group B consists of the whole population whereas the smaller group S corresponds to half of the population. Every odd round an example from S arrives and every even round an example from $B \setminus S$ arrives. The algorithm has access to one global expert $\mathcal{F} = \{f\}$ as well as one group-specific expert per group: $\mathcal{F}(g) = \{f(g)\}$ for $g \in \{B, S\}$.

- Both group-specific experts have always loss $\ell_{t,f(g)} = 0.2$ if $g \in \mathcal{G}(t)$.
- The global expert is really bad at predicting group S: $\ell_{t,f} = 1$ if $g \in S$ but makes no mistakes on the remaining population: $\ell_{t,f} = 0$ if $g \in B \setminus S$.

The high-level idea on why IC does not hold is the following. Group B prefers to use expert $f(S)$ on members of group S and expert f on $B \setminus S$; this is achieved if it hides expert $f(B)$. However, if it does not, AdaNormalHedge ends up using often expert $f(B)$ on $B \setminus S$ which leads to a much higher loss. Intuitively, since $f(B)$ and f make predictions on exactly the same set of examples and $f(B)$ has lower total loss, then $f(B)$ gets much higher weight than f — the algorithm therefore uses $f(B)$ instead of f on $B \setminus S$.

More formally, suppose first that group B hides expert $f(B)$. The sleeping regret guarantee for expert $f(S)$ guarantees that expert $f(S)$ is selected in all but a vanishingly small number of rounds. As a result, asymptotically, the loss accumulated from group S is $0.2 \cdot (T/2)$. Given that $f(B)$ is not an option (as it is hidden), in members $B \setminus S$ the algorithm can only select expert f incurring 0 loss.

We now show that, if $f(B)$ is not hidden, it incurs more loss in members of $B \setminus S$ without gaining on S. In this case, we show below that expert f is selected with probability $p_{t,f} \leq 1/2$ after a few initial rounds. This leads to an additional loss of at least $0.2 \cdot (T/4)$ on examples of $B \setminus S$ since we select expert $f(B)$ which has higher loss than f on these examples in at least half of the even rounds in expectation. As a result, by not hiding expert $f(B)$, the algorithm selects it often which leads in an additional loss that is linear in T – this directly implies that group B is better off by hiding this expert and enhancing the overall performance.

What is left is to show why the probability of selecting expert f is indeed $p_{f,t} \leq 1/2$ after a few inital steps. The sleeping regret guarantee for expert $f(S)$ implies that the cumulative (across rounds) probability of selecting expert f on examples in S until round t is at most $\sqrt{t}$ up to constants and log factors. As a result, the expected loss of the algorithm until round t is at most $\hat{\ell}_t \leq 0.2 \cdot t/2 + \sqrt{t}$ and the total instantaneous regret of experts f and $f(B)$ on odd rounds (i.e., members of group S) is

$$\sum_{\substack{\tau \leq t \\ \tau \text{ is odd}}} r_{\tau,f} \geq 0.8 \cdot t/2 - \sqrt{t} \qquad \text{and} \qquad \sum_{\substack{\tau \leq t \\ \tau \text{ is odd}}} r_{\tau,f(B)} \leq \sqrt{t} \qquad \text{respectively.}$$

On even rounds (i.e., members of $B \setminus S$), the algorithm selects either f or $f(B)$; therefore its loss is at most 0.2. This means that the instantaneous regret on these rounds is:

$$\sum_{\substack{\tau \leq t \\ \tau \text{ is even}}} r_{\tau,f} \geq -0.2 \cdot t/2 \qquad \text{and} \qquad \sum_{\substack{\tau \leq t \\ \tau \text{ is even}}} r_{\tau,f(B)} \leq 0.2 \cdot t/2 \qquad \text{respectively.}$$

As a result, after a few initial rounds, the cumulative instantaneous regret of f is consistently negative and also smaller than the one of $f(B)$. This means that, by the construction of the potential function, the weight of f is 0 as $\Phi(R_{f,t+1}+1, C+1) = \Phi(R_{f,t+1}-1, C+1) = 1$. Since Φ is an increasing function on its first argument and the probability is proportional on the weight, this means that f has the smallest probability across all other experts who fire and therefore has probability of being selected at most $1/2$ which is what we wanted to show. Note that, when $f(B)$ is hidden, the weight still becomes 0 but now f is the sole alternative and is therefore always selected in members of $B \setminus S$. ◀

The reason why this negative result arises is that, by hiding a subset of the experts, the group can potentially lead the algorithm to use different experts in different disjoint parts of the population. Sleeping experts algorithms penalize each expert for its overall performance at times when it fires and does not distinguish disjoint subpopulations where it performs much better.

4.2 Incentive Compatibility in a computationally inefficient way

Multiplicative weights for each disjoint subgroup

We now turn our attention to the use of separate algorithms for each disjoint intersection of groups. This suffers from an exponential dependence on the number of groups but satisfies both IR and IC. In some sense, it therefore serves as an existential proof that satisfying these quantities in an online manner is feasible and creates an intriguing open question of whether this can be achieved in a computationally efficient manner.

We run separate multiplicative weights algorithms for each disjoint group intersection. More formally, for every $S \in 2^{|\mathcal{G}|}$, we run sub-algorithm $\mathcal{A}(S)$ on examples t where $g \in S$ if and only if $g \in \mathcal{G}_t$. We denote by $\mathcal{A}_t$ this sub-algorithm. We assume that experts are not added adaptively for this part (if a new expert appears then we reinitialize the algorithm). The sub-algorithm $\mathcal{A}(S)$ has as experts all experts that fire at examples associated with S so all members of $\mathcal{F}$ or $\mathcal{F}(g)$ for some $g \in S$. We let $N(\mathcal{A})$ denote the number of those experts for ub-algorithm $\mathcal{A}$.

For sub-algorithm $\mathcal{A}$, each expert i is initialized with weight $w_{t,i}(\mathcal{A}) = 1$. The algorithm selects experts proportionally to the weights in the corresponding sub-algorithm, i.e. $p_{t,i} = \frac{w_{t,i}(\mathcal{A}_t)}{\sum_{j \in \mathcal{F}(S)} w_{t,j}(\mathcal{A}_t)}$. We then multiplicatively update weights with learning rate η only for $\mathcal{A}_t$: $w_{t+1,i}(\mathcal{A}) = w_{t,i} \cdot (1-\eta)^{\ell_{t,i} \cdot \mathbf{1}\{\mathcal{A}=\mathcal{A}_t\}}$. Denoting by $T(\mathcal{A})$ the size of the disjoint subgroup, we should let $\eta = \sqrt{\log(N(\mathcal{A}))/T(\mathcal{A})}$ for a guarantee sublinear to this size. To deal with the fact that we do not know the size of each disjoint subgroup in advance we apply the so called doubling trick, assuming that it is 2^r (initial $r = 2$) and reinitializing the algorithm by increasing r – this can happen at most $\log(T)$ times.

This algorithm satisfies the vanishing subgroup regret property (thus also the asymptotic IR property) as any group consists of multiple disjoint subgroups and the group has vanishing regret within each of them; other than the regret term, it cannot hope to do better if it is served outside of the system with its own functions. We now show that these separate multiplicative weights algorithms also achieve the asymptotic IC property. For that, we use a nice property of multiplicative weights establishing that multiplicative weights not only does not do worse than the best expert, but it also does not do better. This was first formalized by Gofer and Mansour [20] and was used in a fairness context by Blum et al. [7] to establish that equality of average losses across different groups is preserved when combining experts that have equally good performance across these groups.

▶ **Theorem 9.** *Running separate multiplicative weights algorithms for each disjoint intersection among groups induces an asymptotically IC mechanism, i.e. no group can asymptotically benefit by hiding any of its experts.*

Proof. One essential step of the proof is the property that multiplicative weights with a fixed learning rate has performance almost equal to the one of the best expert. This is exactly shown in the proof of Theorem 3 in [7] which establishes that for any sub-algorithm and any fixed learning rate, the performance of the sub-algorithm is equal to the performance of the best expert $L^\star$ in these rounds plus, up to constants, $\eta \cdot L^\star + \log(N(\mathcal{A}))/\eta$. Since we run each sub-algorithm with a fixed learning rate for at most 2^r rounds, this is, up to constants less than $\sqrt{2^r \log(N(\mathcal{A}))}$. Summing across all $r = 2 \dots T(\mathcal{A})$, this is at most $\sqrt{T(\mathcal{A}) \log(N(\mathcal{A}))}$.

To now establish the asymptotic IC property, note that the intervals that have fixed learning rates are not affected by any groups' decision to hide a subset of their predictors. As a result, if some predictor is removed, then multiplicative weights will then have performance (asymptotically) close to the one of the best expert without the hidden one; this performance can only be worse (up to the regret term). This holds for any disjoint subgroup; it therefore still holds summing across all the (possibly exponential) disjoint subgroups. ◀

4.3 Open problem: Computationally efficient Incentive Compatibility

In Section 4.1, we showed that AdaNormalHedge does not induce an IC mechanism as it used a single weight that deteriorated significantly in some disjoing subgroups and made some experts not usable in places that were essential and where hiding some experts would help with that. Using a single weight for each sleeping expert and updating it based on its instantaneous regret is not unique to AdaNormalHedge but is present to other algorithms such as the one of Blum and Mansour [8]. Since the algorithms do not distinguish between instantaneous regret obtained by different disjoint subgroups, the same construction can extend to those as well. On the other hand, in Section 4.2, we also showed that separate multiplicative weights for each subgroup provide the asymptotic IC property as they have the nice property that the performance of the algorithm is exactly as good as the one of the best expert in this group. On the negative side, having one sub-algorithm per disjoint subgroup is computationally costly as it means that we have exponential number of sub-algorithms.

These two results lead to the following open question: can we design a computationally efficient algorithm (not enumerating over all disjoint subgroups) that satisfies the subgroup regret guarantee? Besides its application to subgroup fairness, this question has independent technical interest as it seems to require a fundamentally new approach for the sleeping experts problem.

5 Impossibility results for fixed averages of FNR and FPR

In this section we demonstrate that if rather than minimizing the *fraction of errors*, each group wishes to minimize the unweighted average of its False Negative Rate (FNR) and False Positive Rate (FPR), or any fixed nontrivial weighted average of these two quantities, then guarantees of the form given in earlier sections are intrinsically not possible when there is no zero-error predictor.[5]

[5] Minimizing just FNR (resp. just FPR) is trivial by predicting positive (resp. negative) on every example.

False negative and false positive rates

Many fairness notions explicitly consider false negative and false positive rates. For example, the notion of Equalized Odds [22] imposes that both these rates should be the same for all groups of interest, and the notion of Equality of Opportunity [22] imposes equality for just the FNR. Given the attention paid to false negative and false positive rates, it is natural to consider the objective of minimizing their average (or minimizing their maximum, which our negative results will also apply to). More formally, under this objective, the loss of the algorithm corresponds to $\frac{1}{|t:y_t=+|}\sum_{t:y_t=+}\hat{\ell}_t + \frac{1}{|t:y_t=-|}\sum_{t:y_t=-}\hat{\ell}_t$. If we have just one group and aim to achieve performance compared to the one of the best expert $f^\star \in \mathcal{F}(g)$ for this objective, i.e. $\frac{1}{|t:y_t=+|}\sum_{t:y_t=+}\ell_{t,f^\star} + \frac{1}{|t:y_t=-|}\sum_{t:y_t=-}\ell_{t,f^\star}$, this is feasible even in an online setting by running a no-regret algorithm and weighting each example based on the number of examples with the same label that exist. Also note that, unlike balance notions, *if groups are disjoint* then simultaneously optimizing this objective for both groups does not create some inherent conflict between groups, e.g. necessitating to have performance on some group that is worse than necessary.

Unfortunately, we show that while minimizing the unweighted average of FNR and FPR seems like a benign objective, it can be impossible to produce a global prediction strategy that, on each group, performs nearly as well as the best predictor given for that group under this objective. That is, even though all groups appear to have objectives that are "aligned" they may not be simultaneously satisfiable. This impossibility result holds due to purely statistical reasons even in the batch setting and has nothing to do with the online or non-i.i.d. nature of examples. Note that if the populations are not overlapping, the batch setting for this goal is straightforward: among the available classifiers, for each group select the one with the best performance according to the given objective. The following theorem shows that, with overlapping populations, this is no longer possible.

▶ **Theorem 10.** *Consider overlapping groups wishing to achieve performance on their members comparable to their group-specific predictors with respect to the objective of unweighted average of false positive and false negative rates. Even in the batch setting, there exist settings where it is impossible to simultaneously achieve this goal for both groups.*

Proof. Assume two groups $\mathcal{G} = \{A, B\}$ that have 80% of their examples disjoint from the other group and the remainder 20% in common, as illustrated in Figure 1. All the non-overlapping examples of group A have positive label and the non-overlapping examples of group B have negative label. With respect to the shared portion, the examples have labels that are uniformly distributed: conditioned on being in the intersection, the probability of the label being positive is 0.5.

Regarding the predictors, we have two predictors $\mathcal{F} = \{f_A, f_B\}$. Predictor f_A correctly predicts positive in the non-overlapping examples $(A \setminus B)$, and predicts negative in the overlapping part $A \cap B$. The false positive rate of this predictor is 0 and the false negative rate is 1/9. Analogously, predictor f_B predicts negative on the examples in $B \setminus A$ and predicts positive in $A \cap B$, resulting in a false positive rate on examples in B of 1/9 and a false negative rate of 0. Therefore, for both $g \in \{A, B\}$, f_g has a generalization error of 1/18 with respect to the unweighted average of false positive and false negative rates.

We now show that this performance cannot (even approximately) be simultaneously achieved for both groups by combining these two predictors even in the batch setting. In particular, since examples in $A \cap B$ all have uniformly random labels, we can only select some probability p to predict a positive label for points in the intersection. Even if we perfectly classify all the examples not in the intersection, if $p > 1/2$ then the false positive

rate of A is higher than $1/2$ (as it misclassifies half of the negative examples); otherwise the false negative rate of B is no less than $1/2$. This means that one of the two populations will necessarily have unweighted average of false positive and false negative rates higher than $1/4$ and therefore will not achieve performance even approximately as good as its best predictor. ◀

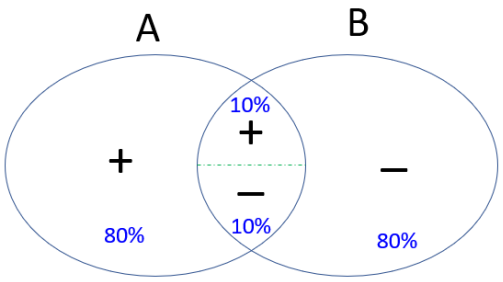

Figure 1 Construction illustrating that unweighted average of false negative and false positive rate cannot be simultaneously optimized with respect to overlapping populations (Theorem 10).

Discussion

The above result illustrates the additional complications caused by overlapping groups and highlights a subtlety in the positive results we provided in the previous sections. In particular, the key distinction is that for the objective of average loss (or error rate), the average contribution of any given example is the same across all groups; a misclassification is equally damaging for all groups an example belongs to. This is not the case in the setting considered here of minimizing the average (or maximum or any fixed nontrivial combination) of FPR and FNR where the harm of each misclassified example needs to be weighted differently across groups depending on their proportion of positive and negative examples.

6 Conclusions

In this paper, we consider settings where different overlapping populations coexist and we wish to design algorithms that do not treat any population unfairly. We consider a notion of fairness that corresponds to predicting as well as humanly (or algorithmically) possible on each given group, rather than based on requirements for equality. This framework can directly incorporate a designer's goal of good overall prediction by creating one extra group (for the designer) that includes all the examples. Our results extend to the more realistic one-sided feedback (apple tasting) setting and have a nice game-theoretic interpretation. Our work makes a step towards identifying fairness notions that work well in online settings and are compatible with the existence of multiple parties, each with their own interests in mind. Our impossibility results with respect to the average (or maximum) of false negative and false positive rates demonstrate that satisfying the interests of different overlapping populations is quite subtle, further highlighting the positive results.

Regarding incentives, we show how to efficiently achieve Individual Rationality and how to inefficiently achieve both Individual Rationality and Incentive Compatibility. Achieving IR and IC together in a computationally efficient way (without enumerating across all disjoint

intersections of subgroups) is a very interesting question that seems to require novel learning-theoretic ideas as we discuss in Section 4.3. On the apple tasting front, we provide three distinct guarantees; the resulting algorithms are near-optimal but suffer from orthogonal shortcomings as we discuss in Section 3.2. Avoiding these and achieving an optimal guarantee for sleeping experts with apple tasting is an interesting open question.

A Proof of Theorem 3

Theorem 3 restated

Let $\mathcal{A}$ be an algorithm with regret bounded by $\mathcal{O}\sqrt{T \cdot \log(|\mathcal{H}|)}$ when compared to an expert class $\mathcal{H}$, run on T examples and split the examples in disjoint intersections, where each intersection corresponds to a distinct profile of subgroup memberships. For each intersection I, randomly selecting an exploration point every $(T(I))^{1/3}$ examples and running separate versions of $\mathcal{A}$ for each I provides subgroup regret on group $g \in \mathcal{G}$ of

$$\mathcal{O}\left(\left(2^{|\mathcal{G}|}\right)^{1/3} \cdot (T(g))^{2/3} \cdot \sqrt{\log(N)}\right)$$

where $T(g) = |t : g \in \mathcal{G}(t)|$ is the size of the g-population and $N = |\mathcal{F}| + \sum_{g \in \mathcal{G}} |\mathcal{F}(g)|$.

Proof. The guarantee follows from three observations:

1. Among the exploration points, we run a classical experts algorithm so, on these examples, we have a regret guarantee that is square-root of the number of these examples.
2. For each phase, the exploration point is randomly selected and therefore the regret that we incur in the exploration point is an unbiased estimator of the average regret we incur in the whole phase (since the distribution of the algorithm in the phase is the same). As a result, the total regret in a phase is in expectation $(T(I))^{1/3}$ times the regret at the exploration point.
3. A particular group can have examples in at $2^{|G|}$ intersections (as this is all the possible membership relationships with respect to the demographic groups).

We now formalize these three ideas, to obtain the guarantee. Let $\mathcal{F}(I)$ be the set of experts that are either global or belong to some $g \in I$, and update $\mathcal{F}(g)$ to include both the global experts and the group-specific experts. Initially we split the performance of our algorithm across all the intersections I such that $g \in I$. Let $f^\star$ be the comparator with the minimum cumulative loss on g.

$$Reg(g) = \sum_{t:g \in \mathcal{G}(t)} \sum_{f \in \mathcal{F}(g)} p_{t,f} \ell_{t,f} - \sum_{t:g \in \mathcal{G}(t)} \ell_{t,f^\star} = \sum_{I:g \in I} \sum_{t:g \in \mathcal{G}(t) \cap I} \left(\sum_{f \in \mathcal{F}(g)} p_{t,f} \ell_{t,f} - \ell_{t,f^\star} \right)$$

Focusing on a particular intersection I we connect its regret to the performance of the exploration points. Denote by $t(r, I)$ the exploration point for phase r in intersection I. Also denote by $\tau(r)$ the beginning of the r-th phase. We use the fact that the exploration point is an unbiased representation on the regret at a phase (as it is selected uniformly and the algorithm is only updated at the end of the phase). Applying the guarantee for $\mathcal{A}$ on the exploration times of all phases, we obtain:

$$\begin{aligned}
\sum_{t:g \in \mathcal{G}(t) \cap I} \left(\sum_{f \in \mathcal{F}(g)} p_{t,f} \ell_{t,f} - \ell_{t,f^\star} \right) &= \sum_{r=1}^{(T(I))^{2/3}} \sum_{t=\tau_r}^{\tau_{r+1}-1} \left(\sum_{f \in \mathcal{F}(g)} p_{t,f} \ell_{t,f} - \ell_{t,f^\star} \right) \cdot \mathbf{1}\{g \in \mathcal{G}(t) \cap I\} \\
&= (T(I))^{1/3} \cdot \sum_{r=1}^{(T(I))^{2/3}} \mathbb{E}\left[\sum_{f \in \mathcal{F}(g)} p_{t(r,I),f} \ell_{t(r,I),f} - \ell_{t(r,I),f^\star} \right] \\
&\leq (T(I))^{1/3} \sqrt{(T(I))^{2/3} \log(|\mathcal{F}|)} = (T(I))^{2/3} \cdot \sqrt{\log(|\mathcal{F}|)}
\end{aligned}$$

where the expectations are taken over the random selections of $t(r, I)$.

Combining the above and applying Holder inequality, we obtain:

$$\mathcal{R}(g) = \sum_{I:g\in I}\sum_{t:g\in\mathcal{G}(t)\cap I}\left(\sum_{f\in\mathcal{F}(g)} p_{t,f}\ell_{t,f} - \ell_{t,f^\star}\right) \leq \sum_{I:g\in I}(T(I))^{2/3}\cdot\sqrt{\log(|\mathcal{F}|)}$$
$$\leq \left(\sum_{I:g\in I} 1\right)^{1/3}\cdot\left(\sum_{I:g\in I}(T(I))\right)^{2/3}\sqrt{\log(|\mathcal{F}|} \leq \left(2^{|\mathcal{G}|}\right)^{1/3}\cdot(T(g))^{2/3}\cdot\sqrt{(\log(|\mathcal{F}|)}.$$

Finally, we need to control how much we are losing via the exploration rounds. Since we apply pay-per-feedback we lose 1 every time we inspect (an upper bound on the apple tasting loss). For any intersection, we have exactly $(T(I))^{2/3}$ such exploration points so we are not losing something more compared to what we previously discussed which completes the proof. ◀

B Proof of Theorem 4

Theorem 4 restated

Let $\mathcal{A}$ be an algorithm with sleeping regret bounded by $\mathcal{O}\left(\sqrt{T(h)\cdot\log(|\mathcal{H}|)}\right)$ for any expert $h\in\mathcal{H}$ where $\mathcal{H}$ is any class. Randomly selecting an exploration point every $T^{1/3}$ examples (irrespective of what groups they come from) and running $\mathcal{A}$ on these points provides subgroup regret on group $g\in\mathcal{G}$ of

$$\mathcal{O}\left(T^{1/6}\cdot(T(g))^{-1/2}\cdot\sqrt{\log(N)}\right)$$

where $T(g) = |t : g\in\mathcal{G}(t)|$ is the size of the g-population and $N = |\mathcal{F}| + \sum_{g\in\mathcal{G}}|\mathcal{F}(g)|$.

Proof. The guarantee follows from two observations:

1. Given that we run a sleeping experts algorithm across the exploration points, if we just focused on those examples, we simultaneously satisfy regret on them that is square-root of their size.
2. Within any phase the exploration point is uniformly at random selected. As a result, it is an unbiased estimator of the average regret we incur in the whole phase. Note that this is now the average across all rounds and not only rounds where we have members of the particular group which results to the dependence on the time-horizon T.

We now formalize these ideas. As before, we connect the regret on a group to the one of the exploration points. Denote by $t(r)$ the random variable that corresponds to the exploration point. Now the size of the phases is fixed in advance so r-th phase starts at $\tau_r = r\cdot T^{1/3}$. Similarly as before, we denote by $f^\star$ the comparator with the minimum cumulative loss on g. Applying linearity of expectation and Jensen's inequality, we obtain:

$$Reg(g) = \sum_{t:g\in\mathcal{G}(t)}\sum_{f\in\mathcal{F}(g)} p_{t,f}\ell_{t,f} - \sum_{t:g\in\mathcal{G}(t)}\ell_{t,f^\star}$$
$$= \sum_{r=1}^{T^{2/3}}\sum_{t=\tau_r}^{\tau_{r+1}-1}\left(\sum_{f\in\mathcal{F}(g)} p_{t,f}\ell_{t,f} - \ell_{t,f^\star}\right)\cdot\mathbf{1}\{g\in\mathcal{G}(t)\}$$

$$\ldots = T^{1/3} \cdot \sum_{r=1}^{T^{2/3}} \mathbb{E}\left[\left(\sum_{f\in\mathcal{F}(g)} p_{t(r),f}\ell_{t(r),f} - \ell_{t(r),f^\star}\right)\cdot \mathbf{1}\{g \in \mathcal{G}(t(r))\}\right]$$
$$\leq T^{1/3} \cdot \mathbb{E}\left[\sqrt{\sum_{r=1}^{T^{2/3}} \mathbf{1}\{g \in \mathcal{G}(t(r))\}\cdot \log(N)}\right]$$
$$\leq T^{1/3} \cdot \sqrt{\mathbb{E}\left[\sum_{r=1}^{T^{2/3}} \mathbf{1}\{g \in \mathcal{G}(t(r))\}\cdot \log(N)\right]}$$
$$= T^{1/3} \cdot \sqrt{T(g)\cdot T^{-1/3}\cdot \log(N)} = T^{1/6}\cdot\sqrt{T(g)\cdot\log(N)}.$$

The expectation is taken over the random selections of the exploration times $t(r)$. The second-to-last equality holds as each member of group g has probability $T^{-1/3}$ to be an exploration point and therefore the expected number of exploration points in the group is $T(g)\cdot T^{-1/3}$.

Finally, for the pay-for-feedback model, we need to also consider the effect of inspected rounds in loss (we are losing 1 every time that we inspect). The number of these rounds on examples in g is at most $T(g)\cdot T^{-1/3} \leq (T(g))^{2/3}$ so lower order than the term we already have. ◀

C Proof of Theorem 5

Theorem 5 restated

Applying the algorithm described in the third reduction (Section3.2 provides subgroup regret on group $g \in \mathcal{G}$ of

$$\mathcal{O}\left(|\mathcal{G}|\cdot(T(g))^{3/4}\cdot\sqrt{\log(N)}\right)$$

where $T(g) = |t : g \in \mathcal{G}(t)|$ is the size of the g-population and $N = |\mathcal{F}| + \sum_{g\in\mathcal{G}}|\mathcal{F}(g)|$.

Proof. There are three important components to prove this guarantee.

1. The number for relevant phases of each group (phases where they have at least one example) is at most $T(g)$. This provides an upper bound on the number of phases that we need to consider with respect to group g.
2. Using a similar analysis as before, we can create a guarantee about the regret we are incurring in the exploration points and multiply it by the $(T(g))^{1/4}$ which is the size of the phase. This would have created a completely unbiased estimator if there was no overlap with other groups.
3. A final complication is that exploration may occur due to other groups so we need to understand how much we lose there. For that, we observe that smaller groups are explored with higher probability (the interaction with larger groups does not therefore significantly increase their probability of inspection). On the other hand, larger groups do not often collide with significantly smaller groups due to the latters' size.

More formally, to analyze the subgroup regret for $g \in \mathcal{G}$, let's consider a fictitious setting where all phases have equal size for group g. This can be done by padding 0s in the end of the phase. This fictitious setting has the same loss as the original (as it only differs in that it has some more examples with zero loss). For this fictitious setting, the exploration point is

an unbiased estimator of the average regret. We first analyze the subgroup regret assuming that the points of inspection in other groups do not overlap with g. Applying similar ideas as in the previous theorem:

$$\begin{aligned}
Reg(g) &= \sum_{t:g\in\mathcal{G}(t)} \sum_{f\in\mathcal{F}(g)} p_{t,f}\ell_{t,f} - \sum_{t:g\in\mathcal{G}(t)} \ell_{t,f^\star} \\
&= \sum_{r=1}^{T(g)} \sum_{t=\tau_r}^{\tau_{r+1}-1} \left(\sum_{f\in\mathcal{F}(g)} p_{t,f}\ell_{t,f} - \ell_{t,f^\star} \right) \cdot \mathbf{1}\{g\in\mathcal{G}(t)\} \\
&= (T(g))^{1/4} \cdot \sum_{r=1}^{T(g)} \mathbb{E}\left[\left(\sum_{f\in\mathcal{F}(g)} p_{t(r),f}\ell_{t(r,g),f} - \ell_{t(r,g),f^\star} \right) \cdot \mathbf{1}\{g\in\mathcal{G}(t(r,g)), t(r,g)\le t_{r+1}\} \right] \\
&= (T(g))^{1/4} \cdot \sum_{r=1}^{T(g)} \mathbb{E}\left[\left(\sum_{f\in\mathcal{F}(g)} p_{t(r),f}\tilde{\ell}_f(r,g) - \tilde{\ell}_{f^\star(r,g)} \right) \right] \\
&\le (T(g))^{1/4} \cdot \sqrt{T(g)\log(N)} = (T(g))^{3/4}\sqrt{\log(N)}
\end{aligned}$$

The expectation is taken over the random selections of the exploration times $t(r,g)$. The last inequality holds as the number of non-zero entries in the previous sum is at most the number of phases and we run $\mathcal{A}$ on the estimated losses.

Let's understand now how much group g is harmed by the fact that some of its examples may be inspected by overlapping groups. As a result, we need to count in the regret the contribution of these examples as well. Note that each group has at most one exploration point within a phase – this is the reason why we get the dependence on $|\mathcal{G}|$ in our bound.

Group g is only affected by others' exploration if this happens on examples that are also members of group g. We first consider the effect of smaller groups than g. For any group g' with $T(g') \le T(g)$ the exploration points at group g' are at most the size of the group times the probability that each example is an exploration point for g', i.e. $T(g')\cdot(T(g'))^{-1/4} = (T(g'))^{3/4}$. Since the size of g' is smaller than the size of g, this contributes at most an extra term of $(T(g))^{3/4}$ in the regret.

Let's now consider groups g' with $T(g') > T(g)$. Then, even if all examples of g are also examples of g', the probability that each of them is an exploration point due to g' is $(T(g'))^{-1/4}$. Hence the expected number of exploration points of g' on examples in g is at most $T(g)\cdot(T(g'))^{1/4} \le (T(g))^{3/4}$. ◀

Instance Complexity and Unlabeled Certificates in the Decision Tree Model

Abstract

Instance complexity is a measure of goodness of an algorithm in which the performance of one algorithm is compared to others per input. This is in sharp contrast to worst-case and average-case complexity measures, where the performance is compared either on the worst input or on an average one, respectively.

We initiate the systematic study of instance complexity and optimality in the query model (a.k.a. the decision tree model). In this model, instance optimality of an algorithm for computing a function is the requirement that the complexity of an algorithm on any input is at most a constant factor larger than the complexity of the best correct algorithm. That is we compare the decision tree to one that receives a certificate and its complexity is measured only if the certificate is correct (but correctness should hold on any input). We study both deterministic and randomized decision trees and provide various characterizations and barriers for more general results.

We introduce a new measure of complexity called *unlabeled*-certificate complexity, appropriate for graph properties and other functions with symmetries, where only information about the structure of the graph is known to the competing algorithm. More precisely, the certificate is some permutation of the input (rather than the input itself) and the correctness should be maintained even if the certificate is wrong. First we show that such an unlabeled certificate is sometimes very helpful in the worst-case. We then study instance optimality with respect to this measure of complexity, where an algorithm is said to be instance optimal if for every input it performs roughly as well as the best algorithm that is given an unlabeled certificate (but is correct on every input). We show that instance optimality depends on the group of permutations in consideration. Our proofs rely on techniques from hypothesis testing and analysis of random graphs.

We thank some of the referees of the paper for helpful comments.

1 Introduction

Worst-case analysis is the hallmark of theoretical computer science. An algorithm is evaluated based on its performance on the worst input and we want to find the algorithm whose performance is the best according to this criterion. Nevertheless, in some cases one might not be interested only in worst-case complexity of a function f. For instance, when the worst case is inherently "very bad" for all algorithms (and then measuring the algorithms by its worst case input gives meaningless comparisons), when the worst case is very rare, or when there is some prior information about the distribution of the inputs.

In this work we consider a new measure of complexity for problems we call *the instance complexity*. Here, we compare a given algorithm to one that has additional information about the input. That is, we are interested in the best algorithm for a given problem that performs as well as possible on every input compared to the best algorithm that *knows* (something about) the input. The instance complexity (denoted IC) of a problem is the overhead of solving the problem on every input vs. solving the problem on a given instance, provided that algorithms the specific instance is a correct algorithm (on all inputs). Here is one way to define this notion. Suppose that we have a collection of algorithms $\mathcal{A}$ that are correct on all on inputs.

▶ **Definition 1.1** (Instance complexity). *Let f be a function, and A an algorithm that evaluates f. Let $\mathrm{cost}(A, x)$ be the cost of algorithm A on input x, where cost is some non-negative value that we want to optimize (e.g. runtime, space, etc.). We say that f is* instance optimizable *and that A is* instance optimal *if for every input x, and for every algorithm $A' \in \mathcal{A}$ (that evaluates f correctly on every input) the following holds:*

$$\mathrm{cost}(A, x) \in O\left(\mathrm{cost}(A', x)\right).$$

In the definition above, we compare the cost of A on every input with the cost of an algorithm that has the input hardwired. One can relax the hint given to the competing algorithm A' so that it only knows *something* about the input (e.g., an unknown permutation of the input, a subset of the coordinates, etc). Finally, note that both algorithms A and A' should be correct on all inputs, but the competing algorithm is evaluated in terms of cost *only when the hint it is given is correct w.r.t. the input.*

The term "Instance optimality" was coined by Fagin, Lotem and Naor [19] in the context of finding items with the top k aggregate scores in a database of sorted lists. It has appeared in the theoretical computer science literature in several other contexts and forms. For previous works on instance complexity in other settings see Appendix B.

We initiate the systematic study of instance complexity in the *query* model (a.k.a. the *decision tree* model). In this model the input is given through an oracle, and the goal is to minimize the number of queries made to the input oracle. The query complexity model helps us understand the power of various resources (such as randomness and non-determinism) and inherent difficulties in computing a function. Not only is it a simple and clean model, but sometimes results in this model carry over to different models (i.e., "lifting" [43, 28]). See Section 2 for more details about the decision tree model, formal definitions, and known results.

We study two different notions of instance complexity. In the first notion the hint is simply the full input. The instance complexity, IC, of an algorithm is the maximal ratio between its complexity on a given input and the complexity of any other algorithm that *knows* the specific input (but is correct on all inputs). In the second notion the hint is some *unlabeled version of the input*; namely, the input is given in an (adversarially) permuted order. This is relevant when the function we wish to compute treats the input as symmetric, e.g., as in graph properties.[2] We call this notion *unlabeled instance complexity*, uIC,[3] and for a given algorithm define it to be the maximal ratio between its complexity on a given input and the complexity of any other algorithm that *knows* an *unlabeled version of the input* (but is correct on all inputs).

Models for instance complexity. Instance optimality captures the fact that an algorithm is not only optimal for a worst-case input or a random one, but that it is optimal for *every* input (up to constant factors). In the context of decision tree complexity, we formalize this in the following way: An algorithm is instance optimal if for every input x its complexity is at most a constant factor larger than the complexity of any decision tree whose goal is to be as efficient as possible on x (yet correct on all inputs). This naturally leads to comparing the efficiency of the decision tree on an input to the complexity of a decision tree that gets that input as a certificate. Thus, a function is instance optimizable if there is an algorithm such that for **every** input (not just the worst case input) its complexity on that input is at most a constant factor larger than the certificate complexity of the function on the same input. To show that an algorithm is *not* instance optimal it is possible to argue about inputs where the running time is not the worst case.

For example, the parity function is instance optimal, since any algorithm, on any input must read the entire input (see Example 3.1 for detail). The OR function on the other hand is not instance optimal. This is because for any algorithm, A, there exists an input, x, and another algorithm A^*, such that A does n queries on input x while A^* does 1 query (see Example 3.3 for detail).

We wish to emphasize that instance optimality is a fundamentally different notion than worst case complexity. Notice that for the OR function, in the worst case the certificate complexity is $\Theta(n)$ and any algorithm without a certificate also requires $\Theta(n)$ queries yet the OR function is not instance optimal.

We define a similar notion for randomized algorithms. Namely, an algorithm is said to be randomized instance optimal if for every input x its expected complexity is at most a constant factor larger than the randomized certificate complexity of the function on x. We will consider randomized algorithms with two-sided error.

We introduce the notion of **unlabeled certificate complexity** in which the certificate is not the input, but a permutation thereof. This is relevant when the function is invariant under a *family of permutations* (e.g., a graph property or a symmetric function, such as threshold). We show that this is sometimes very helpful, *even in the worst-case*, in the sense that there are functions where the unlabeled certificate complexity is much smaller than the randomized complexity. Having this notion in hand, it is natural to define (randomized-) unlabeled instance optimality, where the standard (randomized) decision tree algorithm is

[2] A graph property is a set of graphs closed under graph isomorphism; see Section 2.3.

[3] The closest notion considered in previous literature is in geometric algorithms by Afshani et al. [2], see Appendix B.

required to have complexity (input-by-input) at most a constant factor larger than the best algorithm that gets a permutation (from the family) of the input as a certificate and computes the value of the function correctly. The algorithm that gets the unlabeled certificate is required to be correct on all inputs, but its complexity is measured only in case the certificate is correct.

1.1 Our Results

We lay the foundation for the study of instance optimality and unlabeled certificate complexity in the decision tree model by providing a host of results including various examples, relations, separations, and more. Our results fall short of a (complete) characterization of which functions are instance optimal and which are not and when unlabeled certificates help and when they do not. However, our results demonstrate that the theory of instance optimality and unlabeled complexity is rich, and contains non-trivial and sometimes surprising phenomena. Thus we believe that this theory deserves further research, and hope that this work will inspire such research.

Below, our results are stated in the order corresponding to the above models: deterministic and randomized instance optimality (Section 1.1.1), and then unlabeled certificate complexity (Section 1.1.2).

1.1.1 Deterministic and Randomized Instance Optimality

We start off by observing that even in the simplest setting of deterministic decision trees, instance optimality is a non-trivial property: there are functions that are instance optimizable and functions that are not. Also, monotonicity does not directly affect instance optimizability. Furthermore, we construct a function that is *strictly* instance optimal (*strict* means that the decision tree has no additional overhead over the one that has a certificate), but once composed with itself, results in a function that is not instance optimal.

▶ **Theorem 1.2** (Deterministic instance optimality). *The following holds:*

1. *There is a monotone function that is* not *deterministic instance optimal while the Majority function is deterministic instance optimizable (and monotone).*
2. *The Addressing and Parity functions are examples of non-monotone functions that are strictly instance optimizable.*
3. *Among the monotone functions, the only ones that can be* strictly *instance optimizable are functions that depend on 0 or 1 variables.*
4. *The composition of two (strictly) instance optimal functions is not necessarily instance optimal.*

In the randomized case, the situation is somewhat different. While the parity and addressing functions behave similarly, the majority function becomes *not* instance optimizable! But, there *are* other instance optimizable monotone functions. Also, there are (non-monotone) graph properties that are instance optimizable. We further provide two results that capture a wide range of functions: (1) random functions are instance optimal and (2) a relation between instance optimizability and properties related to *sensitivity* (see Sections 3.2.1 and 3.2.2). As in the deterministic setting, the composition of instance optimal functions is not necessarily instance optimal.

One notable question left open is whether there is a *monotone* graph property that is randomized instance optimizable. We conjecture that such functions do not exist.

▶ **Theorem 1.3** (Randomized instance optimality). *The following holds:*

1. *The Addressing and Parity functions are randomized instance optimizable functions.*
2. *The Majority function is* not *randomized instance optimizable. Thus, deterministic instance optimality does not imply randomized instance optimality. The other direction is true as well: There exists a function that is randomized instance optimizable but not deterministic instance optimizable (see Section 3.2.3).*
3. *There exists a* monotone *function that is randomized instance optimizable.*
4. *There exists a graph property that is randomized instance optimizable.*
5. *A random function is randomized instance optimizable with high probability.*
6. *The composition of two randomized instance optimal functions is not necessarily randomized instance optimal.*

We consider the computational complexity of figuring out whether a function is instance optimizable and whether a given algorithm is instance optimal. A good time complexity in this setting is polynomial in the size of the representation of the function, i.e. exponential in n for a Boolean function with input $\{0,1\}^n$. We do not have an algorithm for the former problem (deciding whether a function is instance optimizable), but for the latter we show that an algorithm can be *verified* to be instance optimal in time that is polynomial in the domain size of the problem. Naively, one has to work in time *exponential* in the domain size and go over all possible decision trees and test against each one (see Section 3.5).

▶ **Theorem 1.4** (Complexity of checking if an algorithm is instance optimal). *Given a function f on n input variables (given by a truth-table of size 2^n), and a randomized algorithm T, there exists an algorithm U that decides in time $2^{O(n)}$ whether T is an instance optimal algorithm.*

We also consider *proximity property testing*[4] where the goal is to decide whether an object has some property or whether it is *far* from having it [26, 25]. Here it is possible to characterize the properties that are randomized instance optimizable: it is exactly those that can be tested in $O(1)$ queries (see Section 3.6).

1.1.2 Unlabeled Certificate Complexity

We introduce the study of the **unlabeled certificate complexity**. We show that an unlabeled certificate can help significantly in the worst case for graph properties. That is, we construct a function for which an algorithm that has an isomorphic copy of the graph as a certificate outperforms an algorithm that isn't given any certificate.

▶ **Theorem 1.5** (Unlabeled certificate complexity). *In both the randomized and deterministic setting, there exists a graph property for which the unlabeled certificate complexity is $O(n \log n)$ while any algorithm with no certificate requires $\Omega(n^2)$ queries.*

Having the notion of unlabeled certificates we define **unlabeled randomized instance complexity and optimality**. Here the situation changes again. Whereas the majority function is not randomized instance optimizable, it *is* (almost) unlabeled randomized instance

[4] We use the term "proximity property testing" so as not to confuse the reader with the case where we are testing whether the given graph satisfies a property, rather than being close to a graph that satisfies the property.

optimizable.[5] However, when viewed as a *graph property*, the majority function becomes *not* unlabeled randomized instance optimizable. The group of permutations we consider in the latter is the group of all isomorphic copies of the graph. In addition, we show that being a graph property is not directly related to unlabeled instance optimality. We say a function is **labelling instance optimal** if the unlabeled certificate performs as well as the labeled certificate for every input up to a constant. All instance optimal functions are also labelling instance optimal. We show that (up to log factors) the converse is not true: there exists a function which is within $O(\log n)$ of being labelling instance optimal, but not instance optimal in the normal sense.

▶ **Theorem 1.6** (Unlabeled instance optimality)**.** *The following holds:*

1. *The majority function is unlabeled randomized instance optimizable within* $O(\log \log n)$.
2. *The graph property of having more edges than non-edges is far from being unlabeled randomized-instance optimizable – it is at best within* $\tilde{\Omega}(n)$ *from being unlabeled randomized-instance optimizable, where* n *is the number of vertices in the graph.*
3. *The graph property of having at least one edge is unlabeled randomized instance optimizable and not labelling instance optimal.*
4. *There exists a function that is* $O(\log n)$ *away from being labelling instance optimal, but is not instance optimal in the normal sense.*

An impatient reader can skip ahead to Section 4, which is about unlabeled complexity, and contains the proofs of the items in Theorem 1.5 and Theorem 1.6.

The saga of the majority. As we shall see, the *majority* function behaves differently under different notions of instance optimality. While it is deterministic instance optimizable, it is *not* randomized instance optimizable (Lemma 3.5). Having only a permutation of the input as a certificate does not provide additional power to the one receiving it, i.e., it is (almost) unlabeled randomized instance optimizable (Lemma 4.4). On the other hand, viewing majority as a graph property, getting a permutation of the graph may help and majority becomes a function that is *not* unlabeled randomized instance optimizable (Lemma 4.5).

2 The Query Model and Instance Optimality

The query model is one of the simplest computational models and has been studied widely. See, for example, Buhrman and de Wolf [12], Jukna [34, Chapter 14] and O'Donnell [41, Chapter 8.6] for a survey. We give some standard definitions of *decision trees* and several related complexity measures such as *deterministic*, *randomized* and *certificate* complexity, and then briefly recall the known connections between them.

A decision tree is an algorithm for computing the value of a function on an a-priori unknown input. Let $f\colon \{0,1\}^n \to \{0,1\}$ be a Boolean function over a set of n input variables $x_1, \ldots, x_n$. A deterministic decision tree T over a set of input variables $x_1, \ldots, x_n$ is a rooted binary tree. Every internal vertex is labeled with an input variable. The leaves of the tree are labeled by 0 or 1, and every internal vertex has one outgoing edge labeled by 0 and the other by 1. The computation of the tree is done in the natural way from the root to the

[5] In this result, the optimality ratio is a super-constant function ($\log \log$) of the input size. In such cases, where the optimality ratio is a super constant function $g(n)$ of the input size, we will say that the function is *within* $g(n)$ *of being (unlabeled /randomized-) instance optimizable.*

leaves according to the assignment of the input variables. We denote by $T(x)$ the output of the decision tree T on input x. We say that the decision tree T computes f if for any input x it holds that $f(x) = T(x)$.

Denote by $\mathcal{T} = \mathcal{T}_n$ the set of all decision trees on functions of n inputs. The complexity (i.e., cost) of a decision tree $T \in \mathcal{T}$ on input x, denoted by $\mathrm{D}(T, x)$, is the length of the path from the root to the leaf corresponding to x, or in other words, the number of queries made by the algorithm to the input x. For a function f, denote by $\mathcal{T}_f$ the set of all decision trees in $\mathcal{T}$ that compute f:

$$T \in \mathcal{T}_f \iff \forall x\colon T(x) = f(x).$$

The following two definitions deal with the worst-case deterministic and certificate decision tree complexity measures. Roughly speaking, the deterministic complexity measures the smallest possible cost over all decision trees that compute f.

▶ **Definition 2.1** (Worst-case deterministic complexity)**.** *The* ***worst-case deterministic*** *decision tree complexity of* $f\colon \{0,1\}^n \to \{0,1\}$*, denoted by* $\mathrm{D}(f)$*, is*

$$\mathrm{D}(f) = \min_{T \in \mathcal{T}_f} \max_{x \in \{0,1\}^n} \mathrm{D}(T, x).$$

The certificate complexity measures the minimal number of bits a decision tree has to query in order to *verify* the output of the function on a specific input (rather than to compute it). That is, we still want the decision tree to compute f correctly on all inputs, but we measure its complexity only with respect to a fixed input.

▶ **Definition 2.2** (Worst-case certificate complexity)**.** *The* ***certificate*** *complexity of* f *on input* x *is*

$$\mathrm{C}(f, x) = \min_{T \in \mathcal{T}_f} \mathrm{D}(T, x),$$

The ***worst-case certificate*** *complexity of* f *is* $\mathrm{C}(f) = \max_x \mathrm{C}(f, x)$*.*

Throughout this paper we use the term "decision tree" and "algorithm" synonymously. Since in the decision tree model we are only interested in the number of queries made by a given algorithm, the two terms are equivalent. We also use the terms "certificate complexity", "queries made by an algorithm with a certificate" and "queries made by any algorithm" synonymously. "Certificate complexity" and "an algorithm with a certificate" are synonyms since when arguing that the certificate complexity of a given function is some value, q one has to prove that some algorithm with access to a certificate only has to make q queries. This is the same as "queries made by any algorithm" since the certificate complexity is the decision tree with the lowest complexity, that is the algorithm that makes fewest queries.

We proceed with the randomized variants of the above two definitions. In randomized complexity it is common to talk about zero-error (Las Vegas), one-sided and two-sided (BPP style) algorithms. We will discuss only the latter for simplicity. There are two (equivalent) ways to view a *randomized* decision tree: one as a tree that has vertices that are coin flips. The other, which we will mostly use, as a probability distribution Δ over the set of all deterministic decision trees $\mathcal{T}$. Given an input x, the algorithm first samples a decision tree from the distribution and then executes it. The randomized decision tree complexity of a distribution (i.e., a randomized decision tree) Δ on input x, denoted by $\mathrm{R}(\Delta, x)$, is the expected number of queries made by the chosen tree on input x.

A distribution Δ is *correct* for a function f if for any input x, a randomly chosen decision tree $T \leftarrow \Delta$ outputs the value $f(x)$ with probability $2/3$ over the choice of T.[6] We denote by $\boldsymbol{\Delta}_f$ the set of all distributions Δ that are correct for f:

$$\Delta \in \boldsymbol{\Delta}_f \iff \forall x\colon \Pr_{T\leftarrow\Delta}[T(x) = f(x)] \geq 2/3.$$

Analogously to the deterministic setting, the worst-case randomized complexity measures the smallest possible (expected) cost over all randomized decision trees that compute f.

▶ **Definition 2.3** (Worst-case randomized complexity)**.** *The* ***worst-case randomized*** *decision tree complexity of f, denoted by $\mathrm{R}(f)$, is*

$$\mathrm{R}(f) = \min_{\Delta\in\boldsymbol{\Delta}_f} \max_x \underbrace{\mathop{\mathbb{E}}_{T\leftarrow\Delta}[\mathrm{D}(T,x)]}_{\mathrm{R}(\Delta,x)}.$$

For randomized certificate complexity, we still want the decision tree to be correct on every input with high probability, but the complexity is measured only on a fixed input.

▶ **Definition 2.4** (Worst-case randomized certificate complexity)**.** *The* ***randomized certificate*** *complexity of a function f on input x is*

$$\mathrm{RC}(f,x) = \min_{\Delta\in\boldsymbol{\Delta}_f} \mathop{\mathbb{E}}_{T\leftarrow\Delta}[\mathrm{D}(T,x)],$$

The worst-case randomized certificate complexity of f is $\mathrm{RC}(f) = \max_x \mathrm{RC}(f,x)$.

2.1 Instance Complexity and Optimality

Adapting the general notion of instance optimality (see Definition 1.1) to the setting of query complexity is done by fixing a class of query algorithms (say, deterministic or randomized ones) and then asking whether there exists an algorithm in this class that is "the best" on every input. Such an algorithm must have complexity at most a constant factor larger than the complexity of every other algorithm on *every* input. In particular, it has to be at most a constant factor worse than an algorithm that is designed for any specific x^*, and if it finds any inconsistencies between the given input x and x^*, reads the whole input. This leads us to the observation that a sufficient and necessary condition for instance optimality of a function in the query model is the existence of a deterministic (resp. randomized) decision tree whose complexity is at most a constant factor larger than the deterministic (resp. randomized) *certificate* decision complexity of the function per input.

The strongest notion one could hope for is what we call *strict* instance optimality, where the certificate does not help, even in low order constant factors (i.e., the optimality ratio is 1 and there is no additive term). More precisely, there exists a deterministic decision tree such that on every input x the decision tree complexity on x is upper bounded by the certificate decision tree complexity of f on input x.

▶ **Definition 2.5** (Strict optimality)**.** *A function f is* strict *instance optimizable if there exists a deterministic decision tree T such that for every input x:*

$$\mathrm{D}(T,x) = \mathrm{C}(f,x).$$

[6] The value of $2/3$ is arbitrary, since we can get any constant by amplification (i.e., by sampling several decision trees from Δ, executing them and taking the majority result).

Being optimal on every input without any overhead is a very strong requirement (and indeed not many non-trivial functions satisfy it; see below), so we relax it by allowing multiplicative and additive slack in the overhead for the decision tree without the certificate. For this we need to talk about a sequence of functions.

▶ **Definition 2.6** (D-Instance optimality). *A sequence of functions $f = \{f_n\}_{n\in\mathbb{N}}$ is* D-instance optimizable *if there exists a sequence of deterministic decision trees $T = \{T_n\}_{n\in\mathbb{N}}$, where each $T_n \in \mathcal{T}_{f_n}$, and (universal) constants $c_1, c_2 \geq 0$ such that on every input $x \in \{0,1\}^n$, it holds that*

$$\mathrm{D}(T_n, x) \leq c_1 \cdot \mathrm{C}(f_n, x) + c_2.$$

▶ **Definition 2.7** (R-Instance optimality). *A sequence of functions $f = \{f_n\}_{n\in\mathbb{N}}$ is* R-instance optimizable *if there exists a sequence of distributions over decision trees $\Delta = \{\Delta_n\}_{n\in\mathbb{N}}$, where each $\Delta_n \in \boldsymbol{\Delta}_{f_n}$, and (universal) constants $c_1, c_2 \geq 0$ such that on every input $x \in \{0,1\}^n$, it holds that*

$$\mathrm{R}(\Delta_n, x) \leq c_1 \cdot \mathrm{RC}(f_n, x) + c_2.$$

We refer to the *constant factor* c_1 above as the *optimality ratio*. The above deterministic (resp. randomized) algorithm is called *instance optimal*.

While we mostly talk about being within a constant of the best on any instance we will also consider being within some function $g(n)$. If we have an algorithm T such that for $g(n)$ for every input $x \in \{0,1\}^n$ it hold that

$$\mathrm{D}(T, x) \leq g(n) \cdot \mathrm{C}(f_n, x),$$

then we say that f is within g of being instance optimizable.

2.2 Unlabeled Complexity and Optimality

We introduce a new complexity measure for decision trees that we call *unlabeled certificate complexity*. Roughly speaking, the unlabeled complexity is the amount of queries an algorithm that is given some *permutation* of the certificate needs to perform.

This notion only makes sense for functions that are invariant under some permutation group Γ, such as symmetric properties or graph properties. In the case of symmetric functions, we consider the group of all permutations over the inputs, and in the case of graph properties, we focus on the group of permutations over the vertices (i.e., all isomorphic copies of the graph). We denote by Γ the group of permutations.

The idea behind the notion is to model the situation where the algorithm has a lot of knowledge about the input, such as the graph structure (e.g. the degree sequence), but not the actual labels of the graph. We refer to a decision tree that gets such a certificate as an *unlabeled certificate* decision tree.

As before, we expect an unlabeled decision tree T to correctly compute f on every input, but we will measure its complexity over all inputs that are consistent with the certificate under the given group of permutations.

▶ **Definition 2.8** (Worst-case unlabeled certificate complexity). *The* ***unlabeled certificate*** *complexity of a function f that is invariant under Γ on input x is*

$$\mathrm{AC}(f, \Gamma, x) = \min_{T\in\mathcal{T}_f} \max_{\pi\in\Gamma} \mathrm{D}(T, \pi(x)).$$

The ***worst-case certificate complexity*** *of f under Γ is $\mathrm{AC}(f, \Gamma) = \max_x \mathrm{AC}(f, \Gamma, x)$.*

For randomized unlabeled certificate complexity, the definition is analogous but we allow the decision tree to be randomized and to err.

▶ **Definition 2.9** (Worst-case randomized unlabeled certificate complexity)**.** *The* ***randomized unlabeled certificate*** *complexity of a function f invariant under Γ on input x is*

$$\mathrm{RAC}(f,\Gamma,x) = \min_{\Delta\in\boldsymbol{\Delta}_f} \max_{\pi\in\Gamma} \mathop{\mathbb{E}}_{T\leftarrow\Delta}[\mathrm{D}(T,\pi(x))],$$

The ***worst-case randomized unlabeled certificate complexity*** *of f under Γ is* $\mathrm{RAC}(f,\Gamma) = \max_x \mathrm{RAC}(f,\Gamma,x)$.

It follows immediately that the unlabeled certificate complexity of a function is lower bounded by its certificate complexity and upper bounded by its deterministic complexity. That is, for any Γ such that f is invariant under Γ we have

$$\mathrm{C}(f) \le \mathrm{AC}(f,\Gamma) \le \mathrm{D}(f).$$

The same holds in the randomized case:

$$\mathrm{RC}(f) \le \mathrm{RAC}(f,\Gamma) \le \mathrm{R}(f).$$

Throughout the paper we let the default Γ be the set of all graph isomorphisms. That is, if our function is a graph property, and Γ is not specified, then Γ is the set of all graph isomorphisms.

Given this new notion of unlabeled certificates one can define instance optimality with respect to it. Here, we are trying to compete with the best algorithm that is given some permutation of the certificate, rather than the exact certificate as in the definitions of Section 2.1. If an algorithm is instance optimal in this sense, this means that even the knowledge about the graph structure does not help improve the performance.

Namely, we can ask whether having access to a permutation of a certificate reduces the complexity by more than a constant factor compared to a decision tree that gets no certificate at all.

▶ **Definition 2.10** (Unlabeled instance optimality)**.** *A sequence of functions $f = \{f_n\}_{n\in\mathbb{N}}$ invariant under a sequence of family of permutations $\{\Gamma_n\}_{n\in\mathbb{N}}$, is* unlabeled D-instance optimizable *(resp.* unlabeled R-instance optimizable*) if there exists a sequence of deterministic (resp. randomized) decision trees $T = \{T_n\}_{n\in\mathbb{N}}$, where each $T_n \in \mathcal{T}_{f_n}$, and constants $c_1, c_2 \ge 0$ such that on every input x, it holds that*

$$\mathrm{D}(T,x) \le c_1 \cdot \mathrm{AC}(f_n,\Gamma_n,x) + c_2 \qquad (\textit{resp. } \mathrm{R}(T,x) \le c_1 \cdot \mathrm{RAC}(f_n,\Gamma_n,x) + c_2)$$

We can also compare the labeled certificate to the unlabeled certificate. A function is labelling instance optimal if the number of queries required to evaluate the function given an unlabeled certificate is at most a constant times the number queries required to evaluate the function with a labeled certificate.

▶ **Definition 2.11** (labelling instance optimality)**.** *A sequence of functions $f = \{f_n\}_{n\in\mathbb{N}}$ invariant under a sequence of family of permutations $\{\Gamma_n\}_{n\in\mathbb{N}}$, is* labelling D-instance optimizable *(resp.* labelling R-instance optimizable*) if there exists a sequence of deterministic (resp. randomized) decision trees $T = \{T_n\}_{n\in\mathbb{N}}$, where each $T_n \in \mathcal{T}_{f_n}$, and constants $c_1, c_2 \ge 0$ such that on every input x, it holds that*

$$\mathrm{AC}(T,x) \le c_1 \cdot \mathrm{C}(f_n,\Gamma_n,x) + c_2 \qquad (\textit{resp. } \mathrm{RAC}(T,x) \le c_1 \cdot \mathrm{RC}(f_n,\Gamma_n,x) + c_2)$$

2.3 Additional Definitions & Known Relations

Graph properties. In some of our result we will be interested in graph properties. A graph property is a set of graphs closed under graph isomorphism. That is Ψ is a graph property if for every graph $G = (V, E)$ and every permutation π over V, it holds that $G \in \Psi$ if and only if $\pi(G) \in \Psi$, where $\pi(G) = (V, E')$ and $E' = \{(\pi(u), \pi(v)) \mid (u, v) \in E\}$).

Sensitivity. Two central notions in the analysis of Boolean functions are the *sensitivity* and *block sensitivity*, introduced by Cook, Dwork and Reischuk [14] and Nisan [40], respectively. They both measure how sensitive a function f is to changes in its input. Let $f\colon \{0,1\}^n \to \{0,1\}$ be a function and $x \in \{0,1\}^n$ be an input. The *sensitivity* of f on x, denoted $\mathsf{s}(f, x)$, is the number of bit positions i such that $f(x) \neq f(x \oplus e_i)$, where $e_i \in \{0,1\}^n$ is a vector that is 1 at coordinate i and 0 everywhere else. The sensitivity of f, denoted by $\mathsf{s}(f)$, is $\max_x \mathsf{s}(f, x)$.

Block sensitivity is a useful generalization of sensitivity. The *block sensitivity* of f on x, denoted $\mathsf{bs}(f, x)$, is the maximum number t such that there is collection $B = \{B_1, \ldots, B_t\}$ of *disjoint* subsets of $[n]$ with $f(x) \neq f(x \oplus B_i)$ for all $i \in [t]$. The overall block sensitivity $\mathsf{bs}(f)$ of f is the maximum of $\mathsf{bs}(f, x)$ over all x. Note that sensitivity is just block sensitivity where the blocks are restricted to be of size 1.

It is not hard to see that $\mathsf{s}(f) \leq \mathsf{bs}(f) \leq \mathrm{C}(f)$. The biggest known gap between $\mathsf{s}(f)$ and $\mathsf{bs}(f)$ is quadratic (see Rubinstein [45] and Ambainis and Sun [6]). Showing that this gap is at most polynomial has been a major open problem for many years, until it had been resolved recently by [32], who showed that for all f, $\mathsf{bs}(f)$ is bounded by $\mathsf{s}(f)^4$.

More relations. In general, all worst-case complexity measures discussed above are known to have a polynomial relationship and figuring out the precise relationships is a major research program.

▶ **Proposition 2.12.** *For every Boolean function f we have:*

1. $\mathrm{RC}(f) \leq \mathrm{C}(f) \leq \mathrm{D}(f) \leq n$ *and* $\mathrm{R}(f) \leq \mathrm{D}(f)$.
2. $\mathrm{C}(f) \leq \mathsf{s}(f) \cdot \mathsf{bs}(f)$ *(see [40] and [12, Theorem 2]).*
3. $\mathrm{D}(f) \leq \mathsf{s}(f) \cdot \mathsf{bs}(f)^2 \leq \mathsf{bs}(f)^3$ *(see [12, Corollary 1]).*
4. $\mathsf{bs}(f) \leq \mathsf{s}(f)^4$ *(see [32]).*
5. $\mathrm{D}(f) \leq \mathrm{C}(f)^2$ *(see [10, 49] and, for example, [34, Theorem 14.3]).*
6. $\mathsf{bs}(f) \leq 3\mathrm{RC}(f) \leq 3\mathrm{R}(f)$ *(see [40] and [1]) and* $\mathsf{bs}(f) \leq \mathrm{D}(f)$.

▶ **Proposition 2.13.** *For every* monotone *Boolean function f it holds that* $\mathrm{C}(f) = \mathsf{s}(f) = \mathsf{bs}(f)$ *(see [40] [12, Proposition 3]) and hence* $\mathrm{D}(f) \leq \mathsf{s}(f)^2$.

Yao's Minimax Principle. When proving lower bounds on the randomized query complexity of a function f it is often easier to rephrase the problem by applying Yao's [52] Minimax Principle (see [39] Chapter 2). In words, it says that in order to prove a lower bound on the randomized decision tree complexity, it is enough to come up with one particularly bad distribution over *inputs* which fools all deterministic algorithms. Often Yao's Minimax principle is used by saying that if t expected queries are required to distinguish between two input distributions with high probability (where the function outputs 1 where the input is chosen from one distribution but when the input is chosen from the second distribution the function outputs 0), then any deterministic algorithm must perform at least t queries.

3 Properties Of Instance Optimal Functions

This section is devoted to showing several results regarding properties of instance optimal function in both the deterministic and randomized setting. We prove Theorem 1.2 and Theorem 1.3, as well as showing, given a truth table representing a function, and an algorithm, how to test if the algorithm is instance optimal in time polynomial in the size of the truth table. Lastly we give a characterization of which functions are R-instance optimal in the proximity property testing model.

3.1 Deterministic Instance Optimality

We show that there are functions which are D-instance optimizable and there are functions which are not. We also prove that there are no non-trivial monotone functions whose optimality ratio is 1 (i.e., *strict* D-instance optimizable). The arguments in this section are simple and provide good examples for the notions discussed.

Let $\mathrm{Parity}\colon \{0,1\}^n \to \{0,1\}$ be the parity function on n variables, defined as $\mathrm{Parity}(x) = \bigoplus_{i=1}^{n} x_i$. Assume that n is a power of 2 and let $\mathrm{Addr}\colon [n] \times \{0,1\}^n \to \{0,1\}$ be the addressing function defined as $\mathrm{Addr}(i, x_1, \ldots, x_n) = x_i$. Both of these functions are D-instance optimizable. In both cases the argument is that on all instances the certificate complexity has the same value (n and $1 + \log n$, respectively) and it is possible to achieve it with a straightforward deterministic algorithm.

▶ **Example 3.1** (Item 2 of Theorem 1.2)**.** The Parity function and the Addr function are strict D-instance optimizable.

Proof. The proof for both Parity and Addr being strict D-instance optimizable rely on a common statement that follows from the definitions of deterministic and certificate complexity: given a function $f\colon \{0,1\}^n \to \{0,1\}$, for any decision tree $T \in \mathcal{T}_f$ and any input $x \in \{0,1\}^n$, it holds that $\mathrm{D}(T, x) \geq \mathrm{C}(f, x)$. For the Parity and Addr functions the straightforward trees $T_{\mathrm{Parity}} \in \mathcal{T}_{\mathrm{Parity}}$ (that reads the whole input) and $T_{\mathrm{Addr}} \in \mathcal{T}_{\mathrm{Addr}}$ (that reads the address part plus the resulting address) satisfy $D(T_{\mathrm{Parity}}, x) = n$ and $D(T_{\mathrm{Addr}}, x) = \log n + 1$ for every $x \in \{0,1\}^n$. Thus, it remains to prove that $\mathrm{C}(\mathrm{Parity}, x) \geq n$ and $\mathrm{C}(\mathrm{Addr}, x) \geq \log n + 1$. We do this by showing that any decision tree (that is always correct) must make at least n queries for Parity and at least $\log n + 1$ queries for addressing. We show that for any algorithm that makes less queries, we can change bits that the algorithm does not query, and this will change the value of the function, thus making the algorithm err.

For Parity, consider an algorithm that on some input x queries less than n input locations. Since there is a location that the algorithm does not query and the function's output depends on all locations, by flipping the value of an unqueried bit, the output of the function must change, but the algorithm cannot notice this and hence it is wrong either on x or on x with the flipped bit.

For Addr, consider an algorithm that on some input x reads $k \leq \log n$ values. These k bits can either fully fix the index i, but then there are two possible values for the bit in the i-th position (which determine the value of the function) that the algorithm cannot distinguish. The other case is that the algorithm did not query the value of the index i in full. Denote by $\ell > 0$ the number of bits of i that the algorithm did not query. There are 2^ℓ possibilities for the value of i. The algorithm can query only $k - (\log n - \ell)$ locations out of the possible n. Since $k - (\log n - \ell) < 2^\ell$, there must be a way to assign values to the unread location so as to fool the algorithm to output the wrong answer. ◀

We show that there is a *monotone* function that is D-instance optimizable (unlike the parity and addressing functions that are not monotone). However, the function is not *strict* D-instance optimizable. The function is the majority function $\mathrm{Maj}\colon \{0,1\}^n \to \{0,1\}$ defined as

$$\mathrm{Maj}(x_1,\ldots,x_n) = 1 \iff \sum_{i=1}^{n} x_i \geq \frac{n}{2}.$$

▶ **Example 3.2** (Item 1(i) of Theorem 1.2)**.** The majority function is D-instance optimizable.

Proof. In order to determine the output of Maj on an input $x \in \{0,1\}^n$, every decision tree has to find (at least) $n/2+1$ locations (in x) that have the same value, 0 or 1. Since the algorithm is deterministic, this can take up to n queries in the worst case. On the other hand, an algorithm with a certificate for x can query exactly $n/2+1$ locations that have the same value. Any algorithm that has a certificate for x that queries at most $n/2$ queries can be fooled to output the wrong answer. We get that for every input x it holds that $C(\mathrm{Maj}, x) = n/2+1$ and $D(\mathrm{Maj}, x) \leq n$, as needed. ◀

To complete the picture, we give a (monotone) function that is not D-instance optimizable.

▶ **Example 3.3** (Item 1(ii) of Theorem 1.2)**.** The OR function (that outputs '1' iff the Hamming weight of the input is at least 1) is not D-instance optimizable.

Proof. An algorithm with a certificate can make just one query on every input with Hamming weight 1 (to a location where there is supposedly a '1'). However, every decision tree (not getting a certificate) that is correct on every input must query all the coordinates on one of these inputs, as otherwise we can fool it to output the wrong answer. This is done by planting '0's at the points it queries and a '1' at a point that it does not query. ◀

Strict instance optimality. Both the addressing and parity functions were shown to be *strict* D-instance optimizable (the algorithm with the certificate could not outperform the one without the certificate even by a multiplicative small constant term). On the other hand, in our analysis of the instance optimality of the majority function, we showed that an algorithm with a certificate may perform twice as fast than the one that does not have the certificate. Namely, the optimality ratio of the majority function is 2.

These examples are no coincidence: No non-trivial (that is not constant or dictatorship) *monotone* function can be strictly D-instance optimizable.

▶ **Lemma 3.4** (Item 3 of Theorem 1.2)**.** *There are no* strict *D-instance optimizable* monotone *functions except those that depend on* 0 *or* 1 *variables.*

Proof. Consider the DNF of the function i.e. the OR of all the minimal terms that make the function '1'. Suppose that the function has only one term. It cannot be of length 1, since the function does not depend on one variable. Therefore, if all the variables in the term but one are set to '1', the certificate size is 1, but for any decision tree all the variables in the term must be read and if the one set to '0' is the last one, then the complexity on that input is greater than 1.

So suppose that there are at least two terms in the conjunction. Due to the monotonicity of the function they are not on exactly the same sets of variables. Consider the two instances, one satisfying the first term and the other satisfying the second one (and nothing else). A certificate verifier just needs to access the variables of one term, but a deterministic (or even probabilistic) will have to ask on a variable that appears in one term but not the other and hence will not have the same complexity and the instance satisfying the other term. ◀

3.2 Randomized Instance Optimality

The question we consider is whether randomness changes anything w.r.t. instance optimality. It is not hard to see that the parity function and the addressing function are not only D-instance optimizable but they are also R-instance optimal (the proof of Example 3.1 actually shows it). However, the situation changes for the majority function: we show that, in contrast to Example 3.2, the majority function is *not* R-instance optimizable. We complement the picture in this section with an example of a *monotone* function that is also R-instance optimal.

▶ **Lemma 3.5** (Item 2 of Theorem 1.3, first part)**.** *The majority function is* not *R-instance optimizable.*

Proof. Given that the deterministic certificate size of majority is always of size $\Theta(n)$, we must use the fact that the algorithm may err. We will give a distribution $\mathcal{D}$ on the inputs such that any algorithm that does not get a certificate (but may be tailored to inputs that come from the distribution $\mathcal{D}$) must query $\Omega(n)$ bits in order to be correct with probability at least $2/3$. On the other hand, for any input x from this distribution $\mathcal{D}$, an algorithm with a certificate for x only needs to query $O(\sqrt{n})$ of the bits to be correct with high probability.

For $x \in \{0,1\}^n$ let $wt(x)$ stands for the Hamming weight of x. The hard distribution on inputs $x \in \{0,1\}^n$ is to choose uniformly at random from the set $wt(x) \geq n/2 + \sqrt{n}$ and the set $wt(x) \leq n/2 - \sqrt{n}$ (in the former Maj is 1 and in the latter it is 0). Consider a randomized decision tree for Maj that is correct on this distribution with probability at least $2/3$, i.e. distinguishes between the case that $wt(x) \geq n/2 + \sqrt{n}$ and the case that $wt(x) \leq n/2 - \sqrt{n}$ with probability at least $2/3$.

We show that this task requires $\Omega(n)$ queries on a uniform input of Hamming weight $n/2 + \sqrt{n}$. First, by symmetry, notice that the best strategy for the algorithm is to sample random locations in x and query them. Second, the lower bound follows from the fact that $\Omega\left(1/\varepsilon^2\right)$ samples are needed to distinguish (with constant probability) a biased random coin that outputs heads with probability $1/2 + \varepsilon$ from one that outputs heads with probability $1/2 - \varepsilon$.[7]

On the other hand, given a certificate for an x of Hamming weight at least $n/2 + \sqrt{n}$, there is a randomized algorithm that makes $q = 10\sqrt{n}$ queries and outputs the right answer with probability at least $2/3$. The algorithm, given a certificate $x^* \in \{0,1\}^n$ and an input $x \in \{0,1\}^n$, does:

1. Query x at q random locations i where x^*_i is 1.
2. If all queries return 1, output 1.
3. Otherwise, read the whole input and output the majority value.

The algorithm makes a mistake only if at Step 2 all queries returned '1', but the Hamming weight of x was less than $n/2$. This can happen only if there is a set $I \subseteq [n]$ of coordinates of size at least $|I| \geq \sqrt{n}$ such that $x^*_i = 1$ but $x_i = 0$ for every $i \in I$, *and* the algorithm did not query at any of them. The probability that this happens is at most

$$\left(1 - \frac{\sqrt{n}}{n}\right)^q = \left(1 - \frac{1}{\sqrt{n}}\right)^{10\sqrt{n}} \leq 1/3.$$

Thus, this algorithm outputs the correct result with probability at least $2/3$, as needed. ◀

[7] See, for example, Claim 5.6 here: `http://www.tau.ac.il/ mansour/advanced-agt+ml/scribe5-lower-bound-MAB.pdf` (Accessed: June 2018).

We give an explicit monotone function that is R-instance optimizable. We call this function the *lexicographic threshold* function.

▶ **Lemma 3.6** (Item 3 of Theorem 1.3)**.** *There exists an explicit monotone function that is R-instance optimizable.*

Proof. Consider the lexicographic order of strings in $\{0,1\}^n$ under $\geq_{\text{lex}}$. Let $b = 1010\ldots1010 \in \{0,1\}^{2n}$ and define $\text{LTF}_n\colon \{0,1\}^{2n} \to \{0,1\}$ as $\text{LTF}_n(x) = 1$ if and only if $x \geq_{\text{lex}} b$. Denote by $b_{[i]}$ the substring $b_1 \ldots b_i$ where b_i is the i-th bit of b from left to right.

We show that the randomized query complexity of LTF is roughly equal to the randomized query complexity of LTF given access to a certificate for the input. That is, we show that any randomized query algorithm for LTF that has access to a certificate for the input must work (roughly) as hard as an algorithm that does not have access to a certificate.

Our algorithm, that we denote by P_n, is to read bit by bit from left to right. Denote by $x_{[i]}$ the substring read by the algorithm (ordered left to right) until iteration i. Initially, $x_{[0]} = \perp$ and $i = 0$. At iteration $1 \leq i \leq 2n-1$, the algorithm returns 1 if $x_{[i]} >_{\text{lex}} b_{[i]}$, returns 0 if $x_{[i]} <_{\text{lex}} b_{[i]}$ and continues to the next iteration otherwise (i.e., if $x_{[i]} =_{\text{lex}} b_{[i]}$). If the algorithm reaches $i = 2n$, it returns 1 (since the last bit of b is 0). Note that the algorithm is deterministic. The number of queries that this algorithm does depends on the input and is $2n-1$ in the worst case.

We prove that for every input x it holds that $\mathbb{E}[P_n(x)] \leq 2\text{RC}(\text{LTF}, x)$.

For any x let $\mathsf{pref}(x)$ be the length of the prefix of x that algorithm P_n reads before it stops. In other words, it is the length of the prefix of x that agrees with the string b. Consider a pair of locations $2i-1$ and $2i$ that are smaller than $\mathsf{pref}(x)$. If the probability that A reads at least one of them is smaller than $2/3$, then algorithm A may err with probability at least $1/3$. If instead of input x it is given input x' that is flipped in locations $2i-1$ or $2i$, then the value of $\text{LTF}_n(x') \neq \text{LTF}_n(x)$, but A distinguishes the two inputs with probability less than $2/3$. ◀

▶ Remark 3.7 (Quantum instance optimality). In the quantum case, the Parity function is *not* instance optimal. Based on Grover's algorithm [29], it is known that *quantum* certificate complexity is exactly the square root of randomized certificate complexity (up to a constant factor). An explicit statement appears in Aaronson [1], where this claim is shown to be true on an input-by-input basis. On the other hand, computing Parity requires $n/2$ queries (quantumly) as shown by Farhi et al. [20] and Beals et al. [8].[8]

3.2.1 Sensitivity and Instance Optimality

We show that a function for which the decision tree complexity for every input is (roughly) equal to its sensitivity, then the function is instance optimizable. This is not true in the opposite direction.

▶ **Lemma 3.8.** *Let f be an n-input Boolean function. If there is a (randomized) decision tree for f s.t. for any x the complexity on input x is $\Theta(\mathsf{s}(f,x))$, then this algorithm is instance optimal.*

Proof. Let f be an n-input Boolean function. Assume that there is a decision tree algorithm (randomized or deterministic) whose complexity for every input x is $O(\mathsf{s}(f,x))$. For the deterministic case we show that any algorithm A that does not err must query $\mathsf{s}(f,x))$

[8] We thank Scott Aaronson for bringing these results to our attention.

location on x: suppose that there is an index i such that $f(x) \neq f(x \oplus e_i)$ that A does not query x_i. Then, on input $x \oplus e_i$ the algorithm A makes the same decision as on input x and thus must err.

For the randomized case, we show that any algorithm (that does not err with probability larger than $1/3$ on any input) must query at least as many points in expectation as $2\mathsf{s}(f,x)/3$ on input x before deciding the output of the function.

Consider two input distributions: one with the point x and the other one is on $\mathsf{s}(f,x)$ points of the form $x \oplus e_i$ for a random $i \in [n]$ such that $f(x) \neq f(x \oplus e_i)$. If an algorithm makes at most j queries, then the probability of distinguishing the two distributions is at most $j/\mathsf{s}(f,x)$. That is, the output distribution of such an algorithm when given one or the other distribution can differ by at most $j/\mathsf{s}(f,x)$. Therefore, if the expected number of queries the randomized algorithms makes on x is less than $2\mathsf{s}(f,x)/3$, then the expected difference is less than $2/3$ which means that the algorithm will err with probability at least $1/3$. ◀

From this lemma we can obtain many results concerning the instance optimality of many algorithms. For instance, we can recover our results for the parity, addressing and lexicographic threshold functions.

The lemma actually holds for block-sensitivity as well (with essentially the same proof). But this still does not give a tight characterization, as there are functions where the block-sensitivity is lower than the randomized certificate complexity (by some polynomial factor) [1, 24].

3.2.2 Random Functions are Instance Optimizable

Consider the uniform distribution of Boolean functions, i.e. selecting at random one from the set of size 2^{2^n} functions $\{0,1\}^n \to \{0,1\}$. A random Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ is instance optimizable with probability $1 - 2^{-cn}$ for some constant c and the naive algorithm that reads the *entire input* is an instance optimal algorithm. A proof follows.

What we need to show is that for such a random function on *all* inputs any algorithm must read a large fraction of the bits.

For input $x \in \{0,1\}^n$ consider all $\binom{n}{2}$ elements at (Hamming) distance 2. We have that except with probability $\ll 2^{-n}$ we will have at least $\binom{n}{2}/4$ values x' of distance 2 from x such that $f(x) \neq f(x')$.

Consider first a deterministic algorithm for x that queries k locations. If the algorithm is not to err, then it must cover all those x''s in the sense that it queries at least one of the two bits where x and x' differ. Now if it queries only $k \in o(n)$ locations it can cover at most $\binom{k}{2} + k(n-k)$ such x', but this is much smaller than $\binom{n}{2}/4$.

To get a lower bound for a randomized algorithm, consider the set of locations that have probability at least $1/8$ to be queried. If this set does not cover an x' at distance 2 from x where $f(x') \neq f(x)$, then we have that the algorithms errs with probability at least $3/4$ when the input is x'. So again we get that this set should be large and the expected number of location queried is $\Theta(n)$. So, altogether, we get that on all inputs x an algorithm tailored for x must ask $\Omega(n)$ queries and therefore the naive algorithm is instance optimal. This proves Item 5 of Theorem 1.3.

▶ Remark 3.9. It would have been nice if we could show the above claim (that random functions are instance optimizable) by showing that such functions have high block sensitivity *on any input*. But note that to use the union bound we need to get probability less than 2^{-n} and that just won't work. Instead, we gave a direct proof.

3.2.3 A Separation From Deterministic Instance Optimality

As we have seen, deterministic instance optimality does not imply randomized instance optimality (e.g., the Majority function, Lemma 3.2 and 3.5). There are several examples for the other direction, utilizing cases where there is a difference between the worst case deterministic and randomized complexities. In particular the following example:

▶ **Lemma 3.10** (Item 2 of Theorem 1.3, second part)**.** *There exists a function that is R-instance optimal but not D-instance optimal.*

Proof. Let $g(x_1)$ (where $|x_1| = n$) be a function for which $\mathrm{D}(g) \in \Omega(n)$, $\mathrm{R}(g) \in o(n)$ and $\mathrm{C}(g) \in o(n)$ in the worst case. Such functions are known, for example Saks and Wigderson [46] or Ambainis et al. [5]. Let Parity_ℓ be the parity function of all the bits of the input string of length ℓ. Let x be the concatenation of x_1 and x_2, and let $f(x) = g(x_1) \oplus \mathrm{Parity}_\ell(x_2)$ where we set $\ell = |x_2| = \mathrm{R}(g)$. For this length we have $\mathrm{C}(\mathrm{Parity}, x_2) = \mathrm{R}(g)$ on all inputs x_2.

Regarding the deterministic complexity of f, we have that $\mathrm{D}(f) = \mathrm{D}(g) + \mathrm{D}(\mathrm{Parity}_\ell) \geq \mathrm{D}(g) \in \Omega(n)$. Similarly $\mathrm{C}(f, x) = \mathrm{C}(g, x_1) + \mathrm{C}(\mathrm{Parity}_\ell, x_2) \in o(n)$ and thus on the worst case input, the certificate outperforms the deterministic algorithm, and thus f is not D instance optimal.

On the other hand, in the randomized case: let Δ_g be the best randomized algorithm to evaluate g in the worst case. Let $\Delta_{\mathrm{Parity}_\ell}$ be the algorithm that evaluates Parity_ℓ by simply querying the entire input. Let Δ_f be the algorithm that evaluates f by doing both Δ_g and$\Delta_{\mathrm{Parity}_\ell}$. We have, for any x, $\mathrm{R}(\Delta_f, x) = \mathrm{R}(\Delta_g, x_1) + \mathrm{R}(\Delta_{\mathrm{Parity}_\ell}, x_2) \in O(\mathrm{R}(g))$. Similarly $\mathrm{RC}(f, x) = \mathrm{RC}(g, x_1) + \mathrm{RC}(\mathrm{Parity}_\ell, x_2) > \mathrm{RC}(\mathrm{Parity}_\ell, x_2) \in \Omega(R(g))$ and thus f is R-instance optimal. ◀

3.3 Instance Optimality and Graph Properties

In this section we study the instance optimizability of a specific set of functions, ones that test graph properties.[9] Our motivation comes from our example in Lemma 3.6 of a monotone function which is R-instance optimizable: the function is very "far" from being a graph property as the location of each bit greatly influences its effect on the outcome of the function. This raises the question of whether non-symmetry is necessary for R-instance optimizability of monotone functions.

As a first step, we ask the following question: if we restrict our attention to graph properties, then is it possible that having a certificate *always* "helps"? In Lemma 3.11 we show that it is not the case. Specifically, we give an explicit graph property that is instance optimal. The graph property that we use is the *scorpion* property. An n vertex graph $G = (V, E)$ is a *scorpion* graph if it contains 3 special vertices: a vertex b (body) of degree $n - 2$, a vertex t (tail) of degree 2 and a vertex s (sting) of degree 1. The tail is adjacent to both b and s. Edges in between the remaining $n - 3$ vertices in $V \setminus \{b, s, t\}$ may be present or not.

▶ **Lemma 3.11** (Item 4 of Theorem 1.3)**.** *The scorpion graph property is R-instance optimal.*

Proof. We first show that a deterministic algorithm can test whether a given graph is a scorpion graph with $O(n)$ queries. This is a result of Best et al. [9]. We provide a proof of this in Appendix A for completeness.

[9] We consider finite and undirected graphs with neither self loops nor parallel edges. A graph property is an invariant that depends only on the abstract structure of the graph (and not on specific graph representations). See Section 2.3.

▷ Claim 3.12 ([9]). Testing whether a given n vertex graph is a scorpion graph takes at most $O(n)$ queries.

To complete the proof we show that on any instance G the complexity is $\Omega(n)$:

▷ Claim 3.13. For any graph G the best randomized algorithm on G that is correct on all inputs with probability at least $2/3$ must make $\Omega(n)$ queries in expectation.

Proof. Consider first a graphs that is a scorpion. The sensitivity of such a graph is at least $n-1$: there is a unique vertex that is the body (of degree $n-2$). If any of its $n-2$ adjacent edges is missing, then the graph ceases to be a scorpion. So as in the proof of Lemma 3.8 any correct algorithm must make $\Omega(n)$ queries in expectation. Consider now a graph that is not a scorpion. We partition its vertices into $n/3$ groups of triples and know that if for any one of the triples we completely change the neighborhood the triple can become the b, t and s of the scorpion graph (and the corresponding graph will satisfy the property). So consider the following two distributions on graphs: one is simply G the other one starts with G, picks a triple at random and changes the neighborhoods so they become the body, tail and sting. Differentiating between these two distributions implies that the number of triples touched (i.e. at least one edge in their neighborhood is queried) is close to $n/3$, but since each edge belongs to at most two triples we get that $\Omega(n)$ edges must be queried in expectation. ◁

◀

3.3.1 Conjecture: monotone graph properties are not instance optimizable

One of the most famous conjectures in the literature of query complexity is the *evasiveness conjecture* (a.k.a. the Aanderaa-Rosenberg conjecture). Roughly speaking, the conjecture says that for any non-trivial graph property any deterministic decision tree algorithm must query at least a constant fraction of all the edges (in the worst case). This conjecture was resolved by Rivest and Vuillemin [44]. In another version, called the *Aanderaa-Karp-Rosenberg conjecture* (AKR conjecture), the specific constant is also conjectured to be 1. This was resolved for graphs of prime power order (number of vertices) by Kahn, Saks and Sturtevant [35].

Yao [52, §4, Question (2)] asked whether an analogue of the Rivest-Vuillemin result holds for monotone graph properties and *no-error* randomized algorithms. Namely, whether a constant fraction of edges must be queried in expectation for any non-trivial monotone graph property by any randomized decision tree algorithm. The first result related to this question was of Yao [53] who showed a lower bound of $\Omega(n \cdot \log^{1/12} n)$. This was improved by King [36] and then by Hajnal [30] to $\Omega(n^{5/4})$ and $\Omega(n^{4/3})$, respectively. The currently best lower bound is $\Omega(n^{4/3} \cdot \log^{1/3} n)$ of Chakrabarti and Khot [13].

If the algorithm is allowed to make two-sided errors the best lower bound we are aware of is that of Jain and Zhang [33]. One could also pose a conjecture analogous to Yao's for such algorithms:

▶ **Conjecture 3.14.** *Any randomized decision tree algorithm has to query a constant fraction of edges for any non-trivial monotone graph property P, even if it is allowed to make an error with probability $1/3$. That is, $R(P)$ is $\Theta(n^2)$ for any non-trivial monotone graph property P on n-vertex graphs.*

We make a conjecture regarding instance optimality of graph properties, namely that every *monotone* graph property is not R-instance optimizable. That is, a randomized algorithm that gets a certificate will always be better than any randomized algorithm (that has no

certificate) on *some* input. The examples we gave in previous sections do not rule out this conjecture: the scorpion property is not monotone, the lexicographic threshold function is not a graph property, and the majority function (which can be phrased as a graph property) is not R-instance optimizable. Recall that the majority function is D-instance optimal, so the conjecture is false for deterministic computation.

▶ **Conjecture 3.15.** *Every non-trivial monotone graph property is not R-instance optimizable.*

We do not know what is the relationship between Conjectures 3.14 and 3.15.

3.4 Composition of Instance Optimal Functions

Given boolean function $f\colon \{0,1\}^n \to \{0,1\}$ and $g\colon \{0,1\}^m \to \{0,1\}$. The composition of f and g, denoted $f \circ g\colon \{0,1\}^{nm} \to \{0,1\}$, is defined as the value of $f(g(\vec{x_1}), ..., g(\vec{x_n}))$ where each $\vec{x_i}$ is an independent vector of m bits. Most classical notions in query complexity (such as deterministic and certificate complexities, degree, sensitivity and more) are known to behave well under composition (see for example Tal [48, Lemma 3.1]). In this section we show that instance optimality, on the other hand, does not compose. That is, the composition of two instance optimal functions is not necessarily instance optimal.

▶ **Lemma 3.16** (Item 4 of Theorem 1.2 and Item 6 of Theorem 1.3)**.** *There exist two functions that are both strictly D-instance optimal and R-instance optimal, but their composition results in a function that is neither R nor D instance optimal.*

Proof. Let $f\colon \{0,1\}^n \to \{0,1\}$ have input of the form: $(a_1, b_1), ..., (a_{n/2}, b_{n/2})$. The function f outputs b_i where i is the first index for which $a_i = 1$. We also define $a_{n/2} = 1$, regardless of the true input. The lemma follows immediately from the claims below.

▷ Claim 3.17. The function f is strictly D-instance optimal.

Proof. Consider the naive algorithm that queries each a_i in order until it finds an i for which $a_i = 1$ and then queries b_i. WLOG suppose the naive algorithm outputs 0. Suppose towards a contradiction that there exists an algorithm A that makes at most k queries for some input X, while the naive algorithm makes $k+1$ queries. We will show that by changing the values of bits that A did not query we can make A output the wrong value. If A makes at most k queries one of two things must be true:

1. For some $i < k$, A does not query any one of a_i and b_i.
2. A doesn't query a_k or A doesn't query b_k. If Item 1 does not occur, then this must occur (since if for every $i < k$, A queries either a_i or b_i, then querying both a_k and b_k would require $k+1$ total queries).

For the first case, if $a_i = b_i = 1$ then A makes an error. For the second case, we have two options: either A queries a_k or A queries b_k. Suppose A queries a_k. Note that $a_k = 1$ since the naive algorithm makes $k+1$ queries. If $b_k = 1$ then A has made an error. For the second option, suppose A queries b_k. If $a_k = 0$ but $a_{k+1} = b_{k+1} = 1$ then A has made an error. Note that the maximum number of queries the naive algorithm makes is $k + 1 = \frac{n}{2}$ since we know automatically that $a_{n/2} = 1$. ◁

▷ Claim 3.18. The function f is R-instance optimal.

Proof sketch. This is very similar to the proof of Lemma 3.6, that the lexicographic function is R-instance optimal. Essentially, any algorithm that is correct on 2/3 of the input must query the a_i's in order, since otherwise the input can be set to fool the algorithm. ◁

▷ Claim 3.19. For any algorithm $\Delta \in \mathbf{\Delta}_{f\circ f}$ (i.e., that computes $f \circ f$ on all inputs correctly with probability 2/3) there exists an input, x, for which $\mathrm{C}(f \circ f, x) \in O(n)$ while $\mathrm{R}(\Delta, x) \in \Omega(n^2)$.

