We first show that for each $x \in X$, $x \notin V(\hat{H})$ must hold. Indeed, assume for contradiction that $x \in V(\hat{H})$, so x belongs to some connected component of $V(\hat{H})$. Assume first that $x \in V(C_i)$. Recall that the sub-path of $P_{i,j}$ from x to u is precisely $P_{x,u}$, so this path lies in $\mathcal{P}_{i,j}$. But its length is less than the length of $P_{i,j}$, contradicting the choice of $P_{i,j}$. Otherwise, x belongs to some connected component C_ℓ of $\mathcal{C}$ with $\ell \ne i$. The sub-path of $P_{i,j}$ from v to x is precisely $P_{v,x}$, so this path must lie in $\mathcal{P}_{i,\ell}$. Since its length is less than the length of $P_{i,j}$, this contradicts the choice of the components C_i, C_j. We conclude that $x \notin V(\hat{H})$.

Since $V(\hat{H})$ contains all vertices of $V_{\le D-1}$, and every vertex in X is a good vertex, it must be the case that $X \subseteq V_D$. Consider again some vertex $x \in X$. Since x is a good vertex and $x \in V_D$, there must be an edge $e_x = (x, x') \in E'_1$, connecting x to some vertex $x' \in V_{\le D-1}$. In particular, x' must belong to some connected component of $\mathcal{C}$, and the edge e_x lies in graph L. Assume that $X = \{x_1, x_2, \ldots, x_q\}$, where the vertices are indexed in the order of their appearance on $P_{i,j}$, from v to u. Consider the sequence $\tilde{\sigma} = (v, x'_1, x'_2, \ldots, x'_q, u)$ of vertices. All these vertices belong to $V(\hat{H})$, and $v \in C_i$, while $u \in C_j$. For convenience, denote $v = x'_0 = x_0$ and $u = x'_{q+1} = x_{q+1}$. Then there must be an index $1 \leq a \leq q$, such that x'_a and x'_{a+1} belong to distinct connected components of $\mathcal{C}$. Note that the sub-path of $P_{i,j}$ between x_a and x_{a+1} is precisely $P_{x_a,x_{a+1}}$ – the shortest path connecting x_a to x_{a+1} in H. Since no good vertices lie between x_a and x_{a+1} on this path, and since we have assumed that event B does not happen, the length of this path is at most M. Therefore, there is a path in graph L, connecting x'_a to x'_{a+1}, whose length is at most $M + 2$. This path connects a pair of vertices that belong to different connected components of $\hat{H}$, contradicting the construction of $\hat{H}$. ◀

Consider now the tree $\hat{T}$ and the graph $\hat{H}$. Recall that $\hat{T}$ is a rooted tree of depth $D - 1$, $V(\hat{T}) = V(\hat{H})$, $|V(\hat{H})| \leq |V(H)| \leq n$, and, assuming the event B did not happen, $\hat{H}$ is a connected graph. Moreover, set E'_2 of edges is a subset of $E(\hat{T}) = E_2$, obtained by adding every edge of $E(\hat{T})$ to E'_2 with probability p, independently from other edges. Therefore, assuming that event B did not happen, we can use the induction hypothesis on the graph $\hat{H}$, the tree $\hat{T}$, and the set E'_2 of edges as R. Let B' be the bad event that the diameter of $\hat{H} \cup E'_2$ is greater than $(\frac{101 \ln n}{p})^{D-1}$. Note that the event B' only depends on the random choices made in selecting the edges of E'_2. From the induction hypothesis, the probability that B' happens is at most $\frac{D-1}{n^{48}}$.

Lastly, we show that, if neither of the events B, B' happens, then $\mathrm{diam}(H') \leq (\frac{101 \ln n}{p})^D$.

▶ **Observation 12.** *If neither of the events B, B' happens, then* $\mathrm{diam}(H') \leq (\frac{101 \ln n}{p})^D$.

Proof. Consider any pair $x_1, x_2 \in V$ of vertices. It is sufficient to show that, if events B, B' do not happen, then $\mathrm{dist}_{H'}(x_1, x_2) \leq (\frac{101 \ln n}{p})^D$.

Let x'_1 be a good node in $V(H)$ that is closest to x_1, and define x'_2 similarly for x_2. From Observation 10, $\mathrm{dist}_H(x_1, x'_1) \leq M$. If $x'_1 \in V_{\leq D-1}$, then we define $x''_1 = x'_1$, otherwise we let x''_1 be the node of V_{D-1} that is connected to x'_1 by an edge of E'_1, and we define x''_2 similarly for x_2. Therefore, $x''_1, x''_2 \in V_{\leq D-1} = V(\hat{H})$, and, assuming event B does not happen, $\mathrm{dist}_{H'}(x_1, x''_1) \leq M + 1$, and $\mathrm{dist}_{H'}(x_2, x''_2) \leq M + 1$. Since we have assumed that the bad event B' does not happen, $\mathrm{dist}_{\hat{H} \cup E'_2}(x''_1, x''_2) \leq (\frac{101 \ln n}{p})^{D-1}$. Recall that for every edge $e = (u, v) \in \hat{H} \cup E'_2$, if $e \in E'_2$ then $e \in E(H')$; otherwise, $e \in E(\hat{H})$, and there is a path in graph $H \cup E'_1$ of length at most $M + 2$ connecting u to v in H. Therefore, $\mathrm{dist}_{H'}(x''_1, x''_2) \leq (M + 2) \cdot \mathrm{dist}_{\hat{H}}(x''_1, x''_2) \leq (\frac{101 \ln n}{p})^{D-1} \cdot (M + 2)$.

Altogether, since $M = (50 \ln n)/p$,

$$\begin{aligned} \mathrm{dist}_{H'}(x_1, x_2) &\leq \mathrm{dist}_{H'}(x_1, x''_1) + \mathrm{dist}_{H'}(x''_1, x''_2) + \mathrm{dist}_{H'}(x_2, x''_2) \\ &\leq \left(\frac{101 \ln n}{p}\right)^{D-1} \cdot (M + 2) + (2M + 2) \\ &\leq \left(\frac{101 \ln n}{p}\right)^{D}. \end{aligned}$$ ◀

The probability that either B or B' happen is bounded by $\frac{D}{n^{48}}$. Therefore, with probability at least $1 - \frac{D}{n^{48}}$, neither of the events happens, and $\mathrm{diam}(H') \leq (\frac{101 \ln n}{p})^D$. ◀

3 Low-Diameter Packing of Edge-Disjoint Trees: Proof of Theorem 2

The main tool in the proof of Theorem 2 is the following theorem.

▶ **Theorem 13.** *Let k, D, n be any positive integers with $k > 1000 \ln n$, let $\frac{707 \ln n}{k} \leq p \leq 1$ be a real number, and let G be an n-vertex k-edge-connected graph of diameter D. Let G' be a sub-graph of G with $V(G') = V(G)$, where every edge $e \in E(G)$ is added to G' with probability p independently from other edges. Then, with probability at least $1 - 1/\mathsf{poly}(n)$, G' is a connected graph, and its diameter is bounded by $k^{D(D+1)/2}$.*

Karger [14] has shown that, if G is a k-connected graph, and G' is obtained by sub-sampling the edges of G with probability $\Omega(\log n/k)$, then G' is a connected graph with high probability. Theorem 13 further shows that the diameter of G' is with high probability bounded by $k^{D(D+1)/2}$, where D is the diameter of G.

Theorem 2 easily follows from Theorem 13: Let $r = \lfloor k/(707 \ln n) \rfloor$. We partition $E(G)$ into subsets $E_1, \ldots, E_r$ by choosing, for each edge $e \in E(G)$, an index i independently and uniformly at random from $\{1, 2, \ldots, r\}$ and then adding e to E_i. For each $1 \leq i \leq r$, we define a graph G_i by setting $V(G_i) = V(G)$ and $E(G_i) = E_i$. Finally, for each graph G_i, we compute an arbitrary BFS tree T_i, and return the resulting collection $\mathcal{T} = \{T_1, \ldots, T_r\}$ of trees. It is immediate to verify that the graphs $G_1, \ldots, G_r$ are edge-disjoint, and so are the trees of $\mathcal{T}$. Moreover, applying Theorem 13 to each graph G_i with $p = 1/r$, we get that with probability $1 - 1/\mathsf{poly}(n)$, $\operatorname{diam}(T_i) \leq 2 \operatorname{diam}(G_i) \leq O(k^{D(D+1)/2})$. Using the union bound over all $1 \leq i \leq r$ completes the proof of Theorem 2. It now remains to prove Theorem 13. We provide a proof sketch here; a formal proof appears in the full version of the paper.

Proof Sketch of Theorem 13: We use the well known result of Karger [14], that shows that the probability that the graph G' is not connected is at most $O(1/\mathsf{poly}(n))$. It remains to bound the diameter of G'. Throughout the proof, for a graph H, we denote by $\mathcal{D}(H, p)$ be the distribution of graphs, where the vertex set of the resulting graph is $V(H)$, and each edge of H is included in the graph with probability p independently from other edges.

Denote $G = (V, E)$, and let T be a BFS tree of G, rooted at an arbitrary node r of G. Since G has diameter at most D, the depth of T is at most D. Recall that $G' \sim \mathcal{D}(G, p)$. We define a different (but equivalent) sampling algorithm for generating a random graph G' from $\mathcal{D}(G, p)$ as follows. The algorithm consists of $D + 1$ phases. In the 0th phase, we sample all edges in $E \setminus E(T)$ independently with probability p each. For each $1 \leq i \leq D$, in the ith phase, we sample all edges that connect a vertex at distance $(D - i + 1)$ from r to a vertex at distance $(D - i)$ from r in T. Let E' be the set of all sampled edges at the end of this algorithm. We denote by $G' = (V, E')$ the final graph that we obtain. Clearly, G' is generated from the distribution $\mathcal{D}(G, p)$. We denote by T' the subgraph of T with $V(T') = V(T)$ and $E(T') = E(T) \cap E'$. Clearly, $T' \sim \mathcal{D}(T, p)$.

Consider a pair $u, u' \in V$ of distinct vertices. We say that they are *joined at phase i* for $0 \leq i \leq D$, if u and u' belong to the same connected component of the graph induced by all edges sampled in the first i phases, but they lie in different connected components of the graph induced by all edges sampled in the first $(i - 1)$ phases. Note that, if G' is connected, then every pair (u, u') of distinct vertices of V are joined at phase i for some $0 \leq i \leq D$. The following lemma allows us to bound the diameter of G'.

▶ **Lemma 14.** *For each $0 \leq i \leq D$, with probability $1 - O(1/\mathsf{poly}(n))$, for every pair x, y of vertices that are joined at phase i, x and y are at distance at most $7^i (101 \ln n/p)^{D+(D-1)+\cdots+(D-i)}$ in G'.*

Observe that, by applying the union bound over all $0 \le i \le D$, Lemma 14 implies Theorem 13, since $k \ge 707 \ln n/p$. We defer the proof of Lemma 14 to the full version of the paper, and only provide its proof sketch here. Assume for simplicity that the edges in $E \setminus E(T)$ only connect vertices that are at distance D from r in T (this also turns out to be the hardest case). The proof is by induction on i. In the base case where $i = 0$, let C be a connected component of the graph induced by all edges sampled in phase 0. Intuitively, we can view the algorithm as using a random subgraph of T to "fix" the diameter of C, like in Theorem 9. Therefore, with high probability, for every pair x, y of vertices of C, the distance from x to y in $C \cup T'$ is at most $(101 \ln n/p)^D$. Similarly, let C' be a connected component of the the subgraph of G induced by all edges sampled in phases $0, 1, \ldots, i$; we call C' a *phase-i cluster*. We view C' as consisting of a number of phase-$(i-1)$ clusters $C''_1, \ldots, C''_k$, connected to each other by edges that were sampled in the ith phase. Therefore, if $\hat{C}'$ is a graph obtained from C' by contracting each cluster $C''_1, \ldots, C''_k$ into a single vertex, then $\hat{C}'$ is a connected graph. Denote by T_i the subtree of T induced by all nodes that are at distance at most $(D - i)$ from r in T, and denote $T'_i = T' \cap T_i$. Clearly $T'_i \sim \mathcal{D}(T_i, p)$. We can again view our algorithm as using a random subgraph T'_i of T_i to "fix" the diameter of $\hat{C}'$, like in Theorem 9. Therefore, with high probability, for every pair x, y of vertices of $\hat{C}'$, the distance from x to y in $\hat{C}' \cup T'_i$ is at most $(101 \ln n/p)^{D-i}$. Note however that every vertex of $\hat{C}'$ is in fact a contracted level-$(i-1)$ cluster. Moreover, from the induction hypothesis, if C'' is a level-$(i-1)$ cluster, and x', y' is a pair of vertices in C'', then with high probability, the distance from x' to y' in $C'' \cup T'$ is at most $7^{i-1} \cdot (101 \ln n/p)^{D+(D-1)+\cdots+(D-i+1)}$. Therefore, with high probability, the distance between a pair $u, v \in V(C')$ of vertices in $C' \cup T'$ is at most $7^i \cdot (101 \ln n/p)^{D+(D-1)+\cdots+(D-i)}$.

4 Lower Bound: Proof of Theorem 3

In this section we provide the proof of Theorem 3. We start by proving the following slightly weaker theorem; we then extend it to obtain the proof of Theorem 3.

▶ **Theorem 15.** *For all positive integers k, D, η, α such that $k/(4D\alpha\eta)$ is an integer, there exists a k-edge connected graph G with $|V(G)| = O\left(\left(\frac{k}{2D\alpha\eta}\right)^D\right)$ and diameter at most $2D$, such that, for any collection $\mathcal{T} = \{T_1, \ldots, T_{k/\alpha}\}$ of k/α spanning trees of G that causes edge-congestion at most η, some tree $T_i \in \mathcal{T}$ has diameter at least $\frac{1}{4} \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$.*

Notice that the main difference from Theorem 3 is that the graph G is no longer required to be simple; the number of vertices of $V(G)$ is no longer fixed to be a prescribed value; and the diameter of G is $2D$ instead of $2D + 2$.

Proof. For a pair of integers $w > 1, D \ge 1$, we let $T_{w,D}$ be a tree of depth D, such that every vertex lying at levels $0, \ldots, D-1$ of $T_{w,D}$ has exactly w children. In other words, $T_{w,D}$ is the full w-ary tree of depth D. We denote $N_{w,D} = |V(T_{w,D})| = 1 + w + w^2 + \cdots + w^D \le w^{D+1}/(w-1)$. We assume that for every inner vertex $v \in V(T_{w,D})$, we have fixed an arbitrary ordering of the children of v, denoted by $a_1(v), \ldots, a_w(v)$.

A *traversal* of a tree T is an ordering of the vertices of T. A *post-order traversal* on a tree T, $\pi(T)$, is defined as follows. If the tree consists of a single node v, then $\pi(T) = (v)$. Otherwise, let r be the root of the tree and consider the sequence $(a_1(r), \ldots, a_w(r))$ of its children. For each $1 \le i \le w$, let T_i be the sub-tree of T rooted at the vertex $a_i(r)$. We then let $\pi(T)$ be the concatenation of $\pi(T_1), \pi(T_2), \ldots, \pi(T_w)$, with the vertex r appearing at the end of the sequence; see Figure 1 for an illustration. For simplicity, we assume that $V(T_{w,D}) = \{v_1, v_2, \ldots, v_{N_{w,D}}\}$, where the vertices are indexed in the order of their appearance in $\pi(T_{w,D})$, so the traversal visits these vertices in this order.

Next, we define a graph $G_{w,D}$, as follows. The vertex set of $G_{w,D}$ is the same as the vertex set of $T_{w,D}$, namely $V(G_{w,D}) = V(T_{w,D})$. The edge set of $G_{w,D}$ consists of two subsets: $E_1 = E(T_{w,D})$, and another set E_2 of edges that contains, for each $1 \le i < N_{w,D}$, k parallel copies of the edge (v_i, v_{i+1}). We then set $E(G_{w,D}) = E_1 \cup E_2$. For convenience, we call the edges of E_1 *blue edges*, and the edges of E_2 *red edges*; see Figures 1 and 2.

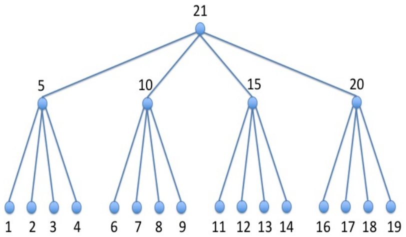

Figure 1 Tree $T_{4,2}$ with vertices indexed according to post-order traversal.

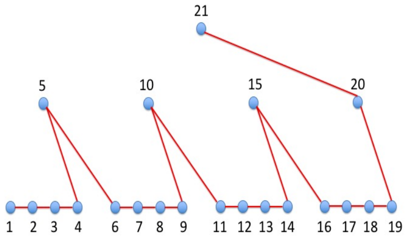

Figure 2 The edge set E_2 in $G_{4,2}$ (only a single copy of each edge is shown).

It is easy to verify that graph $G_{w,D}$ must be k-edge connected, since for any partition of $V(G_{w,D})$, there is some index $1 \le i < N_{w,D}$ with v_i, v_{i+1} separated by the partition, and so k parallel edges connecting v_i to v_{i+1} must cross the partition.

We now fix an integer $w = k/(2D\alpha\eta)$ (note that $w \ge 2$), and we let $T = T_{w,D}$ be the corresponding tree and $G = G_{w,D}$ the corresponding graph. For convenience, we denote $N_{w,D}$ by N. Recall that $N \le w^{D+1}/(w-1) = O\left(\left(\frac{k}{2D\alpha\eta}\right)^D\right)$. As observed before, G is k-edge connected. Since the depth of T is D, and $T \subseteq G$, it is easy to see that the diameter of G is at most $2D$.

We now consider any collection $\mathcal{T} = \{T_1, \ldots, T_{k/\alpha}\}$ of k/α spanning trees of G that causes edge-congestion at most η. Our goal is to show that some tree $T_i \in \mathcal{T}$ has diameter at least $\frac{1}{4} \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$.

For convenience, we denote $V(G) = V(T) = V$. We say that a vertex $x \in V$ is an *ancestor* of a vertex $y \in V$ if x is an ancestor of y in the tree T, that is, $x \ne y$, and x lies on the unique path connecting y to the root of T.

Let $L \subseteq V$ be the set of vertices that serve as leaves of the tree T. We denote by $u = v_1$ a vertex of L that has the lowest index, and by u' the vertex of L with the largest index. It is easy to see that $u' = v_{N-D}$, as every vertex whose index is greater than that of u' is an ancestor of u'. For each $1 \le j \le k/\alpha$, we denote by P_j the unique path that connects u to u' in tree T_j. Let $\mathcal{P} = \{P_j \mid 1 \le j \le k/\alpha\}$. It is enough to show that at least one of the paths P_j has length at least $\frac{1}{4} \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$. In order to do so, we show that $\sum_{j=1}^{k/\alpha} |E(P_j)|$ is sufficiently large. At a high level, we consider the red edges (v_i, v_{i+1}) (the edges of E_2), and show that many of the paths in $\mathcal{P}$ must contain copies of each such edge. This in turn will imply that $\sum_{P_j \in \mathcal{P}} |E(P_j)|$ is large, and that some path in $\mathcal{P}$ is long enough.

For each vertex $v_i \in L$ such that $v_i \ne u'$, we let $S_i = \{v_1, \ldots, v_i\}$, and we let $\overline{S}_i = \{v_{i+1}, \ldots, v_N\}$. Notice that, since $u \in S_i$ and $u' \in \overline{S}_i$, every path in $\mathcal{P}$ must contain an edge of $E_G(S_i, \overline{S}_i)$. Note that the only red edges in $E_G(S_i, \overline{S}_i)$ are the k parallel copies of the edge (v_i, v_{i+1}). In the next observation, we show that the number of blue edges in $E_G(S_i, \overline{S}_i)$ is bounded by Dw.

▶ **Observation 16.** *For each vertex $v_i \in L$ such that $v_i \neq u'$, for every blue edge $e \in E_G(S_i, \overline{S}_i)$, at least one endpoint of e must be an ancestor of v_i.*

Proof. We consider a natural layout of the tree T, where for every inner vertex x of the tree, its children $a_1(x), \ldots, a_w(x)$ are drawn in this left-to-right order (see Figure 3). Consider the path Q connecting the root of T to v_i, so every vertex on Q (except for v_i) is an ancestor of v_i. All vertices lying to the left of Q in the layout are visited before v_i by $\pi(T)$. All vertices lying to the right of Q, and on Q itself (excluding v_i) are visited after v_i. It is easy to see that the vertices of Q separate the two sets in T, and so the only blue edges connecting S_i to $\overline{S}_i$ are edges incident to the vertices of $V(Q) \setminus \{v_i\}$. ◀

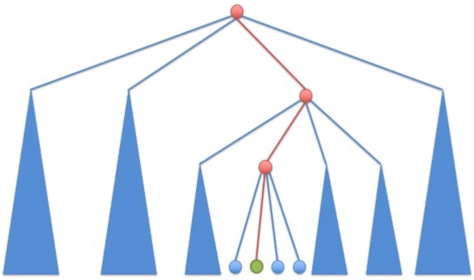

Figure 3 A layout of the tree T. Vertex v_i is shown in green and path Q in red. All vertices lying to the left of Q in this layout appear before v_i in $\pi(T)$, and all vertices lying to the right of Q or on Q (except for v_i) appear after v_i in $\pi(T)$.

Since every vertex of the tree T has at most w children, and since the depth of the tree is D, we obtain the following corollary of Observation 16.

▶ **Corollary 17.** *For each vertex $v_i \in L$ such that $v_i \neq u'$, at most Dw blue edges lie in $E_G(S_i, \overline{S}_i)$.*

Since the trees in $\mathcal{T}$ cause edge-congestion η, at most $Dw\eta$ trees of $\mathcal{T}$ may contain blue edges in $E_G(S_i, \overline{S}_i)$. Each of the remaining $\frac{k}{\alpha} - Dw\eta \geq \frac{k}{2\alpha}$ trees contains a copy of the red edge (e_i, e_{i+1}) (recall that $w = k/(2D\alpha\eta)$.) Therefore, $\sum_{P_j \in \mathcal{P}} |E(P_j)| \geq |L| \cdot \frac{k}{2\alpha} \geq \frac{Nk}{4\alpha}$, since $|L| \geq |N|/2$. We conclude that at least one path $P_j \in \mathcal{P}$ must have length at least $\frac{Nk}{4\alpha} / \frac{k}{\alpha} \geq \frac{N}{4}$, and so the diameter of T_j is at least $\frac{N}{4}$. Since $N \geq w^D \geq \left(\frac{k}{2D\alpha\eta}\right)^D$, the diameter of T_j is at least $\frac{1}{4} \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$. ◀

We are now ready to complete the proof of Theorem 3. First, we show that we can turn the graph G into a simple graph, and ensure that $|V(G)| = n$, if $n \geq 3k \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$. Let $G'_{w,D}$ be the graph obtained from $G_{w,D}$ as follows. For each $1 \leq i \leq N$, we replace the vertex v_i with a set $X_i = \{x_i^1, x_i^2 \ldots, x_i^k\}$ of k vertices that form a clique. For each $1 \leq i < N$, the k red edges connecting v_i to v_{i+1} are replaced by the perfect matching $\{(x_i^t, x_{i+1}^t)\}_{1 \leq t \leq k}$ between vertices of X_i and vertices of X_{i+1}. Each blue edge (v_i, v_j) is replaced by a new edge (x_i^1, x_j^1). Since $n \geq 3k \cdot \left(\frac{k}{2D\alpha\eta}\right)^D > k|V(G)| + k$, we add $n - k|V(G)| > k$ new vertices that form a clique, and for each newly-added vertex, we add an edge connecting it to x_N^1 (recall that the vertex v_N is the root of T). We denote $G' = G'_{w,D}$ for simplicity. It is not hard to see that G' has n vertices and it is k-edge connected. Moreover, G' has diameter at most $2D+2$, since its subgraph induced by vertices of $\{x^1_i\}_{1\le i\le N}$ has diameter $2D$, and every other vertex of G' is a neighbor of one of the vertices in $\{x^1_i\}_{1\le i\le N}$. The tree T' is defined exactly as before, except that every original vertex v_j is now replaced with its copy x^1_j. Let L denote the set of all leaf vertices in T'.

Assume that we are given a collection $\mathcal{T}=\{T_1,\dots,T_{k/\alpha}\}$ of k/α spanning trees of G' that causes edge-congestion at most η. For each $1\le i\le k/\alpha$, we denote by Q_i the unique path that connects x^1_1 to x^1_{N-D} in T_i and denote $\mathcal{Q}=\{Q_i\mid 1\le i\le k/\alpha\}$. For each every leaf vertex $x^1_j\in L$, we define a cut $(W_j,\overline{W_j})$ as follows: $W_j=\bigcup_{1\le s\le j}X_s$ and $\overline{W_j}=V(G')\setminus W_j$. Using reasoning similar to that in Corollary 17, it is easy to see that for every leaf vertex $x^1_j\in L$, the set $E_{G'}(W_j,\overline{W_j})$ of edges contains at most Dw blue edges – the edges of the tree T'. Since the trees in $\mathcal{T}$ cause edge-congestion at most η, at most $Dw\eta$ trees of $\mathcal{T}$ may contain blue edges in $E_{G'}(W_j,\overline{W_j})$. Therefore, for each of the remaining $\frac{k}{\alpha}-Dw\eta\ge\frac{k}{2\alpha}$ trees T_i, path Q_i must contain a red edge from $\{(x^t_j,x^t_{j+1})\}_{1\le t\le k}$. Therefore, the sum of lengths of all paths of $\mathcal{Q}$ is at least $\frac{Nk}{4\alpha}$, and so at least one path $Q_i\in\mathcal{Q}$ must have length at least $\frac{N}{4}$. We conclude that some tree $T_i\in\mathcal{T}$ has diameter at least $\frac{1}{4}\cdot\left(\frac{k}{2D\alpha\eta}\right)^D$.

Lastly, we extend our results to edge-independent trees. We use the same simple graph G' and the same tree T' as before, setting the congestion parameter $\eta=2$. Assume that we are given a collection $\mathcal{T}'=\{T'_1,\dots,T'_{k/\alpha}\}$ of k/α edge-independent spanning trees of G' and let $x\in V(G')$ be their common root vertex. For each $1\le i\le k/\alpha$, we denote by Q'_i the unique path that connects vertex x^1_1 to vertex x^1_{N-D} in tree T'_i, and we denote $\mathcal{Q}'=\{Q'_i\mid 1\le i\le k/\alpha\}$. Note that, for each $1\le i\le k/\alpha$, the path Q'_i is a sub-path of the path obtained by concatenating the path Q''_i, connecting x^1_1 to x in T'_i, with the path Q'''_i, connecting x^1_{N-D} to x in T'_i. Since the trees in $\mathcal{T}'$ are edge-independent, the paths in $\{Q''_i\}_{1\le i\le k/\alpha}$ are edge-disjoint and so are the paths in $\{Q'''_i\}_{1\le i\le k/\alpha}$. Therefore, the paths of $\mathcal{Q}'$ cause edge-congestion at most 2. The remainder of the proof is the same as before and is omitted here.

5 Tree Packing for (k,D)-Connected Graphs: Proof of Theorem 4

In this section we provide a proof sketch of Theorem 4. The full proof is deferred to the full version of the paper. The main tool that we use is the following theorem, whose proof appears in the full version of the paper.

▶ **Theorem 18.** *There is an efficient algorithm, that, given a (k,D)-connected graph G and a subset $S\subseteq V(G)$ of its vertices, computes a bi-partition (S',S'') of S, and a flow f from vertices of S'' to vertices of S', such that the following hold:*

1. *every vertex of S'' sends at least $k/2$ flow units;*
2. *every flow-path has length at most $2D$;*
3. *the total amount of flow through any edge is at most 3; and*
4. *$|S'|\le\frac{|S|}{2}+1$.*

Our algorithm consists of two phases. In the first phase, we define a partition of the vertices of G into layers $L_1,\dots,L_h$, where $h=O(\log n)$. Additionally, for each $1\le i\le h$, we define a flow f_i in graph G between vertices of L_i and vertices of $L_1\cup\cdots\cup L_{i-1}$. In the second phase, we use the layers and the flows in order to construct the desired set of spanning trees.

Phase 1: Partitioning into layers. We use a parameter $h=\Theta(\log n)$, whose exact value will be set later. We now define the layers $L_h,\dots,L_1$ in this order, and the corresponding flows $f_h,\dots,f_1$. In order to define the layer L_h, we let $S=V(G)$, and we apply Theorem

18 to the graph G and the set S of its vertices, to obtain a partition (S', S'') of S, with $|S'| \leq |S|/2 + 1$, and the flow f between the vertices of S'' and the vertices of S', where every vertex of S'' sends at least $k/2$ units of flow, each flow-path has length at most $2D$, and the edge-congestion caused by f is at most 3. We then set $L_h = S''$ and $f_h = f$, and continue to the next iteration.

Assume now that we have constructed layers $L_h, \ldots, L_i$. We now show how to construct layer L_{i-1}. Let $S = V(G) \setminus (L_h \cup \cdots \cup L_i)$. We apply Theorem 18 to the graph G and the set S of its vertices, to obtain a partition (S', S'') of S, with $|S'| \leq |S|/2 + 1$, and the corresponding flow f. We then set $L_{i-1} = S''$, $f_{i-1} = f$, and continue to the next iteration. If we reach an iteration where $|S| \leq 2$, we arbitrarily designate one of the two vertices as s and the other as s', and compute a flow of value at least k between the two vertices, such that the edge-congestion of the flow is at most 2, and every flow-path has length at most $2D$. We add vertex s' to the current layer, and we add vertex s to the final layer L_1. If we reach an iteration where $|S| = 1$, then we add the vertex of S to the final layer L_1 and terminate the algorithm. The number h of layers is chosen to be exactly the number of iterations in this algorithm. Notice that $h \leq 2 \log n$ must hold. Also observe that, for all $1 < i \leq h$, flow f_i originates at vertices of L_i, terminates at vertices of $L_1 \cup \cdots \cup L_{i-1}$, uses flow-paths of length at most $2D$, and causes edge-congestion at most 3.

Phase 2: Constructing the trees. In order to construct the spanning trees $T_1, \ldots, T_k$, we start by letting each tree contain all vertices of G and no edges. We then process every vertex $v \in V(G)$ one-by-one. Assume that $v \in L_i$, for some $1 \leq i \leq h$. Consider the following experiment. Let $\mathcal{Q}(v)$ be the set of all flow-paths that carry non-zero flow in f_i, and connect v to vertices of $L_1 \cup \cdots \cup L_{i-1}$. Let $F(v)$ be the total amount of flow that f_i sends on all paths $P \in \mathcal{Q}(v)$; recall that $F(v) \geq k/2$ must hold. We choose a path $P \in \mathcal{Q}(v)$ at random, where the probability to choose a path P is precisely $f_i(P)/F(v)$. We repeat this experiment k times, obtaining paths $P_1(v), \ldots, P_k(v)$. For each $1 \leq j \leq k$, we add all edges of $P_j(v)$ to T_j. Consider the graphs $T_1, \ldots, T_k$ at the end of this process. Notice that each such graph T_j may not be a tree. We fist show that the diameter of each such tree is $O(D \log n)$.

▷ Claim 19. For all $1 \leq j \leq k$, $\operatorname{diam}(T_j) \leq O(D \log n)$.

Proof. Fix an index $1 \leq j \leq k$. Let r be the unique vertex lying in L_1. We prove that for all $1 \leq i \leq h$, for every vertex $v \in L_i$, there is a path connecting v to r in T_j, of length at most $2D(i-1)$, by induction on i. The base of the induction is when $i = 1$ and the claim is trivially true. Assume now that the claim holds for layers $L_1, \ldots, L_{i-1}$. Let v be any vertex at layer L_i. Consider the path $P_j(v)$ that we have selected. Recall that this path has length at most $2D$, and it connect v to some vertex $u \in L_1 \cup \cdots \cup L_{i-1}$. By the induction hypothesis, there is a path P in T_j of length at most $2D(i-2)$, that connects u to r. Since all edges of $P_j(v)$ are added to T_j, the path $P_j(v)$ is contained in T_j. By concatenating path $P_j(v)$ with path P, we obtain a path connecting v to r, of length at most $2D(i-1)$. ◁

Lastly, using standard analysis of the Randomized Rounding technique, we show that, with probability at least $(1 - 1/\mathsf{poly}(n))$, every edge of G lies in at most $O(\log n)$ graphs $T_1, \ldots, T_k$. For each $1 \leq j \leq k$, we can now let T'_j be a BFS tree of the graph T_j, rooted at the vertex r. We conclude that each tree T'_j has diameter at most $O(D \log n)$, and the resulting set $\{T'_1, \ldots, T'_k\}$ of trees cause edge-congestion $O(\log n)$ with high probability.

6 Overview of the Applications to Distributed Computation

Our improved distributed algorithms in highly-connected graphs are based on the following basic tool, which follows by combining Karger's edge sampling and the diameter-fixing Theorem 9.

▷ Claim 20 (Basic Distributed Tool). There is a randomized algorithm that, given a k-edge connected n-vertex graph G and a congestion bound $\eta \in [1, k]$, computes, in $\widetilde{O}((101k \ln n/\eta)^D)$ rounds, a collection of k spanning trees that cause total edge-congestion at most $O(\eta \cdot \log n)$, and have diameter at most $O((101k \ln n/\eta)^D)$ each. Moreover, the algorithm can compute k spanning subgraphs with similar congestion and diameter bounds in $O(D + \eta \log n)$ rounds. The round complexity, the diameter, and the congestion bounds hold with high probability.

Approximation of Minimum-Cut. Ghaffari and Kuhn [10, 7] gave a very simple approach for finding an $O(\log n)$-approximation for the minimum cut problem that is based on Karger's edge sampling technique. The round complexity of their algorithm is $O(\sqrt{n})$ for constant diameter graphs. Combining Theorem 13 with Ghaffari and Kuhn's algorithm immediately leads to an $\widetilde{O}(\lambda)$ algorithm for graphs with constant diameter, where λ is the size of the minimum-cut.

To provide a more general approach for improved algorithms in highly-connected graphs, we next describe the notion of low-congestion shortcuts.

Low-Congestion Shortcuts. This notion, introduced by Ghaffari and Haeupler [9], provides a modular framework for solving global graph problems in the distributed setting.

▶ **Definition 21** (Low-Congestion Shortcuts, [9]). *Given a graph $G = (V, E)$, and a partition $S_1, \ldots, S_N$ of V into disjoint subsets, such that for all $1 \le i \le N$, graph $G[S_i]$ is connected, an (α, β)-shortcut is a collection $\{H_1, \ldots, H_N\}$ of subgraphs of G, that satisfy the following:*

(1) *for each edge $e \in E$, there are at most α subgraphs $G[S_i] \cup H_i$ containing e; and*

(2) *the diameter of each subgraph $G[S_i] \cup H_i$ is at most β.*

Ghaffari and Haeupler [9] showed that the quality of algorithms for several basic problems depend on the sum of α (i.e., congestion) and β (i.e., the dilation). The quantity of $\alpha + \beta$ is usually referred to as the *quality* of the shortcuts. As observed by [9] for every n-vertex graph G and any collection of vertex-disjoint subsets $S_1, \ldots, S_N$, there exist (α, β) shortcuts for with $\alpha + \beta = O(D + \sqrt{n})$. Our key result is in providing a nearly optimal construction for low-congestion shortcuts in highly connected graphs of constant diameter.

▶ **Theorem 22.** *[Improved Shortcuts in Highly Connected Graphs] There is a randomized algorithm that, for a sufficiently large n, given any k-connected n-vertex graph G of diameter $D = O(\log n / \log \log n)$, together with a partition $\{S_1, \ldots, S_N\}$ of $V(G)$, such that for all $1 \le i \le N$, $G[V_i]$ is a connected graph, w.h.p. computes (α, β) shortcuts, with*

$$\alpha + \beta = \widetilde{O}(\min\{\sqrt{n/k} + n^{D/(2D+1)}\}, n/k),$$

in $\widetilde{O}(\alpha + \beta)$ rounds.

The construction of the shortcuts from Theorem 22 serves the basis for the proof of Theorem 6. In the full version of the paper we describe further algorithmic applications of our results for additional graph problems. The proof of Theorem 7 is based on a careful implementation of Claim 20.

7 Open Problems

For brevity, let us say that a collection $\mathcal{T}$ of spanning trees of a (k, D)-connected graph G is an (α, D')-packing iff $|\mathcal{T}| \geq k/\alpha$ and the diameter of every tree in $\mathcal{T}$ is at most D'. A major remaining open question is: for which values of α and D' can we guarantee the existence of an (α, D')-packing $\mathcal{T}$ of edge-disjoint spanning tree in every (k, D)-connected graph. In particular, is the following statement true: every (k, D)-connected graph G contains a collection of $\Omega(k/\mathsf{poly}\log n)$ edge-disjoint trees of diameter $O(D \cdot \mathsf{poly}\log n)$ each. The only upper bounds that we have are the ones guaranteed by Theorem 2, and we do not have any lower bounds. We also do not have any upper bounds, except for those guaranteed by Theorem 1, if we allow a constant, or more generally any sub-logarithmic congestion. Additionally, obtaining an analogue of the algorithm from Theorem 4 in the distributed setting remains a very interesting open question.

Finally, most of our results are mainly meaningful for the setting where $k = \Omega(\log n)$. It will be very interesting to consider the case of small connectivity $k = O(1)$. One can show that any k-edge connected graph with $k = O(1)$ of diameter D is a $(k, \mathsf{poly}(D))$-connected graph. Is it possible to show that any k-edge-connected graph of diameter D, for some constant $k \geq 3$, has at least two edge-disjoint trees of depth at most $\mathsf{poly}(D)$?

Abstract

In this paper, we consider the problem of assigning 2-dimensional vector jobs to identical machines online so to minimize the maximum load on any dimension of any machine. For arbitrary number of dimensions d, this problem is known as vector scheduling, and recent research has established the optimal competitive ratio as $O\left(\frac{\log d}{\log \log d}\right)$ (Im et al. FOCS 2015, Azar et al. SODA 2018). But, these results do not shed light on the situation for small number of dimensions, particularly for $d = 2$ which is of practical interest. In this case, a trivial analysis shows that the classic list scheduling greedy algorithm has a competitive ratio of 3. We show the following improvements over this baseline in this paper:

- We give an improved, and tight, analysis of the list scheduling algorithm establishing a competitive ratio of 8/3 for two dimensions.
- If the value of OPT is known, we improve the competitive ratio to 9/4 using a variant of the classic best fit algorithm for two dimensions.
- For any fixed number of dimensions, we design an algorithm that is provably the best possible against a fractional optimum solution. This algorithm provides a proof of concept that we can simulate the optimal algorithm online up to the integrality gap of the natural LP relaxation of the problem.

1 Introduction

In the online load balancing problem, the goal is to allocate n jobs appearing online on a set of m identical machines so as to minimize the maximum load on any machine (called *makespan*). This problem was introduced in the 1960s by Graham [26, 27], who gave the list scheduling algorithm that assigns each arriving job to the machine with minimum

load, and achieves a competitive ratio[2] of 2.[3] Since then, there has been a long line of work that aims to improve this constant below 2, both when the optimal value OPT is unknown [10, 37, 1, 19, 18, 11, 25, 28, 2], and when OPT is known [9, 40, 4, 38, 39, 21, 20, 12]. The current record is a competitive ratio of 1.916 due to Albers [2] for unknown OPT, and 1.5 due to Bohm et al. [12] for known OPT.

Recent research has further expanded the scope of this problem to vector jobs that have multiple dimensions, the resulting problem being called *vector scheduling* [15, 7, 43, 29, 8, 30]. As earlier, the goal is to minimize the makespan of the assignment, which now represents the maximum load across all machines *and all dimensions.* This problem arises in data centers where jobs with multiple resource requirements have to be allocated to machine clusters to make efficient use of limited resources such as CPU, memory, and network bandwidth [24, 44, 41, 17, 31, 32].

It is now known that the right dependence of the competitive ratio for vector scheduling on the number of dimensions d is $\Theta(\log d/\log\log d)$ [29]. While this gives a satisfactory answer when the number of dimensions is large, in the practical context, the number of dimensions is usually small since they represent distinct computational resources. In particular, the majority of the systems scheduling literature (e.g., see [24] and follow-up papers) considers only two resources, CPU and memory, since they often tend to be the most critical bottleneck resources. Unfortunately, the existing bounds for vector scheduling do not shed any light on this case since we are interested in optimizing the constant in the competitive ratio. In this paper, we initiate the study of the *online 2-dimensional scheduling* problem, or 2DSCHED in short.

1.1 Results and Techniques

Baseline. Graham's list scheduling algorithm can be naturally extended to $d > 1$ dimensions by assigning each job to the machine that minimizes the makespan after the assignment. This algorithm has a competitive ratio of 3 for $d = 2$ (and $d + 1$ for general d). To see this, assume wlog the optimum makespan OPT $= 1$ by scaling. Since the average load on each dimension is at most OPT, it follows that there is always some machine where the sum of loads on its two dimensions is at most 2. Consequently, this machine has a load of at most 2 on each of its dimensions. Now, note that the load of any single job cannot exceed OPT on any dimension; hence, the maximum load on a machine after the greedy assignment of a job cannot exceed 3.

Unfortunately, despite the aforementioned recent progress, no existing algorithms are known to have a competitive ratio better than 3. Thus, our goal is to break the 3-competitive ratio barrier for the problem. This requires a new approach since the existing analytical methods are based on potential functions, concentrations, or volume bounds, and they all seem to inevitably lose a considerable constant factor in the competitive ratio.

A Novel Analytical Technique: Characterizing Reachable States

Our new approach is to directly characterize the set of reachable states of the algorithm. To illustrate our approach, let us take a close look at the above analysis of list scheduling. For the analysis to be tight, a configuration (machine loads) must be created where half

[2] The *competitive ratio* of an online minimization problem is the maximum ratio between the objective of the algorithm and that of an (offline) optimal solution, see e.g., [13].

[3] The competitive ratio is actually $2 - 1/m$ for m machines, but we will ignore $o(1)$ terms throughout since we consider instances of arbitrary problem size in this paper.

the machines have a load of (roughly, ignoring lower order terms) $(2, 0)$ and the remaining half have a load of $(0, 2)$. If a job of load $(1, 1)$ now arrives, then the maximum load will increase to 3 no matter where the job is assigned. But, do we ever create such imbalance in the configurations of the machines?

To rule out such states/configurations, we need to define the set of reachable states of the algorithm. Our first contribution is to develop a general framework that allows us to characterize the set of reachable states of not only the greedy algorithm, but of a much larger class of algorithms that we call *priority-based algorithms*. Roughly speaking, these are algorithms where the newly arriving job is assigned to minimize a "disutility function" that maps the current load of the machines (i.e., the current state) and the load of the current job to a real number. For such algorithms, our main observation is that if m machines come to have load vectors $c = (c_1, c_2, ..., c_m)$ – meaning that this configuration is reachable – then any pair (c_i, c_j) is a reachable state for the same algorithm on just two machines. Furthermore, we identify a specific pair (c_i, c_j) that captures the essential characteristics of the algorithm under consideration.

Using this framework, we show that the greedy makespan minimization algorithm that we described above is 8/3-competitive – and our analysis is tight. We defer the lower bound to the full version of the paper.

▶ **Theorem 1** (Section 4). *There exists a priority-based algorithm that is* $8/3$*-competitive for the 2DSCHED problem with unknown* OPT*. Furthermore, this analysis is tight.*

If we know the value of OPT, then we obtain a better competitive ratio of 2.25 by using a different algorithm that explicitly minimizes the difference of the loads on the two dimensions without violating the preset threshold $\alpha \cdot \text{OPT}$, where $\alpha = 2.25$ is the desired competitive ratio. Again, this analysis is tight, the proof of which we defer to the full version of the paper. This "balance algorithm" can be thought of as a generalization of the popular *best fit* strategy used in bin packing (see [33, 35] for one-dimensional bin packing).

▶ **Theorem 2** (Section 5). *There exists a priority-based algorithm that is* 2.25*-competitive for the 2DSCHED problem with known* OPT*. Furthermore, this analysis is tight.*

Recall that the minimum makespan problem for $d = 1$ has been widely studied for both the known and unknown OPT scenarios, and our results obtain corresponding bounds for the 2DSCHED problem.

As further evidence of the generality of our analysis framework, we also analyze a natural extension of the popular *first fit* rule used for bin packing problems. (The reader is referred to [23, 6] for multi-dimensional first fit bin packing and [16] for a full survey on one-dimensional first fit bin packing.) In this algorithm, given a target competitive ratio, the algorithm assigns a new job to the first bin that does not violate the competitiveness guarantee. This can be implemented as stated if OPT is known, and has a tight competitive ratio of 2.5. (The proof of the next theorem is deferred to the full version of the paper.)

▶ **Theorem 3.** *The first fit algorithm is* 2.5*-competitive for the 2DSCHED problem with known* OPT*. Furthermore, this analysis is tight.*

We also show that if the first fit algorithm is suitably augmented with a framework for guessing the value of OPT and adjusting this guess over time, then it has a competitive ratio better than the naïve bound of 3 for unknown OPT. (The proof of the next theorem is also deferred to the full version of the paper.)

▶ **Theorem 4.** *The first fit algorithm is* 2.89*-competitive for the 2DSCHED problem with unknown* OPT*.*

While we only showcase the power of our framework by giving tight analyses of the algorithms described above, we believe that our framework has the potential to find more applications. This is because it reduces characterizing the reachable states for an arbitrary number of machines to those for only two machines, making the search space of the worst-case assignment much more tractable from an analytical perspective. In fact, our framework is easily extendable to arbitrary d, so that we only need to consider reachable states pretending that there are only d machines. While we currently know how to analytically characterize the reachable states only when $d = 2$, and therefore the results in this paper are only for this case, it is plausible (and an interesting direction of future work) to further extend such a characterization to higher dimensions analytically and/or numerically using the fact that the number of available machines is small. In that case, our framework would be useful in providing results for online vector scheduling in $d > 2$ dimensions, e.g., in cases of three or four dimensions that are also of practical interest.

A Near-optimal Algorithm

We now switch our attention to a different type of algorithmic result. Note that the competitive ratio of all the known algorithms for $d \geq 2$ are based on their comparison against the fractional optimum. That is, as long as the total load vector is $m \cdot \vec{1}$, and each job load vector is at most $\vec{1}$, an α-competitive algorithm produces a schedule where the load vector on each machine is at most $\alpha \cdot \vec{1}$. Note that when $d = 1$, the competitive ratio 2 is also obtained against the fractional optimum and even the best competitive ratio 1.916 against the actual optimum is not far from 2.

Our next result is to give an online algorithm whose competitive ratio nearly matches the best one can hope for against the fractional optimum for any fixed d. Here our high-level approach is as follows. We first use a variant of the algorithm in [29] to assign jobs to groups of machines, ensuring that every group receives at most $1 + \epsilon$ times its share of the load in an optimal fractional solution. Then, we assign jobs to machines within each group. We differentiate between "big" jobs and "small" jobs in this assignment. For the big jobs, we use discretization to bound the number of job types, and then use an optimal decision tree to make the actual assignments. Note that the optimal decision tree can be found *offline* for every possible job arrival pattern since the total number of big jobs in a group is small, and the one that matches the online sequence can be pressed into service in the online algorithm. To assign small jobs using the decision tree, we batch and encapsulate small jobs of similar load vectors into *bin* vectors. To enable this online, we pre-allocate some bin vectors. Thus, we can effectively reduce the problem of assigning small jobs to the scalar bin packing using pre-allocation and the decision tree.

▶ **Theorem 5** (Section 6). *For any $d \geq 1$ and $\epsilon > 0$, assuming that the value of the optimum makespan*[4] *is known a priori, there exists a deterministic online algorithm for the online vector load balancing problem whose competitive ratio is $(1 + \epsilon)c_d^*$, where c_d^* is the best competitive ratio one can hope for against the fractional optimum. Furthermore, the running time of the algorithm is polynomial in n for any fixed d, ϵ.*[5] *(For a more formal statement of this result, see Definition 23 and Theorem 24.)*

Before closing this section, we note the contrast between the first set of results based on the new analysis framework, and the last result that yields the nearly best competitive ratio against the fractional optimum. While the near optimality of the last solution is attractive,

[4] More accurately, the value of the fractional optimum makespan.

[5] More precisely, the running time is polynomial in n and $(d/\epsilon)^{d^{(d/\epsilon)^{O(d)}}}$.

the first set of algorithms are much more practical since the complexity of obtaining an optimal decision tree is likely to be prohibitive for the last algorithm. Furthermore, the last result does not give a numerical performance guarantee, unlike the first set of algorithms. Indeed, these two sets of results complement each other, and cumulatively provide the first insights into the 2DSched problem.

1.2 Related Work

The online load balancing problem for 1-dimensional jobs has had a long history. It was introduced by Graham in the 1960s [26, 27], who gave the list scheduling algorithm with a competitive ratio of 2. In the last three decades, there have been a series of results for improving the competitive ratio below 2 and obtaining lower bounds on the competitive ratio [10, 37, 1, 19, 18, 11, 25, 28, 2]. The best algorithm known is a 1.916-competitive algorithm due to Albers [2]. These results address the situation where the online algorithm does not know the value of OPT. Azar and Regev [9] introduced the problem of online load balancing when OPT is known, and called this problem *bin stretching*. For bin stretching, a series of results [40, 4, 38, 39, 21, 20, 12] have led to a 1.5-competitive algorithm due to Böhm et al. [12].

Recent research has expanded the scope of this problem to vector jobs, the resulting problem being called vector scheduling. Matching upper and lower bounds of $O(\log d/\log\log d)$ have been derived for d dimensions [15, 7, 43, 29]. Note that since the competitive ratio is super-constant, OPT can be assumed to be known by a standard guess and double trick. All these results are for an arbitrary number of machines and jobs. There is a large literature on variations, generalizations, and special cases of these problems, such as optimizing norms other than makespan, considering non-identical machines, focusing on a small constant number of machines, handling only jobs of small size, etc. that we omit here for brevity. The reader is referred to several excellent surveys on the topic, e.g., by Azar [5], Sgall [46, 47], Pruhs, Sgall, and Torng [45], Albers [3], etc.

The online load balancing problem is also related to the online bin packing problem, where the capacity of every machine is fixed and the goal is to minimize the number of machines used. For a single dimension, this problem has been studied since the work of Johnson in the 1970s; see, e.g., [34, 36] and surveys [22, 48]. For vector jobs, the problem was introduced by Garey et al. [23] and has been extensively studied in the last few years [7, 6, 8].

We note that some results of a flavor similar to Theorem 5 are known for other scheduling problems. Specifically, Lübbecke et al. [42] showed online algorithms of competitive ratios arbitrarily close to the optimum for the objective of minimizing total weighted completion time and its generalizations on unrelated machines. Various types of priority-based algorithms have been extensively studied for various scheduling problems. See [14] for the relevant pointers and follow-up works.

Roadmap

We present the general framework for analyzing priority based algorithms in Section 3 and use it to analyze the greedy algorithm in Section 4 for unknown OPT and the balance algorithm in Section 5 for known OPT. Finally, we present the near-optimal algorithm against the fractional optimum in Section 6.

2 Preliminaries

In this paper, we focus on the online 2-dimensional scheduling problem, or 2DSCHED in short. In this problem, a set of n jobs $\mathbf{V}$, indexed by $j \in [n]$, and represented by 2-dimensional non-negative vectors $v_j = (v_j(1), v_j(2))$ arrive in an online sequence. On arrival, a job must be assigned to one of a given set of m identical machines M, indexed by $i \in [m]$. The goal of the algorithm is to minimize the *makespan*, which is defined as the maximum load on any dimension of any machine. Formally, for any machine i, let V_i^j denote the set of vectors assigned to this machine after the arrival of the j'th vector. Then, we say that machine i's *configuration* is given by $c_i^j = \sum_{v_{j'} \in V_i^j} v_{j'}$, which is (we may omit the superscript j if it is clear from the context):

$$(c_i^j(1), c_i^j(2)) = \left(\sum_{v_{j'} \in V_i^j} v_{j'}(1), \sum_{v_{j'} \in V_i^j} v_{j'}(2) \right).$$

For any value k, we say $c_i \leq \vec{k}$ if $c_i(1) \leq k$ *and* $c_i(2) \leq k$; otherwise, we say $c_i \nleq \vec{k}$ if at least one of these inequalities are violated, i.e., if $c_i(1) > k$ *or* $c_i(2) > k$. Analogously, we define $c_i \geq \vec{k}$ if $c_i(1) \geq k$ *and* $c_i(2) \geq k$; otherwise, we say $c_i \ngeq \vec{k}$.

Let us denote the optimal offline configuration by OPT; overloading notation, let OPT also represent the makespan of this configuration. The online algorithm is said to be α-competitive if $c_i^n \leq \vec{a}$ for all $i \in [m]$, where $a = \alpha \cdot \text{OPT}$. We show two sets of results, the first when the value of OPT is known and the second when OPT is unknown to the algorithm. Note that if OPT is unknown, then its value is not used in the definition of the algorithm. Nevertheless, for the sake of the analysis, we normalize and set $\text{OPT} = 1$, which also implies that for all job vectors $v_j \in V$, we have $v_j(1), v_j(2) \in [0, 1]$, and $\sum_{j \in [n]} v_j/m \leq \vec{1}$. For convenience, we call the first coordinate the *left* coordinate, and the second coordinate the *right* coordinate. We call a job a *left vector* if its left coordinate is larger than or equal to its right coordinate, and a *right vector* otherwise.

3 Priority-based Algorithms

In this section, we give a framework to analyze a large class of algorithms that prioritize machines based on their current load. More specifically, such an algorithm computes a certain disutility for each machine only using its current load and the arriving job's load and assigns it to a machine with the least disutility. Thus, this class of algorithms are completely determined by the disutility function: $u : (c, g) \to [0, \infty]$ where $c \in [0, \infty)^2$ represents a machine's current load vector, and $g \in [0, \infty)^2$ a job's load vector. Formally, given a set $[m]$ of machines, the algorithm PRIORITY(u) assigns job j to machine $i^* := \arg\min_{i \in [m]} u(c_i^{j-1}, v_j)$ breaking ties arbitrarily but consistently. Here, as mentioned before, c_i^{j-1} denotes machine i's load just before assigning job j. After assigning job j, we update $c_{i^*}^j = c_{i^*}^{j-1} + v_j$ while keeping $c_i^j = c_i^{j-1}$ for all $i \neq i^*$. If $u(c_i^{j-1}, v_j) = \infty$ for all $i \in [m]$, then PRIORITY(u) declares failure.

3.1 Analysis Framework: Zooming in on Jobs Assigned to Two Machines

Now we present our general framework to analyze the above type of priority-based algorithms. The key to this framework is to define the set of reachable configurations.

▶ **Definition 6.** *We say that an ordered tuple $C = (c_1, c_2, \ldots, c_m)$, which we call a configuration, where $c_i \in [0, \infty)^2$, is reachable by* Priority(u) *if machines have load vectors $c_1, c_2, \ldots, c_m$ after* Priority(u) *assigns some sequence of jobs $[n]$ to machines $[m]$, such that $||v_j||_\infty \leq 1$ for all $j \in [n]$ and $\sum_{j \in [n]} v_j \leq m \cdot \vec{1}$. The set of reachable configurations is denoted by $\mathcal{R}_m(u)$.*

Unfortunately, it seems extremely challenging to characterize the reachable configurations for m machines in general. Our key observation is that the priority-based choices made by our algorithms allows us to focus on the loads of only two machines.

▶ **Observation 7.** *For any disutility function u and configuration $C = (c_1, c_2, \ldots, c_m) \in \mathcal{R}_m(u)$, and for any pair $i \neq j \in [m]$, we have $(c_i, c_j) \in \mathcal{R}_2(u)$.*

Proof. For notional convenience, say machines i and j have load vectors c_i and c_j, respectively. Consider the jobs that are assigned to machines i and j. If we assign those jobs to machines i and j pretending that no other machines exist, the two machines i and j each would get assigned exactly the same set of jobs. This is because Priority(u) prioritizes machines only based on their current respective load vector and the arriving job's load vector. Thus, we have shown $(c_i, c_j) \in \mathcal{R}_2(u)$. ◀

Now, the looming question is which pair of machines we should focus on. If α is the target competitive ratio we want to establish, we would like to focus on critical machines, i.e., where one of the coordinates has a load exceeding $\alpha - 1$ since they cannot accommodate a job of load vector $\vec{1}$. Also, we would like to focus on a pair where the "average" load between the two dimensions is not so high to draw a contradiction – more precisely, a convex combination of the load vectors of the two machines should be capped by $\vec{1}$. To denote such a pair, we will often use the notation $p = (p_f, p_s)$, where $p_f, p_s \in [0, \infty)^2$,

▶ **Definition 8.** *For an unordered pair of configuration $p = (p_f, p_s)$, we define*
- *$p \in \mathcal{L}(\alpha)$ iff $p_f + \vec{1} \nleq \vec{\alpha}$ and $p_s + \vec{1} \nleq \vec{\alpha}$, and we say p is* overloaded*; and*
- *$p \in \mathcal{F}$ iff for all $\lambda \in [0, 1]$, we have $\lambda \cdot p_f + (1 - \lambda) \cdot p_s \nleq \vec{1}$, and we say p is* overflown*.*

The next lemma shows that there will always be at least one pair of configurations that has not overflown.

▶ **Lemma 9.** *For any $C = (c_1, c_2, \ldots, c_m) \in \mathcal{R}_m(u)$ such that $c_i \neq \vec{0}$ for all $i \in [m]$, there exist $k \neq \ell \in [m]$ such that $(c_k, c_\ell) \notin \mathcal{F}$.*

Proof. Let $q = \frac{\sum_{i \in [m]} c_i}{m}$; note $q \leq \vec{1}$ since $C \in \mathcal{R}_m(u)$. Clearly, q is in the convex hull of the vectors, $c_1 \ldots, c_m$. However, the convex hull doesn't include $\vec{0}$. Since the convex hull is in two-dimensional space, this means there exists $\gamma \in (0, 1]$, such that $\gamma \cdot q$ is on the segment (c_k, c_ℓ) for some $k, \ell \in [m]$. Thus, there exists $\lambda \in [0, 1]$ such that

$$\lambda \cdot c_k + (1 - \lambda) \cdot c_\ell = \gamma \cdot q.$$

As $q \leq \vec{1}$, we have $(c_k, c_\ell) \notin \mathcal{F}$. ◀

The following observation is immediate from the definition of $\mathcal{L}(\alpha)$ and $\mathcal{F}$, it will be useful to first enlist the different cases in terms of these individual coordinate values.

▶ **Observation 10.** *For any $\alpha > 2$, if $(p_f, p_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$, then we have:*
- *either $p_f(2), p_s(1) > 1$ and $p_f(1), p_s(2) < 1$;*
- *or, $p_f(1), p_s(2) > 1$ and $p_f(2), p_s(1) < 1$.*

If the algorithm Priority(u) reaches a state where no machine can accommodate another job of load $\vec{1}$, then using Lemma 9, we can find a pair of configurations in $\mathcal{L}(\alpha) \setminus \mathcal{F}$. Then, using the facts that the pair is overloaded yet not overflown, we can determine the sign of a certain function $V(p_f, p_s)$ defined on the configuration's load vectors; this function will be useful to draw a contradiction later. Formally, for a pair of configuration (p_f, p_s), define

$$V(p_f, p_s) := \frac{p_f(2) \cdot (p_s(1) - 1) + p_s(2) \cdot (1 - p_f(1))}{p_s(1) - p_f(1)} - 1 \tag{1}$$

▶ **Lemma 11.** *For $\alpha > 2$, if $(p_f, p_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$, then we have $V(p_f, p_s) \leq 0$.*

Proof. Since $p_f + 1, p_s + 1 \nleq \vec{\alpha}$ and $\alpha > 2$, we can assume wlog that $p_f(2) > 1$; the other case $p_f(1) > 1$ can be handled similarly. Then, we must have

$$p_s(2) < 1 \text{ and } p_s(1) > 1 \text{ and } p_f(1) < 1,$$

since $(p_f, p_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$; see Observation 10. Define

$$f(\lambda, k) := \lambda \cdot p_f(k) + (1 - \lambda) \cdot p_s(k).$$

Since $(p_f, p_s) \notin \mathcal{F}$, there must exist $\lambda^* \in [0, 1]$ such that $f(\lambda^*, 1), f(\lambda^*, 2) \leq 1$. Observe $f(\lambda, k)$ is monotonically decreasing in λ when $k = 1$, and monotonically increasing when $k = 2$. For

$$\tilde{\lambda} = \frac{p_s(1) - 1}{p_s(1) - p_f(1)} \in [0, 1], \text{ i.e., } 1 - \tilde{\lambda} = \frac{1 - p_f(1)}{p_s(1) - p_f(1)},$$

we have $f(\tilde{\lambda}, 1) = 1$. Since $f(\lambda, 1)$ is monotonically decreasing, $\lambda^* \geq \tilde{\lambda}$. Since $f(\lambda, 2)$ is monotonically increasing, we have

$$f(\tilde{\lambda}, 2) = \frac{p_f(2) \cdot (p_s(1) - 1) + p_s(2) \cdot (1 - p_f(1))}{p_s(1) - p_f(1)} \leq f(\lambda^*, 2) \leq 1,$$

as desired. ◀

Having established the sign of $V(p_f, p_s)$, we now observe that it is an increasing function in any of the coordinates of the two configurations p_f, p_s.

▶ **Observation 12.** *For $\alpha > 2$ and $p = (p_f, p_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$ we have*

$$\left(\frac{\partial V(p_f, p_s)}{\partial p_f(1)}, \frac{\partial V(p_f, p_s)}{\partial p_f(2)}, \frac{\partial V(p_f, p_s)}{\partial p_s(1)}, \frac{\partial V(p_f, p_s)}{\partial p_s(2)} \right) > \vec{0}.$$

Proof. By taking partial derivatives on $p_f(1), p_f(2), p_s(1), p_s(2)$ respectively, we have

$$\begin{aligned} &\left(\frac{\partial V(p_f, p_s)}{\partial p_f(1)}, \frac{\partial V(p_f, p_s)}{\partial p_f(2)}, \frac{\partial V(p_f, p_s)}{\partial p_s(1)}, \frac{\partial V(p_f, p_s)}{\partial p_s(2)} \right) \\ &= \left(\frac{(p_f(2) - p_s(2)) \cdot (p_s(1) - 1)}{(p_f(1) - p_s(1))^2}, \frac{1 - p_s(1)}{p_f(1) - p_s(1)}, \frac{(p_f(2) - p_s(2)) \cdot (1 - p_f(1))}{(p_f(1) - p_s(1))^2}, \frac{p_f(1) - 1}{p_f(1) - p_s(1)} \right) \\ &> \vec{0}, \end{aligned}$$

where the last inequalities follow from Observation 10. ◀

▶ **Corollary 13.** *For any $\alpha > 2$, if $(p_f, p_s), (p'_f, p'_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$, and $p_f \geq p'_f$ and $p_s \geq p'_s$, then we have $V(p_f, p_s) \geq V(p'_f, p'_s)$.*

We now have all the pieces for the refined analysis of $\textsc{Priority}(u)$. Suppose we want to show $\textsc{Priority}(u)$ is α-competitive. Towards this end, it is sufficient to show that if $C = (c_1, c_2, \ldots, c_m) \in \mathcal{R}_m(u)$, then we have $c_i + \vec{1} \leq \vec{\alpha}$ for some $i \in [m]$. For the sake of contradiction, suppose not. Then, by Lemmas 9 and 11, we have $(c_k, c_\ell) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$ for some $k, \ell \in [m]$, and $V(c_k, c_\ell) \leq 0$. Further, by Observation 7, we know $(c_k, c_\ell) \in \mathcal{R}_2(u)$. This leads to the following lemma.

▶ **Lemma 14.** *If $\mathcal{R}_2(u) \cap \mathcal{L}(\alpha) \setminus \mathcal{F} = \emptyset$, then $\textsc{Priority}(u)$ is α-competitive.*

Note that this lemma allows us to analyze $\textsc{Priority}(u)$ pretending that there are only *two* machines. Now showing the condition $\mathcal{R}_2(u) \cap \mathcal{L}(\alpha) \setminus \mathcal{F} = \emptyset$ of the lemma depends on α and the disutility function u governing $\textsc{Priority}(u)$.

4 Greedy Algorithm: Unknown opt

In this section we consider the natural algorithm that assigns an arriving job to the machine yielding the minimum makespan. We recover this algorithm by setting the disutility function u to be the following:

$$\textsc{Max}(c, g) = ||c + g||_\infty \tag{2}$$

We call this algorithm $\textsc{Priority}(\textsc{Max})$. Our goal in this section is to prove the following theorem.

▶ **Theorem 15** (Upper Bound of Theorem 1). *$\textsc{Priority}(\textsc{Max})$ is $8/3$-competitive for the 2DSched problem.*

To show Theorem 15, we will set $\alpha = 8/3$ and use Lemma 14. We begin with an easy observation, which immediately follows from $||v_j||_\infty \leq 1$ for all jobs j. (The latter is a consequence of normalizing $\textsc{opt}$ in the analysis, and not an assumption on the input.)

▶ **Observation 16.** *For any $p = (p_s, p_f) \in \mathcal{R}_2(\textsc{Max})$, we have $|\, ||p_s||_\infty - ||p_f||_\infty| \leq 1$.*

It is straightforward to show $\textsc{Priority}(\textsc{Max})$ is 3-competitive using this observation. To obtain a tighter bound, we will show the following:

▶ **Lemma 17.** *For $\alpha = 8/3$, we have $(\mathcal{R}_2(\textsc{Max}) \cap \mathcal{L}(\alpha)) \setminus \mathcal{F} = \emptyset$.*

Note that Lemma 17 implies Theorem 15 by applying it to Lemma 14. So, the rest of this section is devoted to proving Lemma 17.

For a pair of configurations (p_f, p_s), define

$$H_1(p_f, p_s) := p_s(2) + p_f(1) - p_s(1) + 1$$
$$H_2(p_f, p_s) := p_s(2) + p_f(1) - p_f(2) + 1$$

▶ **Lemma 18.** *For a pair of configurations $p = (p_f, p_s)$, we have $p \notin \mathcal{R}_2(\textsc{Max})$ if*

$$\min\{H_1(p_f, p_s), H_2(p_f, p_s), H_1(p_s, p_f), H_2(p_s, p_f)\} < 0.$$

Proof. Assume for the sake of contraction that there exists $(p_f, p_s) \in \mathcal{R}_2(\textsc{Max})$ such that the minimum is non-negative. Further, assume that (p_f, p_s) is one among such configurations that is reachable by the minimum number of jobs assigned. Clearly, $(p_f, p_s) \neq ((0, 0), (0, 0))$. Since (p_f, p_s) is unordered, assume wlog that there exist c, g such that $p_f = c + g$ and $(c, p_s) \in \mathcal{R}_2(\textsc{Max})$ and $g \leq \vec{1}$ can be assigned to (a machine of load) c according to $\textsc{Priority}$ $(\textsc{Max})$, meaning $||c + g||_\infty \leq ||p_s + g||_\infty$. We consider two cases.

Case 1. $H_1(p_f, p_s) < 0$; this is symmetric to $H_2(p_s, p_f) < 0$. We have

$$H_1(c, p_s) = p_s(2) + c(1) - p_s(1) + 1 \leq p_s(2) + c(1) + g(1) - p_s(1) + 1 = H_1(p_f, p_s) < 0,$$

which is a contradiction to the minimality of (p_f, p_s).

Case 2. $H_2(p_f, p_s) < 0$; this is symmetric to $H_1(p_s, p_f) < 0$. In this case we have

$$0 > H_2(p_f, p_s) = p_s(2) + p_f(1) - p_f(2) + 1 \geq p_s(2) - p_f(2) + 1 \geq p_s(2) - p_f(2) + g(2);$$

hence we have $p_s(2) + g(2) < p_f(2)$. If $g(1) < p_f(2) - p_s(1)$, then

$$||c + g||_\infty = ||p_f||_\infty \geq p_f(2) > ||p_s + g||_\infty,$$

which is a contradiction to Priority(Max) assigning g to c. Therefore, we have $g(1) \geq p_f(2) - p_s(1)$. Then, we have

$$\begin{aligned} H_1(c, p_s) &= p_s(2) + c(1) - p_s(1) + 1 = p_s(2) + p_f(1) - g(1) - p_s(1) + 1 \\ &\leq p_s(2) + p_f(1) - p_f(2) + 1 = H_2(p_f, p_s) < 0, \end{aligned}$$

which is also a contradiction. ◀

We are now ready to prove Lemma 17.

Proof of Lemma 17. Since $(p_f, p_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$ and $\alpha = 8/3$, we assume wlog that $p_f(2) > \alpha - 1 = 5/3$ and $p_s(1) > \alpha - 1 = 5/3$ (see Observation 10; the other case is symmetric). Then, we have

$$H_1(p_f, p_s) = p_s(2) + p_f(1) - p_s(1) + 1 \geq 0 \text{ by Lemma 18,}$$

which yields

$$p_s(2) + p_f(1) \geq 2/3.$$

Letting $p_f(1) = x$, we have

$$p_s(2) \geq 2/3 - x.$$

Note that

$$p_f \geq p'_f := (x, 5/3 + \epsilon); \quad \text{and} \quad p_s \geq p'_s := (5/3 + \epsilon, 2/3 - x)$$

for sufficiently small $\epsilon > 0$. Thus, $(p'_s, p'_f) \notin \mathcal{F}$. Also notice $(p'_s, p'_f) \in \mathcal{L}(\alpha)$. Therefore, by Corollary 13, we have

$$V(p_f, p_s) \geq V(p'_f, p'_s) \geq 0.$$

By taking the limit $\epsilon \to 0$, we have

$$V(p_f, p_s) > \lim_{\epsilon \to 0} V(p'_f, p'_s) = \frac{(3x-1)^2}{3 \cdot (5 - 3x)} \geq 0,$$

which is a contradiction to $(p_f, p_s) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$ by Lemma 11. ◀

5 Balance Algorithm: Known opt

In this section, we consider another priority-based greedy algorithm, $\textsc{Priority}(\textsc{Bal})$. The rule $\textsc{Bal}$ is defined as follows:

$$\textsc{Bal}(c,g) = \begin{cases} d(c)\cdot d(g) & c+g \le \alpha\cdot\textsc{opt} \\ \infty & \text{otherwise,} \end{cases} \tag{Bal-α}$$

where $d(v) := v(2) - v(1)$ measures the signed difference between v's right load and left load.

In other words, $\textsc{Priority}(\textsc{Bal})$ tries to minimize the difference between the left and right loads over all machines, without violating a pre-defined threshold α. Note that this algorithm needs to know the value of $\textsc{opt}$, which is wlog assumed to be 1 by scaling. The $\textsc{Priority}(\textsc{Bal})$ algorithm keeps the machines in sorted order of the (signed) difference between the loads on the two coordinates (the left load minus the right load we say that the machines are maintained in left to right order where the rightmost (resp., leftmost) machine has the largest difference between the loads on the first and second coordinate (resp., second and first coordinate). Recall that a left (resp., right) vector is one whose first (resp., second) coordinate is larger. The $\textsc{Priority}(\textsc{Bal})$ algorithm assigns a left (resp., right) vector to the rightmost (resp., leftmost) machine that can accommodate it, i.e., whose load on any dimension does not exceed the desired competitive ratio α after the assignment. In order to achieve it, given a left (right) vector the algorithm would prefer to assign to the most unbalanced right (left) machine that can accommodate the vector.

▶ **Theorem 19** (Upper Bound of Theorem 2). *$\textsc{Priority}(\textsc{Bal})$, knowing $\textsc{opt}$ a priori, is 2.25-competitive for the 2DSched problem.*

To prove Theorem 19, thanks to Lemma 14, it suffices to show the following.

▶ **Lemma 20.** *For $\alpha = 2.25$, we have $(\mathcal{R}_2(\textsc{Bal}) \cap \mathcal{L}(\alpha)) \setminus \mathcal{F} = \emptyset$.*

The remainder of this section is devoted to proving Lemma 20. Instead of analysing directly $\mathcal{R}_2(\textsc{Bal})$, we introduce a slightly modified rule of $\textsc{Bal}$, which is not subject to α:

$$\textsc{Bal-No-Lim}(c,g) = d(c)\cdot d(g) \tag{3}$$

Note that $\mathcal{R}_2(\textsc{Bal-No-Lim}) \cap \{v \mid v \in [0,\alpha]^2\} \subseteq \mathcal{R}_2(\textsc{Bal})$ and the subtle difference between $\mathcal{R}_2(\textsc{Bal-No-Lim})$ and $\mathcal{R}_2(\textsc{Bal})$. The closure $\mathcal{R}_2(\textsc{Bal-No-Lim})$ attempts to assign a vector g to only mitigate the difference of the left and right loads of the two machines. If we can assign g to the machine i^* that achieves this, then this assignment would be exactly the same as $\textsc{Priority}(\textsc{Bal})$ would make. However, in the closure $\mathcal{R}_2(\textsc{Bal-No-Lim})$, if g would overflow machine i^*, it doesn't add it to the other machine even if it would be possible under $\textsc{Priority}(\textsc{Bal})$. This is summarized in the following observation.

▶ **Observation 21.** *For two pairs of configuration $p = (c_a, c_b), p' = (c_a + g, c_b)$, such that p' is reachable in $\mathcal{R}_2(\textsc{Bal})$ by assigning a job of load $g \in [0,1]^2$ into (a machine of load) c_a in the pair p, if $(c_a + g, c_b) \in \mathcal{R}_2(\textsc{Bal}) \setminus \mathcal{R}_2(\textsc{Bal-No-Lim})$ and $(c_a, c_b) \in \mathcal{R}_2(\textsc{Bal-No-Lim})$, then $c_b + g \not\le \vec{\alpha}$ and $(d(c_a) - d(c_b)) \cdot d(g) > 0$.*

For a pair of configuration (c_s, c_f), define

$$H_3(c_f, c_s) := d(c_s) - d(c_f) + 1 = c_s(2) - c_s(1) - c_f(2) + c_f(1) + 1$$

▶ **Lemma 22.** *For a pair of configuration $p = (p_s, p_f)$, if $H_3(p_f, p_s) < 0$ or $H_3(p_s, p_f) < 0$, then we have $p \notin \mathcal{R}_2(\textsc{Bal-No-Lim})$.*

Proof. Assume for the purpose of contradiction that $p \in \mathcal{R}_2(\textsc{Bal-No-Lim})$. Assume $H_3(p_f, p_s) < 0$, since the case $H_3(p_s, p_f) < 0$ is symmetric. There must exist a vector g such that $p_f = c + g$, and $(c, p_s) \in \mathcal{R}_2(\textsc{Bal-No-Lim})$, for which $\textsc{Priority}$ ($\textsc{Bal-No-Lim}$) assigned to c, hence we have

$$\textsc{Bal-No-Lim}(c) - \textsc{Bal-No-Lim}(p_s) = (d(c) - d(p_s)) \cdot d(g) \leq 0.$$

We consider two cases.

Case 1. $g(2) > g(1)$: Clearly, $g(2) - g(1) \leq 1$. However, $d(p_s) - d(p_f) + 1 = H_3(p_f, p_s) < 0$, hence

$$d(p_s) < d(p_f) - 1 = d(c + g) - 1 = c(2) + g(2) - c(1) - g(1) - 1 \leq c(2) - c(1) = d(c).$$

Therefore, $(d(c) - d(p_s)) \cdot (g(2) - g(1)) > 0$, which is a contradiction.

Case 2. $g(2) \leq g(1)$: We have

$$c(2) - c(1) - 1 \geq c(2) + g(2) - c(1) - g(1) - 1 = p_f(2) - p_f(1) - 1 > p_s(2) - p_s(1).$$

Therefore, we have $H_3(c, p_s) < 0$ hence $(c, p_s) \notin \mathcal{R}_2(\textsc{Bal-No-Lim})$, which is a contradiction. ◀

We now have all the pieces to prove Lemma 20.

Proof of Lemma 20. Assume for the purpose of contradiction that there exists a pair $p = (c_r, c_\ell) \in \mathcal{R}_2(\textsc{Bal}) \cap \mathcal{L}(\alpha)) \setminus \mathcal{F}$. Let $\langle p^\emptyset, p^1, \dots p^n = p\rangle$ a sequence of reachable pairs i.e. for all i, $p^i \in \mathcal{R}_2(\textsc{Bal})$ and p^{i+1} is reachable from p^i by a single vector assignment under $\textsc{Priority}(\textsc{Bal})$.

Case 1. For all $i \in [n]$, $p^i \in \mathcal{R}_2(\textsc{Bal-No-Lim})$. Since $p = (c_r, c_\ell) \in \mathcal{R}_2(\textsc{Bal-No-Lim}) \cap \mathcal{L}(\alpha)$, assume wlog that $c_r(2) > \alpha - 1$, $c_\ell(1) > \alpha - 1$. In addition, since $(c_r, c_\ell) \in \mathcal{R}_2(\textsc{Bal-No-Lim})$, by Lemma 22, we have $H_3(c_r, c_\ell) = c_\ell(2) - c_\ell(1) - c_r(2) + c_r - 1 \geq 0$. Therefore, we have

$$0 \leq H_3(c_r, c_\ell) \leq H_3((c_r(1), \alpha - 1), (\alpha - 1, c_\ell(1)) = 3 - 2 \cdot \alpha + c_r(1) + c_\ell(2).$$

By setting $c_r(1) = x$, we have $c_\ell(2) \geq 2 \cdot \alpha - 3 - x$. Note $x \in [0, 1]$ since $c_\ell(1) > 1$ and $(c_r, c_\ell) \notin \mathcal{F}$. For $\alpha = 2.25$, we have

$$V(c_r, c_\ell) > V((x, \alpha - 1), (\alpha - 1, 2 \cdot \alpha - 3 - x)) = \frac{(4x - 3)^2}{20 - 16x} \geq 0,$$

which is a contradiction to $p \in \mathcal{L}(\alpha) \setminus \mathcal{F}$ by Lemma 11.

Case 2. $p^i \notin \mathcal{R}_2(\textsc{Bal-No-Lim})$ for some $i \in [n]$. Let i be the first index such that $p^i \notin \mathcal{R}_2(\textsc{Bal-No-Lim})$, let $p^{i-1} = (c_a, c_b)$, $p^i = (c_a + g, c_b)$. Note that $c_r \geq c_a$ and $c_\ell \geq c_b$. By Observation 21 we have $c_b + g \nleq \vec{\alpha}$. Assuming wlog that $c_b(1) + g(1) > \alpha$, we have $c_b(1) > \alpha - g(1) > 1$ since $g \leq \vec{1}$ and $\alpha > 2$. For the same reason, we have $c_r(2) > \alpha - 1$, and $c_r(1), c_\ell(2) \leq 1$ (since $(c_r, c_\ell) \in \mathcal{L}(\alpha) \setminus \mathcal{F}$).

Since $V(c_r, c_\ell)$ is monotone increasing, we have $V(c_r, c_\ell) > V(\langle c_a(1) + g, \alpha - 1\rangle, c_b)$. Moreover, by our assumption $p^{i-1} = (c_a, c_b) \in \mathcal{R}_2(\textsc{Bal-No-Lim})$, by Lemma 22, we have

$$\begin{array}{rcccl} H_3(c_a, c_b) & = & c_b(2) - c_b(1) - c_a(2) + c_a(1) + 1 & \geq & 0, \\ c_a(1) & \geq & \max\{c_a(2) - c_b(2) + c_b(1) - 1, 0\} & \geq & \max\{c_b(1) - c_b(2) - 1, 0\}. \end{array}$$

Recall that $c_r(1) \leq 1$, and we have $c_a(1) \geq c_b(1) - c_b(2) - 1$, and $g(1) > \alpha - c_b(1)$. Therefore, $1 \geq c_r(1) \geq g(1) + c_a(1) \geq \alpha - c_b(1) + c_a(1) \geq \alpha - c_b(2) - 1$, which yields $c_b(2) \geq \alpha - 2$. Thus,

$$V(c_r, c_\ell) > V(\langle \alpha - c_b(1) + \max\{c_b(1) - c_b(2) - 1, 0\}, \alpha - 1\rangle, \langle c_b(1), c_b(2)\rangle).$$

We lower bound V by considering two cases:

Case A. If $c_b(1) - c_b(2) < 1$, then

$$V(c_r, c_\ell) > V(\langle \alpha - c_b(1), \alpha - 1\rangle, \langle c_b(1), c_b(2)\rangle) \geq V(\langle \alpha - c_b(1), \alpha - 1\rangle, \langle c_b(1), c_b(1) - 1\rangle).$$

Case B. If $c_b(1) - c_b(2) \geq 1$, then

$$V(c_r, c_\ell) > V(\langle \alpha - c_b(2) - 1, \alpha - 1\rangle, \langle c_b(1), c_b(2)\rangle) \geq V(\langle \alpha - c_b(2), \alpha - 1\rangle, \langle 1 + c_b(2), c_b(2)\rangle).$$

Setting $x = c_b(1) - 1 (\geq \alpha - 2)$ in the first case and $x = c_b(2)$ in the second case, we get that $x \geq \alpha - 2$ in both cases. So, we have

$$V(c_r, c_\ell) > V(\langle \alpha - 1 - x, \alpha - 1\rangle, \langle 1 + x, x\rangle) \geq 0.$$

By setting $\alpha = 2.25$, for $x \geq \alpha - 2 = 0.25$, we have

$$V(c_r, c_\ell) > V(\langle \alpha - 1 - x, \alpha - 1\rangle, \langle 1 + x, x\rangle) = \frac{(2x-1)^2}{8x-1} \geq 0,$$

which is a contradiction to $p \in \mathcal{L}(\alpha) \setminus \mathcal{F}$ by Lemma 11. ◀

6 A Nearly Optimal Algorithm Against the Fractional Optimal Solution

Recall that all algorithms we developed and analyzed were based on the two most obvious lower bounds for the optimal solution, the total load vector of all jobs and the maximum job size on any dimension. Therefore, the benchmark we used can do better than the offline optimum solution. For example, consider three job vectors $(1, 1, 0), (1, 0, 1), (0, 1, 1)$ to be scheduled on 2 machines. Since one of the two machines must receive at least two jobs, the optimum makespan cannot be smaller than 2. However, this instance still has an average load of 1 on all dimensions and no job has size greater than 1 on any dimensions. In other words, the benchmark can distribute all jobs equally across all machines. For this reason, we will call this benchmark the fractional optimum solution.

▶ **Definition 23.** *For any number of dimensions $d \geq 1$, the optimum competitive ratio c_d^* against the fractional optimum solution is defined as*

$$\inf_A \sup_J \frac{\max_{i \in [m], k \in [d]} \Lambda_i^{J,m}(k)}{\max\{\|\sum_{j \in J} v_j / m\|_\infty, \max_{j \in J, k \in [d]} v_j(k)\}},$$

where A denotes an arbitrary deterministic online algorithm, J an arbitrary sequence of jobs, m the number of machines, and $\Lambda_i^{J,m}$ the load vector of machine i under the assignment of jobs J to machines $[m]$ by the algorithm A.

Our goal is to develop and analyze an algorithm that performs nearly as well as the fractional optimum solution.

▶ **Theorem 24.** *For any $d \geq 1$ and $\epsilon > 0$, assuming that the value of the optimum makespan*[6] *is known a priori, there exists a deterministic online algorithm for the vector scheduling problem whose competitive ratio is $(1+\epsilon)c^*_d$. Further, the running time is polynomial in n for any fixed d, ϵ.*[7]

6.1 Assigning Jobs to Groups

The first stage of the algorithm is executed only when $m \geq (1 + \frac{1}{\epsilon})\alpha$ where $\alpha := \frac{250}{\epsilon^3} \log d$. We group machines so that every group has exactly α machines; to simplify the notation we assume that α is an integer to omit ceilings. The only one possible group that has less than α machines is discarded. We assign jobs to the (remaining) groups and obtain the following lemma using an algorithm and analysis very similar to [29]; hence, we defer the details to the full version of the paper.

▶ **Lemma 25.** *For a sufficiently small $\epsilon > 0$, there exists an online algorithm that assigns jobs to the groups, each consisting of $\alpha := \frac{250}{\epsilon^3} \log d$ machines, such that every group's total load is at most $(1+\epsilon)\alpha d\vec{1}$.*

Note that the average load vector a machine should handle increases by a factor of at most $\frac{m}{m-(\alpha-1)} \leq \frac{1+1/\epsilon}{1+1/\epsilon-1} = 1+\epsilon$. We also slightly modify each job's load vector: For each job j, we minimally increase v_j, so that we have $v_j(k) \geq (\epsilon/d)||v_j||_\infty$. This is wlog since increasing job load vectors can only increase the algorithm's makespan and we fixed the optimum to be 1.

▶ **Lemma 26.** *The preprocessing step increases the total load vector to at most $(1+\epsilon)m\vec{1}$.*

Proof. For the sake of contradiction, suppose the total load is more than $(1+\epsilon)m$ on some dimension. It means the load increased by more than ϵm on the dimension. We know that job j contributes to the increase by at most $(\epsilon/d)||v_j||_\infty$. Thus, the increase is at most $\sum_j (\epsilon/d)||v_j||_\infty$. However, we know $\sum_j ||v_j||_\infty \leq md$ since the total load of all jobs across all dimensions is md. Therefore, the increase is at most ϵm, which is a contradiction. ◀

Since we are only concerned with assigning jobs to groups of machines at this stage, to simplify notation we pretend each group is a machine. By a machine i, we mean the i-th group which consists of α machines.

We now restate the problem: We are given $m' = \lfloor \frac{m}{\alpha} \rfloor$ machines. Let $[n]$ denote the set of all jobs arriving, which satisfies the following properties.

- Property (i): The total job load vector, i.e., $\sum_{j\in[n]} v_j$ is at most $m'\alpha(1+\epsilon)^2\vec{1}$.
- Property (ii): For all $j \in [n]$, $||v_j||_\infty \leq 1$.
- Property (iii): For all $j \in [n]$, $\min_k v_j(k) \geq (\epsilon/d)||v_j||_\infty$.

Our goal is to assign jobs to m' machines so that each group receives jobs of total load at most $(1+7\epsilon)\alpha\vec{1}$, which would immediately imply Lemma 25 by scaling ϵ.

The algorithm has two procedures. The algorithm pretends there are two sets M_1 and M_2 of machines, where $|M_1| = |M_2| = m'$. The first procedure assigns all jobs to machines M_1 and identifies a set J^2 of jobs, which will be assigned to machines M_2 by the second procedure. However, this is a shadow process: What really happens is that only jobs in

[6] More accurately, the value of the fractional optimum makespan.

[7] More precisely, the running time is polynomial in n and $(d/\epsilon)^{d^{(d/\epsilon)^{O(d)}}}$.

$[n] \setminus J^2$ remain on machines M_1 and the other jobs J^2 are assigned to machines M_2. Further, the algorithm pairs machines between M_1 and M_2 arbitrarily and combine the load vectors of the paired machines. To prove Lemma 25, it suffices to show the following two lemmas (with scaling ϵ):

▶ **Lemma 27.** *The makespan of the assignment of $[n] \setminus J^2$ to M_1 is at most $((1+\epsilon)^5\alpha+1)\vec{1} \leq (1+6\epsilon)\alpha\vec{1}$.*

▶ **Lemma 28.** *The makespan of the assignment of J^2 to M_2 is at most $\epsilon\alpha\vec{1}$.*

We are now ready to describe the algorithm.

- **First procedure (assignment by a potential function):** Let $\beta := (1+\epsilon)^3$. Let $f(x) := \beta^x$. Each job j is assigned to a machine $i \in M_1$ such that $\Phi(j)$ is minimized. For every $i \in M_1$, let $\Lambda^1_{i,j}$ denote machine i's load vector right after assigning job j to some machine in M_1. If $\Lambda^1_{i,j}(k) \geq \beta\alpha + 1$, then j is added to queue J^2 so that it can be scheduled by the second procedure.

$$\Phi_{i,k}(j) := f\left(\Lambda^1_{i,j}(k) - \frac{\beta}{m'} \sum_{j' \in [j]} v_{j'}(k)\right) \qquad \forall i \in M_1, j \in [n], k \in [d]$$

$$\Phi(j) := \sum_{i \in M_1} \sum_{k=1}^{d} \Phi_{i,k}(j)$$

- **Second procedure (assignment by greedy):** This procedure is only concerned with the jobs J^2 that are passed from the first procedure. It allocates each job in J^2 (in the order that the jobs arrive in) to one of the machines in M_2 such that the resulting makespan, $\max_{i \in M_2, k \in [d]} \Lambda^2_{i,j}(k)$ is minimized; here $\Lambda^2_{i,j}$ is analogously defined as $\Lambda^1_{i,j}$ is defined in the first procedure.

Note that Lemma 27 immediately follows due to the way the first procedure is defined. The proof of Lemma 28 constitutes the heart of the analysis in this stage of the algorithm. Since this closely follows techniques in [29], we defer the details of this analysis to the full version of the paper.

6.2 Assigning Jobs to Machines Within Each Group

We need to define a fair amount of notation to formally describe our algorithm. We assume that the input consists of m machines and the average load of all jobs to be assigned is at most $(1+\epsilon)m$ on all dimensions for some $\epsilon > 0$.

For ease of reference, we list the following definitions.

- Let $\beta := \frac{\epsilon}{2md}$; $\Delta := \frac{\epsilon^2}{d(1+1/\beta)^d}$; and $\delta := \epsilon\beta\Delta/(2dm)$.
- A vector is said to be a type vector if it is in $\{0, \beta, 2\beta, \cdots, 1\}^d \setminus \{\vec{0}\}$ and has 1 on at least one dimension. Let $\mathcal{Q}$ denote the set of all type vectors. Note that $|\mathcal{Q}| \leq (1+1/\beta)^d \leq (2/\beta)^d$.
- We say a job j is small if $||v_j||_\infty < \Delta$; otherwise it is big.
- The volume of a job j is defined as its total size over all dimensions.

We discretize big jobs and small jobs in different manners:

- Big jobs: For a big job j, we round its load on every dimension down to the nearest integer multiple of δ. Let $\mathcal{B}$ denote the set of all possible load vectors of big jobs after discretization.

- Small jobs: For a small job j, let $p_j = ||v_j||_\infty$. Then, we discretize v_j/p_j by rounding each entry down to the nearest integer multiple of β. Let q_j denote the resulting discretized vector of v_j/p_j; note that $q_j \in \mathcal{Q}$. After rounding, we can express each small job j as $p_j q_j$.

We are now ready to describe our algorithm. Below, assume that jobs are already discretized. We will later show that the effect of discretization is negligible on the competitive ratio.

6.2.1 Building a decision tree

We build a decision tree T to assign big jobs. To simplify the analysis later, we assume wlog that the total load vector T receives is exactly $m(1+4\epsilon)\vec{1}$. Each node of the decision tree T corresponds to the current loads of all the m machines. Each node u has at most $m|\mathcal{B}|$ children. Each edge (u, w) is associated with a pair (i, j) where $j \in \mathcal{B}$ and $i \in [m]$, meaning that if a big job j is assigned to machine i, then the machine loads vectors change from u to w. Since the total volume of jobs is at most $(1 + 4\epsilon)md \leq 5md$ and every big job has volume at least Δ, the decision tree has depth at most $5md/\Delta$ and the number of nodes is at most $(m|\mathcal{B}|)^{5md/\Delta}$. We only need to keep nodes whose machine load vectors don't contradict the assumption that the total load of all jobs on each dimension is exactly $(1 + 4\epsilon)m$.

Given that every node of the decision tree T corresponds to a configuration (machine load vectors) that can be reached via a valid sequence of big jobs along with their assignment, our goal is to compute the minimum makespan we can achieve from each node u. Formally, if u is a leaf node, define $g(u)$ to be the makespan norm of the machine load vectors corresponding to u. Otherwise, let $u_{i,j}$ denote u's child such that the edge $(u, u_{i,j})$ is associated with (i, j). Then, define $g(u) := \min_i \max_j g(u_{i,j})$.

We can use the tree T to assign big jobs as follows. Let u be the node corresponding to the current machine load vectors. If a big job j arrives, then we assign j to machine i with the minimum $g(u_{i,j})$.

The following observation is immediate due to the optimal nature of the decision tree for big jobs. In other words, the observation says that the decision tree yields a nearly optimal algorithm against the fractional optimum.

▶ **Observation 29.** *Let r denote the root of T. Then, $g(r) \leq (1 + 4\epsilon)c^*_d$.*

Proof. Since we assumed that the total load vector is exactly $(1+4\epsilon)m\vec{1}$, the denominator in Definition 23 is exactly $(1 + 4\epsilon)$. Since we know the decision tree gives an optimal algorithm for big jobs, we have $g(r)/(1 + 4\epsilon) \leq c^*_d$, as desired. ◀

6.2.2 Batching smalls jobs of the same type

We will first describe how we batch small jobs and assign them using the above decision tree T assuming that we can wait until we collect enough volume of jobs for each type. For each type vector $q \in \mathcal{Q}$, we create a buffer $F(q)$. The buffer has capacity Δ/ϵ. When a small job j of vector $p_j q_j$ arrives, we add it to buffer $F(q_j)$; j uses p_j space of the buffer. There are two events that trigger emptying a buffer. When we empty a buffer $F(q)$, we encapsulate the load vectors of all jobs in $F(q)$ into a "bin" vector $(\Delta/\epsilon)q$, and assign it using the decision tree T. The buffer is emptied when either we cannot add a job j since it would exceed the capacity Δ/ϵ or after all jobs arrive.

This procedure is well defined due to the following lemma.

▶ **Lemma 30.** *Every bin vector is in $\mathcal{B}$.*

Proof. Consider any bin vector $(\Delta/\epsilon)q$. To show that this is in $\mathcal{B}$, we need to show the following three: (i) it has size at least Δ on some dimensions; (ii) each of its entries is a multiple of δ; and (iii) it has size no more than 1 on every dimension. First, (i) follows since $||q||_\infty = 1$ due to the way we defined small job types. To see (ii), consider q's entry on each dimension – we know that its value must be $\ell\beta$ for some integer ℓ. So, it suffices to show that $(\Delta/\epsilon)(\ell\beta)/\delta$ is an integer. Recall that $\delta := \epsilon\beta\Delta/(2dm)$. Thus, we have, $(\Delta/\epsilon)(\ell\beta)/\delta = \frac{\Delta}{\epsilon}(\ell\beta)\frac{2dm}{\epsilon\beta\Delta}$, which is an integer assuming that $1/\epsilon$ is an integer. To see (iii), note that the maximum size over all dimensions is at most $(\Delta/\epsilon) = \frac{\epsilon}{d(1+1/\beta)^d} < 1$. ◀

6.2.3 Batching small jobs online

In the online setting we cannot wait to aggregate small jobs of the same type. To handle this issue, we pre-allocate one "bin" vector of each type. That is, before any jobs arrive, we pretend that one job of each load vector q arrives and assign it using the decision tree T. Then, batching jobs of the same type vector q in $F(q)$ is actually done on the machine that received the bin vector. Therefore, we can assign small jobs upon their arrival without waiting.

We have fully described our online algorithm to assign jobs upon their arrival. We now shift our focus to the analysis. When a job j is encapsulated into a type vector v of type $q \in \mathcal{Q}$, we say v contains job j.

▶ **Observation 31.** *Every bin vector of each type $q \in \mathcal{Q}$, possibly except one, has total size of jobs at least $(1-\epsilon)(\Delta/\epsilon)$.*

Proof. Since small jobs are aggregated only when they are of the same type, for each type $q \in \mathcal{Q}$, we can focus on the scalar quantities, job sizes p_j and the buffer size Δ/ϵ. The observation follows from the fact that we empty buffer $B(q)$ only when the total size of jobs in the buffer $B(q)$ exceeds $(1-\epsilon)(\Delta/\epsilon)$, or at the end after all jobs arrive. The only exception is due to the pre-allocation, which corresponds to emptying the buffer at the end. ◀

▶ **Lemma 32.** *If the total job load vector is at most $(1+\epsilon)m\vec{1}$, then the decision tree, due to batching and preallocation, receives jobs of total load vector at most $(1+4\epsilon)m\vec{1}$.*

Proof. By Observation 31, the total load vector T receives is at most $(1+\epsilon)m\vec{1}/(1-\epsilon) \le (1+3\epsilon)m\vec{1}$, plus $\sum_{q\in\mathcal{Q}}(\Delta/\epsilon)q$. Further, we have $\sum_{q\in\mathcal{Q}}(\Delta/\epsilon)q = |\mathcal{Q}|(\Delta/\epsilon)\vec{1} \le (1+1/\beta)^d \cdot \frac{\epsilon^2}{d(1+1/\beta)^d}\frac{1}{\epsilon}\vec{1} \le \epsilon\vec{1}$. ◀

Therefore, the algorithm sends to the decision tree T big jobs (including bin vectors which are big) of total load vector at most $(1+4\epsilon)m\vec{1}$. Note that sending less loads only helps our algorithm. By Observation 29, our algorithm's makespan is at most $(1+4\epsilon)c^*_d$-competitive if all jobs are discretized. We now show that when replacing each discretized vector with the original vector, every machine's load increases by at most $2\epsilon\vec{1}$. Knowing that the optimum makespan is 1, this will mean that the competitive ratio of our algorithm is at most $(1+6\epsilon)c^*_d$-competitive. By scaling ϵ appropriately, we obtain Theorem 24.

We complete the analysis by proving the following lemma.

▶ **Lemma 33.** *Restoring the discretized jobs load vectors to their original vectors increases each machine's load vector by at most $2\epsilon\vec{1}$.*

Proof. For the sake of contradiction, suppose the total load increases by more than 2ϵ on some fixed dimension d on some fixed machine i. In the first case, suppose at least ϵ increase was due to big jobs. Then, since discretizing a big job reduces its load by less than δ on each dimension, this means that the total number of big jobs assigned to the machine i is at least ϵ/δ. Since a big job has a volume Δ or more, the total volume of jobs assigned to machine i is at least $(\epsilon/\delta) \cdot \Delta = \epsilon/(\epsilon\Delta/2dm) \cdot \Delta = 2dm$, which is a contradiction to the fact that each machine has makespan at most $(1+4\epsilon)$, thus volume at most $(1+4\epsilon)d$. Now suppose at least ϵ increase was due to small jobs. Let S be the set of all small jobs assigned to machine i. We know that discretizing a small job j reduces its load by at most $p_j\beta$ on the fixed dimension d. Thus, we have $\sum_{j \in S} p_j\beta > \epsilon$. As a result, we have $\sum_{j \in S} p_j > \epsilon/\beta = \epsilon/(\epsilon/2md) = 2md$. This implies that the total volume of the jobs in S is at least $\sum_{j \in S} p_j \geq 2md$, which is a contradiction as before. ◀

6.3 Putting the Pieces Together

In Section 6.1 we showed if we use the first phase of the algorithm, then we can assign jobs to groups of machines so that each group has $m' = O(\frac{1}{\epsilon^3}\log d)$ machines and receives load at most $(1+\epsilon)m'\vec{1}$. Otherwise, we can pretend all jobs are assigned to the single group of all machines. In either case, we can assign jobs to groups of machines so that each group has $m' = O(\frac{1}{\epsilon^4}\log d)$ machines and receives load at most $(1+\epsilon)m'\vec{1}$. Then, using the procedure in 6.2, we can assign jobs to machines within group, so that each machine's load vector is at most $(1+6\epsilon)c_d^*\vec{1}$. Thus, we have found an online algorithm whose competitive ratio is $(1+\epsilon)c_d^*$ by appropriately scaling ϵ.

It now remains to show the running time of our algorithm. Since the running time is mostly dominated by the second phase, we will focus on the second phase. It is an easy exercise to see the running time is polynomially bounded by the size of decision tree and n. As discussed, the number of nodes is $(m|\mathcal{B}|)^{5md/\Delta}$, where $|\mathcal{B}| \leq (2/\delta)^d$. By the above discussion, we have $m = O(\frac{1}{\epsilon^4}\log d)$. Recall that $\beta := \frac{\epsilon}{2md}$, $\Delta := \frac{\epsilon^2}{d(1+1/\beta)^d}$, $\delta := \epsilon\beta\Delta/(2dm)$. By calculation, one can show that the tree size is $(d/\epsilon)^{d^{(d/\epsilon)^{O(d)}}}$. Thus, we have shown the running time.

This completes the proof of Theorem 24.

7 Open Problems

This paper gives the first non-trivial results for the online vector scheduling problem with a small number of dimensions. The most interesting open question is to better understand the competitive ratio of "practical" algorithms when $d > 2$. For instance, what is the competitive ratio of Priority(Max) when $d > 2$? Or, can we extend Priority(Bal) for $d = 2$ to higher dimensions? Even for $d = 2$, in our analysis, we used as the lower bound the fractional optimum where job vectors can be fractionally assigned to machines. This is inherently limited by the integrality gap of the fractional assignment. Can we obtain better lower bounds for the true optimum, and thereby improve the competitive ratio for the problem? For instance, for $d = 2$, is there a 2-competitive algorithm?

Abstract

The girth is one of the most basic graph parameters, and its computation has been studied for many decades. Under widely believed fine-grained assumptions, computing the girth exactly is known to require $mn^{1-o(1)}$ time, both in sparse and dense m-edge, n-node graphs, motivating the search for fast approximations. Fast good quality approximation algorithms for undirected graphs have been known for decades. For the girth in directed graphs, until recently the only constant factor approximation algorithms ran in $O(n^\omega)$ time, where $\omega < 2.373$ is the matrix multiplication exponent. These algorithms have two drawbacks: (1) they only offer an improvement over the mn running time for dense graphs, and (2) the current fast matrix multiplication methods are impractical. The first constant factor approximation algorithm that runs in $O(mn^{1-\varepsilon})$ time for $\varepsilon > 0$ and all sparsities m was only recently obtained by Chechik et al. [STOC 2020]; it is also combinatorial.

It is known that a better than 2-approximation algorithm for the girth in dense directed unweighted graphs needs $n^{3-o(1)}$ time unless one uses fast matrix multiplication. Meanwhile, the best known approximation factor for a combinatorial algorithm running in $O(mn^{1-\varepsilon})$ time (by Chechik et al.) is 3. Is the true answer 2 or 3?

The main result of this paper is a (conditionally) tight approximation algorithm for directed graphs. First, we show that under a popular hardness assumption, any algorithm, even one that exploits fast matrix multiplication, would need to take at least $mn^{1-o(1)}$ time for some sparsity m if it achieves a $(2-\varepsilon)$-approximation for any $\varepsilon > 0$. Second we give a 2-approximation algorithm for the girth of unweighted graphs running in $\tilde{O}(mn^{3/4})$ time, and a $(2+\varepsilon)$-approximation algorithm (for any $\varepsilon > 0$) that works in weighted graphs and runs in $\tilde{O}(m\sqrt{n})$ time. Our algorithms are combinatorial.

We also obtain a $(4+\varepsilon)$-approximation of the girth running in $\tilde{O}(mn^{\sqrt{2}-1})$ time, improving upon the previous best $\tilde{O}(m\sqrt{n})$ running time by Chechik et al. Finally, we consider the computation of roundtrip spanners. We obtain a $(5+\varepsilon)$-approximate roundtrip spanner on $\tilde{O}(n^{1.5}/\varepsilon^2)$ edges in $\tilde{O}(m\sqrt{n}/\varepsilon^2)$ time. This improves upon the previous approximation factor $(8+\varepsilon)$ of Chechik et al. for the same running time.

1 Introduction

One of the most basic and well-studied graph parameters is the *girth*, i.e. the length of the shortest cycle in the graph. Computing the girth in an m-edge, n-node graph can be done by computing all pairwise distances, that is, solving the All-Pairs Shortest Paths (APSP) problem. This gives an $\tilde{O}(mn)$ time algorithm for the general version of the girth problem: directed or undirected integer weighted graphs and no negative weight cycles[1].

The $\tilde{O}(mn)$ running time for the exact computation of the girth is known to be tight, up to $n^{o(1)}$ factors, both for sparse and dense weighted graphs, under popular hardness hypotheses from fine-grained complexity [21, 14]. In unweighted graphs or graphs with integer weights of magnitude at most M, one can compute the girth in $\tilde{O}(Mn^{\omega})$ time [19, 12, 17, 8] where $\omega < 2.373$ is the exponent of $n \times n$ matrix multiplication [22, 13]. This improves upon mn only for somewhat dense graphs with small weights, and moreover is not considered very practical due to the large overhead of fast matrix multiplication techniques.

Due to the subcubic equivalences of [21], however, it is known that even in unweighted dense graphs, any algorithm that computes the girth in $O(n^{3-\varepsilon})$ time needs to use fast matrix multiplication techniques, unless one can obtain a subcubic time combinatorial Boolean Matrix Multiplication (BMM) algorithm. Thus, under popular fine-grained complexity assumptions, if one wants to have a fast combinatorial algorithm, or an algorithm that is faster than mn for sparser graphs, one needs to resort to *approximation*.

Fast approximation algorithms for the girth in undirected graphs have been known since the 1970s, starting with the work of Itai and Rodeh [12]. The current strongest result shows a 2-approximation in $\tilde{O}(n^{5/3})$ time [18]; note that if the graph is dense enough this algorithm is sublinear in the input. Such good approximation algorithms are possible for undirected graphs because of known strong structural properties. For instance, as shown by Bondy and Simonovits [4], for any integer $k \geq 2$, if a graph has at least $100kn^{1+1/k}$ edges, then it must contain a $2k$ cycle, and this gives an immediate upper bound on the girth. There are no such structural results for directed graphs, making the directed girth approximation problem quite challenging.

Zwick [24] showed that if the maximum weight of an edge is M, one can obtain in $\tilde{O}(n^{\omega}\log(M/\varepsilon)/\varepsilon)$ time a $(1+\varepsilon)$-approximation for APSP, and this implies the same for the girth of directed graphs. As before, however, this algorithm does not run fast in sparse graphs, and can be considered impractical.

The first nontrivial approximation algorithms (both for sparse graphs and combinatorial) for the girth of directed graphs were achieved by Pachocki et al. [15]. The current best result by Chechik et al. [6, 7] achieves for every integer $k \geq 1$, a randomized $O(k \log k)$-approximation algorithm running in time $\tilde{O}(m^{1+1/k})$. The best approximation factor that Chechik et al. obtain in $O(mn^{1-\varepsilon})$ time for $\varepsilon > 0$ is 3, in $\tilde{O}(m\sqrt{n})$ time.

[1] If the weights are nonnegative, running Dijkstra's algorithm suffices. If there are no negative weight cycles, one can use Johnson's trick to make the weights nonnegative at the cost of a single SSSP computation which can be achieved for instance in $\tilde{O}(m\sqrt{n}\log M)$ time if M is the largest edge weight magnitude via Goldberg's algorithm [11], so as long as the weights have at most $\tilde{O}(\sqrt{n})$ bits, the total time is $\tilde{O}(mn)$.

What should be the best approximation factor attainable in $O(mn^{1-\varepsilon})$ time for $\varepsilon > 0$? It is not hard to show (see e.g. [20], the construction in Thm 4.1.3) that graph triangle detection can be reduced to triangle detection in a directed graph whose cycle lengths are all divisible by 3. This, coupled with the combinatorial subcubic equivalence between triangle detection and BMM [21] implies that any $O(n^{3-\varepsilon})$ time algorithm for $\varepsilon > 0$ that achieves a $(2-\delta)$-approximation for the girth implies an $O(n^{3-\varepsilon/3})$ time algorithm for BMM, and hence fast matrix multiplication techniques are likely necessary for faster $(2-\varepsilon)$-approximation of the directed girth.

1.1 Our results

We first give a simple extension to the above hardness argument for $(2-\varepsilon)$-approximation, giving a conditional lower bound on the running time of $(2-\varepsilon)$-girth approximation algorithms under the so called k-Cycle hardness hypothesis [3, 16, 14].

The k-Cycle hypothesis states that for every $\varepsilon > 0$, there is a k such that k-cycle in m-edge directed unweighted graphs cannot be solved in $O(m^{2-\varepsilon})$ time (on a $O(\log n)$ bit word-RAM).

The hypothesis is consistent with all known algorithms for detecting k-cycles in directed graphs, as these run at best in time $m^{2-c/k}$ for various small constants c [23, 2, 14, 9], even using powerful tools such as matrix multiplication. Moreover, as shown by Lincoln et al. [14] any $O(mn^{1-\varepsilon})$ time algorithm (for $\varepsilon > 0$) that, for odd k, can detect k-cycles in n-node m-edge directed graphs with $m = \Theta(n^{1+2/(k-1)})$, would imply an $O(n^{k-\delta})$ time algorithm for k-clique detection for $\delta > 0$. If the cycle algorithm is "combinatorial", then the clique algorithm would be "combinatorial" as well, and since all known $O(n^{k-\delta})$ time k-clique algorithms use fast matrix multiplication, such a result for k-cycle would be substantial.

In Section 5, with a very simple reduction we show:

▶ **Theorem 1.** *Suppose that for some constants $\varepsilon > 0$ and $\delta > 0$, there is an $O(m^{2-\varepsilon})$ time algorithm that can compute a $(2-\delta)$-approximation of the girth in an m-edge directed graph. Then for every constant k, one can detect whether an m-edge directed graph contains a k-cycle, in $O(m^{2-\varepsilon})$ time, and hence the k-Cycle Hypothesis is false.*

Thus, barring breakthroughs in Cycle and Clique detection algorithms, we know that the best we can hope for using an $O(mn^{1-\varepsilon})$ time algorithm for the girth of directed graphs is a 2-approximation.

The main result of this paper is the first ever $O(mn^{1-\varepsilon})$ time for $\varepsilon > 0$ 2-approximation algorithm for the girth in directed graphs. This result is conditionally tight via the above discussion.

▶ **Theorem 2.** *There is an $\tilde{O}(mn^{3/4})$ time randomized algorithm that 2-approximates the girth in directed unweighted graphs whp. For every $\varepsilon > 0$, there is a $(2+\varepsilon)$-approximation algorithm for the girth in directed graphs with integer edge weights that runs in $\tilde{O}(m\sqrt{n}/\varepsilon)$ time. The algorithms are randomized and are correct whp.*

If one wanted to obtain a $(4+\varepsilon)$-approximation to the girth via Chechik et al.'s $O(k \log k)$ approximation algorithms, the best running time one would be able to achieve is $\tilde{O}(m\sqrt{n})$. Here we show how to get an improved running time for a $(4+\varepsilon)$ approximation.

▶ **Theorem 3.** *For every $\varepsilon > 0$, there is a $(4+\varepsilon)$-approximation algorithm for the girth in directed graphs with integer edge weights that runs in $\tilde{O}(mn^{\sqrt{2}-1}/\varepsilon)$ time. The algorithm is randomized and correct whp.*

In fact, we obtain a generalization of the above algorithms that improves upon the algorithms of Chechik et al. for all constants k.

▶ **Theorem 4.** *For every $\varepsilon > 0$ and integer $k \geq 1$, there is a $(2k+\varepsilon)$-approximation algorithm for the girth in directed graphs with integer edge weights that runs in $\tilde{O}(mn^{\alpha_k}/\varepsilon)$ time, where $\alpha_k > 0$ is the solution to $\alpha_k(1+\alpha_k)^{k-1} = 1 - \alpha_k$. The algorithms are randomized and correct whp.*

For example, let's consider α_1 in the above theorem. It is the solution to $\alpha_1 = 1 - \alpha_1$, giving $\alpha_1 = 1/2$ and recovering the result of Theorem 2 for weighted graphs. On the other hand, α_2 is the solution to $\alpha_2(1+\alpha_2) = 1 - \alpha_2$, which gives $\alpha_2 = \sqrt{2} - 1$ and recovering Theorem 3. Finally, say we wanted to get a $6 + \varepsilon$ approximation, then we need α_3, which is the solution to $\alpha_3(1+\alpha_3)^2 = 1 - \alpha_3$, giving $\alpha_3 \leq 0.354$, and thus there's an $\tilde{O}(mn^{0.354}/\varepsilon)$ time $(6+\varepsilon)$-approximation algorithm. Note that there is only one positive solution to the equation defining α_k in Theorem 4.

As k grows, α_k grows as $\Theta(\log k/k)$, and so the algorithm from Theorem 4 has similar asymptotic guarantees as the algorithm of Chechik et al. as it achieves an $O(\ell \log \ell)$ approximation in $\tilde{O}(mn^{1/\ell})$ time. The main improvements lie in the improved running time for small constant approximation factors.

Our approximation algorithms on weighted graphs can be found in section 4. If we are aiming for an algorithm running in $T(n,m)$ time, we first suppose that the maximum edge weight of the graph is M and we obtain an algorithm in $T(n,m)\log M$ time. We show how to remove the $\log M$ factor using standard techniques in the full version [10].

Roundtrip Spanners. Both papers that achieved nontrivial combinatorial approximation algorithms for the directed girth were also powerful enough to compute sparse approximate roundtrip spanners.

A c-approximate roundtrip spanner of a directed graph $G = (V,E)$ is a subgraph $H = (V,E')$ of G such that for every $u,v \in V$, $d_H(u,v) + d_H(v,u) \leq c \cdot (d_G(u,v) + d_G(v,u))$. Similar to what is known for spanners in undirected graphs, it is known [5] that for every integer $k \geq 2$ and every n, every n-node graph contains a $(2k-1+o(1))$-approximate roundtrip spanner on $O(kn^{1+1/k}\log n)$ edges; the $o(1)$ error can be removed if the edge weights are at most polynomial in n and the result then is optimal, up to log factors under the Erdös girth conjecture.

The best algorithms to date for computing sparse roundtrip spanners, similarly to the girth, achieve an $O(k\log k)$ approximation in $\tilde{O}(m^{1+1/k})$ time [7]. The best constant factor approximation achieved for roundtrip spanners in $O(mn^{1-\varepsilon})$ time for $\varepsilon > 0$ is again achieved by Chechik et al.: a $(8+\varepsilon)$ approximate $O(n^{1.5})$-edge (in expectation) roundtrip spanner can be computed in $\tilde{O}(m\sqrt{n})$ expected time. We improve this latter result:

▶ **Theorem 5.** *There is an $\tilde{O}(m\sqrt{n}\log^2(M)/\varepsilon^2)$ time randomized algorithm that computes a $(5+\varepsilon)$-approximate roundtrip spanner on $\tilde{O}(n^{1.5}\log^2(M)/\varepsilon^2)$ edges whp, for any n-node m-edge directed graph with edge weights in $\{1,\ldots,M\}$.*

2 Preliminary Lemmas

We begin with some preliminary lemmas. The first two will allow us to decrease all degrees to roughly m/n, while keeping the number of vertices and edges roughly the same. The last lemma, implicit in [6], is a crucial ingredient in our algorithms.

The following lemma was proven by Chechik et al. [6]:

▶ **Lemma 6.** *Given a directed graph $G = (V, E)$ with $|V| = n, |E| = m$, we can in $O(m+n)$ time construct a graph $G' = (V', E')$ with $V \subseteq V'$, so that $|V'| \leq O(n)$, $|E'| \leq O(m+n)$, for every $v \in V'$, $deg(v) \leq \lceil m/n \rceil$, and so that for every $u, v \in V$, $d_{G'}(u, v) = d_G(u, v)$, and so that any path p between some nodes $u \in V$ and $v \in V$ in G' (possibly $u = v$) is in one-to-one correspondence with a path in G of the same length.*

The proof of the above lemma introduces edges of weight 0, even if the graph was originally unweighted. In the lemma below which is proved in the the full version [10], we show how for an unweighted graph we can achieve essentially the same goal, but without adding weighted edges. This turns out to be useful for our unweighted girth approximation.

▶ **Lemma 7.** *Given a directed unweighted graph $G = (V, E)$ and $|V| = n, |E| = m$, we can in $\tilde{O}(m+n)$ time construct an unweighted graph $G' = (V', E')$ with $V \subseteq V'$, so that $|V'| \leq O(n \log n)$, $|E'| \leq O(m + n \log n)$, for every $v \in V'$ out-deg$(v) \leq \lceil m/n \rceil$, and so that there is an integer t such that for every $u, v \in V$, $d_{G'}(u, v) = t \cdot d_G(u, v)$, and so that any path p between some nodes $u \in V$ and $v \in V$ in G' (possibly $u = v$) is in one-to-one correspondence with a path in G of length $1/t$ of the length of p.*

In particular, the lemma will imply that the girth of G' is exactly t times the girth of G, and that given a c-roundtrip spanner of G', one can in $\tilde{O}(m+n)$ time obtain from it a c-roundtrip spanner of G. We note that it is easy to obtain the same result but where both the in- and out-degrees are $O(m/n)$ (see the proof in the full version [10]).

Now we can assume that the degree of each node is no more than $O(m/n)$. This will allow us for instance to run Dijkstra's algorithm or BFS from a vertex within a neighborhood of w nodes in $\tilde{O}(mw/n)$ time.

Another assumption we can make without loss of generality is that our given graph G is strongly connected. In linear time we can compute the strongly connected components and then run any algorithm on each component separately. We know that any two vertices in different components have infinite roundtrip distance.

A final lemma (implicit in [6]) will be very important for our algorithms:

▶ **Lemma 8.** *Let $G = (V, E)$ be a directed graph with $|V| = n$ and integer edge weights in $\{1, \ldots, M\}$. Let $S \subseteq V$ with $|S| > c \log n$ (for $c \geq 100/\log(10/9)$) and let d be a positive integer. Let R be a random sample of $c \log n$ nodes of S and define $S' := \{s \in S \mid d(s, r) \leq d, \forall r \in R\}$. Suppose that for every $s \in S$ there are at most $0.2|S|$ nodes $v \in V$ so that $d(s, v), d(v, s) \leq d$. Then $|S'| \leq 0.8|S|$.*

Proof. The proof will consist of two parts. First we will show that the number of ordered pairs $s, s' \in S$ for which $d(s, s'), d(s', s) \leq d$ is small. Then we will show that if $|S'| > 0.8|S|$, then with high probability, the number of ordered pairs $s, s' \in S$ for which $d(s, s'), d(s', s) \leq d$ is large, thus obtaining a contradiction.

(1) If for every $s \in S$ there are at most $0.2|S|$ nodes $v \in V$ so that $d(s, v), d(v, s) \leq d$, then the number of ordered pairs $s, s' \in S$ for which $d(s, s'), d(s', s) \leq d$ is clearly at most $0.2|S|^2$.

(2) Suppose now that $|S'| > 0.8|S|$. First, consider any $s \in S$ for which there are at least $0.1|S|$ nodes $s' \in S$ such that $d(s, s') > d$. The probability that $d(s, r) \leq d$ for all $r \in R$ is then at most $0.9^{c \log n} \leq 1/n^{100}$. Thus, via a union bound, with high probability at least $1 - 1/n^{99}$, for every $s \in S'$, there are at least $0.9|S|$ nodes $s' \in S$ such that $d(s, s') \leq d$.

Now, if $|S'| > 0.8|S|$, with high probability, there are at least $0.8|S| \times 0.9|S| = 0.72|S|^2$ ordered pairs (s, s') with $s, s' \in S$ and $d(s, s') \leq d$. There are at most $\binom{|S|}{2} \leq |S|^2/2$ ordered pairs (s, s') such that exactly one of $\{d(s, s') \leq d, d(s', s) \leq d\}$ holds. Hence, with high probability there are at least $0.22|S|^2 > 0.2|S|^2$ ordered pairs (s, s') with $s, s' \in S$ and both $d(s, s') \leq d$ and $d(s', s) \leq d$. Contradiction. ◀

3 2-Approximation for the Girth in Unweighted Graphs

Here we show how to obtain a genuine 2-approximation for the girth in unweighted graphs.

▶ **Theorem 9.** *Given a directed unweighted graph G on m edges and n nodes, one can in $\tilde{O}(mn^{3/4})$ time compute a 2-approximation to the girth.*

Note that this is the first part of Theorem 2. The pseudocode for the algorithm of Theorem 9 can be found in Algorithm 1, and we will refer to it at each stage of the proof.

We will consider two cases for the girth: when it is $\geq n^\delta$ and when it is $< n^\delta$, for some $\delta > 0$ we will eventually set to $1/4$. We will assume that all out-degrees in the graph are $O(m/n)$.

3.1 Large girth

Pick a random sample R of $100n^{1-\delta}\log n$ nodes, run BFS to and from each $s \in R$. Return

$$\min_{s\in R}\min_{v\neq s} d(s,v) + d(v,s).$$

If the girth is $\geq n^\delta$, with high probability, R will contain a node s on the shortest cycle C. Since any cycle must contain two distinct nodes, $\min_{s\in R}\min_{v\neq s} d(s,v)+d(v,s)$ is the weight of a shortest cycle that contains some node of R, and with high probability it must be the girth. Thus in $\tilde{O}(mn^{1-\delta})$ time we have computed the girth exactly. See Procedure HighGirth in Algorithm 1.

3.2 Small girth

Now let us assume that the girth is at most n^δ. For a vertex u and integer $j \in \{0,\dots,n^\delta\}$, define

$$B^j(u) := \{x \in V \mid d(u,x) = j\} \text{ and } \bar{B}^j(u) := \{x \in V \mid d(u,x) \leq j\}.$$

We will try all choices of integers i from 3 to n^δ to estimate the girth when it is $\leq i$.

Our algorithm first computes a random sample Q of size $O(n^{1-t}\log n)$ for a parameter t, does BFS from and to all nodes in Q, and computes for each $i \in \{1,\dots,n^\delta\}$, $V'_i = \{v \in V \mid \exists q \in Q: \ d(v,q) \leq i \text{ and } d(q,v) \leq i\}$. The running time needed to do this for all $i \leq n^\delta$ is $\tilde{O}(mn^{1-t+\delta})$ [2].

If $V'_i \neq \emptyset$, the girth of G must be $\leq 2i$.

Now, pick the smallest i for which $V'_{i+1} \neq \emptyset$. Then $V'_k = \emptyset$ for all $k \leq i$, and we have certified that the girth is $\leq 2i+2$. If the girth is $\geq i+1$, we already have a 2-approximation. Otherwise, the girth must be $\leq i$.

Consider any $u \in V$, and $j \leq i$. Suppose that for all $j \leq i$, $|B^j(u)| \leq 100n^t$. Then, for u and for all $v \in B^j(u)$ for $j \leq i$, we could compute the distances from u to v in G efficiently: We do this by running BFS from u but stopping when a vertex outside of $\cup_{j=0}^{i} B^j(u)$ is found. Note that the number of vertices in $\cup_{j=0}^{i} B^j(u)$ is $O(n^t \cdot i)$, and since we assumed that the degree of every vertex is $O(m/n)$, we get a total running time of $O(mn^{t-1} \cdot i)$. If this works for all vertices u, then we would be able to compute all distances up to i exactly in total time $O(m \cdot in^t) \leq O(mn^{t+\delta})$.

[2] The running time is actually less, $\tilde{O}(n^{2-t+\delta} + mn^{1-t})$ but this won't matter for our algorithm.

Unfortunately, however, some $B^j(u)$ balls can be larger than $100n^t$. In this case, for every $j \leq i$, we will compute a small set of nodes $B'^j(u)$ that will be just as good as $B^j(u)$ for computing short cycles.

▷ Claim 10. Fix i: $1 \leq i \leq n^\delta$. Suppose that for every $j \leq i$ we are given black box access to sets $B'^j(u) \subseteq \bar{B}_j(u)$ of nodes such that (1) In $t(n)$ time we can check whether a node is in $B'^j(u)$, (2) $|B'^j(u)| \leq 100n^t$ whp, and (3) for any cycle C of length $\leq i$ containing u, and every $j \leq i$, any node of C that is in $B^j(u)$ is also in $B'^j(u)$.

Then there is an $O(mn^{t-1+\delta}t(n))$ time algorithm that can find a shortest cycle through u, provided that cycle has length $\leq i$.

Proof. Let us assume that there is some cycle C of length $\leq i$ containing u. Also, assume that we are given the sets $B'^j(u)$ for all $j \leq i$ as in the statement of the lemma.

Then we can compute a modified BFS out of u. We will show by induction that when considering distance $j \leq i$, our modified BFS will have found a set $N_j(u)$ of nodes such that for every $x \in N_j(u)$, $d(u,x) \leq j$, and so that for any cycle C of length $\leq i$ containing u, any node of C that is in $B^j(u)$ is also in $N_j(u)$.

Initially, $N_0(u) = \{u\}$, so the base case is fine. Let's make the induction hypothesis for j that for every $x \in N_j(u)$, $d(u,x) \leq j$, and for a shortest cycle C of length $\leq i$ containing u, any node of C that is in $B^j(u)$ is also in $N_j(u)$.

Our modified BFS proceeds as follows: Given $N_j(u)$, we go through each $z \in N_j(u)$, and if $z \in B'^j(u)$, we go through all out-neighbors y of z, and if y has not been visited until now, we place y into $N_{j+1}(u)$. See Procedure ModBFS in Algorithm 1 (parameter t is set to 1/2 here).

Clearly, since $d(u,z) \leq j$ (by the induction hypothesis), we have that $d(u,y) \leq j+1$ for each out-neighbor y of z. Now consider a shortest cycle C containing u of length $\leq i$. To complete the induction we only care about $j < |C|$.

Assume that the induction hypothesis for j holds. Let x be the node on C at distance $j+1$ from u along C, and let x' be its predecessor on C, i.e. the node on C at distance j from u along C. Since C is a shortest cycle containing u and since $x' \neq x$, we must have that $d(u,x') = j$ so that $x' \in B^j(u)$. Also, either $u = x$, or $d(u,x) = j+1$ and so $x \in B^{j+1}(u)$.

We know by the induction hypothesis that $x' \in N_j(u)$ and also that $x' \in B'^j(u)$ by the definition of $B'^j(u)$. Thus, we would have gone through the edges out of x', and x would have been discovered. If $u = x$, then the cycle C will be found. Otherwise, $d(u,x) = j+1$, and x cannot have been visited until now, so our modified BFS will insert x into $N_{j+1}(u)$ thus completing the induction.

The running time of the modified BFS is determined by the fact that there are $i \leq n^\delta$ levels, each of $N_j(u) \cap B'^j(u)$ contains $\leq O(n^t)$ nodes, and we traverse the $O(m/n)$ edges out of every $x \in N_j(u) \cap B'^j(u)$. The running time is thus asymptotically $t(n) \times n^\delta \times n^t \times m/n$ which is $O(mn^{t+\delta-1}t(n))$. ◁

Now we want to explain how to compute the sets $B'^j(u)$. We use Lemma 8 from the preliminaries. Suppose that the girth is at most i and for every $k \leq i$, $V'_k = \emptyset$.

Let u be a node on a cycle C of length at most i. Let x be any node on C so that $x \in B^j(u)$ for some integer $j \leq i$. Then we must have that for every $y \in \bar{B}^j(u)$:

$$d(x,y) \leq d(x,u) + d(u,y) \leq |C| - d(u,x) + d(u,y) \leq i - j + j = i.$$

This inequality is crucial for our algorithm. See Figure 1 for a depiction of it.

In other words, we obtain that x is in $\{w \in B^j(u) \mid d(w,y) \leq i, \ \forall y \in \bar{B}^j(u)\}$.

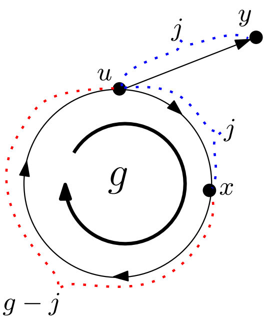

Figure 1 Here there is a cycle of length g containing u. A node x on the cycle is at distance j from u along the cycle and another node y is at distance $\leq j$ from u. Then the distance from x to y is at most g since one way to go from x to y is to go from x to u along the cycle at a cost of $g - j$, and then from u to y at a cost of $\leq j$. If the cycle is a shortest cycle containing u and if $x \neq u$, then the distance in the graph from u to x is j, as the path along the cycle needs to be a shortest path.

Suppose that we are able to pick a random sample $R^j(u)$ of $c \log n$ vertices from $\bar{B}^j(u)$ (we will show how later). Then we can define

$$\bar{B}'^j(u) := \{z \in \bar{B}^j(u) \mid d(z, y) \leq i, \ \forall y \in R^j(u)\}.$$

Using Lemma 8 we will show that if $|\bar{B}^j(u)| \geq 10n^t$, then $|\bar{B}'^j(u)| \leq 0.8\bar{B}^j(u)$ and if x is in $\{w \in B^j(u) \mid d(w, y) \leq i, \ \forall y \in \bar{B}^j(u)\}$, then whp $x \in \bar{B}'^j(u)$. We will then repeat the argument to obtain $B'^j(u)$ of size $O(n^t)$.

Consider any $s \in V$ with at least $0.2|\bar{B}^j(u)|$ nodes $v \in V$ so that $d(s, v), d(v, s) \leq i$. As $|\bar{B}^j(u)| \geq 10n^t$ (as otherwise we would be done), $0.2|\bar{B}^j(u)| \geq 2n^t$, and so with high probability, for s with the property above, our earlier random sample Q contains some q with $d(s, q), d(q, s) \leq i$, and so $V'_i \neq \emptyset$ which we assumed didn't happen. Thus with high probability, for every $s \in V$, there are at most $0.2|\bar{B}^j(u)|$ nodes $v \in V$ so that $d(s, v), d(v, s) \leq i$. Hence we also have that every $z \in \bar{B}^j(u)$ has at most $0.2|\bar{B}^j(u)|$ nodes $v \in V$ so that $d(s, v), d(v, s) \leq i$.

Thus we can apply Lemma 8 to $\bar{B}^j(u)$ and conclude that $|\bar{B}'^j(u)| \leq 0.8|\bar{B}^j(u)|$, while also any node $x \in B^j(u)$ on the cycle C (containing u) is also in $\bar{B}'^j(u)$.

We will iterate this process until we arrive at a subset of $\bar{B}^j(u)$ that is smaller than $10n^t$ and still contains all $x \in B^j(u)$ on an $\leq i$-length cycle C.

We do this as follows. Let $B^j_0(u) = \bar{B}^j(u)$. For each $k = 0, \ldots, 2\log n$, let $R^j_k(u)$ be a random sample of $O(\log n)$ vertices of $B^j_k(u)$. Define $B^j_{k+1}(u) = \{z \in B^j_k(u) \mid d(z, y) \leq i, \ \forall y \in \cup_{\ell=0}^k R^j_\ell(u)\}$. We get that for each k, $|B^j_k(u)| \leq 0.8^k|\bar{B}^j(u)|$ so that at the end of the last iteration, $|B^j_{2\log n}(u)| \leq 10n^t$ and we can set $B'^j(u)$ to $B^j_{2\log n}(u)$.

It is not immediately clear how to obtain the random sample $R^j_k(u)$ from $B^j_k(u)$ as $B^j_k(u)$ is unknown. We do it in the following way, adapting an argument from Chechik et al. [7]. For each $j \leq i$ and $k \leq 2\log n$ we independently obtain a random sample $S_{j,k}$ of V by sampling each vertex independently with probability $p = 100 \log n/n^t$. For each of the (in expectation) $O(n^{1-t+\delta} \log^2(n))$ vertices in the sets $S_{j,k}$ we run BFS to and from them, to obtain all their distances.

Now, for $j \leq i$ and k, to obtain the random sample $R^j_k(u)$ of the unknown $B^j_k(u)$, we assume that we already have $R^j_\ell(u)$ for $\ell < k$, and define

$$T^j_k(u) = \{s \in S_{j,k} \mid s \in \bar{B}^j(u) \text{ and } d(s, y) \leq i, \ \forall y \in \cup_{\ell<k} R^j_\ell(u)\}.$$

Forming the set $T_k^j(u)$ is easy since we have the distances $d(s,v)$ for all $s \in S_{j,k}$ and $v \in V$, so we can check whether $s \in \bar{B}^j(u)$ and $d(s,y) \leq i,\ \forall y \in \cup_{\ell<k} R_\ell^j(u)$ in polylogarithmic time for each $s \in S_{j,k}$. See Procedure RandomSamples in Algorithm 1.

Now since $S_{j,k}$ is independent from all our other random choices, $T_k^j(u)$ is a random sample of $B_k^j(u)$ essentially created by selecting each vertex with probability p. If $B_k^j(u) \geq 100n^t$, with high probability, $T_k^j(u)$ has at least $10 \log n$ vertices so we can pick $R_k^j(u)$ to be a random sample of $10 \log n$ vertices of $T_k^j(u)$, and they will also be a random sample of $10 \log n$ vertices of $B_k^j(u)$.

Once we have the sets $R_k^j(u)$ for each u and $j \leq i$, $k \leq 2 \log n$, we run our modified BFS from each u from Claim 10 where when we are going through the vertices $x \in N_j(u)$ we check whether $x \in B'^j(u)$ by checking whether $d(x,r) \leq i$ for every $r \in \cup_k R_k^j(u)$. This only gives a polylogarithmic overhead so we can run the modified BFS in time $\tilde{O}(mn^{t-1+\delta})$ time. We can run it through all $u \in V$ in total time $\tilde{O}(mn^{t+\delta})$ time, and in this time we will be able to compute the length of the shortest cycle if that cycle is of length $\leq i$.

Putting it all together. In $\tilde{O}(mn^{1-\delta})$ time we compute the girth exactly if it is $\geq n^\delta$. In $\tilde{O}(mn^{1-t+\delta})$ time, we obtain i so that we have a 2-approximation of the girth if the girth is $> i$. In additional $\tilde{O}(mn^{1-t+\delta} + mn^{t+\delta})$ time we compute the girth exactly if it is $\leq i$.

To optimize the running time we set $t = 1/2$, $1 - \delta = 0.5 + \delta$, obtaining $\delta = 1/4$, and a running time of $\tilde{O}(mn^{3/4})$. The final algorithm is in Algorithm 1.

4 Weighted Graphs: Girth and Roundtrip Spanner

One of the main differences between our weighted and unweighted algorithms is that for weighted graphs we do not go through each distance value i up to n^δ, but we instead process intervals of possible distance values $[(1+\varepsilon)^i, (1+\varepsilon)^{i+1})$ for small $\varepsilon > 0$. This will affect the approximation, so that we will get a $(2+O(\varepsilon))$-approximation. However, it will also enable us to have a smaller running time of $\tilde{O}(m\sqrt{n}\log(M)/\varepsilon)$, and to be able to output an $\tilde{O}(n^{1.5}\log(M)/\varepsilon)$-edge $(5+O(\varepsilon))$-approximate roundtrip spanner in $\tilde{O}(m\sqrt{n}\log(M)/\varepsilon^2)$ time, where M is the maximum edge weight.

Fix $\varepsilon > 0$. For a vertex u and integer j, define (differently from the previous section)

$$B^j(u) := \{x \in V \mid (1+\varepsilon)^j \leq d(u,x) < (1+\varepsilon)^{j+1}\} \text{ and } \bar{B}^j(u) := \{x \in V \mid d(u,x) < (1+\varepsilon)^{j+1}\}.$$

We include a boundary case $B^\emptyset(u) := \{x \in V \mid d(u,x) = 0\}$. Recall that we originally started with a graph with positive integer weights, but our transformation to vertices of degree $O(m/n)$ created some 0 weight edges. We note that any distance of 0 involves at least one of the auxiliary vertices and no roundtrip distance can be 0.

In our algorithms including our $(2+\epsilon)$-approximation algorithm, we do a restricted version of Dijkstra from every vertex where before running these Dijkstras, we need to efficiently sample a set of vertices $R^j(u)$ of size $O(\log n)$ from a subset of $B^j(u)$, without computing the set $B^j(u)$. The following lemma is given as input the target approximation factor 2β, a parameter i as an estimated size of cycles the algorithm is handling at a given stage and a parameter α as the target running time $\tilde{O}(mn^\alpha)$ of our algorithms. It outputs the sample sets in this running time. The proof of the lemma is similar to the sampling method of the previous section and is included in the full version [10].

Algorithm 1 2-Approximation algorithm for the girth in unweighted graphs.

```
Procedure HighGirth($G = (V, E)$)
    Let $R \subseteq V$ be a uniform random sample of $100n^{3/4} \log n$ nodes.
    foreach $s \in R$ do
        Do BFS from $s$ in $G$
    Let $g$ be the length of the shortest cycle found by the BFS searches.
    Return $g$.
Procedure RandomSamples($G = (v, E), i$)
    foreach $j \in \{1, \dots, i\}$ do
        foreach $k \in \{1, \dots, 2 \log n\}$ do
            Let $S_{j,k} \subseteq V$ be a uniform random sample of $100\sqrt{n} \log n$ vertices.
            foreach $s \in S_{j,k}$ do
                Do BFS to and from $s$ to compute for all $v$, $d(s, v)$ and $d(v, s)$.
    foreach $u \in V$ do
        foreach $j \in \{1, \dots, i\}$ do
            $R^j(u) \leftarrow \emptyset$.
            foreach $k \in \{1, \dots, 2 \log n\}$ do
                $T^j_k(u) \leftarrow \{s \in S_{j,k} \mid d(u, s) \leq j$ and for all $y \in R^j(u) : \ d(s, y) \leq i\}$.
                if $|T^j_k(u)| < 10 \log n$ then
                    $R^j(u) \leftarrow R^j(u) \cup T^j_k(u)$
                    Exit this loop (over $k$).
                else
                    Let $R^j_k(u)$ be a uniform random sample of $10 \log n$ nodes from
                      $T^j_k(u)$.
                    $R^j(u) \leftarrow R^j(u) \cup R^j_k(u)$.
    Return the sets $R^j(u)$ for all $j \leq i$, $u \in V$, and $d(s, v), d(v, s)$ for all $s \in \cup_{j,k} S_{j,k}$
      and $v \in V$.
Procedure ModBFS($G = (v, E), u, i, R^1(u), \dots, R^i(u)), d(\cdot)$
    // $d(\cdot)$ contains $d(s, v), d(v, s)$ for all $s \in \cup_{j,k} S_{j,k}$ and $v \in V$.
    $Visited \leftarrow$ empty hash table
    $N_0 \leftarrow \{u\}$
    $Visited.insert(u)$
    foreach $j$ from $0$ to $i - 1$ do
        $N_{j+1} \leftarrow$ empty linked list
        foreach $x \in N_j$ do
            if for every $s \in R^j(u)$, $d(x, s) \leq i$ then
                foreach $y$ s.t. $(x, y) \in E$ and $y \notin Visited$ do
                    if $y = u$ then
                        Stop and return $j + 1$
                    $N_{j+1}.insert(y)$
                    $Visited.insert(y)$
    Return $\infty$ // No $\leq i$ length cycle found through $u$
```

```
Procedure $\textit{GirthApprox}(G = (V,E))$
    $g_{high} \leftarrow \textsc{HighGirth}(G)$
    Let $Q \subseteq V$ be a uniform random sample of $100n^{1/2}\log n$ nodes.
    foreach $s \in Q$ do
        Do BFS from and to $s$ in $G$
    Let $i$ be the minimum integer s.t. $\exists s \in Q$ and $\exists v \in V$ with $d(s,v) \leq i+1$ and
      $d(v,s) \leq i+1$.
    $g_{med} \leftarrow 2(i+1)$
    Let $i$ be the min of $i$ and $n^{1/4}$
    Run $\textsc{RandomSamples}(G,i)$ to obtain sets $R^j(u)$ for all $j \leq i$, $u \in V$, and $d(\cdot)$
      containing $d(s,v), d(v,s)$ for all $s \in \cup_{j,k} S_{j,k}$ and $v \in V$
    foreach $u \in V$ do
        $g_u \leftarrow \textsc{ModBFS}(G, u, i, R^1(u), \ldots, R^i(u), d(\cdot))$
    $g \leftarrow \min\{g_{high}, g_{med}, \min_{u \in V} g_u\}$
    Return $g$
```

▶ **Lemma 11.** *Let M be the maximum edge weight of the graph and suppose that $i \in \{1,\ldots,\log_{1+\epsilon} Mn\}$, $\beta > 0$ and $0 < \alpha < 1$ are given. Suppose that Q is a given sampled set of size $\tilde{O}(n^\alpha)$ vertices. Let $d = \beta(1+\epsilon)^{i+1}$. Let $V_i' = \{v \in V \mid \exists q \in Q : \ d(v,q) \leq d$ and $d(q,v) \leq d\}$. In $\tilde{O}(mn^\alpha)$ time, for every $u \in V$ and every $j = \{1,\ldots,\log_{(1+\epsilon)}(Mn)\}$, one can output a sample set $R_i^j(u)$ of size $O(\log^2 n)$ from $\bar{Z}_i^j(u) = \bar{B}^j(u) \setminus V_i'$, where the number of vertices in $Z_i^j(u) = B^j(u) \setminus V_i'$ of distance at most d from all vertices in $R_i^j(u)$ is at most $O(n^{1-\alpha})$ whp.*

Now we focus on our $(2+O(\epsilon))$-approximation algorithm for the girth and $(5+O(\epsilon))$-approximate roundtrip spanner. We are going to prove the following Theorem, which consists of Theorem 5 and the second part of Theorem 2 with a $\log M$ factor added to their running times.

▶ **Theorem 12.** *Let G be an n-node, m-edge directed graph with edge weights in $\{1,\ldots,M\}$. Let $\varepsilon > 0$. One can compute a $(5+\varepsilon)$-roundtrip spanner on $\tilde{O}(n^{1.5}\log^2 M/\varepsilon^2)$ edges in $\tilde{O}(m\sqrt{n}\log^2(M)/\varepsilon^2)$ time, whp. In $\tilde{O}(m\sqrt{n}\log(M)/\varepsilon)$ time, whp, one can compute a $(2+\varepsilon)$-approximation to the girth.*

We will start with a sampling approach, similar to that in the unweighted girth approximation. The pseudocode of the girth algorithm can be found in the full version [10].

▶ **Lemma 13.** *Let $G = (V,E)$ be a directed graph with $|V| = n$ and integer edge weights in $\{1,\ldots,M\}$. Let d be a positive integer, $\varepsilon \geq 0$, and let $Q \subseteq V$ be a random sample of $100\sqrt{n}\log n$ vertices. In $\tilde{O}(m\sqrt{n})$ time we can compute shortest paths trees $T^{in}(q), T^{out}(q)$ into and out of each $q \in Q$. Let H be the subgraph of G consisting of the edges of these trees $T^{in}(q), T^{out}(q)$. Let $V' = \{v \in V \mid \exists q \in Q,\ d(v,q) \leq d$ and $d(q,v) \leq d\}$. Then:*

- ***Girth approximation:*** *If $V' \neq \emptyset$, then the girth of G is at most $2d$.*
- ***Additive distance approximation:*** *For any $u,v \in V$, if the shortest u to v path contains a node of V', then $d_H(u,v) \leq d(u,v) + 2d$.*
- ***Sparsity:*** *The number of edges in H is $\tilde{O}(n^{1.5})$.*

Proof. Given a directed $G = (V,E)$ with $|V| = n$, $|E| = m$ and edge weights in $\{1,\ldots,M\}$, let us first take a random sample $Q \subseteq V$ of $100\sqrt{n}\log n$ vertices. Run Dijkstra's algorithm from and to every $q \in Q$. Determine $V' \subseteq V$ defined as those $v \in V$ for which there is some

$q \in Q$ with $d(v,q), d(q,v) \leq d$. If $V' \neq \emptyset$, we get that the girth of G is at most $2d$. Suppose that we insert all edges of the in- and out- shortest paths trees rooted at all $q \in Q$ into a subgraph H. Then we have only inserted $\tilde{O}(n^{1.5})$ edges as each tree has $\leq n-1$ edges.

Consider some $u, v \in V$ such that there is some node $x \in V'$ on the shortest $u-v$ path. Let $q \in Q$ be such that $d(x,q), d(q,x) \leq d$. Then

$$d_H(u,v) \leq d(u,q) + d(q,v) \leq d(u,x) + d(x,q) + d(q,x) + d(x,v) \leq d(u,v) + 2d. \qquad \blacktriangleleft$$

Our approach below will handle the roundtrip spanner and the girth approximation at the same time.

We will try all choices of integers i from 0 to $\log_{1+\varepsilon}(Mn)$ to estimate roundtrip distances in the interval $[(1+\varepsilon)^i, (1+\varepsilon)^{i+1})$, and to estimate the girth if it is $< (1+\varepsilon)^{i+1}$.

Fix a choice for i for now.

Our algorithm first applies the approach of Lemma 13 by setting $d = (1+\varepsilon)^{i+2}$ (we will see later why). We compute a random sample Q of size $O(\sqrt{n}\log n)$, do Dijkstra's from and to all nodes in Q, and add the edges of the computed shortest paths trees to our roundtrip spanner H. We also compute

$$V_i' = \{v \in V \mid \exists q \in Q: \ d(v,q) \leq (1+\varepsilon)^{i+2} \text{ and } d(q,v) \leq (1+\varepsilon)^{i+2}\}.$$

By Lemma 13, if $V_i' \neq \emptyset$, the girth of G must be $\leq 2(1+\varepsilon)^{i+2}$. For the choice of i where $(1+\varepsilon)^i \leq g \leq (1+\varepsilon)^{i+1}$, we will get an approximation factor of $2(1+\varepsilon)^2 \leq 2(1+3\varepsilon)$. Just as with the algorithm for unweighted graphs, we can pick the minimum i so that $V_i' \neq \emptyset$, use $2(1+\varepsilon)^{i+2}$ as one of our girth estimates and then proceed from now on with a single value $i-1$ considering only the interval $[(1+\varepsilon)^{i-1}, (1+\varepsilon)^i)$.

By Lemma 13, we also get that for any $u, v \in V$ for which the u-v shortest path contains a node of V_i', H gives a good additive estimate of $d(u,v)$, i.e. $d(u,v) \leq d_H(u,v) \leq d(u,v) + 2(1+\varepsilon)^{i+2}$.

Suppose that also $(1+\varepsilon)^i \leq d(u \leftrightarrows v) \leq (1+\varepsilon)^{i+1}$, and that we somehow also get a good estimate for $d(v,u)$ (either because the v-u shortest path contains a node of V', or by adding more edges to H), so that also $d(v,u) \leq d_H(v,u) \leq d(v,u) + 2(1+\varepsilon)^{i+2}$. Then,

$$d(u \leftrightarrows v) \leq d_H(u \leftrightarrows v) \leq d(u \leftrightarrows v) + 4(1+\varepsilon)^{i+2} \leq d(u \leftrightarrows v)(1 + 4(1+3\varepsilon)) \leq d(u \leftrightarrows v)(5+12\varepsilon).$$

In other words, we would get a $5 + O(\varepsilon)$-roundtrip spanner, as long as by adding $\tilde{O}(n^{1.5})$ edges to H, we can get a good additive approximation to the weights of the u-v shortest paths that do not contain nodes of V_i', for all u, v with $(1+\varepsilon)^i \leq d(u \leftrightarrows v) \leq (1+\varepsilon)^{i+1}$. We will in fact compute these shortest paths exactly. For the girth g itself, we will show how to compute it exactly, if no node of V_i' hit the shortest cycle, where i is such that $(1+\varepsilon)^{i-1} \leq g \leq (1+\varepsilon)^i$.

Fix i. Let $Z_i = V \setminus V_i'$ and $d = (1+\varepsilon)^{i+1}$. We can focus on the subgraph induced by Z_i.

Consider any $u \in Z_i$, and $j \leq i$. Define $Z_i^j(u) = Z_i \cap B^j(u)$ and $\bar{Z}_i^j(u) = Z_i \cap \bar{B}^j(u)$. We also add the boundary case $Z_i^{\emptyset} = Z_i \cap B^{\emptyset}(u) = \{x \in Z_i \mid d(u,x) = 0\}$.

If for all $j \in \{\emptyset\} \cup \{1, \ldots, i\}$, $|Z_i^j(u)| \leq 100\sqrt{n}$, running Dijkstra's algorithm from u in the graph induced by Z_i, up to distance $(1+\varepsilon)^{i+1}$ would be cheap. Unfortunately, however, some $Z_i^j(u)$ balls can be larger than $100\sqrt{n}$. In this case, similarly to our approach for the unweighted case, we will replace $Z_i^j(u)$ with a set $Z_i'^j(u) \subseteq \bar{Z}_i^j(u)$ of size $O(\sqrt{n})$ with the guarantee that for any $v \in V$ with $(1+\varepsilon)^i \leq d(u \leftrightarrows v) < (1+\varepsilon)^{i+1}$ for which the shortest u-v path does not contain a node of V_i', every node of this u-v shortest path that is in $Z_i^j(u)$ is also in $Z_i'^j(u)$.

The following lemma shows how to use such replacement sets.

▶ **Lemma 14.** *Let u and i be fixed. Suppose that for every $j \in \{\emptyset\} \cup \{1, \dots, i\}$ we are given black box access to sets $Z'^j_i(u) \subseteq \bar{Z}^j_i(u)$ of nodes such that (1) Checking whether a node z is in $Z'^j_i(u)$ takes $t(n)$ time, (2) $|Z'^j_i(u)| \le 100\sqrt{n}$ whp, and (3) for any v such that $(1+\varepsilon)^i \le d(u \leftrightarrows v) \le (1+\varepsilon)^{i+1}$, and every $j \le i$, every node on the shortest path P from u to v that is in $Z^j_i(u)$ is also in $Z'^j_i(u)$.*

Then there is an $\tilde{O}(m \log(M) t(n)/(\varepsilon\sqrt{n}))$ time algorithm that finds a shortest path from u to any v with $(1+\varepsilon)^i \le d(u \leftrightarrows v) \le (1+\varepsilon)^{i+1}$ and s.t. the shortest u-v path does not contain a node of V'_i. The algorithm returns $\tilde{O}(n^{0.5}\log(M)/\varepsilon)$ edges whose union contains all these shortest paths.

Proof. Assume we have the sets $Z'^j_i(u)$ for $j \in \{\emptyset\} \cup \{1, \dots, i\}$ as in the statement of the lemma.

Then we will define a modified Dijkstra's algorithm out of u. The algorithm begins by placing u in the Fibonacci heap with $d[u] = 0$ and all other vertices with $d[\cdot] = \infty$. When a vertex x is extracted from the heap with estimate $d[x]$, we determine the j for which $(1+\varepsilon)^j \le d[x] < (1+\varepsilon)^{j+1}$; here j could be the boundary case that we called $\emptyset$ if $d[x] = 0$. Then we check whether x is in Z'^j_i. If it is not, we ignore it and extract a new vertex from the heap. Otherwise if $x \in Z'^j_i$, we go through all its out-edges (x, y), and if $d[y] > d[x] + w(x, y)$, we update $d[y] = d[x] + w(x, y)$. For any new cycle to u found, we update the best weight found, and in the end we return it.

Since we only go through the edges of at most $O(\sqrt{n}\log(Mn)/\varepsilon)$ vertices and the degrees are all $O(m/n)$, the runtime is $O(m\log(Mn)/(\varepsilon\sqrt{n}))$. For the same reason, the modified shortest paths tree whose edges we add to our roundtrip spanner has at most $O(\sqrt{n}\log(Mn)/\varepsilon)$ edges.

Let v be such that $(1+\varepsilon)^i \le d(u \leftrightarrows v) \le (1+\varepsilon)^{i+1}$ and for which the shortest u-v path does not contain a node of V'_i. We will show by induction that our modified Dijkstra's algorithm will compute the shortest path from u to v exactly.

The induction will be on the distance from u. Let's call the nodes on the shortest u to v path, $u = u_0, u_1, \dots, u_t = v$. The induction hypothesis for u_k is that u_k is extracted from the heap with $d[u_k] = d(u, u_k)$. Let us show that u_{k+1} will also be extracted from the heap with $d[u_{k+1}] = d(u, u_{k+1})$. The base case is clear since u is extracted first.

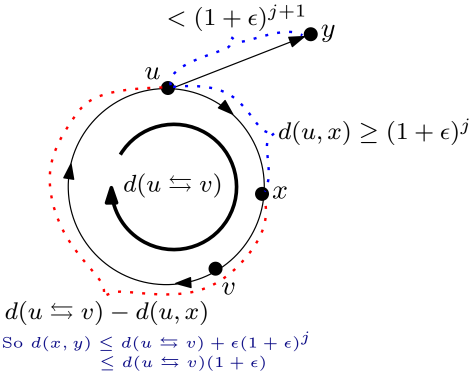
When u_k is extracted from the heap, by the induction hypothesis, $d[u_k] = d(u, u_k)$. Let j be such that $(1+\varepsilon)^j \le d[u_k] < (1+\varepsilon)^{j+1}$. As no node on the u-v shortest path is in V'_i, we get that $u_k \in Z^j_i$. By the assumptions in the lemma, we also have that $u_k \in Z'^j_i$. Thus, when u_k is extracted, we will go over its edges. In particular, (u_k, u_{k+1}) will be scanned, and $d[u_{k+1}]$ will be set to (or it already was) $d[u_k] + w(u_k, u_{k+1}) = d(u, u_{k+1})$. This completes the induction.

It is also not hard to see that the girth will be computed exactly if u is on a shortest cycle, the girth is in $[(1+\varepsilon)^i, (1+\varepsilon)^{i+1})$ and V'_i is empty. ◀

Now we compute the sets $Z'^j_i(u)$. First consider $u, v \in V$ with $(1+\varepsilon)^i \le d(u \leftrightarrows v) < (1+\varepsilon)^{i+1}$. Let x be any node on the u to v roundtrip path (cycle) so that $x \in Z^j_i(u)$ for some integer $j \le i$. Recall that this means $(1+\varepsilon)^j \le d(u, x) < (1+\varepsilon)^{j+1}$. Then for every y with $d(u, y) < (1+\varepsilon)^{j+1}$ and so for each $y \in \bar{Z}^j_i(u)$ we must have (see Figure 2) that

$$d(x, y) \le d(x, u) + d(u, y) \le d(u \leftrightarrows v) - d(u, x) + d(u, y) \le d(u \leftrightarrows v) - (1+\varepsilon)^j + (1+\varepsilon)^{j+1}$$

$$= d(u \leftrightarrows v) + \varepsilon(1+\varepsilon)^j \le d(u \leftrightarrows v) + \varepsilon(1+\varepsilon)^i \le d(u \leftrightarrows v)(1+\varepsilon) \le (1+\varepsilon)^{i+2}.$$



$< (1+\epsilon)^{j+1}$
y
u
$d(u,x) \geq (1+\epsilon)^j$
$d(u \leftrightarrows v)$
x
v
$d(u \leftrightarrows v) - d(u,x)$
So $d(x,y) \leq d(u \leftrightarrows v) + \epsilon(1+\epsilon)^j$
$\leq d(u \leftrightarrows v)(1+\epsilon)$

Figure 2 Here u and v have roundtrip distance more than $(1+\varepsilon)^j$. A node x on the shortest u-v path is at distance at least $(1+\varepsilon)^j$ from u, and another node y is at distance at most $(1+\varepsilon)^{j+1}$ from u. Then the distance from x to y is at most $d(u \leftrightarrows v)(1+\varepsilon)$ since one way to go from x to y is to go from x to u along the u-v roundtrip cycle at a cost of at most $d(u \leftrightarrows v) - (1+\varepsilon)^j$, and then from u to y at a cost of at most $(1+\varepsilon)^{j+1}$.

In other words, x must be in $\{w \in \bar{Z}_i^j(u) \mid d(w,y) \leq (1+\varepsilon)^{i+2},\ \forall y \in \bar{Z}_i^j(u)\}$.

We apply Lemma 11 for $\beta = (1+\epsilon)$ and $\alpha = 1/2$. It outputs sets $R_i^j(u)$ of size $O(\log^2 n)$ vertices, where the number of vertices in $\bar{Z}_i^j(u)$ that are at distance $(1+\epsilon)^{i+2}$ from all vertices in $R_i^j(u)$ is $O(\sqrt{n})$. So all vertices $x \in Z_i^j(u)$ that are in a roundtrip path $u - v$ with $(1+\varepsilon)^i \leq d(u \leftrightarrows v) < (1+\varepsilon)^{i+1}$ are in this set, so we let $Z_i'^j(u) = \{w \in \bar{Z}_i^j(u) | d(w,y) \leq (1+\epsilon)^{i+2},\ \forall y \in R_i^j(u)\}$.

Now that we have the random samples, we implement the modified Dijkstra's algorithm from Lemma 14 with only a polylogarithmic overhead as follows:

Fix some j. Let's look at the vertices x with $(1+\varepsilon)^j \leq d[x] < (1+\varepsilon)^{j+1}$ that the modified Dijkstra's algorithm extracts from the heap. Since $d[x]$ is always an overestimate, $d(u,x) \leq d[x] < (1+\varepsilon)^{j+1}$, and so $x \in \bar{B}^j(u)$. Now, since x is already in $\bar{B}^j(u)$, to check whether $x \in Z_i'^j(u)$, we only need to check whether $x \in Z_i$ (easy) and whether $d(x,y) \leq (1+\varepsilon)^{i+2}$ for all $y \in R_i^j(u)$ (this takes $O(\log^2 n)$ time since we have all the distances to the nodes in the random samples).

The final running time is $\tilde{O}(m\sqrt{n}\log^2(M)/\varepsilon^2)$ since we need to run the above procedure $O(\log(Mn)/\varepsilon)$ times, once for each i, and each procedure costs $\tilde{O}(m\log(M)\sqrt{n}/\varepsilon)$ time. As we mentioned before, to estimate the girth to within a $(2+\varepsilon)$-factor, we do not need to run the procedure for all i but (as with the algorithm for unweighted graphs), only for the minimum i for which $V'_{i+1} \neq \emptyset$. Thus the running time for the girth becomes $\tilde{O}(m\sqrt{n}\log(M)/\varepsilon)$.

4.1 $(4+\epsilon)$-Approximation Algorithm for the Girth in $\tilde{O}(mn^{\sqrt{2}-1})$ Time

In this section we are going to prove the modified version of Theorem 3, where a $\log M$ factor is added to the running time with M being the maximum edge weight.

▶ **Theorem 15.** *For every $\varepsilon > 0$, there is a $(4+\varepsilon)$-approximation algorithm for the girth in directed graphs with edge weights in $\{1,\ldots,M\}$ that runs in $\tilde{O}(mn^{\sqrt{2}-1}\log(M)/\varepsilon)$ time.*

Proof. Suppose that we want an $\tilde{O}(mn^{\alpha})$ time girth approximation algorithm. Let $\beta = 2(1+\epsilon)$. As a first step, we sample a set Q of $\tilde{O}(n^{\alpha})$ vertices and do in and out Dijkstra from them.

We let $V_i' = \{v \in V \mid \exists q \in Q : \ d(v,q) \leq \beta(1+\varepsilon)^{i+1} \text{ and } d(q,v) \leq \beta(1+\varepsilon)^{i+1}\}$. If $V_i' \neq \emptyset$ for some i, then we have that the girth g is at most $2\beta(1+\epsilon)^{i+1}$. If $(1+\epsilon)^i \leq g \leq (1+\epsilon)^{i+1}$, this is a $2\beta(1+\epsilon) \leq 4(1+3\epsilon) = 4 + O(\epsilon)$ approximation.

So take the minimum i where $V_{i+1}' \neq \emptyset$. Let $g' = (1+\epsilon)^{i+1}$ be our current upper bound for the girth g. We initially mark all vertices “on”, meaning that they are not processed yet. For each on vertex u, we either find the smallest cycle of length at most g' passing through u where all vertices of the cycle are on, or conclude that there is no cycle of length at most g' passing through u. When a vertex u is processed, we mark it as “off”. We proceed until all vertices are off.

We apply Lemma 11 for $\beta = 2(1+\epsilon)$. Note that since $V_i' = \emptyset$, $Z_i^j(u) = B^j(u)$ is all the vertices at distance $[(1+\epsilon)^j, (1+\epsilon)^{j+1})$ from u. The lemma outputs sets $R_i^j(u) \subseteq Z_i^j(u)$, where $|R_i^j(u)| = O(\log^2 n)$ and the number of vertices in $B^j(u)$ at distance $\beta g'$ from $R_i^j(u)$ is at most $O(n^{1-\alpha})$ whp. Fix some on vertex u. We do modified Dijkstra from u up to vertices with distance at most $g'/2$ from u as follows:

We begin by placing u in the Fibonacci heap with $d[u] = 0$ and all other on vertices with $d[\cdot] = \infty$. When a vertex x is extracted from the heap with estimate $d[x]$, we determine the j for which $(1+\varepsilon)^j \leq d[x] < (1+\varepsilon)^{j+1}$; here j could be the boundary case that we called $\emptyset$ if $d[x] = 0$. Then we check whether $d(x,r) \leq g' - (1+\epsilon)^j + (1+\epsilon)^{j'+1}$ for all $r \in R_i^{j'}(u)$ for all j'. If x does not satisfy this condition, we ignore it and extract a new vertex from the heap. Otherwise, we go through all its out-edges (x,y), and if $d[y] > d[x] + w(x,y)$, we update $d[y] = d[x] + w(x,y)$. We stop when the vertex u extracted from the heap has $d[u] > g'/2$.

Let $S_i(u)$ be the set of all the vertices visited in the modified out-Dijkstra. Simillarly, let $T_i(u)$ be all the vertices visited in the analogous modified in-Dijkstra (using an analogous version of Lemma 11).

Suppose that there is a vertex v with $d(u \leftrightarrows v) \leq g'$, where all vertices in the uv cycle C are on. Without loss of generality, suppose that $d_C(u,v) \leq g'/2$. So $d(u,v) \leq g'/2$. Moreover, suppose that $v \in Z_i^j(u)$, i.e. $(1+\epsilon)^j \leq d(u,v) \leq (1+\epsilon)^{j+1}$. So for any vertex $w \in Z_i^{j'}(u)$ for some j' we have that $d(v,w) \leq d(v,u) + d(u,w) \leq g' - (1+\epsilon)^j + (1+\epsilon)^{j'+1}$. Since all vertices on the uv path that is part of the cycle are on and the length of this path is at most $g'/2$, we visit v in the out-Dijkstra, i.e. $v \in S_i(u)$. Similarly, if $d(v,u) \leq g'/2$, we visit v in the in-Dijkstra and so $v \in T_i(u)$.

If both $S_i(u)$ and $T_i(u)$ have size at most n^α, we do Dijkstra from u in the induced subgraph on $S_i(u) \cup T_i(u)$, and see if there is a cycle of length at most g' passing through u (and find the smallest such cycle), which takes $O(\frac{m}{n} n^\alpha)$ time. We take the length of this cycle as one of our estimates. The modified in and out Dijkstras take $O(\log^2 n . \frac{\log nM}{\varepsilon} . n^\alpha . \frac{m}{n})$, as checking the conditions for each x extracted from the heap takes $O(\log^2 n . \frac{\log nM}{\varepsilon})$ time. So in $\tilde{O}(\frac{\log M}{\varepsilon} n^\alpha . \frac{m}{n})$ time we process u and mark it as ”off and proceed to another vertex.

Suppose $S_i(u)$ has size bigger than n^α (the case where $T_i(u)$ has size bigger than n^α is similar). Note that by Lemma 11 we have $|S_i(u)| \leq O(n^{1-\alpha})$ because for each $r \in R_i^j(u)$, we have that $d(x,r) \leq g' - (1+\varepsilon)^j + (1+\varepsilon)^{j+1} \leq g' + \varepsilon(1+\varepsilon)^j \leq g' + \varepsilon g'/2 \leq \beta g'$. So it is a subset of vertices that are at distance at most $\beta g'$ from all samples in R_i^j for all j. Our new goal is the following: We want to either find the smallest cycle of length at most g' passing through $S_i(u)$ that contains no off vertices, or say that there is no cycle of length $\leq g'$ passing through any of the vertices in $S_i(u)$ whp.

For this, we do another Modified Dijkstra from u as follows:

We begin by placing u in the Fibonacci heap with $d[u] = 0$ and all other on vertices with $d[\cdot] = \infty$. When a vertex x is extracted from the heap with estimate $d[x]$, we determine the j for which $(1+\varepsilon)^j \leq d[x] < (1+\varepsilon)^{j+1}$; here j could be the boundary case that we called

$\emptyset$ if $d[x] = 0$. Then we check whether $d(x, r) \leq \beta g' = 2(1+\varepsilon)g'$ for all $r \in R_i^j(u)$. If it is not, we ignore it and extract a new vertex from the heap. Otherwise, we go through all its out-edges (x, y), and if $d[y] > d[x] + w(x, y)$, we update $d[y] = d[x] + w(x, y)$. We stop when the vertex u extracted from the heap has $d[u] > 3g'/2$.

We show that if there is a cycle of length at most g' going through $v \in S_i(u)$ containing to off vertex, all vertices of the cycle are among the vertices we visit in the modified Dijkstra: Suppose that $d(w \leftrightarrows v) \leq g'$, and suppose that $v \in Z_i^j(u)$ and $w \in Z_i^{j'}(u)$. Then for every $r \in R_i^{j'}(u)$, we have that $d(w, r) \leq d(w, v) + d(v, r) \leq g' - d(v, w) + g' - (1+\varepsilon)^j + (1+\varepsilon)^{j'+1}$. Since $d(v, w) \geq (1+\varepsilon)^{j'} - (1+\varepsilon)^{j+1}$, we have $d(w, r) \leq 2g' + \varepsilon(1+\varepsilon)^{j'} + \varepsilon(1+\varepsilon)^j \leq 2g' + 3\varepsilon g'/2 + \varepsilon g'/2 = \beta g'$. Since the uw path that goes through v is a path of length at most $\beta g'$ that has no off vertices, we visit w in the modified Dijkstra.

By Lemma 11 the total number of vertices visited in the modified Dijkstra is at most $O(n^{1-\alpha})$. Let the subgraph on these vertices be G'. We recurse on G', and find a $4 + O(\varepsilon)$ approximation of the girth in G'. The girth in G' is a lower bound on the minimum cycle of length $\leq g'$ passing through any vertex in $S_i(u)$ that has no off vertex. We take this value as one of our estimates. So we have processed all vertices in $S_i(u)$ and we mark them off. This takes $O(\frac{m}{n}.\frac{\log M}{\varepsilon}.((n^{1-\alpha})^{1+\alpha}))$, and we have marked off at least n^α vertices. So we spend $O(\frac{m}{n}.\frac{\log M}{\varepsilon}.n^{1-\alpha^2-\alpha})$ for processing each vertex. Letting $1 - \alpha^2 - \alpha = \alpha$, we have that $\alpha = \sqrt{2} - 1$. So the total running time is $\tilde{O}(mn^{\sqrt{2}-1} \log(M)/\varepsilon)$. Our final estimate of the girth is the minimum of all the estimates we get through processing vertices. ◀

4.2 $(2k + \epsilon)$-Approximation Algorithm For the Girth

In this section we are going to prove a modified version of Theorem 4, where a $\log M$ factor is added to the running time with M being the maximum edge weight. The proof is a generalization of the proof of Theorem 15.

▶ **Theorem 16.** *For every $\varepsilon > 0$ and integer $k \geq 1$, there is a $(2k+\varepsilon)$-approximation algorithm for the girth in directed graphs with edge weights in $\{1, \ldots, M\}$ that runs in $\tilde{O}(mn^{\alpha_k} \log(M)/\varepsilon)$ time, where $\alpha_k > 0$ is the solution to $\alpha_k(1+\alpha_k)^{k-1} = 1 - \alpha_k$.*

Suppose that we are aiming for a $2k(1 + O(\epsilon))$ approximation algorithm for the girth, in $\tilde{O}(mn^\alpha \log M/\varepsilon)$ time, where we set α later. So basically we want to spend $\tilde{O}(\frac{m}{n}\frac{\log M}{\varepsilon}n^\alpha)$ per vertex. Let $\beta = k + k^2\epsilon + k\epsilon = k + O(\varepsilon)$. As before, first we sample a set Q of $\tilde{O}(n^\alpha)$ and do in and out Dijkstra from each vertex $q \in Q$. Let i_{min} be the minimum number i such that the set $V_i' = \{v \in V \mid \exists q \in Q : \ d(v, q) \leq \beta(1+\varepsilon)^{i+1}$ and $d(q, v) \leq \beta(1+\varepsilon)^{i+}\}$ is non-empty. So our initial estimate of the girth is $2\beta(1+\epsilon)^{i_{min}+1}$.

Let $i = i_{min} - 1$ and let $g' = (1+\varepsilon)^{i+1}$ be our estimate of the girth. Initially we mark all vertices as “on”, and as we process each vertex, we either find a smallest cycle of length at most g' with no “off” vertex, or we say that there is no cycle of length at most g' passing through it whp, and we mark the vertex as off.

We apply Lemma 11 for $\beta = k + k^2\epsilon + k\epsilon$ and the set Q as input. It gives us the sets $R_i^j(u)$ of size $O(\log^2 n)$ for all j, such that the number of vertices in $\bar{B}^j(u) = \{w \in V | d(u, w) \leq (1+\epsilon)^{j+1}\}$ that are at distance at most $\beta g'$ from all $r \in R_i^j(u)$ is at most $O(n^{1-\alpha})$ whp.

We take an on vertex u and do “modified” Dijkstra from (to) u, stopping at distance $g'/2$, such that the set of vertices we visit contains any cycle of length g' that passes through u that has no off vertex. We explain this modified Dijkstra later.

We call the set of vertices that we visit in the modified out-Dijkstra $S_i^1(u)$. If $S_i^1(u) \leq n^\alpha$, we do an analogous modified in-Dijkstra from u, and let $T_i^1(u)$ be the set of vertices visited in this in-Dijkstra. If $T_i^1(u) \leq n^\alpha$, then we do Dijkstra from u in the subgraph induced by

$S_i^1(u) \cup T_i^1(u)$, and hence find a smallest cycle of length $\le g'$ that passes through u with no off vertex. We take the length of this cycle as one of our estimates for the girth. If there is no such cycle, we don't have any estimate from u. Now we mark u as off and proceed the algorithm by taking another on vertex. Our modified Dijkstras takes $O(\log^2 n.\frac{\log Mn}{\varepsilon}.\frac{m}{n}|S|)$ time if S is the set of vertices visited by the Dijkstra. Hence for processing u we spend $O(\log^2 n.\frac{\log Mn}{\varepsilon}.\frac{m}{n}n^{\alpha})$ time.

So suppose that either $S_i^1(u)$ or $T_i^1(u)$ have size bigger than n^{α}. Without loss of generality assume that $|S_i^1(u)| \ge n^{\alpha}$ (the other case is analogous). For $1 \le l \le k$, define sets $S_i^l(u)$ as the set of on vertices $w \in V$ such that there is a path of length at most $(2l-1)g'/2$ from u to w that contains no off vertex, and if $w \in B^j(u)$, then for all $r \in R_i^{j'}(u)$ for all j', we have $d(w,r) \le (l + l^2\varepsilon)g' + (1+\epsilon)^{j'+1} - (1+\epsilon)^j$. Once we explain our modified Dijkstras, it will be clear that S_i^1 defined here is indeed the set of vertices visited in the first modified out-Dijkstra.

We set $S_i^0(u) = \{u\}$. We prove the following useful lemma in the full version [10].

▶ **Lemma 17.** *For all $l \in \{1, \dots, k\}$, we have that $S_i^{l-1}(u) \subseteq S_i^l(u)$. Moreover, if $w \in V$ is in a cycle of length at most g' with some vertex in $S_i^{l-1}(u)$ such that the cycle contains no off vertex, then we have $w \in S_i^l(u)$.*

Our algorithm will do at most k modified Dijkstras from u, where we prove that the set of vertices visited in the lth Dijkstra is $S_i^l(u)$. After performing each Dijkstra we decide if we continue to the next modified Dijkstra from u or proceed to another on vertex.

Suppose that at some point we know that the set $S_i^{l-1}(u)$ is the set of vertices visited in the $(l-1)$th modified Dijkstra, and we want to proceed to the lth Dijkstra. Our new goal is the following: We want to catch a minimum cycle of length $\le g'$ passing through S_i^l with no off vertex. For this, we do the lth modified Dijkstra form u as follows.

We begin by placing u in the Fibonacci heap with $d[u] = 0$ and all other on vertices with $d[\cdot] = \infty$. When a vertex x is extracted from the heap with estimate $d[x]$, we determine the j for which $(1+\varepsilon)^j \le d[x] < (1+\varepsilon)^{j+1}$; here j could be the boundary case that we called $\emptyset$ if $d[x] = 0$. Then we check whether $d(x,r) \le (l + l^2\varepsilon)g' - (1+\epsilon)^j + (1+\epsilon)^{j'+1}$ for all $r \in R_i^{j'}(u)$ for all j'. If x does not satisfy this condition, we ignore it and extract a new vertex from the heap. Otherwise, we go through all its out-edges (x,y), and if $d[y] > d[x] + w(x,y)$, we update $d[y] = d[x] + w(x,y)$. We stop when the vertex u extracted from the heap has $d[u] > (2l-1)g'/2$.

It is clear by definition that the set of vertices that this modified Dijkstra visits is $S_i^l(u)$. Now if $|S_i^l(u)| \le c(|S_i^{l-1}(u)|.n^{\alpha})^{\frac{1}{1+\alpha}}$ for some constant c, we recurse on the subgraph induced by $S_i^l(u)$, i.e. $G[S_i^l(u)]$, to get an $2k + O(\varepsilon)$ approximation of the girth on this subgraph. The girth in $G[S_i^l(u)]$ is a lower bound on the minimum cycle of length $\le g'$ passing through $S_i^{l-1}(u)$ with no off vertex. So we take this value as one of our estimates and we mark all vertices of $S_i^{l-1}(u)$ as off. The running time of this recursion is $\tilde{O}(\frac{m}{n}\frac{\log M}{\varepsilon}|S_i^l(u)|^{1+\alpha})$ as the average degree is $O(\frac{m}{n})$. Since we process $S_i^{l-1}(u)$ vertices in this running time, we spend $\tilde{O}(\frac{m}{n}\frac{\log M}{\varepsilon}.|S_i^l(u)|/|S_i^{l-1}(u)|) \le \tilde{O}(\frac{m}{n}.\frac{\log M}{\varepsilon}.n^{\alpha})$ for each vertex.

Note that $|S_i^k(u)| \le O(n^{1-\alpha})$. This is because for all $x \in S_i^k \cap B^j(u)$ and for all $r \in R_i^j(u)$, we have that $d(x,r) \le (k+k^2\varepsilon)g' + (1+\epsilon)^{j+1} - (1+\epsilon)^j \le (k+k^2\varepsilon)g' + \epsilon(1+\epsilon)^j \le (k+k^2\varepsilon)g' + \epsilon(2k-1)g'/2 \le (k+k^2\epsilon+k\varepsilon)g' = \beta g'$. So $S_i^k(u)$ is a subset of all vertices in $B^j(u)$ with distance at most $\beta g'$ from all $r \in R_i^j(u)$, and so by Lemma 11 it has size at most $O(n^{1-\alpha})$.

When all vertices are marked off, we take the minimum value of all the estimates as our estimate for g.

Since we have that $S_i^l(u) \leq O(n^{1-\alpha})$, if we set α appropriately, for some $l < k$ we have that $|S_i^{l+1}(u)| \leq (|S_i^l(u)|.n^{\alpha})^{\frac{1}{1+\alpha}}$. For $k = 1$, setting $\alpha = 1/2$ gives us the algorithm of Theorem 12. For $k > 1$, the following lemma determines α. The proof of the lemma can be found in the full version [10].

▶ **Lemma 18.** *For $k > 1$, let the sets S_i^l for $l = 1, \dots, k$ be such that $S_i^l \subseteq S_i^{l+1}$ for all $l < k$, $S_i^1 \geq n^{\alpha}$ and $S_i^k \leq O(n^{1-\alpha})$. Let $0 < \alpha < 1$ satisfy $\alpha(1+\alpha)^{k-1} = 1 - \alpha$. Then there is $l < k$ and a constant c such that $|S_i^{l+1}| \leq c(|S_i^l|.n^{\alpha})^{\frac{1}{1+\alpha}}$.*

Note that for $k = 2$, Lemma 18 sets $\alpha = \sqrt{2} - 1$ and thus gives us the algorithm of Theorem 15.

5 Hardness

Our hardness result is based on the following k-Cycle hypothesis (see [14, 3, 16]).

▶ **Hypothesis 1** (k-Cycle Hypothesis)**.** *In the word-RAM model with $O(\log m)$ bit words, for any constant $\varepsilon > 0$, there exists a constant integer k, so that there is no $O(m^{2-\varepsilon})$ time algorithm that can detect a k-cycle in an m-edge graph.*

All known algorithms for detecting k-cycles in directed graphs with m edges run at best in time $m^{2-c/k}$ for various small constants c [23, 2, 14, 9], even using powerful tools such as fast matrix multiplication. Refuting the k-Cycle Hypothesis above would resolve a big open problem in graph algorithms. Moreover, as shown by Lincoln et al. [14] any algorithm for directed k-cycle detection, for k-odd, with running time $O(mn^{1-\varepsilon})$ for $\varepsilon > 0$ whenever $m = \Theta(n^{1+2/(k-1)})$ would imply an $O(n^{k-\delta})$ time algorithm for k-clique detection for $\delta > 0$. If the cycle algorithm is "combinatorial", then the clique algorithm would be "combinatorial" as well, and since all known $O(n^{k-\delta})$ time k-clique algorithms use fast matrix multiplication, such a result for k-cycle would be substantial.

We will show that under Hypothesis 1, approximating the girth to a factor better than 2 would require $mn^{1-o(1)}$ time, and so up to this hypothesis, our approximation algorithm is optimal for the girth in unweighted graphs.

▶ **Theorem 19.** *Suppose that for some constants $\varepsilon > 0$ and $\delta > 0$, there is an $O(m^{2-\varepsilon})$ time algorithm that can compute a $(2-\delta)$-approximation of the girth in an m-edge directed graph. Then for every constant k, one can detect whether an m-edge directed graph contains a k-cycle, in $O(m^{2-\varepsilon})$ time, and hence the k-Cycle Hypothesis is false.*

Proof. The proof is relatively simple. Suppose that for some constants $\varepsilon > 0$ and $\delta > 0$, there is an $O(m^{2-\varepsilon})$ time algorithm that can compute a $(2-\delta)$-approximation of the girth in an m-edge directed graph.

Now let $k \geq 3$ be any constant integer and let G be an n-node, m-edge graph. First randomly color each vertex of G with one of k colors. Let C be any k-cycle in G. With probability $1/k^k$, for each $i = 0, \dots, k-1$, the ith vertex of C is colored i.

Now, for each $0 \leq i \leq k-1$, let V_i be the vertices colored i. For each vertex $u \in V_i$, and each directed edge (u, v) out of u, keep (u, v) if and only if $v \in V_{i+1}$ where the indices are taken mod k. This builds a graph G' which is a subgraph of G and contains a k-cycle if G does with probability $\geq 1/k^k$.

G' has two useful properties. (1) Any cycle of G' has length divisible by k, and (2) (which follows from (1)) the girth of G' is k if G' contains a k-cycle and it is $\geq 2k$ otherwise.

As G' has at most m edges (it is a subgraph of G), we can use our supposedly fast $2-\delta$ approximation algorithm to determine whether the girth is k or larger in $O(m^{2-\varepsilon})$ time. By iterating the construction $O(k^k \log n)$ times, we get that the k-cycle problem in G can be solved in $\tilde{O}(k^k m^{2-\varepsilon})$ time, and as k is a constant, we are done. The approach can be derandomized with standard techniques (e.g. [1]). ◀

Abstract

We introduce symmetric arithmetic circuits, i.e. arithmetic circuits with a natural symmetry restriction. In the context of circuits computing polynomials defined on a matrix of variables, such as the determinant or the permanent, the restriction amounts to requiring that the shape of the circuit is invariant under row and column permutations of the matrix. We establish unconditional, nearly exponential, lower bounds on the size of any symmetric circuit for computing the permanent over any field of characteristic other than 2. In contrast, we show that there are polynomial-size symmetric circuits for computing the determinant over fields of characteristic zero.

1 Introduction

Valiant's conjecture [23], that VP $\neq$ VNP, is often referred to as the algebraic counterpart to the conjecture that P $\neq$ NP. It has proved as elusive as the latter. The conjecture is equivalent to the statement that there is no polynomial-size family of arithmetic circuits for computing the permanent of a matrix, over any field of characteristic other than 2. Here, arithmetic circuits are circuits with input gates labelled by variables from some set X or constants from a fixed field $\mathbb{F}$, and internal gates labelled with the operations $+$ and $\times$. The output of such a circuit is some polynomial in $\mathbb{F}[X]$, and we think of the circuit as a compact representation of this polynomial. In particular, if the set of variables X form the entries of an $n \times n$ matrix, i.e. $X = \{x_{ij} \mid 1 \leq i, j \leq n\}$, then PERM_n denotes the polynomial $\sum_{\sigma \in \mathbf{Sym}_n} \prod x_{i\sigma(i)}$, which is the permanent of the matrix.

While a lower bound for the size of general arithmetic circuits computing the permanent remains out of reach, lower bounds have been established for some restricted classes of circuits. For example, it is known that there is no sub-exponential family of *monotone* circuits for the permanent [17, 18]. An exponential lower bound for the permanent is also known for *depth-3* arithmetic circuits [15] over finite fields. In both these cases, the exponential lower bound obtained for the permanent also applies to the determinant, i.e. the family of polynomials $\{\mathrm{DET}_n\}_{n \in \mathbb{N}}$, where DET_n is $\sum_{\sigma \in \mathbf{Sym}_n} \mathrm{sgn}(\sigma) \prod x_{i\sigma(i)}$. However, the determinant is in VP and so there do exist polynomial-size families of circuits for the determinant.

In this paper, we consider a new restriction on arithmetic circuits based on a natural notion of symmetry, and we show that it distingushes between the determinant and the permanent. That is to say, we are able to show nearly exponential lower bounds on the size of any family of symmetric arithmetic circuits for computing the permanent, while establishing the existence of polynimial-size symmetric circuits for computing the determinant. We prove the upper bound on the determinant for fields of characteristic zero, and conjecture that it holds for all fields. Our lower bound for the permanent is established for all fields of characteristic other than 2, which is the best that can be hoped for as the permanent and the determinant coincide for fields of characteristic 2.

We next define (informally) the notion of symmetry we use. A formal definition follows in Section 3. The permanent and the determinant are not symmetric polynomials in the usual meaning of the word, in that they are not invariant under arbitrary permutations of their variables. However, they do have natural symmetries, i.e. permutations of the variables induced by row and column permutations. Specifically, PERM_n is invariant under arbitrary permutations of the rows and columns of the matrix (x_{ij}), while DET_n is invariant under simultaneous permutations of the rows and columns. We say that an arithmetic circuit C (seen as a labelled directed acyclic graph) for computing DET_n is *symmetric* if the action of any permutation $\sigma \in \mathbf{Sym}(n)$ on its input variables (i.e. taking x_{ij} to $x_{\sigma(i)\sigma(j)}$) extends to an automorphism of C. Similarly, a circuit C for computing PERM_n is symmetric if the action of $(\sigma, \pi) \in \mathbf{Sym}(n) \times \mathbf{Sym}(n)$ on the inputs (taking x_{ij} to $x_{\sigma(i)\pi(j)}$) extends to an automorphism of C.

This notion of symmetry has been studied previously in the context of Boolean circuits for deciding graph properties, or properties of relational structures (see [13, 20, 2]). Specifically, such symmetric circuits arise naturally in the translation into circuit form of specifications of properties in a logic or similar high-level formalism. Similarly, we can think of a symmetric arithmetic circuit as a straight-line program which treats the rows and columns of a matrix as being indexed by unordered sets. Many natural algorithms have this property. For example, Ryser's formula for computing the permanent naturally yields a symmetric circuit.

Polynomial-size families of symmetric Boolean circuits with threshold gates form a particularly robust class, with links to fixed-point logics [2]. This allows us to deploy methods for proving inexpressiblity in such logics to prove lower bounds on the size of symmetric circuits. A close link has also been established between the power of such circuits and linear programming extended formulations with a geometric notion of symmetry [5]. Our lower bound for the permanent is established by first giving a symmetry-preserving translation of arithmetic circuits to Boolean circuits with threshold gates, and then establishing a lower bound there for computing the permanent of a 0-1-matrix.

The lower bounds for symmetric Boolean circuits are based on a measure we call the *counting width* of graph parameters (the term is introduced in [11]). This is also sometimes known as the Weisfeiler-Leman dimension. In short, we have, for each k an equivalence relation $\equiv^k$, known as the k-dimensional Weisfeiler-Leman equivalence, that is a coarse approximation of isomorphism, getting finer with increasing k. The counting width of a graph parameter μ is the smallest k, as a function of the graph size n, such that μ is constant on $\equiv^k$-classes of graphs of size n. From known results relating Boolean circuits and counting width [2, 5], we know that the existence of subexponential size symmetric circuits computing μ implies a sub-linear upper bound on its counting width. Hence, using the standard relationship between the permanent of a 0-1-matrix and the number of perfect matchings in a bipartite graph, we obtain our lower bound for the permanent in fields of characteristic zero by showing a linear lower bound on the counting width of $\mu(G)$ – the number of perfect matchings in G. Indeed, showing the same for $\mu(G) \pmod p$ for every prime $p > 2$ establishes the lower bound for the permanent in all odd positive characteristics.

The linear lower bound on the counting width of the number of perfect matchings is a result of interest in its own right, quite apart from the lower bounds it yields for circuits for the permanent. Indeed, there is an interest in determining the counting width of concrete graph parameters (see, for instance, [4]), and the result here is somewhat surprising. The decision problem of determining whether a graph has any perfect matching is known to have constant counting width. Indeed, the width is 2 for bipartite graphs [7]. For general graphs, it is known to be strictly greater than 2 but still bounded above by a constant [3].

Related Work. Landsberg and Ressayre [19] establish an exponential lower bound on the complexity of the permanent (specifically over the complex field $\mathbb{C}$) under an assumption of symmetry, and it is instructive to compare our results with theirs. Their lower bound is for the *equivariant determinantal complexity* of the permanent. The determinantal complexity (DC) of a polynomial $p \in \mathbb{F}[X]$ refers to the size of the smallest matrix M with entries that are affine linear forms in X such that $\det(M) = p$. Since every polynomial in VP has DC that is at most quasi-polynomial, an exponential lower bound on the DC of the permanent would show that circuits computing PERM_n must have size at least 2^{n^δ} for some positive δ, and hence separate VP from VNP. Landsberg and Ressayre establish exponential lower bounds on any *equivariant* determinantal representation of the permanent, that is one that preserves all the symmetries of the permanent function. This includes not just the permutations on entries that we consider, but the entire projective symmetry group. This does not, unfortunately, yield any lower bounds for symmetric circuits in the sense we consider. This is because the translation of circuits to determinantal representations that establishes that every polynomial in VP has DC at most quasi-polynomial does not preserve symmetries. A symmetric circuit does not, in general, yield a determinantal representation invariant under row-column permutations, let alone the much richer group of symmetries considered in [19]. The latter group also includes continuous group actions that have no counterpart in the realm of circuits and is specific to algebraically-closed fields of characteristic zero. It remains an interesting question to investigate whether there is a deeper connection between the lower bounds presented here and their results.

Outline. In Section 2 we introduce some preliminary definitions and notation. In Section 3, we introduce the key definitions and properties of symmetric circuits. Section 4 establishes the upper bound for symmetric circuit size for the determinant, by translating Le Verrier's method to symmetric circuits. Finally the lower bound for the permanent is established in Sections 5 and 6. The first of these gives the symmetry-preserving translation from arithmetic circuits to Boolean circuits with threshold gates, and the second gives the main construction proving the linear lower bound for the counting width of the number of perfect matchings in a bipartite graph.

2 Background

In this section we discuss relevant background and introduce notation.

We write $\mathbb{N}$ for the positive integers and $\mathbb{N}_0$ for the non-negative integers. For $m \in \mathbb{N}_0$, $[m]$ denotes the set $\{1, \dots, m\}$. For a set X we write $\mathcal{P}(X)$ to denote the powerset of X.

2.1 Counting Width

For any $k \in \mathbb{N}$, the k-dimensional Weisfeiler-Leman equivalence (see [8]), denoted $\equiv^k$ is an equivalence relation on graphs that provides an over-approximation of isomorphism in the sense that for isomorphic graphs G and H, we have $G \equiv^k H$ for all k. Increasing values of

k give finer relations, so $G \equiv^{k+1} H$ implies $G \equiv^{k} H$ for all k. The equivalence relation is decidable in time $n^{\mathcal{O}(k)}$, where n is the size of the graphs. If $k \geq n$, then $G \equiv^{k} H$ implies that G and H are isomorphic. The Weisfeiler-Leman equivalences have been widely studied and they have many equivalent characterizations in combinatorics, logic, algebra and linear optimization. One of their many uses has been to establish inexpressibility results in logic. These can be understood through the notion of *counting width*.

A *graph parameter* is a function from graphs to $\mathbb{N}$ which is isomorphism invariant. Examples are the chromatic number, the number of connected components or the number of perfect matchings. For a graph parameter μ and any fixed $n \in \mathbb{N}$, there is a smallest value of k such that μ is $\equiv^{k}$-invariant. This motivates the definition.

▶ **Definition 1.** *For any graph parameter μ, the* counting width *of μ is the function $\nu : \mathbb{N} \to \mathbb{N}$ such that $\nu(n)$ is the smallest k such that for all graphs G, H of size n, if $G \equiv^{k} H$, then $\mu(G) = \mu(H)$.*

The *counting width* of a class of graphs $\mathcal{C}$ is the counting width of its indicator function. This notion of counting width for classes of graphs was introduced in [11], which we here extend to graph parameters. Note that for any graph parameter $\nu(n) \leq n$.

Cai, Fürer and Immerman [8] first showed that there is no fixed k for which $\equiv^{k}$ coincides with isomorphism. Indeed, in our terminology, they construct a class of graphs with counting width $\Omega(n)$. Since then, many classes of graphs have been shown to have linear counting width, including the class of Hamiltonian graphs and the class of 3-colourable graphs (see [5]). In other cases, such as the class of graphs that contain a perfect matching, it has been proved that they have counting width bounded by a constant [3]. Our interest in counting width stems from the relation between this measure and lower bounds for symmetric circuits. Roughly, if a class of graphs is recognized by a family of polynomial-sized symmetric threshold circuits, it has bounded counting width (a more precise statement is given in Theorem 13).

Our lower bound construction in Section 6 is based on the graphs constructed by Cai et al. [8]. While we review some of the details of the construction in Section 6, a reader unfamiliar with the construction may wish to consult a more detailed introduction. The original construction can be found in [8] and a version closer to what we use is given in [10].

2.2 Circuits

We provide a general definition that incorporates both Boolean and arithmetic circuits.

▶ **Definition 2** (Circuit). *A* circuit *over the* basis $\mathbb{B}$ *with* variables X *and* constants K *is a directed acyclic graph with a labelling where each vertex of in-degree* 0 *is labelled by an element of $X \cup K$ and each vertex of in-degree greater than* 0 *is labelled by an element of* $\mathbb{B}$.

Let $C = (G, W)$, where $W \subset G \times G$, be a circuit with constants K. We call the elements of G *gates*, and the elements of W *wires*. We call the gates with in-degree 0 *input gates* and gates with out-degree 0 *output gates*. We call those input gates labelled by elements of K *constant gates*. We call those gates that are not input gates *internal gates*. For $g, h \in G$ we say that h is a *child* of g if $(h, g) \in W$. We write $\mathrm{child}(g)$ to denote the set of children of g. We write C_g to denote the sub-circuit of C rooted at g. Unless otherwise stated we always assume a circuit has exactly one output gate.

If K is a field $\mathbb{F}$, and $\mathbb{B}$ is the set $\{+, \times\}$, we have an *arithmetic circuit* over $\mathbb{F}$. If $K = \{0, 1\}$, and $\mathbb{B}$ is a collection of Boolean functions, we have a *Boolean circuit* over the basis $\mathbb{B}$. We define two Boolean bases here. The *standard basis* $\mathbb{B}_{\mathrm{std}}$ contains the functions

$\wedge$, $\vee$, and $\neg$. The *threshold basis* $\mathbb{B}_t$ is the union of $\mathbb{B}_{\text{std}}$ and $\{t_{\geq k} : k \in \mathbb{N}\}$, where for each $k \in \mathbb{N}$, $t_{\geq k}$ is defined for a string $\vec{x} \in \{0,1\}^*$ so that $t_{\geq k}(\vec{x}) = 1$ if, and only if, the number of 1s in $\vec{x}$ at least k. We call a circuit defined over this basis a *threshold circuit*. Another useful function is $t_{=k}$, which is defined by $t_{=k}(x) = t_{\geq k}(x) \wedge \neg t_{\geq k+1}(x)$. We do not explicitly include it in the basis as it is easily defined in $\mathbb{B}_t$.

In general, we require that a basis contain only functions that are invariant under all permutations of their inputs (we define this notion formally in Definition 4). This is the case for the arithmetic functions $+$ and $\times$ and for all of the Boolean functions in $\mathbb{B}_t$ and $\mathbb{B}_{\text{std}}$. Let C be a circuit defined over such a basis with variables X and constants K. We evaluate C for an assignment $M \in K^X$ by evaluating each gate labelled by some $x \in X$ to $M(x)$ and each gate labelled by some $k \in K$ to k, and then recursively evaluating each gate according to its corresponding basis element. We write $C[M](g)$ to denote the value of the gate g and $C[M]$ to denote the value of the output gate. We say that C computes the function $M \mapsto C[M]$.

It is conventional to consider an arithmetic circuit C over $\mathbb{F}$ with variables X to be computing a polynomial in $\mathbb{F}[X]$, rather than a function $\mathbb{F}^X \to \mathbb{F}$. This polynomial is defined via a similar recursive evaluation, except that now each gate labelled by a variable evaluates to the corresponding formal variable, and we treat addition and multiplication as ring operations in $\mathbb{F}[X]$. Each gate then evaluates to some polynomial in $\mathbb{F}[X]$. The polynomial computed by C is the value of the output gate.

For more details on arithmetic circuits see [22] and for Boolean circuits see [24].

3 Symmetric Circuits

In this section we discuss different symmetry conditions for functions and polynomials. We also introduce the notion of a symmetric circuit.

3.1 Symmetric Functions

There is a natural extension of a group action on a set X to functions on X and powers of X.

▶ **Definition 3.** *For any group G, we say that a function $F : K^X \to K$, along with an action of G on X is a G-*symmetric function*, if for every $\sigma \in G$, $\sigma F = F$.*

We are interested in some specific group actions, and we define these next.

▶ **Definition 4.**

- *If $G = \textbf{Sym}(X)$, we call a G-symmetric function $F : K^X \to K$* fully symmetric*.*
- *If $G = \textbf{Sym}(X) \times \textbf{Sym}(Y)$, we call a G-symmetric function $F : K^{X\times Y} \to K$* matrix symmetric*.*
- *If $G = \textbf{Sym}(X)$ we call a G-symmetric $F : K^{X\times X} \to K$, with the natural action of G on $X \times X$* square symmetric*.*

Examples of fully symmetric functions are those that appear as labels of gates in a circuit, including $+$, $\times$, $\wedge$, $\vee$ and $t_{\geq k}$. Matrix symmetric functions are those where the input is naturally seen as a matrix and the result in invariant under aribtrary row and column permutations. The canonical example for us of a matrix symmetric function is the permanent. The determinant is not matrix symmetric over fields of characteristic other than 2, but it is square symmetric. The determinant is also invariant under taking matrix transposes, and we also consider this variation.

▶ **Definition 5.** *Let G be the group generated by the diagonal of $\textbf{Sym}(X) \times \textbf{Sym}(X)$ and the permutation $\sigma_t \in \textbf{Sym}(X) \times \textbf{Sym}(X)$ defined such that $\sigma_t(x, y) = (y, x)$. A function $F : K^{X\times X} \to K$ that is G-symmetric with respect to the natural action of G on $X \times X$ is said to be* transpose symmetric*.*

Finally, another useful notion of symmetry in functions is where the inputs are naturally partitioned into sets.

▶ **Definition 6.** *If $X = \biguplus_{i \in I} X_i$, $G = \prod_{i \in I} \textbf{\textit{Sym}}(X_i)$, and $F : K^X \to K$ is G-symmetric with respect to the natural action of G on X, we say that it is* partition symmetric*.*

Unless otherwise stated we treat the permanent, perm : $\mathbb{F}^{X \times Y} \to \mathbb{F}$ as a matrix symmetric function, and the determinant det : $\mathbb{F}^{X \times X} \to \mathbb{F}$ as a transpose symmetric function.

3.2 Symmetric Circuits

Symmetric Boolean circuits have been considered in the literature, particularly in connection with definability in logic. In that context, we are considering circuits which take relational structures (such as graphs) as inputs and we require their computations to be invariant under re-orderings of the elements of the structure. Here, we generalize the notion to arbitrary symmetry groups, and also consider them in the context of arithmetic circuits. In order to define symmetric circuits, we first need to define the automorphisms of a circuit.

▶ **Definition 7** (Circuit Automorphism)**.** *Let $C = (G, W)$ be a circuit over the basis $\mathbb{B}$ with variables X and constants K. For $\sigma \in \textbf{\textit{Sym}}(X)$, we say that a bijection $\pi : G \to G$ is an* automorphism *extending σ if for every gate g in C we have that*

- *if g is a constant gate then $\pi(g) = g$,*
- *if g is a non-constant input gate then $\pi(g) = \sigma(g)$,*
- *if $(h, g) \in W$ is a wire, then so is $(\pi h, \pi g)$*
- *if g is labelled by $b \in \mathbb{B}$, then so is $\pi(g)$.*

We say that a circuit C with variables X is *rigid* if for every permutation $\sigma \in \textbf{Sym}(X)$ there is at most one automorphism of C extending σ.

We are now ready to define the key notion of a symmetric circuit.

▶ **Definition 8** (Symmetric Circuit)**.** *For a G-symmetric function $F : K^X \to K$, a circuit C computing F is said to be* symmetric *if for every $\sigma \in G$, the action of σ on X extends to an automorphism of C. We say C is* strictly symmetric *if it has no other automorphisms.*

For a gate g in a symmetric circuit C, the *orbit* of g, denoted by $\textbf{Orb}(g)$, is the the set of all $h \in C$ such that there exists an automorphism π of C with $\pi(g) = h$. We write $|\textbf{Orb}(C)|$ for the maximum size of an orbit in C, and call it the *orbit size* of C.

Though symmetric arithmetic circuits have not previously been studied, symmetric Boolean circuits have [13, 20, 2]. It is known that polynomial-size symmetric threshold circuits are more powerful than polynomial-size symmetric circuits over the standard basis [2]. In particular, the majority function is not computable by any family of polynomial-size symmetric circuits over the standard basis. On the other hand, it is also known [12] that adding any fully symmetric functions to the basis does not take us beyond the power of the threshold basis. Thus, $\mathbb{B}_t$ gives the robust notion, and that is what we use here. It is also this that has the tight connection with counting width mentioned above.

3.3 Polynomials

In the study of arithmetic complexity, we usually think of a circuit over a field $\mathbb{F}$ with variables in X as expressing a polynomial in $\mathbb{F}[X]$, rather than computing a function from $\mathbb{F}^X$ to $\mathbb{F}$. The distinction is significant when $\mathbb{F}$ is a finite field, as it is possible for distinct polynomials to represent the same function.

The definitions of symmetric functions given in Section 3.1 extend easily to polynomials. So, for a group G acting on X, a polynomial $p \in \mathbb{F}[X]$ is said to be G-symmetric if $\sigma p = p$ for all $\sigma \in G$. We define *fully symmetric*, *matrix symmetric*, *square symmetric* and *transpose symmetric* polynomials analogously. Every matrix symmetric polynomial is also square symmetric. Also, every transpose symmetric polynomial is square symmetric. The permanent PERM_n is both matrix symmetric and transpose symmetric, while the determinant DET_n is transpose symmetric, but not matrix symmetric. In this paper, we treat PERM_n as a matrix symmetric polynomial and DET_n as a transpose symmetric polynomial. It is clear that a G-symmetric polynomial determines a G-symmetric function.

An arithmetic circuit C expressing a G-symmetric polynomial is said to be *symmetric* if the action of each $\sigma \in G$ on the inputs of C extends to an automorphism of C.

Standard *symmetric polynomials* are, in our terminology, fully symmetric. In particular, the homogeneous polynomial $\sum_{i\in[n]} x_i^r$ is fully symmetric. There is a known lower bound of $\Omega(n \log r)$ on the size of any circuit expressing this polynomial [6]. Notably, the matching upper bound is achieved by a symmetric circuit. Similarly, we have tight upper and lower bounds for the elementary symmetric polynomials $\sum_{S\subseteq[n]:|S|=k} \prod_{i\in S} x_i$ over infinite fields [21]. Again, the upper bound is achieved by symmetric circuits.

The best known upper bound for general arithmetic circuits for expressing the permanent is given by Ryser's formula: $\mathrm{PERM}_n = (-1)^n \sum_{S\subseteq[n]} (-1)^{|S|} \prod_{i=1}^n \sum_{j\in S} x_{ij}$. It is easily seen that this expression is symmetric, and it yields a symmetric circuit of size $\mathcal{O}(2^n n^2)$. Our main result, Theorem 12, gives us a near matching lower bound on the size of symmetric circuits for expressing PERM_n.

A symmetric circuit C expressing a G-symmetric polynomial p is also a symmetric circuit computing the function determined by p. In establishing our upper bound for the determinant, we show the existence of small symmetric circuits for the polynomial, and hence also for the function. For the lower bound on the permanent, we show that there are no small symmetric circuits for computing the function, hence also none for the polynomial. For a discussion of functional lower bounds, as opposed to polynomial lower bounds, see [14].

4 An Upper-Bound for the Determinant

In this section we show that for any field $\mathbb{F}$ of characteristic 0 there is a polynomial-size family of symmetric arithmetic circuits over $\mathbb{F}$ computing $\{\mathrm{DET}_n\}$. We define this family using Le Verrier's method for calculating the characteristic polynomial of a matrix. We review this method briefly, and direct the reader to Section 3.4.1 in [16] for more detail.

The characteristic polynomial of an $n \times n$ matrix M is

$$\det(xI_n - M) = \prod_{i=1}^{n}(x - \lambda_i) = x^n - p_1 x^{n-1} + p_2 x^{n-2} - \ldots + (-1)^n p_n,$$

where $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of M, counted with multiplicity. It is known that $p_n = \det(M)$ and $p_1 = \mathrm{Tr}(M)$. Le Verrier's method gives, for each $i \in [n]$, the linear recurrence given by $p_i = \frac{1}{i}[p_{i-1}s_1 - p_{i-2}s_2 + \ldots \pm s_i]$ where $p_0 = 1$ and for each $j \in [n]$, $s_j = \mathrm{Tr}(M^j)$.

The determinant can thus be computed as follows. First, for each $k \in [n]$ we compute entries in the matrix M^k. Then for each $k \in [n]$ we compute $s_k = \mathrm{Tr}(M^k)$. Finally, we recursively compute each p_i and output p_n. There is a natural arithmetic circuit Φ with variables $M = \{m_{ij} : i, j \in [n]\}$ implementing this algorithm.

To see that Φ is symmetric we pick some $\sigma \in \mathbf{Sym}(n) \times \mathbf{Sym}(n)$ such that σ is either in the diagonal or $\sigma(i,j) = (j,i)$ for all $i,j \in [n]$. We now retrace the description of the algorithm implemented by Φ and show how the action of σ on the input gates extends naturally to an automorphism π of Φ. For each input gate labelled by a variable v let $\pi(v) = \sigma(v)$, and let π fix each constant gate. For each gate v computing $(M^k)_{ij}$ let $\pi(v)$ be the gate computing $(M^k)_{\sigma(i,j)}$. For each $k \in [n]$ let v_k be the gate computing the trace of M^k. Then v_k is the sum of those gates computing the diagonal of M^k, which is fixed setwise by π, and so we let $\pi(v_k) = v_k$. We note that each p_i is defined in terms of $s_1, \dots, s_i$ and constants $-1, 1, \frac{1}{2}, \dots, \frac{1}{i}$. All of these gates are fixed by π and so we can take π to fix all remaining gates in the circuit.

It is possible to show that the construction of Φ for a given $n \in \mathbb{N}$ can be carried out in time $\mathcal{O}(n^3)$. In particular, we have the following.

▶ **Theorem 9.** *For $\mathbb{F}$ a field of characteristic 0, there exists a family of symmetric arithmetic circuits $(\Phi_n)_{n\in\mathbb{N}}$ over $\mathbb{F}$ computing $\{\mathrm{DET}_n\}$ as a family of transpose symmetric polynomials and for which the function $n \mapsto \Phi_n$ is computable in time $\mathcal{O}(n^3)$.*

Le Verrier's method explicitly involves multiplications by $\frac{1}{k}$ for $k \in [n]$, and so cannot be directly applied to fields of positive characteristic. There are many known algorithms for computing the determinant over fields of positive characteristic, and it seems reasonable to conjecture that some could be implemented symmetrically.