The above claim implies that instance optimality does not compose in both the randomized and the deterministic case. This is true since our upper bound uses a deterministic decision tree while the lower bound is for any randomized decision tree.

Proof. Consider $f' \circ f''$. where both f' and f'' are f as defined above. Denote the input of f' by $[a_1^{\mathsf{out}}(\vec{x}_{1,1}), b_1^{\mathsf{out}}(\vec{x}_{1,2})], ..., [a_{n/2}^{\mathsf{out}}(\vec{x}_{n/2,2}), b_{n/2}^{\mathsf{out}}(\vec{x}_{n/2,2})]$, and similarly the input of each f'' by $\vec{x}_{i,j} = (a_1^{\mathsf{in}}, b_1^{\mathsf{in}}), ..., (a_{n/2}^{\mathsf{in}}, b_{n/2}^{\mathsf{in}})$. Note that a_i^{in} and b_i^{in} consists of a single bit. On the other hand $a_i^{\mathsf{out}}(\vec{x}_{i,1})$ and $b_i^{\mathsf{out}}(\vec{x}_{i,2})$ are functions on n bits.

Consider an input of the following form: for every i, $\vec{x}_{i,2}$ has $a_1^{\mathsf{in}} = 1$ (and thus for all i, $b_i^{\mathsf{out}}(\vec{x}_{i,2})$ can be computed in $O(1)$). Suppose that for all $i \neq \frac{n}{2}$, $\vec{x}_{i,2}$ has $b_1^{\mathsf{in}} = 0$, (and thus for all $i \neq \frac{n}{2}$, $b_i^{\mathsf{out}}(\vec{x}_{i,2}) = 0$), and $\vec{x}_{n/2,2}$ has $b_1^{\mathsf{in}} = 1$ (and thus $b_{n/2}^{\mathsf{out}}(\vec{x}_{n/2,2}) = 1$). Suppose that for every i, $\vec{x}_{i,1}$ has $a_k^{\mathsf{in}} = 0$ for every $k \neq \frac{n}{2}$, and $a_{n/2}^{\mathsf{in}} = 1$ (and thus for all i, computing $a_i^{\mathsf{out}}(\vec{x}_{i,1})$ requires $\Omega(n)$ queries). Suppose there exists a single i^*, which is chosen uniformly at random from $[1, \frac{n}{2} - 1]$, such that $\vec{x}_{i^*,1}$ has $b_{n/2}^{\mathsf{in}} = 1$ (and thus $a_{i^*}^{\mathsf{out}}(\vec{x}_{i^*,1}) = 1$). Similarly, suppose $\vec{x}_{n/2,1}$ has $b_{n/2}^{\mathsf{in}} = 1$ (and thus $a_{n/2}^{\mathsf{out}}(\vec{x}_{n/2,1}) = 1$). For all $i \neq i^*$, $\frac{n}{2}$ suppose $\vec{x}_{i,1}$ has $b_{n/2}^{\mathsf{in}} = 0$ (and thus for $i \neq i^*$, $\frac{n}{2}$, we have $a_i^{\mathsf{out}}(\vec{x}_{i,1}) = 0$).

Consider the following certificate algorithm: First the algorithm determines all of $b_i^{\mathsf{out}}(\vec{x}_{i,2})$. To do this, for every $\vec{x}_{i,2}$ the algorithm queries a_1^{in}, b_1^{in}. If for any $i \neq \frac{n}{2}$, either $a_1^{\mathsf{in}} \neq 1$ or $b_1^{\mathsf{in}} \neq 0$ then the input doesn't match the certificate (and in this case the algorithm can query everything, and we don't care about the number of queries). This requires $O(n)$ queries, since for every $b_i^{\mathsf{out}}(\vec{x}_{i,2})$ the algorithm makes two queries and there are $O(n)$ such b_i^{out}. Since for all $i < \frac{n}{2}$, $b_i^{\mathsf{out}}(\vec{x}_{i,2}) = 0$, if the certificate algorithm finds a single $i < \frac{n}{2}$ for which $a_i^{\mathsf{out}}(\vec{x}_{i,1}) = 1$ then the algorithm with a certificate knows that the output is 0. Thus the algorithm with a certificate can query all of the bits of $\vec{x}_{i^*,1}$ in $O(n)$ queries. If the certificate is truthful all of the $a_i^{\mathsf{in}} = 0$, except for $i = \frac{n}{2}$ for which $a_{n/2}^{\mathsf{in}} = 1$ and $b_{n/2}^{\mathsf{in}} = 1$, and thus $a_{i^*}^{\mathsf{out}}(\vec{x}_{i^*,1}) = 1$ (once again, if the queries do not match the certificate, then the certificate can query everything, and the number of queries is irrelevant). Thus the certificate algorithm outputs 0 in $O(n)$ queries.

On the other hand any randomized algorithm without a certificate will take $\Omega(n^2)$ queries. Suppose that for every i the randomized algorithm is given the value of each $b_i^{\mathsf{out}}(\vec{x}_{i,2})$, without any queries. The output of the function is '1' iff there exists an $i < \frac{n}{2}$ for which $a_i^{\mathsf{out}}(\vec{x}_{i,1}) = 1$. That is, the algorithm needs to output the OR function of $\frac{n}{2} - 1$ many $a_i^{\mathsf{out}}(\vec{x}_{i,1})$. In order to compute a single $a_i^{\mathsf{out}}(\vec{x}_{i,1})$ correctly with probability $\frac{2}{3}$ any randomized algorithm must make at least $k \in \Omega(n)$ queries due to Claim 3.18. That is $k = cn$ for some constant c. Consider any randomized algorithm that makes at most $\frac{cn^2}{10}$ queries. This algorithm, can determine at most $\frac{cn^2/10}{cn} = \frac{n}{10}$ many $a_i^{\mathsf{out}}(\vec{x}_{i,1})$ correctly with probability $\frac{2}{3}$ (since the input $\vec{x}_{i,1}$ and $\vec{x}_{i',1}$ are independent for each i and i'). Suppose the algorithm has determined $\frac{n}{10}$ many $a_i^{\mathsf{out}}(\vec{x}_{i,1})$ correctly with probability 1 (which is more than what any randomized algorithm can do). Since the single i^* that satisfies $a_{i^*}^{\mathsf{out}}(\vec{x}_{i^*,1}) = 1$ is distributed uniformly at random among all the possible $\frac{n}{2} - 1$ many i's, and since any randomized algorithm knows the value of at most $\frac{n}{10}$ many $a_i^{\mathsf{out}}(\vec{x}_{i,1})$, and since $\frac{n}{10} < \frac{2}{3}(\frac{n}{2} - 1)$, any randomized algorithm that makes at most $\frac{cn^2}{10}$ will succeed with probability less than $\frac{2}{3}$. ◁

◀

3.5 Testing Instance Optimality

In this section, we deal with the computational complexity of the problem of constructing and verifying instance optimal algorithms. The input is a function, i.e., the truthtable and the output is a decision tree.

We give an algorithm[10] U (for *universal*) that for a function f and an instance x, outputs an *optimal* randomized certificate tree for f on x. Thus, if one wants to test whether a given decision tree T is instance optimal for a problem f, then it is enough to compare its complexity on input x to the complexity of the output of U on f and input x for every $x \in \{0,1\}^n$. A different interpretation of U is that if one wants to prove that f is instance optimizable, then one has to give a decision tree that performs just as well as the decision tree generated by U for every input.

The running time of U for a problem f and input x is polynomial in the domain size of f and thus the total running time of testing whether a decision tree is instance optimal is a polynomial in the domain size of f

▶ **Theorem 3.20** (Theorem 1.4 rephrased). *There exists an algorithm U that gets as an input a function $f\colon \{0,1\}^n \to \{0,1\}$, and a certificate y for the input to the function, and generates in time $2^{O(n)}$ a correct randomized decision tree T_y for f such that $\mathrm{R}(\mathrm{T}_y, y) \in O(\mathrm{RC}(f,y))$.*

Proof. Let $f\colon \{0,1\}^n \to \{0,1\}$ be a Boolean function and $y \in \{0,1\}^n$ be a certificate for the input. For a subset $S \subseteq [n]$ let $y_S \in \{0,1\}^n$ be the incidence vector of S, i.e., a string whose i-th bit is:

$$(y_S)_i = \begin{cases} y_i & \text{if } i \notin S \\ \bar{y}_i & \text{if } i \in S \end{cases}$$

The algorithm U is given as Algorithm 1. On a high level, it uses the truth table of f to construct a linear program whose variables are all the possible inputs to f and the output is a set of n numbers $p_1, \ldots, p_n \in [0,1]$ that correspond to the probability that the certificate verification tree should query the ith input bit.

Each such bit should be queried independently and the result is a non-adaptive verifier. The algorithm takes exponential time (its input is a function f whose description may be exponential and it solves an exponentially large linear program) but the representation of the decision tree is small – just a set of probabilities $\{p_i\}_i$.

[10] Throughout the paper the term "algorithm" was used synonymously with the term "decision tree". In this section the term "algorithm" has a different meaning. Specifically, in this section the model the algorithm works in is RAM rather than the query model.

Algorithm 1 Randomized Decision Tree Generation Algorithm.

procedure $U(f, y)$
  Solve the linear program

$$\begin{aligned} \text{minimize} \quad & \sum_{i=1}^{n} p_i \\ \text{subject to} \quad & 0 \leq p_i \leq 1 \ , \forall 1 \leq i \leq n \\ & \sum_{i \in S} p_i \geq 1 \ , \forall S \subseteq [n] \text{ such that } f(y_S) \neq f(y) \end{aligned}$$

end procedure

The certificate verification algorithm is:

Repeat c times:
for $1 \leq i \leq n$ **do**
  query x at location i with probability p_i.
  if the result is equal to y_i **then** continue.
  else query x at all locations and output $f(x)$.
  end if
end for
output $f(y)$.

First note that there is always a solution for the linear program by setting all the p_i's to 1.

We begin by proving that Algorithm 1 satisfies correctness. Namely, that the resulting decision tree computes f correctly on every input (with sufficiently high probability). If $y = x$, then clearly the decision tree generated by Algorithm 1 outputs the correct value with probability 1 (since $f(x) = f(y)$). Otherwise, assume that $y \neq x$. Either the decision tree finds the differing point or not. In the former, it outputs $f(x)$ as needed. In the latter, there are two cases again: either $f(x) \neq f(y)$ or $f(x) = f(y)$. In the latter, we are done again by construction.

We are left with calculating the probability that the differing point is not recognized in case $f(x) \neq f(y)$. Let $S = \{i_1, \ldots, i_k\} \subseteq [n]$ be a subset of size $k \leq n$ of indices such that $x_i \neq y_i$ for $i \in S$. Algorithm 1 is wrong only if it does not query on any x_i such that $i \in S$. But since $f(y) \neq f(y_S)$ (since $y_S = x$) Algorithm 1 ensures that $\sum_{i \in S} p_i \geq 1$. Let $q_i = 1 - p_i$ (i.e., q_i is the probability that the decision tree does not query on x_i) and the probability of the algorithm being wrong is $\prod_{i \in S} q_i$. By the inequality of arithmetic and geometric means, we get that

$$\prod_{i \in S} q_i \leq \left(\frac{\sum_{i \in S} q_i}{k} \right)^k \leq \left(\frac{k-1}{k} \right)^k \leq e^{-1} < 0.4.$$

Hence, Algorithm 1 succeeds with probability at least 0.6. By standard amplification (running the algorithm repeatedly c times and outputting $f(y)$ only if there was never a disagreement), we get an algorithm whose success probability is at least 2/3.

To prove that Algorithm 1 is optimal in terms of the number of queries it makes, let T' be a randomized algorithm that computes f. Assume towards contradiction that $\mathrm{R}(\mathrm{T}', x) \in o(\mathrm{R}(\mathrm{T}, x))$, where T is the randomized decision tree generated by Algorithm 1. We will reach a contradiction by giving an input x' to T' for which it must error with probability

at least 1/3. By definition, $\mathrm{R}(\mathrm{T}, x) = \sum_{i=1}^{n} p_i$ and denote by p'_i the probability that T' queries x_i (on input x). Since $\mathrm{R}(\mathrm{T}', x) \in o(\mathrm{R}(\mathrm{T}, x))$, there exists some $S \subseteq [n]$ for which $\sum_{i \in S} p'_i \in o(1)$ and $f(x) \neq f(x')$ where $x' = x_S$. This is true since otherwise the p'_i's (times some constant) would be a solution to the linear program. Clearly, T' computes f correctly on x' with probability at most $o(1)$, contradicting the assumption. ◀

The conclusion is therefore that when given a function and a decision tree, in order to check whether the decision tree is instance optimal (with a given constant and some slackness) one may go over all inputs, for each one compute the certificate complexity as in Algorithm 1 and compare it to the complexity of the decision tree on that input. So only time proportional to polynomial in the truth table size is required.

▶ Remark 3.21. Aaronson [1, Lemma 5] showed that there is a non-adaptive verifier whose query complexity is similar to the best adaptive verifier. While Aaronson starts with the adaptive verifier and defines from it a non-adaptive one, we construct the non-adaptive verifier directly from the function.

We leave open the question of the complexity of testing whether a given function is instance optimizable.

▶ **Question 3.22.** *What is the complexity of testing whether a given function f is instance optimizable (within some c).*

3.6 Instance Optimality of Proximity Property Testing

Consider instance optimality in *proximity-to-property testing*: the task in proximity property testing, as defined by Goldreich, Goldwasser and Ron [26] (see [25] for a current survey), is to decide whether an object has some property or whether it is *far* from having it (according to some measure of distance). This is actually a function with "don't cares": if the object is close to satisfying the property but does not satisfy it, then any answer is acceptable; in this sense it is different than the other functions considered in the paper which are full domain.

There are several examples and characterizations of problems that can be tested within query complexity that only depends on the proximity parameter (see, for example, [26, 3, 27]). In this case, when the proximity parameter is constant, the number of queries is also constant which means that every such property is "trivially" instance optimizable: both the tester that has a certificate and the tester that does not have it can decide the property within a constant number of queries.

We observe that these properties, namely the ones that are testable within a constant number of queries, are *the only properties that are R-instance optimizable*: the tester that gets a certificate can always efficiently check (using $O(1/\delta)$ queries sampled at random) that its certificate is $\delta/2$-close to the object. If the certificate satisfies the property or if it $\delta/2$ close to satisfying the property, then it outputs "accept". Otherwise it outputs "reject". Here, we are using the fact that we are allowing two-sided errors.

4 Unlabeled Certificates

In this section we switch gears and study the notion of *unlabeled certificates* (see Section 2.2 for formal definitions). In the previous section the competing algorithm received as a certificate the entire input (this can be though of as an "untrusted hint" where the hint is the entire input), whereas in this section the certificate is a *permutation of the input* (the "untrusted hint" is a permutation of the input, where the permutation is chosen adversarially).

The unlabeled certificate makes sense especially for functions that are symmetric under some class of permutations. For instance, if the input is a graph property, the unlabeled certificate will be an isomorphic copy of the graph. That means that the algorithm should always be correct (even if the unlabeled certificate is not an isomorphic copy of graph), but the runtime of the algorithm is only measured when the unlabeled certificate is indeed isomorphic to the graph.

We study both the worst case complexity and the instance complexity of unlabeled certificates. For the worst case, roughly speaking, suppose we have a graph property, and suppose we are given an isomorphic copy of the graph as a certificate. It turns out that there exists a function for which such a certificate helps almost as much as an unlabeled certificate can possibly help. See Section 4.1 for more details.

In the case of instance complexity of unlabeled certificates, we say a function is unlabeled instance optimal if there exists an algorithm that performs as well as the unlabeled complexity (up to a multiplicative constant) for every input. We show that the group of permutations considered is important. Specifically, the majority property is randomized unlabeled instance optimal (where the unlabeled certificate is simply the hamming weight, since the function is symmetric under any permutation of the input), whereas the graph property of having more edges than non edges (now the group of allowed permutations are all isomorphisms of the graph) is far from being unlabeled instance optimal. See Section 4.2 for more details.

4.1 Unlabeled Certificates In the Worst Case

4.1.1 The Power of Unlabeled Certificates

We construct an example of a function (graph property) for which an algorithm that receives an isomorphic copy of the graph as a certificate outperforms any algorithm that has no certificate, thus showing a separation between algorithms receiving unlabeled certificates and algorithms with no certificate in the worst case. The separation is almost the largest possible.

▶ **Theorem 4.1** (Theorem 1.5 rephrased)**.** *There exists a graph property f for which* $\mathrm{AC}(f) \in O(n \log n)$ *while* $\mathrm{R}(f) \in \Omega(n^2)$.

That is, we show a function f for which $\mathrm{R}(f) \in \widetilde{\Omega}(\mathrm{AC}(f)^2)$. Since $\mathrm{D}(f) \geq \mathrm{R}(f)$, and $\mathrm{AC}(f) \geq \mathrm{RAC}(f)$, we also know that there exists a function where $D(f) \in \widetilde{\Omega}(\mathrm{AC}(f)^2)$ and $\mathrm{R}(f) \in \widetilde{\Omega}(\mathrm{RAC}(f)^2)$. Up to log factors, this example is tight in the deterministic setting since $\mathrm{D}(f) < \mathrm{C}(f)^2$ (see for example [34, Theorem 14.3]). In the randomized setting, the best known separation between $\mathrm{R}(f)$ and $\mathrm{RC}(f)$ is $\mathrm{R}(f) \in O(\mathrm{RC}(f)^2)$, and improving this separation is a major open research problem. In fact, if $\mathrm{D}(f) \in O(\mathsf{bs}(f)^2)$ then for all total functions f, $\mathrm{R}(f) \in O(\mathrm{RC}(f)^2)$, in which case our example is also tight in the randomized setting, up to log factors.

Our starting point in the construction is the property that every vertex has degree at least $\log n$. If one has a labeled certificate of the graph, then for each vertex it is easy to check $\log n$ neighbors and see that they indeed exist. But the problem with an unlabeled certificate is that there is no clear way to figure out who the vertices in the graph correspond to in the certificate and hence finding the $\log n$ neighbors might be lengthy and require $\Omega(n)$ queries per vertex. To overcome this we add some gadgets in order to uniquely define the vertices in a manner that allows to find their "identities" with relatively few queries.

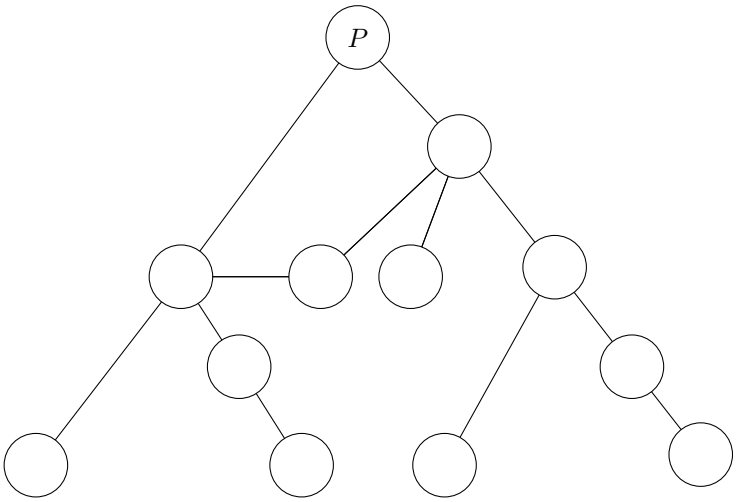

Figure 1 Example of binary tree illustrating Conditions 3 and 4.

▶ **Construction 4.2.** *The function outputs '1' iff all of the following conditions holds:*

1. *There are* exactly 2 *vertices of degree* 1, T_1 *and* T_2*, both of which have an edge to a special vertex, denote this vertex by* P*.*
2. *There is a vertex of degree* $n-3$ *that is adjacent to all vertices except* T_1 *and* T_2*. Call this vertex* B*.*
3. *Vertex* P *is the root of a "binary tree" of size* $10\log n$*. Every "right" child consists of an intermediate vertex. See Figure 1 where such a tree is shown. All vertices in the tree are also adjacent to* B*, this is not shown in the figure. Condition 4 is also shown in the figure.*
4. *There are* 2 *extra vertices, both adjacent to* P*'s right child, and one of which is also adjacent to* P*'s left child. This makes both of* P*'s immediate children also have degree* 5*. See Figure 1.*
5. *All the* $10\log n$ *leaves have degree different than* 5*. This makes* P *and its immediate children the only vertices of degree* 5*.*
6. *We call the set of remaining vertices* ($n - O(\log n)$ *in number) the "crowd" (denoted by* C*). The neighbor of every vertex in the crowd either also belongs to the crowd, or is a leaf of the tree described in Condition 3 or is the vertex* B *from Condition 2. Furthermore, all vertices in the crowd must have degree at least* $\log n$ *on the subgraph induced by* C *(that is, every vertex in* C *must have at least* $\log n$ *neighbors also in* C*).*[11]
7. *No two vertices in the crowd have the same neighborhood when restricted to the leaves of the tree. Note that this is possible since we have more than* $\log n$ *leaves.*

See Figure 2 for an illustration.

Proof. Note that if the function outputs 1, then T_1 and T_2 are the only vertices of degree 1. Thus, once we find T_1 or T_2 we can also find P in $O(n)$ queries by finding T_1's (or T_2's) only neighbor. If we know which vertex is B, then in $O(n)$ queries we can find T_1 and T_2, as they are the only vertices not adjacent to B. Once we find P we can check if Condition 1 is

[11] This condition can be replaced with any condition that can be solved in $O(n\log n)$ queries with a labeled certificate, but requires $\Omega(n^2)$ queries without a certificate.

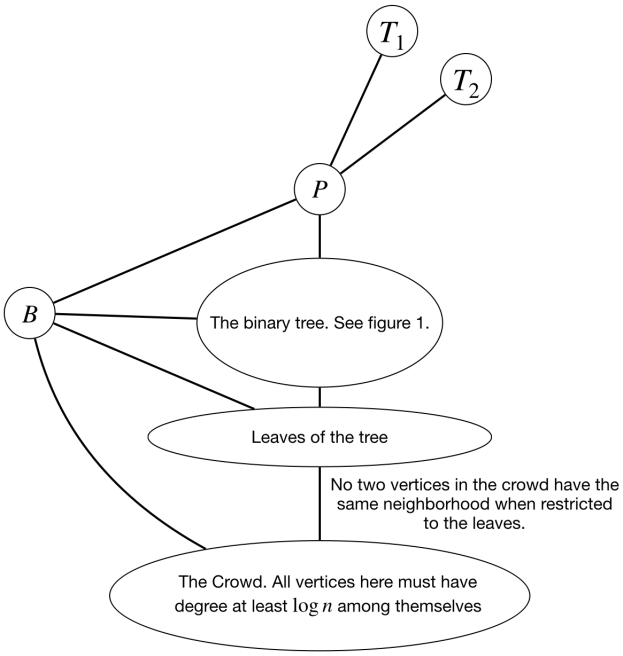

Figure 2 An illustration of Construction 4.2.

met by querying all of P's neighbors, and for each one making $O(n)$ queries to see if their only neighbor is P. If only 2 of P's 5 neighbors have this property then Condition 1 is met. Similarly once we find P, T_1 and T_2 we can check in $O(n)$ queries that Condition 2 is met by checking that one of P's neighbor has degree $n-3$ and is not adjacent to T_1 and T_2 as a neighbor. We can similarly check that Condition 4 is met in $O(n)$ queries given P. If we find a vertex, v, of degree 5 we can find P in $O(n)$ queries by checking if v has exactly two neighbors of degree 5, if it does then $v = P$, otherwise $v \neq P$ since P has 2 neighbors of degree 5, and these two neighbors don't have an edge between them.

The first phase of the algorithm is to find out either T_1, T_2 or B, and afterwards in $O(n)$ queries we also find P. We do this without using the unlabeled certificate similar to the way we check if a graph is a scorpion [9], see Appendix A. Start by picking an arbitrary vertex, v, and querying all of its neighbors. If $\deg(v) \in \{1, 5, n-3\}$ we are done, as v must be T, P (or one of P's immediate children) or B respectively. If $\deg(v) > n-3$ then output 0 since then we can't have two vertices of degree 1. So assume $\deg(v) \notin \{1, 5, n-3, n-2, n-1\}$. Let N_0 denote the set of all of v's neighbors, and let $N_1 = \overline{N_0} \setminus \{v\}$. Notice that if the function outputs 1 then $B \in N_0$ and $T_1, T_2 \in N_1$ since T_1 and T_2 are only adjacent to P, and $v \neq P$. Furthermore $P \in N_1$ because all of P's neighbors have degree $1, 5$ or $n-3$. Iteratively pick $x \in N_0$ and $y \in N_1$, and make a query to see if x is adjacent to y. If x and y are adjacent then y can't be T_1 or T_2 (since T_1 and T_2 only have an edge to P which is also in N_1), so remove y from N_0. If x and y are not adjacent then x can't be B unless y is T_1 or T_2, so remove x from N_0. Eventually N_0 will be empty, in which case y must be either T_1 or T_2. Thus in $O(n)$ queries we find P, and using $O(n)$ further queries we can check if Conditions 1, 2 and 4 are met.

Once we find P we proceed to find the leaves of the tree in $O(n \log n)$ queries. If at any point the structure does not match the tree (each vertex having one child of degree $2+1$ and one of degree $3+1$, where the $+1$ if for the edge with B) output 0 (Condition 3). Once

we find the leaves of the tree, for each leaf we make $n-1$ queries to check if each leaf has degree different than 5 (Condition 5) and to find the neighborhood of all the leaves. Having the neighborhood of each leaf allows us to check if Condition 7 is met, that no two vertices in the crowd have the same neighborhood when restricted to the leaves. If it is met then we can determine the isomorphism (for the vertices in C [12]), between the unlabeled certificate and the true (labeled) certificate. Note that the leaves of the tree are distinguishable since we know exactly which is a right child and which is a left child due to the intermediate right children, and this allows us to determine the isomorphism. With the (labeled) certificate we can check if Condition 6 is met in $O(n \log n)$.

Lower bound for randomized algorithms. It remains to show that the randomized complexity of this function is $\Omega(n^2)$. Suppose the algorithm is given (without any queries) all of the vertices of degree less than $\log n$, their neighbors, the vertex of degree $n-3$, as well as being told which vertices are the leaves of the tree. Suppose that all conditions except 6 are met. It remains to check if Condition 6 is met – that all vertices in C have at least $\log n$ neighbors also in C. Consider the following two input distributions:

1. The vertices in C are split into 3 sets, C_1, C_2 and C_3, where $|C_1| = \log(n) - 1$ and $|C_2| = |C_3| \in \Omega(n)$. The subgraphs induced by C_1 and C_3 are cliques, and every vertex in C_1 is connected to every vertex in C_2. For every vertex in C_2 we pick a vertex at random from C_3 and add an edge. Pick an edge uniformly at random from all edges that have one vertex in C_2 and one in C_3. Call the pair of endpoints of the edge the "marked pair".
2. Same as distribution 1, except the edge which is the marked pair is removed.

For the first distribution Condition 6 is met, since every vertex in C_2 has degree $\log n$ (on the subgraph induced by C) because it has $\log n - 1$ neighbors from C_1 and a single neighbor from C_3. In the second distribution Condition 6 is not met since there exists a single vertex in C_2 with degree $\log n - 1$.

Differentiating between the first distribution and the second distribution requires $\Omega(n^2)$ queries: Suppose that the algorithm A that attempts to distinguish between the two cases is given the partition of the vertices in C into C_1, C_2 and C_3 "for free", as well as being given for free that C_1 and C_3 are cliques. Furthermore, suppose that each query not only tells us if (u, v) is an edge, but also tells us if (u, v) is the marked pair. Note that the two distributions are identical, except that the second distribution does not contain the marked pair as an edge, and thus it is possible to tell apart the two distributions with any advantage (even if algorithm is allowed to err) if and only if the marked pair is queried.

Consider an arbitrary algorithm A. Let $N = |C_2| = |C_3| \in \Omega(n)$. At any point during the execution of A, call a vertex $u \in C_2$ "unmatched" if its adjacent edge has not been discovered yet, call it "thin" if thus far A has made at most $\frac{N}{2}$ queries that involve u, and call it "thick" if A has made at least $\frac{N}{2}$ queries that involve u. We can also think of the choice of the edges as well as the marked one as happening when the queries are made (principle of deferred decision): given an unmatched vertex u with q_u queries made so far, when a new slot is queried, it is matched with probability $1/(n - q_u - 1)$ and if it matched it is chosen as the marked one with probability proportional to the number of unmatched vertices.

[12] We do not have the full isomorphism, but we do know the mapping of the isomorphism for each of the vertices in the crowd – the vertices for which we want to check if they all have degree at least $\log n$ on the subgraph induced on C.

We do not charge the algorithm for queries made to thick vertices: once a vertex u becomes thick the next time A decides to query u it queries all the slots adjacent to it and gets the edge (or the marked pair); this modification does not result in a big change in the complexity, since it at most halves the total number of queries we charge A for making in any given execution. Thus, when considering an execution of A, we assume it can only choose among thin vertices.

We will first show that if A has made at most $q = \frac{1}{200}N^2$ queries so far, then the number of unmatched vertices is at least $N/2$ whp. Consider q independent trials (corresponding to the queries), each successful with probability at most $2/N$ (a vertex becoming matched). By the Chernoff Bound, the probability that q independent (and identical) trials, each successful with probability $\frac{2}{N}$ have more than $\frac{N}{2}$ successes is[13]

$$\Pr[\text{More than } N/2 \text{ vertices become matched}] \leq 2^{-N/2}.$$

Thus any algorithm that thus far has made less than $\frac{1}{200}N^2$ queries, has at least $\frac{N}{2}$ unmatched vertices with high probability.

We conclude that under the assumption that the number of unmatched vertices is at least $N/2$ the probability that A queries the marked pair in the next round is bounded by $4/N^2$: The probability that a given thin vertex u is part of the matched pair is $\frac{2}{N}$ (since there are at least $N/2$ unmatched vertices), and given that we query a vertex that is part of the marked pair, the probability that we query the marked pair is at most $2/N$ (since u is thin). So we get that the probability that A finds the marked pair in q rounds is bounded by $4q/N^2$ (union bound) plus the probability of not having $N/2$ unmatched vertices (which is negligible). So altogether, an algorithm operating with $q = \frac{1}{200}N^2$ queries has a limited probability of success and we get that the worst-case randomized complexity of f (Definition 2.3) is $\Omega(N^2) = \Omega(n^2)$. ◀

▶ Remark 4.3. The technique or gadget used in the above construction in order to make each vertex unique has additional applications. For instance, it can be used to turn an arbitrary function into a graph property while the complexity increases by an additive $O(n \cdot \log n)$ factor, resulting in the first known graph property with separation between the deterministic and randomized complexity. We explore this in future work.

4.2 Unlabeled Instance Optimality

4.2.1 Unlabeled Certificates of Majority

Our first example regarding unlabeled instance complexity is that while the majority function is not R-instance optimizable (Lemma 3.5), it is (almost) *unlabeled* R-instance optimizable. Namely, knowing the Hamming weight of the input does not help in significantly reducing the number of queries made to the input.[14]

Here, the optimality ratio is super-constant, that is, the unlabeled decision tree has an asymptotic advantage over the standard decision tree but it is only doubly-logarithmic in the input size (and this is tight).

[13] We use the following form of Chernoff: $\forall t \geq 2e\,\mathbb{E}[X]$, $\Pr[X \geq t] \leq 2^{-t}$. Indeed in this case $\mathbb{E}[X] = q\frac{2}{N} = \frac{N}{100}$. And $\frac{N}{2} > 2e\frac{N}{100}$.

[14] The majority is a symmetric function, and so in this case Γ contains all permutations of the n inputs, thus the full information is given by the hamming weight of the input.

▶ **Lemma 4.4** (Item 1 of Theorem 1.6). *The majority function is within $O(\log\log n)$ of being unlabeled R-instance optimizable.*

Proof. Consider an algorithm with an unlabeled certificate, which in the case of majority can be thought of as the number of 1's in the input. Suppose that the Hamming weight is $n/2+\varepsilon n$. Then the algorithm must make at least $\Omega(1/\varepsilon^2)$ queries to the input. This follows by fixing the distribution that with probability $1/2$ outputs a random input of Hamming weight $n/2+\varepsilon n$ and with probability $1/2$ outputs a random input of Hamming weight $n/2-\varepsilon n$. By the same fact we used in Lemma 3.5, $\Omega(1/\varepsilon^2)$ queries are required to distinguish the two cases.

We show that without a certificate, we can work with almost the same number of samples: $\Theta(1/\varepsilon^2\cdot\log\log(1/\varepsilon))$. The decision is obviously based on where the majority of the coordinates we read vote, but the issue is when to stop. This is a case of *sequential hypothesis testing* and the danger is that we are trying too many hypotheses and may fail in one of the trials, even though there is decent a probability of not failing in any particular one.

We use a recent result of Daskalakis and Kawase [15] who studied the following problem: Given sample access to an unknown distribution p over $\{0,1\}$ and an explicit distribution q over the same domain. How many samples are needed to reject the hypothesis "$p=q$" when $p\neq q$, while never rejecting when $p=q$. Daskalakis and Kawase showed that $\Theta(1/\mathsf{d}_{p,q}^2\cdot\log\log(1/\mathsf{d}_{p,q}))$ queries are needed and sufficient, where $\mathsf{d}_{p,q}$ is the total variation distance between p and q. We sketch the upper bound directly for our case next.

The algorithm samples a coordinate $i\leftarrow[n]$ uniformly at random and queries its input at i. Let t be the number of queries made so far and let t_0 be the number of 0's and t_1 the number of 1's (where $t_0+t_1=t$). Whenever t is a power of 2, the algorithm decides whether to stop or go on:

1. if $t\geq n$, read the whole input and output the majority value.
2. if $t_b > t/2+2\sqrt{t\cdot\log\log n}$, output the bit b.

We need to show two properties of the algorithm. First, that after enough iterations, it stops with the right answer. Second, that the probability that it stops too early, before making enough queries, is small. For the latter, since our test is done only when t is a power of two, the test is performed at most $\log n$ times. Thus, if we wish that no error will be made by stopping too early we need to reduce the probability of error per test to be at most $1/(3\log n)$. Assume that the input has $n/2+\varepsilon n$ 1's (the case with 0 majority is analogous). We start by showing that the probability that the algorithm halts and outputs the wrong answer is small. Denote by $T_b^{(t)}$ the random variable corresponding to the number of b's seen until query t, for $b\in\{0,1\}$. ($T_b^{(t)}$ is the sum of t independent random variables.) By a union bound, the probability that the algorithm makes a mistake it at most

$$\sum_{t=2^i}\Pr\left[T_0^{(t)}\geq\frac{t}{2}+2\sqrt{t\cdot\log\log n}\right],$$

where the sum is over all t's that are powers of 2. We bound each of these terms separately using Chernoff's bound.[15] Since the input contains $n/2+\varepsilon n$ 1's, it holds that $\mathbb{E}[T_0^{(t)}]=t/2-\varepsilon t$.

[15] We use the additive version of Chernoff's bound [4, Appendix A.1]. Let $X=\sum_{i=1}^n X_i$ be a sum of identically distributed independent random variables $X_1,\ldots,X_n\in\{0,1\}$. Let $\mu=\mathbb{E}[X]=\sum_{i=1}^n\mathbb{E}[X_i]$. It holds that for $a>0$, $\Pr[X>\mu+a]\leq\exp(-2a^2/n)$.

Hence, for every $t \in [n]$:

$$\begin{aligned}\Pr\left[T_0^{(t)} \geq \frac{t}{2} + 2\sqrt{t \cdot \log\log n}\right] &= \Pr\left[T_0^{(t)} \geq \left(\frac{t}{2} - \varepsilon t\right) + \left(\varepsilon\sqrt{t} + 2\sqrt{\log\log n}\right) \cdot \sqrt{t}\right] \\ &\leq \exp\left(-2\left(\varepsilon\sqrt{t} + 2\sqrt{\log\log n}\right)^2\right) \\ &\leq \exp\left(-8\log\log n\right) \leq \log^{-8} n.\end{aligned}$$

Thus, the overall probability that the algorithm makes a mistake is less than $\log n \cdot \log^{-8} n < 1/3$.

We show that with probability at least $2/3$ our algorithm halts (with the correct output) after at most $t' = \min\{2n, 25(\log\log n)/\varepsilon^2\}$ queries. This will finish the proof of the claim. Again, consider an input with $n/2 + \varepsilon n$ 1's. If ε is such that $t' \geq n$, then we are done. Otherwise, by the same Chernoff bound:

$$\begin{aligned}\Pr\left[T_1^{(t')} < \frac{t'}{2} + 2\sqrt{t' \cdot \log\log n}\right] &= \Pr\left[T_1^{(t')} \leq \left(\frac{t}{2} + \varepsilon t\right) - \left(\varepsilon\sqrt{t} - 2\sqrt{\log\log n}\right) \cdot \sqrt{t}\right] \\ &\leq \exp\left(-2\left(\varepsilon\sqrt{t} - 2\sqrt{\log\log n}\right)^2\right) < 1/3.\end{aligned}$$

◀

4.2.2 Unlabeled Certificates of Graph Properties

Our next result is that there exists a graph property which is *not* unlabeled R-instance optimizable. It is our "old friend" the majority property, but this time the group of permutations Γ considered is that of the vertices (rather than the edges), which demonstrates the significance of picking the most appropriate Γ.

▶ **Lemma 4.5** (Item 2 of Theorem 1.6). *There exists a graph property – majority of edges – which is not unlabeled R-instance optimizable. There is a distribution where any correct algorithm takes $\Omega(n^2)$ queries but an algorithm receiving an unlabeled certificate requires only $O(n \log n)$ queries.*

Proof. The graph property is that the graph $G = (V, E)$ with n vertices contains at least $\binom{n}{2}/2$ edges. The hard distribution for (certificateless) randomized decision trees will be a random graph that has either $\binom{n}{2}/2 + n$ edges or $\binom{n}{2}/2 - n$ edges.

On the one hand, a randomized algorithm that has no certificate cannot distinguish random graphs that have $\binom{n}{2}/2 + n$ edges from random graphs that have $\binom{n}{2}/2 - n$ edges unless it makes $\Omega(n^2)$ queries to the input and recovers a constant fraction of the graph. This is the fact we used in the proof of Lemma 3.5. The rest of the proof is devoted to showing that using an unlabeled certificate can significantly help.

We design a decision tree algorithm that has access to an unlabeled certificate and makes only $O(n \cdot \log n)$ queries to the input in expectation on the above distribution and decides the property correctly on all inputs with probability $2/3$. The algorithm works in two steps after which the algorithms recovers the *exact* graph (and not a permutation thereof) or figures out that it was given the wrong certificate. Then, we are back in the case of Lemma 3.5 where the (exact) certificate helps compared to the algorithm without the certificate.

Denote by $G = (V, E)$ the real graph we are querying and denote by $G' = (V, E')$ the permuted graph we have as a certificate. That is, $E' = \{(\pi(u), \pi(v)) \mid (u, v) \in E\})$ for some unknown permutation π. The first step of our algorithm is to sample a random set of $k = c \cdot \log n$ vertices $A = \{v_1, \ldots, v_k\}$ (for some large enough constant $c > 0$) and query all edges (v_i, v_j) for all $i, j \in [k]$. We call the set A the *anchor*. This costs at most $k^2 \in O(\log^2 n)$

queries. Denote by G_A the induced subgraph that the algorithm just queried. The algorithm then tests how many isomorphic subgraphs there are to G_A in G'. If there are no copies, we query all the edges in the graph, as the certificate is not a permutation of the input graph. If there is more than one copy, then we are unlucky (see below) and again we query all edges. If there is exactly one isomorphic subgraph, we have just identified the vertices in A and we can use them as an *anchor* to identify the other vertices.

The next step of the algorithm is to query the input on all possible neighbors for each vertex in the anchor A. This costs $n \cdot k \in O(n \cdot \log n)$ additional queries. For a vertex $v \in V \setminus A$, let $v(A) = (E(v, v_1), \ldots, E(v, v_k))$ be the incidence vector w.r.t. neighborhood in A. For each such $v \in V \setminus A$, look for a vertex in the certificate with the same "fingerprint", i.e., same list of vertices in A (again, if we find no match, we output $\perp$).

At this point, the algorithm completely recovers the permutation between the input and the certificate and thus we are almost done: as in Lemma 3.5, the algorithm checks using $O(n)$ random queries that the input graph corresponds to the certificate; if it does the algorithm answers accordingly (i.e., by the majority of the edges of the ceritificate) and if not the algorithm queries all the edges and answers according to the result. By the correctness of Lemma 3.5 we get that the algorithm is correct with high probability.

The fact that the algorithm is efficient, that is, if it is given a permutation of the true graph then the expected number of queries it makes is $O(n \log n)$, follows from the two claims below. They show that we will indeed recognize the vertices in A uniquely and then each other vertex in $V \setminus A$ (with very good probability). The overall complexity of the algorithm is $O(n \cdot \log n)$ queries with probability $1 - 1/n$ (the probability is over the distribution of the graphs and the random choices of the algorithm).

▷ Claim 4.6. With all but $1/n$ probability, there is only one induced subgraph of G that is isomorphic to G_A.

Proof. In Alon-Spencer [4, §10], Subsection titled "THE PROBABILISTIC LENS: Counting Subgraphs" the following is shown. Let $G = (V, E)$ be a $G(n, p)$ graph (i.e., a graph on n vertices with edge probability $p \in (0, 1)$) and let $S \subseteq V$ be a subset of k vertices. Let G_S be the induced subgraph of G to the vertices in S. Then, the probability that there is an isomorphic copy to G_S in G besides the one induced by S is at most

$$\sum_{g=1}^{t} \left(n^2 \cdot p^{1/3 - k/6} \right)^g .$$

Letting $p = 1/2 \pm n/\binom{n}{2}$ and $k = 100 \log n$, we get that the above probability is bounded by $1/n^2$.

The above holds for a $G(n, p)$ graph while our graph is sampled from a different distribution. Our distribution is such that the given graph is a random one conditioned on having $\binom{n}{2}/2 \pm n$ edges. But, a random $G(n, p)$ graph has inverse-polynomial probability of ending up with $p \cdot \binom{n}{2}$ edges so we can get the result for these graphs by conditioning. More generally, it is known that random graphs with m edges have similar properties to ones with edge probability $p = m/\binom{n}{2}$; see, for example, Frieze and Karonski [23, Lemma 1.2]. ◁

▷ Claim 4.7. With probability less than $1/n$, there exist distinct $v, v' \in V \setminus A$ such that $v(A) = v'(A)$.

Proof. For every two distinct $v, v' \in V \setminus A$ the probability that $v(A) = v'(A)$ is 2^{-k}. Applying a union bound over all possible such pairs, we get that there exist distinct $v, v' \in V \setminus A$ such that $v(A) = v'(A)$ with probability at most

$$|V \setminus A|^2 \cdot 2^{-k} \leq n^2/2^{c \cdot \log n} \leq 1/n^2,$$

where the last inequality follows for $c > 4$. ◁

This concludes the proof that majority is not instance optimal in this sense. ◀

Lastly, we show that even when considering graph properties (that is, the permutation group considered is over the vertices of the graph), there is a (monotone) graph property which is unlabeled R-instance optimizable:

▶ **Lemma 4.8** (Item 3 of Theorem 1.6)**.** *There exists a monotone graph property ("there exists at least one edge") which is unlabeled R-instance optimizable. But not labelling R-instance optimal.*

Proof. The graph property is that the graph $G = (V, E)$ contains at least one edge. Let $n = |V|$, and let m be the number of edges.The instance optimal randomized decision tree algorithm is the one that just samples random edges in the graph (without repetition) and queries on them until it either finds an edge or until it exhausts all the edges in the graph. If the input graph has $m \geq 1$ edges, the expected number of queries the algorithm makes is bounded by $\binom{n}{2}/m$.

In the unlabeled certificate case, we need to argue that for any $m \in \{0, \ldots, \binom{n}{2}\}$ and any graph G no randomized decision tree algorithm given G', an isomorphic copy of G, as an unlabeled certificate can be correct (on all graphs) with probability at least $2/3$ by querying in expectation $o\left(\binom{n}{2}/m\right)$.

Consider a distribution $\mathcal{D}_G$ on graphs such that with probability $1/2$ the output is a random isomorphic copy of the graph G and with probability $1/2$ the output is the empty graph (no edges at all). Consider the first k queries of any decision tree T. We will argue that for $k = \binom{n}{2}/(8m)$, with high probability T will not query any edge (when the graph it queries is a random isomorphic copy of G), and thus have no way of telling if the graph is indeed an isomorphic copy of G' or the empty graph. Note that as long as T doesn't query any edges, T is non-adaptive. Since T makes k queries, the probability that it queries at least one edge is the same as the probability that a k-edge graph H and a random permutation of a m-edge graph G intersect. We argue that this is roughly on the order of $k \cdot m/n^2$. More precisely, by a union bound and assuming the first $i-1$ rounds returned no edges, if T makes k queries, then with probability at most:

$$\sum_{i=1}^{k} \frac{m}{\binom{n}{2} - i + 1} \leq \frac{2mk}{n^2 - 2n - 2k} \leq 1/4$$

it will query an edge. Therefore, with probability at least $2/3$ it will not query any edge and thus have no way of knowing whether the graph has an edge or not. This means that $\Omega\left(\binom{n}{2}/m\right)$ queries must be made in expectation, same as the naive algorithm that does not get a certificate nor does it know m and therefore the property of having at least one edge is unlabeled R-instance optimizable.

The function is not labelling R-instance optimal, since if there exists one edge the algorithm with a (labeled) certificate requires only $O(1)$ queries. ◀

4.2.3 Labelling Instance Optimal

All instance optimal functions are also labelling instance optimal since for every x $\mathrm{C}(f,x) \leq \mathrm{AC}(f,\Gamma,x) \leq \mathrm{D}(f,x)$ and $\mathrm{RC}(f,x) \leq \mathrm{RAC}(f,\Gamma,x) \leq \mathrm{R}(f,x)$. We show that, up to log factors, the converse is not true; i.e, there exists a function that is within $O(\log(n))$ of being labelling D-instance optimal (resp. labelling R-instance optimal) but is not D-instance optimal (resp. R-instance optimal).

▶ **Lemma 4.9** (Item 4 of Theorem 1.6). *The function defined in Construction 4.2 is within $O(\log(n))$ of being labelling D-instance optimal, and labelling R-instance optimal, but is neither D-instance optimal nor R-instance optimal.*

Proof. We know the function isn't D nor R instance optimal since in the worst case the algorithm that has access to an unlabeled certificate does significantly better than the algorithm that has no certificate due to Theorem 4.1.

We will show that for every input $\mathrm{RC}(f,x) \in \Omega(n)$. Since for all inputs $\mathrm{AC}(f,x) \in \widetilde{O}(n)$ both D and R instance optimality follows. Notice that all the conditions except for Condition 3 make a requirement about the degree of a given vertex (or multiple vertices). $\Omega(n)$ queries are necessary to determine the degree of a given vertex with high probability. Condition 3 claims that we have a binary tree of size $O(\log(n))$ and thus this condition also requires $\Omega(n)$ queries with a certificate. ◀

4.2.4 Unlabeled Instance Optimality of Proximity Property Testing

It turns out that *every* proximity property, given an (unlabeled) certificate, can be done with at most $\tilde{O}(\sqrt{n})$ queries (with two-sided errors). This follows from a result of Fischer and Matsliah [22] who studied the query complexity of graph isomorphism in the proximity property testing model. One of their results determines the query complexity of this problem where one of the graphs is "known" to the algorithm and while allowing two-sided errors (this is in the dense graph model). They showed that, in this setting, $\tilde{O}(\sqrt{n})$ queries suffice and $\Omega(\sqrt{n})$ queries are necessary in general. Thus, in the unlabeled model, we can use this algorithm to first test proximity between the object and the given unlabeled certificate (using $\tilde{O}(\sqrt{n})$ queries). Then, if they are close, answer according to whether the certificate possess the property. If they are far, query the whole object and just compute the output precisely.

So, for a proximity property to be instance optimizable, it is necessary to prove that $O(\sqrt{n})$ queries are sufficient in the worst case.

5 Open Questions and Future Research

This work raises several open problems and research directions. Conjecture 3.15 is about the lack of monotone graph properties which are R-instance optimal.

▶ **Conjecture 5.1** (Conjecture 3.15, repeated). *Every non-trivial monotone graph property is not R-instance optimizable.*

In section Section 3.5 we showed that given a truth-table representing a function, we can test if a given algorithm is instance optimal in time polynomial in the size of the truth-table. It remains open if we can test if a given function is instance optimizable in time polynomial in the size of the truth table. Another question is, given a decision tree (instead of a truth table), can we test whether the function it evaluates is instance optimizable.

▶ **Question 5.2** (Question 3.22, repeated). *What is the complexity of testing whether a given function f is instance optimizable (within some c).*

As we observed in Section 3.6, there is a clean characterization of (randomized) instance optimality in the context of proximity testing. Also, we know that unlabeled certificates help (with properties which require many queries to test), but we do not have a full characterization.

▶ **Question 5.3.** *Are there unlabeled instance optimizable properties in the proximity testing model, with worst case complexity $\omega(1)$?*

Another question is whether analogues of the Aanderaa-Rosenberg conjecture holds for unlabeled certificate decision tree complexity. The randomized variant of this question for monotone properties is also open.

▶ **Question 5.4.** *Can the result of Rivest and Vuillemin [44] be extended to algorithms with an unlabeled certificate? Namely, do deterministic decision tree algorithms require querying a constant fraction of the edges for any non-trivial monotone graph property, even given a permutation of the given graph?*

In this work we considered two types of hints regarding the input, i.e. side information where the competing algorithm is measured only when it is correct: the full input and a permutation of the input. A natural question is what other types of hints are useful to study, e.g. partial inputs (that do not contain a certificate), such as the degree sequence.

A Efficiently Testing Scorpion Graphs

▷ Claim A.1 (Restatement of Claim 3.12, [9]). Testing whether a given n vertex graph is a scorpion graph takes at most $O(n)$ queries.

Proof. Let $G = (V, E)$ be an n vertex graph. We give an algorithm that does at most $O(n)$ queries to the graph G. Denote by $d(v)$ the degree of a vertex $v \in V$. Observe that once we find one of the special vertices (i.e., the body, the tail or the sting), we can locate all other special vertices with at most $3n$ queries and then check that the graph is a scorpion graph. For example, once we find a vertex b with $d(b) = n - 2$, then the vertex must be the body (if the graph is a scorpion). Going over all the neighbors of b we locate the only vertex $s \in V$ that is not a neighbor of b. This must be the sting vertex (again, if the graph is a scorpion). Then, going over all the edges adjacent to s, we locate the tail vertex t and verify that $d(t) = 2$. In total, we made $3n$ queries to the edges in G. Thus, the goal now is to locate one of the special vertices.

We begin with an arbitrary vertex $v \in V$. If $d(v) \in \{0, n-1\}$ then G is not a scorpion graph. Otherwise, if $d(v) \in \{1, 2\}$ then either v is one of the special vertices or a neighbor of v is one of the special vertices. If $d(v) = n - 2$ then v must be the body vertex. In any such case we can identify all the special vertices and checking if the graph is a scorpion graph using at most $4n$ queries to G.

Assume now that $3 \leq d(v) \leq n - 3$. Denote by N_0 the set of neighbors of v. Let $N_1 = \bar{N_0} \setminus \{v\}$. The body of G (if G is a scorpion) must be in N_0 and the sting and the tail must be in N_1. At this point we iteratively choose $x \in N_0$ and $y \in N_1$ such that if $(x, y) \in E$ then $N_1 = N_1 \setminus \{y\}$ (as y can not be the sting) and choose a new $y \in N_1$, and otherwise (i.e., if $(x, y) \notin E$), $N_0 = N_0 \setminus \{x\}$ (as x can not be the body unless y is the sting) and choose a new $x \in N_0$. This process terminates after at most n queries since after every query a vertex is deleted. Moreover, if G is a scorpion then at the end of the iterations $N_0 = \emptyset$ and y is the sting. To see this, notice that the body can not be deleted from N_0 by any vertex in N_1 that is not the sting, and once the sting is encountered all the vertices in N_0 will be deleted. ◁

B Instance Optimality in Other Settings

The term "Instance optimality" was coined by Fagin, Lotem and Naor [19] in the context of finding items with the top k aggregate scores in a database of sorted lists.[16] It has appeared in the theoretical computer science literature in several other contexts and forms. Here are a number of examples:

- **Competitive online analysis.** The competitive ratio of an algorithm A is its worst case performance relative to the best offline (see [11, 21]). This is a slightly different form of instance optimality since the comparison here is to an algorithm that is not necessarily from the same class.
- **Approximation algorithms.** Comparing the size (or value) that the best algorithm can find to the one the approximating algorithm finds.
- **Self-adjusting data structures.** Is it possible to construct an optimal binary search tree, i.e., with smallest possible search time, for an access sequence given online? Sleator and Tarjan [47] conjectured that Splay Trees are instance optimal in this sense and resolving it has been a central issue in the area. See also Demaine et al. [16].

[16] We note that the term "Instance Complexity" has been used by Orponen et al. [42] in a different meaning, one related to Kolmogorov Complexity.

- **Database operations.** Demaine et al. [17] studied the problem of finding intersections, unions, or differences of a collection of sorted sets. While the worst-case complexity of these problems is straightforward, they consider algorithms whose complexity depends on the particular instance.
- **Computational geometry.** Baran and Demaine [7] gave an instance optimal algorithm for the nearest-point-on-curve problem (where one needs to find a point on a curve that is nearest to a given point). Instance optimal algorithms for convex hull and set maxima were given by Afshani et al. [2]. Their notion is particularly related to the unlabeled model we consider in Section 4, where the algorithm is competing against the best one for the given set of points in some order.
- **Learning Theory.** A fundamental question in learning theory is to produce an accurate as possible approximation of an unknown distribution (over a discrete support) given independent draws from it. Valiant and Valiant [50] gave an algorithm that outputs an approximation whose expected distance from the real distribution is equal to the minimum possible expected error that could be obtained by any algorithm that *knows* the true yet unlabeled distribution and simply needs to assign labels. Another work of Valiant and Valiant [51] studied the identity testing problem: Given the explicit description of a distribution, decide whether a set of samples was drawn from it or from a distribution with some distance from it. They gave an algorithm in which the number of queries depends on the given distribution.
- **Distributed computing.** A series of works studied the possibility of instance optimal algorithms for eventual Byzantine agreement (a.k.a. Consensus) and simultaneous Byzantine agreement [18, 38, 31]. In these problems the inputs are the votes of the players and the failure pattern. They provided several positive and negative results for various notions of instance optimality appropriate for the setting.
- **Cryptography.** The notion of *precise zero knowledge* bounds the knowledge gained by a player in terms of its actual computation rather than standard zero knowledge that bounds the knowledge of a player in terms of his *potential* computational power (see Micali and Pass [37]).

In this work, we concentrated on cases where the domain is full and there is no promise regarding the input (as opposed to, say the work of Fagin et al. [19], where the assumption is that each column is sorted).

On the Impossibility of Probabilistic Proofs in Relativized Worlds

sliu18@berkeley.edu

Abstract

We initiate the systematic study of probabilistic proofs in relativized worlds, where the goal is to understand, for a given oracle, the possibility of "non-trivial" proof systems for deterministic or nondeterministic computations that make queries to the oracle.

This question is intimately related to a recent line of work that seeks to improve the efficiency of probabilistic proofs for computations that use functionalities such as cryptographic hash functions and digital signatures, by instantiating them via constructions that are "friendly" to known constructions of probabilistic proofs. Informally, negative results about probabilistic proofs in relativized worlds provide evidence that this line of work is inherent and, conversely, positive results provide a way to bypass it.

We prove several impossibility results for probabilistic proofs relative to natural oracles. Our results provide strong evidence that tailoring certain natural functionalities to known probabilistic proofs is inherent.

1 Introduction

The study of relativized complexity classes originally aspired to shed light on the structural relationships between *un*relativized complexity classes. However, it was soon realized that many interesting complexity classes have contradictory relativization results. For instance, Baker et al. [9] showed that there exist oracles A and B such that $\mathrm{P}^A = \mathrm{NP}^A$ and $\mathrm{P}^B \neq \mathrm{NP}^B$.

Subsequent works sought to circumvent this difficulty by considering relativized worlds where the oracle is sampled from a "natural" distribution, and thereby avoid specially-crafted oracles that can force an equality/inequality on the complexity classes being compared. For instance, Bennett and Gill [20] proved that, with probability 1 over a random oracle R, it holds that $\mathrm{P}^R \neq \mathrm{NP}^R \neq \text{co-}\mathrm{NP}^R$ and $\mathrm{P}^R = \mathrm{BPP}^R$. Since these relativization results agreed with what people believed to be true in the unrelativized case, Bennett and Gill proposed the *Random Oracle Hypothesis*, which states that structural relationships between complexity classes that hold with probability 1 over a random oracle also hold in the unrelativized case. However, this hypothesis was later disproved by Chang et al. [22], who showed that, with probability 1 over a random oracle R, $\mathrm{IP}^R \neq \mathrm{PSPACE}^R$. (We know that, without oracles, IP = PSPACE [34, 41].)

These works indicate that, in general, relativization results are not helpful for understanding the relationships between unrelativized complexity classes. At best they provide us with relativization barriers, which nowadays are not considered so strong since we know of non-relativizing techniques.

1.1 New motivation: the efficiency of probabilistic proofs

We revisit relativization with a new motivation: the efficiency of probabilistic proofs. Superficially, relativization and probabilistic proofs seem unrelated. Yet they are deeply connected, as we explain.

Probabilistic proofs such as interactive proofs [28] and probabilistically checkable proofs [8] have played important roles in the study of hardness of approximation since the seminal work of [25]. In recent years, they became the subject of intense study due to their application to constructing highly-efficient cryptographic proofs (such as succinct arguments), and a major research goal today is to improve the efficiency of probabilistic proofs. We now illustrate, via an example, how relativization results tell us important facts about the efficiency of probabilistic proofs.

▶ **Example 1.** Let $\mathcal{H} = \{H_s \colon \{0,1\}^{|s|} \to \{0,1\}^{|s|}\}_{s\in\{0,1\}^*}$ be a family of "hash functions" (the precise security property in this discussion is unimportant), and consider the following NP language:

$$L_s = \{(n, y) \in \mathbb{N} \times \{0,1\}^{|s|} \mid \exists\, x \in \{0,1\}^{|s|} \text{ s.t. } H_s^n(x) = y\} \ .$$

The efficiency measures (proof length, randomness complexity, query complexity, and others) of a PCP for the language L_s typically depend on the size of an arithmetic circuit that iteratively applies H_s, for n times, to a candidate witness x and checks if the result is y. The size of such a circuit is $\Omega(n\,|H_s|)$, i.e., it depends on the size of a circuit for expressing the computation of H_s. Since there are many NP languages of interest to practitioners that involve cryptographic computations such as hash functions, researchers have been designing specialized families of hash functions that can be represented via small arithmetic circuits [6, 2, 29, 4, 3, 30].

We ask: *is optimizing the arithmetic circuit complexity of hash functions necessary?*

We now explain why the answer to this question is connected to relativization statements about probabilistic proofs. Informally, suppose that for any family of hash functions $\mathcal{H}$ it holds that $\mathrm{NP}^{\mathcal{H}} \subseteq \mathrm{PCP}^{\mathcal{H}}$. In other words, every language that can be decided by a nondeterministic polynomial-time machine that makes oracle calls to a hash function has a PCP verifier that may make oracle calls to the same hash function. Now the "oracle language" $\mathcal{L} = \{L_s\}_{s\in\{0,1\}^*}$, which is in the relativized complexity class $\mathrm{NP}^{\mathcal{H}}$, can be decided via a computation that involves n calls to the hash function but does not depend on the complexity of the hash function itself (as this computation happens inside the oracle). Hence, since we assumed that $\mathrm{NP}^{\mathcal{H}} \subseteq \mathrm{PCP}^{\mathcal{H}}$, we can obtain a probabilistic proof for $\mathcal{L}$ whose efficiency does *not* depend on the complexity of the hash function (which is wonderful).

In sum, probabilistic proofs that "relativize with respect to hash functions" obviate the need to design hash functions with small complexity and, conversely, negative results about such relativizations provide strong evidence that efforts to design "PCP-friendly" hash functions are inherent.

The above example illustrates a general connection. On the one hand, constructing probabilisitic proofs in relativized worlds could provide drastic efficiency improvements to probabilistic proofs. On the other hand, ruling out probabilistic proofs in relativized worlds

would provide a complexity-theoretic justification for why practitioners may be "stuck" with the task of designing "PCP-friendly" realizations of various functionalities (hash functions, signatures, encryption, and so on).

1.2 Our question: are there PCPs for computations in relativized worlds?

We initiate the systematic study of probabilistic proofs for relativized computations.

In this work an *oracle* is a collection $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ where each $\mathcal{A}_n$ is a distribution over functions on n-bit inputs. A *sample* from $\mathcal{A}$ is a function $A\colon \{0,1\}^* \to \{0,1\}^*$ obtained by sampling a function f_n from each $\mathcal{A}_n$ and then setting A to equal f_n for n-bit inputs. (See Section 2.1 for definitions.)

We wish to understand for what oracles $\mathcal{A}$ there are probabilistically checkable proofs (PCPs) in a relativized world where all machines have oracle access to a sample from $\mathcal{A}$. Below we make this question more precise, distinguishing between the case of PCPs for relativized *nondeterministic* computations ("do PCPs provide any savings in witness length?") and the case of PCPs for relativized *deterministic* computations ("do PCPs provide any savings in computation length?").

The complexity classes that we study are the natural relativized extensions of DTIME, NTIME, and PCP. Note that complexity classes relative to an oracle $\mathcal{A}$ are sets of *oracle languages* (see Definition 11) rather than sets of languages, because the sample from $\mathcal{A}$ affects whether a particular instance is in the language or not. The informal definitions below are made precise in Section 2.4.

$\mathrm{DTIME}(t(n))^{\mathcal{A}}$	oracle languages that are decidable by a *deterministic* machine that runs in time $O(t(n))$ and has oracle access to a sample from $\mathcal{A}$
$\mathrm{NTIME}(t(n))^{\mathcal{A}}$	oracle languages that are decidable by a *nondeterministic* machine that runs in time $O(t(n))$ and has oracle access to a sample from $\mathcal{A}$
$\mathrm{PCP}(t(n), q(n))^{\mathcal{A}}$	oracle languages that are decidable by a *PCP verifier* that runs in time $O(t(n))$, makes $O(q(n))$ queries to a proof string, and has oracle access to a sample from $\mathcal{A}$

We introduce two incomparable questions, which concern the (im)possibility of "non-trivial" PCPs for relativized nondeterministic computations and for relativized deterministic computations.

1. **PCPs for NTIME.** For every oracle $\mathcal{A}$ it holds that $\mathrm{NTIME}(t(n))^{\mathcal{A}} \subseteq \mathrm{PCP}(t(n), t(n))^{\mathcal{A}}$ because a PCP verifier can read in full a witness provided in the PCP proof, and then run the nondeterministic decider on the witness. We ask: for what oracles $\mathcal{A}$ can we have *any* non-trivial improvement on this trivial inclusion? Namely, we consider PCP verifiers that may make $o(t(n))$ queries to the PCP proof, which in general prevents the PCP verifier from reading a witness from the PCP proof. We additionally allow the PCP verifier to incur a polynomial blow-up in running time: it may run in time $\mathrm{poly}(t(n))$, and in particular can make $\mathrm{poly}(t(n))$ queries to the sample from $\mathcal{A}$. (The queries to the PCP proof are still $o(t(n))$.) This amounts to asking:

   Given an oracle $\mathcal{A}$, is it the case that $\mathrm{NTIME}(t(n))^{\mathcal{A}} \subseteq \mathrm{PCP}(\mathrm{poly}(t(n)), o(t(n)))^{\mathcal{A}}$*?*

   We will say that an oracle $\mathcal{A}$ *separates* NTIME and PCP if the answer to this question is negative.
2. **PCPs for DTIME.** For every oracle $\mathcal{A}$ it holds that $\mathrm{DTIME}(t(n))^{\mathcal{A}} \subseteq \mathrm{PCP}(t(n), 0)^{\mathcal{A}}$ because a PCP verifier can simply run the deterministic decider. We similarly ask: for what oracles $\mathcal{A}$ can we have *any* non-trivial improvement on this trivial inclusion? Namely,

we consider PCP verifiers that run in time $o(t(n))$, which in general prevents a PCP verifier from simply running the deterministic decider. We additionally allow the PCP verifier to ask any number of queries to the proof or to the sample from $\mathcal{A}$ (as bounded by its running time). This amounts to asking:

Given an oracle $\mathcal{A}$, is it the case that $\mathrm{DTIME}(t(n))^{\mathcal{A}} \subseteq \mathrm{PCP}(o(t(n)), o(t(n)))^{\mathcal{A}}$*?*

We will say that an oracle $\mathcal{A}$ *separates* DTIME and PCP if the answer to this question is negative.

What is known? Recall that, for unrelativized complexity classes, we have excellent PCPs. All nondeterministic computations have a constant-query PCP verifier that runs in polylogarithmic time: $\mathrm{NTIME}(t(n)) \subseteq \mathrm{PCP}(\mathrm{poly}(n, \log t(n)), O(1))$ [24, 19, 37]. In particular, PCPs simultaneously provide exponential savings in witness length and in computation length.

However, for relativized complexity classes, known relativization results tell us very little. The main relevant prior work is by Hartmanis et al. [31], who claim that, with probability 1 over a random function $R\colon \{0,1\}^* \to \{0,1\}$, $\mathrm{NP}^R \not\subseteq \mathrm{PCP}(\mathrm{poly}(n), \log n)^R$. This provides a negative result for the special case where $\mathcal{A}$ is a "random oracle", $t(n)$ is polynomially bounded, and the PCP verifier makes $O(\log n)$ queries to the PCP proof. (In Section 1.4 we discuss other related work.)

However, even for the case of a random oracle, our goal is to rule out *any* non-trivial PCP for *any* nondeterministic computation (ruling out any savings in witness length), and also for any *deterministic* computation (ruling out any savings in computation length, even if there is no witness).

More generally, we are interested to answer these questions for oracles beyond random oracles.

Some intuition. If the PCP verifier could "learn" the oracle in a small number of queries, then we may be able to rely on known techniques to construct PCPs for *un*relativized computations because each oracle call could be replaced by a subroutine that simulates the learned oracle. Conversely, if the oracle is "hard" to learn, then known techniques do not seem to apply because it is not clear how they could deal with oracle calls, and so we may expect that non-trivial PCPs in this case are impossible. Our goal will be to show that, for hard-enough oracles, non-trivial PCPs are indeed impossible (regardless of the techniques that could be used to construct the PCPs).

Beyond PCPs. There are several models of probabilistic proofs beyond PCPs, such as interactive proofs (IPs) [28], interactive PCPs (IPCPs) [33], and interactive oracle proofs (IOPs) [18, 39]. One may ask: why do we focus only on PCPs in our presentation? The answer is that, for the goals of this paper, the PCP model is equivalent to the IOP model (see Remark 6), and the IOP model subsumes the other models as special cases. So, for the goals of this paper, it suffices to study PCPs. All results in Section 1.3 directly translate to IPs, IPCPs, and IOPs.

1.3 Our results

We prove that, for several oracles of cryptographic interest, non-trivial PCPs for relativized computations do not exist – this holds both for deterministic computations (DTIME) and for nondeterministic computations (NTIME). Moreover, we establish several structural results about "hard oracles" for PCPs. These initial results provide us with valuable insights into the efficiency limitations of PCPs, and provide a useful starting point for further investigations into this new direction.

We now summarize our results in more detail.

(1) Random functions. We begin with the oracle that intuition suggests is the "hardest" oracle for PCPs because it is "maximally unlearnable", the *random oracle*. Namely, we consider the oracle $\mathcal{R} = \{\mathcal{R}_n\}_{n\in\mathbb{N}}$ where each $\mathcal{R}_n$ is the uniform distribution over all functions $R_n \colon \{0,1\}^n \to \{0,1\}$.[1] Our first result shows that the intuition is correct, i.e., we prove that the oracle $\mathcal{R}$ separates DTIME and PCP and also separates NTIME and PCP.

▶ **Theorem 2** (informal). *Let $\mathcal{R}$ be the random oracle. For any $t \colon \mathbb{N} \to \mathbb{N}$,*

$$\mathrm{DTIME}(t)^{\mathcal{R}} \not\subseteq \mathrm{PCP}(o(t), o(t))^{\mathcal{R}} \quad \textit{and} \quad \mathrm{NTIME}(t)^{\mathcal{R}} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{R}} \ .$$

The above theorem tells us that we cannot, in general, expect to construct PCPs for cryptographic computations that involve random oracles, such as Fiat–Shamir signatures [26]. The natural alternative would be to somehow instantiate the random oracle, and incur, within the PCP, the cost of the hash function used in place of the random oracle. This is indeed what Valiant [43] did in his construction of *incrementally verifiable computation* (IVC): Valiant needed to construct a PCP for the computation of a SNARK verifier that uses random oracles and, lacking suitable PCPs for this relativized computation, considered instead the SNARK verifier obtained by instantiating the random oracle. Our Theorem 2 rules out PCPs for computations that use random oracles, and in particular gives strong evidence that Valiant's approach was in some sense justified.

One may argue that, while they give us useful insights, random oracles do not tell us much about other oracles because they are too special in that they have no structure. We now consider two oracles with structure: one with group structure and another with low-degree structure.

(2) Random generic groups. Many group-based cryptographic primitives are stated (and sometimes also analyzed) with respect to a *generic group*. This means that the primitive relies only on the fact that a certain prime-order group is available but does not rely on whether the group is instantiated, say, with a multiplicative subgroup of a finite field or an elliptic curve group. This motivates the question of whether there are PCPs with respect to a *random (generic) group oracle*, which is the oracle $\mathcal{O} = \{\mathcal{O}_n\}_{n\in\mathbb{N}}$ where each $\mathcal{O}_n$ is a random presentation of a group of order n. We prove that the answer is negative, i.e., that the oracle $\mathcal{O}$ separates NTIME and PCP.

▶ **Theorem 3** (informal). *Let $\mathcal{O}$ be the random group oracle. For any $t \colon \mathbb{N} \to \mathbb{N}$,*

$$\mathrm{NTIME}(t)^{\mathcal{O}} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{O}} \ .$$

The above theorem tells us that, in general, the representation of a group matters to a PCP. For example, if we return to the iterative hash computation of Example 1 and set the hash function to be the Pedersen hash function (a function that is collision resistant over any group where extracting discrete logarithms is hard), we should pick a group tailored to the PCP at hand. This is consistent with the fact that applied cryptographers working with probabilistic proofs have had to carefully design group instantiations for such computations.

[1] More generally, we consider the uniform distribution over functions $R_n \colon \{0,1\}^n \to \{0,1\}^{\ell(n)}$ for some $\ell(n)$.

E.g., `Jubjub` [44] is an elliptic curve in the Zcash cryptocurrency that is used to instantiate a Pedersen hash function in a way that is "friendly" to probabilistic proofs. Our theorem provides strong evidence that these efforts are necessary.

(3) Random low-degree functions. Probabilistic proofs are typically achieved by relying on low-degree functions that encode information associated to the computation being checked. This fact extends to relativized complexity classes in the sense that results such as IP = PSPACE *algebrize* with respect to every oracle [1]. In the language of this paper, this means that for every oracle $\mathcal{A}$, it holds that $\mathrm{PSPACE}^{\mathcal{A}} \subseteq \mathrm{IP}^{\hat{\mathcal{A}}}$ where $\hat{\mathcal{A}}$ is the low-degree extension of $\mathcal{A}$ (each sample in $\mathcal{A}$ is replaced with some low-degree extension of it).

However in this paper we are interested to understand relativization results, not algebrization results, and the above discussion raises the question of what happens when we compare DTIME/NTIME and PCP in a relativized world where the oracle is a random low-degree function. Namely, we consider the oracle $\mathcal{P} = \{\mathcal{P}_n\}_{n\in\mathbb{N}}$ where $\mathcal{P}_n$ is the uniform distribution over all low-degree polynomials on n variables (for given field and degree parameters). Note that $\mathcal{P}$ can be viewed as a low-degree extension of the random oracle $\mathcal{R}$.

We prove that $\mathcal{P}$ separates NTIME and PCP.

▶ **Theorem 4** (informal). *Let $\mathcal{P}$ be the random low-degree oracle. For any $t\colon \mathbb{N}\to\mathbb{N}$,*

$$\mathrm{NTIME}(t)^{\mathcal{P}} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{P}} \ .$$

Interlude on separation types. We have so far considered relativized complexity classes in which a single machine is granted oracle access to a sample $A\colon \{0,1\}^* \to \{0,1\}^*$ from the oracle $\mathcal{A}$, and is required to "work" for the language defined by A with probability 1 over the choice of A. For example, $\mathrm{DTIME}(t)^{\mathcal{A}}$ is the class of all oracle languages $\mathcal{L} = \{L_A\}_{A\in\mathcal{A}}$ for which there exists a deterministic machine M, which runs in time $O(t(n))$, such that

$$\Pr_{A\leftarrow\mathcal{A}}\Big[\, M^A \text{ decides the language } L_A \,\Big] = 1 \ .$$

We use analogous definitions for NTIME and PCP, as discussed in Section 2.4. We consider these definitions to be the natural ones to use for the goals of this paper. We sometimes refer to separations between these complexity classes as *uniform separations*, to distinguish them from those below.

We could alternatively study separations where all machines are allowed to *non-uniformly depend* on A, thereby granting all machines more power. In this direction, there are two natural definitions.

- *Somewhere separation.* We say that $\mathcal{A}$ provides a somewhere separation for DTIME and PCP if there exists $A\in\mathcal{A}$ such that $\mathrm{DTIME}(t)^A \not\subseteq \mathrm{PCP}(o(t), o(t))^A$. And similarly for NTIME.
- *Almost-everywhere separation.* We say that $\mathcal{A}$ provides an almost-everywhere separation for DTIME and PCP if $\mathrm{DTIME}(t)^A \not\subseteq \mathrm{PCP}(o(t), o(t))^A$ holds with probability 1 over a random choice of sample $A\leftarrow\mathcal{A}$. (Note that this leaves open the possibility that there is no separation for a set of functions of measure 0 in $\mathcal{A}$.) And similarly for NTIME.

An almost-everywhere separation is, in general, strictly stronger than an a somewhere separation. However, the relation between these and uniform separations is not a priori clear.

We provide clarity on this comparison: in the full version we prove that uniform separations are equivalent to somewhere separations, at least when comparing DTIME/NTIME and PCP. Namely, we prove that, for any oracle $\mathcal{A}$, $\mathrm{DTIME}(t)^{\mathcal{A}} \not\subseteq \mathrm{PCP}(o(t), o(t))^{\mathcal{A}}$ if and only if there exists a function A in $\mathcal{A}$ such that $\mathrm{DTIME}(t)^A \not\subseteq \mathrm{PCP}(o(t), o(t))^A$. And similarly for NTIME.

Almost-everywhere separation for random functions. For the random oracle $\mathcal{R}$, we strengthen the separations in Theorem 2 to almost-everywhere separations (via a different, longer proof). We learn that the random oracle $\mathcal{R}$ is particularly "hard" for PCPs.

▶ **Theorem 5** (informal). *Let $\mathcal{R}$ be the random oracle. For any $t\colon \mathbb{N} \to \mathbb{N}$,*

$$\Pr_{R \leftarrow \mathcal{R}} \left[\mathrm{DTIME}(t)^R \not\subseteq \mathrm{PCP}(o(t), o(t))^R \right] = 1$$
$$\textit{and} \quad \Pr_{R \leftarrow \mathcal{R}} \left[\mathrm{NTIME}(t)^R \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^R \right] = 1 \ .$$

The above theorem also directly improves on the classical work of Hartmanis et al. [31], who showed that $\Pr_{R \leftarrow \mathcal{R}}[\mathrm{NP}^R \not\subseteq \mathrm{PCP}(\mathrm{poly}(n), \log n)^R] = 1$. The improvement is that our result rules out any non-trivial PCP for any nondeterministic computation, and also rules out any non-trivial PCP for any deterministic computation.

We prove Theorem 5 by building on techniques of Chang et al. [22] that were used to prove that $\Pr_{R \leftarrow \mathcal{R}}[\mathrm{IP}^R \neq \mathrm{PSPACE}^R] = 1$. These techniques rely on the fact that every function R in $\mathcal{R}$ has many other functions in $\mathcal{R}$ that are close to it in all but finitely many points.

We do not know how to extend these techniques to oracles such as the random group oracle $\mathcal{O}$ or the random low-degree oracle $\mathcal{P}$, because in these cases any two samples are far from one another. In this light, we view the techniques that we use to prove Theorems 2 to 4 as more flexible. Moreover, we consider the separations proved in these theorems as sufficient for our motivations.

Structural results: beyond $\mathcal{R}$, $\mathcal{O}$, $\mathcal{P}$. Our results thus far concern separations for specific oracles of interest. There are other oracles of interest that demand understanding (e.g., pseudorandom functions) and, more generally, the study of separations could benefit from general statements. In Section 3 we prove several useful structural results about oracles that are "hard" for PCPs.

1. *Robustness.* We prove that the separating property is "robust" with respect to small perturbations. In more detail, we prove that for every oracle $\mathcal{A}$ that separates DTIME/NTIME and PCP there exists a distance function ϵ such that any other oracle that is ϵ-close to $\mathcal{A}$ also separates DTIME/NTIME and PCP. This statement can also be viewed as telling us that the set of separating oracles is *open* with respect to statistical distance (see Definition 8).
   We can apply the above result to any of the separations that we have proved. For example, if apply it to Theorem 2 then we learn that all oracles that are "almost" uniformly random (close enough to the random oracle $\mathcal{R}$) separate DTIME/NTIME and PCP. In fact, in the full version, we use additional techniques to quantify (a bound on) this distance threshold, proving that all oracles that are $\frac{1}{3e}$-close to uniformly random separate NTIME and PCP.
2. *Monotonicity.* We prove that the separating property is "monotone" in that, for every oracle $\mathcal{A}$ that separates DTIME/NTIME and PCP, if another oracle $\mathcal{B}$ contains $\mathcal{A}$ as a marginal distribution then $\mathcal{B}$ also separates DTIME/NTIME and PCP. I.e., $\mathcal{B}$ inherits the hardness of $\mathcal{A}$.
   We rely on monotonicity in the proof of Theorem 4, where we reduce the problem of showing separation for random *low-degree* polynomials to the problem of showing separation for random *multilinear* polynomials (which we then solve).

3. *Conditioning.* We prove that the separating property is preserved by (finite) conditioning. Namely, given an oracle $\mathcal{A}$ and a function $\mathfrak{f}\colon D \to \{0,1\}^*$ over a finite domain D, we denote by $\mathcal{A}^{D,\mathfrak{f}}$ the oracle where samples are conditioned to equal $\mathfrak{f}$ on D. We prove that if $\mathcal{A}$ separates DTIME/NTIME and PCP then $\mathcal{A}^{D,\mathfrak{f}}$ also separates DTIME/NTIME and PCP.

▶ Remark 6 (beyond PCPs). Research in the last few years has shown that using known PCPs is not the best choice for constructing efficient succinct arguments. Instead, it is better to construct succinct arguments from IOPs [18, 39], which are a multi-round generalization of PCPs that enables significant improvements in asymptotic and concrete efficiency [15, 14, 13, 10, 12, 11, 17, 16, 40]. So the reader may rightfully ask: why did we prove all of our results for PCPs instead of IOPs, if these latter are more powerful?

The answer is that *all of our results extend, in a generic way, to IOPs as well.* This is because our results about PCPs only consider the PCP verifier's time complexity and query complexity, and IOPs do *not* provide any benefits over PCPs when only considering these complexity measures. Indeed, any IOP can be "unrolled" into a PCP, possibly of exponentially larger size, while preserving the verifier's time complexity and query complexity, regardless of oracle. In particular, for every oracle $\mathcal{A}$, the complexity class $\mathrm{IOP}(T,q)^{\mathcal{A}}$ (oracle languages for $\mathcal{A}$ decidable by an IOP verifier with time complexity T and query complexity q) equals the complexity class $\mathrm{PCP}(T,q)^{\mathcal{A}}$ (oracle languages for $\mathcal{A}$ decidable by a PCP verifier with time complexity T and query complexity q).

Finally, we additionally obtain analogous impossibility results for interactive proofs (IPs) [28] and interactive PCPs (IPCPs) [33], as both are special cases of IOPs.

1.4 Related work

NP vs. PCP in relativized worlds. Fortnow [27] uses diagonalization to obtain a function $R\colon \{0,1\}^* \to \{0,1\}$ such that, for every $k \in \mathbb{N}$, $\mathrm{NP}^R \not\subseteq \mathrm{PCP}(\mathrm{poly}(n), n^k)^R$. Hartmanis et al. [31] report a stronger result: with probability 1 over a random function $R\colon \{0,1\}^* \to \{0,1\}$, $\mathrm{NP}^R \not\subseteq \mathrm{PCP}(\mathrm{poly}(n), \log n)^R$. We do not know of a version of [31] that contains a proof of this result, so we cannot comment on the techniques used to prove it. As already discussed, our Theorem 5 strengthens this latter result to hold for any non-trivial PCP.

Barriers for relativization and others. PCP constructions involve the use of non-relativizing techniques. A line of works [27, 5, 1, 32, 7] has developed frameworks that seek to capture the class of such techniques, along with other non-relativizing ones, within formal models, in order to prove barriers for these techniques (e.g., to show that they do not suffice to resolve the P vs. NP question or other difficult questions in complexity theory).

The emphasis and techniques in this work are complementary to the foregoing line of works.

Our emphasis is on establishing impossibility results for PCPs *regardless* of techniques used, as opposed to proving barriers for the PCP techniques that are known today.

Moreover, the axiomatic approaches employed in some of the works cited above cannot be used to even formulate questions that involve PCP verifiers with specific running times or query complexities. E.g., they rely on Cobham's axiomatization of the notion of polynomial time [23], so cannot express exact running times. This means that we would not be able to phrase questions about non-trivial PCPs (as we do in Section 1.2).

1.5 Open problems

The separations that we prove in this paper are for "information-theoretic" oracles $\mathcal{A}$. What can be said about hard "cryptographic" oracles $\mathcal{A}$? E.g., if $\mathcal{A}$ is a pseudo-random function, then must it be the case that $\mathcal{A}$ separates DTIME/NTIME and PCP? What about if $\mathcal{A}$ is a decryption oracle?

More generally, the holy grail in this research direction would be to distill a crisp, and operationally useful, criterion that gives sufficient and necessary condition for an oracle $\mathcal{A}$ that separates DTIME/NTIME and PCP.

2 Definitions

2.1 Oracles

An oracle is a collection of distributions over functions, with one distribution per input length.

▶ **Definition 7.** *An* **oracle** *with output length $\ell\colon \mathbb{N} \to \mathbb{N}$ (with $\ell(n) > 0$ for every $n \in \mathbb{N}$) is a collection $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ where each $\mathcal{A}_n$ is a distribution over functions $f\colon \{0,1\}^n \to \{0,1\}^{\ell(n)}$.*

We can obtain a *sample* $A\colon \{0,1\}^* \to \{0,1\}^*$ from $\mathcal{A}$ by sampling a function f_n from each $\mathcal{A}_n$ and then setting A to equal f_n for inputs of size n. We write "$A \leftarrow \mathcal{A}$" to denote that A is a sample that follows this distribution, and "$A \in \mathcal{A}$" to denote that A is in the support of this distribution. We denote by $\mathrm{supp}(\mathcal{A})$ the support of $\mathcal{A}$.

An oracle $\mathcal{A}$ induces a corresponding probability measure $\mu_{\mathcal{A}}$ over the space of functions from binary strings to binary strings: given a subset $S \subseteq \{0,1\}^*$ and a set X of functions from S to $\{0,1\}^*$, $\mu_{\mathcal{A}}(X)$ is the probability that the restriction to S of a sample A from $\mathcal{A}$ belongs to X.

▶ **Definition 8.** *Two oracles $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ and $\mathcal{B} = \{\mathcal{B}_n\}_{n\in\mathbb{N}}$ have (statistical) distance $\epsilon\colon \mathbb{N} \to \mathbb{N}$ if, for every $n \in \mathbb{N}$, the statistical distance between the distributions $\mathcal{A}_n$ and $\mathcal{B}_n$ is at most $\epsilon(n)$.*

We write "$g \leftarrow \mathcal{A}_{\leq n}$" to denote that g is a function on $\{0,1\}^{\leq n}$ that is sampled from the distribution $\mathcal{A}_{\leq n} := \mathcal{A}_1 \times \cdots \times \mathcal{A}_n$. We write "$g \in \mathcal{A}_{\leq n}$" to denote that g is in the support of this distribution, and denote by $\mathrm{supp}(\mathcal{A}_{\leq n})$ the support of $\mathcal{A}_{\leq n}$.

▶ **Definition 9.** *An oracle $\mathcal{B}$* **contains** *an oracle $\mathcal{A}$ if for all $n \in \mathbb{N}$ it holds that $\mu_{\mathcal{B}}(\mathrm{supp}(\mathcal{A}_{\leq n})) > 0$ and, for every $\mathfrak{f} \in \mathrm{supp}(\mathcal{A}_{\leq n})$, $\mu_{\mathcal{B}}(\mathfrak{f}) = \mu_{\mathcal{B}}(\mathrm{supp}(\mathcal{A}_{\leq n})) \cdot \mu_{\mathcal{A}}(\mathfrak{f})$.*

The definition below provides an operation to *condition* an oracle to take known values.

▶ **Definition 10.** *Fix a subset $D \subseteq \{0,1\}^*$ and function $\mathfrak{f}\colon D \to \{0,1\}^*$.*

- *Given a function $A\colon \{0,1\}^* \to \{0,1\}^*$, we define $A^{D,\mathfrak{f}}\colon \{0,1\}^* \to \{0,1\}^*$ to be the function obtained by setting the values of A on D to $\mathfrak{f}$:*

$$A^{D,\mathfrak{f}} = \begin{cases} \mathfrak{f}(x) & \text{if } x \in D \\ A(x) & \text{if } x \notin D \end{cases}.$$

- *Given an oracle $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ (such that there exists some $A \in \mathrm{supp}(\mathcal{A})$ agreeing with $\mathfrak{f}$ on D), we define $\mathcal{A}^{D,\mathfrak{f}} = \{\mathcal{A}_n^{D,\mathfrak{f}}\}_{n\in\mathbb{N}}$ to be the oracle where samples are conditioned to equal $\mathfrak{f}$ on D. In more detail, each distribution $\mathcal{A}_n^{D,\mathfrak{f}}$ equals the distribution $\mathcal{A}_n$ conditioned on the event that the sampled function agrees with $\mathfrak{f}$ on $D \cap \{0,1\}^n$.*

2.2 Languages and oracle languages

A language L is a subset of $\{0,1\}^*$. We denote by $L(\mathbb{x})$ the bit that specifies whether a string $\mathbb{x} \in \{0,1\}^*$ is in L ($L(\mathbb{x}) = 1$) or not ($L(\mathbb{x}) = 0$).

We also consider oracle languages because we study relativized complexity classes.

▶ **Definition 11.** *Let $\mathcal{U} := \{F\colon \{0,1\}^* \to \{0,1\}^*\}$ be the set of all functions on binary strings. An* **oracle language** *$\mathcal{L}$ is a collection of languages indexed by functions $F \in \mathcal{U}$, namely, $\mathcal{L} = \{L_F\}_{F\in\mathcal{U}}$ where each L_F is a subset of $\{0,1\}^*$.*

A language L can be viewed as a special case of an oracle language $\{L_F\}_{F\in\mathcal{U}}$ where each $L_F = L$.

▶ **Definition 12.** *Let $\ell\colon \mathbb{N} \to \mathbb{N}$ be a computable function. An oracle language $\mathcal{L} = \{L_F\}_{F\in\mathcal{U}}$ is* **ℓ-bounded** *if, for all functions $F \in \mathcal{U}$ and inputs $\mathbb{x} \in \{0,1\}^*$, whether $\mathbb{x} \in L_F$ only depends on F's values at locations of size at most $\ell(|\mathbb{x}|)$. Namely, $L_F(\mathbb{x}) = L_{F'}(\mathbb{x})$ for every F' that agrees with F on the set $\bigcup_{1\le i\le \ell(|\mathbb{x}|)}\{0,1\}^i$.*

2.3 Machines that query oracles

We consider several notions of (Turing) machines that query oracles, as defined below. Informally, an *oracle machine* is given black-box access to a function $A\colon \{0,1\}^* \to \{0,1\}^*$, which the machine can query, any number of times, at any input of its choice. Each query costs the machine a single computational step, regardless of the function A. In more detail, we consider the following definition.

▶ **Definition 13.** *An* **oracle machine** *M is a machine that has two special tapes called* oracle query tape *and* oracle answer tape*, and two special states called* Query *and* Answer*. The special tapes are in addition to the machine's regular read/write tapes (of which there can be one or multiple) and the special states are in addition to the machine's regular start, accept, reject, and other states. We denote by $M^A(\mathbb{x})$ the output of M on input $\mathbb{x} \in \{0,1\}^*$ and with access to oracle $A\colon \{0,1\}^* \to \{0,1\}^*$, which is computed as follows. The input $\mathbb{x}$ is written in a designated read/write tape, and execution proceeds as normal except if the machine enters the* Query *state. Let $y \in \{0,1\}^*$ be the contents of the oracle query tape when this happens. In the following step, the contents of the oracle answer tape are replaced with $A(y) \in \{0,1\}^*$, and the machine enters the* Answer *state.*

Definition 13 considers *deterministic* oracle machines. In Section 2.4 we use these machines to extend the notion of languages decidable in deterministic bounded time to work with oracles.