5 From Arithmetic To Boolean Circuits

In this section we establish the following symmetry-preserving translation from arithmetic circuits to threshold circuits.

▶ **Theorem 10.** *Let G be a group acting on a set of variables X. Let Φ be a symmetric arithmetic circuit over a field $\mathbb{F}$ with variables X and computing a G-symmetric function. Let $B \subseteq \mathbb{F}$ be finite. Then there is a symmetric threshold circuit C with variables X, such that for all $M \in \{0,1\}^X$ we have $C[M] = 1$ if, and only if, $\Phi[M] \in B$ and $|\boldsymbol{Orb}(C)| = |\boldsymbol{Orb}(\Phi)|$.*

We use Theorem 10 in Section 6 to transfer a lower bound on threshold circuits to arithmetic circuits, a crucial step in establishing our lower bound for the permanent.

We prove Theorem 10 by first establishing a similar translation from arithmetic circuits over a field $\mathbb{F}$ to Boolean circuits over a basis $\mathbb{B}^{\mathbb{F}}_{\mathrm{arth}}$ of partition symmetric functions. We then complete the proof by replacing each gate labelled by a partition symmetric function with an appropriate symmetric threshold circuit.

To enable this second step, we show that each partition symmetric function can be computed by a rigid strictly symmetric threshold circuit. The proof of this result follows from the fact that if a function $F : \{0,1\}^A \to \{0,1\}$ is partition symmetric, then its output for $h \in \{0,1\}^A$ depends only on the *number* of elements in each part of A that h maps to 1. We can thus evaluate F by counting the number of 1s in each part, a procedure which we now show can be implemented via a symmetric threshold circuit.

▶ **Lemma 11.** *Let F be a partition symmetric function. There exists a rigid strictly symmetric threshold circuit $C(F)$ computing F.*

Proof. Let $A := \biguplus_{q\in Q} A_q$ be a disjoint union of finite sets A_q indexed by Q, and $F : \{0,1\}^A \to \{0,1\}$ be a partition symmetric function. The fact that F is partition symmetric means that whether $F(h) = 1$ for some $h \in \{0,1\}^A$ is determined by the number of $a \in A_q$

(for each q) for which $h(a) = 1$. Write h_q for this number. Then, there is a set $c_F \subseteq \mathbb{N}_0^Q$ such that $F(h) = 1$ if, and only if, $(h_q)_{q\in Q} \in c_F$. Since each A_q is finite, so is c_F. Then $F(h) = 1$ if, and only if, the following Boolean expression is true: $\bigvee_{c\in c_F} \bigwedge_{q\in Q}(h_q = c(q))$. We can turn this expression into a circuit C with an OR gate at the output, whose children are AND gates, one for each $c \in c_F$, let us call it $\wedge_c$. The children of $\wedge_c$ are a set of gates, one for each $q \in Q$, let us call it $T_{c,q}$, which is labelled by $t_{=c(q)}$ and has as children all the inputs $a \in A_q$.

This circuit C is symmetric and rigid, but not necessarily strictly symmetric, as it may admit automorphisms that do not respect the partition of the inputs A as $\biguplus_{q\in Q} A_q$. To remedy this, we create pairwise non-isomorphic gadgets G_q, one for each $q \in Q$. Each G_q is a one-input, one-output circuit computing the identity function. For example, G_q could be a tower of single-input AND gates, and we choose a different height for each q. We now modify C to obtain $C(F)$ by inserting between each input $a \in A_q$ and each gate $T_{c,q}$ a copy G_q^a of the gadget G_q.

Clearly $C(F)$ computes F. We now argue $C(F)$ is rigid and strictly symmetric. To see that it is symmetric, consider any $\sigma \in \prod_{q\in Q} \mathbf{Sym}(A_q)$ in its natural action on A. This extends to an automorphism of $C(F)$ that takes the gadget G_q^a to $G_q^{\sigma a}$ while fixing all gates $T_{c,q}$ and $\wedge_c$. To see that there are no other automorphisms, suppose π is an automorphism of $C(F)$. It must fix the output OR gate. Also π cannot map a gate $T_{c,q}$ to $T_{c',q'}$ for $q' \neq q$ because the gadgets G_q and $G_{q'}$ are non-isomorphic. Suppose that π maps $\wedge_c$ to $\wedge_{c'}$. Then, it must map $T_{c,q}$ to $T_{c',q}$. Since the labels of these gates are $t_{=c(q)}$ and $t_{=c'(q)}$ respectively, we conclude that $c(q) = c'(q)$ for all q and therefore $c = c'$. ◀

We now define for each field $\mathbb{F}$ the basis $\mathbb{B}^{\mathbb{F}}_{\text{arth}}$. The functions in this basis are intended to be Boolean analogues of addition and multiplication. Let $Q \subseteq \mathbb{F}$ be finite, $A = \biguplus_{q\in Q} A_q$ be a disjoint union of non-empty finite sets, and $c \in \mathbb{F}$. We define a function $+^A_{Q,c} : \{0,1\}^A \to \{0,1\}$ that given $h \in \{0,1\}^A$ computes the sum over all q of the number of elements of A_q that h maps to 1, weighted by q, and returns 1 if this sum equals c. We also define an analogous function for multiplication $\times^A_{Q,c} : \{0,1\}^A \to \{0,1\}$. Formally, these functions are defined for $h \in \{0,1\}^A$ as follows: $+^A_{Q,c}(h) = 1$ if, and only if, $\sum_{q\in Q} |\{a \in A_q : h(a) = 1\}| \cdot q = c$ and $\times^A_{Q,c}(h) = 1$ if, and only if, $\prod_{q\in Q} q^{|\{a\in A_q : h(a)=1\}|} = c$. Both $+^A_{Q,c}$ and $\times^A_{Q,c}$ are partition symmetric. Let $\mathbb{B}^{\mathbb{F}}_{\text{arth}}$ be the set of all functions $+^A_{Q,c}$ and $\times^A_{Q,c}$.

We aim to prove Theorem 10 by first defining for a given symmetric arithmetic circuit a corresponding symmetric circuit over a partition symmetric basis. To ensure unambiguous evaluation, the circuit must include for each gate labelled by a partition symmetric function a corresponding partition on its children. Let C be a circuit with variables X and let g be a gate in C labelled by a partition symmetric function $F : \{0,1\}^A \to \{0,1\}$, where $A = \biguplus_{q\in Q} A_q$ is a disjoint union of finite non-empty sets. We associate with g a bijection $L_g : A \to \text{child}(g)$. We evaluate g for an input as follows. For $M \in \{0,1\}^X$ we let $L_g^M : A \to \{0,1\}$ be defined such that $L_g^M(a) = C[M](L_g(a))$ for all $a \in A$. Let $C[M](g) = F(L_g^M)$.

Proof of Theorem 10. For $v \in \Phi$ let Q_v be the set of possible evaluations of v if the input gates are assigned to 0 or 1, i.e. $Q_v = \{\Phi[M](v) : M \in \{0,1\}^X\}$. The restriction to 0-1-matrices ensures that Q_v is finite. Let z be the output gate of Φ. If $Q_z \subseteq B$ let C be the circuit consisting of a single gate labelled by 1 and if $Q_z \cap B = \emptyset$ let C consist of a single gate labelled by 0. Suppose that neither of these two cases hold.

We now construct a $\mathbb{B}^{\mathbb{F}}_{\text{arth}} \cup \mathbb{B}_{\text{std}}$-circuit D from Φ by replacing each internal gate v in Φ with a family of gates (v, q) for $q \in Q_v$ such that $D[M](v, q) = 1$ if, and only if, $\Phi[M](v) = q$. Each (v, q) is labelled by a function of the form $+^A_{Q,q}$ or $\times^A_{Q,q}$, depending on if v is an addition or multiplication gate. We also add a single output gate in D that has as children exactly those gates (z, q) where $q \in Q_z \cap B$. We define D from Φ recursively as follows. Let $v \in \Phi$.

- If v is an non-constant input gate in Φ let $(v, 1)$ be an input gate in D labelled by the same variable as v and let $(v, 0)$ be a NOT-gate with child $(v, 1)$.
- If v is a constant gate in Φ labelled by some field element q let (v, q) be a constant gate in D labelled by 1.
- Suppose v is an internal gate. Let $Q = \bigcup_{u \in \text{child}(v)} Q_v$. For $q \in Q$ let $A_q = \{u \in \text{child}(v) : q \in Q_u\}$. Let $A = \biguplus_{q \in Q} A_q$. For each $c \in Q_v$ let (v, c) be a gate in D such that if v is an addition gate or multiplication gate then (v, c) is labelled by $+^{A}_{Q,c}$ or $\times^{A}_{Q,c}$, respectively. The labelling function $L_{(v,c)} : A \to \text{child}(v, c)$ is defined for $u \in A$ such that if $u \in A_q$ then $L_{(v,c)}(u) = (u, q)$.

We add one final OR-gate w to form D with $\text{child}(w) = \{(z, q) : q \in B \cap Q_z\}$.

We now show that D is a symmetric circuit. Let $\sigma \in G$ and π be an automorphism of Φ extending σ. Let $\pi' : D \to D$ be defined such that for each gate $(v, c) \in D$, $\pi'(v, c) = (\pi(v), c)$ and for the output gate w, $\pi'(w) = w$. It can be verified by induction that π' is an automorphism of C extending σ.

We now show that $|\mathbf{Orb}(D)| = |\mathbf{Orb}(\Phi)|$. It suffices to prove that for $v, u \in \Phi$ and $c \in Q_v$ that $u \in \mathbf{Orb}(v)$ if, and only if, $(u, c) \in \mathbf{Orb}(v, c)$. The forward direction follows from the above argument establishing that D is symmetric. Let $v, u \in \Phi$ and $c \in Q_v$ and suppose $(u, c) \in \mathbf{Orb}(v, c)$. For each gate $t \in \Phi$ pick some $c_t \in Q_t$ such that if $t = u$ or $t = v$ then $c_t = c$ and for all $t_1, t_2 \in \Phi$, if $Q_{t_1} = Q_{t_2}$ then $c_{t_1} = c_{t_2}$. Let π' be an automorphism of D such that $\pi'(v, c) = (u, c)$. Let $\pi : \Phi \to \Phi$ be defined for $t \in \Phi$ such that $\pi'(t, c_t) = (\pi(t), c_t)$. We now show that π is an automorphism of Φ, and so $u \in \mathbf{Orb}(v)$. Note that, since π' preserves the labelling on the gates in D, it follows that for all $t \in \Phi$, $Q_t = Q_{\pi(t)}$ and so $c_{\pi(t)} = c_t$. Let $t, t' \in \Phi$ and suppose $\pi(t) = \pi(t')$. Then $\pi'(t, c_t) = (\pi(t), c_t) = (\pi(t), c_{\pi(t)}) = (\pi(t'), c_{\pi(t')}) = (\pi(t'), c_{t'}) = \pi'(t', c_{t'})$, and so $(t, c_t) = (t', c_{t'})$ and $t = t'$. It follows that π is injective, and so bijective. Let $t, s \in \Phi$. Then $t \in \text{child}(s) \iff (t, c_t) \in \text{child}(s, c_s) \iff \pi'(t, c_t) \in \text{child}(\pi'(s, c_s)) \iff (\pi(t), c_t) \in \text{child}(\pi(s), c_s) \iff \pi(t) \in \text{child}(\pi(s))$. The first and last equivalences follow from the construction of the circuit. The remaining conditions for π to be an automorphism can be easily verified.

Let $M \in \{0, 1\}^X$. We now show by induction that for all $v \in \Phi$ and $c \in Q_v$, $\Phi[M](v) = c$ if, and only if, $D[M](v, c) = 1$. Let $v \in \Phi$. If v is an input gate then the claim holds trivially. Suppose v is an internal gate and let $c \in Q_v$. Suppose v is an addition gate. Then (v, c) is labelled by the function $+^{A}_{Q,c}$ where $Q = \bigcup_{u \in \text{child}(v)} Q_u$, for $q \in Q$, $A_q = \{u \in \text{child}(v) : q \in Q_u\}$, and $A = \biguplus_{q \in Q} A_q$. Then

$$\begin{aligned}
\Phi[M](v) = c &\iff \sum_{u \in \text{child}(v)} \Phi[M](u) = c \iff \sum_{q \in Q} |\{u \in \text{child}(v) : \Phi[M](u) = q\}| \cdot q = c \\
&\iff \sum_{q \in Q} |\{u \in A_q : D[M](u, q) = 1\}| \cdot q = c \\
&\iff \sum_{q \in Q} |\{u \in A_q : L^{M}_{(v,c)}(u) = 1\}| \cdot q = c \\
&\iff D[M](v, c) = 1
\end{aligned}$$

A similar argument suffices if v is a multiplication gate. It follows that $D[M](w) = 1$ if, and only if, there exists $c \in B$ such that $D[M](z, c) = 1$ if, and only if, $\Phi[M] \in B$.

We define C from D by replacing each internal gate $(v, c) \in D$ labelled by some $F \in \mathbb{B}^{\mathbb{F}}_{\text{arth}}$ with the rigid strictly symmetric threshold circuit $C(F)$ computing F defined in Lemma 11. C computes the same function as D. Since $C(F)$ is symmetric, C is symmetric. Since $C(F)$ is rigid and *strictly* symmetric, $|\mathbf{Orb}(C)| = |\mathbf{Orb}(D)| = |\mathbf{Orb}(\Phi)|$. ◀

6 A Lower-Bound for the Permanent

We now establish the lower bound on symmetric arithmetic circuits for the permanent.

▶ **Theorem 12.** *If $\mathbb{F}$ is a field with char$(\mathbb{F}) \neq 2$, then for any $\epsilon > 0$ there is no family of symmetric arithmetic circuits over $\mathbb{F}$ of orbit size $\mathcal{O}(2^{n^{1-\epsilon}})$ computing $\{\mathrm{PERM}_n\}$.*

Our proof establishes something stronger. We actually show that there are no symmetric arithmetic circuits of orbit size $\mathcal{O}(2^{n^{1-\epsilon}})$ that compute the function perm(M) for matrices $M \in \mathbb{F}^{n\times n}$. Indeed, the lower bound holds even when restricting the input to matrices $M \in \{0,1\}^{n\times n}$. Theorem 12 is proved by showing lower bounds on the counting widths of functions which determine the number of perfect matchings in a bipartite graph. The connection of orbit size to counting width comes through the following theorem (see [2, 5]).

▶ **Theorem 13.** *Let $(C_n)_{n\in\mathbb{N}}$ be a family of symmetric threshold circuits of orbit size $s = \mathcal{O}(2^{n^{1-\epsilon}})$ for some $\epsilon > 0$ deciding a class of graphs $\mathcal{C}$. Then, the counting width of $\mathcal{C}$ is $\mathcal{O}(\frac{\log s}{\log n})$.*

If G is a bipartite graph, let $\mu(G)$ denote the number of perfect matchings in G and, for a prime number p, we write $\mu^p(G)$ for the congruence class of $\mu(G) \pmod p$. It is well known if G is a balanced bipartite graph with vertex bipartition $V(G) = A \cup B$, and $M_G \in \{0,1\}^{A\times B}$ is the biadjacency matrix of G, then the permanent of M_G (say, over the rational field $\mathbb{Q}$) is the number of distinct perfect matchings of G. Moreover, since M_G is a 0-1-matrix, $\mathrm{perm}_{\mathbb{F}}(M_G) = \mathrm{perm}_{\mathbb{F}'}(M_G)$ whenever $\mathbb{F}'$ is a subfield of $\mathbb{F}$. In particular, for any field $\mathbb{F}$ of characteristic zero, $\mathrm{perm}_{\mathbb{F}}(M_G) = \mathrm{perm}_{\mathbb{Q}}(M_G) = \mu(G)$ and for any field $\mathbb{F}$ of characteristic p, $\mathrm{perm}_{\mathbb{F}}(M_G) = \mathrm{perm}_{\mathbb{F}_p}(M_G) = \mu^p(G)$. To avoid unnecessary case distinctions, we write $\mu^c(G)$ where c is either 0 or a prime p, with the understanding that $\mu^0(G) = \mu(G)$. Then, we can say that for any field $\mathbb{F}$ with char$(\mathbb{F}) = c$, $\mathrm{perm}_{\mathbb{F}}(M_G) = \mu^c(G)$.

Combining Theorem 10 with Theorem 13 gives us the following consequences.

▶ **Corollary 14.** *If there exists a family of symmetric circuits of orbit size $s = \mathcal{O}(2^{n^{1-\epsilon}})$ over a field $\mathbb{F}$ of characteristic c computing $\{\mathrm{PERM}_n\}$, then the counting width of μ^c is $\mathcal{O}(\frac{\log s}{\log n})$.*

Proof. Let k be the counting width of μ^c. Then, by definition, we can find for each $n \in \mathbb{N}$, a pair of balanced bipartite graphs G_n and H_n on at most $2n$ vertices such that $G_n \equiv^{k(n)-1} H_n$ but $\mu(G_n) \neq \mu(H_n)$. Let $B_n = \{\mu(G_n)\}$. Then, by Theorem 10 and the assumption that there is a family of symmetric circuits over $\mathbb{F}$ computing $\{\mathrm{PERM}_n\}$ of orbit size $s = \mathcal{O}(2^{n^{1-\epsilon}})$, there is a family of symmetric Boolean threshold circuits of orbit size $s = \mathcal{O}(2^{n^{1-\epsilon}})$ which decides for a matrix $M \in \{0,1\}^{n\times n}$ whether perm$(M) \in B_n$. In other words, when $c = 0$, this family of circuits then decides whether a balanced bipartite graph G on $2n$ vertices has exactly $\mu(G_n)$ perfect matchings, and when $c = p$ for some prime p, it decides whether G has $\mu^p(G_n)$ perfect matchings, modulo p. It follows by Theorem 13 that the counting width of this decision problem is $\mathcal{O}(\frac{\log s}{\log n})$. Since the counting width of this decision problem is, by choice of G_n, k, it follows that $k = \mathcal{O}(\frac{\log s}{\log n})$. ◀

Thus, to establish Theorem 12, we aim to prove the following.

▶ **Theorem 15.** *There are, for each $k \in \mathbb{N}$, a pair of balanced bipartite graphs X and Y with $\mathcal{O}(k)$ vertices, such that $X \equiv^k Y$, and $\mu(X) - \mu(Y) = 2^l$ for some $l > 0$.*

Before giving the proof of Theorem 15 we show how Theorem 12 now follows.

Proof of Theorem 12. By Theorem 15, we have for each k, a pair of graphs X and Y with $\mathcal{O}(k)$ vertices such that $\mu(X) \neq \mu(Y)$ and $X \equiv^k Y$ thus, the counting width of μ is $\Omega(n)$. Moreover, since $\mu(X) - \mu(Y)$ is a power of 2, it follows that for any prime $p \neq 2$, $\mu(X) \not\equiv \mu(Y) \pmod{p}$. Hence, the counting width of μ^p is also $\Omega(n)$.

Suppose then that $\mathbb{F}$ is a field of characteristic $c \neq 2$ and that there is a family of symmetric arithmetic circuits over $\mathbb{F}$ of orbit size $s = \mathcal{O}(2^{n^{1-\epsilon}})$ computing $\{\mathrm{PERM}_n\}$. Then, it follows from Corollary 14 that the counting width of μ^c is at most $k = \mathcal{O}(\frac{\log s}{\log n}) = \mathcal{O}(n^{1-\epsilon})$, giving a contradiction. ◀

The construction used to prove Theorem 15 is an adaptation of a standard construction by Cai, Fürer and Immerman [8] which gives non-isomorphic graphs X and Y with $X \equiv^k Y$ for arbitrary k (see also [10]). We tweak it somewhat to ensure that both graphs have perfect matchings (indeed, they are both balanced bipartite graphs). The main innovation is in the analysis of the number of perfect matchings the graphs contain.

Gadgets. In what follows, $G = (V, E)$ is always a 3-regular 2-connected graph. From this, we first define a graph $X(G)$. The vertex set of $X(G)$ contains, for each edge $e \in E$, two vertices that we denote e_0 and e_1. For each vertex $v \in V$ with incident edges f, g and h, $X(G)$ contains five vertices. One of these we call the *balance vertex* and denote v_b. The other four are called *inner vertices* and there is one v_S, for each subset $S \subseteq \{f, g, h\}$ of even size. For each $v \in V$, the neighbours of v_b are exactly the four vertices of the form v_S. Moreover, for each $e \in \{f, g, h\}$, $X(G)$ contains the edge $\{e_1, v_S\}$ if $e \in S$ and the edge $\{e_0, v_S\}$ otherwise. There are no other edges in $X(G)$.

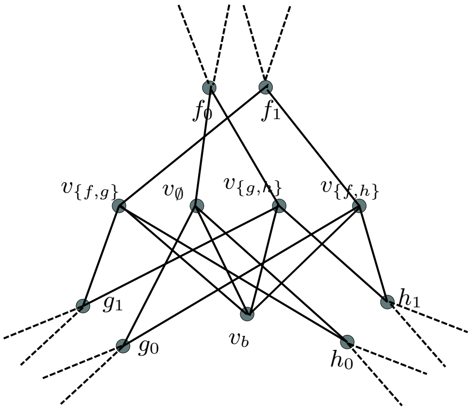

Figure 1 A gadget in $X(G)$ corresponding to vertex v with incident edges f, g, h.

The construction of $X(G)$ from G essentially replaces each vertex v with incident edges f, g and h with the gadget depicted in Figure 1, where the dashed lines indicate edges whose endpoints are in other gadgets. The vertices e_0, e_1 for each $e \in \{f, g, h\}$ are shared with neighbouring gadgets.

For any fixed vertex $x \in V$ with incident edges f, g, h, the graph $\tilde{X}_x(G)$ is obtained by modifying the construction of $X(G)$ so that, for the one vertex x, the gadget contains inner vertices x_S for subsets $S \subseteq \{f, g, h\}$ of odd size. Again, for each $e \in \{f, g, h\}$, $X(G)$ contains the edge $\{e_1, v_S\}$ if $e \in S$ and the edge $\{e_0, v_S\}$ otherwise.

If we remove the balance vertices v_b, the graphs $X(G)$ and $\tilde{X}_x(G)$ are essentially the Cai-Fürer-Immerman (CFI) graphs associated with G. The balance vertex v_b is adjacent to all the inner vertices associated with v and so does not alter the automorphism structure of $X(G)$ (or $\tilde{X}_x(G)$) at all. Nor do these vertices alter any other essential properties of the CFI construction. In particular, since G is connected, we have the following lemma.

▶ **Lemma 16.** *For any $x, y \in V$, $\tilde{X}_x(G)$ and $\tilde{X}_y(G)$ are isomorphic.*

With this in mind, we refer simply to the graph $\tilde{X}(G)$ to mean a graph $\tilde{X}_x(G)$ for some fixed x, and we refer to x as the special vertex of G.

By known properties of the CFI construction, we also have the following (see [10, Theorem 3]).

▶ **Lemma 17.** *If the treewidth of G is greater than k, then $X(G) \equiv^k \tilde{X}(G)$.*

The purpose of the balance vertices is to change the structure of the perfect matchings. Indeed, if we let CFI(G) denote the subgraph of $X(G)$ that excludes the balance vertices, it is easily seen that this contains no perfect matchings. It is a bipartite graph where one part contains the $4|V|$ inner vertices and the other part contains the $2|E| = 3|V|$ edge vertices and so no perfect matching is possible. But, $X(G)$ is a bipartite graph where in one part we have the $4|V|$ inner vertices and in the other the $3|V|$ edge vertices along with the $|V|$ balance vertices. In short, this is a 4-regular bipartite graph and so contains perfect matchings. We next analyse the structure of the set of such perfect matchings. In particular, we show that $X(G)$ and $\tilde{X}(G)$ contain different numbers of perfect matchings.

In the sequel, we write X to denote either one of the graphs $X(G)$ or $\tilde{X}(G)$, $V(X)$ to denote its vertices and $E(X)$ to denote its edges. We continue to use V and E for the vertices and edges of G. Also, for each $v \in V$, we write I_v to denote the set of four inner vertices in X associated with v.

Non-Uniform Matchings. Let $M \subseteq E(X)$ be a perfect matching in X. For each $v \in V$ and $e \in E$ incident on v, we define the projection $p^M(v, e)$ of M on (v, e) to be the value in $\{0, 1, 2\}$ which is the number of edges between $\{e_0, e_1\}$ and I_v that are included in M. These satisfy the following equations:

$p(u, e) + p(v, e) = 2$ for each edge $e = \{u, v\} \in E$; and

$p(v, f) + p(v, g) + p(v, h) = 3$ for each vertex $v \in V$ with incident edges f, g, h.

The first of these holds because M must include exactly one edge incident on each of e_0 and e_1. The second holds because M must include an edge between v_b and one vertex of I_v. Thus, the three remaining vertices in I_v must be matched with vertices among $f_0, f_1, g_0, g_1, h_0, h_1$.

One solution to the set of equations is obtained by taking the constant projection $p^M(v, e) = 1$ for all such pairs (v, e). Say that a matching M is uniform if $p^M(v, e) = 1$ everywhere and non-uniform otherwise.

▶ **Lemma 18.** *The number of non-uniform matchings in $X(G)$ is the same as in $\tilde{X}(G)$.*

Proof. It suffices to prove that for any non-constant projection p, the number of matchings M with $p^M = p$ is the same for both $X(G)$ and $\tilde{X}(G)$. For then, taking the sum over all possible projections gives the result. So, let p be a non-constant projection. Then, for some edge $e = \{u, v\} \in E$, we have $p(u, e) = 2$ and $p(v, e) = 0$. Then, let $X(G)^-$ and $\tilde{X}(G)^-$ be the subgraphs of $X(G)$ and $\tilde{X}(G)$ respectively obtained by removing the edges between $\{e_0, e_1\}$ and I_v. It is clear that any matching M in $X(G)$ with $p^M = p$ is also a perfect matching in $X(G)^-$, and similarly for $\tilde{X}(G)$. However, $X(G)^-$ and $\tilde{X}(G)^-$ are isomorphic. This follows by an argument analogous to the proof of Lemma 16. Since G is 2-connected, there is a path p from u to the special vertex x that does not involve the edge e. We can then define an isomorphism from $X(G)$ to $\tilde{X}(G)$ by mapping e_0 to e_1, for each edge f on the path p, mapping f_0 to f_1 and extending this using the induced automorphisms of the gadgets corresponding to $v_1, \ldots, v_{t-1}$. We conclude that the numbers of such matchings are the same for both. ◀

Now, we aim to show that the number of uniform matchings of $X(G)$ is different to that of $\tilde{X}(G)$. For this, it is useful to first analyse the orientations of the underlying graph G.

Orientations. An *orientation* of G is a directed graph obtained from G by assigning to each edge $\{u, v\} \in E$ a direction. There are exactly $2^{|E|}$ distinct orientations of G. We say that a vertex $v \in V$ is *odd* with respect to an orientation $\overrightarrow{G}$ of G if it has an odd number of incoming directed edges and *even* otherwise. For an orientation $\overrightarrow{G}$ of G, we write $\mathrm{odd}(\overrightarrow{G})$ for the set of its odd vertices. We say that the orientiation $\overrightarrow{G}$ is *odd* if $|\mathrm{odd}(\overrightarrow{G})|$ is odd, and we say it is *even* otherwise. Since G is 3-regular, it is not hard to see that $|V|$ is always even and $|E|$ is even if, and only if, $|V|/2$ is. Moreover, in all orientations of G, $|\mathrm{odd}(\overrightarrow{G})| = |E| \pmod 2$.

▶ **Lemma 19.** *If $|V|/2$ is even, then all orientations of G are even. If $|V|/2$ is odd, then all orientations of G are odd.*

Proof. Note that since G is 3-regular, $3|V| = 2|E|$, so $|V|$ is always even. Moreover, $|V|/2$ is even if, and only if, $|E|$ is. For an orientation $\overrightarrow{G}$, let $\mathrm{in}(v)$ denote the number of edges incoming to the vertex v. Then, $|E| = \sum_v \mathrm{in}(v)$. But, $\sum_v \mathrm{in}(v) \equiv |\mathrm{odd}(\overrightarrow{G})| \pmod 2$. ◀

Thus, we say that a graph G is *odd* if $|E|$ is odd, and hence all orientations of G are odd, and G is *even* if $|E|$ is even and hence all orientations of G are even.

We can now quantify exactly, for any set $S \subseteq V$ the number of distinct orientations $\overrightarrow{G}$ with $\mathrm{odd}(\overrightarrow{G}) = S$. To do this, we first establish an auxiliary lemma.

▶ **Lemma 20.** *If $G = (V, E)$ is even, then for every set $S \subseteq V$ with $|S|$ even, there is an orientation $\overrightarrow{G}$ of G with odd$(\overrightarrow{G}) = S$. Similarly if $G = (V, E)$ is odd, then for every set $S \subseteq V$ with $|S|$ odd, there is an orientation $\overrightarrow{G}$ of G with odd$(\overrightarrow{G}) = S$.*

Proof. It suffices to show, for any set $S \subseteq V$ and any pair of vertices $u, v \in V$, if there is an orientation $\overrightarrow{G}$ of G with $\mathrm{odd}(\overrightarrow{G}) = S$, then there is also an orientation $\overrightarrow{G}'$ with $\mathrm{odd}(\overrightarrow{G}') = S \triangle \{u, v\}$. Now, consider any simple path from u to v in G and let $\overrightarrow{G}'$ be the orientation obtained from $\overrightarrow{G}$ by reversing the direction of every edge on this path. ◀

▶ **Lemma 21.** *For every set $S \subseteq V$ with $|S| = |E| \pmod 2$, there are exactly $2^{|V|/2+1}$ distinct orientations $\overrightarrow{G}$ with odd$(\overrightarrow{G}) = S$.*

Proof. Let A be the $V \times E$ incidence matrix of the graph G. This defines a linear transformation from the vector space $\mathbb{F}_2^E$ to $\mathbb{F}_2^V$. The additive group of $\mathbb{F}_2^E$ has a natural action on the orientations of G: for a vector $\pi \in \mathbb{F}_2^E$, and an orientation $\overrightarrow{G}$, define $\pi\overrightarrow{G}$ to be the orientation obtained from $\overrightarrow{G}$ by changing the orientation of each edge e with $\pi(e) = 1$. Indeed, fixing one particular orientation $\overrightarrow{G}$, the action generates all orientations and gives a bijective correspondence between the vectors in $\mathbb{F}_2^E$ and the orientations of G. Similarly, the additive group of $\mathbb{F}_2^V$ has a natural action on the powerset of V: for a vector $\sigma \in \mathbb{F}_2^V$ and a set $S \subseteq V$, let σS be the set $S \triangle \{v \mid \sigma(v) = 1\}$. Again, for any fixed set S, this action generates all subsetes of V and gives a bijection between $\mathbb{F}_2^V$ and the powerset of V.

Then, it can be seen that $\mathrm{odd}(\pi\overrightarrow{G}) = (A\pi)\mathrm{odd}(\overrightarrow{G})$. Indeed, if $v \in V$ is a vertex with incident edges f, g, h, then $(A\pi)(v) = \pi(f)+\pi(g)+\pi(h) \pmod 2$. In other words $(A\pi)(v) = 1$ just in case the direction of an odd number of edges incident on v is flipped by π. Thus, the set of vertices $\{v \mid (A\pi)(v) = 1\}$ are exactly the ones that change from being odd to even or vice versa under the action of π, i.e. $\{v \mid (A\pi)(v) = 1\} = \mathrm{odd}(\overrightarrow{G}) \triangle \mathrm{odd}(\pi\overrightarrow{G})$ for any orientation $\overrightarrow{G}$.

Fixing a particular orientation $\vec{G}$, the action of $\mathbb{F}_2^E$ generates all orientation $\pi\vec{G}$, and A maps this to the collection of all sets $\text{odd}(\vec{G})\triangle\text{odd}(\pi\vec{G})$. Then, by Lemmas 19 and 20 the image of A consists of exactly the set of vectors with an even number of 1s. Hence, the image of A has dimension $|V|-1$ and so its kernel has size $2^{|E|}/2^{|V|-1}$. Since $|E| = 3|V|/2$, this is $2^{|V|/2+1}$. By linearity, the pre-image of any vector v in the image of A has exactly this size. Thus, for each even size set $T \subseteq V$, there are exactly $2^{|V|/2+1}$ vectors $\pi \in \mathbb{F}_2^E$ with $\text{odd}(\pi\vec{G}) = T\triangle\text{odd}(\vec{G})$. ◀

Matchings in Gadgets. Any uniform perfect matching M of X induces an orientation of G, which we denote $\vec{G}^M$: any edge $e = \{u, v\} \in E$ is oriented from u to v in $\vec{G}^M$ if M contains an edge between e_0 and a vertex in I_u and an edge between e_1 and a vertex in I_v.

Furthermore, every orientation arises from some perfect matching. To see this, consider again the gadget in Figure 1. This has eight subgraphs induced by taking the vertices $\{v_b\}\cup I_v$, together with exactly one vertex from each of the sets $\{f_0, f_1\}$, $\{g_0, g_1\}$ and $\{h_0, h_1\}$. We claim that each of these eight subgraphs contains a perfect matching. Indeed, it suffices to verify this for the two cases $S = I_v \cup \{v_b\} \cup \{f_0, g_0, h_0\}$ and $T = I_v \cup \{v_b\} \cup \{f_0, g_0, h_1\}$ as the other six are obtained from these by automorphisms of the gadget. In what follows, we also write S and T for the subgraphs of the gadget in Figure 1 induced by these sets. It is easily seen by inspection that S has exactly four perfect matchings and T has exactly two perfect matchings.

Hence, for any orientation $\vec{G}$, we get a matching $M \subseteq X$ with $\vec{G}^M = \vec{G}$ by choosing one matching from each gadget. To be precise, for each vertex $v \in V$, define the *relevant subgraph* of X at v to be the subgraph induced by $I_v \cup \{v_b\}$ along with the vertices e_1 for each edge e incoming at v in $\vec{G}$ and e_0 for each edge e outgoing at v in $\vec{G}$. In $X(G)$, the relevant subgraph at v is isomorphic to S if v is even in $\vec{G}$ and it is isomorphic to T if v is odd in $\vec{G}$. The same is true for all vertices in $\tilde{X}(G)$, apart from the special vertex x. For this one, the relevant subgraph is isomorphic to S if x is odd and to T if x is even. In either case, we get a perfect matching M with $\vec{G}^M = \vec{G}$ by independently choosing exactly one matching in each relevant subgraph. There are 4 such choices when the relevant subgraph is like S and 2 choices when it is like T.

Uniform Matchings. It follows that for any orientation $\vec{G}$ of G, the number of uniform perfect matchings M of $X(G)$ with $\vec{G}^M = \vec{G}$ is $2^{|\text{odd}(\vec{G})|}4^{|V|-|\text{odd}(\vec{G})|}$. The number of uniform perfect matchings in $\tilde{X}(G)$ depends on whether the special vertex x is odd in $\vec{G}$ or not. If it is, the number is $2^{|\text{odd}(\vec{G})|-1}4^{|V|-|\text{odd}(\vec{G})|+1}$ otherwise it is $2^{|\text{odd}(\vec{G})|+1}4^{|V|-|\text{odd}(\vec{G})|-1}$. Thus, if we denote the number of uniform perfect matchings in X by $\#MX$, then we have $\#MX(G) = \sum_{\vec{G}} 2^{|\text{odd}(\vec{G})|}4^{|V|-|\text{odd}(\vec{G})|}$ where the sum is over all orientations of G. Then, by Lemma 21, $\#MX(G) = 2^{|V|/2+1}\sum_{S\subseteq V\,:\,|S|\equiv|E| \pmod 2} 2^{|S|}4^{|V|-|S|}$. By the same token, $\#M\tilde{X}(G) = 2^{|V|/2+1}\sum_{S\subseteq V\,:\,|S|\not\equiv|E| \pmod 2} 2^{|S|}4^{|V|-|S|}$.

Finally, to show that $\#MX(G)$ and $\#M\tilde{X}(G)$ are different, let P_m denote the number $\sum_{S\subseteq[2m]:|S|\text{even}} 2^{|S|}4^{2m-|S|}$ and Q_m denote the number $\sum_{S\subseteq[2m]:|S|\text{odd}} 2^{|S|}4^{2m-|S|}$.

▶ **Lemma 22.** *For all $m \geq 1$, $P_m - Q_m = 4^m$.*

Proof. We prove this by induction on m. For $m = 1$, there are exactly two odd sized subsets and two even sized subsets of $[2m]$. So $P_m = 20$ and $Q_m = 16$. For larger values of m, we have the following identity, where S ranges over subsets of $[2m-2]$

$$\begin{aligned}P_m &= \sum_{|S|\text{even}} 2^{|S|}4^{2m-|S|} + 2\sum_{|S|\text{odd}} 2^{|S|+1}4^{2m-|S|-1} + \sum_{|S|\text{even}} 2^{|S|+2}4^{2m-|S|}\\ &= 16P_{m-1} + 16Q_{m-1} + 4P_{m-1}\\ &= 20P_{m-1} + 16Q_{m-1}.\end{aligned}$$

Here, in the first line, the first sum accounts for all even size subsets of [2m] that exclude the last two elements, the second one for those that include exactly one of the last two elements and the third sum for all that include the last two elements.

Similarly, we have

$$\begin{aligned}Q_m &= \sum_{|S|\text{odd}} 2^{|S|}4^{2m-|S|} + 2\sum_{|S|\text{even}} 2^{|S|+1}4^{2m-|S|-1} + \sum_{|S|\text{odd}} 2^{|S|+2}4^{2m-|S|}\\ &= 16Q_{m-1} + 16P_{m-1} + 4Q_{m-1}\\ &= 20Q_{m-1} + 16P_{m-1}.\end{aligned}$$

Thus, $P_m - Q_m = 4P_{m-1} - 4Q_{m-1}$. By, induction hypothesis, the right hand side is $4 \cdot 4^{m-1}$ and we're done. ◀

Proof of Theorem 15. By a standard expander graph construction (e.g. [1]), for any k, we can find a 3-regular graph G with treewidth at least k and $2n = \mathcal{O}(k)$ vertices. Then $X(G)$ and $\tilde{X}(G)$ both have $\mathcal{O}(k)$ vertices and by Lemma 17 we have $X(G) \equiv^k \tilde{X}(G)$. Moreover, $X(G)$ and $\tilde{X}(G)$ have the same number of non-uniform perfect matchings by Lemma 18. The number of uniform matchings is $2^{n+1}P_n$ in one case and $2^{n+1}Q_n$ in the other (which is which depends on whether n is even or odd). Either way, $|\mu(X(G)) - \mu(\tilde{X}(G))| = 2^{3n+1}$, which is a power of 2 as required. ◀

7 Concluding Discussion

We have introduced a novel restriction of arithmetic circuits, which is based on a natural notion of symmetry. On this basis, we have shown a fundamental difference between circuits for the determinant and the permanent. The former admits a description through polynomial-size symmetric circuits and the latter does not.

There are several ways in which our results could be tightened. The first would be to show the existence of polynomial-size circuits for computing the determinant over arbitrary fields. Our construction for fields of characteristic zero is based on Le Verrier's method, which does not easily transfer to other fields as it relies on division by arbitrarily large integers. There are general methods for simulating such division on small fields, but it is not immediately clear if they can be carried out symmetrically. However, there are many efficient ways of computing a determinant and it seems likely that some method that works on fields of positive characteristic could be implemented symmetrically. It should be noted, however, that Gaussian elimination is not such a method. Known results about the expressive power of fixed-point logic with counting (see, e.g. [9]) tell us that there is no polynomial-size family of symmetric circuits that can carry out Gaussian elimination. On the other hand, we do know that the determinant, even over finite fields, can be computed by exactly such a family of Boolean circuits, as shown by Holm [16]. It is when we restrict to *arithmetic* circuits, and also require symmetry, that the question is open.

The notions of symmetry used in our upper bound for the determinant and the lower bound for the permanent are slightly different. Essentially, we consider symmetric circuits for the determinant where we require that each *simultaneous* row and column permutation extend to an automorphism of the circuit, while for the permanent we require that each permutation generated by separate row and column permutations extend to an automorphism of the circuit. We could improve the result by showing that the lower bound for the permanent still holds even if we only require the circuits be symmetric with respect to simultaneous row and column permutations. We think this could be established by adapting our construction to analyse the counting width of the number of cycle covers of general graphs.

We could consider more general symmetries. For example, the determinant has other symmetries besides simultaneous row and column permutations. The construction we use already yields a circuit which is symmetric not only with respect to these but also transposition of rows and columns. We could consider a richer group that allowed for even permutations of the rows and columns. Could our upper bound be improved by constructing circuits for the determinant that are symmetric with respect to larger groups of permutations?

Finally, it is reasonable to think that there are polynomials in VP which do not admit polynomial-size symmetric arithmetic circuits, by analogy with the case of Boolean circuits. Can we give an explicit example of such a polynomial?

Abstract

We give the first polynomial-time approximation scheme (PTAS) for the stochastic load balancing problem when the job sizes follow Poisson distributions. This improves upon the 2-approximation algorithm due to Goel and Indyk (FOCS'99). Moreover, our approximation scheme is an efficient PTAS that has a running time double exponential in $1/\epsilon$ but nearly-linear in n, where n is the number of jobs and ϵ is the target error. Previously, a PTAS (not efficient) was only known for jobs that obey exponential distributions (Goel and Indyk, FOCS'99).

Our algorithm relies on several probabilistic ingredients including some (seemingly) new results on scaling and the so-called "focusing effect" of maximum of Poisson random variables which might be of independent interest.

1 Introduction

We consider the following fundamental problem in scheduling theory: given n jobs with job sizes $w_1, \ldots, w_n \geq 0$, assign jobs to m machines such that the maximum load of any machine (i.e., the total size of jobs assigned to the machine) is minimized. In other words, we want to partition $[n]$ into sets $S_1, \ldots, S_m$ so as to minimize $\max_{i \in [m]} \sum_{j \in S_i} w_j$. Often referred to as *load balancing* or *makespan minimization*, this is one of the classical NP-complete problems and along with its many variants, has been extensively studied both in theoretical computer

science as well as operations research. While the exact problem is hard, this problem admits a polynomial time approximation scheme (PTAS) [12] and later work improved this to an efficient PTAS [16, 15, 14, 1]. Several other variants of this problem have also been studied – this includes (i) the *related machines case* where the machines can have different speeds [13]; (ii) the *unrelated machines case* where the job size itself depends on the machine on which it is scheduled [20]; and (iii) the *precedence constrained case* where there are precedence constraints on schedule of jobs [7, 5].

All the aforementioned variants of this problem have the common feature that the job sizes are known in advance to the algorithm designer. However, in many situations, there might be *uncertainty* in the job size. An obvious way to model this uncertainty is via the framework of stochastic optimization as follows – we have m machines and n jobs where the size of the i^{th} job is given by the random variable $\mathbf{W}_i$. If we now assign the jobs to m machines (given by $S_1, \ldots, S_m$), then the load of the j^{th} machine is given by the random variable $\sum_{i \in S_j} \mathbf{W}_i$. Similar to the case when the job sizes are *deterministic*, in *stochastic load balancing*, one would like to minimize the maximum load. However, since the maximum load (across machines) is itself a random variable – arguably, the most natural objective is to then minimize the expected maximum load. In other words, we seek to find a partition of $[n]$ into sets $S_1, \ldots, S_m$ so as to minimize $\mathbf{E}\left[\max_{j \in [m]} \sum_{i \in S_j} \mathbf{W}_i\right]$.

Throughout this paper, we assume that the random variables $\{\mathbf{W}_i\}_{i=1}^n$ are independent – that is the job sizes are independent of each other. Further, note that the algorithm designer is assumed to know the distribution of the random variables $\{\mathbf{W}_i\}_{i=1}^n$ (though, of course, not the actual realizations of the loads).

To our knowledge, Kleinberg, Rabani and Tardos [18] were the first to consider this problem in the algorithms community. They gave a $O(1)$-factor approximation algorithm for this problem. Soon thereafter, Goel and Indyk [9] considered the problem of obtaining better approximation for special classes of random variables – in particular, (i) if each $\{\mathbf{W}_i\}$ is an exponential random variable, they obtain a PTAS (though not an efficient one); (ii) if each $\{\mathbf{W}_i\}$ is a Poisson random variable, then they obtain a 2-approximation algorithm. In fact, this 2-approximation is obtained by considering the (deterministic) instance with loads $\{w_1, \ldots, w_n\}$ where $w_i = \mathbf{E}[\mathbf{W}_i]$ and then applying Graham's heuristic [10] on this instance.

Somewhat more complicated variants of this problem have also been considered – as an example, Gupta *et al.* [11] considered the problem of stochastic load balancing on unrelated machines. Here, the load of job i on machine j is given by a random variable $\mathbf{W}_{i,j}$. For this variant, [11] gave a $O(1)$ approximation algorithm (thus extending the guarantee of [18] to the case of unrelated machines). Similarly, Molinaro [22] considered the problem of minimizing the expected ℓ_p norm of the loads (the version we have can be seen as minimizing the expected ℓ_∞ norm of the loads). Despite all this impressive progress, the only case where we have a PTAS for stochastic load balancing is when all the loads $\{\mathbf{W}_i\}$ are exponential random variables. As the main result of this paper, we obtain an efficient PTAS for stochastic load balancing when all the loads are Poisson random variables.

▶ **Theorem 1.** *There is an algorithm* $\textsc{PoiScheduling}(n, m, \{\lambda_i\}_{i=1}^n, \epsilon)$ *that given an instance of the load balancing problem with n jobs and m machines where the size of the i^{th} job is* $\mathbf{W}_i = \mathsf{Poi}(\lambda_i)$ *(i.e. a Poisson random variable with mean λ_i), and a parameter $0 < \epsilon < 1$, outputs a job assignment whose expected maximum load satisfies $L \leq (1+\epsilon)L^*$, where L^* is the expected maximum load of an optimal assignment. The algorithm runs in time* $2^{2^{O(1/\epsilon^2)}} + O(n \log^2 n \log\log^2 n)$.

Theorem 1 is the first PTAS for stochastic load balancing with Poisson jobs. Prior to this result, the best known approximation algorithm for this setting was due to Goel and Indyk [9] (mentioned earlier) and had an approximation factor of 2. In fact, our PTAS is also an *efficient PTAS* – i.e., the running time remains polynomial in n even for some $\epsilon = o(1)$. In contrast, the PTAS from [9] for exponential random variables was *not* an efficient PTAS. Finally, we point out that our running time is doubly exponential in the error parameter ϵ. While this can be potentially improved to a singly exponential dependence in ϵ, it is unlikely to be improved further – in particular, [6] showed that under the ETH, any PTAS for even the deterministic load balancing problem must have a singly exponential dependence on ϵ[1].

1.1 Our techniques

At a high level, to design an algorithm for stochastic load balancing, we must come up with an *algorithmically tractable proxy* for the objective function $\mathbf{E}[\max_{j\in[m]} \sum_{i\in S_j} \mathbf{W}_i]$. However, the expected maxima of random variables (and more generally stochastic processes) can be notoriously difficult to reason about. Indeed, we point out that in the last fifty years, significant effort in probability theory has been devoted towards understanding the maximum of even simple families of random variables such as Gaussians [8, 24]. Despite this challenge, the hope is that by exploiting structural properties of Poisson random variables along with appropriate algorithmic primitives, we will be able to design an efficient PTAS for stochastic load balancing for Poisson jobs.

The starting points of our algorithm are two natural heuristics which have previously been analyzed in the context of stochastic load balancing.

1. The first heuristic is to construct an instance of (deterministic) load balancing where the size of the i^{th} job is $w_i = \mathbf{E}[\mathbf{W}_i]$. One can then apply the PTAS (say from [1]) to get an allocation of the n jobs into m machines. The obvious pitfall here is that the actual job size is a Poisson random variable which may typically be very far from its mean. In other words, this heuristic has a good guarantee provided

$$\mathbf{E}[\max_{j=1}^{m} \mathsf{Poi}(\mu_j)] \approx \max_{j=1}^{m}[\mathbf{E}\ [\mathsf{Poi}(\mu_j)]],$$

   where μ_j is the expected load size of the j^{th} machine[2]. Of course, the above relation may be far from true and indeed, we want to point out that while the left hand side $\mathbf{E}[\max_{j=1}^{m} \mathsf{Poi}(\mu_j)]$ is just a function of $\mu_1, \ldots, \mu_j$, it is far from being a linear function of $\mu_1, \ldots, \mu_j$. It is easy to create an instance where the optimum obtained by replacing each Poisson load by its expectation is a constant factor away from the true optimum.
   Despite this limitation, this heuristic is in fact of both theoretical and practical value. In particular, from a theoretical aspect, recall that $\mathsf{Poi}(\lambda)$ concentrates around λ (with standard deviation $\sqrt{\lambda}$). This can be leveraged to show that if the optimum allocation must necessarily have at least one machine with a (sufficiently) large load, then the allocation for the deterministic load balancing problem provides a near optimal allocation for the stochastic version as well.
2. The second heuristic is a *greedy algorithm* – namely, we first assign an arbitrary order to the jobs and *iteratively assign each job to the machine with the least current expected load.* This is the same as the Graham's rule [10], and is precisely how the authors of [9] obtained

[1] One can reduce an instance of deterministic load balancing to one of Poisson load balancing by scaling up all job sizes such that they all become at least $\omega(\epsilon^{-2}\log m)$. By Chernoff bounds and union bound this reduction preserves $(1+O(\epsilon))$-approximation.

[2] Note that $\mathsf{Poi}\,(\lambda_1) + \mathsf{Poi}\,(\lambda_2) = \mathsf{Poi}\,(\lambda_1+\lambda_2)$ if $\mathsf{Poi}\,(\lambda_1)$ and $\mathsf{Poi}\,(\lambda_2)$ are independent, so every machine's load is still a Poisson random variable.

a 2-approximation for load balancing Poisson jobs. The underlying rationale for this rule is the following cruical fact about Poisson random variables. Suppose $\mu_1 \geq \mu_2 \geq \mu_3 \geq \mu_4$ such that $\mu_1+\mu_4 = \mu_2+\mu_3$. Then, $\mathbf{E}[\max\{\mathsf{Poi}(\mu_1), \mathsf{Poi}\ (\mu_4)\}] \geq \mathbf{E}[\max\{\mathsf{Poi}(\mu_2), \mathsf{Poi}(\mu_3)\}]$. This fact can in fact be extended to prove that if there is an allocation such that the expected load is the same across all machines, then that is an optimum allocation. Of course, such an allocation might not exist – however, heuristically we might hope that if all the job sizes are small, then we can approximately equalize the expected load on the machines and that such an allocation might have a near-optimal expected maximum load.

It turns out that these heuristics (even when rigorously analyzed) are not sufficient to provide a PTAS for stochastic load balancing in all regimes of job sizes and (number of) machines. Therefore we need some other observations. The first crucial observation is that if there is a job size λ which is more than the average load (i.e. the total expected job size divided by m), then in the optimal allocation, such a job is assigned its own separate machine (Observation 17). This observation can be iteratively applied so that we are now left with job sizes $\{\lambda_i\}_{i=1}^{n'}$ and m' machines such that

$$\max_{i=1}^{n'}\{\lambda_i\} \leq \frac{\sum_{i=1}^{n'} \lambda_i}{m'} := \mu.$$

In other words, no job is larger than the average expected load across the m' machines, i.e., μ. With this simplification, we discuss another *familiar trick* in the context of allocation problems – namely we create a *rounded instance* such that each job size (now call it $\{\lambda'_i\}_{i=1}^{n'}$) is now in the interval $[\epsilon\mu, 2\mu]$. The rounding procedure we apply is identical to the rounding procedure used by [1] in the context of deterministic load balancing. A key property is that the number of different (expected) job sizes in this modified instance is a constant – i.e., only dependent on the target error parameter ϵ.

This rounding step highlights a key technical challenge our algorithm faces – namely, it is possible that by "multiplicatively dilating" the job sizes, the expected maximum load of the machines can change significantly. In other words, suppose $\mu_1, \ldots, \mu_m \geq 0$, then is it the case that for any $0 < \delta < 1$,

$$\mathbf{E}[\max_{j=1}^{m} \mathsf{Poi}((1+\delta)\mu_j)] \approx (1+O(\delta))\mathbf{E}[\max_{j=1}^{m} \mathsf{Poi}(\mu_j)]\ ? \qquad (1)$$

While intuitively this looks reasonable, it is not clear if this is true in full generality. Fortunately for us, we obtain the following dichotomy:

1. When μ is very large (this corresponds to the Case 1 in the analysis), we are able to show that the first heuristic above provides a PTAS – in other words, just substituting each stochastic job $\mathbf{W}_i$ with a deterministic job w_i such that $w_i = \mathbf{E}[\mathbf{W}_i]$ and then applying the PTAS for the deterministic case [1, 14, 15] gives a PTAS for the stochastic case. The underlying reason is that in this case, the expected maximum is essentially the same as the expected heaviest load across the m machines.

   The same algorithm also works if μ is in a "certain intermediate range" and m is sufficiently large (this corresponds to Case 3 in the analysis). In fact, in this case, even the greedy heuristic described earlier provides a PTAS. The underlying reason why the deterministic PTAS works is the following: in this regime, the expected maximum remains essentially the same even if all the loads were to go up by a factor of 2.
2. Outside of the above two cases, our heuristics (greedy or deterministic scheduling) fail to provably work. However, in these cases, we are able to prove (1). In other words, we are able to show that dilating or contracting each job size by a factor of $(1+\delta)$ affects

the expected maximum by only a factor of $1 \pm O(\delta)$. Thus, we can apply the rounding procedure from [1] to reduce to the case where the number of different job sizes is a constant. In fact, this is enough to obtain a PTAS for the stochastic load balancing problem though not an efficient PTAS.

Finally, to get an efficient PTAS, we leverage a third property of the "maximum of Poisson random variables" – namely, the so-called "focusing effect" [3, 2, 4]. Roughly speaking, it says that suppose we have m independent Poisson random variables (call them $\mathbf{X}_1, \ldots, \mathbf{X}_m$), each with mean μ, then there is an integer I such that $(\max_{i=1}^m \mathbf{X}_i) \in [I, I+1]$ with probability $1 - o(1)$ as $m \to \infty$. We extend this to (certain instances of) independent but not identically distributed Poisson random variables. Essentially such a "focusing effect", whenever it holds, allows us to express the expected maximum of the loads of m machines as a linear function of the allocation and then employ an integer linear program (ILP) to find the optimal allocation.

To explain how an ILP comes into the picture, first of all, we can assume that m (i.e., the number of machines) is sufficiently large in terms of the target error parameter δ. If this is not the case, then we can simply employ dynamic programming to find a good allocation (it is now an efficient PTAS because m is a constant). Once m is large, we show the following:

(a) Either there is a transition point $t = t(\mu_1, \ldots, \mu_m)$ such that $\max\{\mathsf{Poi}(\mu_1), \ldots, \mathsf{Poi}(\mu_m)\}$ sharply concentrates within $1 \pm O(\delta)$ of the transition point. In this case, we want to find the smallest t^*, for which there is an allocation with loads $\mu_1, \ldots, \mu_m$ such that $t^* = t(\mu_1, \ldots, \mu_m)$. We use ILP and binary search to find such t^*. Observe that in this case, the smallest such t^* will minimize the expected maximum load (up to $1 \pm O(\delta)$).

(b) Otherwise, there is a transition point $t = t(\mu, m)$ such that $\max\{\mathsf{Poi}(\mu_1), \ldots, \mathsf{Poi}(\mu_m)\}$ sharply concentrates in the set $[t-1, t]$. Observe that t only depends on μ and m, and hence can be easily computed. With the knowledge of t, we now use an ILP to find an assignment $\mu_1, \ldots, \mu_m$ which maximizes the probability that $\max\{\mathsf{Poi}(\mu_1), \ldots, \mathsf{Poi}(\mu_m)\} = t - 1$ and thus minimizes the expected maximum load.

1.2 Organization

In Section 2, we formally state the problem, establish some notations, and describe some properties of Poisson random variables that we will utilize. In Section 3 we give an overview of our concentration and scaling results for the maximum of Poisson random variables. In Section 4 we present our efficient polynomial-time approximation scheme and its analysis.

2 Preliminaries

We use $\mathsf{Poi}(\lambda)$ to denote a Poisson random variable with mean λ. Recall that $\mathbf{Pr}[\mathsf{Poi}(\lambda) = k] = e^{-\lambda} \cdot \frac{\lambda^k}{k!}$ for $k \in \mathbb{N}$. In the stochastic load balancing problem considered in this paper, we are given n jobs and m machines where the job sizes are independent Poisson random variables $\mathsf{Poi}(\lambda_1), \mathsf{Poi}(\lambda_2), \ldots, \mathsf{Poi}(\lambda_n)$. We will call λ_i the size of job i. Our goal is to assign the jobs to the machines so that the expected maximum load

$$L \stackrel{\text{def}}{=} \mathbf{E}\left[\max_{j=1}^{m} \sum_{i \in S_j} \mathsf{Poi}(\lambda_i)\right] \tag{2}$$

is minimized, where S_j is the set of jobs assigned to machine j.

It is well known that the sum of two independent Poisson random variables also follows a Poisson distribution, i.e. $\mathsf{Poi}\left(\lambda_1\right)+\mathsf{Poi}\left(\lambda_2\right) = \mathsf{Poi}\left(\lambda_1+\lambda_2\right)$. Therefore if we let $\mu_j = \sum_{i \in S_j} \lambda_i$, we can write (2) as $L = \mathbf{E}\left[\max_{j=1}^{m} \mathsf{Poi}\left(\mu_j\right)\right]$. We will call μ_j the load of machine j.

Henceforth, our analysis of Poisson random variables will mainly serve the purpose of characterizing the expected maximum load, and therefore we will use μ and $\mu_1, \mu_2, \ldots, \mu_m$ to denote the means when stating useful claims about Poisson distributions.

▶ **Definition 2.** *We write $\mathsf{M}(m, \mu)$ to denote the random variable whose value is the maximum of m i.i.d.* $\mathsf{Poi}\left(\mu\right)$*.*

In [9] the authors proved that Poisson distributions are log-concave:

▶ **Proposition 3** ([9])**.** *For any $t \geq 0$, the function*

$$f_t(\mu) = \log \mathbf{Pr}\left[\mathsf{Poi}\left(\mu\right) \leq t\right] \tag{3}$$

is decreasing and concave with respect to μ.

For any random variables $\mathbf{X}$ and $\mathbf{Y}$ taking values on $\mathbb{N}$, we say $\mathbf{X}$ *stochastically dominates* $\mathbf{Y}$, denoted by $\mathbf{X} \geq_{\mathrm{sd}} \mathbf{Y}$, if $\mathbf{Pr}\left[\mathbf{X} \geq k\right] \geq \mathbf{Pr}\left[\mathbf{Y} \geq k\right]$ holds for every $k \in \mathbb{N}$. Note that for independent $\mathbf{X}, \mathbf{Y}$ we have $\mathbf{Pr}\left[\max\left\{\mathbf{X}, \mathbf{Y}\right\} \geq k+1\right] = 1 - \mathbf{Pr}\left[\mathbf{X} \leq k\right]\mathbf{Pr}\left[\mathbf{Y} \leq k\right]$. Now by Proposition 3 we have the following:

▶ **Proposition 4** (Lemma 2.1 of [9])**.** *Given $0 \leq \mu_1 \leq \mu_1' \leq \mu_2' \leq \mu_2$ such that $\mu_1 + \mu_2 = \mu_1' + \mu_2'$, it holds that* $\max\left\{\mathsf{Poi}\left(\mu_1\right), \mathsf{Poi}\left(\mu_2\right)\right\} \geq_{\mathrm{sd}} \max\left\{\mathsf{Poi}\left(\mu_1'\right), \mathsf{Poi}\left(\mu_2'\right)\right\}$*.*

Poisson random variables satisfy exponential tail bounds:

▶ **Proposition 5** (Theorem 4.4, Theorem 4.5 of [21])**.** *Let $\mathbf{X}$ be a Poisson random variable with mean μ. For $0 < \delta < 1$ we have*

$$\mathbf{Pr}\left[\mathbf{X} \geq (1+\delta)\mu\right] \leq e^{-\mu\delta^2/3}, \tag{4}$$

$$\mathbf{Pr}\left[\mathbf{X} \leq (1-\delta)\mu\right] \leq e^{-\mu\delta^2/2}. \tag{5}$$

In our analysis we will need to use Stirling's approximation to deal with factorials:

▶ **Proposition 6** (Stirling's approximation [23])**.** *For any integer $n > 0$,*

$$e\left(\frac{n}{e}\right)^n \leq \sqrt{2\pi n}\left(\frac{n}{e}\right)^n e^{1/(12n+1)} \leq n! \leq \sqrt{2\pi n}\left(\frac{n}{e}\right)^n e^{1/12n} \leq en\left(\frac{n}{e}\right)^n. \tag{6}$$

3 Concentration and Scaling Results for Maximum of Poissons

In this section we present our concentration and scaling results for the maximum of independent Poisson random variables $\mathsf{Poi}\left(\mu_1\right), \mathsf{Poi}\left(\mu_2\right), \ldots, \mathsf{Poi}\left(\mu_m\right)$, which will be used to prove the correctness of our algorithm. Full proofs of these results are deferred to the full version of the paper.

Throughout we assume $\mu_1 \geq \mu_2 \geq \ldots \geq \mu_m \geq 0$, and define $\mu = (\sum_{j=1}^{m} \mu_j)/m$. We use δ as an error parameter, which measures how well the maximum of Poissons is concentrated. We consider five different cases based on the relationship between μ, m, and μ_j's, and state our results for each of them. Note that while the ranges of μ in these cases are disjoint, we prove our lemmas below for slightly overlapping ranges of μ for ease of analyzing our algorithm in Section 4.

Fix $\delta \in (0, 1/10]$. We prove our results for the following cases respectively:

Case 1: $\frac{6}{\delta^2} \log m < \mu$.

Case 2: $\frac{1}{2^{1/\delta+1}} \log m < \mu \le \frac{6}{\delta^2} \log m$ and $m \ge 2^{2^{\frac{2}{\delta}}}$.

Case 3: $\frac{1}{m^\delta} < \mu \le \frac{1}{2^{1/\delta+1}} \log m$, $m \ge 2^{\frac{2}{\delta} \log \frac{2}{\delta}}$, and $\forall j, \mu_j \in [\mu/4, 4\mu]$.

Case 4: $\frac{4 \log m}{m} < \mu \le \frac{1}{m^\delta}$, $m \ge 2^{100/\delta^2}$, and $\forall j, \mu_j \in [\mu/4, 4\mu]$.

Case 5: $\mu \le \frac{4 \log m}{m}$, $m \ge 1000(1/\delta) \log^2(1/\delta)$, and $\forall j, \mu_j \in [\mu/4, 4\mu]$.

For Case 1 we show that $\max_{j=1}^m \mathsf{Poi}(\mu_j)$ is concentrated within $(1 \pm O(\delta))\mu_1$. For each of Case 2, Case 3, and Case 4 we define a certain transition point and show that $\max_{j=1}^m \mathsf{Poi}(\mu_j)$ is concentrated around this point. For Case 5 we show that $\max_{j=1}^m \mathsf{Poi}(\mu_j)$ takes value 0 or 1 with high probability. For all cases we show that the maximum value is robust to contraction or dilation of μ_j's. In particular $\max_{j=1}^m \mathsf{Poi}(\mu_j)$ does not blow up by more than $1 + O(\delta)$ when we scale all μ_j's by $1 + \delta$. We call these *scaling results*.

▶ **Lemma 7** (Case 1). *Suppose $\delta \in (0, 1/10]$ and $\mu > \frac{6}{\delta^2} \log m$. Then*

$$\mu_1 \le \mathbf{E}\left[\max_{j=1}^m \mathsf{Poi}(\mu_j)\right] \le (1 + 5\delta)\mu_1. \tag{7}$$

▶ **Lemma 8** (Case 2). *Suppose $\delta \in (0, 1/10]$, $\frac{1}{2^{1/\delta+1}} \log m < \mu \le \frac{12}{\delta^2} \log m$, and $m \ge 2^{2^{\frac{2}{\delta}}}$. Define transition point $t_2 = t_2(\mu_1, \mu_1, \dots, \mu_m)$ as the largest integer satisfying*[3]

$$\sum_{j=1}^m \mathbf{Pr}\left[\mathsf{Poi}(\mu_j) \ge t_2\right] \ge \frac{1}{3}. \tag{8}$$

Then for any random variable $\mathbf{X}$ taking values on $\mathbb{N}$, we have

$$(1 - 6\delta)\mathbf{E}\left[\max\{t_2, \mathbf{X}\}\right] \le \mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}(\mu_j), \mathbf{X}\right\}\right] \le (1 + 10\delta)\mathbf{E}\left[\max\{t_2, \mathbf{X}\}\right], \tag{9}$$

and

$$\mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}((1+\delta)\mu_j), \mathbf{X}\right\}\right] \le (1 + 16\delta)\mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}(\mu_j), \mathbf{X}\right\}\right]. \tag{10}$$

▶ **Lemma 9** (Case 3). *Suppose $\delta \in (0, 1/10]$, $\frac{1}{m^\delta} < \mu \le \frac{1}{2^{1/\delta+1}} \log m$, and $m \ge 2^{\frac{2}{\delta} \log \frac{2}{\delta}}$. Define transition point $t_3 = t_3(m, \mu) = \frac{\log m}{\log \frac{1}{\mu} + \log \log m}$. Then for any random variable $\mathbf{X}$ on $\mathbb{N}$ we have*

$$(1 - 4\delta)\max\{t_3, \mathbf{X}\} \le \max\{\mathsf{M}(m, \mu), \mathbf{X}\} \le (1 + 14\delta)\max\{t_3, \mathbf{X}\}, \tag{11}$$

and

$$\mathbf{E}\left[\max\{\mathsf{M}(m, 4\mu), \mathbf{X}\}\right] \le (1 + 20\delta)\,\mathbf{E}\left[\max\{\mathsf{M}(m, \mu), \mathbf{X}\}\right]. \tag{12}$$

[3] The choice of $\frac{1}{3}$ in the definition of t_2 is arbitrary. In principle any constant bounded away from both 1 and 0 suffices.

▶ **Lemma 10** (Case 4). *Suppose $\delta \in (0, 1/10]$, $\frac{4\log m}{m} < \mu \le \frac{2}{m^\delta}$, $m \ge 2^{100/\delta^2}$, and $\mu_1, \dots, \mu_m \in [\mu/4, 4\mu]$. Define transition point $t_4 = t_4(m, \mu) = \lceil \gamma_4(m, \mu) \rceil$ where $\gamma_4(m, \mu) = \frac{\log m}{\log \frac{4}{\mu} + \log\log m}$. Let $\mathbf{W}$ be a Bernoulli random variable taking values on $t_4 - 1$ and t_4 where $\mathbf{Pr}\left[\mathbf{W} = t_4 - 1\right] = \prod_{j=1}^m \mathbf{Pr}\left[\mathsf{Poi}\left(\mu_j\right) \le t_4 - 1\right]$. Then for any random variable $\mathbf{X}$ on $\mathbb{N}$ we have*

$$(1 - 5\delta)\mathbf{E}\left[\max\left\{\mathbf{W}, \mathbf{X}\right\}\right] \le \mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right] \le (1 + 16\delta)\mathbf{E}\left[\max\left\{\mathbf{W}, \mathbf{X}\right\}\right], \quad (13)$$

and

$$\mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}\left((1+\delta)\mu_j\right), \mathbf{X}\right\}\right] \le (1 + 16\delta)\mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right]. \quad (14)$$

▶ **Lemma 11** (Case 5). *Suppose $\delta \in (0, 1/10]$, $\mu \le \frac{8\log m}{m}$, $m \ge 1000(1/\delta)\log^2(1/\delta)$, and $\forall j, \mu_j \in [\mu/4, 4\mu]$. Let $\mathbf{W}$ be a 0/1 Bernoulli random variable with $\mathbf{E}\left[\mathbf{W}\right] = 1 - \prod_{j=1}^m \mathbf{Pr}\left[\mathsf{Poi}\left(\mu_j\right) = 0\right] = 1 - e^{-m\mu}$. Then for any random variable $\mathbf{X}$ on $\mathbb{N}$ we have*

$$\max\left\{\mathbf{W}, \mathbf{X}\right\} \le \mathbf{E}\left[\max_{j=1}^m \mathsf{Poi}\left(\mu_j\right)\right] \le (1 + 10\delta)\max\left\{\mathbf{W}, \mathbf{X}\right\}, \quad (15)$$

and

$$\mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}\left((1+\delta)\mu_j\right), \mathbf{X}\right\}\right] \le (1 + 10\delta)\,\mathbf{E}\left[\max\left\{\max_{j=1}^m \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right]. \quad (16)$$

4 An Efficient Polynomial-time Approximation Scheme

Our PTAS for stochastic load balancing is heavily inspired by the approach of [1, 15] for the deterministic load balancing problem. Thus, we first begin with a recap of their approach.

4.1 Recap of the PTAS for deterministic load balancing

Consider any instance of *deterministic* load balancing where the job sizes are $\{\lambda_i\}_{i=1}^n$ and we have m machines – the goal is to find an assignment with smallest maximum load. The algorithms in [1, 15] proceed in two phases: In phase I, we assign "big" jobs to separate machines. Here big jobs are the maximal set of jobs whose size is greater than the remaining average load. In other words, it is the maximal set $B \subseteq [n]$ satisfying that $\forall i \in B$, $\lambda_i > (\sum_{i \notin B} \lambda_i)/(m - |B|) := \mu$. Exploiting the convexity of the objective function (i.e. the function $\max\{x_1, x_2, \dots, x_m\}$), [1, 15] show that an optimum assignment (i) assigns the jobs in B to their own separate machines; (ii) assigns the remaining jobs to the remaining machines in a way such that each of these machines have a load between $\mu/2$ and 2μ.

With this, we are only left with the problem of assigning the small jobs, i.e., the jobs not in B. A second key step here is to round the sizes of the remaining jobs, such that (i) the number of different job sizes is now[4] $\tilde{O}(1/\epsilon)$ and (ii) the potential number of different assignments to any single machine is $2^{\tilde{O}(1/\epsilon)}$. Crucially, both these numbers are just dependent on the target error parameter ϵ. With this rounding, [1, 14] formulate the problem of finding an optimal assignment on the remaining (rounded) jobs as an integer linear program with

[4] Recall that $\tilde{O}(f)$ denotes $O(f \log^c f)$ for some constant c.

$2^{\tilde{O}(1/\epsilon)}$ variables – referred to as a *configuration-IP*. The *configuration-IP* can be solved in time exponential in the number of variables and linear in the input length using algorithms in [19, 17].

▶ **Theorem 12** ([17]). *There is an algorithm ILP that solves an integer linear program with p variables in time $p^{O(p)}O(n)$ where n is the length of input.*

This leads to an overall running time of $2^{2^{\tilde{O}(1/\epsilon)}} + O(n \log n)$ [1], where the running time $O(n \log n)$ comes from the pre-processing step of sorting the job sizes (to find the big jobs).

▶ **Theorem 13** ([1]). *There is an algorithm DetScheduling that given an instance of the load balancing problem with n jobs and m machines where the jobs have deterministic sizes $\lambda_1, \lambda_2, \ldots, \lambda_n$, and a parameter $0 < \epsilon < 1$, outputs a job assignment whose maximum load is at most $(1+\epsilon)$ of the maximum load of an optimum assignment. The algorithm runs in time $2^{2^{\tilde{O}(1/\epsilon)}} + O(n \log n)$.*

The authors in [15] then use a *sparsification technique* to show that the *configuration-IP* has an optimum solution with a small support size, which leads to an improved running time of $2^{O(1/\epsilon)\log^4(1/\epsilon)} + O(n \log n)$. Later by improving the runtime of solving the ILP, a running time of $2^{O(1/\epsilon)\log^2(1/\epsilon)} + O(n \log n)$ was achieved [16].

4.2 Overview of our approach

We now give an overview of our approach for the stochastic load balancing problem. Recall that we have n jobs and m machines where the i^{th} job has size $\mathsf{Poi}(\lambda_i)$. Similar to the deterministic case [1, 15], we define "big" jobs as the maximal set of jobs whose (expected) size is greater than the remaining (expected) average load, i.e. the maximal set $B \subseteq [n]$ satisfying that $\forall i \in B$

$$\lambda_i > \frac{\sum_{i \notin B} \lambda_i}{m - |B|}. \tag{17}$$

By Proposition 3, the objective function is convex with respect to the machine loads (similar to [1, 15]). Thus, we assign the jobs in B to separate machines (see Lines 2–5 of Algorithm 1).

Assigning the small jobs (i.e., the jobs outside B) is however somewhat more complicated. As stated in Section 1.1, there are two principal difficulties in applying the approaches from [1, 15] to handling the remaining jobs. One is to discretize the job sizes, and the other is to formulate the problem of minimizing the expected maximum load as an integer linear program. The key to circumventing both these difficulties lies in the (technical) results on concentration and scaling of maximum of Poisson random variables proven in Section 3. To understand their role, let us begin with some notation. Let $m^{(1)} = m - |B|$ denote the number of the remaining machines. Consider an assignment of the remaining jobs and let $\mathsf{Poi}(\mu_1), \mathsf{Poi}(\mu_2), \ldots, \mathsf{Poi}(\mu_{m^{(1)}})$ be the corresponding distributions of the machine loads. Suppose $\mu_1 \geq \mu_2 \geq \ldots \geq \mu_{m^{(1)}}$ and let $\mu = (\sum_{j=1}^{m^{(1)}} \mu_j)/m^{(1)}$. By an argument similar to the deterministic case [1, 15] (see Observation 18), we can restrict ourselves to the case when $\mu_j \in [\mu/2, 2\mu]$ for all $j \in [m^{(1)}]$. Let $\delta \in (0, 1)$ be a target error parameter (roughly speaking, we set $\delta \approx \Theta(\epsilon)$).

Our results in Section 3 first imply that when μ is sufficiently large in terms of $1/\delta$ and $m^{(1)}$ (the condition of Lemma 7), or μ is in a certain intermediate range but $m^{(1)}$ is large enough in terms of $1/\delta$ (the condition of Lemma 9), it suffices to find an assignment by running the deterministic load balancing algorithm in Theorem 13. When μ does not satisfy the above conditions but $m^{(1)}$ is sufficiently large in terms of $1/\delta$, we have the following dichotomy:

1. $\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left(\mu_j\right)$ is concentrated within $(1 \pm O(\delta))$ of a certain transition point $t = t(\mu_1, \ldots, \mu_{m^{(1)}})$ (Lemma 8), or
2. takes value $\lceil t \rceil - 1$ or $\lceil t \rceil$ with high probability, where the transition point $t = t(m^{(1)}, \mu)$ only depends on $m^{(1)}$ and μ (Lemmas 10 and 11).

Further, in all of the cases,

$$\mathbf{E}\left[\max_{j=1}^{m} \mathsf{Poi}\left((1+\delta)\mu_j\right)\right] \leq (1+O(\delta))\mathbf{E}\left[\max_{j=1}^{m} \mathsf{Poi}\left(\mu_j\right)\right] \tag{18}$$

(Lemmas 8, 10, and 11). Finally, when m is sufficiently small in terms of δ, we can use dynamic programming to get an efficient PTAS.

Let us now see how the above structural results are useful in algorithm design − first of all, (18) immediately allows us to discretize the job sizes by rounding up their means to the nearest integer power of $(1 + \delta)$, with proper handling of jobs with size below a certain threshold[5]. Once the job sizes are rounded, the existence of the transition points (rather, the precise definitions of these transition points in Section 3) can be used to construct integer linear programs which can find a near optimal solution. As an example, if we are in Case 4 as defined above, by Lemma 10 minimizing the expected maximum is the same as finding $\mu_1, \mu_2, \ldots, \mu_{m^{(1)}}$ such that the probability that the maximum load is $\lceil t \rceil$ is minimized. This finishes our overview of the PTAS.

4.3 Our PTAS

We give a full description of our efficient PTAS in Algorithm 1 as PoiScheduling, which calls Rounded (Algorithms 2), ILPScheduling (Algorithm 3), and DPScheduling as subroutines. The detailed description of DPScheduling is deferred to the full version as it uses mostly standard ideas.

PoiScheduling first handles the "big" jobs in the same way as deterministic case (Lines 2–5 of Algorithm 1). As before μ denotes the remaining average machine load (i.e. RHS of (17)) and $m^{(1)}$ denote the number of the remaining machines. PoiScheduling then does one of the following for the remaining jobs:

1. When μ is large enough to meet the condition of Case 1, or μ and $m^{(1)}$ meet the condition of Case 3, PoiScheduling directly uses the algorithm for deterministic case as a blackbox (Lines 7–9 of Algorithm 1).
2. When μ and $m^{(1)}$ meet the condition of Case 2, Case 4, or Case 5, PoiScheduling first rounds the sizes of the remaining jobs in the same way as [15] (Line 6 of Algorithm 1). Then for Case 2 it uses integer linear programming in conjunction with a binary search to find the smallest transition point t_2 achievable by an assignment of the remaining jobs, where the ILPs have linear objective functions and *configuration-IP* from [1, 15] as feasibility constraints (Lines 10–12 of Algorithm 1). Case 4 and Case 5 are also handled by integer linear programs (Lines 13-15 and Lines 16-17 of Algorithm 1 respectively).
3. When none of the conditions of Case 1 - Case 5 is met, namely $m^{(1)} \leq 2^{2^{O(1/\epsilon)}}$ and $\mu \leq O(\epsilon^{-2} \log m)$, PoiScheduling finds an assignment by dynamic programming (Line 19 of Algorithm 1).

PoiScheduling uses Rounded, ILPScheduling and DPScheduling as subroutines. Roughly speaking, Rounded takes a multi-set of job sizes and a parameter δ as input and outputs a multi-set of job sizes such that the number of different job sizes only depends

[5] The specific rounding scheme we use is identical to the one used in [15].

on δ. ILPScheduling takes the jobs and the number of machines m, and a function f as input. The goal of ILPScheduling is to find an assignment with loads $\mu_1, \dots, \mu_m$ such that $\sum_{j=1}^{m} f(\mu_j)$ is minimized. DPScheduling takes the jobs and number of machine, and an error parameter ϵ as input and returns an assignment of jobs with at most $(1+\epsilon)$ error with respect to an optimum assignment by a dynamic programming.

By using the algorithm in [17] (Theorem 12) to solve the integer linear programs, PoiScheduling achieves a running time double exponential in $1/\epsilon$ and nearly-linear in n. Note that although the algorithm in Theorem 12 needs integral coefficients, we can compute the coefficients with a high precision (inverse polynomial precision) which is sufficient to get our desired approximation and does not affect our running time, so we don't get into the details. We also note that while it is possible to use the sparsification technique in [15] to improve our running time of solving integer linear programs to single exponential in $1/\epsilon$, our dynamic program for the case when $1/\epsilon \geq \Omega(\log\log m)$ still takes time double exponential in $1/\epsilon$.

The performance of PoiScheduling is characterized in Theorem 1. The performances of Rounded and DPScheduling are characterized in Lemmas 14 and 15 respectively. We do not give a separate lemma for ILPScheduling but analyze it in our proofs directly.

Note that Lemma 14 below only gives guarantees for how the job sizes and individual machine loads change after rounding; the lemma itself does not make assertions about the expected maximum load. Instead, guarantees for the latter will follow from our scaling results in Section 3.

▶ **Lemma 14** ([15]). *The algorithm $\{\lambda'_i\}_{i=1}^{n'} = \textsc{Rounded}(\{\lambda_i\}_{i=1}^{n}, \mu, \delta)$ runs in time $O(n)$. Suppose all $\lambda_i \leq \mu$, $\delta \in (0,1)$, and $\mu = (\sum_{i=1}^{n} \lambda_i)/m$ for an integer m. The number of different sizes in $\{\lambda'_i\}_{i=1}^{n'}$ is bounded by $O(\frac{1}{\delta}\log\frac{1}{\delta})$, and each $\lambda'_i = \delta\mu + k\delta^2\mu$ for some $k \in \mathbb{Z}_{\geq 0}, k \leq \frac{2}{\delta^2}$. n' is bounded by $O(m/\delta)$. For any assignment of $\{\lambda_i\}_{i=1}^{n}$ to m machines with loads $\mu_1, \mu_2, \dots, \mu_m$, there is an assignment of $\{\lambda'_i\}_{i=1}^{n'}$ to m machines with loads $\mu'_1, \mu'_2, \dots, \mu'_m$ such that all $\mu'_j \leq (1+5\delta)\mu_j$. Conversely, for any assignment $\{\lambda'_i\}_{i=1}^{n'}$ to m machines with loads $\mu'_1, \mu'_2, \dots, \mu'_m$, there is an assignment of $\{\lambda_i\}_{i=1}^{n}$ to m machines with loads $\mu_1, \mu_2, \dots, \mu_m$ such that all $\mu_j \leq (1+5\delta)\mu'_j$, and the latter assignment can be found in $O(n)$ time given the former assignment if both $\{\lambda_i\}_{i=1}^{n}$ and $\{\lambda'_i\}_{i=1}^{n'}$ are sorted.*

▶ **Lemma 15.** *Given jobs $\{\nu_i\}_{i=1}^{n^{(0)}}$, $\{\lambda_i\}_{i=1}^{n^{(1)}}$, number of machines m, and $\epsilon \in (0, \frac{1}{10}]$. Let $m^{(1)} = m - n^{(0)}$, $\mu = (\sum_{i=1}^{n^{(1)}} \lambda_i)/m^{(1)}$, and $\delta = \max\left\{\frac{\epsilon}{1000m^{(1)}}, 2^{-10^9/\epsilon^2}\right\}$. Suppose all $\lambda_i \leq \mu$, all $\nu_i > \mu$, and $\mu \leq 6000000\epsilon^{-2}\log m^{(1)}$. Then $\textsc{DPScheduling}(\{\nu_i\}_{i=1}^{n^{(0)}}, \{\lambda_i\}_{i=1}^{n^{(1)}}, m, \epsilon)$ finds in $O(n^{(0)}\epsilon^{-4}\log^2 m^{(1)}) + (m^{(1)}/\delta)^{O(\frac{1}{\delta}\log\frac{1}{\delta})}$ time an assignment with expected maximum load $L \leq (1+\epsilon)L^*$, where L^* is the expected maximum load of an optimum assignment.*

A detailed proof of Lemma 15 is deferred to the full version of the paper. First we show how to prove Theorem 1 using the lemma.

4.4 Proof of Theorem 1

The following lemma shows that if Algorithm 1 does not use dynamic programming to find an assignment, then we have a good approximation.

▶ **Lemma 16.** *If Algorithm 1 returns an assignment without going into Line 19, then $L \leq (1+\epsilon)L^*$, where L, L^* is the expected maximum load of the assignment returned by Algorithm 1 and the optimum assignment respectively.*

Algorithm 1 $\textsc{PoiScheduling}(n, m, \{\lambda_i\}_{i=1}^{n}, \epsilon)$.

```
Input  : Number of jobs $n$, number of machines $m$, job sizes $\{\lambda_i\}_{i=1}^{n}$, and $\epsilon \in (0,1)$
Output : A job assignment $\phi : [n] \to [m]$
$\mu \leftarrow (\sum_{i=1}^{n} \lambda_i)/m$, and sort $\{\lambda_i\}_{i=1}^{n}$ such that $\lambda_1 \le \lambda_2 \le \ldots \le \lambda_n$.
$n^{(1)} \leftarrow n$ and $m^{(1)} \leftarrow m$.
while $\lambda_{n^{(1)}} > \mu$ do
    Assign the job with size $\lambda_{n^{(1)}}$ to the empty machine $m^{(1)}$: $\phi(n^{(1)}) \leftarrow m^{(1)}$.
    $\mu \leftarrow \frac{m^{(1)}\mu - \lambda_{n^{(1)}}}{m^{(1)}-1}$, $n^{(1)} \leftarrow n^{(1)} - 1$, and $m^{(1)} \leftarrow m^{(1)} - 1$.
$\delta \leftarrow \frac{\epsilon}{1000}$ and $\{\lambda'_i\}_{i=1}^{n'} \leftarrow \textsc{Rounded}(\{\lambda_i\}_{i=1}^{n^{(1)}}, \mu, \delta)$.
if $\mu > \frac{6}{\delta^2} \log m^{(1)}$ or $\left(\frac{1}{(m^{(1)})^{\delta}} < \mu \le \frac{1}{2^{1/\delta+1}} \log m^{(1)}$ and $m^{(1)} \ge 2^{\frac{2}{\delta}\log\frac{2}{\delta}}\right)$ then
    // Case 1, Case 3
    Create a new instance with $m^{(1)}$ machines and deterministic job sizes $\{\lambda_i\}_{i=1}^{n^{(1)}}$.
    Run $\textsc{DetScheduling}$ in Theorem 13 to find a $(1 + \frac{\epsilon}{5})$-optimum assignment
      $\phi' : [n^{(1)}] \to [m^{(1)}]$.
else if $\frac{1}{2^{\delta+1}} \log m^{(1)} < \mu \le \frac{6}{\delta^2} \log m^{(1)}$ and $m^{(1)} \ge 2^{2^{2/\delta}}$ then
    // Case 2
    Use binary search to find the smallest $t_2 \in [\mu, 100\mu \log m^{(1)}]$ s.t. there is an
      assignment of $\{\lambda'_i\}_{i=1}^{n'}$ with loads $\{\mu_j\}_{j=1}^{m^{(1)}}$ s.t. $\sum_{j=1}^{m^{(1)}} \mathbf{Pr}[\mathsf{Poi}(\mu_j) > t_2] < \frac{1}{3}$; this
      is by $(\mathtt{opt}, \phi') \leftarrow \textsc{ILPScheduling}(\{\lambda'_i\}_{i=1}^{n'}, m^{(1)}, x \to \mathbf{Pr}[\mathsf{Poi}(x) > t_2])$ for
      each guess of $t_2$ and checking if $\mathtt{opt} < \frac{1}{3}$.
    $(\mathtt{opt}, \phi') \leftarrow \textsc{ILPScheduling}(\{\lambda'_i\}_{i=1}^{n'}, m^{(1)}, x \to \mathbf{Pr}[\mathsf{Poi}(x) > t_2])$.
else if $\frac{4 \log m^{(1)}}{m^{(1)}} < \mu \le \frac{1}{(m^{(1)})^{\delta}}$ and $m^{(1)} \ge 2^{100/\delta^2}$ then
    // Case 4
    $t_4 \leftarrow \left\lceil \frac{\log m^{(1)}}{\log\frac{4}{\mu} + \log\log m^{(1)}} \right\rceil$.
    Find an assignment of $\{\lambda'_i\}_{i=1}^{n'}$ with loads $\{\mu_j\}_{j=1}^{m^{(1)}}$ s.t. $\prod_{j=1}^{m^{(1)}} \mathbf{Pr}[\mathsf{Poi}(\mu_j) < t_4]$ is
      maximized, by
      $(\mathtt{opt}, \phi') \leftarrow \textsc{ILPScheduling}(\{\lambda'_i\}_{i=1}^{n'}, m^{(1)}, x \to -\ln(\mathbf{Pr}[\mathsf{Poi}(x) < t_4]))$.
else if $\mu \le \frac{4 \log m^{(1)}}{m^{(1)}}$ and $m^{(1)} \ge 1000(1/\delta)\log^2(1/\delta)$ then
    // Case 5
    Find an assignment of $\{\lambda'_i\}_{i=1}^{n'}$ with loads $\{\mu_j\}_{j=1}^{m^{(1)}}$ s.t. $\prod_{j=1}^{m^{(1)}} \mathbf{Pr}[\mathsf{Poi}(\mu_j) = 0]$ is
      maximized, by
      $(\mathtt{opt}, \phi') \leftarrow \textsc{ILPScheduling}(\{\lambda'_i\}_{i=1}^{n'}, m^{(1)}, x \to -\ln(\mathbf{Pr}[\mathsf{Poi}(x) = 0]))$.
else
    $\phi' \leftarrow \textsc{DPScheduling}(\{\lambda_i\}_{i=n^{(1)}+1}^{n}, \{\lambda_i\}_{i=1}^{n^{(1)}}, m, \epsilon)$.
If $\phi'$ is an assignment of the rounded jobs $\{\lambda'_i\}_{i=1}^{n'}$, use Lemma 14 to covert it to an
  assignment of $\{\lambda_i\}_{i=1}^{n^{(1)}}$ such every machine's load overflows by no more than $(1 + 5\delta)$.
Return the assignment $\phi \cup \phi'$.
```

Algorithm 2 Rounded($\{\lambda_i\}_{i=1}^n$, μ, δ).

```
Input  : Job sizes $\{\lambda_i\}_{i=1}^n$, $\mu$ s.t. all $\lambda_i \le \mu$, and $\delta \in (0,1)$
Output : Rounded job sizes $\{\lambda'_i\}_{i=1}^{n'}$
$n' \leftarrow 0$ and $S \leftarrow 0$.
for $i \leftarrow 1$ to $n$ do
    if $\lambda_i \ge \delta\mu$ then
        $n' \leftarrow n' + 1$.
        $\nu \leftarrow (1+\delta)^k \delta\mu$ where $k$ is the unique integer s.t.
          $(1+\delta)^{k-1}\delta\mu < \lambda_i \le (1+\delta)^k \delta\mu$.
        $\lambda_{n'} \leftarrow l\delta^2\mu$ where $l$ is the unique integer s.t. $(l-1)\delta^2\mu < \nu \le l\delta^2\mu$.
    else
        $S \leftarrow S + \lambda_i$.
$S^{\#} \leftarrow k\delta\mu$ where $k$ is the unique integer s.t. $(k-1)\delta\mu < S \le k\delta\mu$.
$\lambda'_i \leftarrow \delta\mu$ for each $i = n'+1, \dots, n' + S^{\#}/(\delta\mu)$ and $n' \leftarrow n' + S^{\#}/(\delta\mu)$.
return $\{\lambda'_i\}_{i=1}^{n'}$
```

Algorithm 3 ILPScheduling($\{\lambda_i\}_{i=1}^n$, m, f).

```
Input  : Job sizes $\{\lambda_i\}_{i=1}^n$, number of machines $m$, and a function $f : \mathbb{R} \to \mathbb{R}$
Output : An optimum value opt and a job assignment $\phi : [n] \to [m]$
$\mu \leftarrow (\sum_{i=1}^n \lambda_i)/m$.
Let $\pi_1 < \pi_2 < \dots < \pi_d$ be all different sizes in $\{\lambda_i\}_{i=1}^n$ and $\vec{\pi} \leftarrow (\pi_1, \pi_2, \dots, \pi_d)^T$.
Let $n_k$ be the number of jobs with size $\pi_k$ and $\vec{n} \leftarrow (n_1, n_2, \dots, n_d)^T$ (so
  $\sum_{k=1}^d n_k = n$).
$Q \leftarrow \left\{\vec{c} \in \mathbb{Z}_{\ge 0}^d : \vec{c}^T\vec{\pi} \le 4\mu\right\}$ (the set of possible assignments to a single machine).
Solve the following integer linear programming using Theorem 12:

    $\min \sum_{\vec{c} \in Q} x_{\vec{c}}\, f(\vec{c}^T\vec{\pi})$
    $s.t. \sum_{\vec{c} \in Q} x_{\vec{c}} = m$
          $\sum_{\vec{c} \in Q} x_{\vec{c}}\vec{c} = \vec{n}$
          $x_{\vec{c}} \in \mathbb{Z}_{\ge 0}, \ \forall \vec{c} \in Q.$                    (19)

Return the optimum value of the ILP and an assignment $\phi$ extracted from its
  solution.
```

We will provide a detailed proof of Lemma 16 in the next section. Roughly speaking, for Case 1 and Case 3, where we do not use the rounded jobs, using the guarantee of the deterministic load balancing algorithm we show that the maximum expected load of any machine is bounded. Then by using the concentration results from Section 3, we can bound the expected maximum load.

For three other cases, where the assignment obtained is for the rounded jobs, the proof consists of two main steps. In the first step, we compare the individual machine loads of the output assignment (of unrounded jobs) and the assignment of the rounded jobs given by ILPScheduling by Lemma 14. Then by the concentration and scaling results from Section 3, we bound the expected maximum load of the output assignment using the transition point of rounded jobs. In the second step, we bound the expected maximum of an optimum assignment of rounded jobs by that of an optimum assignment of unrounded jobs by scaling results from Section 3. Thus, we bound the expected maximum load of an output assignment by that of an optimum assignment.

Now we prove Theorem 1.

Proof of Theorem 1. First we analyze the running time when PoiScheduling does not use dynamic programming. If the algorithm invokes the efficient PTAS for deterministic case in Theorem 13, the running time is bounded by $2^{2^{\tilde{O}(1/\epsilon)}} + O(n \log n)$. Otherwise the algorithm will first do the rounding. By Lemma 14 after the rounding the number of different job sizes in $\{\lambda'_i\}_{i=1}^{n'}$ becomes $O(\frac{1}{\delta} \log \frac{1}{\delta}) = O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$ and all job sizes are between $\delta\mu$ and 2μ. Now for each machine of $1, 2, \ldots, m^{(1)}$, we only need to consider the assignments to it with load at most 4μ. Therefore each machine can have at most $O(1/\delta) = O(1/\epsilon)$ jobs, and the number of different job profiles that can be assigned to one machine is at most $(1/\epsilon)^{O(1/\epsilon)} = 2^{O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})}$, which is the number of variables in the ILP. By Theorem 12 the ILP can be solved in $2^{2^{O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})}} O(\log n)$ time. Since for Case 2 we need to do a binary search on interval $[\mu, 100\mu \log m^{(1)}]$, the total running time is bounded by $2^{2^{O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})}} O(\log n \log \log n)$.

If PoiScheduling uses dynamic programming, we have $\delta \geq 2^{-10^9/\epsilon^2}$ and $m^{(1)} \leq 2^{2^{O(1/\epsilon)}}$. Therefore the total running time is bounded by $2^{2^{O(1/\epsilon^2)}} + O(n\epsilon^{-4} \log^2 n)$ by Lemma 15. Combining these two cases gives us the desired running time.

The approximation guarantee directly follows from Lemmas 16 and 15. ◀

5 Proof of Correctness using Concentration Results

In this section, we will prove the correctness of Algorithm 1 using the concentration results in Section 3. We refer to the case in Lemma 16 as the case with "large m" and the other case as the one with "small m". Here we only give the proof for large m but defer the proof for small m to the full version of the paper.

5.1 Analysis for large m

In this subsection, we prove that if Algorithm 1 does not call DPScheduling (Line 19), then $L < (1 + \epsilon)L^*$ where L^* is the expected maximum load of an optimum assignment and L is the expected maximum load of the returned assignment by Algorithm 1. In our analysis, by large m we mean that the condition on Line 7, 10, 13, or 16 is satisfied. By small m we mean that none of those conditions is satisfied, i.e. the algorithm calls DPScheduling. In this subsection, we will also consider the case when the algorithm finishes assigning all jobs before Line 6.

▶ **Lemma 16.** *If Algorithm 1 returns an assignment without going into Line 19, then $L \leq (1 + \epsilon)L^*$, where L, L^* is the expected maximum load of the assignment returned by Algorithm 1 and the optimum assignment respectively.*

Proof of Lemma 16. Let χ be the set of jobs each of which is assigned to a single machine in the first loop of Algorithm 1. Let Λ be the (multi-)set of the sizes of the jobs in χ. Let $\boldsymbol{\chi} = \{\mathsf{Poi}\,(\lambda)\,|\lambda \in \Lambda\}$ and $\mathbf{X} = \max_{\lambda\in\Lambda} \mathsf{Poi}\,(\lambda)$. Consider μ and $m^{(1)}$ as same as Algorithm 1 after Line 6. Suppose the algorithm returns an assignment where machine j has load μ_j. Let $\left\{\mu_j^{(1)}\right\}_{j=1}^{m^{(1)}}$ be the machine loads corresponding to the assignment ϕ' obtained *before* Line 20.

That is, if ϕ' is an assignment of the rounded jobs, $\mu_j^{(1)}$'s are the corresponding rounded loads. Without loss of generality, we assume $\mu_1^{(1)} \geq \mu_2^{(1)} \geq \ldots \geq \mu_{m^{(1)}}^{(1)}$. Let $\mu^{(1)} = \frac{\sum_{j=1}^{m^{(1)}} \mu_j^{(1)}}{m(1)}$. Note that if Algorithm 1 does not return an assignment using rounded jobs (Line 9), then $\mu = \mu^{(1)}$. There are six possible cases:

Case 0: The algorithm finishes assigning all jobs before Line 6. Then it must be the case that $n \leq m$. Therefore assigning every job to a single machine is the optimum solution.

Case 1: $\mu > \frac{6}{\delta^2} \log m^{(1)}$ and the algorithm goes to Lines 7–9. First we state an observation. Note that this is the same observation as **Observation 2.1** in [1] for deterministic case. Both our observation and the one in [1] follow from the convexity of the objective function with respect to the machine loads.

▶ **Observation 17.** *There is an optimum assignment such that each job in χ is solely assigned to a separate machine.*

Proof. Suppose in an optimum assignment there is a job in χ with size λ_i which is assigned to a machine with another job of size λ_j and suppose i is the biggest index such that a job with size λ_i shares its machine with another job. Let μ' be the value of μ in Algorithm 1 just before assigning λ_i to a machine, so we know $\lambda_i > \mu'$. By removing λ_j from its machine, all the other machines should have load at least μ', otherwise we can assign λ_j to a machine with load less than μ' and by Proposition 4, the expected maximum decreases which contradicts the optimality. But μ' is the average load of remaining machines (machines that do not contain any jobs from $\{\lambda_k | k > i\}$) and now each one has load more than μ', a contradiction. ◀

Let L^*_{DET} be the optimum answer of deterministic case for job sizes of $\{\lambda_i\}_{i=1}^{n^{(1)}}$ and $m^{(1)}$ machines, where $n^{(1)} = n - |\chi|$. Note that $L^* \geq L^*_{DET}$ and $L^* \geq \max_{\lambda \in \Lambda} \lambda$, by Observation 17. Since $\delta = \frac{\epsilon}{1000}$, by Lemma 7 we get:

$$\begin{aligned} L &= \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right] \\ &\leq \mathbf{E}\left[\max\left\{\mathsf{Poi}\left((1+\epsilon/5)L^*_{DET}\right), \max_{j=2}^{m^{(1)}} \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right] \qquad \text{(by Theorem 13)} \\ &\leq (1+5\delta)\max\left\{(1+\epsilon/5)L^*_{DET}, \max_{\lambda\in\Lambda}\lambda\right\} \qquad \text{(by (7) in Lemma 7)} \\ &\leq (1+\epsilon/200)(1+\epsilon/5)L^* < (1+\epsilon)L^*. \qquad (20) \end{aligned}$$

Case 2: The algorithm goes to Lines 10–12. By calling ILPScheduling multiple times, Algorithm 1 finds the smallest transition point t_2 for rounded jobs on $m^{(1)}$ machines as defined in Lemma 8. Note that if $\hat{L}$ is the optimum expected maximum for rounded version, then $\hat{L} \leq (1+80\delta)L^*$ (by (10) in Lemma 8 and Lemma 14). Since $\delta = \frac{\epsilon}{1000}$, $m^{(1)} > 2^{2^{100/\epsilon}}$ and $\frac{1}{2^{1/\delta+1}} \log m^{(1)} < \mu^{(1)} \log m^{(1)} \leq (1+5\delta)\frac{6}{\delta^2} \log m^{(1)} < \frac{12}{\delta^2} \log m^{(1)}$ (Lemma 14), then by Lemma 8 we get:

$$\begin{aligned} L &= \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right] \\ &\leq \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left((1+5\delta)\mu_j^{(1)}\right), \mathbf{X}\right\}\right] \qquad \text{(Lemma 14)} \end{aligned}$$

$$\begin{aligned}
\dots &\le (1+80\delta)\mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}}\mathsf{Poi}\left(\mu_j^{(1)}\right),\mathbf{X}\right\}\right] \quad \text{(by (10) in Lemma 8)}\\
&\le (1+10\delta)(1+80\delta)\mathbf{E}\left[\max\{t_2,\mathbf{X}\}\right] \quad \text{(by (9) in Lemma 8)}\\
&\le \frac{(1+10\delta)(1+80\delta)}{1-6\delta}\hat{L} \quad \text{(by (9) in Lemma 8)}\\
&\le \frac{(1+10\delta)(1+80\delta)^2}{1-6\delta}L^*\\
&< (1+\epsilon)L^*
\end{aligned}$$

Case 3: $\frac{1}{(m^{(1)})^\delta} < \mu \le \frac{1}{2^{1/\delta+1}}\log m^{(1)}$ and $m^{(1)} \ge 2^{\frac{2}{\delta}\log\frac{2}{\delta}}$, and the algorithm goes to Lines 7–9. First we state an observation which is the same as **Observation 2.2** in [1] for deterministic case and again follows from the convexity of the objective function with respect to the machine loads

▶ **Observation 18.** *If for each i, $\lambda_i \le \mu$, then for each load μ_j in an optimum assignment we have $\mu/2 \le \mu_j \le 2\mu$.*

Proof. Suppose a machine has load $\mu_j > 2\mu$ and a job assigned to the machine is λ_i. $\lambda_i \le \mu$, so $\mu_j - \lambda_i > \mu$, so any other machines has load at least μ, a contradiction. So $\mu_j \le 2\mu$.

Suppose a machine has load $\mu_j < \mu/2$. So there is a machine with load $\mu_k > \mu$, so it has at least two jobs assigned. So there is a job λ_i in μ_k such that $\lambda_i \le \mu_k/2$, by taking it from μ_k its load would be $\mu_k - \lambda_i \ge \mu_k/2 > \mu/2 > \mu_j$, a contradiction as by reassigning λ_i to μ_j by Proposition 4 the expected maximum decreases. So $\mu/2 \le \mu_j$. ◀

Since $\delta = \frac{\epsilon}{1000}$ and $m^{(1)} > 2^{\frac{2}{\delta}\log\frac{2}{\delta}}$, the conditions of Lemma 9 holds and we get:

$$\begin{aligned}
L &= \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}}\mathsf{Poi}(\mu_j),\mathbf{X}\right\}\right]\\
&\le \mathbf{E}\left[\max\left\{\mathsf{M}(m^{(1)},(1+\epsilon/5)2\mu),\mathbf{X}\right\}\right] \quad \text{(Observation 18 and Theorem 13)}\\
&\le \mathbf{E}\left[\max\left\{\mathsf{M}(m^{(1)},4\mu),\mathbf{X}\right\}\right] \quad \text{(Proposition 3)}\\
&\le (1+20\delta)\,\mathbf{E}\left[\max\left\{\mathsf{M}(m^{(1)},\mu),\mathbf{X}\right\}\right] \quad \text{(by (12) in Lemma 9)}\\
&< (1+\epsilon)L^*.
\end{aligned}$$

Case 4: The algorithm goes to Lines 13–15. By putting $\delta = \frac{\epsilon}{1000}$ and Observation 18, an optimum assignment of rounded jobs satisfies the condition of Lemma 10. Let $\mathbf{W}$ be the Bernoulli random variable as described in Lemma 10 but with respect to the machine loads of an optimum assignment of the rounded jobs, then $(1-5\delta)\mathbf{E}[\max\{\mathbf{W},\boldsymbol{X}\}] \le \hat{L}$ where $\hat{L}$ is the optimum expected maximum of rounded version. By finding an assignment maximimizing $\prod_{j=1}^{m^{(1)}}\mathbf{Pr}[\mathsf{Poi}(\mu_j) \le t_4 - 1]$, the value of $\mathbf{E}[\max\{\mathbf{W},\boldsymbol{X}\}]$ would be minimized. Let the corresponding optimum $\mathbf{W}$ be $\mathbf{W}^*$. So we have $(1-5\delta)\mathbf{E}[\max\{\mathbf{W}^*,\mathbf{X}\}] \le (1-5\delta)\mathbf{E}[\max\{\mathbf{W},\mathbf{X}\}] \le \hat{L}$. Note that $\hat{L} \le (1+80\delta)L^*$ by (14) in Lemma 10 and Lemma 14.

As $\frac{4\log m}{m} < \mu^{(1)} \le (1+5\delta)\frac{1}{m^{\delta}} \le \frac{2}{m^{\delta}}$, by Lemma 10:

$$\begin{aligned}
L &= \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left(\mu_j\right), \mathbf{X}\right\}\right] \\
&\le \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left((1+5\delta)\mu_j^{(1)}\right), \mathbf{X}\right\}\right] \quad \text{(Lemma 14)} \\
&\le (1+80\delta)\mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left(\mu_j^{(1)}\right), \mathbf{X}\right\}\right] \quad \text{(by (14) in Lemma 10)} \\
&\le (1+16\delta)(1+80\delta)\mathbf{E}\left[\max\left\{\mathbf{W}^*, \mathbf{X}\right\}\right] \quad \text{(by (13) in Lemma 10)} \\
&\le \frac{(1+16\delta)(1+80\delta)}{1-5\delta}\hat{L} \\
&\le \frac{(1+16\delta)(1+80\delta)^2}{1-20\delta}L^* \\
&< (1+\epsilon)L^*. \qquad (21)
\end{aligned}$$

Case 5: The algorithm returns an assignment on Line 17. With the same argument as the previous case, by maximizing $\prod_{j=1}^{m^{(1)}} \mathbf{Pr}\left[\mathsf{Poi}\left(\mu_j\right)=0\right]$, the value $\mathbf{E}\left[\max\left\{\mathbf{W}, \boldsymbol{X}\right\}\right]$ as defined in Lemma 11 would be minimized. Let the corresponding optimum $\mathbf{W}$ be $\mathbf{W}^*$. So we have $\mathbf{E}\left[\max\left\{\mathbf{W}^*, \mathbf{X}\right\}\right] \le \hat{L}$ where $\hat{L}$ is the optimum expected maximum of rounded jobs with $m^{(1)}$ machines and $\hat{L} \le (1+50\delta)L^*$ by (16) in Lemma 11 and Lemma 14. So we get:

$$\begin{aligned}
L &\le \mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left((1+5\delta)\mu_j^{(1)}\right), \mathbf{X}\right\}\right] \quad \text{(Lemma 14)} \\
&\le (1+50\delta)\mathbf{E}\left[\max\left\{\max_{j=1}^{m^{(1)}} \mathsf{Poi}\left(\mu_j^{(1)}\right), \mathbf{X}\right\}\right] \quad \text{(by (16) in Lemma 11)} \\
&\le (1+10\delta)(1+50\delta)\mathbf{E}\left[\max\left\{\mathbf{W}^*, \mathbf{X}\right\}\right] \quad \text{(by (15)) in Lemma 11)} \\
&\le (1+10\delta)(1+50\delta)\hat{L} \\
&\le (1+10\delta)(1+50\delta)^2 L^* \\
&< (1+\epsilon)L^*.
\end{aligned}$$

So for all cases we have $L < (1+\epsilon)L^*$ and we are done. ◀

Abstract

We prove that it is PPAD-hard to compute a Nash equilibrium in a tree polymatrix game with twenty actions per player. This is the first PPAD hardness result for a game with a constant number of actions per player where the interaction graph is acyclic. Along the way we show PPAD-hardness for finding an ϵ-fixed point of a 2D-LinearFIXP instance, when ϵ is any constant less than $(\sqrt{2}-1)/2 \approx 0.2071$. This lifts the hardness regime from polynomially small approximations in k-dimensions to constant approximations in two-dimensions, and our constant is substantial when compared to the trivial upper bound of 0.5.

1 Introduction

A *polymatrix game* is a succinctly represented many-player game. The players are represented by vertices in an *interaction graph*, where each edge of the graph specifies a two-player game that is to be played by the adjacent vertices. Each player picks a *pure strategy*, or *action*, and then plays that action in all of the edge-games that they are involved with. They then receive the *sum* of the payoffs from each of those games. A *Nash equilibrium* prescribes a mixed strategy to each player, with the property that no player has an incentive to unilaterally deviate from their assigned strategy.

Constant-action polymatrix games have played a central role in the study of equilibrium computation. The classical PPAD-hardness result for finding Nash equilibria in bimatrix games [4] uses constant-action polymatrix games as an intermediate step in the reduction [4,5]. Rubinstein later showed that there exists a constant $\epsilon > 0$ such that computing an ϵ-approximate Nash equilibrium in two-action bipartite polymatrix games is PPAD-hard [16], which was the first result of its kind to give hardness for constant ϵ.

These hardness results create polymatrix games whose interaction graphs contain cycles. This has lead researchers to study *acyclic* polymatrix games, with the hope of finding tractable cases. Kearns, Littman, and Singh claimed to produce a polynomial-time algorithm for finding a Nash equilibrium in a two-action tree *graphical game* [12], where graphical

games are a slight generalization of polymatrix games. However, their algorithm does not work, which was pointed out by Elkind, Goldberg, and Goldberg [10], who also showed that the natural fix gives an exponential-time algorithm.

Elkind, Goldberg, and Goldberg also show that a Nash equilibrium can be found in polynomial time for two-action graphical games whose interaction graphs contain only paths and cycles. They also show that finding a Nash equilibrium is PPAD-hard when the interaction graph has pathwidth at most four, but there appear to be some issues with their approach. Later work of Barman, Ligett, and Piliouras [1] provided a QPTAS for constant-action tree polymatrix games, and then Ortiz and Irfan [14] gave an FPTAS for this case. All three papers, [1, 10, 14], leave as a main open problem the question of whether it is possible to find a Nash equilibrium in a tree polymatrix game in polynomial time.

Our contribution. In this work we show that finding a Nash equilibrium in twenty-action tree polymatrix games is PPAD-hard. Combined with the known PPAD containment of polymatrix games [5], this implies that the problem is PPAD-complete. This is the first hardness result for polymatrix (or graphical) games in which the interaction graph is acyclic, and decisively closes the open question raised by prior work: tree polymatrix games cannot be solved in polynomial time unless PPAD is equal to P.

Our reduction produces a particularly simple class of interaction graphs: all of our games are played on *caterpillar* graphs (see Figure 3) which consist of a single path with small one-vertex branches affixed to every node. These graphs have pathwidth 1, so we obtain a stark contrast with prior work: two-action path polymatrix games can be solved in polynomial time [10], but twenty-action pathwidth-1-caterpillar polymatrix games are PPAD-hard.

Our approach is founded upon Mehta's proof that 2D-LinearFIXP is PPAD-hard [13]. We show that her reduction can be implemented by a synchronous arithmetic circuit with *constant width.* We then embed the constant-width circuit into a caterpillar polymatrix game, where each player in the game is responsible for simulating all gates at a particular level of the circuit. This differs from previous hardness results [5, 16], where each player is responsible for simulating exactly one gate from the circuit.

Along the way, we also substantially strengthen Mehta's hardness result for LinearFIXP. She showed PPAD-hardness for finding an exact fixed point of a 2D-LinearFIXP instance, and an ϵ-fixed point of a kD-LinearFIXP instance, where ϵ is polynomially small. We show PPAD-hardness for finding an ϵ-fixed point of a 2D-LinearFIXP instance when ϵ is any constant less than $(\sqrt{2}-1)/2 \approx 0.2071$. So we have lifted the hardness regime from polynomially small approximations in k-dimensions to constant approximations in two-dimensions, and our constant is substantial when compared to the trivial upper bound of 0.5.

Related work. The class PPAD was defined by Papadimitriou [15]. Years later, Daskalakis, Goldberg, and Papadimitriou (DGP) [5] proved PPAD-hardness for graphical games and 3-player normal form games. Chen, Deng, and Teng (CDT) [4] extended this result to 2-player games and proved that there is no FPTAS for the problem unless PPAD = P. The observations made by CDT imply that DGP's result also holds for polymatrix games with constantly-many actions (but with cycles in the interaction graph) for an exponentially small ϵ. More recently, Rubinstein [17] showed that there exists a *constant* $\epsilon > 0$ such that computing an $\epsilon - NE$ in binary-action bipartite polymatrix games is PPAD-hard (again with cycles in the interaction graph).

Etessami and Yiannakakis [11] defined the classes FIXP and LinearFIXP and they proved that LinearFIXP = PPAD. Mehta [13] strengthened these results by proving that two-dimensional LinearFIXP equals PPAD, building on the result of Chen and Deng who proved that 2D-discrete Brouwer is PPAD-hard [3].

On the positive side, Cai and Daskalakis [2], proved that NE can be efficiently found in polymatrix games where every 2-player game is zero-sum. Ortiz and Irfan [14] and Deligkas, Fearnley, and Savani [7] produced QPTASs for polymatrix games of bounded treewidth (in addition to the FPTAS of [14] for tree polymatrix games mentioned above). For general polymatrix games, the only positive result to date is a polynomial-time algorithm to compute a $(\frac{1}{2} + \delta)$-NE [9]. Finally, an empirical study on algorithms for exact and approximate NE in polymatrix games can be found in [6].

2 Preliminaries

Polymatrix games. An n-player *polymatrix game* is defined by an undirected *interaction graph* $G = (V, E)$ with n vertices, where each vertex represents a player, and the edges of the graph specify which players interact with each other. Each player in the game has m actions, and each edge $(v, u) \in E$ of the graph is associated with two $m \times m$ matrices $A^{v,u}$ and $A^{u,v}$ which specify a bimatrix game that is to be played between the two players, where $A^{v,u}$ specifies the payoffs to player v from their interaction with player u.

Each player in the game selects a single action, and then plays that action in *all* of the bimatrix games with their neighbours in the graph. Their payoff is the *sum* of the payoffs that they obtain from each of the individual bimatrix games.

A *mixed strategy* for player i is a probability distribution over the m actions of that player, a *strategy profile* is a vector $\mathbf{s} = (s_1, s_2, \dots, s_n)$ where s_i is a mixed strategy for player i. The *vector of expected payoffs* for player i under strategy profile $\mathbf{s}$ is $\mathbf{p}_i(\mathbf{s}) := \sum_{(i,j)\in E} A^{i,j} s_j$. The *expected payoff* to player i under $\mathbf{s}$ is $s_i \cdot \mathbf{p}_i(\mathbf{s})$. A strategy profile is a *mixed Nash equilibrium* if $s_i \cdot \mathbf{p}_i(\mathbf{s}) = \max \mathbf{p}_i(\mathbf{s})$ for all i, which means that no player can unilaterally change their strategy in order to obtain a higher expected payoff. In this paper we are interested in the problem of computing a Nash equilibrium of a *tree* polymatrix game, which is a polymatrix game in which the interaction graph is a tree.

Arithmetic circuits. For the purposes of this paper, each gate in an arithmetic circuit will operate only on values that lie in the range $[0, 1]$. In our construction, we will use four specific gates, called *constant introduction* denoted by c, *bounded addition* denoted by $+^b$, *bounded subtraction* denoted by $-^b$, and *bounded multiplication by a constant* denoted by $*^b c$. These gates are formally defined as follows.

- c is a gate with no inputs that outputs some fixed constant $c \in [0, 1]$.
- Given inputs $x, y \in [0, 1]$ the gate $x +^b y := \min(x + y, 1)$.
- Given inputs $x, y \in [0, 1]$ the gate $x -^b y := \max(x - y, 0)$.
- Given an input $x \in [0, 1]$, and a constant $c \geq 0$, the gate $x *^b c := \min(x * c, 1)$.

These gates perform their operation, but also clip the output value so that it lies in the range $[0, 1]$. Note that the constant c in the $*^b c$ gate is specified as part of the gate. Multiplication of two inputs is not allowed.

We will build arithmetic circuits that compute functions of the form $[0, 1]^d \to [0, 1]^d$. A circuit $C = (I, G)$ consists of a set $I = \{\mathtt{in}_1, \mathtt{in}_2, \dots, \mathtt{in}_d\}$ containing d input nodes, and a set $G = \{g_1, g_2, \dots, g_k\}$ containing k gates. Each gate g_i has a type from the set $\{c, +^b, -^b, *^b c\}$, and if the gate has one or more inputs, these are taken from the set $I \cup G$. The connectivity structure of the gates is required to be a directed acyclic graph.

The *depth* of a gate, denoted by $d(g)$ is the length of the longest path from that gate to an input. We will build *synchronous* circuits, meaning that all gates of the form $g_x = g_y +^b g_z$ satisfy $d(g_x) = 1 + d(g_y) = 1 + d(g_z)$, and likewise for gates of the form $g_x = g_y -^b g_z$. There are no restrictions on c-gates, or $*^b c$-gates.

The *width* of a particular level i of the circuit is defined to be $w(i) = |\{g_j : d(g_j) = i\}|$, which is the number of gates at that level. The *width* of a circuit is defined to be $w(C) = \max_i w(i)$, which is the maximum width taken over all the levels of the circuit.

Straight line programs. A convenient way of specifying an arithmetic circuit is to write down a straight line program (SLP) [11].

SLP 1 Example.

```
x ← 0.5
z ← x $+^b$ in1
x ← x $*^b$ 0.5
out1 ← z $+^b$ x
```

SLP 2 `if` and `for` example.

```
x ← in1 $*^b$ 1
for $i$ in $\{1, 2, \dots, 10\}$ do
    if $i$ is even then
        x ← x $+^b$ 0.1
    end
end
out1 ← x $*^b$ 1
```

Each line of an SLP consists of a statement of the form `v` ← `op`, where `v` is a *variable*, and `op` consists of exactly one arithmetic operation from the set set $\{c, +^b, -^b, *^b c\}$. The inputs to the gate can be any variable that is defined before the line, or one of the inputs to the circuit. We permit variables to be used on the left hand side in more than one line, which effectively means that we allow variables to be overwritten.

It is easy to turn an SLP into a circuit. Each line is turned into a gate, and if variable `v` is used as the input to gate g, then we set the corresponding input of g to be the gate g' that corresponds to the line that most recently assigned a value to `v`. SLP 1 above specifies a circuit with four gates, and the output of the circuit will be 0.75 $+^b$ $\texttt{in}_1$.

For the sake of brevity, we also allow `if` statements and `for` loops in our SLPs. These two pieces of syntax can be thought of as macros that help us specify a straight line program concisely. The arguments to an `if` statement or a `for` loop must be constants that do not depend on the value of any gate in the circuit. When we turn an SLP into a circuit, we unroll every `for` loop the specified number of times, and we resolve every `if` statement by deleting the block if the condition does not hold. So the example in SLP 2 produces a circuit with seven gates: two gates correspond to the lines `x` ← `in1` $*^b$ `1` and `out1` ← `x` $*^b$ `1`, while there are five gates corresponding to the line `x` ← `x` $+^b$ `0.1`, since there are five copies of the line remaining after we unroll the loop and resolve the `if` statements. The output of the resulting circuit will be 0.5 $+^b$ $\texttt{in}_1$.

Liveness of variables and circuit width. Our ultimate goal will be to build circuits that have small width. To do this, we can keep track of the number of variables that are *live* at any one time in our SLPs. A variable `v` is live at line i of an SLP if both of the following conditions are met.

- There exists a line with index $j \leq i$ that assigns a value to `v`.
- There exists a line with index $k \geq i$ that uses the value assigned to `v` as an argument.

The number of variables that are live at line i is denoted by $\text{live}(i)$, and the number of variables *used by* an SLP is defined to be $\max_i \text{live}(i)$, which is the maximum number of variables that are live at any point in the SLP.

Figure 1 Reducing ϵ-`ThickDisBrouwer` to `2D-Brouwer`.

3 Hardness of 2D-Brouwer

In this section, we consider the following problem. It is a variant of two-dimensional Brouwer that uses only our restricted set of bounded gates.

▶ **Definition 2** (`2D-Brouwer`). *Given an arithmetic circuit $F : [0,1]^2 \to [0,1]^2$ using gates from the set $\{c, +^b, -^b, *^b\ c\}$, find $x \in [0,1]^2$ such that $F(x) = x$.*

As a starting point for our reduction, we will show that this problem is `PPAD`-hard. Our proof will follow the work of Mehta [13], who showed that the closely related `2D-LinearFIXP` problem is `PPAD`-hard. There are two differences between `2D-Brouwer` and `2D-LinearFIXP`.

- In `2D-LinearFIXP`, all internal gates of the circuit take and return values from $\mathbb{R}$ rather than $[0,1]$.
- `2D-LinearFIXP` takes a circuit that uses gates from the set $\{c, +, -, *c, \max, \min\}$, where none of these gates bound their outputs to be in $[0,1]$.

In this section, we present an altered version of Mehta's reduction, which will show that finding an ϵ-solution to `2D-Brouwer` is `PPAD`-hard for a constant ϵ.

Discrete Brouwer. The starting point for Mehta's reduction is the two-dimensional discrete Brouwer problem, which is known to be `PPAD`-hard [3]. This problem is defined over a discretization of the unit square $[0,1]^2$ into a grid of points $G = \{0, 1/2^n, 2/2^n, \dots, (2^n - 1)/2^n\}^2$. The input to the problem is a Boolean circuit $C : G \to \{1,2,3\}$ the assigns one of three colors to each point. The coloring will respect the following boundary conditions.

- We have $C(0,i) = 1$ for all $i \geq 0$.
- We have $C(i,0) = 2$ for all $i > 0$.
- We have $C(\frac{2^n-1}{2^n}, i) = C(i, \frac{2^n-1}{2^n}) = 3$ for all $i > 0$.

These conditions can be enforced syntactically by modifying the circuit. The problem is to find a grid square that is *trichromatic*, meaning that all three colors appear on one of the four points that define the square.

▶ **Definition 3** (`DiscreteBrouwer`). *Given a Boolean circuit $C : \{0,1\}^n \times \{0,1\}^n \to \{1,2,3\}$ that satisfies the boundary conditions, find a point $x, y \in \{0,1\}^n$ such that, for each color $i \in \{1,2,3\}$, there exists a point (x', y') with $C(x', y') = i$ where $x' \in \{x, x+1\}$ and $y' \in \{y, y+1\}$.*

Our first deviation from Mehta's reduction is to insist on the following stronger boundary condition, which is shown in Figure 1a.

- We have $C(i, j) = 1$ for all i, and for all $j \leq \epsilon$.
- We have $C(i, j) = 2$ for all $j > \epsilon$, and for all $i \leq \epsilon$.
- We have $C(i, j) = C(j, i) = 3$ for all $i > \epsilon$, and all $j \geq 1 - \epsilon$.

The original boundary conditions placed constraints only on the outermost grid points, while these conditions place constraints on a border of width ϵ. We call this modified problem ϵ-ThickDisBrouwer, which is the same as DiscreteBrouwer, except that the function is syntactically required to satisfy the new boundary conditions.

It is not difficult to produce a polynomial time reduction from DiscreteBrouwer to ϵ-ThickDisBrouwer. It suffices to increase the number of points in the grid, and then to embed the original DiscreteBrouwer instance into the $[\epsilon, 1 - \epsilon]^2$ square in the middle of the instance.

▶ **Lemma 4.** *DiscreteBrouwer can be reduced in polynomial time to ϵ-ThickDisBrouwer.*

Embedding the grid in $[0, 1]^2$. We now reduce ϵ-ThickDisBrouwer to 2D-Brouwer. One of the keys steps of the reduction is to map points from the continuous space $[0, 1]^2$ to the discrete grid G. Specifically, given a point $x \in [0, 1]$, we would like to determine the n bits that define the integer $\lfloor x \cdot 2^n \rfloor$.

Mehta showed that this mapping from continuous points to discrete points can be done by a linear arithmetic circuit. Here we give a slightly different formulation that uses only gates from the set $\{c, +^b, -^b, *^b c\}$. Let L be a fixed constant that will be defined later.

SLP 3 ExtractBit(x, b).

```
b ← 0.5
b ← x $-^b$ b
b ← b $*^b$ L
```

SLP 4 ExtractBits(x, b$_1$, b$_2$, . . . , b$_n$).

```
for $i$ in $\{1, 2, \ldots, n\}$ do
    ExtractBit(x, b$_i$)
    y ← b$_i$ $*^b$ 0.5
    x ← x $-^b$ y
    x ← x $*^b$ 2
end
```

SLP 3 extracts the first bit of the number $x \in [0, 1]$. The first three lines of the program compute the value $b = (x -^b 0.5) *^b L$. There are three possibilities.

- If $x \leq 0.5$, then $b = 0$.
- If $x \geq 0.5 + 1/L$, then $b = 1$.
- If $0.5 < x < 0.5 + 1/L$, then b will be some number strictly between 0 and 1.

The first two cases correctly decode the first bit of x, and we call these cases *good decodes*. We will call the third case a *bad decode*, since the bit has not been decoded correctly.

SLP 4 extracts the first n bits of x, by extracting each bit in turn, starting with the first bit. The three lines after each extraction erase the current first bit of x, and then multiply x by two, which means that the next extraction will give us the next bit of x. If any of the bit decodes are bad, then this procedure will break, meaning that we only extract the first n bits of x in the case where all decodes are good. We say that x is *well-positioned* if the procedure succeeds, and *poorly-positioned* otherwise.

Multiple samples. The problem of poorly-positioned points is common in PPAD-hardness reductions. Indeed, observe that we cannot define an SLP that always correctly extracts the first n bits of x, since this would be a discontinuous function, and all gates in our arithmetic circuits compute continuous functions. As in previous works, this is resolved by taking multiple samples around a given point. Specifically, for the point $p \in [0,1]^2$, we sample k points $p_1, p_2, \dots, p_k$ where $p_i = p + \left(\frac{i-1}{(k+1)\cdot 2^{n+1}}, \frac{i-1}{(k+1)\cdot 2^{n+1}}\right)$. Mehta proved that there exists a setting for L that ensures that there are at most two points that have poorly positioned coordinates. We have changed several details, and so we provide our own statement here.

▶ **Lemma 5.** *If $L = (k+2)\cdot 2^{n+1}$, then at most two of the points p_1 through p_k have poorly-positioned coordinates.*

Evaluating a Boolean circuit. Once we have decoded the bits for a well-positioned point, we have a sequence of 0/1 variables. It is easy to simulate a Boolean circuit on these values.

- The operator $\neg\, x$ can be simulated by $1 -^b x$.
- The operator $x \vee y$ can be simulated by $x +^b y$.
- The operator $x \wedge y$ can be simulated by applying De Morgan's laws and using $\vee$ and $\neg$.

Recall that C outputs one of three possible colors. We also assume, without loss of generality, that C gives its output as a *one-hot vector*. This means that there are three Boolean outputs $x_1, x_2, x_3 \in \{0,1\}^3$ of the circuit. The color 1 is represented by the vector $(1,0,0)$, the color 2 is represented as $(0,1,0)$, and color 3 is represented as $(0,0,1)$. If the simulation is applied to a point with well-positioned coordinates, then the circuit will output one of these three vectors, while if it is applied to a point with poorly positioned coordinates, then the circuit will output some value $x \in [0,1]^3$ that has no particular meaning.

The output. The key idea behind the reduction is that each color will be mapped to a displacement vector, as shown in Figure 1b. Here we again deviate from Mehta's reduction, by giving different vectors that will allow us to prove our approximation lower bound.

- Color 1 will be mapped to the vector $(0,1)\cdot\epsilon$.
- Color 2 will be mapped to the vector $(1, 1-\sqrt{2})\cdot\epsilon$.
- Color 3 will be mapped to the vector $(-1, 1-\sqrt{2})\cdot\epsilon$.

These are irrational coordinates, but in our proofs we argue that a suitably good rational approximation of these vectors will suffice. We average the displacements over the k different sampled points to get the final output of the circuit. Suppose that x_{ij} denotes output i from sampled point j. Our circuit will compute

$$\mathtt{disp}_x = \sum_{j=1}^{k} \frac{(x_{2j} - x_{3j})\cdot\epsilon}{k}, \qquad \mathtt{disp}_y = \sum_{j=1}^{k} \frac{(x_{1j} + (1-\sqrt{2})(x_{2j}+x_{3j}))\cdot\epsilon}{k}.$$

Finally, we specify $F : [0,1]^2 \to [0,1]^2$ to compute $F(x,y) = (x + \mathtt{disp}_x \cdot \epsilon, y + \mathtt{disp}_y \cdot \epsilon)$.

Completing the proof. To find an approximate fixed point of F, we must find a point where both $\mathtt{disp}_x$ and $\mathtt{disp}_y$ are close to zero. The dotted square in Figure 1b shows the set of displacements that satisfy $\|x - (0,0)\|_\infty \le (\sqrt{2}-1)\cdot\epsilon$, which correspond to the displacements that would be $(\sqrt{2}-1)\cdot\epsilon$-fixed points.

The idea is that, if we do not sample points of all three colors, then we cannot produce a displacement that is strictly better than an $(\sqrt{2}-1)\cdot\epsilon$-fixed point. For example, if we only have points of colors 1 and 2, then the displacement will be some point on the dashed line between the red and blue vectors in Figure 1b. This line touches the box of $(\sqrt{2}-1)\cdot\epsilon$-fixed points, but does not enter it. It can be seen that the same property holds for the other pairs of colors: we specifically chose the displacement vectors in order to maximize the size of the inscribed square shown in Figure 1b.

The argument is complicated by the fact that two of our sampled points may have poorly positioned coordinates, which may drag the displacement towards $(0,0)$. However, this effect can be minimized by taking a large number of samples. We show show the following lemma.

▶ **Lemma 6.** *Let $\epsilon' < (\sqrt{2}-1)\cdot\epsilon$ be a constant. There is a sufficiently large constant k such that, if $\|x - F(x)\|_\infty < \epsilon'$, then x is contained in a trichromatic square.*

Since ϵ can be fixed to be any constant strictly less than 0.5, we obtain the following.

▶ **Theorem 7.** *Given a `2D-Brouwer` instance, it is `PPAD`-hard to find a point $x \in [0,1]^2$ s.t. $\|x - F(x)\|_\infty < (\sqrt{2}-1)/2 \approx 0.2071$.*

Reducing `2D-Brouwer` to `2D-LinearFIXP` is easy, since the gates $\{c, +^b, -^b, *^b c\}$ can be simulated by the gates $\{c, +, -, *c, \max, \min\}$. This implies that it is `PPAD`-hard to find an ϵ-fixed point of a `2D-LinearFIXP` instance with $\epsilon < (\sqrt{2}-1)/2$.

It should be noted that an ϵ-approximate fixed point can be found in polynomial time if the function has a suitably small Lipschitz constant, by trying all points in a grid of width ϵ. We are able to obtain a lower bound for constant ϵ because our functions have exponentially large Lipschitz constants.

4 Hardness of 2D-Brouwer with a constant width circuit

In our reduction from `2D-Brouwer` to tree polymatrix games, the number of actions in the game will be determined by the width of the circuit. This means that the hardness proof from the previous section is not a sufficient starting point, because it produces `2D-Brouwer` instances that have circuits with high width. In particular, the circuits will extract $2n$ bits from the two inputs, which means that the circuits will have width at least $2n$.

Since we desire a constant number of actions in our tree polymatrix game, we need to build a hardness proof for `2D-Brouwer` that produces a circuit with constant width. In this section we do exactly that, by reimplementing the reduction from the previous section using gadgets that keep the width small.

Bit packing. We adopt an idea of Elkind, Goldberg, and Goldberg [10], to store many bits in a single arithmetic value using a *packed* representation. Given bits $b_1, b_2, \ldots, b_k \in \{0,1\}$, the packed representation of these bits is the value $\text{packed}(b_1, b_2, \ldots, b_k) := \sum_{i=1}^{k} b_i/2^i$. We will show that the reduction from the previous section can be performed while keeping all Boolean values in a single variable that uses packed representation.

Working with packed variables. We build SLPs that work with this packed representation, two of which are shown below.

SLP 5 FirstBit(x, b) +0 variables.

```
// Extract the first bit of x
   into b
b ← 0.5
b ← x $-^b$ b
b ← b $*^b$ L

// Remove the first bit of x
b ← b $*^b$ 0.5
x ← x $-^b$ b
x ← x $*^b$ 2
b ← b $*^b$ 2
```

SLP 6 Clear(I, x) +2 variables.

```
x' ← x $*^b$ 1
for $i$ in $\{1, 2, \dots, k\}$ do
    b ← 0
    FirstBit(x', b)
    if $i \in I$ then
        b ← b $*^b$ $\frac{1}{2^i}$
        x ← x $-^b$ b
    end
end
```

The FirstBit SLP combines the ideas from SLPs 3 and 4 to extract the first bit from a value $x \in [0, 1]$. Repeatedly applying this SLP allows us to read out each bit of a value in sequence. The Clear SLP uses this to set some bits of a packed variable to zero. It takes as input a set of indices I, and a packed variable $x = \text{packed}(b_1, b_2, \dots, b_k)$. At the end of the SLP we have $x = \text{packed}(b'_1, b'_2, \dots, b'_k)$ where $b'_i = 0$ whenever $i \in I$, and $b'_i = b_i$ otherwise.

It first copies x to a fresh variable x'. The bits of x' are then read-out using FirstBit. Whenever a bit b_i with $i \in I$ is decoded from x', we subtract $b_i/2^i$ from x. If $b_i = 1$, then this sets the corresponding bit of x to zero, and if $b_i = 0$, then this leaves x unchanged.

We want to minimize the the width of the circuit that we produce, so we keep track of the number of *extra* variables used by our SLPs. For FirstBit, this is zero, while for Clear this is two, since that SLP uses the fresh variables x' and b.

Packing and unpacking bits. We implement two SLPs that manipulated packed variables. The Pack(x, y, S) operation allows us to extract bits from $y \in [0, 1]$, and store them in x, while the Unpack(x, y, S) operation allows us to extract bits from x to create a value $y \in [0, 1]$. This is formally specified in the following lemma.

▶ **Lemma 8.** *Suppose that we are given* $\mathtt{x} = \text{packed}(b_1, b_2, \dots, b_k)$*, a variable* $\mathtt{y} \in [0, 1]$*, and a sequence of indices* $S = \langle s_1, s_2, \dots, s_j \rangle$*. Let* y_j *denote the* j*th bit of* y*. The following SLPs can be implemented using at most two extra variables.*

- *Pack(x, y, S) modifies* x *so that* $\mathtt{x} = \text{packed}(b'_1, b'_2, \dots, b'_k)$ *where* $b'_i = y_j$ *whenever there exists an index* $s_j \in S$ *with* $s_j = i$*, and* $b'_i = b_i$ *otherwise.*
- *Unpack(x, y, S) modifies* y *so that* $\mathtt{y} = \mathtt{y} +^b \sum_{i=1}^{j} b_{s_i}/2^i$

Simulating a Boolean operations. As described in the previous section, the reduction only needs to simulate or- and not-gates. Given $\mathtt{x} = \text{packed}(b_1, b_2, \dots, b_k)$, and three indices i_1, i_2, i_3, we implement two SLPs, which both modify x so that $\mathtt{x} = \text{packed}(b'_1, b'_2, \dots, b'_k)$. SLP 7 implements $\mathtt{Or}(\mathtt{x}, \mathtt{i}_1, \mathtt{i}_2, \mathtt{i}_3)$, which ensures that $b'_{i_3} = b_{i_1} \vee b_{i_2}$, and $b'_i = b_i$ for $i \neq i_3$. SLP 8 implements $\mathtt{Not}(\mathtt{x}, \mathtt{i}_1, \mathtt{i}_2)$, which ensures that $b'_{i_2} = \neg b_{i_1}$, and $b'_i = b_i$ for $i \neq i_2$.

These two SLPs simply unpack the input bits, perform the operation, and then pack the result into the output bit. The Or SLP uses the Unpack operation to set $\mathtt{a} = b_{i_1} +^b b_{i_2}$. Both SLPs use three extra variables: the fresh variable a is live throughout, and the pack and unpack operations use two extra variables. The variable b in the Not SLP is not live concurrently with a pack or unpack, and so does not increase the number of live variables. These two SLPs can be used to simulate a Boolean circuit using at most three extra variables.

SLP 7 Or($\mathtt{x}, \mathtt{i}_1, \mathtt{i}_2, \mathtt{i}_3$) +3 variables.

```
a ← 0
Unpack(x, a, $\langle \mathtt{i}_1 \rangle$)
Unpack(x, a, $\langle \mathtt{i}_2 \rangle$)
Pack(x, a, $\langle \mathtt{i}_3 \rangle$)
```

SLP 8 Not($\mathtt{x}, \mathtt{i}_1, \mathtt{i}_2$) +3 variables.

```
a ← 0
Unpack(x, a, $\langle \mathtt{i}_1 \rangle$)
b ← 1
a ← b $-^b$ a
Pack(x, a, $\langle \mathtt{i}_2 \rangle$)
```

▶ **Lemma 9.** *Let C be a Boolean circuit with n inputs and k gates. Suppose that $x = \text{packed}(b_1, \dots, b_n)$, gives values for the inputs of the circuit. There is an SLP* Simulate(C, x) *that uses three extra variables, and modifies x so that $x = \text{packed}(b_1, \dots, b_n, b_{n+1}, \dots, b_{n+k})$, where b_{n+i} is the output of gate i of the circuit.*

Implementing the reduction. Finally, we can show that the circuit built in Theorem 7 can be implemented by an SLP that uses at most 8 variables. This SLP cycles through each sampled point in turn, computes the x and y displacements by simulating the Boolean circuit, and then adds the result to the output.

▶ **Theorem 10.** *Given a* 2D-Brouwer *instance, it is* PPAD*-hard to find a point $x \in [0,1]^2$ with $\|x - F(x)\|_\infty < \frac{\sqrt{2}-1}{2}$ even for a synchronous circuit of width eight.*

5 Hardness for tree polymatrix games

Now we show that finding a Nash equilibrium of a tree polymatrix game is PPAD-hard. We reduce from the low-width 2D-Brouwer problem, whose hardness was shown in Theorem 10. Throughout this section, we suppose that we have a 2D-Brouwer instance defined by a synchronous arithmetic circuit F of width eight and depth n. The gates of this circuit will be indexed as $g_{i,j}$ where $1 \leq i \leq 8$ and $1 \leq j \leq n$, meaning that $g_{i,j}$ is the ith gate on level j.

Modifying the circuit. The first step of the reduction is to modify the circuit. First, we modify the circuit so that all gates operate on values in $[0, 0.1]$, rather than $[0, 1]$. We introduce the operators $+^b_{0.1}$, $-^b_{0.1}$, and $*^b_{0.1}$, which bound their outputs to be in $[0, 0.1]$. The following lemma states that we can rewrite our circuit using these new gates. The transformation simply divides all c-gates in the circuit by ten.

▶ **Lemma 11.** *Given an arithmetic circuit $F : [0,1]^2 \to [0,1]^2$ that uses gates from $\{c, +^b, -^b, *^b\}$, we can construct a circuit $F' : [0, 0.1]^2 \to [0, 0.1]^2$ that uses the gates from $\{c, +^b_{0.1}, -^b_{0.1}, *^b_{0.1}\}$, so that $F(x, y) = (x, y)$ if and only if $F'(x/10, y/10) = (x/10, y/10)$.*

Next we modify the structure of the circuit by connecting the two outputs of the circuit to its two inputs. Suppose, without loss of generality, that $g_{7,1}$ and $g_{8,1}$ are the inputs and that $g_{7,n}$ and $g_{8,n}$ are outputs. Note that the equality $x = y$ can be implemented using the gate $x = y *^b_{0.1} 1$. We add the following extra equalities, which are shown in Figure 2.

- We add gates $g_{9,n-1} = g_{7,n}$ and $g_{10,n-1} = g_{8,n}$.
- For each j in the range $2 \leq j < n - 1$, we add $g_{9,j} = g_{9,j+1}$ and $g_{10,j} = g_{10,j+1}$.
- We modify $g_{7,1}$ so that $g_{7,1} = g_{9,2}$, and we modify $g_{8,1}$ so that $g_{8,1} = g_{10,2}$.

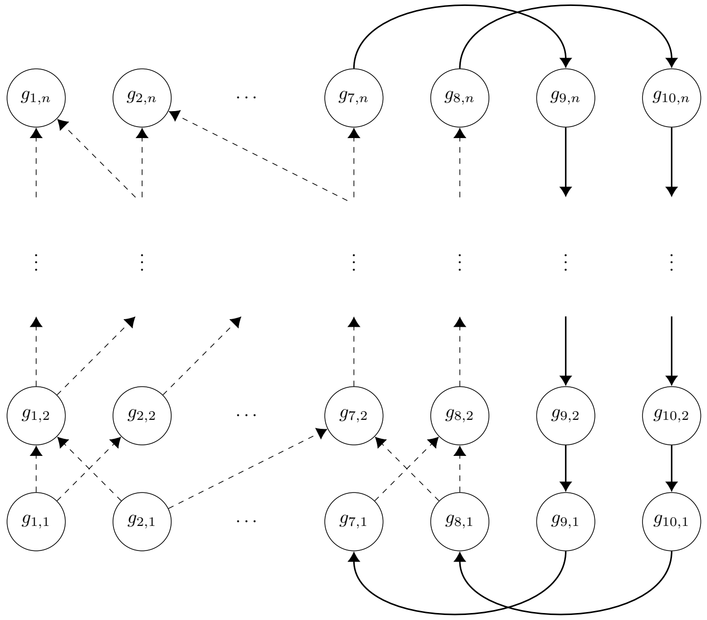

Figure 2 Extra equalities to introduce feedback of $g_{7,n}$ and $g_{8,n}$ to $g_{7,1}$ and $g_{8,1}$ respectively.

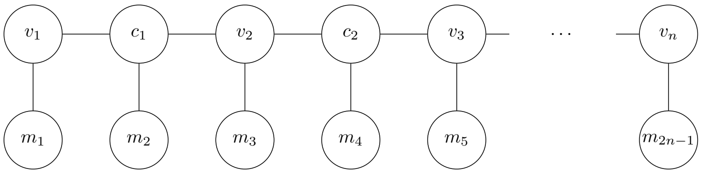

Figure 3 The structure of the polymatrix game.

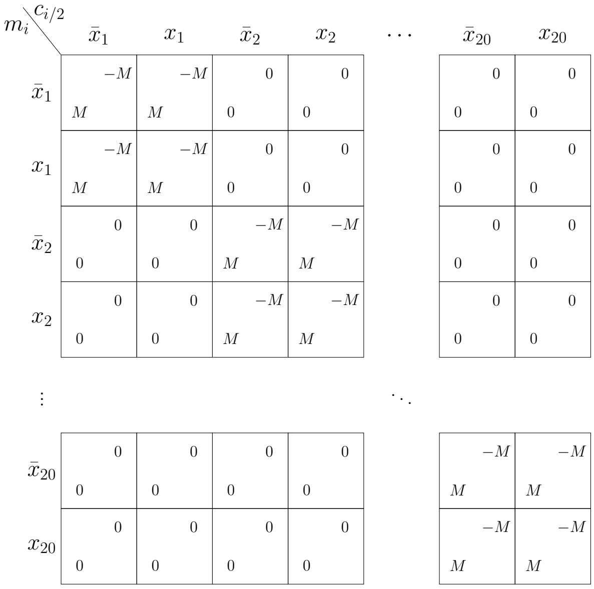
Note that these gates are backwards: they copy values from higher levels in the circuit to lower levels, and so the result is not a circuit, but a system of constraints defined by gates, with some structural properties. Firstly, each gate $g_{i,j}$ is only involved in constraints with gates of the form $g_{i',j+1}$ and $g_{i',j-1}$. Secondly, finding values for the gates that satisfy all of the constraints is PPAD-hard, since by construction such values would yield a fixed point of F.

The polymatrix game. The polymatrix game will contain three types of players.

- For each $i = 1, \dots, n$, we have a *variable* player v_i.
- For each $i = 1, \dots, n-1$, we have a *constraint* player c_i, who is connected to v_i and v_{i+1}.
- For each $i = 1, \dots, 2n-1$, we have a *mix* player m_i. If i is even, then m_i is connected to $c_{i/2}$. If i is odd, then m_i is connected to $v_{(i+1)/2}$.

The structure of this game is shown in Figure 3. Each player has twenty actions, which are divided into ten pairs, x_i and $\bar{x}_i$ for $i = 1, \dots, 10$.

Forcing mixing. The role of the mix players is to force the variable and constraint players to play specific mixed strategies: for every variable or constraint player j, we want $s_j(x_i) + s_j(\bar{x}_i) = 0.1$ for all i, which means that the same amount of probability is assigned to each pair of actions. To force this, each mix player plays a high-stakes hide-and-seek against their



$m_i \backslash c_{i/2}$	$\bar{x}_1$	x_1	$\bar{x}_2$	x_2	$\cdots$	$\bar{x}_{20}$	x_{20}
$\bar{x}_1$	$-M$ M	$-M$ M	0 0	0 0		0 0	0 0
x_1	$-M$ M	$-M$ M	0 0	0 0		0 0	0 0
$\bar{x}_2$	0 0	0 0	$-M$ M	$-M$ M		0 0	0 0

$\bar{x}_{20}$	0 0	0 0	0 0	0 0		$-M$ M	$-M$ M
x_{20}	0 0	0 0	0 0	0 0		$-M$ M	$-M$ M

Figure 4 The hide and seek game that forces $c_{j/2}$ to play an appropriate mixed strategy. The same game is used to force $v_{(j-1)/2}$ mixes appropriately.

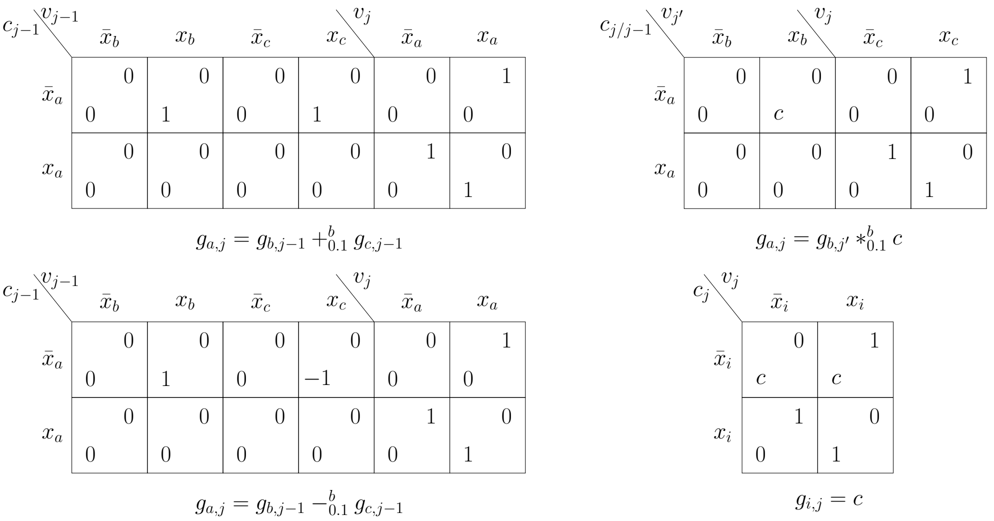
opponent, which is shown in Figure 4. This zero-sum game is defined by a 20×20 matrix Z and a constant M. The payoff Z_{ij} is defined as follows. If $i \in \{x_a, \bar{x}_a\}$ and $j \in \{x_a, \bar{x}_a\}$ for some a, then $Z_{ij} = M$. Otherwise, $Z_{ij} = 0$. For each i the player m_i plays against player j, which is either a constraint player $c_{i'}$ or a variable player $v_{i'}$. We define the payoff matrix $A^{m_i,j} = Z$ and $G^{j,m_i} = -Z$. The following lemma shows that if M is suitably large, then the variable and constraint players must allocate probability 0.1 to each of the ten action pairs.

▶ **Lemma 12.** *Suppose that all payoffs in the games between variable and constraint players use payoffs in the range $[-P, P]$. If $M > 40 \cdot P$ then in every mixed Nash equilibrium $\mathbf{s}$, the action s_j of every variable and constraint player j satisfies $s_j(x_i) + s_j(\bar{x}_i) = 0.1$ for all i.*

Gate gadgets. We now define the payoffs for variable and constraint players. Actions x_i and $\bar{x}_i$ of variable player v_j will represent the output of gate $g_{i,j}$. Specifically, the probability that player v_j assigns to action x_i will be equal to the output of $g_{i,j}$. In this way, the strategy of variable player v_j will represent the output of every gate at level j of the circuit. The constraint player c_j enforces all constraints between the gates at level j and the gates at level $j + 1$. To simulate each gate, we will embed one of the gate gadgets from Figure 5, which originated from the reduction of DGP [5], into the bimatrix games that involve c_j.

The idea is that, for the constraint player to be in equilibrium, the variable players must play x_i with probabilities that exactly simulate the original gate. Lemma 12 allows us to treat each gate independently: each pair of actions x_i and $\mathbf{s}_i$ must receive probability 0.1 in total, but the split of probability between x_i and $\mathbf{s}_i$ is determined by the gate gadgets.

Formally, we construct the payoff matrices A^{v_i,c_i} and $A^{c_i,v_{i+1}}$ for all $i < n$ by first setting each payoff to 0. Then, for each gate, we embed the corresponding gate gadget from Figure 5 into the matrices. For each gate $g_{a,j}$, we take the corresponding game from Figure 5, and embed it into the rows x_a and $\bar{x}_a$ of a constraint player's matrix. The diagrams specify specific actions of the constraint and variable players that should be modified.



c_{j-1} \ v_{j-1}					v_j	
	$\bar{x}_b$	x_b	$\bar{x}_c$	x_c	$\bar{x}_a$	x_a
$\bar{x}_a$	0 0	0 1	0 0	0 1	0 0	1 0
x_a	0 0	0 0	0 0	0 0	1 0	0 1

$g_{a,j} = g_{b,j-1} +^b_{0.1} g_{c,j-1}$

$c_{j/j-1}$ \ $v_{j'}$			v_j	
	$\bar{x}_b$	x_b	$\bar{x}_c$	x_c
$\bar{x}_a$	0 0	0 c	0 0	1 0
x_a	0 0	0 0	1 0	0 1

$g_{a,j} = g_{b,j'} *^b_{0.1} c$

c_{j-1} \ v_{j-1}					v_j	
	$\bar{x}_b$	x_b	$\bar{x}_c$	x_c	$\bar{x}_a$	x_a
$\bar{x}_a$	0 0	0 1	0 0	0 -1	0 0	1 0
x_a	0 0	0 0	0 0	0 0	1 0	0 1

$g_{a,j} = g_{b,j-1} -^b_{0.1} g_{c,j-1}$

c_j \ v_j	$\bar{x}_i$	x_i
$\bar{x}_i$	0 c	1 c
x_i	1 0	0 1

$g_{i,j} = c$

Figure 5 DGP polymatrix game gadgets.

For gates that originated in the circuit, the gadget is always embedded into the matrices $A^{v_{j-1},c_{j-1}}$ and A^{c_{j-1},v_j}, the synchronicity of the circuit ensures that the inputs for level j gates come from level $j-1$ gates. We have also added extra multiplication gates that copy values from the output of the circuit back to the input. These gates are of the form $g_{i,j} = g_{i',j+1}$, and are embedded into the matrices A^{v_j,c_j} and $A^{c_j,v_{j+1}}$.

The following lemma states that, in every Nash equilibrium, the strategies of the variable players exactly simulate the gates that have been embedded.

▶ **Lemma 13.** *In every mixed Nash equilibrium* **s** *of the game, the following are satisfied for each gate $g_{i,j}$.*

- *If $g_{i,j} = c$, then $s_{v_j}(x_i) = c$.*
- *If $g_{i,j} = g_{i_1,j-1} +^b_{0.1} g_{i_2,j-1}$, then $s_{v_j}(x_i) = s_{v_{j-1}}(x_{i_1}) +^b_{0.1} s_{v_{j-1}}(x_{i_2})$.*
- *If $g_{i,j} = g_{i_1,j-1} -^b_{0.1} g_{i_2,j-1}$, then $s_{v_j}(x_i) = s_{v_{j-1}}(x_{i_1}) -^b_{0.1} s_{v_{j-1}}(x_{i_2})$.*
- *If $g_{i,j} = g_{i_1,j'} *^b_{0.1} c$, then $s_{v_j}(x_i) = s_{v_{j'}}(x_{i_1}) *^b_{0.1} c$.*

Lemma 13 says that, in every Nash equilibrium of the game, the strategies of the variable players exactly simulate the gates, which by construction means that they give us a fixed point of the circuit F. Also note that it is straightforward to give a path decomposition for our interaction graph, where each node in the decomposition contains exactly two vertices from the game, meaning that the graph has pathwidth 1. So we have proved the following.

▶ **Theorem 14.** *It is* `PPAD`*-hard to find a Nash equilibrium of a tree polymatrix game, even when all players have at most twenty actions and the interaction graph has pathwidth 1.*

6 Open questions

For polymatrix games, the main open question is to find the exact boundary between tractability and hardness. Twenty-action pathwidth-1 tree polymatrix games are hard, but two-action path polymatrix games can be solved in polynomial time [10]. What about two-action tree polymatrix games, or path-polymatrix games with more than two actions?

For `2D-Brouwer` and `2D-LinearFIXP`, the natural question is: for which ϵ is it hard to find an ϵ-fixed point? We have shown that it is hard for $\epsilon = 0.2071$, while the case for $\epsilon = 0.5$ is trivial, since the point $(0.5, 0.5)$ must always be a 0.5-fixed point. Closing the gap between these two numbers would be desirable.

Abstract

We give a deterministic, nearly logarithmic-space algorithm for mild spectral sparsification of undirected graphs. Given a weighted, undirected graph G on n vertices described by a binary string of length N, an integer $k \leq \log n$ and an error parameter $\varepsilon > 0$, our algorithm runs in space $\widetilde{O}(k \log(N \cdot w_{\max}/w_{\min}))$ where $w_{\max}$ and $w_{\min}$ are the maximum and minimum edge weights in G, and produces a weighted graph H with $\widetilde{O}(n^{1+2/k}/\varepsilon^2)$ edges that spectrally approximates G, in the sense of Spielmen and Teng [52], up to an error of ε.

Our algorithm is based on a new bounded-independence analysis of Spielman and Srivastava's effective resistance based edge sampling algorithm [51] and uses results from recent work on space-bounded Laplacian solvers [41]. In particular, we demonstrate an inherent tradeoff (via upper and lower bounds) between the amount of (bounded) independence used in the edge sampling algorithm, denoted by k above, and the resulting sparsity that can be achieved.

1 Introduction

The graph sparsification problem is the following: given a weighted, undirected graph G, compute a graph H that has very few edges but is a close approximation to G for some definition of approximation. In general, graph sparsifiers are useful for developing more efficient graph-theoretic approximation algorithms. Algorithms whose complexity depend on the number of edges in the graph will be more efficient when run on the sparser graph H, and if H approximates G in an appropriate way, the result on H may be a good approximation to the desired result on G. In this work, we present an algorithm that can be implemented deterministically in small space and achieves sparsification in the *spectral sense* of Spielman and Teng [52]. (See Section 1.2 below for a more formal statement of our main result.)

1.1 Background

Motivated by network design and motion planning, Chew [10] studied *graph spanners*, which are sparse versions of graphs that approximately preserve the shortest distance between each pair of vertices. Benczúr and Karger [6] defined *cut sparsifiers* whose notion of approximation is that every cut of H has size within a $(1 \pm \varepsilon)$ factor of the size of the corresponding cut in G. They showed that every graph G on n vertices has a cut sparsifier H with $O(n \cdot \log n/\varepsilon^2)$ edges and gave a randomized algorithm for computing such cut sparsifiers. Their algorithm runs in nearly linear time (i.e., $\widetilde{O}(m)$ where m is the number of edges in G and the $\widetilde{O}(\cdot)$ notation hides polylogarithmic factors) and they used it to give a faster algorithm for approximating minimum s-t cuts.

Spielman and Teng introduced *spectral sparsifiers*, which define approximation between the graph and its sparsifier in terms of the quadratic forms of their *Laplacians* [52]. The Laplacian of an undirected graph is the matrix $L = D - A$ where A is the adjacency matrix of the graph and D is the diagonal matrix of vertex degrees (i.e. D_{ii} equals the weighted degree of vertex i). H is said to be an *ε-spectral approximation* of G if for all vectors $v \in \mathbb{R}^n$, we have that $v^\top \widetilde{L} v \in (1 \pm \varepsilon) \cdot v^\top L v$, where $\widetilde{L}$ and L are the Laplacians of H and G, respectively. Spectral sparsifiers generalize cut sparsifiers, which can be seen by observing that when $v \in \{0,1\}^n$, v is the characteristic vector of some set of vertices $S \subseteq [n]$ and $v^\top L v$ equals the sum of the weights of the edges cut by S.

Spielman and Teng showed that all graphs have spectral sparsifiers with $O(n \cdot \log^{O(1)} n/\varepsilon^2)$ edges and gave a nearly linear time randomized algorithm for computing them with high constant probability. Their spectral sparsifiers were a key ingredient that they used to develop the first nearly linear time algorithm for solving Laplacian systems. These fast Laplacian solvers spawned a flurry of improvements and simplifications [16, 26, 28, 27, 30, 31, 34, 44] as well as extensions to directed graphs [15, 14, 13] and to the space-bounded setting [18, 41, 1]. Spectral sparsification and the nearly linear time Laplacian solvers that use them have been critical primitives that have enabled the development of faster algorithms for a wide variety of problems including max flow [37, 11, 17, 24, 33], random generation of spanning trees, [25, 40, 49], and other problems in computer science [43, 29].

Spielman and Srivastava [51] gave a spectral sparsification algorithm that both simplified and improved upon the algorithm of Spielman and Teng. They show that randomly sampling edges, independently with probabilities proportional to their *effective resistances* produces a good spectral sparsifier with high probability. Viewing a graph as an electrical network, the effective resistance of an edge (a, b) is the potential difference induced between them when a unit of current is injected at a and extracted at b (or vice versa). More formally, the effective resistance of an edge (a, b) in a graph with Laplacian L is $R_{ab} = (e_a - e_b)^\top L^+ (e_a - e_b)$, where e_i denotes the ith standard basis vector and L^+ denotes the *Moore-Penrose pseudoinverse* of L[1]. Spielman and Srivastava proved the following theorem.

▶ **Theorem 1** (spectral sparsification via effective resistance sampling [51, 50]). *Let $G = (V, E, w)$ be a weighted graph on n vertices and for each edge $(a, b) \in E$ with weight w_{ab}, define $p_{ab} = \min\{1, 4 \cdot \log n \cdot w_{ab} \cdot R_{ab}/\varepsilon^2\}$, where R_{ab} is the effective resistance of (a, b) as defined above. Construct a sparsifier H by sampling edges from G independently such that each edge (a, b) in G is added to H with probability p_{ab}. For edges that get added to H, reweight them with weight w_{ab}/p_{ab}. Let L and $\widetilde{L}$ be the Laplacians of G and H, respectively. Then, with high probability,*

1. *H has $O(n \cdot (\log n)/\varepsilon^2)$ edges, and,*
2. *$\widetilde{L}$ ε-spectrally approximates L.*

Furthermore, this procedure can be implemented to run in time $\widetilde{O}(\frac{m}{\varepsilon^2} \cdot \log(w_{\max}/w_{\min}))$, where m is the number of edges in G and $w_{\max}, w_{\min}$ are the maximum and minimum edge weights of G, respectively.[2]

The sparsity achieved by the Spielman and Srivastava sparsifiers was improved by Batson, Spielman and Srivastava [5], who gave a deterministic algorithm for computing ε-spectral sparsifiers with $O(n/\varepsilon^2)$ edges, which is asymptotically optimal, however, their algorithm is less efficient, running in time $O(m \cdot n^3/\varepsilon^2)$. Work on these optimal sparsifiers continued with another slightly faster deterministic algorithm [53] followed by an $O(n^{2+\varepsilon})$-time randomized algorithm [2], and culminating in the randomized algorithms of Lee and Sun who achieved almost-linear time [35] and finally nearly-linear time [36].

1.2 Our Main Result

In this work we study the deterministic *space complexity* of computing spectral sparsifiers. Our main result is a deterministic, nearly-logarithmic space algorithm for computing *mild spectral sparsifiers*, that is, graphs with $O(n^{1+\alpha}/\varepsilon^2)$ edges for any constant $\alpha > 0$.

▶ **Theorem 2** (see also Theorem 19). *Let G be a connected, weighted, undirected graph on n vertices, $k \in \mathbb{N}$ an independence parameter and $\varepsilon > 0$ an error parameter. There is a deterministic algorithm that on input G, k, and ε, outputs a weighted graph H that is an ε-spectral sparsifier of G and has $O(n^{1+2/k} \cdot (\log n)/\varepsilon^2)$ edges. The algorithm runs in space $O(k \log(N \cdot w) + \log(N \cdot w) \log\log(N \cdot w))$, where $w = w_{\max}/w_{\min}$ is the ratio of the maximum and minimum edge weights in G and N is the length of the input.*

The closest analogue to spectral sparsifiers in the space-bounded derandomization literature is the *derandomized square* of Rozenman and Vadhan [47], a graph operation that produces a sparse approximation to the square of a graph.[3] The derandomized square was introduced to give an alternative proof to Reingold's celebrated result that Undirected S-T Connectivity can be solved in deterministic logspace [46]. Murtagh, Sidford, Reingold,

[1] L^+ is a matrix with the same kernel as L that acts as an inverse of L on the orthogonal complement of the kernel. See Section 2.2 for a formal definition.

[2] In their original paper, [51], they fix the number of edges in the sparsifier in advance resulting in a slightly different theorem statement and analysis. The version we cite here and what we model our algorithm after was presented later in [50].

[3] The *square* of a graph G is a graph on the same vertex set whose edges correspond to all walks of length 2 in G.

and Vadhan [41] showed that the derandomized square actually produces a *spectral sparsifier* of the square of a graph and this was a key observation they used to develop a deterministic, nearly logarithmic space algorithm for solving Laplacian systems. Later the sparsification benefits of the derandomized square were also used in nearly logarithmic space algorithms for deterministically approximating random walk probabilities and for solving Laplacian systems in Eulerian directed graphs [42, 1].

For a d-regular graph G on n vertices, its square G^2 has degree d^2 and the derandomized square computes an ε-spectral approximation to G^2 with degree $O(d/\varepsilon^2)$. On the other hand, applying our sparsification to G^2 results in an ε-spectral approximation with on average $O(n^\alpha/\varepsilon^2)$ edges adjacent to each vertex for any constant α, which is independent of d and much sparser when $d = \omega(n^\alpha)$. Also, our algorithm can sparsify any undirected graph, not just squares. Our algorithm does not replace the derandomized square, however, because the derandomized square can be iterated very space efficiently, a property that is used in all of its applications thus far. Nevertheless, given the success of spectral sparsification and Laplacian solvers in the nearly-linear time context and the fruit borne of porting these techniques to the logspace setting, we are hopeful that our spectral sparsifiers will have further applications in derandomization of space-bounded computation.

1.3 Techniques

Our deterministic space-efficient algorithm is modeled after the effective resistance based sampling algorithm of Spielman and Srivastava (Theorem 1). Although the Spielman and Srivastava procedure is randomized and does not achieve optimal sparsity, the known algorithms that do ([5, 53, 2, 35, 36]) are more involved and often sequential in nature so do not seem as amenable to small-space implementations.

To derandomize the Spielman-Srivastava algorithm, we follow the standard approach of first reducing the number of random bits used to logarithmic, and then enumerating over all random choices of the resulting algorithm. Following [39, 3], a natural way to reduce the number of random bits used is to do the edge sampling only k-wise independently for some $k \ll |E|$ rather than sampling every edge independently from all other edges.

Let k be our bounded-independence parameter. Namely, we are only guaranteed that every subset of k edges is chosen independently (with the right marginals), however there may be correlations between the choices in tuples of size $k+1$. It is well known that such a sampling can be performed using fewer random bits. By [51], we know that $k = |E|$ will, with high probability, produce an ε-spectral sparsifier with $O(n \cdot \log n/\varepsilon^2)$ edges in expectation. What about much smaller values of k? In Section 3, we prove the following:

▶ **Theorem 3** (informal; see Theorem 9). *Let G be a connected weighted undirected graph on n vertices with Laplacian L, $k \in \mathbb{N}$ an independence parameter and $\varepsilon > 0$ an error parameter. Let H be the graph which is the output of Spielman and Srivastava's sampling-based sparsification algorithm (Theorem 1), when the edge sampling is done in a k-wise independent manner, and let $\widetilde{L}$ be the Laplacian of H. Then, with high constant probability, $\widetilde{L}$ ε-approximates L and H has $O(n^{1+2/k} \cdot (\log n)/\varepsilon^2)$ edges.*

A first thing to observe is that $k = \log n$ gives the same result as in [51]. More importantly, the above shows that the result *interpolates*: Even for a constant k, Theorem 3 gives a *mild sparsification* that sparsifies dense graphs to $O(n^{1+\alpha})$ expected edges, where $\alpha > 0$ is an arbitrarily small constant.

We prove Theorem 3 by extending the arguments in [51, 50]. For every edge $(a, b) \in E$, we define a random matrix X_{ab} that corresponds to the choice made by the sparsification algorithm, in such a way that $X = \sum_{(a,b)\in E} X_{a,b}$ relates to the resulting Laplacian $\widetilde{L}$.[4] Let Π be the orthogonal projection onto the image of L. Following [51, 50], we show that $\widetilde{L}$ ε-spectrally approximates L (equivalently, that H is an ε-spectral sparsifier for G) with high probability if $X - \Pi$ has bounded moments. Deriving a tail bound that relies on the first k moments alone, we can proceed with the analysis as if the X_{ab}'s were *truly independent*. More specifically, we bound $\mathrm{Tr}(\mathbb{E}_X[(X - \Pi)^k])$ using a matrix concentration result due to Chen, Gittens and Tropp [9]. For the complete details, as well as how our argument differs from [51, 50], see Section 3.

Getting a Deterministic Algorithm

Theorem 3 readily gives a simple, randomness-efficient algorithm, as k-wise independent sampling of edges only requires $O(k \cdot \log(N \cdot w))$ random bits [23, 3] (See Lemma 8). However, more work is needed to obtain a space-efficient deterministic algorithm. First, we need to be able to compute the marginal sampling probabilities, which depend on the effective resistances R_{ab}. Fortunately, the recent work of Murtagh et al. [41] allows us to approximate the effective resistances using only $O(\log(N \cdot w) \log\log(N \cdot w))$ space and we show that the k-wise independent sampling procedure can tolerate the approximation.

Next, to obtain a deterministic algorithm, we can enumerate over all possible random choices of the algorithm in space $O(k \cdot \log(N \cdot w))$ and compute a candidate sparsifier H for each. We are guaranteed that at least one (indeed, most) of the resulting graphs H is a good sparsifier for G but how can we identify which one? To do this, it suffices for us, given Laplacians L and $\widetilde{L}$, to distinguish the case that $\widetilde{L}$ is an ε-spectral approximation of L from the case that $\widetilde{L}$ is not a $2 \cdot \varepsilon$-spectral approximation of L. We reduce that problem to that of approximating the spectral radius of $M = ((\widetilde{L} - L)L^+/\varepsilon)^2$, where L^+ is the pseudoinverse of L, which can be approximated in nearly logarithmic space by [41]. In fact, it will be sufficient to check whether the trace of a logarithmically high power of M is below a certain threshold to deduce that the spectral radius of M does not exceed 1. In Section 5.2, we show that the latter case implies that $\widetilde{L}$ indeed ε-approximates L.

The deterministic, nearly logarithmic space Laplacian solver of [41] only worked for *multigraphs*, i.e. graphs with integer edge weights. To get our result for arbitrary weighted graphs, we extend the work of [41] and give a deterministic, nearly logarithmic space Laplacian solver for arbitrary undirected weighted graphs. Combining this extension with the k-wise independent analysis of the edge sampling algorithm (Theorem 3) and the verification procedure described above lets us prove our main result Theorem 2.

1.4 Lower Bounds for Bounded-Independence Sampling

Having established an upper bound on the amount of independence required for the edge-sampling procedure (Theorem 3), a natural goal would be to come up with a corresponding lower bound. Theorem 3 tells us that in order to sparsify to $\widetilde{O}(n^{1+\alpha})$ expected edges, we can use k-wise independent sampling for $k = 2/\alpha$. Can a substantially smaller choice of k perform just as well? In Section 4, we show that our upper bound of $k = 2/\alpha$ is tight up to a small constant factor.

[4] Specifically, $X = L^{+/2}\widetilde{L}L^{+/2}$, where $L^{+/2}$ is the square-root of the pseudoinverse of L.

▶ **Theorem 4** (informal; see Theorem 11). *For every small enough $\alpha > 0$ there exist infinitely many connected graphs $G = (V = [n], E)$ with all effective resistances equal that are d-regular with $d = \Omega(n^{\alpha})$ and a distribution $\mathcal{D} \sim \{0,1\}^{|E|}$ that is k-wise independent for $k = \lfloor 4/3\alpha \rfloor$ with marginals $1/2$ that would fail to produce an ε-spectral sparsifier of G to within any $\varepsilon > 0$ with high probability.*

Our family of "bad graphs" will be dense graphs having large girth. Namely, given a girth g and an integer $d \geq 3$, we consider graphs $G = (V = [n], E)$ satisfying $d \geq n^{\gamma/g} + 1$ for some constant $0 < \gamma < 2$ [32]. Getting an infinite family of graphs with γ approaching 2 (and specifically attaining the *Moore bound*), even non-explicitly, has been the subject of extensive study (see [21] and references therein). See also Section 4.1 for a further discussion. Given a sparsification parameter $\alpha > 0$, we set $k \approx \gamma/\alpha$ and take a graph G on n vertices with girth $g = k + 1$ and degree $d > n^{\gamma/g} + 1$.

Our construction of the distribution $\mathcal{D}$ is inspired by Alon and Nussboim [4]: choose a partition of the vertices $V = V_0 \uplus V_1$ uniformly at random, and for every edge $e = (u, v) \in E$, include it in the sample if and only if either $u, v \in V_0$ or $u, v \in V_1$. Clearly, sampling edges according to $\mathcal{D}$ results in a disconnected graph almost surely. However, we show that $\mathcal{D}$ is indeed k-wise independent, relying on the fact that the girth of G is $k + 1$.

To obtain Theorem 4 we use the family of graphs given by Lazebnik et al. [32] who obtained $\gamma = 4/3$. Indeed, any improvement in γ would bring our upper bound of $k \approx 2/\alpha$ and lower bound of $k \approx \gamma/\alpha$ closer together.

1.5 Open Problems

An interesting open problem is to achieve improved sparsity, e.g. $O(n \cdot (\log n)/\varepsilon^2)$ matching [51]. Our algorithm would require space $\Omega(\log^2 n)$ to achieve this sparsity, due to setting $k = \Omega(\log n)$. We remark that previous work implies that this can be done in *randomized* logarithmic space. Indeed, Doron et al. [18] gave a randomized algorithm for solving Laplacian systems in logarithmic space (without $\log\log(\cdot)$ factors), and this implies that one can approximate effective resistances and hence implement the Spielman-Srivastava edge sampling with full independence in randomized logspace. It is also an interesting question whether there is a nearly logspace algorithm (even randomized) that produces spectral sparsifiers of optimal sparsity (i.e., $O(n/\varepsilon^2)$ edges).

Finally, while it is not known how to compute spectral sparsifiers of arbitrary *directed* graphs, there has been progress on sparsifying Eulerian digraphs in the nearly-linear time literature [15, 14, 13, 12]. Given the recent advance of a nearly-logarithmic space solver for Eulerian Laplacian systems [1], an interesting question is sparsifying Eulerian graphs in small space.

2 Preliminaries

We will work with undirected weighted graphs, $G = (V, E, w)$, where w is a vector of length $|E|$ and each edge $(a, b) \in E$ is associated with a positive weight $w_{ab} > 0$. At times we refer to undirected *multigraphs*, which are weighted graphs where all of the weights are integers. The adjacency matrix of G is a symmetric, real-valued matrix A in which $A_{ij} = w_{ij}$ if $(i, j) \in E$ and $A_{ij} = 0$ otherwise.

For any matrix A, its *spectral norm* $\|A\|$ is $\max_{\|x\|=1}\|Ax\|_2$, which is also the largest singular value of A. For any square matrix A, its *spectral radius*, denoted $\rho(A)$, is the largest absolute value of its eigenvalues. When A is real and symmetric, the spectral norm equals the spectral radius. The spectral norm is sub-multiplicative, i.e., $\|AB\| \le \|A\|\,\|B\|$. We denote by $A^\top$ the transpose of A. We denote by $\mathbf{1}$ the all-ones vector, by $\mathbf{0}$ the all-zeros vector, and e_a is the vector with 1 in the a-th coordinate and 0 elsewhere, where e_a's dimension will be understood from context (i.e., e_a is the a-th standard basis vector).

The *trace* of a matrix $A \in \mathbb{R}^{n\times n}$, is $\mathrm{Tr}(A) = \sum_{i\in[n]} A_{ii}$, which also equals the sum of its eigenvalues. The trace is invariant under cyclic permutations, i.e., $\mathrm{Tr}(AB) = \mathrm{Tr}(BA)$. The expectation of a *random matrix* is the matrix of the coordinate-wise expectations. More formally, if A is a random matrix, then $\mathbb{E}[A] = \widehat{A}$ where $\widehat{A}_{ij} = \mathbb{E}[A_{ij}]$ for all $i,j \in [n]$. The trace and the expectation are both linear functions of a matrix and they commute. That is, for all random matrices A, we have $\mathrm{Tr}(\mathbb{E}[A]) = \mathbb{E}[\mathrm{Tr}(A)]$ (see, e.g.,[45]).

2.1 PSD Matrices and Spectral Approximation

A symmetric matrix $A \in \mathbb{R}^{n\times n}$ is *positive semi-definite* (PSD), denoted $A \succeq 0$, if for every $x \in \mathbb{R}^n$ it holds that $x^\top Ax \ge 0$, or equivalently, if all its eigenvalues are non-negative. We write $A \succeq B$ if $A - B \succeq 0$.

▶ **Definition 5.** *Let A and B be $n \times n$ symmetric PSD matrices. For a real $\varepsilon > 0$, we say that A is an* ε-spectral approximation *of B, denoted $A \approx_\varepsilon B$, if*

$$(1-\varepsilon)B \preceq A \preceq (1+\varepsilon)B.$$

When A and B share an eigenvector basis $v_1,\ldots,v_n$, Definition 5 is equivalent to requiring $(1-\varepsilon)\mu_i \le \lambda_i \le (1+\varepsilon)\mu_i$, where $\lambda_1,\ldots,\lambda_n$ are the eigenvalues of A corresponding to $v_1,\ldots,v_n$ and $\mu_1,\ldots,\mu_n$ are the eigenvalues of B corresponding to $v_1,\ldots,v_n$.

2.2 The Moore-Penrose Pseudoinverse

Let A be any linear operator. The *Moore-Penrose pseudoinverse* of A, denoted A^+, is defined as follows. If $A = U\Sigma V^\top$ is the singular value decomposition (SVD) of A, the pseudoinverse is given by $A^+ = V\Sigma^+U^\top$ where Σ^+ is the matrix obtained by taking the reciprocal of each nonzero diagonal element of Σ, and leaving the zeros intact. When A is a symmetric PSD matrix, the SVD coincides with the eigen-decomposition and so if $\lambda_1,\ldots,\lambda_n$ are the eigenvalues of A then A^+ shares the same eigenvector basis and has eigenvalues $\lambda_1^+,\ldots,\lambda_n^+$, where $\lambda_i^+ = 1/\lambda_i$ if $\lambda_i \ne 0$ and $\lambda_i^+ = 0$ otherwise.

Also note that if A is real then A^+ is real-valued as well.

A *square root* of a matrix A is any matrix X that satisfies $X^2 = A$. When A is symmetric and PSD, it has a unique symmetric PSD square root, which we write as $A^{1/2}$. If $A = U\Sigma U^\top$ is the eigen-decomposition of A then $A^{1/2} = U\sqrt{\Sigma}U^\top$ where $\sqrt{\Sigma}$ is obtained by taking the square root of each diagonal element of Σ. We denote by $A^{+/2}$ the matrix $(A^+)^{1/2} = (A^{1/2})^+$.

2.3 The Graph Laplacian and Effective Resistance

Given a graph G on n vertices with an adjacency matrix A and degree matrix D (i.e., D is a diagonal matrix where $D_{ii} = \sum_{j=1}^n A_{ij}$ equals the weighted degree of vertex i in G), the *Laplacian* of G is the matrix

$$L = D - A.$$

For every undirected weighted graph $G = (V, E, w)$, its Laplacian L is symmetric and PSD, with smallest eigenvalue 0. The zero eigenvalue has multiplicity one if and only if G is connected. In this case, $\ker(L_G) = \operatorname{span}(\{\mathbf{1}\})$. For every edge $(a, b) \in E$, define the *edge Laplacian* of (a, b) to be

$$L_{ab} = (e_a - e_b)(e_a - e_b)^\top = (e_b - e_a)(e_b - e_a)^\top.$$

Note that $L = \sum_{(a,b)\in E} w_{ab} \cdot L_{ab}$.

It is often helpful to associate G with an electric circuit, where an edge $(a, b) \in E$ corresponds to a resistor of resistance $1/w_{ab}$. For each pair of vertices a and b, the *effective resistance* between them, denoted by R_{ab}, is the energy of the electrical flow that sends one unit of current from a to b. The effective resistance can be calculated using the pseudoinverse of the Laplacian:

$$R_{ab} = (e_a - e_b)^\top L^+(e_a - e_b).$$

(See [8] for more information on Laplacians and viewing graphs as electrical networks). A useful fact about effective resistances is Foster's Theorem:

▶ **Theorem 6** ([22]). *For every undirected weighted graph $G = (V, E, w)$ on n vertices it holds that*

$$\sum_{(a,b)\in E} w_{ab} \cdot R_{ab} = n - 1.$$

2.4 Bounded-Independence Sampling

Given a probability vector $p \in [0, 1]^m$, let $\operatorname{Bernoulli}(p)$ denote the distribution X over $\{0, 1\}^m$ where the bits are independent and for each $i \in [m]$, $\mathbb{E}[X_i] = p_i$. For a set $I \subseteq [m]$ and a string $z \in \{0, 1\}^m$, we let $z|_I \in \{0, 1\}^{|I|}$ be the restriction of z to the indices in I.

▶ **Definition 7.** *We say a distribution $X \sim \{0, 1\}^m$ is k-wise independent with marginals $p \in [0, 1]^m$ if for every set $I \subseteq [m]$ with $|I| \le k$, it holds that $X|_I = \operatorname{Bernoulli}(p|_I)$. We refer to X as a k-wise independent sample space with marginals p.*

Consider $G = (V, E, w)$ with $|E| = m$. Throughout, when we say *sampling edges in a k-wise independent manner*, we refer to the process of picking an element $x \in \{0, 1\}^m$ from a k-wise independent sample space uniformly at random and taking those edges $e \in E$ for which $x_e = 1$.

For $p \in [0, 1]^m$ and a positive integer t, we define $\lfloor p \rfloor_t$ to be the vector p' obtained by truncating every element of p after t bits. Thus, for each $i \in [m]$, $p'_i = 2^{-t}\lfloor 2^t p_i \rfloor$, and so $|p_i - p'_i| \le 2^{-t}$. The following lemma states that we can construct small k-wise independent sample spaces with any specified marginals.

▶ **Lemma 8** (following [23, 3]). *For every $m, k, t \in \mathbb{N}$ and $p \in [0, 1]^m$ there exists an explicit k-wise independent distribution $X \sim \{0, 1\}^m$ with marginals $\lfloor p \rfloor_t$, that can be sampled with $r = O(k \cdot \max\{t, \log m\})$ truly random bits. Furthermore, given $\rho \in \{0, 1\}^r$, the element $x \in \operatorname{Supp}(X)$ corresponding to the random bits ρ can be computed in $O(k \cdot \max\{t, \log m\})$ space.*

3 Sparsification via Bounded-Independence Sampling

In Section 1, we briefly introduced the Spielman-Srivastava sparsification algorithm [51] based on (truly) independent edge sampling, with probabilities proportional to the effective resistances of the edges. In this section, we explore the tradeoff between the amount of independence used in the edge sampling process and the resulting sparsity that can be achieved.

In particular, we analyze the algorithm Sparsify (see Algorithm 1). The algorithm gets as input an undirected, weighted, dense graph $G = (V, E, w)$ on n vertices, approximate effective resistances $\widetilde{R}_{ab}$ for each edge $(a, b) \in E$, a bounded independence parameter $k \le \log n$, a desired approximation error $\varepsilon > 0$, and a parameter $\delta > 0$ governing the success probability, and outputs a sparser graph H whose Laplacian ε-spectral approximates the Laplacian of G with probability at least $1 - 2\delta$.

Algorithm 1 Computing a spectral sparsifier via bounded independence sampling.

```
Sparsify($G = (V, E, w)$, $\{\widetilde{R}_{ab}\}_{(a,b)\in E}$, $k$, $\varepsilon$, $\delta$).
1. Initialize $H$ to be the empty graph on $n = |V(G)|$ vertices.
2. Set $s \leftarrow \frac{18e\log n}{\varepsilon^2} \cdot \left(\frac{n}{\delta}\right)^{2/k}$.
3. For every edge $(a, b) \in E$, set $p_{ab} \leftarrow \min\left\{1, w_{ab} \cdot \widetilde{R}_{ab} \cdot s\right\}$.
4. For every edge $(a, b) \in E$, add $(a, b)$ to $H$ with weight $w_{ab}/p_{ab}$ with probability $p_{ab}$.
   Do this sampling in a $k$-wise independent manner, following Lemma 8.
5. Return $H$.
```

First we will analyze Sparsify for the case where the effective resistances are given exactly, i.e. $\widetilde{R}_{ab} = R_{ab}$ for all $(a, b) \in E$. Then, in Section 3.2 we will analyze the more general case where we are given approximations to the effective resistances. This latter case is useful algorithmically because more efficient algorithms are known for estimating effective resistances than for computing them exactly, both in the time-bounded and space-bounded settings [51, 41].

3.1 Sparsification With Exact Effective Resistances

In this section we give our main theorem about Sparsify.

▶ **Theorem 9** (spectral sparsification via bounded independence). *Let $G = (V, E, w)$ be an undirected connected weighted graph on n vertices with Laplacian L and effective resistances $R = \{R_{ab}\}_{(a,b)\in E}$. Let $0 < \varepsilon < 1$, $0 < \delta < 1/2$ and let $k \le \log n$ be an even integer. Let H be the output of* Sparsify$(G, R, k, \varepsilon, \delta)$ *and let $\widetilde{L}$ be its Laplacian. Then, with probability at least $1 - 2\delta$ we have:*

1. *$\widetilde{L} \approx_\varepsilon L$, and,*
2. *H has $O\left(\frac{1}{\delta^{1+2/k}} \cdot \frac{\log n}{\varepsilon^2} \cdot n^{1+\frac{2}{k}}\right)$ edges.*

Spielman and Srivastava showed that by using truly independent sampling (i.e., $k = |E|$) in Sparsify, one can compute an ε-spectral sparsification of G with $O(n \cdot \log n/\varepsilon^2)$ edges, with high constant probability [51]. One immediate consequence of Theorem 9 is that $\log n$-wise independent sampling suffices to match the sparsity that truly independent sampling achieves. Another consequence of Theorem 9 is that for any constant $0 < \alpha < 1$ and any constant $\gamma < \alpha/2$, for $k \approx 2/(\alpha - 2\gamma)$, k-wise independent sampling achieves a spectral sparsifier with error $\varepsilon = n^{-\gamma}$ and $O(n^{1+\alpha})$ expected edges, with high constant probability.

The proof of Theorem 9 is modeled after Spielman and Srivastava's argument [51]. One difference is that the sparsification algorithm in [51] fixes the number of edges to be sampled in advance rather than having the number of edges be a random variable. They then prove spectral approximation by reducing the problem to a question about concentration of random matrices, which they resolve with a matrix Chernoff bound due to Rudelson and Vershynin [48]. We follow a variant of this argument for the case where the number of edges in the sparsifier is random and use a matrix concentration bound of Chen, Gittens, and Tropp [9]. This variant, for truly independent sampling, has appeared before in [50]. Our argument is modified to address the fact that we only use k-wise independent sampling, and the proof is given in the full version of the paper.

3.2 Sparsification With Approximate Effective Resistances

Spielman and Srivastava showed that the original version of spectral sparsification through effective resistance sampling (with fully independent sampling and fixing the number of edges in advance) is robust to small changes in the sampling probabilities. In this section we show the same is true of Sparsify. As said, this is useful because more efficient algorithms are known for estimating effective resistances than for computing them exactly, and we will also use this fact for our space-bounded algorithm for sparsification in Section 5.

The lemma below says that if we only have small multiplicative approximations to the effective resistances then the guarantees of Theorem 9 still hold with a small loss in the sparsity.

▶ **Lemma 10.** *Let $G = (V, E, w)$ be an undirected connected weighted graph on n vertices with Laplacian L. Let $0 < \varepsilon < 1$, $0 < \delta < 1/2$ and let $k \le \log n$ be an even integer. For each $(a, b) \in E$, let $\widetilde{R}_{ab}$ be such that*

$$(1-\alpha)\cdot R_{ab} \le \widetilde{R}_{ab} \le (1+\alpha)\cdot R_{ab},$$

where R_{ab} is the effective resistance of (a, b) and $0 < \alpha < 1$. Let $\widetilde{R} = \{\widetilde{R}_{ab}/(1-\alpha)\}_{(a,b)\in E}$. Let H be the output of Sparsify$(G, \widetilde{R}, k, \varepsilon, \delta)$ *and let $\widetilde{L}$ be its Laplacian. Then, with probability at least $1 - 2\delta$ we have:*

1. *$\widetilde{L} \approx_{\varepsilon} L$, and,*
2. *H has $O\left(\frac{1+\alpha}{1-\alpha} \cdot \frac{1}{\delta^{1+2/k}} \cdot \frac{\log n}{\varepsilon^2} \cdot n^{1+\frac{2}{k}}\right)$ edges.*

A proof of Lemma 10 can be found in the full version. Note that we could equivalently define Sparsify to take approximate sampling probabilities as input (i.e., $(1-\alpha)p_{ab} \le \widetilde{p}_{ab} \le (1+\alpha)p_{ab}$) rather than α-approximate effective resistances and the same lemma applies.

4 Lower Bounds for Bounded-Independence Sampling

In this section we give a lower bound for sampling-based bounded independence sparsification. Our lower bound will hold even for unweighted, simple, regular graphs in which all the effective resistances are the same, so for this section, assume $G = (V = [n], E)$ is such a graph. In Section 3 we measure sparsity in terms of the number of edges in the graph. We use this measure rather than average degree because in weighted graphs, the degree of a vertex v typically refers to the sum of the weights of the edges incident to v, whereas in sparsification algorithms we are trying to minimize the number of edges incident to v, regardless of their weight. In this section, we will sometimes refer to average degree rather than number of edges. When we refer to the average degree of a weighted graph, we mean the average number of edges incident to each vertex. For simple, unweighted graphs, these quantities are the same.

Fix some $\alpha > 0$. Theorem 9 tells us that if we want to sparsify G to within error ε and expected degree $s = O\left(n^{\alpha} \cdot \log n/\varepsilon^2\right)$, we can do so by sampling each edge with probability $p = s \cdot (n-1)/|E|$ in a k-wise independent manner, where $k = 2/\alpha$ (rounded to an even integer).[5] We now prove that $k \geq 4/3\alpha$ is essential for such a sampling procedure, at least for constant α.

▶ **Theorem 11** (lower bound for spectral sparsification via bounded independence)**.** *Fix $c > 0$. For every $\alpha \in (0, 4/15]$, there exist infinitely many n's for which the following holds.*

There exists a connected graph $G = (V = [n], E)$ whose effective resistances are all equal and a distribution $\mathcal{D} \sim \{0,1\}^{|E|}$ that is k-wise independent for $k = \lfloor 4/3\alpha \rfloor$ with marginals $1/2$ that would fail to sparsify G to within any error $\varepsilon > 0$ and expected degree $s = c \log n \cdot n^{\alpha_0}$, where $\alpha_0 \geq (1-2\alpha)\alpha$.

More specifically, sampling a subgraph of G according to $\mathcal{D}$ would result in a disconnected graph with probability at least $1 - 2/2^n$.

We note that a disconnected graph fails to be a good spectral sparsifier of a connected graph, which is implicit in Theorem 11. Formally:

▷ Claim 12. Let G and $\widetilde{G}$ be undirected graphs on n vertices with Laplacians L and $\widetilde{L}$, respectively. If G is connected and $\widetilde{G}$ is disconnected then $\widetilde{L} \not\approx_{\varepsilon} L$ for any $\varepsilon > 0$.

We give a proof of Claim 12 in the full version of the paper.

4.1 Moore-Like Graphs With a Given Girth

Toward proving Theorem 11, we will need, for every bounded-independence parameter k, an infinite family of graphs satisfying certain properties. Recall that the *girth* of a graph G is the length of the shortest cycle in G. We will need an infinite family of girth-g graphs having large degree. Formally:

▶ **Definition 13.** *Given $\gamma > 0$ and $g \colon \mathbb{N} \to \mathbb{N}$, an infinite family of graphs $\{G_i = (V_i = [n_i], E_i)\}_{i \in \mathbb{N}}$ is* (g, γ)-Moorish *if for every $i \in \mathbb{N}$, G_i is connected, has girth at least $g(n_i)$ and is d_i-regular for some $d_i \geq n_i^{\gamma/g(n_i)} + 1$.*

The problem of finding such families of graphs, or even proving their existence in some regime of parameters, has been widely studied in extremal graph theory. A simple counting argument ([20], see also [8]) shows that (g, γ)-Moorish families of graphs can only exist when $\gamma \leq 2$:

▶ **Lemma 14** (the Moore bound, see, e.g., [8])**.** *Every d-regular graph of girth g on n vertices satisfies $n \geq 2 \cdot ((d-1)^{g/2} - 1)/(d-2)$.*

Still, no families with γ approaching 2 for arbitrary girths are known. The Ramanujan graphs of Lubotzky, Phillips and Sarnak [38] were shown to obtain $\gamma \geq 4/3$ by Biggs and Boshier [7]. Lazebnik, Ustimenko and Woldar [32] slightly improved upon [38] in the lower-order terms, but more importantly for us, the family they construct consists of *edge-transitive graphs.*

[5] We used the fact that for every $(a,b) \in E$, $p_{ab} \leftarrow \min\{1, R_{ab}s\} = R_{ab}s = R \cdot s$, which can be argued as follows. When all effective resistances equal R, we have $R = (n-1)/|E|$ due to Theorem 6. Now, if G has $n \cdot s$ edges or fewer, then it already achieves the desired sparsity so without loss of generality we can assume that $|E| > n \cdot s$. Hence, $R \cdot s < (n-1)s/ns < 1$. Also, the resulting graph should indeed be a weighted one, however all its weights will be the same, $1/p$.

▶ **Theorem 15** ([32]). *For every prime power d and even integer $g \geq 6$ there exists a d-regular explicit simple, edge-transitive graph with $n \leq 2d^{g-\lfloor \frac{g-3}{4} \rfloor -4}$ vertices and girth g. In particular, for every prime power d there exists a $(g, \gamma = 4/3)$-Moorish family of edge-transitive graphs, where $\mathrm{Im}(g) = \{6, 8, \dots\}$.*

Intuitively, in an edge-transitive graph the local environment of every edge (i.e., the vertices and edges adjacent to it) looks the same. More formally, an edge-transitive graph is one in which any two edges are equivalent under some element of its automorphism group. As the computation of the effective resistance is not affected by an automorphism, we can conclude the following claim.

▷ Claim 16. Let $G = (V, E)$ be an unweighted edge-transitive graph. Then, for every two edges $e = (a, b)$ and $e' = (a', b')$ in E it holds that $R_{ab} = R_{a'b'}$.

4.2 The Lower Bound Proof

We next prove our main result for this section, showing that Moorish edge-transitive graphs cannot be sparsified via bounded-independence edge sampling when k is too small. Our proof can be seen as an extension of an argument by Alon and Nussboim [4], who studied the bounded independence relaxation of the usual Erdős-Rényi random graph model, where it is only required that the distribution of any subset of k edges is independent. They provide upper and lower bounds on the minimal k required to maintain properties that are satisfied by a truly random graph, and in particular they show that there exists a pairwise independent distribution $\mathcal{D}$ over edges with marginals $1/2$ such that a random graph sampled from $\mathcal{D}$ is disconnected almost surely.

As a warm-up, we extend the argument in [4] and show that *3-wise* independence also does not suffice, even for the special case of sparsifying the complete graph.

▶ **Lemma 17.** *Let $G = (V = [n], E)$ be the complete graph. There exists a distribution $\mathcal{D} \sim \{0,1\}^{|E|}$ that is 3-wise independent with marginals $1/4$ such that sampling a subgraph of G according to $\mathcal{D}$ would result in a disconnected graph with probability at least $1 - 2/2^n$.*

Proof. We first set some notations. Let $\mathcal{G}(A, p)$ be the usual Erdős-Rényi model, in which each edge between two vertices in A is included in the graph with probability p. Let $\mathcal{B}(A)$ be the natural distribution over complete bipartite graphs: Choose a partition $A = A_1 \uplus A_2$ uniformly at random and include all edges between A_1 and A_2.

We construct $\mathcal{D} \sim \{0,1\}^{|E|}$ as follows. Choose a partition $[n] = V_0 \uplus V_1$ uniformly at random. On V_0, draw a graph from $\mathcal{G}(V_0, 1/2)$ and on V_1, draw a graph from $\mathcal{B}(V_1)$. Clearly, sampling G' according to $\mathcal{D}$ would result in a disconnected graph unless $V_0 = \varnothing$ or $V_1 = \varnothing$, which occurs with probability at most $2/2^n$, so what is left to show is that $\mathcal{D}$ is 3-wise independent with marginals $1/4$.

This is equivalent to saying that for every $T \subseteq E$ with $|T| \leq 3$, $\Pr[\forall e \in T,\ \mathcal{D}(e) = 1] = 1/4^{|T|}$. Let us first consider the case $|T| = 1$, i.e. $T = e$ for a single edge $e \in E$. Notice that $\mathcal{D}(e) = 1$ only if both endpoints of e appear in the same side of the partition $V_0 \uplus V_1$, which occurs with probability $1/2$, and given that this occurs, e appears in $\mathcal{G}(V_0, 1/2)$ or $\mathcal{B}(V_1)$ with probability $1/2$. Thus, $\Pr[\mathcal{D}(e) = 1] = 1/4$, as desired.

Next, fix a set $T \subseteq E$ of $t \in \{2, 3\}$ edges and note that we can assume without loss of generality that these edges form either a path or a triangle (for $t = 3$), as disjoint paths will occur independently. If T forms a path, then similarly,

$$\Pr[T \in \mathcal{D}^{-1}(1)] = \Pr[V(T) \subseteq V_0] \cdot 2^{-t} + \Pr[V(T) \subseteq V_1] \cdot 2^{-t} = 2^{-(t+1)} \cdot 2^{-t} + 2^{-(t+1)} \cdot 2^{-t} = 4^{-t},$$

which is what we want. If T forms a triangle, then using the fact that a bipartite graph is triangle-free,

$$\Pr[T \in \mathcal{D}^{-1}(1)] = \Pr[V(T) \subseteq V_0] \cdot \frac{1}{8} = 4^{-3},$$

concluding the proof. ◀

The above lemma shows that one cannot sparsify the complete graph via ($k = 3$)-wise independent edge sampling. For a general k, we indeed need to resort to Moore-like graphs.

Proof of Theorem 11. Recalling that $k = \lfloor 4/3\alpha \rfloor$, let $g = k+1$ or $g = k+2$, whichever is even. Set d_0 to be the first prime power larger than

$$1 + \max\left\{2^{6^2/\alpha^8}, (2c)^{6/\alpha^2}\right\}.$$

By Theorem 15, for every prime power $d \geq d_0$ there exists $n = n(g,d)$ and a girth-g, edge-transitive, d-regular graph graph $G = (V = [n], E)$ (note that by our assumption that $\alpha \leq 4/15$, indeed $g \geq 6$). From here onwards, fix such a d and $n = n(g,d)$, observing that $\{n(g,d)\}_{d \geq d_0}$ is infinite.

Choose α_0 so that $c \log n \cdot n^{\alpha_0} = d/2$ so that marginals $1/2$ correspond to expected sparsity s. Using the fact that $d \geq n^{4/3g} + 1$, it can be verified that $\alpha_0 \geq (1-2\alpha) \cdot \alpha$. Using the fact that $d \geq n^{4/3g} + 1$,

$$\alpha_0 \geq \frac{4}{3g} - \frac{\log(2c \log n)}{\log n} \geq \frac{4}{\frac{4}{\alpha} + 6} - \frac{\log(2c \log n)}{\log n} \geq \left(1 - \frac{3\alpha}{2}\right)\alpha - \frac{\log(2c \log n)}{\log n}.$$

As $n \leq (d-1)^{\frac{3g}{4}}$ and $n \geq 2 \cdot \frac{(d-1)^{\frac{g}{2}-1}}{d-2} \geq (d-1)^{\frac{g}{2}-1}$, the latter being the Moore bound, we have

$$\frac{\log(2c \log n)}{\log n} \leq \frac{\log(2c) + \log \frac{3g}{4} + \log\log(d-1)}{\left(\frac{g}{2} - 1\right)\log(d-1)} \leq \frac{\log(2c)}{\log(d-1)} + 2 \cdot \frac{\log\log(d-1)}{\log(d-1)} \leq \frac{\alpha^2}{2},$$

where we used $\frac{\log(2c)}{\log(d-1)} \leq \frac{\alpha^2}{6}$, $\log \frac{3g}{4} \leq \frac{g}{2} - 1$ and $\frac{\log\log(d-1)}{\log(d-1)} \leq \frac{\alpha^2}{6}$. Thus, overall, $\alpha_0 \geq (1-2\alpha)\alpha$.

We now give a k-wise independent distribution with marginals $1/2$ that fails to yield a good spectral sparsifier for G, namely it will be disconnected with high probability.

To do so, construct $\mathcal{D} \sim \{0,1\}^{|E|}$ as follows. Choose a partition $[n] = V_0 \uplus V_1$ uniformly at random. Each random partition gives rise to an element $D \sim \mathcal{D}$ in which for $e = (u,v) \in E$, $D(e) = 1$ (i.e., the edge e is chosen to survive) if and only if either $u, v \in V_0$ or $u, v \in V_1$.

▷ Claim 18. The distribution $\mathcal{D}$ is k-wise independent with marginals $1/2$.

Proof. As in the proof of Lemma 17, it suffices to show that for every set $T \subseteq E$ of $t \leq k$ edges of G we have $\Pr[T \subseteq \mathcal{D}^{-1}(1)] = 2^{-t}$. First, similar to Lemma 17, note that we can assume without loss of generality that T is a connected component, since whenever T_1 and T_2 are over disjoint sets of vertices, $\Pr[T_1 \cup T_2 \subseteq \mathcal{D}^{-1}(1)] = \Pr[T_1 \subseteq \mathcal{D}^{-1}(1)] \cdot \Pr[T_2 \subseteq \mathcal{D}^{-1}(1)]$. As the girth of G is larger than t, it must be the case that A is a tree.

In such a case, where T contains no cycles, $\Pr[T \in \mathcal{D}]$ is equal to the probability that all $t+1$ vertices in T belong to the same partition, which is $2 \cdot 2^{-(t+1)} = 2^{-t}$. ◁

By the way $\mathcal{D}$ was constructed, it is clear that sampling G' according to $\mathcal{D}$ would result in a disconnected graph unless $V_0 = \varnothing$ or $V_1 = \varnothing$, which occurs with probability $1 - 2/2^n$, meaning that G' almost surely does not ε-approximate G, for *any* ε. ◀

We again stress that by the work in Section 3, we know that *any* k-wise independent distribution over the edges of G with marginals $s \cdot (n-1)/|E|$ for $k = \lceil 2/\alpha \rceil$ would produce an ε-spectral sparsifier with expected degree $O(s)$ with high constant probability.

The above also implies that any improvement upon Moorish families of edge-transitive graphs will improve our lower bound. Assuming the existence of a $(g, \gamma = 2)$-Moorish family of edge-transitive graphs we are able to show that the result of Section 3 is essentially tight.

5 Spectral Sparsifiers in Deterministic Small Space

In this section we show that Sparsify can be derandomized space efficiently.

▶ **Theorem 19** (deterministic small-space sparsification). *Let G be an undirected, connected, weighted graph on n vertices with Laplacian L. There is a deterministic algorithm that, when given G, an even integer k and $0 < \varepsilon < 1$ outputs a weighted graph H with Laplacian $\widetilde{L}$ satisfying:*

1. *$\widetilde{L} \approx_\varepsilon L$, and,*
2. *H has $O\left(\frac{\log n}{\varepsilon^2} n^{1+2/k}\right)$ edges.*

The algorithm runs in space $O(k \log(N \cdot w) + \log(N \cdot w) \log\log(N \cdot w))$, where $w = w_{\max}/w_{\min}$ is the ratio of the maximum and minimum edge weights in G and N is the bitlength of the input.

We use the standard model of space-bounded computation. The machine has a read-only input tape, a constant number of read/write work tapes, and a write-only output tape. We say the machine runs in space s if throughout the computation, it only uses s total tape cells on the work tapes. The machine may write outputs to the output tape that are larger than s (in fact as large as $2^{O(s)}$) but the output tape is write-only. We use the following fact about the composition of space-bounded algorithms.

▶ **Lemma 20.** *Let f_1 and f_2 be functions that can be computed in space $s_1(n), s_2(n) \geq \log n$, respectively, and f_2 has output of length $\ell_1(n)$ on inputs of size n. Then $f_2 \circ f_1$ can be computed in space*

$$O(s_2(\ell_1(n)) + s_1(n)).$$

The natural way to derandomize Sparsify would be to iterate over all elements of the corresponding k-wise independent sample space. More formally, given $\{p_{ab}\}_{(a,b)\in E}$, let I_{ab} be the indicator random variable that is 1 if and only if edge (a, b) is chosen. If the I_{ab}'s are k-wise independent so that $\Pr[I_{ab} = 1] = p_{ab}$ (or some good approximation of p_{ab}), we are guaranteed to succeed with nonzero probability. Hence, at least one assignment to the I_{ab}'s taken from the k-wise independent is guaranteed to work. From Section 2.4 we know the sample space is small enough that we can afford to enumerate over all elements in it. Towards proving Theorem 19, there are still three issues to consider:

1. Approximating the effective resistances R_{ab} for every $(a, b) \in E$, space efficiently. Fortunately, we can do this with high accuracy using the result of Murtagh, Reingold, Sidford, and Vadhan [41] for approximating the pseudoinverse of a Laplacian, which we state shortly.

2. Verifying that a given set of random choices in Sparsify provides a sparse and accurate approximation to the input graph. The sparsity requirement is easy to check. To check that $\widetilde{L} \approx_\varepsilon L$, we devise a verification algorithm that uses the algorithm of [41]. The details are given in Lemma 25.
3. The Laplacian solver of [41] only works for multigraphs (graphs with integer edge weights) and we want an algorithm that works for general weighted graphs. To fix this, we extend the work of [41] by giving a simple reduction from the weighted case to the multigraph case. The details can be found in the full version of the paper.

5.1 Algorithm for Approximating Effective Resistances

A key ingredient in our deterministic sparsification algorithm is a deterministic nearly logarithmic space algorithm for approximating the pseudoinverse of an undirected Laplacian.

▶ **Theorem 21** ([41]). *Given an undirected, connected multigraph G with Laplacian $L = D - A$ and $\varepsilon > 0$, there is a deterministic algorithm that computes a symmetric PSD matrix $\widetilde{L^+}$ such that $\widetilde{L^+} \approx_\varepsilon L^+$, and uses space $O(\log N \cdot \log\log \frac{N}{\varepsilon})$, where N is the bitlength of the input (as a list of edges).*

Note that the space complexity above assumes that the multigraph is given as a list of edges. If we instead think of parallel edges as integer edge weights, then N should be replaced by $N \cdot w_{\max}$, where $w_{\max}$ is the maximum edge weight in G since an edge of weight w gets repeated w times in the edge-list representation. To work with general weighted graphs, we extend the result of [41].

▶ **Lemma 22** (small space laplacian solver for weighted graphs). *Given an undirected connected weighted graph $G = (V, E, w)$ with Laplacian $L = D - A$, and $0 < \varepsilon < 1$, there exists a deterministic algorithm that computes a symmetric PSD matrix $\widetilde{L^+}$ such that $\widetilde{L^+} \approx_\varepsilon L^+$, and uses space $O(\log(N \cdot w) \log\log(N \cdot w/\varepsilon))$, where $w = w_{\max}/w_{\min}$ is the ratio of the maximum and minimum edge weights in G and N is the bitlength of the input.*

A proof of Lemma 22 can be found in the full version. Lemma 22 immediately gives an algorithm for computing strong multiplicative approximations to effective resistances.