We also use *nondeterministic* oracle machines, which are defined similarly as above except that they can, in any computational step, choose to make a nondeterministic choice as in the standard definition of a nondeterministic machine. In Section 2.4 we use these machines to extend the notion of languages decidable in nondeterministic bounded time to work with oracles.

We also use *probabilistic* oracle machines that use randomness and can make queries to a proof string $\pi \in \{0,1\}^*$ (in addition to the oracle A). These machines are defined similarly as above except that they can, in any computational step, receive a bit of randomness, or query a location of the proof string π via two dedicated tapes (a *proof query tape* and a *proof answer tape*). In Section 2.4 we use these machines to extend the notion of probabilistic proofs to work with oracles.

Throughout this paper we call oracle machines simply "machines", as it will be clear from context when we are referring to an oracle machine (of one of the foregoing types).

▶ Remark 14. Oracle machines are often defined with *one* special tape, instead of *two* as in Definition 13. The machine writes its query to the oracle in this one tape, and in the following step the tape's contents are *replaced* with the oracle's answer. Note that, with one oracle tape, the machine has to write each query "from scratch" because the prior query was deleted. This difference is not significant, because writing each query from scratch is at most quadratically slower than not having to do that (due to having two oracle tapes). However, this difference matters when studying questions that are sensitive to such costs. Thus in this paper we use machines with two oracle tapes.

2.4 Complexity classes with oracles

We define, for a given oracle $\mathcal{A}$, the complexity classes $\mathrm{DTIME}(t)^{\mathcal{A}}$, $\mathrm{NTIME}(t)^{\mathcal{A}}$, and $\mathrm{PCP}(t,q)^{\mathcal{A}}$.

Deterministic time. A deterministic machine M is a *D-decider* for a language L if for every $\mathbb{x} \in \{0,1\}^*$ it holds that $M(\mathbb{x}) = L(\mathbb{x})$. The complexity class $\mathrm{DTIME}(t)$ consists of all languages L for which there exists a deterministic machine M that runs in time $O(t(n))$ and is a D-decider for L. We now provide a definition that considers the more general case of oracle languages that are decidable by deterministic machines with access to an oracle.

▶ **Definition 15.** *Let $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ be an oracle and let $t\colon \mathbb{N} \to \mathbb{N}$ be a function.* $\mathrm{DTIME}(t)^{\mathcal{A}}$ *is the class of all oracle languages $\mathcal{L} = \{L_A\}_{A\in\mathcal{A}}$ for which there exists a deterministic machine M, which runs in time $O(t(n))$, such that*

$$\Pr_{A\leftarrow\mathcal{A}}\left[M^A \text{ is a D-decider for } L_A\right] = 1 \ .$$

Nondeterministic time. A nondeterministic machine M is a *ND-decider* for a language L if for every $\mathbb{x} \in \{0,1\}^*$ it holds that $M(\mathbb{x}) = L(\mathbb{x})$. The complexity class $\mathrm{NTIME}(t)$ consists of all languages L for which there exists a nondeterministic machine M that runs in time $O(t(n))$ and is a ND-decider for L. We now provide a definition that considers the more general case of oracle languages that are decidable by nondeterministic machines with access to an oracle.

▶ **Definition 16.** *Let $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ be an oracle and let $t\colon \mathbb{N} \to \mathbb{N}$ be a function.* $\mathrm{NTIME}(t)^{\mathcal{A}}$ *is the class of all oracle languages $\mathcal{L} = \{L_A\}_{A\in\mathcal{A}}$ for which there exists a nondeterministic machine M, which runs in time $O(t(n))$, such that*

$$\Pr_{A\leftarrow\mathcal{A}}\left[M^A \text{ is a ND-decider for } L_A\right] = 1 \ .$$

Probabilistic proofs. A probabilistic machine M is a *PCP-verifier* for a language L if: for every $\mathbb{x} \in L$ there exists $\pi \in \{0,1\}^*$ such that $\Pr[M^\pi(\mathbb{x}) = 1] \geq 2/3$; for every $\mathbb{x} \notin L$ and $\pi \in \{0,1\}^*$ it holds that $\Pr[M^\pi(\mathbb{x}) = 0] \geq 2/3$. The complexity class $\mathrm{PCP}(t,q)$ consists of all languages L for which there exists a probabilistic machine M that runs in time $O(t(n))$, makes $O(q(n))$ queries to the proof string, and is a PCP-verifier for L. Below we consider the more general case of oracle languages that are decidable by probabilistic machines with access to an oracle.

▶ **Definition 17.** *Let $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ be an oracle and let $t, q\colon \mathbb{N} \to \mathbb{N}$ be functions.* $\mathrm{PCP}(t,q)^{\mathcal{A}}$ *is the class of all oracle languages $\mathcal{L} = \{L_A\}_{A\in\mathcal{A}}$ for which the there exists a probabilistic machine M, which runs in time $O(t(n))$ and makes $O(q(n))$ queries to the proof string, such that*

$$\Pr_{A\leftarrow\mathcal{A}}\left[\, M^A \text{ is a PCP-verifier for } L_A \,\right] = 1 \ .$$

▶ **Definition 18.** *Let $\mathcal{L} = \{L_A\}_{A\in\mathcal{A}}$ be an oracle language. An oracle machine M* **fails** *on an input $\mathbb{x} \in \{0,1\}^*$ and function $A \in \mathcal{A}$ for $\mathcal{L}$ if the following holds: if $\mathbb{x} \in L_A$ then $\Pr_r[M^{A,\pi}(\mathbb{x};r) = 1] < \frac{2}{3}$ for every proof π; else if $\mathbb{x} \notin L_A$ then $\Pr_r[M^{A,\pi}(\mathbb{x};r) = 1] > \frac{1}{3}$ for some proof π.*

We conclude this section with several technical remarks.

▶ Remark 19 (bounded oracle languages). For every oracle $\mathcal{A}$ and oracle language $\mathcal{L}$ in the complexity class $\mathrm{DTIME}(t)^{\mathcal{A}}$, $\mathrm{NTIME}(t)^{\mathcal{A}}$, or $\mathrm{PCP}(t,q)^{\mathcal{A}}$, there exists a $O(t)$-bounded oracle language $\mathcal{L}^*$ such that for every oracle $A \in \mathcal{A}$ it holds that $L_A = L^*_A$. The language $\mathcal{L}^*$ is naturally defined by $\mathcal{L}$'s $\mathrm{DTIME}^{\mathcal{A}}$ decider, $\mathrm{NTIME}^{\mathcal{A}}$ decider, or $\mathrm{PCP}^{\mathcal{A}}$ verifier. In particular, we can assume without loss of generality that oracle languages in these complexity classes are $O(t)$-bounded.

▶ Remark 20 (index over $\mathcal{A}$ instead of $\mathcal{U}$). We sometimes define an oracle language $\mathcal{L}$ in $\mathrm{DTIME}(t)^{\mathcal{A}}$ or in $\mathrm{NTIME}(t)^{\mathcal{A}}$ only for functions in (the support of) an oracle $\mathcal{A}$. In this case it is understood that L_F is defined by the $\mathrm{DTIME}^{\mathcal{A}}$ or $\mathrm{NTIME}^{\mathcal{A}}$ decider of $\{L_A\}_{A\in\mathcal{A}}$ for all functions $F \in \mathcal{U} \setminus \mathcal{A}$.

▶ Remark 21 (relativized classes for a single function). Definitions 15 to 17 capture, as a special case, relativized classes where the oracle is a single function $A\colon \{0,1\}^* \to \{0,1\}^*$ rather than a distribution over functions (let $\mathcal{A}$ be the oracle that puts all the probability mass on A). In this case the relativized classes can be "collapsed" to sets of languages rather than sets of oracle languages.

3 Structural properties of separation

We prove structural properties about the non-containments $\mathrm{DTIME}(t)^{\mathcal{A}} \not\subseteq \mathrm{PCP}(T,q)^{\mathcal{A}}$ (Theorem 22) and $\mathrm{NTIME}(t)^{\mathcal{A}} \not\subseteq \mathrm{PCP}(T,q)^{\mathcal{A}}$ (Theorem 23). We use these in later sections.

▶ **Theorem 22** (DTIME & PCP)**.** *Let $t, T\colon \mathbb{N} \to \mathbb{N}$ be time bound functions and $q\colon \mathbb{N} \to \mathbb{N}$ a query bound function. Let $\mathcal{A}$ be an oracle such that $\mathrm{DTIME}(t)^{\mathcal{A}} \not\subseteq \mathrm{PCP}(T,q)^{\mathcal{A}}$. Then the following holds.*

1. Robustness: *there exists a positive function $\epsilon\colon \mathbb{N} \to \mathbb{R}$ ($\epsilon(n) > 0$ for every $n \in \mathbb{N}$) such that, for every oracle $\mathcal{B}$ that is ϵ-close to $\mathcal{A}$, it also holds that $\mathrm{DTIME}(t)^{\mathcal{B}} \not\subseteq \mathrm{PCP}(T,q)^{\mathcal{B}}$.*
2. Monotonicity: *for every oracle $\mathcal{B}$ that contains $\mathcal{A}$, it also holds that $\mathrm{DTIME}(t)^{\mathcal{B}} \not\subseteq \mathrm{PCP}(T,q)^{\mathcal{B}}$.*
3. Conditioning: *for every function $\mathfrak{f}\colon D \to \{0,1\}^*$, it also holds that $\mathrm{DTIME}(t)^{\mathcal{A}^{D,\mathfrak{f}}} \not\subseteq \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{f}}}$.*

▶ **Theorem 23** (NTIME & PCP)**.** *Theorem 22 also holds with $\mathrm{NTIME}(t)$ in place of $\mathrm{DTIME}(t)$.*

The above theorems are direct corollaries of general properties that we prove, as we now explain.

For the rest of this section we fix: (a) an oracle language $\mathcal{L}$ that is ℓ-bounded for some $\ell\colon \mathbb{N} \to \mathbb{N}$; (b) a time bound function $T\colon \mathbb{N} \to \mathbb{N}$; (c) a query bound function $q\colon \mathbb{N} \to \mathbb{N}$; (d) an oracle $\mathcal{A}$.

We shall provide an equivalent formulation for the condition "$\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$" (Claim 26), and then use it to derive several general properties about this condition: robustness (Lemma 27), monotonicity (Lemma 28), and conditioning (Lemma 29).

By taking $\mathcal{L}$ to be an oracle language in either $\mathrm{DTIME}(t)^{\mathcal{A}}$ or $\mathrm{NTIME}(t)^{\mathcal{A}}$ (which implies that the oracle language is $O(t)$-bounded), we can then derive the corresponding property in Theorem 22 or Theorem 23 respectively. We are left to state and prove the claim and lemmas mentioned above.

▶ **Definition 24.** *We denote by $\mathbf{M}_{T,q}$ the set of probabilistic oracle machines that, on inputs of length n, read $O(q(n))$ proof bits and run in $O(T(n))$ time.*

▶ **Definition 25.** *For every $n \in \mathbb{N}$, $s(n) := \max\{\ell(n), 2^{T(n)}\}$ and $S_n := \bigcup_{1 \le i \le s(n)} \{0,1\}^i$.*

▷ Claim 26. The following two conditions are equivalent:

1. $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$.
2. For every machine $M \in \mathbf{M}_{T,q}$ there exist an input $\mathbb{x} \in \{0,1\}^*$ and function $\mathfrak{f}\colon S_{|\mathbb{x}|} \to \{0,1\}^*$ with $\mu_{\mathcal{A}}(\mathfrak{f}) > 0$ such that, for every function $F\colon \{0,1\}^* \to \{0,1\}^*$ that agrees with $\mathfrak{f}$ on $S_{|\mathbb{x}|}$, M fails on input $\mathbb{x}$ and function F for $\mathcal{L}$. (The function F need not be in $\mathrm{supp}(\mathcal{A})$.)

Proof. We separately consider the two directions.

(1) ⇒ (2). If $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$, then for every $M \in \mathbf{M}_{T,q}$ there exists a function $F \in \mathrm{supp}(\mathcal{A})$ such that M^F fails to verify L_F on some input $\mathbb{x}$. Consider the function $\mathfrak{f}\colon S_{|\mathbb{x}|} \to \{0,1\}^*$ obtained by restricting F to $S_{|\mathbb{x}|}$. Since the running time of M^F on input $\mathbb{x}$ is at most $O(T(|\mathbb{x}|))$, it cannot distinguish between having access to the function F and access to any other function F' that agrees with $\mathfrak{f}$. Moreover, since $\mathcal{L}$ is ℓ-bounded, $L_F(\mathbb{x}) = L_{F'}(\mathbb{x})$ for every F' that agrees with $\mathfrak{f}$. Therefore, $M^{F'}(\mathbb{x})$ fails for every F' that agrees with $\mathfrak{f}$. The set of all such oracles has positive measure in $\mathcal{A}$ (i.e., $\mu_{\mathcal{A}}(\mathfrak{f}) > 0$), because any finite prefix of any function in $\mathcal{A}$ has positive measure.

(2) ⇒ (1). The condition directly implies that, for every $M \in \mathbf{M}_{T,q}$, M^A is not a PCP-verifier for L_A for a set of functions A with positive measure in $\mathcal{A}$. Therefore $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$. ◀

▶ **Lemma 27** (robustness). *If $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$, then there exists a positive function $\epsilon\colon \mathbb{N} \to \mathbb{R}$ ($\epsilon(n) > 0$ for every $n \in \mathbb{N}$) such that, for every oracle $\mathcal{B}$ that is ϵ-close to $\mathcal{A}$, $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{B}}$.*

Proof. For every $n \in \mathbb{N}$, define $X_n := \{\mathfrak{f}\colon S_n \to \{0,1\}^* \mid \mu_{\mathcal{A}}(\mathfrak{f}) > 0\}$ to be the set of all functions over S_n that have positive measure in $\mathcal{A}$. We define the distance function as $\epsilon(n) := \min_{\mathfrak{f} \in X_n} \mu_{\mathcal{A}}(\mathfrak{f})$.

By Claim 26, from $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$ we deduce that for any $M \in \mathbf{M}_{T,q}$ there exist an input $\mathbb{x}$ and function $\mathfrak{f}\colon S_{|\mathbb{x}|} \to \{0,1\}^*$ with $\mu_{\mathcal{A}}(\mathfrak{f}) > 0$ such that, for every function $F\colon \{0,1\}^* \to \{0,1\}^*$ that agrees with $\mathfrak{f}$ on $S_{|\mathbb{x}|}$, M fails on input $\mathbb{x}$ and function F for $\mathcal{L}$. Since the oracle $\mathcal{B}$ is ϵ-close to $\mathcal{A}$ we deduce, from the definition of ϵ, that $\mu_{\mathcal{B}}(\mathfrak{f}) > 0$ as well.

Since the above holds for every $M \in \mathbf{M}_{T,q}$, by Claim 26 we conclude that $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{B}}$. ◀

▶ **Lemma 28** (monotonicity). *If $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$, then, for every oracle $\mathcal{B}$ that contains $\mathcal{A}$, it holds that $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{B}}$.*

Proof. From Claim 26, since $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$, we know that for every $M \in \mathbf{M}_{T,q}$ there exist an input $\mathbb{x}$ and function $\mathfrak{f}\colon S_{|\mathbb{x}|} \to \{0,1\}^*$ with $\mu_{\mathcal{A}}(\mathfrak{f}) > 0$ such that, for every function $F\colon \{0,1\}^* \to \{0,1\}^*$ that agrees with $\mathfrak{f}$ on $S_{|\mathbb{x}|}$, M fails on input $\mathbb{x}$ and function F for $\mathcal{L}$. Due to containment (Definition 9), since $\mathfrak{f} \in \mathrm{supp}(\mathcal{A}_{\leq s(|\mathbb{x}|)})$, we deduce that

$$\mu_{\mathcal{B}}(\mathfrak{f}) = \mu_{\mathcal{B}}\left(\mathrm{supp}(\mathcal{A}_{\leq s(|\mathbb{x}|)})\right) \cdot \mu_{\mathcal{A}}(\mathfrak{f}) > 0 \ .$$

Since the above holds for every $M \in \mathbf{M}_{T,q}$, by Claim 26 we conclude that $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{B}}$. ◀

▶ **Lemma 29** (conditioning). *Let $I \subseteq \mathbb{N}$ be finite, and set $D := \bigcup_{i\in I}\{0,1\}^i$. If $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$, then there exists a function $\mathfrak{g}\colon D \to \{0,1\}^*$ such that, letting $\mathcal{L}^{\mathfrak{g}} := \{L_F^{\mathfrak{g}}\}_{F\in\mathcal{U}}$ where each $L_F^{\mathfrak{g}} := L_{F^{D,\mathfrak{g}}}$, for every $\mathfrak{f}\colon D \to \{0,1\}^*$ in the support of $\mathcal{A}$ it holds that $\mathcal{L}^{\mathfrak{g}} \notin \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{f}}}$.*

Proof. Consider the following set of functions over D:

$$G_{D,\mathcal{A}} := \{\mathfrak{g}\colon D \to \{0,1\}^* \mid \exists A \in \mathrm{supp}(\mathcal{A}) \text{ that agrees with } \mathfrak{g} \text{ on } D\} \ .$$

First, we argue that, since $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}}$, there exists $\mathfrak{g} \in G_{D,\mathcal{A}}$ such that $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{g}}}$. Suppose by way of contradiction that $\mathcal{L} \in \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{g}}}$ for every $\mathfrak{g} \in G_{D,\mathcal{A}}$. Then every oracle $\mathcal{A}^{D,\mathfrak{g}}$ has a PCP-verifier $M_{\mathfrak{g}} \in \mathbf{M}_{T,q}$ for $\mathcal{L}$. We use the PCP-verifiers $\{M_{\mathfrak{g}}\}_{\mathfrak{g}\in G_{D,\mathcal{A}}}$ to construct a PCP-verifier M that shows that $\mathcal{L} \in \mathrm{PCP}(T,q)^{\mathcal{A}}$ (a contradiction): $M^{A,\pi}(\mathbb{x})$ first queries all locations in D to identify which $\mathfrak{g} \in G_{D,\mathcal{A}}$ is consistent with A; then it rules according to $M_{\mathfrak{g}}^{A,\pi}(\mathbb{x})$. By construction, the machine M is in $\mathbf{M}_{T,q}$ because querying all locations in D takes a constant amount of time and involves a constant number of queries. (The size of D is a finite constant.)

Next, we use $\mathcal{L} \notin \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{g}}}$ to argue that $\mathcal{L}^{\mathfrak{g}} \notin \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{f}}}$. By definition of $\mathcal{L}^{\mathfrak{g}}$, for every $F \in \mathrm{supp}(\mathcal{A}^{D,\mathfrak{g}})$ we have $L_F = L^{\mathfrak{g}}_{F^{D,\mathfrak{f}}}$. Moreover, since D is the union of binary strings of certain lengths, there is a bijection between functions $F \in \mathrm{supp}(\mathcal{A}^{D,\mathfrak{g}})$ and functions $F^{D,\mathfrak{f}} \in \mathrm{supp}(\mathcal{A}^{D,\mathfrak{f}})$, and $\mu_{\mathcal{A}^{D,\mathfrak{g}}}(F) = \mu_{\mathcal{A}^{D,\mathfrak{f}}}(F^{D,\mathfrak{f}})$. This means that if the oracle $\mathcal{A}^{D,\mathfrak{f}}$ has a PCP-verifier $M_{\mathfrak{f}} \in \mathbf{M}_{T,q}$ for $\mathcal{L}^{\mathfrak{g}}$, then we can construct a machine $M_{\mathfrak{g}}$ that, relative to the oracle $\mathcal{A}^{D,\mathfrak{g}}$, is a PCP-verifier for $\mathcal{L}$: $M_{\mathfrak{g}}^{A,\pi}(\mathbb{x})$ runs $M_{\mathfrak{f}}(\mathbb{x})$ except that $M_{\mathfrak{g}}$ answers any query $y \in D$ from $M_{\mathfrak{f}}$ with $\mathfrak{f}(y)$ instead of $A(y)$. One can verify that $M_{\mathfrak{g}} \in \mathbf{M}_{T,q}$, which means that $\mathcal{L} \in \mathrm{PCP}(T,q)^{\mathcal{A}^{D,\mathfrak{g}}}$, a contradiction. ◀

4 Separations for random functions

We define the notion of a random oracle and then state our separation results for it.

▶ **Definition 30.** *A* **random oracle** *with output length $\ell\colon \mathbb{N} \to \mathbb{N}$ is the oracle $\mathcal{R} = \{\mathcal{R}_n\}_{n\in\mathbb{N}}$ where each $\mathcal{R}_n$ is the uniform distribution over functions $f\colon \{0,1\}^n \to \{0,1\}^{\ell(n)}$.*

The probability measure of $\mathcal{R}$ is uniform, in the sense that, for any choice of distinct binary strings $x_1,\ldots,x_m$ of lengths $n_1,\ldots,n_m$ and choice of binary strings $b_1,\ldots,b_m$ of lengths $\ell(n_1),\ldots,\ell(n_m)$, the set $S := \{A \mid A(x_1) = b_1,\ldots,A(x_m) = b_m\}$ has measure $\mu_{\mathcal{R}}(S) = 1/(\Pi_{i=1}^m 2^{\ell(n_i)})$.

▶ **Theorem 31.** *Let $\mathcal{R}$ be the random oracle with output length $\ell\colon \mathbb{N} \to \mathbb{N}$.*

1. *For any function $t\colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n)$,*

$$\mathrm{NTIME}(t)^{\mathcal{R}} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{R}} \ .$$

2. *For any function $t\colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n) \bigcap o(2^n)$,*

$$\mathrm{DTIME}(t)^{\mathcal{R}} \not\subseteq \mathrm{PCP}(o(t), o(t))^{\mathcal{R}} \ .$$

▶ Remark 32. In Section 7 we prove a stronger (almost-everywhere) separation result. We provide a standalone proof of Theorem 31 because the techniques used to prove it can be modified to apply to other oracles. We do not know how to prove stronger separations for other oracles.

4.1 Proof of Part 1 of Theorem 31

We exhibit an oracle language $\mathcal{L}$ that is in $\mathrm{NTIME}(t)^{\mathcal{R}}$ but not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{R}}$.

Oracle language. Let $e_{k,i}$ denote the $\lceil \log k \rceil$-bit string that represents the index $i \in [k]$. The oracle language $\mathcal{L} = \{L_R\}_{R \in \mathcal{R}}$ is defined as follows:

$$L_R := \left\{ 0^n \;\middle|\; \exists\, w \in \{0,1\}^{t(n)} \text{ s.t. } \begin{array}{c} R(w \| e_{t(n),1})_1 = 0 \\ R(w \| e_{t(n),2})_1 = 0 \\ \vdots \\ R(w \| e_{t(n),t(n)})_1 = 0 \end{array} \right\} .$$

Note that L_R does not contain any string that is not all-zeros. Strings of the form 0^n may or may not be in L_R, depending on the answers from R.

In NTIME. We argue that $\mathcal{L}$ is in $\mathrm{NTIME}(t)^{\mathcal{R}}$. Consider the nondeterministic machine that, for inputs of the form 0^n, expects as nondeterministic witness a string $w \in \{0,1\}^{t(n)}$ and checks, via $t(n)$ calls to R, if R returns a string whose first bit is zero on input $w \| e_{t(n),i}$ for every $i \in \{1, \ldots, t(n)\}$. The machine rejects any input not of the form 0^n. This machine, for any given R, decides the language L_R on every input. The machine's running time is $O(t(n))$: writing the first query costs $O(t(n))$ steps and updating the query tape with each new subsequent query costs $O(1)$ steps.

Not in PCP. We argue that $\mathcal{L}$ is not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{R}}$. Suppose by way of contradiction that $\mathcal{L}$ has a PCP-verifier $M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}$, and denote by $T(n)$ the running time of M on input of size n. For every $n \in \mathbb{N}$, define the domain $S_n := \bigcup_{1 \le i \le T(n)} \{0,1\}^i$ and the following set X_n of functions over S_n:

$$X_n = \left\{ f \colon S_n \to \{0,1\}^* \;\middle|\; \begin{array}{l} \exists\, ! \, w \in \{0,1\}^{t(n)} \text{ such that both conditions below hold} \\ \bullet\ \forall i \in [t], f(x \| e_{t,i}) = 01^{\ell(t + \lceil \log t \rceil) - 1} \\ \bullet\ \forall y \notin \{w \| e_{t,j}\}_{j \in [t]}, f(y) = 1^{\ell(|y|)} \end{array} \right\} .$$

Note that, for every $n \in \mathbb{N}$, every function $f \in X_n$ has measure $\mu_{\mathcal{R}}(\{f\}) > 0$.

We also use $\mathbf{1}$ to denote the all-one function that on an input $z \in \{0,1\}^*$ returns $1^{\ell(|z|)}$. We derive a contradiction from the following two (contradicting) statements.

- Lemma 33: For every $n \in \mathbb{N}$ and function R agreeing with some $f \in X_n$ there exists a proof π such that $M^{\mathbf{1},\pi}(0^n)$ queries $\mathbf{1}$ at some "witness location" $w \| e_{t(n),i}$ of R with probability at least $\frac{1}{3}$.
- Lemma 34: For every $n \in \mathbb{N}$ there exists a function R agreeing with some $f \in X_n$ such that for any proof π it holds that $M^{\mathbf{1},\pi}(0^n)$ queries $\mathbf{1}$ at some "witness location" $w \| e_{t(n),i}$ of R with probability only $o(1)$.

We are left to prove the lemmas. We abbreviate $t(n)$ with t as the choice of n is clear from context.

▶ **Lemma 33.** *If $M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}$ is a PCP-verifier for $\mathcal{L}$, then for every $n \in \mathbb{N}$ and function R agreeing with some $f \in X_n$ there exists a proof π s.t.*

$$\Pr_r\left[M^{\mathbf{1},\pi}(0^n;r) \text{ queries } \mathbf{1} \text{ at some } w\|e_{t,i} \text{ s.t. } R(w\|e_{t,i})_1 = 0\right] > \frac{1}{3} \ .$$

Proof. By definition of X_n, $0^n \in L_R$ for any R agreeing with some $f \in X_n$. Therefore, for every such R, there exists a proof π such that $M^{R,\pi}(0^n)$ accepts with probability at least $\frac{2}{3}$. We also note that since $M^{R,\pi}(0^n)$ has running time $T(n)$, it cannot make oracle queries outside the set S_n.

We now argue that for every R agreeing with some $f \in X_n$ there exists a proof π such that

$$\Pr_r\left[M^{R,\pi}(0^n;r) \text{ queries } R \text{ at some } w\|e_{t,i} \text{ s.t. } R(w\|e_{t,i}) = 0\right] > \frac{1}{3} \ . \tag{1}$$

Suppose Equation (1) does not hold. Then more than $\frac{2}{3}$ of the time $M^{R,\pi}(0^n;r)$ does not query the witness bits. If we change R slightly by flipping the first bit of $R(w\|e_{t,i})$ from 0 to 1, and denote the new oracle by R_i, then $0^n \notin L_{R_i}$. However, the machine $M^{R_i,\pi}(0^n;r)$ cannot detect the change in more than $\frac{2}{3}$ of the time. So $M^{R_i,\pi}(0^n;r)$ accepts with probability at least $\frac{1}{3}$. Moreover, $M^{R'_i,\pi}(0^n;r)$ makes the same mistake for any function R'_i that agrees with R_i on S_n. This conclusion contradicts the fact that M verifies $L_{R'_i}$ on 0^n for all such functions R'_i. So Equation (1) holds.

Furthermore, if $w\|e_{t,i}$ is the first query made by $M^{R,\pi}(0^n;r)$ such that $R(w\|e_{t,i}) = 01^{\ell(t+\lceil \log t \rceil)-1}$, then $M^{\mathbf{1},\pi}(0^n;r)$ would also make the query $w\|e_{t,i}$. This is because M has the same view in the two cases at the time it makes the query $w\|e_{t,i}$. The lemma follows. ◀

▶ **Lemma 34.** *If $M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}$ is a PCP-verifier for $\mathcal{L}$, then for every $n \in \mathbb{N}$ there exists R agreeing with some $f \in X_n$ such that for every proof $\pi \in \{0,1\}^*$,*

$$\Pr_r\left[M^{\mathbf{1},\pi}(0^n;r) \text{ queries } \mathbf{1} \text{ at some } w\|e_{t,i} \text{ s.t. } R(w\|e_{t,i})_1 = 0\right] \in o(1) \ .$$

Proof. For the sake of contradiction, suppose there exists some $n \in \mathbb{N}$ such that for every R agreeing with some $f \in X_n$ there exists a proof π for which the above probability is $\Omega(1)$. Then, by averaging, there exists some randomness r^* such that, for a $\Omega(1)$-fraction of the functions R agreeing with some $f \in X_n$, there exists a proof π such that $M^{\mathbf{1},\pi}(0^n;r^*)$ queries some $w\|e_{t,i}$ s.t. $R(w\|e_{t,i})_1 = 0$. So across all possible proofs, $M^{\mathbf{1},\cdot}(0^n;r^*)$ need to make at least $\Omega(|X_n|) = \Omega(2^t)$ distinct queries.

However, since the randomness is fixed and M is in $\mathbf{M}_{\mathrm{poly}(t),o(t)}$, $M^{\mathbf{1},\cdot}(0^n;r^*)$ can only make at most $2^{o(t)} \cdot \mathrm{poly}(t)$ distinct queries, which leads to a contradiction because $\Omega(2^t) \gg 2^{o(t)} \cdot \mathrm{poly}(t)$. ◀

4.2 Proof of Part 2 of Theorem 31

We exhibit an oracle language $\mathcal{L}$ that is in $\mathrm{DTIME}(t)^{\mathcal{R}}$ but not in $\mathrm{PCP}(o(t),o(t))^{\mathcal{R}}$.

Oracle language. Let $u_{n,i}$ denote the n-bit string whose i-th bit is 1 and all other bits are zero. The oracle language $\mathcal{L} = \{L_R\}_{R\in\mathcal{R}}$ is defined as follows:

$$L_R := \left\{(x,y) \in \{0,1\}^n \times \{0,1\}^n \;\middle|\; F_R^{\frac{t(n)}{n}}(x) = y\right\} \ ,$$

where $F_R(x) := R(x \oplus u_{n,1})_1 \| R(x \oplus u_{n,2})_1 \| \ldots \| R(x \oplus u_{n,n})_1$.

In DTIME. We argue that $\mathcal{L}$ is in $\mathrm{DTIME}(t)^{\mathcal{R}}$. Consider the deterministic machine that on input (x, y): (a) copies $x_0 := x$ to the query tape; (b) for $j \in \{1, \ldots, t(n)/n\}$, calls R on inputs $\{x_{j-1} \oplus u_{n,i}\}_{i \in [n]}$ to get $x_j := F_R(x_{j-1})$, and copies x_j to the query tape; (c) accepts if $y = x_{t(n)/n}$. Each of the $t(n)/n$ iterations takes time $O(n)$, so the running time of the machine is $O(t(n))$.

Not in PCP. We argue that $\mathcal{L}$ is not in $\mathrm{PCP}(o(t), o(t))^{\mathcal{R}}$. We begin with a combinatorial claim and some notation.

- Recall that the entropy function $H\colon [0,1] \to [0,1]$ is $H(z) := -z\log_2(z) - (1-z)\log_2(1-z)$. For every $\epsilon \in \left(0, \frac{1}{2}\right)$ and $n \in \mathbb{N}$, there exist a list $C_{\epsilon,n} = \{a_0, a_1, \ldots, a_k\}$ of $\Omega\left(\sqrt{n}2^{(1-H(\epsilon))n}\right)$ distinct n-bit binary strings such that the relative hamming distance between any two distinct strings in $C_{\epsilon,n}$ is at least ϵn. These binary strings are the codewords obtained by the greedy approach of constructing a code in $\{0,1\}^n$ with minimum distance ϵn.
- Choose $\epsilon^* \in \left(0, \frac{1}{2}\right)$ such that for all large enough $n \in \mathbb{N}$ it holds that $|C_{\epsilon^*,n}| > \frac{t(n)}{n}$. Define the domain $S_n := \cup_{1 \le i \le t(n)}\{0,1\}^i$ and a set of functions X_n on S_n:

$$X_n := \{g\colon S_n \to \{0,1\}^* \mid \forall\, a_i \in C_{\epsilon^*,n}, a_{i+1} = g(a_i \oplus u_{n,1})_1 \| \cdots \| g(a_i \oplus u_{n,n})_1\} \quad .$$

  Therefore for every $g \in X_n$ and $a_i \in C_{\epsilon^*,n}$ it holds that $F_g(a_i) = a_{i+1}$, and $F_g^{\frac{t(n)}{n}}(a_0) = a_{t(n)/n}$.
- For every $i \in [k]$ and $g \in X_n$, define the function $g^{(i)}\colon S_n \to \{0,1\}^*$ to be

$$g^{(i)}(z) := \begin{cases} (a_0)_j \| 0^{\ell(|z|)-1} & \text{if } z = a_i \oplus u_{n,j} \text{ for some } j \in [n] \\ g(z) & \text{if } z \neq a_i \oplus u_{n,j} \text{ for every } j \in [n] \end{cases} \quad .$$

  Therefore for every $i' \neq i$ and $a_{i'} \in C_{\epsilon^*,n}$, $F_{g^{(i)}}(a_{i'}) = a_{i'+1}$, and $F_{g^{(i)}}(a_i) = a_0$.

We argue that any PCP-verifier M for $\mathcal{L}$ must have running time $\Omega(t(n))$.

- Since M is a PCP-verifier for $\mathcal{L}$, for every $n \in \mathbb{N}$ and every $g \in X_n$ there exists a proof π such that $M^{g,\pi}(a_0, a_{t(n)/n})$ accepts with probability at least $\frac{2}{3}$. Then, via Lemma 35 below, we deduce that for every n large enough there exists a randomness r such that $M^{g,\pi}(a_0, a_{t(n)/n}; r)$ makes at least $\frac{t(n)}{3n}$ queries of the form $F_g^i(a_0)$ for some $i \in [\frac{t(n)}{n}]$.
- Since the relative hamming distance between each pair of queries $F_g^i(a_0)$ and $F_g^j(a_0)$ is at least ϵn, the running time of $M^{g,\pi}(a_0, a_{t(n)/n}; r)$ is at least $\frac{t(n)}{3n} \cdot \epsilon n \in \Omega(t(n))$.

We have shown that any PCP-verifier for $\mathcal{L}$ has running time in $\Omega(t(n))$, and so $\mathcal{L} \notin \mathrm{PCP}(o(t), o(t))^{\mathcal{R}}$.

▶ **Lemma 35.** *If M is a PCP-verifier for $\mathcal{L}$ then, for every large enough $n \in \mathbb{N}$ and every $g \in X_{\epsilon^*,n}$, there exists a proof π and randomness r such that $M^{g,\pi}(a_0, a_{t(n)/n}; r)$ makes at least $\frac{t(n)}{3n}$ queries of the form $F_g^i(a_0)$ for some $i \in [\frac{t(n)}{n}]$.*

Proof. Since M is a PCP-verifier for $\mathcal{L}$, for large enough n, $(a_0, a_{t(n)/n}) \in L_R$ for every R that agrees with some $g \in X_n$. So for every $g \in X_n$ there exists a proof π such that $M^{g,\pi}(a_0, a_{t(n)/n})$ accepts with probability at least $\frac{2}{3}$. If we change one assignment of g to obtain $g^{(i)}$, then $F_{g^{(i)}}^{t(n)/n}(a_0) \neq a_{t(n)/n}$. So $M^{g^{(i)},\pi}(a_0, a_{t(n)/n})$ should accept with probability at most $\frac{1}{3}$. This implies that for at least $\frac{1}{3}$ fraction of randomness r, $M^{g,\pi}(a_0, a_{t(n)/n}; r)$ queries a_i. By averaging, there exists r^* such that $M^{g,\pi}(a_0, a_{t(n)/n}; r^*)$ makes $\frac{t(n)}{3n}$ distinct queries of the form $F_g^i(a_0)$. ◀

5 Separation for random low-degree functions

We define the notion of a random *low-degree* oracle and then state our separation result for it.

▶ **Definition 36.** *Let q be a prime power, $\mathbb{F}_q$ the finite field of size q, and $d \in \mathbb{N}$ a degree bound. The* **random oracle over $\mathbb{F}_q$ with degree d** *is the oracle $\mathcal{P}[q,d] = \{\mathcal{P}_n\}_{n\in\mathbb{N}}$ where each $\mathcal{P}_n$ is the uniform distribution over polynomials $f\colon \mathbb{F}_q^n \to \mathbb{F}_q$ of degree at most d in each variable. (In particular, $\mathcal{P}[2,1]$ equals the random oracle $\mathcal{R}$ from Definition 30.)*

▶ **Theorem 37.** *For any function $t\colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n)$, prime power $q \in \mathbb{N}$, and degree bound $d \in \mathbb{N}$*

$$\mathrm{NTIME}(t)^{\mathcal{P}[q,d]} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{P}[q,d]} \ .$$

Proof. We first focus on the special case of $d = 1$, i.e., the case of random multilinear polynomials. We show in Lemma 38 that $\mathcal{P}[q,1]$ separates NTIME and PCP. Next, we simply observe that for any field $\mathbb{F}_q$ and degree d, the low degree random oracle $\mathcal{P}[q,d]$ contains the multilinear random oracle $\mathcal{P}[q,1]$. Therefore, by Lemma 28, $\mathcal{P}[q,d]$ also separates NTIME and PCP. ◀

Now we prove the separation for the special case of $d = 1$.

▶ **Lemma 38.** *For any function $t\colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n)$, and any prime power $q \in \mathbb{N}$,*

$$\mathrm{NTIME}(t)^{\mathcal{P}[q,1]} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{P}[q,1]} \ .$$

Proof. We exhibit $\mathcal{L}$ that is in $\mathrm{NTIME}(t)^{\mathcal{P}[q,1]}$ but not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{P}[q,1]}$.

Let $e_{k,i}$ denote the vector in $\mathbb{F}_q^k$ that has 1 in the i-th coordinate and 0 everywhere else. Let $\mathcal{L} = \{L_P\}_{P\in\mathcal{P}[q,1]}$ be the oracle language where

$$L_P := \left\{ 0^n \;\middle|\; \exists\, x \in \mathbb{F}_q^{t(n)} \text{ s.t. } P(x) = 1 \text{ and } \begin{array}{c} P(x + e_{t(n),1}) = 0 \\ P(x + e_{t(n),2}) = 0 \\ \vdots \\ P(x + e_{t(n),t(n)}) = 0 \end{array} \right\} .$$

It's clear that L_P is in $\mathrm{NTIME}(t)^P$ for every $P \in \mathcal{P}[q,1]$. Let $q\colon \mathbb{N} \to \mathbb{N}$ be some superpolynomial function. For every $n \in \mathbb{N}$, we define the following set of functions over the domain $S_n = \{\mathbb{F}_q^i \mid i \le q(t(n))\}$.

$$X_n = \left\{ f\colon S_n \to \mathbb{F}_q \;\middle|\; \begin{array}{l} \forall x \in \mathbb{F}_q^{t(n)},\ f(x) = \prod_{i=1}^{t(n)} (b_i - x_i) \text{ where } b \in \mathbb{F}_q^{t(n)} \\ \forall x \in S_n \setminus \mathbb{F}_q^{t(n)},\ f(x) = 0 \end{array} \right\} .$$

Note for every $n \in \mathbb{N}$, every function $f \in X_n$ has its measure $\mu_{\mathcal{P}[q,1]}(\{f\}) > 0$.

We also use $\mathbf{0}$ to denote the all zero function.

Suppose by way of contradiction that $\mathcal{L}$ has a PCP-verifier $M \in \mathbf{M}_t$. Use $T(n)$ to denote the running time of M on input of size n. Note that $T(n) \in \mathrm{poly}(t(n))$, so there exists a number $n^* \in \mathbb{N}$ such that $\forall n \ge n^*, q(t(n)) \ge T(n)$. We derive a contradiction from the following two steps. First in Claim 39, we show that for every $n \ge n^*$ and oracle polynomial P agreeing with some $f \in X_n$ there exists some proof π such that the PCP-verifier $M^{\mathbf{0},\pi}$, which has oracle access to $\mathbf{0}$ and π, queries $\mathbf{0}$ at some x satisfying $P(x) \neq 0$ with probability at least $\frac{1}{3}$. Next, in Claim 40, we show that for every $n \ge n^*$ there exists some oracle polynomial

P agreeing with some $f \in X_n$ such that for any proof $\pi \in \{0,1\}^*$, the PCP-verifier $M^{\mathbf{0},\pi}$, which has oracle access to $\mathbf{0}$ and π, queries P at some x satisfying $P(x) \neq 0$ with probability only $o(1)$. These two statements are in contradiction. Thus $\mathcal{L}$ does not have a PCP-verifier. Therefore $\mathcal{P}[q,1]$ separates NTIME and PCP. ◀

In the proofs of the two lemmas we abbreviate $t(n)$ with t whenever the choice of n is clear from the context.

▷ Claim 39. If $M \in \mathbf{M}_t$ is the PCP-verifier for $\mathcal{L}$, then for every $n \geq n^*$ and oracle polynomial P agreeing with some $f \in X_n$, there exists π s.t.

$$\Pr_r[M^{\mathbf{0},\pi}(0^n;r) \text{ queries } \mathbf{0} \text{ at some } y \in \mathbb{F}_q^{t(n)} \text{ s.t. } P(y) \neq 0] > \frac{1}{3} \ .$$

Proof. We first observe that for every function $f(x) = \prod_{i=1}^{t(n)}(b_i - x_i)$ in X_n, the element $y = (b_1 - 1) \| \ldots \| (b_{t(n)} - 1) \in \mathbb{F}_q^{t(n)}$ satisfies $f(y) = 1$ and $f(y + e_{t(n),i}) = 0$ for every $i \in [t(n)]$. Therefore for every P agreeing with f over $\mathbb{F}_q^{t(n)}$, $0^n \in L_P$. As a result, for every such P, there exists some proof $\pi \in \{0,1\}^*$ such that $M^{P,\pi}(0^n)$ accepts with probability at least $\frac{2}{3}$. We also note that since $M^{P,\pi}(0^n)$ has running time $T(n) \leq q(t(n))$, M cannot make oracle queries outside the set S_n.

For every P agreeing with some $f \in X_n$, use π_P to denote the accepting proof for P. We additionally note that for every oracle P' agreeing with $\mathbf{0}$ over S_n, it holds that $0^n \notin L_{P'}$. So for any π_P, $M^{P',\pi_P}(0^n)$ accepts with probability at most $\frac{1}{3}$.

This implies that

$$\Pr_r[M^{P,\pi_P}(0^n;r) \text{ queries } P \text{ at } x \text{ s.t. } P(x) \neq \mathbf{0}(x) = 0] \geq \frac{1}{3} \ . \tag{2}$$

Let y be the first oracle query made by $M^{P,\pi_P}(0^n;r)$ such that $P(y) \neq \mathbf{0}(y) = 0$. If we replace P with $\mathbf{0}$, $M^{\mathbf{0},\pi_P}(0^n;r)$ would still make the oracle query y. We deduce that

$$\Pr_r[M^{\mathbf{0},\pi_P}(0^n;r) \text{ queries } P_0 \text{ at } x \text{ s.t. } P(x) \neq \mathbf{0}(x) = 0] \geq \frac{1}{3} \ . \quad \triangleleft$$

▷ Claim 40. If $M \in \mathbf{M}_t$ is the PCP-verifier for $\mathcal{L}$, there exists P agreeing with some $f \in X_n$ s.t. for all $\pi \in \{0,1\}^*$,

$$\Pr_r[M^{\mathbf{0},\pi}(0^n;r) \text{ queries } \mathbf{0} \text{ at } x \text{ s.t. } P(x) \neq 0] \in o(1) \ .$$

Proof. Suppose for every P agreeing with some $f \in X_n$ there exists a proof π that the aforementioned probability is $\Omega(1)$. Then, by an averaging argument, there exists some randomness r^* such that for $\Omega(1)$ fraction of oracles P agreeing with some $f \in X_n$, there exists π s.t. $M^{\mathbf{0},\pi}(0^n;r^*)$ queries some x s.t. $P(x) \neq 0$. Additionally, for any $x \in \mathbb{F}_q^{t(n)}$, there are exactly $(q-1)^{t(n)}$ multilinear functions $f \in X_n$ such that $f(x) \neq 0$. So across all possible proofs, $M^{\mathbf{0},\cdot}(0^n;r^*)$ need to make at least $\Omega(|X_n| / (q-1)^t \text{poly}(t)) = \Omega((q/(q-1))^t) \in \Omega(\exp(t))$ distinct queries.

However, since the randomness is fixed and M is in $\mathbf{M}_t$, $M^{\mathbf{0},\cdot}(0^n;r^*)$ can make at most $2^{o((t)} \cdot \text{poly}(t)$ distinct queries. However, $\Omega(\exp(t)) \gg 2^{o(t)} \cdot \text{poly}(t)$, so we derive a contradiction. $\triangleleft$

6 Separation for random generic groups

We present the definition of the generic group model (GGM) [38, 42, 21, 35, 36].

▶ **Definition 41** (groups and their representations). *An abelian group of order p is a pair $\mathbb{G} = (S, +)$ where S is a set of size p and $+ \colon S \times S \to S$ is a function that satisfies the axioms of a group operation. We denote by $\mathbf{0}$ the identity of $\mathbb{G}$. A representation of $\mathbb{G}$ is an injective function $\sigma \colon S \to \{0,1\}^{\lceil \log_2 p \rceil}$, and its inverse $\sigma^{-1} \colon \{0,1\}^{\lceil \log_2 p \rceil} \to S$ maps each image $\sigma(g) \in \{0,1\}^{\lceil \log_2 p \rceil}$ to its pre-image $g \in S$ and each string $s \in \{0,1\}^{\lceil \log_2 p \rceil} \setminus \sigma(S)$ to the identity $\mathbf{0} \in S$.*

▶ **Definition 42** (group oracles). *Let $\mathbb{G}$ be a group of order p, and σ a representation of $\mathbb{G}$. The group oracle corresponding to $(\mathbb{G}, \sigma)$ is the function $O \colon \{0,1\}^{4\lceil \log_2 p \rceil} \to \{0,1\}^{\lceil \log_2 p \rceil}$ such that $O(c_a, c_b, a, b) = \sigma(c_a \times \sigma^{-1}(a) + c_b \times \sigma^{-1}(b))$. To obtain the identity element of the group simply query $O(0^{\lceil \log_2 p \rceil}, 0^{\lceil \log_2 p \rceil}, a, b) = \sigma(\mathbf{0})$.*

▶ **Definition 43.** *The* **random group oracle** *is the oracle $\mathcal{O} = \{\mathcal{O}_p\}_{p \in \mathbb{N}}$ where each $\mathcal{O}_p$ is the uniform distribution over all group oracles for groups of size p. Namely, a sample from $\mathcal{O}_p$ is obtained as follows: sample a random group $\mathbb{G}$ of order p, sample a random representation σ of $\mathbb{G}$, and output the group oracle $O \colon \{0,1\}^{4\lceil \log_2 p \rceil} \to \{0,1\}^{\lceil \log_2 p \rceil}$ corresponding to $(\mathbb{G}, \sigma)$.*

▶ **Theorem 44.** *In the generic group model, $t \colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n)$,*

$$\mathrm{NTIME}(t)^{\mathcal{O}} \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{O}} \ .$$

Proof. We exhibit an oracle language $\mathcal{L}$ that is in $\mathrm{NTIME}(t)^{\mathcal{O}}$ but not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{O}}$.

Oracle language.

Define $p(n)$ to be the largest prime number no larger than $2^{t(n)}$, so we know that $p(n) \in (2^{t(n)-1}, 2^{t(n)}]$. Let $\mathcal{L} = \{L_O\}_{O \in \mathcal{O}}$ be the oracle language where

$$L_O := \left\{ 0^n \;\middle|\; \exists\, x \in \{0,1\}^{t(n)}, x < p(n) - 1, \text{ s.t. } \sigma^{-1}(x) + \sigma^{-1}(x^{\oplus t(n)}) = \mathbf{0} \right\} \ ,$$

where $x^{\oplus t(n)}$ is the string identical to x everywhere except for the $t(n)$-th bit.

In NTIME. We note that numbers in $[p(n)]$ can be represented by binary strings of length $\Theta(t(n))$. So it's clear that L_O is in $\mathrm{NTIME}(t)^O$ for every $O \in \mathcal{O}$.

Not in PCP. We argue that $\mathcal{L}$ is not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{O}}$. Consider an oracle O s.t. $0^n \notin L_O$. We show that for any PCP-verifier $M \in \mathbf{M}_t$, if M^O is correct on 0^n then we can construct another oracle O' for which $M^{O'}$ is not correct on 0^n (Lemma 45). Therefore there exists some O^* for which M^{O^*} is not correct on 0^n. Additionally, the language $\mathcal{L}$ is by definition $4t$-bounded and the running time of M is bounded by $2^{t(n)}$. Since M^{O^*} fails on 0^n, for every function F that agrees with O^* on $\bigcup_{1 \le i \le 2^{t(n)}} \{0,1\}^i$, M^F also fails on 0^n. So by Claim 26, we conclude that $\mathcal{L} \notin \mathrm{PCP}(\mathrm{poly}(t), o(t))^{\mathcal{O}}$. ◀

▶ **Lemma 45.** *For any PCP-verifier $M \in \mathbf{M}_t$ and any oracle $O \in \mathcal{O}$ such that $0^n \notin L_O$, if M^O is correct on 0^n then there exists O' for which $M^{O'}$ is not correct on 0^n.*

Proof. Use σ to denote O's representation of the order $p(n)$ group. Define the set of pairs of strings

$$I(O) := \{(u, v) \in (\{0,1\}^{t(n)})^2 \ \mid \ u, v < p(n) - 1,\ \sigma^{-1}(u) + \sigma^{-1}(v^{\oplus t(n)}) = \mathbf{0}\} \ .$$

Note that if we use $O^{(u,v)}$ to denote the oracle identical to O except for its permutation function for the group of order $p(n)$, which is defined as

$$\sigma^{(u,v)}(g) := \begin{cases} u & \text{if } \sigma(g) = v \\ v & \text{if } \sigma(g) = u \\ \sigma(g) & \text{otherwise} \end{cases} .$$

Note that for any $(u,v) \in I(O)$, we have $(\sigma^{(u,v)})^{-1}(v) + (\sigma^{(u,v)})^{-1}(v^{\oplus t(n)}) = \mathbf{0}$. So $0^n \in L_{O^{(u,v)}}$.

Consider the pairs of strings $(u,v) \in I(O)$ for which M^O queries all of (u,v) with "low" probability:

$$X_\star(O) := \left\{ (u,v) \in I(O) \;\middle|\; \text{for } i = u,v, \sum_{\pi \in \{0,1\}^*} \Pr_r \left[\begin{array}{l} M^{O,\pi}(0^n;r) \text{ queries } O \text{ at } i \\ \text{or gets back } i \text{ from } O \end{array} \right] < \frac{1}{6} \right\} .$$

We argue that $|X_\star(O)| > 0$, and for every $(u,v) \in X_\star(O)$ it holds that $M^{O^{(u,v)}}$ is *not* correct on 0^n.

Consider the set of strings $u \in \{0,1\}^{\lceil \log_2 p(n) \rceil}$, $u < p(n) - 1$ that M^O queries with "high" probability:

$$X_c(O) := \left\{ u \in \{0,1\}^{t(n)} \;\middle|\; u < p(n) - 1 \,, \sum_{\pi \in \{0,1\}^*} \Pr_r \left[\begin{array}{l} M^{O,\pi}(0^n;r) \text{ queries } O \text{ at } u \\ \text{or gets back } u \text{ from } O \end{array} \right] \geq \frac{1}{6} \right\} .$$

Observe that

$$|X_c(O)| \leq \Big(c \cdot t(n)\Big) \cdot \Big(2^{o(t(n))} \cdot \mathrm{poly}(t(n))\Big) = 2^{o(t(n))} \;. \tag{3}$$

This is because, in any given execution, M can make at most $\mathrm{poly}(t(n))$ queries to O (also can get at most $\mathrm{poly}(t(n))$ symbols from O) and $o(t(n))$ queries to the given proof string, which means that

$$\sum_{u \in \{0,1\}^{t(n)},\, u < p(n)-1} \; \sum_{\pi \in \{0,1\}^*} \Pr_r \left[\begin{array}{l} M^{O,\pi}(0^n;r) \text{ queries } O \text{ at } u \\ \text{or gets back } u \text{ from } O \end{array} \right] \leq 2^{o(t(n))} \mathrm{poly}(t(n)) \;.$$

We deduce that $|X_\star(O)|$ is large:

$$|X_\star(O)| \geq (p(n) - 3) - 2 \cdot 2|X_c(O)| = 2^{t(n)} - 2^{o(t(n))} \;.$$

Next, for every $(u,v) \in X_\star(O)$ it holds that

$$\forall\, \pi \in \{0,1\}^*, \text{ for } i = u,v, \Pr_r \left[\begin{array}{l} M^{O,\pi}(0^n;r) \text{ queries } O \text{ at } i \\ \text{or gets back } i \text{ from } O \end{array} \right] < \frac{1}{6} \;.$$

Therefore,

$$\begin{aligned} \forall\, \pi \in \{0,1\}^*, \quad & \Pr_r[M^{O,\pi}(0^n;r) \text{ queries } O \text{ at } u \text{ or } v] \\ & \leq \sum_{i=u,v} \Pr_r \left[\begin{array}{l} M^{O,\pi}(0^n;r) \text{ queries } O \text{ at } i \\ \text{or gets back } i \text{ from } O \end{array} \right] \\ & < 2 \cdot \frac{1}{6} = \frac{1}{3} \;. \end{aligned}$$

This means that for every $(u,v) \in X_\star(O)$ it holds that M cannot distinguish between O and $O^{u,v}$ with probability greater than or equal to $\frac{1}{3}$.

We know that M^O is correct on 0^n, namely, for every proof string π it holds that $M^{O,\pi}(0^n)$ accepts with probability no more than $1/3$. We also know that for every $(u,v) \in I(O)$ it holds that 0^n is in $L_{O^{(u,v)}}$. But the foregoing argument tells us that for every $(u,v) \in X_\star(O)$ it holds that for every proof string π we have that $M^{O^{(u,v)},\pi}(0^n)$ accepts with probability less than $1/3 + 1/3 = 2/3$. We deduce that, for every $(u,v) \in X_\star(O)$, $M^{O^{(u,v)}}$ is *not* correct on 0^n. ◀

7 Almost-everywhere separation for random functions

We strengthen the separation for random functions in Theorem 31. The difference is that now the choice of machine M, which is the candidate PCP-verifier for L_R, *depends* on the sample R.

▶ **Theorem 46.** *Let $\mathcal{R}$ be a random oracle with output length $\ell\colon \mathbb{N} \to \mathbb{N}$.*

1. *For any function $t\colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n)$,*

$$\Pr_{R \leftarrow \mathcal{R}}\left[\mathrm{NTIME}(t)^R \not\subseteq \mathrm{PCP}(\mathrm{poly}(t), o(t))^R\right] = 1 \ .$$

2. *For any function $t\colon \mathbb{N} \to \mathbb{N}$ with $t(n) \in \Omega(n) \bigcap o(2^n)$,*

$$\Pr_{R \leftarrow \mathcal{R}}\left[\mathrm{DTIME}(t)^R \not\subseteq \mathrm{PCP}(o(t), o(t))^R\right] = 1 \ .$$

7.1 Proof of Part 1 of Theorem 46

We prove the statement by arguing that, for every oracle R in a certain set of measure 1 (derived below), there exists a language L_R that is in $\mathrm{NTIME}(t)^R$ but not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^R$.

We first define the language $L_R \subseteq \{0,1\}^*$ for any $R \in \mathcal{R}$. The language is defined as follows:

$$L_R = \left\{ 0^n \;\middle|\; \exists\, w \in \{0,1\}^{t(n)} \text{ s.t. } \begin{array}{l} R(w \| e_{t(n),1})_1 = 0 \\ R(w \| e_{t(n),2})_1 = 0 \\ \quad \vdots \\ R(w \| e_{t(n),t(n)})_1 = 0 \end{array} \right\} \ .$$

The language L_R is in $\mathrm{NTIME}(t)^R$ for every $R \in \mathcal{R}$ (via the same argument as in Section 4.1). We are left to argue that L_R is not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^R$ for R in a certain set of measure 1. For this, we state a lemma (which we prove later on below), and then conclude the proof of the theorem.

▶ **Lemma 47.** *For every $M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}$, $\Pr_{R \leftarrow \mathcal{R}}\left[M^R \text{ is a PCP-verifier for } L_R\right] = 0$.*

Let S_M be the set of oracles $R \in \mathcal{R}$ for which M^R is a PCP-verifier for L_R. Lemma 47 tells us that S_M has measure zero, that is, $\mu_{\mathcal{R}}(S_M) = 0$. Since the set $\mathbf{M}_{\mathrm{poly}(t),o(t)}$ is countable (it is a subset of the countable set of all machines) and measures are countably sub-additive, we deduce that

$$\mu_{\mathcal{R}}\left(\bigcup_{M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}} S_M\right) \leq \sum_{M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}} \mu_{\mathcal{R}}(S_M) = 0 \ .$$

We conclude that

$$\Pr_{R \leftarrow \mathcal{R}} \left[\exists\, M \in \mathbf{M}_{\mathrm{poly}(t),o(t)} \text{ s.t. } M^R \text{ is a PCP-verifier for } L_R \right] = 0 \ ,$$

which shows that L_R is not in $\mathrm{PCP}(\mathrm{poly}(t), o(t))^R$ for all R in a set of measure 1.

This completes the proof, and so we are only left with proving Lemma 47.

Before proving Lemma 47, we define two disjoint sets of oracles, $S_{n,0}$ and $S_{n,1}$, and then prove certain properties about them (see Lemmas 50 to 52 below).

▶ **Definition 48.** *For every $n \in \mathbb{N}$, function $R \in \mathcal{R}_n$, and string $w \in \{0,1\}^{t(n)}$, we define the function $\mathbf{F}[R,w]\colon \{0,1\}^* \to \{0,1\}^*$ to be*

$$\mathbf{F}[R,w](z)_j := \begin{cases} 0 & \text{if } j = 1 \text{ and } z = w \| e_{t(n),i} \text{ for some } i \in [t(n)] \\ R(z)_j & \text{otherwise} \end{cases} .$$

Moreover, given $S \subseteq \mathcal{R}_n$, we define $\mathbf{F}[S, \{0,1\}^{t(n)}]$ to be the set $\{\mathbf{F}[R,w] \,|\, R \in S\,,\, w \in \{0,1\}^{t(n)}\}$.

▶ **Definition 49.** *For every $n \in \mathbb{N}$, $S_{n,0}$ is the set of functions $R \in \mathcal{R}_n$ for which $0^n \notin L_R$, that is, for which for every $w \in \{0,1\}^{t(n)}$ there exists an index $i \in [t(n)]$ such that $R(w \| e_{t(n),i})_1 \neq 0$. Also, $S_{n,1}$ equals the set $\mathbf{F}[S_{n,0}, \{0,1\}^{t(n)}]$, which is disjoint from $S_{n,0}$ (since $0^n \in L_R$ for every $R \in S_{n,1}$).*

▶ **Lemma 50.** *For every subset $S \subseteq S_{n,0}$, we have $\mu_{\mathcal{R}}(S) \leq \mu_{\mathcal{R}}(\mathbf{F}[S, \{0,1\}^{t(n)}])$.*

Proof. Each $R \in S$ yields $2^{t(n)}$ distinct functions $\mathbf{F}[R,w]$ as w ranges over $\{0,1\}^{t(n)}$. On the other hand, each $R' \in \mathbf{F}[S, \{0,1\}^{t(n)}]$ has at most $2^{t(n)} - 1$ "pre-images" in S: there exists precisely one w such that $R(w \| e_{t(n),i})_1 = 0$ for all $i \in \{1, \ldots, t(n)\}$. So if $R' = \mathbf{F}[R,w]$, R and R' can only be different in the first bit at locations of the form $w \| e_{t(n),i}$ for $i \in \{1, \ldots, t(n)\}$. There are $2^{t(n)} - 1$ different assignments to the first bits at $w \| e_{t(n),i}$ each of which gives rise to a preimage of R' in S (we exclude the all-zero assignment). We deduce that $2^{t(n)} \mu_{\mathcal{R}}(S) \leq \left(2^{t(n)} - 1\right) \mu_{\mathcal{R}}(\mathbf{F}[S, \{0,1\}^{t(n)}])$, and so $\mu_{\mathcal{R}}(S) \leq \mu_{\mathcal{R}}(\mathbf{F}[S, \{0,1\}^{t(n)}])$. ◀

▶ **Lemma 51.** $\lim_{n \to \infty} \mu_{\mathcal{R}}(S_{n,0}) = 1/e$.

Proof. For any $n \in \mathbb{N}$ the measure of $S_{n,0}$ in $\mathcal{R}$ is $\mu_{\mathcal{R}}(S_{n,0}) = (1 - \frac{1}{2^{t(n)}})^{2^{t(n)}}$. Therefore:

$$\lim_{n \to \infty} \mu_{\mathcal{R}}(S_{n,0}) = \lim_{N \to \infty} \left(1 - \frac{1}{N}\right)^N = \lim_{N \to \infty} e^{N\left(1 - \frac{1}{N}\right)} = \lim_{N \to \infty} e^{\left(1 - \frac{1}{N}\right)' / \left(\frac{1}{N}\right)'} = 1/e \ . \quad \blacktriangleleft$$

▶ **Lemma 52.** *For every function $R \in S_{n,0}$, if M^R is correct on 0^n then there are at least $2^{t(n)} - 2^{o(t(n))}$ strings $w \in \{0,1\}^{t(n)}$ for which $M^{\mathbf{F}[R,w]}$ is* not *correct on 0^n. (Note that $\mathbf{F}[R,w] \in S_{n,1}$.)*

Proof. Fix a constant $c > 0$ to be determined later. Consider the set of strings $w \in \{0,1\}^{t(n)}$ for which M^R queries all of $\{w \oplus e_{t(n),1}, \ldots, w \oplus e_{t(n),t(n)}\}$ with "low" probability:

$$X_\star(R) := \left\{ w \in \{0,1\}^{t(n)} \;\middle|\; \forall\, i \in [t(n)]\,,\ \sum_{\pi \in \{0,1\}^*} \Pr_r[M^{R,\pi}(0^n; r) \text{ queries } R \text{ at } w \oplus e_{t(n),i}] < \frac{1}{c \cdot t(n)} \right\} .$$

We argue that $|X_\star(R)|$ is large, and for every $w \in X_\star(R)$ it holds that $M^{\mathbf{F}[R,w]}$ is *not* correct on 0^n.

Consider the set of strings $w \in \{0,1\}^{t(n)}$ that M^R queries with "high" probability:

$$X_c(R) := \left\{ w \in \{0,1\}^{t(n)} \;\middle|\; \sum_{\pi \in \{0,1\}^*} \Pr_r[M^{R,\pi}(0^n;r) \text{ queries } R \text{ at } w\,] \geq \frac{1}{c \cdot t(n)} \right\} .$$

Observe that

$$|X_c(R)| \leq \Big(c \cdot t(n)\Big) \cdot \Big(2^{o(t(n))} \cdot \mathrm{poly}(t(n))\Big) = 2^{o(t(n))} . \tag{4}$$

This is because, in any given execution, M can make at most $\mathrm{poly}(t(n))$ queries to R and $o(t(n))$ queries to the given proof string, which means that

$$\sum_{w \in \{0,1\}^{t(n)}} \sum_{\pi \in \{0,1\}^*} \Pr_r[M^{R,\pi}(0^n;r) \text{ queries } R \text{ at } w] \leq 2^{o(t(n))}\mathrm{poly}(t(n)) .$$

We deduce, via Equation (4), that $|X_\star(R)|$ is large:

$$|X_\star(R)| \geq 2^{t(n)} - t(n)|X_c(R)| = 2^{t(n)} - 2^{o(t(n))} .$$

Next, for every $w \in X_\star(R)$ it holds that

$$\forall\, \pi \in \{0,1\}^*,\ \forall\, i \in [t(n)],\ \Pr_r[M^{R,\pi}(0^n;r) \text{ queries } R \text{ at } w \oplus e_{t(n),i}] < \frac{1}{c \cdot t(n)} .$$

Therefore,

$$\begin{aligned} \forall\, \pi \in \{0,1\}^*, \quad & \Pr_r[M^{R,\pi}(0^n;r) \text{ queries } R \text{ at any } w \oplus e_{t(n),i}] \\ & \leq \sum_{i \in [t(n)]} \Pr_r[M^{R,\pi}(0^n;r) \text{ queries } R \text{ at } w \oplus e_{t(n),i}] \\ & < t(n) \cdot \frac{1}{c \cdot t(n)} = \frac{1}{c} . \end{aligned}$$

This means that for every $w \in X_\star(R)$ it holds that M cannot distinguish between R and $R' := \mathbf{F}[R,w]$ with probability greater than $\frac{1}{c}$ (the probability is over M's randomness r).

We know that M^R is correct on 0^n, namely, for every proof string π it holds that $M^{R,\pi}(0^n)$ accepts with probability less than $1/3$. We also know that for every $w \in \{0,1\}^{t(n)}$ it holds that 0^n is in $L_{\mathbf{F}[R,w]}$. But the foregoing argument tells us that for every $w \in X_\star(R)$ it holds that for every proof string π we have that $M^{\mathbf{F}[R,w],\pi}(0^n)$ accepts with probability less than $1/3 + 1/c$.

Choosing $c \geq 3$, we deduce that, for every $w \in X_\star(R)$, $M^{\mathbf{F}[R,w]}$ is *not* correct on 0^n. ◀

Proof of Lemma 47. Fix $M \in \mathbf{M}_{\mathrm{poly}(t),o(t)}$. It suffices to show that, for some $\epsilon \in [0,1)$ and every $n \in \mathbb{N}$, M^R is correct on input 0^n for at most an ϵ-fraction of oracles R. Indeed, this fact would imply that:

$$\begin{aligned} & \Pr_{R \leftarrow \mathcal{R}}\left[\, M^R \text{ is a PCP-verifier for } L_R \,\right] \\ & \leq \Pr_{R \leftarrow \mathcal{R}}\left[\, \forall n \in \mathbb{N},\ M^R \text{ is correct on } 0^n \,\right] \\ & = \prod_{n \in \mathbb{N}} \Pr_{R \leftarrow \mathcal{R}}\left[\, M^R \text{ is correct on } 0^n \;\middle|\; M^R \text{ is correct on } 0^i \text{ for all } i < n \,\right] \\ & = \prod_{n \in \mathbb{N}} \Pr_{R \leftarrow \mathcal{R}}\left[\, M^R \text{ is correct on } 0^n \,\right] \\ & \leq \lim_{n \to \infty} \epsilon^n = 0 , \end{aligned}$$

as claimed. Above "correct" on input 0^n means that if $0^n \in L_R$ then there exists a proof string π such that $M^{R,\pi}(0^n)$ accepts with probability at least $2/3$, and if $0^n \notin L_R$ then for every proof string π it holds that $M^{R,\pi}(0^n)$ rejects with probability at least $2/3$.

We are left to argue that M^R is correct on input 0^n for at most an ϵ-fraction of oracles R. Consider the following sets of oracles:

$$U_{n,\mathsf{all}} := \left\{ R \in \mathcal{R} \,|\, M^R \text{ is incorrect on } 0^n \right\} ,$$
$$U_{n,0} := \left\{ R \in S_{n,0} \,|\, M^R \text{ is incorrect on } 0^n \right\} ,$$
$$U_{n,1} := \left\{ R' \in S_{n,1} \,|\, M^{R'} \text{ is incorrect on } 0^n \right\} .$$

Note that $U_{n,0} \cup U_{n,1} \subseteq U_{n,\mathsf{all}}$. Also, $U_{n,0}$ and $U_{n,1}$ are disjoint, because $S_{n,0}$ and $S_{n,1}$ are disjoint.

We want to prove that $\mu_{\mathcal{R}}(U_{n,\mathsf{all}}) > 1 - \epsilon$. We do so as follows:

$$\begin{aligned}
\mu_{\mathcal{R}}(U_{n,\mathsf{all}}) &\geq \mu_{\mathcal{R}}(U_{n,0}) + \mu_{\mathcal{R}}(U_{n,1}) \\
&\geq \Big(\mu_{\mathcal{R}}(S_{n,0}) - \mu_{\mathcal{R}}(S_{n,0} \setminus U_{n,0})\Big) + \mu_{\mathcal{R}}(U_{n,1}) \\
&\geq_{[a]} \Big(\mu_{\mathcal{R}}(S_{n,0}) - \mu_{\mathcal{R}}(S_{n,0} \setminus U_{n,0})\Big) + \frac{2^{t(n)} - 2^{o(t(n))}}{2^{t(n)}} \cdot \mu_{\mathcal{R}}\left(\mathbf{F}[S_{n,0} \setminus U_{n,0}, \{0,1\}^{t(n)}]\right) \\
&\geq_{[b]} \Big(\mu_{\mathcal{R}}(S_{n,0}) - \mu_{\mathcal{R}}(S_{n,0} \setminus U_{n,0})\Big) + \frac{2^{t(n)} - 2^{o(t(n))}}{2^{t(n)}} \cdot \mu_{\mathcal{R}}(S_{n,0} \setminus U_{n,0}) \\
&= \mu_{\mathcal{R}}(S_{n,0}) - \frac{2^{o(t(n))}}{2^{t(n)}} \cdot \mu_{\mathcal{R}}(S_{n,0} \setminus U_{n,0}) \\
&\geq \mu_{\mathcal{R}}(S_{n,0}) - \frac{2^{o(t(n))}}{2^{t(n)}} \cdot \mu_{\mathcal{R}}(S_{n,0}) \\
&= \left(1 - \frac{2^{o(t(n))}}{2^{t(n)}}\right) \cdot \mu_{\mathcal{R}}(S_{n,0}) \ .
\end{aligned}$$

Above, the third inequality (labeled $[a]$) follows from Lemma 52; the fourth inequality (labeled $[b]$) follows from Lemma 50 applied to the set $S_{n,0} \setminus U_{n,0}$.

Finally, by Lemma 51 we know that $\lim_{n\to\infty} \mu_{\mathcal{R}}(S_{n,0}) = 1/e > 1/3$, so if we set $\epsilon := 2/3$ then the above expression is greater than $1 - \epsilon$ for large enough n. ◀

7.2 Proof of Part 2 of Theorem 46

We prove the statement by arguing that, for every oracle R in a certain set of measure 1 (derived below), there exists a language L_R that is in $\mathrm{DTIME}(t)^R$ but not in $\mathrm{PCP}(o(t), o(t))^R$.

We first define the language $L_R \subseteq \{0,1\}^*$ for any $R \in \mathcal{R}$. The language is defined as follows:

$$L_R := \{(x,y) \in \{0,1\}^n \times \{0,1\}^n \,|\, F_{R,n}(x) = y\} \ ,$$

where $F_{R,n}(x)_i := \bigoplus_{j \in \left\{(i-1)\frac{t(n)}{n}+1,\ldots,i\frac{t(n)}{n}\right\}} R(x \| e_{t(n),j})_1$ for $i \in \{1,\ldots,n\}$.

We argue that the language L_R is in $\mathrm{DTIME}(t)^R$ for every $R \in \mathcal{R}$. Consider the deterministic machine that on input (x,y): (a) copies $x \| e_{t(n),1}$ to the query tape; (b) for $i \in \{1,\ldots,n\}$, calls R on inputs $\{x \| e_{t(n),j}\}_{j \in \left\{(i-1)\frac{t(n)}{n}+1,\ldots,i\frac{t(n)}{n}\right\}}$ to get $z_i := F_{R,n}(x)_i$; (c) accepts if $y = z$. Writing down x takes time n, querying all bits of the form $x \| e_{t(n),j}$ takes $O(t(n))$ time, computing z and comparing it with y takes $O(t(n))$ time. So the running time of the machine is $O(t(n))$. We are left to argue that L_R is not in $\mathrm{PCP}(o(t), o(t))^R$ for R in a certain set of measure 1. For this, we state a lemma (which we prove later on below), and then conclude the proof of the theorem.

▶ **Lemma 53.** *For every* $M \in \mathbf{M}_{o(t),o(t)}$, $\Pr_{R\leftarrow\mathcal{R}}\left[M^R \text{ is a PCP-verifier for } L_R\right] = 0$.

Using the same arguement as in the proof of Theorem 46, we conclude that

$$\Pr_{R\leftarrow\mathcal{R}}\left[\exists\, M \in \mathbf{M}_{o(t),o(t)} \text{ s.t. } M^R \text{ is a PCP-verifier for } L_R\right] = 0 \ ,$$

which shows that L_R is not in $\mathrm{PCP}(o(t), o(t))^R$ for all R in a set of measure 1.

This completes the proof, and so we are only left with proving Lemma 53.

Before proving Lemma 53, we define for every $n \in \mathbb{N}$ 2^n disjoint sets of oracles, $S_{n,y}$ where $y \in \{0,1\}^n$, and then prove certain properties about them (see Remark 56 and Lemma 57 below).

▶ **Definition 54.** *For every* $n \in \mathbb{N}$ *and* $y \in \{0,1\}^n$, $S_{n,y}$ *is the set of functions* $R \in \mathcal{R}_n$ *for which* $(0^n, y) \in L_R$, *that is, for which* $F_{R,n}(0^n) = y$. *We note that by definition the sets are disjoint.*

▶ **Definition 55.** *For every* $n \in \mathbb{N}$, *function* $R \in \mathcal{R}_n$, *index* $i \in [n]$ *and coordinate index* $j \in \left[\frac{t(n)}{n}\right]$, *we define the function* $\mathbf{F}[R,i,j]\colon \{0,1\}^* \to \{0,1\}^*$ *to be*

$$\mathbf{F}[R,i,j](z)_k := \begin{cases} 1 - R(z)_k & \text{if } k = 1 \text{ and } z = 0^n \| e_{t(n),(i-1)\frac{t(n)}{n}+j} \\ R(z)_k & \text{otherwise} \end{cases} \ .$$

Moreover, given $S \subseteq \mathcal{R}_n$, *we define* $\mathbf{F}[S,i,j]$ *to be the set* $\{\mathbf{F}[R,i,j] \mid R \in S\}$.

From the definitions of the set $S_{n,y}$ and the map $\mathbf{F}[\ ,\ ,\ ]$, we immediately obtain the following claim.

▶ Remark 56. We note that for any $R \in S_{n,y}$, $i \in [n]$ and $j \in [t(n)/n]$, (a) $\mathbf{F}[R,i,j] \notin S_{n,y}$, since flipping the first bit at $0^n \| e_{t(n),(i-1)t(n)/n+j}$ results in $F_{R,n}(0^n)_i \neq F_{\mathbf{F}[R,i,j],n}(0^n)_i$; (b) the number of preimages of R under the maps $\{\mathbf{F}[\ ,i,j]\}_{i\in[n],j\in[t(n)/n]}$ is exactly $t(n)$.

▶ **Lemma 57.** *For every function* $R \in S_{n,y}$, *if* M^R *is correct on* $(0^n, y)$ *then there are at least* $t(n) - o(t(n))$ *pairs* $(i,j)_{i\in[n],j\in[t(n)/n]}$ *for which* $M^{\mathbf{F}[R,i,j]}$ *is* not *correct on* $(0^n, y)$.

Proof. Fix a constant $c > 0$. Let π be the proof such that $\Pr_r[M^{R,\pi}(0^n, y; r)] \geq \frac{2}{3}$. Consider the set of $t(n)$ queries

$$X(R) := \left\{0^n \| e_{t(n),(i-1)t(n)/n+j} \;\middle|\; i \in [n],\ j \in [t(n)/n]\right\} \ .$$

Define the subset of $X(R)$ which $M^{R,\pi}$ queries with "low" probability:

$$X_\star(R) := \left\{ w \in X(R) \;\middle|\; \Pr_r[M^{R,\pi}(0^n; r) \text{ queries } R \text{ at } w] < \frac{1}{c} \right\} \ .$$

We argue that $|X_\star(R)|$ is large, and for every $w \in X_\star(R)$, $w = 0^n \| e_{t(n),(i-1)t(n)/n+j}$ it holds that $M^{\mathbf{F}[R,i,j],\pi}$ is *not* correct on $(0^n, y)$.

Consider the set of strings $w \in X(R)$ that M^R queries with "high" probability:

$$X_c(R) := \left\{ w \in X(R) \;\middle|\; \Pr_r[M^{R,\pi}(0^n; r) \text{ queries } R \text{ at } w\ ] \geq \frac{1}{c} \right\} \ .$$

Observe that

$$|X_c(R)| \leq c \cdot o(t(n)) \in o(t(n)) \ . \tag{5}$$

This is because, in any given execution, M can make at most $o(t(n))$ queries to R which means that

$$\sum_{w \in X(R)} \Pr_r[M^{R,\pi}(0^n; r) \text{ queries } R \text{ at } w] \leq o(t(n)) \ .$$

We deduce, via Equation (5), that $|X_\star(R)|$ is large:

$$|X_\star(R)| \geq t(n) - |X_c(R)| = t(n) - o(t(n)) \ .$$

Next, for every $w \in X_\star(R)$ it holds that

$$\Pr_r[M^{R,\pi}(0^n; r) \text{ queries } R \text{ at } w] < \frac{1}{c} \ .$$

This means that for every $w \in X_\star(R)$, $w = 0^n \| e_{t(n),(i-1)t(n)/n+j}$, it holds that M cannot distinguish between R and $R' := \mathbf{F}[R, i, j]$ with probability greater than $\frac{1}{c}$ (the probability is over M's randomness r).

We know that $M^{R,\pi}$ is correct on $(0^n, y)$, namely, $M^{R,\pi}(0^n)$ accepts with probability at least $1/3$. We also know that for every $(i, j) \in [n] \times [t(n)/n]$ it holds that $(0^n, y) \notin L_{\mathbf{F}[R,i,j]}$ (part (a) of Remark 56). But the foregoing argument tells us that for every $0^n \| e_{t(n),(i-1)t(n)/n+j} \in X_\star(R)$ it holds that $M^{\mathbf{F}[R,i,j],\pi}(0^n)$ accepts with probability greater than $1/3 + 1/c$.

Choosing $c \geq 3$, we deduce that, for every $0^n \| e_{t(n),(i-1)t(n)/n+j} \in X_\star(R)$, $M^{\mathbf{F}[R,i,j]}$ is *not* correct on $(0^n, y)$. ◀

Proof of Lemma 53. Fix $M \in \mathbf{M}_{o(t),o(t)}$. It suffices to show that, for some $\epsilon \in [0, 1)$ and every $n \in \mathbb{N}$, M^R is correct on inputs $(0^n, y)_{y \in \{0,1\}^n}$ for at most an ϵ-fraction of oracles R. Indeed, this fact would imply that:

$$\begin{aligned}
&\Pr_{R \leftarrow \mathcal{R}} \left[M^R \text{ is a PCP-verifier for } L_R \right] \\
&\leq \Pr_{R \leftarrow \mathcal{R}} \left[\forall n \in \mathbb{N},\ M^R \text{ is correct on } (0^n, y)_{y \in \{0,1\}^n} \right] \\
&= \prod_{n \in \mathbb{N}} \Pr_{R \leftarrow \mathcal{R}} \left[M^R \text{ is correct on } (0^n, y)_{y \in \{0,1\}^n} \;\middle|\; M^R \text{ is correct on } (0^i, y)_{y \in \{0,1\}^i} \text{ for all } i < n \right] \\
&= \prod_{n \in \mathbb{N}} \Pr_{R \leftarrow \mathcal{R}} \left[M^R \text{ is correct on } (0^n, y)_{y \in \{0,1\}^n} \right] \\
&\leq \lim_{n \to \infty} \epsilon^n = 0 \ ,
\end{aligned}$$

as claimed. Above "correct" on input $(0^n, y)$ means that if $(0^n, y) \in L_R$ then there exists a proof string π such that $M^{R,\pi}(0^n, y)$ accepts with probability at least $2/3$, and if $(0^n, y) \notin L_R$ then for every proof string π it holds that $M^{R,\pi}(0^n, y)$ rejects with probability at least $2/3$.

We are left to argue that M^R is correct on inputs $(0^n, y)_{y \in \{0,1\}^n}$ for at most an ϵ-fraction of oracles R. Consider the following sets of oracles:

$$\begin{aligned}
U_{n,\mathsf{all}} &:= \left\{ R \in \mathcal{R} \,|\, M^R \text{ is incorrect on } (0^n, y) \text{ for some } y \in \{0,1\}^n \right\} \ , \\
U_{y,\mathsf{all}} &:= \left\{ R \in S_{n,y} \,|\, M^R \text{ is incorrect on } (0^n, y') \text{ for some } y' \in \{0,1\}^n \right\} \ , \\
U_{y,y} &:= \left\{ R \in S_{n,y} \,|\, M^R \text{ is incorrect on } (0^n, y) \right\} \ .
\end{aligned}$$

We want to prove that $\mu_{\mathcal{R}}(U_{n,\mathsf{all}}) > 1 - \epsilon = 1/3$. We do so as follows:

$$\begin{aligned}
\mu_{\mathcal{R}}(U_{n,\mathsf{all}}) &= \sum_{y\in\{0,1\}^n} \mu_{\mathcal{R}}(U_{y,\mathsf{all}}) \\
&\geq_{[a]} \frac{1}{t(n)} \cdot \sum_{y\in\{0,1\}^n} \mu_{\mathcal{R}}(S_{n,y} \setminus U_{y,y}) \cdot (t(n) - o(t(n))) \\
&\geq \sum_{y\in\{0,1\}^n} \mu_{\mathcal{R}}(S_{n,y} \setminus U_{y,\mathsf{all}}) \cdot \frac{t(n) - o(t(n))}{t(n)} \\
&= (1 - \mu_{\mathcal{R}}(U_{n,\mathsf{all}})) \cdot \frac{t(n) - o(t(n))}{t(n)} \\
&\geq \frac{t(n) - o(t(n))}{2t(n)} > \frac{1}{3}
\end{aligned}$$

In the inequality labeled $[a]$, the $\frac{1}{t(n)}$ term comes from part (b) of Remark 56 that each $R \in \mathcal{R}_n$ has $t(n)$ preimages under the maps $\{\mathbf{F}[\ , i, j]\}_{i\in[n], j\in[t(n)/n]}$; the term $\mu_{\mathcal{R}}(S_{n,y} \setminus U_{y,y}) \cdot (t(n) - o(t(n)))$ is the measure of all $R' \in \cup_{i,j}\mathbf{F}[S_{n,y}, i, j]$ for which $M^{R',\pi}(0^n, y)$ fails (Lemma 57). ◀

Abstract

Comparator circuits are a natural circuit model for studying the concept of *bounded fan-out* computations, which intuitively corresponds to whether or not a computational model can make "copies" of intermediate computational steps. Comparator circuits are believed to be weaker than general Boolean circuits, but they can simulate Branching Programs and Boolean formulas. In this paper we prove the first superlinear lower bounds in the general (non-monotone) version of this model for an explicitly defined function. More precisely, we prove that the n-bit Element Distinctness function requires $\Omega((n/\log n)^{3/2})$ size comparator circuits.

1 Introduction

One of the central open problems in circuit complexity is to prove superlinear lower bounds on the size of general Boolean circuits for explicitly defined functions. While theorists have been outstandingly successful at analyzing some restricted circuit models – for instance, exponential lower bounds are known when the circuit is monotone [22], or bounded-depth [11] – the progress remains modest for less restricted classes of circuits:

1. The best lower bounds for the *Boolean formula size* of explicit functions over n variables are of the form $\Omega(n^{3-o(1)})$ [12, 18, 26, 5, 7, 19, 27, 4, 8]. The first such bound is due to Håstad [12] and the current largest bound (improving lower order terms) is due to Tal [27].
2. The best lower bounds for *branching programs*, which capture small-space computation and can simulate formulas, are $\Omega((n/\log n)^2)$ for the deterministic model by Nechiporuk [21] and $\Omega(n^{3/2}/\log n)$ for the non-deterministic- and parity- models by Pudlák[1] [15], and Karchmer and Wigderson [15], respectively.
3. The best lower bounds for *span programs* over $GF(2)$, which can simulate all of the above models, is $\Omega(n^{3/2}/\log n)$ by Beimel, Gál, and Paterson [3], following the initial $\Omega(n \log\log\log^* n)$ lower bounds by Karchmer and Wigderson [15].
4. Finally (and, perhaps, most notoriously) the best lower bounds for *general* Boolean circuits are $5n - o(n)$, due to Iwama and Morizumi [13].

[1] Pudlák's result is unpublished, and referenced by Karchmer and Wigderson in their paper [15].

Improving any of these lower bounds is an outstanding open problem; however, the problem of proving *any* superlinear lower bound on general Boolean circuits is perhaps the most interesting. Span programs form a remarkable model here, since they can simulate all models above for which we have superlinear lower bounds – this means that improving the lower bounds for span programs is one of the outstanding open question at the "frontier" of current techniques for proving lower bounds in general non-monotone circuit models.

In this paper we identify a new problem at the frontier: the complexity of non-monotone *comparator circuits*. A comparator circuit is a circuit composed purely of *comparator gates*, each of which maps a pair of bits (x, y) to $(x \wedge y, x \vee y)$. It is known that, just like span programs, comparator circuits can efficiently simulate non-deterministic branching programs [6], and thus lower bounds for comparator circuits imply lower bounds on branching programs and formulas. However, like branching programs, comparator circuits are known to be stronger than boolean formulas, as it is easy to construct comparator circuits computing Parity in $O(n)$ size (unlike formulas, which require $\Omega(n^2)$ size [16]). Similarly, like span programs, comparator circuits are believed to be weaker than general non-monotone circuits [6, 24]. However, it appears that comparator circuits may be *incomparable* to, or possibly even stronger than span programs: the class of functions computable by polynomial-size comparator circuits is conjectured to be incomparable to NC [25], and this conjecture is supported by oracle separations [6]. In contrast, the class of functions computable by polynomial-size span programs over finite fields is contained in NC^2. Furthermore, while we already had superlinear lower bounds for span programs [3, 15], there have been *no* superlinear lower bounds known for the comparator circuit size of any explicit function.

Continuing the line of work proving superlinear lower bounds for formulas, branching programs, and span programs, we prove the *first* superlinear lower bounds on the size of comparator circuits computing an explicit Boolean function. Let $n = 2m \log m$, and let $ED_n : \{0,1\}^n \to \{0,1\}$ be the n-bit *Element Distinctness* function, which takes m integers in the range $\{1, 2, \ldots, m^2\}$ as input (each encoded as $2 \log m$ bits) and outputs 1 iff all of the integers are distinct. Our main result is the following:

▶ **Theorem 1.** *The size of any comparator circuit computing the n-bit Element Distinctness function ED_n is at least $\Omega((n/\log n)^{3/2})$.*

In fact, we prove the stronger statement, that the number of *wires* of any comparator circuit computing ED_n is at least $\Omega((n/\log n)^{3/2})$. (See Section 2 for definitions.)

The above result provides a new and natural class of circuits for which we can obtain superlinear size lower bounds, and thus represents progress towards the goal of proving superlinear lower bounds for general non-monotone circuits. We believe that the techniques we employ are also interesting. The current best $\Omega(n^{3-o(1)})$ lower bounds for formulas follow by restriction based techniques, which we do *not* use for our lower bounds. In fact, as we discuss in Section 5, there seem to be obstacles to obtaining superlinear lower bounds for comparator circuits this way. Instead, we use a generalized version of the classic *Nechiporuk method* [21], which was used for obtaining the current best lower bounds for branching programs and span programs stated above. However, it is not possible to apply Nechiporuk's method directly to estimate the number of gates of comparator circuits, because the partial computations corresponding to subcircuits over disjoint subsets of inputs may significantly overlap (see Remark 8 and Section 1.2 for more details.) Instead, we need to exploit some interesting structure of comparator circuits to enable a more general version of the method. For these reasons we believe that our above lower bound (and comparator circuits more generally) are particularly interesting.

1.1 Comparator Circuits and Bounded Fanout Computation

Let us first describe comparator circuits more formally. As stated above, a *comparator gate* computes the map $(x, y) \mapsto (x \wedge y, x \vee y)$ where $x, y \in \{0, 1\}$; that is, the gate outputs both the AND and the OR of its input bits. A *comparator circuit* is a Boolean circuit whose inputs are labeled by input literals (i.e. either variables x_i or their negations $\overline{x}_i$), and is composed entirely of comparator gates; the comparator circuit is said to be *monotone* if no input literal is negated. We emphasize here that every comparator gate in the circuit has exactly two inputs and two outputs, and the (Boolean) output of the circuit is obtained by fixing some designated output of a comparator gate in the circuit.

The definition of a comparator gate suggests a convenient method of visualizing such circuits, depicted in Figure 1. We draw m lines from left-to-right – we call these lines *wires*[2] – that are initially labeled with input literals or the Boolean constants $0, 1$. We connect wires together with *comparator gates*: each gate is drawn connecting a pair of wires; one of the inputs is drawn with a *circle* (representing the output of the $\wedge$ gate) and the other with an *arrow* (representing the output of the $\vee$ gate).

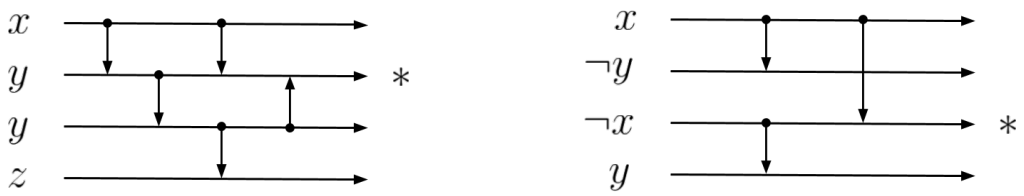

Figure 1 Examples of comparator circuits, with outputs designated. The left is a simple monotone comparator circuit, the right is a non-monotone comparator circuit for parity.