▶ **Lemma 23.** *Let $G = (V, E, w)$ be an undirected, connected, weighted graph and let R_{ab} be the effective resistance of $(a, b) \in E$. There is an algorithm that computes a real number $\widetilde{R}_{ab}$ such that*

$$(1-\varepsilon) \cdot R_{ab} \leq \widetilde{R}_{ab} \leq (1+\varepsilon) \cdot R_{ab}$$

and uses space $O(\log(N \cdot w) \cdot \log\log \frac{N \cdot w}{\varepsilon})$, where $w = w_{\max}/w_{\min}$ is the ratio of the maximum and minimum edge weights in G and N is the bitlength of the input.

See the full version for a proof of Lemma 23.

Next we show how we test whether two matrices spectrally approximate each other. We will need the following claim about the space complexity of matrix multiplication.

▷ Claim 24. Given $n \times n$ matrices $M_1, \ldots, M_k$, their product $M_1 \cdot \ldots \cdot M_k$ can be computed using $O(\log N \cdot \log k)$ space, where N is the bitlength of $(M_1, \ldots, M_k)$.

The proof of Claim 24 uses the natural divide and conquer algorithm and the fact that two matrices can be multiplied in logarithmic space. A detailed proof can be found in [41].

5.2 Testing for Spectral Proximity

In this section we give our deterministic, small-space procedure for verifying that two Laplacians spectrally approximate one another.

▶ **Lemma 25.** *There exists a deterministic algorithm that, given undirected, connected, weighted graphs $\widetilde{G}$ and G with Laplacians $\widetilde{L}, L$, and $\varepsilon, \alpha > 0$, outputs* `YES` *or* `NO` *such that*

1. *If $\widetilde{L} \approx_\varepsilon L$, then the algorithm outputs* `YES`*, and,*
2. *If $\widetilde{L} \not\approx_{\varepsilon \cdot \sqrt{1+\alpha}} L$ then the algorithm outputs* `NO`*.*

The algorithm uses space $O(\log(N \cdot w) \cdot \log\log \frac{N \cdot w}{\alpha\varepsilon} + \log(N \cdot w) \cdot \log \frac{1}{\alpha})$, where $w = w_{\max}/w_{\min}$ is the ratio of the maximum and minimum edge weights in G and $\widetilde{G}$ and N is the bitlength of the input.

The high level idea for the proof is that testing whether two matrices L and $\widetilde{L}$ spectrally approximate each other can be reduced to approximating the spectral radius of a particular matrix

$$M = \left(\frac{(\widetilde{L} - L)L^+}{\varepsilon} \right)^2 .$$

In fact, it will be sufficient to check whether the trace of a sufficiently high power of M is below a certain threshold to deduce whether the spectral radius of M does not exceed 1. For intuition, replace the matrices with scalars m, ℓ, and $\widetilde{\ell}$ where

$$m = \frac{(\widetilde{\ell} - \ell)^2}{(\varepsilon \cdot \ell)^2}.$$

Then, $m \leq 1$ implies $\sqrt{m} \leq 1$, which implies $|\widetilde{\ell} - \ell| \leq \varepsilon \cdot \ell$ – the kind of relative closeness we want between the matrices $\widetilde{L}$ and L when aiming for spectral approximation. The proof of Lemma 25 can be found in the full version.

5.3 Completing the Proof of Theorem 19

We can now prove the main result of this section. As noted above, the algorithm proceeds by first approximating the sampling probabilities and then sparsifying G where the surviving edges are chosen from a small k-wise independent sample space whose marginals are set properly. Each potential sparsifier is checked using the algorithm given in Section 5.2.

Proof of Theorem 19. Set $\delta = \frac{1}{4}$, $\widehat{\varepsilon} = \frac{4\varepsilon}{5}$ and

$$s = \frac{18e \log n}{\widehat{\varepsilon}^2} \cdot \left(\frac{n}{\delta}\right)^{2/k},$$

for α soon to be determined. These parameters are chosen in accordance with the parameters required for Sparsify to succeed with probability 1/2 and approximation error $\widehat{\varepsilon}$ (see Lemma 10). Set $\alpha' = \alpha/(4+\alpha)$. We compute approximate effective resistances $\widetilde{R}_{ab}$ for each edge (a, b) in G using Lemma 23, so that

$$(1 - \alpha')R_{ab} \leq \widetilde{R}_{ab} \leq (1 + \alpha')R_{ab}.$$

This takes $O(\log(N \cdot w) \log\log((N \cdot w)/\alpha))$ space. Then, we compute approximate sampling probabilities as follows:

$$\widetilde{p}_{ab} = \alpha' \cdot \left\lfloor \frac{1}{\alpha'} \cdot \min\left\{1, w_{ab} \cdot \widetilde{R}_{ab} \cdot s/(1 - \alpha')\right\} \right\rfloor$$

That is, we truncate the required (approximate) sampling probabilities to $\log \frac{1}{\alpha'}$ bits of precision. In particular, denoting the precise sampling probabilities by $p^\star_{ab} = \min\{1, w_{ab} \cdot R_{ab} \cdot s\}$, we have

$$\begin{aligned}\min\{1, w_{ab} \cdot \widetilde{R}_{ab} \cdot s/(1-\alpha')\} - p^*_{ab} &\leq w_{ab} \cdot s \cdot R_{ab} \cdot \left(\frac{1+\alpha'}{1-\alpha'} - 1\right) \\ &= p^*_{ab} \cdot \frac{2\alpha'}{1-\alpha'} \leq \alpha/2\end{aligned}$$

Furthermore, we have an additional error of α' due to the truncation so $|\widetilde{p}_{ab} - p^\star_{ab}| \leq \alpha/2 + \alpha' \leq \alpha$.

We want to set α so that $\widetilde{p}_{ab}$ is a multiplicative approximation to p^*_{ab} for all $(a,b) \in E$, which requires α to be smaller than $\min_{(a,b)\in E)}\{p^*_{ab}\}$.

▷ Claim 26. Let $d_{\max}$ be the maximum weighted degree over all vertices in G. Then, for all $(a,b) \in E$, $p^\star_{ab} \geq 1/d_{\max}$.

Proof. Since $s > 1$ and $w_{ab} \geq 1$ (all edge weights are positive integers) we have $p^\star_{ab} \geq R_{ab}$. Let $\lambda_{\min}(C)$ denote the minimal nonzero eigenvalue of a matrix C. To lower bound R_{ab}, we use the variational characterization of eigenvalues and the definition of effective resistance to write

$$\begin{aligned}R_{ab} &= (e_a - e_b)^\top L^+ (e_a - e_b) \geq \lambda_{\min}(L^+) \cdot \|e_a - e_b\|^2 \\ &= \frac{2}{\|L\|} \geq \frac{1}{d_{\max}}.\end{aligned}$$

Note that we can indeed consider the minimal nonzero eigenvalue of L^+ because $e_a - e_b$ is perpendicular to the one-dimensional kernel of L (the all-ones vector). ◁

In light of the above, we can set α so that $1/\alpha = 2 \cdot d_{\max} = O(N \cdot w)$ and get a 1/2-multiplicative approximation to the sampling probabilities.

Now, consider the k-wise independent sample space $\mathcal{D} \subseteq \{0,1\}^{|E|}$ guaranteed to us by Lemma 8, substituting $t = \lceil \log(1/\alpha') \rceil$. By Lemma 8, each element of $\mathcal{D}$ can be sampled using

$$O(k \cdot \max\{\log(1/\alpha'), \log|E|\}) = O(k \cdot \log(N \cdot w))$$

space. For each element of $\mathcal{D}$, construct the corresponding sparse graph. Note that the space used to cycle through each element can be reused. Lemma 10 tells us that at least $1 - 2\delta = 1/2$ of the Laplacians of the resulting graphs $\widehat{\varepsilon}$-approximate the Laplacian of G and have

$$O\left(\frac{1+1/2}{1-1/2} \cdot \frac{1}{\delta^{1+2/k}} \cdot \frac{\log n}{\widehat{\varepsilon}^2} \cdot n^{1+\frac{2}{k}}\right) = O\left(\frac{\log n}{\varepsilon^2} \cdot n^{1+\frac{2}{k}}\right)$$

edges. For each of these graphs, we run the verification algorithm with accuracy parameter 9/16, which is guaranteed to find a graph with the above sparsity whose Laplacian approximates the Laplacian of G with error

$$\widehat{\varepsilon} \cdot \sqrt{1 + \frac{9}{16}} = \frac{4\varepsilon}{5} \cdot \sqrt{\frac{25}{16}} = \varepsilon$$

in space

$$O\left(\log(N \cdot w) \log\log \frac{16N \cdot w}{9\widehat{\varepsilon}} + \log(N \cdot w) \log \frac{16}{9}\right) = O\left(\log(N \cdot w) \log\log \frac{N \cdot w}{\varepsilon}\right).$$

Again, the space used for the verification process can be reused. Adding up the space complexities gives us a total of

$$O\left(k\log(N\cdot w)+\log(N\cdot w)\log\log\frac{N\cdot w}{\varepsilon}\right)$$

space. Note that the final result is vacuous when $\varepsilon \leq 1/n$ so we can without loss of generality assume that $\varepsilon \geq 1/n$. This gives a total space complexity of $O(k\log(N\cdot w)+\log(N\cdot w)\log\log(N\cdot w))$. ◀

Abstract

Many graph properties are expressible in first order logic. Whether a graph contains a clique or a dominating set of size k are two examples. For the solution size as its parameter the first one is W[1]-complete and the second one W[2]-complete meaning that both of them are hard problems in the worst-case. If we look at both problem from the aspect of average-case complexity, the picture changes. Clique can be solved in expected FPT time on uniformly distributed graphs of size n, while this is not clear for Dominating Set. We show that it is indeed unlikely that Dominating Set can be solved efficiently on random graphs: If yes, then every first-order expressible graph property can be solved in expected FPT time, too. Furthermore, this remains true when we consider random graphs with an arbitrary constant edge probability. We identify a very simple problem on random matrices that is equally hard to solve on average: Given a square boolean matrix, are there k rows whose logical AND is the zero vector? The related Even Set problem on the other hand turns out to be efficiently solvable on random instances, while it is known to be hard in the worst-case.

1 Introduction

The worst-case analysis of problems has a long tradition and has led to a complexity theory that allows us easily to classify many problems. Such complexity theories do not only exist for the time complexity, but also for other resources such as space. There are complexity classes for approximations, parallel computations, randomization, parameterized algorithms, and many more. Usually they come with complete problems under certain reductions.

The average-case analysis of problems is less developed, but Levin showed quite early that there exist problems that are hard to solve even on random inputs [19]. He considered problems together with input distributions and defined reductions that take the probability distribution into account. This also led to complete problems for an analogue of NP in the average-case

world. This theory has been constantly refined. For example, Gurevich [17] showed some inherent limitations of these techniques. Ben-David et al. showed a rare connection to the worst-case world: If all problems in NP with a "simple" probability distribution on the inputs can be solved in average polynomial time, then NEXPTIME = EXPTIME [1]. Such connections are extremely rare and the latter one together with all others suffer from a severe problem: They rely on quite unnatural probability distributions. Up to today no connection seems to exist that shows, e.g., that if some natural problem in NP is hard to solve on average under a uniform distribution, then P $\neq$ NP. Such a result would be a big breakthrough.

It has to be noted, however, that it is in general not easy even to find problems that are hard on average (with a uniform distribution). Having such problems is crucial in cryptography. The RSA system is based on the assumption that factoring the product of two primes is hard on average, but we cannot prove today that the existence of an algorithm that can factor in polynomial time on average would imply some unexpected collapse between worst-case complexity classes.

Many problems that are hard in the worst-case become easy on average. Take for example the three-coloring problem on graphs. While NP-complete this problem can be solved in constant time on average when drawing the graph from a uniform distribution of all graphs of size n: It is easy to see that you can find a triangle in expected constant time by just looking for one among the first three vertices, then the next three and so on. Each time you find a triangle with probability $\frac{1}{8}$ and you find a triangle on average with only eight tries. See for example [4] for a similar but more complicated example.

The same holds for finding any fixed size subgraph or induced subgraph. This means that p-CLIQUE, the problem of finding a clique of size k, can be solved in expected $f(k)\mathit{poly}(n)$ time for some function f if the input is a uniformly distributed graph of size n. Parameterized complexity shows that it is unlikely to solve the same problem in $f(k)\mathit{poly}(n)$ time in the worst-case [9]. Fountoulakis, Friedrich, and Hermelin showed that finding cliques is in FPT if the probability in the random graph is an almost arbitrary function of its size [14].

In this paper we look at first-order model checking on uniformly distributed random graphs and more generally on Erdős–Rényi graphs with a constant edge probability. In this model we assume that each possible edge in a graph with n vertices exists independently with a probability of p. While in the worst-case the FO model checking problem seems to become harder the more quantifier alternations we have, this hierarchy collapses when looking at the average time complexity. We will show that the dominating set problem is as hard as the whole model checking problem. We also identify a very natural problem on boolean matrices that has the same complexity: Does a random boolean matrix have k rows whose logical AND is the zero vector? We conclude that this matrix problem and the dominating set problem are hard on *average* (unless the very general model checking problem is easy, which would be unexpected). Finally we consider also the Even Set problem, which has been finally shown to be W[1]-hard in the worst-case [2] and is similar to the above mentioned matrix problem. Nevertheless it turns out that Even Set can be efficiently solved on random instances.

Among the techniques "half"-reductions play an important role. While in a reduction f from A to B you require that $w \in A$ iff $f(w) \in B$, we often need only one direction: Showing "if $w \in A$ then $f(w) \in B$" is sufficient if $f(w) \in B$ holds with a very small probability. Having an algorithm for B we can then solve A as follows. Compute $f(w)$ and find out whether $f(w) \in B$ holds. If not, conclude that $w \notin A$. If yes, then solve $w \in A$ with a very slow, but simple algorithm. As this happens with a small probability it does not spoil the expected running time.

2 Preliminaries

Parameterized complexity

Parameterized complexity was introduced by Downey and Fellows in a series of papers to investigate further what makes problems hard to solve (see, e.g., [5, 6, 7, 8, 9, 13, 22]). Instead of measuring the run time solely as a function on the input length, it may also depend on other parameters of the input. A parameterized problem has therefore a parameter k and the input length n and we classify a problem as *fixed parameter tractable* if it can be solved in time $f(k)\mathit{poly}(n)$ for some computable function f. If an NP-hard problem is fixed parameter tractable, then it runs in polynomial time for every fixed value of k and the degree of the polynomial does not depend on k. In particular this means that there exist efficient algorithms for scenarios where the parameter is small.

In this paper we will look at distributional problems on random graphs and boolean matrices. Here a distributional problem will be a parameterized problem together with a probability distribution of the inputs. Usually we will denote such a distributional problem by stating the problem and the probability distribution separately.

We use the notation of Flum and Grohe [13] for parameterized problems. The first two important problems we consider are the dominating set problem on undirected graphs and a simple problem on boolean matrices:

▶ **Definition 1.**

p-Dominating Set

Input:	A graph G and $k \in \mathbf{N}$.
Parameter:	k
Problem:	Is there a dominating set of size $\leq k$ for G?

p-Matrix($\wedge$)

Input:	A boolean matrix $M \in \{0,1\}^{n \times n}$ and $k \in \mathbf{N}$.
Parameter:	k
Problem:	Are there k rows in M whose logical AND is the zero vector?

Logic on graphs and the zero-one law

We use graphs as a structure (V, E) where V is the vertex set and E the binary edge relation. Instead of Euv we will write $u \sim v$, which expresses that there is an edge between u and v in an undirected graph. First-order (FO) formulas on graphs are atomic formulas of the form $x = y$ or $x \sim y$ or one of the following: $\phi \wedge \psi$, $\phi \vee \psi$, $\neg\phi$, $\forall x\phi$, $\exists x\phi$, where ϕ and ψ are already FO-formulas. The semantics are as expected. A sentence is a formula without free variables.

▶ **Definition 2.** We define the first-order model checking problems on graphs. The more general problem on relational structures can be reduced to this more special problem [13].

p-MC(FO)

Input:	A first-order sentence ϕ and a graph G
Parameter:	$\lvert\phi\rvert$, the length of ϕ
Problem:	Does ϕ hold in G, i.e., $G \models \phi$?

For example, the formula $\exists x_1 \exists x_2 \ldots \exists x_k \forall y \bigvee_i (x_i = y \vee x_i \sim y)$ expresses that a graph has a dominating set of size at most k. If a formula ϕ holds for a graph G we write $G \models \phi$. If a formula ϕ follows from a set of formulas Φ we write $\Phi \models \phi$. This is the case iff there is a formal derivation of ϕ from Φ, which we write as $\Phi \vdash \phi$. Sometimes we will use colored graphs, which we represent by a graph G and a coloring function χ mapping vertices to a set of colors. Formulas can speak about colors via atomic formulas of the form $\chi(x) = \mathit{red}$ and we write $(G, \chi) \models \phi$ if the formula ϕ is true for G with colors χ.

By $G(n,p)$ we denote an Erdős–Rényi-graph with n vertices and edge probability p, where edges exist independently from each other with a probability of exactly $p \in [0,1]$. Fagin [11] proved the zero-one law for first-order sentences, which states that for every sentence ϕ either $\lim_{n\to\infty} \Pr[G(n,1/2) \models \phi] = 0$ or $\lim_{n\to\infty} \Pr[G(n,1/2) \models \phi] = 1$. With other words, a graph property that is expressible in first-order logic either holds asymptotically almost surely or almost never. Given ϕ as an input, it can be decided whether the limit is 0 or 1 and Grandjean showed that it turns out to be a PSPACE-complete problem [15]. An important role in the proof of the zero-one law play the so-called *extension axioms* (not to be confused with the axiom of extension in Zermelo–Fraenkel set theory). They state that every constant-size set of vertices is connected in every possible way to other vertices. For a set or vector of variables $x_1, \ldots, x_k$ we will often write $\bar{x}$. With this notation an extension axiom can be written as

$$\forall \bar{x} \forall \bar{y} \exists z \Big(\bigwedge_{i,j} x_i \neq y_j \to \bigwedge_i (x_i \sim z \wedge y_i \not\sim z) \Big).$$

For an extension axiom it is easy to see that it holds almost surely, but if we look at the whole set Φ of all extension axioms it turns out that there is only one countable model up to isomorphisms, the so-called *Rado graph*, which contains every finite and countable infinite graph as an induced subgraph. Hence by the Łoś–Vaught Theorem [20, 23], $\Phi \models \phi$ or $\Phi \models \neg\phi$ for every first-order sentence ϕ. This means also that either $\Phi \vdash \phi$ or $\Phi \vdash \neg\phi$. To find out out which one is true we can just enumerate all proofs. Note that in a proof only a finite number of formulas from Φ are used and the proof itself is of course also finite. The result by Grandjean states that this can be done in polynomial space.

All these observations suggest that FO-model checking should be easy on random graphs: Just find out from ϕ alone whether it holds almost surely or almost never. Then verify that this is indeed the case for the given G. The strategy of using an abundance of witnesses suggests itself, just as the triangle finding described in the introduction. While this intuition is correct for purely existential formulas, life becomes much harder when considering formulas with quantifier alternations.

In worst-case complexity FO-model checking with a fixed number of quantifier alternations form the complete problems for the A-hierarchy [12]. Among known results about the relationship to other complexity classes are W[t] $\subseteq$ A[t] and W[1] = A[1]. To today's knowledge this hierarchy appears to be proper, see e.g. [3]. A collapse of the A-hierarchy implies a collapse of both the W-hierarchy and of the polynomial hierarchy.

In this paper we investigate how hard FO-model checking is on average, which could be interpreted as looking at the average-case analogue to the A-hierarchy. In the worst-case model checking purely existential formulas is already W[1] = A[1]-complete, while it is easy to see that you can achieve expected FPT time (because of abundance of witnesses). If we turn to edge probabilities apart from $\frac{1}{2}$ and look at Erdős–Rényi graphs $G(n,p)$ with a constant p the problem stays in expected FPT time. Grohe showed that for sparse Erdős–Rényi graphs $G(n, d(n)/n)$ with $d(n) = n^{o(1)}$ the whole p-MC(FO) can be solved in expected FPT time [16]. The latter result also holds for graphs with vertex colors and it turns out that for colored random graphs Grohe's result is optimal with regard to the edge density: For no $\epsilon > 0$ and $G(n, n^\epsilon/n)$ is it possible to solve colored-p-MC(FO) in expected FPT time unless AW[$*$] $\subseteq$ FPT/poly [10].

Universal sets, bisectors, and colorings

▶ **Definition 3.** Let $n \in \mathbf{N}$ and $k \in \mathbf{N}$ with $n \geq 2k$.

1. A family $\mathcal{U}$ of functions $[n] \mapsto \{0, 1\}$ is called an (n, k)-*universal set* if for every subset $M \subseteq [n]$ of size $|M| = k$ and every $M' \subseteq M$ there is a function $f \in \mathcal{U}$ such that $f(t) = 0$ for every $t \in M'$ and $f(t) = 1$ for every $t \in M - M'$.
2. A family $\mathcal{B}$ of functions $[n] \mapsto \{0, 1\}$ is called a k-*universal bisector family* if for every subset $M \subseteq [n]$ of size $|M| = k$ there is a function $f \in \mathcal{B}$ such that $f(t) = 0$ for every $t \in M$ and every function f bisects $[n]$ in two sets of almost the same size: $|f^{-1}(0)| = \lceil n/2 \rceil$.
3. A family $\mathcal{C}$ of functions $[n] \mapsto \{\mathit{black}, \mathit{white}, \mathit{gray}\}$ is called a k-*universal coloring* if for every subset $M \subseteq [n]$ of size $|M| = k$ and every $M' \subseteq M$ there is a function $f \in \mathcal{C}$ such that $f(t) = \mathit{black}$ for every $t \in M'$ and $f(t) = \mathit{white}$ for every $t \in M - M'$. Moreover, $|f^{-1}|(\mathit{gray}) = \lceil n/2 \rceil$ for every $f \in \mathcal{C}$.

(n, k)-universal sets are a well-known concept that has been used, e.g., in the derandomization of algorithms. Naor, Schulman, and Srinivasan designed such a family that can be constructed in linear time and has size $2^k k^{O(\log k)} \log n$ [21].

The concept of a universal bisector is somehow orthogonal to (n, k)-universal sets. Combining both concepts leads to (n, k)-universal colorings that will always color half of the nodes gray.

A simple idea to build a k-universal bisector family of small size is this: For every size k subset M of $[2k]$ we define the function

$$b_M \colon [n] \to \{0, 1\},\ b_M(t) = \begin{cases} 0 & \text{if } t \bmod 2k \in M \\ 1 & \text{otherwise,} \end{cases} \tag{1}$$

where $a \bmod b$ is the remainder when dividing a by b.

Assume that $S \subseteq [n]$ with $|S| \leq k$. If we choose M such that it contains $t \bmod 2k$ for every $t \in S$ (and some more elements), then clearly $b_M(i) = 0$ for every $i \in S$. Hence, we have a k-universal bisector family. If n is a multiple of $2k$ then $|b_M^{-1}(0)| = n/2$ because every group of $2k$ elements is split equally. The last group, however, can be split unevenly leading to an error of $O(k)$. Algorithmically such a family of functions that bisects with a small error would be sufficient for our purposes. It is, however, possible to achieve perfect balance at a small cost in the size of the family, which makes their application slightly easier. The next lemma shows that universal bisector families exist.

We leave the smallest possible size of such families as an open question as it is not a critical issue for the results of this paper, but give two comments on the issue: If $n = 2k$ you have to use all $\binom{2k}{k} = \Theta(k^{-1/2} 4^k)$ possible balanced bipartitions and it seems that a size of $O^*(4^k)$ is already optimal. If n is much bigger, however, a random perfect bipartition works with a relatively high probability of $\Omega^*(2^{-k})$ and suggests that families of size $O^*(2^k)$ exist, although it is not immediately clear how to construct families of that size.

▶ **Lemma 4.** *For every $k \in \boldsymbol{N}$ and $n \geq 2k(2k + 1)$ there is a k-universal bisector family of size $O(4^k k)$. A table of all functions in the family can be computed in time $O(4^k kn)$, which is linear in the size of the table.*

Proof. We use a slight modification of the construction in (1). Let $n = 2kd + r$ with $r < 2k$. Let us call the last r elements of $[n]$ the *jokers*. We define

$$b_M(t) = \begin{cases} 0 & \text{if } t < 2kd \text{ and } t \bmod 2k \in M, \\ 1 & \text{if } t < 2kd \text{ and } t \bmod 2k \notin M, \\ t \bmod 2 & \text{if } t \geq 2kd. \end{cases}$$

Such a function $b_M(t)$ maps exactly $\lceil n/2 \rceil$ elements to 0 and is therefore perfectly balanced, but those function do not give us a universal family of bisectors. If S contains odd jokers, not all of S is mapped to 0. We can overcome this problem by using $2k + 1$ families build in this way, but where each family uses a different interval in $[n]$ to place the jokers. In that way for each $S \subseteq [n]$ of size up to $2k$ there will be one family where S does not contain a joker (by the pigeon-hole principle). There is enough space for these intervals if $n \geq 2k(2k + 1)$ and the resulting universal family of bisectors has size $(2k + 1)4^k$. ◀

Combining k-universal bisectors and (n, k)-universal sets leads easily to (n, k)-universal colorings.

▶ **Lemma 5.** *For every $k \in \boldsymbol{N}$ and $n \geq 2k(2k+1)$ there is an (n, k)-universal coloring family of size $8^k k^{O(\log k)} \log n$. A table of all functions in the family can be computed in linear time.*

Proof. We use a k-universal bisector family $\mathcal{B}$ of size $O(4^k k)$ from Lemma 4 and an (n, k)-universal set $\mathcal{U}$ of size $2^k k^{O(\log k)} \log n$ according to [21]. For $f \in \mathcal{U}$ and $g \in \mathcal{B}$ we define a function $h\colon [n] \to \{\mathit{black}, \mathit{white}, \mathit{gray}\}$ as follows:

$$h(v) = \begin{cases} \mathit{gray} & \text{if } g(v) = 1 \\ \mathit{black} & \text{if } g(v) = 0 \text{ and } f(v) = 0 \\ \mathit{white} & \text{if } g(v) = 0 \text{ and } f(v) = 1 \end{cases}$$

It is easy to see that the set of all such h's forms an (n, k)-universal family of colorings. ◀

3 Results

We define the following three formulas:

$$\phi \equiv \forall \bar{x} \forall \bar{y} \exists z \Big(\bigwedge_{i,j=1}^{k} x_i \neq y_j \to \bigwedge_{i=1}^{k} (x_i \sim z \wedge y_i \nsim z) \Big)$$

$$\phi' \equiv \forall \bar{x} \forall \bar{y} \exists z \Big(\bigwedge_{i=1}^{k} \big(\chi(x_i) = \mathit{black} \wedge \chi(y_i) = \mathit{white} \big) \to \chi(z) = \mathit{gray} \wedge \bigwedge_{i=1}^{k} (x_i \sim z \wedge y_i \nsim z) \Big)$$

$$\phi'' \equiv \forall \bar{x} \forall \bar{y} \exists z \Big(\bigwedge_{i=1}^{k} \big(\chi(x_i) = \mathit{black} \wedge \chi(y_i) = \mathit{white} \big) \to \chi(z) = \mathit{gray} \wedge \bigwedge_{i=1}^{k} (x_i \nsim z \wedge y_i \nsim z) \Big)$$

The next lemma uses k in the formulas ϕ and ϕ' as the parameter.

▶ **Lemma 6.** *If there is an algorithm that, given a graph $G = G(n, 1/2)$ and a coloring $\chi\colon \mathcal{G} \to \{\mathit{gray}, \mathit{black}, \mathit{white}\}$, can decide in expected FPT time whether $(G, \chi) \models \phi'$, then there is an algorithm that can decide for $G = G(n, 1/2)$ in expected FPT time whether $G \models \phi$.*

Proof. Let X be a $2k$-universal family of colorings. Given a graph G first solve $(G,\chi) \models \phi'$ for every $\chi \in X$ in expected FPT time. If the answer is *yes* for every χ, then we can conclude $G \models \phi$, as by using a universal family of colorings, we have covered all distinguishable ways to color the nodes of G: Assume that $(G,\chi) \models \phi'$ for every $\chi \in X$, but $G \not\models \phi$. Then there exist $\bar{x}, \bar{y}$ where $\bar{x}$ and $\bar{y}$ are distinct such that for all z, $\bigwedge_{i=1}^{k}(x_i \sim z \wedge y_i \not\sim z)$ is unsatisfied. However, as $|\bar{x}| = |\bar{y}| = k$ and X is a $2k$-universal family of colorings, there is in particular a coloring $\chi \in X$ such that $\chi(\bar{x}) = \mathit{black}$ and $\chi(\bar{y}) = \mathit{white}$. If we assume that $G \not\models \phi$ for these particular $\bar{x}, \bar{y}$, then clearly also $(G,\chi) \not\models \phi'$ for these choices of χ and $\bar{x}, \bar{y}$.

We cannot tell whether $G \models \phi$ holds or not if $(G,\chi) \not\models \phi'$ for at least one coloring $\chi \in X$. The probability that this happens is exponentially small in n as we will show in the following. The negation of ϕ' reads

$$\exists\bar{x}\exists\bar{y}\forall z\Big(\bigwedge_{i=1}^{k}\big(\chi(x_i) = \mathit{black} \wedge \chi(y_i) = \mathit{white}\big) \wedge \Big(\chi(z) = \mathit{gray} \rightarrow \bigvee_{i=1}^{k}(x_i \not\sim z \vee y_i \sim z)\Big)\Big).$$

Once the coloring and $\bar{x}, \bar{y}$ are fixed, the probability that a gray vertex z is not connected to some x_i or connected to some y_i, is exactly $1 - 2^{-2k}$. This happens with all $\frac{n}{2} + O(k)$ many gray vertices with a probability of $(1 - 2^{-2k})^{\frac{n}{2}+O(k)}$. Altogether the probability of $G \not\models \phi'$ is

$$\sum_{\chi \in X} P[(G,\chi) \not\models \phi'] \leq |X| \binom{n}{k}\binom{n-k}{k}\Big(1 - \frac{1}{2^{2k}}\Big)^{\frac{n}{2}+O(k)} =$$

$$= 8^k n^{O(k)}\Big(1 - \frac{1}{2^{2k}}\Big)^{\frac{n}{2}+O(k)} = e^{-n2^{-2k-1}+O(k\log n)},$$

because there are $|X| \leq 8^k \mathit{poly}(n)$ (Lemma 5) many colorings and at most $\binom{n}{k}\binom{n-k}{k} = n^{O(k)}$ ways to choose $\bar{x}$ and $\bar{y}$. In that case, we can solve $G \models \phi$ by brute force in $n^{O(k)}$ time. For big enough n, the expected running time of the complete algorithm then remains in expected FPT time as long as $(G,\chi) \models \phi'$ is decidable in expected FPT time. The tradeoff works as long as n^k is subexponential and for large k the problem is automatically in FPT even in the worst-case. ◀

Let $\bar{G}_\chi = (V, E')$ be defined as follows: If $\chi(u) = \mathit{gray}$ and $\chi(v) = \mathit{black}$ or $\chi(u) = \mathit{black}$ and $\chi(v) = \mathit{gray}$ then $uv \in E'$ iff $uv \notin E$. Otherwise $uv \in E'$ iff $uv \in E$.

Informally speaking, $\bar{G}_\chi$ is the same graph as G, but edges are replaced by non-edges and vice versa between a vertex pair that is colored black and gray. It is important to note that if G is random then $\bar{G}_\chi$ is also random, although the edge probability of the flipped edges of $\bar{G}_\chi$ are inverted. This poses no problem if the edge probability is 1/2, but wrecks havoc when it is not. Edge probabilities different from 1/2 are discussed in Section 4.

▶ **Lemma 7.** *Let G be a graph and χ a coloring. Then $(G,\chi) \models \phi'$ iff $(\bar{G}_\chi,\chi) \models \phi''$.*

Proof. The only difference between ϕ' and ϕ'' is $x_i \sim z$ versus $x_i \not\sim z$. This subformula is only relevant when x_i is black and z is gray, as it is guarded by that condition. ◀

A coloring $\chi \colon [n] \to \{\mathit{black}, \mathit{white}, \mathit{gray}\}$ is *balanced* if $\lceil n/2 \rceil$ numbers are mapped to *gray*.

▶ **Lemma 8.** *If we can solve p-*MATRIX*$(\wedge)$ on random $n \times n$-matrices in expected FPT time, then we can solve $(G,\chi) \models \phi''$ for every balanced coloring χ on $G(n,1/2)$ in expected FPT time.*

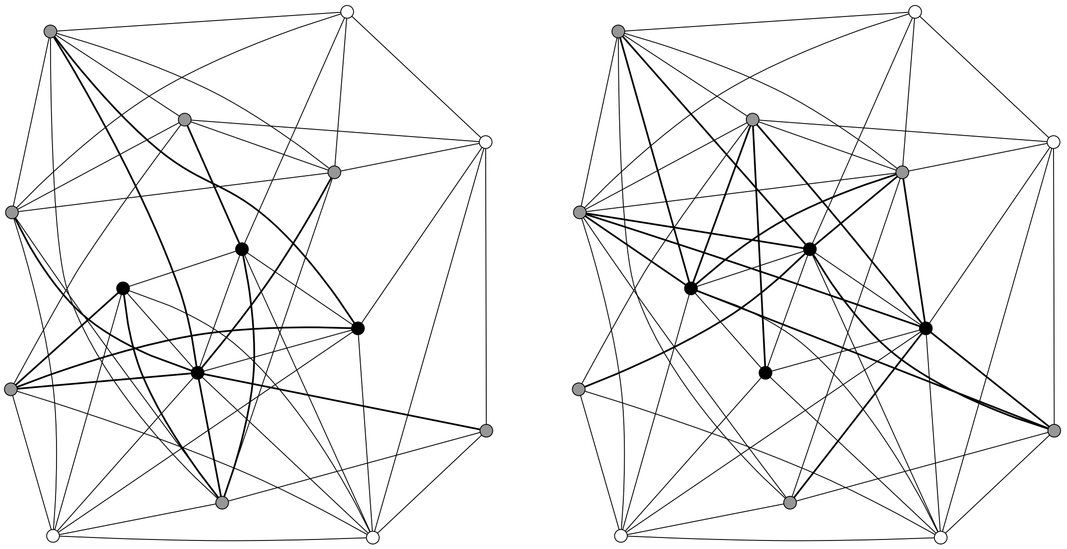

Figure 1 A graph G (left) with a node coloring χ and the corresponding graph $\bar{G}_\chi$ (right) with gray-black edges flipped.

Proof. Let $G = (V, E)$ be a random graph with n vertices and $\chi\colon \mathcal{G} \to \{\mathit{gray}, \mathit{black}, \mathit{white}\}$ be a balanced coloring. Assume first that n is even and that $V = \{v_1, \dots, v_{n/2}, u_1, \dots, u_{n/2}\}$ where v_i are not gray and u_i are gray. We construct a matrix $M \in \mathbf{F}_2^{n/2 \times n/2}$ such that $M_{ij} = 0$ iff $v_i u_j \in E$. This matrix is random and therefore we can find out in expected FPT time whether there are $2k$ rows $i_1, \dots, i_{2k}$ whose logical AND is 0. If this is not the case then $(G, \chi) \models \phi''$: Choosing $\bar{x}$ and $\bar{y}$ corresponds to picking $2k$ rows $i_1, \dots, i_{2k}$ of M. Choosing z corresponds to picking a column j of M. As M is a no-instance regardless what $i_1, \dots, i_{2k}$ are, the AND of the corresponding rows is never 0. So there is a column j with $M_{ij} = 1$ for all $i \in \{i_1, \dots, i_{2k}\}$ and correspondingly in G there is a gray z for every black $\bar{x}$, white $\bar{y}$ that is non-adjacent to all of $\bar{x}$ or $\bar{y}$ and we can conclude $(G, \chi) \models \phi''$.

Otherwise (if there are no such $2k$ rows) we can test in time $n^{O(k)}$ whether $(G, \chi) \models \phi''$. The probability for this to happen is at most $\binom{n}{2k}(1 - \frac{1}{2^{2k}})^{n/2}$ because there are $\binom{n}{2k}$ ways to choose $2k$ rows and for each column the probability is 2^{-2k} that it contains ones in all selected rows.

It remains to consider an odd n. In that case χ colors $\lceil n/2 \rceil$ vertices gray. Using the above construction leads to a matrix M with one more column than rows. The premise of the lemma allows us, however, only to assume that p-MATRIX$(\wedge)$ is solvable on square matrices. If we just remove the last column of M we are left with a random square matrix. The probability is still exponentially small that the truncated matrix is a yes-instance of p-MATRIX$(\wedge)$, but if it is a no-instance we can conclude that M is also a no-instance and then $(G, \chi) \models \phi''$ follows. Otherwise, we can again use a brute-force solution in time $n^{O(k)}$. ◀

▶ **Lemma 9.** *If we can solve p-DOMINATING SET on $G(n, 1/2)$ in expected FPT time, then we can solve p-MATRIX$(\wedge)$ on random matrices in expected FPT time.*

Proof. (Sketch) Let $M \in \mathbf{F}_2^{n \times n}$ be a random matrix. Let $\bar{M} = M \oplus 1$ (pointwise negation of M). Then M contains k rows whose AND is zero iff the directed graph H with $\bar{M}$ as its adjacency matrix has a dominating set of size k, which corresponds to the logical OR of k rows in $\bar{M}$ to be equal to the one vector.

Figure 2 Structure of the main proof. “Solving” means that the problem can be solved in expected FPT time. $A \longrightarrow B$ means that if A is in expected FPT time then so is B.

By using k-universal bisector families we can assume that a dominating set is among the first third of the vertices and that the k rows of a solution can be found in the upper third of $\bar{M}$. Decompose $\bar{M}$ into nine blocks and rearrange them as follows:

$$\bar{M} = \begin{pmatrix} A & B & C \\ D & E & F \\ G & H & I \end{pmatrix} \quad \rightarrow \quad M' = \begin{pmatrix} D' & B & A^T \\ B^T & E' & C \\ A & C^T & F' \end{pmatrix}$$

Here B^T is the transposed matrix B and A' is a symmetric matrix built from the upper triangular part of A. It is easy to see that M' is symmetric and random, if M is random. This means that M' is the adjacency matrix of a random, undirected graph G. It is also clear that if $\bar{M}$ contains k rows whose logical OR is the one vector, then M' contains $3k$ such rows and G has a dominating set of size $3k$. We can construct G and find out whether it has a dominating set of size $3k$. If not, then we know that M does not contain k rows whose logical AND is the zero vector. Otherwise, we can run a brute-force $n^{O(k)}$ algorithm, because the probability that we have to do this is at most $\binom{n}{3k}(1 - \frac{1}{2^{3k}})^{n-3k}$. ◀

▶ **Lemma 10.** *If there is an algorithm that can decide $G \models \phi$ on $G(n, 1/2)$ in expected FPT time, then there is an algorithm that solves p-MC(FO) on $G(n, 1/2)$ in expected FPT time.*

Proof. Let Φ be the set of extension axioms and ψ be a first-order formula on the logic of graphs. Remember that then either $\Phi \vdash \psi$ or $\Phi \vdash \neg\psi$ [11]. We can enumerate all proofs that use axioms in Φ in ascending order of length. Eventually we will find a proof $\Phi' \vdash \psi$ or $\Phi' \vdash \neg\psi$ for a finite subset $\Phi' \subseteq \Phi$. In our formulation of extension axioms (where $\bar{x}$ and $\bar{y}$ have the same size and only $x_i \neq y_j$, but not $x_i \neq x_j$, $y_i \neq y_j$ is required), a longer axiom implies all shorter ones. Therefore there is a single extension axiom ϕ with $2k + 1$ variables such that $\phi \vdash \psi$ or $\phi \vdash \neg\psi$. The length of ϕ and k are bounded by a function of the length of ψ because the whole proof that we found depends only on ψ. We decide in expected FPT time on the parameter $|\phi|$ and therefore also on the parameter $|\psi|$ whether $G \models \phi$. If the answer is *yes* we can conclude whether $G \models \psi$ holds and we are done. The answer is *no* only with an exponentially small probability in the number n of vertices if $|\phi|$ is small (for example if $|\phi| = O(\log n)$): There are $n - 2k$ possibilities to choose z outside of $\bar{x}$ and $\bar{y}$ and then the probability that z is correctly connected to them is exactly 2^{-2k}. Hence the probability of *no* is at most $n^{2k}(1-2^{-2k})^{n-2k} = \Omega(e^{-n/2k+k\log n})$ and we can use a brute-force $n^{O(k)}$ algorithm in that case. ◀

▶ **Theorem 11.** *p-Dominating Set can be solved on $G(n,1/2)$ in expected FPT time iff p-MC(FO) can be solved on $G(n,1/2)$ in expected FPT time.*

Proof. Assume p-Dominating Set can be solved on $G(n,1/2)$ in expected FPT time. By Lemmas 9, 8, 7, 6, and 10 we can conclude that p-MC(FO) can be solved on $G(n,1/2)$ in expected FPT time. The other direction is trivial as p-Dominating Set is a special case of p-MC(FO), where the length of the formula is linear in the size of the sought-after dominating set. See Figure 2 for an overview. ◀

4 Playing with the probability

Up to now we were looking at the uniform distribution of graphs, which corresponds to an edge probability of 1/2. It seems at first glance that all the proof techniques should also work for an arbitrary constant probability of $0 < p < 1$. A close look at the proofs, however, shows that Lemma 7 uses the fact that $p = 1/2$ in a crucial way: We flip gray–black edges, which changes their probability from p to $1-p$, which is only harmless when $p = 1/2$. The next lemma shows that we can prove a variant for an arbitrary edge probability.

▶ **Lemma 12.** *If we can solve $G \models \phi''$ on $G(n,p)$ in expected FPT time for some rational number $0 < p \le 1/2$, then we can also solve $G \models \phi'$ on $G(n,p)$ in expected FPT time.*

Proof. Let G' be a graph and χ a coloring and $\bar{G}'_\chi$ be the same graph with edges between a black and gray vertex flipped. Then $(\bar{G}'_\chi, \chi) \models \phi''$ iff $(G', \chi) \models \phi'$. However, if the edge probability in G' is p then the edge probability in $\bar{G}'_\chi$ is different: $1-p$ for gray–black edges and p for the others. Assume we can change that by turning every gray–black edge that is present in $\bar{G}'_\chi$ into a non-edge with probability $\frac{p}{1-p}$ such that the resulting probability for each edge is exactly p. Let us call the resulting graph $\bar{G}''_\chi$, which is distributed as $G(n,p)$ if G' is distributed as $G(n,p)$.

It is easy to see that $(G', \chi) \models \phi'$ follows from $(\bar{G}''_\chi) \models \phi''$ because ϕ'' remains true when removing edges. Nevertheless, the probability of $(\bar{G}''_\chi) \models \phi''$ is exponentially close to one. Therefore we can solve $(G', \chi) \models \phi'$ as follows: First find out whether $(\bar{G}''_\chi, \chi) \models \phi''$ in expected FPT time. If the answer is yes, we can conclude that $(G', \chi) \models \phi'$. Otherwise, we solve $(G', \chi) \models \phi'$ in $n^{O(k)}$ time.

We have, however, assumed that we can delete an edge with probability $p/(1-p)$, which would be true for a randomized algorithm. Using bisector families iteratively by applying the next family on the vertices that were mapped to 0 we can assume that the $\bar{x}$, $\bar{y}$ that are witnesses for $(\bar{G}''_\chi, \chi) \not\models \phi''$ are among the first ϵn vertices for any $\epsilon > 0$. Instead of testing whether ϕ'' holds on the whole graph we can now test only the subgraph induced by the first ϵn black and white vertices and all gray vertices. There are at most ϵn^2 edges between a relevant black and some gray vertex. Hence, we need only to simulate ϵn^2 coin tosses with a heads probability of $p(1-p)$, which is a rational number. Using von Neumann's trick we can simulate such a coin toss using expected $O(1)$ random bits [24]. Chernoff bounds show that the total number of such bits needed remains $O(\epsilon n^2)$ with a probability exponentially close to one. We can thus use the edges between gray vertices, there are $\binom{n/2}{2}$ many, as a coin toss with probability p. If we run out of simulated random bits, we can use a brute-force algorithm. ◀

Finally, we show that changing the probability does not make the problems harder or easier. This shows a certain robustness of the average-case complexity of p-MC(FO), p-Matrix($\wedge$), and p-Dominating Set.

▶ **Theorem 13.** *Let $0 < p, q < 1$, $p, q \in \mathbf{Q}$. p-MC(FO) can be solved on $G(n,p)$ in expected FPT time iff dominating set can be solved on $G(n,q)$ in expected FPT time.*

Proof. You can check that all steps in Figure 2 work for a probability other than $1/2$ except Lemma 7 (Lemmas 8 and 9 change p to $1-p$ and together leave it untouched). Plugging in Lemma 12 instead makes the whole chain work for any $0 < p \leq 1/2$. If we can solve p-MC(FO) on $G(n,p)$ we can solve it on $G(n,1-p)$, too, by complementing the graph and interchanging $\sim$ and $\not\sim$ in the formula. So far this shows that all problems in Figure 2 are in expected FPT or none of them on inputs distributed with an edge probability p for the graph problems and a probability of p that an entry is 1 for p-Matrix($\wedge$), but we still have to show that we can change the probability to q without making the problem harder or easier.

For this purpose we use p-Matrix($\wedge$). Let M be a matrix with probabilty p and we assume that $p < q$, otherwise we can invert the matrix and use $1-p$ and $1-q$. Similar to the proof of Lemma 12 we use iterated bisectors to reduce the problem of finding k rows to finding them in the first ϵn rows. We can then take a square submatrix consisting of the first ϵn rows and columns. Using the entries outside of this submatrix as coin tosses with heads probability p, we simulate coin tosses with a head probability of $1-q/p$. As before the probability is exponentially small that we do not succeed in the simulation (and have to use a brute-force algorithm). We use the $1-q/p$-coins to change a 1 in the submatrix to a 0 with probability $1-q/p$. Then the probability of a 1 in the submatrix becomes q. Now we can use the postulated algorithm to solve p-Matrix($\wedge$) on the transformed submatrix. If the answer is no for all bisectors then we can answer no. If the answer is at least once yes, which happens with an exponentially small probability, we can use a brute-force algorithm. ◀

The technique used above relies on p and q being rational numbers as we need to simulate a coin toss with head probability $1-q/p$, which is not necessarily possible for uncomputable probabilies (or even for very inefficiently computable ones).

5 Average Case Complexity of Even Set

The problem p-Matrix($\wedge$) turned out to be as hard as p-MC(FO) on random graphs. Instead of looking for k rows whose logical AND is the zero vector, we can also consider the related problem where we look for k rows whose exclusive or is zero. This variant is actually a problem well-known under the name Even Set and has many other equivalent definitions.

▶ **Definition 14.**

p-Even Set
Input: A matrix $A \in \mathbf{F}_2^{n\times n}$ and a number $k > 0$
Parameter: k
Problem: Are there k rows in A whose exclusive or is $\mathbf{0}$?

This problem was one of the original open problems in Downey and Fellows' book on parameterized complexity [8] and one of the few that has not been solved for a long time. Bhattacharyya et al. recently succeeded to classify the problem as W[1]-hard [2] under randomized fpt-reductions. As the problem is very similar to p-Matrix($\wedge$) we could expect that it is similarly hard on random matrices. It turns out, however, that we can solve it on uniformly distributed boolean square matrices in expected FPT time.

▶ **Theorem 15.** *p-Even Set can be solved in expected FPT time on uniformly distributed random square matrices.*

Proof (Sketch). Assume that M is a boolean $n/2 \times n$ matrix for an even n and $\Pr[M_{ij}] = 1/2$ independently for every $1 \leq i \leq n/2$, $1 \leq j \leq n$. It is easy to see and well-known (see, e.g., [18]) that the probability that M has not full rank is exponentially small in n.

Hence, we can proceed as follows to solve p-Even Set: First use a universal bisector family on a square matrix to select half the rows to form an $n/2 \times n$ matrix. If the original matrix was a yes-instance of p-Even Set, then it contained k rows whose exclusive or is the zero vector. Then the same holds for at least one of the transformed $n/2 \times n$ matrices. We check all of them for full rank. If all have full rank, then we conclude that the original matrix was a no-instance. Otherwise we use a brute-force $n^{O(k)}$ algorithm. This happens with small probability: As the $n/2 \times n$-matrices are random, all of them have full rank with high probability. The proof can easily be adjusted for odd n. ◀

It has to be noted that p-Even Set might behave quite differently on rectangular matrices. If a matrix has n columns, but n^2 rows it seems impossible to reduce the problem back to a square matrix and it is quite possible that the problem is then hard on average.

6 Conclusion

We have shown that the dominating set problem, which is with one quantifier alternation fairly low in the hierarchy of first-order definable properties, is nevertheless as hard to solve on average as any other problem that is first-order expressible. Stronger evidence for hardness under random instances would be a theorem that bridges the worlds of average-case and worst-case complexities. For example, some collapse in the W- or A-hierarchies implied by an efficient algorithm for dominating set on average instances would be a breakthrough.

A detail that is missing in this paper is the generalization of Theorem 13 to non-rational probability. We believe that more complicated techniques beyond the scope of this paper prove a generalization to even non-computable numbers, but we leave it as an open question to find a simple argument, which probably exists.

Abstract

We study the maximum weight perfect f-factor problem on any general simple graph $G = (V, E, \omega)$ with positive integral edge weights w, and $n = |V|$,$m = |E|$. When we have a function $f : V \to \mathbb{N}_+$ on vertices, a perfect f-factor is a generalized matching so that every vertex u is matched to exactly $f(u)$ different edges. The previous best results on this problem have running time $O(mf(V))$ [Gabow 2018] or $\tilde{O}(W(f(V))^{2.373}))$ [Gabow and Sankowski 2013], where W is the maximum edge weight, and $f(V) = \sum_{u\in V} f(u)$. In this paper, we present a scaling algorithm for this problem with running time $\tilde{O}(mn^{2/3} \log W)$. Previously this bound is only known for bipartite graphs [Gabow and Tarjan 1989]. The advantage is that the running time is independent of $f(V)$, and consequently it breaks the $\Omega(mn)$ barrier for large $f(V)$ even for the unweighted f-factor problem in general graphs.

1 Introduction

Suppose we are given an undirected simple graph $G = (V, E, \omega)$ on n vertices and m edges, with positive integer edge weights $\omega : E \to \{1, 2, \cdots, W\}$. Let $f : V \to \mathbb{N}_+$ be a function that maps vertices to positive integers. An f-factor is a subset of edges $F \subseteq E$ such that $\deg_F(u) \le f(u)$ for all $u \in V$, and F is a *perfect* f-factor if $\deg_F(u) = f(u)$ for all $u \in V$. In this paper we are concerned with computing a perfect f-factor with maximum edge weights[1]

For polynomial running time algorithms, the previous best result on this problem has running time [2]$\tilde{O}(mf(V))$ [8], where conventionally $f(V) = \sum_{v\in V} f(v)$. When edge weights are small integers, a pseudo-polynomial running time of $\tilde{O}(W\,(f(V))^{2.373})$ was obtained using algebraic approaches by [9]. For unweighted graphs, one can achieve $\tilde{O}(m\sqrt{f(V)})$ running time using algorithms from [13, 6]. Faster algorithms with running time independent of $f(V)$ were obtained previously but only in bipartite graphs: [11] gave a scaling algorithm that runs in time $\tilde{O}(m^{2/3}n^{5/3} \log W)$ solving the more general min-cost unit-capacity max-flow problem,

[1] Of course, original definition of f-factors means perfect ones (e.g. in [16]), but we follow the definition from [13] which does not require perfectness for convenience.

[2] In this paper $\tilde{O}(\cdot)$ hides $\log n$ factors.

and the time bound for bipartite f-factor was later improved to $\tilde{O}(m \min\{n^{2/3}, m^{1/2}\} \cdot \log W)$ in [10], and the time bound for min-cost flow was further improved to $\tilde{O}(mn^{1/2})$ and $\tilde{O}(m^{10/7} \log W)$ using algebraic approaches [15, 1]. For the maximum weight f-factor problem, if one is willing to settle for approximate solutions instead of the exact maximum, linear time algorithms can be found from [13, 2]. A closely related problem is the min-cost perfect b-matching, in which every edge can be matched multiple times. There are several classical results for b-matchings [10, 4, 7, 8].

In this paper we prove the following result, which is the first one to break the $\Omega(mn)$ barrier for perfect f-factors in general graphs.

▶ **Theorem 1.** *There is a deterministic algorithm that computes a maximum weight perfect f-factor in $\tilde{O}(mn^{2/3} \log W)$ time.*

1.1 Technical overview

Our algorithm is based on the scaling approach for maximum weight matching in general graphs that runs in time $\tilde{O}(m\sqrt{n} \log W)$ from [3] and the blocking flow method in [5, 14, 12]. Here we begin with a sketch of our idea on finding a perfect f-factor in an unweighted graph. To generalize it to weighted graphs, we will adapt the scaling algorithmic framework for maximum weight perfect matching from [3].

The algorithm for the unweighted case uses primal-dual approach for f-factors which was presented in [8]. It maintains a set of dual variables $y : V \to \mathbb{Z}$ and $z : 2^V \to \mathbb{N}$, as well as a laminar family of blossoms $\Omega \subseteq 2^V$ and a compatible f-factor F, which are initialized as $y = 0, z = 0, F = \Omega = \emptyset$. Basically, the algorithm invokes for $Cn^{2/3}$ times the Edmonds search procedure under an approximate complementary slackness constraint on F, y, z, Ω, where C is a sufficiently large constant. The key idea is that when G is a simple graph, after that we wish to prove that the total deficiency of the current f-factor F is bounded by $O(n^{2/3})$, namely $\sum_{v \in V}(f(v) - \deg_F(v)) \leq O(n^{2/3})$. If this is true, then we only need extra $O(n^{2/3})$ rounds of Edmonds searches to reach a perfect f-factor.

Let F^* be an arbitrary perfect f-factor. To upper bound the total deficiency $\sum_{v \in V}(f(v) - \deg_F(v)) \leq O(n^{2/3})$, we need to bound the total number of edge-disjoint augmenting walks in $F^* \oplus F$. Consider any augmenting walk which is specified by a sequence of consecutive edges $(u_1, u_2), (u_2, u_3), \cdots, (u_{2s-1}, u_{2s})$, where $(u_{2i-1}, u_{2i}) \in F^*, (u_{2i}, u_{2i+1}) \in F$, and all u_i's but u_1, u_{2s} are saturated vertices ($\deg_F(u_i) = f(u_i)$). If we start the search for y-values of all vertices equal to some positive constant, then y-values of unsaturated vertices remain equal. Since u_1, u_{2s} are both unsaturated vertices, we have $y(u_1) = y(u_{2s}) = -Cn^{2/3}$.

No blossoms. For bipartite graphs, we do not need to consider blossoms, so we can use the idea from [12, 5]. By approximate complementary slackness we know: $y(u_{2i-1}) + y(u_{2i}) \geq -2, y(u_{2i}) + y(u_{2i+1}) \leq 0$. Then we have $y(u_{2i+1}) - y(u_{2i-1}) \leq 2$, $y(u_{2s-1}) \geq Cn^{2/3}$. Consider the sequence of duals: $y(u_1), y(u_3), \cdots, y(u_{2s-1})$. This sequence starts with a small value $y(u_1) = -Cn^{2/3}$ but ends with a large value $y(u_{2s-1}) \geq Cn^{2/3}$, and so intuitively many of the differences $y(u_{2i+1}) - y(u_{2i-1})$ should be positive. However, given the upper bound $y(u_{2i+1}) - y(u_{2i-1}) \leq 2$, we would know many differences $y(u_{2i+1}) - y(u_{2i-1})$ can only belong to a very narrow range $\{1, 2\}$. In this case, since $y(u_{2i-1}) + y(u_{2i}) \geq -2, y(u_{2i}) + y(u_{2i+1}) \leq 0$, it must be $-1 - y(u_{2i+1}) \leq y(u_{2i}) \leq -y(u_{2i+1})$. In words, this augmenting walk contains an edge in $V_q \times V_{-q}$, where $V_x = \{|y(u) - x| \leq 1 \mid u \in V\}$, $q = y(u_{2i})$.

Since there are many different such pairs $y(u_{2i-1}), y(u_{2i+1})$, intuitively we can imagine this augmenting walk contains edges in $V_q \times V_{-q}$ for $\Omega(n^{2/3})$ different integer q's. If the number of augmenting walks is $\omega(n^{2/3})$, there will be $\Omega(n^{2/3})$ different $V_q \times V_{-q}$'s intersecting

$\omega(n^{2/3})$ augmenting walks each. By the pigeon-hole principle, there exists one such q such that $|V_q \cup V_{-q}| \leq O(n^{1/3})$. As G is a simple graph, the total number of edge-disjoint augmenting walks that contains an edge in $V_q \times V_{-q}$ is at most $|V_q \cup V_{-q}|^2 = O(n^{2/3})$, which comes to a contradiction.

Handling blossoms. The major difficulty for general graphs comes from the blossoms. We use the generalized blossoms introduced in [8], and utilize the blossom dissolution technique from [3], but it will become much more complicated for f-factors. To analyze the influence of blossoms, let us divide Ω into two categories: large and small. A blossom $B \in \Omega$ is large if $|B| \geq n^{1/3}$. For small blossoms, we know by definition, the total number of edges contained in any small blossoms is bounded by $n^{4/3}$. So if $F^* \oplus F$ contains $\geq Cn^{2/3}$ augmenting walks, then most augmenting walks contain $O(n^{2/3})$ small blossom edges. To restore the argument we discussed in previous paragraphs, we could safely remove those vertices incident to any edges belonging to small blossoms from the sequence $u_1, u_3, u_5, \cdots, u_{2s-1}$, and we could still work with a very long sequence of vertices that are not removed (if C is large).

As for large blossoms, we could prove that $\sum_{\text{large } B\in\Omega} z(B) \leq O(n^{4/3})$. Basically, this is because the total number of root large blossoms is always bounded by $n^{2/3}$, and so each round of Edmonds search could increase this sum by at most $n^{2/3}$, and therefore the algorithm could raise $\sum_{\text{large } B\in\Omega} z(B)$ to at most $Cn^{4/3}$ during $Cn^{2/3}$ executions of Edmonds search. Once we have a good handle of the total sum $\sum_{\text{large } B\in\Omega} z(B) \leq O(n^{4/3})$, we could argue that the "average influence" of large blossoms on each augmenting walk is bounded by $O(n^{2/3})$, if $F^* \oplus F$ has more than $Cn^{2/3}$ augmenting walks.

1.2 Structure of our paper

In Section 2 we define the notations and basic concepts we will use in the paper, while in Section 3 the algorithm is given. A brief analysis of the running time of the algorithm is given in Section 4. Due to page limit, many details of the proofs are omitted, which can be found in the full version of this paper.

2 Preliminaries

2.1 Notations

Our input is a weighted simple graph $G = (V, E, \omega)$ without self-loops and a function $f : V \to \mathbb{N}_+$. For $S \subseteq V$, define $f(S) = \sum_{v\in S} f(v)$, and let $\delta(S)$ and $\gamma(S)$ be sets of edges with exactly one endpoint and both endpoints in S, respectively, and $\delta(v)$ is an abbreviation for $\delta(\{v\})$. For any edge subset $F \subseteq E$, define $\delta_F(S) = \delta(S) \cap F$, $\omega(F) = \sum_{e\in F} \omega(e)$, and $\deg_F(u) = |F \cap \{(u, v) \in E\}|$. $F \subseteq E$ is called an f-factor if $\deg_F(u) \leq f(u)$ for all $u \in V$. For an f-factor F, the **deficiency** of u in F is defined as $f(u) - \deg_F(u)$ and u is **saturated** by F if $f(u) - \deg_F(u) = 0$. When all vertices are saturated, F is called a perfect f-factor. Edges in F are called **matching edges**. For a graph G and a subset of vertices U, $G[U]$ denotes the subgraph of G induced by U.

2.2 Blowup graphs

Instead of running on the original graph, our algorithm will be operating on an auxiliary weighted graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mu)$ which is called the *blowup graph.* $\mathcal{V}$ contains all original vertices in V. For each edge $e = (u, v)$ in the original graph, add two vertices e_u, e_v to $\mathcal{V}$ and add three edges $(u, e_u), (e_u, e_v), (e_v, v)$ to $\mathcal{E}$. All vertices in V are called *original* vertices, and the newly added vertices are called *auxiliary* vertices. Then assign $\mu(u, e_u) = \mu(v, e_v) = \omega(u, v)$, $\mu(e_u, e_v) = 0$ and $f(e_u) = f(e_v) = 1$.

The purpose of transferring original graph G to $\mathcal{G}$ is mainly to avoid edges contained in the sets $I(B)$ for disjoint blossoms B. (See subsection Blossom.) Note that the number of vertices in $\mathcal{G}$ is $n + 2m$, so we need to carefully analyze the running time. It is easy to see the following, whose proof is in the full version of this paper.

▶ **Lemma 2.** *Computing maximum weight perfect f-factor in G and $\mathcal{G}$ are equivalent.*

2.3 LP formulation

Computing maximum weight perfect f-factor on the blowup graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mu)$ can be expressed as a linear program [8]:

$$\begin{aligned}
\text{maximize} \quad & \sum_{e \in \mathcal{E}} \mu(e)x(e) \\
\text{subject to} \quad & \sum_{e \in \delta(v)} x(e) = f(v), \forall v \in \mathcal{V} \\
& \sum_{e \in \gamma(B) \cup I} x(e) \leq \left\lfloor \frac{f(B) + |I|}{2} \right\rfloor, \forall B \subseteq \mathcal{V}, I \subseteq \delta(B) \\
& 0 \leq x(e) \leq 1, \forall e \in \mathcal{E}
\end{aligned}$$

Its dual LP is written as the following.

$$\begin{aligned}
\text{minimize} \quad & \sum_{v \in \mathcal{V}} f(v)y(v) + \sum_{B \subseteq \mathcal{V}, I \subseteq \delta(B)} \left\lfloor \frac{f(B) + |I|}{2} \right\rfloor z(B, I) + \sum_{e \in \mathcal{E}} u(e) \\
\text{subject to} \quad & yz(e) + u(e) \geq \mu(e), \forall e \in \mathcal{E} \\
& z(B, I) \geq 0, u(e) \geq 0
\end{aligned}$$

Here $yz(u, v)$ is defined as: $yz(u, v) = y(u) + y(v) + \sum_{B, I : (u,v) \in \gamma(B) \cup I, I \subseteq \delta(B)} z(B, I)$.

2.4 Blossoms

We follow the definitions and the terminology of [8, 13] for f-factor blossoms. A blossom is specified by a tuple $(B, \mathcal{E}_B, \beta(B), \eta(B))$, where $B \subseteq \mathcal{V}$ is a subset of vertices, $\mathcal{E}_B \subseteq \mathcal{E}$ a subset of edges, $\beta(B) \in B$ a special vertex which is called the **base**, and $\eta(B)$ is either null or an edge from $\delta(\beta(B)) \cap \delta(B)$. Blossoms follow an inductive definition below.

▶ **Definition 3** (Blossom, [8, 13]). *A single vertex v forms a trivial blossom, also called a singleton. Here $B = \{v\}$, $\mathcal{E}_B = \emptyset$, $\beta(B) = v$, and $\eta(B)$ is null. Inductively, let $B_0, B_1, \cdots, B_{l-1}$ be a sequence of disjoint singletons or non-trivial blossoms. Suppose there exists a closed walk $C_B = \{e_0, e_1, \cdots, e_{l-1}\}$ starting and ending with B_0 such that $e_i \in B_i \times B_{i+1}$, ($B_l = B_0$). The vertex set $B = \bigcup_{i=0}^{l-1} B_i$ is identified as a blossom if the following are satisfied.*

1. *Base. If B_0 is a singleton, the two edges incident to B_0 on C_B, i.e., e_0 and e_{l-1}, must both be matched or both be unmatched.*
2. *Alternation. Fix a $B_i, i \neq 0$. If B_i is a singleton, exactly one of e_{i-1} and e_i is matched. If B_i is a non-trivial blossom, $\eta(B_i) = e_{i-1}$ or e_i.*

The edge set of the blossom B is $\mathcal{E}_B = C_B \cup (\cup_{i=0}^{l-1}\mathcal{E}_{B_i})$ and its base is $\beta(B) = \beta(B_0)$. If B_0 is not a singleton, $\eta(B) = \eta(B_0)$. Otherwise, $\eta(B)$ may either be null or one edge in $\delta(B) \cap \delta(B_0)$ that is the opposite type of e_0 and e_{l-1}.

A blossom is called **root blossom** if it is not contained in any other blossom. Blossoms have two different types: **light** and **heavy**. If B_0 is a singleton, B is light/heavy if e_0 and e_{l-1} are both unmatched/matched. Otherwise, B is light/heavy if B_0 is light/heavy.

▶ **Definition 4.** *Given an f-factor F, an alternating walk on $\mathcal{G}$ is a sequence of consecutive edges $(u_1, u_2), (u_2, u_3), \cdots, (u_{l-1}, u_l)$ such that:*

- *$(u_i, u_{i+1}) \in \mathcal{E}$ are different edges $1 \leq i < l$.*
- *exactly one of $(u_{i-1}, u_i), (u_i, u_{i+1})$ belongs to F, $1 < i < l$.*

This walk is called an augmenting walk if both $(u_1, u_2), (u_{l-1}, u_l) \notin F$.

When searching for an augmenting walk, a blossom behaves as a unit in the graph. These properties are formally stated by the following lemma.

▶ **Lemma 5** ([8, 13])**.** *Let v be an arbitrary vertex in B. There exists an even length alternating walk $P_0(v)$ and an odd length alternating walk $P_1(v)$ from $\beta(B)$ to v using edges in $\mathcal{E}_B$. Moreover, the terminal edge of $P_{0,1}(v)$ incident to $\beta(B)$ must have a different type than $\eta(B)$, if $\eta(B)$ is defined.*

We also introduce the notion of **maturity** of blossoms below.

▶ **Definition 6** (Mature Blossom, [8, 13])**.** *A blossom is mature with respect to an f-factor F if the following requirements are satisfied.*

1. *Every vertex $v \in B \setminus \{\beta(B)\}$ is saturated, namely $\deg_F(v) = f(v)$.*
2. *The deficiency of $\beta(B)$ is at most 1. Furthermore, if it is 1, then B must be a light blossom and $\eta(B)$ is null; otherwise, $\eta(B)$ is defined.*

Our algorithm always keeps a set Ω of mature blossoms and maintains a non-negative value $z(B)$ for each $B \in \Omega$. For each blossom B, define a set $I(B) \subseteq \delta(B)$ as $I(B) = \delta_F(B) \oplus \{\eta(B)\}$.

2.5 Augmenting path

To find augmentations, we need to work with the contraction graph $\widehat{\mathcal{G}}$ where every root blossom is contracted to a single node.

▶ **Definition 7** ([8, 13])**.** *Let F, Ω and $\widehat{\mathcal{G}}$ be an f-factor, a set of blossoms and the graph obtained by contracting every root blossom in the Ω, respectively. $\widehat{P} = \langle B_0, e_0, B_1, e_1, \cdots, B_l \rangle \in \widehat{\mathcal{G}}$ is called an augmenting path if the following requirements are satisfied.*

1. *The terminals B_0 and B_l must be unsaturated singletons or unsaturated light blossoms. If $\widehat{P}$ is a closed path ($B_0 = B_l$), B_0 must be a singleton and the deficiency of $\beta(B_0)$ is at least 2. Otherwise B_0 and B_l can be either singletons or blossoms and their deficiency must be positive.*
2. *If the terminal vertex B_0 (B_l) is a singleton, then the incident terminal edges e_0 (e_{l-1}) must be unmatched. Otherwise, they can be either matched or unmatched.*
3. *Let B_i, $0 < i < l$ be an internal singleton or blossom. If B_i is a singleton, then exactly one of e_{i-1} and e_i is matched. If B_i is a non-trivial blossom, then $\eta(B_i) = e_{i-1}$ or e_i.*

To avoid misunderstanding, we emphasize the difference between the augmenting path and the augmenting walk. First they are defined on $\widehat{\mathcal{G}}$ and $\mathcal{G}$ respectively. Second, an augmenting walk can pass through a vertex in $\mathcal{G}$ several times but an augmenting path can pass through a vertex in $\widehat{\mathcal{G}}$ (except the endpoint) only once. In the following parts, these two concepts are used in different scenarios.

Next we define a concept of the alternating path, which is weaker than the concept of the augmenting path.

▶ **Definition 8.** *Let F, Ω and $\widehat{\mathcal{G}}$ be an f-factor, a set of blossoms and the graph obtained by contracting every root blossom in the Ω. A simple path $\widehat{P} = \langle B_0, e_0, B_1, e_1, \cdots, B_l\rangle$ is called an alternating path if it satisfies the following requirements.*

1. *The terminals B_0 must be unsaturated singletons or unsaturated light blossoms.*
2. *If the terminal vertex B_0 is a singleton, then the incident terminal edges e_0 must be non-matching. Otherwise, they can be either matching or non-matching.*
3. *For each $1 \leq i < l$, if B_i is a singleton, then exactly one of e_{i-1}, e_i is matched. Otherwise, $\eta(B_i) = e_{i-1}$ or e_i.*

2.6 Complementary slackness

Throughout the algorithm, we will be maintaining an f-factor F, a set of mature blossoms Ω, dual functions $y : \mathcal{V} \to \mathbb{N}$, $z : \Omega \to \mathbb{N}_{\geq 0}$ and $yz : \mathcal{E} \to \mathbb{N}$. For an f-factor F, we define two kinds of complementary slackness: complementary slackness and approximate complementary slackness.

▶ **Definition 9** (Complementary Slackness). *In the blowup graph $\mathcal{G}$, an f-factor F, duals y, z, as well as a laminar family of blossoms Ω satisfy* complementary slackness *if the following requirements hold.*

1. *Dominance. For each $e \in \mathcal{E}$, $yz(e) \geq \mu(e)$.*
2. *Tightness. For each $e \in F$, $yz(e) = \mu(e)$.*

▶ **Definition 10** (Approximate Complementary Slackness). *In the blowup graph $\mathcal{G}$, an f-factor F, duals y, z, as well as a laminar family of blossoms Ω satisfy* approximate complementary slackness *if the following requirements hold.*

1. *Dominance. For each $e \in \mathcal{E}$, $yz(e) \geq \mu(e) - 2$.*
2. *Tightness. For each $e \in F$, $yz(e) \leq \mu(e)$.*

▶ **Lemma 11** ([13]). *Let F be a perfect f-factor associated with duals y, z and blossoms Ω, and define F^* to be a maximum weight perfect f-factor. Suppose F, Ω, y, z satisfy approximate complementary slackness, then*

$$\mu(F) \geq \mu(F^*) - f(\mathcal{V})$$

Proof. We first define $u : \mathcal{E} \to \mathbb{N}$ as

$$u(e) = \begin{cases} \mu(e) - yz(e), & \text{if } e \in F \\ 0, & \text{otherwise} \end{cases}$$

According to the approximate domination and tightness properties, we have $u(e) \geq 0$ for all $e \in \mathcal{E}$. Moreover, $yz(e) + u(e) \geq \mu(e) - 2$ for all $e \in \mathcal{E}$. This gives the following:

$$\begin{aligned}
\mu(F) &= \sum_{e\in F}(yz(e) + u(e)) = \sum_{v\in V} deg_F(v)y(v) + \sum_{B\in\Omega} |F \cap (\gamma(B) \cup I(B))|z(B) + \sum_{e\in F} u(e) \\
&= \sum_{v\in V} f(v)y(v) + \sum_{B\in\Omega} \left\lfloor \frac{f(B) + |I(B)|}{2} \right\rfloor z(B) + \sum_{e\in\mathcal{E}} u(e) \\
&\geq \sum_{v\in V} deg_{F^*}(v)y(v) + \sum_{B\in\Omega} |F^* \cap (\gamma(B) \cup I(B))|z(B) + \sum_{e\in F^*} u(e) \\
&\geq \sum_{e\in F^*} (\mu(e) - 2) \geq \mu(F^*) - f(\mathcal{V})
\end{aligned}$$ ◀

2.7 Edmonds search

In this subsection, we introduce two different implementations of Edmonds search. Suppose we have an f-factor F, a set of blossoms Ω, and duals y, z satisfying some kind of slackness condition. The purpose of Edmonds search is to reduce total deficiency of F by eligible augmenting paths. We need two different notions of eligibility, namely eligibility and approximate eligibility, compatible with Definition 9 or Definition 10.

▶ **Definition 12** (Eligibility, [8]). *An edge $e \in \mathcal{E}$ is eligible if $yz(e) = \mu(e)$.*

▶ **Definition 13** (Approximate Eligibility, [13]). *An edge $e \in E$ is approximately eligible if it satisfies one of the following.*

1. *$e \in \mathcal{E}_B$ for some $B \in \Omega$.*
2. *$e \notin F$ and $yz(e) = \mu(e) - 2$.*
3. *$e \in F$ and $yz(e) = \mu(e)$.*

Let $\widehat{\mathcal{G}_{\text{elig}}}$ be the subgraph of $\widehat{\mathcal{G}}$ consisting of eligible edges. A root blossom $B' \in \Omega$ is called reachable from an unsaturated root blossom B via an alternating path in $\widehat{\mathcal{G}_{\text{elig}}}$, if there is an alternating path that starts at B and ends at B'. To find augmenting paths and blossoms in $\widehat{\mathcal{G}_{\text{elig}}}$, we start from any unsaturated node u_0 in the contraction graph $\widehat{\mathcal{G}}$ and grow a search tree $\widehat{T}$ rooted at u_0; this method was also described in [8, 13]. All nodes in $\widehat{T}$ are classified as **outer/inner**. Initially the root is outer. Next we use a DFS-like approach to build the entire $\widehat{T}$. During the process, we keep track of a tree path $\langle u_0, e_0, u_1, \cdots, e_{l-1}, u_l\rangle$ from the root, which is guaranteed to be an alternating path. According to the type of u_l, the next edge e_l and node u_{l+1} are selected by the rules below:

1. u_l is outer. If u_l is a singleton, then scan the next non-matching edge e_l and find the other endpoint u_{l+1}. If u_l is a nontrivial blossom, then scan the next edge e_l and find the other endpoint u_{l+1}.
2. u_l is inner. If u_l is a singleton, then scan the next matching edge e_l and find the other endpoint u_{l+1}. If u_l is nontrivial blossom, then assign $e_l = \eta(u_l)$ (if it was not scanned before) and find the other endpoint u_{l+1}.

After finding u_{l+1}, we try to classify it as outer or inner: if u_{l+1} is a singleton, then u_{l+1} is outer if e_l is matched; otherwise, u_{l+1} is outer if $e_l = \eta(u_{l+1})$. Issues may arise if (1) u_{l+1} was already classified by previous tree searches and there is a conflict between the new label and the old label; or (2) u_{l+1} is an unsaturated then the tree search has found a new augmenting path. In either case we can construct a new blossom or reduce the total deficiency.

In the end, when all reachable singletons or root blossoms are classified as outer or inner, let $\widehat{\mathcal{V}}_{\text{out}}$ be the set of all outer singletons or root blossoms, and let $\widehat{\mathcal{V}}_{\text{in}}$ be the set of all inner singletons or root blossoms. Define $\mathcal{V}_{\text{out}}, \mathcal{V}_{\text{in}}$ to be the set of all vertices in $\mathcal{V}$ contained in outer and inner root blossoms, respectively. Next we introduce a meta procedure that will be a basic building block, which is dual adjustment. A dual adjustment performs the following step: decrement $y(v)$ for all $v \in \mathcal{V}_{\text{out}}$, and increment $y(v)$ for all $v \in \mathcal{V}_{\text{in}}$; after that, increment by 2 all $z(B)$ for all $B \in \widehat{\mathcal{V}}_{\text{out}}$, and decrement by 2 all $z(B)$ for all $B \in \widehat{\mathcal{V}}_{\text{in}}$. This is summarized as the AdjustDuals algorithm 1.

We introduce two different implementations of Edmonds search: the EdmondsSearch algorithm 2 and the PQ-Edmonds algorithm 3, which both rely on the AdjustDuals subroutine 1. The EdmondsSearch algorithm searches from all unsaturated root blossoms, and it requires that the y-values of all unsaturated vertices have the same parity. It reserves approximate complementary slackness under the approximate eligibility, so it only needs to perform one step of augmentation before dual-adjustment:

Algorithm 1 AdjustDuals(F, Ω, y, z).

```
classify every root blossom in $\Omega$ as outer or inner;
let $\widehat{\mathcal{V}_{\text{out}}}/\widehat{\mathcal{V}_{\text{in}}}$ be the set of all outer/inner root blossoms in $\widehat{\mathcal{G}_{\text{elig}}}$ including singletons;
  let $\mathcal{V}_{\text{out}}/\mathcal{V}_{\text{in}}$ be the set of all vertices in $\mathcal{V}$ contained in outer/inner root blossoms;
adjust the duals $y, z$ as follows:

    $y(v) \leftarrow y(v) - 1, v \in \mathcal{V}_{\text{out}}$
    $y(v) \leftarrow y(v) + 1, v \in \mathcal{V}_{\text{in}}$
    $z(B) \leftarrow z(B) + 2, \text{for non-singleton } B \in \widehat{\mathcal{V}_{\text{out}}}$
    $z(B) \leftarrow z(B) - 2, \text{for non-singleton } B \in \widehat{\mathcal{V}_{\text{in}}}$
```

Algorithm 2 EdmondsSearch(F, Ω, y, z).

```
/* Precondition:  y-values of unsaturated vertices must all be of the
   same parity                                                        */
find a maximal set $\widehat{\Psi}$ of a vertex-disjoint augmenting paths in $\widehat{\mathcal{G}_{\text{elig}}}$ and extend $\widehat{\Psi}$ to a
  set $\Psi$ of vertex-disjoint augmenting walks in $\mathcal{G}_{\text{elig}}$;
update $F \leftarrow F \oplus \bigcup_{P \in \Psi} P$;
find a maximal set $\Omega'$ of mature blossoms reachable from unsaturated vertices in $\widehat{\mathcal{G}_{\text{elig}}}$;
update $\Omega \leftarrow \Omega \cup \Omega'$ and $\widehat{\mathcal{G}_{\text{elig}}}$;
run AdjustDuals($F, \Omega, y, z$);
for every matching edge $(u, v)$ that does not satisfy the dominance condition, choose
  an auxiliary node $u$, $y(u) \leftarrow \mu(u, v) - y(v) - \sum_B z(B)$;
recursively remove all root blossoms whose dual values are zero;
```

▶ **Lemma 14** ([13]). *In the EdmondsSearch algorithm, after augmentation and blossom formation, $\widehat{\mathcal{G}_{elig}}$ does not contain any augmenting paths.*

Proof. Suppose that, after the augmentation and blossom formation, there is an augmenting path P in $\widehat{\mathcal{G}_{\text{elig}}}$. Since $\widehat{\Psi}$ is maximal, P must intersect some augmenting path $P' \in \widehat{\Psi}$ at a vertex v. However, after the augmentation and blossom formation every edge in P' will become ineligible, so the matching edge $(v, v') \in P$ is no longer in $\widehat{\mathcal{G}_{\text{elig}}}$, contradicting the fact that P consists of eligible edges. ◀

The PQ-Edmonds algorithm searches for augmenting paths only from a set U of unsaturated vertices whose y-values share the same parity, halting after finding an augmenting path from vertices in U or making D dual adjustments.

The following two lemmas describe the properties of the EdmondsSearch algorithm and the PQ-Edmonds algorithm[3] which are from [8, 13]. Their proofs are presented in the full version of this paper.

[3] In the original paper [8], their algorithm actually searches from all unsaturated root blossoms. This slack can be remedied by the following reduction. For each unsaturated vertex $v \notin U$, match v to $f(v) - \deg_F(v)$ new temporary vertices whose duals are equal to $-y(v)$ and the matching edges have zero weight. The proof is described in the full version of this paper.

Algorithm 3 PQ-Edmonds(F, Ω, y, z, U, D).

```
/* Precondition:  $\{y(u)|u \in U\}$ must all be of the same parity   */
while less than $D$ dual adjustments have been made so far do
    if an augmenting path $P$ from vertices in $U$ is found then
        update $F \leftarrow F \oplus P$;
        break;
    end
    find a maximal set $\Omega'$ of mature blossoms reachable from $U$ in $\widehat{\mathcal{G}_{\text{elig}}}$;
    update $\Omega \leftarrow \Omega \cup \Omega'$ and $\widehat{\mathcal{G}_{\text{elig}}}$;
    run AdjustDuals$(F, \Omega, y, z)$;
    recursively remove all root blossoms whose dual values are zero;
end
for every matching edge $(u, v)$ that does not satisfy the dominance condition, choose
  an auxiliary node $u$, $y(u) \leftarrow \mu(u, v) - y(v) - \sum_B z(B)$;
```

▶ **Lemma 15.** *The EdmondsSearch algorithm preserves* ***approximate complementary slackness*** *under the* ***approximate eligibility*** *definition. Furthermore, one execution can be implemented in $O(m)$ time.*

▶ **Lemma 16.** *The PQ-Edmonds algorithm preserves the* ***complementary slackness*** *under the* ***eligibility*** *definition. Furthermore, one execution can be implemented in $O(m \log n)$ time. Moreover, the $y(u)$ for unsaturated vertex u not in U will not be increased during the algorithm.*

3 The Scaling Algorithm

Our algorithm follows the idea of the scaling algorithm in [3] for maximum weight perfect matching. The scaling algorithm maintains an f-factor F, a family of blossoms Ω, as well as duals y, z, and it is divided into $\lceil \log(2f(\mathcal{V})W) \rceil$ iterations. Edge weights $\mu(e)$ are rescaled to $2f(\mathcal{V})\mu(e)$ and they all have $\lceil \log(2f(\mathcal{V})W) \rceil$ bits. Throughout the algorithm we assume y always assigns integer values and z always assigns even non-negative integers. For any $B \in \Omega$, B is called a *large blossom* if $|B \cap V| \geq n^{1/3}$, i.e., the number of original vertices in B is at least $n^{1/3}$; otherwise it is deemed a *small blossom*.

Let $\bar{\mu}$ be the edge weight function that keeps track of the scaled edge weights in each iteration. Initially before the first iteration, assign $F, \Omega = \emptyset$, $y, z, \bar{\mu} = 0$. At the beginning of each iteration, define F_0 to be the f-factor from the previous iteration. Empty the matching $F \leftarrow \emptyset$, and update weights and duals as following.

$$\bar{\mu}(e) \leftarrow 2\left(\bar{\mu}(e) + \text{the next bit of } 2f(\mathcal{V})\mu(e)\right)$$
$$y(u) \leftarrow 2y(u) + 3$$
$$z(B) \leftarrow 2z(B)$$

The whole procedure is shown in the Scaling algorithm 5, involving an important subroutine: the Dissolve algorithm 4. Note that here we only provide a stretch of the proof ideas, while the whole proofs can be found in the full version of this paper.

Algorithm 4 Dissolve(B, y, z, Ω).

```
for $u \in B$ or there exists $v \in B$ such that $(u, v) \in I(B)$ do
    $y(u) \leftarrow y(u) + z(B)/2$;
end
$z(B) \leftarrow 0$ and remove it from $\Omega$;
```

3.1 Correctness

In this subsection, we will show that the Scaling algorithm indeed returns the maximum weight perfect f-factor in G, and in the next subsection we will analyze its time complexity. Some proofs of the statements here are omitted and can be found in the full version of this paper.

Define $\zeta(B) = (e_u, e_v)$, if $(u, e_u) = \eta(B)$ and e_v is the auxiliary vertex adjacent to e_u. It is not hard to see that:

▶ **Lemma 17.** *For any blossom $B \in \Omega$ in $\mathcal{G}$, the edge $e \in \delta(B)$ has the form of (u, e_u) where $u \in B$ is an original vertex and e_u is an auxiliary vertex.*

▶ **Lemma 18.** *There are two properties right after the scaling step (Line 3-6):*
1. *For each $e \in \mathcal{E}$, $\bar{\mu}(e) \leq yz(e)$.*
2. *For each $e \in F_0$, $\bar{\mu}(e) \geq yz(e) - 6$.*

▶ **Lemma 19.** *There are two properties right after the blossom dissolution step (Line 7-15):*
1. *For each $(u, v) \notin F_0 \cup \bigcup_{i=1}^{l} \gamma(B_i) \cup I(B_i)$, $\bar{\mu}(u, v) \leq 0$.*
2. *For each $(u, v) \in \mathcal{E}$, $\bar{\mu}(u, v) \leq 2\min\{y(u), y(v)\}$.*

Proof. Let $\bar{\mu}_1, y_1, z_1, \Omega_1$ be the edge weights, duals and blossoms at the beginning of the step of blossom dissolution, respectively. Let $\Omega_1' \subseteq \Omega_1$ be the set of all blossoms that are dissolved in Line 7-9 before the step of reweighting. By Lemma 18: (Note that for auxiliary edges adjacent to edges in $I(B)$, blossom dissolution can only cause $\bar{\mu}(u, v)$ to become smaller.)

$$\begin{aligned}\bar{\mu}(u, v) &\leq \bar{\mu}_1(u, v) - y_1(u) - y_1(v) - \sum_{\substack{B \in \Omega_1' \\ (u,v) \in \gamma(B) \cup I(B)}} z_1(B) \\ &\leq yz_1(u, v) - y_1(u) - y_1(v) - \sum_{\substack{B \in \Omega_1' \\ (u,v) \in \gamma(B) \cup I(B)}} z_1(B) \\ &= \sum_{\substack{B \in \Omega_1 \setminus \Omega_1' \\ (u,v) \in \gamma(B) \cup I(B)}} z_1(B)\end{aligned}$$

The last term is zero when $(u, v) \notin \bigcup_{i=1}^{l} \gamma(B_i) \cup I(B_i)$.

Hence, by the end of the step of blossom dissolution,

$$y(u) = \frac{1}{2} \sum_{\substack{B \in \Omega_1 \setminus \Omega_1' \\ \exists (u,w) \in \gamma(B) \cup I(B)}} z_1(B) \geq \frac{1}{2} \sum_{\substack{B \in \Omega_1 \setminus \Omega_1' \\ (u,v) \in \gamma(B) \cup I(B)}} z_1(B) \geq \frac{1}{2}\bar{\mu}(u, v)$$

By symmetry, we can also prove $y(v) \geq \frac{1}{2}\bar{\mu}(u, v)$. Then $\bar{\mu}(u, v) \leq 2\min\{y(u), y(v)\}$. ◀

Next we study what happens during the step of augmentation within small blossoms. If a matching edge (u, e_u) is newly added to F in line 17, for some small blossom B_i, $(u, e_u) \in I_{F_0}(B_i) \setminus \{\eta(B_i)\}$. The following statements will be proved in the full version.

Algorithm 5 Scaling($\mathcal{V}, \mathcal{E}, \mu, f$).

```
1  $y, z \leftarrow 0,\ F, \Omega \leftarrow \emptyset$;
2  for $iter = 1, \cdots, \lceil \log(2f(\mathcal{V})W) \rceil$ do
       /* scaling                                                        */
3      $\bar{\mu}(e) \leftarrow 2\,(\bar{\mu}(e) + \text{the next bit of } 2f(\mathcal{V})\mu(e))$;
4      $y(u) \leftarrow 2y(u) + 3$;
5      $z(B) \leftarrow 2z(B)$;
6      $F_0 \leftarrow F,\ F \leftarrow \emptyset$;
       /* blossom dissolution (Line 7-15)                                */
7      while exists a large blossom $B \in \Omega$, or a root blossom $B$ with $z(B) \le 12$ do
8          run Dissolve($B, y, z, \Omega$);
9      end
10     $\bar{\mu}(u,v) \leftarrow \bar{\mu}(u,v) - y(u) - y(v), \forall (u,v) \in \mathcal{E}$;
11     $y(u) \leftarrow 0, \forall u \in \mathcal{V}$;
12     let $B_1, B_2, \cdots, B_l$ be all the root small blossoms not dissolved yet;
13     while exists a blossom $B \in \Omega$ do
14         run Dissolve($B, y, z, \Omega$);
15     end
       /* $\Omega$ now becomes empty.                                     */
       /* augmentation within small blossoms (Line 16-27)                */
16     if $(u,v) \in I_{F_0}(B_j) \setminus \{\eta(B_j)\}$ for some previous root small blossom $B_j$ then
17         $F \leftarrow F \cup \{(u,v)\}$;
18         if $u \in B_j, v \notin B_j$, $y(v) \leftarrow \bar{\mu}(u,v) - y(u)$;
19     end
20     for $i = 1, 2, \cdots, l$ do
21         while $\max\{y(u) \mid \deg_F(u) < f(u), u \in B_i\} > 6$ do
22             let $Y_1, Y_2$ be the largest and second largest $y$ values of unsaturated vertices
                in $B_i$;
23             define $U \subseteq B_i$ to be the set of unsaturated vertices whose $y$ values equal to
                $Y_1$;
24             define $H_i = \mathcal{G}[B_i \cup$ all the endpoints of $I_{F_0}(B_i) \setminus \{\eta(B_i)\}]$;
25             run PQ-Edmonds($F, \Omega, y, z, U, Y_1 - Y_2$) in subgraph $H_i$;
26         end
27     end
       /* deficiency reduction                                           */
28     run EdmondsSearch($F, \Omega, y, z$) on the entire graph $G$ for $\lceil Cn^{2/3} \rceil + 6$ times;
29 end
   /* weight adjustment                                                  */
30 for an edge $(u,v) \in \mathcal{E}$ such that $yz(u,v) < \mu(u,v)$ do
31     $\mu(u,v) \leftarrow yz(u,v)$;
32 end
   /* PQ-deficiency reduction                                            */
33 repeat PQ-Edmonds($F, \Omega, y, z, \{u \mid u \in \mathcal{V}$ is unsaturated$\}, \infty$) on the entire graph $G$
     until the total deficiency becomes zero;
```

- At the beginning of the step of augmentation within small blossoms, $\bar{\mu}(u, e_u) \geq y(u) + y(e_u) - 6$.
- After we have added (u, e_u) to F and reassigned $y(e_u) \leftarrow \bar{\mu}(u, e_u) - y(u)$, the complementary slackness is preserved. Plus, $y(e_u) \geq \frac{1}{2}\bar{\mu}(u, e_u) - 6$.
- Within the while-loop, for any $u \in B_i$ reachable via alternating paths from U, $y(u) \geq Y_1$. Plus, $y(e_u) \geq 0$ at any moment. Also from Lemma 16, the y-values of unsaturated vertices outside current U cannot increase.

Then we can conclude the correctness of the algorithm:

▶ **Lemma 20.** *The Scaling algorithm 5 returns a maximum weight perfect f-factor in G.*

Proof. First we claim that approximate complementary slackness is maintained until the step of weight adjustment (Line 30-32). By Lemma 19, the tightness of complementary slackness is satisfied after the step of blossom dissolution. For each edge e newly added to F, $yz(e) = \mu(e)$ and the dominance of complementary slackness is satisfied. For the edges in H_i, the PQ-Edmonds preserve complementary slackness by Lemma 16. For the edge (u, v) where u and v does not belong to any H_i, the duals does not change. For the edge (u, v) where $u \in H_i$ and v does not belong to any H_j, we have $\mu(u, v) \leq 0$, $\mu(u, v) \leq 2y(v)$ and $y(u) \geq 0$ by Lemma 19. The complementary slackness is maintained after the step of augmentation within small blossoms. Since complementary slackness is stronger than approximate complementary slackness and the EdmondsSearch algorithm preserves approximate complementary slackness by Lemma 15, approximate complementary slackness is maintained at the end of each iteration.

Let μ, μ' be the edge weights respectively before and after the step of weight adjustment on line 30-32. As y, z, μ, Ω satisfy approximate complementary slackness, y, z, μ', Ω satisfy complementary slackness, we know for each edge e, $\mu(e) - \mu'(e) \in [0, 2]$. Since PQ-Edmonds algorithm preserves complementary slackness by Lemma 16, complementary slackness is maintained with respect to edge weights μ' after Algorithm 5. Now, again by $\mu(e) - \mu'(e) \in [0, 2], \forall e \in \mathcal{E}$, we know, y, z, F, Ω still satisfy approximate complementary slackness with respect to μ after Algorithm 5 is completed.

After the step of PQ-deficiency reduction, the total deficiency becomes zero. Then, according to Lemma 11, $\mu(F^*) - \mu(F) \leq f(\mathcal{V})$. Since for every edge $e \in \mathcal{E}$, $\mu(e)$ is an integral multiple of $2f(\mathcal{V})$, therefore it must be $\mu(F) = \mu(F^*)$. Hence F is a maximum weight perfect f-factor of $\mathcal{G}$. ◀

4 Running Time Analysis

Recall that an alternating walk on $\mathcal{G}$ is a sequence of edges $(u_1, u_2), (u_2, u_3), \cdots, (u_{l-1}, u_l)$ such that: (1) $(u_i, u_{i+1}) \in \mathcal{E}$ are different edges; (2) exactly one of $(u_{i-1}, u_i), (u_i, u_{i+1})$ belongs to F, $1 < i < l$. And this walk is called an augmenting walk if both $(u_1, u_2), (u_{l-1}, u_l) \notin F$.

▶ **Lemma 21.** *The running time of each iteration is $\tilde{O}(mn^{2/3})$, thus $\tilde{O}(mn^{2/3} \log W)$ for all iterations.*

Proof. We analyze the running time of the t-th iteration, where $t \geq 1$. Clearly the scaling step and the blossom dissolution step only take linear time. By Lemma 15, the deficiency reduction step takes $\tilde{O}(mn^{2/3})$ in total. So the only technical part is the running time of the augmentations within small blossoms.

For each small blossom B_i, $|B_i \cap V|$, i.e. the number of original vertices in B_i, is less than $n^{1/3}$. According to the properties of the blowup graph, the number of vertices in B_i is $O(n^{2/3})$. When we add edges in $I_{F_0}(B_i) \setminus \{\eta(B_i)\}$ to F, the overall deficiency of vertices in

B_i is at most $1 + 3\binom{|B_i \cap V|}{2} < 1.5n^{2/3}$. After one execution of the PQ-Edmonds algorithm, the overall deficiency is reduced by one, or the largest y value of unsaturated vertices in B_i is equal to Y_2; the former case could happen at most $1.5n^{2/3}$ times, while the latter case could happen at most $|B_i| = O(n^{2/3})$ times since every time this case happens we add at least one more unsaturated vertex to U. Thus the PQ-Edmonds algorithm is invoked for at most $O(n^{2/3})$ times. By Lemma 16, for each small blossom B_i, each instance of the PQ-Edmonds algorithm takes $O(m(B_i) \log n)$ time, where $m(B_i)$ denotes the number of edges in B_i. Thus, the total running time of the augmentations within small blossoms is $\tilde{O}(mn^{2/3})$. ◀

Now we only need to analyze the running time for the PQ-deficiency reduction step at the end of the Scaling algorithm 5.

▶ **Lemma 22.** *Let F_t denote the f-factor at the end of the t-th scaling iteration. For any $t \geq 1$, $F_{t-1} \oplus F_t$ contains at most $O(n^{2/3})$ edge-disjoint augmenting walks in $\mathcal{G}$, where augmenting walks are w.r.t. F_t. (For the F_1, we can imagine an arbitrary perfect f-factor F_0, but do not need to compute it explicitly.)*

Then we can see the total deficiency of F_t is at most $O(n^{2/3}t)$ for any $t \geq 1$, and the overall running time of our algorithm is bounded by $\tilde{O}(mn^{2/3} \log W)$ by Lemma 16.

The rest of this subsection is devoted to the proof of Lemma 22 in the t-th iteration. With a slight abuse of notations, let $F_0 = F_{t-1}$ and $F = F_t$ and when talking about augmenting walks, we always mean augmenting walks in $F_0 \oplus F$ w.r.t. F. (F-edges are considered as matching edges and F_0-edges are considered as non-matching edges.) Let $\bar{\mu}_{\text{old}}, y_{\text{old}}, z_{\text{old}}, \Omega_{\text{old}}$ denote the edge weights, duals, and blossoms at the beginning of the blossom dissolution step, respectively; and let $\Omega_{\text{old}}^{\text{large}}$ be the set of all blossoms in Ω_{old} that were dissolved in the blossom dissolution phase before the reweighting step. Similarly, $\bar{\mu}, y, z, \Omega$ denote the edge weights, duals, and blossoms at the end of the t-th iteration, respectively; and Ω^{large} denotes the set of all large blossoms in Ω.

Instead of directly working with duals y, define variables $\widehat{y}$ for vertices as follows:

$$\widehat{y}(u) = y(u) + \frac{1}{2} \sum_{\substack{X \in \Omega^{\text{large}} \text{ s.t.} \\ \exists (u,v) \in \gamma(X) \cup I(X)}} z(X)$$

When $\eta(B) \in I(B)$, $\eta(B)$ is not a matching edge. Then $\zeta(B)$ may be a matching edge and its yz-value will increase by $z(B)/2$ after the dissolution of blossom B. (Recall that $\zeta(B) = (e_u, e_v)$, if $(u, e_u) = \eta(B)$.)

Consider any subwalk $\rho = \langle u_1, u_2, \cdots, u_{2s+1} \rangle$ of an augmenting walk in $F_0 \oplus F$ starting with an edge not in F. Then, for $1 \leq i \leq s$, since $(u_{2i-1}, u_{2i}) \notin F$ and $(u_{2i}, u_{2i+1}) \in F$, by approximate complementary slackness we have

$$y(u_{2i-1}) + y(u_{2i}) + \sum_{\substack{X \in \Omega \\ (u_{2i-1}, u_{2i}) \in \gamma(X) \cup I(X)}} z(X) \quad \geq \quad \bar{\mu}(u_{2i-1}, u_{2i}) - 2 \tag{1}$$

$$y(u_{2i}) + y(u_{2i+1}) + \sum_{\substack{X \in \Omega \\ (u_{2i}, u_{2i+1}) \in \gamma(X) \cup I(X)}} z(X) \quad \leq \quad \bar{\mu}(u_{2i}, u_{2i+1}) \tag{2}$$

Plugging in the definition of $\widehat{y}$, we get:

$$\widehat{y}(u_{2i-1}) + \widehat{y}(u_{2i}) + \sum_{\substack{X \in \Omega \setminus \Omega^{\text{large}} \\ (u_{2i-1}, u_{2i}) \in \gamma(X) \cup I(X)}} z(X) \geq \bar{\mu}(u_{2i-1}, u_{2i}) - 2 \tag{3}$$

and since $(u_{2i}, u_{2i+1}) \in F$, we have:

$$\widehat{y}(u_{2i}) + \widehat{y}(u_{2i+1}) = y(u_{2i}) + y(u_{2i+1}) + \sum_{\substack{X\in\Omega^{\text{large}}\\(u_{2i},u_{2i+1})\in\gamma(X)\cup I(X)}} z(X) + \frac{1}{2}\sum_{\substack{X\in\Omega^{\text{large}}\\(u_{2i},u_{2i+1})\in\{\eta(X),\zeta(X)\}}} z(X)$$

$$\widehat{y}(u_{2i}) + \widehat{y}(u_{2i+1}) + \sum_{\substack{X\in\Omega\setminus\Omega^{\text{large}}\\(u_{2i},u_{2i+1})\in\gamma(X)\cup I(X)}} z(X) \le \bar{\mu}(u_{2i}, u_{2i+1}) + \frac{1}{2}\sum_{\substack{X\in\Omega^{\text{large}}\\(u_{2i},u_{2i+1})\in\{\eta(X),\zeta(X)\}}} z(X)$$

Taking a subtraction we have

$$\begin{aligned}\widehat{y}(u_{2i+1}) - \widehat{y}(u_{2i-1}) \le 2 + \bar{\mu}(u_{2i}, u_{2i+1}) - \bar{\mu}(u_{2i-1}, u_{2i}) + \frac{1}{2}\sum_{\substack{X\in\Omega^{\text{large}}\\(u_{2i},u_{2i+1})\in\{\eta(X),\zeta(X)\}}} z(X)\\ + \sum_{\substack{X\in\Omega\setminus\Omega^{\text{large}}\\(u_{2i-1},u_{2i})\in\gamma(X)\cup I(X)}} z(X) - \sum_{\substack{X\in\Omega\setminus\Omega^{\text{large}}\\(u_{2i},u_{2i+1})\in\gamma(X)\cup I(X)}} z(X)\end{aligned} \tag{4}$$

By the derivation presented in Lemma 19,

$$\begin{aligned}\bar{\mu}(u_{2i}, u_{2i+1}) \le yz_{\text{old}}(u_{2i}, u_{2i+1}) - y_{\text{old}}(u_{2i}) - y_{\text{old}}(u_{2i+1}) - \sum_{\substack{X\in\Omega^{\text{large}}_{\text{old}}\\(u_{2i},u_{2i+1})\in\gamma(X)\cup I(X)}} z_{\text{old}}(X)\\ = \sum_{\substack{X\in\Omega_{\text{old}}\setminus\Omega^{\text{large}}_{\text{old}}\\(u_{2i},u_{2i+1})\in\gamma(X)\cup I(X)}} z_{\text{old}}(X)\end{aligned} \tag{5}$$

Now, as $(u_{2i-1}, u_{2i}) \in F_0$, again by Lemma 18 we are able to prove:

$$\bar{\mu}(u_{2i-1}, u_{2i}) \ge -6 + \sum_{\substack{X\in\Omega_{\text{old}}\setminus\Omega^{\text{large}}_{\text{old}}\\(u_{2i-1},u_{2i})\in\gamma(X)\cup I(X)}} z_{\text{old}}(X) - \frac{1}{2}\sum_{\substack{X\in\Omega^{\text{large}}_{\text{old}}\\(u_{2i-1},u_{2i})\in\{\eta(X),\zeta(X)\}}} z_{\text{old}}(X) \tag{6}$$

So for (u_{2i-1}, u_{2i}) not an η-edge or ζ-edge for old large blossoms,

$$\bar{\mu}(u_{2i-1}, u_{2i}) \ge -6 \tag{7}$$

Also define the function Z for an augmenting walk ρ as:

$$\mathrm{Z}(\rho) = \frac{1}{2}\sum_{\substack{e\in\rho, X\in\Omega\\e\in\{\eta(X),\zeta(X)\}}} z(X) + \frac{1}{2}\sum_{\substack{e\in\rho, X\in\Omega_{\text{old}}\\e\in\{\eta(X),\zeta(X)\}}} z_{\text{old}}(X)$$

Let $\widehat{F}, \widehat{\Omega}, \widehat{z}$ denote any f-factor together with a compatible set of blossoms as well as their duals, and let ρ be an arbitrary alternating walk. For any blossom $X \in \widehat{\Omega}$, define the following quantity:

$$\mathrm{Diff}(\rho, X, \widehat{F}) \overset{\text{def}}{=} |\rho \cap \widehat{F} \cap (\gamma(X) \cup I(X))| - |\rho \cap (\gamma(X) \cup I(X)) \setminus \widehat{F}|$$

By a summation of (4) plugging in (5) and (6) over all $1 \le i \le s$,

$$\begin{aligned}\widehat{y}(u_{2s+1}) - \widehat{y}(u_1) \le & 8s + \mathrm{Z}(\rho) - \sum_{X\in\Omega\setminus\Omega^{\text{large}}} z(X)\cdot \mathrm{Diff}(\rho, X, F)\\ & - \sum_{X\in\Omega_{\text{old}}\setminus\Omega^{\text{large}}_{\text{old}}} z_{\text{old}}(X)\cdot \mathrm{Diff}(\rho, X, F_0)\end{aligned} \tag{8}$$

We consider augmenting walks $\rho = \langle u_1, u_2, \cdots, u_{2s}\rangle$ in $F_0 \oplus F$ starting and ending with edges not equal to $\eta(X)$ or $\zeta(X)$ for all $X \in \Omega^{\text{large}} \cup \Omega^{\text{large}}_{\text{old}}$, and u_1, u_{2s} are not equal to $\beta(X)$ for all $X \in \Omega^{\text{large}} \cup \Omega^{\text{large}}_{\text{old}}$. This only excludes $O(n^{2/3})$ augmenting walks. Thus, $\widehat{y}(u_1) = \widehat{y}(u_{2s}) = -Cn^{2/3}$. For convenience, we only consider augmenting walks starting and ending with non-matching edges ($\notin F$) not in $\gamma(X) \cup I(X)$ for current small blossoms X, otherwise we can just choose the first and last such edges on every augmenting walk and consider the subwalk between them, and we can get similar results.