The most studied examples of comparator circuits in the literature are *sorting networks*, which are typically studied in a more general (i.e. non-Boolean) setting. A sorting network is a mathematical model of a sorting algorithm which is *input-oblivious*: the algorithm performs the same sequence of compare-and-swap operations on its input sequence of integers for all possible inputs. There are n wires traveling from left to right, each labeled with a distinct input variable, and a sequence of *comparator gates* connecting the wires. (Note that a comparator gate, intuitively, just *sorts* its inputs in order, with the larger input sent to the $\vee$ output and the smaller to the $\wedge$ output.) The goal is to construct the *fastest* network – where fastest can mean "shallowest", with the smallest depth connecting inputs to outputs, or with the fewest possible comparator gates – that sorts all n inputs. Shallow sorting networks have many applications in theory and practice, and thus have been extensively studied in theoretical computer science, with much effort spent on finding the shallowest possible networks (see [1, 2, 17, 9]). A restricted version of comparator circuits appeared implicitly in a paper by Graham [10]. His model is equivalent to *read once* comparator circuits, where each literal is used on at most one wire. Graham [10] showed that there exists a Boolean function on 11 variables that cannot be computed by this model, and it was proved by Robere [23] that the s, t- connectivity problem cannot be solved by read once monotone comparator circuits.

[2] We note that this differs from the standard usage of the word "wires" in circuit complexity, which is usually used to mean the edges in the underlying directed graph of the circuit.

Studying comparator circuits as a circuit model for general computation arguably began with the work of Subramanian [25], who showed that comparator circuits are a natural model for extending the study of *bounded fan-out* circuits beyond Boolean formulas. Subramanian considered different classes of circuits depending on whether or not the gates in the circuit could simulate a COPY gate: that is, the gate that takes some input x and outputs two copies of x. For example, when a gate can "fan-out" its output then we are allowing the gate to implicitly copy its output many times over. On the other hand, it is easy to see that a circuit constructed of comparator gates can *not* simulate a COPY gate, as the Hamming weight of the *output* of a comparator gate is always the same as the Hamming weight of the *input* of a comparator gate. Thus comparator circuits form an interesting intermediate class between Boolean formulas and Boolean circuits: they cannot create copies of intermediate computations, and so are apparently weaker than Boolean circuits; but, the ability to compute AND and OR simultaneously makes them apparently more powerful than Boolean formulas.

Let CC denote the class of languages computable by AC^0-uniform polynomial-size comparator circuits. This complexity class has an interesting characterization as the class of problems reducible to the *stable marriage* problem [25]. Closer to our purposes, Subramanian showed that if a circuit composed from gates chosen from a set S has "bounded fanout", in the sense that the gates from S cannot simulate a COPY gate, and all the gates in S compute monotone functions, then the corresponding circuit value problem for circuits with gates from S is either in NC or is CC-hard [25]. Despite their inability to copy, polynomial-size comparator circuits can compute everything in NL [20, 6] (which is conjectured to be strictly more powerful than polynomial-size Boolean formulas), and appear to be incomparable with NC [25]. Therefore, CC is a natural class to continue the study of bounded fan-out computation past NC^1, along with being a candidate for a class C satisfying $\mathsf{NL} \subset C \subset \mathsf{P}$ and $C \neq \mathsf{NC}$. The computational complexity of the class CC was recently analyzed by Cook, Filmus and Le [6] where, among other things, the question of uniformity and oracle separations with other classes was addressed.

However, a natural question left open by [6] is that of *lower bounds*. In the monotone case, since monotone comparator circuits are simulated by monotone circuits, exponential lower bounds are implied by the known lower bounds for monotone circuits (for instance, by Razborov [22]), and exponential separations between monotone comparator circuits and monotone circuits have been proved in [24]. Lower bounds for general Boolean circuits imply lower bounds for comparator circuits, but other than such implications, we are not aware of any previous nontrivial lower bounds for general (non-monotone) comparator circuits. In particular, before our work, no superlinear lower bounds have been obtained for comparator circuits computing an explicit Boolean function.

1.2 Techniques

To prove Theorem 1 we recruit a classic tool from non-monotone circuit lower bounds: the *Nechiporuk method* [21]. This method was invented by Nechiporuk to prove lower bounds on the size of deterministic branching programs and formulas, and is currently one of the few techniques capable of proving superlinear lower bounds against non-monotone computation. The idea of the method is as follows, in the setting of branching programs (the argument for formulas is identical, see e.g. [29]). Consider a branching program B computing a Boolean function f on n variables. First, observe that fixing the values outside of a subset $S \subseteq [n]$ of the variables to constants results in a branching program that computes a subfunction of the original function on the variables in the subset S. It follows that as we range over all substitutions to $[n] \setminus S$, the number of different branching programs obtained must be

at least as large as the number of different subfunctions of f on S. Thus, to obtain a lower bound, take any partition of the input variables $[n] = Y_1 \cup Y_2 \cup \cdots \cup Y_n$ and let h_i be the number of nodes of the branching program B labeled with variables from the set Y_i. Recall that the size of a deterministic branching program is the number of its nodes, and each node is labeled by exactly one input variable. Thus, the size of the branching program B is $|B| = \sum_i h_i$ and, in turn, we can lower-bound each h_i by relating it to the number of subfunctions of f on the variables Y_i obtained by restricting $[n] \setminus Y_i$ in all possible ways. This yields lower bounds for functions with large number of different subfunctions.

The Nechiporuk method works well for branching programs as the sets of nodes of the program associated with disjoint subsets of inputs are disjoint. The situation is similar for Boolean formulas: each leaf of the formula is labeled by a variable (or negated variable), and again the sets of leaves associated with disjoint subsets of inputs are disjoint. In fact, this property (that the subcircuits corresponding to disjoint subsets of inputs are disjoint) is true for *all* prior applications of the method. For example, in the application to non-deterministic and parity branching programs [15], the *edges* of the program are now labeled by variables, and thus the sets of edges corresponding to disjoint subsets of variables are disjoint. Similarly, in span programs over $GF(2)$ [3], the rows are labeled by variables and so once again, subsets of rows corresponding to disjoint subset of variables are disjoint.

In principle, one could imagine generalizing this method to other circuit models, as long as the subcomputations corresponding to disjoint subsets of input variables do not overlap much. On the negative side, the method can provably *not* be applied to general Boolean circuits [28], which intuitively makes sense as circuits can copy intermediate computations as many times as they like.

So: what about comparator circuits? At first glance it seems like the method should not be applicable to comparator circuits either, since the circuits contain gates with fanout *two*, and this implies that the computation of the circuits on disjoint sets of variables can badly overlap, just like general Boolean circuits and unlike formulas, branching programs or span programs. Indeed, as we discuss in Remark 8, the set of gates of a comparator circuit contributing to the computation on a given subset of variables can potentially involve *all* the gates of the original circuit.

We can, however, overcome this problem. Our key observation is the following: the idea of Nechiporuk's method may be still applicable in situations where the subcomputations badly overlap, as long as we are able to bound the size of the computation by some (not too fast growing) function of the number of occurrences of input literals. This is simply because the *occurrences of input literals* (or in other words the *input queries*) made by the computation will always be disjoint over disjoint subsets of variables.

Let us elaborate further in the case of comparator circuits. In comparator circuits, the number of *wires* – which, we recall, refers to the number of distinct left-to-right lines in Figure 1 – corresponds exactly to the number of occurrences of input literals in the circuit. The fact that comparator circuits cannot simulate COPY gates suggests the following question. If F is a Boolean formula with ℓ leaves then it is easy to see that the number of internal gates s of F is *exactly* $s = \ell - 1$. In other words, the size of the formula F is *linearly* related to the number of its leaves, and this is a result of F having bounded fanout. Does a similar relation hold for comparator circuits between *gates* and *wires*?

First, observe that since each gate in the comparator circuit connects two wires, in order for each wire to be connected to the output gate we must have $\ell - 1 \leq s$, where s is the number of gates, just like in formulas. However, is it the case that $s = O(\ell)$? Or even $s = O(\text{poly}(\ell))$? Surprisingly, we are able to show that $s \leq \binom{\ell}{2}$ assuming that none of the gates in the circuit

are "useless" in a specific technical sense and can be removed (cf. Section 3); furthermore, we show that this relationship is sharp. For the special case of read once comparator circuits, essentially this statement was proved implicitly by Graham [10].

▶ **Theorem 2.** *Let C be any comparator circuit with ℓ wires and s gates such that every gate in C is useful. Then $s \leq \ell(\ell-1)/2$.*

It is precisely this relationship between wires and gates which allows us to overcome the "overlapping subcomputations" issue in applying Nechiporuk's method, and it seems to be a remarkable property of this model. As far as we know, our results are the first generalization of Nechiporuk's method to such a scenario.

2 Definitions

For any positive integer m let $[m] := \{1, 2, \ldots, m\}$, and if n is an integer satisfying $m \leq n$ let $[m, n] := \{m, m+1, \ldots, n\}$. If S is a set then $\wp(S)$ denotes the power set of S.

Throughout we will be interested in Boolean functions $f : \{0,1\}^n \to \{0,1\}$. If $x \in \{0,1\}^n$ then x_i is the value of the ith bit in x. If $x, y \in \{0,1\}^n$ are binary strings then $x \leq y$ if $x_i \leq y_i$ for all $i \in [n]$. If $x \in \{0,1\}^n$ then $|x|$ is the Hamming weight of x.

A *comparator gate* is the function $C : \{0,1\}^2 \to \{0,1\}^2$ computing the map $(x, y) \mapsto (x \wedge y, x \vee y)$. It is natural to think of a comparator gate C as "sorting" the input (x, y), as the smaller input goes to the first coordinate and the larger input goes to the second. A *comparator circuit* is a circuit composed of comparator gates with arbitrary Boolean literals as input. For later convenience, we use the following, alternative definition of a comparator circuit. A comparator circuit C is defined by a tuple (W, G, I, o), where

- W is a set of elements called *wires*,
- $I : W \to \{x_1, \ldots, x_n, \overline{x}_1, \ldots, \overline{x}_n, 0, 1\}$ is an initial labeling of each wire with an input literal or Boolean constant,
- $G \subseteq W^2$ is an ordered list of *comparator gates*,
- $o \in W$ is the designated output wire.

Each comparator gate $g = (i, j) \in G$ is specified by the pair of wires the gate connects: the AND output of the gate is interpreted as the first coordinate and the OR output of the gate is interpreted as the second coordinate. A comparator circuit computes a Boolean function in the natural way: given an assignment to the input literals, we evaluate the comparator gates one by one in order according to G, and then output the Boolean value labeled on the output wire, o. We define the *size* of the comparator circuit to be the number of gates in the circuit, and note that the number of wires in the circuit will also be an interesting complexity measure.

3 Wires vs. Gates in Comparator Circuits

▶ **Definition 3.** *Let C be a comparator circuit with m wires, let $g = (i, j)$ be a gate in C, and let $v_i(x), v_j(x)$ be the values of the wires i, j, respectively, on input x just before applying the gate g. Then g is* useful *if there is a pair of inputs x, y to C such that $(v_i(x), v_j(x)) = (1, 0)$ and $(v_i(y), v_j(y)) = (0, 1)$. If g is not useful then we say it is* useless.

Equivalently, if a gate g is useless then for every pair of inputs (x, y) either $(v_i(x), v_j(x)) = (v_i(y), v_j(y))$ or $v_i = v_j$ for one of x, y. The next proposition states that gates that are not useful can be removed without loss of generality.

▶ **Proposition 4.** *Let C be a comparator circuit with ℓ wires and s gates computing some Boolean function f. Then there exists a comparator circuit C' with (at most) ℓ wires and $s' \leq s$ gates computing f such that every gate in C' is useful. Moreover, the labels of the wires that are not removed remain the same in C' as in C.*

Proof. Let $g = (i, j)$ be any gate in C such that g is not useful. Let $v_i(x), v_j(x)$ be the values of the wires i, j before applying g on input x. Since g is not useful, then it follows that for every pair of inputs x, y to the circuit either $(v_i(x), v_j(x)) = (v_i(y), v_j(y))$ or one of x, y satisfies $v_i = v_j$.

Let $O \subseteq \{0,1\}^n$ be the set of inputs such that for all $x \in O$, exactly one of $v_i(x), v_j(x)$ is 1. Since g is useless, it follows that either $(v_i(x), v_j(x)) = (0, 1)$ for every x in O or $(v_i(x), v_j(x)) = (1, 0)$ for every x in O.

Assume that the outputs of g are ordered so that $g(0, 1) = (0, 1)$ and $g(1, 0) = (0, 1)$. The proof for the other type of gates is symmetric. Consider the following two cases.

Case 1: For all $x \in O$, $(v_i(x), v_j(x)) = (0, 1)$.

We claim that for all $x \in \{0,1\}^n$, applying g does not change the value of any wire, and so g can be removed without affecting the computation C. This is because for every $x \in \{0,1\}^n$, either $x \in O$ and so applying g does not change any value (since $g(0, 1) = (0, 1)$), or $x \notin O$, and by the definition of the set O we must have $v_i(x) = v_j(x)$, and so applying g will not change the values of the wires.

Case 2: For all $x \in O$, $(v_i(x), v_j(x)) = (1, 0)$.

By definition $g(1, 0) = (0, 1)$, and so we perform the following operation: remove g, and for each wire i, j find the *first* gate h using that wire as an input. If it is the same gate for both wires, then h is redundant, so remove it and continue searching forward along each wire. Otherwise, let $h_i = (k, \ell)$ where exactly one of k, ℓ is i and let $h_j = (k', \ell')$ where exactly one of k', ℓ' is j. Let the wire i feed into the gate h_j and the wire j feed into the gate h_i. Switching the wires this way will simulate the action of the gate g that we just eliminated.

Once you have found a non-redundant gate h for each of the two wires $\{i, j\}$ (or if no such gate exists), then stop.

To see that this operation does not affect the output of the circuit, consider the following two cases:

1. $v_i(x) = v_j(x)$. In this case, performing this operation will not affect the computation of the circuit as either of the h gates will receive the same input, regardless of which wire they are connected to.
2. $v_i(x) \neq v_j(x)$. In this case, $(v_i(x), v_j(x)) = (1, 0)$, and $g(1, 0) = (0, 1)$, so by removing g and switching the inputs of the h gates we ensure that in the new circuit the computation will be the same.

By proceeding from the inputs of the circuit to the outputs we can apply this operation to remove every useless gate in the circuit. In each case, the output of the circuit will not be affected.

Finally, notice that if a wire is not connected to any remaining gate in C', we may remove it, except if the wire is designated as the output of the circuit. The wires that are not removed, retain the same label as in the original circuit C, and the proof of the proposition is complete. ◀

Now we can prove the main theorem of this section, which we restate from the Introduction.

▶ **Theorem 2.** *Let C be any comparator circuit with ℓ wires and s gates such that every gate in C is useful. Then $s \leq \ell(\ell-1)/2$.*

Proof. For $j = 1, 2, \ldots, s$ let g_j denote the jth gate of C, and let C_j be the subcircuit of C consisting of the first j gates of C. Let C_0 be the circuit C with all of its gates removed. We say that two inputs $x, y \in \{0,1\}^n$ are *useful with respect to the pair* (i,j) if $w_i(x) = 1, w_i(y) = 0$ and $w_j(x) = 0, w_j(y) = 1$, where w_i, w_j are the outputs of wires i and j of the comparator circuit C. If there exist two inputs $x, y \in \{0,1\}^n$ that are useful with respect to (i,j) then we say that (i,j) is a *useful pair*.

Let U_j denote the collection of all useful pairs in the circuit C_j. We show that the size of U_j decreases by at least one after applying each gate: that is $|U_j| \leq |U_{j-1}| - 1$ for all j. Since $|U_0| \leq \binom{ell}{2}$, it follows that the number of gates in C is at most $\binom{\ell}{2}$.

Let $1 \leq j \leq s$ be an integer, and suppose the gate g_j connects two wires (a,b). Since g_j is useful we have that (a,b) is a useful pair in U_{j-1}. It is also clear that $(a,b) \notin U_j$, as applying the gate g_j removes all useful inputs with respect to (a,b). However, we are not finished, as applying the gate g_j could have introduced a new useful pair (c,d): so, $(c,d) \in U_j$ and $(c,d) \notin U_{j-1}$. The proof will be complete once we prove the following claim, which states that if such a new useful pair is introduced, then there must exist another distinct useful pair that was removed.

▷ Claim 5. Suppose there exists a useful pair $(c,d) \in U_j$ such that $(c,d) \notin U_{j-1}$. Then there is another useful pair (α, β), uniquely associated with (c,d), such that $(\alpha,\beta) \neq (a,b)$, $(\alpha,\beta) \in U_{j-1}$, and $(\alpha,\beta) \notin U_j$.

Proof of Claim. It is clear that while $(c,d) \neq (a,b)$, it cannot be the case that $c, d \notin \{a,b\}$: that is, at least one of c or d must be equal to a or b. This is because applying the gate g_j only modifies the outputs of wires a and b, and so any new useful pair must include one of these modified outputs.

First assume that $c = a$ (and we note that the other cases ($c = b, d = a, d = b$) follow by nearly identical proofs). It follows that $(a,d) \in U_j$ and $(a,d) \notin U_{j-1}$. We show that this implies that $(b,d) \in U_{j-1}$ and $(b,d) \notin U_j$. For any wire t let v_t denote the output of the tth wire *before* applying the gate g_j, and let w_t denote the output of the tth wire *after* applying the gate g_j. Since (a,d) is a useful pair it follows that there exists a pair of inputs $x, y \in \{0,1\}^n$ such that $w_a(x) = 1, w_d(x) = 0$ and $w_a(y) = 0, w_d(y) = 1$. Now, since $(a,d) \notin U_{j-1}$ we can deduce the values of v_a, v_b, and v_d on inputs x and y. It is obvious that $v_d(x) = w_d(x)$ and $v_d(y) = w_d(y)$ as the gate g_j is not connected to the wire d. We can also conclude that $v_a(x) = v_b(x) = 1$, as the gate g_j connects a to b and $w_a(x) = 1$ (for if $v_b(x) = 0$, then $w_a(x) \neq 1$, as the 1 would have been moved to the $\vee$ output of g_j). Finally, since $(a,d) \notin U_{j-1}$ we know that $v_a(y) = 1$ and $v_b(y) = 0$. For if $v_a(y) = 0$, it would follow that (a,d) is a useful pair in U_{j-1} (a contradiction). Thus $v_a(y) = 1$, and since $w_a(y) = 0$, the only possibility is that the gate g_j moved a 1 from wire a to wire b on input y. We now record the values of v_a, v_b, v_d and w_a, w_b, w_d on inputs x and y:

	x	y
v_a	1	1
v_b	1	0
v_d	0	1
w_a	1	0
w_b	1	1
w_d	0	1

By examining the table it is easy to see that (b, d) is a useful pair in U_{j-1}, as $v_b(x) = 1, v_d(x) = 0$ and $v_b(y) = 0, v_d(y) = 1$. We show that $(b, d) \notin U_j$, proving the claim in this case.

To see this, suppose that $(b, d) \in U_j$. Then there must exist an input z such that $w_b(z) = 0, w_d(z) = 1$, on which we can similarly deduce the values of v_a, v_b, v_d. Clearly $v_d(z) = 1$ since the gate g_j connects the two wires (a, b). Since $w_b(z) = 0$, it must be that $v_a(z) = v_b(z) = 0$. However, this means that $v_a(z) = 0, v_d(z) = 1$, and from the table we can see that $v_a(x) = 1, v_d(x) = 0$. This means that (a, d) is a useful pair in U_{j-1}, a contradiction! ◁

We make a final remark on the uniqueness property. We technically have four cases to prove here, as the new useful pair must be in one of the following forms:

1. (a, d)
2. (b, d)
3. (c, a)
4. (c, b)

In the proof above we showed that if the new useful pair is of the form (a, d), then this implies that $(b, d) \in U_{j-1}$ and $(b, d) \notin U_j$. In the other three cases (which proceed by identical proofs), other uniquely associated pairs are introduced. In general, if $\alpha \in \{a, b\}$ and $\beta \in \{a, b\}$, $\beta \neq \alpha$, and the new useful pair is of the form (α, d) then the same proof shows that (β, d) is in U_{j-1} and not in U_j. Similarly, if the new useful pair is of the form (c, α) then a similar proof shows that (c, β) is in U_{j-1} and not in U_j. These facts together prove uniqueness. ◀

To see that the upper bound given in the previous theorem is sharp, consider the following comparator circuit C_n which sorts its n inputs via the "bubblesort" method: the circuit incrementally bubbles the largest value from the top wire down as far as it can go, and then the second wire, and so on. This circuit has n wires and $\binom{n}{2}$ gates, and it is not hard to see that every gate is useful.

4 Lower Bound for Element Distinctness

Let $n = 2m \log m$, and recall the definition of the Element Distinctness function ED_n: it takes $n = 2m \log m$ input bits divided into m blocks of $2 \log m$ bits each, interpreted as m integers in the range $\{1, \ldots, m^2\}$, and decides whether all m numbers are distinct.

In this section we prove our main lower bound, restated here for convenience:

▶ **Theorem 1.** *The size of any comparator circuit computing the n-bit Element Distinctness function ED_n is at least $\Omega((n/\log n)^{3/2})$.*

We note that the lower bound holds for any function with a similar number of subfunctions; for instance, the *Indirect Storage Access function* [29].

We will need the following Lemma. Recall that in a comparator circuit, each of the wires is labeled with either a constant $0, 1$, some input variable or its negation.

▶ **Lemma 6.** *Let $\ell \geq 1$ be an integer. For any fixed labeling of ℓ wires, the number of different Boolean functions that can be computed by comparator circuits with ℓ wires with the given labeling is at most ℓ^{ℓ^2}.*

Proof. By Proposition 4, every comparator circuit C with ℓ wires is equivalent to another comparator circuit C' with (at most) ℓ wires that has no useless gates. By Theorem 2 the number of gates of C' is at most $\binom{\ell}{2}$. Recall also that C' keeps the same labeling of the wires (that are not removed) as C; and if a wire is not connected to any remaining gate in C', we may remove it, except if the wire is designated as the output of the circuit.

To prove the lemma it is enough to estimate the number of different comparator circuits with at most ℓ wires of a given labeling and at most $\binom{\ell}{2}$ gates. For each gate, there are at most $\binom{\ell}{2}$ choices for the pair of wires it takes as inputs, and two choices for the ordering of the $\wedge$ output and $\vee$ output of the gate. In addition, we have at most ℓ choices to designate one of the wires as the output. Thus the number of possible such comparator circuits is at most $\ell \cdot (2\binom{\ell}{2})^{\binom{\ell}{2}} \leq (\ell)^{(\ell^2)}$. ◀

▶ Remark 7. We can also bound the number of different Boolean functions on n variables that are computed by comparator circuits with s gates by $(2(n+1)s)^{2s}$ using a similar counting argument. Note that here we do not assume a fixed labeling, and we use that the number of wires is at most the number of gates, assuming that each wire is connected to the output gate.

If the subsets of gates used in subcircuits over disjoint subsets of inputs would not overlap much, then a straightforward application of Nechiporuk's method seemingly would yield nearly quadratic lower bounds using this counting argument. However, as we discuss in some more details in Remark 8, the subsets of gates can badly overlap. Thus, even though a counting argument in terms of gates is available, Nechiporuk's argument is not applicable directly to the gates of comparator circuits.

Note that we could have also stated a similar bound for comparator circuits with ℓ wires and n input variables, without considering a fixed labeling of the wires. We find the current version of Lemma 6 more convenient for our purposes. We are now ready to prove Theorem 1.

Proof of Theorem 1. We prove the stronger statement, that the number of wires of any comparator circuit computing ED_n is at least $\Omega((n/\log n)^{3/2})$. Recall that the size of a comparator circuit is the number of its gates, and the number of gates in a comparator circuit with w wires, where each wire is connected to the output gate, is at least $w-1$. Thus, a lower bound on the number of wires implies lower bounds on the size of the comparator circuit.

Partition the $n = 2m\log m$ input variables into m groups of $2\log m$ variables each, such that the variables in the i-th group represent the i-th integer in the input. For $i = 1, \ldots, m$ let S_i be the set of variables in the i-th group. Let N_i denote the number of different subfunctions over the variables in S_i that can be obtained by fixing all variables outside S_i to constants. It is known (see e.g. [14]) that $N_i = 2^{\Omega(n)}$ for each $i = 1, \ldots, m$.

Let C be a comparator circuit computing ED_n with w wires. Let w_i denote the number of wires of C labeled by a variable from the i-th group. Then $w = \sum_{i=1}^{m} w_i$.

For a given $i \in [m]$, consider a fixed assignment α of constants 0 or 1 to all variables outside of S_i. Consider the resulting comparator circuit $C_{i,\alpha}$ over the variables in S_i. Applying Proposition 4 to $C_{i,\alpha}$ we can obtain a comparator circuit $C'_{i,\alpha}$ over variables from S_i with no useless gates. Notice that if a wire is labeled by constant 0 or 1 then any gate directly using this wire must be useless (in the formal sense of Definition 3). Note also that after removing all useless gates, wires with constant label are not connected to any remaining gates. Thus, they can be removed, except when designated as the output wire. Note however, that if a wire with constant label that is not connected to any gate is designated as the output wire, then the function computed is constant 1 or 0. Thus, unless the function computed by $C'_{i,\alpha}$ is constant, all wires in $C'_{i,\alpha}$ are labeled by variables or their negation from S_i, regardless of the particular assignment α.

This fact has two important consequences for us. First, it means that the number of wires of $C'_{i,\alpha}$ is at most w_i. Second, it means that for given i, unless the function computed by $C'_{i,\alpha}$ is constant, the wires of $C'_{i,\alpha}$ have the same labels (by variables or negated variables from S_i) regardless of the particular assignment α. (To see this, recall that in Proposition 4 the labels of the wires that are not removed remain the same as in the original circuit.)

This allows us to conclude using Lemma 6 that $N_i \leq 2 + w_i^{(w_i^2)}$ for $i = 1, \ldots, m$. Thus, we have for $i = 1, \ldots, m$ that

$$w_i^2 \geq \frac{\log(N_i - 2)}{\log w_i} \geq \frac{\Omega(n)}{\log w_i} .$$

Note that if $\log w_i > \frac{1}{2}\log n$ then $w_i \geq \sqrt{n}$. On the other hand, if $\log w_i \leq \frac{1}{2}\log n$ then we get $w_i^2 \geq \frac{\Omega(n)}{\log n}$. Thus, for $i = 1, \ldots, m$ we have $w_i \geq \Omega(\frac{\sqrt{n}}{\sqrt{\log n}})$, which yields $w \geq \Omega((n/\log n)^{3/2})$. ◀

▶ Remark 8. It is crucial in the above argument that the set of *wires* used by the subcircuits $C'_{i,\alpha}$ is the same for fixed i regardless of the assignment α, and that these sets do not overlap for different values of i. One could try to consider a similar argument directly for gates instead of wires. For instance, one could define $G_{i,\alpha}$ as the set of gates participating in the circuit $C'_{i,\alpha}$, and consider $G_i = \cup G_{i,\alpha}$. But for different assignments α, the circuits $C'_{i,\alpha}$ may retain different gates of the original circuit, and the sets G_i may badly overlap. In particular, for some values of i, G_i may contain all gates of the original circuit.

5 Conclusion and Future Work

In this paper we have proved the first superlinear lower bound on the size of comparator circuits computing an explicit Boolean function. As we have remarked above, we actually prove a superlinear lower bound on the number of *wires*, or equivalently, *input queries*, of any comparator circuit for ED_n, which is stronger than a lower bound on the number of gates. Furthermore, by our Theorem 2, there is at most a quadratic separation between the number of wires and the number of gates in any minimal comparator circuit. A natural problem is to try and prove a lower bound on the number of gates directly. However, as we discuss above in Remark 8 this would require a different technique.

We remark that it seems quite difficult to apply restriction techniques to obtain *wire* lower bounds for comparator circuits. This is for a simple reason: observe that restricting one input to a single comparator will restrict exactly one output of the gate and re-wire the other input to the other output. This implies that if we have a comparator circuit with m wires, and we restrict values to t of them, then we are left with a new comparator circuit with exactly $m - t$ unrestricted wires after propagating this rewiring process. Note that some wires could possibly be removed if they are "separated" from the output gate, but, if the topology of the circuit is highly connected (e.g. is an expander) then we should expect this to be very unlikely.

Finally, we remark on a second natural open problem. As we discuss in the introduction, the key structural property of comparator circuits that enabled us to apply Nechiporuk's method to comparator circuits is Theorem 2, relating the number of wires to the number of gates. The crucial intuition in the proof of this Theorem is that comparator circuits *cannot* copy intermediate computations. There is a rich structure of circuit classes extending comparator circuits which cannot copy intermediate computations, as explored by Subramanian [25]. Can one extend any of our results to these more general classes?

Abstract

The *index erasure problem* is a quantum state generation problem that asks a quantum computer to prepare a uniform superposition over the image of an injective function given by an oracle. We prove a tight $\Omega(\sqrt{n})$ lower bound on the quantum query complexity of the *non-coherent* case of the problem, where, in addition to preparing the required superposition, the algorithm is allowed to leave the ancillary memory in an arbitrary function-dependent state. This resolves an open question of Ambainis, Magnin, Roetteler, and Roland (CCC 2011), who gave a tight bound for the coherent case, the case where the ancillary memory must return to its initial state.

To prove our main result, we first extend the so-called *automorphism principle* (Høyer et al. STOC 2007) to the *general adversary method* for state conversion problems (Lee et al. STOC 2011), which allows one to exploit the symmetries of these problems to lower bound their quantum query complexity. Using this method, we establish a strong connection between the quantum query complexity of non-coherent symmetric state generation problems and the well-known *Krein parameters* of *association schemes*. Krein parameters are usually hard to determine, nevertheless, we give a novel way of computing certain Krein parameters of a commutative association scheme defined over partial permutations. We believe the study of this association scheme may also be of independent interest.

1 Introduction

For proving lower bounds in the *oracle query model*, one assumes access to an oracle O_f that evaluates a black-box function $f\colon [n] \to [m]$ on input queries, where $[n] := \{1, 2, \cdots, n\}$ and $[m] := \{1, 2, \cdots, m\}$, and the goal is to prove that any algorithm for solving the computational problem at hand must make a certain number of oracle queries. This principle for proving lower bounds applies to both classical and quantum computation, and in the latter we let the oracle to be queried in a superposition.

Quantum query algorithms are known to surpass their classical counterparts for many important classical tasks, such as unstructured search, game tree evaluation, random walks, and others (see [17, 1] for recent surveys). Classical tasks aside, one may also be interested in *quantum mechanical tasks*, such as *quantum state generation*. A quantum state generation problem simply asks for a certain quantum state $|\psi_f\rangle$ to be generated on the target register. In this paper, we consider a particular state generation problem known as Index Erasure.

Given an injective function $f\colon [n] \to [m]$ via a black-box oracle O_f, Index Erasure is the task of preparing the quantum state that is the uniform superposition over the image of f, namely,

$$|\psi_f\rangle := \frac{1}{\sqrt{n}} \sum\nolimits_{x=1}^{n} |f(x)\rangle\,.$$

The name of the problem stems from the fact that a quantum computer can prepare the uniform superposition $\frac{1}{\sqrt{n}} \sum_{x=1}^{n} |x\rangle\,|f(x)\rangle$ using a single query to O_f, yet the task of ignoring or *erasing* the first register that records the *index* x is non-trivial. Indeed, if one could solve Index Erasure using a poly-logarithmic number of queries, one would obtain a time-efficient algorithm for Graph Isomorphism (we present more details in Appendix A).

The question of the complexity of Index Erasure was first raised by Shi in [23], where he already observed that the problem can be solved in $\mathrm{O}(\sqrt{n})$ queries by an algorithm based on Grover's search. In the same paper, Shi also introduced the Set Equality problem, which asks to decide whether two injective functions f, f' given via black-box oracles $O_f, O_{f'}$ have the same image or have disjoint images, given a promise that either is the case. Set Equality can be easily reduced to Index Erasure via the swap test, increasing the number of oracle queries by at most a constant factor; therefore, when Midrijānis presented an $\Omega((n/\log n)^{1/5})$ lower bound on the quantum query complexity of Set Equality [16], the same lower bound automatically applied to Index Erasure, ruling out the existence of poly-logarithmic query algorithms for these two problems.

Quantum state generation comes in two forms: the *coherent state generation*, where all memory aside from the target state must return to its initial state, $|\mathbf{0}\rangle := |0 \cdots 0\rangle$, and the *non-coherent state generation*, where there is no such a requirement, namely, where the ancillary memory can remain in some function-dependent state $|t_f\rangle$. Ambainis, Magnin, Roetteler, and Roland devised the *hybrid adversary method* [2], which they used to prove a tight $\Omega(\sqrt{n})$ lower bound for Index Erasure in the *coherent* regime, and left the non-coherent case as an open question. Later, the lower bound for Set Equality was improved to a tight $\Omega(n^{1/3})$ [26, 4], which in turn led to an improved query lower bound for the non-coherent Index Erasure.

In this paper, we close the gap for the non-coherent Index Erasure problem, by proving a tight lower bound on its quantum query complexity under the condition that the range of the black-box function f is sufficiently large. More formally, we show the following.

▶ **Theorem 1** (Main Result). *The bounded-error quantum query complexity of* Index Erasure *is* $\Theta(\sqrt{n})$ *in the non-coherent state generation regime, provided that* $m \geq n^{3\sqrt{n}}$.

To the best of our knowledge, the proof of Theorem 1 is the first application of the general adversary method of Lee, Mittal, Reichardt, Špalek, and Szegedy [15] for a non-coherent state generation problem. We outline the proof below.

1.1 Outline of the Proof of the Main Result

The symmetries of Index Erasure are paramount in our proof. The product $S_n \times S_m$ of two symmetric groups act on a function $f\colon [n] \to [m]$ as $(\pi, \rho)\colon f \mapsto \rho * f * \pi^{-1}$, where $(\pi, \rho) \in S_n \times S_m$ and $*$ denotes the composition of functions. This group action on injective functions defines a representation of $S_n \times S_m$. This representation is multiplicity-free, meaning that it contains no more than one instance of any irrep (irreducible representation) of $S_n \times S_m$. Moreover, it consists of those and only those irreps $\lambda \otimes \lambda'$ where the Young diagram $\lambda \vdash n$ is contained in the Young diagram $\lambda \vdash m$ and the skew shape λ'/λ has no more than one cell per column. Throughout the paper, we often abuse the terminology and we interchangeably use the terms partition λ of n, denoted $\lambda \vdash n$, the Specht module corresponding to λ (which is irreducible and distinct for every λ), and the n-cell Young diagram corresponding to λ.

Two types of irreps are of particular interest to us. Given $\lambda \vdash n$, we call the irrep $\lambda \otimes \bar{\lambda}$ where $\bar{\lambda} \vdash m$ is obtained from λ by adding $m-n$ cells to the first row of λ a *minimal* irrep and the irrep $\lambda \otimes (m-n, \lambda)$ where $(m-n, \lambda) \vdash m$ is obtained from λ by adding one cell to each of the first $m-n$ columns of λ (alternatively, by adding the part $m-n$ to λ) a *maximal* irrep, where we assume $m \geq 2n$. In other words, if $\theta \vdash k$ and $\lambda := (n-k, \theta) \vdash n$, then $(n-k, \theta) \otimes (m-k, \theta)$ is a minimal irrep and $(n-k, \theta) \otimes (m-n, n-k, \theta)$ is a maximal irrep. In particular, to lower bound the quantum query complexity of the non-coherent Index Erasure, we use essentially the same adversary matrix Γ as [2] used for the coherent Index Erasure, which is specified through minimal irreps.

An adversary matrix is a symmetric real matrix whose rows and columns are labeled by all the functions in the domain of the problem, and it is the central object of most adversary methods. In our case, the adversary matrix acts on the same $m^{\underline{n}}$-dimensional space as the representation matrices of $S_n \times S_m$ mentioned above, where $m^{\underline{n}} := m!/(m-n)!$ is the total number of functions. Similarly to [2], we choose

$$\Gamma := \sum\nolimits_{k=0}^{\sqrt{n}} \left(\sqrt{n} - k\right) \sum_{\theta \vdash k} E_{(n-k,\theta)\otimes(m-k,\theta)},$$

where $E_{\lambda\otimes\lambda'}$ is the orthogonal projector on the irrep $\lambda \otimes \lambda'$ (note that we have only used projectors on certain minimal irreps to construct Γ). We also note that the Gram matrices $T_{\lambda\otimes\lambda'} = m^{\underline{n}} E_{\lambda\otimes\lambda'}/d_{\lambda\otimes\lambda'}$, where $d_{\lambda\otimes\lambda'} := \operatorname{tr}[E_{\lambda\otimes\lambda'}]$ is the dimension of $\lambda \otimes \lambda'$, play an important role in our proof.

In order to take advantage of the inherent symmetries of the Index Erasure problem, we first extend the *automorphism principle* of Høyer, Lee, and Špalek [13] to the *general adversary method* for state generation and conversion problems [15] (see Corollary 3 and Theorem 4). This extension leads us to consider the Gram matrix corresponding to the final state $|\psi_f, t_f\rangle$ of an algorithm run with oracle O_f (assuming no error). The Gram matrix corresponding to $|\psi_f\rangle$ is

$$\frac{n}{m} T_{(n)\otimes(m)} + \left(1 - \frac{n}{m}\right) T_{(n)\otimes(m-1,1)} =: T^{\odot},$$

therefore the Gram matrix corresponding to $|\psi_f, t_f\rangle$ is $T^{\odot} \circ T$, where $T_{f,f'} := \langle t_f | t_{f'} \rangle$ and $\circ$ denotes the Schur (i.e., entrywise) matrix product. For the coherent regime lower bound, $\langle \mathbf{0} | \mathbf{0} \rangle = 1$ and $T = J = T_{(n)\otimes(m)}$ is the all-ones matrix. For the non-coherent regime, one of the consequences of the generalization of the automorphism principle is that it suffices to consider T such that $T_{f,f'} = T_{\sigma(f),\sigma(f')}$ for all functions f, f' and all $\sigma \in S_n \times S_m$.

To prove the $\Omega(\sqrt{n})$ lower bound, we must show, for all such Gram matrices T, that

$$\operatorname{tr}\left[\Pi_\Gamma \frac{T^{\odot} \circ T}{m^{\underline{n}}}\right] = o(1), \tag{1.1}$$

where Π_Γ is the orthogonal projector on the image of Γ, and that $\|\Gamma \circ \Delta_x\| = \mathrm{O}(1)$ for all $x \in [n]$, where Δ_x is the binary matrix with $(\Delta_x)_{f,f'} := 1$ if and only if $f(x) \neq f'(x)$.[1] Here we only need to prove the former condition because we use essentially the same adversary matrix as [2], and the latter condition is shown in their work. On the other hand, showing condition (1.1) was a triviality in [2] because $T = J$ in the coherent regime and thus the trace evaluates to n/m.

We now present the three main simplifying steps used to narrow the scope of condition (1.1). First, we use linearity to show that it suffices to prove

$$\operatorname{tr}\left[\Pi_\Gamma \frac{T_{(n)\otimes(m-1,1)} \circ T_{\lambda\otimes\lambda'}}{m^{\underline{n}}}\right] = o(1)$$

for all irreps $\lambda \otimes \lambda'$. That is, we can restrict our attention from a continuum of choices for T to a finite set $\{T_{\lambda\otimes\lambda'}\}_{\lambda\otimes\lambda'}$ of choices, where we have also used that the term $T_{(n)\otimes(m-1,1)}$ "dominates" $T_{(n)\otimes(m)}$ in $T^{\odot}$.

Second, we use the connection between $T_{(n)\otimes(m-1,1)}$ and a specific primitive idempotent of the Johnson (association) scheme to obtain

$$\operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}} \frac{T_{(n)\otimes(m-1,1)} \circ T_{\lambda\otimes\lambda'}}{m^{\underline{n}}}\right] = o(1)$$

as a sufficient condition, where we have to consider only Young diagrams $\lambda \vdash n$ that have less than $\sqrt{n}$ cells below the first row.

Third, for such λ, we show that the dimension of $\lambda\otimes\bar{\lambda}$ is much smaller than the dimension of any other $\lambda \otimes \lambda'$ (thus the nomenclature "minimal irrep"); therefore, we show it suffices to prove

$$\operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}} \frac{T_{(n)\otimes(m-1,1)} \circ T_{\lambda\otimes\bar{\lambda}}}{m^{\underline{n}}}\right] = o(1). \tag{1.2}$$

It is convenient to think of (1.1) and its simplifications in terms of the following association scheme. For a pair of functions (f, f'), consider the orbit $\mathcal{O}_\mu := \{(\sigma(f), \sigma(f')) \colon \sigma \in S_n \times S_m\}$, and let A_μ be the binary matrix with $(A_\mu)_{h,h'} = 1$ if and only if $(h, h') \in \mathcal{O}_\mu$. Here we use μ to label distinct orbits and let $\mathcal{C}_n$ be the set of all of them. The set of matrices $\{A_\mu \colon \mu \in \mathcal{C}_n\}$ forms a symmetric association scheme, denoted $\mathcal{A}_{n,m}$, which we call the *partial permutation scheme* due to the bijection $f \leftrightarrow (f(1), f(2), \cdots, f(n))$ between injective functions $f \colon [n] \to [m]$ and n-partial permutations of $[m]$.

In the terminology of (commutative) association schemes, the projectors $E_{\lambda\otimes\lambda'}$ are called the *primitive idempotents*, and their entries corresponding to the orbit $\mathcal{O}_\mu$ multiplied by $m^{\underline{n}}$ are called *dual eigenvalues* of the association scheme, which we denote as $q_{\lambda\otimes\lambda'}(\mu)$. The *valency* $v_\mu^{(m)}$ is the size of $\mathcal{O}_\mu$ divided by $m^{\underline{n}}$, thus, in terms of dual eigenvalues, the left hand side of condition (1.2) can be written as

$$\frac{\sum_{\mu\in\mathcal{C}_n} v_\mu^{(m)} \cdot q_{(n)\otimes(m-1,1)}(\mu) \cdot q^2_{\lambda\otimes\bar{\lambda}}(\mu)}{m^{\underline{n}} d_{(n)\otimes(m-1,1)} d_{\lambda\otimes\bar{\lambda}}}. \tag{1.3}$$

[1] The terms in condition (1.1) and similar expressions are written in such a way to emphasize that $\frac{T^{\odot}\circ T}{m^{\underline{n}}}$ is a density operator.

One of the crucial results of our paper relates the dual eigenvalues corresponding to a minimal irrep $(n-k,\theta)\otimes(m-k,\theta)$ in the $\mathcal{A}_{n,m}$ scheme to the dual eigenvalues corresponding to the maximal irrep $\theta\otimes(n-k,\theta)$ in the $\mathcal{A}_{k,n}$ scheme, where $\theta\vdash k$. This relation allows us to express the terms under the sum in (1.3) as polynomials in m. The condition $m\geq n^{3\sqrt{n}}$ in Theorem 1 ensures that it suffices to restrict the sum to those $\mu\in\mathcal{C}_n$ whose corresponding polynomials are of maximum degree, and for such μ, we relate their valencies $v_\mu^{(m)}$ in the $\mathcal{A}_{n,m}$ scheme to valencies of the $\mathcal{A}_{k,n}$ scheme, which together with certain properties of dual eigenvalues allow us to obtain the desired bound.

1.2 Additional Results on the Partial Permutation Scheme

In the context of quantum query complexity, the partial permutation association scheme was already considered in [21], where a conjecture on its eigenvalues implied tight adversary bounds for the Collision and Set Equality problems. Along these lines, our work shows a connection between quantum query complexity and the *Krein parameters* $q_{i,j}(k)$ of association schemes (see Section 5 for a formal definition). Indeed, condition (1.2) is equivalent to the conditions

$$q_{\lambda\otimes\bar{\lambda},\,\lambda\otimes\bar{\lambda}}((n)\otimes(m-1,1))=o(d_{\lambda\otimes\bar{\lambda}})\quad\text{and}\quad q_{\lambda\otimes\bar{\lambda},\,(n)\otimes(m-1,1)}(\lambda\otimes\bar{\lambda})=o(m)$$

on the Krein parameters of $\mathcal{A}_{n,m}$, and (1.3) gives an expression of these parameters in terms of dual eigenvalues.

The Krein parameters of an association scheme are important because they are the *dual structure constants* of its corresponding *Bose-Mesner algebra*. While the structure constants of Bose-Mesner algebras admit an obvious combinatorial meaning, its dual structure constants do not (e.g., they can be irrational) and are difficult to interpret. Indeed, the question of whether or not there exists a "good" interpretation of these constants has been asked often in algebraic combinatorics, so it seems interesting that we are able to relate these constants to the quantum query complexity of suitably symmetric state generations problems in the non-coherent regime. We are unaware of any previously known connection between quantum computing and the Krein parameters of association schemes.

Aside from computer science, we believe that the partial permutation scheme is of independent interest in combinatorics, as it generalizes both the Johnson scheme and the conjugacy class scheme of S_n. We include other new results on the partial permutation association scheme in the appendix, including a procedure that facilitates the calculation of dual eigenvalues corresponding to maximal irreps when $m\gg n$. We are unaware of any previously known results on the dual eigenvalues or Krein parameters of the partial permutation association scheme.

1.3 Organization of the paper

The paper is organized as follows. In Section 2, we present preliminaries on the quantum query model, with emphasis on state generation problems, including Index Erasure, the general adversary method, and the automorphism principle. In Section 3, we present preliminaries on the representation theory, particularly focusing on the symmetric group and its action on partial permutations. The automorphism principle of the general adversary method requires us to analyze highly symmetric matrices, which are elements of the Bose–Mesner algebra corresponding to the partial permutation scheme. In Section 4, we formally define this association scheme, establishing the labeling of various its parameters and computing some of them, as well as addressing its connection to the Johnson scheme. With this formalism at

our disposal, in Section 5, we show that the proof for $\Omega(\sqrt{n})$ lower bound on the quantum query complexity of the non-coherent INDEX ERASURE can be reduced to upper bounds on certain Krein parameter of the partial permutation scheme. Finally, we place the required bounds on these Krein parameters in Section 6. We defer some proofs and additional results on the partial permutation scheme to the appendix.

2 Quantum state generation

In this paper, we address limitations of quantum query algorithms for solving the INDEX ERASURE problem. We assume that the reader is familiar with foundations of quantum computing (see [18] for an introductory reference), some of which we review here. The basic memory unit of a quantum computer is a qubit, which is a two-dimensional complex Euclidean space $\mathbb{C}[\{0,1\}]$ having *computational* orthonormal basis $\{|0\rangle, |1\rangle\}$. Similarly, a k-qubit system corresponds to Euclidean space $\mathbb{C}[\{0,1\}^k]$ and it has computational basis $\{|b\rangle : b \in \{0,1\}^n\}$. Unit vectors $|\Psi\rangle \in \mathbb{C}[\{0,1\}^k]$ are called (pure) *quantum states* and they represent superpositions over various computations basis states.

Quantum bits are often grouped together in *registers* for the ease of algorithm design and analysis. If $|\psi\rangle, |\phi\rangle$ are states of two registers, then the state of the joint system is $|\psi\rangle \otimes |\phi\rangle$. We often shorten the notation $|\psi\rangle \otimes |\phi\rangle$ to $|\psi\rangle |\phi\rangle$ or $|\psi, \phi\rangle$. Due to *entanglement*, not always the state of the joint system can be written as a tensor product of states of the individual registers.

Quantum information is processed by unitary transformations, which correspond to square matrices U such that $UU^* = U^*U = I$, and they map quantum states to quantum states. This unitary processing of quantum information implies that any (noiseless) quantum computation is reversible.

2.1 Quantum query model

In the oracle model, we are given an access to a black-box oracle O_f that evaluates some unknown function $f\colon [n] \to [m]$. The goal of a query algorithm is to perform some computational task that depends on f, for example, to compute some function of f, such as $\textsc{Parity}(f) := f(1) \oplus f(2) \oplus \cdots \oplus f(n)$ when $m = 2$. In quantum computing, one can query the oracle in superposition. On the other hand, due to the requirement for reversibility, the oracle is typically designed so that it preserves the input query x. Namely, given $|x, y\rangle$ as an input, the oracle O_f outputs $|k, y \oplus f(x)\rangle$ (see Figure 1). Here and below we may assume $x, y, f(x)$ to be represented in binary. Even if f is injective – as it is for INDEX ERASURE – unless one knows how to compute the inverse of f, implementing $|x\rangle \mapsto |f(x)\rangle$ in practice might be much harder than $|x, y\rangle \mapsto |k, y \oplus f(x)\rangle$.

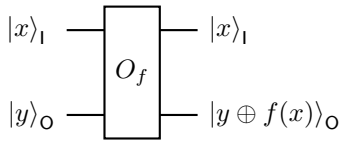

Figure 1 A schematic of a quantum oracle O_f. We assume that y and $f(x)$ are encoded in binary, and thus O_f is its own inverse.

A quantum query algorithm with oracle O_f consists of

- four registers: the input and output registers I and O for accessing the black-box function f, the target register T for storing the result of the computation, and an additional workspace register W;
- an indexed sequence of unitary transformations $U_0, U_1, \cdots, U_Q$ acting on those four registers.

The quantum query algorithm starts its computation in state $|\mathbf{0}\rangle := |00\cdots0\rangle$, and then performs $2Q+1$ unitary operations, alternating between U_i, which acts on all the registers, and O_f, which acts on registers IO. Thus the final state of the computation is

$$|\Psi_f\rangle := U_Q(O_f \otimes I_{\mathsf{TW}})U_{Q-1}(O_f \otimes I_{\mathsf{TW}})\cdots U_1(O_f \otimes I_{\mathsf{TW}})U_0\,|\mathbf{0}\rangle\,,$$

where I_{TW} is the identity operator on registers TW. Figure 2 gives a schematic of a quantum query algorithm. Note that Q is the number of oracle queries performed by the algorithm, and we also refer to it as the *query complexity of the algorithm*.

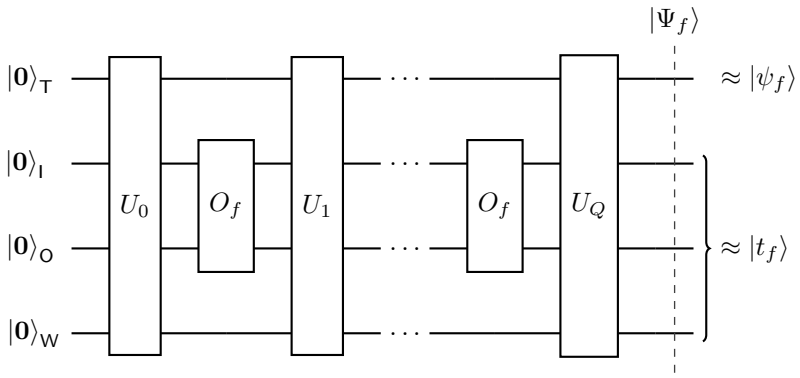

Figure 2 A schematic of a quantum algorithm that uses an oracle O_f. The registers labeled $\mathsf{T}, \mathsf{I}, \mathsf{O}, \mathsf{W}$ are, respectively, the target, input, output, and workspace registers of the algorithm. The target register of the final state $|\Psi_f\rangle$ of the algorithm should be in a state close to the target state $|\psi_f\rangle$.

In this paper we are interested in quantum query algorithms whose goal is to generate a specific f-dependent state $|\psi_f\rangle$ by accessing f via O_f. We note that this generalizes classical function evaluation by a quantum algorithm, where each $|\psi_f\rangle$ is asked to be a computational basis vector. In the next section we describe two distinct regimes of quantum state generation, as well as why they are exactly the same for classical function evaluation.

2.2 Coherent vs. Non-coherent State Generation

When we talk about quantum state generation with oracle O_f, we implicitly assume the domain $[n]$ and the range $[m]$ of f to be fixed. A *quantum state generation* problem is thus specified by a subset $\mathcal{F}$ of functions in form $f\colon [n] \to [m]$, which we call the *domain of the problem*, a complex Euclidean space called the *target space*, and, for every $f \in \mathcal{F}$, a quantum state $|\psi_f\rangle$ in the target space called the *target state*.

One may consider quantum state generation in two regimes: coherent and non-coherent. In the *coherent* state generation regime, all the computational memory other than the target register (i.e., registers IOW) must be returned to its initial state $|\mathbf{0}\rangle$. Therefore, if one was running an algorithm for a superposition of oracles, the final quantum state would be a

superposition of the target states. In contrast, for *non-coherent* state generation, one does not place any requirements on the ancillary memory. More precisely, in the coherent case, for every input $f \in \mathcal{F}$ we require that the final state $|\Psi_f\rangle$ satisfies

$$\Re\langle\psi_f, \mathbf{0}|\Psi_f\rangle \geq \sqrt{1-\epsilon},$$

where $|\mathbf{0}\rangle$ is the initial state of the ancillary registers and a constant $\epsilon \geq 0$ is the desired precision [15] and $\Re$ denotes the real part of the number it precedes. We call the minimum among quantum query complexities among quantum query algorithms that achieve this task the *(ϵ-error) quantum query complexity of the coherent version of the problem*. On the other hand, in the non-coherent case, the final state $|\Psi_f\rangle$ has to satisfy

$$\|(\langle\psi_f| \otimes I)|\Psi_f\rangle\| = \max_{|t_f\rangle} \Re\langle\psi_f, t_f|\Psi_f\rangle \geq \sqrt{1-\epsilon},$$

where the maximum is over unit vectors $|t_f\rangle$ on the system of registers IOW [15], and we analogously define the quantum query complexity of the non-coherent version of the problem.

It is worth noting that evaluation of classical functions can be considered as a special case of quantum state generation, where one is asked to prepare the computational basis state $|\psi_f\rangle$. Since quantum mechanics permits cloning of orthogonal states (computational basis states, in this case), there is no difference between coherent and non-coherent function evaluation, if one is willing to tolerate a two-fold increase in query complexity: at the end of a non-coherent computation, one can copy the target register into an additional register, and then run the whole computation in reverse, restoring all but this additional register to their initial state.

Also, note that an algorithm for the coherent case of a problem solves its non-coherent case as well. Looking on it from the other side: a lower bound on the non-coherent version of the problem is a lower bound on the coherent version as well.

2.3 Index Erasure

The domain of Index Erasure is the set of all injective functions $f\colon [n] \to [m]$. These functions are in one-to-one correspondence with n-partial permutations of $[m]$ and thus $|\mathcal{F}| = m^{\underline{n}} := m!/(m-n)!$. Index Erasure is the task of preparing the quantum state that is the uniform superposition

$$|\psi_f\rangle := \frac{1}{\sqrt{n}} \sum_{x=1}^{n} |f(x)\rangle$$

over the image of f. Note that the state

$$\frac{1}{\sqrt{n}} \sum_{x=1}^{n} |x\rangle|f(x)\rangle$$

can be prepared using a single query to O_f. This would give us the superposition that we seek if we could only ignore or *erase* the first register that records the *index* x, which gives the problem its namesake.

The question of the complexity of Index Erasure was first raised by Shi [23]. As for the upper bound, there is a simple quantum query algorithm for coherent Index Erasure given access to O_f. Thinking of the injective function f as a database with entries in $[m]$, for any $y \in [m]$ we may use Grover's algorithm with O_f to find the unique index x of f such that $f(x) = y$. In other words, there is a circuit that sends the superposition

$$\frac{1}{\sqrt{n}}\sum_{x=1}^{n}|f(x)\rangle \quad \text{to} \quad \frac{1}{\sqrt{n}}\sum_{x=1}^{n}|x\rangle|f(x)\rangle.$$

Inverting this circuit effectively "erases" the index register, which implies that the quantum query complexity of Index Erasure is $\mathrm{O}(\sqrt{n})$.

The first non-trivial lower bounds on the quantum query complexity of Index Erasure were obtained via the Set Equality problem, which asks to decide whether two injective functions f, f' given via black-box oracles $O_f, O_{f'}$ have the same image or have disjoint images, given a promise that either is the case. Set Equality can be easily reduced to non-coherent (and, thus, coherent too) Index Erasure via the swap test, increasing the number of oracle queries by at most a constant factor. Thus, when Midrijānis presented an $\Omega((n/\log n)^{1/5})$ lower bound on the quantum query complexity of Set Equality [16], the same lower bound automatically applied to Index Erasure. Ambainis, Magnin, Roetteler, and Roland devised the *hybrid adversary method* [2], which they used to prove a tight $\Omega(\sqrt{n})$ lower bound for Index Erasure in the *coherent* regime, and left the non-coherent case as an open question. Later, the lower bound for Set Equality was improved to a tight $\Omega(n^{1/3})$ [26, 4], which in turn led to an improved query lower bound for the non-coherent Index Erasure.

The focus of this work is to prove a tight lower bound on the quantum query complexity of Index Erasure in the *non-coherent* case. To show this, we use the so-called *general adversary method* [15] which we review in Section 2.4.

Finally, we note that if one were able to solve Index Erasure using poly-logarithmic number of queries, one would obtain a time-efficient algorithm for Graph Isomorphism. In Appendix A we refer to two similar tests for Graph Isomorphism based on Index Erasure, one on the coherent version, one on the non-coherent version of the problem. However, Midrijānis' lower bound on Set Equality ruled out efficiency of such tests.

2.4 General Adversary Method

The general adversary method places optimal lower bounds on the quantum query complexity of any state conversion problem [15]. State conversion problems generalize state generation problems, yet in this paper it will suffice to introduce the adversary bound only for the latter.

The general adversary bound is stated via the γ_2 and filtered γ_2 norms, which are defined as follows. Let M be any matrix and let $\Delta = \{\Delta_x \colon x \in [n]\}$ be a family of matrices of the same dimensions as M. Define

$$\begin{aligned}\gamma_2(M) &:= \max_{\Gamma'}\{\|M \circ \Gamma'\| \colon \|\Gamma'\| \le 1\},\\ \gamma_2(M|\Delta) &:= \max_{\Gamma}\left\{\|M \circ \Gamma\| \colon \max_{x\in[n]}\|\Delta_x \circ \Gamma\| \le 1\right\},\end{aligned}$$

where $\circ$ denotes the Schur (i.e., entrywise) product of two matrices and, thus, Γ and Γ' are required to have the same dimensions as M. One can show that $\gamma_2(\cdot)$ is a norm over the set of all matrices and $\gamma_2(\cdot|\Delta)$ is a norm over the set of matrices M that has $M_{f,f'} = 0$ whenever $(\Delta_x)_{f,f'} = 0$ for all $x \in [n]$ (see [15] for details). The two norms are called the γ_2 *norm* and the *filtered* γ_2 *norm*, respectively.

The general adversary bound employs various real symmetric matrices whose rows and columns are labeled by black-box functions $f \in \mathcal{F}$ in the same order. The family of *difference matrices* Δ is defined as follows. For each $x \in [n]$, the Δ_x is a binary matrix such that

$(\Delta_x)_{f,f'} := 1$ if and only if $f(x) \neq f'(x)$. A *state matrix* is any positive-semidefinite matrix T such that $T \circ I = I$. In other words, it is a Gram matrix corresponding to some family of unit vectors. Note that $\gamma_2(\cdot|\Delta)$ is a norm on the set of matrices whose diagonals are all-zeros, and a difference of any two state matrices belongs to this set.

Let $\mathcal{T}$ be the set of all state matrices. Note that $\mathcal{T}$ is a compact set and it is closed under the Schur product. Two particular state matrices of our interest are the all ones matrix J, which corresponds to the family $\{|\mathbf{0}\rangle : f \in \mathcal{F}\}$, and the *target matrix* $T^{\odot}$ defined as $(T^{\odot})_{f,f'} := \langle\psi_f|\psi_{f'}\rangle$.

Theorem 2 is a special case of [15, Theorem 4.9].

▶ **Theorem 2.** *The ϵ-error quantum query complexity of a non-coherent state generation problem with the target matrix $T^{\odot}$ and the family of difference matrices Δ is both*

$$\Omega\big(\mathsf{Adv}_{2\sqrt{2\epsilon}}\big) \quad \textit{and} \quad \mathrm{O}\big(\mathsf{Adv}_{\epsilon^4/16}\,\epsilon^{-2}\log\epsilon^{-1}\big),$$

where

$$\mathsf{Adv}_{\delta} := \min_{R,T\in\mathcal{T}}\{\gamma_2(J-R|\Delta)\colon \gamma_2(R-T^{\odot}\circ T)\leq\delta\}. \tag{2.1}$$

In the case of coherent state generation, one imposes $T = J$ in the expression for Adv_{δ}.

In the expression for Adv_{δ}, the state matrix T essentially corresponds to the ancillary states that are prepared in addition to the target states. Thus, assuming there were no error, $T^{\odot} \circ T$ would be the Gram matrix corresponding to the final states of the whole system. However, since one allows some error – determined by the parameter δ – it suffices that the state matrix R corresponding *exactly* to the final states of the algorithm is close to $T^{\odot} \circ T$.

When applying the adversary bound, it is convenient to actually apply it to the zero-error case therefore eliminating the matrix R from the consideration. In particular, this leads to the following corollary of Theorem 2.

A symmetric matrix Γ that satisfies $\|\Delta_x \circ \Gamma\| \leq 1$ for all x is called an *adversary matrix*. Let Π_{Γ} denote the orthogonal projector on the image of Γ.

▶ **Corollary 3.** *Let Γ be an adversary matrix for a non-coherent state generation problem with the target matrix $T^{\odot}$ and the family of difference matrices Δ, let ω be a principal eigenvector of Γ of norm 1, and let*

$$\eta' := \max_{T\in\mathcal{T}} \omega^{\top}(T^{\odot}\circ T\circ\Gamma/\|\Gamma\|)\,\omega.$$

The ϵ-error quantum query complexity of the problem is

$$\Omega\big((1-\eta'-2\sqrt{2\epsilon})\,\|\Gamma\|\,\big).$$

If ω is a uniform superposition over $\mathcal{F}$, then $\eta' \leq \eta$ for

$$\eta := \max_{T\in\mathcal{T}} \mathrm{tr}\left[\Pi_{\Gamma}(T^{\odot}\circ T)/|\mathcal{F}|\right].$$

Proof. For the first part of the corollary, suppose $R, T \in \mathcal{T}$ satisfy $\gamma_2(R - T^{\odot} \circ T) \leq 2\sqrt{2\epsilon}$ and are thus a feasible solution to the minimization in $\mathsf{Adv}_{2\sqrt{2\epsilon}}$. We have

$$\begin{aligned}
\gamma_2(J-R|\Delta) \geq& \|(J-R)\circ\Gamma\| \\
\geq& \|(J-T^{\odot}\circ T)\circ\Gamma\| - \|\Gamma\|\big\|(R-T^{\odot}\circ T)\circ\Gamma/\|\Gamma\|\big\| \\
\geq& \,\omega^{\top}\Gamma\,\omega - \omega^{\top}(T^{\odot}\circ T\circ\Gamma)\,\omega - 2\sqrt{2\epsilon}\|\Gamma\| \\
\geq& (1-\eta'-2\sqrt{2\epsilon})\|\Gamma\|.
\end{aligned}$$

For the second part, note that, if ω is a uniform superposition over $\mathcal{F}$, then, for any two symmetric $|\mathcal{F}| \times |\mathcal{F}|$ matrices M, M', we have $\omega^\top (M \circ M')\, \omega = \operatorname{tr}[MM']/|\mathcal{F}|$. The inequality $\eta' \leq \eta$ results from both $T^\odot \circ T$ and $\Pi_\Gamma - \Gamma/\|\Gamma\|$ being positive-semidefinite. ◀

2.5 Automorphism Principle for State Generation

The *automorphism principle* of [13] addresses the adversary bound for function evaluation problems and states that, without loss of generality, the optimal adversary matrix can be required to respect symmetries of the problem. Here we generalize the automorphism principle to state generation problems.[2]

The wreath product $S_m \wr S_n$ of groups S_m and S_n is the group whose elements are $(\pi, \boldsymbol{\sigma}) \in S_n \times S_m^n$ and whose group operation is

$$\big(\pi', (\sigma'_1, \cdots, \sigma'_n)\big)\big(\pi, (\sigma_1, \cdots, \sigma_n)\big) = \big(\pi'\pi, (\sigma'_1 \sigma_{(\pi')^{-1}(1)}, \cdots, \sigma'_n \sigma_{(\pi')^{-1}(n)})\big)$$

(see [14, Ch. 4]). Similarly to (3.1) below, the action of $S_m \wr S_n$ on $f\colon [n] \to [m]$ is given by

$$\big((\pi, \boldsymbol{\sigma}) f\big)(x) = \sigma_x(f(\pi^{-1}(x)) \qquad \text{for all } x \in [n]. \tag{2.2}$$

The action of a subgroup $G \leq S_m \wr S_n$ on the set of black-box functions $\mathcal{F}$ is *closed* if $g(f) \in \mathcal{F}$ for all $f \in \mathcal{F}$ and $g \in G$.

Suppose M is a symmetric $|\mathcal{F}| \times |\mathcal{F}|$ matrix whose rows and columns are labeled by $f \in \mathcal{F}$ in the same order and suppose the action of a subgroup $G \leq S_m \wr S_n$ on $\mathcal{F}$ is closed. We say that M is *G-invariant* if $M_{g(f),g(f')} = M_{f,f'}$ for all $f, f' \in \mathcal{F}$ and $g \in G$. Similarly, a vector $\omega \in \mathbb{C}[\mathcal{F}]$ is G-invariant if $\omega_{g(f)} = \omega_f$ for all $f \in \mathcal{F}$ and $g \in G$. A subgroup G is an *automorphism group* for a state generation problem with a target matrix $T^\odot$ if G's action on $\mathcal{F}$ is closed and $T^\odot$ is G-invariant.[3]

Note that the free product of two automorphism groups is an automorphism group, so one can consider the maximum automorphism group of a problem. For example, the maximum automorphism group of Parity is the whole wreath product $S_2 \wr S_n$ while the maximum automorphism groups of Or and Index Erasure are, respectively,

$$\{(\pi, (\varepsilon, \cdots, \varepsilon))\colon \pi \in S_n\} \cong S_n,$$
$$\{(\pi, (\sigma, \cdots, \sigma))\colon \pi \in S_n \,\&\, \sigma \in S_m\} \cong S_n \times S_m,$$

where ε is the identity permutation in S_2.

▶ **Theorem 4.** *Let G be an automorphism group for a non-coherent state generation problem. The value of Adv_δ remains the same if one restricts the minimization in the expression defining Adv_δ and the maximization in the expressions defining the γ_2 and filtered γ_2 norms to R, T, Γ, Γ' that are all G-invariant and imposes that $(J - R) \circ \Gamma$ has an G-invariant principal eigenvector.*

The proof of Theorem 4 considers two type of symmetrizations of matrices R, T, Γ, Γ', depending on whether they are arguments in a minimization or a maximization. We defer the proof to Appendix D.

[2] One can easily see that the automorphism principle generalizes even further to state conversion problems.
[3] The G-invariance of $T^\odot$ is equivalent to the existence of a unitary representation U_g of G acting on the target space such that $U_g|\psi_f\rangle = |\psi_{g(f)}\rangle$ for all $f \in \mathcal{F}$ and $g \in G$.

Note that the ability to restrict T and Γ to be G-invariant carries over from Theorem 2 to Corollary 3. The ability to restrict T will be paramount in our proof (see Section 5). On the other hand, the ability to restrict Γ is optional. Namely, Corollary 3 provides an adversary bound regardless of what restrictions one imposes on Γ, yet for too strict restrictions this bound would not be optimal.

For Index Erasure, it is convenient to think of every black-box function $f \in \mathcal{F}$ as a n-partial permutation over the set of symbols $[m]$. As observed in [2], the set of $|\mathcal{F}| \times |\mathcal{F}|$ matrices indexed by $\mathcal{F}$ that are $(S_n \times S_m)$-invariant under the aforementioned action (2.2) afford a *commutative matrix algebra*. In particular, it is the Bose–Mesner algebra of a symmetric association scheme defined over partial permutations, which we formally define in Section 4.

3 Representation Theory Preliminaries

Our main result builds upon finite group representation theory, especially that of the symmetric group. We refer the reader to [6] for a more thorough introduction to group representation theory and [22] for more details on the representation theory of the symmetric group. Throughout this section, let $H, K \leq G$ be subgroups of a finite group G, let $\mathcal{V}$ be a finite-dimensional vector space over $\mathbb{C}$, and for any set X, let $\mathbb{C}[X]$ denote the vector space of dimension $|X|$ of complex-valued functions over X.

3.1 The Representation Theory of the Symmetric Group

A *representation* $(\phi, \mathcal{V})$ of a finite group G is a homomorphism $\phi : G \to GL(\mathcal{V})$ where $GL(\mathcal{V})$ is the *general linear group*, that is, the group of $(\dim \mathcal{V}) \times (\dim \mathcal{V})$ invertible matrices. It is customary to be less formal and denote the representation $(\phi, \mathcal{V})$ simply as ϕ when $\mathcal{V}$ is understood, or as $\mathcal{V}$ when ϕ is understood. For any representation ϕ, we define its *dimension* to be $d_\phi := \dim \phi := \dim \mathcal{V}$. When working concretely with a representation ϕ, we abuse terminology and let $\phi(g)$ refer to a $(\dim \phi) \times (\dim \phi)$ matrix realization of ϕ. Two representations ρ, ϕ are *equivalent* if there exists a matrix P such that $\rho(g) = P^{-1}\phi(g)P$ for all $g \in G$.

Let $(\phi, \mathcal{V})$ be a representation of G, and let $\mathcal{W} \leq \mathcal{V}$ be a *G-invariant* subspace, that is, $\phi(g)w \in \mathcal{W}$ for all $w \in \mathcal{W}$ and for all $g \in G$. We say that $(\phi|_{\mathcal{W}}, \mathcal{W})$ is a *subrepresentation* of ϕ where $\phi|_{\mathcal{W}}$ is the restriction of ϕ to the subspace $\mathcal{W}$. A representation $(\phi, \mathcal{V})$ of G is an *irreducible representation* (or simply, a *G-irrep*) if it has no proper subrepresentations. The *trivial representation* $(1, \mathbb{C})$ defined such that $1 : g \to 1$ for all $g \in G$ is clearly an irrep of dimension one for any group G.

It is well-known that there is a bijection between the set of inequivalent G-irreps and its conjugacy classes $\mathcal{C}$, and that any representation $\mathcal{V}$ of G decomposes uniquely as a direct sum of inequivalent G-irreps

$$\mathcal{V} \cong \bigoplus_{i=1}^{|\mathcal{C}|} m_i \mathcal{V}_i$$

where m_i is the number of occurrences of the G-irrep $\mathcal{V}_i$ in the decomposition. We call the representation $m_i\mathcal{V}_i$ the *ith isotypic component* of $\mathcal{V}$.

A natural way to find representations of groups is to let them act on sets. In particular, for any group G acting on a set X, let $(\phi, \mathbb{C}[X])$ be the *permutation representation* of G on X defined such that

$$(\phi(g)[\zeta])(x) := \zeta(g^{-1}x)$$

for all $g \in G$, $\zeta \in \mathbb{C}[X]$, and $x \in X$. If we let G act on itself, then we obtain the *left regular representation*, which admits the following decomposition into G-irreps

$$\mathbb{C}[G] \cong \bigoplus_{i=1}^{|\mathcal{C}|} d_{\mathcal{V}_i} \mathcal{V}_i.$$

We denote the *Fourier transform* of $\gamma \in \mathbb{C}[G]$ with respect to the representation ϕ as

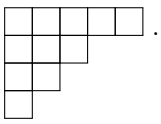
$$\phi(\gamma) := \sum_{g \in G} \gamma(g)\phi(g),$$

which is a linear operator on $\mathcal{V}$.

Let $\mathrm{Sym}(X)$ denote the *symmetric group* on the symbol set X. If $X = [m] := \{1, 2, \cdots, m\}$, then we define $S_m := \mathrm{Sym}(X)$. It is well-known that the conjugacy classes of S_m are given by the cycle-types of permutations of S_m, which in turn are in one-to-one correspondence with *integer partitions* $\lambda \vdash m$, i.e.,

$$\lambda := (\lambda_1, \lambda_2, \cdots, \lambda_k) \vdash m \text{ such that } \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k \geq 0 \text{ and } \sum_{i=1}^{k} \lambda_i = m.$$

We may visualize λ as a *Young diagram*, a left-justified table of cells that contains λ_i cells in the ith row. When referencing a Young diagram, we alias λ as the *shape*. For example, the Young diagram below has shape $(5, 3, 2, 1) \vdash 11$:



A *standard Young tableau* of shape λ is a Young diagram with unique entries from $[n]$ that are strictly increasing along rows and strictly increasing along columns, e.g.,

1	2	5	8	9
3	6	7		
4	10			
11				

We may write the left regular representation of S_m as

$$\mathbb{C}[S_m] \cong \bigoplus_{\lambda \vdash m} d_\lambda \mathcal{V}_\lambda.$$

where d_λ is the number of standard Young tableau of shape λ, which can be counted elegantly via the *hook rule* (see [22] for a proof).

▶ **Theorem 5** (The Hook Rule). *Let $\lambda \vdash m$, and for any cell $c \in \lambda$ of the Young diagram of λ define the* hook-length $\mathsf{h}_\lambda(c)$ *to be the total number of cells below c in the same column and to the right of c in the same row, plus 1. Then we have*

$$d_\lambda = \frac{m!}{\mathsf{H}(\lambda)} \quad \textit{where} \quad \mathsf{H}(\lambda) := \prod_{c \in \lambda} \mathsf{h}_\lambda(c).$$

Another well-known result is the *branching rule*, which describes how an S_m-irrep decomposes into (S_{m-1})-irreps (see [22] for a proof). We say that a cell of a Young diagram is an *inner corner* if it has no cells to its right and no cells below it.

▶ **Theorem 6** (The Branching Rule). *If $\mathcal{V}_\lambda$ is a S_m-irrep, then*

$$\mathcal{V}_\lambda \cong \bigoplus_{\lambda^-} \mathcal{V}_{\lambda^-}$$

where λ^- ranges over all shapes obtainable by removing an inner corner from λ and $\mathcal{V}_{\lambda^-}$ is the corresponding (S_{m-1})-irrep.

The hook rule and the branching rule can be used to prove the following theorem. We defer its proof to Appendix D.

▶ **Theorem 7.** *Let $\theta \vdash k$ and $\theta^+ \vdash (k+1)$ be any shape obtained by adding an inner corner to θ. For all $m \geq 2(k+1)$, we have*

$$\frac{d_{(m-k-1,\theta^+)}}{d_{(m-k,\theta)}} \geq \frac{m}{k} \cdot \left(1 - \frac{2k+1}{m}\right).$$

Note that the above fraction is greater than 1 when $m > 3k+1$. For any $\lambda = (\lambda_1, \lambda_2, \cdots, \lambda_\ell) \vdash n$, henceforth, let $\bar{\lambda} := (\lambda_1 + (m-n), \lambda_2, \cdots, \lambda_\ell) \vdash m$. Theorem 7 has the following corollary.

▶ **Corollary 8.** *Let $\lambda \vdash n$ be a shape such that $\lambda_1 \geq n - \sqrt{n}$ and let $\lambda' \vdash m$ be any shape that covers λ such that λ'/λ is a horizontal strip. Then $d_{\lambda'}/d_{\bar{\lambda}} \in \Omega(m/\sqrt{n})$.*

3.2 The Representation Theory of Partial Permutations

Let $S_{n,m}$ denote the collection of *n-partial permutations of* $[m]$, that is, n-tuples

$$f := (f(1), f(2), \cdots, f(n))$$

with no repeated elements such that $f(x) \in [m]$ for all $x \in [n]$. Injective functions from $[n]$ to $[m]$ are in one-to-one correspondence with $S_{n,m}$, and it is not hard to see that $|S_{n,m}| = m^{\underline{n}}$, and when $m = n$ we recover the symmetric group S_n on n symbols. To understand the representation theory of $S_{n,m}$ we must first broaden our Young tableau vocabulary.

For any $\lambda \vdash m$, let $l(\lambda)$ denote the *length* of λ, that is, the number of parts in the partition. We say that a shape λ *covers* a shape μ if $\mu_i \leq \lambda_i$ for each i. If λ and μ are two shapes such that λ covers μ, then we obtain the *skew shape* λ/μ by removing the cells corresponding to μ from λ. For instance, the shape $(5,3,2,1)$ covers $(2,2,1)$, so we may consider the skew shape $(5,3,2,1)/(2,2,1)$:

A skew shape is a *horizontal strip* if each column has no more than one cell. For example, the skew shape $(5,3,2,1)/(3,3,1)$ is a horizontal strip, but the skew shape above is not.

Henceforth, we let $S_n \times S_m$ act on $S_{n,m}$ as follows:

$$(\tau, \sigma) \cdot (f_1, \cdots, f_n) = (\sigma^{-1}(f_{\tau^{-1}(1)}), \cdots, \sigma^{-1}(f_{\tau^{-1}(n)})) \text{ for all } (\tau, \sigma) \in S_n \times S_m. \tag{3.1}$$

The stabilizer of the *identity n-partial permutaton* $f_{\text{id}} := (1, 2, \cdots, n) \in S_{n,m}$ in $S_n \times S_m$ is isomorphic to the group

$$\text{diag}(S_n) \times S_{m-n} = \{(\tau, \tau, \pi) : \tau \in \text{Sym}([n]), \pi \in \text{Sym}(\{n+1, \cdots, m\}).$$

Using Pieri's rule (see [24]), one can show that the permutation representation of $(S_n \times S_m)$ acting on $S_{n,m} \cong (S_n \times S_m)/(\text{diag}(S_n) \times S_{m-n})$ is *multiplicity-free*, that is, its decomposition has at most one copy of any $(S_n \times S_m)$-irrep, as shown in Theorem 9.

▶ **Theorem 9** ([5]). *The complex-valued functions over n-partial permutations $\mathbb{C}[S_{n,m}]$ admits the following decomposition into $(S_n \times S_m)$-irreps:*

$$\mathbb{C}[S_{n,m}] \cong \bigoplus_{\mu,\lambda} \mathcal{V}_\mu \otimes \mathcal{V}_\lambda$$

where μ, λ ranges over all pairs $\mu \vdash n, \lambda \vdash m$ such that λ/μ is a horizontal strip.

Let $\mathrm{Irr}(S_{n,m})$ denote the set of $(S_n \times S_m)$-irreps that appear in Theorem 9. Every multiplicity-free permutation representation gives rise to a commutative association scheme (see [3]), so a consequence of Theorem 9 is the existence a symmetric association scheme $\mathcal{A}_{n,m}$ over $S_{n,m}$ that we call *the partial permutation association scheme*. In Section 4, we discuss this association scheme in more detail.

A coarser decomposition of $\mathbb{C}[S_{n,m}]$ into irreducibles of S_m can be obtained by identifying $S_{n,m}$ with the set of *tabloids* (i.e., Young tableaux with unordered rows) of shape $(m-n, 1^n)$ and applying Young's rule (see [22]). This representation is known as the $(m-n, 1^n)$-*permutation representation*, which we denote as $\mathcal{M}^{(m-n,1^n)}$. Its isotypic components can be determined combinatorially via the *Kostka numbers* $K_{\lambda,\mu}$ (see [22]).

▶ **Theorem 10.** *The complex-valued functions over n-partial permutations $\mathbb{C}[S_{n,m}]$ admits the following decomposition into S_m-irreps:*

$$\mathbb{C}[S_{n,m}] \cong \mathcal{M}^{(m-n,1^n)} \cong \bigoplus_{\lambda \vdash m} K_{\lambda,(m-n,1^n)}\ \mathcal{V}_\lambda.$$

Note that Theorem 9 gives a multiplicity-free orthogonal decomposition of the λ-isotypic component $K_{\lambda,(m-n,1^n)}\mathcal{V}_\lambda$ of $\mathcal{M}^{(m-n,1^n)}$ into $(S_n \times S_m)$-irreps

$$K_{\lambda,(m-n,1^n)}\mathcal{V}_\lambda \cong \bigoplus_{\mu} \mathcal{V}_\mu \otimes \mathcal{V}_\lambda$$

where the sum ranges over all $\mu \vdash n$ such that λ/μ is a horizontal strip.

The following two types of irreps in $\mathrm{Irr}(S_{n,m})$ will be of particular importance.

▶ **Definition 11** (Minimal and Maximal Irreps). *For any $\lambda \vdash n$, the* minimal irrep *and* maximal irrep *(w.r.t. λ) is $\lambda \otimes \bar{\lambda} \in Irr(S_{n,m})$ and $\lambda \otimes (m-n, \lambda) \in Irr(S_{n,m})$ respectively.*

If $\lambda_1 \geq n - \sqrt{n}$, Theorem 7 implies that the minimal and maximial irreps w.r.t. λ are indeed of the least and largest dimension over all irreps of the form $\lambda \otimes \mu \in \mathrm{Irr}(S_{n,m})$ for sufficiently large m.

For $\lambda \vdash m$, let E_λ be the orthogonal projector onto the λ-isotypic component $K_{\lambda,(m-n,1^n)}\mathcal{V}_\lambda$ of $\mathcal{M}^{(m-n,1^n)}$, which we may write as

$$E_\lambda = \frac{d_\lambda}{m!}\mathcal{M}^{(m-n,1^n)}(\overline{\chi_\lambda})$$

where $\mathcal{M}^{(m-n,1^n)}(\overline{\chi}_\lambda) = \sum_{\sigma \in S_m} \chi_\lambda(\sigma^{-1})\mathcal{M}^{(m-n,1^n)}(\sigma)$ is the Fourier transform of the function $\overline{\chi}_\lambda \in \mathbb{C}[S_m]$ with respect to the permutation representation of S_m acting on $S_{n,m}$. In particular, for any $\zeta \in \mathbb{C}[S_{n,m}]$ and $f \in S_{n,m}$, we have

$$[E_\lambda \zeta](f) = \frac{d_\lambda}{m!} \sum_{\sigma \in S_m} \chi_\lambda(\sigma)\zeta(\sigma^{-1} f)$$

using the well-known fact that $\chi_\lambda(\sigma^{-1}) = \chi_\lambda(\sigma)$ for any $\sigma \in S_m$, $\lambda \vdash m$. From our foregoing discussion, we also have that

$$E_\lambda E_{\mu\otimes\lambda} = E_{\mu\otimes\lambda}$$

where $E_{\mu\otimes\lambda}$ is the orthogonal projector onto $(\mathcal{V}_\mu \otimes \mathcal{V}_\lambda)$ for all $(\mu \otimes \lambda) \in \mathrm{Irr}(S_{n,m})$.

For any integer $k \geq 0$, one may think of the following as a "low-frequency" subspace of $\mathbb{C}[S_{n,m}]$ parameterized by k:

$$\mathcal{U}_k := \bigoplus_{\substack{(\mu\otimes\lambda)\in\mathrm{Irr}(S_{n,m}) \\ m-\lambda_1\leq k}} \mathcal{V}_\mu \otimes \mathcal{V}_\lambda \cong \bigoplus_{\substack{\lambda\vdash m \\ m-\lambda_1\leq k}} K_{\lambda,(m-n,1^n)}\mathcal{V}_\lambda.$$

Equivalently, we have

$$\mathcal{U}_k \cong \{\zeta \in \mathbb{C}[S_{n,m}] : \lambda(\zeta) = 0 \text{ for all } \lambda \vdash m \text{ such that } m - \lambda_1 > k\}$$

where we have identified $\mathbb{C}[S_{n,m}]$ with the space of functions $\zeta \in \mathbb{C}[S_m]$ that are constant on the cosets S_m/S_{m-n}. Let $\alpha = \{(x_1, \alpha(x_1)), (x_2, \alpha(x_2)), \cdots, (x_k, \alpha(x_k))\}$, be an injective function from $[n]$ to $[m]$, which we represent as a set of k ordered pairs, and define

$$S_\alpha := \{f \in S_{n,m} : f(x_j) = \alpha(x_j) \text{ for all } 1 \leq j \leq k\}.$$

Theorem 12 shows that the characteristic functions of S_α have "low Fourier-complexity", namely, they are supported on the "low" Fourier levels of $\mathbb{C}[S_{n,m}]$ (i.e., $\mathrm{Irr}(S_{n,m})$), which are in reverse-lexicographic order on the partitions $\lambda' \vdash m$ corresponding to their S_m-irrep. One can compare these functions to the so-called *k-juntas* in area of Boolean functions, as their output is determined by examining no more than k "coordinates" of its input [19]. Such junta generalizations have been fundamental to some recent developments in extremal combinatorics (see [8, 7] for example). The proof of Theorem 12 resembles [8, Theorem 7], which we defer to Appendix D.

▶ **Theorem 12.** *Let $1_\alpha \in \mathbb{C}[S_{n,m}]$ be the characteristic function of the family S_α. Then $1_\alpha \in \mathcal{U}_k$.*

An immediate corollary of this theorem is the following.

▶ **Corollary 13.** *Let $1_\alpha \in \mathbb{C}[S_{n,m}]$ be the characteristic function of the family S_α. Then $E_{\mu\otimes\lambda}1_\alpha = 0$ for all λ with more than k cells below the first row.*

4 The Partial Permutation Association Scheme

The theory of association schemes will be a convenient language for describing the algebraic and combinatorial components of our work. We refer the reader to Bannai and Ito's reference [3] for a more thorough treatment.

▶ **Definition 14** (Association Schemes). *A* symmetric association scheme *is a collection of $d+1$ binary $|X| \times |X|$ matrices $\mathcal{A} = \{A_0, A_1, \cdots, A_d\}$ over a set X that satisfy the following axioms:*

1. *A_i is symmetric for all $0 \leq i \leq d$,*
2. *$A_0 = I$ where I is the identity matrix,*
3. *$\sum_{i=0}^{d} A_i = J$ where J is the all-ones matrix, and*
4. *$A_iA_j = A_jA_i \in Span\{A_0, A_1, \cdots, A_d\} =: \mathfrak{A}$ for all $0 \leq i, j \leq d$.*

The matrices $A_1, A_2, \cdots, A_d$ are called the associates*, and the algebra $\mathfrak{A}$ is called the* Bose–Mesner *algebra of the association scheme.*

Since the all-ones matrix commutes with every associate, the matrices of an association scheme have constant row sum and constant column sum. Also, since the matrices of a symmetric association scheme are symmetric and commute with each other, they are simultaneously diagonalizable (equivalently, they share a system of orthonormal eigenvectors), which implies that $\mathfrak{A}$ admits a unique basis of *primitive idempotents* $E_0, E_1, \cdots, E_d$, i.e., $E_i^2 = E_i$ for all $0 \leq i \leq d$ and $\sum_{i=0}^{d} E_i = I$.

Since the permutation representation of $S_n \times S_m$ acting on $S_{n,m}$ is multiplicity-free (see Theorem 9), the orbits $A_0, A_1, \cdots, A_d$ (so-called *orbitals*) of the action of $S_n \times S_m$ on ordered pairs $S_{n,m} \times S_{n,m}$ forms a *symmetric association scheme* (see [3] for a proof). We abuse the notation, and also use A_i to denote the binary matrix with entries 1 corresponding to exactly those pairs that are in the orbit A_i. Let $\mathcal{A}_{n,m} := \{I, A_1, \cdots, A_d\}$ denote the *n-partial permutation association scheme of* $[m]$.

Although it is well-known that permutation representation of $S_n \times S_m$ acting on $S_{n,m}$ is multiplicity-free (see [2, 5, 12] for example), the parameters of its corresponding association scheme $\mathcal{A}_{n,m}$ have not been worked out (to the best of our knowledge). We now give a more in-depth treatment of the partial permutation association scheme.

4.1 The Associates

The following is a more combinatorial definition of the associates of $\mathcal{A}_{n,m}$ that gives a combinatorial bijection between the associates of $\mathcal{A}_{n,m}$ and $\mathrm{Irr}(S_{n,m})$, which are the eigenspaces of the association scheme. The bijection is readily observed by thinking of each element of $S_{n,m}$ graphically as a maximum matching of the complete bipartite graph $K_{n,m}$ (see Figure 3).

Let $f_{\mathrm{id}} = (1, 2, \cdots, n)$ denote the *identity n-partial permutation*, which we can view as the maximum matching of $K_{n,m}$ that pairs 1 with 1, 2 with 2, and so on (e.g., the red matching in Figure 3). For any two maximum matchings f, f' of $K_{n,m}$, let $G(f, f')$ be the multigraph whose edge multiset is the multiset union $f \cup f'$. Clearly $G(f, f') = G(f', f)$ and this graph is composed of disjoint even cycles and disjoint even paths. Let c denote the number of disjoint cycles and let $2\lambda_i$ denote the length of an even cycle. Let p denote the number of disjoint paths and let $2\rho_i$ denote the length of an even path. If we order the cycles and paths respectively from longest to shortest and divide each of their lengths by two, assuming $m \geq 2n$, we see that the graphs $G(f, f')$ are in bijection (up to graph isomorphism) with pairs $(\lambda|\rho)$ of integer partitions $\lambda = (\lambda_1, \lambda_2, \cdots, \lambda_c), \rho = (\rho_1, \rho_2, \cdots, \rho_p)$ such that $(\lambda_1, \cdots, \lambda_c, \rho_1, \cdots, \rho_p) \vdash n$. Let $\mathrm{d}(f, f') := (\lambda|\rho)$ denote this bijection, which we refer to as the *cycle-path type of f' with respect to f*. Note that $\mathrm{d}(\sigma(f), \sigma(f')) = \mathrm{d}(f, f')$ for all n-partial permutations f, f' and all $\sigma \in S_n \times S_m$. If one of the arguments is the identity matching, then we say $\mathrm{d}(f) := \mathrm{d}(f_{\mathrm{id}}, f)$ is *the cycle-path type of f*. Illustrations of the graphs $G_{(\varnothing|n)}$ and $G_{(n-1|1)}$, and $G_{(\varnothing|1^n)}$ are provided in Figure 3 where $n = 3$ and $m = 6$.

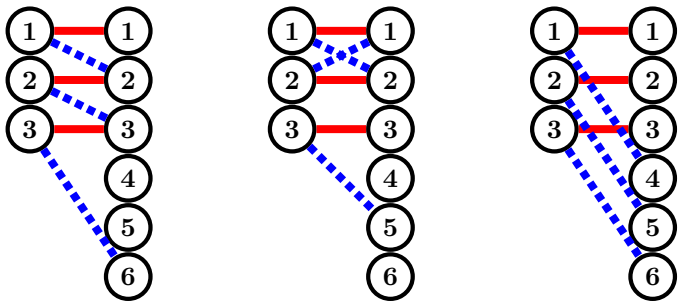


Figure 3 $(2, 3, 6)$ on the left has type $(\varnothing|3)$, $(2, 1, 5)$ has type $(2|1)$, and $(4, 5, 6)$ has type $(\varnothing|1^3)$.

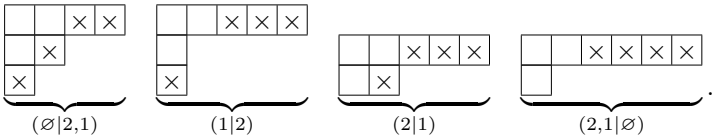
Let $\mathcal{C}_n := \{(\lambda|\rho)\colon |\lambda| + |\rho| = n\}$ where λ and ρ are partitions. When $m \geq 2n$, $\mathcal{C}_n$ is the set of all cycle-path types. Note that $(\varnothing|1^n)$ is not a cycle-path type when $m < 2n$, and for $m = n$, all cycle-path types are of form $(\lambda|\varnothing)$, where $\lambda \vdash n$. We can decompose $\mathcal{C}_n$ as a disjoint union $\mathcal{C}_n = \bigcup_{k=0}^{n} \mathcal{C}_{n,k}$, where $\mathcal{C}_{n,k}$ consists of all $(\lambda|\rho) \in \mathcal{C}_n$ such that $l(\rho) = n - k$.

Recall that any irrep in $\mathrm{Irr}(S_{n,m})$ is of the form $\lambda \otimes \lambda'$ where λ'/λ is a horizontal strip of size $m - n$. To see that cycle-path types $(\tau|\rho)$ have a natural correspondence with these irreducibles, consider a Young diagram of λ' such that the cells of λ'/λ are marked. Every columns of λ in λ' with a marked cell below it corresponds to a part in ρ whereas an unmarked column correspond to a part in τ. For instance, taking $\lambda = (2, 1)$ and $m = 7$, we have



Note that marked singleton columns correspond to paths of length zero (i.e., isolated nodes). For each cycle-path type $(\tau|\rho)$, the $(\tau|\rho)$-*associate* of $\mathcal{A}_{n,m}$ is the following $m^{\underline{n}} \times m^{\underline{n}}$ binary matrix:

$$(A_{(\tau|\rho)})_{i,j} = \begin{cases} 1, & \text{if } \mathrm{d}(i,j) = (\tau|\rho) \\ 0, & \text{otherwise} \end{cases}$$

where $i, j \in S_{m,n}$.

4.2 The Valencies and Multiplicities

For each $0 \leq i \leq d$, let $d_i := \operatorname{tr} E_i$ denote the *multiplicity* of the ith eigenspace of an association scheme, that is, the dimension of its ith eigenspace. For each $0 \leq i \leq d$, define the *valency* v_i to be the row sum of an arbitrary row of A_i (equivalently, the largest eigenvalue of A_i). We now give formulas for the valencies $v^{(m)}_{(\lambda|\rho)}$ and multiplicities $d_{(\lambda|\rho)}$ of $\mathcal{A}_{n,m}$.[4]

For each $(\lambda|\rho)$, define the $(\lambda|\rho)$-*sphere* to be the following set:

$$\Omega_{(\lambda|\rho)} := \{f \in S_{n,m} : \mathrm{d}(f) = (\lambda|\rho)\}.$$

The spheres partition $S_{n,m}$ and it useful to think of them as conjugacy classes. Indeed, when $n = m$, these spheres are the conjugacy classes of S_m. Note that $v^{(m)}_{(\lambda|\rho)} = |\Omega_{(\lambda|\rho)}|$, and basic combinatorial reasoning reveals the following.

▶ **Proposition 15.** *For any cycle-path type $(\lambda|\rho)$, the size of the $(\lambda|\rho)$-sphere is*

$$v^{(m)}_{(\lambda|\rho)} = |\Omega_{(\lambda|\rho)}| = \frac{n!}{\prod_{i=1}^{n} i^{\ell_i} \ell_i! r_i!} (m-n)^{\underline{l(\rho)}}$$

where $\lambda = (1^{\ell_1}, \cdots, n^{\ell_n})$, $\rho = (1^{r_1}, \cdots, n^{r_n})$, and $l(\rho) = r_1 + \cdots + r_n$.

We omit the superscript (m) of the valency when m is clear from the context.

The multiplicities $d_{(\tau|\rho)}$ are easy to deduce due to the fact that each eigenspace of the scheme is isomorphic to an irrep $\mu \otimes \lambda$ of $S_n \times S_m$, and that $\dim \mu \otimes \lambda = \dim \mu \cdot \dim \lambda$. As we have seen, these dimensions are counted by the hook rule. In particular, for a cycle-path type $(\tau|\rho)$, let $\tau \cup \rho$ be the union of the set of parts of the two partitions. Then we have $d_{(\tau|\rho)} = d_{\lambda \otimes \lambda'}$ such that $\lambda = (\tau \cup \rho)^\top \vdash n$, $\lambda' = (\tau \cup (m - n, \rho^\top)^\top)^\top$, and '$\top$' denotes the transpose partition.

[4] The "m" in the superscript (m) of the valency simply indicates the size of the domain of any $f \in S_{n,m}$. It is a notational convenience that will make some of our proofs easier to follow later in the paper.

4.3 The Johnson Ordering of $\mathcal{A}_{n,m}$

The *Johnson scheme* $\mathcal{J}(m,n)$ is a symmetric association scheme defined over the n-subsets of $[m]$. The ith associate $A_i \in \mathcal{J}(m,n)$ of the Johnson scheme is defined such that $(A_i)_{X,Y} = 1$ if $n - |X \cap Y| = i$, and is 0 otherwise for any two n-subsets X, Y. It is well-known that the ith eigenspace of $\mathcal{J}(m,n)$ is isomorphic to the S_m-irrep associated to the partition $(m-i,i) \vdash m$. For proofs of these facts and more, see [10]. Henceforth, let E_i be the primitive idempotent of the Johnson scheme that projects onto $\mathcal{V}_{(m-i,i)}$.

There exists a natural ordering of the $S_{n,m}$ that we call *the Johnson ordering* that shows the Johnson scheme is a "quotient" of $\mathcal{A}_{n,m}$. First, we order $S_{n,m}$ first by the corresponding n-subsets (the particular order does not matter). Next, we lexicographically order all $n!$ n-partial permutations that correspond to the same n-subset (i.e., share the same image). For example, for $n = 3$, we could have:

$$(1,2,3),(1,3,2),(2,1,3),(2,3,1),(3,1,2),(3,2,1),$$
$$(1,2,4),(1,4,2),(2,1,4),(2,4,1),(4,1,2),(4,2,1),$$
$$(1,3,4),(1,4,3),\cdots$$

Both S_n and S_m act on the indices and entries of an n-partial permutation respectively, and so each of their actions correspond to some collection of $m^{\underline{n}} \times m^{\underline{n}}$ permutation matrices (i.e., their corresponding permutation representations). The action of S_m on $S_{m,n}$ is transitive, but S_n's action has $\binom{m}{n}$ orbits, one for each n-subset. Note that on all $n!$ permutations of S_n corresponding to any given n-subset, the action of S_n corresponds to the regular representation of S_n.

Given $\lambda \vdash n$ and $\lambda' \vdash m$, let E_λ and $E_{\lambda'}$ be the orthogonal projectors on the λ-isotypic and λ'-isotypic subspaces, respectively. Since the actions of S_n and S_m on $S_{n,m}$ commute, E_λ and $E_{\lambda'}$ also commute, and we have $E_{\lambda \otimes \lambda'} = E_\lambda E_{\lambda'}$. From the specific way we ordered $S_{n,m}$ in the previous paragraph, for any $\lambda \vdash n$ we have

$$E_\lambda = I_{\binom{m}{n}} \otimes F_\lambda = \underbrace{F_\lambda \oplus F_\lambda \oplus \cdots \oplus F_\lambda}_{\binom{m}{n} \text{ times}},$$

where F_λ is the $n! \times n!$ orthogonal projector on the λ-isotypic subspace of the regular representation of S_n. Hence, we can write $E_{\lambda \otimes \lambda'}$ as a product of two block matrices:

$$E_{\lambda \otimes \lambda'} = \begin{pmatrix} B^{\lambda'}_{1,1} & B^{\lambda'}_{1,2} & \cdots \\ B^{\lambda'}_{2,1} & B^{\lambda'}_{2,2} & \\ \vdots & & \ddots \end{pmatrix} \begin{pmatrix} F_\lambda & 0 & \cdots \\ 0 & F_\lambda & \\ \vdots & & \ddots \end{pmatrix} = \begin{pmatrix} B^{\lambda'}_{1,1} F_\lambda & B^{\lambda'}_{1,2} F_\lambda & \cdots \\ B^{\lambda'}_{2,1} F_\lambda & B^{\lambda'}_{2,2} F_\lambda & \\ \vdots & & \ddots \end{pmatrix},$$

where the first matrix is $E_{\lambda'}$, in which each block $B^{\lambda'}_{i,j}$ is some $n! \times n!$ matrix.

Note that $F_{(n)} = J/n!$, where J is the $n! \times n!$ all-ones matrix. Thus, from the expression above, we have

$$E_{(n)\otimes(m-1,1)} = J/n! \otimes E_1 = \begin{pmatrix} b_{1,1} J & b_{1,2} J & \cdots \\ b_{2,1} J & b_{2,2} J & \\ \vdots & & \ddots \end{pmatrix},$$

where $b_{i,j}$ are scalars, $1/m^{\underline{n}}$ times the dual eigenvalues described above. Thus we have

$$E_{(n)\otimes(m-1,1)} \circ E_{\lambda\otimes\lambda'} = \begin{pmatrix} b_{1,1}B^{\lambda'}_{1,1}F_\lambda & b_{1,2}B^{\lambda'}_{1,2}F_\lambda & \cdots \\ b_{2,1}B^{\lambda'}_{2,1}F_\lambda & b_{2,2}B^{\lambda'}_{2,2}F_\lambda & \\ \vdots & & \ddots \end{pmatrix}, \tag{4.1}$$

which is orthogonal to E_μ (and thus $E_{\mu\otimes\mu'}$) for all $\mu \vdash n$ such that $\mu \neq \lambda$.

4.4 The Dual Eigenvalues of $\mathcal{A}_{n,m}$

A classic result in the theory of association schemes is that the primitive idempotents can be written as a linear combination of associates weighted by the dual eigenvalues of the scheme (see [9, Ch. 2.1]). In our case, we have

$$E_{\lambda\otimes\lambda'} = \frac{1}{m^{\underline{n}}} \sum_{(\mu|\rho)\in\mathcal{C}_n} q_{\lambda\otimes\lambda'}(\mu|\rho) A_{(\mu|\rho)},$$

and these coefficients $q_{\lambda\otimes\lambda'}(\mu|\rho)$ are the *dual eigenvalues* of $\mathcal{A}_{m,n}$.

The dual eigenvalues corresponding to minimal and maximal irreps play a central role in the proof of our main result. Let us consider matrices in the Bose–Mesner algebra $\mathfrak{A}_{n,m}$ of the partial permutation association scheme. By symmetry, every such matrix can be specified by a row or column corresponding to a single n-partial permutation of $[m]$.

Note that

$$(E_{\lambda\otimes\lambda'})_{f,h} = \frac{q_{\lambda\otimes\lambda'}(\mathrm{d}(f,h))}{m^{\underline{n}}}$$

and that

$$\sum_{f\in S_{n,m}} q_{\lambda\otimes\lambda'}(\mathrm{d}(f,h))\ 1_f = m^{\underline{n}}\,(E_{\lambda\otimes\lambda'})_h \in \lambda\otimes\lambda'$$

for all $\lambda\otimes\lambda'$ and $f,h \in S_{n,m}$, where $1_f \in \mathbb{C}[S_{n,m}]$ denotes the binary unit vector with the unique 1 in position f. The projector $E_{\lambda'}$ onto the λ'-isotypic component can be written as

$$(E_{\lambda'})_{f,h} = \frac{d_{\lambda'}}{m!} \sum_{\sigma\in S_m} \chi_{\lambda'}(\sigma^{-1})(V_\sigma)_{f,h}.$$

where $V_\sigma : 1_f \mapsto 1_{\sigma * f}$ for all $f,h \in S_{n,m}$. The foregoing, and the fact that $E_{\lambda'}E_{\lambda\otimes\lambda'} = E_{\lambda\otimes\lambda'}$ implies the following proposition.

▶ **Proposition 16.** *For any $f,h \in S_{n,m}$, $\lambda \vdash n$, and $\lambda' \vdash m$, we have*

$$q_{\lambda\otimes\lambda'}\big(\mathrm{d}(f,h)\big) = \frac{d_{\lambda'}}{m!} \sum_{\sigma\in S_m} \chi_{\lambda'}(\sigma)\, q_{\lambda\otimes\lambda'}\big(\mathrm{d}(\sigma^{-1} * f, h)\big).$$

▶ **Lemma 17.** *Let $q_i(j)$ be a dual eigenvalue of the Johnson scheme $\mathcal{J}(m,n)$. Then we have*

$$q_1(j) = \frac{\binom{n}{m}}{\binom{m-2}{n-1}} \left(n - j - \frac{n^2}{m}\right).$$

Moreover, if $m \geq n^2$, then $q_i(j) \geq 0$ for all $j \neq n$.

Proof. Let $p_i(j)$ denote the j-th eigenvalue of the i-th associate of the Johnson scheme $\mathcal{J}(m,n)$. It is well-known (see [10] for example) that

$$p_i(j) = \sum_{r=i}^{n} (-1)^{(r-i+j)} \binom{r}{i} \binom{m-2r}{n-r} \binom{m-r-j}{r-j}.$$

Let P be the $(n+1) \times (n+1)$ matrix defined such that $P_{j,i} = p_i(j)$. As their name suggests, the dual eigenvalues $Q_{j,i} := q_i(j)$ are formally dual to the eigenvalues of the association scheme, that is, $Q = \binom{m}{n} P^{-1}$. Inverting P reveals that

$$Q_{j,1} = q_1(j) = \frac{\binom{m}{n}}{\binom{m-2}{n-1}} \left(n - j - \frac{n^2}{m} \right),$$

which is non-negative for all $m \geq n^2$ and $j \neq n$, which completes the proof. ◀

▶ **Lemma 18.** *For all $\mu \in \mathcal{C}_{n,k}$, we have*

$$q_{(n)\otimes(m-1,1)}(\mu) = \frac{(km - n^2)(m-1)}{n(m-n)}.$$

Proof. Recall that the ith eigenspace of the Johnson scheme $\mathcal{J}(m,n)$ is isomorphic to the S_m-irrep associated to the partition $(m-i,i) \vdash m$, and that E_i denotes the primitive idempotent of the Johnson scheme that projects onto its $(m-i,i)$ eigenspace. Since

$$E_{(n)\otimes(m-1,1)} = \frac{J}{n!} \otimes E_1,$$

Lemma 17 implies that

$$\begin{aligned} E_1 &= \frac{1}{\binom{n}{m}} \sum_{j=0}^{n} \left[\frac{\binom{n}{m}}{\binom{m-2}{n-1}} \left(n - j - \frac{n^2}{m} \right) \right] A_j \\ &= \frac{1}{\binom{m-2}{n-1}} \sum_{j=0}^{n} \left(n - j - \frac{n^2}{m} \right) A_j. \end{aligned}$$

Since $(A_j)_{X,Y} = 1$ only if $|X \cap Y| = n - j$, we have the dual eigenvalue

$$\left(m^n E_{(n)\otimes(m-1,1)}\right)_{f,h} = m^n \frac{|\mathrm{im}\ f \cap \mathrm{im}\ h| - n^2/m}{n!\binom{m-2}{n-1}} = \frac{(m-1)(|\mathrm{im}\ f \cap \mathrm{im}\ h| m - n^2)}{n(m-n)}.$$

It follows that

$$q_{(n)\otimes(m-1,1)}(\mu) = \frac{(km - n^2)(m-1)}{n(m-n)}$$

for all $\mu \in \mathcal{C}_{n,k}$, which completes the proof. ◀

5 A sufficient condition on Krein parameters

Recall that $\circ$ denotes the Schur (entrywise) product of two matrices.

▶ **Definition 19** (Krein Parameters). *Let $\mathcal{A}$ be an association scheme on v vertices with d associates. For any $0 \leq i,j \leq d$, there exist constants $q_{i,j}(k)$ such that*

$$E_i \circ E_j = \frac{1}{v} \sum_{k=0}^{d} q_{i,j}(k) E_k,$$

which are called the Krein parameters *of $\mathcal{A}$. More explicitly, we have*

$$q_{i,j}(k) = v\frac{\operatorname{tr}\left[E_k(E_i \circ E_j)\right]}{d_k}.$$

For more details on the Krein parameters of an association scheme, see [3]. The Krein parameters can alternatively be written as

$$q_{i,j}(k) = \frac{1}{vd_k}\sum_{\ell=0}^{d}\frac{q_i(\ell)q_j(\ell)\overline{q_k(\ell)}}{v_\ell} = \frac{d_i d_j}{v}\sum_{\ell=0}^{d}\frac{\overline{p_i(\ell)p_j(\ell)}p_k(\ell)}{v_\ell^2}, \tag{5.1}$$

where $p_i(j)$ denotes the j-th eigenvalue of A_i and $q_i(j)$ denotes the jth *dual eigenvalue* of E_i (see [9, Chap. 2.4] for a proof).

To prove the lower bound on non-coherent Index Erasure, we use the same adversary matrix Γ as [2] used for the coherent case.[5] For simplifying the equations, without loss of generality let us assume that n is a square. As in [2], we choose

$$\Gamma := \sum_{k=0}^{\sqrt{n}}(\sqrt{n}-k)\sum_{\lambda\vdash k}E_{(n-k,\lambda)\otimes(m-k,\lambda)},$$

and thus the orthogonal projection onto its image is

$$\Pi_\Gamma := \sum_{\lambda\colon|\lambda|<\sqrt{n}}E_{(n-|\lambda|,\lambda)\otimes(m-|\lambda|,\lambda)}.$$

Note that the sole principal eigenvector ω of Γ is the uniform superposition over $\mathcal{F}$ (i.e., $\omega_f = 1/\sqrt{m^{\underline{n}}}$ for all $f\in\mathcal{F}$). Thus, as per Corollary 3, we are interested in the quantity

$$\eta = \max_{T\in\mathcal{T}}\operatorname{tr}\left[\Pi_\Gamma\frac{(T\circ T^{\odot})}{m^{\underline{n}}}\right].$$

For any primitive idempotent $E_{\lambda\otimes\lambda'}$, let

$$T_{\lambda\otimes\lambda'} := \left(\frac{m^{\underline{n}}}{\operatorname{tr}E_{\lambda\otimes\lambda'}}\right)E_{\lambda\otimes\lambda'} = \left(\frac{m^{\underline{n}}}{d_{\lambda\otimes\lambda'}}\right)E_{\lambda\otimes\lambda'}$$

be its corresponding state matrix. In [2] it is shown that the target matrix can be written as

$$T^{\odot} = \frac{n}{m}T_{(n)\otimes(m)} + \left(1-\frac{n}{m}\right)T_{(n)\otimes(m-1,1)}.$$

In the coherent case, recall that $T = J$, and therefore

$$\eta = \operatorname{tr}\left[\Pi_\Gamma\frac{T^{\odot}}{m^{\underline{n}}}\right] = \frac{n}{m}\operatorname{tr}\left[\frac{T_{(n)\otimes(m)}}{m^{\underline{n}}}\right] = \frac{n}{m}.$$

The most technically involved part of the proof of the lower bound by [2] is proving that $\|\Delta_x\circ\Gamma\| = \mathrm{O}(1)$. Since we are using the same adversary matrix Γ, we already have the above bound on $\|\Delta_x\circ\Gamma\|$. Our goal is to show that $\operatorname{tr}\left[\Pi_\Gamma(T\circ T^{\odot})/m^{\underline{n}}\right]$ is small for *all* state matrices T.

[5] Technically, the adversary matrix used here is $\sqrt{n}$ times that of [2] as the adversary method they use places slightly different conditions on the adversary matrix.

By dividing the elements in the set $\mathcal{T}$ by $m^{\underline{n}}$ we obtain the set of all density matrices (positive-semidefinite Hermitian matrices with trace 1) of the Bose–Mesner algebra $\mathfrak{A}_{n,m}$. Note that $(T \circ T')/m^{\underline{n}}$ is a density matrix for all $T, T' \in \mathcal{T}$.

For any $T \in \mathcal{T}$, we have

$$\operatorname{tr}\left[\Pi_\Gamma \frac{\big(T \circ T_{(n)\otimes(m)}\big)}{m^{\underline{n}}}\right] = \operatorname{tr}\left[\Pi_\Gamma \frac{T}{m^{\underline{n}}}\right] \leq 1,$$

therefore

$$\operatorname{tr}\left[\Pi_\Gamma \frac{\big(T \circ T^{\odot}\big)}{m^{\underline{n}}}\right] \leq \frac{n}{m} + \left(1 - \frac{n}{m}\right) \operatorname{tr}\left[\Pi_\Gamma \frac{\big(T \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right].$$

Our goal is to bound the latter term:

$$\left(1 - \frac{n}{m}\right) \operatorname{tr}\left[\Pi_\Gamma \frac{\big(T \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right]. \tag{5.2}$$

First note that

$$\mathcal{T} = \left\{\sum_\chi c_\lambda T_\chi \colon \sum_\chi c_\chi = 1 \text{ and } c_\chi \geq 0\right\},$$

where the sums range over $\chi \in \operatorname{Irr}(S_{n,m})$. Hence,

$$\begin{aligned}\max_{T\in\mathcal{T}} \operatorname{tr}\left[\Pi_\Gamma \frac{\big(T \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right] &= \max_{\substack{\{c_\chi \geq 0\}_\chi \\ \sum_\chi c_\chi = 1}} c_\chi \operatorname{tr}\left[\Pi_\Gamma \frac{\big(T_\chi \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right] \\ &= \max_\chi \operatorname{tr}\left[\Pi_\Gamma \frac{\big(T_\chi \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right].\end{aligned}$$

The following proposition simplifies (5.2).

▶ **Proposition 20.** *For any $\lambda = (n - |\nu|, \nu)$ and $\bar{\lambda} = (m - |\nu|, \nu)$, we have*

$$\operatorname{tr}\left[\Pi_\Gamma \frac{\big(T_{\lambda\otimes\lambda'} \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right] = \operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}} \frac{\big(T_{\lambda\otimes\lambda'} \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}}\right].$$

Proof. By Equation (4.1), if $|\nu| < \sqrt{n}$, then we have

$$\begin{aligned}\Pi_\Gamma \frac{\big(T_{\lambda\otimes\lambda'} \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}} &= \sum_{\mu\colon |\mu|<\sqrt{n}} E_{(n-|\mu|,\mu)\otimes(m-|\mu|,\mu)} \frac{\big(T_{\lambda\otimes\lambda'} \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}} \\ &= E_{(n-|\nu|,\nu)\otimes(m-|\nu|,\nu)} \frac{\big(T_{\lambda\otimes\lambda'} \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}} \\ &= E_{\lambda\otimes\bar{\lambda}} \frac{\big(T_{\lambda\otimes\lambda'} \circ T_{(n)\otimes(m-1,1)}\big)}{m^{\underline{n}}};\end{aligned}$$

otherwise, the left-hand and right-hand side are both 0, which completes the proof. ◀

The proposition above now allows us to bound (5.2) for all $\lambda \vdash n$ having no more than $\sqrt{n}$ cells under its first row.

▶ **Corollary 21.** *Suppose $\lambda \vdash n$ has no more than $\sqrt{n}$ cells below the first row. Then*

$$\operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}}\frac{\left(T_{(n)\otimes(m-1,1)}\circ T_{\lambda\otimes\lambda'}\right)}{m^{\underline{n}}}\right] \in \mathrm{O}(\sqrt{n}/m)$$

for all $\lambda' \neq \bar{\lambda}$.

Proof. Let $\operatorname{sum}[\cdot]$ denote the sum of the entries of the matrix. We have

$$\begin{aligned}\operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}}\frac{\left(T_{(n)\otimes(m-1,1)}\circ T_{\lambda\otimes\lambda'}\right)}{m^{\underline{n}}}\right] &= \frac{1}{d_{\lambda\otimes\lambda'}}\operatorname{sum}\left[E_{\lambda\otimes\bar{\lambda}}\circ T_{(n)\otimes(m-1,1)}\circ E_{\lambda\otimes\lambda'}\right]\\ &= \frac{d_{\lambda\otimes\bar{\lambda}}}{d_{\lambda\otimes\lambda'}}\operatorname{tr}\left[E_{\lambda\otimes\lambda'}\frac{\left(T_{(n)\otimes(m-1,1)}\circ T_{\lambda\otimes\bar{\lambda}}\right)}{m^{\underline{n}}}\right]\end{aligned}$$

Since $\left(T_{(n)\otimes(m-1,1)}\circ T_{\lambda\otimes\bar{\lambda}}\right)/m^{\underline{n}}$ is a density matrix, the trace on the right-hand side is at most 1. We now have

$$\leq \frac{d_{\bar{\lambda}}}{d_{\lambda'}} \in \mathrm{O}(\sqrt{n}/m),$$

where the asymptotic bound follows from Corollary 8, completing the proof. ◀

We therefore have

$$\eta = \mathrm{O}\left(\frac{n}{m} + \operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}}\frac{\left(T_{\lambda\otimes\bar{\lambda}}\circ T_{(n)\otimes(m-1,1)}\right)}{m^{\underline{n}}}\right]\right),$$

and it remains to bound the value

$$\begin{aligned}\operatorname{tr}\left[E_{\lambda\otimes\bar{\lambda}}\frac{\left(T_{\lambda\otimes\bar{\lambda}}\circ T_{(n)\otimes(m-1,1)}\right)}{m^{\underline{n}}}\right] &= \frac{m^{\underline{n}}}{(m-1)d_{\lambda\otimes\bar{\lambda}}}\operatorname{sum}\left[E_{(n)\otimes(m-1,1)}\circ E_{\lambda\otimes\bar{\lambda}}\circ E_{\lambda\otimes\bar{\lambda}}\right]\\ &= \frac{\sum_{\mu\in\mathcal{C}_n} v_\mu^{(m)}\cdot q_{(n)\otimes(m-1,1)}(\mu)\cdot q^2_{\lambda\otimes\bar{\lambda}}(\mu)}{m^{\underline{n}}(m-1)d_{\lambda\otimes\bar{\lambda}}}. \qquad (5.3)\end{aligned}$$

In the next section we show that, under the assumption that $m \geq n^{3\sqrt{n}}$, the value of (5.3), and thus η, is in $\mathrm{O}(1/\sqrt{n})$.

Note that, according to the expression (5.1) for Krein parameters, (5.3) is equal to

$$\frac{q_{\lambda\otimes\bar{\lambda},\,\lambda\otimes\bar{\lambda}}((n)\otimes(m-1,1))}{d_{\lambda\otimes\bar{\lambda}}} = \frac{q_{\lambda\otimes\bar{\lambda},\,(n)\otimes(m-1,1)}(\lambda\otimes\bar{\lambda})}{m-1},$$

and therefore the task of bounding (5.3) is the task of bounding Krein parameters

$$q_{\lambda\otimes\bar{\lambda},\,\lambda\otimes\bar{\lambda}}((n)\otimes(m-1,1)) \quad\text{and}\quad q_{\lambda\otimes\bar{\lambda},\,(n)\otimes(m-1,1)}(\lambda\otimes\bar{\lambda}).$$

6 Bounding relevant Krein parameters

Let $(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$ denote the space of the columns of matrices in the Bose–Mesner algebra $\mathfrak{A}_{n,m}$ corresponding to f_{id}. For brevity, we call such columns *characteristic columns*. Note that, due to symmetry, $\phi \in (\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$ is the characteristic column of exactly one matrix in

$\mathfrak{A}_{n,m}$, in effect defining one-to-one correspondence between $(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$ and $\mathfrak{A}_{n,m}$. Since the characteristic column of any primitive idempotent $E_{\lambda\otimes\lambda'}$ is an eigenvector of the $(\lambda\otimes\lambda')$-eigenspace of $\mathcal{A}_{n,m}$, we have $\dim[(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}} \cap (\lambda\otimes\lambda')] \geq 1$. Since the characteristic columns of $\mathcal{A}_{n,m}$ form an orthogonal basis for $(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$, we have that $\dim(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}} = |\mathcal{C}_n|$. These facts imply the following proposition.

▶ **Proposition 22.** *For any $\lambda\otimes\lambda' \in \mathrm{Irr}(S_{n,m})$, we have* $\dim[(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}} \cap (\lambda\otimes\lambda')] = 1$.

We let $1_f \in \mathbb{C}[S_{n,m}]$ denote the binary unit vector with the unique 1 in position f. For $\mu \in \mathcal{C}_n$, let

$$1_\mu := \sum_{f\colon \mathrm{d}(f)=\mu} 1_f.$$

6.1 Assignments

We call an injective function $\alpha\colon D \to [n]$ with $D = \mathrm{dom}(\alpha) \subseteq [n]$ an *assignment*. Let $|\alpha| := |\mathrm{dom}(\alpha)| = |\mathrm{im}(\alpha)|$, which we call the *weight* of α. We say that $f \in S_{n,m}$ *agrees* with α if $f(x) = \alpha(x)$ for all $x \in \mathrm{dom}(\alpha)$, and we write $\alpha \rightsquigarrow f$; in other words, $f \in S_\alpha$ In particular, there are $(m-|\alpha|)^{\underline{n-|\alpha|}}$ partial permutations in $S_{n,m}$ that agree with α. Recall that

$$1_\alpha = \sum_{f\colon \alpha\rightsquigarrow f} 1_f.$$

For any assignment α and any permutation $\pi \in S_n$, define assignments α^{-1} and $\alpha * \pi^{-1}$ with domains $\mathrm{im}(\alpha)$ and $\pi(\mathrm{dom}(\alpha))$ respectively in the natural way. Note that the image of both α and $\alpha*\pi^{-1}$ is the same. Since the action of $\pi \in S_n$ maps $f \in S_{n,m}$ to $f*\pi^{-1}$, we have $\alpha \rightsquigarrow h$ if and only if $\pi(\alpha) \rightsquigarrow \pi(h)$. Hence, $V_\pi 1_\alpha = 1_{\pi(\alpha)}$, where $\pi \mapsto V_\pi$ is the representation of S_n defined as $V_\pi : 1_f \mapsto 1_{f*\pi^{-1}}$.

Consider $X := \{x_1, \cdots, x_k\} \subseteq [n]$ with $x_i < x_{i+1}$ for all i, and define $\alpha_X\colon [k] \to [n]$ such that $i \mapsto x_i$. Note that the set of all $\alpha^{-1} * \alpha_X$ such that $\mathrm{im}(\alpha) = X$ equals $S_{k,n}$, where we think of $S_{k,n}$ as the set of injective functions from $[k]$ to $[n]$. We define the cycle-path type of α to be

$$\mathrm{d}(\alpha) := \mathrm{d}(\alpha^{-1} * \alpha_X, \alpha_X) \in \mathcal{C}_k.$$

See Figure 4 for an illustration.

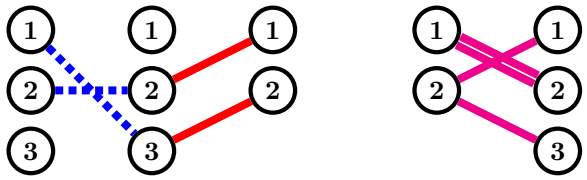


Figure 4 As an example, consider $n = 3$ and an assignment $\alpha\colon D \to [n]$ with $D = \{1,2\}$ defined as $\alpha(1) := 3$ and $\alpha(2) := 2$. The image of α is $X = \{2,3\}$, and thus α_X maps 2 to 1 and 3 to 2. The left picture depicts α with blue dashed lines and α_X^{-1} with red solid lines. The right picture depicts the multigraph resulting from the union of edges corresponding to $\alpha^{-1} * \alpha_X$ and α_X, from which we can see that $\mathrm{d}(\alpha) = (1|1)$.

Corollary 13 immediately implies the following proposition.

▶ **Proposition 23.** *For any assignment α and $\lambda' \vdash m$ such that $m - \lambda'_1 > |\alpha|$, we have $E_{\lambda'} 1_\alpha = 0$.*

6.2 Dual eigenvalues of minimal irreps

Suppose $\theta \vdash k$, and let us analyze the idempotent corresponding to the irrep $(n-k,\theta) \otimes (m-k,\theta)$. For a cycle-path type $\nu \in \mathcal{C}_k$, define

$$\phi_\nu := \sum_{\alpha\colon \mathrm{d}(\alpha)=\nu} 1_\alpha.$$

Note that $\phi_\nu \in (\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$. Consider the irrep

$$\xi_\theta := \theta \otimes (n-k,\theta) \in \mathrm{Irr}(S_k \times S_n).$$

We will be interested in its dual eigenvalues $q_{\xi_\theta}(\nu)$ for the $\mathcal{A}_{k,n}$ scheme.

▶ **Lemma 24.** *The characteristic column of $m^{\underline{n}} E_{(n-k,\theta)\otimes(m-k,\theta)}$ equals*

$$\phi_{\xi_\theta} := \frac{d_{(m-k,\theta)}}{\binom{n}{k} d_\theta} \sum_{\nu \in \mathcal{C}_k} q_{\xi_\theta}(\nu)\phi_\nu, \tag{6.1}$$

i.e., for any $\mu \in \mathcal{C}_n$ and $f \in S_{n,m}$ with $\mathrm{d}(f) = \mu$, we have $q_{(n-k,\theta)\otimes(m-k,\theta)}(\mu) = (\phi_{\xi_\theta})_f$.

Proof. First, note that $\phi_{\xi_\theta} \in (\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$ as $\phi_\nu \in (\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$ for all $\nu \in \mathcal{C}_k$. Recall that Proposition 22 implies that the intersection of $(\mathfrak{A}_{n,m})_{f_{\mathrm{id}}}$ and the $((n-k,\theta)\otimes(m-k,\theta))$-isotypic subspace is one-dimensional. Using this fact and the expression of the primitive idempotents in the $\mathcal{A}_{n,m}$ basis, to prove the first statement of the lemma, it suffices to show that

1. ϕ_{ξ_θ} belongs to the $(n-k,\theta)$-isotypic,
2. ϕ_{ξ_θ} belongs to the $(m-k,\theta)$-isotypic, and
3. that ϕ_{ξ_θ} has the right scaling $d_{(m-k,\theta)}/\binom{n}{k}d_\theta$.

Let us first prove statement (3). Any assignment α with $\mathrm{d}(\alpha) \neq (1^k|\varnothing)$ is incompatible with f_{id}, that is, $\alpha \not\rightsquigarrow f_{\mathrm{id}}$. By linearity, it follows that $(\phi_\nu)_{f_{\mathrm{id}}} = 0$ for $\nu \neq (1^k|\varnothing)$. On the other hand, there are $\binom{n}{k}$ assignments α with $\mathrm{d}(\alpha) = (1^k|\varnothing)$, and they all agree with f_{id}. We deduce that $(\phi_{(1^k|\varnothing)})_{f_{\mathrm{id}}} = \binom{n}{m}$, and

$$\begin{aligned}(\phi_{\xi_\theta})_{f_{\mathrm{id}}} = \frac{d_{(m-k,\theta)}}{d_\theta} q_{\xi_\theta}(1^k|\varnothing) &= d_{(n-k,\theta)} \cdot d_{(m-k,\theta)} \\ &= q_{(n-k,\theta)\otimes(m-k,\theta)}(1^n|\varnothing) \\ &= m^{\underline{n}} \left(E_{(n-k,\theta)\otimes(m-k,\theta)}\right)_{f_{\mathrm{id}},f_{\mathrm{id}}},\end{aligned}$$

where we have used the fact that $q_{\lambda\otimes\lambda'}(1^k|\varnothing)$ is the dimension of $(\lambda \otimes \lambda') \in \mathrm{Irr}(S_{k,n})$. This completes the proof of statement (3).

We now prove statement (1). Equation (6.1) can be written as

$$\phi_{\xi_\theta} = \frac{d_{(m-k,\theta)}}{\binom{n}{k} d_\theta} \sum_{\substack{X\subset[n]\\|X|=k}} \phi_{\xi_\theta,X},$$

where we define

$$\phi_{\xi_\theta,X} := \sum_{\nu\in\mathcal{C}_k} q_{\xi_\theta}(\nu) \sum_{\substack{\alpha\\ \mathrm{d}(\alpha)=\nu\\ \mathrm{im}(\alpha)=X}} 1_\alpha = \sum_{\substack{\alpha\\ \mathrm{im}(\alpha)=X}} q_{\xi_\theta}(\mathrm{d}(\alpha^{-1} * \alpha_X, \alpha_X)) 1_\alpha.$$

Hence,

$$\begin{aligned}
\left[E_{(n-k,\theta)}\right]\phi_{\xi_\theta,X} &= \sum_{\pi\in S_n}\sum_{\substack{\alpha\\ \mathrm{im}(\alpha)=X}} \frac{d_{(n-k,\theta)}\chi_{(n-k,\theta)}(\pi)}{n!} q_{\xi_\theta}(\mathrm{d}(\alpha^{-1}*\alpha_X,\alpha_X))1_{\alpha*\pi^{-1}}\\
&= \sum_{\pi\in S_n}\sum_{\substack{\tilde\alpha*\pi\\ \mathrm{im}(\tilde\alpha*\pi)=X}} \frac{d_{(n-k,\theta)}\chi_{(n-k,\theta)}(\pi)}{n!} q_{\xi_\theta}(\mathrm{d}((\tilde\alpha*\pi)^{-1}*\alpha_X,\alpha_X))1_{\tilde\alpha*\pi*\pi^{-1}}\\
&= \sum_{\substack{\tilde\alpha\\ \mathrm{im}(\tilde\alpha)=X}} \left(\sum_{\pi\in S_n} \frac{d_{(n-k,\theta)}\chi_{(n-k,\theta)}(\pi)}{n!} q_{\xi_\theta}(\mathrm{d}(\pi^{-1}*\tilde\alpha^{-1}*\alpha_X,\alpha_X))\right)1_{\tilde\alpha}\\
&= \sum_{\substack{\tilde\alpha\\ \mathrm{im}(\tilde\alpha)=X}} q_{\xi_\theta}(\mathrm{d}(\tilde\alpha^{-1}*\alpha_X,\alpha_X)1_{\tilde\alpha}\\
&= \phi_{\xi_\theta,X},
\end{aligned}$$

where the second to last equality follows from Proposition 16. By linearity, we deduce that $E_{(n-k,\theta)}\phi_{\xi_\theta} = \phi_{\xi_\theta}$, and thus ϕ_{ξ_θ} belongs to the $(n-k,\theta)$-isotypic subspace, completing the proof of statement (1).

Finally, we prove statement (2). Consider the irreps $\lambda\otimes\lambda' \in \mathrm{Irr}(S_{n,m})$ in the $(n-k,\theta)$-isotypic, which are of the form $(n-k,\theta)\otimes\lambda'$. If $\lambda' \neq (m-k,\theta)$, then λ' has more than k cells below its first row. But then Proposition 23 implies that ϕ_{ξ_θ} is orthogonal to all such $(n-k,\theta)\otimes\lambda'$ irreps, which finishes the proof of the first part of the lemma.

The second part of the lemma is a restatement of the first that is seen by expressing the primitive idempotents in the $\mathcal{A}_{n,m}$ basis, which completes the proof of the lemma. ◀

Recall that, for every $1 \le k \le \sqrt{n}$ and every $\theta \vdash k$, to upper bound

$$\frac{\sum_{\mu\in\mathcal{C}_n} v_\mu^{(m)} \cdot q_{(n)\otimes(m-1,1)}(\mu)\cdot q^2_{(n-k,\theta)\otimes(m-k,\theta)}(\mu)}{m^{\underline{n}}\ (m-1)\ d_{(n-k,\theta)}d_{(m-k,\theta)}} \tag{6.2}$$

$$= \frac{\sum_{\ell=k}^{n}\left((\ell m-n^2)\sum_{\mu\in\mathcal{C}_{n,\ell}} v_\mu^{(m)}\cdot q^2_{(n-k,\theta)\otimes(m-k,\theta)}(\mu)\right)}{m^{\underline{n}}\ n(m-n)\ d_{(n-k,\theta)}d_{(m-k,\theta)}} \tag{6.3}$$

where the second equality follows from Lemma 18. We break the latter sum into two parts, $\ell = k$ and $\ell > k$, then bound these parts individually.

6.3 Case $\ell = k$

Given a partition $\rho = (1^{r_1}, 2^{r_2}, \cdots, n^{r_n})$, define

$$\breve\rho := (1^{r_2}, 2^{r_3}, \cdots, (n-1)^{r_n}) \vdash |\rho| - l(\rho).$$

In terms of Young diagrams, the shape $\breve\rho$ is obtained from ρ by removing the first column. Similarly, for $\mu = (\lambda|\rho) \in \mathcal{C}_n$, define $\breve\mu := (\lambda|\breve\rho)$. In particular, for $\mu \in \mathcal{C}_{n,k}$, we have $\breve\mu \in \mathcal{C}_k$. Also note that, as long as $k \le n/2$, the operation $\rho \mapsto \breve\rho$ defines a one-to-one correspondence between $\mathcal{C}_{n,k}$ and $\mathcal{C}_k$.

Consider $f \in \Omega_\mu$ such that $\mu \in \mathcal{C}_{n,k}$. There exists exactly one assignment α of weight k such that $\alpha \rightsquigarrow f$. Moreover, this assignment satisfies $\mathrm{d}(\alpha) = \breve\mu$. Hence $(\phi_{\breve\mu})_f = 1$ and $(\phi_\nu)_f = 0$ for $\nu \in \mathcal{C}_k \setminus \{\breve\mu\}$. Lemma 24 then implies

$$q_{(n-k,\theta)\otimes(m-k,\theta)}(\mu) = \frac{d_{(m-k,\theta)}}{\binom{n}{k} d_\theta} q_{\xi_\theta}(\breve\mu). \tag{6.4}$$

We also relate the valencies of μ and $\breve\mu$ as follows.

▶ **Proposition 25.** *For $\mu \in \mathcal{C}_{n,k}$, we have $v_\mu^{(m)} = \binom{n}{k}(m-n)^{\underline{n-k}} v_{\breve{\mu}}^{(n)}$.*

Proof. Let $(\lambda|\rho) := \mu$ and $\rho = (1^{r_1}, \cdots, n^{r_n})$, so that $\breve{\mu} = (\lambda|\breve{\rho})$ and $\breve{\rho} = (2^{r_1}, \cdots, (n-1)^{r_n})$. We also have $l(\rho) = n-k$ and $l(\breve{\rho}) = n-k-r_1$. Using Proposition 15, we get

$$\frac{v_{(\lambda|\rho)}^{(m)}}{v_{(\lambda|\breve{\rho})}^{(n)}} = \frac{n!(m-n)^{\underline{n-k}}/r_1!}{k!(n-k)^{\underline{n-k-r_1}}} = \frac{n!(m-n)^{\underline{n-k}}}{k!(n-k)!} = \binom{n}{k}(m-n)^{\underline{n-k}}.$$

Rearranging gives the desired result. ◀

Finally, we need

$$\sum_{\nu \in \mathcal{C}_k} v_\nu^{(n)} q_{\xi_\theta}^2(\nu) = n^{\underline{k}} d_\theta d_{(n-k,\theta)}, \tag{6.5}$$

which holds because, for the primitive idempotent E_{ξ_θ} of $\mathcal{A}_{k,n}$, we have

$$d_{\xi_\theta} = \operatorname{Tr}\big[E_{\xi_\theta}\big] = \operatorname{Tr}\big[E_{\xi_\theta}^2\big] = n^{\underline{k}} \sum_{\nu \in \mathcal{C}_k} v_\nu^{(n)} \left(\frac{q_{\xi_\theta}(\nu)}{n^{\underline{k}}}\right)^2.$$

Putting everything together, we get

$$\begin{aligned}
&\frac{(km-n^2)\sum_{\mu \in \mathcal{C}_{n,k}} v_\mu^{(m)} q^2_{(n-k,\theta)\otimes(m-k,\theta)}(\mu)}{m^{\underline{n}} n(m-n) d_{(n-k,\theta)} d_{(m-k,\theta)}} \\
&= \frac{(km-n^2)\sum_{\nu \in \mathcal{C}_k} \binom{n}{k}(m-n)^{\underline{n-k}} v_\nu^{(n)} \left(\frac{d_{(m-k,\theta)}}{\binom{n}{k} d_\theta} q_{\xi_\theta}(\nu)\right)^2}{m^{\underline{n}} n(m-n) d_{(n-k,\theta)} d_{(m-k,\theta)}} \\
&= \frac{km-n^2}{n(m-n)} \cdot \frac{(m-n)^{\underline{n-k}}}{m^{\underline{n}}} \cdot \frac{d_{(m-k,\theta)} \sum_{\nu \in \mathcal{C}_k} v_\nu^{(n)} q_{\xi_\theta}^2(\nu)}{\binom{n}{k} d_{(n-k,\theta)} (d_\theta)^2} \\
&= \frac{km-n^2}{n(m-n)} \cdot \frac{(m-n)^{\underline{n-k}}}{m^{\underline{n}}} \cdot \frac{k! d_{(m-k,\theta)}}{d_\theta} \\
&\le \frac{km-kn}{n(m-n)} \cdot \frac{(m-n)^{\underline{n-k}}}{m^{\underline{n}}} \cdot \frac{k! m^{\underline{k}}/\mathsf{H}(\theta)}{k!/\mathsf{H}(\theta)} \\
&= \frac{k}{n} \cdot \frac{(m-n)^{\underline{n-k}}}{(m-k)^{\underline{n-k}}} \\
&\le k/n,
\end{aligned}$$

where the first equality is from (6.4) and Proposition 25, the third equality is from (6.5), and for the first inequality we have used

$$d_{(m-k,\theta)} = m!/\mathsf{H}((m-k,\theta)) \le m^{\underline{k}}/\mathsf{H}(\theta).$$

6.4 Case $\ell > k$

Now consider $f \in \Omega_\mu$ such that $\mu \in \mathcal{C}_{n,\ell}$ for $\ell > k$. There are exactly $\binom{\ell}{k}$ assignments α of weight k that agree with f. We therefore have

$$\left|\left(\sum_{\nu \in \mathcal{C}_k} q_{\xi_\theta}(\nu)\phi_\nu\right)_f\right| \le \max_{\nu \in \mathcal{C}_k} |q_{\xi_\theta}(\nu)| \cdot \left(\sum_{\nu \in \mathcal{C}_k} \phi_\nu\right)_f \qquad = q_{\xi_\theta}\big((1^k|\varnothing)\big)\binom{\ell}{k} = d_{\xi_\theta}\binom{\ell}{k},$$

and Lemma 24 implies

$$|q_{(n-k,\theta)\otimes(m-k,\theta)}(\mu)| = |(\phi_{\xi_\theta})_f| \leq d_{(m-k,\theta)} d_{(n-k,\theta)} \ell^{\underline{k}} / n^{\underline{k}}. \tag{6.6}$$

We can also see that

$$\sum_{\mu \in \mathcal{C}_{n,\ell}} v_\mu^{(m)} = \ell! \binom{n}{\ell}^2 (m-n)^{\underline{n-\ell}}, \tag{6.7}$$

as that is the number of elements of $S_{n,m}$ whose image overlaps $[n]$ in ℓ points. Putting everything together, we have

$$\begin{aligned}
&\frac{\sum_{\ell=k+1}^{n} \left((\ell m - n^2) \sum_{\mu \in \mathcal{C}_{n,\ell}} v_\mu^{(m)} \cdot q^2_{(n-k,\theta)\otimes(m-k,\theta)}(\mu) \right)}{m^{\underline{n}} n (m-n) d_{(n-k,\theta)} d_{(m-k,\theta)}} \\
&\leq \frac{\sum_{\ell=k+1}^{n} (\ell m - n^2) \ell! \binom{n}{\ell}^2 (m-n)^{\underline{n-\ell}} \left(d_{(m-k,\theta)} d_{(n-k,\theta)} \ell^{\underline{k}} / n^{\underline{k}} \right)^2}{m^{\underline{n}} n (m-n) d_{(n-k,\theta)} d_{(m-k,\theta)}} \\
&= d_{(m-k,\theta)} d_{(n-k,\theta)} \sum_{\ell=k+1}^{n} \frac{(m-n)^{\underline{n-\ell}}}{m^{\underline{n}}} \frac{\ell m - n^2}{n(m-n)} \binom{n-k}{\ell-k}^2 \ell! \\
&\leq m^k n^k \sum_{\ell=k+1}^{n} \frac{m^{\underline{n-\ell}}}{m^{\underline{n}}} n^{2(\ell-k)} n^\ell \\
&\leq \frac{m^k}{n^k} \sum_{\ell=k+1}^{\infty} \left(\frac{n^3}{m-n} \right)^\ell \\
&= \frac{m^k}{n^k} \cdot \frac{n^{3k+3}}{(m-n)^k} \cdot \frac{1}{m-n-n^3} \\
&\leq 2 \frac{n^{2k+3}}{m},
\end{aligned}$$

where the first inequality follows from (6.6) and (6.7), and the last from $(1-n/m)^k \geq 1 - kn/m$. This completes the proof of the main result.

7 Concluding Remarks and Open Questions

While we have proven a tight $\Omega(\sqrt{n})$ lower bound on the bounded-error quantum query complexity of Index Erasure, the requirement $m \geq n^{3\sqrt{n}}$ on the range of injective functions seems unreasonably strict. We suspect that the same lower bound holds whenever $m \geq c \cdot n$ for any constant $c > \frac{1}{1-\epsilon}$, and we leave proving such a lower bound as an open problem.

When $n = m$, the n-partial permutation association scheme is simply the conjugacy-class association scheme of S_n (see [10]), whose eigenvalues are a normalization of the irreducible characters of S_n. While there is no known closed-formula for computing these normalized characters, they do admit elegant determinantal and combinatorial expressions (i.e., the Jacobi-Trudi and Murnaghan-Nakayama identities). Strahov [25] gave a generalization of the Murnaghan-Nakayama rule for $n = m - 1$, which gives a combinatorial expression for the eigenvalues of $S_{m-1,m}$ association scheme, but for arbitrary $n < m - 1$, there is no known Murnaghan-Nakayama-type rule for expressing the eigenvalues of the $S_{n,m}$ association scheme. Such an expression would give a deeper understanding of the dual eigenvalues of this scheme, and may allow one to extend our lower bound to smaller m.

Finally, our proof suggests a general strategy for deriving lower bounds on the quantum query complexity of sufficiently symmetric state conversion problems in the non-coherent regime. It would be interesting to use our approach to find such lower bounds for other such problems in the non-coherent regime.

A Connection to the graph isomorphism

Suppose we are given two rigid graphs G_0 and G_1 on k vertices (e.g., as $k \times k$ adjacency matrices), and we are asked to decide whether there exists a permutation of vertices $\pi \in S_k$ such that $\pi(G_0) = G_1$. Let $S_k(G) := \{\pi(G) \colon \pi \in S_k\}$ and

$$|S_k(G)\rangle := \frac{1}{\sqrt{k!}} \sum_{\pi \in S_k} |\pi(G)\rangle.$$

For a rigid graph G, the function $\pi \mapsto \pi(G)$ is injective and $|S_k(G)\rangle$ is the uniform superposition over the image of this function. Note that $S_k(G_0) = S_k(G_1)$ and $\langle S_k(G_0)|S_k(G_1)\rangle = 1$ if $G_0 \cong G_1$ and $S_k(G_0) \cap S_k(G_1) = \emptyset$ and $\langle S_k(G_0)|S_k(G_1)\rangle = 0$ if $G_0 \ncong G_1$.

Here we present two algorithms for Graph Isomorphism based on ability to generate the state $|S_k(G)\rangle|t_G\rangle$, where $|t_G\rangle$ is the final state of the ancillary memory. Both algorithms always return 0 when the graphs are isomorphic and return 1 with probability 1/2 when the graphs are non-isomorphic.

A.1 Coherent test

Suppose we prepare a quantum state

$$\frac{1}{\sqrt{2}} \sum_{b \in \{0,1\}} |b\rangle|S_k(G_b)\rangle|t_{G_b}\rangle,$$

where the first register specifies whether we create the superposition over permutations of G_0 or G_1 in the second register. Then we apply the Hadamard gate on the first register and measure. This procedure returns 0 with probability

$$\frac{1}{2} + \frac{1}{2}\Re\big[\langle S_k(G_0)|S_k(G_1)\rangle \langle t_{G_0}|t_{G_1}\rangle\big].$$

If $G_0 \ncong G_1$, then $|S_k(G_0)\rangle$ and $|S_k(G_1)\rangle$ are orthogonal states, and the measurement returns 1 with probability 1/2. On the other hand, if $G_0 \cong G_1$, then the probability of outputting 0 completely depends on $\Re[\langle t_{G_0}|t_{G_1}\rangle]$, on which we do not place any restrictions in the non-coherent case. However, in the coherent case, $\Re[\langle t_{G_0}|t_{G_1}\rangle] = 1$ and 0 would be always output whenever $G_0 \cong G_1$.

A.2 Non-coherent test

Now suppose we first prepare a quantum state

$$\frac{1}{\sqrt{2}}\Big(|0\rangle + |1\rangle\Big)|S_k(G_0)\rangle|S_k(G_1)\rangle|t_{G_0}\rangle|t_{G_1}\rangle,$$

and then use the content of the first register to decide whether to swap the next two registers, obtaining

$$\frac{1}{\sqrt{2}}\Big(|0\rangle|S_k(G_0)\rangle|S_k(G_1)\rangle + |1\rangle|S_k(G_1)\rangle|S_k(G_0)\rangle\Big)|t_{G_0}\rangle|t_{G_1}\rangle.$$

Then we apply the Hadamard gate on the first register and measure. This procedure returns 0 with probability

$$\frac{1}{2} + \frac{1}{2}\big\|\langle S_k(G_0)|S_k(G_1)\rangle\big\|^2.$$

Note that the ancillary memory states $|t_{G_0}\rangle$ play no role in this test.

We note that our $\Omega(\sqrt{n})$ lower bound for non-coherent Index Erasure does not apply here because of the condition $m = \Omega(n^{\sqrt{n}})$. In this context, n is the number of vertex permutations, $k!$, and m is the number of rigid graphs, which is of order $2^{\binom{k}{2}}$ [11, Corollary 2.3.3]. Nonetheless, the $\Omega(n^{1/3})$ lower bound (via Set Equality) still applies, which tells us that both Graph Isomorphism tests based on Index Erasure are inefficient. However, this dose not rule out an efficient preparation of $|S_k(G)\rangle$ by exploiting some inner workings of the oracle O_G (that is, by not treating it as a black-box).

B Dual Eigenvalues of Maximal Irreps

In Lemma 24 we essentially expressed dual eigenvalues for irreps of form $(n-k,\theta)\otimes(m-k,\theta)$ via dual eigenvalues for irreps of form $\lambda\otimes(m-n,\lambda)$, where $\theta\vdash k$ and $\lambda\vdash n$. Here we address obtaining the dual eigenvalues for irreps of form $\lambda\otimes(m-n,\lambda)$, in particular, obtaining the column vector $(m^{\underline{n}}E_{\lambda\otimes(m-n,\lambda)})_{f_{\mathrm{id}}}$, whose entries are the dual eigenvalues.

Of course, since we have $E_{\lambda\otimes(m-n,\lambda)} = E_{(m-n,\lambda)}$, we have

$$(m^{\underline{n}}E_{\lambda\otimes(m-n,\lambda)})_{f_{\mathrm{id}}} = m^{\underline{n}}E_{(m-n,\lambda)}1_{f_{\mathrm{id}}},$$

where

$$E_{(m-n,\lambda)} = \frac{d_{(m-n,\lambda)}}{m!}\sum_{\pi\in S_m}\chi_{(m-n,\lambda)}(\pi)V_\pi$$

and $V_\pi\colon 1_f \mapsto 1_{\pi * f}$. Below, however, we present an expression for $(m^{\underline{n}}E_{\lambda\otimes(m-n,\lambda)})_{f_{\mathrm{id}}}$ that might be more usefull when $n \ll m$, especially when n is constant.

Suppose $m \geq 2n$ and consider a $2n$-tuple

$$\boldsymbol{a} := (a_1^{(0)}, a_2^{(0)}, \cdots, a_n^{(0)}, a_1^{(1)}, a_2^{(1)}, \cdots, a_n^{(1)}) \in [m]^{2n}$$

of distinct elements. Consider the idempotent

$$E_{\boldsymbol{a}} := \frac{I - V_{(a_1^{(0)},a_1^{(1)})}}{2}\cdot\frac{I - V_{(a_2^{(0)},a_2^{(1)})}}{2}\cdot\cdots\cdot\frac{I - V_{(a_n^{(0)},a_n^{(1)})}}{2}.$$

The image of $E_{\boldsymbol{a}}$ is orthogonal to all λ'-isotypic subspaces for all $\lambda'\vdash m$ with $\lambda'_1 > m-n$ [4, Lemma 8]. For the $\mathcal{A}_{n,m}$ scheme, this means that the image of $E_{\boldsymbol{a}}$ is orthogonal to all irreps $\lambda\otimes\lambda'$ such that $\lambda' \neq (m-n,\lambda)$. On the other hand, for the vector

$$\phi_{\boldsymbol{a}} := \sum_{b\in\{0,1\}^n}(-1)^{|b|}1_{\boldsymbol{a}^b},$$

where $\boldsymbol{a}^b\colon [n]\to[m]\colon x\mapsto a_x^{(b_x)}$, we have $E_{\boldsymbol{a}}\phi_{\boldsymbol{a}} = \phi_{\boldsymbol{a}}$.

Now consider $a_x^{(0)} = x$ for all $x \in [n]$ and $(m-n)^{\underline{n}}$ choices of distinct $a_1^{(1)}, a_2^{(1)}, \cdots, a_n^{(1)}$ from $\{n+1, n+2, \cdots, m\}$, with their corresponding vectors $\phi_{\boldsymbol{a}}$. By adding all these vectors and then dividing the result by $(m-n)^{\underline{n}}$, we obtain

$$\phi_{\max} := \sum_{\ell=0}^{n} \frac{(-1)^\ell}{(m-n)^{\underline{\ell}}} 1_{(1^{n-\ell}|1^\ell)} \in (\mathfrak{A}_{n,m})_{f_{\mathrm{id}}},$$

where, for $\mu \in \mathcal{C}_n$, 1_μ is the characteristic column of A_μ, namely, $1_\mu = \sum_{f \in \Omega_\mu} 1_f$.

Now consider $\lambda \vdash n$ and the projector

$$E_\lambda = \frac{d_\lambda}{n!} \sum_{\pi \in S_n} \chi_\lambda(\pi) V_\pi$$

on the λ-isotypic subspace. By the above discussion, we have

$$E_\lambda \phi_{\max} = E_{\lambda \otimes (m-n,\lambda)} \phi_{\max},$$

which is proportional to the characteristic column of $E_{\lambda\otimes(m-n,\lambda)} 1_{f_{\mathrm{id}}}$, and the coefficient of proportionality is

$$\frac{1_{f_{\mathrm{id}}}^\top E_\lambda \phi_{\max}}{1_{f_{\mathrm{id}}}^\top E_{\lambda\otimes(m-n,\lambda)} 1_{f_{\mathrm{id}}}} = \frac{(d_\lambda/n!) d_\lambda}{d_\lambda d_{\lambda'}/m^{\underline{n}}} = \frac{d_\lambda m^{\underline{n}}}{d_{\lambda'} n!},$$

where we have used that $1_{f_{\mathrm{id}}}^\top V_\pi 1_{(1^{n-\ell}|1^\ell)} = 0$ whenever π is not the identity permutation ε or $\ell \neq 0$ (or both), $1_{(1^n|\varnothing)} = 1_{f_{\mathrm{id}}}$, and $\chi_\lambda(\varepsilon) = d_\lambda$. Hence,

$$(m^{\underline{n}} E_{\lambda\otimes(m-n,\lambda)})_{f_{\mathrm{id}}} = \frac{d_{\lambda'} n!}{d_\lambda} E_\lambda \phi_{\max} = d_{\lambda'} \sum_{\pi \in S_n} \chi_\lambda(\pi) V_\pi \phi_{\max}.$$

C Partial Permutations and RSK Correspondence

A well-known fact is that S_m admits the following representation-theoretic count

$$|S_m| = \sum_{\lambda \vdash m} (d_\lambda)^2 \tag{C.1}$$

where d_λ is the number of standard Young tableau of shape $\lambda \vdash m$ (see [22]). An elegant combinatorial proof of this fact follows from *Robinson-Schensted Correspondence*, a well-known combinatorial procedure that associates to each permutation $\sigma \in S_m$ a unique pair of standard Young tableaux of the same shape, and vice versa (see [22]).

Knuth generalized this correspondence to a wider class of combinatorial objects called *generalized permutations*, which are $2 \times m$ arrays of integers

$$\begin{pmatrix} i_1 & i_2 & \cdots & i_m \\ j_1 & j_2 & \cdots & j_m \end{pmatrix} \text{ such that } i_1 \leq \cdots \leq i_m \text{ and if } i_r = i_{r+1}, \text{then } j_r \leq j_{r+1}.$$

Robinson-Schensted-Knuth Correspondence (RSK) associates a pair of semistandard Young tableau of the same shape to each generalized permutation, and vice versa (see [22]). We may encode each n-partial permutation $(j_1, j_2, \cdots, j_n) \in S_{n,m}$ as a generalized permutation as follows:

$$(j_1, j_2, \cdots, j_n) \longleftrightarrow \begin{pmatrix} 1 & 2 & \cdots & n & n+1 & \cdots & n+1 \\ j_1 & j_2 & \ldots & j_n & j_{n+1} & \cdots & j_m \end{pmatrix},$$

where $j_{n+1}, \cdots, j_m \in [m] \setminus \{j_1, \cdots, j_n\}$ are ordered from least to greatest. Applying RSK to n-partial permutations associates to each $(j_1, j_2, \cdots, j_n) \in S_{n,m}$ a standard Young tableau P and a semistandard Young tableau Q of the same shape $\lambda \vdash m$. The subtableau of cells labeled $n+1$ in Q form a horizontal strip on $m-n$ cells. Ignoring this horizontal strip results in a standard Young tableau of shape $\mu \vdash n$ such that λ/μ is a horizontal strip, and so we arrive at the following theorem.

▶ **Theorem 26.** *RSK gives an explicit bijection between $S_{n,m}$ and pairs (P, Q) where P is a standard Young tableau of shape $\lambda \vdash m$ and Q is a standard Young tableau of shape $\mu \vdash n$ such that λ/μ is a horizontal strip.*

As a corollary, we get a combinatorial proof of a natural generalization of Equation (C.1).

▶ **Corollary 27.** *The number of n-partial permutations of $[m]$ can be counted as follows:*

$$|S_{n,m}| = \sum_{\mu,\lambda} d_\mu d_\lambda$$

where the sum runs over pairs $\mu \vdash n, \lambda \vdash m$ such that λ/μ is a horizontal strip.

D Proofs

Theorem 7 (restated). *Let $\theta \vdash k$ and $\theta^+ \vdash (k+1)$ be any shape obtained by adding an inner corner to θ. For all $m \geq 2(k+1)$, we have*

$$\frac{d_{(m-k-1,\theta^+)}}{d_{(m-k,\theta)}} \geq \frac{m}{k} \cdot \left(1 - \frac{2k+1}{m}\right).$$

Proof. Recall that, by the hook rule, $\mathsf{H}(\theta) d_\theta = |\theta|!$. First, [20, Claim 6.3] states that

$$\frac{d_{(m-|\theta^+|,\theta)}}{d_{(m-|\theta|,\theta)}} \geq 1 - \frac{2k}{m}.$$

We reprove this claim here for completeness. Note that when we add a cell to the end of the top row of $(m-|\theta^+|, \theta)$ to obtain $(m-|\theta|, \theta)$, this increases the hook-lengths of the cells in the top row by 1, and the rest of the hook-lengths are unchanged. If we just consider the "overhang" and ignore everything else in the first row, then the product of the hook-lengths with respect to $(m-|\theta|, \theta)$ is $(m-2k)!$ whereas it is $(m-2k-1)!$ with respect to $(m-|\theta^+|, \theta)$. This gives us

$$\frac{d_{(m-|\theta^+|,\theta)}}{d_{(m-|\theta|,\theta)}} \geq \frac{m-2k}{m} = 1 - \frac{2k}{m},$$

which proves the claim.

Since $(m-|\theta^+|, \theta)$ is a partition of $(m-1)$, it corresponds to an (S_{m-1})-irrep. When we added one cell to $(m-|\theta^+|, \theta)$ to obtain $(m-|\theta^+|, \theta^+)$, only one hook-length in the first row increased, and before the increment it was at least $m-2k-1$. Thus, in the following derivation, all the other hook-lengths of the first rows of $(m-|\theta^+|, \theta)$ and $(m-|\theta^+|, \theta^+)$ have cancelled out.

$$\begin{aligned}\frac{d_{(m-|\theta^+|,\theta^+)}}{d_{(m-|\theta^+|,\theta)}} &\geq \frac{m!}{(m-1)!} \cdot \frac{m-2k-1}{m-2k} \cdot \frac{\mathsf{H}(\theta)}{\mathsf{H}(\theta^+)} \\ &= m\left(1 - \frac{1}{m-2k}\right) \frac{k! d_{\theta^+}}{(k+1)! d_\theta} \geq \frac{m}{k+1}\left(1 - \frac{1}{m-2k}\right),\end{aligned}$$

where in the middle equality we have used hook-length formula once more, and the last inequality follows from the branching rule (namely, that $d_{\theta^+} \geq d_\theta$). Combining these two inequalities gives the result. ◀

Theorem 12 (restated). *Let $1_\alpha \in \mathbb{C}[S_{n,m}]$ be the characteristic function of the family S_α. Then $1_\alpha \in \mathcal{U}_k$.*

Proof. Let $\mathrm{Stab}_{S_m}(S_\alpha)$ be the stabilizer of S_α, which consists of all the permutations of $[m] \setminus \mathrm{im}(\alpha)$ and, thus, $\mathrm{Stab}_{S_m}(S_\alpha) \cong S_{m-k}$. Let $\lambda \vdash m$ be any irrep of S_m such that $m - \lambda_1 > k$ and let $\lambda(\pi)$ be a matrix that represents $\pi \in S_m$. Finally, let $1_{\mathrm{Stab}(S_\alpha)} \in \mathbb{C}[S_m]$ be the characteristic function of $\mathrm{Stab}_{S_m}(S_\alpha)$, and recall from Section 3.1 that its Fourier transform is

$$\lambda(1_{\mathrm{Stab}(S_\alpha)}) = \sum_{\pi \in S_m} 1_{\mathrm{Stab}(S_\alpha)}(\pi)\, \lambda(\pi) = \sum_{\pi \in S_{m-k}} \left(\lambda \downarrow^{S_m}_{S_{m-k}}\right)(\pi).$$

Since λ has more than k cells below its first row, by the branching rule, no irrep μ of $\lambda \downarrow^{S_m}_{S_{m-k}}$ is isomorphic to the trivial representation $(m-k)$. This, and the fact that $\langle \chi^{(m-k)}, \chi^\mu \rangle = 0$ for any $\mu \vdash m-k$ with $\mu \neq (m-k)$, implies that, for each irrep μ of the multiset of irreps $\lambda \downarrow^{S_m}_{S_{m-k}}$, we have $\sum_{\pi \in S_{m-k}} \mu(\pi) = 0$. This gives us

$$\lambda(1_{\mathrm{Stab}(S_\alpha)}) = \bigoplus_{\mu \in \lambda \downarrow^{S_m}_{S_{m-k}}} \sum_{\pi \in S_{m-k}} \mu(\pi) = 0,$$

which completes the proof. ◀

Theorem 4 (restated). *Let G be an automorphism group for a non-coherent state generation problem. The value of Adv_δ remains the same if one restricts the minimization in the expression defining Adv_δ and the maximization in the expressions defining the γ_2 and filtered γ_2 norms to R, T, Γ, Γ' that are all G-invariant and imposes that $(J - R) \circ \Gamma$ has an G-invariant principal eigenvector.*

Proof. In this proof, let M denote a generic symmetric matrix whose rows and columns are labeled by black-box functions $f \in \mathcal{F}$ in the same order. Let $g(M)$ be obtained by permuting the rows and the columns of M according to the action of $g \in G$ of $\mathcal{F}$ (see (2.2)). Namely, entrywise we define $g(M)$ as

$$(g(M))_{f,f'} := M_{g^{-1}(f), g^{-1}(f')}.$$

Similarly, for a vector $\omega \in \mathbb{C}[\mathcal{F}]$, define $g(\omega)$ entrywise as $(g(\omega))_{f'} := \omega_{g^{-1}(f)}$. For the sake of conciseness, we also occasionally write M^g and ω^g instead of $g(M)$ and $g(\omega)$, respectively. Note that M is G-invariant if $M^g = M$ for all $g \in G$, and $T^\odot, I, J$ are G-invariant. Also note that $(M \circ M')^g = M^g \circ M'^g$.

Let $\Delta = \{\Delta_1, \cdots, \Delta_n\}$ be the family of difference matrices. This family is closed under the action of G is the following sense.

▷ Claim 28. We have $(\pi, \boldsymbol{\sigma})(\Delta_x) = \Delta_{\pi(x)}$ for all $(\pi, \boldsymbol{\sigma}) \in G$.

Proof. Fix $(\pi, \boldsymbol{\sigma}) \in G$ and let $g := (\pi, \boldsymbol{\sigma})^{-1}$. Note that $g = (\pi^{-1}, \boldsymbol{\sigma}')$ for some $\boldsymbol{\sigma}' \in S_m^n$. From (2.2), we have $(g(f))(x) = (g(f'))(x)$ if and only if $f(\pi(x)) = f'(\pi(x))$. As a result, we have

$$((\pi, \boldsymbol{\sigma})(\Delta_x))_{f,f'} = (\Delta_x)_{g(f), g(f')} = 1$$

if and only if $f(\pi(x)) = f'(\pi(x))$. ◀

Note that M^g equals M with its rows and columns permuted. Since permuting rows and columns do not affect the γ_2 norm, we have $\gamma_2(M^g) = \gamma_2(M)$ for all $g \in G$. And, if the diagonal of M is all-zeros, then Claim 28 also implies that $\gamma_2(M^g|\Delta) = \gamma_2(M|\Delta)$ for all $g \in G$.

▶ **Lemma 29.** *Restricting $R, T \in \mathcal{T}$ to be G-invariant does not change the optimal value of the minimization problem defining Adv_δ.*

Proof. Let R, T be an optimal solution of the minimization in (2.1). We define their respective G-symmetrizations as

$$\overline{R} := \frac{1}{|G|}\sum_{g\in G} g(R) \qquad \text{and} \qquad \overline{T} := \frac{1}{|G|}\sum_{g\in G} g(T),$$

which are both clearly in $\mathcal{T}$. Since $g(T^\odot) = T^\odot$ for all $g \in G$, the triangle inequality yields

$$\begin{aligned}\gamma_2(\overline{R} - T^\odot \circ \overline{T}) = \gamma_2\left(\frac{1}{|G|}\sum_{g\in G} g(R - T^\odot \circ T)\right) &\le \frac{1}{|G|}\sum_{g\in G}\gamma_2\big(g(R - T^\odot \circ T)\big)\\ &= \frac{1}{|G|}\sum_{g\in G}\gamma_2(R - T^\odot \circ T) = \gamma_2(R - T^\odot \circ T) \le \delta.\end{aligned}$$

Hence we have show that the pair $\overline{R}, \overline{T}$ is a feasible solution to the minimization in (2.1), and it remains to show that it is also optimal. And, again by the triangle inequality,

$$\begin{aligned}\gamma_2(J - \overline{R}|\Delta) = \gamma_2\left(\frac{1}{|G|}\sum_{g\in G} g(J - R)\middle|\Delta\right) &\le \frac{1}{|G|}\sum_{g\in G}\gamma_2\big(g(J - R)|\Delta\big)\\ &= \frac{1}{|G|}\sum_{g\in G}\gamma_2(J - R|\Delta) = \gamma_2(J - R|\Delta) = \mathsf{Adv}_\delta.\end{aligned}$$

◀

Now, fix G-invariant $R, T \in \mathcal{T}$ and let $M := J - R$, which is also G-invariant. Let us now show that the maximization in

$$\gamma_2(M|\Delta) = \max_{\Gamma}\left\{\|M \circ \Gamma\| \colon \forall x\ \|\Delta_x \circ \Gamma\| \le 1\right\}$$

can be restricted to G-invariant Γ.

The proof is very similar to that of the automorphism principle in [15]. Fix an optimal solution Γ, and without loss of generality assume that the largest eigenvalue of $M \circ \Gamma$ is positive and let it correspond to an eigenvector $\omega \in \mathbb{C}[\mathcal{F}]$ of norm 1. Namely,

$$\|M \circ \Gamma\| = \omega^\top (M \circ \Gamma)\omega.$$

Define the G-symmetrization $\overline{\omega}$ of ω entrywise as

$$\overline{\omega}_f := \sqrt{\frac{1}{|G|}\sum_{g\in G} |(\omega^g)_f|^2},$$

and note that $\overline{\omega}$ also has norm 1. Without loss of generality, all the entries of $\overline{\omega}$ are strictly positive (the rows and columns corresponding to f such that $\overline{\omega}_f = 0$ can be removed from the consideration), and thus we can entrywise define a vector μ as $\mu_f := 1/\overline{\omega}_f$. Let us define

$$\overline{\Gamma} := \mu\mu^\top \circ \frac{1}{|G|} \sum_{g \in G} \Gamma^g \circ \omega^g \omega^{g\top},$$

which is clearly G-invariant.

Let us start by showing that $\|\overline{\Gamma} \circ \Delta_x\| \leq 1$ for all x. Note that $\|\Gamma^g \circ \Delta_x\| \leq 1$ for all x and all $g \in G$ due to Claim 28, $\|\Gamma \circ \Delta_x\| \leq 1$ if and only if $I \pm \Gamma \circ \Delta_x$ is positive-semidefinite, and

$$I \circ \mu\mu^\top \circ \frac{1}{|G|} \sum_{g \in G} \omega^g \omega^{g\top} = I.$$

We thus have that

$$I \pm \overline{\Gamma} \circ \Delta_x = \mu\mu^\top \circ \frac{1}{|G|} \Big(\sum_{g \in G} \omega^g \omega^{g\top} \circ (I \pm \Gamma^g \circ \Delta_x) \Big)$$

is positive-semidefinite as the sum and the entrywise product of positive-semidefinite matrices are positive-semidefinite. Thus, indeed, $\|\overline{\Gamma} \circ \Delta_x\| \leq 1$ for all x.

Now let us use the fact that ω is a principal eigenvector of $M \circ \Gamma$, and, therefore, ω^g is a principal eigenvector of $M \circ \Gamma^g$ for all $g \in G$ (recall that M is G-invariant). We have

$$\begin{aligned} \|M \circ \overline{\Gamma}\| \geq \overline{\omega}\, \overline{\Gamma}\, \overline{\omega}^\top &= \sum_{f,f' \in \mathcal{F}} \Big(\frac{1}{|G|} \sum_{g \in G} (M \circ \Gamma^g \circ \omega^g \omega^{g\top}) \Big)_{f,f'} \\ &= \frac{1}{|G|} \sum_{g \in G} \omega^{g\top} (M \circ \Gamma^g) \omega^g = \|M \circ \Gamma\|. \end{aligned}$$

Thus $\overline{\Gamma}$ is also an optimal solution of the maximization above. Also note that $\overline{\omega}$ is the principal eigenvector of $M \circ \overline{\Gamma}$.

A similar argument shows that, for G-invariant $M' := R - T^{\odot} \circ T$, one can restrict the maximization in

$$\gamma_2(M') = \max_{\Gamma'} \big\{ \|M' \circ \Gamma'\| \colon \|\Gamma'\| \leq 1 \big\}$$

to G-invariant Γ'. ◀

Optimal Single-Choice Prophet Inequalities from Samples

Abstract

We study the single-choice Prophet Inequality problem when the gambler is given access to samples. We show that the optimal competitive ratio of 1/2 can be achieved with a single sample from each distribution. When the distributions are identical, we show that for any constant $\varepsilon > 0$, $O(n)$ samples from the distribution suffice to achieve the optimal competitive ratio (≈ 0.745) within $(1+\varepsilon)$, resolving an open problem of [9].

1 Introduction

Consider the classic single-choice Prophet Inequality problem. Offline, there are n distributions $\mathcal{D}_1, \ldots, \mathcal{D}_n$ presented to a gambler. For $i = 1$ to n, a random variable X_i is drawn independently from $\mathcal{D}_i$ and revealed online. The gambler must then decide immediately and irrevocably whether to accept X_i (and achieve reward X_i, ending the game), or reject X_i (continuing the game, but never revisiting X_i again). The goal of the gambler is to devise a stopping rule which maximizes their expected reward. The performance of potential stopping rules is typically measured by their *competitive ratio* in comparison to a prophet (who knows all X_i in advance and achieves expected reward $\mathbb{E}[\max_i\{X_i\}]$). Typically, prophet inequalities are designed assuming that the distributions presented offline are fully known. This paper focuses on the setting where the gambler is instead presented with offline samples from the $\mathcal{D}_i$, rather than complete knowledge.

In the classic setting, seminal work of Krengel and Sucheston provides a strategy guaranteeing a competitive ratio of 1/2, which is the best possible [22].[1] Samuel-Cahn later proved that simply setting a threshold equal to the *median* of $\max_i\{X_i\}$ (i.e. a value T such that $\Pr[\max_i\{X_i\} > v] = 1/2$) also achieves the optimal competitive ratio of 1/2 [25], and

[1] To see that no better than 1/2 is possible, consider an instance where X_1 is deterministically 1, and X_2 is $1/\varepsilon$ with probability ε, and 0 otherwise. The prophet achieves $2-\varepsilon$ (taking X_2 when it is large, and X_1 otherwise), while the gambler achieves only 1 (they must decide whether to take X_1 without knowing if X_2 is large).

it was later shown that a threshold of $\mathbb{E}[\max_i\{X_i\}]/2$ suffices as well [21]. These last two thresholds are remarkably simple, but certainly require a non-trivial number of samples to estimate well.

Our first result establishes that *a single sample* from each $\mathcal{D}_i$ suffices to achieve the optimal competitive ratio of $1/2$. The algorithm is also exceptionally simple: if $\tilde{X}_1, \ldots, \tilde{X}_n$ denote independent samples from $\mathcal{D}_1, \ldots, \mathcal{D}_n$, simply set $\max_i\{\tilde{X}_i\}$ as a threshold.

▶ **Definition 1** (Single Sample Algorithm)**.** *Given as input $\tilde{X}_1, \ldots, \tilde{X}_n$, set a threshold $T = \max_i\{\tilde{X}_i\}$ and accept the first random variable exceeding T.*

▶ **Theorem 2.** *The Single Sample Algorithm guarantees a competitive ratio of $1/2$.*

A subsequent line of works considers the special case where each $\mathcal{D}_i$ is identical (which we'll refer to as $\mathcal{D}$). Here, work of Hill and Kertz provided the first improved competitive ratio (of $1 - 1/e$) [19], and this was recently improved to the optimal competitive ratio of $\alpha \approx 0.745$ [10]. Our second result establishes that a *linear number of samples* from $\mathcal{D}$ suffices to achieve the optimal competitive ratio, up to ε. Since our algorithm simply replaces the quantile-based thresholds of [10] with samples, we call it Samples-CFHOV (the five authors of [10]). The algorithm and analysis are fairly simple and we provide a formal description in Section 4.

▶ **Theorem 3.** *With $O(n/\varepsilon^6)$ samples, Samples-CFHOV achieves a competitive ratio of $\alpha - O(\varepsilon)$.*

1.1 Related Work

Over the past decade, prophet inequalities have been studied from numerous angles within the TCS community [7, 3, 21, 17, 15, 23, 16, 24, 12, 14, 6, 2, 11, 4, 18, 13, 8]. All of these works assume explicit knowledge of the given distributions. The limited prior work most related to ours considers sample access to the underlying distributions. On this front, Azar et al. consider prophet inequalities subject to combinatorial constraints, and establish that limited samples suffice to obtain constant competitive ratios in many settings [5]. In comparison to this work, our paper considers only *optimal* competitive ratios, and the simple single-choice setting.

In the i.i.d. model (each value is drawn from the same $\mathcal{D}$), a $(1 - 1/e)$-approximation was first shown in [19], and recent work achieved the same guarantee with $n - 1$ samples from $\mathcal{D}$ [9]. This ratio was later improved to ≈ 0.738 [1], and then to $\alpha \approx 0.745$ [10], where α is the optimal achievable competitive ratio [19, 20]. The most related work in this sequence to ours is [9], who establish that a competitive ratio of $\alpha - \varepsilon$ is achievable with $O(n^2)$ samples (for any constant ε), and that $\Omega(n)$ samples are necessary. They also establish a formal barrier to achieving $\alpha - \varepsilon$ with $o(n^2)$ samples. In comparison, we circumvent their barrier to achieve a competitive ratio of $\alpha - \varepsilon$ with $O(n)$ samples, resolving one of their open problems.

Roadmap

In Section 2, we provide brief preliminaries. Section 3 contains our 2-approximation with a single sample. Section 4 contains our $(\alpha - \varepsilon)$-approximation with linearly many samples.

2 Preliminaries

There are n distributions, $\mathcal{D}_1, \ldots, \mathcal{D}_n$. Online, a gambler sees a random variable X_i drawn from $\mathcal{D}_i$ one at a time, and must immediately and irrevocably decide whether to accept (and get reward X_i) or reject (and see X_{i+1}, throwing away X_i forever). Strategies for a gambler are often termed *stopping rules*, and the competitive ratio of a stopping rule is the worst-case ratio (over all possible n, and $\mathcal{D}_1, \ldots, \mathcal{D}_n$) between its expected reward and $\mathbb{E}[\max_i\{X_i\}]$.

Our algorithms will not have knowledge of any $\mathcal{D}_i$, but instead will have access to samples. Our algorithms will treat these samples as the only offline input, and decide whether to accept or reject an element based only on the value of that element and the samples.[2] Here, we will count the number of samples from each distribution as our sample complexity.

We will also consider the *i.i.d. setting*, where each $\mathcal{D}_i = \mathcal{D}$. Here, we will count the total number of samples from $\mathcal{D}$ as our sample complexity. In this setting, we will let $\alpha \approx 0.745$ denote the optimal competitive ratio for an algorithm with knowledge of $\mathcal{D}$.

Continuous versus Discrete Random Variables

All of our algorithm definitions are straight-forward for continuous distributions. For distributions with point masses, the following "reduction" to continuous is needed. Instead of thinking of $\mathcal{D}$ as a single-variate distribution, we will (overload notation and) think of $\mathcal{D}$ as a bivariate distribution with the first coordinate drawn from $\mathcal{D}$, and the second "tie-breaker" coordinate drawn independently and uniformly from $[0, 1]$. Then $(X_1, t_1) > (X_2, t_2)$ if either $X_1 > X_2$, or $X_1 = X_2$ and $t_1 > t_2$. Observe that because the tie-breaker coordinate is continuous, the probability of having $(X_1, t_1) = (X_2, t_2)$ for any two values during a run of any algorithm is zero. Therefore, if we define $F_{\mathcal{D}}(X, t) := \Pr_{(Y,u)\leftarrow(\mathcal{D},U([0,1]))}[(Y, u) < (X, t)]$, we have that $F_{\mathcal{D}}(X, t) < F_{\mathcal{D}}(Y, u) \Leftrightarrow (X, t) < (Y, u)$. We will not explicitly reference this tie-breaker random variable in the definition of our algorithms, but simply refer to $X \leftarrow \mathcal{D}$ as the pair (X, t).

Adversaries

Prophet Inequalities are typically studied against an *offline adversary*. That is, the adversary simply picks the distributions $\mathcal{D}_1, \ldots, \mathcal{D}_n$ (and their indices), which is all presented to the gambler offline. Some prophet inequalities hold against the stronger *almighty adversary*, which selects the set of distributions $\{\mathcal{D}_1, \ldots, \mathcal{D}_n\}$ offline, then decides in which order to reveal the random variables $X_1, \ldots, X_n$ based on their realization. Note that previous competitive ratios of $1/2$ in the non-i.i.d. setting hold against an almighty adversary, and Theorem 2 does as well. Previous competitive ratios of α in the i.i.d. setting hold against the offline adversary (and are impossible to achieve against the almighty adversary), so Theorem 3 holds against the offline adversary as well.

3 The Non-I.I.D. Case: Optimal Ratio with a Single Sample From $\mathcal{D}_i$

The Single Sample Algorithm proceeds as follows. It takes as input $\tilde{X}_i$ drawn independently from each $\mathcal{D}_i$, sets a threshold $T = \max_i\{\tilde{X}_i\}$, and accepts the first element exceeding T. Our goal in this section is to prove Theorem 2 that this algorithm obtains $\frac{1}{2}$ the reward, in expectation, of the omniscient prophet that always selects the highest value.

[2] In principle, sample-based algorithms might also consider previously viewed elements, but our algorithms don't.

Our analysis will use the principle of deferred decisions: instead of first drawing the samples $\tilde{X}$, and then revealing the actual draws X, we will jointly draw $2n$ samples $Y_1, \ldots, Y_n, Z_1, \ldots, Z_n$, and then for each i randomly decide which of $\{Y_i, Z_i\}$ is equal to $\tilde{X}_i$ and which is equal to X_i. Formally, consider the following Deferred-Decisions procedure for drawing $X, \tilde{X}$:

1. Draw $Y_1, \ldots, Y_n$ and $Z_1, \ldots, Z_n$ independently each from $\mathcal{D}_1, \ldots, \mathcal{D}_n$.
2. For ease of notation later, for all i, relabel so that $Y_i > Z_i$.
3. Independently, flip n fair coins. If coin i is heads, set $X_i := Y_i$ and $\tilde{X}_i := Z_i$. Otherwise, set $X_i := Z_i$ and $\tilde{X}_i := Y_i$.

▶ **Observation 4.** *The output of the Deferred-Decisions procedure correctly generates $\tilde{X}_1, \ldots, \tilde{X}_n$ and $X_1, \ldots, X_n$ as independent draws from $\mathcal{D}_1, \ldots, \mathcal{D}_n$.*

Our analysis will proceed by directly comparing, for any fixed $Y_1, \ldots, Y_n, Z_1, \ldots, Z_n$, the expected reward of the gambler over the randomness in the coin flips of step three to the expected reward of the prophet over the randomness in the coin flips of step three. We note that this analysis is similar to that of the rehearsal algorithm of [5] for k-uniform matroids (whose competitive ratio is asymptotically optimal for large k), and that prior to this it was folklore knowledge that the Single Sample Algorithm achieves a competitive ratio of at least $1/4$. The novelty in our analysis is precisely nailing down the tight competitive ratio.

3.1 Analysis Setup

For a fixed $Y_1, \ldots, Y_n, Z_1, \ldots, Z_n$, sort the values into descending order, and relabel them as $W_1, \ldots, W_{2n}$. If W_j is equal to Y_i (or Z_i), we say that W_j *comes from* i, and denote this with $\text{index}(W_j) = i$. Call the *pivotal index* j^* the minimum j such that there exists an $\ell > j$ with $\text{index}(W_\ell) = \text{index}(W_j)$. That is, the pivotal index j^* is such that there are exactly $j^* - 1$ Y random variables exceeding the largest Z random variable.

Our analysis will make use of the following concept: for each $W_1, \ldots, W_{j^*-1}$, let C_j denote the outcome of the coinflip for $\text{index}(W_j)$ (which assigns either Y_i or Z_i to arrive as a sample and the other to arrive as a real value). Observe, importantly, that the random variables $C_1, \ldots, C_{j^*-1}$ are independent (because they are independent coin flips for different indices). Also importantly, observe that the random variable C_{j^*} is deterministic conditioned on $C_1, \ldots, C_{j^*-1}$ (because it is exactly the same coin flip as one of the earlier indices).

3.2 The Prophet's Expected Reward

▶ **Proposition 5.** *For fixed $W_1, \ldots, W_{2n}$ and pivotal index j^*, the prophet's expected reward, over the randomness in the coin flips of step three, is $\sum_{j=1}^{j^*-1} W_j/2^j + W_{j^*}/2^{j^*-1}$.*

Proof. Observe that the prophet achieves expected reward equal to $\max_i\{X_i\}$, so we just want to compute the probability that this is $W_1, \ldots, W_{2n}$. For each $j < j^*$, W_j is equal to $\max_i\{X_i\}$ if and only if C_j is heads, and C_ℓ is tails for all $\ell < j$ (recall that all W_j's are Y random variables for $j < j^*$). Because each of the coin flips are independent, this occurs with probability precisely $1/2^j$.

For j^*, W_{j^*} is equal to $\max_i\{X_i\}$ if and only if C_ℓ is tails for all $\ell < j^*$, and coin C_{j^*} is tails. Observe, however, that by definition of the pivotal index j^*, that when C_ℓ is tails for all $\ell < j^*$ we have C_{j^*} as tails as well (because it is the same coin as one of the first $j^* - 1$). Therefore, whenever all of the first $j^* - 1$ coins are tails, $\max_i\{X_i\} = W_{j^*}$ (and this happens with probability $1/2^{j^*-1}$).