In an augmenting walk satisfying those conditions, since its first and last edges are in F_0 and not equal to η or ζ edges of old large blossoms, $\bar{\mu}(u_{2s-1}, u_{2s}) \geq -6$, and also (u_{2s-1}, u_{2s}) cannot be in a large blossom, by (1) we have $\widehat{y}(u_{2s-1}) \geq -\widehat{y}(u_{2s}) - 8 = Cn^{2/3} - 8$. Then by (8), if $\mathrm{Z}(\rho)$ is less than $n^{2/3}$, and $\mathrm{Diff}(\rho, X, F)$ and $\mathrm{Diff}(\rho, X, F_0)$ are non-negative, then we can see the length of such an augmenting walk is $\Omega(n^{2/3})$ when C is a large constant. We have the following statement for $\mathrm{Diff}(\rho, X, F)$ and $\mathrm{Diff}(\rho, X, F_0)$, which is proven in the full version.

▶ **Lemma 23.** *Consider any blossom $X \in \Omega \cup \Omega_{old}$ and any augmenting walk ρ in $F_0 \oplus F$, in any maximal consecutive subwalk of $\rho \cap (\gamma(X) \cup I(X))$, the number of matching edges is at least the number of non-matching edges. (For $X \in \Omega$, edges in F are matching edges, and for $X \in \Omega_{old}$, edges in F_0 are matching edges.)*

So $\mathrm{Diff}(\rho, X, F)$ and $\mathrm{Diff}(\rho, X, F_0)$ are both nonnegative. It is also not hard to see the following observations:

- For old and new large blossoms, $\sum_{B \in \Omega^{\text{large}}_{\text{old}}} z_{\text{old}}(B)$ and $\sum_{B \in \Omega^{\text{large}}} z(B)$ are both $O(n^{4/3})$. This is because the number of root large blossoms at a given time are bounded by $O(n^{2/3})$ and large blossoms can only be formed and dual-adjusted in the $O(n^{2/3})$ EdmondsSearch steps in the deficiency reduction step.
- The total number of non-matching edges in $\gamma(B) \cup I(B)$ for all small blossoms B is bounded by $O(n^{4/3})$, that is, $\sum_{B \in \Omega \setminus \Omega^{\text{large}}} |(\gamma(B) \cup I(B)) \setminus F|$ and $\sum_{B \in \Omega_{\text{old}} \setminus \Omega^{\text{large}}_{\text{old}}} |(\gamma(B) \cup I(B)) \setminus F_0|$ are both $O(n^{4/3})$. This is because the number of edges in $\gamma(B)$ for every blossom B is bounded by $O(|B|^2)$, the size of root small blossoms is less than $n^{1/3}$, and every root blossom has at most one non-matching edge in $I(B) \setminus \gamma(B)$,

Therefore, if we assume the number of augmenting walks in $F_0 \oplus F$ is larger than $K \cdot n^{2/3}$ for a large constant K, then we still have $\Omega(n^{2/3})$ augmenting walks ρ satisfying the following conditions:

(a) Starting and ending with edges not equal to η-edge or ζ-edge for all old large blossoms.
(b) Starting and ending with vertices not equal to the base for all old large blossoms.
(c) $\mathrm{Z}(\rho) < n^{2/3}$
(d) The total number of non-matching edges on ρ in $\gamma(X) \cup I(X)$ for all old and new small blossoms X is less than $n^{2/3}$. As in Lemma 23, the number of maximal consecutive subwalks in $\rho \cap (\gamma(X) \cup I(X))$ containing those edges is also bounded by $n^{2/3}$. We call all the edges in such subwalks “skip edges”.

Among vertices $u_1, u_2, \cdots, u_{2s-1}$, we pick the vertices with odd subscript which are original vertices in G, plus the two endpoints, and obtain the list: $u_1 (= v_1), u_p (= v_2), u_{p+6} (= v_3), \cdots, u_{p+6q} (= v_{q+2}), u_{2s-1} (= v_{q+3})$, where p is 3,5 or 7. Consider all the differences $\widehat{y}(v_{i+1}) - \widehat{y}(v_i)$ for $i = 1, \cdots, q+2$. For the subwalk $[v_i, v_{i+1}]$ in ρ containing skip edges or the η or ζ-edges of old or new large blossoms, the sum of the differences $\widehat{y}(v_{i+1}) - \widehat{y}(v_i)$ is at most $O(n^{2/3})$, by (c),(d) and Lemma 23. For subwalk $[v_i, v_{i+1}]$ in ρ which does not contain skip edges or η or ζ-edges, from (4), $\widehat{y}(u_{2j+1}) - \widehat{y}(u_{2j-1}) \leq 8$ for (u_{2j+1}, u_{2j-1}) in the subwalk, so $\widehat{y}(v_{i+1}) - \widehat{y}(v_i) \le 24$, Since the sum of all $\widehat{y}(v_{i+1}) - \widehat{y}(v_i)$ is $\widehat{y}(u_{2s-1}) - \widehat{y}(u_1)$, which is at least $2Cn^{2/3}$, if C is a large constant, the number of subwalks $[v_i, v_{i+1}]$ in ρ which does not contain skip edges or η, ζ-edges and satisfies $0 < \widehat{y}(v_{i+1}) - \widehat{y}(v_i) \le 24$ is $\Omega(n^{2/3})$. Moreover, there are $\Omega(n^{2/3})$ different values of $\widehat{y}(v_i)$ in ρ. When v_i is not u_1 and v_{i+1} is not u_{2s-1}, then $v_i = u_{p+6k}$ and $v_{i+1} = u_{p+6k+6}$. Then we can see $\widehat{y}(u_{p+6k+2}) - \widehat{y}(u_{p+6k})$, $\widehat{y}(u_{p+6k+4}) - \widehat{y}(u_{p+6k+2})$ and $\widehat{y}(u_{p+6k+6}) - \widehat{y}(u_{p+6k+4})$ are at most 8, and also by (1),(2),(7) and Lemma 19, (remember p is odd)

$$\widehat{y}(u_{p+6k+3}) + \widehat{y}(u_{p+6k+4}) \le 0$$
$$\widehat{y}(u_{p+6k+2}) + \widehat{y}(u_{p+6k+3}) \ge -8$$

So we have $\widehat{y}(u_{p+6k+3}) \ge -\widehat{y}(u_{p+6k}) - 16$ and $\widehat{y}(u_{p+6k+3}) \le -\widehat{y}(u_{p+6k+6}) + 8 < -\widehat{y}(u_{p+6k}) + 8$. Note that u_{p+6k} and u_{p+6k+3} are original vertices in G, and their $\widehat{y}$-values are $\ge -Cn^{2/3}$, so their $\widehat{y}$-values are also $< Cn^{2/3} + 8$.

Given an interval $[a, b]$ of integers, define $V_{[a,b]} = \{v \in V | \widehat{y}(v) \in [a, b]\}$. For an edge $(u, v) \in E$ such that $u \in V_{[a,b]}$ and $v \in V_{[a',b']}$, we say the auxiliary edges $(u, e_u), (e_u, e_v), (e_v, v)$ are "between" the pair of intervals $[a, b]$ and $[a', b']$. If we divide the original vertices in G by their $\widehat{y}$-values into intervals of length 48, then every augmenting walk we consider will go through auxiliary edges between $\Omega(n^{2/3})$ pairs of intervals of the form $[a, a+48], [-a, -a+48]$. Any constant fraction of those $\Theta(n^{2/3})$ pairs of intervals contains $O(n^{1/3})$ vertices each, so there are at most $O(n^{2/3})$ auxiliary edges between any of such pair of intervals. Thus the number of augmenting walks satisfying (a),(b),(c),(d) is bounded by $O(n^{2/3})$.

The Outer Limits of Contention Resolution on Matroids and Connections to the Secretary Problem

Abstract

Contention resolution schemes have proven to be a useful and unifying abstraction for a variety of constrained optimization problems, in both offline and online arrival models. Much of prior work restricts attention to product distributions for the input set of elements, and studies contention resolution for increasingly general packing constraints, both offline and online. In this paper, we instead focus on generalizing the input distribution, restricting attention to matroid constraints in both the offline and online random arrival models. In particular, we study contention resolution when the input set is arbitrarily distributed, and may exhibit positive and/or negative correlations between elements. We characterize the distributions for which offline contention resolution is possible, and establish some of their basic closure properties. Our characterization can be interpreted as a distributional generalization of the matroid covering theorem. For the online random arrival model, we show that contention resolution is intimately tied to the secretary problem via two results. First, we show that a competitive algorithm for the matroid secretary problem implies that online contention resolution is essentially as powerful as offline contention resolution for matroids, so long as the algorithm is given the input distribution. Second, we reduce the matroid secretary problem to the design of an online contention resolution scheme of a particular form.

1 Introduction

The notion of a contention resolution scheme (CRS) abstracts a familiar task in constrained optimization: converting a (random) set-valued solution which is *ex-ante* (i.e., on average) feasible for a packing problem to one which is *ex-post* (i.e., always) feasible. Unlike randomized rounding algorithms more broadly, which in general may be catered to both the constraint and objective function at hand, a contention resolution scheme is specific only to the constraints of the problem, and preserves solution quality in a manner which is largely agnostic to the objective function[1] – element by element. Since they were formalized by Chekuri et al [10], CRSs have been connected to a variety of online and offline computational tasks, including rounding the solutions of mathematical programs [10], online mechanism design and stochastic probing [17, 1], and prophet inequalities [17, 25].

[1] In its most general form, a CRS approximately preserves all linear objective functions simultaneously, whereas a *monotone* CRS approximately preserves all submodular objectives [10].

Starting with [10], prior work defines an (offline) contention resolution scheme for a set system $(\mathcal{E}, \mathcal{I})$ – where $\mathcal{E}$ is a *ground set* of *elements* and $\mathcal{I} \subseteq 2^{\mathcal{E}}$ is a downwards-closed family of *feasible sets* – as an algorithm which takes as input the marginal probabilities $x \in [0,1]^{\mathcal{E}}$ of a product distribution $\mathcal{D}$ supported on $2^{\mathcal{E}}$ as well as a random set $R \sim \mathcal{D}$ of *active elements*, and must output a feasible subset S of R. The contention resolution scheme is α-competitive if $\mathbf{Pr}[i \in S] \geq \frac{1}{\alpha} \mathbf{Pr}[i \in R]$ holds for all product distributions of interest – typically those with marginals x in the convex hull of indicator vectors of $\mathcal{I}$ (ex-ante feasibility). In *online* contention resolution schemes, first explored by Feldman et al [17] and subsequently by Adamczyk and Włodarczyk [1] and Lee and Singla [25], the active elements R arrive sequentially and the decision to include an element in S must irrevocably be made online.

The existing literature on (offline and online) contention resolution has mostly restricted attention to ex-ante-feasible and given product distributions, and varied the set system (e.g. matroids, knapsacks, and their intersections), all the while drawing connections to applications such as stochastic online problems, approximation algorithms, mechanism design, and prophet inequalities. In this paper, we restrict our attention to matroid constraints,[2] and instead focus on generalizing the class of input distributions. Our main goal is to understand the power and limitations of contention resolution, offline and online, in the presence of correlations in the input distribution and without regard to ex-ante feasibility. A secondary goal is to understand how knowledge of the distribution influences contention resolution. In pursuit of both goals, we draw connections between contention resolution and the secretary problem on matroids, shedding light on challenges posed by the matroid secretary conjecture in the process.

Results

Our first set of results develops an understanding of offline contention resolution on matroids. We begin with a characterization of the class of *α-uncontentious distributions*: those distributions $\mathcal{D} \in \Delta(2^{\mathcal{E}})$ permitting α-competitive offline contention resolution for a given matroid. Most notably, we show that a distribution is α-uncontentious if and only if it satisfies a family of $2^{|\mathcal{E}|}$ inequalities, one for each subset of the ground set. Moreover, we observe that our inequality characterization is the natural generalization of the *matroid base covering theorem* (see e.g. [31]) from covering a set of elements to covering a distribution over sets of elements. In other words, we show that *contention resolution is the natural distributional generalization of base covering.* Leveraging our characterization, we establish some basic closure properties of the class of uncontentious distributions, and present some examples of uncontentious distributions exhibiting negative and positive correlation between elements. Finally, we examine whether knowledge of the distribution $\mathcal{D}$ is essential to contention resolution, and exhibit an impossibility result: any contention resolution scheme which has nontrivial guarantees for all α-uncontentious distributions cannot be *prior-independent*, in that it cannot make do with a finite number of samples from the distribution, even for very simple matroids.

Our second set of results concerns online contention resolution on matroids in the random arrival model, and in particular its connection to the matroid secretary problem. First, we show that a competitive secretary algorithm for a matroid implies that online contention resolution is essentially as powerful as offline contention resolution for that same matroid: a γ-competitive secretary algorithm implies that any α-uncontentious distribution permits $\gamma\alpha$-competitive online contention resolution.

[2] Though some of our results hold beyond matroids; we discuss those in the conclusion section.

Second, we provide evidence that contention resolution might hold the key to resolving the matroid secretary conjecture. As our most technically-involved result, we leverage our characterization of uncontentious distributions to show that the random set of *improving elements* in a weighted matroid – as originally defined by Karger [20] – is $O(1)$-uncontentious. Since the improving elements can be recognized online, and moreover hold a constant fraction of the weighted rank of the matroid in expectation, our result can be loosely interpreted as a reduction from the matroid secretary problem to online contention resolution for a particular uncontentious distribution. There is one major caveat to this interpretation of our result, however: not only does the set of active (improving) elements arrive online, but so does the description of the uncontentious distribution from which that set is drawn. Though we present our proof of this result in an elementary form, the underlying arguments are reminiscent of – and inspired by – those often encountered in the analysis of martingales: we condition on carefully-chosen random variables, and employ a delicate charging argument between different probability events.

Third, in response to feedback on the previous version of this manuscript, we show that our aforementioned result – that improving elements are uncontentious – cannot be derived as a consequence of prior work.

Additional Discussion of Related Work

Contention Resolution Schemes

Contention resolution schemes were introduced by Chekuri et al [10], motivated by the problem of maximizing a submodular function subject to packing constraints. In particular, offline CRS were used to transform a randomized rounding algorithm which respects the packing constraints ex-ante to one which respects them ex-post, at the cost of the competitive ratio of the CRS. Their focus – like that of all related work prior to ours – was on product input distributions, in which case the optimal competitive ratio of an offline CRS was shown to equal the worst-case *correlation gap* (first studied by [2, 7]) of the weighted rank function associated with the packing constraint. The characterization result of [10] result forms the basis for ours.

Online contention resolution was first studied by Feldman et al [17], and applied to a number of online selection problems. They show that simple packing constraints – such as matroids, knapsacks, and matchings – permit constant competitive online contention resolution schemes even when elements arrive in an unknown and adversarial order. Moreover, they show how to combine competitive online schemes for different constraints in order to yield competitive online schemes for their intersection. Lee and Singla [25] obtain optimal online CRS in both the known adversarial-order model as well as the random-arrival model. Adamczyk and Włodarczyk [1] restrict attention to the random-arrival model, and obtain a particularly elegant algorithm and argument based on martingales, as well as improved competitive ratios for intersections of matroids and knapsacks.

Prophet Inequalities

Contention resolution is intimately tied to *prophet inequality* problems, also known as *Bayesian online selection* problems. In the traditional model for these problems, independent real-valued random variables with known distributions arrive online in a known but adversarial order, and the goal is to select a subset of the variables with maximum sum, subject to a packing constraint. An α-competitive algorithm for a Bayesian online selection problem is also referred to as a prophet inequality with ratio α, for historical reasons. Krengel, Sucheston, and Garling [22, 23] proved the first (classical) single-choice prophet inequality with ratio 1/2 for selecting a single variable (i.e., a 1-uniform matroid packing constraint). Motivated by applications in algorithmic mechanism design, more recent work (e.g. [18, 3, 8, 32]) pursued prophet inequalities for more general packing constraints. Of particular note is the work of Kleinberg and Weinberg [21], who proved an optimal prophet inequality with ratio 1/2 for matroids. Also notable is polylogarithmic prophet inequality for general packing constraints due to Rubinstein [28]. The (easier) variant of Bayesian online selection problems in which the variables arrive in a uniformly random order has also received recent interest, resulting in improved prophet inequalities for various packing constraints [15, 14, 5].

It was shown by Feldman et al [17] that an online CRS yields a prophet inequality with the same competitive ratio, and in the same arrival model. A weak converse is also true, as shown by Lee and Singla [25]: a stronger form of prophet inequality – in particular one which competes against the *ex-ante relaxation* of the Bayesian online selection problem – yields an online CRS with the same competitive ratio and in the same arrival model.

Beyond Known Product Distributions

The vast majority of work on contention resolution or prophet inequalities, and all such work discussed thus far, restricts attention to known product distributions, and crucially exploits the product structure and knowledge of the distribution. We note the few exceptions next.

Rinott et al [27] and Samuel-Cahn [29] show that the single-choice prophet inequality, and some slight generalizations, continue to hold for negatively dependent random variables. It is known [19] that there is no single-choice prophet inequality with ratio better than the number of variables in the presence of arbitrary positive correlation. Moreover, we are unaware of any nontrivial positive results for a class of distributions exhibiting positive correlation, in either prophet inequality or contention resolution models. We note that whereas [25] and [1] use specially-crafted correlated distributions as benchmarks, their results and techniques do not appear to shed light on contention resolution or prophet inequalities in the presence of correlation more generally.

Some work has relaxed the requirement that the distributions be known in prophet inequality problems. Azar et al [4] study prophet inequality problems when only a single sample is given from each distribution, and obtain constant competitive ratios for a variety of constraints. Wang [30] obtains an optimal algorithm for the single-choice prophet inequality, with ratio 1/2, in the same single-sample model. Correa et al [11] study the single-choice prophet inequality with i.i.d. variables drawn from an unknown distribution, and characterize the relationship between the competitive ratio and the number of samples available from the distribution.

Secretary Problems

In a *generalized secretary problem*, a set of adversarially chosen variables arrive online in a random order, and the goal is to select a subset of the variables with maximum sum subject to a packing constraint. The (classical) single-choice *secretary problem*, corresponding to a 1-uniform matroid constraint, was introduced and solved by Dynkin [13]. The *matroid secretary problem* was introduced by Babaioff et al [6], and has since spawned a long line of work. Constant-competitive algorithms have been discovered for most natural matroids and for some alternative models – see [12] for a semi-recent survey – though the general conjecture remains open. The state of the art for the general matroid secretary problem is a $O(\log\log \mathbf{rank})$-competitive algorithm due to Lachish [24], which was henceforth simplified by Feldman et al [16].

2 Preliminaries

2.1 Matroid Theory Basics

We use standard definitions from matroid theory; for details see [26, 31]. A matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ consists of a *ground set* $\mathcal{E}$ of *elements*, and a family $\mathcal{I} \subseteq 2^{\mathcal{E}}$ of *independent sets*, satisfying the three *matroid axioms*. A *weighted matroid* $(\mathcal{M}, w)$ consists of a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ together with weights $w \in \mathbb{R}^{\mathcal{E}}$ on the elements. We use the standard notions of a *dependent set*, *circuit*, *flat*, and *minor* in a matroid. We denote the *rank* of a matroid $\mathcal{M}$ as $\mathbf{rank}(\mathcal{M})$, and the rank of a set of elements A in $\mathcal{M}$ as $\mathbf{rank}_{\mathcal{M}}(A)$, or $\mathbf{rank}(A)$ when $\mathcal{M}$ is clear from context. Overloading notation, we use $\mathbf{rank}_w^{\mathcal{M}}(A)$ to denote the *weighted rank* of a set A – the maximum weight of an independent subset of A – in the weighted matroid $(\mathcal{M}, w)$, though we omit the superscript $\mathcal{M}$ when the matroid is clear from context. We note that both rank and weighted rank are submodular set functions on the ground set of the matroid. For $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ and $A \subseteq \mathcal{E}$, we denote the *restriction* of $\mathcal{M}$ to A as $\mathcal{M}|A$, *deletion* of A as $\mathcal{M} \setminus A$, and *contraction* by A as $\mathcal{M}/A$.

When $\mathcal{E}$ is clear from context, and $S \subseteq \mathcal{E}$, we use $\mathbf{1}_S \in \{0,1\}^{\mathcal{E}}$ to denote the vector indicating membership in S. We often reference the *matroid polytope* $\mathcal{P}(\mathcal{M})$ of a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$, defined as the convex hull of $\{\mathbf{1}_S : S \in \mathcal{I}\}$, or equivalently as the family of $x \in [0,1]^{\mathcal{E}}$ satisfying $\sum_{i \in S} x_i \leq \mathbf{rank}_{\mathcal{M}}(S)$ for all $S \subseteq \mathcal{E}$.

Throughout this paper we assume that any weighted matroid has distinct weights. This assumption is made merely to simplify some of our proofs, and – using standard tie-breaking arguments – can be shown to be without loss of generality in as much as our results are concerned. Under this assumption, we define $\mathbf{OPT}_w^{\mathcal{M}}(A)$ as the (unique) maximum-weight independent subset of A of minimum cardinality (excluding zero-weight elements), and we omit the superscript when the matroid is clear from context.

2.2 The Matroid Secretary Problem

In the *matroid secretary problem*, originally defined by [6] there is matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ with nonnegative weights $w : \mathcal{E} \to \mathbb{R}_+$ on the elements. Elements $\mathcal{E}$ arrive online in a uniformly random order Π, and an online algorithm must irrevocably accept or reject an element when it arrives, subject to accepting an independent set of $\mathcal{M}$. The algorithm is given $\mathcal{M}$ at the outset (as an independence oracle), but the weights w are chosen adversarially before the order Π is drawn and then are revealed online. The goal of the online algorithm is to maximize the expected weight of the accepted set of elements. We say that an algorithm is *α-competitive* for a class of matroids if for every matroid $\mathcal{M}$ in that class and every adversarial choice of w, the expected weight of the accepted set (over the random choice of Π and any internal randomness of the algorithm) is at least an α fraction of the maximum weight of an independent set of $(\mathcal{M}, w)$.

The *matroid secretary conjecture*, posed by [6], postulates that the matroid secretary problem admits an (online) algorithm which is constant-competitive for all matroids.

2.3 Miscellaneous Notation and Terminology

We denote the natural numbers by $\mathbb{N}$, and the nonnegative real numbers by $\mathbb{R}_+$. Given a set $\mathcal{A}$ with weights $w \in \mathbb{R}^{\mathcal{A}}$, and a subset $B \subseteq \mathcal{A}$, we use the shorthand $w(B) = \sum_{i \in B} w_i$. We use $[n]$ as shorthand for the set $1, \ldots, n$. For a set A, we use $\Delta(A)$ to denote the family of distributions over A, and 2^A to denote the family of subsets of A.

Let $\mathcal{A}$ be a finite ground set. For a distribution $\mathcal{D}$ supported on $2^{\mathcal{A}}$, we define the vector $x \in [0,1]^{\mathcal{A}}$ of *marginals* of $\mathcal{D}$ by $x_i = \mathbf{Pr}_{B\sim\mathcal{D}}[i \in B]$, and refer to x_i as the *marginal probability* of i in $\mathcal{D}$. When marginals $x \in [0,1]^{\mathcal{A}}$ are given, we use $\mathbf{Ind}(x)$ to denote the distribution of the random set $B \subseteq \mathcal{A}$ which includes each element $i \in \mathcal{A}$ independently with probability x_i. We also use $\mathbf{Ind}_p(\mathcal{A})$ as shorthand for $\mathbf{Ind}(x)$ when $x_i = p$ for all $i \in \mathcal{A}$.

3 Understanding Contention Resolution

3.1 The Basics of Contention Resolution

The definitions below are parametrized by a given matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$.

▶ **Definition 3.1.** *A* contention resolution map (CRM) ϕ *is a randomized function from* $2^{\mathcal{E}}$ *to* $\mathcal{I}$ *with the property that* $\phi(R) \subseteq R$ *for all* $R \subseteq \mathcal{E}$*. Such a map is* α-competitive *for a distribution* $\mathcal{D} \in \Delta(2^{\mathcal{E}})$ *if, for* $R \sim \mathcal{D}$*, we have* $\mathbf{Pr}[i \in R] \leq \alpha\,\mathbf{Pr}[i \in \phi(R)]$ *for all* $i \in \mathcal{E}$*.*

The following is known from Chekuri et al [10].

▶ **Theorem 3.2** ([10]). *Every product distribution with marginals in* $\mathcal{P}(\mathcal{M})$ *admits an* $\frac{e}{e-1}$*-competitive CRM.*

▶ **Definition 3.3.** *An* online random-order contention resolution map *(henceforth* online CRM *for short) is a contention resolution map* ϕ *which can be implemented as an algorithm in the online random-arrival model. In the online random-arrival model,* $\mathcal{E}$ *is presented to the algorithm in a uniformly random order* $(e_1, \ldots, e_n)$*, and at the ith step the algorithm learns whether* e_i *is* active *– i.e.,* $e_i \in R \sim \mathcal{D}$ *– and if so must make an irrevocable decision on whether to include* e_i *in* $\phi(R)$*.*

The following is known from Lee and Singla [25].

▶ **Theorem 3.4** ([25]). *Every product distribution with marginals in* $\mathcal{P}(\mathcal{M})$ *admits a* $\frac{e}{e-1}$*-competitive online CRM.*

3.2 Uncontentious Distributions and their Characterization

As shorthand, we refer to distributions which permit competitive (offline) CRMs as *uncontentious.*

▶ **Definition 3.5.** *Fix a matroid* $\mathcal{M} = (\mathcal{E}, \mathcal{I})$*. For* $\alpha \geq 1$*, we say that a distribution* $\mathcal{D} \in \Delta(2^{\mathcal{E}})$ *is* α-uncontentious *if it admits an* α*-competitive contention resolution map.*

For convenience, we also refer to a random set $R \sim \mathcal{D}$ as α-uncontentious if its distribution $\mathcal{D}$ is α-uncontentious. We prove the following characterization of uncontentious distributions.

▶ **Theorem 3.6.** *Fix a matroid* $\mathcal{M} = (\mathcal{E}, \mathcal{I})$*, and let* $\mathcal{D}$ *be a distribution supported on* $2^{\mathcal{E}}$*. The following are equivalent for every* $\alpha \geq 1$*.*

(a) *$\mathcal{D}$ is α-uncontentious (i.e., admits an α-competitive contention resolution map).*

(b) *For every weight vector $w \in \mathbb{R}_+^{\mathcal{E}}$, the following holds for $R \sim \mathcal{D}$:* $\mathbf{E}[\mathbf{rank}_w(R)] \geq \frac{\mathbf{E}[w(R)]}{\alpha}$.

(c) *For every $\mathcal{F} \subseteq \mathcal{E}$, the following holds for $R \sim \mathcal{D}$:* $\mathbf{E}[|R \cap \mathcal{F}|] \leq \alpha\,\mathbf{E}[\mathbf{rank}(R \cap \mathcal{F})]$.

Proof. Property (a) implies property (c) by applying an α-CRM ϕ to R, noting that $\phi(R) \cap \mathcal{F}$ is necessarily an independent subset of $R \cap \mathcal{F}$.

$$\begin{aligned}\mathbf{E}[\mathbf{rank}(R \cap \mathcal{F})] &\geq \mathbf{E}[|\phi(R) \cap \mathcal{F}|] \\ &= \sum_{i \in \mathcal{F}} \mathbf{Pr}[i \in \phi(R)] \\ &\geq \frac{1}{\alpha} \sum_{i \in \mathcal{F}} \mathbf{Pr}[i \in R] \\ &= \frac{1}{\alpha} \mathbf{E}[|R \cap \mathcal{F}|].\end{aligned}$$

Property (c) implies property (b) by a summation argument. Sort and number the elements $\mathcal{E} = (e_1, \ldots, e_n)$ in decreasing order of weights $w_1 \geq w_2 \geq \ldots \geq w_n \geq 0$, where w_i denotes the weight of e_i. Denote $\mathcal{E}_i = \{e_1, \ldots, e_i\}$, and let $\mathcal{E}_0 = \emptyset$, and $w_{n+1} = 0$. Recalling that the greedy algorithm computes the maximum weight independent subset of a matroid:

$$\begin{aligned}\mathbf{E}[\mathbf{rank}_w(R)] &= \mathbf{E}\left[\sum_{i=1}^{n} w_i \left(\mathbf{rank}(R \cap \mathcal{E}_i) - \mathbf{rank}(R \cap \mathcal{E}_{i-1})\right)\right] && \text{(Greedy alg. on } \mathcal{M}|R) \\ &= \mathbf{E}\left[\sum_{i=1}^{n} (w_i - w_{i+1}) \mathbf{rank}(R \cap \mathcal{E}_i)\right] && \text{(Reverse summations)} \\ &\geq \frac{1}{\alpha} \mathbf{E}\left[\sum_{i=1}^{n} (w_i - w_{i+1}) |R \cap \mathcal{E}_i|\right] && \text{((c) and linearity of exp.)} \\ &= \frac{1}{\alpha} \mathbf{E}\left[\sum_{i=1}^{n} w_i \left(|R \cap \mathcal{E}_i| - |R \cap \mathcal{E}_{i-1}|\right)\right] && \text{(Reverse summations)} \\ &= \frac{1}{\alpha} \mathbf{E}[w(R)].\end{aligned}$$

Property (b) implies property (a) by a duality argument identical to that presented in [10]. We present a self-contained proof here. Let $x = x(\mathcal{D}) \in [0,1]^{\mathcal{E}}$ denote the marginals of $\mathcal{D}$. The distribution $\mathcal{D}$ is α-uncontentious if the optimal value of the following LP, with variables β and λ_ϕ for each deterministic CRM ϕ, is at least $\frac{1}{\alpha}$.

$$\begin{array}{ll} \text{maximize} & \beta \\ \text{subject to} & \sum_\phi \lambda_\phi \, \mathbf{Pr}_{R \sim \mathcal{D}}[i \in \phi(R)] \geq \beta x_i, \quad \text{for } i \in \mathcal{E}. \\ & \sum_\phi \lambda_\phi = 1 \\ & \lambda \succeq 0 \end{array}$$

The dual of the preceding LP is the following

$$\begin{array}{ll} \text{minimize} & \mu \\ \text{subject to} & \sum_{i \in \mathcal{E}} w_i \, \mathbf{Pr}_{R \sim D}[i \in \phi(R)] \leq \mu, \quad \text{for all CRM } \phi. \\ & \sum_{i \in \mathcal{E}} w_i x_i = 1 \\ & w \succeq 0 \end{array}$$

It is not hard to see that, at optimality, the binding constraint on μ corresponds to the CRM ϕ which maps each set R to its maximum weight independent subset according to weights w. It follows that the optimal value of the dual, and hence the primal, equals the minimum over all weight vectors $w \succeq 0$ of the ratio $\frac{\mathbf{E}[\mathbf{rank}_w(R)]}{\sum_i w_i x_i}$. (b) implies that this quantity is at least $\frac{1}{\alpha}$, as needed. ◀

We note that the equivalence between (a) and (b) is essentially implicit in the arguments of [10]. Condition (c) is the most notable part of Theorem 3.6, in no small part because it is reminiscent of the *matroid base covering theorem* (see e.g., [31]). This theorem can equivalently be stated as follows: a (deterministic) set $T \subseteq \mathcal{E}$ in a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ can be *covered by* (i.e., expressed as a union of) $\alpha \in \mathbb{N}$ independent sets if and only if $|S| \leq \alpha\, \mathbf{rank}_{\mathcal{M}}(S)$ for all $S \subseteq T$. In light of part (c) of Theorem 3.6, a set T of elements can be covered by α independent sets if and only if the point distribution on T is α-uncontentious. Therefore, *we can interpret contention resolution as a distributional generalization of base covering.*

3.3 Elementary Properties of Uncontentious Distributions

We state some elementary, yet quite useful, properties of uncontentious distributions.

▶ **Proposition 3.7.** *Fix a matroid $\mathcal{M}$. Every α-uncontentious distribution $\mathcal{D}$ for $\alpha \geq 1$ has marginals $x(\mathcal{D}) \in \alpha\mathcal{P}(\mathcal{M})$.*

Proof. Let $x = x(\mathcal{D})$ and $R \sim \mathcal{D}$. From Theorem 3.6 (c), for every set of ground set elements $\mathcal{F}$ we have

$$\sum_{i \in \mathcal{F}} x_i = \mathbf{E}[|R \cap \mathcal{F}|] \leq \alpha\, \mathbf{E}[\mathbf{rank}_{\mathcal{M}}(R \cap \mathcal{F})] \leq \alpha\, \mathbf{rank}_{\mathcal{M}}(\mathcal{F}).$$

These are the inequalities describing $\alpha\mathcal{P}(\mathcal{M})$. ◀

▶ **Proposition 3.8.** *Fix a matroid. A mixture of α-uncontentious distributions is α-uncontentious.*

Proof. Follows directly from Theorem 3.6 (b) and linearity of expectations. ◀

▶ **Proposition 3.9.** *Fix a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$, and let $\mathcal{M} = (\mathcal{E}', \mathcal{I}')$ be a minor of $\mathcal{M}$, with $\mathcal{E}' \subseteq \mathcal{E}$. If a random set $R \subseteq \mathcal{E}'$ is α-uncontentious in $\mathcal{M}'$, then R is also α-uncontentious in $\mathcal{M}$.*

Proof. An independent set of $\mathcal{M}'$ is also independent in $\mathcal{M}$. Therefore, the proposition follows by simply applying the same CRM in the context of the larger matroid $\mathcal{M}$. ◀

▶ **Proposition 3.10.** *Fix a matroid. Let R be an α-uncontentious random set, and let $R' \sim \mathbf{Ind}_p(R)$ for some $p \in [0, 1]$. The random set R' is α-uncontentious as well.*

Proof. We use Theorem 3.6 (b). For any weight vector w, submodularity of the weighted rank function implies that $\mathbf{E}[\mathbf{rank}_w(R')] \geq p\, \mathbf{E}[\mathbf{rank}_w(R)]$. It follows that $\mathbf{E}[w(R')] = p\, \mathbf{E}[w(R)] \leq p\alpha\, \mathbf{E}[\mathbf{rank}_w(R)] \leq \alpha\, \mathbf{E}[\mathbf{rank}_w(R')]$. ◀

We note that Proposition 3.10 is tight when both p and α are absolute constants. In particular, the random set R' cannot be guaranteed to be α'-uncontentious for a constant $\alpha' < \alpha$, even if p is a very small constant. To see this, consider the a 1-uniform matroid with elements $[n]$, and the following 2-uncontentious random set R: For every singleton $i \in [n]$ we have $\mathbf{Pr}[R = \{i\}] = \frac{1}{n+1}$, and $\mathbf{Pr}[R = [n]] = \frac{1}{n+1}$.

3.4 Examples of Uncontentious Distributions

We now present some examples of uncontentious distributions in order to develop a feel for them. As mentioned previously, and shown in [10], every product distribution with marginals in the matroid polytope is $\frac{e}{e-1}$-uncontentious. Combined with Proposition 3.8, this extends to mixtures of product distributions.

▶ **Proposition 3.11.** *Fix a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$, and let $\mathcal{D} \in \Delta(2^{\mathcal{E}})$ be a mixture of product distributions, each with marginals in $\mathcal{P}(\mathcal{M})$. It follows that $\mathcal{D}$ is $\frac{e}{e-1}$-uncontentious.*

Going beyond product distributions and their mixtures, if a distribution satisfies a certain strong notion of negative correlation, defined in [9], then it also is $\frac{e}{e-1}$-uncontentious.

▶ **Proposition 3.12.** *Fix a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$, and let $\mathcal{D} \in \Delta(2^{\mathcal{E}})$ be a distribution with marginals $x = x(D) \in \mathcal{P}(\mathcal{M})$. Assume that $\mathcal{D}$ satisfies the* property of increasing submodular expectations*: for every submodular function f we have $\mathbf{E}_{R \sim \mathcal{D}}[f(R)] \geq \mathbf{E}_{S \sim \mathbf{Ind}(x)}[f(S)]$.*[3] *It follows that $\mathcal{D}$ is $\frac{e}{e-1}$-uncontentious.*

Proof. This is immediate by combining Theorem 3.6 (b) with the property of increasing submodular expectations and the fact that $\mathbf{Ind}(x)$ is $\frac{e}{e-1}$-uncontentious. ◀

As shown in [9], the property of increasing submodular expectations is stronger than the following standard notion of negative correlation for $R \sim \mathcal{D}$: For all sets T, $\mathbf{Pr}[T \subseteq R] \leq \prod_{i \in T} \mathbf{Pr}[i \in R]$ and $\mathbf{Pr}[T \subseteq \overline{R}] \leq \prod_{i \in T}(1 - \mathbf{Pr}[i \in R])$.[4] However, we can show that there are distributions exhibiting positive correlation which are also uncontentious for specific matroids. We now list some examples of uncontentious distributions exhibiting positive correlation.

▶ **Example 3.13.** Let $\mathcal{M}$ be a k-uniform matroid with n elements where $2 \leq k \leq n$. Let the random set R be empty with probability $1/2$, and a uniformly random base of $\mathcal{M}$ otherwise.

It is clear that R is 1-uncontentious, since it is supported on the family of independent sets. However, for each distinct pair of elements i and j, we have $\mathbf{Pr}[i \in R] = \mathbf{Pr}[j \in R] = \frac{k}{2n}$, yet $\mathbf{Pr}[i \in R | j \in R] = \mathbf{Pr}[j \in R | i \in R] = \frac{k-1}{n-1} > \frac{k}{2n}$.

The next example will feature repeatedly in this paper, since it is the random set of improving elements for the rank 1 matroid.

▶ **Example 3.14.** Consider the 1-uniform matroid with elements $[n] = \{1, \ldots, n\}$. For $k = 0, 1, \ldots, n-1$, let $R = \{1, \ldots, k\}$ with probability $2^{-(k+1)}$, and let $R = [n]$ with remaining probability 2^{-n}. The random set R is 2-uncontentious, as evidenced by the CRM ϕ with $\phi(\{1, \ldots, k\}) = \{k\}$ and $\phi(\emptyset) = \emptyset$, and a simple calculation. Note the positive correlation between elements $i < j$: $\mathbf{Pr}[j \in R] = 2^{-j}$, and $\mathbf{Pr}[j \in R | i \in R] = 2^{i-j} > \mathbf{Pr}[i \in R]$.

As a generalization of the previous example, we get the following.

▶ **Example 3.15.** Let $\mathcal{M}$ be a matroid with m pairwise-disjoint bases $B_1, \ldots, B_m$. For each $k = 1, \ldots, m-1$, let $R = \cup_{i=1}^{k} B_i$ with probability 2^{-k}, and let $R = \cup_{i=1}^{m} B_m$ with the remaining probability 2^{1-m}. The set R is 2-uncontentious, as evidenced by the CRM $\phi(\cup_{i=1}^{k} B_i) = B_k$. However, for $e_i \in B_i$ and $e_j \in B_j$ with $i < j$, we have $\mathbf{Pr}[e_j \in R] = 2^{1-j}$ and $\mathbf{Pr}[e_j \in R | e_i \in R] = 2^{i-j} > \mathbf{Pr}[e_j \in R]$.

[3] In fact, it suffices for $\mathcal{D}$ to satisfy the (weaker) property of increasing expectations for matroid rank functions (or, equivalently, their weighted sums).

[4] A natural question is whether negative correlation suffices for the distribution to be $\frac{e}{e-1}$-uncontentious. This is open as far as we know.

3.5 Contention Resolution Schemes, Universality, and Prior Dependence

A *contention resolution scheme (CRS)* Φ for a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ and class of distributions $\mathbb{D} \subseteq \Delta(2^{\mathcal{E}})$ is an algorithm which takes as input a (possibly partial) description of a distribution $\mathcal{D} \in \mathbb{D}$ and a sample $R \sim \mathcal{D}$, and outputs $S \in \mathcal{I}$ satisfying $S \subseteq R$. In effect, Φ is a collection of contention resolution maps $\phi_{\mathcal{D}}$, one for each $\mathcal{D} \in \mathbb{D}$. In much of the prior work on contention resolution, $\mathbb{D}$ was taken to be the class of product distributions with marginals in $\mathcal{P}(\mathcal{M})$, and each $\mathcal{D} \in \mathbb{D}$ is described completely via its marginals $x \in \mathcal{P}(\mathcal{M})$. In such a setting, the notion of a CRS offers little beyond the notion of a CRM, as each distribution gets its own dedicated CRM. More generally, however, we allow $\mathbb{D}$ to be an arbitrary class of distributions, and we allow the description to be partial and/or random; for example, $\mathcal{D}$ may be described by m independent samples from $\mathcal{D}$.

Next, we set the stage by defining some desirable contention resolution schemes, and establish some limitations on their existence.

▶ **Definition 3.16.** *Fix a matroid. For $\beta \geq \alpha > 1$, an* α-universal β-competitive CRS *is a CRS which is β-competitive for the class of α-uncontentious distributions.*

By definition, there exists an (offline) α-universal α-competitive CRS for every α and every matroid. The notion of a universal scheme becomes more interesting when we restrict dependence on the prior, as per the following definitions.

▶ **Definition 3.17.** *Fix a matroid. A contention resolution scheme Φ is said to be* prior-independent *if it is not given a complete description of $\mathcal{D}$ as input, but rather is given a set of independent samples from $\mathcal{D}$. When the number of samples is m, we say Φ is a* prior-independent m-sample scheme*. The number of samples may be function of the size of the matroid. If $m = 0$, we say the scheme is* oblivious*: the scheme consists of a single contention resolution map.*

We now show that, if a scheme is universal, it cannot be prior-independent with any finite number of samples, even for very simple matroids.

▶ **Theorem 3.18.** *Let $\mathcal{M}$ be the 1-uniform matroid on n elements. For every finite m, and every $1 < \alpha \leq \beta < n$, there does not exist a β-competitive α-universal CRS for $\mathcal{M}$ which is prior independent with m samples.*

To prove Theorem 3.18, we first show that a prior-independent universal scheme implies the existence of an oblivious universal scheme; then we show that an oblivious universal scheme does not exist for the uniform matroid. This is captured in the two following lemmas.

▶ **Lemma 3.19.** *Fix a matroid $\mathcal{M}$. If there exists a β-competitive α-universal CRS Φ which is prior-independent with m samples, then there exists an oblivious β-competitive α-universal scheme Φ'.*

Proof. Let $\mathcal{D}$ be any α-uncontentious distribution. Let $\epsilon \in (0, 1)$, and let $\mathcal{D}' = \mathcal{D}'(\epsilon)$ be the mixture of $\mathcal{D}$ with the point distribution on the empty set with proportions ϵ and $1 - \epsilon$ respectively. By Proposition 3.8 and the fact that the point distribution on the empty set is 1-uncontentious, it follows that $\mathcal{D}'$ is α-uncontentious.

The CRS Φ induces a CRM $\phi_{\mathcal{D}'}$ on the distribution $\mathcal{D}'$, and by assumption $\phi_{\mathcal{D}'}$ is β-competitive for $\mathcal{D}'$. Since Φ is prior-independent with m samples, its induced CRM $\phi_{\mathcal{D}'}$ is a mixture over CRMs ϕ_S, where $S = (S_1, \ldots, S_m)$ is a random vector of m samples from $\mathcal{D}'$.

With probability at least $(1-\epsilon)^m$, we have $S = \emptyset^m := (\emptyset, \ldots, \emptyset)$. For $\phi_{\mathcal{D}'}$ to be β-competitive, in particular when with probability ϵ it is queried with a draw $R \sim D$, a simple calculation shows that $\phi_{\emptyset^m}$ must be β'-competitive for $\mathcal{D}$ for $\beta' = \frac{(1-\epsilon)^m}{1/\beta + (1-\epsilon)^m - 1}$. As ϵ tends to 0, β' tends to β, and a basic analytic argument implies that $\phi_{\emptyset^m}$ is β-competitive for $\mathcal{D}$. Since $\mathcal{D}$ was chosen arbitrarily among α-uncontentious distributions, and $\phi_{\emptyset^m}$ does not depend on $\mathcal{D}$, it follows that the oblivious scheme Φ' with $\phi'_{\mathcal{D}} = \phi_{\emptyset^m}$ for every $\mathcal{D}$ is β-competitive and α-universal. ◀

▶ **Lemma 3.20.** *The 1-uniform matroid with n elements does not admit an oblivious β-competitive α-universal CRS for any $1 < \alpha \leq \beta < n$.*

Proof. Let $[n]$ be the ground set of the matroid, and fix α such that $1 < \alpha < n$. An oblivious CRS consists of a single CRM ϕ. There exists at least one element $i \in [n]$ such that $\mathbf{Pr}[i \in \phi([n])] \leq 1/n$. Let $\epsilon = \alpha - 1 > 0$, and consider the following random set R: For each $j \in [n] \setminus i$ we have $R = \{j\}$ with probability $\frac{1}{n-1+\epsilon}$, and $R = [n]$ with the remaining probability $\frac{\epsilon}{n-1+\epsilon}$. The random set R is α-uncontentious: consider the CRM ϕ' with $\phi'(\{j\}) = j$ for $j \neq i$, and $\phi'([n]) = i$. However, our original CRM ϕ is no better than n-competitive for R, since its probability of selecting i is no more than $\frac{1}{n}\mathbf{Pr}[R = [n]] = \frac{1}{n}\mathbf{Pr}[i \in R]$. ◀

4 An Online Universal CRS from a Secretary Algorithm

We show that competitive matroid secretary algorithms imply that every contention resolution scheme can be made online, in the random arrival model, without much loss.

▶ **Theorem 4.1.** *Suppose that there is a γ-competitive online algorithm for the secretary problem on matroid $\mathcal{M}$. It follows that every α-uncontentious distribution admits an online $\gamma\alpha$-competitive contention resolution map. In other words, for every α there exists an online $\gamma\alpha$-competitive α-universal contention resolution scheme for $\mathcal{M}$.*

We interpret the above theorem as follows: the design of competitive universal online schemes is a necessary technical hurdle towards resolving the matroid secretary conjecture.

We now proceed with proving Theorem 4.1. Let $\mathcal{M} = (\mathcal{E}, \mathcal{I})$, and let $\mathcal{D} \in \Delta(2^{\mathcal{E}})$. Recall that an online CRM operates in the following model: a set of active elements $R \sim \mathcal{D}$ and a random permutation Π are (independently) sampled by nature, then $\mathcal{E}$ arrive online in order Π. When $i \in \mathcal{E}$ arrives, it is revealed whether $i \in R$, and if so the online CRS must determine whether to select i. The online CRM must only select an independent subset of R.

Suppose we are given a secretary algorithm $\mathcal{A}$ for $\mathcal{M}$ with competitive ratio γ. Without loss of generality, we assume that $\mathcal{A}$ selects only non-zero weight elements. Consider the following online CRM ϕ_w for $\mathcal{M}$, parametrized by a weight vector $w \in \mathbb{R}_+^{\mathcal{E}}$. When element i arrives, if $i \in R$ then it is presented to $\mathcal{A}$ with weight w_i, and if $i \notin R$ then it is presented to $\mathcal{A}$ with weight 0. ϕ_w selects precisely the elements selected by $\mathcal{A}$.

▶ **Lemma 4.2.** *For every distribution $\mathcal{D}$, we have $\mathbf{E}_{R\sim\mathcal{D}}[w(\phi_w(R))] \geq \frac{1}{\gamma}\mathbf{E}_{R\sim\mathcal{D}}[\mathbf{rank}_w(R)]$.*

Proof. Condition on the choice of R, and let $w'_i = w_i$ if $i \in R$ and $w'_i = 0$ otherwise. $\mathcal{E}$ are presented to $\mathcal{A}$ in a uniformly random order, with weights w'_i, and $\phi_w(R) \subseteq R$ is the set of elements selected by $\mathcal{A}$. Since $\mathcal{A}$ is γ-competitive, it follows that $\mathbf{E}[w'(\phi_w(R))] \geq \frac{1}{\gamma}\mathbf{rank}_{w'}(\mathcal{M})$. Since $w'(\phi_w(R)) = w(\phi_w(R))$ and $\mathbf{rank}_{w'}(\mathcal{M}) = \mathbf{rank}_w(R)$, we are done. ◀

▶ **Lemma 4.3.** *If $\mathcal{D}$ is α-uncontentious, then $\mathbf{E}_{R\sim\mathcal{D}}[w(\phi_w(R))] \geq \frac{1}{\gamma\alpha}\mathbf{E}_{R\sim\mathcal{D}}[w(R)]$.*

Proof. Combining the previous lemma with Theorem 3.6 (b). ◀

Recall that we are assuming for now that we know the α-uncontentious distribution $\mathcal{D}$, and we can design an online CRM $\phi_{\mathcal{D}}$ accordingly. $\phi_{\mathcal{D}}$ will be a random mixture of the maps ϕ_w described above; in particular, we will show that there exists a distribution $\mathcal{W} = \mathcal{W}(\mathcal{D})$ over weight vectors such that the (randomized) online CRM $\phi_{\mathcal{W}}$ which samples $w \sim \mathcal{W}$ upfront then invokes ϕ_w is an online $\gamma\alpha$-CRM for $\mathcal{D}$.

For each element $i \in \mathcal{E}$, let $x_i = \mathbf{Pr}_{R\sim\mathcal{D}}[i \in R]$. For each weight vector w and $i \in \mathcal{E}$, let $y_i(w) = \mathbf{Pr}_{R\sim\mathcal{D}}[i \in \phi_w(R)]$. For each distribution $\mathcal{W}$ over weight vectors and element $i \in \mathcal{E}$, let $y_i(\mathcal{W}) = \mathbf{Pr}_{R\sim\mathcal{D}}[i \in \phi_{\mathcal{W}}(R)] = \mathbf{Pr}_{R\sim\mathcal{D},w\sim\mathcal{W}}[i \in \phi_w(R)]$. Let $\mathcal{Y} = \left\{y(\mathcal{W}) : \mathcal{W} \in \Delta(\mathbb{R}_+^{\mathcal{E}})\right\} \subseteq [0,1]^{\mathcal{E}}$ be the family of all inclusion probabilities achievable by some online CRM of the form $\phi_{\mathcal{W}}$. It is immediate that $\mathcal{Y} = \mathbf{convexhull}(\left\{y(w) : w \in \mathbb{R}_+^{\mathcal{E}}\right\})$, and hence $\mathcal{Y}$ is a convex subset of $[0,1]^{\mathcal{E}}$.

An online $\alpha\gamma$-CRM for $\mathcal{D}$ of the form $\phi_{\mathcal{W}}$ exists if and only if $\mathcal{Y}$ intersects with the upwards closed convex set $\frac{x}{\alpha\gamma} + \mathbb{R}_+^{\mathcal{E}}$. Suppose for a contradiction that this intersection is empty; by the separating hyperplane theorem, this implies that there exists $w \in \mathbb{R}_+^{\mathcal{E}}$ such that $\frac{1}{\alpha\gamma}\sum_i w_i x_i > \sum_i w_i y_i$ for all $y \in \mathcal{Y}$. In particular, $\frac{1}{\alpha\gamma}\sum_i w_i x_i > \sum_i w_i y_i(w)$. Since $\sum_i w_i x_i = \mathbf{E}_{R\sim\mathcal{D}}\, w(R)$ and $\sum_i w_i y_i(w) = \mathbf{E}_{R\sim\mathcal{D}}[w(\phi_w(R))]$, we get a contradiction with Lemma 4.3. This concludes the proof of the theorem.

5 From Contention Resolution to a Secretary Algorithm?

One might hope that online contention resolution is equivalent to the secretary problem on matroids. In particular, does a competitive universal online CRS imply a competitive secretary algorithm? We make partial progress towards this question. In particular, we reduce the secretary problem to online contention resolution on a particular uncontentious distribution derived from the matroid and sample of its elements: the distribution of “improving elements”, as originally defined by Karger [20] for purposes different from ours.

▶ **Definition 5.1.** *Fix a matroid $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ with weights $w \in \mathbb{R}_+^{\mathcal{E}}$, and let $p \in (0,1)$. The random set R of* improving elements *with parameter p is sampled as follows: Let $S \sim \mathbf{Ind}_p(\mathcal{E})$, and let $R = R(S) = \{i \in \mathcal{E} : \mathbf{rank}_w(S \cup i) > \mathbf{rank}_w(S)\}$. Equivalently, R is the set of elements in $\mathcal{E} \setminus S$ which are not spanned by higher weight elements in S. Another equivalent definition is $R = \{i \in \mathcal{E} \setminus S : i \in \mathbf{OPT}_w(S \cup i)\}$.*

The maximum-weight independent subset of the improving elements is $(1-p)$-approximately optimal in expectation:

▶ **Fact 5.2.** *Fix a weighted matroid $(\mathcal{M}, w)$, and let R be the random set of improving elements with parameter p. Each element of $\mathbf{OPT}_w(\mathcal{M})$ is in R with probability $1-p$. It follows that $\mathbf{E}[w(R)] \geq \mathbf{E}[\mathbf{rank}_w(R)] \geq (1-p)\mathbf{rank}_w(\mathcal{M})$.*

Note that the random set R of improving elements does not follow a product distribution. In fact, elements are (weakly) positively correlated in general. This is illustrated by the special case of the 1-uniform matroid on $[n]$ with weights $w_1 > w_2 > \ldots > w_n$, and $p = 1/2$: the distribution of R is as described in Example 3.14. As our main result in this section, we nevertheless show that the random set of improving elements is uncontentious.

▶ **Theorem 5.3.** *Let $\mathcal{M} = (\mathcal{E}, \mathcal{I})$ be a matroid with weights $w \in \mathbb{R}_+^{\mathcal{E}}$, and let $p \in (0,1)$. The random set of improving elements with parameter p is $\frac{1}{p}$-uncontentious.*

Theorem 5.3 and Fact 5.2, taken together, essentially reduce the matroid secretary problem to online contention resolution for the distribution of the random set of improving elements, with one caveat we will discuss shortly. In particular, consider the following blueprint for a secretary algorithm:

1. Let S be the first $\mathbf{Binom}(|\mathcal{E}|, p)$ elements arriving online.
2. Let $R = R(S) \subseteq \mathcal{E} \setminus S$ be a sample of the set of improving elements with parameter p.
3. After observing S, the elements of $\mathcal{E} \setminus S$ arrive online in random order and are presented as such to an online contention resolution algorithm, along with their membership status in R. Note that membership in R can be determined "on the spot" as required for online contention resolution.[5]

Now given a β-competitive α-universal online CRS, we set $p = \frac{1}{\alpha}$ and obtain a $\frac{\beta}{1-p}$-competitive secretary algorithm. However, the following caveat prevents us from proving a formal theorem of this form: we cannot provide the online CRS with a complete description of the prior distribution. In particular, the distribution $\mathcal{D}$ of improving elements – while fully described by the weighted matroid $(\mathcal{M}, w)$ and the parameter p – can not be fully described to the contention resolution algorithm prior to its invocation, since entries of w are revealed online. As such, we learn both the sample $R \sim \mathcal{D}$ and the distribution $\mathcal{D}$ gradually as elements arrive. An oblivious universal online CRS would resolve this difficulty, but unfortunately we proved in Theorem 3.18 that such a CRS can not exist even for simple matroids and even offline. A reduction from the matroid secretary problem to contention resolution must therefore require a CRS which can make do with only partial knowledge of the prior. We leave exploration of these possibilities for future work, and discuss them further in the Conclusion section.

5.1 Proof of Theorem 5.3

Let p, S, and R be as in Definition 5.1. We prove that R is uncontentious by leveraging (c) from Theorem 3.6. In particular we will show that, for arbitrary $F \subseteq \mathcal{E}$, we have $\mathbf{E}[\mathbf{rank}(R \cap F)] \geq p\,\mathbf{E}[|R \cap F|]$. We break this up into the following three lemmas.

▶ **Lemma 5.4.** $\mathbf{E}[\mathbf{rank}(R \cap F)] \geq (1-p)\,\mathbf{E}[|F \cap \mathbf{OPT}_w(S \cup F)|]$

Proof. Let $T = S \setminus F$, and note that $S \cup F = T \uplus F$. We condition on the random variable T and show conditionally that $\mathbf{E}[\mathbf{rank}(R \cap F)] \geq (1-p)|F \cap \mathbf{OPT}_w(T \uplus F)|]$.

Take $i \in F \cap \mathbf{OPT}_w(T \uplus F)$. We will show that i is in R, and hence is in $R \cap F$, with probability $1-p$. Since $i \in S \cup i \subseteq T \uplus F$ and $i \in \mathbf{OPT}_w(T \uplus F)$, it follows from the matroid axioms that $i \in \mathbf{OPT}_w(S \cup i)$. With probability $1-p$ we also have $i \notin S$, in which case $i \in R$ by definition. Since $F \cap \mathbf{OPT}_w(T \uplus F)$ is an independent set, the claim follows. ◀

▶ **Lemma 5.5.** $|F \cap \mathbf{OPT}_w(S \cup F)| \geq |F \cap \mathbf{OPT}_w(S)|$

Proof. We prove this by induction on a set T with $S \subseteq T \subseteq S \cup F$, initialized to $T = S$ at the base case. Consider how the value of $|F \cap \mathbf{OPT}_w(T)|$ changes as we add elements of $F \setminus S$ to T one by one. When adding an element $i \in F \setminus T$ to T, there are three cases:

- $i \notin \mathbf{OPT}_w(T \cup i)$: In this case, $\mathbf{OPT}_w(T \cup i) = \mathbf{OPT}_w(T)$ and $|F \cap \mathbf{OPT}_w(T \cup i)| = |F \cap \mathbf{OPT}_w(T)|$.
- i is not spanned by T, and $i \in \mathbf{OPT}_w(T \cup i)$: In this case, $\mathbf{OPT}_w(T \cup i) = \mathbf{OPT}_w(T) \cup \{i\}$, and therefore $|F \cap \mathbf{OPT}_w(T \cup i)| = 1 + |F \cap \mathbf{OPT}_w(T)|$.
- i is spanned by T, and $i \in \mathbf{OPT}_w(T \cup i)$: In this case, elementary application of the matroid axioms implies that $\mathbf{OPT}_w(T \cup i) = \mathbf{OPT}_w(T) \cup \{i\} \setminus \{j\}$ for some $j \in T$. Since $i \in F$, it follows that $|F \cap \mathbf{OPT}_w(T \cup i)|$ is either equal to $|F \cap \mathbf{OPT}_w(T)|$ or exceeds it by 1, depending on whether $j \in F$. ◀

[5] Technically, a CRM requires that elements of $\mathcal{E}$ – rather than merely $\mathcal{E} \setminus S$ – be presented in uniform random order along with their membership status in R. This is easily accomplished by appropriately interleaving the elements of S – none of which are in R – among the elements of $\mathcal{E} \setminus S$.

▶ **Lemma 5.6.** $\mathbf{E}[|\mathbf{OPT}_w(S) \cap F|] \geq \frac{p}{1-p} \mathbf{E}[|R \cap F|]$

Proof. For each $i \in F$, we will show that $\mathbf{Pr}[i \in \mathbf{OPT}_w(S)] \geq \frac{p}{1-p} \mathbf{Pr}[i \in R]$, which suffices.

Take $i \in F$, and let $S_{>i} = \{j \in S : w_j > w_i\}$. Conditioning on $S_{>i}$, there are two cases:

- $i \in \mathbf{span}(S_{>i})$: It follows that $i \notin \mathbf{OPT}_w(S)$ and $i \notin R$, with certainty.
- $i \notin \mathbf{span}(S_{>i})$: With probability p we have $i \in S$ and therefore $i \in \mathbf{OPT}_w(S)$ and $i \notin R$. With the remaining probability $(1-p)$ we have $i \notin S$ and therefore $i \in R$ and $i \notin \mathbf{OPT}_w(S)$.

In both cases, the conditional probability that $i \in \mathbf{OPT}_w(S)$ is at least $\frac{p}{1-p}$ times the conditional probability that $i \in R$. The lemma follows. ◀

5.2 Where Prior Work Fails

There has been speculation in the community that contention resolution for improving element distributions can be accomplished online using the ideas of Feldman et al [17]. If this were true, then a stronger (online) form of our Theorem 5.3 would follow. We show that such conjecture is fatally flawed: there exists no $o(n)$-competitive online CRS in the worst-case arrival model, even when both the order and the distribution of improving elements are known to the algorithm. In other words, any competitive online CRS for improving element distributions must make and exploit assumptions on the arrival order. This rules out direct application of the arguments and techniques of Feldman et al [17], which – in holding for an (unknown) worst-case arrivals – cannot exploit the uniform arrival order. The same can be said for the work of Lee and Singla [25], which operates in the known worst-case arrival model.

We prove the following theorem, then elaborate on how algorithms from prior work tend to fail on simple examples.

▶ **Theorem 5.7.** *Let $\mathcal{M}$ be a matroid on n elements. There is no $o(n)$-competitive online CRS for (known) improving element distributions on M in the worst-case arrival model. This holds even for the 1-uniform matroid, for every constant parameter p of the distribution of improving elements, and even when the arrival order is known to the algorithm.*

Proof. Let $\{1, \ldots, n\}$ denote the ground set of of a 1-uniform matroid, listed in decreasing order of weight. Let R be the random set of improving elements with parameter p. Note that R is supported on sets of the form $\{1, \ldots, k\}$ for $k = 0, \ldots, n$. In the special case of $p = 1/2$, the distribution of R is as described in Example 3.14. In general, $\mathbf{Pr}[R = \{1, \ldots, k\}] = p(1-p)^k$. The random set R is $1/p$ uncontentious, as shown by Theorem 5.3. Concretely, the offline CRM $\phi(\{1, \ldots, k\}) = k$ is $\frac{1}{p}$-competitive.

Now suppose that elements are known to arrive online in the order $1, 2, 3, \ldots, n$, and consider an α-competitive online CRM for some $\alpha \geq 1$. Let $T \subseteq R$ be the (random) set of elements selected by the CRM. Conditioned on $i \in R$, the CRM must select i with probability at least $\frac{1}{\alpha}$. Formally, $\mathbf{Pr}[i \in T | i \in R] \geq \frac{1}{\alpha}$.

When element i arrives, the CRM learns whether $i \in R$, and if so must decide whether to select i. Since the online CRM has only observed elements $1, \ldots, i$, and must make its decision on the spot, it cannot distinguish between different sets of the form $R = \{1, \ldots, k\}$ for $k \geq i$. In other words, it cannot distinguish between the different realizations of R which include i, and must therefore select i with probability at least $\frac{1}{\alpha}$ in every realization of R which includes i. Formally, $\frac{1}{\alpha} \leq \mathbf{Pr}[i \in T | i \in R] = \mathbf{Pr}[i \in T | R = \{1, \ldots, k\}]$ for every $k \geq i$.

Since i was chosen arbitrarily, we can take $k = n$ and conclude that $\mathbf{Pr}[i \in T | R = \{1, \ldots, n\}] \geq \frac{1}{\alpha}$ for all i. Feasibility requires that $\sum_{i=1}^{n} \mathbf{Pr}[i \in T | R = \{1, \ldots, n\}] \leq 1$. Therefore, $\alpha \geq n$. ◀

It is instructive to examine where the algorithm of Feldman et al [17] fails in the special case of the 1-uniform matroid on n elements, even when improving elements are presented in a uniformly random order. Indeed, we will argue that no "simple tricks" seem to save the day. Recall that the algorithm of [17] defines a sequence of nested flats $\emptyset \subset F_1 \subset F_2 \subset \ldots \subset F_k$, and runs the greedy online algorithm on each contracted submatroid F_i/F_{i-1}. The 1-uniform matroid contains only a single non-empty flat, containing all elements. Therefore, the algorithm of [17] reduces merely to the naive greedy online algorithm which simply selects the first element it encounters, which in the case of a uniform arrival order is a uniformly random improving element.

Now, let $[n] = \{1, \ldots, n\}$ denote the ground set of the 1-uniform matroid listed in decreasing order of weight, and consider the distribution of improving elements R with parameter $p = 1/2$ as described in Example 3.14. Element k is improving with probability 2^{-k}, yet is selected by the algorithm with probability $\sum_{i=k}^{n-1} 2^{-(i+1)} \cdot \frac{1}{i} + 2^{-n} \cdot \frac{1}{n} < \frac{2^{-k}}{k} = \frac{\mathbf{Pr}[k \in R]}{k}$. Intuitively, when k is improving, so are elements $1, \ldots, k-1$, which easily span k and are not distinguished from k by the algorithm. It is easy to show that the algorithm suffers the same fate for any other choice of p.

One might be tempted to employ other tricks, such as for example "canceling" each element in R with independent constant probability in order to reduce contention and place the marginal probability vector deep in the matroid polytope. Such tricks are doomed to fail all the same: the algorithm groups all elements into the same (unique) flat, and in doing so does not distinguish between the "uncanceled" elements of R, so cannot select element k with probability exceeding $\frac{\mathbf{Pr}[k \in R]}{k}$.

It is hopefully now clear that any online CRS for improving element distributions must make and exploit assumptions on the arrival order. Whereas this rules out obvious extensions of Feldman et al [17] and Lee and Singla [25], one might hope that the algorithm of Adamczyk and Włodarczyk [1] might fare better, since they do exploit the random ordering assumption. Sadly, their algorithm also fails for the 1-uniform matroid: it also does not distinguish between different improving elements in this special case, and therefore also selects element k with probability no more than $\frac{\mathbf{Pr}[k \in R]}{k}$. That being said, we are more hopeful that the techniques of [1], if combined with significant new ideas, might yield progress on online contention resolution for positively correlated distributions.

6 Conclusions and Open Problems

In this paper, we begin an exploration of the power and limitations of contention resolution beyond known product distributions, as well as its connections to secretary problems. We hope that our results are a first step towards broader application of the techniques behind contention resolution and online selection. Most notably, our results highlight approaches to resolving the matroid secretary conjecture. We identify several intriguing open questions in pursuit of these agendas.

- Can the result of Theorem 4.1 be shown unconditionally; i.e., can we show a competitive universal online CRS for matroids without assuming the matroid secretary conjecture? We believe this to be a reasonable first step towards proving the matroid secretary conjecture. As we show in Section 5.2, prior work on online contention resolution fails in the presence of even the modest positive correlation exhibited by (uncontentious) improving element distributions on simple matroids. Therefore, we believe significant new ideas are required.

- Recalling the caveat to our results from Section 5, can a tighter connection be made between the secretary problem and contention resolution? Is there a natural model of contention resolution on matroids which permits a reduction both from and to the matroid secretary problem? The knee-jerk approaches using duality-like arguments fail to establish such an equivalence, so new ideas appear to be required.
- The caveat to our results from Section 5 suggests that resolving contention with limited knowledge of the prior is closely related to the matroid secretary conjecture. Recalling our impossibility result of Theorem 3.18, we can start by examining prior-independent contention resolution for interesting classes of distributions. For example, is there a competitive prior-independent (or even oblivious) CRS for ex-ante-feasible product distributions?
- Can Theorem 4.1 be made computationally efficient? Given only oracle access to an arbitrary uncontentious distribution and an arbitrary algorithm for the matroid secretary problem, this is unclear.
- Is there an analogue of our characterization of uncontentious distributions for prophet inequality problems? In particular, can we characterize joint distributions of random variables which permit competitive prophet inequalities with respect to a given matroid?
- Do more general set systems permit a characterization of uncontentious distributions with a finite set of inequalities, a-la Theorem 3.6?

We restricted our attention to matroids in the paper, though some notes are in order on extensions of our results to more general constraints. In the characterization of Theorem 3.6, the equivalence of (a) and (b) holds for a general downwards-closed set systems, and is implicit in the arguments of [10]. The equivalence with (c) exploits the matroid structure, however. Theorem 4.1 also holds for general downwards-closed set systems, and our proof does not invoke the matroid assumption. The results and arguments of Section 5, in particular Theorem 5.3, heavily rely on the matroid structure and do not appear to be easily extensible beyond matroids. We leave further extensions of our results beyond matroids for future work.

Abstract

Algorithmic extension problems of partial graph representations such as planar graph drawings or geometric intersection representations are of growing interest in topological graph theory and graph drawing. In such an extension problem, we are given a tuple $(G, H, \mathcal{H})$ consisting of a graph G, a connected subgraph H of G and a drawing $\mathcal{H}$ of H, and the task is to extend $\mathcal{H}$ into a drawing of G while maintaining some desired property of the drawing, such as planarity.

In this paper we study the problem of extending partial 1-planar drawings, which are drawings in the plane that allow each edge to have at most one crossing. In addition we consider the subclass of IC-planar drawings, which are 1-planar drawings with independent crossings. Recognizing 1-planar graphs as well as IC-planar graphs is NP-complete and the NP-completeness easily carries over to the extension problem. Therefore, our focus lies on establishing the tractability of such extension problems in a weaker sense than polynomial-time tractability. Here, we show that both problems are fixed-parameter tractable when parameterized by the number of edges missing from H, i.e., the edge deletion distance between H and G. The second part of the paper then turns to a more powerful parameterization which is based on measuring the vertex+edge deletion distance between the partial and complete drawing, i.e., the minimum number of vertices and edges that need to be deleted to obtain H from G.

1 Introduction

In the last decade, algorithmic extension problems of partial *planar* graph drawings have received a lot of attention in the fields of graph algorithms and graph theory as well as in graph drawing and computational geometry. In this problem setting, the input consists of a planar graph G, a connected subgraph H of G, and a planar drawing $\mathcal{H}$ of H; the question is then whether $\mathcal{H}$ can be extended to a planar drawing of G. This extension problem is motivated from applications in network visualization, where important patterns (subgraphs) are required to have a special layout, or where new vertices and edges in a dynamic graph must be inserted into an existing (partial) connected drawing, which must remain stable to preserve its mental map [31]. A major result on the extension of partial planar drawings is the linear-time algorithm of Angelini et al. [2] which can answer the above question as well as provide the desired planar drawing of G (if it exists). The result of Angelini et al. contrasts other extension problems in the context of computational geometry and graph drawing, which are typically NP-complete [7, 9–13, 16, 23–26, 30, 32], even in settings where recognition is polynomial-time solvable. On the other end of the planarity spectrum, Arroyo et al. [3, 4] studied drawing extension problems, where the number of crossings per edge is not restricted, yet the drawing must be *simple*, i.e., any pair of edges can intersect in at most one point. They showed that the simple drawing extension problem is NP-complete [3], even if just one edge is to be added [4].

In this paper, we study the algorithmic extension problem of partial drawings of 1-planar graphs, one of the most natural and most studied generalizations of planarity [17, 27, 33], and of partial drawings of IC-planar graphs, a natural restriction of 1-planarity [1, 5, 29, 35]. A 1-planar graph is a graph that admits a drawing in the plane with at most one crossing per edge; for IC-planarity, we additionally require that no two crossed edges are adjacent. Unlike planarity testing, recognizing 1-planar graphs is NP-complete [20, 28], even if the graph is a planar graph plus a single edge [8]. Recognition of IC-planar graphs also remains NP-complete [6].

Contributions. Given a graph G, a connected subgraph H, and a 1-planar drawing $\mathcal{H}$ of H, the 1-Planar Extension problem asks whether $\mathcal{H}$ can be extended by inserting the remaining vertices $V_{\text{add}} = V(G) \setminus V(H)$ and edges $E_{\text{add}} = E(G) \setminus E(H)$ of G into $\mathcal{H}$ while maintaining the property of being 1-planar. The IC-Planar Drawing Extension problem is then defined analogously, but for IC-planarity.

The NP-completeness of these extension problems is a simple consequence of the NP-completeness of the recognition problem [6, 20, 28] (see also Section 3). With this in mind, the aim of this paper is to establish the tractability of the problems when $\mathcal{H}$ is almost a complete 1-planar drawing of G. To capture this setting, we turn to the notion of *fixed-parameter tractability* [15, 19] and consider two natural parameters which capture how complete $\mathcal{H}$ is: the *edge deletion distance* between H and G (denoted by k), and the *vertex+edge deletion distance* between H and G (denoted by κ). More precisely, k is equal to $|E(G) \setminus E(H)|$ and κ is equal to $|V(G) \setminus V(H)| + |E(G[V(H)]) \setminus E(H)|$. We refer to Section 3 for formal definitions and a discussion of the parameters.

After introducing necessary notation in Section 2 and introducing the problem formally in Section 3, we consider the edge deletion distance k in **Section 4**. Our first result is:

▶ **Theorem 1.** *1-Planar Drawing Extension is* FPT *when parameterized by k.*

The proof of Theorem 1 involves the use of several ingredients:

1. Introducing and developing a notion of *patterns*, which are combinatorial objects that capture critical information about the potential interaction of newly added edges with $\mathcal{H}$;
2. a pruning procedure that reduces our instance to an equivalent sub-instance where H has treewidth bounded in k;
3. an embedding graph, which carries information about the drawing $\mathcal{H}$; and finally
4. completing the proof by constructing a formula Φ in Monadic Second Order Logic to check whether a pattern can "fit" in the embedding graph, using Courcelle's Theorem [14].

Next, we turn towards the question of whether one can obtain an *efficient* fixed-parameter algorithm for the extension problem. In particular, due to the use of Courcelle's Theorem [14] to model-check Φ, the algorithm obtained in the proof of Theorem 1 will have a prohibitive dependency on the parameter k. In this direction, we note that it is not immediately obvious how one can design an efficient and "formally clean" purely combinatorial algorithm for the pattern-fitting task (i.e., the task we relegate to model checking Φ in the embedding graph). At the very least, using a direct translation of the model-checking procedure would come at a significant cost in terms of presentation clarity.

That being said, one can observe that the main reason for the use of patterns is that it is not at all obvious where (i.e., in which cell of the drawing) one should place the vertices used to extend $\mathcal{H}$. Indeed, our second result for parameter k assumes that $V_{\text{add}} = \emptyset$ and avoids using Courcelle's Theorem.

▶ **Theorem 2.** *1-Planar Drawing Extension parameterized by k can be solved in time $\mathcal{O}(k^{2k} \cdot n^{\mathcal{O}(1)})$ if $V(G) = V(H)$.*

This algorithm uses entirely different techniques – notably, it prunes the search space for inserting each individual edge via a combination of geometric and combinatorial arguments, and then applies exhaustive branching. We note that the techniques used to prove Theorem 1 and 2 can be directly translated to also obtain analogous results for the IC-planarity setting.

In **Section 5**, we turn our attention to the vertex+edge deletion distance κ as a parameter, which represents a more relaxed way of measuring how complete $\mathcal{H}$ is than k – indeed, while $\kappa \leq k$, it is easy to construct instances where $\kappa = 1$ but k can be arbitrarily large. For our third result, we start with IC-planar drawings.

▶ **Theorem 3.** *IC-Planar Drawing Extension is* FPT *parameterized by κ.*

The proof of Theorem 3 requires a significant extension of the toolkit developed for Theorem 1. The main additional complication lies in the fact that the number of edges that are missing from H is no longer bounded by the parameter. To deal with this, we show that the added vertices can only connect to the boundary of a cell in a bounded number of "ways" (formalized via a notion we call *regions*), and we use this fact to develop a more general notion of patterns and embedding graphs than those used for Theorem 1.

Finally, in **Section 6**, we present a first step towards the tractability of 1-Planar Drawing Extension parameterized by κ. We note that the techniques developed for the other parameterizations and problem variants cannot be applied to solve this case – the main difference compared to the setting of Theorem 3 is that the "missing" vertices can be incident to many edges with crossings, which prevents the use of our bounded-size patterns to capture the behavior of new edges. As our final contribution, we investigate the special case of $\kappa = 2$, i.e., when adding two new vertices.

▶ **Theorem 4.** *1-Planar Drawing Extension is polynomial-time tractable if $\kappa \leq 2$.*

We note that even this, seemingly very restricted, subcase of 1-Planar Drawing Extension was non-trivial and required the combination of several algorithmic techniques (this contrasts to the case of $|V_{\text{add}}| = 1$, whose polynomial-time tractability is a simple corollary of one of our lemmas). In particular, the algorithm uses a new two-step “delimit-and-sweep” approach: first, we apply branching to find a curve with specific properties that bounds the instance by a left and right “delimiter”. The second step is then a left-to-right sweep of the instance that iteratively pushes the left delimiter towards the right one while performing dynamic programming combined with branching and network-flow subroutines.

Albeit being a special case, we believe these delimited instances with two added vertices can play a role in a potential XP algorithm parameterized by κ – the existence of which we leave open for future work.

Further Related Work. In addition to the given related work on extension problems, it is also worth noting that identifying a substructure of bounded treewidth and applying Courcelle’s Theorem to decide an MSO formula on it has been preciously used for a graph drawing problem by Grohe [21], namely to identify graph drawings of bounded crossing number. Both the way in which one arrives at bounded treewidth and the nature of the employed MSO formula are substantially different from our approach, which is not surprising as the problem of generating drawings from scratch and the problem of extending partial drawings are in general fundamentally different. Specifically in the case of generating drawings, the MSO formula could essentially encode the existence of a drawing with bounded crossing number by inductively planarizing crossings of pairs of edges; here the planarity of the planarization can of course be captured via excluded $K_{3,3}$ and K_5 minors by MSO. This approach is not possible in our setting. There are examples of 1-planar graphs which have partial drawings which cannot be extended to a 1-plane drawing. Thus a planarization with respect to the added parts of a solution needs to be compatible with the partial drawing and cannot be encoded by an MSO formula straightforwardly.

2 Preliminaries

Let G be a simple graph, $V(G)$ its vertices, and $E(G)$ its edges. We use standard graph terminology [18]. For $r \in \mathbb{N}$, we write $[r]$ as shorthand for the set $\{1, \ldots, r\}$. We also assume a basic understanding of parameterized complexity theory [15, 19], Monadic Second Order (MSO) Logic and Courcelle’s Theorem [14].

A *drawing* $\mathcal{G}$ of G in the plane $\mathbb{R}^2$ is a function that maps each vertex $v \in V(G)$ to a distinct point $\mathcal{G}(v) \in \mathbb{R}^2$ and each edge $e = uv \in E(G)$ to a simple open curve $\mathcal{G}(e) \subset \mathbb{R}^2$ with endpoints $\mathcal{G}(u)$ and $\mathcal{G}(v)$. In a slight abuse of notation we often identify a vertex v and its drawing $\mathcal{G}(v)$ as well as an edge e and its drawing $\mathcal{G}(e)$. Throughout the paper we will assume that: (i) no edge passes through a vertex other than its endpoints, (ii) any two edges intersect in at most one point, which is either a common endpoint or a proper *crossing* (i.e., edges cannot touch), and (iii) no three edges cross in a single point. For a drawing $\mathcal{G}$ of G and $e \in E(G)$, we use $\mathcal{G} - e$ to denote the drawing of $G - e$ obtained by removing the drawing of e from $\mathcal{G}$, and for $J \subseteq E(G)$ we define $\mathcal{G} - J$ analogously.

We assume that readers are familiar with the notion of *planarity* and *faces*. The *boundary* of a face is the set of edges and vertices whose drawing delimits the face. Further, $\mathcal{G}$ induces for each vertex $v \in V(G)$ a cyclic order of its neighbors by using the clockwise order of its incident edges. This set of cyclic orders is called a *rotation scheme*. Two planar drawings $\mathcal{G}_1$ and $\mathcal{G}_2$ of the same graph G are *equivalent* if they have the same rotation scheme and the same outer face; equivalence classes of planar drawings are also called *embeddings*. A *plane* graph is a planar graph with a fixed embedding.

A drawing $\mathcal{G}$ is *1-planar* if each edge has at most one crossing and a graph G is *1-planar* if it admits a 1-planar drawing. Similarly to planar drawings, 1-planar drawings subdivide the plane into connected regions, which we call *cells* in order to distinguish them from the faces of a planar drawing. The *planarization* $G^\times$ of a 1-planar drawing $\mathcal{G}$ of G is a graph $G^\times$ with $V(G) \subseteq V(G^\times)$ that introduces for each crossing c of $\mathcal{G}$ a *dummy vertex* $c \in V(G^\times)$ and that replaces each pair of crossing edges uv, wx in $E(G)$ by the four *half-edges* uc, vc, wc, xc in $E(G^\times)$, where c is the crossing of uv and wx. In addition all crossing-free edges of $E(G)$ belong to $E(G^\times)$. Obviously, $G^\times$ is planar and the drawing $\mathcal{G}^\times$ of $G^\times$ corresponds to $\mathcal{G}$ with the crossings replaced by the dummy vertices.

3 Extending 1-Planar Drawings

Given a graph G and a subgraph H of G with a 1-planar drawing $\mathcal{H}$ of H, we say that a drawing $\mathcal{G}$ of G is an *extension* of $\mathcal{H}$ if the planarization $H^\times$ of $\mathcal{H}$ and the planarization $\mathcal{G}^\times$ of $\mathcal{G}$ restricted to $\mathcal{H}^\times$ have the same embedding. We formalize our problem of interest as:

1-Planar Drawing Extension
Instance: A graph G, a connected subgraph H of G, and a 1-planar drawing $\mathcal{H}$ of H.
Task: Find an 1-planar extension of $\mathcal{H}$ to G, or correctly identify that there is none.

The IC-Planar Drawing Extension problem is then defined analogously. Both problem definitions follow previously considered drawing extension problems, where the connectivity of H is considered a well-motivated and standard assumption [22, 30, 31].

Given an instance $(G, H, \mathcal{H})$ of 1-Planar Drawing Extension, a *solution* is a 1-planar drawing $\mathcal{G}$ of G that is an extension of $\mathcal{H}$. We refer to $V_{\text{add}} := V(G) \setminus V(H)$ as the *added vertices* and to $E_{\text{add}} := E(G) \setminus E(H)$ as the *added edges*. Let $V_{\text{inc}} = \{v \in V(H) \mid \exists vw \in E_{\text{add}}\}$, i.e., V_{inc} is the set of vertices of H that are incident to at least one added edge. We also distinguish added edges whose endpoints are already part of the drawing, and added edges with at least one endpoint yet to be added into the drawing – notably, we let $E^H_{\text{add}} := \{vw \in E_{\text{add}} \mid v, w \in V(H)\}$ and $E^{\neg H}_{\text{add}} := E_{\text{add}} \setminus E^H_{\text{add}}$. This distinction will become important later, since it opens up two options for how to quantify how “complete” the drawing of $\mathcal{H}$ is. It is worth noting that, without loss of generality, we may assume each vertex in V_{add} to be incident to at least one edge in E_{add} and hence $|V_{\text{add}} \cup V_{\text{inc}}| \leq 2|E_{\text{add}}|$.

Given the NP-completeness of recognizing 1-planar [20, 28] and IC-planar [6] graphs we get as an immediate consequence that also the corresponding extension problems are NP-complete. In view of the NP-completeness of the problem, it is natural to ask about its complexity when H is nearly “complete”, i.e., we only need to extend the drawing $\mathcal{H}$ by a small part of G. In this sense, deletion distance represents the most immediate way of quantifying how far H is from G, and the parameterized complexity paradigm [15, 19] offers complexity classes that provide a more refined view on “tractability” in this setting.

The most immediate way of capturing the completeness of H in this way is to parameterize the problem via the *edge deletion distance* to G – formalized by setting $k = |E_{\text{add}}|$. The aim of Section 4 is to establish the fixed-parameter tractability of 1-Planar Drawing Extension parameterized by k. A second parameter that we consider is the *vertex+edge deletion distance* to G, i.e., the minimum number of vertices and edges that need to be deleted from G to obtain H. We call this parameter κ and set $\kappa = |V_{\text{add}}| + |E^H_{\text{add}}|$. The parameterization by κ is the topic of Section 5 and 6. Since we can always assume that each added vertex is incident to at least one added edge, $|V_{\text{add}}| + |E^H_{\text{add}}| \leq |E_{\text{add}}|$ and so parameterizing by κ leads to a more general (and difficult) parameterized problem.

4 Using Edge Deletion Distance for Drawing Extensions

The main goal of this section is to establish the fixed-parameter tractability of 1-Planar Drawing Extension parameterized by the edge deletion distance k.

We note that one major obstacle faced by a fixed-parameter algorithm is that it is not at all obvious how to decide where the vertices in V_{add} should be drawn in an augmented drawing of H. As a follow-up, we will show that when $V_{\text{add}} = \emptyset$ (i.e., $V(H) = V(G)$), it is possible to obtain a more self-contained combinatorial algorithm with a significantly better runtime; this is presented in Subsection 4.2.

4.1 A Fixed-Parameter Algorithm for 1-Planar Drawing Extension

Our first step towards a proof of the desired tractability result is the definition of a *pattern*, which is a combinatorial object capturing essential information about a potential 1-planar extension of $\mathcal{H}$. The formal definition of pattern is given in Definition 1. Definition 2 then defines the notion of *derived patterns*, which create a link between solutions to an instance of 1-Planar Drawing Extension and patterns.

To given an intuition of the patterns, assume that a pattern consists of a tuple (S, Q, C) and let $(G, H, \mathcal{H})$ be a 1-Planar Drawing Extension instance. Then, the general intuition is that S represents the set of faces in $\mathcal{H}^\times$ which contain at least a part of the drawing of an edge in E_{add} in a hypothetical 1-planar extension $\mathcal{G}$ of $\mathcal{H}$. Crucially, our aim is to keep the size of patterns bounded in k, and so we only “anchor” S to $\mathcal{H}^\times$ by storing information about which faces will contain individual edges in E_{add}, vertices from V_{add}, and be adjacent to individual vertices in V_{inc}; this is captured by the mapping Q. The third piece of information we store is C, which represents the cyclic order of how edges in E_{add} exit or enter the boundary of each face (including the case where an edge crosses through an edge into the same face, i.e., occurs twice when traversing the boundary of that face).

▶ **Definition 1.** *A* pattern *for an instance $(G, H, \mathcal{H})$ is a tuple (S, Q, C) where*

1. *S is a set of at most $2k$ elements;*
2. *Q is a mapping from $V_{add} \cup E_{add} \cup V_{inc}$ which maps:* **(a)** *vertices in V_{add} to elements of S,* **(b)** *edges in E_{add} to ordered pairs of elements of S, and* **(c)** *vertices in V_{inc} to subsets of S.*
3. *C is a mapping from S that maps each $s \in S$ to a cyclically ordered multiset of pairs $((e_1, q_1), (e_2, q_2), \dots, (e_\ell, q_\ell))$, where each e_i is in E_{add} and each q_i is in $V_{inc} \cup \{\text{crossing}\}$. Moreover, C must satisfy the following conditions:* **(a)** *for each $s \in S$ and each tuple $(e, q) \in C(s)$ such that $q \in V_{inc}$, it must hold that $s \in Q(q)$ and e is incident to q in G;* **(b)** *for each $e \in E_{add}$ and $s \in S$, if e occurs in at least one tuple in $C(s)$, then $s \in Q(e)$ and $C(s)$ contains at most two tuples of the form $(e, *)$, where $*$ is an arbitrary element;* **(c)** *for each $s \in S$, each tuple occurs at most once in $C(s)$ with the exception of tuples containing* “crossing”*, which may occur twice.*

Let $\mathcal{P}$ be the set of all patterns for our considered instance $(G, H, \mathcal{H})$. Let $\#\text{pat}(k) = 2k \cdot (2^{2k})^{3k} \cdot ((2k)! \cdot 2^{3k})^{2k}$ and note that $|\mathcal{P}| \leq \#\text{pat}(k) \in 2^{\mathcal{O}(k^2 \log k)}$. In particular, the number of possible patterns can be bounded by first considering $2k$ options for $|S|$, multiplying this by the at most $(2^{2k})^{3k}$-many ways of choosing Q, and finally multiply this by the number of choices for C which can be bounded as follows: for each $s \in S$, $C(s)$ is a set that forms a subset (of size at most $2k$) of the $3k$-cardinality set of tuples (note that $e = \{a, b\} \in E_{\text{add}}$ can only occur in the tuples (e, a), (e, b) and $(e, \text{crossing})$).

The intuition behind patterns will be formalized in the next definition, which creates a link between solutions to our instance and patterns.

▶ **Definition 2.** *Let $(G, H, \mathcal{H})$ be a* 1-Planar Drawing Extension *instance. For each solution $\mathcal{G}$ of $(G, H, \mathcal{H})$ we define a derived pattern $P = (S, Q, C)$ as follows:*

- *S is the set of faces of $\mathcal{H}^\times$ which have a non-empty intersection with $\mathcal{G}(e)$ for some $e \in E_{add}$.*
- *For $v \in V_{add}$ we set $Q(v)$ to the face f of $\mathcal{H}^\times$ for which $\mathcal{G}(v)$ lies inside f, for $e \in E_{add}$ we set $Q(e)$ to the set of at most two faces which have a non-empty intersection with $\mathcal{G}(e)$, and for $w \in V_{inc}$ we set $Q(w)$ to all faces in S incident to w in $\mathcal{G}$.*
- *For a face $s \in S$ we consider all edges $e = uv \in E_{add}$ with a non-empty intersection between $\mathcal{G}(e)$ and s. It follows that there is an edge $e' \in E(H)$ on the boundary of s such that $\mathcal{G}(e)$ crosses $\mathcal{G}(e')$, or $u \in V_{inc}$ and u is on the boundary of s, or both. We set $C(s)$ as the ordered set of these crossing points or vertices when traversing s in clockwise fashion.*

Our next task is to define *valid patterns*; generally speaking, these are patterns which are not malformed and could serve as derived patterns for a hypothetical solution. One notable property that every valid pattern must satisfy is that all vertices and edges mapped by Q to some $s \in S$ can be drawn in a 1-planar way while respecting $C(s)$.

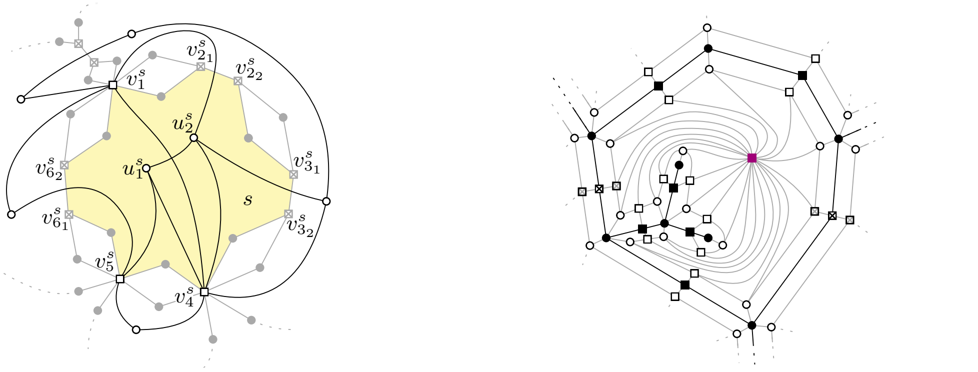
▶ **Definition 3.** *For an instance $(G, H, \mathcal{H})$, a pattern $P = (S, Q, C)$ is* valid *if there exists a* pattern graph *G_P with a 1-planar drawing $\mathcal{G}_P$ satisfying the following properties:*

- *$V_{add} \cup V_{inc} \subseteq V(G_P)$ and $E_{add} \subseteq E(G_P)$.*
- *$\mathcal{G}_P - E_{add}$ is a planar drawing.*
- *S is a subset of the inner faces of $\mathcal{G}_P - E_{add}$.*
- *Each $v \in V_{add}$ is contained in the face $Q(v)$ of $\mathcal{G}_P - V_{add} - E_{add}$.*
- *Each $e \in E_{add}$ is contained in the face(s) $Q(e)$ of $\mathcal{G}_P - E_{add}$.*
- *Each $v \in V_{inc}$ is incident to the faces $Q(v)$ of $\mathcal{G}_P - E_{add}$.*
- *When traversing the inner side of the boundary of each face s of $\mathcal{G}_P - E_{add}$ in clockwise fashion, the order in which each edge $e \in E_{add}$ is seen in $\mathcal{G}_P$ together with the information whether e crosses here or ends in its endpoint in V_{inc}, is precisely $C(s)$.*

Note that the instance $(G, H, \mathcal{H})$ in the definition of a valid pattern is only important to define V_{add}, V_{inc}, and E_{add}. Moreover, observe that for each solution $\mathcal{G}$ of an instance $(G, H, \mathcal{H})$, the derived pattern is valid by definition. An illustration of a pattern graph is provided in Part (a) of Figure 1. We also remark that, when comparing a pattern graph to a hypothetical solution which draws an edge into the outer face of $\mathcal{H}$, we will map the outer face to an inner face of the pattern graph.

▶ **Lemma 4.** *Given pattern $P = (S, Q, C)$, in time $\mathcal{O}((k!)^k \cdot k^{2k+1})$ we can either construct a pattern graph G_P together with the drawing $\mathcal{G}_P$ satisfying all the properties of Definition 3 or decide that P is not valid.*

Proof Sketch. The idea is to build a planarized version G'_P of the pattern graph with size bounded in $\mathcal{O}(k)$. To build the graph we introduce for every $s \in S$ a cycle containing the vertices in $C(s)$. We further subdivide each edge on a cycle by dummy vertices and identify the vertices corresponding to the same vertex in V_{inc} or the same crossing. Finally we add each vertex in V_{add} and connect it to the necessary vertices on the face's boundary. Crossings between these in-face edges can then be guessed since there are only $O(k)$ such crossings. Finding the drawing $\mathcal{G}'_P$ that adheres to Definition 3 can then be done by iterating all possible rotation schemes. To turn $\mathcal{G}'_P$ into a 1-plane drawing replace all crossing vertices by crossing



(a) A pattern graph as constructed in Lemma 4. The face representing $s \in S$ is yellow, gray disks are dummy vertices. Black circles are in V_{add}. Squares are either in V_{inc} or represent crossings.

(b) An example of an embedding graph. The white vertices are shadow-vertices, the purple one the face vertex, and gray edges got added.

Figure 1 Examples for the definition of a pattern and the embedding graph.

edges (see also Part (a) of Figure 1a). For the reverse direction, simply observe that from a given pattern graph we can delete and contract all "unecessary" vertices and edges. Then all that remains are the cycles of vertices representing a set $C(s)$ and vertices in V_{add}. ◀

Next, we will define an annotated ("labeled") graph representation of $\mathcal{H}$ and $\mathcal{H}^{\times}$'s faces. The *embedding graph* H^* of $\mathcal{H}$ is obtained from $\mathcal{H}^{\times}$ by:

1. subdividing each uncrossed edge e (resulting in vertex v_e);
2. creating a vertex for each face f of $\mathcal{H}^{\times}$ (resulting in vertex v_f);
3. traversing the boundary of each face f[1] and whenever we see a vertex v (including the vertices created in Step 1) we create a shadow copy of v and place it right next to v in the direction we saw v from. Add a cycle connecting the shadow vertices we created in f in the order they were created, and direct it in clockwise fashion[2];
4. connecting v_f to all shadow-vertices created by traversing f, and all shadow copies of a vertex v to the original v.

Observe that the embedding graph is a connected plane graph. We label the vertices of the embedding graph to distinguish original vertices, edge-vertices, face-vertices, crossing-vertices and shadow-vertices, and use at most $2k$ special labels to identify vertices in V_{inc}. An illustration of the embedding graph is provided in Part (b) of Figure 1. Next, we show that it suffices to restrict our attention to the parts of H^* which are "close" to vertices in V_{inc}.

▶ **Lemma 5.** *Let $I = (G, H, \mathcal{H})$ be an instance of 1-Planar Drawing Extension. Let Z be the set of all vertices in H^* of distance at least $4k + 7$ from each vertex in V_{inc}. Let G', H', and $\mathcal{H}'$ be obtained by deleting all vertices in Z from G, H, and $\mathcal{H}$ respectively. Then:*

1. *If I is a YES-instance, then each connected component of G' contains at most one connected component of H'*[3]*;*

[1] formally, we draw a curve in f that closely follows the boundary until it forms a closed curve.

[2] Note that this may create multiple shadow copies of a vertex. The reason we use shadow copies of vertices instead of using the original vertices is that when traversing the inner boundary of a face, a vertex may be seen multiple times, and such shadow-vertices allow us to pinpoint from which part of the face we are visiting the given vertex.

[3] This can be seen not to hold in general if we allow H to be disconnected.

2. *I is a YES-instance if and only if for each connected component A of H' the restriction of $\mathcal{H}'$ to $H'[A]$ can be extended to a drawing of the connected component of G' containing A. Moreover, given such a 1-planar extension for every connected component of G', we can output a solution for I in linear time.*

We split the proof of Lemma 5 into proofs for the two individual points.

Proof of Point 1. For the sake of contradiction let J be a connected component of G' that contains two distinct connected components H'_1 and H'_2 of H'. Since J is a connected component, there must be a path P from a vertex $v_1 \in H'_1$ to a vertex $v_2 \in H'_2$ in $J - (H'_1 \cup H'_2)$, and moreover P must have length at most k. By definition, both v_1 and v_2 are in V_{inc}. To complete the proof, it suffices to show that in any solution $\mathcal{G}$, v_1 and v_2 have distance at most $4k+4$ in H^*.

Moreover, in any solution $\mathcal{G}$, two consecutive vertices of P are either drawn in the same face of $\mathcal{H}^\times$ or in two adjacent faces of $\mathcal{H}^\times$. Observe that the distance in H^* between two face-vertices for the faces that share an edge is 4, and that the distance from an original vertex v to a face-vertex of a face incident to v is 2. Therefore, if $(G, H, \mathcal{H})$ is a YES-instance, then the distance between v_1 and v_2 in H^* must be at most $4k+4$. ◀

Proof of Point 2. The forward direction is obvious. For the backward direction, let $G_1, \dots, G_r$ be the connected components of G' and for $i \in [r]$ let H_i and $\mathcal{H}_i$ be the restriction of H' and $\mathcal{H}'$, respectively, to G_i. Moreover, let $\mathcal{H}_i^\times$ be the planarization derived from $\mathcal{H}_i$ and note that H_i is connected for all $i \in [r]$ by Point 1. Now let us fix an arbitrary $i \in [r]$ such that H_i is not empty and let $\mathcal{G}_i$ be a 1-planar extension of $\mathcal{H}_i$ to G_i.

Observe that each face of $\mathcal{H}^\times$ is completely contained in precisely one face of $\mathcal{H}_i^\times$. Moreover, if a face f of $\mathcal{H}_i^\times$ contains at least two faces f_1 and f_2 of $\mathcal{H}^\times$, then both v_{f_1} and v_{f_2} are at distance at least $4k+4$ of any vertex in $V_{\text{inc}} \cap V(H_i)$ in H^*. Indeed, if this were not the case, then w.l.o.g. the vertices on the boundary of v_{f_1} would have distance at most $4k+6$ from some $w \in V_{\text{inc}} \cap V(H_i)$ in H^*, which would mean that f_1 is also a face in $\mathcal{H}_i^\times$. By the same distance-counting argument introduced at the end of the Proof of Point 1, This implies that no edge in a path P of G from a vertex $v \in H_i$ whose internal vertices all lie in V_{add} can be drawn in any face of $\mathcal{H}^\times$ contained in f.

To complete the proof, let $G_1, \dots, G_p$, $p \le r$ be the connected components of G' that contain a vertex in H and $G_{p+1}, \dots, G_r$ the remaining connected components of G'. We obtain a solution $\mathcal{G}$ to the instance I by simply taking the union of $\mathcal{H}$ and $\mathcal{G}_i$ for $i \in [p]$ and then for $i \in \{p+1, \dots, r\}$ shifting $\mathcal{G}_i$ so that $\mathcal{G}_i$ do not intersect any other part of the drawing. ◀

Since $|V_{\text{inc}}| \le 2k$, Lemma 5 allows us to restrict our attention to a subgraph of diameter at most $(4k+7) \cdot 2 \cdot 2k = 16k^2 + 28k$. This will be especially useful in view of the following known fact, that allows us to assume that the treewidth of our instances is bounded.

▶ **Proposition 6** ([34]). *A planar graph G with radius at most r has treewidth at most $3r+1$.*

▶ **Lemma 7.** *1-Planar Drawing Extension is* FPT *parameterized by $k + \text{tw}(H^*)$ if and only if it is* FPT *parameterized by k, where H^* is the embedding graph of $\mathcal{H}$.*

Proof. The backward direction is trivial. For the forward direction, assume that that there exists an algorithm $\mathcal{B}$ which solves 1-Planar Drawing Extension in time $f(k + \text{tw}(H^*)) \cdot |V(G)|^c$ for some constant c and computable function f. Now, consider the following algorithm $\mathcal{A}$ for 1-Planar Drawing Extension: $\mathcal{A}$ takes an instance $(G_0, H_0, \mathcal{H}_0)$ and constructs

$(G_1, H_1, \mathcal{H}_1)$ by applying Lemma 5. Recall that by Point 1 of Lemma 5, $(G_0, H_0, \mathcal{H}_0)$ is either NO-instance, in which case $\mathcal{A}$ correctly outputs "NO", or each connected component of G_1 contains at most one connected component of H_1.