As the first j^*-1 coins either contain some heads, or are all tails (and we have counted the prophet's reward in all such cases), we have now fully accounted for the prophet's expected reward over the randomness in the coin flips. ◀

3.3 The Single Sample Algorithm's Expected Reward

▶ **Proposition 6.** *For fixed $W_1, \ldots, W_{2n}$ and pivotal index j^*, the gambler's expected reward, over the randomness in the coin flips of step three, is at least $\sum_{j=1}^{j^*-2} W_j/2^{j+1} + W_{j^*-1}/2^{j^*-1}$.*

Proof. Consider the case where C_1 is tails. In this case, the gambler gets no reward because the threshold is higher than all revealed elements. For $j < j^* - 1$, consider next the case where $C_1, \ldots, C_j$ are heads, but C_{j+1} is tails. In this case, the gambler gets reward *at least* W_j (because the gambler will accept the first non-sample random variable exceeding W_{j+1}, and these random variables have values $W_1, \ldots, W_j$). The probability that this occurs is exactly $1/2^{j+1}$.

Consider also the case where $C_1, \ldots, C_{j^*-1}$ are all heads. Then the threshold is set at W_{j^*}, and the gambler will get at least W_{j^*-1}. This occurs with probability exactly $1/2^{j^*-1}$. ◀

3.4 Proof of Theorem 2

Proof. We can immediately see that:

$$\sum_{j=1}^{j^*-2} W_j/2^{j+1} + W_{j^*-1}/2^{j^*-1} \geq \sum_{j=1}^{j^*-1} W_j/2^{j+1} + W_{j^*}/2^{j^*}$$
$$= \frac{1}{2} \cdot \left(\sum_{j=1}^{j^*-1} W_j/2^j + W_{j^*}/2^{j^*-1} \right).$$

By Propositions 5 and 6, the right-hand side is exactly half the prophet's expected reward, conditioned on $W_1, \ldots, W_{2n}$ and j^*, and the left-hand side is exactly the gambler's expected reward (again conditioned on $W_1, \ldots, W_{2n}$ and j^*). As the gambler achieves half the prophet's expected reward for all $W_1, \ldots, W_{2n}$ and j^*, the guarantee holds in expectation as well. ◀

4 The I.I.D. Case: Optimal Ratio with Linear Samples From $\mathcal{D}$

We begin with a brief overview of the algorithm from [10] and its main features, followed by a formal specification of our algorithm.

4.1 Overview of [10] and Samples-CFHOV

The algorithm of [10] (with one slight modification due to [9]) proceeds as follows. We'll refer to this algorithm as Explicit-CFHOV.

1. As a function only of n, and independently of $\mathcal{D}$, define monotone increasing probabilities $0 \leq p_1 \leq \ldots p_n \leq 1$.
2. For all i such that $p_i \leq \delta = \varepsilon^2/n$, update $p_i := 0$ (this is the [9] modification).
3. Accept X_i if and only if $F_{\mathcal{D}}(X_i) > 1 - p_i$. Observe that this is identical to accepting X_i if and only if $X_i > \sigma_i = F_{\mathcal{D}}^{-1}(1-p_i)$. Also observe that X_i exceeds σ_i with probability p_i.

▶ **Theorem 7** ([10, 9]). *In the i.i.d. setting, Explicit-CFHOV has competitive ratio $\alpha - \varepsilon$.*[3]

[3] Without step two, the algorithm achieves a competitive ratio of α.

That is, Explicit-CFHOV sets, for each $i \in [n]$, a probability p_i independent of $\mathcal{D}$, and sets a threshold σ_i for accepting X_i which is exceeded with probability exactly p_i.

If instead of explicit access to $\mathcal{D}$, we're given m i.i.d. samples from $\mathcal{D}$, the challenge is simply that we can no longer compute $F_{\mathcal{D}}(X_i)$ exactly and run Explicit-CFHOV. The algorithm of [9] observes that $m = O(n^2)$ samples suffices to estimate the quantiles sufficiently well. Our algorithm observes that in fact $m = O(n)$ samples suffice (which is asymptotically tight, by a lower bound in [9]). Our algorithm proceeds as follows, which we call Samples-CFHOV.

1. **As a function only of n, and independently of $\mathcal{D}$**, define monotone increasing probabilities $0 \le p_1 \le \dots p_n \le 1$, exactly as in Explicit-CFHOV.
2. Round down each p_i to the nearest integer power of $(1+\varepsilon)$; we denote the rounded value by $\lfloor p_i \rfloor \in \{(1+\varepsilon)^{-1}, (1+\varepsilon)^{-2} \dots\}$.
3. Set $\tilde{p}_i := \lfloor p_i \rfloor / (1+\varepsilon)$ (that is, we have rounded down each p_i, then further divided by $(1+\varepsilon)$).
4. From our m samples, let τ_i denote the value of the $(\tilde{p}_i \cdot m)$-th highest sample.
5. Accept X_i if and only if $X_i > \tau_i$.

That is, Samples-CFHOV provides an estimate τ_i of σ_i via the m samples. Intuitively, we are trying to overestimate σ_i so that it is unlikely that Samples-CFHOV will ever choose to accept an element that Explicit-CFHOV would not. We'll prove Theorem 3 as a corollary of Theorem 8:

▶ **Theorem 8.** *For any distribution $\mathcal{D}$, with $m = O(n/\varepsilon^6)$ samples, the expected value achieved by Samples-CFHOV is at least a $(1 - O(\varepsilon))$-fraction of that of Explicit-CFHOV.*

We briefly remark that our proof of Theorem 8 actually holds for any choice of p_i's (all $\notin (0, \delta)$). That is, if Explicit-CFHOV achieves a competitive ratio of $\gamma(\vec{p})$ with a particular choice of $\vec{p}$, Samples-CFHOV achieves a competitive ratio of $\gamma(\vec{p}) - O(\varepsilon)$ (as long as each $p_i \notin (0, \delta)$).

4.2 Brief Comparison to [9]

The algorithm employed by [9] using $O(n^2)$ samples is conceptually similar in that they also wish to set thresholds τ_i such that $F_{\mathcal{D}}(\tau_i) \approx 1 - p_i$. The main difference is that we target a multiplicative $(1-\varepsilon)$-approximation to each, whereas they target an additive $1/n$-approximation for each threshold. That is, they aim to ensure that for each p_i, the threshold τ_i has $|F_{\mathcal{D}}(\tau_i) - p_i| \le 1/n$. They prove, using the Dvoretzky-Kiefer-Wolfowitz Inequality, that $O(n^2)$ samples suffice for this, then further argue that these small additive errors in the CDF don't cost much.

The same paper also establishes a barrier to moving beyond $\Omega(n^2)$ samples. Specifically, they establish that $\Omega(n^2)$ samples are necessarily just to guarantee for a *single* i with $p_i \approx 1/2$ that $|F_{\mathcal{D}}(\tau_i) - p_i| \le 1/n$. Our approach circumvents this bound by seeking a significantly weaker guarantee for such i (only that $|F_{\mathcal{D}}(\tau_i) - p_i| \le O(\varepsilon p_i)$ – see Equation (1)). So the two key differences in our approach is (a) we show that $O(n)$ samples suffice to learn the thresholds up to a multiplicative $(1+\varepsilon)$ error in the CDF and (b) establishing that this (significantly weaker) estimation suffices for a good approximation.

4.3 Proof of Theorem 8

Our proof breaks down into two simple claims. The first establishes that with high probability, our sample-based thresholds are "good." The second establishes that "good" thresholds yield a good approximation. Below, recall that $\delta = \varepsilon^2/n$.

▶ **Lemma 9.** *With $m = 12\ln(1/\varepsilon)/(\varepsilon^3\delta) = O(n/\varepsilon^6)$ samples, with probability at least $1-\varepsilon$, we have that for every i (simultaneously),*

$$\frac{p_i}{(1+\varepsilon)^3} \leq \Pr_{x\sim\mathcal{D}}[x > \tau_i] \leq p_i. \tag{1}$$

Note that Equation (1) does not reference the values of the actual elements $X_1, \ldots, X_n$ at all – it is just a claim about the thresholds $\vec{\tau}$ being set. That is, the probability $1-\varepsilon$ is taken only over the randomness in *drawing the samples* (and in particular independent of the values of the actual elements). We will call a set of thresholds "good" if they satisfy Equation (1).

Proof. Recall that τ_i is set by first rounding down p_i to $\lfloor p_i \rfloor$, then further dividing by $(1+\varepsilon)$ to $\tilde{p}_i$, then set equal to the $(\tilde{p}_i \cdot m)$-th highest of m samples. To proceed, let L_i be such that

$$\Pr_{x\sim\mathcal{D}}[x > L_i] = \lfloor p_i \rfloor.$$

Similarly, let H_i be such that

$$\Pr_{x\sim\mathcal{D}}[x > H_i] = (1+\varepsilon)^{-2}\lfloor p_i \rfloor.$$

Then (1) certainly holds whenever $L_i < \tau_i < H_i$. The remainder of the proof establishes that we are likely to have $L_i < \tau_i < H_i$ for all i.

Indeed, observe that we expect to see $\lfloor p_i \rfloor m$ samples greater than L_i. We say that $\lfloor p_i \rfloor$ is *bad* if the number of samples greater than L_i is *not* in the range $\Big[(1+\varepsilon)^{-1}(\lfloor p_i \rfloor m), (1+\varepsilon)(\lfloor p_i \rfloor m)\Big]$. Note that whenever neither $\lfloor p_i \rfloor$ nor $(1+\varepsilon)^{-2}\lfloor p_i \rfloor$ is bad, then we indeed have $L_i < \tau_i < H_i$.

Because the number of samples greater than p is an average of m independent $\{0,1\}$ random variables with expectation p, the multiplicative Chernoff bound implies that the the probability that a particular p is bad is upper bounded by:

$$\Pr[p \text{ is bad}] < e^{-\varepsilon^2 pm/3}.$$

If all $p \in \{(1+\varepsilon)^{-1}, \ldots, \delta\}$ are not bad, then our desired claim holds. Taking union bound over this $(1+\varepsilon)$-multiplicative net, we have that the probability that some $p \in \{(1+\varepsilon)^{-1}, (1+\varepsilon)^{-2} \ldots, \delta\}$ is bad is bounded by:

$$\sum_{i=0}^{O(\ln(1/\delta)/\varepsilon)} e^{-\varepsilon^2(1-\varepsilon)^{-i}\delta m/3} \leq \sum_{i=0}^{\infty} e^{-\varepsilon^2(1-\varepsilon)^{-i}\delta m/3} \leq \sum_{i=0}^{\infty} e^{-\varepsilon^3 i\delta m/6} \leq e^{-\varepsilon^3\delta m/12}$$

Above, the first term is simply a union bound over all p in this net. The second inequality follows as $(1-\varepsilon)^{-i} \geq \varepsilon i/2$ for all $\varepsilon \in (0,1)$ and $i \geq 0$. The final inequality holds (at least) when $m \geq 6/(\varepsilon^3\delta)$. Therefore, setting $m = 12\ln(1/\varepsilon)/(\varepsilon^3\delta)$ satisfies the desired claim. ◀

Next, we wish to show that whenever the thresholds are "good", the algorithm performs well in expectation. Below, let t_1 denote the stopping time of Explicit-CFHOV (i.e. the random variable denoting the element it chooses to accept), and let t_2 denote the stopping time of Samples-CFHOV.

▷ Claim 10. Conditioned on (1) holding for every i, $t_2 \geq t_1$. That is, Samples-CFHOV selects an element *later* than Explicit-CFHOV.

Proof. For every i, we have that by (1), the threshold used by Samples-CFHOV is at least the threshold used by Explicit-CFHOV. Therefore, the first time they deviate (if any) is when Explicit-CFHOV accepts an element but Samples-CFHOV does not. ◁

▶ **Lemma 11.** *Conditioned on* (1) *holding for every i, the following holds for every v:*

$$\Pr[X_{t_2} > v] \geq \frac{1}{(1+\varepsilon)^3} \Pr[X_{t_1} > v]. \tag{2}$$

Proof. We prove that (2) holds uniformly for every $i \in [n]$, i.e.

$$\Pr[(X_{t_2} > v) \wedge (t_2 = i)] \geq \frac{1}{(1+\varepsilon)^3} \Pr[(X_{t_1} > v) \wedge (t_1 = i)]. \tag{3}$$

The event $(X_{t_b} > v) \wedge (t_b = i)$ (for either $b \in \{1, 2\}$) occurs if and only if the corresponding algorithm *doesn't* stop before i, and X_i is larger than both v and the threshold set (by the corresponding algorithm). Of course, whether or not an algorithm stops before i is completely independent of X_i. We claim that the following holds on the probability that the two algorithms accept X_i (conditioned on making it to X_i). Intuitively, Claim 12 establishes that, even though the threshold τ_i is stricter than σ_i, we are still roughly as likely to accept an X_i exceeding v using τ_i versus σ_i, for all v.

▷ Claim 12. Conditioned on (1) holding for every i, then for every v and i such that $p_i \geq \delta$:

$$(1+\varepsilon)^3 \Pr[(X_i > v) \wedge (X_i > \tau_i)] \geq \Pr[(X_i > v) \wedge (X_i > \sigma_i)].$$

Proof. We consider the following three cases: perhaps $v > \tau_i$, or perhaps $v \in (\sigma_i, \tau_i)$, or perhaps $v < \sigma_i$. We claim that the following three inequalities hold:

$$v \geq \tau_i \Rightarrow \quad \Pr[(X_i > v) \wedge (X_i > \tau_i)] = \Pr[X_i > v] = \Pr[(X_i > v) \wedge (X_i > \sigma_i)].$$

$$v \in (\sigma_i, \tau_i) \Rightarrow \quad \Pr[(X_i > v) \wedge (X_i > \sigma_i)] \leq \Pr[X_i > \sigma_i] \leq \frac{\Pr[X_i > \tau_i]}{(1+\varepsilon)^3} = \frac{\Pr[(X_i > v) \wedge (X_i > \tau_i)]}{(1+\varepsilon)^3}.$$

$$v < \sigma_i \Rightarrow \quad \Pr[(X_i > v) \wedge (X_i > \sigma_i)] = \Pr[X_i > \sigma_i] \leq \frac{\Pr[X_i > \tau_i]}{(1+\varepsilon)^3} = \frac{\Pr[(X_i > \tau_i) \wedge (X_i > v)]}{(1+\varepsilon)^3}.$$

Indeed, the first implication follows as v exceeds both σ_i and τ_i. The second implication follows as $v > \sigma_i$, and then by condition (1). The third implication follows from condition (1). ◁

Claim 12 is the heart of the proof, and we can now wrap up. Observe that $\Pr[(X_{t_2} > v) \wedge (t_2 = i)] = \Pr[t_2 \geq i] \cdot \Pr[(X_i > v) \wedge (X_i > \tau_i)]$. Similarly, $\Pr[(X_{t_1} > v) \wedge (t_1 = i)] = \Pr[t_1 \geq i] \cdot \Pr[(X_i > v) \wedge (X_i > \sigma_i)]$. By the work above, $(1+\varepsilon)^3 \Pr[(X_i > v) \wedge (X_i > \tau_i)] \geq \Pr[(X_i > v) \wedge (X_i > \sigma_i)]$. By Claim 10, $\Pr[t_2 \geq i] \geq \Pr[t_1 \geq i]$. Therefore, we've proven the desired claim for every $i \in [n]$. As $\Pr[X_{t_b} > v] = \sum_i \Pr[(X_{t_b} > v) \wedge (t_b = i)]$, this completes the proof of Lemma 11. ◀

Proof of Theorem 8. The proof of Theorem 8 now follows as a direct corollary of Lemmas 9 and 11. Lemma 11 asserts that whenever the thresholds are "good", Samples-CFHOV achieves at least a $1/(1+\varepsilon)^3$ fraction of the expected reward of Explicit-CFHOV (this is because the expected reward of Samples-CFHOV is simply $\int_0^\infty \Pr[X_{t_2} > v]dv \geq \int_0^\infty \Pr[X_{t_1} > v]dv/(1+\varepsilon)^3$, and the expected reward of Explicit-CFHOV is precisely $\int_0^\infty \Pr[X_{t_2} > v]dv$). Lemma 9 asserts that the thresholds are good with probability at least $1-\varepsilon$. So together, Samples-CFHOV achieves at least a $\frac{1-\varepsilon}{(1+\varepsilon)^3}$ of the expected reward of Explicit-CFHOV. ◀

Abstract

State-of-the-art posted-price mechanisms for submodular bidders with m items achieve approximation guarantees of $O((\log\log m)^3)$ [1]. Their truthfulness, however, requires bidders to compute an NP-hard demand-query. Some computational complexity of this form is unavoidable, as it is NP-hard for truthful mechanisms to guarantee even an $m^{1/2-\varepsilon}$-approximation for any $\varepsilon > 0$ [21]. Together, these establish a stark distinction between computationally-efficient and communication-efficient truthful mechanisms.

We show that this distinction disappears with a mild relaxation of truthfulness, which we term implementation in advised strategies. Specifically, *advice* maps a tentative strategy either to that same strategy itself, or one that dominates it. We say that a player follows advice *as long as they never play actions which are dominated by advice*. A poly-time mechanism guarantees an α-approximation in implementation in advised strategies if there exists advice (which runs in poly-time) for each player such that an α-approximation is achieved whenever all players follow advice. Using an appropriate bicriterion notion of approximate demand queries (which can be computed in poly-time), we establish that (a slight modification of) the [1] mechanism achieves the same $O((\log\log m)^3)$-approximation in implementation in advised strategies.

1 Introduction

Combinatorial auctions have been at the forefront of Algorithmic Game Theory since its inception as a lens through which to study the relative power of *algorithms* for honest agents versus *mechanisms* for strategic agents. Specifically, there are n buyers with combinatorial valuations $v_1(\cdot), \ldots, v_n(\cdot)$ over subsets of m items, and the designer wishes to allocate the items so as to maximize the *welfare*, $\sum_i v_i(S_i)$ (where S_i is the set allocated to bidder i). Without concern for computation/communication/etc., the celebrated Vickrey-Clarke-Groves

mechanism [41, 9, 28] provides a black-box reduction from precisely optimal mechanisms to precisely optimal algorithms. Of course, precisely optimal algorithms are NP-hard and require exponential communication in most settings of interest (for example, when buyers have submodular valuations over the items, which we'll take as the running example for the rest of the introduction), rendering VCG inapplicable. On the algorithmic front, poly-time/poly-communication constant-factor approximation algorithms are known [38, 30, 33, 4, 42, 24] and a central direction in algorithmic mechanism design is understanding whether these guarantees are achievable by computationally/communication efficient truthful mechanisms as well.

From the communication complexity perspective, this problem is still wide open: state-of-the-art truthful mechanisms guarantee an $O((\log\log m)^3)$-approximation [1], yet no lower bounds separate achievable guarantees of mechanisms from algorithms (that is, it could very well be the case that truthful, poly-communication mechanisms can achieve the same guarantees as poly-communication algorithms). From the computational perspective, however, a landmark result of Dobzinski and Vondrak establishes that for all $\varepsilon > 0$, an $m^{1/2-\varepsilon}$-approximation is NP-hard for truthful mechanisms [21]. As poly-time algorithms guarantee a $e/(e-1)$-approximation [42], this establishes a strong separation between computationally-efficient algorithms and computationally-efficient truthful mechanisms.

So while the communication perspective has seen exciting progress in recent years [15, 3], the computational perspective is generally considered fully resolved. In this paper, we present a new dimension to the computational perspective, motivated by the following two examples. Consider first the truthful mechanism of [1]. The core of the mechanism is a posted-price mechanism: it visits each bidder one at a time, posts a price p_j on each remaining item j, and offers the option to purchase any set S of items at total price $\sum_{j\in S} p_j$ (see Section 4 and Appendix B for a full description of their mechanism, which also includes randomization, pre-procesesing, and learning). The auxiliary parts of the mechanism run in poly-time,[1] and the offered prices can also be computed in poly-time. While it might sound like this mechanism should be poly-time, the catch is that it's NP-hard for the buyer find their utility-maximizing set, called a *demand query*. Therefore, the mechanism is either not truthful (because the buyers do not select their utility-maximizing sets), or requires solving an NP-hard problem (because the buyers pick their favorite sets). Still, the analysis of [1] and related mechanisms [12, 18, 31, 11, 26, 14, 22, 14] seems fairly robust, suggesting that perhaps they should maintain their guarantees under reasonable strategic behavior. Indeed, the focus of this paper is a novel solution concept (described below) under which the [1] $O((\log\log m)^3)$-approximation is maintained in polynomial time.

A New Solution Concept: Implementation in Advised Strategies. To get intuition for our solution concept, consider the following example due to [39]: there is only a single buyer, but the buyer can receive only k of the m items (this is the one-buyer case of Combinatorial Public Projects). Since there is just a single buyer, the obvious mechanism for the designer simply allows the buyer to pick any set of size k for free (call this the "Set-For-Free" mechanism). The same catch is that it is NP-hard for the buyer to pick their favorite set, so Set-For-Free is again not truthful (because the buyer picks a suboptimal set) or solving an NP-hard problem (because they find their favorite set). In fact, [39] establishes that it is NP-hard for truthful mechanisms to achieve a $m^{1/2-\varepsilon}$-approximation for any $\varepsilon > 0$. Algorithmically, a poly-time $e/(e-1)$-approximation is known [35], providing again a strong separation.

[1] Rather, they can be slightly modified to run in poly-time – see Section 4 and Appendix B.

We ask instead: what should one reasonably expect to happen if a strategic buyer participated in Set-For-Free? Consider the set S output by the poly-time algorithm of [35]. It is certainly reasonable for the buyer to select some set $T \neq S$: perhaps a different heuristic finds a better set. But it seems irrational for the buyer to select some set T with $v(T) < v(S)$. We therefore pose that there should be *some* reasonable solution concept under which Set-For-Free guarantees an $e/(e-1)$-approximation. Indeed, Set-For-Free guarantees an $e/(e-1)$-approximation under our proposed "implementation in advised strategies."

Formally, we will think of Set-For-Free as simply asking the buyer to report a set of size at most k, and then awarding them that set for free. In addition, the designer provides *advice*: a Turing machine $A(\cdot,\cdot)$ which takes as input the buyer's valuation $v(\cdot)$ (possibly as a circuit/Turing machine itself, or accessing it via value queries) and a tentative set T, then recommends a set S to purchase that is at least as good as T. Specifically in Set-For-Free, we will think of the advice as running the [35] approximation algorithm to get a set S' and outputting $S := \arg\max\{v(T), v(S')\}$. We say that a bidder *follows advice* if they select a set S with $A(v, S) = S$. The idea is that it seems irrational for the buyer to select a set without this property, when the advice gives a poly-time algorithm to improve it.

For a general mechanism, we think of advice as a Turing machine which takes as input the current state of the mechanism, the buyer's valuation, and a tentative action, then advises an (maybe the same, maybe different) action to take. Importantly, we say that advice is *useful* if for all strategies s, either the advice maps s to itself, or to another strategy which dominates it (see Section 2 for full definition). Intuitively, this suggests that it is irrational for a buyer to use a strategy which advice does not map to itself. We postpone to Section 2 a formal definition of what it means to follow advice, but note here that our definition is a natural relaxation of dominant strategies: if a mechanism has a dominant strategy s, then the only strategy which follows advice that recommends s is s itself. We say that mechanism guarantees a poly-time α-approximation in implementation in advised strategies whenever the mechanism itself concludes in poly-time, and there exists poly-time advice A such that an α-approximation is guaranteed whenever all bidders follow advice A. Again, note that the assumption on bidder behavior is quite permissive: they need not play a dominant, or even undominated strategy. We just assume they do not play a strategy which the advice itself dominates.

Advice via Approximate Demand Queries. We now revisit posted-price mechanisms, which achieve approximation guarantees of $O((\log\log m)^3)$, but whose truthfulness requires buyers to compute NP-hard demand queries. Instead, we pursue guarantees in implementation in advised strategies. For a posted-price mechanism with price vector $\mathbf{p}$, our proposed advice will take as input a tentative set T for purchase, and the buyer's valuation $v(\cdot)$, and recommend a set S guaranteeing $v(S) - \mathbf{p}(S) \geq v(T) - \mathbf{p}(T)$.[2] More specifically, our advice will compute a tentative recommendation S' independently of T, then simply recommend $\arg\max\{v(S') - \mathbf{p}(S), v(T) - \mathbf{p}(T)\}$. Again, our behavioral assumption does not assume that the buyer will purchase the set S' tentatively recommended, just that they will not irrationally ignore the advice in favor of a lower-utility set.

The remaining challenge is now to find concrete advice under which the [1] approximation guarantees are maintained. A first natural attempt is simply an approximate demand oracle: have a tentative recommendation S' with $v(S') - \mathbf{p}(S') \geq c \cdot \max_T\{v(T) - \sum_{j\in T} p_j\}$. Unfortunately, even this is NP-hard for any $c = \Omega(1/m^{1-\varepsilon})$ (for any $\varepsilon > 0$) [25]. Instead,

[2] Throughout the paper we will use notation $\mathbf{p}(S) := \sum_{i\in S} \mathbf{p}_i$.

we design bicriterion approximate demand oracles. Specifically, for some $c, d < 1$, a (c, d)-approximate demand oracle produces a set S' satisfying $v(S') - \mathbf{p}(S') \geq c \cdot \max_T\{v(T) - \mathbf{p}(T)/d\}$. That is, the guaranteed utility is at least an c-fraction of the optimum *if all prices were increased by a factor of* $1/d$. We design a simple greedy $(1/2, 1/2)$-approximation in poly-time (based on [33]), and further establish that the [1] mechanism maintains its approximation guarantee up to an additional $\min\{c, d\}$ factor when bidders follow advice provided in this manner by a (c, d)-approximate demand oracle. This allows us to conclude the main result of this paper:

▶ **Theorem 1.** *There exists a poly-time mechanism which achieves an* $O((\log\log m)^3)$*-approximation to the optimal welfare for any number of submodular buyers in implementation in advised strategies.*

1.1 Roadmap

Combinatorial auctions have a long history within AGT, along with related problems like Combinatorial Public Projects. The most related work is overviewed in Section 1, but we provide additional context in Section 1.2. Section 2 contains a formal definition of implementation in advised strategies, repeating our motivating examples and providing additional discussion.

In Section 3, we design our poly-time $(1/2, 1/2)$-approximate demand oracles for submodular valuations. The proof is fairly simple, but we include the complete proof in the body for readers unfamiliar with [33] (readers familiar with [33] will find the outline simliar).

In Section 4, we establish that existing posted-price mechanisms maintain their approximation guarantees as long as buyers follow advice given by $(\Omega(1), \Omega(1))$-approximate demand oracles. We include a complete analysis of the main lemma of [26] concerning "fixed price auctions" for readers unfamiliar with this aspect (readers familiar with [26] will find the outline similar). We defer all aspects of the analysis of [1] to Appendix B.

Finally, in Section 5, we design simple poly-time $(\frac{1}{\sqrt{m}}, \frac{1}{1+\sqrt{m}})$-approximate demand oracles for subadditive valuations. This is essentially the best possible even for XOS valuations,[3] due to known lower bounds on welfare-maximization with value queries [17] and the results of Section 4.

1.2 Discussion and Related Work

There is a vast literature studying combinatorial auctions, which we will not attempt to overview in its entirety here. We summarize the lines of work most relevant to ours below.

VCG-based Mechanisms. The Vickrey-Clarke-Groves mechanism provides a poly-time/poly-communication black-box reduction from precise welfare maximization with a truthful mechanism to precise welfare maximization with an algorithm for any class of valuation functions [41, 9, 28]. The same reduction applies for "maximal-in-range" approximation algorithms, but this approach provably cannot achieve sub-polynomial approximations in poly-time (unless P = NP) or subexponential communication [8, 7, 10]. Still, in some regimes (e.g. arbitrary monotone valuations with poly-time/poly-communication, or XOS valuations with poly-time), no better than a $\Theta(\sqrt{m})$-approximation is achievable even with honest players, and a $\Theta(\sqrt{m})$-approximation is achievable via truthful VCG-based mechanisms [32, 17].

[3] More precisely, it is unconditionally hard to obtain a $(1/m^{1/2-\varepsilon}, 1/m^{1/2-\varepsilon})$-approximate demand query for XOS valuations using polynomially many black-box value queries.

Combinatorial Auctions in the Computational Model. Taking the above discussion into account, valuation function classes above XOS (including subadditive, or arbitrary monotone) are "too hard", in the sense that $\Theta(\sqrt{m})$ is the best approximation achievable in poly-time even without concern for incentives, and this guarantee can be matched by VCG-based truthful mechanisms. Other valuation function classes like Gross Substitutes are "easy", in the sense that precise welfare maximization is achievable in poly-time, so the VCG mechanism is poly-time as well. Submodular valuations are a fascinating middle ground. Here, an algorithmic $e/(e-1)$-approximations is possible in poly-time (and it is NP-hard to do better) [42, 34, 19], but a long series of works establishes that it is NP-hard for a truthful mechanism to even achieve an $m^{1/2-\varepsilon}$-approximation (for any $\varepsilon > 0$) [36, 7, 8, 10, 13, 20, 19, 21].

On this front, our work establishes that significantly better ($O((\log\log m)^3)$) guarantees are achievable with a slightly relaxed solution concept, matching the state-of-the-art in the communication model. In addition to the standalone motivation for the communication model discussed below, our work establishes that resolving key open questions (e.g. is there a constant-factor approximation in the communication model for submodular valuations?) may have strong implications in the computational model as well (via implementation in advised strategies).

Combinatorial Auctions in the Communication Model. In the communication model, only arbitrary monotone valuations are "too hard" per the above discussion: a 2-approximation is possible for subadditive valuations, and a $\frac{1}{1-(1-1/n)^n}$-approximation is possible for XOS valuations in poly-communication, both of which are tight [24, 17, 23]. Yet, no truthful constant-factor approximations are known (the state-of-the-art is $O((\log\log m)^3)$ for submodular/XOS [1] or $O(\log m \log\log m)$ for subadditive [12]). On the lower bounds side, *no* separations are known between the approximation ratios of truthful mechanisms and non-truthful algorithms using $\text{poly}(n, m)$ communication, even for *deterministic* truthful mechanisms (where the $O(\sqrt{m})$-approximation of [17] remains the state-of-the-art). Determining whether such a separation exists is the central open problem of this agenda (e.g. [15, 3]).

On this front, our work in some sense unifies the state-of-the-art for submodular valuations in the communication and computational models via implementation in advised strategies. So in addition to the standalone interest in establishing (or disproving) a separation in the communication model, such a result will now likely have implications in the computational model as well.

Posted Price Mechanisms. Posted-price mechanisms are ubiquitous in mechanism design, owing to their simplicity and surprising ability to guarantee good approximations through a variety of lenses [31, 11, 26, 14, 22, 1]. Very recent work also establishes posted-price mechanisms as the unique class of mechanisms which is "strongly obviously strategy-proof" [37]. One minor downside of these mechanisms is that they require buyers to compute NP-hard demand queries. Our work formally mitigates this downside under implementation in advised strategies. For example, our work immediately extends the price of anarchy bounds of [11] to hold in equilibria which are poly-time learnable for submodular buyers (previously the equilibria required computation of demand queries).

Combinatorial Public Projects. Combinatorial Public Projects is a related problem, which has also received substantial attention. Here, the designer may select any set of k items, but *every* bidder receives all k items (instead of the bidders each receiving disjoint sets of

items, as in auctions). We used the single submodular bidder Combinatorial Public Projects problem as a motivating example due to the hardness results established in [39]: no poly-time truthful mechanism can achieve an approximation ratio better than $O(\sqrt{m})$ (unless P = NP). Contrast this with the general communication model, where Set-For-Free is truthful and precisely optimizes welfare. Follow up work of [6] establishes that while the single-bidder CPPP is inapproximable only because demand queries are NP-hard, the strong multi-bidder inapproximability results of [36, 8] hold even when bidders have access to demand oracles.

[31, 14, 1] already establish that the aforementioned computational separations no longer hold with demand oracles (so the story for combinatorial auctions differs greatly from combinatorial public projects). Our work further establishes that the same guarantees are achievable in truly polynomial time, under a relaxed solution concept.

(c, d)-Approximate Demand Oracles. To the best of our knowledge, bicriterion approximate demand oracles have not previously been considered. However, prior work regarding approximation algorithms for nonnegative submodular functions with bounded curvature subject to a matroid constraint designs a randomized $(1 - 1/e, 1 - 1/e)$-approximate demand oracle for submodular functions (under a different name) [40, 27, 29]. We include our $(1/2, 1/2)$-approximate demand oracles for submodular functions as they are deterministic and significantly simpler (note also that determinism makes our related solution concepts significantly cleaner).

Related Solution Concepts. The most related existing solution concept to ours is Algorithmic Implementation in Undominated Strategies [2]. Here, a mechanism achieves an α-approximation if whenever players play *any undominated strategy*, the resulting allocation is an α-approximation (and for all dominated strategies, there is a poly-time algorithm to find an undominated one which dominates it). For posted-price mechanisms, this solution concept has no bite as the only undominated strategy is to pick the utility-maximizing set, and it is not possible to find this set in poly-time. We establish in Observation 10 that implementation in advised strategies is a relaxation of algorithmic implementation in undominated strategies. The purpose of our novel solution concept is to have bite even when it is NP-hard to find an undominated strategy.

2 Implementation in Advised Strategies

Motivated by the example of [39], we first relax the requirement that a mechanism be truthful, instead requiring that a mechanism achieve its approximation guarantee whenever players behave in a manner which is not clearly irrational. Before proposing our formal definition, let's examine it applied to two motivating examples.

Example One: [39]. There is a single buyer with submodular valuation function $v(\cdot)$. The seller's mechanism (Set-For-Free) allows the buyer to state any set of size k, and receive that set for free. Recall that it is NP-hard for the buyer to find their favorite set of size k – so if the mechanism is to be truthful, it is not poly-time (unless P = NP). The buyer can indeed find an $e/(e-1)$-approximation in poly-time [35], but assuming the buyer will run this particular algorithm (or any specific approximation algorithm) is perhaps too strong an assumption.

Instead, we assume simply that the buyer picks a set yielding *at least as much utility* as this $e/(e-1)$-approximation. Specifically, we will think of the designer as providing a poly-time mechanism (Set-For-Free – the buyer states a set of size k and receives that set

for free), and a poly-time *advice algorithm* (takes as input the buyer's valuation function $v(\cdot)$, and a tentative set S, then runs the $e/(e-1)$-approximation to get a set T and outputs $\arg\max\{v(S), v(T)\}$, tie-breaking for S). Intuitively, we are claiming that it is certainly rational for the buyer to purchase a set other than T, but that it is irrational to purchase a set with $v(S) < v(T)$.

Example Two: Posted-Price Mechanisms. Consider now any posted-price mechanism. Again, we think of the designer as providing a poly-time mechanism (for all i, computes in poly-time a price vector to offer bidder i, based on interactions with bidders $< i$), along with a poly-time advice algorithm (takes as input the buyer's valuation function $v(\cdot)$, a tentative set S, computes in poly-time a set T and outputs $\arg\max\{v(S) - \mathbf{p}(S), v(T) - \mathbf{p}(T)\}$, again tie-breaking for S). Again note that we are claiming that it may be rational for the buyer to purchase a set other than T, but that it is irrational to purchase a set yielding lower utility than T.

Importantly, we emphasize that we assume the buyer achieves at least as much *utility* as recommended (a well-justified behavioral assumption, although not particularly convenient for welfare guarantees), and *not* that the buyer picks a set guaranteeing them at least as much welfare (more convenient for analyzing welfare guarantees, but an unmotivated assumption). With these instantiations in mind, we now build up language to present our formal definition.

▶ **Definition 2** (Mechanism as an Extended Form Game)**.** *Formally, a* mechanism *is just an extended form game: at every state, it solicits actions from one or more players and (possibly randomly) updates its state. With probability one, the mechanism eventually reaches a terminal state, and (possibly randomly) outputs an allocation of items and payments charged.*

A mechanism is poly-time *if every state update is poly-time computable, and the mechanism reaches a terminal state with probability one after* $\text{poly}(n, m)$ *updates.*

▶ **Definition 3** (Strategies, Utility, and Dominance)**.** *A* strategy $s(\cdot)$ *for player i is simply a mapping from the current state x of the mechanism to an action $s(x)$.*

We denote by $u_i(v_i, \vec{s})$ the expected utility of player i when their valuation function is $v_i(\cdot)$ and the players use strategy profile $\vec{s}$.

Strategy $s(\cdot)$ dominates *strategy $s'(\cdot)$ for player i with valuation $v_i(\cdot)$ if for all s_{-i}, $u_i(v_i, s_i; \vec{s}_{-i}) \geq u_i(v_i, s'_i; \vec{s}_{-i})$, and there exists an $\vec{s}_{-i}$ such that $u_i(v_i, s_i; \vec{s}_{-i}) > u_i(v_i, s'_i; \vec{s}_{-i})$.*

▶ **Definition 4** (Advice)**.** *Advice is a function $A(\cdot, \cdot, \cdot)$ which takes as input the valuation $v_i(\cdot)$ of a player, a state x of a mechanism, and a tentative action a, then (possibly randomly) outputs an advised action $A(v_i, x, a)$. We say that advice is poly-time if it is poly-time computable.*

Observe that every advice $A(\cdot, \cdot, \cdot)$, valuation function $v_i(\cdot)$, and tentative strategy $s(\cdot)$ induces a strategy $A^{v_i,s}(\cdot)$ with $A^{v_i,s}(x) := A(v_i, x, s(x))$.

▶ **Definition 5** (Useful Advice)**.** *We say that advice A is* useful *if:*

1. *For all $s(\cdot)$, and all $v_i(\cdot)$, either $A^{v_i,s}(\cdot) = s(\cdot)$, or $A^{v_i,s}(\cdot)$ dominates $s(\cdot)$ (for valuation $v_i(\cdot)$).*
2. *For all $s(\cdot)$ and all $v_i(\cdot)$, $A^{v_i,A^{v_i,s}}(\cdot) = A^{v_i,s}(\cdot)$ (Advice is idempotent – applying advice to $s(\cdot)$ twice is the same as applying it once).*

Intuitively, Property 1 guarantees that the bidder should indeed follow advice given by A instead of whatever strategy they had originally planned. Property 2 guarantees essentially that the bidder does not get "stuck" in an exponentially-long loop trying to repeatedly improve their strategy via advice (because the loop terminates after one iteration). Let us briefly observe the following implication of our definition (which we explore further when revisiting our two main examples):

▶ **Observation 6.** *Let $A(\cdot,\cdot,\cdot)$ be useful, and let $A(v_i, x, a) \neq a$. Then for all s such that $s(x) = a$, $A^{v_i,s}(\cdot)$ dominates $s(\cdot)$.*

Intuitively, useful advice A separates strategies into *advised* strategies (where $A^{v_i,s}(\cdot) = s(\cdot)$), and *ill-advised* strategies (where $A^{v_i,s}(\cdot)$ dominates $s(\cdot)$). We say that a bidder follows advice if they use an advised strategy.

▶ **Definition 7** (Follows Advice)**.** *We say that $s(\cdot)$ is advised for $v_i(\cdot)$ under A if $A^{v_i,s}(\cdot) = s(\cdot)$. A bidder with valuation $v_i(\cdot)$* follows advice *A if they use a strategy which is advised under A.*

Intuitively, we are claiming that it is irrational for a player to use an ill-advised strategy $s(\cdot)$ (because they could instead use the strategy $A^{v_i,s}(\cdot)$, which dominates it).

▶ **Definition 8** (Implementation in Advised Strategies)**.** *We say that a mechanism M guarantees an α-approximation in* implementation in advised strategies *with advice A if A is useful and for all $v_1(\cdot), \ldots, v_n(\cdot)$, if all players follow advice A, the resulting allocation in M achieves (expected) welfare at least $\alpha \cdot \text{OPT}(v_1, \ldots, v_n)$. If both M and A are poly-time, we say that M guarantees a poly-time α-approximation in implementation in advised strategies (without referencing A).*

Let's now briefly revisit our two examples through the formal definitions. First, recall the single-bidder mechanism Set-For-Free. Set-For-Free is poly-time: it takes as input a set and simply outputs that set, and terminates after one iteration. Consider the advice algorithm which takes as input $v(\cdot)$, and a set S, then runs the $e/(e-1)$-approximation algorithm of [35] to get a set T and outputs $\arg\max\{v(S), v(T)\}$, tie-breaking for S (the mechanism has only a single non-terminal state, so this completely specifies the advice). Then the advice indeed recommends a dominating strategy whenever it recommends $T \neq S$, and is idempotent (tie-breaking in favor of S is subtly necessary for this claim – if instead the advice tie-broke for T, then it might recommend an action distinct from S which does not dominate it). Moreover, observe that the bidder follows advice if and only if they choose a higher value set than produced by the algorithm, and therefore we're guaranteed a $e/(e-1)$-approximation whenever the bidder follows advice.

Posted-price mechanisms with poly-time computable prices are poly-time: they iteratively take as input a set from bidder i, assign that set to bidder i, then run a poly-time computation to determine the prices for bidder $i+1$. They terminate after n iterations. We will later design poly-time *approximate demand oracles*, which take as input $v_i(\cdot)$ and the price vector $\mathbf{p}$, and output a recommended set $D(v_i, \mathbf{p})$ in poly-time. For a posted-price mechanism, there are multiple non-terminal states, each corresponding to a different price vector $\mathbf{p}$. Our advice, on input $v_i, S, \mathbf{p}$, will advise the set $\arg\max\{v(S) - \mathbf{p}(S), v(D(v_i, \mathbf{p})) - \mathbf{p}(D(v_i, \mathbf{p}))\}$, again tie-breaking in favor of S.[4] If a strategy follows advice, it must, for all $\mathbf{p}$, select a set S satisfying $v_i(S) - \mathbf{p}(S) \geq v_i(D(v_i, \mathbf{p})) - \mathbf{p}(D(v_i, \mathbf{p}))$. It's not immediately clear why this property should provide meaningful welfare guarantees, but we will later argue that the right pairing of mechanism and notion of approximate demand oracle achieves polynomial-time welfare guarantees which match state-of-the-art guarantees for computationally-unbounded bidders.

[4] Subtly, note that tie-breaking in favor of T would violate the definition of usefulness, via Observation 6. Indeed, consider the strategy $s(\cdot)$ which purchases a utility-maximizing set on all prices $\neq \mathbf{p}$, and set S on $\mathbf{p}$. Then any advice which tie-breaks in favor of T on prices $\mathbf{p}$ does not map $s(\cdot)$ to itself, and does not dominate $s(\cdot)$ (because it generates the same utility on prices $\mathbf{p}$, and cannot generate strictly higher utility on any other prices, because $s(\cdot)$ is optimal).

Brief Discussion of Definitions. We chose our definitions with the goal of (a) providing a strict relaxation of truthfulness, and (b) doing so in a way that permits all rational behavior while (c) still eliminating enough irrational behavior to guarantee good welfare. We include in Appendix A a brief example motivating our decision to think of advice as *improving a given strategy* as opposed to *outright proposing a replacement strategy.* We conclude by establishing that implementation in advised strategies is a strict relaxation of truthfulness and algorithmic implementation in undominated strategies.

▶ **Observation 9.** *If player i with valuation v_i has a dominant strategy $s^*(\cdot)$ in mechanism M, and $A^{v_i,s}(\cdot) := s^*(\cdot)$ for all $s(\cdot)$, then the only strategy which follows advice is $s^*(\cdot)$ itself.*

▶ **Observation 10.** *Let M achieve an α-approximation in algorithmic implementation in undominated strategies. Then M achieves an α-approximation in implementation in advised strategies.*

Proof. Recall that algorithmic implementation in undominated strategies implies for all $v_i(\cdot)$ the existence of a poly-time function $f_{v_i}(\cdot)$ which takes as input a strategy $s(\cdot)$ and outputs a new strategy $f_{v_i}(s)$ such that if $s(\cdot)$ is dominated, $f_{v_i}(s)$ dominates s. Extend this so that $f_{v_i}(s) := s$ when $s(\cdot)$ is undominated. Now simply define $A^{v_i,s}(\cdot) := f_{v_i}(s)$, and then A is useful and poly-time. Moreover, the advised strategies are exactly the undominated strategies, so because M achieves an α-approximation whenever all players use undominated strategies, it also achieves an α-approximation whenever all players follow advice. ◀

Of course, the whole point of our definitions is that the designer may not be able to find a dominant (or even undominated) strategy in poly-time, and implementation in advised strategies has bite even under these circumstances while the previous solution concepts do not.

3 Approximate demand oracles

In this section, we develop our poly-time advice for posted-price mechanisms in the form of an *approximate demand oracle*. Recall that a demand oracle for valuation function $v(\cdot)$ takes as input a price vector $\mathbf{p}$ and outputs a set in $\arg\max_{S\subseteq M}\{v(S) - \mathbf{p}(S)\}$. Recall also that implementing a demand oracle is NP-hard when $v(\cdot)$ is submodular. In fact, it is NP-hard to even guarantee better than a m-approximation when $v(\cdot)$ is submodular (more precisely, for any $\varepsilon > 0$ it is NP-hard to guarantee a set T satisfying $v(T) - \mathbf{p}(T) \geq \frac{1}{O(m^{1-\varepsilon})} \cdot \max_S\{v(S) - \mathbf{p}(S)\}$ [25]). Motivated by this, we pursue instead a bicriterion approximation. Specifically:

▶ **Definition 11.** *For any $c, d \leq 1$, a (c, d)-*approximate demand oracle *takes as input a valuation function $v(\cdot)$ and a price vector $\mathbf{p}$ and outputs a set of items S such that*

$$v(S) - \mathbf{p}(S) \geq c \cdot \max_T\{v(T) - \mathbf{p}(T)/d\}.$$

That is, a (c, d)-demand oracle outputs a set guaranteeing at least a c-fraction of the optimal utility *if all prices were blown up by a factor of* $1/d$. We refer to the utility of the optimal bundle with these higher prices (i.e. $\max_T\{v(T) - \mathbf{p}(T)/d\}$) as the *benchmark* (so our goal is to be c-competitive with the benchmark). In this section, we establish that poly-time $(1/2, 1/2)$-approximate demand oracles exist for submodular functions, based on the simple greedy algorithm of [33].

Algorithm 1 SimpleGreedy$(v, \mathbf{p}, M)$.

return S

▶ **Proposition 12.** *When $v(\cdot)$ is submodular, SimpleGreedy is a $(1/2, 1/2)$-approximate demand oracle.*

Proof. Our proof follows by induction on the number of items m. Importantly, observe that SimpleGreedy is recursive. Specifically, if we do not allocate item 1, then the remainder of the for loop is simply SimpleGreedy$(v, \mathbf{p}, M \setminus \{1\})$. If we do allocate item 1, then the remainder of the for loop is simply SimpleGreedy$(v_{\{1\}}, \mathbf{p}, M \setminus \{1\})$, where $v_S(T) := v(S \cup T) - v(S)$. Also importantly, observe that $v_S(\cdot)$ is submodular whenever $v(\cdot)$ is submodular (like [33], this is the only part of the proof which requires submodularity instead of subadditivity).

Now we begin with the base case. Observe that when $m = 1$, SimpleGreedy purchases the item if and only if the value exceeds twice the price. So when SimpleGreedy purchases the item, it is optimal. When SimpleGreedy doesn't purchase the item, the benchmark is 0 (because we compete with the optimal utility when the prices are doubled, which is zero). So in both cases, it guarantees a the required $(1/2, 1/2)$-approximation. This proves the base case.

Now assume that the proposition holds for a fixed $m \geq 1$, and consider the case with $m + 1$ items. First, observe that if SimpleGreedy does not allocate item 1, it is because $v(1) < 2\mathbf{p}(1)$. By submodularity of $v(\cdot)$ (in fact, subadditivity suffices), this implies that $v(S) - 2\mathbf{p}(S) > v(S \cup \{1\}) - 2\mathbf{p}(S \cup \{1\})$ for all $S \ni 1$ (and in particular, that the optimum when prices are doubled does not contain item 1). By the inductive hypothesis, SimpleGreedy finds a $(1/2, 1/2)$-approximation for $v(\cdot)$ on $M \setminus \{1\}$, which by the previous sentence is also a $(1/2, 1/2)$-approximation for $v(\cdot)$ on M, completing the inductive step in this case.

It remains to consider the case where SimpleGreedy allocates item 1. Let $S_2 := S \setminus \{1\}$ denote the set output by SimpleGreedy$(v_{\{1\}}, \mathbf{p}, M \setminus \{1\})$, and let $O^* := \arg\max\{v(Y) - 2\mathbf{p}(Y)\}$ be the optimum bundle if prices were doubled. Then the inductive hypothesis guarantees:

$$v_{\{1\}}(S_2) - \mathbf{p}(S_2) \geq v_{\{1\}}(O^*)/2 - \mathbf{p}(O^* \setminus \{1\}).$$

Suppose first $1 \in O^*$. The inductive hypothesis then implies:

$$\begin{aligned} v(O^*)/2 - \mathbf{p}(O^*) &= v_{\{1\}}(O^*)/2 - \mathbf{p}(O^* \setminus \{1\}) + v(\{1\})/2 - \mathbf{p}(\{1\}) \\ &\leq v_{\{1\}}(S_2) - \mathbf{p}(S_2) + v(\{1\})/2 - \mathbf{p}(\{1\}) \\ &\leq v(S) - \mathbf{p}(S). \end{aligned}$$

Above, the first and third lines are simply expanding the definition of $v_{\{1\}}(\cdot)$, and the second line follows by inductive hypothesis. Observe that this concludes a $(1/2, 1/2)$-approximation in the case that $1 \in O^*$. Now, suppose instead that $1 \notin O^*$. Then we have:

$$\begin{aligned} v(O^*)/2 - \mathbf{p}(O^*) &\leq v(O^* \cup \{1\})/2 - \mathbf{p}(O^*) = v_{\{1\}}(O^*)/2 + v(\{1\})/2 - \mathbf{p}(O^*) \\ &\leq v_{\{1\}}(S_2) - \mathbf{p}(S_2) + v(\{1\})/2 \\ &\leq v_{\{1\}}(S_2) - \mathbf{p}(S_2) + v(\{1\}) - \mathbf{p}(1) \\ &= v(S) - \mathbf{p}(S). \end{aligned}$$

Above, the first line follows by monotonicity and expanding the definition of $v_{\{1\}}(\cdot)$. The second line follows by inductive hypothesis. The third line follows as $v(\{1\}) \geq 2\mathbf{p}(1)$ by assumption that SimpleGreedy allocates item 1. The final line follows again by expanding $v_{\{1\}}(\cdot)$. This concludes both cases of the inductive step, and the proof of the proposition. ◀

This concludes our development of bicriterion approximate demand oracles. The following section establishes that a wide class of posted-price mechanisms that achieve good guarantees when buyers use precise demand queries maintain their guarantees when buyers follow advice given by bicriterion approximate demand oracles.

4 Welfare Guarantees with Approximate Demand Oracles

In this section, we demonstrate that a slight modification of the $O((\log\log m)^3)$ approximation of [1] (which is truthful when buyers implement precise demand oracles) maintains its approximation guarantee when buyers follow advice recommended by a $(1/2, 1/2)$-approximate demand oracle. We begin with the main insight below, followed by a precise statement of our main result.

4.1 Fixed Price Auctions with Approximate Demand Oracles

A key component of the [1] (and related) auctions is the notion of a *Fixed Price Auction*. A fixed price auction simply sets a price $\mathbf{p}(j)$ on item j, visits the buyers one at a time, and offers the buyer the option to purchase any set S of remaining items for price $\mathbf{p}(S)$ (so it is a posted-price mechanism which sets the same prices for all bidders).

A key lemma used by these works establishes that there *exists* a fixed price auction generating good welfare (when bidders implement exact demand oracles) for any instance with submodular bidders (or even XOS bidders).[5] One can view the [14, 1] auctions as attempting to *learn* such a "good" fixed price auction. The key intuition behind our extension is that good fixed price auctions still exist when bidders only implement approximate demand oracles. This is captured formally by Lemma 15 below, which first requires the notion of *supporting prices*.

▶ **Definition 13.** $\mathbf{q}$ *are* supporting prices *for* $v_1(\cdot), \ldots, v_n(\cdot)$ *and allocation* $S_1, \ldots, S_n$ *if:*

- *For all* i, T, $v_i(T) \geq \mathbf{q}(S_i \cap T)$.
- *For all* i, $v_i(S_i) = \mathbf{q}(S_i)$.

▶ **Fact 14.** *When all* $v_i(\cdot)$ *are XOS, supporting prices exist for any allocation* $S_1, \ldots, S_n$.[6]

Much prior work leverages the fact that with precise demand queries, the fixed-price auction with prices $\mathbf{q}/2$ achieves half the optimal welfare. The intuition for our main result is that this key lemma extends to (c, d)-approximate demand queries by losing an additional $\min\{c, d\}$ factor. In the statement below, we will slightly abuse notation and say that a bidder "follows advice given by a (c, d)-approximate demand oracle" if they follow advice given by an algorithm which on input $v(\cdot), S$ computs a (c, d)-approximate demand query T, then advises $\arg\max\{v(S) - \mathbf{p}(S), v(T) - \mathbf{p}(T)\}$.

[5] This lemma appears at least as early as [16].

[6] Recall that submodular functions are XOS, and a function is XOS if it can be written as the maximum of additive functions. Supporting prices for items in S_i are defined by simply taking the additive function which defines $v_i(S_i)$.

▶ **Lemma 15.** *Let* $\mathbf{q}$ *be supporting prices for* $v_1(\cdot), \ldots, v_n(\cdot)$ *and* $S_1, \ldots, S_n$*. Then the fixed-price auction with prices* $d\mathbf{q}/2$ *guarantees welfare at least* $\min\{c, d\} \cdot \sum_i v_i(S_i)/2$ *when all bidders follow advice given by a* (c, d)*-approximate demand oracle.*

Proof. Let $S := \cup_i S_i$. Let also T_i denote the set purchased by bidder i (following advice given by a (c, d)-approximate demand oracle), and denote by $\textsc{Sold} = \bigcup_{i \in N} T_i$. Define $A_i = S_i \setminus \textsc{Sold}$. Because items in A_i are never allocated when bidder i is chosen to act (meaning that bidder i could choose to purchase the set A_i), and bidder i will choose a set guaranteeing at least as much utility as a (c, d)-approximate demand oracle, we have:

$$v_i(T_i) - d\mathbf{q}(T_i)/2 \geq c\left(v_i(A_i) - \frac{d\mathbf{q}(A_i)/2}{d}\right) = c\left(v_i(A_i) - \frac{1}{2}\mathbf{q}(A_i)\right).$$

The welfare achieved ($\sum_{i \in N} v_i(T_i)$) is exactly the sum of the utilities of each bidder ($v_i(T_i) - d\mathbf{q}(T_i)/2$) and the total revenue of the auction ($\sum_{i \in N} d\mathbf{q}(T_i)/2 = d\mathbf{q}(\textsc{Sold})/2$). By the definition of supporting prices (and the fact that $A_i \subseteq S_i$), we know that $v_i(A_i) \geq \mathbf{q}(A_i)$. Thus:

$$\begin{aligned}
\frac{d}{2}\mathbf{q}(\textsc{Sold}) + \sum_{i=1}^{n} v_i(T_i) - \frac{d}{2}\mathbf{q}(T_i) &\geq \frac{d}{2}\mathbf{q}(\textsc{Sold}) + c\left(\sum_{i=1}^{n} v_i(A_i) - \frac{1}{2}\mathbf{q}(A_i)\right) \\
&\geq \frac{d}{2}\mathbf{q}(\textsc{Sold}) + \frac{c}{2}\sum_{i=1}^{n}\mathbf{q}(A_i) \\
&\geq \frac{\min\{c, d\}}{2}\big(\mathbf{q}(\textsc{Sold}) + \mathbf{q}(S \setminus \textsc{Sold})\big) \\
&\geq \frac{\min\{c, d\}}{2}\mathbf{q}(S) = \frac{\min\{c, d\}}{2}\sum_i v_i(S_i).
\end{aligned}$$

The first inequality follows as each bidder follows advice of a (c, d)-approximate demand oracle. The second follows as $v_i(A_i) \geq \mathbf{q}(A_i)$ for all i (by definition of supporting prices). The third follows as $\cup_i A_i = S \setminus \textsc{Sold}$. The final inequality follows by basic arithmetic, and the final equality follows as $\mathbf{q}(S) = \sum_i v_i(S_i)$ by definition of supporting prices. ◀

Lemma 15 captures the main intuition for why existing posted-price guarantees can be extended to accommodate bicriterion approximate demand queries. Of course, the [1] mechanism is not just a single posted-price mechanism, and Lemma 15 is just one technical lemma used along the way (to be more precise, a generalization of Lemma 15 is used along the way, but the overly technical statement hides the intuition). But an outline similar to the proof of Lemma 15 establishes the more general claim. Section 4.2 formally states our main result, and all details of the proof aside from the above intuition can be found in Appendix B.

4.2 Formal Statement of Main Result

▶ **Theorem 16.** *Let* $\mathcal{V}$ *be a subclass of XOS valuations and let* D *be a poly-time* (c, d)*-approximate demand oracle for valuation class* $\mathcal{V}$*. Then there exists a poly-time mechanism for welfare maximization when all valuations are in* $\mathcal{V}$ *with approximation guarantee* $O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\} \cdot (\log\log m)^3\right)$ *in implementation in advised strategies with polynomial time computable advice.*

Theorem 1 now follows from Theorem 16 as submodular valuations are a subclass of XOS which admits poly-time $(1/2, 1/2)$-approximate demand oracles. The poly-time mechanism witnessing Theorem 16 is a slight modification of [1]. The high-level approach of their

mechanism is the following: because $\mathcal{V}$ is XOS, Lemma 15 establishes that there *exists* a fixed-price mechanism which achieves an $1/O(\min\{c,d\}) = O(\max\{1/c, 1/d\})$ approximation in implementation in advised strategies. Of course, implementing this fixed-price auction requires complete knowledge of $v_1(\cdot), \ldots, v_n(\cdot)$, which the seller lacks. The mechanism of [1] essentially tries to iteratively guess a better and better set of fixed prices, and then pick one uniformly at random.

Intuitively, our adapted [1] mechanism works with (c,d)-approximated demand oracles for the same reason that Lemma 15 works with approximate demand oracles. Formally establishing this requires a bit of work, but much of the analysis of [1] treats the $(c,d) = (1,1)$ case of Lemma 15 as a black box, and therefore we can leverage most of their analysis as a black box as well. The generalized Lemma 15 (Lemma 20) provides all the properties of demand queries which their proof requires (and all the properties of approximate demand queries which our adaptation requires). A complete proof appears in Appendix B.

5 Approximate Demand Queries beyond Submodular

In this section, we explore approximate demand queries beyond submodular valuation functions. As the approximation guarantees of [1] hold for XOS valuations with precise demand queries, a poly-time $(\Omega(1), \Omega(1))$-approximate demand query would immediately extend their guarantees to XOS valuations under implementation in advised strategies. Interestingly, this very fact establishes that for all $\varepsilon > 0$, no poly-time $(\Omega(m^{-1/2+\varepsilon}), \Omega(m^{-1/2+\varepsilon}))$-approximate demand oracle exists for XOS valuations using subexponentially-many value queries.

▶ **Proposition 17.** *For all $\varepsilon > 0$, there is no $(\Omega(m^{-1/2+\varepsilon}, \Omega(m^{-1/2+\varepsilon}))$-approximate demand oracle for XOS valuations using $\mathrm{poly}(m)$ value queries.*

Proof. Assume for contradiction that the proposition were false. Then by Theorem 16, there exists an algorithm using $\mathrm{poly}(n,m)$ value queries that approximates the optimal welfare within $O\left(m^{1/2-\varepsilon} \cdot (\log\log m)^3\right) \in O(m^{1/2-\varepsilon/2})$ for XOS valuations. However, Theorem 6.1 of [17] proves that no such algorithm exists. ◀

To complete the picture, we also design poly-time $(\Omega(1/\sqrt{m}), \Omega(1/\sqrt{m}))$-approximate demand oracles for subadditive valuations (defined immediately below, based on the $\Omega(1/\sqrt{m})$-approximation of [17]), which is the best possible using subexponentially-many value queries.

Algorithm 2 SingleOrBundle$(v, \mathbf{p}, M)$.

$j \leftarrow \arg\max_{j \in M} v(j) - \mathbf{p}(j)$
$M^* \leftarrow \{j \in M : v(j) - (1+\sqrt{m})\mathbf{p}(j) > 0\}$
if $v(M^*) - \mathbf{p}(M^*) > v(j) - \mathbf{p}(j)$ **then**
  return M^*
else
  return $\{j\}$

▶ **Proposition 18.** SingleOrBundle$(v, \mathbf{p}, M)$ *is a $(\frac{1}{\sqrt{m}}, \frac{1}{1+\sqrt{m}})$-approximate demand oracle for subadditive valuation functions.*

Proof. Let S be the set that maximizes utility $(v(S) - (1+\sqrt{m}) \cdot \mathbf{p}(S))$. If $S = \emptyset$, then the benchmark is 0, and SingleOrBundle achieves non-negative utility. It remains to consider the case $v(S) - \mathbf{p}(S) > 0$.

In this case, let T be the set returned by SingleOrBundle$(v, \mathbf{p}, M)$. Call an item j *special* if:

$$v(j) - \mathbf{p}(j) \geq \frac{1}{\sqrt{m}}(v(S) - (1+\sqrt{m}) \cdot \mathbf{p}(S)).$$

Observe that if any item j is special, then we conclude:

$$v(T) - \mathbf{p}(T) \geq v(j) - \mathbf{p}(j) \geq \frac{1}{\sqrt{m}}(v(S) - (1+\sqrt{m}) \cdot \mathbf{p}(S)),$$

which is a $(\frac{1}{\sqrt{m}}, \frac{1}{1+\sqrt{m}})$-approximate demand oracle. If no item is special, then $\forall j \in M^*$, $v(j) - \mathbf{p}(j) < \frac{1}{\sqrt{m}}(v(S) - (1+\sqrt{m})\mathbf{p}(S))$. Summing this for all $j \in M^*$ yields:

$$\left(\sum_{j \in M^*} v(j)\right) - \mathbf{p}(M^*) < \frac{|M^*|}{\sqrt{m}}(v(S) - (1+\sqrt{m}) \cdot \mathbf{p}(S)) \leq \sqrt{m} \cdot v(S) \leq \sqrt{m} \cdot v(M^*). \tag{1}$$

The final inequality follows as S cannot contain items for which $v(j) < (1+\sqrt{m})p(j)$, as $v(\cdot)$ is subadditive. We can then conclude that:

$$\begin{aligned} v(M^*) - \mathbf{p}(M^*) &> \frac{1}{\sqrt{m}}\left(\left(\sum_{j \in M^*} v(j)\right) - \mathbf{p}(M^*)\right) - \mathbf{p}(M^*) \\ &= \frac{1}{\sqrt{m}}\left(\sum_{j \in M^*} v(j) - (1+\sqrt{m})\mathbf{p}(j)\right) \\ &\geq \frac{1}{\sqrt{m}}\left(\sum_{j \in S} v(j) - (1+\sqrt{m})\mathbf{p}(j)\right) \\ &\geq \frac{1}{\sqrt{m}}\left(v(S) - (1+\sqrt{m})\mathbf{p}(S)\right). \end{aligned}$$

The first inequality follows directly from (1). The second follows as $v(j) > (1+\sqrt{m})\mathbf{p}(j)$ for all $j \in M^*$, and $S \subseteq M^*$ (because $v(\cdot)$ is subadditive, and S is the utility-maximizing set at prices $(1+\sqrt{m})\mathbf{p}$). The third follows from subadditivity of $v(\cdot)$. We conclude that when there are no special items, the proposition is satisfied as well, completing the proof. ◀

A Brief Discussion of Definitions

The following example will motivate our decision to think of advice as *improving a given strategy* as opposed to *outright proposing a replacement strategy*.

Consider, for example, a single-bidder mechanism where the bidder faces one of k posted-price vectors $\mathbf{p}_1, \dots, \mathbf{p}_k$ chosen uniformly at random, and is asked to submit their desired sets $S_1, \dots, S_k$ before knowing which price is "real." Then the strategy which submits $S_i := \arg\max\{v(S) - \mathbf{p}_i(S)\}$ is dominant. In this case, advice could indeed simply propose this strategy to replace whatever else the bidder might try.

Things get more interesting, however, if the designer cannot recommend a dominant strategy. Consider instead a recommended strategy $T_1, \dots, T_k$ where $T_i \notin \arg\max\{v(S) - \mathbf{p}_i(S)\} \cup \arg\min\{v(S) - \mathbf{p}_i(S)\}$ for any i (call this strategy $\vec{T}$). If the designer shares the sets $T_1, \dots, T_k$ with the buyer, a reasonable buyer should certainly submit sets S_i satisfying $v(S_i) - \mathbf{p}_i(S_i) \geq v(T_i) - \mathbf{p}_i(T_i)$ for all i (because they could just swap any set violating this for T_i and strictly improve their utility). Consider then the strategy which sets $S_j \in \arg\max\{v(S) - \mathbf{p}_j(S)\}$ (for a single $j \in [k]$) and $S_i \in \arg\min\{v(S) - \mathbf{p}_i(S)\}$ for all $i \neq j$ (picks the optimal set for $\mathbf{p}_j$, and worst possible sets for all other $\mathbf{p}_i$, call this strategy $\vec{S}$). We don't want to say that a bidder originally planning to use $\vec{S}$ should instead use $\vec{T}$ (indeed, $\vec{T}$ does not dominate $\vec{S}$, and it's not a priori clear which strategy yields higher expected utility). But we do want to say that a bidder originally planning to use $\vec{S}$ should stick with S_j, and update S_i to T_i for all $i \neq j$. But in order to recommend such a strategy without knowing j in advance, $\vec{T}$ would need to be the dominant strategy itself. So in order for the solution concept to meaningfully apply to posted-price mechanisms without advising the dominant strategy itself, advice should really take the form of improving a tentative strategy rather than outright recommending a replacement. Lemma 29 below provides a representative example of how this solution concept can be harnessed for existing state-of-the-art mechanisms.

B Proof of Theorem 16

The full definition of "implementation in advised strategies" is very powerful, but a bit awkward to carry around. Throughout this appendix, we use the following definition of (c, d)-competitive sets, which simply says that a set of items will give the bidder utility at least as high as a (c, d)-approximate demand oracle.

▶ **Definition 19.** *A set S is a* (c, d)-competitive subset of M for v_i with prices $\mathbf{p}$ *if*

$$v_i(S) - \mathbf{p}(S) \geq c \cdot \max_{T \subseteq M} \{v_i(T) - \mathbf{p}(T)/d\}.$$

We say a bidder i picks (c, d) competitive sets *in a fixed price auction if, when the fixed price auction visits i, they pick a set which is a (c, d)-competitive subset of the collection of remaining items.*

The full proof of theorem 16 is fairly involved. We start off this section by providing the more technical version of lemma 15 in section B.1, which captures most of the properties of fixed price auctions with approximate demand queries which we need. Next in section B.2, we describe the "core algorithm" PriceLearningMechanism of [1]. Then in section B.3, using fairly elementary properties of fixed-price auctions, we prove the correctness of the PriceLearningMechanism, as long as 1) bidders pick (c, d)-competitive sets in every fixed price auction they participate in, and 2) we make the simplifying assumption 21. In section B.4, we remove the simplifying assumption, and prove that there exists poly time computable advice such that, when bidders are following the advice, they always pick (c, d)-competitive sets.

B.1 Generalization of Lemma 15

In this subsection we state and prove the generalization of Lemma 15, which will be used in the analysis of the PriceLearningMechanism.

The first term in the maximum below (and the "moreover" part of the lemma) relates the achieved welfare with the value of the unsold items, and will be used to handle "learning" phases in the mechanism. The second term of the maximum shows that once we have learned the prices well, we definitely get good welfare.

▶ **Lemma 20.** *Suppose* $\{T_i\}_{i \in N} \leftarrow \text{FixedPriceAuction}(M, N, d\mathbf{p})$*, where each bidder i picks a subset of the remaining items which is (c, d)-competitive set for v_i with prices $\mathbf{p}$. Let $\{O_i\}_{i \in N}$ be any allocation with supporting prices $\mathbf{q}$. Let S_i be the set of items j where $\delta\mathbf{q}(j) \leq \mathbf{p}(j) \leq \frac{1}{2}\mathbf{q}(j)$ and $j \in O_i$. Denote $S = \bigcup_{i \in N} S_i$ and $\textsc{Sold} = \bigcup_i T_i$. Then*

$$\sum_i v_i(T_i) \geq \max \begin{cases} \frac{c}{2} \cdot \mathbf{q}(S \setminus \textsc{Sold}), \\ \min\left(\frac{c}{2}, \quad \delta d\right) \cdot \mathbf{q}(S). \end{cases}$$

Moreover, suppose k is the last bidder in N. We also have $v_i(T_k) \geq \frac{c}{2}\mathbf{q}(S_k \setminus \textsc{Sold}_{<k})$, where $\textsc{Sold}_{<k} = \bigcup_{i<k} T_i$.

Proof. Let $A_i = S_i \setminus \textsc{Sold}$. Because items in A_i are never allocated when bidder i is chosen to act (and because each bidder picks a (c, d)-competitive set with prices $\mathbf{p}$), the utility of each bidder i satisfies

$$v_i(T_i) - d \cdot \mathbf{p}(T_i) \geq c \cdot (v_i(A_i) - \mathbf{p}(A_i)).$$

As $A_i \subseteq S_i$, we know $\delta \mathbf{q}(A_i) \leq \mathbf{p}(A_i) \leq \frac{1}{2}\mathbf{q}(A_i)$, and by the definition of supporting prices, we know that $\mathbf{q}(A_i) \leq v_i(A_i)$ Thus, $\{T_i\}_{i \in N}$ achieves welfare

$$\begin{aligned}\sum_{i \in N} v_i(T_i) &= \sum_{i \in N} \big(v_i(T_i) - d \cdot \mathbf{p}(T_i)\big) + d \sum_{i \in N} \mathbf{p}(T_i) \\ &\geq c \sum_{i \in N} \big(v_i(A_i) - \mathbf{p}(A_i)\big) + d \cdot \mathbf{p}(\textsc{Sold}) \\ &\geq \sum_i c(\mathbf{q}(A_i) - \frac{1}{2}\mathbf{q}(A_i)) + d\delta \cdot \mathbf{q}(\textsc{Sold}). \qquad (*)\end{aligned}$$

Observe that $S \setminus \textsc{Sold} = \bigcup_{i \in N} A_i$. Thus, ignoring the term $d\delta\mathbf{q}(\textsc{Sold})$ from (*), we can conclude the auction gets welfare at least $\frac{c}{2}\mathbf{q}(S \setminus \textsc{Sold})$. Moreover, (*) tells us we get welfare at least

$$\min\left(\frac{c}{2}, \delta d\right) \cdot \big(\mathbf{q}(S \setminus \textsc{Sold}) + \mathbf{q}(\textsc{Sold})\big) \geq \min\left(\frac{c}{2}, \delta d\right) \cdot \mathbf{q}(S),$$

from which we can conclude main statement of the lemma.

For the "moreover" component, simply observe that when bidder k was picked by the mechanism, the items in $A' := S_k \setminus \textsc{Sold}_{<k}$ were still available, and that $S_k \subseteq O_k$, so

$$v_i(T_k) \geq v_i(T_k) - d\mathbf{p}(T_k) \geq c(v_i(A') - \mathbf{p}(A')) \geq c(\mathbf{q}(A') - \mathbf{q}(A')/2) = \frac{c}{2}\mathbf{q}(A'). \qquad \blacktriangleleft$$

B.2 The Mechanism

For the reader's convenience, we first briefly describe the mechanism in [1] and quote the mechanism verbatim (the only change we need to make is that every price used by the mechanism is "discounted" by an extra factor of d, plus some slight simplifications in the "removing extra assumptions" step). Then we present a slightly condensed version of the analysis.

High-level overview. Posted price mechanisms for combinatorial auctions typically use the following high-level strategy: attempt to (approximately) *learn* the supporting prices (definition 13) of an optimal allocation, then sell the items at those prices. The key innovation of [1] is to "explore" prices for each item individually using a *price tree* in which each successive layer of the tree corresponds to a finer "granularity" of prices. Initially, each item is set at a price corresponding to the root of the tree, and in each successive round of the mechanism, the price of each item moves one layer down in the tree to a "more precise" price which corresponds to some child node of the old price.

The mechanism of [1] runs several fixed-price auctions for each round (i.e. each layer of the price tree). In each of these successive auctions, each item is priced higher and higher in a way corresponding to the children of the "old" price node of the item. The price in the next round of the mechanism is then the highest price in the next layer where the item was still sold. The idea here is that, in the next layer of prices, we need to make the prices as high as possible such that the items will still sell. Intuitively, this serves to refine our estimate for the supporting prices as we move a layer down in the tree.

In fact, the story is more subtle than this. The mechanism may not actually achieve a better approximation to the prices in each layer, but [1] prove that if you *do not* get a better estimate for the prices, then you can *already* get a good approximation to the optimal welfare at the current prices. These two cases exactly correspond to the "learnable" or "allocatable" cases in lemma 22 below. For this reason, for every layer of the price tree, the mechanism

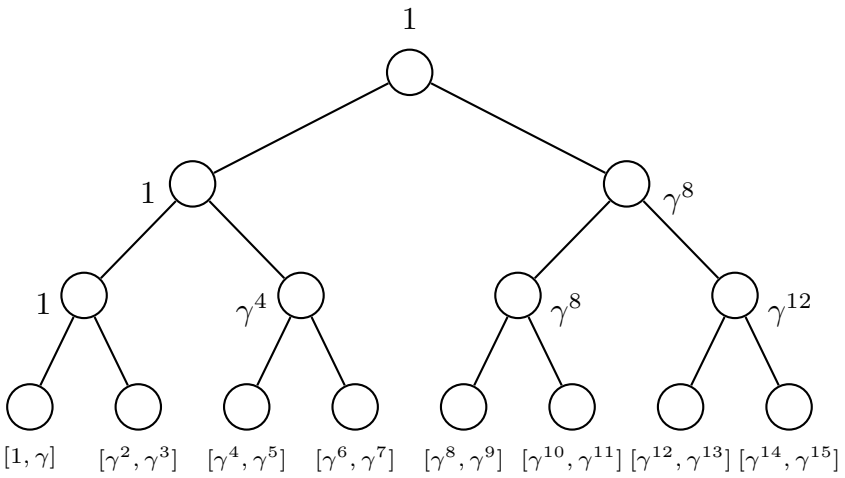

Figure 1 [1, Figure 2] An illustration of a price tree T^e with $\alpha = 2$, $\beta = 3$, and $\psi_{min} = 1$.

has some chance (proportional to the number of layers) of stopping early and allocating the items according to some fixed price auction in that layer. Thus, regardless of whether we always learn prices or if we hit the "allocatable" in some step, we will use a good auction with some probability.

Simplifying Assumption. It's useful for posted price mechanisms to know ahead of time the *range* of possible supporting prices of an optimal allocation. This assumption can be removed in a fairly "modular" way, as done in [1] (though we make some modifications in order to more easily fit our solution concept).

Let $\mathbf{q}$ be the supporting prices of an optimal allocation. Formally, our simplifying assumption is the following:

▶ **Assumption 21.** *There are known numbers ψ_{min}, ψ_{max} such that the supporting prices of any item in $\mathbf{q}$ are either 0 or in $[\psi_{min}, \psi_{max}]$, and ψ_{max}/ψ_{min} is polynomial in m.*

The price tree and mechanism parameters. We now formally describe the price tree in terms of three parameters:

- $\alpha = \Theta(1)$ is the branching factor of the tree (and the number of auctions in each iteration of the mechanism).
- $\beta = \Theta(\log\log(\psi_{max}/\psi_{min})) = \Theta(\log\log m)$ is the number of layers in the price tree (and the number of iterations of the mechanism).
- $\gamma = \Theta(\alpha\beta) = \Theta(\log\log m)$ is the "accuracy factor" of the prices.

We would like the leaves of the price tree correspond to "price buckets"

$$P = \{[\psi_{min}\gamma^i, \psi_{min}\gamma^{i+1}] \mid i = 0, 1, \ldots, k\}$$

for some k large enough that all prices in $[\psi_{min}, \psi_{max}]$ are considered. Informally, we take "learning a price $\mathbf{q}$ correctly" to mean that we find the bucket in P to which $\mathbf{q}$ belongs. We will assign "actual" prices in $\mathbf{p}$ according to the smallest price $\psi_{min}\gamma^i$ in the corresponding bucket. Our goal is that, if we "learn the price of $\mathbf{q}$ correctly", then the price used in $\mathbf{p}$ is within a γ factor of the true price in $\mathbf{q}$.

However, for technical reasons, we need a *gap* of at least γ between the prices of consecutive nodes in each layer of the tree (not just the leaves), so that prices will be guided to the closest leaf node *below* the price in $\mathbf{q}$ (this is desirable because lemma 20 requires prices in $\mathbf{p}$ to be less than in $\mathbf{q}$). To ensure this, the mechanism creates a price gap of factor γ between nodes by splitting P into

$$P^o = \{[\psi_{min}\gamma^{2k-1}, \psi_{min}\gamma^{2k}] \mid k = 1, \dots, \alpha^\beta\}$$
$$P^e = \{[\psi_{min}\gamma^{2k}, \psi_{min}\gamma^{2k+1}] \mid k = 0, \dots, \alpha^\beta - 1\}$$

Trees T^o and T^e are constructed with leaf nodes P^o and P^e respectively. We use T^* to denote either of T^o or T^e, and P^* will denote the corresponding P^o or P^e.

The price tree T^* is an α-branching tree with depth β (i.e. with $\beta + 1$ layers). The leaf nodes correspond, in left-to-right (depth-first search) order, to the price buckets in P^* (in increasing order). Furthermore, any non-leaf node x corresponding to a single price, which is the minimum value in any bucket of any leaf node which is a descendant of x. Thus, the prices corresponding to consecutive level-i nodes differ by a factor of $\gamma^{2\alpha^{\beta+1-i}}$.

Let $\mathbf{p}$ be a "level-i price vector", i.e. a vector in which the price of each item is a price which corresponds to some level-i node. We let $\text{next}_j^{(i)}(\mathbf{p}) = \mathbf{p}'$ denote the price vector constructed as follows: for each item $\ell \in M$, let x be the level-i node whose corresponding price is $\mathbf{p}(\ell)$. Then set $\mathbf{p}'(\ell)$ to the price corresponding to the jth child node of x. Thus, a precise formula is given by $\mathbf{p}'(\ell) = \gamma^{2\alpha^{\beta-i}(j-1)}\mathbf{p}(\ell)$. In words, $\text{next}_j^{(i)}(\mathbf{p})$ sets the price of each item ℓ to be the jth largest "refined price" below the current price of item ℓ.

The mechanism. We start by randomly picking a price tree T^o or T^e. The mechanism then proceeds in β iterations (though it may terminate early) in which a price vector $\mathbf{p}^{(i)}$ is constructed in each iteration i. Initially, $\mathbf{p}^{(1)}$ is the (unique) level-1 price vector of T^*. In each iteration, a $\frac{1}{10\beta}$ fraction of the bidders are selected uniformly at random, and the α different price vectors $\mathbf{p}_j^{(i)} = \text{next}_j^{(i)}(\mathbf{p}^{(i)})$ for $j = 1, \dots, \alpha$ are considered. The mechanism runs fixed price auction with the current set of bidders on prices $d\mathbf{p}_j^{(i)}/2$ for $j = 1, \dots, \alpha$. The new (level-$(i+1)$) vector $\mathbf{p}^{(i+1)}$ is then constructed as follows: for each item ℓ, $\mathbf{p}^{(i+1)}(\ell) = \mathbf{p}_j^{(i)}(\ell)$, where j is the highest index such that item ℓ sold in the auction with prices $d\mathbf{p}_j^{(i)}/2$. (or $\mathbf{p}^{(i)}(\ell)$ if no such j exists). In words, the new price of ℓ is the price of ℓ in the highest auction in iteration i for which item ℓ was sold. For each fixed price auction described in this paragraph, there is a $1/\Omega(\alpha\beta)$ chance that the mechanism will terminate early and return the allocation determined by the auction. This serves to strictly incentivizes bidder to pick good sets, but also serves an important purpose for achieving the desired approximation grantee, as discussed in the overview.

If the mechanism does not terminate early in iteration $1, \dots, \beta$, then the final step of the mechanism is to run a fixed price auction with all of the remaining bidders on prices $d\mathbf{p}^{(\beta)}/2$. (The hope is that, for a large fraction (weighted by $\mathbf{q}$) of the items, the price of the items is in the level-β bin which is closest to the price in $\mathbf{q}$, and thus we can apply lemma 20.)

The exact mechanism in [1] is quoted in Algorithm 3.

B.3 The Modified Analysis

Notation

We follow [1] and depart somewhat from conventional notation for the analysis of the mechanism. We let i denote an iteration of the mechanism, j denote an auction inside some iterations, b denote a bidder, and ℓ denote an item.

Algorithm 3 PriceLearningMechanism(N, M).

procedure PARTITION(N)
  Permute N uniformly at random.
  for $i = 1, 2, ..\beta$ **do**
    Remove $\frac{|N|}{10\beta}$ bidders uniformly at random from N; assign them to the set N_i.
  Put the remaining items in N into $N_{\beta+1}$.
procedure PRICEUPDATE$(A_1,\ldots,A_\alpha, \mathbf{p}_1,\ldots,\mathbf{p}_\alpha)$
  For each $\ell \in M$, let $\mathbf{p}'(\ell) = \mathbf{p}_j(\ell)$ for the
    highest value of j such that ℓ is allocated in A_j (or $\mathbf{p}_1(\ell)$ if no j exists)
  Return $\mathbf{p}'$

Let $(N_1, N_2, ...N_{\beta+1}) \leftarrow$ Partition(N)
Pick one of the modified trees T^o or T^e uniformly at random and denote it by T^*
Let $\mathbf{p}^{(1)}$ be the (unqiue) level-1 (root) price of T^*
for $i = 1, \ldots, \beta$ **do**
  For $j = 1, \ldots, \alpha$, let $\mathbf{p}_j^{(i)} = \text{next}_j^{(i)}(\mathbf{p}^{(i)})$
  For $j = 1, \ldots, \alpha$: run FixedPriceAuction(N_i, M, $d\mathbf{p}_j^{(i)}/2$) and let $A_j^{(i)}$ be the allocation
  With probability $(1/\beta)$, pick $j^* \in [\alpha]$ u.a.r. and return $A_{j^*}^{(i)}$ as the final allocation
  Otherwise, let $\mathbf{p}^{(i+1)} \leftarrow$PriceUpdate$(A_1^{(i)}, ..., A_\alpha^{(i)}, \mathbf{p}_1^{(i)}, ..., \mathbf{p}_\alpha^{(i)})$, and continue
Run FixedPriceAuction$(N_{\beta+1}, M, d\mathbf{p}^{(\beta+1)}/2)$ and return the allocation A^*

Let O be an optimal allocation with supporting prices $\mathbf{q}$ and OPT be the optimal welfare resulting from allocation O. Let $\mathbf{q}^*$ be $\mathbf{q}$ restricted to items whose prices are in some bucket of P^*. Let O^* be the collection of those items. Let $N_1, \ldots, N_{\beta+1}$ denote the groups of bidders from the Partition function. Given $(N_i)_i$ and T^* as picked by the mechanism, define price vectors $\mathbf{q}^{(i)}$ as $\mathbf{q}^*$, restricted to items which are allocated in O^* to bidders from $N_i, N_{i+1}, \ldots, N_{\beta+1}$ (intuitively, we restricted attention to items which could still go to the same bidder in A as in O, and give price 0 to items that can no longer be allocated to the right bidder in O). Call item ℓ correctly priced at iteration i if $\mathbf{q}^{(i)}(\ell)$ is in the bin corresponding to some leaf node which is a child of the node corresponding to $\mathbf{p}^{(i)}(\ell)$. Let $C^{(i)}$ denote all items priced correctly before iteration i begins. Note that $C^{(1)} = O^*$ and that an item can only be in $C^{(i)}$ if it is also in $C^{(j)}$ for $j = 1, \ldots, i-1$, so $C^{(1)} \supseteq C^{(2)} \supseteq \ldots \supseteq C^{(\beta+1)}$. We separate $C^{(i)}$ into $C_1^{(i)}, C_2^{(i)}, ...C_\alpha^{(i)}$, where $C_j^{(i)}$ is the subset of items in $C^{(i)}$ that are priced correctly in $\text{next}_j^{(i)}(\mathbf{p}^{(i)})$. For any set of bidders N' and items D, let $O^D_{N'}$ be the restriction of O^* to items in D and bidders in N'.

Assumptions

Throughout the claims in this section, we assume all bidders pick (c, d)-competitive sets in every fixed price auction they participate in, though we may not restate this assumption in every claim statement[7]. We also assume that the optimal allocation O has supporting prices $\mathbf{q}$.

[7] It is somewhat easier to prove that PriceLearningMechanism is implementable in advised strategies compared to GeneralizedMechanism below. However, we hold off and only demonstrate that Generalized-Mechanism is implementable in advised strategies, both for completeness, and in order to demonstrate that our solution concept "composes well" to be useful for complicated mechanisms.

The following lemma is the heart of the proof of the approximation ratio of mechanism 3.

▶ **Lemma 22** (Learnable-Or-Allocable Lemma from [1]). *Assume 21, and suppose all bidders pick (c, d)-competitive sets in every fixed price auction they participate in. For any iteration $i \in [\beta]$, conditioned on any outcome of first $i-1$ iterations and choice of T^*,*

1. *either* $\mathbb{E}\left[\mathbf{q}^{(i+1)}(C^{(i+1)})\right] \geq \mathbf{q}^{(i)}(C^{(i)}) - \frac{OPT}{3\beta}$*, where the expectation is over N_i;*
2. *or* $\mathbb{E}\left[\text{val}(A_{j^*})^{(i)}\right] \geq \frac{c}{O(\alpha\beta^2)} OPT$.

First we prove a series of claims before proving the Learnable-Or-Allocable lemma, following the same outline as [1]. For claims 23 and 24, we fix some $j \in [\alpha]$ and let $D = C_j^{(i)}$. Note that $\mathbf{q}^{(i)}(C_j^{(i)}) = \mathbf{q}^{(i)}(O^D_{N_{\geq i}})$, as $\mathbf{q}^{(i)}$ zeros out items allocated in O to bidders from $N_{<i}$.

▷ Claim 23. (5.3 from [1]) Deterministically, $\text{val}(A_j^{(i)}) \geq \frac{c}{2} \cdot \mathbf{q}^{(i)}(O^D_{N_i} \setminus A_j^{(i)})$.

Proof. Recall that $O^D_{N_i}$ is the restriction of O^* to items in $C_j^{(i)}$ and bidders in N_i. The definition of item ℓ being "priced correctly" means that $\mathbf{p}^{(i)}(\ell) \leq \mathbf{q}^{(i)}(\ell)$. Thus, for any $\ell \in O^D_{N_i}$ we get that $0 \cdot \mathbf{q}^{(i)}(\ell) \leq d\mathbf{p}^{(i)}(\ell)/2 \leq \mathbf{q}^{(i)}(\ell)/2$. Thus, the claim follows from lemma 20. ◁

▷ Claim 24. (5.4 from [1]) By randomness of choice of N_i from $N_{\geq i}$, $\mathbb{E}\left[\text{val}(A_j^{(i)})\right] \geq (\frac{c}{20\beta}) \cdot \mathbb{E}\left[\mathbf{q}^{(i)}(O^D_{N>i} \setminus A_j^{(i)})\right]$.