Now let us consider a connected component $\mathcal{C}$ of G_1 and the embedding graph $H_1^*[\mathcal{C}]$ of $\mathcal{H}_1[\mathcal{C}]$ and let v_f be a face-vertex in $H_1^*[\mathcal{C}]$. If v_f is at distance at least $4k+9$ from every vertex in $V_{\text{inc}} \cap \mathcal{C}$ in $H_1^*[\mathcal{C}]$, then every vertex on the boundary of f is at distance at least $4k+7$ from every vertex $w \in V_{\text{inc}} \cap \mathcal{C}$ in $H_1^*[\mathcal{C}]$. Let v be an arbitrary vertex incident to f in $\mathcal{H}_1[\mathcal{C}]$. Since each face of $\mathcal{H}_0^\times$ is completely contained in precisely one face of $\mathcal{H}_1^\times[\mathcal{C}]$, it follows that v is at distance at least $4k+7$ from each vertex $w \in V_{\text{inc}} \cap \mathcal{C}$ in H^*. Because $v \in V(H_1[\mathcal{C}])$, this contradicts the fact that every vertex in $V(H_1)$ is at distance at most $4k+6$ from a vertex $w \in V_{\text{inc}}$ in H^*. Hence, every face-vertex in $H_1^*[\mathcal{C}]$ is at distance at most $4k+8$ from a vertex in $V_{\text{inc}} \cap \mathcal{C}$. Moreover, every vertex in $H_1^*[\mathcal{C}]$ is at distance at most 2 from some face-vertex and there are at most $2k$ vertices in $V_{\text{inc}} \cap \mathcal{C}$. Therefore, the radius, and by Proposition 6 the treewidth, of $H_1^*[\mathcal{C}]$ is bounded by $\mathcal{O}(k^2)$.

Now, for each connected component $\mathcal{C}$ of G_1, we solve the instance $(G_1[\mathcal{C}], H_1[\mathcal{C}], \mathcal{H}_1[\mathcal{C}])$ using algorithm $\mathcal{B}$. If $\mathcal{B}$ determines that at least one such (sub)-instance is a NO-instance, then $\mathcal{A}$ correctly outputs "NO". Otherwise, $\mathcal{A}$ outputs a solution for $(G_0, H_0, \mathcal{H}_0)$ that it computes by invoking the algorithm given by Point 2 of Lemma 5. To conclude, we observe that $\mathcal{A}$ is a fixed-parameter algorithm parameterized by k and its correctness follows from Lemma 5. ◀

We now have all the ingredients we need to establish our tractability result.

▶ **Theorem 1.** *1-Planar Drawing Extension is* FPT *when parameterized by k.*

Proof Sketch. We prove the theorem by showing that 1-Planar Drawing Extension is fixed-parameter tractable parameterized by $k + \text{tw}(H^*)$, which suffices thanks to Lemma 7.

To this end, consider the following algorithm $\mathcal{A}$. Initially, $\mathcal{A}$ loops over all of the at most $\#\text{pat}(k)$ many patterns, tests whether each pattern is valid or not using Lemma 4, and stores all valid patterns in a set $\mathcal{P}$. Next, it branches over all valid patterns in $\mathcal{P}$, and for each such pattern $P = (S = \{s_1, \ldots, s_\ell\}, Q, C)$ it constructs an MSO formula $\Phi_P(\mathcal{F})$, where $\mathcal{F}$ is a set of at most $7k$ free variables specified later, the purpose of which is to find a suitable "placement" for P in $\mathcal{H}$ by finding an interpretation in the embedding graph H^*. In particular, Φ_P uses the free variables in $\mathcal{F}$ to find a suitable face-vertex x_i for each $s_i \in S$ and a suitable crossing point for each edge mapped to two elements of S, while also guaranteeing that the cyclic orders specified by C are adhered to. Once we find a suitable placement for P in $\mathcal{H}$, the algorithm constructs an extension by topologically "inserting" the pattern graph G_P into the identified faces of $\mathcal{H}^\times$ and using the crossing points as well as vertices in V_{inc} as "anchors". ◀

4.2 A More Efficient Algorithm for Extending by Edges Only

In this subsection we obtain a more explicit and efficient algorithm than in Theorem 1 for the case where $V(G) = V(H)$. The idea underlying the algorithm is to iteratively identify sufficiently many 1-planar drawings of each added edge into $\mathcal{H}$ that can either all be extended to a 1-planar drawing of G, or none of them can, which allows us to branch over a small number of possible drawings for that edge.

Let $X = \bigcup_{uv \in E_{\text{add}}} \{u, v\}$ be the set of all endpoints of edges in E_{add}, and let us fix an order of the added edges by enumerating $E_{\text{add}} = \{e_1, \ldots, e_k\}$. Now, consider a 1-planar drawing $\mathcal{H}_i$ of $H_i := H + \{e_1, \ldots, e_{i-1}\}$ and assume that we want to add e_i as a curve

$\gamma(e_i)$. For a cell f in $\mathcal{H}_i + \gamma(e_i)$ and vertices x_1, x_2 on the boundary of f, we denote by $b_{\gamma(e_i)}(f, x_1, x_2) \subseteq E(H_{i+1})$ the edges on the x_1-x_2-path along the boundary of f which traverses this boundary in counterclockwise direction. We explicitly note that $b_{\gamma(e_i)}(f, x_1, x_2)$ does not contain any half-edges. In this way $b_{\gamma(e_i)}(f, x_1, x_2)$ is the set of edges of H_{i+1} on the x_1-x_2-path along the boundary of f that are not crossed in $\mathcal{H}_i + \gamma(e_i)$, and hence may still be crossed by drawings of $e_{i+1}, \dots, e_k$ in a 1-planar extension of $\mathcal{H}_i + \gamma(e_i)$ to G.

Let $\gamma_1(e_i)$ and $\gamma_2(e_i)$ be two possible curves for e_i to be drawn into $\mathcal{H}_i$. Then we call $\gamma_1(e_i)$ and $\gamma_2(e_i)$ $\{e_{i+1}, \dots, e_k\}$*-partition equivalent* if there is a bijection π from the cells of $\mathcal{H}_i + \gamma_1(e_i)$ to the cells of $\mathcal{H}_i + \gamma_2(e_i)$ such that

- the vertices in X on the boundaries of the cells are invariant under π, i.e., for each cell f whose boundary intersects X precisely in X' it must hold that $\pi(f)$ intersects X precisely in X' as well; and
- for each pair of cells f, f' of $\mathcal{H}_i + \gamma_1(e_i)$ and ordered pairs of (not necessarily pairwise distinct) vertices $(x_1, x_2), (x_1', x_2') \in X^2$ that
  - are on the boundary of f and f', respectively, and
  - the counterclockwise x_1-x_2-path and the counterclockwise x_1'-x_2'-path along the boundaries of f and f', respectively, does not contain any inner vertices in X,

  the following must hold:

$$\begin{cases} \text{if } |b_{\gamma_1(e_i)}(f, x_1, x_2) \cap b_{\gamma_1(e_i)}(f', x_1', x_2')| \le k, \text{ then} \\ \quad |b_{\gamma_1(e_i)}(f, x_1, x_2) \cap b_{\gamma_1(e_i)}(f', x_1', x_2')| = |b_{\gamma_2(e_i)}(\pi(f), x_1, x_2) \cap b_{\gamma_2(e_i)}(\pi(f'), x_1', x_2')| \\ \text{otherwise} \\ \quad \text{also } |b_{\gamma_2(e_i)}(\pi(f), x_1, x_2) \cap b_{\gamma_2(e_i)}(\pi(f'), x_1', x_2')| > k. \end{cases}$$

Roughly speaking, the first condition guarantees that when extending $\mathcal{H}_i$ by $\{e_{i+1}, \dots, e_k\}$-partition equivalent drawings of e_i, the topological separation of all vertices that might be important when drawing $e_{i+1}, \dots, e_k$ is the same. The second condition ensures that when extending $\mathcal{H}_i$ by $\{e_{i+1}, \dots, e_k\}$-partition equivalent drawings of e_i, the number of edges whose drawings might be crossed by drawings of $\{e_{i+1} \dots, e_k\}$ is the same, or so large that they cannot all be crossed by drawings of $\{e_{i+1} \dots, e_k\}$.

▶ **Lemma 8.** *For any $1 \le i \le k$, if two drawings $\gamma_1(e_i), \gamma_2(e_i)$ of e_i into a drawing $\mathcal{H}_i$ of H_i are $\{e_{i+1}, \dots, e_k\}$-partition-equivalent, they either both can be extended to a 1-planar drawing of G, or none of them can.*

Proof. We show that we can obtain a 1-planar drawing extension of $\mathcal{H}_i + \gamma_2(e_i)$ to $G = H_i + \{e_{i+1}, \dots, e_k\}$ from a 1-planar drawing extension of $\mathcal{H}_i + \gamma_1(e_i)$ to G. Then the claim immediately follows by a symmetric argument when $\gamma_1(e_i)$ and $\gamma_2(e_i)$ are interchanged.

Let π be a bijection between the cells of $\mathcal{H}_i + \gamma_1(e_i)$ and the cells of $\mathcal{H}_i + \gamma_2(e_i)$ that witnesses $\{e_{i+1}, \dots, e_k\}$-partition equivalence of $\gamma_1(e_i)$ and $\gamma_2(e_i)$. Assume we are given a 1-planar drawing extension $\mathcal{G}_1$ of $\mathcal{H}_i + \gamma_1(e_i)$ to G. From this, we will define a 1-planar drawing extension $\mathcal{G}_2$ of $\mathcal{H}_i + \gamma_2(e_i)$ to G. For $e \in E(H_i)$ set $\mathcal{G}_2(e) = \mathcal{H}_i(e)$ and set $\mathcal{G}_2(e_i) = \gamma_2(e_i)$. In this way, $\mathcal{G}_2$ is an extension of $\mathcal{H}_i$.

Note that for any cell f of $\mathcal{H}_i + \gamma_1(e_i)$ the order in which the vertices of X occur on the boundary of f is the same (up to possibly reversal) in which they occur on the boundary of $\pi(f)$ (exactly the same such vertices occur because of $\{e_{i+1}, \dots, e_k\}$-partition equivalence). This is due to the fact that $\mathcal{H}_i + \gamma_1(e_i)$ and $\mathcal{H}_i + \gamma_2(e_i)$ are obtained from the same drawing $\mathcal{H}_i$ and drawing edges into $\mathcal{H}_i$ merely subdivides cells and cannot permute the order on their boundaries.

Now we can define $\mathcal{G}_2(e_j)$ for $j \in \{i+1,\dots,k\}$ as follows: For $J \subseteq \{i+1,\dots,k\}$ such that $\mathcal{G}_1(e_j)$ intersects two cells f and g of $\mathcal{H}_i + \gamma_1(e_i)$ for every $j \in J$, it holds that each $\mathcal{G}_1(e_j)$ crosses the drawing $(\mathcal{H}_i + \gamma_1(e_i))(c_j)$ of an edge $c_j \in E(H_i) \cup \{e_i\}$. In particular, c_j lies on the shared boundary of f and g. Both f and g contain a vertex in X in their boundary, as each of them contain at least one endpoint of e_j. Hence there are $x_1, x_2 \in X$ that are consecutive on the boundary of f neglecting everything but X, and $y_1, y_2 \in X$ that are consecutive on the boundary of g neglecting everything but X such that $c_j \in b_{\gamma_1(e_i)}(f, x_1, x_2) \cap b_{\gamma_1(e_i)}(g, y_1, y_2)$. By partition-equivalence the boundaries of $\pi(f)$ and $\pi(g)$ each contain an endpoint of each e_j, and because $|J| \leq k$, we find distinct $c'_j \in b_{\gamma_2(e_i)}(\pi(f), x_1, x_2) \cap b_{\gamma_2(e_i)}(\pi(g), y_1, y_2)$ (or possibly $c'_j \in b_{\gamma_2(e_i)}(\pi(f), x_2, x_1) \cap b_{\gamma_2(e_i)}(\pi(g), y_2, y_1)$) for each $j \in J$. Without loss of generality the c_j are indexed in the order in which they occur on the counterclockwise x_1-x_2-path along the boundary of f. We re-index the c'_j to conform to the same order (up to reversal), also taking x_1 and x_2 into account, on $\pi(f)$. ◀

The next lemma shows that the number of non-equivalent drawings is bounded by a function of k, which in turn allows us to apply exhaustive branching to prove the theorem.

▶ **Lemma 9.** *For any $1 \leq i \leq k$, the number of ways to draw e_i into a drawing $\mathcal{H}_i$ of H_i that are pairwise not $\{e_{i+1},\dots,e_k\}$-partition-equivalent is at most $4(2k+1) \cdot 2(k+1) \in \mathcal{O}(k^2)$.*

▶ **Theorem 2.** *1-Planar Drawing Extension parameterized by k can be solved in time $\mathcal{O}(k^{2k} \cdot n^{\mathcal{O}(1)})$ if $V(G) = V(H)$.*

Proof. We can pre-compute the intersection of the boundary of each cell of $\mathcal{H}$ with X and for each pair of cells f, f' of $\mathcal{H}$ and ordered pairs of vertices $x_1, x_2 \in X$ and x'_1, x'_2 that are consecutive on the boundaries of f and f' respectively if one neglects everything but X, the cardinality of the set of edges that are on the clockwise x_1-x_2-path along the boundary of f and at the same time on the clockwise x'_1-x'_2-path along the boundary of f' in polynomial time.

As described in the proof of Lemma 9, at any stage, for $1 \leq i \leq k$, we can branch on $\{e_{i+1},\dots,e_k\}$-partition-equivalent drawings $\gamma(e)$ of e using the pre-computed information. This information can be modified within each branch according to the choice of $\gamma(e)$ in constant time because, as described in the proof of Lemma 9 the impact of $\gamma(e)$ involves only few values whose modifications can correctly be computed from the updated pre-computed information up to this stage and the chosen values determining $\gamma(e)$. Correctness of this branching follows from Lemma 8. ◀

5 Using Vertex+Edge Deletion Distance for IC-Planar Drawing Extension

In this section, we show that IC-Planar Drawing Extension parameterized by κ is fixed-parameter tractable. We note that an immediate consequence of this is the fixed-parameter tractability of IC-Planar Drawing Extension parameterized by k.

On a high level, our strategy is similar to the one used to prove Theorem 1, in the sense that we also use a (more complicated) variant of the patterns along with Courcelle's Theorem. However, obtaining the result requires us to extend the previous proof technique to accommodate the fact that the number of edges incident to V_{add}, and hence the size of a pattern, is no longer bounded by κ. This is achieved by identifying so-called *difficult vertices* and *regions* that split up the neighborhood of each face-vertex in the embedding graph into a small number of sections (a situation which can then be handled by a formula in Monadic

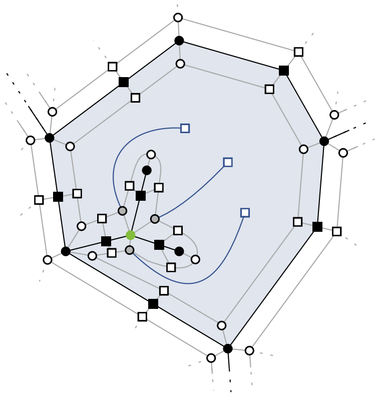


Figure 2 An example of H^* where a vertex $v' \in V_{\text{inc}}$ has several non-difficult shadow copies. Blue vertices are in V_{add}. The green vertex has no difficult shadow copy w.r.t. the blue face in $\mathcal{H}^\times$.

Second Order logic). Less significant complications are that we need a stronger version of Lemma 5 to ensure that the diameter of the resulting graph is bounded, and need to be more careful when using MSO logic in the proof of the main theorem.

Let f be a face of $\mathcal{H}^\times$ and let $\mathcal{G}$ be a solution (i.e., an IC-planar drawing of G) for the instance $(G, H, \mathcal{H})$. Let H^* be the embedding graph of $\mathcal{H}$, and without loss of generality let us assume (via topological shifting) that each edge between a vertex a' on the boundary of f and a vertex $b \in V_{\text{add}}$ placed by $\mathcal{G}$ in f is routed "through" one shadow copy of a'[4]. Let V_{add}^f be the subset of V_{add} drawn by $\mathcal{G}$ in the face f.

Observe that, since shadow vertices are not part of the original instance and instead merely mark possible "parts" of the face that can be used to access a given vertex, it may happen that a solution routes several edges through one shadow vertex. We say that a shadow vertex $v \in N_{H^*}(v_f)$ (where $N_{H^*}(v_f)$ denotes the neighborhood of v_f in H^*) is *difficult* w.r.t. f if $\mathcal{G}$ routes at least two edges through v. Note that it may happen that a vertex $v' \in V_{\text{inc}}$ with more than one neighbor in V_{add} has several shadow copies, none of which are difficult (see Figure 2).

▶ **Lemma 10.** *There are at most $3\kappa^2$ difficult vertices w.r.t. a face f of $\mathcal{H}^\times$.*

Proof. We show that any two of the ℓ added vertices drawn into f in $\mathcal{G}$ are both connected to at most 3 vertices in $N_{H^*}(v_f)$. Then the claim follows. Assume for contradiction that $v_1, v_2 \in V_{\text{add}}$ are drawn into f in $\mathcal{G}$ and $w_1, w_2, w_3, w_4 \in N_{H^*}(v_f)$ are shadow vertices that each route two edges, one of which is incident to v_1 and one of which is incident to v_2. Since H is connected, the boundary of f is connected, and by construction of H^*, w_1, w_2, w_3, w_4 all lie on a cycle in H^* that does not involve any of $\{v_{f'} \mid f' \text{ face in } \mathcal{H}^\times\}$. Hence the following graph H' is a minor of $H^* - \{v_{f'} \mid f' \text{ face in } \mathcal{H}^\times\} + V_{\text{add}} + E_{\text{add}}$: $H' = (\{v_1, v_2, w_1, \dots, w_4, v_f\}, \{v_i w_j \mid i \in \{1, 2, f\}, j \in \{1, \dots, 4\} \cup \{w_i w_{(i \bmod 4)+1} \mid i \in \{1, \dots, 4\})$. H' does not admit a 1-planar drawing in which both v_1 and v_2 lie on the same side of the drawing of the w_1-w_2-w_3-w_4-cycle and v_1 and v_2 are each incident to at most one edge whose drawing is crossed. However the existence of $\mathcal{G}$ implies that exactly such a drawing of H' exists. ◀

[4] The reason one distinguishes which shadow copy of a' the edge is routed through is because this unambiguously identifies which part of the face the edge uses to access a'.

A region R of a vertex $x \in V_{\mathrm{add}}^f$ (or, equivalently, of a face f) is a maximal path $(r_1, \ldots, r_p)$ in $N_{H^*}(v_f)$ with the following properties: (1) $\mathcal{G}$ does not route through any shadow copy of an edge in R; (2) for each vertex r in R, a uncrossed curve can be drawn in $\mathcal{G}$ inside f between r and x; (3) none of the vertices in R are adjacent to $V_{\mathrm{add}}^f \setminus \{x\}$; and (4) r_1 and r_p are adjacent to x.

▶ **Lemma 11.** *There are at most 3κ regions of a face f.*

Proof. Consider a path P in $H^*[N_{H^*}(v_f)]$ that traverses all ℓ regions of a vertex $v \in V_{\mathrm{add}}^f$. It contains at least $\ell - 1$ pairwise disjoint subpaths $P_1, \ldots, P_{\ell-1}$ of paths connecting regions of v that are consecutive in P.

For every P_i ($i \in \{1, \ldots, \ell\}$), by the property that regions are inclusion maximal paths of vertices with certain properties, we find some vertex x in P_i that has to violate one of these properties. This can happen in three ways:

(1) x is a shadow copy of an edge and $\mathcal{G}$ routes through x,
(2) (1) is not the case and the drawing of some edge $e \in E_{\mathrm{add}}$ separates x from v in $\mathcal{H}$, or
(3) (1) and (2) are not the case and x is adjacent to another vertex $w \in V_{\mathrm{add}}^f \setminus \{v\}$.

In case (1) there is an edge $e \in E_{\mathrm{add}}$ such that the drawing of e crosses the boundary of f in $\mathcal{H}$ and routes through x.

In case (2) the edge in question has both endpoints on P, thus $e \in E_{\mathrm{add}}^H$ or the drawing of e crosses either the boundary of f in $\mathcal{H}$ or a drawing of another added edge.

There are at most $|E_{\mathrm{add}}^H|$ edges in E_{add}^H and at most $|V_{\mathrm{add}}|$ edges in $E_{\mathrm{add}} \setminus E_{\mathrm{add}}^H$ that can cross another edge in an IC-planar drawing. Moreover, in both cases (1) and (2), the endpoints of e cannot occur in any P_j with $j \in \{1, \ldots, \ell\} \setminus \{i\}$.

In case (3) either x is contained in a region of w or the drawing of xw in $\mathcal{H}$ crosses an edge and is the only drawing of an edge incident to w that does so. If x is in a region of w, w is separated from $N_{H^*}(v_f) \setminus P_i$ by the edges from v to the outermost vertices of the regions that P_i connects and hence can have no region outside of P_i. There are at most $|V_{\mathrm{add}}|$ many such w.

Thus we find at most $|E_{\mathrm{add}}^H| + |V_{\mathrm{add}}| + 2|V_{\mathrm{add}}|$ such x on P in total and thus $\ell \leq |E_{\mathrm{add}}^H| + |V_{\mathrm{add}}| + 2|V_{\mathrm{add}}| \leq 3\kappa$. This concludes the proof. ◀

The underlying intuition one should keep about regions and difficult vertices is that a solution $\mathcal{G}$ partitions the shadow vertices into those which **(a)** have no edges routed through them, **(b)** have precisely one edge routed through them (in which case they must be part of the respective region), and **(c)** have at least two edges routed through them (in which case they form a difficult vertex).

In the remainder of this section we give some intuition on how the techniques used to prove Theorem 1 need to be extended to obtain Theorem 3. Unlike in the proof of Theorem 1 the number of vertices in V_{inc} is not bounded by κ. Consequently, we cannot track their exact placement through patterns as defined in Definition 1. To circumvent this, we define *extended patterns* that store the necessary details about the cyclic orders in which individual regions, difficult vertices together with crossings, and endpoints of edges in E_{add}^H as well as the single edge per vertex in V_{add} that is allowed to cross, are supposed to appear inside a face. Then, as for patterns, we define how an extended pattern is *derived* from potential solutions.

The proof then proceeds by following the strategy laid down in Subsection 4.1. In particular, we define a notion of validity along with *pattern graphs* for extended patterns (cf. Definition 3). We show that validity can be checked and pattern graphs can be constructed efficiently (cf. Lemma 4). We use analogues to Lemma 5 and Lemma 7 to prune our instances so that they have bounded treewidth. At this point, we have all the ingredients we need to prove our final Theorem 3 – the main complication here compared to the proof of Theorem 1 is that we cannot have explicit labels identifying individual vertices in V_{inc}.

▶ **Theorem 3.** *IC-Planar Drawing Extension is* FPT *parameterized by* κ.

6 Inserting Two Vertices into a 1-Plane Drawing

In this section we show that 1-Planar Drawing Extension is polynomial-time tractable in the case where we are only adding 2 vertices to the graph along with their incident edges (i.e., when $|V_{\text{add}}| = 2$ and $E^H_{\text{add}} = \emptyset$[5]). Already solving this, at first glance simple, case seems to require non-trivial insight into the problem. In the following we call the two vertices in V_{add} the *red* and *blue* vertex, denoted by r and b, respectively.

On a high level, our algorithm employs a "delimit-and-sweep" approach. First, it employs exhaustive branching to place the vertices and identify a so-called "initial delimiter" – a Jordan curve that isolates a part of our instance that we need to focus on. In the second step, it uses such an initial delimiter to solve the instance via a careful dynamic programming subroutine. As our very first step, we exhaustively branch to determine which cells r and b should be drawn in, in $\mathcal{O}(n^2)$ time, and in each branch we add r and b into the selected cell(s) (from now on, we consider these embeddings part of $\mathcal{H}$).

The Flow Subroutine. Throughout this section, we will employ a generic network-flow subroutine that allows us to immediately solve certain restricted instances of 1-Planar Drawing Extension. In particular, assuming we are in the setting where r and b have already been inserted into $\mathcal{H}$, consider the situation where:

- There is a partial mapping λ from the faces of $\mathcal{H}^\times$ to $\{R, B\}$; and
- r and b are in different cells of $\mathcal{H}$.

We say a 1-planar extension of $\mathcal{H}$ to G is λ-*consistent* if the drawing of any edge in $E(G) \setminus E(H)$ which is incident to r intersects the interior of face F of $\mathcal{H}^\times$ only if $\lambda(F) = R$, and correspondingly the drawing of any edge in $E(G) \setminus E(H)$ which is incident to b intersects the interior of face F of $\mathcal{H}^\times$ only if $\lambda(F) = B$ (i.e., λ specifies precisely which kind of edges may enter which face). We use a reduction to network flows to show:

▶ **Lemma 12.** *Given λ as above, it is possible to determine whether there exists a λ-consistent 1-planar extension of $\mathcal{H}$ to G in polynomial time.*

Proof Sketch. Consider the max flow instance θ_1 constructed as follows. θ_1 contains a universal sink t and a universal source s. We add one vertex for each vertex in $N_{E(G)\setminus E(H)}(r)$, and a capacity-1 edge from each such "R-vertex" to t. We add one "f-vertex" for each face f in $\mathcal{H}^\times$ that λ maps to R, and a capacity-1 edge from each such vertex to every R-vertex that lies on the boundary of f. We add an (unlimited-capacity) edge from s to every f-vertex whose face contains r (possibly on its boundary). Finally, we add an edge from every f-vertex whose face contains r to each other f'-vertex of capacity equal to the number of crossable edges that lie on the shared boundary of f and f'. The instance θ_2 is constructed in an analogous fashion for B and b. To conclude the proof, it suffices to show that the drawings of the edges in E_{add} incident to r in a λ-consistent extension $\mathcal{G}$ of $\mathcal{H}$ to G correspond to s-t-flows of values $|N_{E(G)\setminus E(H)}(r)|$ and $|N_{E(G)\setminus E(H)}(b)|$ for θ_1 and θ_2, respectively. ◀

[5] We note that it is trivial to extend the result to the case where the number of added edges is bounded by a fixed constant, via simple exhaustive branching.

▶ **Corollary 13.** *1-Planar Drawing Extension for $|V_{add}| = 1$ and $E^H_{add} = \emptyset$ can be solved in polynomial time.*

Finding an Initial Delimiter. We begin by formally defining the following notion:

▶ **Definition 14.** *A Jordan curve ω in the plane is an* initial delimiter *for $\mathcal{H}$ if:*

1. *ω passes through both r and b but through no other vertex of $\mathcal{H}$,*
2. *whenever ω shares at most one point with the interior of an edge, this point is a proper crossing between ω and that edge,*
3. *the intersection between $\mathcal{H}$ and the exterior of ω (including ω itself) contains a single cell c_r whose boundary contains r, and a single cell c_b whose boundary contains b, and*
4. *the intersection of the boundary of c_r (resp. c_b) and ω is a single simple curve containing r (resp. b) as an interior point.*

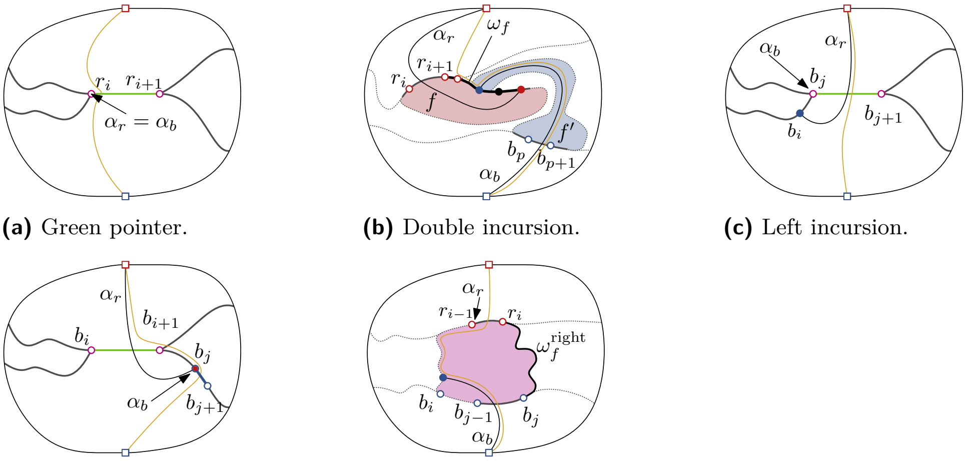
Intuitively, the third condition means that if we add ω onto $\mathcal{H}$, then there are unique cells in the exterior of ω for r and b. A solution for our instance, i.e., a drawing $\mathcal{G}$ of G, is ω-*compatible* if every edge from E_{add} is drawn in the exterior region defined by ω. We state the main result of this subsection below – intuitively, it provides us with a set of initial delimiters that we can exhaustively branch over, and in each branch we can restrict our attention to solutions that are compatible with the chosen initial delimiter. To avoid confusion, we note that the lemma covers the case where r and b are placed in the same cell f (by branching on and placing a constant number of new edges that "separate" the boundary of f).

▶ **Lemma 15.** *For every instance $(G, H, \mathcal{H})$ where $|V_{add}| \leq 2$ and $E^H_{add} = \emptyset$, we can in polynomial time either solve $(G, H, \mathcal{H})$ or construct a set Q of initial delimiters with the following property (or both): if $(G, H, \mathcal{H})$ admits a solution, then Q contains at least one ω such that $(G, H, \mathcal{H})$ also admits an ω-compatible solution.*

Dynamic Programming. We can now proceed with a very high-level sketch of how the algorithm proceeds once we have pre-selected (via branching) an initial delimiter. The general idea is to perform a left-to-right sweep of $\mathcal{H}$ by starting with the boundaries provided by the initial delimiter. The runtime of the algorithm is upper-bounded by the fact that it relies on dynamic programming where the maximum size of the records (representing possible "positions" on our sweep) is polynomial in the input size, and where the possibility of transitioning from one record to the next can be checked in polynomial time. In particular, the "steps" we use to move from one record to the next relies on a situational combination of exhaustive branching and the network-flow subroutine described in Lemma 12.

The intuitive reason we need to combine both of these techniques is that in some parts of our sweep, we will encounter faces where edges from both r and b may enter – there the interactions between these edges are too complicated to be modeled as a simple flow problem, but (as we will show) we can identify separating curves that cut our instance into parts for which we have a mapping λ that can be applied in conjunction with Lemma 12.

We now formalize the records used by our algorithm: a *record* is a tuple (α_r, α_b, T), where α_r is either a vertex in $\mathcal{H}$ or an edge $e \in E_{\text{add}}$ incident to r. α_b is defined symmetrically, and we describe such edges by specifying their endpoint and potential crossing point. T is then an auxiliary element that specifies the "type" of a given record. Finally, we associate each record with a *delimiter* that iteratively pushes our "left" initial delimiter boundary towards the "right" one; everything to the left of the *delimiter* can be ignored, since the assumptions



(a) Green pointer.

(b) Double incursion.

(c) Left incursion.

(d) Right incursion.

(e) Slice.

Figure 3 The five types of records for the dynamic program. The computed delimiters are the orange curves. r and b are the rectangular vertices, colored disks are in R and B, white disks are r_i and b_i depending on their border-color.

we use to select our records guarantee that it cannot be crossed by an edge of the targeted solution.

While we are forced to omit the majority of the details of the algorithm due to space constraints, below we at least provide a brief, intuitive summary of the 5 types of records used (see also Figure 3):

1. **Green Pointer.** $\alpha_r = \alpha_b$ is a vertex incident to an edge on the boundary of c_r and c_b.
2. **Double Incursion.** One edge "covers" a part of one face that is accessed by the other edge from the other side.
3. **Left Incursion.** α_r (or α_b) crosses into c_b (or c_a) and heads "left".
4. **Right Incursion.** α_r (or α_b) crosses into c_b (or c_a) and heads "right".
5. **Slice.** One or both edges cross into a face other than c_r and c_b.

Altogether, by using these records and carefully analyzing the cases that allow us to transition from one record to the other, we obtain a proof of:

▶ **Theorem 4.** *1-Planar Drawing Extension is polynomial-time tractable if $\kappa \leq 2$.*

7 Concluding Remarks

In this paper, we initiated the study of the problem of extending partial 1-planar and IC-planar drawings by providing several parameterized algorithms that target cases where only a few edges and/or vertices are missing from the graph. Our results follow up on previous seminal work on extending planar drawings, but the techniques introduced and used here are fundamentally different [2]. The by far most prominent question left open in our work concerns the (not only parameterized, but also classical) complexity of 1-Planar Extension w.r.t. κ. In particular, can one show that the problem is, at least, polynomial-time tractable for fixed values of κ? While the results presented in Section 6 are a promising start in this direction, it seems that new ideas are needed to push beyond the two-vertex case.

Follow-up work may also focus on extending other types of beyond planar drawings [17].

Abstract

In the well known planted clique problem, a clique (or alternatively, an independent set) of size k is planted at random in an Erdos-Renyi random $G(n, p)$ graph, and the goal is to design an algorithm that finds the maximum clique (or independent set) in the resulting graph. We introduce a variation on this problem, where instead of planting the clique at random, the clique is planted by an adversary who attempts to make it difficult to find the maximum clique in the resulting graph. We show that for the standard setting of the parameters of the problem, namely, a clique of size $k = \sqrt{n}$ planted in a random $G(n, \frac{1}{2})$ graph, the known polynomial time algorithms can be extended (in a non-trivial way) to work also in the adversarial setting. In contrast, we show that for other natural settings of the parameters, such as planting an independent set of size $k = \frac{n}{2}$ in a $G(n, p)$ graph with $p = n^{-\frac{1}{2}}$, there is no polynomial time algorithm that finds an independent set of size k, unless NP has randomized polynomial time algorithms.

1 Introduction

The planted clique problem, also referred to as hidden clique, is a problem of central importance in the design of algorithms. We introduce a variation of this problem where instead of planting the clique at random, an adversary plants the clique. Our main results are that in certain regimes of the parameters of the problem, the known polynomial time algorithms can be extended to work also in the adversarial settings, whereas for other regimes, the adversarial planting version becomes NP-hard. We find the results interesting for three reasons. One is that they concern an extensively studied problem (planted clique), but from a new direction, and we find that the results lead to a better understanding of what aspects of the planted clique problem are made use of by the known algorithms. Another is that extending the known algorithms (based on semidefinite programming) to the adversarial planted setting involves some new techniques regarding how semidefinite programming can be used and analysed. Finally, the NP-hardness results are interesting as they are proven in a semi-random model in which most of the input instance is random, and the adversary controls only a relatively small aspect of the input instance. One may hope that this brings us closer to proving NP-hardness results for purely random models, a task whose achievement would be a breakthrough in complexity theory.

1.1 The random planted clique model

Our starting point is the Erdos-Renyi $G(n,p)$ random graph model, which generates graphs on n vertices, and every two vertices are connected by an edge independently with probability p. We start our discussion with the special case in which $p = \frac{1}{2}$, and other values of p will be considered later. Given a graph G, let $\omega(G)$ denote the size of the maximum clique in G, and let $\alpha(G)$ denote the size of the maximum independent set. Given a distribution D over graphs, we use the notation $G \sim D$ for denoting a graph sampled at random according to D. The (edge) complement of a graph $G \sim G(n, \frac{1}{2})$ is by itself a graph sampled from $G(n, \frac{1}{2})$, and the complement of a clique is an independent set, and hence the discussion concerning cliques in $G(n, \frac{1}{2})$ extends without change to independent sets (and vice versa).

It is well known (proved by computing the expectation and variance of the number of cliques of the appropriate size) that for $G \sim G(n, \frac{1}{2})$, w.h.p. $\omega(G) \simeq 2\log n$ (the logarithm is in base 2). However, there is no known polynomial time algorithm that can find cliques of size $2\log n$ in such graphs. A polynomial time greedy algorithm can find a clique of size $(1 + o(1))\log n$. The existence of $\rho > 1$ for which polynomial time algorithms can find cliques of size $\rho \log n$ is a longstanding open problem.

In the classical planted clique problem, one starts with a graph $G' \sim G(n, \frac{1}{2})$ and a parameter k. In G' one chooses at random a set K of k vertices, and makes this set into a clique by inserting all missing edges between pairs of vertices with K. We refer to K as the planted clique, and say that the resulting graph G is distributed according to $G(n, \frac{1}{2}, k)$. Given $G \sim G(n, \frac{1}{2}, k)$, the algorithmic goal can be one of the following three: find K, find a clique of maximum size, or find any clique of size at least k. It is not difficult to show that when k is sufficiently large (say, $k > 3\log n$), then with high probability K is the unique maximum size clique in $G \sim G(n, \frac{1}{2}, k)$, and hence all three goals coincide. Hence in the planted clique problem, the goal is simply to design polynomial time algorithms that (with high probability over the choice of $G \sim G(n, \frac{1}{2}, k)$) find the planted clique K. The question is how large should k be (as a function of n) so as to make this task feasible.

For some sufficiently large constant $c > 0$ (throughout, we use c to denote a sufficiently large constant), if $k > c\sqrt{n \log n}$, with high probability the the vertices of K are simply the k vertices of highest degree in G (see [13]), and hence K can easily be recovered. Alon, Krivelevich and Sudakov [1] managed to shave the $\sqrt{\log n}$ factor, designing a spectral algorithm that recovers K when $k > c\sqrt{n}$. They also showed that c can be made an arbitrarily small constant, by increased the running time by a factor of $n^{O(\log(\frac{1}{c}))}$ (this is done by "guessing" a set K' of $O(\log(\frac{1}{c}))$ vertices of K, and finding the maximum clique in the subgraph induced on their common neighbors). Subsequently, additional algorithms were developed that find the planted clique when $k > c\sqrt{n}$. They include algorithms based on the Lovasz theta function, which is a form of semi-definite programming [7], algorithms based on a "reverse-greedy" principle [10, 3], and message passing algorithms [4]. There have been many attempts to find polynomial time algorithms that succeed when $k = o(\sqrt{n})$, but so far all of them failed (see for example [11, 8, 16]). It is a major open problem whether there is any such polynomial time algorithm.

Planted clique when $p \neq \frac{1}{2}$ was not studied as extensively, but it is quite well understood how results from the $G(n, \frac{1}{2}, k)$ model transfer to the $G(n, p, k)$ model. For p much smaller that $\frac{1}{2}$, say $p = n^{\delta - 1}$ for some $0 < \delta < 1$ (hence average degree n^{δ}), the problem changes completely. Even without planting, with high probability over the choice of $G \sim G(n,p)$ (with $p = n^{\delta-1}$) we have that $\omega(G) = O(\frac{1}{1-\delta})$, and the maximum clique can be found in polynomial time. This also extends to finding maximum cliques in the planted setting, regardless of the value of k. (We are not aware of such results being previously published, but they are not difficult. See Section 2.2.) For $p > \frac{1}{2}$, it is more convenient to instead look at the equivalent problem in which $p < \frac{1}{2}$, but with the goal of finding a planted independent set instead of a planted clique. We refer to this model as $\bar{G}(n,p,k)$. For $G \sim G(n,p)$ (with $p = n^{\delta-1}$) we have that with high probability $\alpha(G) = \Theta(n^{1-\delta}\log n)$. For $G \sim \bar{G}(n,p,k)$ the known algorithms extend to finding planted independent sets of size $k = cn^{1-\frac{\delta}{2}}$ in polynomial time. We remark that the approach of [1] of making c arbitrarily small does not work for such sparse graphs.

1.2 The adversarial planted clique model

In this paper we introduce a variation on the planted clique model (and planted independent set model) that we refer to as the adversarial planted clique model. As in the random planted clique model, we start with a graph $G' \sim G(n,p)$ and a parameter k. However, now a computationally unbounded adversary may inspect G', select within it a subset K of k vertices of its choice, and make this set into a clique by inserting all missing edges between pairs of vertices with K. We refer to this model as $AG(n,p,k)$ (and the corresponding model for planted independent set as $A\bar{G}(n,p,k)$). As shorthand notation shall use $G \sim AG(n,p,k)$ to denote a graph generated by this process. Let us clarify that $AG(n,p,k)$ is not a distribution over graphs, but rather a family of distributions, where each adversarial strategy (where a strategy of an adversary is a mapping from G' to a choice of K) gives rise to a different distribution.

In the adversarial planted model, it is no longer true that the planted clique is the one of maximum size in the resulting graph G. Moreover, finding K itself may be information theoretically impossible, as K might be statistically indistinguishable from some other clique of size k (that differs from K by a small number of vertices). The three goals, that of finding K, finding a clique of maximum size, or finding any clique of size at least k, are no longer equivalent. Consequently, for our algorithmic results we shall aim at the more demanding goal of finding a clique of maximum size, whereas for our hardness results, we shall want them to hold even for the less demanding goal of finding an arbitrary clique of size k.

1.3 Our results

Our results cover a wide range of values of $0 < p < 1$, where p may be a function of n. For simplicity of the presentation and to convey the main insights of our results, we present here the results for three representative regimes: $p = \frac{1}{2}$, $p = n^{\delta-1}$ for $0 < \delta < 1$, and $p = 1 - n^{\delta-1}$. For the latter regime, it will be more convenient to replace it by the equivalent problem of finding adversarially planted independent sets when $p = n^{\delta-1}$.

Informally, our results show the following phenomenon. We consider only the case that $p \le \frac{1}{2}$, but consider both the planted clique and the planted independent set problems, and hence the results can be translated to $p > \frac{1}{2}$ as well. For clique, we show (Theorem 1 and Theorem 2) how to extend the algorithmic results known for the random planted clique setting to the adversarial planted clique setting. However, for independent set, we show that this is no longer possible. Specifically, when p is sufficiently small, we prove (Theorem 3) that finding an independent set of size k (any independent set, not necessarily the planted one) in the adversarial planted independent set setting is NP-hard. Moreover, the NP-hardness result holds even for large values of k for which finding a random planted independent set is trivial.

▶ **Theorem 1.** *For every fixed $\varepsilon > 0$ and for every $k \geq \varepsilon\sqrt{n}$, there is an (explicitly described) algorithm running in time $n^{O(\log(\frac{1}{\varepsilon}))}$ which almost surely finds the maximum clique in a graph $G \sim AG(n, \frac{1}{2}, k)$. The statement holds for every adversarial planting strategy (choice of k vertices as a function of $G' \sim G(n, \frac{1}{2})$), and the probability of success is taken over the choice of $G' \sim G(n, \frac{1}{2})$.*

▶ **Theorem 2.** *Let $p = n^{\delta-1}$ for $0 < \delta < 1$. Then for every k, there is an (explicitly described) algorithm running in time $n^{O(\frac{1}{1-\delta})}$ which almost surely finds the maximum clique in a graph $G \sim AG(n,p,k)$. The statement holds for every adversarial planting strategy, and the probability of success is taken over the choice of $G' \sim G(n,p)$.*

▶ **Theorem 3.** *For $p = n^{\delta-1}$ with $0 < \delta < 1$, $0 < \gamma < 1$, and $cn^{1-\delta}\log n \leq k \leq \frac{2}{3}n$ (where c is a sufficiently large constant, and the constant $\frac{2}{3}$ was chosen for concreteness – any other constant smaller than 1 will work as well) the following holds. There is no polynomial time algorithm that has probability at least γ of finding an independent set of size k in $G \sim A\bar{G}(n,p,k)$, unless NP has randomized polynomial time algorithms (NP=RP). (The algorithm is required to succeed against every adversarial planting strategy, and the probability of success is taken over the choice of $G' \sim G(n,p)$.)*

1.4 Related work

Some related work was already mentioned in Section 1.1.

Our algorithm for Theorem 1 is based on an adaptation of the algorithm of [7] that applied to the random planted clique setting. In turn, that algorithm is based on the theta function of Lovasz [14].

A work that is closely related to ours and served as an inspiration both to the model that we study, and to the techniques that are used in the proof of the NP-hardness result (Theorem 3) is the work of David and Feige [2] on adversarially planted 3-colorings. That work uncovers a phenomenon similar to the one displayed in the current work. Specifically, for the problem of 3-coloring (rather than clique or independent set) it shows that for certain values of p, algorithms that work in the random planted setting can be extended to the adversarial planted setting, and for other values of p, finding a 3-coloring in the adversarial planted setting becomes NP-hard. However, there are large gaps left open in the picture that emerges from the work of [2]. For large ranges of the values of p, specifically, $n^{-1/2} < p < n^{-1/3}$ and $p < n^{-2/3}$, there are neither algorithmic results nor hardness results in the work of [2]. Unfortunately, the most interesting values of p for the 3-coloring problem, which are $p \leq \frac{c\log n}{n}$, lie within these gaps, and hence the results of [2] do not apply to them. Our work addresses a different problem (planted clique instead of planted 3-coloring), and for our problem, our analysis leaves almost no such gaps. We are able to determine for which values of p the problem is polynomial time solvable, and for which values it is NP-hard. See Section 3 for more details.

Our model is an example of a *semi-random* model, in which part of the input is determined at random and part is determined by an adversary. There are many other semi-random models, both for the clique problem and for other problems. Describing all these models is beyond the scope of this paper, and the interested reader is referred to [5] and references therein for additional information.

2 Overview of the proofs

In this section we provide an overview of the proofs for our three main theorems. Further details, as well as extensions to the results, appear in the full version of our paper [6].

The term *almost surely* denotes a probability that tends to 1 as n grows. The term *extremely high probability* denotes a probability of the form $1 - e^{-n^r}$ for some $r > 0$. By $\exp(x)$ for some expression x we mean e^x.

2.1 Finding cliques using the theta function

In this section we provide an overview of the proof of Theorem 1. Our algorithm is an adaptation of the algorithm of [7] that finds the maximum clique in the random planted model. We shall first review that algorithm, then describe why it does not apply in our setting in which an adversary plants the clique, and finally explain how we modify that algorithm and its analysis so as to apply it in the adversarial planted setting.

The key ingredient in the algorithm of [7] is the theta function of Lovasz, denoted by ϑ. Given a graph G, $\vartheta(G)$ can be computed in polynomial time (up to arbitrary precision, using semidefinite programming (SDP)), and satisfies $\vartheta(G) \geq \alpha(G)$. As we are interested here in cliques and not in independent sets, we shall consider $\bar{G}$, the edge complement of G, and then $\vartheta(\bar{G}) \geq \omega(G)$. The theta function has several equivalent definitions, and the one that we shall use here (referred to as ϑ_4 in [14]) is the following.

Given a graph $G = G(V, E)$, a collection of unit vectors $s_i \in \mathbb{R}^n$ (one vector for every vertex $i \in V$) is an *orthonormal representation* of G, if s_i and s_j are orthogonal ($s_i \cdot s_j = 0$) whenever $(i, j) \in E$. The theta function is the maximum value of the following expression, where maximization is over all orthonormal representations $\{s_i\}$ of G and over all unit vectors h (h is referred to as the *handle*):

$$\vartheta(G) = \max_{h,\{s_i\}} \sum_{i \in V} (h \cdot s_i)^2 \tag{1}$$

The optimal orthonormal representation and the associated handle that maximize the above formulation for ϑ can be found (up to arbitrary precision) in polynomial time by formulating the problem as an SDP (details omitted). Observe that for any independent set S the following is a feasible solution for the SDP: choose $s_i = h$ for all $i \in S$, and choose all remaining vectors s_j for $j \notin S$ to be orthogonal to h and to each other. Consequently, $\vartheta(G) \geq \alpha(G)$, as claimed.

The main content of the algorithm of [7] is summarized in the following theorem. We phrased it in a way that addresses cliques rather than independent sets, implicitly using $\alpha(\bar{G}) = \omega(G)$. We also remind the reader that in the random planted model, the planted clique K is almost surely the unique maximum clique.

▶ **Theorem 4** (Results of [7]). *Consider $G \sim G(n, \frac{1}{2}, k)$, a graph selected in the random planted clique model, with $k \geq c\sqrt{n}$ for some sufficiently large constant c. Then with extremely high probability (over choice of G) it holds that $\vartheta(\bar{G}) = \omega(G)$.*

Moreover, for every vertex i that belongs to the planted clique K, the corresponding vector s_i has inner product larger than $1 - \frac{1}{n}$ with the handle h, and for every other vertex, the corresponding inner product is at most $\frac{1}{n}$.

Given Theorem 4, the following algorithm finds the planted clique when $G \sim G(n, \frac{1}{2}, k)$, and $k \geq c\sqrt{n}$ for some sufficiently large constant c. Solve the optimization problem (1) (on $\bar{G}$) to sufficiently high precision, and output all vertices whose corresponding inner product with h is at least $\frac{1}{2}$.

The algorithm above does not apply to $G \sim AG(n, \frac{1}{2}, k)$, a graph selected in the adversarial planted clique model, for the simple reason that Theorem 4 is incorrect in that model. The following example illustrates what might go wrong,

▶ **Example 5.** Consider a graph $G' \sim G(n, \frac{1}{2})$. In G' first select a random vertex set T of size slightly smaller than $\frac{1}{2}\log n$. Observe that the number of vertices in G' that are in the common neighborhood of all vertices of T is roughly $2^{-|T|}n > \sqrt{n}$. Plant a clique K of size k in the common neighborhood of T. In this construction, K is no longer the largest clique in G. This is because T (being a random graph) is expected to have a clique K' of size $2\log|T| \simeq 2\log\log n$, and $K' \cup K$ forms a clique of size roughly $k + 2\log\log n$ in G. Moreover, as T itself is a random graph with edge probability $\frac{1}{2}$, the value of the theta function on T is roughly $\sqrt{|T|}$ (see [12]), and consequently one would expect the value of $\vartheta(\bar{G})$ to be roughly $k + \sqrt{\log n}$.

Summarizing, it is not difficult to come up with strategies for planting cliques of size k that result in the maximum clique having size strictly larger than k, and the value of $\vartheta(\bar{G})$ being even larger. Consequently, the solution of the optimization problem (1) by itself is not expected to correspond to the maximum clique in G.

We now explain how we overcome the above difficulty. A relatively simple, yet important, observation is the following.

▶ **Proposition 6.** *Let $G \sim AG(n,p,k)$ with $p = 1/2$ and $k > \sqrt{n}$, and let K' be the maximum clique in G (which may differ from the planted clique K). Then with extremely high probability over the choice of $G' \sim G(n, \frac{1}{2})$, for every possible choice of k vertices by the adversary, K' contains at least $k - O(\log n)$ vertices from K, and at most $O(\log n)$ additional vertices.*

Proof. Standard probabilistic arguments show that with extremely high probability, the largest clique in G' (prior to planting a clique of size k) is of size at most $\frac{k}{2}$. When this holds, K' contains at least $\frac{k}{2}$ vertices from K. Each of the remaining vertices of K' needs to be connected to all vertices in $K' \cap K$. Consequently, with extremely high probability, K' contains at most $2\log n$ vertices not from K. This is because a $G' \sim G(n, \frac{1}{2})$ graph, with extremely high probability, does not contain two sets of vertices A and B, with $|A| = 2\log n$, $|B| = \Omega(\sqrt{n})$, such that all pairs of vertices in $A \times B$ induce edges in G.

As $|K'| \geq k$, we conclude that all but $O(\log n)$ vertices of K must be members of K'. ◀

A key theorem that we prove is:

▶ **Theorem 7.** *Let $G \sim AG(n,p,k)$ with $p = 1/2$ and $k = k(n) \geq 10\sqrt{n}$. Then $k \leq \vartheta(\bar{G}) \leq k + O(\log n)$ with extremely high probability over the choice of $G' \sim G(n, \frac{1}{2})$, for every possible choice of k vertices by the adversary.*

We now explain how Theorem 7 is proved. The bound $\vartheta(\bar{G}) \geq k$ was already explained above. Hence it remains to show that $\vartheta(\bar{G}) \leq k + O(\log n)$. In general, to bound $\vartheta(G)$ from above for a graph $G(V,E)$, one considers the following dual formulation of ϑ, as a minimization problem.

$$\vartheta(G) = \min_M[\lambda_1(M)] \tag{2}$$

Here M ranges over all n by n symmetric matrices in which $M_{ij} = 1$ whenever $(i,j) \notin E$, and $\lambda_1(M)$ denotes the largest eigenvalue of M. (Observe that if G has an independent set S of size k, then M contains a k by k block of 1 entries. A Rayleigh quotient argument then implies that $\lambda_1(M) \geq k$, thus verifying the inequality $\vartheta(G) \geq \alpha(G)$.) To prove Theorem 7 we exhibit a matrix M as above (for the graph $\bar{G}$) for which we prove that $\lambda_1(M) \leq k + O(\log n)$.

We first review how a matrix M was chosen by [7] in the proof of Theorem 4. First, recall that we consider $\bar{G}$, and let E be the set of edges of $\bar{G}$ (non-edges of G). We need to associate values with the entries M_{ij} for $(i,j) \in E$ (as other entries are 1). The matrix block corresponding to the planted clique K (planted independent set in $\bar{G}$) is all 1 (by necessity). For every $(i,j) \in E$ where both vertices are not in K one sets $M_{ij} = -1$. For every other pair $(i,j) \in E$ (say, $i \in K$ and $j \notin K$) one sets $M_{i,j} = -\frac{k-d_{i,K}}{d_{i,K}}$, where $d_{i,K}$ is the number of neighbors that vertex i has in the set K. In order to show that $\lambda_1(M) = k$, one first observes that the vector x_K (with value 1 at entries that correspond to vertices of K, and value 0 elsewhere) is an eigenvector of M with eigenvalue k. Then one proves that $\lambda_2(M)$, the second largest eigenvalue of M, has value smaller than k. This is done by decomposing M into a sum of several matrices, bounding the second largest eigenvalue for one of these matrices, and the largest eigenvalue for the other matrices. By Weyl's inequality, the sum of these eigenvalues is an upper bound on $\lambda_2(M)$. This upper bound is not tight, but it does show that $\lambda_2(M) < k$. It follows that the eigenvalue k associated with x_K is indeed $\lambda_1(M)$. Further details are omitted.

We now explain how to choose a matrix M so as to prove the bound $\vartheta(\bar{G}) \le k + O(\log n)$ in Theorem 7. Recall (see Example 5) that we might be in a situation in which $\vartheta(\bar{G}) > \alpha(\bar{G}) > k$ (with all inequalities being strict). In this case, let K' denote the largest independent set in $\bar{G}$, and note that K' is larger than K. In M, the matrix block corresponding to K' is all 1. One may attempt to complete the construction of M as described above for the random planting case, but replacing K by K' everywhere in that construction. If one does so, the vector $x_{K'}$ (with value 1 at entries that correspond to vertices of K', and value 0 elsewhere) is an eigenvector of M with eigenvalue $\alpha(\bar{G}) > k$. However, M would necessarily have another eigenvector with a larger eigenvalue, because $\vartheta(\bar{G}) > \alpha(\bar{G})$. Hence we are still left with the problem of bounding $\lambda_1(M)$, rather than bounding $\lambda_2(M)$. Having failed to identify an eigenvector for $\lambda_1(M)$, we may still obtain an upper bound on $\lambda_1(M)$ by using approaches based on Weyl's inequality (or other approaches). However, these upper bounds are not tight, and it seems difficult to limit the error that they introduce to be as small as $O(\log n)$, which is needed for proving the inequality $\lambda_1(M) \le k + O(\log n)$.

For the above reason, we choose M differently. For some constant $\frac{1}{2} < \rho < 1$, we extend the clique K to a possibly larger clique Q, by adding to it every vertex that has ρk neighbors in K. (In Example 5, the corresponding clique Q will include all vertices of $K \cup T$. In contrast, if K is planted at random and not adversarially, then we will simply have $Q = K$.) Importantly, we prove that if $G' \sim G(n, \frac{1}{2})$, then with high probability $|Q| < k + O(\log n)$ (for every possible choice of planting a clique of size k by the adversary). For the resulting graph G_Q, we choose the corresponding matrix M in the same way as it was chosen for the random planting case. Now we do manage to show that the eigenvector x_Q (with eigenvalue $|Q|$) associated with this M indeed has the largest eigenvalue. This part is highly technical, and significantly more difficult than the corresponding proof for the random planting case. The reason for the added level of difficulty is that, unlike the random planting case in which we are dealing with only one random graph, here the adversary can plant the clique in any one of $\binom{n}{k}$ locations, and our analysis needs to hold simultaneously for all $\binom{n}{k}$ graphs that may result from such plantings. Further details can be found in [6].

Having established that $\vartheta(\bar{G}_Q) = |Q| \le k + O(\log n)$, we use monotonicity of the theta function to conclude that $\vartheta(\bar{G}) \le k + O(\log n)$. This concludes our overview for the proof of Theorem 7.

Given Theorem 7, let us now explain our algorithm for finding a maximum clique in $G \sim AG(n, \frac{1}{2}, k)$.

Given a graph $G \sim AG(n, \frac{1}{2}, k)$, the first step in our algorithm is to solve the optimization problem (1) on the complement graph $\bar{G}$. By Theorem 7, we will have $\vartheta(\bar{G}) \leq k + c \log n$ for some constant $c > 0$. Let $\{s_i\}$ denote the orthonormal representation found by our solution, and let h be the corresponding handle.

The second step of our algorithm it to extract from G a set of vertices that we shall refer to as H, that contains all those vertices i for which $(h \cdot s_i)^2 \geq \frac{3}{4}$.

▶ **Lemma 8.** *For H as defined above, with extremely high probability, at least $k - O(\log n)$ vertices of K are in H, and most $O(\log n)$ vertices not from K are in H.*

Proof. Let T denote the set of those vertices in K for which $(h \cdot s_i)^2 < \frac{3}{4}$. Remove T from G, thus obtaining the graph G_T. This graph can be thought of as a subgraph with $n - |T|$ vertices of the random graph $G' \sim G(n, \frac{1}{2})$, in which an adversary planted a clique of size $k - |T|$. We also have that $\vartheta(\bar{G}_T) \geq \vartheta(\bar{G}) - \sum_{i \in T}(h \cdot s_i)^2 \geq k - \frac{3}{4}|T|$. If $|T|$ is large (larger than $c' \log n$ for some sufficiently large constant $c' > 0$), the gap of $\frac{|T|}{4}$ between the size of the planted clique and the value of the theta function contradicts Theorem 7 for the graph G_T. (Technical remark: this last argument uses the fact that Theorem 7 holds with extremely high probability, as we take a union bound over all choices of T.)

Having established that T is small, let R be the set of vertices not in K for which $(h \cdot s_i)^2 \geq \frac{3}{4}$. We claim that every such vertex $i \in R$ is a neighbor of every vertex $j \in K \setminus T$. This is because in the orthogonal representation (for $\bar{G}$), if i and j are not neighbors we have that $s_i \cdot s_j = 0$, and then the fact that s_i,s_j and h are unit vectors implies that $(h \cdot s_i)^2 < 1 - (h \cdot s_j)^2 \leq \frac{1}{4}$. Having this claim and using the fact that $|K \setminus T| > \sqrt{n}$, it follows that $|R| \leq 2 \log n$. This is because a $G' \sim G(n, \frac{1}{2})$ graph, with extremely high probability, does not contain two sets of vertices A and B, with $|A| = 2 \log n$, $|B| = \sqrt{n}$, such that all pairs of vertices in $A \times B$ induce edges in G. ◀

The third step of our algorithm constructs a set F that contains all those vertices that have at least $\frac{3k}{4}$ neighbors in H.

▶ **Lemma 9.** *With extremely high probability, the set F described above contains the maximum clique in G, and at most $O(\log n)$ additional vertices.*

Proof. We may assume that H satisfies the properties of Lemma 8. Proposition 6 then implies that with extremely high probability, every vertex of the maximum clique in G has at least $\frac{3k}{4}$ neighbors in H, and hence is contained in F. A probabilistic argument (similar to the end of the proof of Lemma 8) establishes that F has at most $O(\log n)$ vertices not from K. As K has at most $O(\log n)$ vertices not from the maximum clique (by Proposition 6), the total number of vertices in F that are not members of the maximum clique is at most $O(\log n)$. ◀

Finally, in the last step of our algorithm we find a maximum clique in F, and this is a maximum clique in G. This last step can be performed in polynomial time by a standard algorithm (used for example to show that vertex cover is fixed parameter tractable). For every non-edge in the subgraph induced on F, at least one of its end-vertices needs to be removed. Try both possibilities in parallel, and recurse on each subgraph that remains. The recursion terminates when the graph is a clique. The shortest branch in the recursion gives the maximum clique. As only $O(\log n)$ vertices need to be removed in order to obtain a clique, the depth of the recursion is at most $O(\log n)$, and consequently the running time (which is exponential in the depth) is polynomial in n.

This completes our overview of our algorithm for finding a clique in $G \sim AG(n, \frac{1}{2}, k)$ when $k > c\sqrt{n}$ for a sufficiently large constant $c > 0$. To complete the proof of Theorem 1 we need to also address the case that $k > \varepsilon\sqrt{n}$ for arbitrarily small constant ε. This we do (as in [1]) by guessing $t \simeq 2\log\frac{c}{\epsilon}$ vertices from K (there are n^t possibilities to try, and we try all of them), and considering the subgraph of G induced on their common neighbors. This subgraph corresponds to a subgraph of $G' \simeq G(n, \frac{1}{2})$ with roughy $n' \simeq 2^{-t}n$ vertices, and a planted clique of size $\varepsilon\sqrt{n} - t \simeq c\sqrt{n'}$. Now on this new graph G" we can invoke the algorithm based on the theta function. (Technical remark. The proof that $\vartheta(\bar{G}") \leq k + O(\log n)$ uses the fact that Theorem 7 holds with extremely high probability.)

The many details that were omitted from the above overview of the proof of Theorem 1 can be found in [6].

2.2 Finding cliques by enumeration

In this section we prove Theorem 2.

Let $p = n^{\delta-1}$ for $0 < \delta < 1$, and consider first $G' \sim G(n, p)$ (hence G' has average degree roughly n^δ). For every size $t \geq 1$, let N_t denote the number of cliques of size t in G'. The expectation (over choice of $G' \sim G(n, p)$) satisfies:

$$\mathbb{E}[N_t] = \binom{n}{t} p^{\binom{t}{2}} \leq \frac{1}{t!} n^{\frac{\delta-1}{2}t^2 + \frac{3-\delta}{2}t}$$

The exponent is maximized when $t = \frac{3-\delta}{2(1-\delta)}$. For the maximizing (not necessarily integer) t, the exponent equals $\frac{(3-\delta)^2}{8(1-\delta)}$. We denote this last expression by e_δ, and note that $e_\delta = O(\frac{1}{1-\delta})$. The expected number of cliques of all sizes is then:

$$\sum_{t\geq 1} \mathbb{E}[N_t] \leq n + \sum_{t \geq 2} \frac{1}{t!} n^{\frac{\delta-1}{2}t^2 + \frac{3-\delta}{2}t} \leq n^{e_\delta}$$

(The last inequality holds for sufficiently large n.) By Markov's inequality, with probability at least $1 - \frac{1}{n}$, the actual number of cliques in G' is at most $n^{e_\delta + 1}$. (Stronger concentration results can be used here, but are not needed for the proof of Theorem 2.)

Now, for arbitrary $1 \leq k \leq n$, let the adversary plant a clique K of size k in G', thus creating the graph $G \sim G(n, p, k)$. As every subgraph of K is a clique, the total number of cliques in G is at least 2^k, which might be exponential in n (if k is large). However, the number of maximal cliques in G (a clique is maximal if it is not contained in any larger clique) is much smaller. Given a maximal clique C in G, consider C', the subgraph of C not containing any vertex from K. C' is a clique in G' (which is nonempty, except for one special case of $C = K$). C' uniquely determines C, as the remaining vertices in C are precisely the set of common neighbors of C' in K (this is because the clique C is maximal). Consequently, the number of maximal cliques in G is not larger than the number of cliques in G'.

As all maximal cliques in a graph can be enumerated in time linear in their number times some polynomial in n (see e.g. [15] and references therein), one can list all maximal cliques in G in time $n^{e_\beta + O(1)}$ (this holds with probability at least $1 - \frac{1}{n}$, over the choice of G', regardless of where the adversary plants clique K), and output the largest one.

This completes the proof of Theorem 2.

2.3 Proving NP-hardness results

In this section we provide an overview of the proof of Theorem 3. Our proof is an adaptation to our setting of a proof technique developed in [2].

Recall that we are considering a graph $G \sim A\bar{G}(n,p,k)$ (adversarial planted independent set) with $p = n^{\delta-1}$ and $0 < \delta < 1$. Let us first explain why the algorithm described in Section 2.1 fails when $k = cn^{1-\frac{\delta}{2}}$ (whereas if the independent set is planted at random, algorithms based on the theta function are known to succeed). The problem is that the bound in Theorem 7 is not true anymore, and instead one has the much weaker bound of $\vartheta(G) \le k + n^{1-\delta}\log n$. Following the steps of the algorithm of Section 2.1, in the final step, we would need to remove a minimum vertex cover from F. However, now the upper bound on the size of this vertex cover is $O(n^{1-\delta}\log n)$ rather than $O(\log n)$. Consequently, we do not know of a polynomial time algorithm that will do so. It may seem that we also do not know that no such algorithm exists. After all, F is not an arbitrary worst case instance for vertex cover, but rather an instance derived from a random graph. However, our NP-hardness result shows that indeed this obstacle is insurmountable, unless NP has randomized polynomial time algorithms. We remark that using an approximation algorithm for vertex cover in the last step of the algorithm of Section 2.1 does allow one to find in G an independent set of size $k - O(n^{1-\delta}\log n) = (1 - o(1))k$, and the NP-hardness result applies only because we insist on finding an independent set of size at least k.

Let us proceed now with an overview of our NP hardness proof. We do so for the case that $k = \frac{n}{3}$ (for which we can easily find the maximum independent set if the planted independent set is random). Assume for the sake of contradiction that ALG is a polynomial time algorithm that with high probability over choice of $G' \sim G(n,p)$, for every planted independent set of size $k = \frac{n}{3}$, it finds in the resulting graph G an independent set of size k.

We now introduce a class $\mathcal{H}$ of graphs that, in anticipation of the proofs that will follow, is required to have the following three properties. (Two of the properties are stated below in a qualitative manner, but they have precise quantitative requirements in the proofs that follow.)

1. Solving maximum independent set on graphs from this class is NP-hard.
2. Graphs in this class are very sparse.
3. The number of vertices in each graph is small.

Given the above requirements, we choose $0 < \varepsilon < \min[\frac{\delta}{2}, 1-\delta]$, and let $\mathcal{H}$ be the class of *balanced* graphs on n^{ϵ} vertices, and of average degree $2 + \delta$. (A graph H is *balanced* if no subgraph of H has average degree larger than the average degree of H.) Given a graph $H \in \mathcal{H}$ and a parameter k', it is NP-hard to determine whether H has an independent of size at least k' or not. We will reach a contradiction to the existence of ALG by showing how ALG could be used in order to find in H an independent set of size k', if one exists. For this, we use the following randomized algorithm ALGRAND.

1. Generate a random graph $G' \sim G(n,p)$.
2. Plant in G' a random copy of H (that is, pick $|H|$ random vertices in G' and replace the subgraph induced on them by H). We refer to the resulting distribution as $G_H(n,p)$, and to the graph sampled from this distribution as G_H. Observe that the number of vertices in G_H that have a neighbor in H is with high probability not larger than $|H|n^{\delta} \le \frac{n}{2}$.
3. Within the non-neighbors of H, plant at random an independent set of size $k - k'$. We refer to the resulting distribution as $G_H(n,p,k)$, and to the graph sampled from this distribution as $\tilde{G}_H$. Observe that with extremely high probability, $\alpha(\tilde{G}_H \setminus H) = k - k'$. Hence we may assume that this indeed holds. If furthermore $\alpha(H) \ge k'$, then $\alpha(\tilde{G}_H) \ge k$.
4. Run ALG on $\tilde{G}_H$. We say that ALGRAND succeeds if ALG outputs an independent set IS of size k. Observe that then at least k' vertices of H are in IS, and hence ALGRAND finds an independent set of size k' in H.

If H does not have an independent set of size k', ALGRAND surely fails to output such an independent set. But if H does have an independent set of size k', why should ALGRAND succeed? This is because ALG (which is used in ALGRAND) is fooled to think that the graph $\tilde{G}_H$ generated by ALGRAND was generated from $A\bar{G}(n,p,k)$, and on such graphs ALG does find independent sets of size k. And why is ALG fooled? This is because the distribution of graphs generated by ALGRAND is statistically close to a distribution that can be created by the adversary in the $A\bar{G}(n,p,k)$ model. Specifically, consider the following distribution that we refer to as $A_HG(n,p,k)$.

1. Generate $G' \sim G(n,p)$.
2. The computationally unbounded adversary finds within G' all subsets of vertices of size $|H|$ such that the subgraph induced on them is H. (If there is no such subset, fail.) Choose one such copy of H uniformly at random.
3. As H is assumed to have an independent set of size k', plant an independent set K of size k as follows. k' of the vertices of K are vertices of an independent set in the selected copy of H. The remaining $k-k'$ vertices of K are chosen at random among the vertices of G' that have no neighbor at all in the copy of H. (Observe that we expect there to be at least roughly $n - |H|n^\delta \geq \frac{n}{2}$ such vertices, and with extremely high probability the actual number will be at least $\frac{n}{3} > k - k'$.)

▶ **Theorem 10.** *The two distributions, $\tilde{G}_H \sim G_H(n,p,k)$ generated by ALGRAND and $G \sim A_HG(n,p,k)$ generated by the adversary, are statistically similar to each other.*

The proof of Theorem 10 appears in [6]. Here we explain the main ideas in the proof. A minimum requirement for the theorem to hold is that $G' \sim G(n,p)$ typically contains at least one copy of H (otherwise $A_HG(n,p,k)$ fails to produce any output). But this by itself does not suffice. Intuitively, the condition we need is that G' typically contains many copies of H. Then the fact that $G_H(n,p)$ of ALGRAND adds another copy of H to G' does not appear to make much of a difference to G', because G' anyway has many copies of H. Hopefully, this will imply that $G' \sim G(n,p)$ and $G_H \sim G_H(n,p)$ come from two distributions that are statistically close. This intuition is basically correct, though another ingredient (a concentration result) is also needed. Specifically, we need the following lemma (stated informally).

▶ **Lemma 11.** *For $G' \in G(n,p)$ (with p and H as above), the expected number of copies of H in G' is very high (2^{n^η} for some $\eta > 0$ that depends on δ and ϵ). Moreover, with high probability, the actual number of copies of H in G' is very close to its expectation.*

The proof of Lemma 11 is based on known techniques (first and second moment methods). It uses in an essential way the fact that the graph H is sparse (average degree barely above 2) and does not have many vertices (these properties hold by definition of the class $\mathcal{H}$). Armed with Lemma 11, we then prove the following Lemma.

▶ **Lemma 12.** *The two distributions $G(n,p)$ and $G_H(n,p)$ are statistically similar to each other.*

Lemma 12 is proved by considering graphs $G' \sim G(n,p)$ that do contain a copy of H (Lemma 11 establishes that this is a typical case), and comparing for each such graph the probability of it being generated by $G_H(n,p)$ with the probability of it being generated by $G(n,p)$. Conveniently, the ratio between these probabilities is the same as the ratio between the actual number of copies of H in the given graph G', and the expected number of copies of H in a random $G' \sim G(n,p)$. By Lemma 11, for most graphs, this ratio is close to 1.

Theorem 10 follows quite easily from Lemma 12. Consequently ALG's performance on the distributions $G_H(n,p,k)$ and $A_HG(n,p,k)$ is similar. By our assumption, ALG finds (with high probability) an independent set of size k in $G \sim A_HG(n,p,k)$, which now implies that it also does so for $\tilde{G}_H \sim G_H(n,p,k)$. But as argued above, finding an independent set of size k in $\tilde{G}_H \sim G_H(n,p,k)$ implies that ALGRAND finds an independent set of size k' in $H \in \mathcal{H}$, thus solving an NP-hard problem. Hence the assumption that there is a polynomial time algorithm ALG that can find independent sets of size k in $G \sim A\bar{G}(n,p,k)$ implies that NP has randomized polynomial time algorithms.

3 Additional results

In the main part of the paper we only described what we view as our main results. The appendix contains all missing proofs, and some additional results and extensions, not described above. For example, one may ask for which value of $p \leq \frac{1}{2}$ the transition occurs from being able to find the maximum independent set in $G \sim A\bar{G}(n,p,k)$ in polynomial time, to the problem becoming NP hard. Our results show a gradual transition. For constant p the problem remains polynomial time solvable, and then, as p continues to decrease, the running time of our algorithms becomes super polynomial, and grows gradually towards exponential complexity. Establishing this type of behavior does not require new proof ideas, but rather only the substitution of different parameters in the existing proofs. Consequently, some theorems that were stated here only in special cases (e.g., Theorem 7 that was stated only for $p = \frac{1}{2}$) are restated in the appendix in a more general way (e.g., replacing $\frac{1}{2}$ by p), and a more general proof is provided.

Though this is not shown in the appendix, our hardness results (for finding adversarially planted independent sets) also imply a gradual transition, providing NP-hardness results when $p = n^{\delta-1}$, and as p grows (e.g., into the range $p = \frac{1}{(\log n)^c}$) the NP-hardness results are replaced by hardness results under stronger assumptions, such as (a randomized version of) the exponential time hypothesis. This is because for $p = \frac{1}{(\log n)^c}$ we need to limit the size of the graphs $H \in \mathcal{H}$ to be only polylogarithmic in n, as for larger sizes the proofs in Section 2.3 fail.

An interesting range of parameters that remains open is that of $p = \frac{d}{n}$ for some large constant d. The case of a random planted independent set of size $\sqrt{\frac{c}{d}}n$ (for some sufficiently large constant $c > 0$ independent of d) was addressed in [9]. In such sparse graphs, the planted independent set is unlikely to be the maximum independent set. The main result in [9] is a polynomial time algorithm that with high probability finds the maximum independent set in that range of parameters. It would be interesting to see whether the positive results extend to the case of adversarial planted independent set. We remark that neither Theorem 1 nor Theorem 3 apply in this range of parameters.

Abstract

We present a simple sublinear-time algorithm for sampling an arbitrary subgraph H *exactly uniformly* from a graph G, to which the algorithm has access by performing the following types of queries: (1) uniform vertex queries, (2) degree queries, (3) neighbor queries, (4) pair queries and (5) edge sampling queries. The query complexity and running time of our algorithm are $\tilde{O}(\min\{m, \frac{m^{\rho(H)}}{\#H}\})$ and $\tilde{O}(\frac{m^{\rho(H)}}{\#H})$, respectively, where $\rho(H)$ is the fractional edge-cover of H and $\#H$ is the number of copies of H in G. For any clique on r vertices, i.e., $H = K_r$, our algorithm is almost optimal as any algorithm that samples an H from any distribution that has $\Omega(1)$ total probability mass on the set of all copies of H must perform $\Omega(\min\{m, \frac{m^{\rho(H)}}{\#H\cdot(cr)^r}\})$ queries.

Together with the query and time complexities of the $(1 \pm \varepsilon)$-approximation algorithm for the number of subgraphs H by Assadi et al. [3] and the lower bound by Eden and Rosenbaum [12] for approximately counting cliques, our results suggest that in our query model, approximately counting cliques is “equivalent to” exactly uniformly sampling cliques, in the sense that the query and time complexities of exactly uniform sampling and randomized approximate counting are within polylogarithmic factor of each other. This stands in interesting contrast to an analogous relation between approximate counting and almost uniformly sampling for self-reducible problems in the polynomial-time regime by Jerrum, Valiant and Vazirani [18].

1 Introduction

“*Given a huge real graph, how can we derive a representative sample?*” is a first question asked by Leskove and Faloutsos in their seminal work on graph mining [20], which is motivated by the practical concern that most classical graph algorithms are too expensive for massive graphs (with millions or billions of vertices), and graph sampling seems essential for lifting the dilemma.

In this paper, we study the question of how to sample a subgraph H uniformly at random from the set of all subgraphs that are isomorphic to H contained in a large graph G in *sublinear time*, where the algorithm is given query access to the graph G. That is, the algorithm only probes a small portion of the graph while still returning a sample with provable performance guarantee. Such a question is relevant for statistical reasons: we might need a few representative and unbiased motifs from a large network [21], or edge-colored subgraphs in a structured database [4], in a limited time. A subroutine for extracting a uniform sample of H is also useful in streaming (e.g., [1]), parallel and distributed computing (e.g., [15]) and other randomized graph algorithms (e.g., [17]).

Currently, our understanding of the above question is still rather limited. Kaufman et al. gave the first algorithm for sampling an edge almost uniformly at random [19]. Eden and Rosenbaum gave a simpler and faster algorithm [13]. Both works considered the *general graph model*, where an algorithm is allowed to perform the following queries, where each query will be answered in constant time:

- **uniform vertex query:** the algorithm can sample a vertex uniformly at random;
- **degree query:** for any vertex v, the algorithm can query its degree d_v;
- **neighbor query:** for any vertex v and index $i \leq d_v$, the algorithm can query the i-th neighbor of v;
- **pair query:** for any two vertices u, v, the algorithm can query if there is an edge between u, v.

In [13], Eden and Rosenbaum gave an algorithm that takes as input a graph with n vertices and m edges (where m is unknown to the algorithm), uses $\tilde{O}(n/\sqrt{m})$ queries[1] in expectation and returns an edge e that is sampled with probability $(1 \pm \varepsilon)/m$ (i.e., almost uniformly at random). This is almost optimal in the sense that any algorithm that samples an edge from an almost-uniform distribution requires $\Omega(n/\sqrt{m})$ queries. In their sublinear-time algorithm for approximately counting the number cliques [10] (see below), Eden, Ron and Seshadhri use a procedure to sample cliques incident to a suitable vertex subset S almost uniformly at random. However, for an arbitrary subgraph H, it is still unclear how to obtain an almost uniform sample in sublinear time.

Approximate counting in sublinear-time. In contrast to sampling subgraphs (almost) uniformly at random, the very related line of research on approximate counting the number of subgraphs in sublinear time has made some remarkable progress in the past few years. Feige gave a $(2 + \varepsilon)$-approximation algorithm with $\tilde{O}(n/\sqrt{m})$ queries for the average degree, which is equivalent to estimating the number of edges, of a graph in the model that only uses vertex sampling and degree queries [14]. He also showed that any $(2 - o(1))$-approximation for the average degree using only vertex and degree queries requires $\Omega(n)$ queries. Goldreich and Ron then gave a $(1 + \varepsilon)$-approximation algorithm with $\tilde{O}(n/\sqrt{m})$ queries for the average degree in the model that allows vertex sampling, degree and neighbor queries [16].

Eden et al. recently gave the first sublinear-time algorithm for $(1 \pm \varepsilon)$-approximating the number of triangles [7]. Later, Eden, Ron and Seshadhri generalized it to $(1 \pm \varepsilon)$-approximating the number of r-cliques K_r [10] in the general graph model that allows vertex sampling, degree, neighbor and vertex-pair queries. The query complexity and running time of their algorithms for r-clique K_r counting are $\tilde{O}(\frac{n}{(\#K_r)^{1/3}} + \min\{m, \frac{m^{r/2}}{\#K_r}\})$ and $\tilde{O}(\frac{n}{(\#K_r)^{1/3}} + \frac{m^{r/2}}{\#K_r})$ respectively, for any $r \geq 3$, where $\#K_r$ is the number of copies of K_r in G. Furthermore, in boths works it was proved that the query complexities of the respective algorithms are optimal up to polylogarithmic dependencies on n, ϵ and r.

[1] Throughout the paper, we use $\tilde{O}(\cdot)$ to suppress any dependencies on the parameter ε, the size of the corresponding subgraph H and $\log(n)$-terms.

Later, Assadi et al. [3] gave a sublinear-time algorithm for $(1 \pm \varepsilon)$-approximating the number of copies of an arbitrary subgraph H in the *augmented general graph model* [2]. That is, besides the aforementioned vertex sampling, degree, neighbor and pair queries, the algorithm is allowed to perform the following type of queries:

- **edge sampling query** the algorithm can sample an edge uniformly at random.

The algorithm in [3] uses $\tilde{O}(\min\{m, \frac{m^{\rho(H)}}{\#H}\})$ queries and $\tilde{O}(\frac{m^{\rho(H)}}{\#H})$ time, where $\rho(H)$ is the fractional edge-cover of H and $\#H$ is the number of copies of H in G. For the special case $H = K_r$, their algorithm performs $\tilde{O}(\min\{m, \frac{m^{r/2}}{\#K_r}\})$ queries and runs in $\tilde{O}(\frac{m^{r/2}}{\#K_r})$ time, which do not have the additive term $\frac{n}{(\#K_r)^{1/3}}$ in the query complexity and running time of the algorithms in [7, 10]. Eden and Rosenbaum provided simple proofs that most of the aforementioned results are nearly optimal in terms of their query complexities by reducing from communication complexity problems [12]. Further investigation of sampling an edge and estimating subgraphs in low arboricity graphs [8, 9] and approximately counting stars [2] has also been performed.

Relation of approximate counting and almost uniform sampling. One of our original motivations is to investigate the relation of approximate counting and almost uniform sampling in the sublinear-time regime. That is, we are interested in the question whether *in the sublinear-time regime, is almost uniform sampling "computationally comparable" to approximate counting, or is it strictly harder or easier, in terms of the query and/or time complexities for solving these two problems?* Indeed, in the polynomial-time regime, Jerrum, Valiant and Vazirani showed that for self-reducible problems (e.g., counting the number of perfect matchings of a graph), approximating counting is "equivalent to" almost uniform sampling [18], in the sense that the time complexities of almost uniform sampling and randomized approximate counting are within polynomial factor of each other. Such a result has been instrumental for the development of the area of approximate counting (e.g., [23]). It is natural to ask if similar relations between approximate counting and sampling hold in the sublinear-time regime.

1.1 Our Results

In this paper, we consider the problem of (almost) uniformly sampling a subgraph in the augmented general graph model. As mentioned above, this model has been studied in [2, 3], in which the authors find that "allowing edge-sample queries results in considerably simpler and more general algorithms for subgraph counting and is hence worth studying on its own". On the other hand, allowing edge sampling queries is also natural in models where neighbor queries are allowed, e.g., in the well-studied bounded-degree model and the general model: most graph representations that allow efficient neighbor queries (e.g., GEXF, GML or GraphML) store edges in linear data structures, which often allows efficient (nearly) uniformly sampling of edges. We refer to [3] for a deeper discussion on allowing edge sampling queries from both theoretical and practical perspectives.

We prove the following upper bound on sampling subgraphs (exactly) uniformly at random and provide a corresponding algorithm in Section 3.

▶ **Theorem 1.** *Let H be an arbitrary subgraph. Let $G = (V, E)$ be a graph with n vertices and m edges. There exists an algorithm in the augmented general graph model that uses $\tilde{O}(\min\{m, \frac{m^{\rho(H)}}{\#H}\})$ queries in expectation, and with probability at least $2/3$, returns a copy of H, if $\#H > 0$. Each returned H is sampled according to the uniform distribution over all copies of H in G. The expected running time of the algorithm is $\tilde{O}(\frac{m^{\rho(H)}}{\#H})$.*

We stress that our sampler is an exactly uniform sampler, i.e., the returned H is sampled from the uniform distribution, while to the best of our knowledge, the previous sublinear-time subgraph sampling algorithms are only *almost* uniform samplers. That is, they return an edge or a clique that is sampled from a distribution that is *close* to the corresponding uniform distribution. Indeed, it has been cast as an open question if it is possible to sample an edge exactly uniformly at random in the general graph model in [11].

Our algorithm is based on one idea from [3] (see also [4]) that uses the fractional edge cover to partition a subgraph H into stars and odd cycles (i.e., Lemma 7). The authors of [3] also provided a scheme called *subgraph-sampler trees* for recursively sampling stars and odd cycles that compose H, while the resulting distribution is not (almost) uniform distribution. Instead, we show that one can sample stars and odd cycles by using rejection sampling in parallel (or, more precisely, sequentially but independently of each other) and check whether they form a copy of H.

To complement our algorithmic result, we give a lower bound on the query complexity for sampling a clique in sublinear time by using a simple reduction from [12]. We show the following theorem and present its proof in Section 4.

▶ **Theorem 2.** *Let $r \geq 3$ be an integer. Suppose $\mathcal{A}$ is an algorithm in the augmented general graph model that for any graph $G = (V, E)$ on n vertices and m edges returns an arbitrary r-clique K_r, if one exists; furthermore, each returned clique K_r is sampled according to a distribution $\mathcal{D}$, such that the total probability mass of $\mathcal{D}$ on the set of all copies of K_r is $\Omega(1)$. Then $\mathcal{A}$ requires $\Omega(\min\{m, \frac{m^{r/2}}{\#K_r \cdot (cr)^r}\})$ queries, for some absolute constant $c > 0$.*

Note that the above theorem gives a lower bound for sampling K_r from almost every non-trivial distribution $\mathcal{D}$. In particular, it holds if $\#K_r > 0$ and $\mathcal{D}$ is a distribution that is only supported on the set of all copies of K_r, e.g., the (almost) uniform distribution on these copies. Together with the query and time complexities of the $(1 \pm \varepsilon)$-approximation algorithm for the number of subgraphs H by Assadi et al. [3] and the lower bound by Eden and Rosenbaum [12] for approximately counting cliques, our Theorems 1 and 2 imply that in the augmented general graph model, *approximately* counting the number of cliques is equivalent to *exactly* sampling cliques in the sense that the query and time complexities of them are within a polylogarithmic factor of each other.

Future Work. Considering real-world applications, it would be interesting to relax the guarantees of the queries available to the algorithm. In particular, one may not be able to sample vertices or edges *exactly* uniformly at random, but only *approximately* uniformly. For example, there exist works that consider weaker query models in which even uniform vertex query is disallowed, and instead they sample vertices almost uniformly at random by performing random walks from some fixed vertex (see, e.g., [5, 6]). Implementing these changes in the model would result in a weaker guarantee for the distribution of sampled subgraphs in Theorem 1 but would be potentially more practical.

2 Preliminaries

Let $G = (V, E)$ be a simple graph with $|V| = n$ vertices and $|E| = m$ edges. For a vertex $v \in V$, we denote by d_v the degree of the vertex, by Γ_v the set of all the neighbors of v, and by E_v the set of edges incident to v. We fix a total order on vertices denoted by $\prec$ as follows:

▶ **Definition 3.** *For any two vertices u and v, we say that $u \prec v$ if $d_u < d_v$ or $d_u = d_v$ and u appears before v in the lexicographic order.*

For any two vertices, we denote by Γ_{uv} the set of the shared neighbors of u and v that are larger than u with respect to "$\prec$", i.e., $\Gamma_{uv} = \{w \mid w \in \Gamma_u \cap \Gamma_v \wedge u \prec w\}$. Sometimes, we view our graph $G = (V, E)$ as a directed graph $(V, \vec{E})$ by treating each undirected edge $e = \{u, v\} \in E$ as two directed edges $\vec{e}_1 = (u, v)$ and $\vec{e}_2 = (v, u)$. The following was proven in [7].

▶ **Lemma 4** ([7]). *For any vertex v, the number of neighbors w of v such that $v \prec w$ is at most $\sqrt{2m}$.*

Given a graph H, we say that a subgraph H' of G is a *copy* or an *instance* of H if H' is isomorphic to H. An isomorphism-preserving mapping from H to a copy of H in G is called an *embedding* of H in G.

Rejection Sampling. Given a starting distribution $\vec{p}$ and a target distribution $\vec{q}$ supported on a set R, let $M := \max_{a \in R} \frac{\vec{q}(a)}{\vec{p}(a)}$. Algorithm 1 is called *rejection sampling*.

Algorithm 1 Rejection sampling with starting distribution $\vec{p}$ and target distribution $\vec{q}$.

```
procedure RejectionSampling($\vec{p}, \vec{q}$)
    $M \leftarrow \max_{a \in R} \frac{\vec{q}(a)}{\vec{p}(a)}$
    while true do
        sample $a$ from $\vec{p}$.
        sample a number $t \in [0, 1]$ uniformly at random.
        if $t \leq \frac{\vec{q}(a)}{M \cdot \vec{p}(a)}$ then
            return $a$
```

Observe that when the algorithm terminates, the probability that a is returned is $\vec{q}(a)$ for every $a \in R$. The following lemma is known.

▶ **Lemma 5** ([22]). *The expected number of iterations of* RejectionSampling*($\vec{p}, \vec{q}$) is M.*

Edge Cover and Graph Decomposition. We use the following definition of the fractional edge cover of a graph and a decomposition result based on it by Assadi et al. [3].

▶ **Definition 6** (Fractional Edge-Cover Number). *A fractional edge-cover of $H(V_H, E_H)$ is a mapping $\psi : E_H \to [0, 1]$ such that for each vertex $v \in V_H$, $\sum_{e \in E_H, v \in e} \psi(e) \geq 1$. The fractional edge-cover number $\rho(H)$ of H is the minimum value of $\sum_{e \in E_H} \psi(e)$ among all fractional edge-covers ψ.*

Let C_k denote the cycle of length k. Let S_k denote a star with k petals, i.e., $S_k = (\{u, v_1, \ldots, v_k\}, \cup_{i \in [k]} \{u, v_k\})$. Let K_k denote a clique on k vertices. It is known that $\rho(C_{2k+1}) = k + 1/2$, $\rho(S_k) = k$ and $\rho(K_k) = k/2$.

▶ **Lemma 7** ([3]). *Any subgraph H can be decomposed into a collection of vertex-disjoint odd cycles $\overline{C_1}, \ldots, \overline{C_o}$ and star graphs $\overline{S_1}, \ldots, \overline{S_s}$ such that*

$$\rho(H) = \sum_{i=1}^{o} \rho(\overline{C_i}) + \sum_{j=1}^{s} \rho(\overline{S_j}).$$

By a result of Atserias, Grohe and Marx [4], the number of instances of H in a graph G with m edges is $O(m^{\rho(H)})$.

3 Sampling an Arbitrary Subgraph H

In this section, we present sampling algorithms for odd cycles and stars and show how to combine them to obtain a sampling algorithm for arbitrary subgraphs. Note that we do not need to know the exact number of edges m to run our algorithm; it is sufficient to have a constant approximation $\hat{m}$ of m so that $m \le \hat{m} \le cm$ for some $c > 1$. Such an approximation can be obtained by using the algorithm from [14, 16]. This increases the query complexity only by a constant factor. For the sake of simplicity, we will continue to use m in the following.

3.1 Sampling an Odd-Length Cycle

We describe our algorithm SampleOddCycle for sampling a uniformly random odd-length k-cycle. For any instance of C_{2k+1} in the input graph, our goal is to guarantee that it will be sampled with probability $\frac{1}{m^{k+1/2}}$. Let $e_1, \dots, e_{2k+1}$ be a sequence of edges that represents a cycle of length $2k+1$. While we can use edge sampling to sample every second edge of the first $2k$ edges sequentially, i.e., $e_1, e_3, \dots, e_{2k-1}$, and query the edges inbetween, i.e., $e_2, \dots, e_{2k-2}$, by vertex pair queries, we use a different strategy to sample e_{2k} and e_{2k+1}. Let $\{u, v\} = e_1$. If u has low degree, i.e., $d_u \le \sqrt{2m}$, we can afford to sample each neighbor of u with probability $1/\sqrt{2m}$ and fail if no neighbor is sampled. In particular, we need that a distinguished neighbor x_1 of u is sampled with probability at least $1/\sqrt{2m}$. However, if $d_u \ge \sqrt{2m}$, this is too costly. Instead, we invoke rejection sampling with the following starting distribution and target distribution.

▶ **Definition 8.** *Let u, v be two vertices such that $d_u > \sqrt{2m}$. Let $\vec{p}_u$ be a (starting) distribution with support Γ_u such that:*

$$\vec{p}_u(w) = \frac{1}{d_u}, \quad w \in \Gamma_u \tag{1}$$

Let $\vec{q}_u$ be a (target) distribution with support Γ_u such that:

$$\vec{q}_u(w) = \begin{cases} \frac{1}{\sqrt{2m}}, & w \in \Gamma_{uv} \\ \left(1 - \frac{|\Gamma_{uv}|}{\sqrt{2m}}\right) \cdot \frac{1}{d_u - |\Gamma_{uv}|}, & w \notin \Gamma_{uv} \end{cases} \tag{2}$$

We note that by Lemma 4, it always holds that $|\Gamma_{uv}| \le \sqrt{2m}$. Furthermore,

$$\sum_{w \in \Gamma_u} \vec{q}_u(w) = \sum_{w \in \Gamma_{uv}} \frac{1}{\sqrt{2m}} + \sum_{w \notin \Gamma_{uv}} \left(1 - \frac{|\Gamma_{uv}|}{\sqrt{2m}}\right) \cdot \frac{1}{d_u - |\Gamma_{uv}|}$$
$$= \frac{|\Gamma_{uv}|}{\sqrt{2m}} + (d_u - |\Gamma_{uv}|)\left(1 - \frac{|\Gamma_{uv}|}{\sqrt{2m}}\right) \cdot \frac{1}{d_u - |\Gamma_{uv}|} = 1.$$

Thus the distribution $\vec{q}_u$ is well-defined. Let $M_u = \max_{w \in \Gamma_u} \frac{\vec{q}_u(w)}{\vec{p}_u(w)}$ (as in Algorithm 1). Then, M_u is bounded as follows.

▶ **Lemma 9.** *Let M_u be defined as above. Recall that $d_u > \sqrt{2m}$. Then $M_u = \frac{d_u}{\sqrt{2m}}$.*

Proof. If $w \in \Gamma_{uv}$, we have that $\frac{\vec{q}_u(w)}{\vec{p}_u(w)} = \frac{d_u}{\sqrt{2m}}$. If $w \notin \Gamma_{uv}$, we have that

$$\frac{\vec{q}_u(w)}{\vec{p}_u(w)} = \frac{d_u(1 - \frac{|\Gamma_{uv}|}{\sqrt{2m}})}{d_u - |\Gamma_{uv}|} = \frac{d_u(\sqrt{2m} - |\Gamma_{uv}|)}{\sqrt{2m}(d_u - |\Gamma_{uv}|)} \le \frac{d_u}{\sqrt{2m}}, \tag{3}$$

where the last inequality uses the fact that $d_u > \sqrt{2m}$. ◀

Algorithm 2 Sampling a wedge.

```
procedure SampleWedge($(G, u, v)$)
    if $d_u \le \sqrt{2m}$ then
        sample a number $i \in \{1, \dots \sqrt{2m}\}$ uniformly at random
        if $i > d_u$ then
            return Fail
        $w \leftarrow i^{th}$ neighbor of $u$
    else
        $w \leftarrow$ RejectionSampling($(\vec{p}_u, \vec{q}_u)$)        ▷ see Definition 8
    return $w$
```

Algorithm 3 Sampling a cycle of length $2k + 1$.

```
procedure SampleOddCycle($(G, 2k + 1)$)
    sample $k$ directed edges $(u_1, v_1), \dots, (u_k, v_k)$ u.a.r. and i.i.d.
    if $u_1, v_1, \dots, u_k, v_k$ is a path of length $2k - 1$ and $u_1 \prec v_1$, $\forall i > 1 : u_1 \prec u_i, v_i$ then
        if SampleWedge($(G, u_1, v_k)$) returns $w$ and $w \prec v_1$ then
            return $\{(u_1, v_1), \dots, (u_k, v_k)\} \cup \{(v_k, w), (w, u_1)\}$
    return Fail
```

As there exists a linear number of automorphisms for every cycle, it is crucial in our algorithm to define a unique embedding based on the order of vertices for every instance of a k-cycle. Otherwise, bounding the probability that an instance is sampled *exactly* uniformly is hard as some instance might be sampled less likely because, e.g., its edges participate in many overlapping cycles. We take care of this by enforcing that only uniquely defined embeddings are sampled in SampleOddCycle. In particular, we sample k directed edges $(u_1, v_1), \dots, (u_k, v_k)$ independently and uniformly at random and require that (i) they induce a path $u_1, v_1, u_2, \dots, v_k$ and (ii) for the first edge (u_1, v_1), u_1 is the smallest vertex according to the order "$\prec$" among all $u_i, v_i, i \ge 1$. Then, we call SampleWedge on the two ends u_1, v_k of this path to close a cycle and define an orientation of this cycle by requiring that $w \prec v_1$, where for $(v_k, w) = e_{2k+1}$. If any of these requirements is not met, we have not sampled the uniquely defined embedding we are looking for, and the algorithm fails.

▶ **Lemma 10.** *For any instance of an odd cycle C_{2k+1} in G, the probability that it will be returned by SampleOddCycle$(G, 2k + 1)$ is $\frac{1}{(2m)^{k+1/2}}$.*

Proof. Let $\mathcal{C}_{2k+1}$ be any instance of a cycle of odd length $2k + 1$ in G. Let x_0 be the smallest vertex on $\mathcal{C}_{2k+1}$ according to the total order "$\prec$". Let x_1, x_{2k} be the two neighbors of x_0 on $\mathcal{C}_{2k+1}$ such that $x_1 \prec x_{2k}$. Then, we let x_i denote the vertices on $\mathcal{C}_{2k+1}$ such that $(x_i, x_{i+1}) \in E(\mathcal{C}_{2k+1})$ for $0 \le i \le 2k - 1$ and $(x_{2k}, x_0) \in E(\mathcal{C}_{2k+1})$. Note that for any $\mathcal{C}_{2k+1}$, there is a *unique* way of mapping its vertices to x_i, for $0 \le i \le 2k$. Thus, SampleOddCycle returns $\mathcal{C}_{2k+1}$ if and only if

1. $u_1 = x_0$ and $v_1 = x_{2k}$;
2. $u_i = x_{2k-2i+3}$ and $v_i = x_{2k-2i+2}$ for $2 \le i \le k$;
3. SampleWedge(G, u_1, v_k) returns x_1.

Event 1 occurs with probability $1/(2m)$, and event 2 occurs with probability $1/(2m)^{k-1}$, as each directed edge is sampled with probability $1/(2m)$.

Now we bound the probability of event 3. In the call to SampleWedge, let $u := u_1$ and $v := v_k$, which satisfies that $u \prec v$. We first note that if $d_u < \sqrt{2m}$ in SampleWedge(G, u_1, v_k), then the vertex x_1 will be sampled with probability $1/\sqrt{2m}$. Now we consider the case that $d_u \geq \sqrt{2m}$. Then, RejectionSampling$(\vec{p}_u, \vec{q}_u)$ will return x_1 with probability $\vec{q}_{u_1}(x_1) = \frac{1}{\sqrt{2m}}$, as x_1 is a common neighbor of u_1, v_k and $u_1 \prec x_1$. Thus in both cases, the probability that event 3 occurs is $\frac{1}{\sqrt{2m}}$. Therefore, the probability that SampleOddCycle returns $\mathcal{C}_{2k+1}$ is $\frac{1}{\sqrt{2m}} \cdot \frac{1}{2m} \cdot (\frac{1}{2m})^{k-1} = \frac{1}{(2m)^{k+1/2}}$. ◀

3.2 Sampling a Star

Similarly to odd cycles, we observe that every k-star admits an exponential number of automorphisms. Therefore, we enforce a unique embedding of every instance of a k-star in our sampling algorithm SampleStar. Let $e_1, \dots, e_k$ be the petals of an instance of a k-star. We sample $e_1, \dots, e_k$ sequentially. If these edges form a star, we output it only if the leaves where sampled in ascending order with respect to "$\prec$".

Algorithm 4 Sampling a star with k petals.

```
procedure SampleStar($(G, k)$)
    Sequentially sample $k$ directed edges $\{(u_1, v_1), \dots, (u_k, v_k)\}$ u.a.r. and i.i.d.
    if $u_1 = u_2 = \dots = u_k$ and $v_1 \prec v_2 \prec \dots \prec v_k$ then
        return $(u_1, v_1, \dots, v_k)$
    return Fail
```

▶ **Lemma 11.** *For any instance of a k-star S_k in G, the probability that it will be returned by the algorithm* SampleStar(G, k) *is* $\frac{1}{(2m)^k}$.

Proof. Consider any instance of S_k with root x and petals $y_1, \dots, y_k$ such that $y_1 \prec \dots y_k$. Note that it will be returned by SampleStar if and only if all the directed edges $(x, y_1), \dots, (x, y_k)$ are sequentially sampled, which occurs with probability $1/(2m)^k$. ◀

3.3 Sampling H

Let H be a subgraph. It can be decomposed into collections of o odd cycles $\overline{C_i}$ and s stars $\overline{S_j}$ as given in Lemma 7. We say that H has a (decomposition) *type* $\overline{T} = \{\overline{C_1}, \dots, \overline{C_o}, \overline{S_1}, \dots, \overline{S_s}\}$.

▶ **Definition 12.** *Given a graph G, for each potential* instance $\mathcal{H}$ *of H, we say that $\mathcal{H}$ can be decomposed into* configurations $\mathcal{T} = \{\mathcal{C}_1, \dots, \mathcal{C}_o, \mathcal{S}_1, \dots, \mathcal{S}_s\}$ *with respect to type $\overline{T} = \{\overline{C_1}, \dots, \overline{C_o}, \overline{S_1}, \dots, \overline{S_s}\}$, if*

1. *$\mathcal{C}_i \cong \overline{C_i}$ for any $1 \leq i \leq o$, and $\mathcal{S}_j \cong \overline{S}_j$, for any $1 \leq i \leq s$*
2. *all the remaining edges of H between vertices specified in $\mathcal{T}$ all are present in G.*

We let $f_{\overline{T}}(H)$ denote the number of all possible configurations $\mathcal{T}$ into which H can be decomposed with respect to $\overline{T}$.