Proof. Consider picking a bidder $k \in N_{>i}$ uniformly at random and running an imaginary fixed price auction on $N_i \cup \{k\}$, where k is the last bidder chosen to act. Then by Lemma 20 (parameters in the lemma take values $N = N_i \cup \{k\}$, $\text{Sold}_{<k} = A_j^{(i)}$, $S_k = O_k^D$), the value bidder k gets from the imaginary fixed price auction satisfy $v_k(T_k) \geq \frac{c}{2} \cdot \mathbf{q}^{(i)}(O_k^D \setminus A_j^{(i)})$. We now take the expectation over the randomness on bidders $N_i \cup k$,

$$\begin{aligned}\mathop{\mathbb{E}}_{N_i, k\in N_{>i}}[v_k(T_k)] \geq \frac{c}{2} \cdot \mathop{\mathbb{E}}_{N_i, k\in N_{>i}}\left[\mathbf{q}^{(i)}(O_k^D \setminus A_j^{(i)})\right] &= \frac{c}{2} \cdot \mathop{\mathbb{E}}_{N_i}\left[\frac{1}{|N_{>i}|} \cdot \sum_{k\in N_{>i}} \mathbf{q}^{(i)}(O_k^D \setminus A_j^{(i)})\right] \\ &= \frac{1}{|N_{>i}|} \cdot \frac{c}{2} \cdot \mathbb{E}\left[\mathbf{q}^{(i)}(O^D_{N_{>i}} \setminus A_j^{(i)})\right].\end{aligned}$$

Observe that the expectation of $\text{val}(A_j^{(i)})$ is the same as the expected welfare of bidders in N_i in the imaginary fixed price auction. Since the bidders in N_i arrive before bidder k, their expected welfare in the imaginary fixed price auction is larger equal to that of bidder k. Thus by linearity of expectation

$$\mathbb{E}\left[\text{val}(A_j^{(i)})\right] \geq \frac{|N_i|}{|N_{>i}|} \cdot \frac{c}{2} \cdot \mathbb{E}\left[\mathbf{q}^{(i)}(O^D_{N_{>i}} \setminus A_j^{(i)})\right] \geq \left(\frac{c}{20\beta}\right) \cdot \mathbb{E}\left[\mathbf{q}^{(i)}(O^D_{N_{>i}} \setminus A_j^{(i)})\right]. \quad ◁$$

▷ Claim 25. (5.2 from [1]) For any j, we have

$$\frac{22\beta}{c} \cdot \mathbb{E}\left[\text{val}(A_j^{(i)})\right] + \mathbb{E}\left[\mathbf{q}^{(i)}(C_j^{(i)} \cap A_j^{(i)})\right] \geq \mathbb{E}\left[\mathbf{q}^{(i)}(C_j^{(i)})\right].$$

Proof. By combining Claim 23 and 24, we have

$$\begin{aligned}\left(\frac{20\beta}{c} + \frac{2}{c}\right)\mathbb{E}\left[\text{val}(A_j^{(i)})\right] &\geq \mathbb{E}\left[\mathbf{q}^{(i)}(O^D_{N>i} \setminus A_j^{(i)})\right] + \mathbb{E}\left[\mathbf{q}^{(i)}(O^D_{N_i} \setminus A_j^{(i)})\right] \\ &= \mathbb{E}\left[\mathbf{q}^{(i)}(C_j^{(i)} \setminus A_j^{(i)})\right].\end{aligned}$$

Because $O^D_{N_{\geq i}}$ is exactly $C^{(i)}_j$. Thus, we get

$$\frac{20\beta+2}{c}\cdot\mathbb{E}\left[\text{val}(A^{(i)}_j)\right]+\mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i)}_j\cap A^{(i)}_j)\right]\geq\mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i)}_j)\right].$$ ◁

The previous claim can be thought of as a preliminary version of the entire learnable-or-allocatable lemma. In expectation, we get something comparable to the items which are correctly priced in auction j of round i (i.e. $\mathbf{q}^{(i)}(C^{(i)}_j)$). The contribution come from either the items which sold in the round they were "supposed to" (i.e. $C^{(i)}_j\cap A^{(i)}_j$) or the welfare of the current allocation (i.e. $A^{(i)}_j$) (with an extra $O(\beta)$ factor). The previous claims dealt with individual auctions within an iteration – next we handle iterations as a whole.

We still have to account for two things: items which sell in auctions where the prices are *too high* and the loss in welfare from the fact that bidders in N_i will no longer be allocated items in later rounds. The proofs in [1] hold as written – only the properties of the price tree and the structure of the auctions are used.

▷ Claim 26. (5.5 from [1])

$$\mathbf{q}^{(i)}(C^{(i+1)})\geq\sum_{j=1}^{\alpha}\mathbf{q}^{(i)}(A^{(i)}_j\cap C^{(i)}_j)-\frac{OPT}{10\beta}.$$

Proof. The key observation here is that the set of "overpriced" items represent a small fraction of the optimal revenue. Let U be the set of items that are allocated in FixedPriceAuction with price above their correct price in round i. The set of items that are allocated in the correct round but not priced correctly is exactly $\left(\bigcup_j A^{(i)}_j\cap C^{(i)}_j\right)\setminus C^{(i+1)}$. This must be a subset of U. Thus, $\mathbf{q}^{(i)}(C^{(i+1)})\geq\sum_{j=1}^{\alpha}\mathbf{q}^{(i)}(A^{(i)}_j\cap C^{(i)}_j)-\mathbf{q}(U)$.

Consider an allocation that gives all items in U to the bidder in the highest priced auction where it is ever allocated. Such an allocation must give welfare $\leq OPT$, but $\geq\gamma\mathbf{q}^{(i)}(U)$ due to the price gap in the tree structure. Thus $\mathbf{q}^{(i)}(U)\leq\frac{1}{\gamma}OPT\leq\frac{OPT}{10\beta}$ (by choosing $\gamma=\theta(\log\log m)\geq 10\beta$) . ◁

▷ Claim 27. (5.6 from [1])

$$\mathbb{E}\left[\mathbf{q}^{(i+1)}(C^{(i+1)})\right]\geq\mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i+1)})\right]-\frac{OPT}{10\beta}.$$

Proof. This follows simply from the fact that $\mathbf{q}^{(i+1)}$ is exactly $\mathbf{q}^{(i)}$ with items corresponding (under O) to bidders in N_i set to zero, and that bidders join N_i with probability $1/(10\beta)$. ◁

Proof of Learnable-Or-Allocable Lemma, Lemma 22. By Claim 26 and 27,

$$\mathbb{E}\left[\mathbf{q}^{(i+1)}(C^{(i+1)})\right]\geq\sum_{j=1}^{\alpha}\mathbb{E}\left[\mathbf{q}^{(i)}(A^{(i)}_j\cap C^{(i)}_j)\right]-\frac{OPT}{5\beta},\tag{2}$$

We now have two cases. First, assume

$$\sum_{j=1}^{\alpha}\mathbb{E}\left[\mathbf{q}^{(i)}(A^{(i)}_j\cap C^{(i)}_j)\right]\geq\mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i)})\right]-\frac{2}{15\beta}OPT.\tag{3}$$

Together with (2) this immediately implies that

$$\mathbb{E}\left[\mathbf{q}^{(i+1)}(C^{(i+1)})\right] \geq \mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i)})\right] - \frac{OPT}{3\beta}.$$

and we are in the "learnable case".

On the other hand, if equation (3) is false, then we can sum the inequality in claim 25 for each $j = 1, \ldots, \alpha$ to get

$$\begin{aligned}\mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i)})\right] &\leq \frac{22\beta}{c}\sum_{j=1}^{\alpha}\mathbb{E}\left[\mathrm{val}(A_j^{(i)})\right] + \sum_{j=1}^{\alpha}\mathbb{E}\left[\mathbf{q}^{(i)}(C_j^{(i)} \cap A_j^{(i)})\right] \\ &< \frac{22\beta}{c}\sum_{j=1}^{\alpha}\mathbb{E}\left[\mathrm{val}(A_j^{(i)})\right] + \mathbb{E}\left[\mathbf{q}^{(i)}(C^{(i)})\right] - \frac{2}{15\beta}OPT.\end{aligned}$$

Thus

$$\begin{aligned}&\frac{22\beta}{c}\sum_{j=1}^{\alpha}\mathbb{E}\left[\mathrm{val}(A_j^{(i)})\right] \geq \frac{2}{15\beta}\cdot OPT \\ &\Rightarrow \mathbb{E}\left[\mathrm{val}(A_{j^*}^{(i)})\right] = \frac{1}{\alpha}\sum_{j=1}^{\alpha}\mathbb{E}\left[\mathrm{val}(A_j^{(i)})\right] \geq \frac{2c}{22 * 15\alpha\beta^2}\cdot OPT = \frac{c}{O(\alpha\beta^2)}\cdot OPT.\end{aligned}$$

and we are in the "allocatable" case. ◀

Theorem 16 now follows readily follow from the Learnable or Allocable Lemma.

▶ **Theorem 28.** *Suppose ψ_{min} and ψ_{max} are given and satisfy assumption 21. Suppose the optimal allocation O has supporting prices $\mathbf{q}$, and suppose bidders pick (c, d)-competitive sets in every fixed price auction they participate in. Then mechanism 3 achieves an $O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\} \cdot (\log\log m)^3\right)$ approximation to the optimal welfare.*

Proof. Note that by the Learnable or Allocable Lemma, in the mechanism there are only two situation that can occur, 1) event E_1: "learnable" occurs in every iteration $i = 1, 2, ...\beta$, or 2) event E_2: "allocable" occurs in some iteration k. Denote the welfare from the mechanism as $Welf$. Then $\mathbb{E}[Welf]$ satisfy the equation

$$\mathbb{E}[Welf] \geq \min\left(\mathbb{E}[Welf \mid E_1], \mathbb{E}[Welf \mid E_2]\right).$$

Now we bound $\mathbb{E}[Welf \mid E_1]$ and $\mathbb{E}[Welf \mid E_2]$, respectively.

- Suppose that "learnable" occurs for each iteration $i = 1, 2, ...\beta$ in the mechanism. Because $C^{(1)}$ consist of items whose prices belong to the bins of P^*, we know that $\mathbb{E}\left[\mathbf{q}^{(1)}(C^{(1)})\right] = OPT/2$. Thus,

  $$\mathbb{E}\left[\mathbf{q}^{\beta+1}(C^{\beta+1})\right] \geq \mathbb{E}\left[\mathbf{q}^{(1)}(C^{(1)}) - \frac{OPT}{3}\right] = \frac{OPT}{2} - \frac{OPT}{3} = \frac{OPT}{6}.$$

  Let $W_{\beta+1}$ be the welfare achieved when the mechanism allocate in the last iteration of fixed price auction. Since for any correctly priced item $j \in C^{(\beta+1)}$, $\frac{1}{2}\mathbf{q}(j) \geq \mathbf{p}(j) \geq \frac{1}{\gamma}\mathbf{q}(j)$, by lemma 20, $W_{\beta+1} \geq \min\left(\frac{c}{2}, \frac{d}{\gamma}\right) \cdot \mathbb{E}\left[\mathbf{q}^{\beta+1}(C^{\beta+1})\right] = O\left(\min\left(c, \frac{d}{\beta}\right)\right) \cdot OPT$.
  It's easy to verify that the mechanism allocates in last iteration with constant probability. Thus, in this case we get $\mathbb{E}[Welf|E_1]$ at least $O\left(\min\left(c, \frac{d}{\beta}\right)\right) \cdot OPT$.

- In the case where "learnable" does not occur for some iteration i, "allocable" must occur at this iteration. Thus

$$\mathbb{E}\left[\text{val}(A^{(i)}_{j^*})\right] = \frac{c}{O(\alpha\beta^2)} \cdot OPT.$$

  The mechanism allocate in iteration i with probability $(1-1/\beta)^{i-1} \cdot 1/\beta = O(1/\beta)$, thus in this case $\mathbb{E}[Welf \mid E_2]$ is at least $\frac{c}{O(\alpha\beta^3)} \cdot OPT$.

Since $\beta = \Theta(\log\log m)$, we conclude that mechanism M achieves an approximation ratio of

$$O\left(\max\left(\frac{1}{c}, \frac{\beta}{d}, \frac{\alpha\beta^3}{c}\right)\right) = \max\left(\frac{1}{c}, \frac{1}{d}\right) \cdot O(\log\log m)^3. \quad \blacktriangleleft$$

B.4 Removing Assumptions

In this section we prove Theorem 16 in full generality by 1) removing the assumption that the supporting price lies in $\{0\} \cup [\psi_{min}, \psi_{max}]$, where $\psi_{max}/\psi_{min} = \text{poly}(m)$, and 2) showing that this generalized mechanism can be implemented in advised strategies. We use a similar (but slightly simplified) extension to PriceLearningMechanism following previous work on truthful mechanisms for XOS bidders [12, 18, 14, 1][8]. Our variation both simplifies the analysis and allows us to satisfy the formal definition of implementation in advised strategies more easily.

The final mechanism is as follows.

Algorithm 4 GeneralizedMechanism(N, M).

1: Pick a subset of bidders $N_{stat} \subseteq N$ by sampling each bidder in N independently and with probability $\frac{1}{2}$. Let $N_{mech} = N \setminus N_{stat}$.
2: Run a second price auction on the grand bundle M with bidders in N_{stat}. Let SPA be the welfare of the resulting allocation. With probability $\frac{1}{2}$, return the resulting allocation and terminate. With the remaining probability, continue.
3: Set $\psi_{min} = \frac{1}{4m^2} \cdot SPA$ and $\psi_{max} = 4m \cdot SPA$.
4: Run PriceLearningMechanism (Mechanism 3) on bidders in N_{mech} with ψ_{min} and ψ_{max} and return the allocation.

First, we show that implementation in advised strategies allows us to force bidders to play truthfully in the second-price auction of mechanism 4, and to pick (c, d)-competitive sets in the PriceLearningMechanism.

▶ **Lemma 29.** *Suppose we are given a (c, d)-approximate demand oracle D for valuations $\mathcal{V}$. Then there exists a useful poly-time computable advice A for mechanism 4 such that, if a strategy s is advised for v_i under A, then any bidder in N_{stat} will play truthfully in the second price auction, and any bidder in N_{mech} will pick (c, d)-competitive sets in every fixed price auction they participate in.*

Proof. As in prior works [1, 12, 14], to formally meet our solution concept we need all actions by a single bidder to happen simultaneously in order to preclude bidders from "threatening" each other (for example, if a different bidder will only let me have items in future auctions if

[8] Prior works have some probability of selling the grand bundle M in a second price auction (to handle "dominant bidders") or running a different algorithm to collect basic "statistics" on the bidders. We combine the two approaches by using the result of the second price auction to calculate the statistics (at the cost of some loss in the polynomial factor in assumption 21).

I lie in the current auction, then truthful play does not dominate lying). Thus, we formally implement GeneralizedMechanism as a game where each bidder can act in exactly one node. If the bidder is assigned in N_{stat}, the mechanisms simultaneously asks all bidders in N_{stat} for a single bid on the grand bundle. If the bidder is put in N_{mech}, and then into N_i for $i < \beta + 1$, then the bidder needs to participate in α fixed-price auctions simultaneously in a single game node. Thus, the bidder reports a list $(T_j)_{j=1,\dots,\alpha}$ of α subsets of M, where T_j is still available in auction j of the mechanism when it is bidder i's turn to pick a set. Bidders in $N_{\beta+1}$ report similarly, but participate in only one auction.

Recall that the advice function $A(v_i, x, a)$ takes as input the valuation function v_i of player i, a node x of the game, and a "tentative" action a which the player may play. The advice works as follows: for a node x which corresponds to a bidder in N_{stat}, A can ignore the tentative action a and recommend truthful play in the second price auction, i.e. $A(v_i, x, a) = v_i(M)$ in this case. If x corresponds to a bidder put in $N_i \subseteq N_{mech}$ for some $i < \beta$, then the tentative action a is some list of sets $(S_1, \dots, S_\alpha)$ which bidder i may choose in each auction. For each of the α auctions, A will run the (c, d)-approximate demand query D (with prices and remaining items known from the node x) to get a sets $T_1, \dots, T_\alpha$. Then, A will return $(S'_1, \dots, S'_\alpha)$, where S'_i is whichever of S_i or T_i that gives bidder i higher utility. The advice behaves similarly for bidders in $N_{\beta+1} \subseteq N_{mech}$.

It's clear that, if D is computable in poly-time, then $A(v_i, x, a)$ is computable in poly-time.

We now show that A is *useful* (definition 5). A satisfies the required idempotency property, because for bidders in N_{stat}, the result of A is a constant, and for bidders in N_{mech}, the result is given by taking the max of sets S_j with the result of D (which is fixed given bidder's valuation v_i and a node x of the game).

For any s_i and for any randomness in the mechanism, it's clear that $A^{v_i,s}$ gets i utility at least as high as s. For, if i is in N_{stat}, then $A^{v_i,s}$ recommends a dominant strategy, and if i is in N_{mech}, then the utility of i is completely determined by the unique node in which i is chosen to act, and $A^{v_i,s}$ will differ from s only in selecting sets with higher utility for i. Moreover, if $s \neq A^{v_i,s}$, then either s and $A^{v_i,s}$ differ for some node corresponding to a bidder in N_{stat}, or s and $A^{v_i,s}$ differ for some node corresponding to a bidder in N_{mech}. In the first case, because $A^{v_i,s}$ is dominant, there exists v_{-i} and random outcomes of the mechanism which get i strictly higher utility. In the second case, there must be some auction in which the advice $A^{v_i,s}$ selects strictly better sets than s, and because there is positive probability that each auction is the allocation returned by the mechanism, there are some random outcomes of the mechanism which get the bidder strictly more utility. Thus, if $A^{v_i,s} \neq s$, then $A^{v_i,s}$ dominates s.

Finally, it's clear that if a bidder plays according to strategy $A^{v_i,s}$for any s, then if the bidder is in N_{stat} then they play truthfully, and if the bidder is in N_{mech} then they select (c, d)-competitive sets. ◀

Now, we show that algorithm 4 successfully allows us to remove assumption 21. Let S be any set of bidders and let $OPT(S)$ denote the optimal welfare possible for bidders in S. We say (ψ_{min}, ψ_{max}) is *correct for* S if $\psi_{min} \leq OPT(S)/m^2$ and $\psi_{max} \geq OPT(S)$. We call a bidder i dominant for a set S if $v_i(O_i) > \frac{OPT(S)}{8}$.

▶ **Lemma 30.** *Let* $\mathbf{q}$ *be the supporting prices of an optimal allocation of items to bidders in some set* S*. If* (ψ_{min}, ψ_{max}) *is correct for* S*, then the supporting prices of a* $(1 - o(1))$ *fraction of the items (weighted by their supporting prices) are in the range* $I = [\psi_{min}, \psi_{max}]$*. More formally,* $\sum_{j \in M} \mathbb{1}[\mathbf{q}(j) \in I] \cdot \mathbf{q}(j) \geq (1 - \frac{1}{m}) \cdot OPT(S)$.

Proof. Since $\psi_{max} \geq OPT(S)$, we know that for all item j, $\mathbf{q}(j) \in [0, \psi_{max}]$. Now we count the sum over supporting prices of items whose supporting price is $\leq OPT(S)/m^2$.

$$\sum_{\mathbf{q}(j) \leq OPT(S)/m^2} \mathbf{q}(j) \leq m \cdot OPT(S)/m^2 = OPT(S)/m.$$

Thus

$$\sum_{j \in [m]} \mathbb{1}\left[\mathbf{q}(j) \in I\right] \cdot \mathbf{q}(j) \geq \sum_{j \in [m]} \mathbf{q}(j) - \sum_{\mathbf{q}(j) \leq OPT(S)/m^2} \mathbf{q}(j) \geq \left(1 - \frac{1}{m}\right) \cdot OPT(S). \quad \blacktriangleleft$$

▶ **Corollary 31.** *For bidders in S and items in M, if (ψ_{min}, ψ_{max}) is correct for S, and $\psi_{max}/\psi_{min} = \text{poly}(m)$, then* PriceLearningMechanism(S, M) *returns an allocation with expected welfare $\frac{1}{r} \cdot (1 - \frac{1}{m}) \cdot OPT(S)$, where $r = O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\} (\log\log m)^3\right)$.*

Proof. Again let $\mathbf{q}$ be the supporting prices of an optimal allocation of items to bidders in some set S. Observe that although Theorem 28 assumes all supporting price to be in $0 \cup [\psi_{min}, \psi_{max}]$, the proof holds as is for approximating $\sum_{j \in [m]} \mathbb{1}\Big[\mathbf{q}(j) \in [\psi_{min}, \psi_{max}]\Big] \cdot \mathbf{q}(j)$ (i.e. the contribution to the optimal welfare of items whose supporting price is in $[\psi_{min}, \psi_{max}]$). If (ψ_{min}, ψ_{max}) is correct for S, then

$$\sum_{j \in [m]} \mathbb{1}\Big[\mathbf{q}(j) \in [\psi_{min}, \psi_{max}]\Big] \cdot \mathbf{q}(j) \geq (1 - \frac{1}{m}) \cdot OPT(S).$$

We conclude that PriceLearningMechanism returns an allocation with expected welfare

$$\frac{1}{r} \cdot \sum_{j \in [m]} \mathbb{1}\Big[\mathbf{q}(j) \in [\psi_{min}, \psi_{max}]\Big] \cdot \mathbf{q}(j) = \frac{1}{r} \cdot (1 - \frac{1}{m}) \cdot OPT(S),$$

where $r = O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\} (\log\log m)^3\right)$. $\blacktriangleleft$

The following lemma follows from a standard application of chernoff bound and is quoted verbatim from [1]. It allows us to show that, with constant probability, a good fraction of the welfare is achievable by bidders in both N_{stat} and N_{mech}.

▶ **Lemma 32.** [12, 18, 14, 1] *Let $O = (O_1, ...O_n)$ be an optimal allocation of items M to bidders N with welfare OPT. Suppose we sample each $i \in N$ w.p. ρ independently to obtain N'. If for every $i \in N$, we have $v_i(O_i) \leq \epsilon \cdot OPT$, then $\sum_{i \in N'} v_i(O_i) \geq (\rho/2) \cdot OPT$ w.p. at least $1 - 2 \cdot \exp(-\frac{\rho}{2\epsilon})$.*

Finally, once the previous lemma has been applied, we will need this lemma to prove that we set the parameters correctly for PriceLearningMechanism.

▶ **Lemma 33.** *If N_{stat} satisfy $OPT(N_{stat}) \geq \frac{1}{4} \cdot OPT$ and $OPT(N_{mech}) \geq \frac{1}{4} \cdot OPT$, then (ψ_{min}, ψ_{max}) is correct for N_{mech}.*

Proof. Assume N_{stat} satisfy $OPT(N_{stat}) \geq \frac{1}{4} \cdot OPT$ and $OPT(N_{mech}) \geq \frac{1}{4} \cdot OPT$. We know that $SPA < OPT(N_{stat})$. Thus

$$4 \cdot OPT(N_{mech}) \geq OPT \geq OPT(N_{stat}) \geq SPA,$$
$$\Rightarrow \psi_{min} = \frac{1}{4m^2} \cdot SPA \leq \frac{1}{m^2} \cdot OPT(N_{mech}).$$

Moreover, since SPA is at least the value of M for any bidder in N_{stat}, we have $m \cdot SPA \geq OPT(N_{stat})$. Thus

$$\psi_{max} = 4m \cdot SPA \geq 4 \cdot OPT(N_{stat}) \geq OPT \geq OPT(N_{mech}).$$

We conclude that (ψ_{min}, ψ_{max}) is correct for N_{mech}. ◀

▶ **Theorem 34.** *For valuation functions $v_1, \ldots, v_n$, suppose the optimal allocation O has supporting prices $\mathbf{q}$. Let D be a (c,d)-approximate demand oracle for valuation in $\{v_1, \ldots, v_n\}$. Then mechanism 4 with advice A as in lemma 29 gets a $O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\} \cdot (\log\log m)^3\right)$ fraction of the optimal welfare in implementation in advised strategies.*

Proof. Lemma 29 shows that there exists poly time computable advice such than, whenever a bidder in N_{stat} follows advice, they play truthfully, and whenever a bidder in N_{mech} follows advice, they pick (c,d)-competitive sets in every fixed price auction they participate in.

Recall that a bidder is *dominant* if they contribute more than a 1/8 fraction of the welfare of an optimal allocation. Next we show that whether there is a dominant bidder or not, the expected welfare from GeneralizedMechanism is an $O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\}(\log\log m)^3\right)$ approximation to OPT in implementation in advised strategy with advice B.

- When there is a dominant bidder, then with $\frac{1}{2}$ probability the dominant bidder would be selected in the N_{stat} group. Conditioned on this, with $\frac{1}{2}$ probability the resulting allocation from running second price auction on the N_{stat} group would be realized. Since a dominant bidder is in N_{stat} group, the welfare from the second price auction is at least $\frac{OPT}{8}$. Thus the expected welfare of GeneralizedMechanism, conditioned on there being a dominant bidder, is at least $\frac{1}{2} \cdot \frac{1}{2} \cdot \frac{OPT}{8} = \frac{OPT}{32}$.
- When there is no dominant bidder, then by Lemma 32, $OPT(N_{stat}) \geq \frac{1}{4} \cdot OPT$ with probability at least $1 - 2e^{-2}$, which means $OPT(N_{stat}) < \frac{1}{4} \cdot OPT$ with probability $< 2e^{-2}$. Symmetrically, $O(N_{mech}) < \frac{1}{4} \cdot OPT$ with probability $< 2e^{-2}$. By union bound, both $OPT(N_{stat})$ and $OPT(N_{mech})$ is $\geq \frac{1}{4} \cdot OPT$ with probability at least $1 - 4e^{-2}$, which is still a positive, constant probability.
  Let's call the event where $OPT(N_{stat}) \geq \frac{1}{4} \cdot OPT$ and $OPT(N_{mech}) \geq \frac{1}{4} \cdot OPT$ the *good* event.
  By Lemma 33, if the good event occurs, then (ψ_{min}, ψ_{max}) is correct for N_{mech}. By construction in GeneralizedMechanism, $\psi_{max}/\psi_{min} = O(m^3)$. By Corollary 31, conditioned on ψ_{min} and ψ_{max} begin set correctly and $\psi_{max}/\psi_{min} = poly(m)$, priceLearningMechanism returns an allocation that achieves welfare $\frac{1}{r} \cdot (1 - \frac{1}{m}) \cdot OPT(N_{mech})$, where $r = O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\}(\log\log m)^3\right)$. Since the good event occurs, $OPT(N_{mech}) \geq \frac{1}{4} \cdot OPT$. We conclude that conditioned on the good event, the expected welfare from PriceLearningMechanism $O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\}(\log\log m)^3\right)$ approximates OPT. As the event "the good event happens and GeneralizedMechanism runs PriceLearningMechanism in setp 4" occurs with constant probability, we conclude that Generalized mechanism achieves expected welfare at least $OPT/O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\}(\log\log m)^3\right)$ when there is no dominant bidder.

Together with the fact that every allocation for XOS valuation functions has supporting prices, we immediately get theorem 16.

▶ **Theorem 16.** *Let $\mathcal{V}$ be a subclass of XOS valuations and let D be a poly-time (c,d)-approximate demand oracle for valuation class $\mathcal{V}$. Then there exists a poly-time mechanism for welfare maximization when all valuations are in $\mathcal{V}$ with approximation guarantee $O\left(\max\left\{\frac{1}{c}, \frac{1}{d}\right\} \cdot (\log\log m)^3\right)$ in implementation in advised strategies with polynomial time computable advice.* ◀

C Approximate Demand Queries vs. Approximate Welfare Approximation

As it happens, both SimpleGreedy and SingleOrBundle were inspired by simple known algorithms for approximate welfare maximization, combined with the following simple observation:

▶ **Proposition 35.** *S is the return of a demand query on prices $\mathbf{p}$ if and only if $(S, M \setminus S)$ is a welfare maximizing bundle for the following two player auction: one bidder has valuation function v, and the other bidder has additive valuation function given by $\mathbf{p}$.*

Proof. The utility of v is $v(S) - \mathbf{p}(S)$, which differs from the welfare $v(S) + \mathbf{p}(M \setminus S)$ only by the constant $\mathbf{p}(M)$. So maximizing these two objectives is equivalent. ◀

In particular, SimpleGreedy is exactly the 2-approximation algorithm from [33] played by a regular bidder and a "price bidder". SingleOrBundle is similarly inspired by the $\sqrt{m}$ approximation of [17]. However, we show below that approximate demand queries do not, in general, reduce to approximate welfare maximization.

▶ **Example 36.** Consider a budget additive valuation v with value 2 for every item and budget of $2\sqrt{m}$. That is, $v(S) = \max\{2|S|, 2\sqrt{m}\}$. Let $\mathbf{p}$ have price 1 for each item, i.e. $\mathbf{p}(S) = |S|$. The result of a demand query on $(v, \mathbf{p})$ is any set of size $\sqrt{m}$, with utility $\sqrt{m}$.

However, consider running an approximate welfare maximization mechanism $\mathcal{A}$ with two bidders: one with valuation $v(S)$ for bundle S and one with valuation $\mathbf{p}(S)$ for bundle S. The optimal allocation is to give any S of size exactly $\sqrt{m}$ to v, and give the rest of the items to $\mathbf{p}$. This has welfare $m + \sqrt{m}$. However, the allocation giving every item to $\mathbf{p}$ has welfare m. Thus, any constant factor approximation algorithm (for which no other grantees hold) may return this allocation, as $m + \sqrt{m} = (1 + o(1))m$.

This corresponds to an approximate demand query giving the bidder the empty set. As this has zero utility, it will fail to be any factor approximation ration of the optimal.

Moreover, the above example would still go through if we consider a few simple variations on the reduction given by Proposition 35. For example, if we discount prices by a constant factor, say d, it's still the case that $d(m - \sqrt{m}) + 2\sqrt{m} = (1 + o(1))dm$, so a constant-factor approximation algorithm $\mathcal{A}$ might give all items to the "price player".

Thus, approximate demand queries do not reduce to approximate welfare maximization (at least not as outlined by Proposition 35).

D Other Algorithms for approximate demand oracles

Here we give another algorithm for computing a $(1/2, 1/2)$-approximate demand oracle. Instead of being inspired by known welfare maximization algorithms, this technique is inspired by known submodular maximization algorithms. Namely, the algorithm MeetInMiddle below is exactly the algorithm DeterministicUSM from [5], run on the submodular function f given by $f(S) = v(S) - \mathbf{p}(S)$. When f is a nonnegative (possibly decreasing) submodular function, [5] shows that it gives a $1/3$ approximation to the maximum value of f. Unfortunately, the submodular utility function we are interested in is possibly negative, so this result does not apply (indeed, it is NP hard to achieve *any* nontrivial approximation ration for possibly negative submodular maximization, as we discussed in section 3).

Algorithm 5 MeetInMiddle$(v, \mathbf{p}, M)$.

$X \leftarrow \emptyset$ and $Y \leftarrow M$
for $j = 1, \ldots, m$ **do** ▷ For items in an arbitrary order
  Set $a_j \leftarrow v(X \cup j) - v(X) - \mathbf{p}(j)$ ▷ Invariant: $Y = X \cup \{j, \ldots, m\}$
  Set $b_j \leftarrow v(Y \setminus j) - v(Y) + \mathbf{p}(j)$
  if $a_j \geq b_j$ **then**
    Set $X \leftarrow X \cup j$
  else
    Set $Y \leftarrow Y \setminus j$
return X ▷ or return Y (as $X = Y$ by now)

For SimpleGreedy and SingleOrBundle, we needed to run an existing algorithm with the "higher" prices $\mathbf{p}/d$ to attain a (c, d)-approximate demand oracle for (i.e. a set S for which $v(S) - \mathbf{p}(S) \geq c \max_T v(T) - \mathbf{p}(T)/d$). Interestingly, we show that MeetInMiddle need to take the lower ("discounted") prices as input in order to provide an approximation guarantee.

We show that

1. For any $\epsilon > 0$, $S =$MeetInMiddle$(v, \mathbf{p}, M)$ is not a (ϵ, ϵ) approximate demand oracle for prices $\epsilon\mathbf{p}$ (i.e. there exists a valuation function v such that $v(S) - \epsilon\mathbf{p}(S) < \max_T\{v(T) - \mathbf{p}(T)\}$).
2. MeetInMiddle$(v, \mathbf{p}/2, M)$ is an $(\frac{1}{2}, \frac{1}{2})$ approximate demand oracle for prices $\mathbf{p}/2$ (i.e. for any submodular v we have $v(S) - \mathbf{p}(S)/2 \geq \frac{1}{2}\max_T\{v(T) - \mathbf{p}(T)\}$).

▶ **Example 37.** For any $\epsilon > 0$, let $K = 4/\epsilon$ and $N = 2 + (K-1)/\epsilon$ and $M = \{1, 2, ...N\}$. Consider the price vector $\mathbf{p}(1) = \frac{K}{2} + 1$ and $\forall i > 1 : \mathbf{p}(i) = 1 - \epsilon$ and the bidder valuation function $v(S) = K$ for any $S \ni 1$ and $v(S) = 1 + (|S| - 1)\epsilon$ for any $S \ni 1$. One can check that the valuation function is submodular.

MeetInMiddle will remove the first item from X, since $v(M-1) - v(M) + \mathbf{p}(1) = \frac{K}{2} + 1 > \frac{K}{2} - 1 = v(1) - \mathbf{p}(1)$. Similarly, one can check that the algorithm will then remove all items except the last item N, which it will keep. Thus the algorithm returns set $T = \{N\}$, so $v(T) - \mathbf{p}(T) = \epsilon$.

However, the optimal set is $O = \{1\}$. We have $\epsilon(v(O) - \mathbf{p}(O)) = \epsilon(\frac{2}{\epsilon} - 1) = 2 - \epsilon$. Thus $v(T) - \epsilon(p(T)) < \epsilon(v(O) - \mathbf{p}(O))$, and MeedInMiddle$(v, \mathbf{p}, M)$ is not a (ϵ, ϵ) approximate demand oracle for all constant $1 > \epsilon > 0$.

▷ Claim 38. If v is submodular, $S =$MeetInMiddle$(v, \mathbf{p}/2, M)$ is an $(\frac{1}{2}, \frac{1}{2})$ approximate demand oracle for prices $\mathbf{p}/2$ (i.e. $v(S) - \mathbf{p}(S)/2 \geq \frac{1}{2}\max_T\{v(T) - \mathbf{p}(T)\}$.

Proof. Let $T \leftarrow$MeetInMiddle$(v, \mathbf{p}/2, M)$ and $O = \arg\max_{S \subseteq M} v(S) - \mathbf{p}(S)$. We use induction on $|M|$.

For the base case, let $|M| = 1$. Observe that $a_1 = v(1) - \mathbf{p}(1)/2 = -b_1$. Thus, $T = \emptyset$ only when $v(1) \geq \mathbf{p}(1)/2$, so T is exactly $\arg\max_S v(S) - \mathbf{p}(S)/2 \geq v(O) - \mathbf{p}(O)$.

Now, let $|M| > 1$, and assume by induction that the claim is true for all $m' < |M|$. Consider the following two cases:

- If $1 \notin T$, then

$$v(1) - \frac{\mathbf{p}(1)}{2} = a_1 < b_1 = v(M \setminus 1) - v(M) + \frac{\mathbf{p}(1)}{2}$$
$$\Rightarrow \mathbf{p}(1) > v(1) + v(M) - v(M \setminus 1) \geq v(1). \qquad (*)$$

  thus $1 \notin O$. If $M' = M \setminus 1$, then $T =$MeetInMiddle$(v, \mathbf{p}/2, M')$ and $O = \arg\max_{S \subseteq M'} v(S) - \mathbf{p}(S)$. By the inductive hypothesis, $v(T) - \frac{1}{2}\mathbf{p}(T) \geq \frac{1}{2}(v(O) - \mathbf{p}(O))$.

- Suppose $1 \in T$. Let $M' = M \setminus 1$ and let O_2 be the set that maximizes utility on M' for v at prices $\mathbf{p}$ (i.e. $O_2 = \arg\max_{S \subseteq M'} v(S) - \mathbf{p}(S)$). The negation of $(*)$ plus the submodularity of v tells us that

$$\mathbf{p}(1) \leq v(1) + v(M) - v(M \setminus 1) \leq v(1) + v(O_2 \cup 1) - v(O_2). \tag{$\dagger$}$$

Define a new submodular function v' on M' such that $v'(S) = v(S \cup 1) - v(1)$ for all $S \subseteq M'$. One can check that an item > 1 is added to X in MeetInMiddle$(v, \mathbf{p}/2, M)$ if and only if it is added to X in MeetInMiddle$(v', \mathbf{p}/2, M')$. Thus, $T \setminus 1 =$MeetInMiddle$(v', \mathbf{p}/2, M')$, and the inductive hypothesis tells us that $v'(T \setminus 1) - \frac{1}{2}\mathbf{p}(T \setminus 1) \geq \frac{1}{2}(v'(O_2') - \mathbf{p}(O_2'))$, where O_2' is the set that maximizes utility on M' for v' on prices $\mathbf{p}$ (i.e. $O_2' = \arg\max_{S \subseteq M'} v'(S) - \mathbf{p}(S)$).
We now analyze two subcases:

- If $1 \in O$, then $O = 1 \cup O_2'$. Thus, applying the inductive hypothesis we know

$$\begin{aligned} v(T) - \frac{\mathbf{p}(T)}{2} &= v(1) - \frac{1}{2}\mathbf{p}(1) + (v'(T \setminus 1) - \frac{1}{2}\mathbf{p}(T \setminus 1)) \\ &\geq v(1) - \frac{1}{2}\mathbf{p}(1) + \frac{1}{2}(v'(O_2') - \mathbf{p}(O_2')) \\ &\geq \frac{1}{2}\big(v(1) + v'(O_2') - \mathbf{p}(1) - \mathbf{p}(O_2')\big) = \frac{1}{2}(v(O) - \mathbf{p}(O))). \end{aligned}$$

- If $1 \notin O$, then $O = O_2$. By rearranging $(\dagger)$, we get

$$\begin{aligned} &\mathbf{p}(1) \leq 2v(1) + v'(O_2) - v(O_2) \\ &\Rightarrow v(O_2) - v'(O_2) \leq 2\left(v(1) - \frac{\mathbf{p}(1)}{2}\right). \end{aligned} \tag{$\S$}$$

Thus

$$\begin{aligned} \frac{1}{2}(v(O) - \mathbf{p}(O)) = \frac{1}{2}\big(v(O_2) - \mathbf{p}(O_2)\big) &= \frac{1}{2}\big(v'(O_2) - \mathbf{p}(O_2) + v(O_2) - v'(O_2)\big) \\ &\leq \frac{1}{2}\big(v'(O_2') - \mathbf{p}(O_2') + v(O_2) - v'(O_2)\big) \\ &\leq v'(T \setminus 1) - \frac{\mathbf{p}(T \setminus 1)}{2} + v(1) - \frac{\mathbf{p}(1)}{2} \\ &= v(T) - \frac{\mathbf{p}(T)}{2}. \end{aligned}$$

Where the first inequality follows from the definition of O_2', and the second follows from the inductive hypothesis combined with $(\S)$. ◁

Toward a General Complexity Theory of Motion Planning: Characterizing Which Gadgets Make Games Hard

Abstract

We begin a general theory for characterizing the computational complexity of motion planning of robot(s) through a graph of "gadgets", where each gadget has its own state defining a set of allowed traversals which in turn modify the gadget's state. We study two general families of such gadgets within this theory, one which naturally leads to motion planning problems with polynomially bounded solutions, and another which leads to polynomially unbounded (potentially exponential) solutions. We also study a range of competitive game-theoretic scenarios, from one player controlling one robot to teams of players each controlling their own robot and racing to achieve their team's goal. Under certain restrictions on these gadgets, we fully characterize the complexity of bounded 1-player motion planning (NL vs. NP-complete), unbounded 1-player motion planning (NL vs. PSPACE-complete), and bounded 2-player motion planning (P vs. PSPACE-complete), and we partially characterize the complexity of unbounded 2-player motion planning (P vs. EXPTIME-complete), bounded 2-team motion planning (P vs. NEXPTIME-complete), and unbounded 2-team motion planning (P vs. undecidable). These results can be seen as an alternative to Constraint Logic (which has already proved useful as a basis for hardness reductions), providing a wide variety of agent-based gadgets, any one of which suffices to prove a problem hard.

1 Introduction

Most hardness proofs are based on **gadgets** – local fragments, each often representing corresponding fragments of the input instance, that combine to form the overall reduction. Garey and Johnson [10] called gadgets "basic units" and the overall technique "local replace-

ment proofs". The search for a hardness reduction usually starts by experimenting with small candidate gadgets, seeing how they behave, and repeating until amassing a sufficient collection of gadgets to prove hardness.

This approach leads to a natural question: what gadget sets suffice to prove hardness? There are many possible answers to this question, depending on the precise meaning of "gadget" and the style of problem considered. Schaefer [17] characterized the complexity of all **Boolean constraint satisfiability** gadgets, with a dichotomy between polynomial problems (e.g., 2SAT, Horn SAT, dual-Horn SAT, XOR SAT) and NP-complete problems (e.g., 3SAT, 1-in-3SAT, NAE 3SAT). At STOC'97, Khanna, Sudan, Trevisan, and Williamson [13] refined this result to characterize **approximability** of constraint satisfaction problems, forking into polynomial, APX-complete, Poly-APX-complete, Nearest-Codeword-complete, and Min-Horn-Deletion-complete. Introduced at CCC'08, **Constraint Logic** [7, 11] proves sufficiency of small sets of gadgets on directed graphs that always satisfy one local rule (weighted in-degree at least 2), in many game types (1-player, 2-player, and team games, both polynomially bounded and unbounded), although the exact minimal sets of required gadgets remain unknown.

The aforementioned general techniques naturally model "global" moves that can be made anywhere at any time (while satisfying the constraints). Nonetheless, the techniques have been successful at proving hardness for problems where moves must be made local to an agent/robot that traverses the instance. For single-player agent-based problems, the **doors-and-buttons** framework (described in [9] and improved by [19] and [18]) is a good example of classifying a universe of abstract motion planning problems which can then be applied. In addition, the **door gadget** used to prove Lemmings [20] and various Nintendo games [2] PSPACE-complete served as a primary example of the form of gadget we wanted to generalize.

In this paper, we analyze which gadgets suffice for hardness in a general **semi-static motion planning problem** where one or more agents/robots traverse a given environment, which only changes in response to the agent's actions, from given start location(s) to given goal location(s). We study a very general model of gadget, where the gadget changes state when it gets traversed by an agent according to a general transition function, enabling and/or disabling certain traversals in the future. We study this model from the traditional single-robot (one-player) perspective, extending our initial work on this case [6], as well as from the perspective of two robots or teams of robots competing to reach their respective goals. We also analyze natural settings where the number of moves is polynomially bounded, because each gadget can be traversed only a bounded number of times, or more general settings where gadgets can be re-used many times and thus the number of moves can be exponential in the environment complexity. In each case, we partially or fully characterize which gadgets suffice to make the motion planning problem hard (NP-hard, PSPACE-hard, EXPTIME-hard, NEXPTIME-hard, or RE-hard, depending on the scenario), and conversely which gadgets result in a polynomially solvable problem (NL or P). Table 1 summarizes our results.

1.1 Gadget Model and Motion-Planning Games

In general, we model a **gadget** as consisting of a finite number of **locations** (entrances/exits) and a finite number of **states**; see Figure 1 for two examples. We may also consider a family of gadgets parameterized by the problem size. In this case we restrict the number of locations and states to be polynomial in the size of the problem. Each state s of the gadget defines a labeled directed graph on the locations, where a directed edge (a, b) with label s'

Table 1 Summary of our results for k-tunnel gadgets (with additional constraints listed in the left column). A "full characterization" means that we give an easily checkable condition on the allowed gadget set that determines the complexity of the corresponding motion planning problem; a "partial characterization" means that we give two easily checkable conditions on the allowed gadget set, one for the easy class and one for the hard class, each of which suffices to establish the complexity of the corresponding motion planning problem.

	1-Player Game	2-Player Game	Team Game
Polynomially Bounded (DAG gadgets)	**NL** vs. **NP-complete**: full characterization [§5]	**P** vs. **PSPACE-complete**: full characterization [§6]	**P** vs. **NEXPTIME-complete**: full characterization [§7]
Polynomially Unbounded (reversible, deterministic gadgets)	**NL** vs. **PSPACE-complete**: full characterization [§2] **Planar**: equivalent [§2.3]	**P** vs. **EXPTIME-complete**: partial characterization [§3]	**P** vs. **RE-complete** (⇒ **Undecidable**): partial characterization [§4]

means that a robot can enter the gadget at location a and exit at location b, and that such a traversal forcibly changes the state of the gadget to s'. Equivalently, a gadget is specified by its **transition graph**,[1] a directed graph whose vertices are state/location pairs, where a directed edge from (s, a) to (s', b) represents that the robot can traverse the gadget from a to b if it is in state s, and that such traversal will change the gadget's state to s'. Gadgets are **local** in the sense that traversing a gadget does not change the state of any other gadgets.

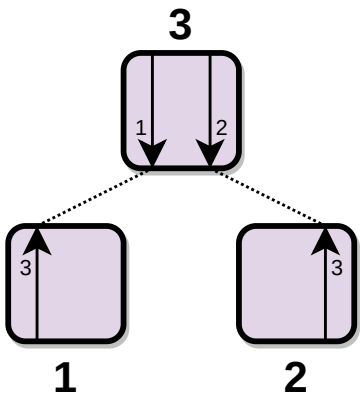
A **system of gadgets** consists of gadgets, their initial states, and a **connection graph** on the gadgets' locations. [2] If two locations a, b of two gadgets (possibly the same gadget) are connected by a path in the connection graph, then the robot can traverse freely between a and b (outside the gadgets). (Equivalently, we can think of locations a and b as being identified, effectively contracting connected components of the connection graph.) These are all the ways that the robot can move: exterior to gadgets using the connection graph, and traversing gadgets according to their current states.

We define a general family of **motion planning** problems involving one or more robots, each with their own start and goal location, in a system of gadgets. In a **one-player game**, we are given a system of gadgets, a single robot that starts at a specified start location, and we want to decide whether there is a sequence of moves that brings the robot to a specified goal location. (This problem is perhaps the most common setting for robot motion planning.)

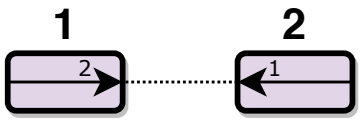
In a **two-player game**, we are given a system of gadgets and the start and goal locations of two robots, and two players alternate moving their own robot by traversing a single gadget (entering at a location reachable from the robot's current location via the connection graph). Both players have complete information about the locations of the robots, the locations of the gadgets, and the states of the gadgets. Here we count gadget traversals as costing one move, and view movement in the connection graph as instantaneous/free. The goal is to decide whether the first player has a **forced win**, that is, their robot can reach their goal

[1] In [6], the transition graph is called the "state space", but we feel that "transition graph" more clearly captures the automaton nature of transitions, which are discrete and directed.

[2] In [6], locations could only be matched to exactly one other location and a 'branching hallway' gadget was introduced to fulfill the need of the connection graph.



(a) The locking 2-toggle gadget (L2T). In the top state 3, you can traverse either tunnel going down, which blocks off the other tunnel until you reverse the initial traversal.



(b) The 1-toggle gadget. Traversing the tunnel reverses the direction that it can be traversed.

Figure 1 Basic gadgets that can be simulated by any interacting-k-tunnel reversible deterministic gadget, as shown in Section 2.1.

location before the second player's does, no matter how the second player responds to the first player's moves. In a **team game**, there are more than two robots, each controlled by a single player, and the robots/players are partitioned into two teams; the goal of each team is to get any one of its player's robot to their goal location. Crucially, after a team game begins, each player has only partial information of the current gadgets' states: they can only see the state of the gadgets reachable by their robot via the connection graph.

We also define **planar motion planning**. In this case, the cyclic order of locations on a gadget is specified, and the system of gadgets must be embedded in the plane without intersections. Specifically, construct the following graph from a system of gadgets: replace each gadget with a wheel graph, which has a cycle of vertices corresponding to the locations on the gadget in the appropriate order, and a central vertex connected to each location. Connect locations on these wheels with edges according to the connection graph. The system of gadgets is **planar** if this graph is planar. In planar motion planning, we restrict the problem to planar systems of gadgets. Note that this allows rotations and reflections of gadgets, but no other permutation of their locations. In some contexts, one may want to disallow reflections of gadgets, which corresponds to imposing a handedness constraint on the planar embedding of each wheel.

1.2 Gadget Types

We define different subclasses of gadgets that naturally model motion planning where the number of moves is either polynomially bounded or unbounded (potentially exponential).

In both cases, we require that the various states of a gadget differ only in their orientations of the possible traversals. More precisely, a ***k*-tunnel** gadget has $2k$ locations, paired in a perfect matching whose pairs are called **tunnels**, such that each state defines which direction(s) each tunnel can be traversed. All of the gadgets we consider in this paper are k-tunnel.

In the polynomial case, we focus on "DAG" gadgets. First define the **state-transition (multi)graph** of a gadget to have a vertex for each state, and a directed edge from s to s' for each possible traversal of the gadget in state s that leads to state s'. (This graph can be

obtained from the transition graph by combining together all vertices with the same state.) Then a gadget is a **DAG** if its state-transition graph is a directed acyclic graph. Such gadgets naturally lead to polynomially bounded motion planning, as every gadget traversal consumes potential within that gadget, as measured by the state (e.g., in a topological ordering of the state-transition graph). The total number of traversals is thus bounded by the total number of states in all gadgets in the system. (It is not enough to require that the transition graph be acyclic, because the robot can use the connection graph and other gadgets to reach other locations of this gadget in between traversals.)

In the polynomially unbounded case, we focus on gadgets that are "deterministic" and "reversible". A gadget is **deterministic** if its transition graph has maximum out-degree ≤ 1; i.e., a robot entering the gadget at some location in some state can exit at only one location and in only one state. A gadget is **reversible** if its transition graph has the reverse of every edge, i.e., it is the bidirectional version of an undirected graph. Thus a robot can immediately undo any gadget traversal.[3] Together, determinism and reversibility are equivalent to requiring that the transition graph is the bidirectional version of a matching.

We also consider **planar motion planning** problems with a **planar** system of gadgets, where the gadgets and connections are drawn in the plane without crossings. Planar gadgets are drawn as small regions (say, disks) with their locations as points in a fixed clockwise order along their boundary. A single gadget type thus corresponds to multiple planar gadget types, depending on the choice of the clockwise order of locations. Connections are drawn as paths connecting the points corresponding to the endpoint locations, without crossing gadget interiors or other connections.

The gadget model described above is an extension of the model introduced in [6], which characterized 2-state deterministic reversible k-tunnel gadgets that make for PSPACE-complete one-player games (polynomially unbounded), and showed that this characterization is the same when restricting to planar systems of gadgets. This prior result corresponds to the 2-state special case of our result in the bottom-left cell of Table 1. In this paper, we generalize that characterization to gadgets with arbitrarily many states, and generalize to 2-player games, team games, and (polynomially bounded) DAG k-tunnel gadgets.

1.3 Our Characterizations

In each type of motion planning problem where we obtain a full characterization of easy vs. hard gadget sets (bounded one-player, bounded two-player, bounded team, and unbounded one-player), we identify a class of gadgets such that motion planning with any single gadget in that class is hard, while motion planning with any collection of gadgets not in the class is easy. Thus, we do not see a difference in hardness between one and multiple gadget types; it is not possible for two "easy" gadgets to combine into a hard motion planning problem. This result is in surprising contrast to Constraint Logic where multiple gadgets were required for hardness in any setting.

For one-player motion planning, the key property of a gadget is **interacting tunnels**: the traversal of some tunnel must affect the traversability of some other tunnel in the same gadget.[4] In the unbounded case (Section 2), we show that any such gadget (that is also

[3] This notion is different than the sense of "reversible" in reversible computing, which would mean that we could derive which move to undo from the current state; here the undoing move only needs to be an option.

[4] This is roughly what [6] calls 'non-trivial' gadgets.

reversible and deterministic) can be used to simulate two specific gadgets, the "locking 2-toggle" and "1-toggle" (shown in Figure 1), which together suffice to prove PSPACE-hardness. This argument involves surprisingly little case analysis, in contrast to the prior work in this area [6], which simply enumerated and analyzed all 2-state gadgets. On the other hand, we show that any fixed collection of gadgets without interacting tunnels reduces (via a shortcutting argument) to graph traversal, which can be solved in NL. We furthermore show that this dichotomy still holds for 1-player planar motion planning (Section 2.3). In the bounded case (Section 5), we examine the naturally bounded class of DAG gadgets. We again obtain a somewhat more complicated full characterization, which mostly depends on the existence of interacting tunnels.

For two-player motion planning, it turns out that interacting tunnels are not required for hardness. In the bounded case (Section 6), we show that PSPACE-completeness holds for any DAG gadget that is **nontrivial**, i.e., has at least one transition in some state. We show that any nontrivial DAG gadget can simulate one of two one-tunnel gadgets, "single-use unidirectional edge" or "single-use bidirectional edge", and surprisingly either suffices to prove PSPACE-completeness. A single use-use edge is a transition in a gadget such that after taking that transition, there are no further transitions between the two associated locations. Obviously, two-player motion planning with trivial gadgets is in P: the robots can only traverse the connection graph, and one merely needs to see which is closer to their goal. In the unbounded case (Section 3), we show that any gadget with interacting tunnels suffices for EXPTIME-completeness, and it remains an open problem whether some weaker condition suffices.

For team motion planning, interacting tunnels are again not required for hardness. In the bounded case (Section 7), we show that NEXPTIME-completeness holds for any nontrivial DAG gadget, again by showing that any single-use edge gadget suffices. In the unbounded case (Section 4), we again show that any gadget with interacting tunnels suffices for undecidability, and it remains an open problem whether some weaker condition suffices.

Armed with the general framework of this paper, it should be much easier to prove hardness of most games that involve motion planning of robots in an environment with nontrivial local state. You simply need to pick a gadget that is hard according to our characterization (with the matching boundedness and number of players/teams), draw a single figure of how to build that gadget within the game of interest, and check that it is possible to connect these gadgets together. While this paper focuses on general theory building, we return to possible applications in Section 8.

2 1-Player Unbounded Motion Planning

In this section, we study reversible, deterministic gadgets, extending the work in [6] which only considered gadgets with two or fewer states. Here we give a complete categorization as either in NL or PSPACE-complete for reversible, deterministic gadget. For the NL half of the characterization, Theorem 2 below shows that 1-player motion planning problems with non-interacting-k-tunnel gadgets is in NL. For the PSPACE-completeness half of the characterization, we introduce a new base gadget, the **locking 2-toggle (L2T)** shown in Figure 1a. In Section 2.1 we show that all interacting-k-tunnel reversible deterministic gadgets are able to simulate the locking 2-toggle. Then in Section 2.2 we show that 1-player motion planning with locking 2-toggles is PSPACE-complete by simulating Nondeterministic Constraint Logic. Section 2.2 shows how to adapt the construction to show these gadgets remain PSPACE-hard even for the planar 1-player motion planning problem.

▶ **Lemma 1.** *1-player motion planning with any set of gadgets is in PSPACE.*

Proof. This was shown in [6], but included here for convenience. A configuration of the system of gadgets consists of the state of each gadget and the location of the robot, and has polynomial length. The algorithm that repeatedly nondeterministically picks a legal transition, and updates the configuration based on it, accepting when the robot reaches the goal location, decides the reachability problem in nondeterministic polynomial space. By Savitch's theorem, the problem is in PSPACE. ◀

▶ **Theorem 2.** *1-player motion planning with any k-tunnel gadget that does not have interacting tunnels is in NL.*

Proof. We first show that if a system of such gadgets has a solution, then it has a solution which visits each location at most once. Suppose there is a solution, and consider the last time a solution of minimal length visits a previously visited location, assuming there is any such time. Let v be the vertex of this last self-intersection. After leaving v for the last time, every transition the robot makes is through a tunnel that it had not previously traversed. Since the gadget does not have interacting tunnels, these tunnels have the same traversability when the robot goes through them as they do originally. We modify the solution by 'shortcutting': remove the portion of the solution between the first visit to v and the last visit to v, so the robot only visits v once, and skips the loop that begins and ends at v. The new path is still a solution: the segment before v is identical to the unmodified solution, and the segment after v consists of tunnels whose traversability is not changed before the robot goes through them. The shortcut path is shorter than the original solution, which was assumed to be minimal. Thus a solution of minimal length has no self-intersections.

We'll want to treat the system of gadgets as though it were a directed graph by replacing each tunnel with an edge in the appropriate direction, or a pair edges if it is traversable in either direction. We can locally walk through all the available transitions in a gadget, assess which locations they lead to, and non-deterministically pick one to try, allowing this to be executed in NL. A path from the start location to the end location in this graph is exactly a solution for the system of gadgets with no self-intersections; the traversability of each tunnel used in such a solution does not change before the tunnel is used.

Since reachability in directed graphs is in NL, the motion planning problem is also in NL. Moreover, if the gadget has any state in which a tunnel can be traversed in one direction but not the other, the motion planning problem is NL-complete, and otherwise it is in L. ◀

2.1 Reducing to Locking 2-Toggles

In this section, we introduce the locking 2-toggle shown in Figure 1a, and we show that all interacting-k-tunnel reversible deterministic gadgets can simulate it. The proof first examines what constraints on a gadget are implied by being interacting-k-tunnel, reversible, and deterministic, and goes on to identify that all such gadgets have a pair of special states with some useful common properties. From this pair of states we construct a 1-toggle, and then combine that with our special states to build a locking 2-toggle. One of the major insights is identifying this special pair of states which belongs to all gadgets in the class, and after that the primary challenge is in preventing undesired transitions, which are plentiful when allowing such a wide class of gadgets.

▶ **Theorem 3.** *Every interacting-k-tunnel reversible deterministic gadget simulates a locking 2-toggle.*

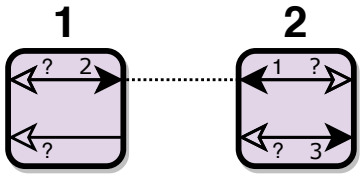


Figure 2 An arbitrary interacting-k-tunnel reversible deterministic gadget. Hollow arrows indicate traversals that may or may not be possible. Solid or absent arrows indicate traversals that are or are not possible, respectively.

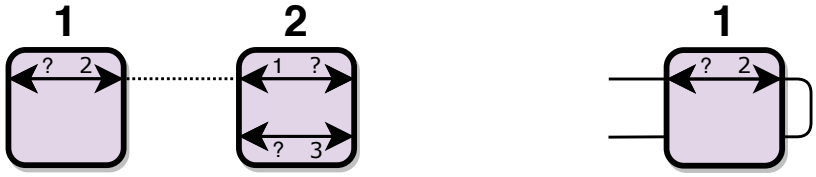

(a) State graph, refining Figure 2. **(b)** Simulating a one-directional edge.

Figure 3 An arbitrary interacting-k-tunnel reversible deterministic gadget which has no one-directional edge.

Proof. We begin by examining an arbitrary interacting-k-tunnel reversible deterministic gadget, as shown in Figure 2. Because the gadget has interacting tunnels, we can find a pair of states in which traversing the top line can change the traversability of the bottom line to the right. Since it is also reversible, the inverse transition is also possible, so traversing the top line can change in either direction the left-to-right traversability of the bottom line. Then without loss of generality, the gadget has the form shown in Figure 2: in state 1, traversing the top line to the right switches to state 2, and the bottom line is not traversable to the right. In state 2, traversing the top line to the left switches to state 1, and the bottom line is traversable to the right, say to state 3 (which may be the same as state 1). All other traversals may or may not be possible in either state, indicated by the question marks.

▶ **Lemma 4.** *Every interacting-k-tunnel reversible deterministic gadget simulates a **one-directional edge**, that is, a tunnel which (in some state) can be traversed in one direction but not the other.*

Proof. If in some state, some edge in the gadget can be traversed in one direction but not the other, then it is a one-directional edge. Otherwise, the gadget has the form shown in Figure 3a. Then the construction in Figure 3b is equivalent to a one-directional edge: currently the gadget is in state 1, so the path from the bottom to the top is blocked by the bottom edge, but from the top, you can go across the top edge, switching the gadget to state 2, and then back across the bottom edge. ◀

▶ **Lemma 5.** *Every interacting-k-tunnel reversible deterministic gadget simulates a 1-toggle (Figure 1b).*

Proof. By the previous lemma, we can build a one-directional edge, which has the structure shown in Figure 4a: in state 1, we can traverse the edge to the right and switch to state 2, but not to the left. In state 2, we can undo this transition, and possibly also traverse the

(a) Form of state graph. **(b)** Simulating a 1-toggle.

Figure 4 A one-directional edge gadget.

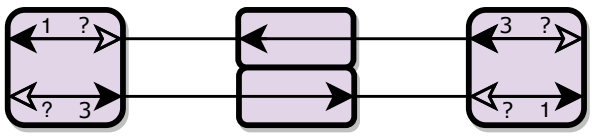

Figure 5 An arbitrary interacting-k-tunnel reversible deterministic gadget and a 1-toggle simulate a locking 2-toggle.

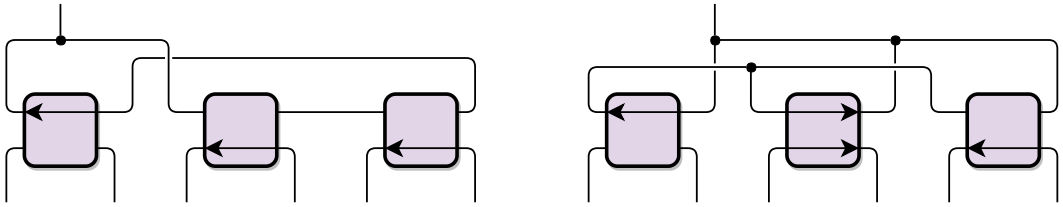
edge to the right. The construction in Figure 4b is then a 1-toggle. In the current state, it can be traversed to the right but not to the left because of the gadget on the left. After making this traversal, it becomes the rotation of the current state, and it cannot be traversed to the right again because of the gadget on the right. ◀

To build a locking 2-toggle, we put the arbitrary gadget (in state 2), an antiparallel pair of 1-toggles, and the rotation of the arbitrary gadget (also in state 2) in series, as in Figure 5. Currently, the top edge is traversable to the left and the bottom edge is traversable to the right, but not in the other direction. After traversing the top edge to the left, the 1-toggles prevents us from traversing either edge to the left, and the leftmost gadget (in state 1) prevents us from traversing the bottom edge to the right, so the only legal traversal is going back across the top edge to the right. Similarly after traversing the bottom edge, the only legal traversal is across the bottom edge in the opposite direction. Thus this construction is equivalent to a (antiparallel) locking 2-toggle.

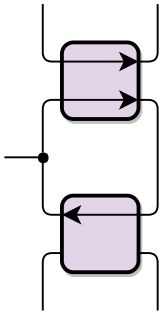
Traversing the simulated locking 2-toggle takes either 4 or 6 transitions of the raw gadget, depending on whether it contains a one-directional edge (from Lemma 4). For simplicity, we can include additional gadgets (e.g. another pair of 1-toggles) to ensure it always takes exactly 6 transitions; this will be relevant to timing considerations in multiplayer games. ◀



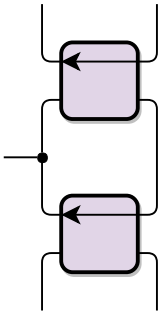
(a) An AND vertex gadget. The leftmost edge has weight two and is pointing in (up). The other edges have weight one and are pointing away (down).

(b) An OR vertex gadget. All edges are weight 2. The leftmost edge is pointing in (up), the middle edge is free, and the rightmost edge is pointing away (down).

Figure 6 Vertex gadgets in the NCL reduction.



(a) An edge gadget pointed up, in the unlocked state. The gadget is accessed by the loose end on the left.



(b) The same edge gadget in the locked state.

2.2 PSPACE-hardness

In this section, we show that 1-player motion planning with the locking 2-toggle is PSPACE-complete by a reduction from Nondeterministic Constraint Logic (NCL). See Appendix A.1 for a definition of NCL. We represent edges by pairs of locking 2-toggles. The construction requires **edge gadgets** which are directed and can be flipped, as well as AND and OR **vertex gadgets** which apply constraints on how many edges must be directed towards them at any given point in time.

▶ **Theorem 6.** *1-player motion planning with the locking 2-toggle is PSPACE-complete.*

Proof. Motion planning with the gadget is in PSPACE by Lemma 1. We use a reduction from Nondeterministic Constraint Logic (NCL) to show PSPACE-hardness. See Appendix A.1 for a definition of NCL.

The **edge gadget**, shown in Figure 7, contains two locking 2-toggles, each of which is also attached to a vertex gadget. It is oriented towards one of the vertices, can be either **locked** or **unlocked**. Specifically, the edge gadget is unlocked (Figure 7a) if either locking 2-toggle is in the middle state (with both lines traversable), and locked (Figure 7b) otherwise. It is oriented towards the vertex attached to the locking 2-toggle whose edge not accessible from the edge gadget is traversable. The robot can access the free line on the left. If the edge gadget is unlocked, the robot can traverse a loop through one edge of each locking 2-toggle to change the orientation of the edge gadget. The edge gadget switches between being locked and unlocked when the robot moves through a vertex gadget to traverse one of the edges not accessible from the edge gadget.

The **vertex gadgets** are shown in Figure 6. The robot can access the free line on the top, and traverse loops to lock and unlock edge gadgets, enforcing the constraints of vertices. Specifically, if all three edges are pointing towards an AND vertex, the robot can traverse a loop to lock both weight-1 edges and unlock the weight-2 edge, or vice versa. If multiple edges are pointing towards an OR vertex, the robot can traverse a loop to unlock the currently locked edge and lock another edge. Observe that for both vertex gadgets, the sum of the weights of locked edges does not change.

Given an NCL graph, we construct a maze of locking 2-toggles. Each edge in the graph corresponds to an edge gadget (Figure 7). Each locking 2-toggle in the edge gadget corresponds to a vertex incident to the edge. When three edges meet at a vertex, we put a vertex gadget on the locking 2-toggles corresponding to that vertex. We use an AND vertex

gadget (Figure 6a) or an OR vertex gadget (Figure 6b) depending on the type of vertex. The vertical "entrance" line on each vertex gadget and horizontal "entrance" line on each edge gadget is connected to the starting location. Each edge is oriented as in the NCL graph. For each vertex, we pick a set of edges initially pointing at the vertex with total weight 2. The edge gadgets corresponding to the chosen edges are locked, and other edge gadgets are unlocked. The goal location is placed inside the edge gadget corresponding to the target edge so that it is reachable if and only if the target edge is unlocked.

If the original NCL graph is solvable, the robot can perform the same sequence of edge flips, visiting vertex gadgets to lock and unlock edges as necessary, and reach the goal location. If the robot can reach the goal location, the same sequence of edge flips solves the NCL graph. So the maze is solvable if and only if the NCL graph was. ◀

This reduction is also possible without edge gadgets, and leads to a system with only one L2T for each constraint logic edge. We use edge gadgets because the reduction is easier to understand, and adaptations of this construction in Sections 2.3, 3, and 4 will need them.

▶ **Corollary 7.** *1-player motion planning with any interacting-k-tunnel reversible deterministic gadget is PSPACE-complete.*

Proof. Hardness follows from Theorems 3, and 6. For any such gadget, we have a reduction from mazes of locking 2-toggles to mazes of that gadget by replacing each locking 2-toggle with a simulation of one built from the arbitrary gadget. Motion planning with the gadget is in PSPACE by Lemma 1. ◀

2.3 Planarity

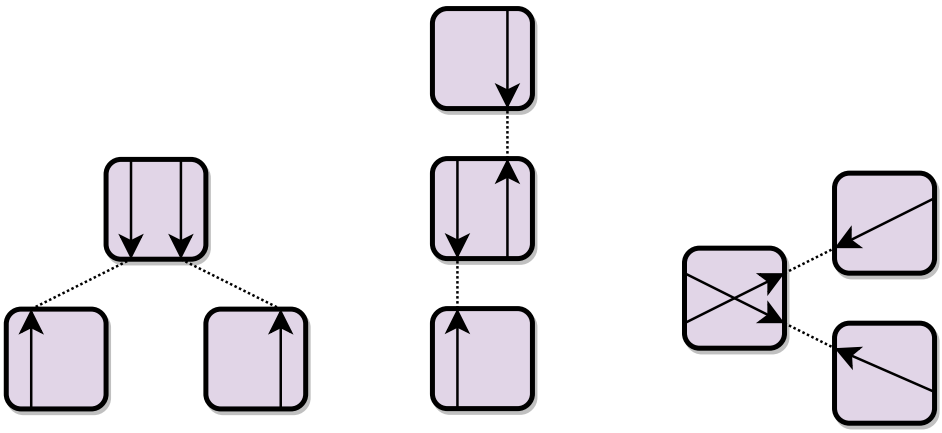
In this section, we show that interacting-k-tunnel reversible deterministic gadgets are PSPACE-complete even for the planar 1-player motion planning problem. We once again work with the locking 2-toggle, showing that each of its planar versions can simulate each other. From there we use the crossing locking 2-toggle to build an A / BA crossover, which is less powerful than a full crossover but will suffice to make our reduction in Section 2.2 planar. An interesting question is whether the locking 2-toggle is powerful enough to build a full crossover, which can be done with any of the 2 state gadgets. Although not needed here, it would allow the multiplayer game results later in this paper to carry over to the planar case.

Recall for the planar problem we allow rotations and reflections of gadgets. This leaves three distinct embeddings of the locking 2-toggle into a plane: parallel, antiparallel, and crossing, shown in Figure 8, and which we abbreviate PL2T, APL2T, and CL2T. (Up to only rotation, there are four, the other being the antiparallel locking 2-toggle with the other handedness). We will allow reflections of gadgets, so these are the three kinds of locking 2-toggles we will consider.

▶ **Lemma 8** ([6])**.** *Parallel, antiparallel, and crossing locking 2-toggles all simulate each other in planar graphs.*

Proof. Figure 9 shows APL2T simulating CL2T, Figure 10 shows CL2T simulating PL2T, and Figure 11 shows PL2T simulating APL2T. Note that we use both APL2Ts of both handednesses, so we need to be able to reflect gadgets. ◀

▶ **Theorem 9.** *Every interacting-k-tunnel reversible deterministic gadget simulates each type of locking 2-toggle in planar graphs.*



(a) A parallel locking 2-toggle (PL2T). **(b)** An antiparallel locking 2-toggle (APL2T). **(c)** A crossing locking 2-toggle (CL2T).

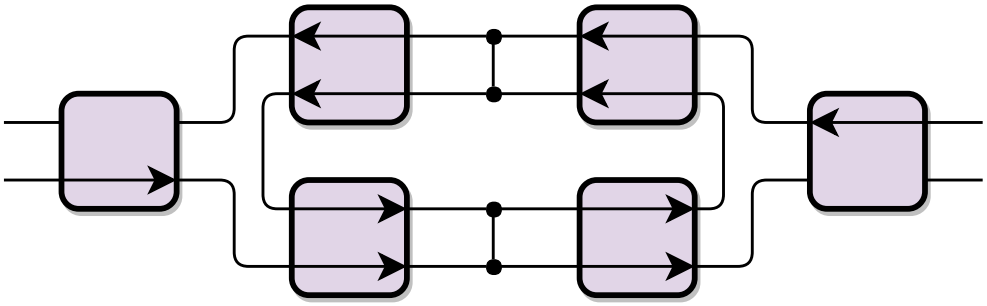

Figure 11 PL2T simulating APL2T. (Based on [6, Figure 13].)

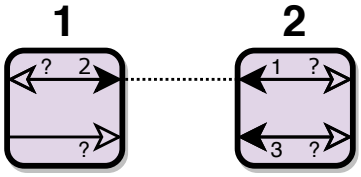

Figure 12 The antiparallel case of an arbitrary interacting-k-tunnel reversible deterministic gadget.

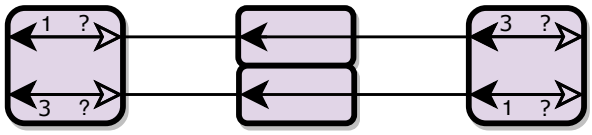

Figure 13 An arbitrary antiparallel interacting-k-tunnel reversible deterministic gadget and a 1-toggle simulate a PL2T.

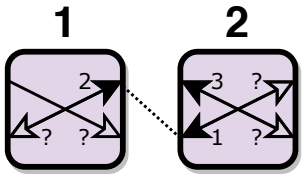

Figure 14 The crossing case of an arbitrary interacting-k-tunnel reversible deterministic gadget.

Proof. We follow the proof of Theorem 3. As before, we assume that traversing a line to switch from state 1 to state 2 makes a traversal on another line legal. This new traversal can be parallel to, antiparallel to, or cross the first traversal; we consider each case. If the new traversal is parallel, the construction in the proof of Theorem 3 works to simulate an APL2T in a planar graph.

If it is antiparallel, the gadget has the form shown in Figure 12. Either the gadget has a one-directional edge, or it has the form in Figure 3a, and simulates a one-directional edge by the construction in Figure 3b. Thus it simulates a 1-toggle by the construction in Figure 4b. Then the construction in Figure 13 simulates a PL2T: currently either edge can be traversed to the left, if the top edge is traversed, the left gadget blocks the bottom edge, and if the bottom edge is traversed, the right gadget blocks the top edge.

Finally, if the new traversal crosses the first traversal, the gadget has the form shown in Figure 14. Either it has a one-directional edge, or the construction in Figure 15 simulates a one-directional edge, similarly to Lemma 4. So the gadget simulates a 1-toggle by the construction in Figure 4b. Then the construction in Figure 16 simulates a PL2T, similarly to the previous case.

Once the gadget simulates some locking 2-toggle, we can use Lemma 8 to simulate all three types. ◀

▶ **Theorem 10.** *1-player planar motion planning with any interacting-k-tunnel reversible deterministic gadget is PSPACE-complete.*

Proof. We begin by constructing some weak crossover gadgets. The crossover locking 2-toggle is itself a very weak crossover. We use it to construct an **A/BA crossover**, shown in Figure 17a. Calling the traversal from top to bottom A and that from left to right B, we can

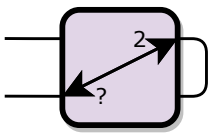

Figure 15 A crossing interacting-k-tunnel reversible deterministic gadget simulates a one-way edge.

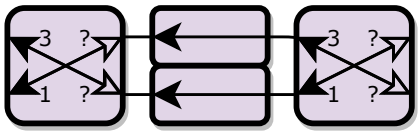

Figure 16 An arbitrary crossing interacting-k-tunnel reversible deterministic gadget and a one-toggle simulate a PL2T.

perform either of the sequences A and BA. Since everything is reversible and deterministic, we can also undo those sequences. The A/BA crossover is sufficient for the rest of the proof; we abbreviate it as shown in Figure 17b.

We modify the proof of Theorem 6, giving a reduction from planar NCL to planar mazes with locking 2-toggles. By Theorem 9, this is sufficient to show PSPACE-hardness. Our gadgets use PL2Ts, CL2Ts, and A/BA crossovers; they do not use APL2Ts.

The edge gadget is shown in Figure 18, and vertex gadgets are shown in Figure 19. Given a planar NCL graph, we construct a mazes as follows.

Pick a rooted spanning tree of the dual of the NCL graph, directed away from the root; the robot will use this tree to navigate the graph. The system of gadgets will contain a vertex for each face f of the NCL graph, which is a vertex of the spanning tree.

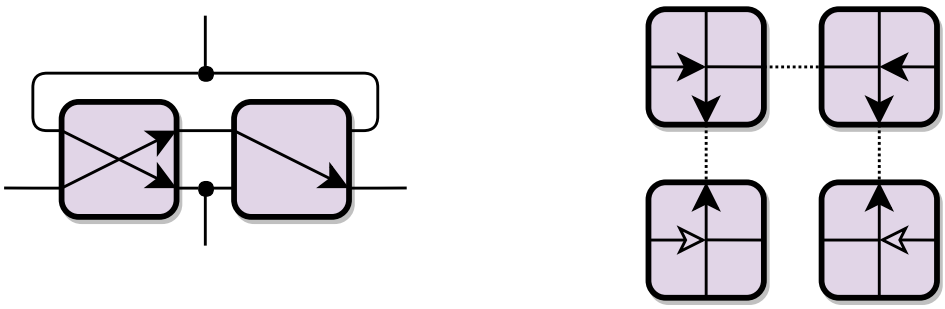
For each edge of the graph, we place an edge gadget. When an edge is in the spanning tree, we orient it so that the A/BA crossover points, from entrance to exit, in the same direction as the edge points in the spanning tree (left to right in Figure 18, and away from the root). If an edge is in the spanning tree and has target f, we connect its exit to f. For each edge e, we connect its entrance to the vertex f corresponding to the face containing its entrance, i.e. the face adjacent to e to which we can connect its entrance without crossings. If e is in the spanning tree, this connects the entrance of e to the source f of e.

Now we place a vertex gadget of the appropriate type for each vertex of the NCL graph, so that the gadget shares a PL2T with each incident edge gadget. AND vertex gadgets must be oriented so the weight-2 edge has the appropriate PL2T (the bottom one in Figure 19a). The entrance of each vertex gadget is connected to the vertex f corresponding to the face containing the entrance.

We set each edge gadget to the orientation of its corresponding edge. For each vertex, we select edges directed towards it with total weight 2, and set the selected edges to locked and other edges to unlocked. The goal location is placed inside the target edge so that reaching it requires flipping the target edge. The starting location is the vertex corresponding to the root of the spanning tree.

Play on this maze proceeds as follows: the robot travels down the spanning tree, crossing edges until it reaches some face. It goes into an edge or vertex attached to that face, and manipulates it. Then the robot travels back up the spanning tree and down a different branch, manipulating another edge or vertex, and so on. The edge and vertex gadgets enforce the NCL constraints. If the target edge can be flipped, the robot can reach the goal location. Thus the maze is solvable if and only if the NCL graph was. The maze is planar by its construction, using the planarity of the NCL graph.

This completes the proof of PSPACE-hardness. Containment in PSPACE is by Lemma 1, so the problem is PSPACE-complete. ◀



(a) Simulating an A/BA crossover using CL2Ts.

(b) A state diagram and notation for the A/BA crossover.

Figure 17 An A/BA crossover gadget: the robot can traverse top to bottom (A), or traverse left to right (B) and then top to bottom. Thinking of the gadget as a crossing pair of 1-toggles, the vertical 1-toggle is always traversable, and the horizontal 1-toggle is traversable when the vertical one is pointing down.

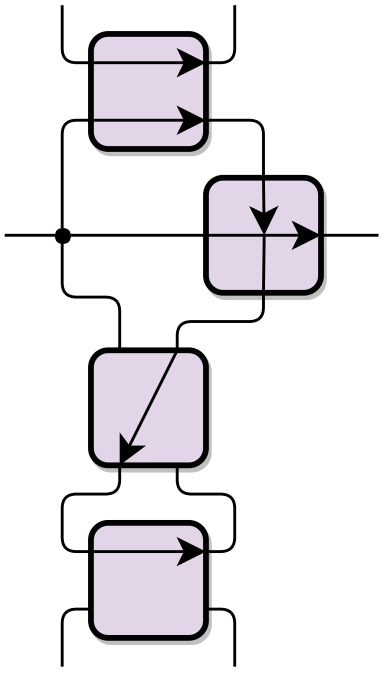


Figure 18 An edge gadget for planar graphs, currently unlocked and directed up. This is analogous to Figure 7, with two changes. First, the bottom PL2T is "twisted" to have the same handedness as the top PL2T for connecting to vertex gadgets; the CL2T is sufficient for the crossing caused by this. Second, the A/BA crossover allows the robot to cross the edge from left to right, regardless of the state of the edge. We call the line on the left the **entrance** and the line on the right, on the other side of the A/BA crossover, the **exit**.

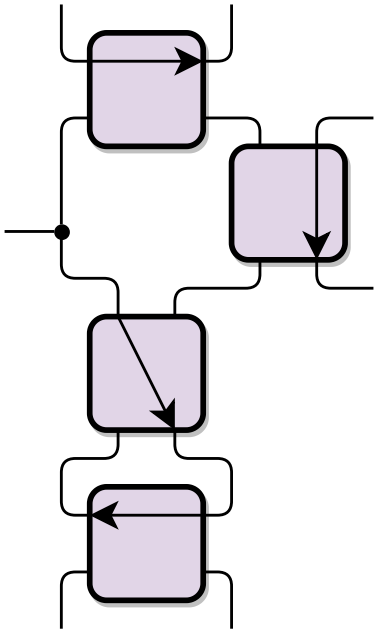
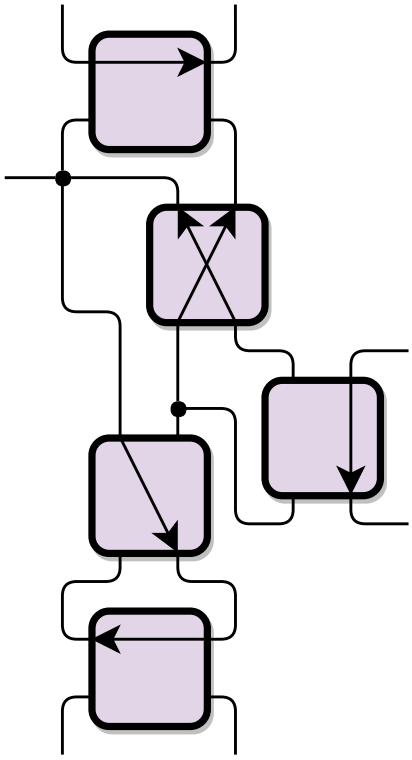


(a) An AND vertex for planar graphs. Currently the weight-2 edge, connected at the bottom PL2T, is directed towards the vertex and locked, and both weight-1 edges are directed away. If the weight-1 edges become directed towards the vertex, the robot can visit the vertex gadget and traverse a loop through all three PL2Ts, locking the weight-1 edges and unlocking the weight-2 edge. The CL2T is a sufficient crossover.



(b) An OR vertex for planar graphs. Currently the edge containing the bottom PL2T is directed towards the vertex, and the other edges are directed away. If multiple edges are ever directed towards the vertex, the robot can visit the vertex gadget, unlock the locked edge, and lock another edge.

Figure 19 NCL vertex gadgets for planar graphs, analogous to the gadgets in Figure 6. In each gadget, each of the three PL2Ts is also part of an edge gadget. The robot enters at the line on the left, called the **entrance**, traverses loops that enforce the NCL constraints, and then leaves at the entrance.

3 2-Player Unbounded Motion Planning

In this section, we analyze 2-player motion planning games with k-tunnel reversible deterministic gadgets. We show that any such game which includes an interacting-tunnels gadget is EXPTIME-complete. We do so by a reduction from 2-player unbounded constraint logic, allowing us to reuse some of the work in the prior section. In addition to building the single player AND and OR vertices, we show how to adapt the gadgets to allow different players to have control of different edges. We also build up the needed infrastructure to enforce turn taking in the simulated game.

The construction of crossovers using interacting-k-tunnel reversible deterministic gadgets with two states should allow one to show hardness for the planar version of this problem with those gadgets and any others that simulate them. Care must be taken with the layout, timing, and interaction between crossovers so we do not go on to prove such a result in this paper. Unfortunately, the crossover created by the locking 2-toggle in Section 2.3 does not suffice and thus leaves the question partially open. In addition, the question of noninteracting-k-tunnels reversible deterministic gadgets has not been resolved. We are not able to show problems with such gadgets are easy, and Section 6 suggests they should be at least PSPACE-hard.

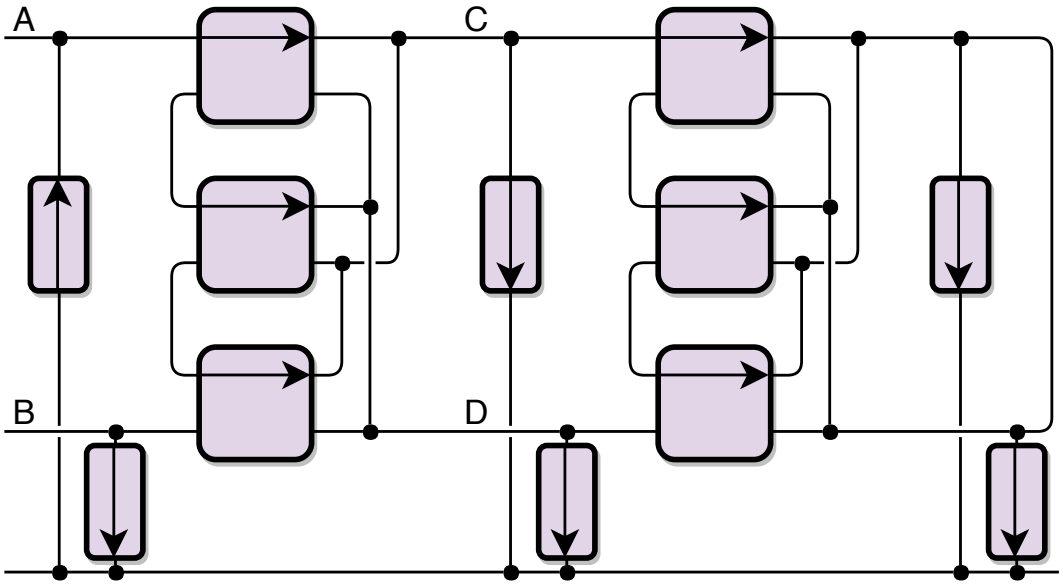


Figure 20 The timer gadget used in the 2CL reduction, made of PL2Ts and 1-toggles. In order to travel between A and B, a player must travel between C and D three times. The timer can be extended to the right; two iterations are shown.

▶ **Lemma 11.** *2-player motion planning with any set of gadgets is in EXPTIME.*

Proof. A configuration of the maze consists of the state of each gadget and the location of the robot, and has polynomial length. There is a polynomial-space alternating Turing machine which nondeterministically guesses moves for each player and keeps track of the configuration, using existential quantifiers for player 1 and universal quantifiers for player 2. This Turing machine accepts exactly when player 1 has a forced win. Thus the problem is in APSPACE = EXPTIME. ◀

▶ **Theorem 12.** *2-player motion planning with the locking 2-toggle gadget is EXPTIME-complete.*

Proof. This game is in EXPTIME by Lemma 11. We use a reduction from 2-player Constraint Logic (2CL) to show EXPTIME-completeness. See Appendix A.1 for a definition of 2CL.

We begin by describing a timer gadget, shown in Figure 20. Suppose one player has access to the bottom line. They can enter the gadget at A, and begin going through the timer, eventually reaching a victory gadget at B. The timer has two key properties:

1. Reaching B takes a number of transitions exponential in the size of the timer. In order to get from A to B, the player goes though the top PL2T to C, recursively travels from C to D, goes around the loop through the top two PL2Ts, goes back from D to C, traverses the bottom loop, once again goes from C to D, and finally proceeds to B. If traveling between C and D takes m transitions, then traveling between A and B takes $3m + 6$ transitions. If the timer gadget is repeated k times, it takes at least 3^k transition to get from A to B.
2. A player in the timer has an opportunity to exit the timer at least every 2 turns, and exiting takes 1 turn; in particular, they can always exit within 3 turns while progressing the timer. The player uses a 1-toggle to exit to the bottom line. They can then later reenter using the same 1-toggle, resuming their work on the timer where they left off. If

the player is in the timer, the next step in progressing the timer is either traversing a loop between to PL2Ts, which takes 2 transitions, or moving horizontally between timer segments, which takes 1 transition. Thus in 3 transition, the player can complete the current or next step and exit to the bottom line.

The constraint logic gadgets are similar to those used in Theorem 6 for the 1-player game, with the modification shown in Figure 21. We have added 1-toggles allowing a player at an edge to visit and configure the incident vertices, without allowing the player to travel to other edges. Each player's goal location is inside the gadget corresponding to their target edge, so that they can reach it if they can flip the edge.

Unlike the 1-player version, we need gadgets to enforce the turn order. The overall construction is shown in Figure 22. The maze consists of three main regions: the White area, the Black area, and the constraint logic. Each player will spend most of their time in their own area, occasionally entering the constraint logic to flip an edge. The players' areas are designed to enforce turn order and progression of the game. A player can never enter the other player's area.

There is a single L2T separating the constraint logic area from each player's area. This prevents both players from being in the constraint logic at the same time.

Each player's area contains an edge selection gadget, which consist of a locking 2-toggle for each edge they can control. The other line in the L2T is accessible by entering the constraint logic area and passing through a delay line four 1-toggles, and is connected to the corresponding edge gadget. In order to access an edge gadget, the player must activate the appropriate L2T, which requires deactivating the previously activated L2T. This ensures that only one edge gadget is accessible by each player at any time. There is a 1-toggle separating the edge selection gadget from the rest of the player's area, so that switching the selected edge requires at least 4 turns (we use one tunnel of a L2T for a 1-toggle).

Each player's area has a timer, of length t_w for White and t_b for black. If a player finishes their timer, they win.

Each player begins inside their edge selection gadget, and White goes first. The game begins with White picking an edge and going to the constraint logic area, while Black goes to their timer.

A round of normal play proceeds as follows:

- White moves from edge selection to the constraint logic area. Black is currently in their timer.
- White enters the constraint logic, walks to their selected edge, and flips it. Black continues working on their timer.
- White returns through their constraint logic delay line. Once they pass the first 1-toggle, Black finishes their current step in the timer and exits, moving towards edge selection.
- White begins working on their timer. Black selects an edge, enters the constraint logic, and flips the edge.
- Black returns through their constraint logic delay line. Once they pass the first 1-toggle, White exits their timer and moves to edge selection.
- White selects an edge as Black enters their timer.

Suppose Black has just flipped an edge gadget; they have nothing to do but return through the delay line of length 4. When Black is past the first 1-toggle, White will leave their timer to flip an edge. Black might try turning around to go back to the constraint logic area. It takes Black at least 6 turns to flip the edge back, during which White has enough time to select an edge and reenter their timer. The game is now in the same situation as before, except that White has progressed their timer; thus Black does not want to do this.

Black might instead try waiting at the central L2T after White has selected an edge. White will then go to their timer, forcing Black to exit eventually. When Black is not next to the central L2T, White exits their timer and moves to constraint logic. Because of the 1-toggle separating edge selection from the central L2T, for Black to change their selected edge, they must spend multiple turns away from the L2T, allowing White to enter constraint logic; similarly if Black works on their timer, White can enter constraint logic. So Black has no choice but to pass the turn to White.

Since White can always exit their timer within 3 turns, and Black has three more 1-toggles to get through when White begins looking to exit, White will reach edge selection before Black can reach edge selection, so White will be the first player ready to enter constraint logic again. Nothing Black can do will prevent White from taking the next turn in the 2CL game. Similarly after White flips an edge, Black will be able to take a turn next. So either player can force the alternation of constraint logic turns.

The sizes of the timers are chosen to satisfy the following. First, if White cannot win the constraint logic, Black should win, so Black's timer is shorter: $t_b < t_w$. Second, if White can win the constraint logic game, White should win first, even if Black ignores the constraint logic game and just works on their timer. If the constraint logic graph has n edges, it takes at most 2^n constraint logic turns for White to win. Each constraint logic turn for White takes 6 turns to select an edge and return to the constraint logic, 8 turns to cross the constraint logic delay line twice, 4 turns to access and flip an edge, and up to 5 turns to access and configure an incident vertex, so 25 turns in total during which Black can work on their timer. Both players might be in their timers simultaneously at most 4 times each cycle, and each time for at most 4 turns, so Black spends at most 41 turns in their timer for each constraint logic turn. Thus, since it takes Black at least 3^{t_b} turns to win through the timer, we need $41 \cdot 2^n < 3^{t_b}$; $t_b = n + 6$ suffices, and we can set $t_w = 2n + 12$.

Using these timer sizes, it is clear that the constraint logic game will resolve before either timer if the players follow normal play. We need the timers so that Black cannot force a draw by sitting in the constraint logic forever, preventing White from winning; White will progress on their timer if Black attempts this.

Hence White has a forced win in the motion planning game if and only if they have a forced win in the constraint logic game. Since 2CL is EXPTIME-complete, the 2-player game on systems of locking 2-toggles is EXPTIME-hard. The maze used in the reduction has only $O(n)$ L2Ts. ◀

▶ **Theorem 13.** *2-player motion planning with any interacting-k-tunnel reversible deterministic gadget is EXPTIME-complete.*

Proof. This game is in EXPTIME by Lemma 11. We adapt the 2CL reduction in the proof of Theorem 12. Replace each locking 2-toggle in that 2CL reduction with the simulation of a locking 2-toggle from the arbitrary gadget in Theorem 3. In the new maze, each tunnel in a simulated L2T takes 6 transitions to traverse, so the game goes 6 times slower.

The simulation still works with two players, as long as both players do not have access to the gadget at the same time. Each L2T in the turn enforcement area is accessible only by one player, and only one player can be in the constraint logic area at any time. The only L2T both players have simultaneous access to is the central gadget which gives access to the constraint logic area, so we look more carefully at that gadget.

The state with both edges traversable is shown in Figure 5 (the 1-toggle simulation still works). Note that the simulation is of an APL2T, but the gadget in the 2CL reduction is a PL2T; this is not a problem because we are not concerned with planarity. Suppose both

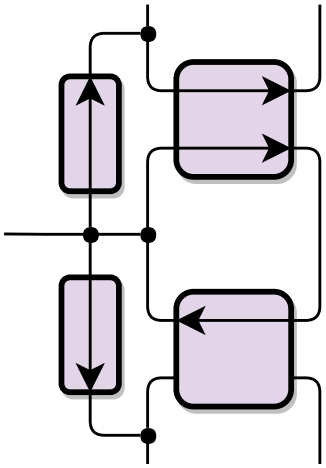

Figure 21 A modified edge gadget for the 2CL reduction. A player can visit the vertex gadgets attached to the edge gadget, and then return to the edge gadget.

players approach the gadget, one from the right on the top line and one from the left on the bottom line. Whoever reaches the gadget first should "win the race", and lock out the other player. The simulation implements this correctly, provided that the player who arrives first is a full turn ahead in the L2T maze, or 6 turns ahead in the new maze. The only time the players might be within 6 turns of each other is at the very beginning of the game, so we put a delay of 6 turns for Black to get from their start location to edge selection to ensure White wins the race by 6 turns. If a player would arrive less than 6 turn before the other player, they should go to their timer instead; since this is a zero-sum game and the players would have to collaborate to break the simulation, one player will choose not to.

The other way players can interact at this gadget is when one player is exiting the constraint logic area, and the other player is waiting just outside and enters as soon as they can. The state of the simulation is shown in Figure 23 (the other possible state is symmetric). One player, say White, has traversed the top edge to enter the constraint logic area, and is about to exit by traversing the top line to the right. Black is waiting at the left end of the bottom line, ready to enter the constraint logic area. The leftmost gadget prevents Black from making any transitions until White begins exiting. Once White begins exiting, the leftmost gadget switches to state 2, so Black can follow parallel to White and one turn behind. As long as White continues through the construction at full speed, Black interacts with the construction as though White has already finished their traversal, so it correctly simulates a L2T. Again breaking the simulation would require the players to cooperate, and the game is zero-sum, so at least one player will ensure the simulation works. ◀

4 Team Unbounded

In this section, we show that team imperfect information games with interacting-k-tunnel reversible deterministic gadgets is RE-complete, implying the problem is Undecidable. The reduction is from Team Private Constraint Logic (TPCL); see Appendix A.1 for a definition. We use many of the ideas and constructions from Section 3, but various modifications are needed to deal with the additional player and the model of player knowledge. Recall in this model we have three players on two different teams, each controlling a single robot.

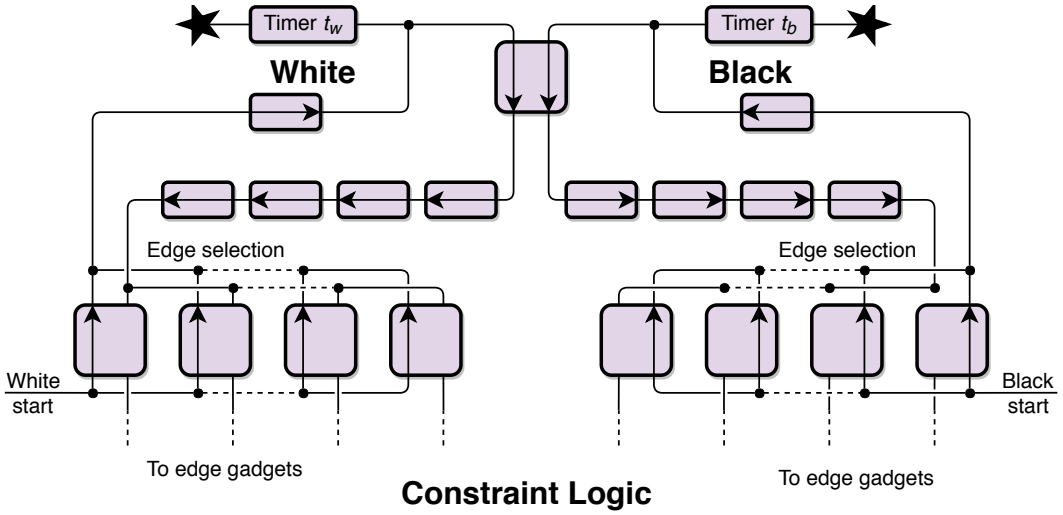

Figure 22 The overall structure and turn enforcement gadget. Each player's edge selection area has a L2T for each edge that player can flip; four are shown for each player. The bottom line from each such L2T connects to the corresponding edge gadget. The timers are as shown in Figure 20, with t_w and t_b repetitions. The inside connection to each timer is connected to its access line, and the outside connection (to a win gadget) is at B in Figure 20. The goal location past each timer is for the player whose side it is on.

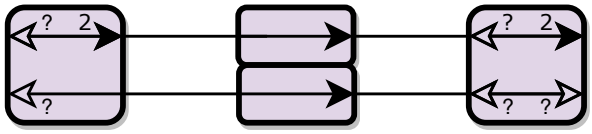

Figure 23 Another state of the construction shown in Figure 5. The leftmost gadget is in state 1, and the rightmost gadget is in state 3.

All players start knowing the configuration of the entire game; however, after that point players can only observe the states of the gadgets that their robots can reach via the connection graph. Adaptations for the planar version and the complexity of such games with noninteracting-tunnel gadgets remains open as in Section 3.

▶ **Lemma 14.** *Team motion planning with any set of gadgets is in RE (recursively enumerable).*

Proof. Suppose the White team has a forced win on some system of gadgets, and consider the tree of possible positions when White follows their winning strategy. The branches in the tree correspond to choices the Black team might make. Since White forces a win, every branch of the tree is finite. Since Black has finitely many choices at each turn, the tree is finitely branching, so by Kőnig's infinity lemma [14], the tree is finite. In particular, there is a finite bound on the number of turns it takes for White to win, so the winning strategy can be described in a finite amount of space. So there are countably many potential winning strategies, and we can sort them lexicographically.

Given a potential winning strategy, the problem of determining whether it is actually a winning strategy is decidable: an algorithm can explore every choice Black might make, and see whether White always wins. There are only finitely many choices to check because the strategy only describes a finite number of turns.

We use the following algorithm to determine whether White has a forced win. For each potential winning strategy in lexicographic order, check whether it is a winning strategy. If it is, accept. This algorithm accepts whenever White has a forced win, and runs forever otherwise, so it recognizes the games in which White has a forced win. ◀

Although [7] only mentions undecidability and not RE-completeness, it follows that TPCL is RE-complete. Containment in RE is given by an argument nearly identical to the proof of Lemma 14. The proof of undecidability is ultimately by a reduction from acceptance of a Turing machine on an empty input, which is RE-complete, implying that TPCL is RE-hard.

▶ **Theorem 15.** *Team motion planning with the locking 2-toggle gadget is RE-complete (and thus undecidable).*

Proof. Containment in RE is given by Lemma 14. For RE-hardness, we use a reduction from TPCL, with a similar construction as in the proof of Theorem 12. The overall construction is shown in Figure 24. Capital letters label L2Ts, and lowercase letters label lengths of delay lines. The two tunnels in the same L2T are labelled the same, instead of being positioned next to each other. The three players B, W_1, and W_2 each have their own region. Each region contains an edge selection area with k edges initially active, access to the constraint logic, and some additional gadgets. We need to ensure the following:

1. Turn order is enforced. That is, the players take turns in the order B, W_1, W_2, and neither team can gain anything by deviating from this. We use L_1 and L_2 to prevent B from being in the constraint logic area at the same time as W_1 or W_2, and appropriate delays to ensure each player is ready for their turn. The timer in W_2's region forces B to eventually pass the turn to W_1.
2. Each player can flip up to k edges each turn. If k edges are initially accessible for each player, the edge selection area allows them to select any k of their edges, and a player must end their turn in order to change their selection.
3. The White players have the correct information about the state of the game. Each of them has a visibility area, which allows them to see the orientation of the appropriate constraint logic edges. We must not allow W_1 and W_2 to both access the same L2T, as they could then use it to communicate. So we need a more complicated mechanism to prevent both White players from being to the constraint logic area at the same time.

For visibility, we modify the edge gadget as shown in Figure 25. The appropriate line is connected to each White player's visibility area if they should be able to see that edge.

A round of normal play proceeds as follows:

- B begins their turn by passing down through L_1 and L_2. W_1 waits next to V, and W_2 walks through their timer.
- B flips some edges, and returns, passing V. When W_1 sees this happen, they go to their visibility area, and then select k edges. W_2 continues in the timer.
- B finishes exiting through the delay b. Once B has passed L_1, W_1 enters the constraint logic area. W_2 reaches the end of the timer, finds S to be closed, and comes back.
- B is stuck on the side of L_1 away from the constraint logic area, and can select edges. W_1 flips edges and returns to just below L_1. W_2 goes to their visibility area, and then selects edges.
- After a number of turns large enough that both White players are definitely ready, W_1 exits L_1. The same round, W_2 enters L_2, passing the turns from W_1 to W_2.
- W_2 takes their turn. B waits just to the right of L_2, and W_1 waits above X.
- W_2 exits L_2 and goes to the timer. B passes through L_2 to take their turn, and W_1 waits.

We place each player's starting location to be at the end of a chain of 1-toggles leading to their region, so they arrive after an appropriate delay. We can set B to have no delay and W_1 and W_2 to have $2k$ delay, so B has time to select edges before the White players arrive. The first turn has slightly strange timing since W_2 starts the timer later than normal, but this is not important.

We consider ways in which player might deviate from normal play, and see that in each case they do not gain anything by deviating.

B enters the constraint logic through L_2 as soon as W_2 passes L_2 on their way out, at which point W_2 enters the timer. B need to be able to take a full turn and go back through S before W_2 reaches the end of the timer; this takes up to $2(b+c+2)+2+11k$ turns, since flipping each edge now takes up to 11 turns. So we need $t > 2(b+c+2)+2+11k$. The timer forces B to return through S within $t+2$ turns, since otherwise W_2 wins.

The gadget V lets W_1 know when B is done, since W_1 can see whether B is past V while waiting at L_1. Specifically, W_1 waits until they see B stay past V for $2c$ turns, and then return. For B to be unable to flip edges after this, we need $4c > t$. Then W_1 goes to visibility and sees the current configuration, selects k edges for their next turn, and waits at L_1 again. For W_1 to have time to do this before B gets out, we need $b > 2k+2$.

Once B exits L_1, W_1 goes in and flips edges. The delay d ensures that if W_1 (or W_2) flips any edges, then B will be ready for their next turn; we need $2d > 2k+4$. W_2 returns through the timer, checks visibility, and selects edges. If W_2 enters constraint logic before W_1 leaves, B can win through X and Y, so W_2 must wait until W_1 leaves. The White players coordinate using the fact that the length of an entire round is bounded, so they can wait long enough to ensure that they are both ready, and then W_1 exits X immediately before W_2 enters Y. Since W_1 was past L_1, B is locked outside of L_1, so W_2 can get past L_2; the W_1 can safely pass the turn to W_2.

While W_1 is past X, B might try going through Z and X, trapping W_1. In this case, W_2 can win through Z, so B will only go through Z if both X and Y are traversable.

During W_2's turn in the constraint logic, W_1 must not be past X to prevent B from winning through X and Y. So B can go through L_1, and go through L_2 as soon as W_2 exits. That is, W_2 cannot pass the turn back to W_1.

W_2 might try to stay in the timer, forcing B to stay out of the constraint logic to prevent W_2 from winning through S. Then W_1 might be able to take extra turns in the constraint logic. If the White team attempts this, B will win through P and Q. If B goes through R and P when Q is not traversable in order to trap W_1, W_2 will win through R; these three L2Ts are analogous to X, Y, and Z.

Assuming the constraints mentioned are satisfied, no player or team can usefully deviate from normal play, and normal play simulates the TPCL game. Thus White has a forced win in the team motion planning game if and only if they have a forced win in the TPCL game.

We can satisfy all the constraints, e.g by $b = 2k+3$, $c = 8k+7$, $d = k+3$, and $t = 31k+27$ (the constraints are not tight, but they suffice). The number of L2Ts in the resulting system of gadgets is only linear in the number of edges in the constraint logic graph. ◀

▶ **Theorem 16.** *Team motion planning with any interacting-k-tunnel reversible deterministic gadget is RE-complete.*

Proof. Containment in RE is given by Lemma 14. For RE-hardness, we adapt the TPCL reduction in Theorem 15 to work for the arbitrary gadget. As in the 2-player case of Theorem 3, it is almost sufficient to replace each L2T with the simulation in Theorem 3. We examine the L2Ts that are shared between two players.

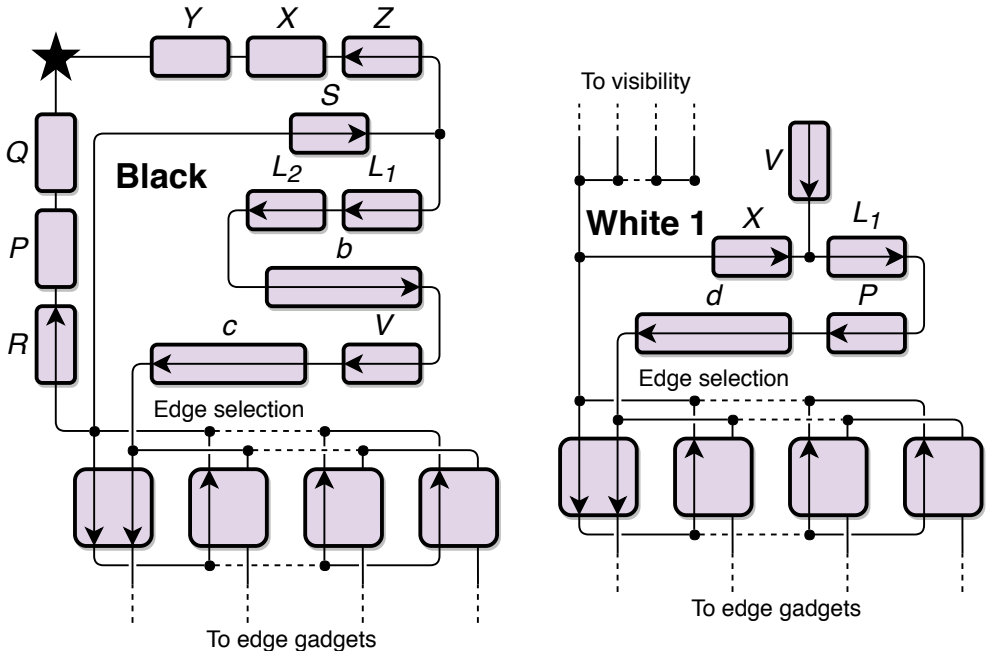

Figure 24 The turn enforcement gadget for the team game. Each player has their own region which contains an edge selection area, a path to the edge gadgets they can control, and some other constructions. Each White player has a visibility area which allows them to see the state of some edge gadgets in constant time. There is no good layout for the whole gadget, so we use pairs of 1-toggles that share a (capital) label to represent L2T. Long boxes with lowercase labels represent chains of 1-toggles with length given by the label. The win gadgets are for the obvious players, and the tunnels currently not traversable (P, Q, R, S, X, Y, and Z) will directed toward the win gadget when they become traversable.

First, L_1 and L_2 are analogous to the central L2T in Theorem 3: if two player are racing to enter, the player who should win is at least 6 turns ahead, and if one player exits and another enters, is works correctly.

For S, P, Q, R, X, Y, and Z, we use a single copy of the arbitrary gadget with 5 extra gadgets for delay, instead of the simulation. Considering the gadget as in Figure 2, we use state 1, and put the bottom edge in the position next to a win gadget. For S, Q, Y, R, and Z, if the bottom edge is traversed from state 2, the game is over, so the gadget is never in a state other than 1 or 2 while the game is going. For P and X, we know that B cannot safely wait past those gadgets, so the game must be about to end in Black victory if they ever reach state 3.

For V and the visibility gadgets on edges, we use the construction in Figure 26. B has three paths to choose from in the process of crossing the bottommost 1-toggle, and always two of them are align with that 1-toggle, so B has two options. The White player, say W_1 can see the state of a gadget in all three paths, and thus determine the orientation. If W_1 goes through one of these gadgets, B will use the other path. If there were only one path, W_1 could go through the gadget, forcing B to either not flip that edge or get a gadget into an unknown state (for L2Ts, we used the fact that W_1 could never traverse that tunnel in one direction). This visibility gadget allows W_1 to see the orientation of a constraint logic edge or V without being able to interfere.

Once we make these replacements, the new maze with the arbitrary gadget has a forced win by White if and only if the maze with L2Ts did. ◀

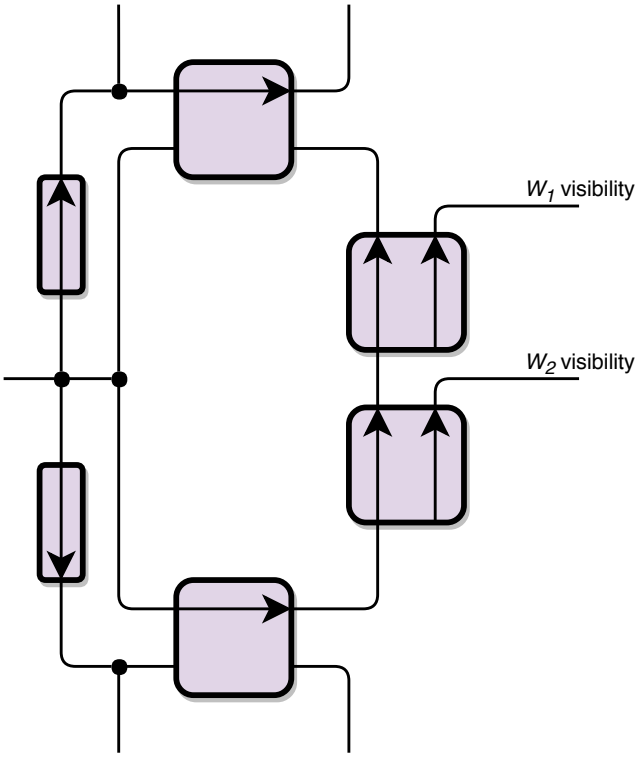

Figure 25 An edge gadget for the TPCL reduction. This is the same as a 2CL edge gadget, except two L2Ts have been added that allow W_1 or W_2 to see the state of the edge if it is connected to their visibility area, but they cannot make any transitions.

5 1-Player Bounded Motion Planning

In this section, we consider a broad class of gadgets which are naturally in NP and give a dichotomy classifying them as NP-complete or in NL. We examine all gadgets in tunnels whose state-transition graph forms a DAG. We will call these DAG gadgets for short. Our proof of hardness further applies to a larger class of gadgets, however a full classification of more general, simple to describe classes of gadgets will require more insight or much more case-work. Also, our constructions require the use of a crossover gadget.

The results in this section can be seen as similar to Viglietta's Metatheorem 1 about location traversal (being implemented by the interacting tunnels in gadgets) and single-use paths [19]. It also bears resemblance to Metatheorem 4 about pressure plates which only affect one door [19]. However, our proof goes through 3SAT rather than Hamiltonian Path, uses a different underlying model which makes different features salient, and gives generalizations in a different direction. Structurally the proof follows that used to show Mario as well as many other games are NP-hard [1].

▶ **Lemma 17.** *All DAG gadgets contain a single-use transition unless they are a transitionless gadget.*

Proof. First, find a node which only has transitions to **terminal states**, ones with no possible further transitions. To find one, begin by removing all terminal states from the graph. Of the remaining nodes, all of them which are now terminal states must have pointed to at least one terminal state in the original graph or it would have been removed, and it

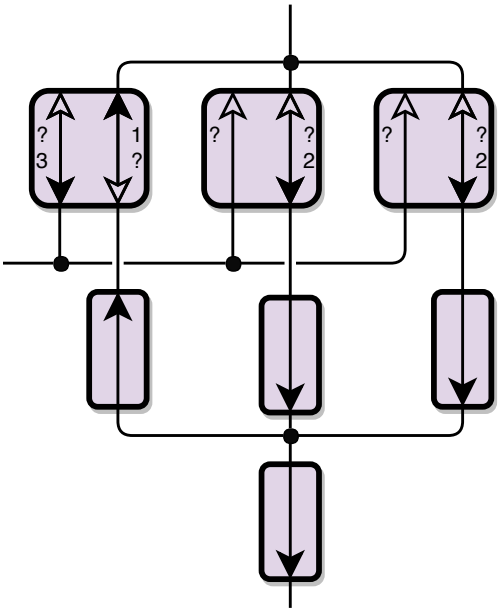

Figure 26 A visibility gadget for the TPCL reduction. The Black player can travel between the top and bottom, and a White player can enter the side to see which direction was traversed most recently.

must have only pointed to terminal states or it would not be a terminal node. Terminal nodes have no transitions. Thus the node we discovered has an available transition which closes all tunnels in the new state. The gadget starting from that state is a single-use gadget. ◀

In a system of gadgets, each DAG gadget can only be traversed polynomially many times. This is the core reason that motion planning involving these gadgets is always in NP.

▶ **Lemma 18.** *1-player motion planning with any set of DAG gadgets is in NP.*

Proof. If a gadget and its state is a sink in the state-transition graph, then no transitions are available from that state. Each time a gadget is traversed the state of the gadget is moved down the graph. All paths from any vertex to a leaf are of polynomial length and thus each gadget can only be traversed polynomially many times before it no longer has any open tunnels. Thus we can give a polynomial size witness consisting of the order in which gadgets are visited, as well as the transition made at each gadget. To verify this certificate we check that each specified transition is legal, and that the location after each transition is connected to the location before the next transition in the witness. ◀

Recall from Theorem 2 that all gadgets without interacting tunnels are in NL. Thus one might hope to show that all interacting-k-tunnel DAG gadgets are NP-complete. This is true for deterministic gadgets but false in general; nondeterministic gadgets require a more careful categorization. We will define two behaviors a DAG gadget might have, "distant opening" and "forced distant closing", and show that either behavior guarantees NP-hardness, while having neither one puts the gadget in NL.

A **distant opening** in a DAG gadget is a transition in some state across a tunnel which opens a different tunnel.

▶ **Lemma 19.** *1-player motion planning with any k-tunnel DAG gadget with a distant opening is NP-hard.*

Proof. We show this problem is hard by a standard reduction from 3SAT. See Appendix A.2 for a definition of 3SAT.

We construct our reduction as follows. We use the tunnel which is traversed in the distant opening and one of the tunnels it opens. Each literal in a 3-CNF formula will be represented by those two tunnels in a single gadget, in the state of the distance opening. Each variable x_i is represented by a connection to two different paths, one which goes through the opening transitions for the x_i literals, and one for the $\neg x_i$ literals. We place a single-use gadget at the start and end of each branch of each variable to ensure only one side of the variable is traversed. The single-use gadget prevents the agent from returning on the same branch, and if the agent returns via the other branch, they will not be able to proceed to the next variable.

Each clause contains connections between the openable tunnels for each of its literals. All variable gadgets are laid out in series followed by the clause gadgets, with the goal location at the end of the clause gadgets. Each clause gadget can only be traversed if at least one of its corresponding variable gadgets has been traversed, allowing at least one passage to be open. The agent can reach the goal location exactly when it has a path through the variable gadgets which makes each clause gadget traversable, which corresponds to a satisfying assignment of the 3-CNF formula. ◀

When a transition across a tunnel closes another tunnel, the situation is more complicated, since the agent may be able to cross the same tunnel through a different transition, choosing not to close the other tunnel. For distant openings, the agent always chooses to open the other tunnel. We will now consider only **monotonically closing** DAG gadgets, which are DAG gadgets with no distant openings. We clarify some terminology regarding k-tunnel DAG gadgets. A **transition** is an edge in the transition graph, which is a legal move between locations which changes the state of the gadget. A **traversal** in a state is an orientation of a tunnel which is open in that state. A traversal may correspond to multiple transitions; a gadget being deterministic is equivalent to each traversal having only one transition. An **orientation** of a set of tunnels in a state contains, for each tunnel in the set, a single traversal of the tunnel the state.

For NP-completeness one might suggest there exist a traversal such that all of its transitions close some other traversal. However, this fails in a simple two tunnel case where one transition closes one direction of the other tunnel and the other transition closes the other direction. This leads us to a more complex definition. A **forced distant closing** in a state of a DAG gadget is a traversal across a tunnel in that state and an orientation of some other tunnels in the state such that, for each transition corresponding to the traversal, the transition closes some traversal in the orientation. The **size** of a forced distant closing is the number of traversals in the orientation.

▶ **Lemma 20.** *1-player motion planning with any monotonic k-tunnel DAG gadget with a forced distant closing is NP-hard.*

Proof. Consider all states which have forced distant closings, and let s be such a state that is minimal in the state-transition DAG, so that after making a transition from state s there are no forced distant closings. We will use a forced distant closing in s with smallest size; say this forced distant closing traverses tunnel t and has size i. We chain the i tunnels in the orientation for the forced distant closing, in the directions specified by the orientation, to make what is effectively a single long tunnel r. We will use the tunnels t and r in a reduction from 3SAT, and they have two important properties:

- If the agent traverses t, it cannot later traverse r: since we are using a forced distant closing, after traversing t at least one (oriented) tunnel in r is not traversable. Since there are no distant openings, this tunnel cannot become traversable again.
- The agent can traverse r from state s: in state s, each tunnel in r is open. The agent begins by traversing the first tunnel in r. This cannot be a forced distant closing for the remaining $i-1$ tunnels, since we assume the smallest forced distant closing has size i. So the agent can choose a transition which leaves the remaining tunnels in r open. After this first traversal, there are no more forced distant closings, so the robot can always choose a transition which leaves the remaining tunnels in r open.

We can now describe the reduction, which is very similar to the reduction in the proof of Lemma 19. Each literal in a 3-CNF formula is represented by a gadget in state s, with the tunnels r chained together. Each variable x_i is represented by a connection to two different paths, one which goes through t for the x_i literals, and one for the $\neg x_i$ literals. We place a single-use gadget at the start and end of each branch of each variable to ensure only one side of the variable is traversed. The single-use gadget prevents the agent from returning on the same branch, and if the agent returns via the other branch, they will not be able to proceed to the next variable.

When the agent goes through the x_i (resp $\neg x_i$) path of a variable, it closes r in the gadget for each literal x_i ($\neg x_i$), which corresponds to assigning x_i to false (true). This is reversed from the reduction for gadgets with distant openings.

Each clause contains connections between the r for each of its literals. All variable gadgets are laid out in series followed by the clause gadgets, with the goal location at the end of the clause gadgets. Each clause gadget can only be traversed if at least one of its corresponding variable gadgets has *not* been traversed, leaving at least one passage r open. The agent can reach the goal location exactly when it has a path through the variable gadgets which leaves each clause gadget traversable, which corresponds to a satisfying assignment of the 3-CNF formula. ◀

▶ **Lemma 21.** *1-player motion planning with any monotonic k-tunnel DAG gadget with no forced distant closing is in NL.*

Proof. The proof follows that of Theorem 2, though we must be more careful to account for optional distant closings. As in Theorem 2, if a system of gadgets has a solution, then a solution of minimal length does not intersect itself. This only requires that the gadget has no distant openings, since then making transitions can never increase traversability, and the shortcutting argument applies.

We locally convert the system of gadgets into a directed graph, and show a path in the graph from the start location to the goal location corresponds to a solution to the system of gadgets which does not intersect itself. Given a (not self-intersecting) path in the graph, we follow the corresponding path through the system of gadgets. When we make a traversal, we must pick a transition to avoid closing tunnels we will need later. This is always possible because there are no forced distant closings; we can always choose a transition which does not close any traversal in the orientation consisting of the traversals the path will later take. By doing this, we ensure that every traversal we need is available when we get to it, so the system of gadgets is solvable.

Suppose there is a solution to the system of gadgets that does not intersect itself. Since it uses each tunnel at most once, and the gadget has no distant openings, the traversability of each tunnel does not change before the solution uses it. Thus the solution is also a path in the directed graph.

So the system of gadgets has a solution iff there is a path from the start location to the end location in the directed graph. Since we can locally convert the system of gadgets to the graph in logarithmic space and solve reachability in NL, the motion planning problem is in NL. ◀

Combining Lemmas 17, 18, 19, 20, and 21, we have our dichotomy:

▶ **Theorem 22.** *1-player motion planning with a k-tunnel DAG gadget is NP-complete if the gadget has a distant opening or forced distant closing, and otherwise is in NL.*

It is natural to wonder whether this condition for hardness can be checked in polynomial time. That is, is there a polynomial-time algorithm which determines whether 1-player motion planning with a given DAG gadget is NP-complete? For all of our other dichotomies, the question of whether a gadget of the appropriate type satisfies the condition for hardness is clearly in P; in fact, in L. But a forced distant closing involves an orientation of the tunnels in the gadget, so there may be exponentially many potential forced distant closings to check. We will show that whenever it is necessary to search through each potential forced distant closing, the number of states of the gadget is exponential in the number of tunnels, so the search takes time polynomial in the number of states.

First, it is easy to determine whether a DAG gadget has a distant opening in polynomial time, since we can iterate through the transitions and see whether each one opens another tunnel. So we consider gadgets with no distant openings, and wish to determine whether they have a forced distant closing.

▶ **Lemma 23.** *Suppose a monotonic DAG gadget has a state s with k open tunnels, and there are no forced distant closings from states reachable from s. Then the gadget has at least 2^k states reachable from s.*

Proof. For each subset of the open tunnels in s, we will find a state that has exactly those tunnels open. Since there are 2^k such subsets, this implies there are at least 2^k states. Assume without loss of generality that each tunnel is traversable from left to right in state s.

Given a subset X of the open tunnels, we perform transitions starting from s as follows. For each tunnel not in X, traverse the tunnel repeatedly until it is closed in both directions; this must happen eventually because the gadget is a DAG. At each traversal, choose a transition which does not close any other tunnel from left to right. If there were no such choice of transition, that traversal with all other tunnels oriented from left to right would be a forced distant closing, which does not exist by assumption.

After making these transitions, we have closed each tunnel not in X without closing any tunnels in X. Since the gadget is monotonic, we have not reopened any tunnel. So the final state has exactly the tunnels in X open. ◀

▶ **Theorem 24.** *Deciding whether a 1-player motion planning with a k-tunnel DAG gadget is NP-complete can be done in polynomial time.*

Proof. The following algorithm checks in polynomial time whether 1-player motion planning with a given a DAG gadget is NP-complete.

- For each transition, see whether it is a distant opening. If it is, accept.
- Iterate through the states of the gadget in reverse order; i.e. check each state reachable from s before checking s. For each state, and for each traversal from that state:

- Suppose the state has k open tunnels other than the tunnel of the traversal. If every transition corresponding to the traversal leaves fewer than k of these tunnels open, accept.
- Enumerate the 2^k orientations of these k open tunnels, and check for each orientation whether it is a forced distant closing with the traversal. If it is, accept.

- Reject.

If the gadget has a distant opening, the algorithm notices it in the first step. Otherwise, we check for each state and traversal whether it has a forced distant closing. If every transition for a traversal reduces the number of other open tunnels, than any orientation of the other tunnels gives a forced distant closing. Otherwise, we check for each orientation whether it gives a forced distant closing. So the algorithm accepts exactly when the gadget has a distant opening or a forced distant closing, which is when 1-player motion planning with the gadget is NP-complete by Theorem 22.

The only step of the algorithm which does not obviously take polynomial time is running through all 2^k orientations of tunnels. Suppose the algorithm reaches this step for some state and traversal. Then there are no forced distant closings after making a transition from this state, since we would have accept already if there were. Also, there is some transition corresponding to the traversal which leaves all k other open tunnels open. By Lemma 23, there are at least 2^k states reachable after making this transition. In particular, the gadget has more than 2^k states, so enumerating the 2^k orientations takes time polynomial in the number of states. Thus the algorithm runs in polynomial time. ◀

6 2-Player Bounded Motion Planning

In this section, we show that it is PSPACE-complete to decide who wins in a 2-player race with any nontrivial DAG gadget (having at least one transition). To do so we give a construction that shows hardness for single-use paths and single-use one-way gadgets by a reduction from QBF. A simpler construction is possible, but this construction is more easily adapted to the team game in Section 7. This gives us a nice example of the 2-player local motion planning problem fitting into the canonical complexity class for two-player bounded games. It is also of interest because of how incredibly simple this gadget is. Two-location gadgets trivially do not have interacting tunnels (there is no other tunnel to interact with) and thus the 1-player version of these problems are contained in NL by Theorem 2.

▶ **Lemma 25.** *2-player motion planning with any set of DAG gadgets is in PSPACE.*

Proof. Since each gadget can undergo only a polynomial number of transitions, the length of the game is polynomially bounded. An alternating Turing machine which uses $\forall$ states to pick Black's moves and $\exists$ state to pick White's moves can simulate the game in polynomial time, so the motion planning problem is in AP = PSPACE. ◀

▶ **Lemma 26.** *2-player motion planning with the single-use bidirectional gadget is PSPACE-complete.*

Proof. Containment in PSPACE follows from Lemma 25. For PSPACE-hardness, we reduce from quantified boolean formulas (QBF). See Appendix A.2 for a definition of QBF.

We begin by describing the gadgets used in the reduction. The variable gadget is shown in Figure 27. Most of the gadget is two branches, corresponding to a variable and its negation. Each branch has a series of forks separated by single-use paths. There will be a number of

forks depending on the number of occurrences of a literal in the formula; two forks are shown. Each side of each fork has two single-use paths in series. The game will be constructed so that White always prefers the top side of a fork to be traversable, and Black prefers them to be not traversable; the top of a fork will be used later in evaluating the formula.

During the game, both players will pass through each variable gadget, with one player taking each of the two branches. White will take the bottom side of each fork on their branch, and Black will take the top side. Afterwards, only the branch which White took will have forks whose top sides are traversable. Thus we consider the assignment of the variable to be the literal corresponding to the branch White takes.

Suppose both players are at the left end of a variable gadget, and it is Player 1's (who may be White or Black) turn. Player 1 picks a branch, and Player 2 must walk down the other branch. Player 1 arrives at the right end of the branches immediately before Player 2. If Player 1 proceeds along the bottom path, Player 2 wins, so Player 1 must take the top path, which takes one turn longer. After traversing the variable gadget, both players are at the right end, and it is Player 2's turn, so the other player gets to choose a branch in the next variable gadget.

The clause gadget is shown in Figure 28. There are three paths from the left end to the right end, corresponding to the literals in a clause. Each path goes through a fork in a variable gadget. After variables are assigned, the single-use paths on each end of the fork are used, as are either those on the top or those on the bottom of each fork. If the top single-use paths are used, that path through the clause gadget is blocked, and if the bottom paths are used, that path is open. White will ultimately win by traversing each clause gadget, so White prefers to use the bottom side of a fork, and Black prefers to use the top side.

Each path has a large amount of delay (gadgets in series) before and after the fork, so that trying to use the clause gadget during variable assignment results in losing before reaching the end of the delay.

The race gadget is shown in Figure 29. It ensures both players proceed though variable gadgets as fast as possible. Let Player 1 be the player who reaches the race gadget first in this situation, immediately before Player 2; they are also the player who did not pick the assignment of the last variable. If Player 1 takes the bottom path, Player 2 will win, so Player 1 takes the top path. Then Player 2 takes the bottom path, and now the two players have been separated.

If Player 1 arrives more than a turn ahead of Player 2, they can take the bottom path. The next turn, before Player two can do anything at the race gadget, Player 1 wins. If Player 2 reaches the race gadget first, they can take the top path and win.

Given a quantified boolean formula with V variables and C clauses, we construct a system of gadgets as follows. We assume the QBF has alternating quantifiers beginning with $\exists$. There is a series of variable gadgets connected end-to-end corresponding to the variables of the formula, in the order of quantification. The goal location inside each variable gadget is a win for alternating players, beginning with Black. The branches of the variable gadget corresponding to x correspond to the literals x and $\neg x$. Each branch of that variable gadget has enough forks that each instance of a x or $\neg x$ in the formula corresponds to a fork, and the two branches have the same number of forks.

There is a clause gadget for each clause in the formula, connected in series. The three branches of a clause gadget correspond to the three literals in the clause. Each branch goes through the fork in the appropriate variable gadget corresponding to that instance of the literal. The delay before and after each fork consists of $9C + 3V$ single-use paths. The right end of the last clause is connected to a White goal location.

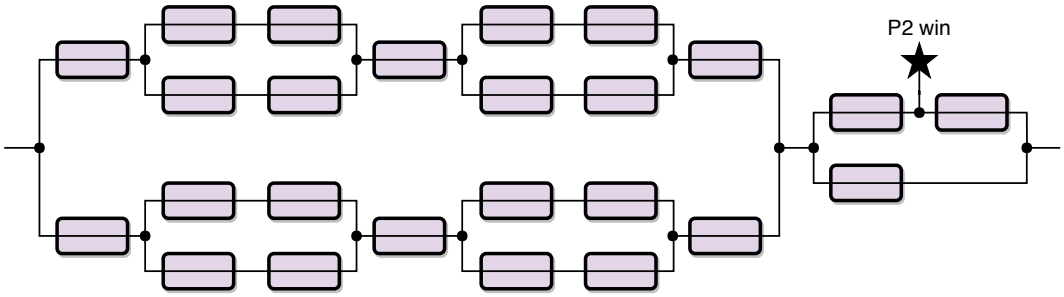

Figure 27 A variable gadget. The players arrive at the left, each take one path across, and exit at the right.

A race gadget is connected to the right end of the last variable gadget, with the goal locations such that Player 1 is the player with a win gadget inside the last variable gadget. The path with a White win gadget, which Black will walk down, is followed by $C(18C+6V+1)+2$ of single-use paths in series leading to a Black win gadget. The other path, which White will walk down, is connected to the first clause gadget.

Both players begin at the left end of the first variable gadget, and White goes first.

The game begins with White choosing a branch of the first variable gadget, corresponding to a choice of variable, and Black taking the other branch. Then Black chooses a branch of the second variable gadget, choosing the assignment of the variable based on the path White is forced to take. The players continue to take turns assigning variables. If either player deviates from this, such as by going into the delay in a clause gadget or by going backwards along another path, the other player will reach the race gadget first and win; the delay in clause gadgets is long enough to ensure that they do not have time to get through the clause gadget before losing. Otherwise both players arrive at the race gadget, and are sent down different branches.

White then proceed through each clause in series. Each branch of a clause is traversable if and only if the corresponding literal is true (since White took the bottom side and Black took the top side of each clause). The single-use paths between forks ensure that White cannot do anything other than progress through each clause gadget. If the formula is satisfied, White has a path through the clauses, and wins after $C(18C + 6V + 1)$ turns. If the formula is not satisfied, Black, who is walking down their long path, wins after slightly longer. Thus White has a forced win if and only if the quantified formula is true. ◀

▶ **Lemma 27.** *2-player motion planning with the single-use one-way gadget is PSPACE-complete.*

Proof. We again reduce from QBF. In the reduction in Lemma 26, neither player ever has to move through a single-use gadget to the left. Thus we can replace each bidirectional single-use gadget with a one-way single-use gadget pointing to the right, and the reduction still works. ◀

▶ **Corollary 28.** *2-player motion planning with any nontrivial DAG gadget is PSPACE-complete.*

Proof. As noted in Section 5 all DAG gadgets contain a single-use transition. This can be bidirectional or one-way, which are both shown to be PSPACE-hard in Lemmas 26 and 27. Containment in PSPACE is given by Lemma 25. ◀

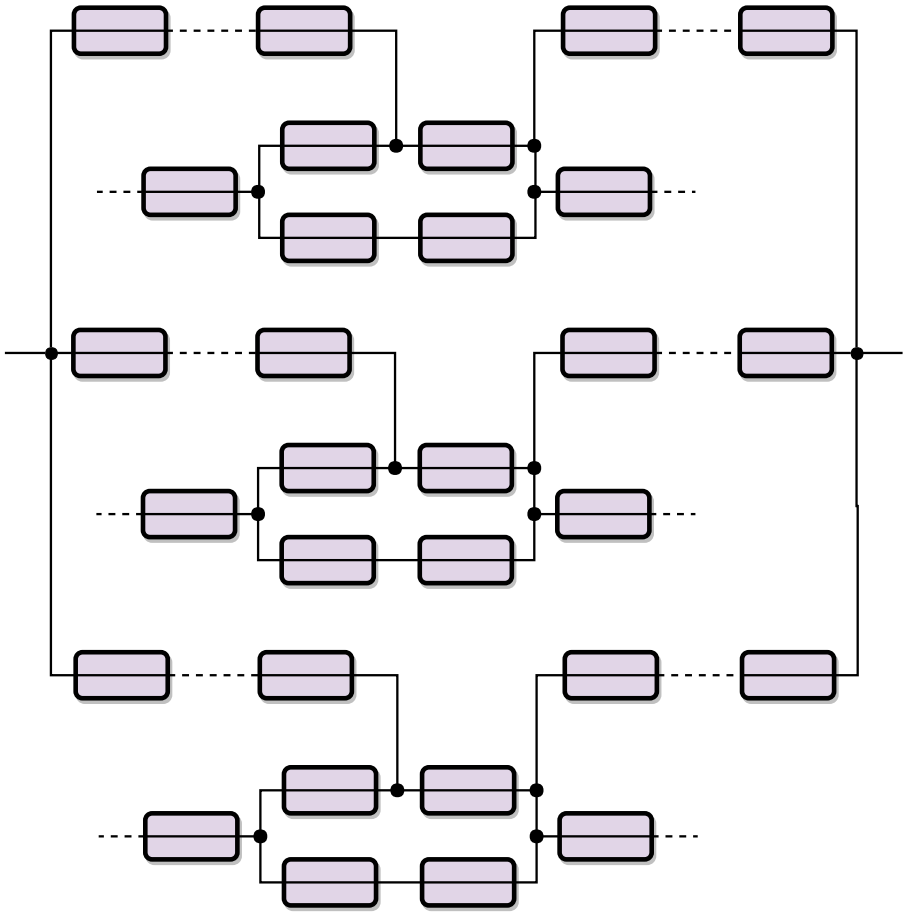

Figure 28 A clause gadget. Each literal is also part of a variable gadget. Each branch has a long series of gadgets so that it takes a large amount of time to traverse.

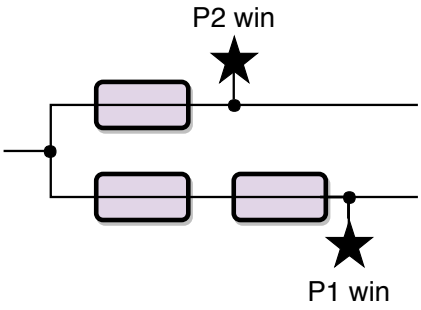

Figure 29 A race gadget. If Player 1 arrives at the left immediately before Player 2, each player ends up on one of the right exits. Otherwise, the player who arrives first wins.

7 Team Bounded Motion Planning

In this section we characterize the complexity of team imperfect information motion planning games with DAG gadgets. Since DAG gadgets are inherently bounded, the problem is in NEXPTIME, shown in Lemma 29. We go on to show in Lemma 30 that any nontrivial DAG gadget is NEXPTIME-complete by first giving a reduction from dependency quantified boolean formula (DQBF) for the single-use gadget. We then show that this proof adapts for single-use one-way gadgets. Since all DAG gadgets with at least one transition contain at least one of these, we achieve hardness for all such DAG gadgets.

▶ **Lemma 29.** *Team motion planning with any set of DAG gadgets is in NEXPTIME.*

Proof. A **partial history** for a player is the sequence of visible gadget states and moves made by that player, up to some point in the game. A **strategy** is a family of functions, one for each White player, that assign to each possible partial history a legal move from the position at the end of the partial history.

Since the gadget is a DAG, the game lasts a polynomial number of turns. Each player has polynomially many choices for each move, so there are only exponentially many possible sequences of moves, and only exponentially many possible partial histories for each player. Thus a strategy can be written in an exponential amount of space.

To determine whether White has a forced win in the team game, first nondeterministically pick a strategy. Then, for each possible sequence of moves the Black players could make, simulate the game with the White players following the strategy. If Black ever wins, reject; if White always wins, accept. This nondeterministic algorithm accepts if and only if there is some strategy White can use to force a win. The algorithm runs in exponential time because there are exponentially many sequences of moves the Black players might make, and the game for each such sequence takes a polynomial amount of time to simulate. Thus the algorithm decides the team game on systems of the gadget in NEXPTIME. ◀

▶ **Lemma 30.** *Team motion planning with the single-use bidirectional gadget is NEXPTIME-complete.*

Proof. Containment in NEXPTIME follows from Lemma 29. For NEXPTIME-completeness, we reduce from dependency quantified boolean formulas (DQBF). See Appendix A.2 for a definition of DQBF. In this reduction White represents the existential variables and Black represents the universal variables.

The reduction uses the same gadgets as that in Lemma 26, except that the clause gadget is modified as in Figure 30. This allows the White player checking the formula to try each literal, and return to the start of the clause gadget if the literal is false. This is necessary because the White player cannot see the state of the literals until arriving at them. For variable gadgets, we do not include the portion with a win gadget for Player 2 (the rightmost quarter or so in Figure 27), since we no longer want players to alternate choosing variables.

We construct the system of gadgets as follows. The overall structure is shown in Figure 31. For each set of variables $\vec{x}_1$, $\vec{x}_1$, $\vec{y}_1$, and $\vec{y}_2$, there is a corresponding set of variable gadgets (without the win gadget component) connected in series, followed by a race gadget. For simplicity, we will put C forks in each branch of each variable, where the formula has C clauses, though usually we need much fewer. Then each variable gadget takes $k = 3C + 1$ turns to traverse. We call the top path of a race gadget the **fast exit** and the bottom path the **slow exit**, since (in normal play) the first (second) player to arrive leaves through the fast (slow) exit. It will become clear which player each win gadget in a race gadget is for.

The turn order will be B, then W_1, then W_2. Both B and W_1 start at the beginning of the variable gadgets for $\vec{x}_1$. W_2 starts next to a delay line of length d_1. The fast exit of the race gadget for $\vec{x}_1$ and the end of this delay line both connect to the beginning of the $\vec{x}_2$ variable gadgets. The slow exit connects to a delay line of length d_2. The end of this delay line and the fast exit of the $\vec{x}_2$ race gadget connect to the beginning of the $\vec{y}_1$ variable gadgets, and the slow exit connects to a delay line of length d_3. The end of this delay line is connected to the *slow* exit of the $\vec{y}_1$ race gadget and the beginning of the $\vec{y}_2$ variable gadgets. The fast exit of the $\vec{y}_1$ race gadget is connected to yet another delay line of length d_4. The slow exit of the $\vec{y}_2$ race gadget is connected to a long delay line of length d_5 followed by a win gadget for B, and the fast exit is connected to a longer delay line of length $d_5 + 3$.

This all serves to accomplish the following. First, B chooses the assignment for $\vec{x}_1$ accompanied by W_1, so W_1 learns the assignment. Then B and W_1 are separated, and B assigns $\vec{x}_2$ accompanied by W_2. Next, W_1 chooses $\vec{y}_1$ accompanied by B, and finally W_2 chooses $\vec{y}_2$ accompanied by B. The delays d_1 through d_4 are chosen so that the White players arrive at exactly the right time; we have $d_1 = |\vec{x}_1|k + 1$, $d_2 = |\vec{x}_2|k - 1$, $d_3 = |\vec{y}_1|k$, and $d_4 = |\vec{y}_2|$. If a player deviates during variable assignment, they will arrive at their next race gadget too late, and lose.

The end of the final delay line for W_1, of length d_4, is connected to the first clause gadget, and the clause gadgets are connected in series corresponding to the clauses of the formula. The delay lines in each branch of each clause gadget have length Vk, where V is the number of variables; this ensures that if a player enters one of the delay lines during variable selection, an opponent will reach a race gadget and win before they accomplish anything. The end of the last clause gadget is connected to a win gadget for W_1. When W_1 reaches each clause gadget, they try the literals one at a time. When they cross the delay line to the fork, if the fork is traversable, they move on to the next clause. Otherwise they return through the other delay line and try the next literal. Each clause takes up to $6Vk + 1$ turns to cross.

If the formula is satisfied, W_1 eventually gets through all the clauses and wins. Otherwise, B wins after walking through their delay line of length d_5, which we can set to $C(6Vk+1)+1$.

We have seen that no player or team can benefit by deviating from normal play, and normal play is equivalent to the game corresponding to the DQBF. Thus White has a forced win if and only if the DQBF is true. ◀

▶ **Lemma 31.** *Team motion planning with the single-use one-way gadget is NEXPTIME-complete.*

Proof. The reduction in Lemma 30 still works when we replace each single-use bidirectional gadget with a one-way bidirectional gadget. We have to be a bit more careful than in Lemma 27: of the two paths in a clause gadget from the beginning to a fork, we need one path to point to the right and the other to point to the left, allowing W_1 to return from that fork. All other gadgets point to the right. ◀

▶ **Corollary 32.** *Team motion planning with any nontrivial DAG gadget is NEXPTIME-complete.*

Proof. Every DAG gadget has a single-use transition, which may be either bidirectional or one-way. Both cases are shown to be NEXPTIME-hard in Lemmas 30 and 31. Containment in NEXPTIME is Lemma 29. ◀

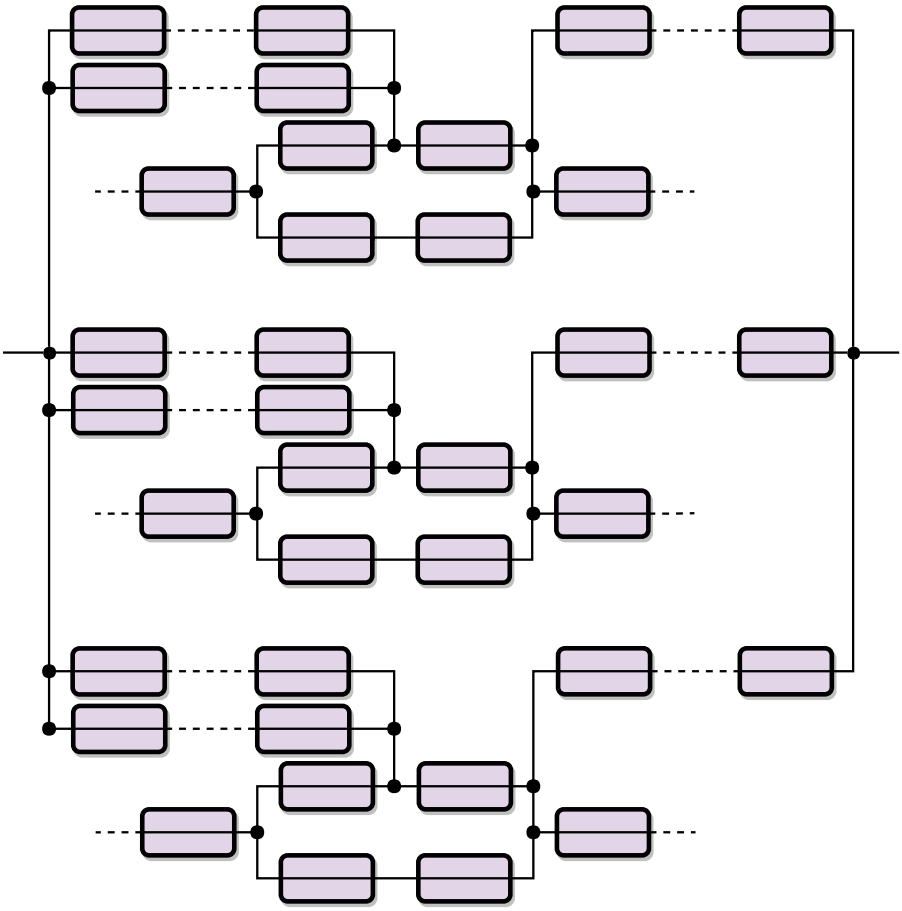

Figure 30 A clause gadget for team games. There are now two paths from the entrance of the clause to each fork, so the White player traversing the clause can return if they discover the fork is not traversable.

8 Applications

In this section we give examples of some known hard problems whose proofs can be simplified by using this motion planning framework.

8.1 PushPull-1F

In this section, we use the results of this paper to provide a simple proof that a Sokoban variant called PushPull-1F is PSPACE-hard, by reducing from motion planning in planar systems of locking 2-toggles (Section 2.3). This problem, and many related problems, were considered in [5] and were shown to be PSPACE-complete in [15] by a reduction from nondeterministic constraint logic; our reduction is much more straightforward using the infrastructure of the gadget framework.

▶ **Definition 33.** *In* ***PushPull-1F****, there is a square grid containing movable blocks, fixed blocks, an agent, and a goal location. The agent can freely move through empty squares, but can't move through blocks. The agent can push or pull one movable block at a time. The agent wins by reaching the goal location. The corresponding decision problem is whether a given instance of PushPull-1F is winnable.*

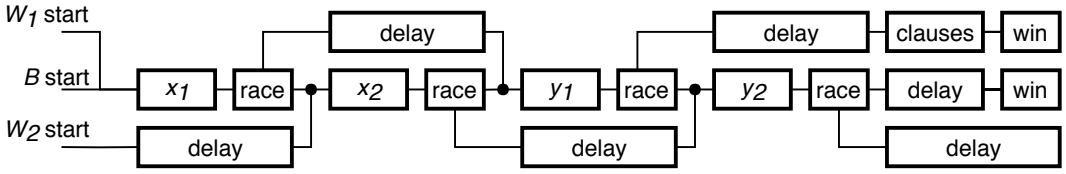

Figure 31 The high-level structure of the DQBF reduction.

In the notation "PushPull-1F", "PushPull" indicates that the agent can both push and pull, "1" indicates the number of blocks which can be moved at a time, and "F" indicates the existence of fixed blocks [5].

▶ **Theorem 34** ([15]). *PushPull-kF is PSPACE-hard for* $k \geq 1$.

Proof. We reduce from 1-player planar motion planning with locking 2-toggles, shown PSPACE-complete in Theorem 10. The (planar) connection graph is implemented using tunnels built with fixed blocks, and the agent and target location are placed appropriately. It suffices to build a gadget which behaves as a locking 2-toggle.

Such a gadget is shown in Figure 32. The two tunnels, currently both traversable, go from top to left and right to bottom. They interact in the center, where traversing either tunnel requires pushing a block into the middle square, which blocks the other tunnel. This is surrounded by four 1-toggles, which prevent additional traversals which aren't possible in a locking 2-toggle. Each 1-toggle is a room with 3 blocks, which can only be entered on one side. Upon entry, the agent can move the blocks to reveal the other exit, but doing so requires blocking the entrance taken, which flips the 1-toggle. ◀

8.2 Mario Kart

Mario Kart is a popular Nintendo racing game whose computational complexity was considered in [3] which showed NP-completeness for 1 player races and PSPACE-completeness for 2 player races with reductions from 3SAT and QSAT respectively. Using results from this paper, the 2 player proof now only needs a single, simple gadget, reducing a several page proof to a paragraph.

▶ **Theorem 35.** *Deciding if a player can force a win in two player Mario Kart is PSPACE-hard.*

Proof. A single-use one-way gadget can be constructed from a ramp and Dash Mushroom in Mario Kart. We place a ramp before a gap in the track long enough that a racer going at the normal maximum speed will not be able to make the jump and will fall onto another track that will take a long time to reach the finish line, ensuring they lose. However, this gap is small enough that, if the player uses a Dash Mushroom before, the increase in speed will allow them to make the jump. We put a single Dash Mushroom power-up before each ramp, ensuring the first racer to arrive can pick up the item and use it to cross the gap. To ensure a racer does not pick up the item and then keep it for later use, we precede the mushroom and ramp with a one-way gadget implemented by a long-fall. Along with the trivial existence of crossovers and the finish line as a location based win condition, Mario Kart is PSPACE-hard by Theorem 27. ◀

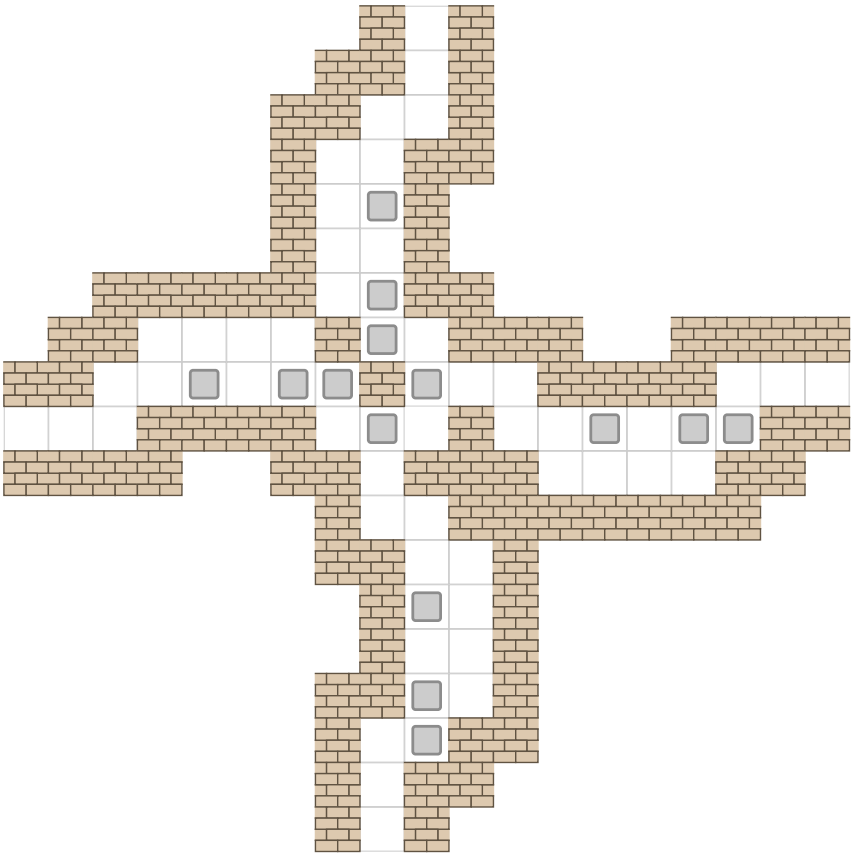

Figure 32 A locking 2-toggle in PushPull-1F.

9 Open Problems

This paper characterizes the complexity of two large classes of gadgets (DAG gadgets and reversible deterministic gadgets). Ideally, we could fully characterize the complexity of motion planning for every gadget type (and set of gadgets) as being easy or hard. There are many specific steps we might take towards this grand goal:

1. Is 2-player motion planning with 1-toggles EXPTIME-complete? This would complete our characterization for 2-player games with k-tunnel reversible deterministic gadgets. As an easier target, we could prove PSPACE-hardness, perhaps by adapting the 2-player proof for one-way closing gadgets.
2. Can we extend our characterizations of k-tunnel reversible deterministic gadgets to remove one of these restrictions? Specifically, non-tunnel gadgets, non-reversible gadgets, and nondeterministic gadgets are all interesting (and challenging) goals.
3. Which motion planning problems remain hard on planar systems of gadgets, like we proved for 1-player reversible deterministic? Are there any examples of gadgets where the planar version of the motion planning problem has a different complexity?

While we focused in this paper on general theory building, we can also explore the application of this motion planning framework to analyze the complexity of specific problems of interest. We conjecture that the results of this paper simplify many past hardness proofs, which can now be reduced to one or two figures showing how to build any hard gadget

according to our characterization, and how to connect gadgets together. See the hardness surveys [8, 11, 12, 4] for a large family of candidate problems. Of course, we also hope that this framework will enable the solution of many open problems in this space.

A Problem Definitions

In this appendix, we give formal definitions for the known hard problems used in this paper. In the paper we use single player, 2-player, and team imperfect information versions of Constraint Logic and Boolean Formula Games. The exact problems are specified in the following sections.

A.1 Constraint Logic

Constraint Logic [7, 11] is a uniform family of games – one-player, two-player, or team, with both bounded and unbounded variants – with the appropriate complexity in each case (as in Table 1). We will only describe the unbounded variants of Constraint Logic, as we use formula games for our bounded reductions. We also do not describe zero-player Constraint Logic, as we do not need it here.

In general, a **constraint graph** is an undirected maximum-degree-3 graph, where each edge has a weight of 1 (called a red edge) or 2 (called a blue edge). A **legal configuration** of a constraint graph is an orientation of the edges such that, at every vertex, the total incoming weight is at least 2. A **legal move** in a legal configuration of a constraint graph is a reversal of a single edge that results in another legal configuration.

In **1-player** Constraint Logic (also called **Nondeterministic Constraint Logic or NCL**), we are given a legal configuration of a constraint graph and a target edge e, and we want to know whether there is a sequence of legal moves ending with the reversal of target edge e. In this game, two types of vertices suffice for PSPACE-completeness: an OR vertex has exactly three incident blue edges, and an AND vertex has exactly one incident blue edge and exactly two incident red edges. We can also assume that each OR vertex can be assigned two "input" edges, and the overall construction is designed to guarantee that at most one input edge is incoming at any time; thus, we only need a "Protected OR" gadget which does not handle the case of two incoming inputs. Furthermore, the problem remains PSPACE-complete for planar constraint graphs.

In **2-player Constraint Logic (2CL)**, each edge of a constraint graph is also colored either black or white, and two players named Black and White alternate making valid moves where each player can only reverse an edge of their color. Given a legal configuration of a constraint graph, a target white edge for White, and a target black edge for Black, the goal is to determine whether White has a forced win, i.e., a strategy for reversing their target edge before Black can possibly reverse their target edge. In this game, six types of vertices suffice for EXPTIME-completeness: AND and OR vertices where all edges are white, AND vertices where all edges are black, AND vertices where the blue edge is white and one or both of the red edges are black, and degree-2 vertices where exactly one edge is black.

In **Team Private Constraint Logic (TPCL)**, there are two players on the White team and one player on the Black team, who play in round-robin fashion. In each move, the player can reverse up to a constant number k of edges of their color. Each player has a target edge to reverse, and can see the orientation of a specified set of edges, including edges of their own color and edges incident to those edges. Given a legal configuration of a constraint graph, the goal is to determine whether the White team has a forced win; i.e., whether one of the White players can reverse their target edge before Black can. In this game, all possible black/white colorings of AND and OR vertices suffice for RE-completeness. (Only undecidability has been claimed before, but RE-completeness follows by the same arguments.)

A.2 Formula Games

A **3-CNF formula** is a boolean formula φ of the form $C_1 \wedge \cdots \wedge C_k$, where each **clause** C_i is the disjunction of up to three **literals**, which are variables or their negations. An **assignment** for such a formula specifies a truth value for each variable, and is **satisfying** if the formula is true under the assignment.

In **3SAT**, we are given a 3-CNF formula, and we want to know whether it has a satisfying assignment. 3SAT is NP-complete [10].

A **partially quantified boolean formula** is a formula of the form $Q_1 x_1 : \cdots : Q_n x_n : \varphi$, where Q_i is one of the quantifiers $\forall$ or $\exists$, x_i is a (distinct) variable, and φ is a 3-CNF formula. An **assignment** for a partially quantified boolean formula specifies a truth value for each variable in φ that is not any x_i, called **free** variables. For a partially quantified boolean formula $\psi = Q_1 x_1 : \cdots : Q_n x_n : \varphi$ with $n > 0$, let $\psi' = Q_2 x_2 : \cdots : Q_n x_n : \varphi$. Given an assignment S for ψ, define assignments $S + x_1$ and $S + \neg x_1$ for ψ' which assign the same truth value as S to each free variable of φ and assign "true" and "false" to x_1, respectively. The truth value of ψ under S is defined recursively as follows:

- If $n = 0$ (so $\psi = \varphi$), ψ is true under S if and only if φ is true under S.
- If $n > 0$ and $Q_1 = \forall$, ψ is true under S if and only if ψ' is true under both $S + x_1$ and $S + \neg x_1$.
- If $n > 0$ and $Q_1 = \exists$, ψ is true under S if and only if ψ' is true under at least one of $S + x_1$ and $S + \neg x_1$.

A **quantified boolean formula** is a partially quantified boolean formula with no free variables. A quantified boolean formula has only one assignment (which is empty), so we say it is true if it is true under this unique assignment.

The truth value of a quantified boolean formula $\psi = Q_1 x_1 : \cdots : Q_n x_n : \varphi$ is equivalent to whether $\exists$ has a forced win in the following game: two players $\exists$ and $\forall$ choose an assignment for φ by assigning variables in the order they are quantified, with player Q_i choosing the truth value of x_i. $\exists$ wins if the assignment satisfies φ.

In **QBF**, we are given a (fully) quantified boolean formula, and we want to know whether it is true. QBF is PSPACE-complete, even if we restrict to formulas with alternating quantifiers beginning with $\exists$. This restriction is equivalent to that $\exists$ and $\forall$ take alternating turns, with $\exists$ going first [10].

A **dependency quantified boolean formula** is a formula of the form $\forall x_1 : \cdots : \forall x_m : \exists y_1(s_1) : \cdots : \exists y_n(s_n) : \varphi$, where x_i and y_j are (distinct) variables, φ is a 3-CNF formula, and s_j is a subset of $\{x_i \mid i \leq m\}$. We also require that every variable in φ is some x_i or y_j (φ has no free variables). A **strategy** for a dependency quantified boolean formula is a collection of functions $f_j : \{\text{true}, \text{false}\}^{s_j} \to \{\text{true}, \text{false}\}$ for $j = 1, \ldots, n$. A strategy **solves**

a dependency quantified boolean formula if for every map $S : \{x_i \mid i \leq m\} \to \{\text{true}, \text{false}\}$, the assignment given by $x_i \mapsto S(x_i)$ and $y_j \mapsto f_j(S|_{s_j})$ satisfies φ. Intuitively, y_j is only allowed to depend on the variables in s_j. A quantified boolean formula is a special case of a dependency quantified boolean formula, where each $s_j = \{x_i \mid i < k\}$ for some k. A dependency quantified boolean formula is **true** if there is a strategy that solves it.

The truth value of a dependency quantified boolean formula $\forall x_1 : \cdots : \forall x_m : \exists y_1(s_1) : \cdots : \exists y_n(s_n) : \varphi$ is equivalent to whether the $\exists$ team has a forced win in the following game, which puts a team of one player $\forall$ against a team of players $\exists_j$ for $j = 1, \ldots, n$: $\forall$ picks a truth value for each x_i. $\exists_j$ sees the truth value for each element of s_j (and nothing else) and picks a truth value for y_j. The $\exists$ team wins if the resulting assignment satisfies φ.

In the **DQBF** problem, we are given a dependency quantified boolean formula, and we want to know whether it is true. DQBF is NEXPTIME-complete even if we restrict to formulas of the form $\forall \vec{x}_1 : \forall \vec{x}_2 : \exists \vec{y}_1(\vec{x}_1) : \exists \vec{y}_2(\vec{x}_2) : \varphi$, where $\vec{x}_i$ and $\vec{y}_i$ may contain multiple variables, and each variable in $\vec{y}_i$ can depend on all the variables in $\vec{x}_i$. This restriction is equivalent to requiring that the $\exists$ team has two players who each choose multiple variables, and they see disjoint exhaustive subsets of the variables $\forall$ picks [16].

Computational Pseudorandomness, the Wormhole Growth Paradox, and Constraints on the AdS/CFT Duality

Abstract

The AdS/CFT correspondence is central to efforts to reconcile gravity and quantum mechanics, a fundamental goal of physics. It posits a duality between a gravitational theory in Anti de Sitter (AdS) space and a quantum mechanical conformal field theory (CFT), embodied in a map known as the AdS/CFT dictionary mapping states to states and operators to operators. This dictionary map is not well understood and has only been computed on special, structured instances. In this work we introduce cryptographic ideas to the study of AdS/CFT, and provide evidence that either the dictionary must be exponentially hard to compute, or else the quantum Extended Church-Turing thesis must be false in quantum gravity.

Our argument has its origins in a fundamental paradox in the AdS/CFT correspondence known as the wormhole growth paradox. The paradox is that the CFT is believed to be "scrambling" – i.e. the expectation value of local operators equilibrates in polynomial time – whereas the gravity theory is not, because the interiors of certain black holes known as "wormholes" do not equilibrate and instead their volume grows at a linear rate for at least an exponential amount of time. So what could be the CFT dual to wormhole volume? Susskind's proposed resolution was to equate the wormhole volume with the quantum circuit complexity of the CFT state. From a computer science perspective, circuit complexity seems like an unusual choice because it should be difficult to compute, in contrast to physical quantities such as wormhole volume.

We show how to create pseudorandom quantum states in the CFT, thereby arguing that their quantum circuit complexity is not "feelable", in the sense that it cannot be approximated by any efficient experiment. This requires a specialized construction inspired by symmetric block ciphers such as DES and AES, since unfortunately existing constructions based on quantum-resistant one way functions cannot be used in the context of the wormhole growth paradox as only very restricted operations are allowed in the CFT. By contrast we argue that the wormhole volume is "feelable" in some general but non-physical sense. The duality between a "feelable" quantity and an "unfeelable" quantity implies that some aspect of this duality must have exponential complexity. More precisely, it implies that either the dictionary is exponentially complex, or else the quantum gravity theory is exponentially difficult to simulate on a quantum computer.

While at first sight this might seem to justify the discomfort of complexity theorists with equating computational complexity with a physical quantity, a further examination of our arguments shows that any resolution of the wormhole growth paradox must equate wormhole volume to an "unfeelable" quantity, leading to the same conclusions. In other words this discomfort is an inevitable consequence of the paradox.

Abstract

We consider submodular function minimization in the oracle model: given black-box access to a submodular set function $f : 2^{[n]} \to \mathbb{R}$, find an element of $\arg\min_S\{f(S)\}$ using as few queries to $f(\cdot)$ as possible. State-of-the-art algorithms succeed with $\tilde{O}(n^2)$ queries [13], yet the best-known lower bound has never been improved beyond n [6].

We provide a query lower bound of $2n$ for submodular function minimization, a $3n/2 - 2$ query lower bound for the non-trivial minimizer of a symmetric submodular function, and a $\binom{n}{2}$ query lower bound for the non-trivial minimizer of an asymmetric submodular function.

Our $3n/2 - 2$ lower bound results from a connection between SFM lower bounds and a novel concept we term the *cut dimension* of a graph. Interestingly, this yields a $3n/2 - 2$ cut-query lower bound for finding the global mincut in an undirected, weighted graph, but we also prove it cannot yield a lower bound better than $n + 1$ for s-t mincut, even in a directed, weighted graph.

1 Introduction

Submodular function minimization (SFM) is a classic algorithmic problem with numerous applications (e.g. [1, 11, 12, 14]): given black-box access to a submodular[1] function $f : 2^{[n]} \to \mathbb{R}$, find an element of $\arg\min\{f(S)\}$. Due to its ubiquity within TCS and without, the problem has received substantial attention over the past four decades within various communities. Seminal work of Grötschel, Lovasz, and Schrijver first established that a minimizer can be found in poly-time [5], and after a long series of improvements the state-of-the-art now requires $\tilde{O}(n^2)$ value queries to $f(\cdot)$ and $\tilde{O}(n^3)$ additional overhead.

[1] $f(\cdot)$ is submodular if $f(X \cup Y) + f(X \cap Y) \leq f(X) + f(Y)$ for all sets X, Y. This is equivalent to $f(S \cup T \cup \{i\}) - f(S \cup T) \leq f(S \cup \{i\}) - f(S)$ for all S, T, i (called *diminishing marginal returns*).

Despite remarkable progress on the algorithmic front, shockingly few *lower bounds* on submodular function minimization are known. It is perhaps unsurprising that computational lower bounds are elusive, but *even query lower bounds are virtually non-existent.* Indeed, state-of-the-art query lower bounds for SFM have remained stagnant at exactly n for the past decade [6]. Our main results are new query lower bounds for three variants of SFM. We briefly provide the formal problem statements and our main results below, followed by an overview of context and related work.

▶ **Definition 1** (Query Complexity of Submodular Function Minimization). *Given as input black-box access to a submodular function $f(\cdot)$ over n elements, output an element of* $\arg\min_S\{f(S)\}$*, along with* $\min_S\{f(S)\}$*. The* query complexity *of SFM is equal to the minimum $q(\cdot)$ such that a deterministic algorithm solves SFM on all instances of n elements with at most $q(n)$ queries.*

- *If $f(\cdot)$ is further assumed* symmetric*, i.e. $f(S) = f([n] \setminus S)$ for all S, this is* Symmetric SFM*.*
- *If we ask for* $\arg\min_{S \notin \{\emptyset,[n]\}}\{f(S)\}$*, this is* Non-Trivial SFM *(we will also use both qualifiers).*[2]

As a representative problem to have in mind, imagine a graph on n nodes with positive edge weights and define $f(S)$ to be the weight of all edges leaving set S (the value of cut S). Then $f(\cdot)$ is submodular, and non-trivial symmetric SFM would count the number of *cut queries* needed to find the mincut. If you seek the minimum s-t cut (and adjust notation so that $f(S)$ is equal to the weight of all edges leaving $S \cup \{s\}$), then this is standard SFM (because it is valid to output $\emptyset$, which implies that the mincut is s). If you seek the global mincut in a directed graph, then this is an instance of Non-Trivial SFM (because it is now invalid to output $\emptyset$). If you seek the global mincut in an undirected graph, then this is an instance of Non-Trivial Symmetric SFM (because it doesn't matter which side of the cut is sending versus receiving). Our main results are below.

▶ **Theorem 2** (Main Results). *The following lower bound the query complexity of SFM:*

- *The query complexity of SFM is at least $2n$.*
- *The query complexity of Non-Trivial Symmetric SFM is at least $3n/2 - 2$.*
- *The query complexity of Non-Trivial SFM is at least $\binom{n}{2}$.*

1.1 New Technique: The Cut Dimension

Our SFM and Non-Trivial SFM lower bounds are direct constructions, and we defer all related intuition and technical details to the corresponding sections. Our Non-Trivial Symmetric SFM lower bound, however, derives from a new framework based on the *cut dimension* of graphs.

▶ **Definition 3** (Global Cut Dimension, special case of Definition 11). *Let G be a directed graph with m edges, and let S be a subset of nodes. Define $\vec{v}^S$ be the vector in $\mathbb{R}^m$ with $v_e^S = 1$ iff the edge e has left endpoint in S and right endpoint not in S (and $v_e^S = 0$ otherwise). Then the* cut dimension *of G is the dimension of span($\{\vec{v}^S,\ S$ is a global mincut$\}$). We also consider the following variants:*

[2] Indeed, note that Symmetric SFM (without the Non-Trivial qualifier) is trivial, as $\emptyset$ (or $[n]$) is always a solution.

- *If G is undirected, then $v_e^S = 1$ iff the edge e has one endpoint in S and the other not in S.*
- *If we seek the min s-t cut, then $v_e^S = 1$ iff the edge e has left endpoint in $S \cup \{s\}$ and right endpoint not in $S \cup \{s\}$. We also take the dimension over min s-t cuts instead of global mincuts. In this case, we call this the s-t Cut Dimension.*

Our main result concerning the cut dimension connects it to SFM lower bounds:

▶ **Theorem 4** (Special case of Theorem 15). *If an undirected graph exists with Global Cut Dimension d, then the query complexity of Non-Trivial Symmetric SFM is at least d.*

If a graph exists with s-t Cut Dimension d, then the query complexity of SFM is at least d.

If a directed graph exists with Global Cut Dimension d, then the query complexity of Non-Trivial SFM is at least d.

Interestingly, we also establish that the Cut Dimension is a *equivalent* to the best achievable lower bounds based on graphs via a canonical perturbation approach. Our $3n/2 - 2$ lower bound for Non-Trivial Symmetric SFM follows immediately from Theorem 4 and the construction of an undirected graph with Global Cut Dimension $3n/2 - 2$. We also establish that every graph has s-t Cut Dimension at most $n + 1$, meaning this approach is useful for Non-Trivial SFM but not SFM.

1.2 Related Work

The first poly-time (and strongly poly-time) algorithms for SFM were given by [5] using the Lovasz extension and the Ellipsoid algorithm [10]. A substantial series of improvements followed over the subsequent four decades [3, 18, 4, 8, 7, 19, 15, 9] The state-of-the-art is an $\tilde{O}(n^2)$ upper bound on the query complexity of SFM [13], an $O(n^3)$ upper bound on the query complexity of Non-Trivial Symmetric SFM [16], and an $\tilde{O}(n^3)$ upper bound on the query complexity of Non-Trivial SFM [13].[3]

Despite this substantial progress on upper bounds, the only unconditional query lower bound is just n (which is surprisingly non-trivial to establish) [6]. [2] give a construction which requires $\Omega(n)$ *queries to the Lovasz extension* (if the algorithm can only query the Lovasz extension), but one can find the minimizer in their construction by simply querying all n singletons.

Our Non-Trivial Symmetric SFM lower bound uses the cut function in graphs. Recent work of [17] establishes that this particular instance of Non-Trivial Symmetric SFM (in unweighted graphs) can be solved by a randomized algorithm in $\tilde{O}(n)$ queries, but our techniques are unrelated.

1.3 Roadmap

Section 2 provides our $2n$ lower bound for SFM, which is a direct construction. Section 3 proves (a generalization of) Theorem 4 and provides a graph with Global Cut Dimension $3n/2 - 2$, yielding our $3n/2 - 2$ lower bound for Non-Trivial Symmetric SFM. Section 4 provides our $\binom{n}{2}$ lower bound for Non-Trivial SFM, which is also a direct construction.

Appendix B contains auxiliary claims concerning cut queries in graphs (i.e., it is impossible to learn precisely a directed graph using cut queries, what can you learn?) which are not necessary for our lower bounds, but likely useful for future work. Appendix A contains one omitted proof.

[3] The final bound follows by a reduction from Non-Trivial SFM to SFM incurring a blowup of $2n$ (for all elements i, run SFM only over sets containing i and not containing $i + 1$, and then only over sets containing i and not $i - 1$).

2 A $2n$ Query Lower Bound for SFM

This section proves our lower bound on SFM.

▶ **Theorem 5.** *The query complexity of SFM is at least* $2n$.

Let us first provide intuition for our construction. We start with an arbitrary permutation σ on $[n]$, and define the *important sets* R_i for $0 \leq i \leq n$ by $R_i := \{\sigma(1), \sigma(2), ..., \sigma(i)\}$ for each $i \in [n] \cup \{0\}$. Observe that there is exactly one important set of each size from 0 to n. These important sets will be the potential minimizers. Intuitively, we will define our function such that: (a) any algorithm must query at least $n-1$ unimportant sets to learn the important sets, and (b) any algorithm must query all $n+1$ important sets to learn the minimizer. In detail:

- Let σ be an arbitrary permutation on $[n]$.
- Define $R_i := \{\sigma(1), \ldots, \sigma(i)\}$ for each $i \in [n] \cup \{0\}$.
- For each $i \in [n] \cup \{0\}$, let $c_i \in \{0, 1\}$.
- Define the function $f^{\vec{c}}_{\sigma}(\cdot)$ such that (below, $j(S)$ denotes the maximum j such that $R_j \subseteq S$):

$$f^{\vec{c}}_{\sigma}(S) = \begin{cases} -c_i & \text{if } S = R_i \text{ for some } 0 \leq i \leq n \\ (|S| - j(S)) \cdot (n + 2 - j(S)) & \text{else} \end{cases}$$

That is, $f^{\vec{c}}_{\sigma}(\cdot)$ is defined to be non-negative on the unimportant sets, and non-positive on the important sets. Intuitively, queries to unimportant sets give information regarding σ, and queries to important sets give information regarding $\vec{c}$. It is not obvious, but straightforward to establish that $f^{\vec{c}}_{\sigma}(\cdot)$ is submodular for all $\sigma, \vec{c}$. The proof of Lemma 6 appears in Appendix A.

▶ **Lemma 6.** *For all* $\sigma, \vec{c}$, $f^{\vec{c}}_{\sigma}$ *is submodular.*

We now provide a complete proof that deterministic algorithms must make $2n$ queries for functions of the form $f^{\vec{c}}_{\sigma}(\cdot)$. We define an adversary which adaptively sets $\sigma, \vec{c}$ as queries are made:

- Initialize $\sigma, \vec{c}$ to be undefined.
- Let i denote the maximum j such that $\sigma(j)$ is defined (so initially $i = 0$).
- When a new query, S, is made:
  1. If $S = R_j$, for some $j \leq i$, answer 0 and set $c_j = 0$. Call this an *important query*.
  2. If $R_i \not\subseteq S$, $j(S)$ is defined. Answer $(|S| - j(S)) \cdot (n + 2 - j(S))$. Call this a *useless query*.
  3. If $R_i \subset S$, $j(S)$ is not yet defined. Pick any $j \notin S$ (such a j must exist as $S \neq R_n$) and set $\sigma(i+1) = j$.[4] Now $j(S) := i$, so answer $(|S| - i) \cdot (n + 2 - i)$. Call this a *decoy query*.
- If the algorithm terminates after $n+1$ (distinct) important queries, σ and $\vec{c}$ are fully defined.
- If the algorithm has made fewer than $n+1$ (distinct) important queries, let x denote the algorithm's guess for the minimum value.
  1. If $x = 0$, set all undefined $c_i := 1$ and complete σ arbitrarily (if necessary).
  2. If $x = -1$, set all undefined $c_i := 0$ and complete σ arbitrarily (if necessary).
  3. If $x \notin \{0, -1\}$, complete $\vec{c}, \sigma$ arbitrarily.

[4] Observe also that $j \neq \sigma(\ell)$ for any $\ell \leq i$, as $R_i \subset S$.

Theorem 5 will follow by proving that the above adversary is consistent and that the adversary has the power to make multiple (distinct) minima unless the algorithm has made at least $n-1$ decoy queries and $n+1$ important queries.

▶ **Observation 7.** *The adversary answers all queries in a way that is consistent with some* $f^{\vec{c}}_{\sigma}(\cdot)$.

Proof. Observe that the adversary answers all queries to R_j with 0, so this is always consistent. Further observe that whenever an unimportant set is queried, either the answer is already determined by σ (and therefore consistent), or one new output of σ is fixed so that the answer is now determined by σ (and therefore consistent now and forever). The precise definition of $f^{\vec{c}}_{\sigma}(\cdot)$ is important for the final claim: as soon as we know that $\sigma(i+1) \notin S$, this fixes the value of $f^{\vec{c}}_{\sigma}(\cdot)$.

Finally, observe that the completion step is also consistent with all previous queries, as they are completely defined by the partial definition of $\sigma, \vec{c}$. ◀

▶ **Lemma 8.** *Algorithms cannnot make* $n+1$ *distinct important queries without* $n-1$ *decoy queries.*

Proof. Observe that each decoy query increases i by one. Observe that the only distinct important queries that can be made are $\emptyset, [n]$, and $R_1, \ldots, R_i$, for a total of $i+2$. If $i < n-1$, then the distinct possible important queries are also $< n+1$. ◀

▶ **Lemma 9.** *Any algorithm making* $< n+1$ *distinct important queries is wrong.*

Proof. If the guess is $\notin \{0, -1\}$, then the guess is clearly wrong. If the guess is 0, then the completion step makes it so that the minimum is -1, so the guess is wrong. If the guess is -1, then the completion step makes it so that the minimum is 0, so the guess is wrong. ◀

Proof of Theorem 5. Lemmas 9 and 8 together assert that the algorithm must make $n-1$ decoy queries and $n+1$ important queries in order to correctly solve SFM on instances of the form $f^{\vec{c}}_{\sigma}(\cdot)$ against the prescribed adversary. Therefore, a total of $2n$ queries must be made. ◀

We conclude this section by noting that our construction witnesses a lower bound of exactly $2n$ (and no better).

▶ **Proposition 10.** *An SFM algorithm exists making* $2n$ *queries for any function of the form* $f^{\vec{c}}_{\sigma}(\cdot)$.

Proof. First, query the $n-1$ sets $[n] \setminus \{i\}$ for all $i \neq 1$. Observe that $f^{\vec{c}}_{\sigma}([n] \setminus \{i\}) \leq 0$ if and only if $\sigma(n) = i$. Similarly, as $[n] \setminus \{i\}$ is missing only a single element (i), this means that if $\sigma(n) \neq i$ then $f^{\vec{c}}_{\sigma}([n] \setminus \{i\}) = (n - \sigma^{-1}(i)) \cdot (n + 3 - \sigma^{-1}(i))$. So the query to $[n] \setminus \{i\}$ reveals $\sigma^{-1}(i)$, for any i. Therefore, these $n-1$ queries completely reveal σ (because σ is a permutation).

After σ is fully revealed, simply query the $n+1$ important sets to find the minimizer. ◀

3 A $3n/2 - 2$ Query Lower Bound for Non-Trivial Symmetric SFM

We begin this section by providing a generalization the cut dimension, first by providing a class of submodular functions which generalize mincuts in graphs.

3.1 Defining the Generalized Cut Dimension

Consider a ground set of n elements, and a disjoint set of m *hyperedges*. We associate with each $S \subseteq [n]$ (including $S = \emptyset$) a set $h(S) \subseteq [m]$ of hyperedges that are active for S. For example, to capture mincuts in an undirected graph we might have the hyperedges simply be the edges of that graph, and $h(S)$ would denote the edges with one endpoint in S and the other not in S.

To each $i \in [m]$, associate a non-negative weight w_i, and define the function $f(\cdot)$ so that $f(S) := \sum_{i \in h(S)} w_i$. If the active sets $h(\cdot)$ satisfy the following inequality, then it is easy to see that $f(\cdot)$ is submodular (below, $X \overline{\cup} Y$ denotes the multiset union of X and Y, which contains two copies of every element in $X \cap Y$):

$$h(S \cap T) \overline{\cup} h(S \cup T) \subseteq h(S) \overline{\cup} h(T).$$

We call such functions *weight-based*. It is easy to see that cuts in graphs or hypergraphs are weight-based. For such functions, there is a meaningful notion of "dimension" associated with the set of minimizers. For every $S \subseteq [n]$, define the vector $\vec{v}^S \in \mathbb{R}^m$ so that $v_i^S = 1$ if and only if $i \in h(S)$ *and* $w_i > 0$, and $v_i^S = 0$ otherwise. For a set $\mathcal{S}$ of subsets of $[n]$, let $\dim(\mathcal{S})$ denote the dimension of the span (over $\mathbb{R}^m$) of the vectors $\{\vec{v}^S\}_{S \in \mathcal{S}}$. We now define the Generalized Cut Dimension:

▶ **Definition 11** (Generalized Cut Dimension)**.** *Let $f(\cdot)$ be weight-based. Then the* Generalized Cut Dimension *of $f(\cdot)$ is equal to dim*$(\arg\min_S\{f(S)\})$*. The* Generalized Non-Trivial Cut Dimension *of $f(\cdot)$ is dim*$(\arg\min_{S \notin \{\emptyset,[n]\}}\{f(S)\})$*.*

We will call a weight-based function symmetric if $h(S) = h([n] \setminus S)$ – it is clear that the resulting submodular function is symmetric.

3.2 Connecting Generalized Cut Dimension to Query Complexity

In this section, we establish the *equivalence* of Generalized Cut Dimension to a canonical "perturbation" approach for lower bounding the query complexity.

▶ **Definition 12** (Perturbation Bound)**.** *Starting from a (symmetric, if desired) weight-based submodular function $f(\cdot)$ with weights $\vec{w}$ and (non-trivial, if desired) minimizers $\mathcal{M}_f$, pick a sufficiently small $\varepsilon > 0$ so that every $\vec{w}'$ with $w'_i \in [(1-\varepsilon)w_i, (1+\varepsilon)w_i]$ induces a (symmetric, if desired) weight-based submodular function $g(\cdot)$ with (non-trivial, if desired) minimizers $\mathcal{M}_g \subseteq \mathcal{M}_f$. Let $\mathcal{G}(f)$ denote the set of all (symmetric, if desired) weight-based functions with $w'_i \in [(1-\varepsilon)w_i, (1+\varepsilon)w_i]$.*

If it is the case that, for any set of $q-1$ queries to f, there exists a $g \in \mathcal{G}(f)$ consistent with those queries such that $\min_S\{g(S)\} \neq \min_S\{f(S)\}$, we say that f witnesses a (Symmetric) Perturbation Bound *of q (if there is a $g(\cdot) \in \mathcal{G}(f)$ with $\min_{S \notin \{\emptyset,[n]\}}\{g(S)\} \neq \min_{S \notin \{\emptyset,[n]\}}\{f(S)\}$, we say that f witnesses a Non-Trivial Perturbation Bound of q).*

We refer to the *Perturbation Bound of f as the maximum possible q such that f witnesses a Peturbation Bound of q (and similarly can define* the *Non-Trivial Perturbation Bound).*