Algorithm 5 Sampling a copy of subgraph H.

```
procedure SampleSubgraph($G, H$)
    Let $\overline{T} = \{\overline{C_1}, \dots, \overline{C_o}, \overline{S_1}, \dots, \overline{S_s}\}$ denote a (decomposition) type of $H$.
    for all $i = 1 \dots o$ do
        if SampleOddCycle($G, |E(\overline{C}_i)|$) returns a cycle $\mathcal{C}$ then
            $\mathcal{C}_i \leftarrow \mathcal{C}$
        else
            return Fail
    for all $j = 1 \dots s$ do
        if SampleStar($G, |V(\overline{S}_j)| - 1$) returns a star $\mathcal{S}$ then
            $\mathcal{S}_j \leftarrow \mathcal{S}$
        else
            return Fail
    Query all edges $(\bigcup_{i \in [o]} V(\mathcal{C}_i) \cup \bigcup_{j \in [s]} V(\mathcal{S}_j))^2$
    if $S := (\mathcal{C}_1, \dots, \mathcal{C}_o, \mathcal{S}_1, \dots, \mathcal{S}_s)$ forms a copy of $H$ then
        flip a coin and with probability $\frac{1}{f_{\overline{T}}(H)}$: return $S$
    return Fail
```

▶ **Lemma 13.** *For any instance of a subgraph H in G, the probability that it will be returned by the algorithm* SampleSubgraph*(G, H) is* $\frac{1}{(2m)^{\rho(H)}}$.

Proof. For any instance $\mathcal{H}$ of H in G, and any configuration $\mathcal{T} = \{\mathcal{C}_1, \dots, \mathcal{C}_O, \mathcal{S}_1, \dots, \mathcal{S}_s\}$ of $\mathcal{H}$ with respect to $\overline{T}$, $\mathcal{H}$ will be returned by SampleSubgraph(G, H) if and only if

1. $\mathcal{C}_i$ is returned in Algorithm 5 for each $1 \le i \le o$, and $\mathcal{S}_j$ is returned in Algorithm 5 for any $1 \le j \le s$;
2. the configuration is returned with probability $\frac{1}{f_{\overline{T}}(H)}$ in Algorithm 5.

By Lemma 10, each $\mathcal{C}_i$ will be returned with probability $\frac{1}{(2m)^{|E(\overline{C_i})|/2}} = \frac{1}{(2m)^{\rho(\overline{C_i})}}$. By Lemma 11 each $\mathcal{S}_j$ will be returned with probability $\frac{1}{(2m)^{|V(\overline{S_j})|-1}} = \frac{1}{(2m)^{\rho(\overline{S_j})}}$. Thus, $\mathcal{T}$ will be returned with probability

$$\prod_{i=1}^{o} \frac{1}{(2m)^{\rho(\overline{C_i})}} \cdot \prod_{j=1}^{s} \frac{1}{(2m)^{\rho(\overline{S_j})}} \cdot \frac{1}{f_{\overline{T}}(H)} = \frac{1}{(2m)^{\rho(H)}} \cdot \frac{1}{f_{\overline{T}}(H)}.$$

Finally, since there are $f_{\overline{T}}(H)$ configurations of $\mathcal{H}$ with respect to $\overline{T}$, the instance will be returned with probability $f_{\overline{T}}(H) \cdot \frac{1}{(2m)^{\rho(H)}} \cdot \frac{1}{f_{\overline{T}}(H)} = \frac{1}{(2m)^{\rho(H)}}$. ◀

3.4 The Final Sampler

Let X_H be an estimate of $\#H$. Such an estimate can be obtained by, e.g., the subgraph counting algorithm of Assadi et al. [3] in expected time $\tilde{O}(m^{\rho(H)}/\#H)$. We show that by sufficiently many calls to SampleSubgraph, we can obtain a uniformly random sample of an instance of H with constant probability.

Algorithm 6 Sampling a copy of subgraph H uniformly at random.

```
1: procedure SampleSubgraphUniformly($(G, H, X_H)$)
2:     for all $j = 1, \ldots, q = 10 \cdot (2m)^{\rho(H)}/X_H$ do
3:         Invoke SampleSubgraph($(G, H)$)
4:         if a subgraph $H$ is returned then return $H$
5:     return Fail
```

▶ **Lemma 14.** *If $\#H \leq X_H \leq 2\#H$, then Algorithm* SampleSubgraphUniformly(G, H, X_H) *returns a copy H with probability at least $2/3$. The distribution induced by the algorithm is (exactly) uniform over the set of all instances of H in G.*

Proof. Since $\#H \leq X_H \leq 2\#H$, the probability that no instance of H is returned in $q = 10 \cdot (2m)^{\rho(H)}/X_H$ invocations is at most

$$\left(1 - \frac{\#H}{(2m)^{\rho(H)}}\right)^q \leq e^{-\frac{\#H}{(2m)^{\rho(H)}} \cdot q} < \frac{1}{3}$$

by Lemma 13. Let $\mathcal{H}$ be an instance of H. By Lemma 13, the probability that SampleSubgraph(H) returns $\mathcal{H}$ is $\frac{1}{(2m)^{\rho(H)}}$. Thus, the probability that SampleSubgraphUniformly(G, H) successfully output an instance of H is

$$\frac{\#H}{(2m)^{\rho(H)}}.$$

Conditioned on the event that SampleSubgraphUniformly(G, H) succeeds, the probability that any specific instance $\mathcal{H}$ will be returned is

$$p_{\mathcal{H}} = \frac{\frac{1}{(2m)^{\rho(H)}}}{\frac{\#H}{(2m)^{\rho(H)}}} = \frac{1}{\#H}.$$

That is, with probability at least $\frac{2}{3}$, an instance $\mathcal{H}$ is sampled from the uniform distribution over all the instances of H in G. ◀

Finally, we prove the expected query and time complexity of SampleSubgraphUniformly.

▶ **Lemma 15.** *The expected query and time complexity of* SampleSubgraphUniformly(G, H, X_H) *is $O(m^{\rho(H)}/X_H)$.*

Proof. We analyze the query complexity of SampleOddCycle$(G, 2k + 1)$ for $d_{u_1} < \sqrt{2m}$ and $d_{u_1} \geq \sqrt{2m}$ separately. The probability that $d_{u_1} < \sqrt{2m}$ is at most 1, and the query complexity is at most $O(1)$ in this case.

To bound the probability that SampleWedge(G, u_1, v_k) is invoked such that $d_{u_1} \geq \sqrt{2m}$, recall that sampling an edge uniformly at random is equivalent to sampling a vertex proportionally to its degree and selecting a neighbor uniformly at random. The probability to sample a neighbor x of u_1 is $1/d_{u_1}$. There at most $2m/\sqrt{2m} = \sqrt{2m}$ vertices that have degree at least $\sqrt{2m}$, so the probability that a uniformly random neighbor v_1 of u_1 has degree at least $\sqrt{2m}$ is at most $\sqrt{2m}/d_{u_1}$. Therefore, the probability that v_1 has degree at least $\sqrt{2m}$, which is implied by the check $u_1 \prec v_1$ in line 3, is bounded by $\sqrt{2m}/d_{u_1}$. By Lemmas 5 and 9, the expected number of queries in SampleWedge(G, u_1, v_k) is at most $M \leq d_{u_1}/\sqrt{2m}$ if $d_{u_1} \geq \sqrt{2m}$. Thus, the expected query complexity of SampleOddCycle$(G, 2k + 1)$ is bounded by

$$\sum_{\substack{u_1\in V\\ d_{u_1}<\sqrt{2m}}} \frac{d_{u_1}}{2m}\cdot O(1) + \sum_{\substack{u_1\in V\\ d_{u_1}\geq\sqrt{2m}}} \frac{d_{u_1}}{2m}\cdot\frac{\sqrt{2m}}{d_{u_1}}\cdot\frac{d_{u_1}}{\sqrt{2m}} \leq O(1) + \sum_{\substack{u_1\in V\\ d_{u_1}\geq\sqrt{2m}}} \frac{d_{u_1}}{2m} = O(1).$$

The expected query complexity of SampleStar(G, k) is bounded by $k \in O(1)$. It follows that the expected query complexity of SampleSubgraph(G, H) is at most $(o + s + |H|^2)\cdot O(1) \subseteq |H|\cdot O(1)$. The expected query complexity of SampleSubgraphUniformly(G, H) is $O((2m)^{\rho(H)}/X_H\cdot|H|^2) = \tilde{O}((2m)^{\rho(H)}/X_H)$. To bound the expected running time, we observe that every loop in our algorithm issues at least one query, and we only perform isomorphism checks on subgraphs of constant size. Thus the running time is still $\tilde{O}((2m)^{\rho(H)}/X_H)$. ◀

The proof of Theorem 1 follows almost directly from Lemmas 14 and 15.

Proof of Theorem 1. For the case that $m \geq m^{\rho(H)}/\#H$, the claim follows from Lemmas 14 and 15. If $m < m^{\rho(H)}/\#H$, we can query the whole graph, which requires $O(m)$ degree and neighbor queries, store the graph and answer the queries of the algorithm from this internal memory. ◀

4 Proof of Theorem 2

In this section, we give the proof of Theorem 2, which follows by adapting the proofs for the lower bounds on the query complexity for approximate counting subgraphs given by Eden and Rosenbaum [12].

▶ **Theorem 16** (see Theorems 4.7 and B.1 in [12]). *For any choices of $n, m, r, c_r > 0$, there exist families of graphs with n vertices and m edges, $\mathcal{F}_0$ and $\mathcal{F}_1$, such that*

- *all graphs in $\mathcal{F}_0$ are K_r-free,*
- *all graphs in $\mathcal{F}_1$ contain at least c_r copies of K_r,*
- *and any algorithm in the augmented general graph model that distinguishes a graph $G \in \mathcal{F}_0$ from $G \in \mathcal{F}_1$ with probability $\Omega(1)$ requires $\Omega(\min\{m, m^{r/2}/c_r(cr)^r\})$ queries for some constant $c > 0$.*

Now we prove our Theorem 2.

Proof of Theorem 2. Let $\mathcal{A}$ be an algorithm that for any graph $G = (V, E)$ on n vertices and m edges returns an arbitrary r-clique K_r, if one exists; and each K_r is sampled according to $\mathcal{D}$, using $f(m, r, \#K_r) \in o(\min\{m, \frac{m^{r/2}}{\#K_r\cdot(cr)^r}\})$ neighbor, degree, pair and edge sampling queries.

Let $n, m, c_r > 0$ and let $\mathcal{F}_0, \mathcal{F}_1$ be the families from Theorem 16. Consider the following algorithm $\mathcal{A}'$: run $\mathcal{A}$ on a graph from $\mathcal{F}_0 \cup \mathcal{F}_1$ and terminate $\mathcal{A}$ if it did not produce a K_r after $f(m, r, c_r)$ queries. If it output a clique, $\mathcal{A}'$ claims that $G \in \mathcal{F}_1$, otherwise it claims that $G \in \mathcal{F}_0$. By the assumption, $\mathcal{A}$ returns a clique after at most $f(m, r, c_r)$ queries with probability $\Omega(1)$ if $G \in \mathcal{F}_1$ because then G contains at least c_r copies of K_r and the probability mass of $\mathcal{D}$ on the set of all copies of K_r is $\Omega(1)$. Otherwise, $G \in \mathcal{F}_0$, which implies that G contains no triangle. Therefore, $\mathcal{A}$ cannot output a triangle from G.

It follows that $\mathcal{A}'$ can distinguish $\mathcal{F}_0$ and $\mathcal{F}_1$, which is a contradiction to Theorem 16. ◀

Abstract

Obtaining strong linear relaxations of capacitated covering problems constitute a significant technical challenge even for simple settings. For one of the most basic cases, the Knapsack-Cover (Min-Knapsack) problem, the relaxation based on *knapsack-cover inequalities* has an integrality gap of 2. These inequalities are exploited in more general problems, many of which admit primal-dual approximation algorithms.

Inspired by problems from power and transport systems, we introduce a general setting in which items can be taken fractionally to cover a given demand. The cost incurred by an item is given by an arbitrary non-decreasing function of the chosen fraction. We generalize the knapsack-cover inequalities to this setting an use them to obtain a $(2+\varepsilon)$-approximate primal-dual algorithm. Our procedure has a natural interpretation as a bucket-filling algorithm which effectively overcomes the difficulties implied by having different slopes in the cost functions. More precisely, when some superior segment of an item presents a low slope, it helps to increase the priority of inferior segments. We also present a rounding algorithm with an approximation guarantee of 2.

We generalize our algorithm to the Unsplittable Flow-Cover problem on a line, also for the setting of fractional items with non-linear costs. For this problem we obtain a $(4+\varepsilon)$-approximation algorithm in polynomial time, almost matching the 4-approximation algorithm known for the classical setting.

1 Introduction

Covering problems have been heavily studied by the combinatorial optimization community. Understanding their polyhedral descriptions, and how to approximate them, is a challenging and important task even for simple variants. One of the main tools for obtaining strong linear relaxations of covering problems are the *knapsack-cover inequalities*, introduced by Carr et al. [9], and have been used extensively [4, 18, 3, 3, 8, 10, 19, 1, 20, 2, 22]. Although the inequalities are exponentially many, they can be approximately separated up to a factor of $1+\varepsilon$ in polynomial time. In many cases they are well adjusted for primal-dual algorithms, which avoid having to solve the relaxation and yield faster combinatorial algorithms [4, 8, 10, 20].

In the classical Knapsack-Cover problem we are given a set of n items N and a demand $D \in \mathbb{N}$. Each item i has an associated covering capacity u_i and cost c_i. The objective is to choose a subset of items covering D at a minimum cost. We introduce a new natural generalization of this problem motivated by applications on the operation of power systems and the design of public transport systems. In this version we can choose items partially at a given cost, which might be non-linear. More precisely, each item $i \in N$ have an associated non-decreasing cost function $f_i : \mathbb{N} \to \mathbb{Q}_{\geq 0} \cup \{\infty\}$. We must choose a number $x_i \in \mathbb{N}$ for each i such that $\sum_{i\in N} x_i \geq D$. The cost of such solution is $\sum_{i\in N} f_i(x_i)$. We can reduce the Knapsack-Cover problem to this setting by considering $f_i(0) = 0$, $f_i(1) = \ldots = f_i(u_i) = c_i$ and $f_i(x) = \infty$ for $x > u_i$. We say that we are in the *list model* if the input contains the numbers $f_i(0), f_i(1), \ldots, f_i(D)$ explicitly as a list. In this case the reduction above is pseudo-polynomial. On the other hand, if each f_i is given by an oracle that outputs $f_i(x)$ for any x, we say that we are in the *oracle model*. In this case the reduction above can be made polynomial. We call our newly introduced problem the *Non-Linear Knapsack-Cover problem*. Our setting also generalizes the *Single-Demand Facility Location* problem studied by Carnes and Shmoys [8]. In this setting each item (facility) has an activation cost b_i and then the cost grows linearly at a rate of a_i, that is, $f_i(0) = 0$, $f_i(x) = b_i + c_i x$ for $x \in \{1, \ldots, u_i\}$, and $f_i(x) = \infty$ otherwise.

More generally, we study the Non-Linear variant of the Unsplittable Flow-Cover problem on a path (UFP-cover), that extends the Non-Linear Knapsack-Cover problem. In the original UFP-cover problem, first considered by Bar-Noy et al. [4], we have a discrete interval $I = \{1, \ldots, k\}$ and a set N of n items, each one characterized by a capacity or height u_i, a cost c_i, and a sub-interval $I_i \subseteq \{1, \ldots, k\}$. We also have a demand D_t for each $t \in I$. The problem consists on selecting the cheapest set of items such that the total height at any point in I is at least the demand, that is, we must pick a set S minimizing $\sum_{i\in S} c_i$ such that $\sum_{i\in S: I_i \ni t} u_i \geq D_t$ for all $t \in I$. In this paper we generalize this problem to the case where items can be taken partially. As before we are giving a non-decreasing function $f_i = \mathbb{N} \to \mathbb{Q}_{\geq 0} \cup \{\infty\}$ for each item. We can choose to set the height of any item to a value $x_i \in \mathbb{N}$ by paying a cost $f_i(x_i)$. We mush choose heights in order to cover the demand at each point $t \in I$ at a minimum total cost $\sum_i f_i(x_i)$. Notice that this setting generalizes Non-Linear Knapsack-Cover.

In this article we provide a generalization of the knapsack-cover inequalities to the Non-Linear Knapsack-Cover problem, which we also apply to Non-Linear UFP-Cover. The obtained relaxations yield primal-dual algorithms matching the classical settings. Namely, for Non-Linear Knapsack-Cover we show a 2-approximation algorithm, and for Non-Linear UFP-Cover a 4-approximation algorithm, both running in polynomial time in the list model. For the oracle model, they can be adapted to yield a $(2+\varepsilon)$- and $(4+\varepsilon)$-approximation, respectively, in polynomial time. Additionally, we show a rounding technique for the Non-Linear Knapsack-Cover case also achieving a 2-approximation for the list model, together with a polynomial time separation algorithm.

Applications

One of our main motivations for considering non-linear cost functions comes from the Unit Commitment Problem (UCP), a prominent problem in the operation of power systems. In its most basic version, a central planner, called Independent System Operator (ISO), must schedule the production of energy generated from a given set of power plants, in order to satisfy a given demand. For the case of one time period, the problem corresponds to Non-Linear Knapsack-Cover. More precisely, items correspond to power plants, and $f_i(x)$ is the cost of producing x units of power by power plant i. A common issue in this setting is that plants incur fixed costs for starting production, and after the resource is available, a minimum amount of energy must be produced. It is worth noticing that after paying the fixed cost the behavior of the cost functions might be non-linear and are often modelled by convex quadratic functions [24].

On the other hand, Non-Linear UFP-Cover appears in the optimization of transport systems. Consider an avenue with several bus stops $\{1,\dots,k\}$. We interpret the avenue as a path network where bus stops correspond to edges. Passengers need to move (in a single direction) within bus stops, and hence, we associate to each passenger a set of consecutive bus stops (i.e., a path) which they need to traverse. The set of paths defines a flow that needs to traverse the network. Hence, we obtain a demand D_t at each bus stop t, representing the total number of passengers (amount of flow) that must traverse it. On the supply side, there are potential bus transit lines, each covering some sub-path of the avenue, and hence covering the demand on some subset of consecutive bus stops $I_i = \{f_i, f_i+1, \dots, l_i\} \subseteq \{1,\dots,k\}$. As the planner of this system, we must choose which lines to operate. Additionally, for each chosen line, we must choose its operation frequency and the type of vehicle to use. Such combinations of frequency and vehicle define the amount of passengers (demand) the line can transport. Assume that for line i and each demand x, we can optimally choose (that is, we have an oracle) the frequency and vehicle combination to minimize the operating cost of the line, which we call $f_i(x)$. In other words, for each line i, we must choose a demand $x_i \geq 0$ to cover, such that the total operation cost $\sum_i f_i(x_i)$ is minimized. It is not hard to see that covering the demand at each bus stop guarantees that all passengers can be transported. Hence, it suffices that $\sum_{i:t\in I_i} x_i \geq D_t$ holds for each bus stop $t \in \{1,\dots,k\}$. Hence, we obtain an instance of Non-Linear UFP-Cover.

We might wonder what type of cost functions f_i one can get in this setting. There is a vast literature concerning economies of scale in public transport lines: for instance, Mohring [21] states that there are economies of scale in public transport, Fielbaum et al. [14] show that they get exhausted. Coulombel and Monchambert [12] propose that the system could face diseconomies of scale when the demand exceeds certain thresholds. Hence, techniques to manage non-linear functions (that can have convex and concave regions) are needed.

Related Work

The use of the primal-dual method to derive approximation algorithms is introduced by Bar-Yehuda and Even [5] and Chvátal [11], becoming one of the major tools for designing approximation algorithms [23]. Bar-Noy et al. [4] are the firsts to consider the primal-dual framework based on knapsack-cover inequalities. However, they pose their algorithm in the equivalent local-ratio framework [6], even before the knapsack-cover inequalities were introduced and without stating the underlying LP-relaxation. Their techniques yield a 4-approximation algorithm and their analysis is tight [10]. Additionally, this problem admits a quasi-polynomial time approximation scheme (QPTAS) [16]. On the other hand, Carnes and Shmoys [8] give an explicit description of the primal-dual method, obtaining a 2-approximation algorithm for Knapsack-Cover, the Single-Demand Facility Location problem, and the more general Single-item Lot-Sizing problem with Linear Holding Costs. Cheung et al. [10] consider the Generalized Min-Sum Scheduling problem on a single machine without release dates; they obtain a $(4+\varepsilon)$-approximation algorithm based on the primal-dual framework on an LP with knapsack-cover inequalities. Finally, McCormick et al. [20] consider covering problems with precedence constraints, where they give a primal-dual algorithm with approximation ratio equal to the width of the precedence relations. We remark that Non-Linear Knapsack-Cover can be modeled within this framework, but applying this result to this case yields an unbounded approximation guarantee.

Outside the primal-dual framework, the literature is rich on the use of the knapsack-cover inequalities and its generalizations together with rounding techniques. The problems considered include the Min-Sum General Scheduling problem on a single [3] and multiple [22, 2] machines, the Uniform [18] and Non-Uniform [19] Capacitated Multi-item Lot-sizing problem, and Capacitated Facility Location [1]. On the other hand, it is not known if there exists a compact set of constraints matching the strength of the knapsack-cover inequalities. Recently, Bazzi et al. [7] gave a formulation with an integrality gap of $2+\varepsilon$ for the Knapsack-Cover problem with a quasipolinomial number of inequalities.

It is also worth mentioning that the most common technique for dealing with non-linear cost functions in capacitated covering problems is a doubling technique: split the cost function in segments where the function doubles. Then, each segment can be considered independently as a single item. This technique removes the precedence dependence between different segments, at factor 4 loss in the approximation ratio; see for example [3]. Similarly, with a randomized shifting strategy an e-approximation is achievable [17, 15]. Our approach strengthen the knapsack-cover inequalities and allows to avoid the extra loss.

Our Contribution

Let z_{ij} be a binary variable that represents whether $x_i \geq j$ in the solution, i.e., if the j-th unitary *segment* of item i is *taken*. Defining $g_{ij} = f_i(j) - f_i(j-1)$, then the cost of any solution is $\sum_{ij} g_{ij} z_{ij}$, and for any solution to be feasible it must hold for all i, j that if $z_{ij} = 1$ then $z_{i,j-1} = 1$. In a greedy algorithm, one might be tempted to take segments with low g_{ij}. This fails as such segments might be preceded by another segment with $g_{ik} \gg g_{ij}$ for $k < j$. This poses two fundamental questions when assessing the value of a segment: (i) how to take into consideration (mandatory) preceding segments of high cost? (ii) how to take into account low costs segments to the right, specially considering segments that finally might not be part of the final solution (since the demand can be completely covered by previous segments)?

We introduce a natural variant of the knapsack-cover inequalities for non-linear cost functions. These generalize the basic version of the inequalities, as well the generalization of Carnes and Shmoys [8] for the Single-Demand Facility Location Problem. Our inequalities are then used to derive a primal-dual algorithm that helps to handle the fundamental questions stated above. Our algorithm can be interpreted as a water-filling algorithm. Each segment j of an item i has a corresponding *bucket* B_{ij} of capacity g_{ij}, representing an inequality in the dual linear program. All buckets for a given item i are placed on a stairway, where bucket B_{ij} is on the j-th step of the stairs. A segment is taken, i.e. we set $z_{ij} = 1$, if its corresponding bucket and all previous ones (which are in lower steps of the stairs) are full. Water reaches buckets through two mechanisms. Water from an external source is poured directly into each bucket at a rate of either 1 or 0 (units of water per time unit). The first time a bucket B_{ij} becomes full, then the water arriving to this bucket spills to bucket $B_{i,j-1}$, which now fills at a rate of 2 (as long as B_{ij} is still receiving water from the external source). If $B_{i,j-1}$ also becomes full and $j > 2$, then the water pouring into B_{ij} and $B_{i,j-1}$ spills to $B_{i,j-2}$ which now fills at a rate of 3, etc. For a bucket to receive water from the external source it must satisfy two properties: (i) its corresponding segment is not yet in the primal solution, and (ii) all previous segments of the item are not enough to cover the remaining demand. Our primal-dual algorithm helps to take care of the tensions implied by the questions above by making buckets filling faster due to water spilled from higher buckets, and prevents spilling water from a bucket if they are so high that they are useless to help covering the remaining demand.

For the case of Non-Linear UFP-Cover, our algorithm works similarly. However, the primal solution constructed with the algorithm might contain redundant segments due to sub-intervals of I that might be covered in subsequent steps of the algorithm. For this reason we need to perform a *reverse-delete* (or pruning) strategy to remove unnecessary segments, in the reverse order in which they were introduced in the primal solution.

We notice that, for both algorithms, our analysis is tight as they achieve the same performance guarantee as their classic variants [8, 10]. Additionally, the integrality gap of our formulation for the Non-Linear Knapsack-Cover problem is also 2, as the same lower bound of the the classical setting holds [9].

Finally, we show a rounding technique for the LP relaxation of the Non-Linear Knapsack-Cover problem and a polynomial time separation algorithm for the generalized knapsack-cover inequalities in the list model. These results, together with some of the proofs and extra details, can be found in the full version of this manuscript [13].

2 A Generalization of the Knapsack-Cover Inequalities for Non-Linear Knapsack-Cover

We first study the Non-Linear Knapsack-Cover problem. Recall that in this setting we consider a demand $D \in \mathbb{N}$ and a set N of n items, each with a non-decreasing function f_i. We assume that all f_i are defined over a common domain $\{0, 1, \dots, m\}$, for some $m \leq D$, and that $f_i(0) = 0$. Hence, each item $i \in N$ has m *segments* of unit length, indexed by a common set $M = \{1, \dots, m\}$, each having a unit cost $g_{ij} = f_i(j) - f_i(j-1) \geq 0$. In what follows we assume that our instance admits a feasible solution. We start by considering the list model.

It is worth mentioning that the problem described can be solved in polynomial time (respectively pseudo-polynomial) in the list (respectively oracle) model by a straightforward adaptation of the classical dynamic program for Knapsack. In the oracle model the problem is (weakly) NP-hard as it contains Knapsack-Cover as a special case. For this model the dynamic program can be turned into an FPTAS also by adapting well known rounding techniques [23]. However, these techniques alone cannot handle Non-Linear UFP-Cover.

2.1 Knapsack-Cover Inequalities for Non-Linear Costs

To write a linear relaxation of this problem, consider $a \in \{0, \dots, m\}^N$, where a_i represents that all segments $j \in \{1, \dots, a_i\}$ have been taken already for item $i \in N$ (and $a_i = 0$ represents that no segment of i is taken yet). We face the residual problem, where we must decide about segments not taken yet, and we must cover the residual demand $D(a) := \max\{D - \sum_{i \in N} a_i, 0\}$. Recall that z_{ij} is a variable that indicates whether the j-th segment of item i is taken. Since we must only cover the residual demand $D(a)$, there is an optimal solution where $z_{ij} = 0$ for $j > a_i + D(a)$; therefore, we conclude that for item i we can only take up to segment $m_i(a) := \min\{m, a_i + D(a)\}$.

F_2^0
F_2^1
F_2^2
$\min\{z_{22}, \boxed{z_{21}}\} + \min\{\boxed{z_{23}}, z_{22}, z_{21}\}$

Figure 1 Example of an inequality in (1) for a given pair (a, F), with $n = 2$ items, $m = 3$ segments and demand $D = 4$. We consider a vector a with $a_1 = 0, a_2 = 1$, and hence $m_1(a) = m_2(a) = 3$. The left side of the figure shows a specific index F. On the right is shown the left-hand-side (LHS) of the convex inequality in (1), where we cover a term with a square if the corresponding term is chosen for the inequality in (2) indexed by (a, F). This yields the inequality $z_{11} + z_{12} + z_{11} + z_{21} + z_{23} \geq D(a)$, where $D(a) = 3$. That is, $2z_{11} + z_{12} + z_{21} + z_{23} \geq D(a)$, implying that $\tau(1, 1, a, F) = 2, \tau(1, 2, a, F) = \tau(2, 1, a, F) = \tau(2, 3, a, F) = 1$, and all the other $\tau(i, j, a, F)$ parameters equal 0.

To obtain a linear program, we relax the condition that $z_{ij} = 1$ implies $z_{ik} = 1$ for $k < j$. To do so, note that in a feasible solution variable z_{ij} should never be larger than $\min\{z_{ij}, z_{i,j-1}, \ldots, z_{i1}\}$, and hence we can replace in our formulation the appearance of z_{ij} by this minimum. We conclude that the following is a relaxation of the Non-Linear Knapsack-Cover problem, which we call [GKC]:

$$\min \sum_{i \in N, j \in M} g_{ij} z_{ij}$$

$$\sum_{i \in N} \sum_{j = a_i + 1}^{m_i(a)} \min\{z_{ij}, z_{i,j-1}, \ldots, z_{i1}\} \geq D(a) \qquad \text{for all } a \in \{0, \ldots, m\}^N, \tag{1}$$

$$z_{ij} \geq 0 \qquad \text{for all } i \in N, j \in M.$$

We call the set of inequalities (1) the *knapsack-cover inequalities for non-linear costs*. This relaxation can be easily linearized. Indeed, if a program has a constraint of the form $\min\{x_1, x_2\} \geq b$, then we can replace it with $x_1 \geq b$ and $x_2 \geq b$. More generally, if the constraint is $\min\{x_1, x_2\} + \min\{x_3, x_4\} \geq b$, then we must consider all constraints $x_i + x_j \geq b$ for all $i \in \{1, 2\}$ and $j \in \{3, 4\}$. More generally, convex inequality in (1) can be replaced with exponentially many linear ones. The linear inequalities are constructed by replacing each summand $\min\{z_{ij}, z_{i,j-1}, \ldots, z_{i1}\}$ in (1) by one of its terms $z_{ij}, z_{i,j-1}, \ldots, z_{i1}$.

Each of the new linear inequalities will be indexed by a pair (a, F). The chosen notation will prove useful when describing and analyzing the water-filling algorithm below, as they will indicate which buckets are spilling water and which are receiving it. Consider a fixed vector a as above. The index F indicates, for each item $i \in N$ and segment $j \in M$, which term z_{ip} is selected from the set $\{z_{ij}, \ldots, z_{i1}\}$ for each i, j. A given F can be thought as an array of containers $(F_i^k)_{i \in N, k \in \{0, \ldots, m-1\}}$. Each item $i \in N$ corresponds to a row of this array, with containers (sets) $F_i^0, \ldots, F_i^{m-1}$. We distribute the set $\{a_i + 1, \ldots, m\}$ within these containers, and thus $\bigcup_{k=0}^{m-1} F_i^k = \{a_i + 1, \ldots, m\}$. Assigning an index $j \in \{a_i + 1, \ldots, m\}$ to F_i^k represents that in that inequality we select $z_{i,j-k}$ from $\{z_{ij}, \ldots, z_{i1}\}$. See Figure 1 for a concrete example of this construction. The obtained set of inequalities is given by

$$\sum_{i\in N}\sum_{k=0}^{m-1}\sum_{j\in F_i^k: j\leq m_i(a)} z_{i,j-k} \geq D(a) \qquad \text{for all } (a,F)\in\mathcal{F}, \tag{2}$$

where $\mathcal{F}$ is the set of all ordered pairs (a, F) with $a \in \{0,\ldots,m\}^n$, and F satisfies (i) $\dot\bigcup_{k=0}^{m-1} F_i^k = \{a_i + 1,\ldots,m\}$, and (ii) if $j \in F_i^k$ then $j - k \geq 1$ for all k, j. Let us consider now a given pair (a, F), an item i, and $j > a_i$. The term z_{ij} might appear several times in the respective constraint (2), depending on how many "minimums" are replaced by z_{ij}. If $k \in F_i^{k-j}$, then $\min\{z_{ik}, z_{i,k-1},\ldots,z_{i1}\}$ is replaced by z_{ij}. Moreover, recall that the residual demand $D(a)$ will never be covered by a segment z_{ij} for $j > m_i(a)$, and hence the number of times that z_{ij} appears in the left-hand-side of the inequality is

$$\tau(i,j,a,F) = |\{k\geq j : k\in F_i^{k-j}, k\leq m_i(a)\}|. \tag{3}$$

For a concrete example consider Figure 1.

With this definition, we obtain a linear relaxation that is equivalent to [GKC].

▶ **Lemma 1.** *The convex program [GKC] is equivalent to*

$$\begin{aligned}
\textit{[P-GKC]:}\min &\sum_{i\in N}\sum_{j\in M} z_{ij}g_{ij} \\
\textit{s.t.} &\sum_{i\in N}\sum_{j=1}^{m}\tau(i,j,a,F)\cdot z_{ij}\geq D(a) \qquad \textit{for all } (a,F)\in\mathcal{F}, \qquad (4)\\
& z\geq 0.
\end{aligned}$$

A routinary computation yields that the dual of this linear program, which we call [D-GKC], is the problem of maximizing $\sum_{(a,F)\in\mathcal{F}} D(a)v_{aF}$ subject to $v \geq 0$ and

$$\sum_{(a,F)\in\mathcal{F}} \tau(i,j,a,F)\cdot v_{aF}\leq g_{ij} \quad \text{for all } i\in N, j\in M. \tag{5}$$

2.2 A 2-approximate Primal-Dual Algorithm

We provide a primal-dual 2-approximation algorithm based on the LP-relaxation [P-GKC] and its dual [D-GKC]. It is worth having in mind the bucket representation of the algorithm given above in the introduction.

Algorithm description

The water-filling algorithm described in the introduction is an intuitive representation of a greedy algorithm for the dual [D-GKC]. Each bucket corresponds to a dual inequality: Each of the inequalities in the dual [D-GKC] represents a bucket, the left hand size corresponds to the amount of water in the bucket, while the right hand side is its capacity. The greedy dual algorithm raises dual variables one by one starting from a dual solution $v \equiv 0$. In each iteration of the main loop, we raise a variable v_{aF}. The index a is chosen such that a_i represents the largest value ℓ for which all buckets $B_{i1},\ldots,B_{i\ell}$ are full (or equivalently, $z_{i1} = \ldots = z_{i\ell} = 1$), for each $i \in N$. To choose F, a segment j will belong to F_i^k if and only if the water from the external source falling into bucket B_{ij} (if any) spills down to bucket $B_{i,j-k}$. Number k is chosen such that it is the smallest number for which $B_{i,j-k}$ is not full, representing the idea that the water of full buckets falls down to the previous buckets on the stairs. Also, buckets receiving water from the external source are the buckets B_{ij} with

$a_i + 1 \leq j \leq m_i(a)$. This way, $\tau(i, j, a, F)$ corresponds to the filling rates of bucket B_{ij} in the current iteration, which considers the water directly from the external source and the water spilled from higher buckets. We stop raising variable v_{aF} as soon as one dual inequality becomes tight, i.e., some bucket B_{ij} becomes full. After, we update the value of z by setting $z_{ik} = 1$ if $B_{i\ell}$ is full for all $\ell \leq k$. Notice as we do not require that $k \leq m_i(a)$, and hence the returned primal solution might not satisfy the total demand exactly. Finally, we update a and F as described above and repeat the main loop until the residual demand $D(a)$ equals 0. The pseudo-code is given in Algorithm 1. The algorithm calls a sub-routine (Line 14) that explains how to update F when a bucket gets full but cannot be taken, which is given in Algorithm 2.

Algorithm 1 Primal-Dual Water-Filling Algorithm for Non-Linear Knapsack-Cover.

```
1:  $z, v \leftarrow 0$;  % primal and dual solutions.
2:  $a \leftarrow 0$;  % $a_i$ represents the largest value for which buckets $B_{i1}, \ldots, B_{i,a_i}$ are full.
3:  $F_i^k \leftarrow \emptyset \quad \forall i \in N, k \in M$;
4:  $F_i^0 \leftarrow M$;  % $j \in F_i^k$ iff water from bucket $B_{ij}$ falls to bucket $B_{i,j-k}$.
5:  while $D(a) > 0$ do
6:      Increase $v_{aF}$ until a dual constraint indexed by $(i, j)$, for some item $i \in N$ and segment
    $j \in M$, becomes tight.   % Bucket $B_{ij}$ becomes full.
          % Update $z_{ij}$:
7:      if $j = a_i + 1$ then
8:          Let $q > a_i$ be the maximum number such that $B_{i,a_i+1}, \ldots, B_{iq}$ are full.
9:          for $\ell = j, \ldots, q$ do
10:             $z_{i\ell} \leftarrow 1$;  % Take available segments.
11:         end for
12:         $a_i \leftarrow q$;
13:     else % If we cannot raise variable $z_{ij}$:
14:         $F \leftarrow \text{Update}(F, i, j, a)$  % Call Algorithm 2 to update the sets $F$
15:     end if
16: end while
17: return $v, z$.
```

Algorithm 2 Updating Buckets Subroutine

```
input  $a, i, j, F$   % $a, F$ represent the current state of the buckets, $i, j$ represent which
is the bucket that just got full.  We require $j > a_i + 1$.
Let $p < j$ be the maximum number so that $B_{ip}$ is not full.
Let $q > j$ be the minimum number so that $B_{iq}$ is not full (and $q = m + 1$ if $B_{ij}, \ldots, B_{im}$
are all full).
for $\ell = j, j + 1, \ldots, q - 1$ do
    $F_i^{\ell-j} \leftarrow F_i^{\ell-j} \setminus \{\ell\}$ and $F_i^{\ell-p} \leftarrow F_i^{\ell-p} \cup \{\ell\}$  % The water from the external source
falling to $B_{i\ell}$, which was previously spilling to bucket $B_{ij}$, now spills to bucket $B_{ip}$.
end for
return $F$
```

Analysis

The algorithm terminates, as each iteration of the main loop (Line 5) corresponds to some bucket that becomes full, so we enter the while loop at most nm times. The main challenge is to show that the algorithm is 2-approximate.

It follows directly that the dual solution constructed is feasible through the execution of the algorithm. The primal solution is feasible as we kept iterating the main loop until the residual demand $D(a)$ is zero. As in most approximate primal-dual algorithms, the crux of the analysis is to show that an approximate form of the complementary slackness conditions are satisfied. This is summarized in the next key lemma.

▶ **Lemma 2.** *Let $\bar{v}, \bar{z}$ be the primal and dual solutions computed by the algorithm. Then,for all $(a, F) \in \mathcal{F}$ such that $\bar{v}_{aF} > 0$, it holds that*

$$\sum_{i\in N}\sum_{j=1}^{m} \tau(i,j,a,F)\bar{z}_{ij} \leq 2D(a).$$

Proof. Let $(\bar{\imath}, \bar{\jmath})$ be the indices of the dual inequality that became tight in the last iteration of the algorithm, and let $\bar{z}, \bar{v}$ be the output primal and dual solutions.

Let us fix a variable $v_{aF} > 0$ and consider the iteration of the main loop of the algorithm where we were raising that variable. For a given item $i \in N$, the expression $\sum_{j\geq 1} \tau(i,j,a,F)\bar{z}_{ij}$ represents the total number of buckets that are receiving water from the external source and whose water is spilling to some bucket that ends up in the final solution. We analyze the last item separately from the other items. Regarding item $\bar{\imath}$, notice that $\sum_{j\geq 1} \tau(\bar{\imath},j,a,F)\bar{z}_{\bar{\imath}j} \leq D(a)$, just because the buckets obtaining water from the external source are in the interval $a_{\bar{\imath}} + 1, \ldots, m_{\bar{\imath}}(a)$, which are at most $D(a)$ many.

Consider now $i \neq \bar{\imath}$ and a bucket B_{ij} that is "part"of $\tau(i, j', a, F)$ for some segment j' included in the final solution, that is, either $j' = j$ or B_{ij} is pouring into $B_{ij'}$, case in which all the buckets between j and j' are full in this iteration of the algorithm. Then, as $\bar{z}_{ij'} = 1$, by construction B_{ij} will be taken as well; that is, $\bar{z}_{ij} = 1$. Additionally, no water (either directly or indirectly) reaches a bucket B_{ik} with $k \leq a_i$, and hence $\tau(i,k,a,F) = 0$. So the quantity $\sum_{i\in N\setminus\{\bar{\imath}\}}\sum_{j\geq 1} \tau(i,j,a,F)\bar{z}_{ij}$ is upper bounded by the total number of buckets in the final solution, of items other than $\bar{\imath}$, that are above a. This number cannot be higher than $D(a)$, otherwise the algorithm would have finished before filling the last bucket $B_{\bar{\imath},\bar{\jmath}}$. ◀

The proof of the next theorem follows from the previous lemma and standard techniques from primal-dual analysis. The details are deferred to the full version.

▶ **Theorem 3.** *Algorithm 1 is a polynomial time 2-approximation algorithm for Non-Linear Knapsack-Cover in the list model.*

The extension of this theorem to the oracle model is given in Section 4.

3 Unsplittable Flow-Cover on the Line

We now show that extending the ideas of Section 2 we can also achieve a 4-approximation for the Non-Linear UFP-Cover problem. Recall that an instance of this problem is given by an interval $I = \{1, \ldots, k\}$, a set N of n items, where each item is characterized by a capacity or height u_i, a cost c_i, and a sub-interval $I_i \subseteq \{1, \ldots, k\}$. We also have a demand D_t for each $t \in I$.

In the non-linear case, we can choose the height of each item from within a set $M = \{1, \ldots, m\}$. In other words, each item consists of a list of (vertical) segments, and one must choose a prefix of them. Again, we first focus on the list model where the costs of segments $g_{i1}, g_{i2}, \ldots, g_{im}$ are given in a list. As before, we use variables $z_{ij} \in \{0,1\}$ to represent if segment j of item i is in the solution. With this the cost is $\sum_{i \in N} \sum_{j \in M} z_{ij} g_{ij}$ and the constraint that each demand must be covered is given by

$$\sum_{i \in N : t \in I_i} \sum_{j \in M} z_{ij} \geq D_t \text{ for all } t \in I. \tag{6}$$

Finally, we require that $z_{i,j+1} = 1 \Rightarrow z_{ij} = 1$ for all $i \in N, j \in \{1, \ldots, m-1\}$.

We now present the problem using the generalized knapsack-cover inequalities, and the relaxation explained in Section 2, applied to each inequality in (6) separately. For this, define $D_t(a) = \max\left(D_t - \sum_{i:t \in I_i} a_i, 0\right)$ and $\tau(i,j,a,F,t) = \{k \geq j : k \in F_i^{k-j}, k \leq m_i(a)\}$, where $m_i(a) = \min\{m, a_i + D_t(a)\}$. The relaxed primal problem, which we call [P-UFP], asks to minimize $\sum_{i,j} z_{ij} g_{ij}$ for $z \geq 0$ subject to

$$\sum_{i:t \in I_i} \sum_{j \geq 1} \tau(i,j,a,F,t) \cdot z_{ij} \geq D_t(a) \quad \text{for all } (t,a,F) \in \mathcal{H}$$

where $\mathcal{H}$ is the set of triplets (t,a,F) where $t \in I$ and $(a,F) \in \mathcal{F}$, as defined in Section 2.2. This yields a dual relaxation [D-UFP], whose objective is $\max \sum_{(a,t,F) \in \mathcal{H}} v_{atF} \cdot D_t(a)$, and we must optimize over all $v \geq 0$ satisfying

$$\sum_{(a,t,F) \in \mathcal{H} : t \in I_i} \tau(i,j,a,F,t) \cdot v_{atF} \leq g_{ij} \qquad \text{for all } i \in N, j \in M. \tag{7}$$

Algorithm Description

Our primal-dual algorithm is given in Algorithm 3. In this case our approach has two phases. During the *growing* phase (Lines 5–15), we construct a dual solution, which then directly implies a feasible primal solution. In the *pruning* phase (Lines 16–20) we remove unnecessary segments from the primal solution. As before, for each item $i \in N$ we have a stair of buckets, where each bucket B_{ij} corresponds to a given inequality in the dual, indexed by $j \in M$ and $i \in N$. In each iteration of the growing phase buckets receive water (that might fall to inferior buckets) from an external source at a rate of 1 or 0. Once we define the rates, the water dynamics work in exactly the same way as in Section 2.2: water reaching a given bucket that is full is spilled to the next bucket to the left until it reaches a bucket that is not full. The only difference is that only some of the items receive water. More precisely, in a given iteration of the growing phase, we select $t \in I$ with largest unsatisfied demand $D_t(a)$ (break ties arbitrarily). This is a greedy criterion to increase the dual objective function as fast as possible. Only buckets for items $i \in I$ such that $t \in I_i$ receive water from the external source. For such an item i, the subset of buckets receiving water from the external source are again buckets B_{ij} with $j \in \{a_i + 1, \ldots, m_i(a)\}$. The water dynamics can be emulated by raising a single dual variable at a time. Notice that the only difference to the dual in Section 2 is that when raising a given variable v_{atF}, only inequalities for items $i \in N$ where $t \in I_i$ are affected, corresponding to the fact that only buckets corresponding to such items receive water from the external source.

When one or more buckets become full, we pick one of these buckets. As before, a full bucket means that the corresponding segment (i,j) is available. We take a given segment, that is, we define a primal variable z_{ij} to 1, as soon as all preceding buckets of item i are available.

In other words, if B_{ij} becomes full for $j = a_i + 1$, then we take set $z_{ij} = \ldots = z_{iq} = 1$ where $B_{ij}, \ldots, B_{iq}$ are full but $B_{i,q+1}$ is not. This is the case even if $q > m_i(a)$. All taken buckets (or segments) are considered to be a "block", denoted by b_{ij} (where j denotes the first segment of the block). After this we update t and continue with a new iteration of the main loop of the growing phase.

Although this first phase gives a feasible primal solution, some blocks might have become redundant, that is, the solution would remain feasible without them. In the second phase we remove redundant blocks when we can. To do this, we check for each block b_{ij}, in reverse order in which they were added, whether removing the block from the primal solution makes the given primal unfeasible. If b_{ij} is redundant and it is the superior block (i.e., the block containing the highest segment that is still in the solution) of its item, we remove it; if b_{ij} is redundant but there are blocks over it in the solution when it is checked, we cannot remove it (the solution would become unfeasible). Note that doing so, all the superior blocks that are in the final solution are not redundant.

Algorithm 3 Primal-Dual Algorithm for Non-Linear UFP-Cover.

```
$z$, $v \leftarrow 0$   % primal and dual solutions.
$a \leftarrow 0$
$F_i^k \leftarrow \emptyset$ for all $i, k \geq 1$; $F_i^0 \leftarrow M$
$\mathcal{B}_i \leftarrow \emptyset$ for all $i$   % Set containing the blocks of item $i$.
while $D_t(a) > 0$ for some $t$ do
    Select $t$ that maximizes $D_t(a)$ (break ties arbitrarily).
    Increase $v_{atF}$ until a dual constraint indexed by $(i, j)$, for some item $i$ and segment $j$,
    becomes tight. Break ties in favor of a bucket with smallest index $j$.
    if $j > a_i + 1$ then
        $F \leftarrow \text{Update}(F, i, j, a)$   % Water pouring into $B_{ij}$ pours into a lower bucket.
    else
        Let $q > a_i$ be the maximum number such that $j' \notin F_i^0$ for all $j' = j+1, \ldots, q$   % we
        take all full buckets that poured into $B_{i,a_i+1}$, even the ones that are now truncated.
        Set $a_i \leftarrow q$
        Set $\mathcal{B}_i \leftarrow \mathcal{B}_i \cup b_{ij}$, with $b_{ij} = \{j, \ldots, q\}$   % $b_{ij}$ is a block that enters the primal
        solution.
    end if
end while
for all $b_{ij}$ in reversed order in which they are defined in the growing phase do
    if $b_{ij}$ can be removed from the primal solution without leaving any demand unsatisfied
    and $j \geq j'$ for all $j'$ such that $b_{ij'} \in \mathcal{B}_i$ then
            % We eliminate redundant blocks, unless they have a superior block over it
        $\mathcal{B}_i \leftarrow \mathcal{B}_i \setminus b_{i,j}$
    end if
end for
return $z$, where $z_{ij} = 1$ for $j \leq \sum_{b_{ik} \in \mathcal{B}_i} |b_{ik}|$.
```

The proof of correctness is analogous as in Section 2.2. To show the approximation factor we need the following key lemma.

▶ **Lemma 4.** *Consider the output (z, v) of the algorithm. Let (a, t, F) such that $v_{atF} > 0$. Then*

$$\sum_{i: t \in I_i} \sum_{j \geq 1} \tau(i, j, a, F, t) \cdot z_{ij} \leq 4 D_t(a).$$

Proof. Let us fix a variable $v_{atF} > 0$ raised in the main loop of the growing phase. Denote by $\mathcal{B}_i$ the set of blocks for each i at the end of the pruning phase. Out of those, consider the ones that are above a, and that contribute to fulfill the demand in t, that is, $S_{ta} = \{b_{ij} \in \cup_{i \in N} \mathcal{B}_i : t \in I_i, j \geq a_i + 1\}$. Let us denote by $\bar{b}_i$ the superior block of each item (i.e. $\bar{b}_i = b_{ij}$ with $b_{ij} \in S_{ta}$ and $j \geq j'$ for all j' such that $b_{ij'} \in \mathcal{B}_i$). For each of these superior blocks, as they were not removed, it must exist some $t_i \in I$ such that its demand would become unsatisfied when removing $\bar{b}_i$, which is of course also true if we look only at the blocks in S_{ta}, i.e.,

$$D_{t_i}(a) > \left(\sum_{b_{kj} \in S_{ta}} |b_{kj}| \right) - |\bar{b}_i|. \tag{8}$$

Inequality (8) is true because we removed the blocks in a reversed order, and the blocks that conform a were introduced before $\bar{b}_i$ in the growing phase. Let us classify the blocks in S_{ta} into two subsets, $S^L_{ta} = \{b_{i\ell} \in S_{ta} : t_i \leq t\}$ and $S^R_{ta} = \{b_{i\ell} \in S_{ta} : t_i > t\}$.

We divide the proof of Lemma 4 into two analogous inequalities. Let us show that

$$\sum_{i: t \in I_i} \sum_{j: b_{ij} \in S^R_{ta}} z_{ij} \tau(i, a, t, F) \leq 2 D_t(a). \tag{9}$$

To do this, define $t^R = \min\{t_i : \bar{b}_i \in S^R_{ta}\}$. Note that t^R is covered by every interval I_i with $\bar{b}_i$ in S^R_{ta}, as they cover t (which is at most t^R) and their t_i (which is larger or equal than t^R). Define (i_1, j_1) such that $t_{i_1} = t^R$ and $\bar{b}_{i_1} = b_{i_1, j_1}$. On the one hand, by definition of τ, we have that $z_{i_1, j_1} \tau(i_1, j_1, a, t, F) \leq \tau(i_1, j_1, a, t, F) \leq D_t(a)$. On the other hand we study

$$\sum_{i: t \in I_i} \sum_{\substack{j: B_{ij} \in S^R_{ta}, \\ (i,j) \neq (i_1, j_1)}} z_{ij} \tau(i, j, a, F, t).$$

Consider an item $i \neq i_1$, and the iteration while increasing variable v_{atF}. The summands are the number of buckets that were spilling over each of the segments above a_i that are in the final solution (because we only sum when $z_{ij} = 1$, and buckets B_{ik} for $k \leq a_i$ do not receive water). This quantity cannot be higher than the sum of the cardinality of all the blocks above a_i in the final solution (recall that when blocks are taken in Line 11, they include truncated buckets that have poured onto the taken segments). For i_1, the same argument holds, but the superior block $\bar{b}_{i_1}$ does not need to be considered because it never poured onto the inferior blocks (otherwise they would have been the same block). Thus it holds that

$$\sum_{i: t \in I_i} \sum_{\substack{j: b_{ij} \in S^R_{ta}, \\ (i,j) \neq (i_1, j_1)}} z_{ij} \tau(i, j, a, F, t) \leq \sum_{\substack{b_{ij} \in S^R_{ta}, \\ (i,j) \neq (i_1, j_1)}} |b_{ij}| \leq D_{t^R}(a) \leq D_t(a). \quad ◀$$

With this lemma we can show the following main results. The first proof follows from standard LP techniques which are completely analogous to the proof of Theorem 3. The extension to the oracle model is given in Section 4.

▶ **Theorem 5.** *Algorithm 3 is a polynomial 4-approximation algorithm for Non-Linear UFP-Cover in the list model.*

4 Arbitrary non-decreasing functions

We now show how to adapt our algorithms in Sections 2 and 3 for the more general oracle model. Here we assume that each function $f_i : \{0, \dots, m\} \to \mathbb{Q}_{\geq 0} \cup \{\infty\}$, where $m \leq D$ is not necessarily polynomially bounded. We assume that each function f_i is given by an oracle, such that a polynomial number of bits is enough to describe all values $f_i(x)$. Using standard techniques, we first approximate each function f_i by a piece-wise constant function with a polynomial number of steps. After, we discuss how to emulate Algorithm 1 and 3 in polynomial time for such functions.

First of all, by scaling we can assume, without loss of generality, that $f_i(x) \in \mathbb{N} \cup \{\infty\}$.

▶ **Lemma 6.** *Consider $\varepsilon > 0$ and let $f : \{1, \dots, m\} \to \mathbb{N} \cup \{\infty\}$ be a non-decreasing function. Let $f_{\max}$ be the maximum finite value of $f(x)$. There exists a non-decreasing piece-wise constant function $\tilde{f}$ such that*

$$f(x) \leq \tilde{f}(x) \leq (1+\varepsilon) f(x) \qquad \textit{for all } x \in \{1, \dots, m\},$$

where $(\tilde{f}(x))_{x \in \mathbb{N}}$ takes at most $\lceil \log_{1+\varepsilon} f_{\max} \rceil + 1$ many different values. The function $\tilde{f}$ can be computed in polynomial time.

Proof. To prove the lemma we can assume that $f(x) > 0$, as the values $f(x) = 0$ just corresponds to separate piece in $\tilde{f}$. For all other $x \in \{1, \dots, m\}$, we can simply set $\tilde{f}(x) = (1+\varepsilon)^{\lceil \log_{1+\varepsilon} f(x) \rceil}$. The constant-wise pieces (intervals) of $\tilde{f}$ can be easily computed in polynomial time with a binary search approach. ◀

We now sketch how to adapt the algorithms of Sections 2 and 3 for this scenario. Let $\tilde{f}_i$ be the obtained function after applying the last lemma to f_i. We partition the set $\{0, 1, \dots, m\}$ in intervals $J_{i1}, J_{i2}, \dots, J_{im_i}$ correspondent to the piece-wise constant pieces of $\tilde{f}_i$, that is $\tilde{f}_i(x) = \tilde{f}_i(x')$ if $x, x' \in J_{ik}$. We denote by $u_{ik} \in \mathbb{N}$ the cardinality of interval $J_{ik} \subseteq \mathbb{N}$. To adapt the algorithms, note that as they originally deal with unitary segments, a piecewise constant function can be replaced (preserving the same costs for any solution) by a piecewise constant function with a pseudopolynomial number of unitary segments. More precisely, if $J_{ik} = \{\ell, \ell+1, \dots, u\}$, then $g_{i\ell} = \tilde{f}_i(\ell) - \tilde{f}_i(\ell - 1)$, and $g_{ir} = 0$ for all $r \in \{\ell+1, \dots, u\}$. Applying our algorithms to this instance would imply a pseudopolynomial running time. However, as all but m_i many buckets for item i has zero capacity g_{ij}, we can handle all of them simultaneously to make our algorithms run in polynomial time.

To do this, we can process all segments in J_{ik} in a single step: when the algorithm begins, all their respective buckets but the first one get instantaneously full, so the first one will receive water at a rate equal to the length of the constant interval (equivalently, the interval J_{ij} is represented by a bucket of height g_{ij} that gets filled at a rate u_{ij}). Any time a bucket pours onto some inferior bucket, its rate also increases by the length of the interval corresponding to the pouring bucket. Truncations, given by the fact that in a given iteration only buckets B_{ij} for $j \in \{a_i + 1, \dots, m_i(a)\}$ get water from the external source for each item i, make these rates diminish accordingly. With these rules, the algorithms can be easily adapted to run in polynomial time implying the following theorems.

▶ **Theorem 7.** *There exists a polynomial time $(2+\varepsilon)$-approximation for the Knapsack-Cover Problem with Non-Linear Costs and arbitrary non-decreasing functions.*

▶ **Theorem 8.** *There exists a $(4+\varepsilon)$-approximation for the Unsplittable Flow-Cover on the Line Problem with Non-Linear Costs and arbitrary non-decreasing functions.*

Abstract

A partition $\mathcal{P}$ of a weighted graph G is (σ,τ,Δ)-sparse if every cluster has diameter at most Δ, and every ball of radius Δ/σ intersects at most τ clusters. Similarly, $\mathcal{P}$ is (σ,τ,Δ)-scattering if instead for balls we require that every shortest path of length at most Δ/σ intersects at most τ clusters. Given a graph G that admits a (σ,τ,Δ)-sparse partition for all $\Delta>0$, Jia et al. [STOC05] constructed a solution for the Universal Steiner Tree problem (and also Universal TSP) with stretch $O(\tau\sigma^2\log_\tau n)$. Given a graph G that admits a (σ,τ,Δ)-scattering partition for all $\Delta>0$, we construct a solution for the Steiner Point Removal problem with stretch $O(\tau^3\sigma^3)$. We then construct sparse and scattering partitions for various different graph families, receiving many new results for the Universal Steiner Tree and Steiner Point Removal problems.

1 Introduction

Graph and metric clustering are widely used for various algorithmic applications (e.g., divide and conquer). Such partitions come in a variety of forms, satisfying different requirements. This paper is dedicated to the study of bounded diameter partitions, where small neighborhoods are guaranteed to intersects only a bounded number of clusters.

The first problem we study is the *Steiner Point Removal* (SPR) problem. Here we are given an undirected weighted graph $G=(V,E,w)$ and a subset of terminals $K\subseteq V$ of size k (the non-terminal vertices are called Steiner vertices). The goal is to construct a new weighted graph $M=(K,E',w')$, with the terminals as its vertex set, such that: (1) M is a graph minor of G, and (2) the distance between every pair of terminals t,t' in M is distorted by at most a multiplicative factor of α, formally, $\forall t,t'\in K,\quad d_G(t,t')\le d_M(t,t')\le\alpha\cdot d_G(t,t')$. Property (1) expresses preservation of the topological structure of the original graph. For example if G was planar, so will M be. Whereas property (2) expresses preservation of the geometric structure of the original graph, that is, distances between terminals. The question is thus: given a graph family $\mathcal{F}$, what is the minimal α such that every graph in $\mathcal{F}$ with a terminal set of size k will admit a solution to the SPR problem with distortion α.

Consider a weighted graph $G = (V, E, w)$ with a shortest path metric d_G. The *weak* diameter of a cluster $C \subseteq V$ is the maximal distance between a pair of vertices in the cluster w.r.t. d_G (i.e., $\max_{u,v\in C} d_G(u, v)$). The *strong* diameter is the maximal distance w.r.t. the shortest path metric in the induced graph $G[C]$ (i.e., $\max_{u,v\in C} d_{G[C]}(u, v)$). A partition $\mathcal{P}$ of G has weak (resp. strong) diameter Δ if every cluster $C \in \mathcal{P}$ has weak (resp. strong) diameter at most Δ. Partition $\mathcal{P}$ is *connected*, if the graph induced by every cluster $C \in \mathcal{P}$ is connected. Given a shortest path $\mathcal{I} = \{v_0, v_1, \dots, v_s\}$, denote by $Z_{\mathcal{I}}(\mathcal{P}) = \sum_{C\in\mathcal{P}} \mathbb{1}_{C\cap\mathcal{I}\neq\emptyset}$ the number of clusters in $\mathcal{P}$ intersecting $\mathcal{I}$. If $Z_{\mathcal{I}}(\mathcal{P}) \le \tau$, we say that $\mathcal{I}$ is τ-*scattered* by $\mathcal{P}$.

▶ **Definition 1** (Scattering Partition). *Given a weighted graph $G = (V, E, w)$, we say that a partition $\mathcal{P}$ is (σ, τ, Δ)-scattering if the following conditions hold:*

- *$\mathcal{P}$ is connected and has weak diameter Δ.*
- *Every shortest path $\mathcal{I}$ of length at most Δ/σ is τ-scattered by $\mathcal{P}$, i.e., $Z_{\mathcal{I}}(\mathcal{P}) \le \tau$.*

*We say that a graph G is (σ, τ)-*scatterable *if for every parameter Δ, G admits an (σ, τ, Δ)-scattering partition that can be computed efficiently.*

The main contribution of this paper is the finding that scattering partitions imply solutions for the SPR problem. The proof appears in Section 3.[1]

▶ **Theorem 2** (Scattering Partitions imply SPR). *Let $G = (V, E, w)$ be a weighted graph such that for every subset $A \subseteq V$, $G[A]$ is $(1, \tau)$-scatterable. Let $K \subseteq V$ be some subset of terminals. Then there is a solution to the SPR problem with distortion $O(\tau^3)$ that can be computed efficiently.*

Jia, Lin, Noubir, Rajaraman, and Sundaram [45] [2] defined the notion of *sparse partitions*, which is closely related to scattering partitions. Let $\mathcal{P}$ be a partition. Given a ball $B = B_G(x, r)$, denote by $Z_B(\mathcal{P}) = \sum_{C\in\mathcal{P}} \mathbb{1}_{C\cap B\neq\emptyset}$ the number of clusters in $\mathcal{P}$ intersecting B.

▶ **Definition 3** (Strong/Weak Sparse Partition). *Given a weighted graph $G = (V, E, w)$, we say that a partition $\mathcal{P}$ is (σ, τ, Δ)-weak (resp. strong) sparse partition if the following conditions hold:*

- *$\mathcal{P}$ has weak (resp. strong) diameterΔ.*
- *Every ball $B = B_G(v, r)$ of radius $r \le \Delta/\sigma$ intersects at most τ clusters, i.e., $Z_B(\mathcal{P}) \le \tau$.*

*We say that a graph G admits an (σ, τ)-*weak *(resp. strong) sparse partition scheme if for every parameter Δ, G admits an efficiently computable (σ, τ, Δ)-weak (resp. strong) sparse partition.*

Jia et al. [45] found a connection between sparse partitions to the *Universal Steiner Tree Problem* (UST).[3] Consider a complete weighted graph $G = (V, E, w)$ (or a metric space (X, d)) where there is a special server vertex $\mathrm{rt} \in V$, which is frequently required to multicast messages to different subsets of clients $S \subseteq V$. The cost of a multicast is the total weight of all edges used for the communication. Given a subset S, the optimal solution is to use the minimal Steiner tree spanning $S \cup \{\mathrm{rt}\}$. In order to implement an infrastructure for multicasting, or in order to make routing decisions much faster (and not compute it from scratch once S is given), a better solution will be to compute a *Universal Steiner Tree* (UST). A UST is a tree T over V, such that for every subset S, the message will be sent using the

[1] In Observation 2 we argue that (σ, τ, Δ)-scattering partition is also $(1, \tau\sigma, \Delta)$-scattering.

[2] Awerbuch and Peleg [8] were the first to study sparse covers (see Definition 5). Their notion of sparse partition is somewhat different from the one used here (introduced by [45]).

[3] A closely related problem is the *Universal Traveling Salesman Problem* (UTSP), see Section 1.4.

sub-tree $T(S)$ spanning $S \cup \{\mathrm{rt}\}$. The stretch of T is the maximum ratio among all subsets $S \subseteq X$ between the weight of $T(S)$ and the weight of the minimal Steiner tree spanning $S \cup \{\mathrm{rt}\}$, $\max_{S\subseteq X} \frac{w(T(S))}{\mathrm{Opt}(S\cup\{\mathrm{rt}\})}$.

Jia et al. [45] proved that given a sparse partition scheme, one can efficiently construct a UST with low stretch (the same statement holds w.r.t. UTSP as well).

▶ **Theorem 4** (Sparse Partitions imply UST, [45]). *Suppose that an n-vertex graph G admits an (σ, τ)-weak sparse partition scheme, then there is a polynomial time algorithm that given a root $\mathrm{rt} \in V$ computes a UST with stretch $O(\tau\sigma^2 \log_\tau n)$.*

Jia et al. [45] constructed $(O(\log n), O(\log n))$-weak sparse partition scheme for general graphs, receiving a solution with stretch polylog(n) for the UST problem. In some instances the communication is allowed to flow only in certain routes. It is therefore natural to consider the case where $G = (V, E, w)$ is not a complete graph, and the UST is required to be a subgraph of G. Busch, Jaikumar, Radhakrishnan, Rajaraman, and Srivathsan [12] proved a theorem in the spirit of Theorem 4, stating that given a (σ, τ, γ)-*hierarchical strong sparse partition*, one can efficiently construct a subgraph UST with stretch $O(\sigma^2\tau^2\gamma \log n)$. A (σ, τ, γ)-hierarchical strong sparse partition is a laminar collection of partitions $\{\mathcal{P}_i\}_{i\ge 0}$ such that $\mathcal{P}_i$ is (σ, τ, γ^i)-strong sparse partition which is a refinement of $\mathcal{P}_{i+1}$.[4] Busch et al. constructed a $\left(2^{O(\sqrt{\log n})}, 2^{O(\sqrt{\log n})}, 2^{O(\sqrt{\log n})}\right)$-hierarchical strong sparse partition, obtaining a $2^{O(\sqrt{\log n})}$ stretch algorithm for the subgraph UST problem. We tend to believe that poly-logarithmic stretch should be possible. It is therefore interesting to construct strong sparse partitions, as it eventually may lead to hierarchical ones.

A notion which is closely related to sparse partitions is *sparse covers*.

▶ **Definition 5** (Strong/Weak Sparse cover). *Given a weighted graph $G = (V, E, w)$, a (σ, τ, Δ)-weak (resp. strong) sparse cover is a set of clusters $\mathcal{C} \subset 2^V$, where all the clusters have weak (resp. strong) diameter at most Δ, and the following conditions hold:*

- *Cover: $\forall u \in V$, exists $C \in \mathcal{C}$ such that $B_G(u, \frac{\Delta}{\sigma}) \subseteq C$.*
- *Sparsity: every vertex $u \in V$ belongs to at most $|\{C \in \mathcal{C} \mid u \in C\}| \le \tau$ clusters.*

*We say that a graph G admits an (σ, τ)-*weak *(resp. strong) sparse cover scheme if for every parameter Δ, G admits an (σ, τ, Δ)-weak (resp. strong) sparse cover that can be computed efficiently.*

It was (implicitly) proven in [45] that given (σ, τ, Δ)-weak sparse cover $\mathcal{C}$, one can construct an (σ, τ, Δ)-weak sparse partition. In fact, most previous constructions of weak sparse partitions were based on sparse covers.

1.1 Previous results

SPR. Given an n-point tree, Gupta [38] provided an upper bound of 8 for the SPR problem (on trees). This result were recently reproved by the author, Krauthgamer, and Trabelsi [33] using the `Relaxed-Voronoi` framework. Chan, Xia, Konjevod, and Richa [14] provided a lower bound of 8 for trees. This is the best known lower bound for the general SPR problem. Basu and Gupta [11] provided an $O(1)$ upper bound for the family of outerplanar graphs.[5] For general n-vertex graphs with k terminals the author [27, 29] recently proved an $O(\log k)$ upper bound for the SPR problem using the `Relaxed-Voronoi` framework, improving upon

[4] We assume here w.l.o.g. that the minimal distance in G is 1.

[5] Actually the manuscript [11] was never published, and thus did not go through a peer review process.

previous works by Kamma, Krauthgamer, and Nguyen [46] ($O(\log^5 k)$), and Cheung [16] ($O(\log^2 k)$) (which were based on the `Ball-Growing` algorithm). Interestingly, there are no results on any other restricted graph family, although several attempts have been made (see [25, 50, 17]).

UST. Given an n-point metric space and root rt, Gupta, Hajiaghayi and Räcke [39] constructed a UST with stretch $O(\log^2 n)$, improving upon a previous $O(\log^4 n/\log\log n)$ result by [45]. [45] is based on sparse partitions, while [39] is based on *tree covers*. Jia et al. [45] proved a lower bound of $\Omega(\log n)$ to the UST problem, based on a lower bound to the online Steiner tree problem by Alon and Azar [6]. Using the same argument, they [45] proved an $\Omega(\frac{\log n}{\log\log n})$ lower bound for the case where the space is the $n \times n$ grid (using [43]). Given a space with doubling dimension ddim, [6] Jia et al. [45] provided a solution with stretch $2^{O(\mathrm{ddim})} \cdot \log n$, using sparse partitions. Given an n vertex planar graph, Busch, LaFortune, and Tirthapura [13] proved an $O(\log n)$ upper bound (improving over Hajiaghayi, Kleinberg, and Leighton [42]). More generally, for graphs G excluding a fixed minor, both Hajiaghayi et al. [42] (implicitly) and Busch et al. [13] (explicitly) provided a solution with stretch $O(\log^2 n)$. Both constructions used sparse covers. Finally, Busch et al. [12] constructed a subgraph UST with stretch polylog(n) for graphs excluding a fixed minor (using hierarchical strong sparse partitions).

Scattering Partitions. As we are the first to define scattering partitions there is not much previous work. Nonetheless, Kamma et al. [46] implicitly proved that general n-vertex graphs are $(O(\log n), O(\log n))$-scatterable.[7]

Sparse Covers and Partitions. Awerbuch and Peleg [8] introduced the notion of sparse covers and constructed $(O(\log n), O(\log n))$-strong sparse cover scheme for n-vertex weighted graphs.[8] Jia et al. [45] induced an $(O(\log n), O(\log n))$-weak sparse partition scheme. Hajiaghayi et al. [42] constructed an $(O(1), O(\log n))$-weak sparse cover scheme for n-vertex planar graph, concluding an $(O(1), O(\log n))$-weak sparse partition scheme. Their construction is based on the [48] clustering algorithm. Abraham, Gavoille, Malkhi, and Wieder [5] constructed $(O(r^2), 2^{O(r)} \cdot r!)$-strong sparse cover scheme for K_r-free graphs. Busch et al. [13] constructed a $(48, 18)$-strong sparse cover scheme for planar graphs [9] and $(8, O(\log n))$-strong sparse cover scheme for graphs excluding a fixed minor, concluding a $(48, 18)$ and $(8, O(\log n))$-weak sparse partition schemes for these families (respectively). For graphs with doubling dimension ddim, Jia et al. [45] constructed an $(1, 8^{\mathrm{ddim}})$-weak sparse scheme. Abraham et al. [3] constructed a $(2, 4^{\mathrm{ddim}})$-strong sparse cover scheme. In a companion paper, the author [28] constructed an $(O(\mathrm{ddim}), O(\mathrm{ddim} \cdot \log \mathrm{ddim}))$-strong sparse cover scheme.[10] Busch et al. [12] constructed $\big(O(\log^4 n), O(\log^3 n), O(\log^4 n)\big)$-hierarchical strong sparse partition for graphs excluding a fixed minor.

[6] A metric space (X, d) has doubling dimension ddim if every ball of radius $2r$ can be covered by 2^{ddim} balls of radius r. The doubling dimension of a graph is the doubling dimension of its induced shortest path metric.

[7] This follows from Theorem 1.6 in [46] by choosing parameters $t = \beta = O(\log n)$ and using union bounds over all n^2 shortest paths. Note that they assume that for every pair of vertices there is a unique shortest path.

[8] More generally, for $k \in \mathbb{N}$, [8] constructed a $(2k-1, 2k \cdot n^{\frac{1}{k}})$-strong sparse cover scheme.

[9] Busch et al. argued that they constructed $(24, 18)$-strong sparse covering scheme. However they measured radius rather than diameter.

[10] More generally, for a parameter $t = \Omega(1)$, [28] constructed $\big(O(t), O(2^{\mathrm{ddim}/t} \cdot \mathrm{ddim} \cdot \log t)\big)$-sparse cover scheme.

1.2 Our Contribution

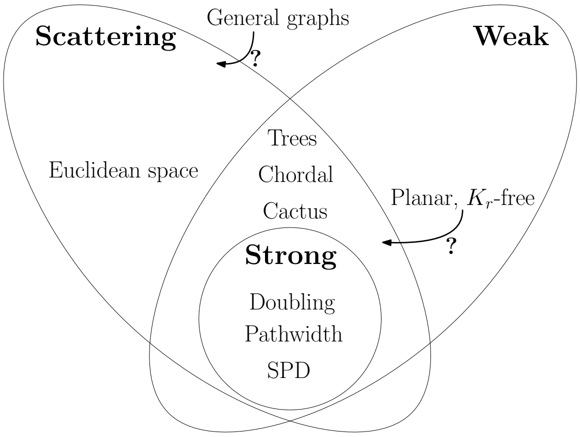

Figure 1 Classification of various graph families according to the possibility of construction different partitions. Graphs with bounded doubling dimension or SPD [14] (pathwidth) admit strong sparse partitions with parameters depending only on the dimension/SPDdepth. Trees, Chordal and Cactus graphs admit both $(O(1), O(1))$-weak sparse and scattering partitions, while similar strong partitions are impossible. $\mathbb{R}^d$ with norm 2 admit $(1, 2d)$ scattering partition while weak sparse partition with constant padding will have an exponential number of intersections. Planar graphs admit $(O(1), O(1))$-weak sparse partitions, while it is an open question whether similar scattering partitions exist. Finally, while sparse partitions for general graphs are well understood, we lack a lower bound for scattering partitions.

Formal statements, and proofs of all our partitions are differed to the full version [31]. The main contribution of this paper is the definition of scattering partition and the finding that good scattering partitions imply low distortion solutions for the SPR problem (Theorem 2). We construct various scattering and sparse partition schemes for many different graph families, and systematically classify them according to the partition types they admit. In addition, we provide several lower bounds. The specific partitions and lower bounds are described below. Our findings are summarized in Table 1, while the resulting classification is illustrated in Figure 1.

Recall that [45] (implicitly) showed that sparse covers imply weak sparse partitions. We show that the opposite direction is also true. That is, given a (σ, τ, Δ)-weak sparse partition, one can construct an $(\sigma + 2, \tau, (1 + \frac{2}{\sigma})\Delta)$-weak sparse cover. Interestingly, in addition we show that strong sparse partitions imply strong sparse covers, while the opposite is not true. Specifically there are graph families that admit $(O(1), O(1))$-strong sparse cover schemes, while there are no constants σ, τ, such that they admit (σ, τ)-strong sparse partitions. Description of our findings on the connection between sparse partitions and sparse covers, and a classification of various graph families are differed to the full version [31].

The scattering partitions we construct imply new solutions for the SPR problem previously unknown. Specifically, for every graph with pathwidth ρ we provide a solution to the SPR problem with distortion poly(ρ), independent of the number of terminals. After trees [38] and outerplanar graphs [11] [5], this is the first graph family to have solution for the SPR problem independent from the number of terminals (although attempts were made). Furthermore, we obtain solution with constant distortion for Chordal and Cactus graphs.[11]

[11] Note that the family of cactus graph is contained in the family of outerplanar graph. Basu and Gupta [11] solved the SPR problem directly on outerplanar graphs with constant distortion. However, this manuscript was never published. See also 5.

Table 1 Summery of the various new/old, weak/strong scattering/sparse partitions.
Table footnotes: ♣ More generally, there is a partition $\mathcal{P}$ s.t. every ball of radius $\frac{\Delta}{8\alpha}$ intersects at most $\tilde{O}(n^{1/\alpha})$ clusters, for all $\alpha > 1$ simultaneously. ■ More generally, it must hold that $\tau \geq n^{\Omega(1/\sigma)}$. ♠ More generally, there is a partition $\mathcal{P}$ s.t. every ball of radius $\Omega(\frac{\Delta}{\alpha})$ intersects at most $O(2^{\mathrm{ddim}/\alpha})$ clusters, for all $\alpha > 1$ simultaneously. ♦ More generally, it must hold that $\tau > (1 + \frac{1}{2\sigma})^d$. ★ Note that this lower bound holds chordal/cactus/planar/K_r-free graphs. More generally, it must hold that $\tau \geq \Omega(n^{2/\sigma+1})$.

The weak sparse partitions we construct imply improved solutions for the UST (and UTSP) problem. Specifically, we conclude that for graphs with doubling dimension ddim a UST (and UTSP) with stretch $\mathrm{poly}(\mathrm{ddim}) \cdot \log n$ can be efficiently computed, providing an exponential improvement in the dependence on ddim compared with the previous state of the art [45] of $2^{O(\mathrm{ddim})} \cdot \log n$. For K_r-minor free graphs we conclude that an UST (or UTSP) with stretch $2^{O(r)} \cdot \log n$ can be efficiently computed, providing a quadratic improvement in the dependence on n compared with the previous state of the art [39] of $O(\log^2 n)$. [12] Finally, for pathwidth ρ graphs (or more generally, graph with SPDdepth ρ) we can compute a UST (or UTSP) with stretch $O(\rho \cdot \log n)$, improving over previous solutions that were exponential in ρ (based on the fact that pathwidth ρ graphs are $K_{\rho+2}$-minor free).

Before we proceed to describe our partitions we make two observations.

[12] This result is a mere corollary obtained by assembling previously existing parts together. Mysteriously, although UTSP on minor free graphs was studied before [42, 13], this corollary was never drawn.

▶ **Observation 1.** *Every (σ, τ, Δ)-strong sparse partition is also scattering partition and weak sparse partition with the same parameters.*

▶ **Observation 2.** *Every (σ, τ, Δ)-scattering partition is also $(1, \sigma\tau, \Delta)$-scattering partition.*

Observation 1 follows as every path of weight $\sigma\Delta$ is contained in a ball of radius $\sigma\Delta$. Observation 2 follows as every shortest path of length $\le \Delta$ can be assembled as a concatenation of at most σ shortest paths of length $\le \frac{\Delta}{\sigma}$.

Next we survey the partitions for various graph families. Formal statements and proofs are differed to the full version [31].

General Graphs. Given an n-vertex general graph and parameter $\Delta > 0$ we construct a single partition $\mathcal{P}$ which is simultaneously $\big(8k, O(n^{1/k} \cdot \log n), \Delta\big)$-strong sparse partition for all parameters $k \ge 1$. Thus we generalize the result of [45] and obtained a strong diameter guarantee. This partition implies that general graphs are $(O(\log n), O(\log n))$-scatterable (reproving [46] via an easier proof), inducing a solution for the SPR problem with stretch $\text{polylog}(|K|)$. While quantitatively better solutions are known, this one is arguably the simplest, and induced by a general framework. Further, we provide a lower bound, showing that if all n-vertex graphs admit (σ, τ)-weak sparse partition scheme, then $\tau \ge n^{\Omega(\frac{1}{\sigma})}$. In particular there is no sparse partition scheme with parameters smaller than $(\Omega(\log n/\log\log n), \Omega(\log n))$. This implies that both our results and [45] are tight up to second order terms. Although we do not provide any lower bound for scattering partitions, we present some evidence that general graphs are not $(O(1), O(1))$-scatterable. Specifically, we define a stronger notion of partitions called *super-scattering* and show that general graphs are not $(1, \Omega(\log n))$-super scatterable.

Trees. Trees are the most basic of the restricted graph families. Weak sparse partitions for trees follows from the existence of sparse covers. Nevertheless, in order to improve parameters and understanding we construct $(4, 3)$-weak sparse partition scheme for trees. Further, we prove that trees are $(2, 3)$-scatterable. Finally, we show that there are no good strong sparse partition for trees. Specifically, we prove that if all n-vertex trees admit (σ, τ)-strong sparse partition scheme, then $\tau \ge \frac{1}{3} \cdot n^{\frac{2}{\sigma+1}}$. This implies that for strong sparse partitions, trees are essentially as bad as general graphs.

Doubling Dimension. We prove that for every graph with doubling dimension ddim and parameter $\Delta > 0$, there is a partition $\mathcal{P}$ which is simultaneously $\big(58\alpha, 2^{\text{ddim}/\alpha} \cdot \tilde{O}(\text{ddim}), \Delta\big)$-strong sparse partition for all parameters $\alpha \ge 1$. Note that this implies an $\big(O(\text{ddim}), \tilde{O}(\text{ddim})\big)$-strong sparse partition scheme.

Euclidean Space. We prove that the d-dimensional Euclidean space $(\mathbb{R}^d, \|\cdot\|_2)$ is $(1, 2d)$-scatterable [13], while for every (σ, τ)-weak sparse partition scheme it holds that $\tau > (1 + \frac{1}{2\sigma})^d$. In particular, if σ is at most a constant, then τ must be exponential. This provides an interesting example of a family where scattering partitions have considerably better parameters than sparse partitions.

[13] In Euclidean space, we say that a partition is (σ, τ, Δ)-scattering if every interval of length Δ/σ intersects at most τ clusters.

SPDdepth.[14] We prove that every graph with SPDdepth ρ (in particular graph with pathwidth ρ) admit $\big(O(\rho), O(\rho^2)\big)$-strong sparse partition scheme. Further, we prove that such graphs admit $(8, 5\rho)$-weak sparse partition scheme.

Chordal Graphs. We prove that every Chordal graph is $(2, 3)$-scatterable.

Cactus Graphs. We prove that every Cactus graph is $(4, 5)$-scatterable.

1.3 Technical Ideas

Scattering Partition Imply SPR. Similarly to previous works on the SPR problem, we construct a minor via a terminal partition. That is, a partition of V into k connected clusters, where each cluster contains a single terminal. The minor is then induced by contracting all the internal edges. Intuitively, to obtain small distortion, one needs to ensure that every Steiner vertex is clustered into a terminal not much further than its closest terminal, and that every shortest path between a pair of terminals intersects only a small number of clusters. However, the local partitioning of each area in the graph requires a different scale, according to the distance to the closest terminal. Our approach is similar in spirit to the algorithm of Englert et al. [25], who constructed a minor with small expected distortion[15] using stochastic decomposition for all possible distance scales. We however, work in the more restrictive regime of worst case distortion guarantee. Glossing over many details, we create different scattering partitions to different areas, where vertices at distance $\approx \Delta$ to the terminal set are partitioned using a $(1, \tau, \Delta)$-scattering partition. Afterwards, we assemble the different clusters from the partitions in all possible scales into a single terminal partition. We use the scattering property twice. First to argue that each vertex v is clustered to a terminal at distance at most $O(\tau) \cdot D(v)$ (here $D(v)$ is the distance to the closest terminal). Second, to argue that every shortest path where all the vertices are at similar distance to the terminal set, intersect the clusters of at most $O(\tau^2)$ terminals.

1.4 Related Work

In the functional analysis community, the notion of *Nagata dimension* was studied. The Nagata dimension of a metric space (X, d), $\dim_N X$, is the infimum over all integers n such that there exists a constant c s.t. X admits a $(c, n+1)$-weak sparse partition scheme. In contrast, in this paper our goal is to minimize this constant c. See [53] and the references therein.

A closely related problem to UST is the *Universal Traveling Salesman Problem* (UTSP). Consider a postman providing post service for a set X of clients with n different locations (with distance measure d_X). Each morning the postman receives a subset $S \subset X$ of the required deliveries for the day. In order to minimize the total tour length, one solution may be to compute each morning an (approximation of an) Optimal TSP tour for the set S. An alternative solution will be to compute a *Universal TSP* (UTSP) tour. This is a universal tour R containing all the points X. Given a subset S, $R(S)$ is the tour visiting all the points in S w.r.t. the order induced by R. Given a tour T denote its length by $|T|$. The *stretch* of R is the maximum ratio among all subsets $S \subseteq X$ between the length of $R(S)$ and the length of the optimal TSP tour on S, $\max_{S\subseteq X} \frac{|R(S)|}{|\mathrm{Opt}(S)|}$.

[14] Every (weighted) path graph has an SPDdepth 1. A graph G has an SPDdepth ρ if there exist a *shortest path* P, such that every connected component in $G \setminus P$ has an SPDdepth $\rho - 1$. This family includes graphs with pathwidth at most ρ, and more. See [2].

[15] A distribution $\mathcal{D}$ over solutions to the SPR problem has expected distortion α if $\forall t, t' \in K$, $\mathbb{E}_{M\sim\mathcal{D}}[d_M(t, t')] \le \alpha \cdot d_G(t, t')$.

All the sparse partition based upper bounds for the UST problem translated directly to the UTSP problem with the same parameters. The first to study the problem were Platzman and Bartholdi [57], who given n points in the Euclidean plane constructed a solution with stretch $O(\log n)$, using *space filling curves*. Recently, Christodoulou, and Sgouritsa [18] proved a lower and upper bound of $\Theta(\log n/\log\log n)$ for the $n \times n$ grid, improving a previous $\Omega(\sqrt[6]{\log n/\log\log n})$ lower bound of Hajiaghayi, Kleinberg, and Leighton [42] (and the $O(\log n)$ upper bound of [57]). For general n vertex graphs Gupta et al. [39] proved an $O(\log^2 n)$ upper bound, while Gorodezky, Kleinberg, Shmoys, and Spencer [36] proved an $\Omega(\log n)$ lower bound. From the computational point of view, Schalekamp and Shmoys [59] showed that if the input graph is a tree, an UTSP with optimal stretch can be computed efficiently.

The *A Priori TSP* problem is similar to the UTSP problem. In addition there is a distribution $\mathcal{D}$ over subsets $S \subseteq V$ and the stretch of tour a R is the expected ratio between the induced solution to optimal $\mathbb{E}_{S\sim\mathcal{D}}\frac{|R(S)|}{|\text{Opt}(S)|}$ (instead of a worst case like in UTSP). Similarly, *A Priori Steiner Tree* was studied (usually omitting rt from the problem). See [44, 59, 36] for further details. Another similar problem is the *Online (or dynamic) Steiner Tree* problem. Here the set S of vertices that should be connected is evolving over time, see [43, 6, 37] and references therein.

Unlike the definition used in this paper (taken from [45]), sparse partitions were also defined in the literature as partitions where only a small fraction of the edges are inter-cluster (see for example [5]). A closely related notion to sparse partitions are padded and separating decompositions. A graph G is β-decomposable if for every $\Delta > 0$, there is a distribution $\mathcal{D}$ over Δ bounded partitions such that for every $u, v \in V$, the probability that u and v belong to different clusters is at most $\beta \cdot \frac{d_G(u,v)}{\Delta}$. Note that by linearity of expectation, a path $\mathcal{I}$ of length Δ/σ intersects at most $1 + \beta/\sigma$ clusters in expectation. For comparison, in scattering partition we replace the distribution by a single partition and receive a bound on the number of intersections in the worst case. See [48, 9, 26, 40, 1, 5, 4, 34, 28] for further details.

Englert et al. [25] showed that every graph which is β-decomposable, admits a distribution $\mathcal{D}$ over solution to the SPR problem with expected distortion $O(\beta\log\beta)$. [15] In particular this implies constant expected distortion for graphs excluding a fixed minor, or bounded doubling dimension.

For a set K of terminals of size k, Krauthgamer, Nguyen and Zondiner [50] showed that if we allow the minor M to contain at most $\binom{k}{2}^2$ Steiner vertices (in addition to the terminals), then distortion 1 can be achieved. They further showed that for graphs with constant treewidth, $O(k^2)$ Steiner points will suffice for distortion 1. Cheung, Gramoz and Henzinger [17] showed that allowing $O(k^{2+\frac{2}{t}})$ Steiner vertices, one can achieve distortion $2t-1$. For planar graphs, Cheung et al. al. achieved $1+\epsilon$ distortion with $\tilde{O}((\frac{k}{\epsilon})^2)$ Steiner points.

There is a long line of work focusing on preserving the cut/flow structure among the terminals by a graph minor. See [56, 54, 15, 55, 25, 19, 51, 7, 35, 52].

There were works studying metric embeddings and metric data structures concerned with preserving distances among terminals, or from terminals to other vertices, out of the context of minors. See [20, 58, 41, 47, 21, 22, 10, 23, 49, 32, 24].

2 Preliminaries

All the logarithms in the paper are in base 2. We use $\tilde{O}$ notation to suppress constants and logarithmic factors, that is $\tilde{O}(f(j)) = f(j)\cdot\text{polylog}(f(j))$.

Graphs. We consider connected undirected graphs $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_{\geq 0}$. Let d_G denote the shortest path metric in G. $B_G(v, r) = \{u \in V \mid d_G(v, u) \leq r\}$ is the ball of radius r around v. For a vertex $v \in V$ and a subset $A \subseteq V$, let $d_G(x, A) := \min_{a \in A} d_G(x, a)$, where $d_G(x, \emptyset) = \infty$. For a subset of vertices $A \subseteq V$, let $G[A]$ denote the induced graph on A, and let $G \setminus A := G[V \setminus A]$.

Special graph families. A graph H is a *minor* of a graph G if we can obtain H from G by edge deletions/contractions, and vertex deletions. A graph family $\mathcal{G}$ is H*-minor-free* if no graph $G \in \mathcal{G}$ has H as a minor. Some examples of minor free graph families are planar graphs (K_5 and $K_{3,3}$ free), outerplanar graphs (K_4 and $K_{3,2}$ free), series-parallel graphs (K_4 free), Cactus graphs (also known as tree of cycles) (⧅ free), and trees (K_3 free).

Given a graph $G = (V, E)$, a *tree decomposition* of G is a tree T with nodes $B_1, \dots, B_s$ (called *bags*) where each B_i is a subset of V such that the following properties hold:

- For every edge $\{u, v\} \in E$, there is a bag B_i containing both u and v.
- For every vertex $v \in V$, the set of bags containing v form a connected subtree of T.

The *width* of a tree decomposition is $\max_i\{|B_i| - 1\}$. The *treewidth* of G is the minimal width of a tree decomposition of G. A *path decomposition* of G is a special kind of tree decomposition where the underlying tree is a path. The *pathwidth* of G is the minimal width of a path decomposition of G.

Chordal graphs are unweighted graphs where each cycle of length greater then 4 contains a chordal. In other words, if the induced graph on a set of vertices V' is the cycle graph, than necessarily $|V'| \leq 3$. Chordal graphs contain interval graphs, subtree intersection graphs and other interesting sub families. A characterization of Chordal graphs is that they have a tree decomposition such that each bag is a clique. That is, there is a tree decomposition T of G where there is no upper bound on the size of a bag, but for every bag $B \in T$ the induced graph $G[B]$ is a clique.

A *Cactus graph* (a.k.a. tree of cycles) is a graph where each edge belongs to at most one simple cycle. Alternatively it can be defined as the graph family that excludes K_4 minus an edge (⧅) as a minor.

Abraham et al. [2] defined *shortest path decompositions* (SPDs) of "low depth". Every (weighted) path graph has an SPDdepth 1. A graph G has an SPDdepth k if there exist a *shortest path* P, such that every connected component in $G \setminus P$ has an SPDdepth $k - 1$. In other words, given a graph, in SPD we hierarchically delete shortest paths from each connected component, until no vertices remain. See [2] for formal definition (or full version [31]). Every graph with pathwidth ρ has SPDdepth at most $\rho + 1$, treewidth ρ implies SPDdepth at most $O(\rho \log n)$, and every graph excluding a fixed minor has SPDdepth $O(\log n)$. See [2, 30] for further details and applications.

3 From Scattering Partitions to SPR: Proof of Theorem 2

We will assume w.l.o.g. that the minimal pairwise distance in the graph is exactly 1, otherwise we can scale all the weights accordingly. The set of terminals denoted $K = \{t_1, \dots, t_k\}$. For every vertex $v \in V$, denote by $D(v) = d_G(v, K)$ the distance to its closest terminal. Note that $\min_{v \in V \setminus K} D(v) \geq 1$.

Similarly to previous papers on the SPR problem, we will create a minor using *terminal partitions*. Specifically, we partition the vertices into k connected clusters, with a single terminal in each cluster. Such a partition induces a minor by contracting all the internal edges in each cluster. More formally, a partition $\{V_1, \dots, V_k\}$ of V is called a terminal partition (w.r.t to K) if for every $1 \leq i \leq k$, $t_i \in V_i$, and the induced graph $G[V_i]$ is connected. For a

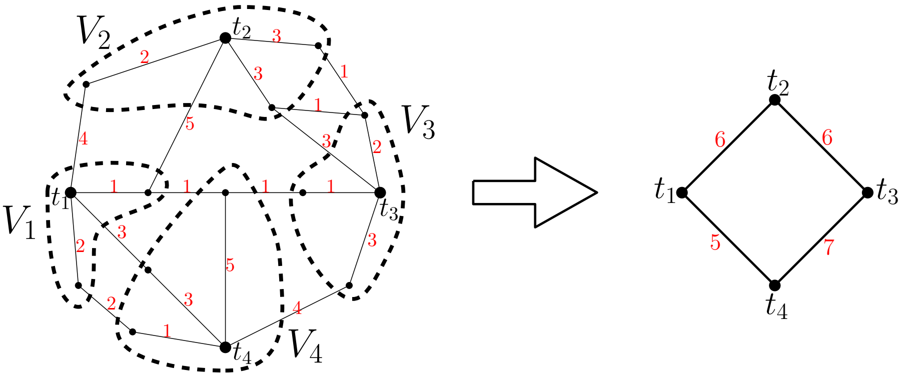

Figure 2 The left side of the figure contains a weighted graph $G = (V, E)$, with weights specified in red, and four terminals $\{t_1, t_2, t_3, t_4\}$. The dashed black curves represent a terminal partition of the vertex set V into the subsets V_1, V_2, V_3, V_4. The right side of the figure represents the minor M induced by the terminal partition. The distortion is realized between t_1 and t_3, and is $\frac{d_M(t_1,t_3)}{d_G(t_1,t_3)} = \frac{12}{4} = 3$.

vertex $v \in V_i$, we say that v is assigned to t_i. See Figure 2 for an illustration. The *induced minor* by the terminal partition $\{V_1, \dots, V_k\}$, is a minor M, where each set V_i is contracted into a single vertex called (abusing notation) t_i. Note that there is an edge in M from t_i to t_j if and only if there are vertices $v_i \in V_i$ and $v_j \in V_j$ such that $\{v_i, v_j\} \in E$. We determine the weight of the edge $\{t_i, t_j\} \in E(M)$ to be $d_G(t_i, t_j)$. Note that by the triangle inequality, for every pair of (not necessarily neighboring) terminals t_i, t_j, it holds that $d_M(t_i, t_j) \geq d_G(t_i, t_j)$. The *distortion* of the induced minor is $\max_{i,j} \frac{d_M(t_i,t_j)}{d_G(t_i,t_j)}$.

3.1 Algorithm

For $i \geq 1$, set $\mathcal{R}_i = \{v \in V \mid 2^{i-1} \leq D(v) < 2^i\}$ to be the set of vertices at distance between 2^{i-1} and 2^i from K. Set $\mathcal{R}_0 = K$. We create the terminal partition in an iterative manner, where initially each set $V_i = \{t_i\}$ is a singleton, and gradually more vertices are joining. We will denote the stage of the terminal partition after i steps, using a function $f_i : V \to K \cup \{\perp\}$. For a yet unassigned vertex v we write $f_i(v) = \perp$, otherwise the vertex v will be assigned to $f_i(v)$. Initially for every terminal t_j, $f_0(t_j) = t_j$ while for every Steiner vertex $v \in V \setminus K$, $f_0(v) = \perp$. In iteration i we will define f_i by "extending" f_{i-1}. That is, unassigned vertices may be assigned (i.e., for v such that $f_{i-1}(v) = \perp$ it might be $f_i(v) = t_j$), while the function will remain the same on the set of assigned vertices ($f_{i-1}(v) \neq \perp \Rightarrow f_i(v) = f_{i-1}(v)$). We will guarantee that all the vertices in $\mathcal{R}_i$ will be assigned in f_i. In particular, after $\log(\max_v D(v))$ steps, all the vertices will be assigned. Denote by V_i the set of vertices assigned by f_i. Initially $V_0 = K = \mathcal{R}_0$. By induction we will assume that $\cup_{j \leq i-1} \mathcal{R}_j \subseteq V_{i-1}$. Let $G_i = G[V \setminus V_{i-1}]$ be the graph induced by the set of yet unassigned vertices. Fix $\Delta_i = 2^{i-1}$. Let $\mathcal{P}_i$ be an $(1, \tau, \Delta_i)$-scattering partition of G_i. Let $\mathcal{C}_i \subseteq \mathcal{P}_i$ be the set of clusters C which contain at least one vertex $v \in \mathcal{R}_i$. All the vertices in $\cup \mathcal{C}_i$ will be assigned by f_i.

We say that a cluster $C \in \mathcal{C}_i$ is at level 1, noting $\delta_i(C) = 1$, if there is an edge $\{v, u_C\}$ (in G) from a vertex $v \in C$ to a vertex $u_C \in V_{i-1}$ of weight at most 2^i. In general, $\delta_i(C) = l$, if l is the minimal index such that there is an edge $\{v, u_C\}$ from a vertex $v \in C$ to a vertex $u_C \in C'$ of weight at most 2^i, such that $\delta_i(C') = l - 1$. In both cases u_C is called the *linking* vertex of C. Next, we define f_i based on f_{i-1}. For every vertex $v \in V_{i-1}$ set $f_i(v) = f_{i-1}(v)$.

For every vertex not in $\cup\mathcal{C}_i$ (or V_{i-1}) set $f_i(v) =\perp$. For a cluster $C \in \mathcal{C}_i$ s.t. $\delta_i(C) = 1$, let $u_C \in V_{i-1}$ be its linking vertex. For every $v \in C$ set $f_i(v) = f_i(u_C)$. Generally, for level l suppose that f_i is already defined on all the clusters of level $l-1$. Let $C \in \mathcal{C}_i$ s.t. $\delta_i(C) = l$. Let u_C be the linking vertex of C. For every $v \in C$, set $f_i(v) = f_i(u_C)$. Note that for every cluster, all the vertices are mapped to the same terminal. This finishes the definition of f_i.

The algorithm continues until there is f_i where all the Steiner vertices are assigned. Set $f = f_i$. The algorithm returns the terminal-centered minor M of G induced by $\{f^{-1}(t_1), \dots, f^{-1}(t_k)\}$.

3.2 Basic Properties

It is straightforward from the construction that $f^{-1}(t_1), \dots, f^{-1}(t_k)$ define a terminal partition. We will prove that every vertex v will be assigned during either iteration $\lceil \log D(v) \rceil$ or $\lceil \log D(v) \rceil - 1$ (Claim 9), to a terminal at distance at most $O(\tau) \cdot D(v)$ from v (Corollary 8). We begin by arguing that in each iteration, the maximum possible level of a cluster is τ.

▷ Claim 6. For every cluster $C \in \mathcal{C}_i$, $\delta_i(C) \leq \tau$.

Proof. Consider a cluster $C \in \mathcal{C}_i$, and let $v \in C$ be a vertex s.t. $D(v) \leq 2^i$. Let $P = \{v = v_0, \dots, v_s\}$ be a prefix of the $D(v)$ length path from v to its closest terminal such that v_s has a neighbor in V_{i-1}. Note that P has (weighted) length at most $2^{i-1} = \Delta_i$ (as all vertices v' for which $D(v') \leq 2^{i-1}$ are necessarily clustered). $\mathcal{P}_i$ is a $(1, \tau, \Delta_i)$-scattering partition. Hence the vertices of P are partitioned to $\tau' \leq \tau$ clusters $C_1, \dots, C_{\tau'}$ where $v_s \in C_1$, $v_0 \in C_{\tau'}$ and there is an edge from C_j to C_{j+1} of weight at most $2^{i-1} < 2^i$, while the edge from v_s towards V_{i-1} is of weight at most 2^i. It holds that $\delta_i(C_1) = 1$, and by induction $\delta(C_j) \leq j$. In particular $\delta(C) \leq \tau' \leq \tau$. ◁

▷ Claim 7. For every vertex v which is assigned during the i'th iteration (i.e., $v \in C \in \mathcal{C}_i$) it holds that $d_G(v, f(v)) \leq 3\tau \cdot 2^i$.

Proof. The proof is by induction on i. For $i = 0$ the assertion holds trivially as every terminal is assigned to itself. We will assume the assertion for $i-1$ and prove it for i. Let $C \in \mathcal{C}_i$ be some cluster, and let $v \in C$. Suppose first that $\delta_i(C) = 1$. Let $u_C \in V_{i-1}$ be the linking vertex of C. By the induction hypothesis $d_G(u_C, f(u_C)) \leq 3\tau \cdot 2^{i-1}$. As the diameter of C is bounded by 2^{i-1}, and the weight of the edge towards u_C is at most 2^i we conclude $d_G(v, f(v)) \leq d_G(v, u_C) + d_G(u_C, f(u_C)) \leq (2^{i-1} + 2^i) + 3\tau \cdot 2^{i-1} = 3 \cdot 2^{i-1} + 3\tau \cdot 2^{i-1}$. Generally, for $\delta_i(C) = l$, we argue by induction that for every $v \in C$ it holds that $d_G(v, f(v)) \leq l \cdot 3 \cdot 2^{i-1} + 3\tau \cdot 2^{i-1}$. Indeed, let u_C by the linking vertex of C. By the induction hypothesis it holds that $d_G(u_C, f(u_C)) \leq (l-1) \cdot 3 \cdot 2^{i-1} + 3\tau \cdot 2^{i-1}$. Using similar arguments, it holds that $d_G(v, f(v)) \leq d_G(v, u_C) + d_G(u_C, f(u_C)) \leq (2^{i-1} + 2^i) + (l-1) \cdot 3 \cdot 2^{i-1} + 3\tau \cdot 2^{i-1} = l \cdot 3 \cdot 2^{i-1} + 3\tau \cdot 2^{i-1}$. Using Claim 6, $d_G(v, f(v)) \leq 3\tau \cdot 2^{i-1} + 3\tau \cdot 2^{i-1} = 3\tau \cdot 2^i$ as required. ◁

▶ **Corollary 8.** *For every vertex v it holds that $d_G(v, f(v)) < 6\tau \cdot D(v)$.*

Proof. Let $i \geq 0$ such that $2^{i-1} < D(v) \leq 2^i$. The vertex v is assigned at iteration i or earlier. By Claim 7 we conclude $d_G(v, f(v)) \leq 3\tau \cdot 2^i < 6\tau \cdot D(v)$. ◀

▷ Claim 9. Consider a vertex v such that $2^{i-1} < D(v) \leq 2^i$. Then v is assigned either at iteration $i-1$ or i.

Proof. Clearly if v remains un-assigned until iteration i, it will be assigned during the i'th iteration. Suppose that v was assigned during iteration j. Then v belongs to a cluster $C \in \mathcal{C}_j$. In particular there is a vertex $u \in C$ such that $D(u) \le 2^j$. As C has diameter at most 2^{j-1}, it holds that

$$2^{i-1} < D(v) \le D(u) + d_G(v,u) \le 2^j + 2^{j-1} = 3 \cdot 2^{j-1} \ .$$

i, j are integers, hence $j \ge i-1$. ◁

3.3 Distortion Analysis

In this section we analyze the distortion of the minor induced by the terminal partition created by our algorithm. We have several variables that are defined with respect to the algorithm. Note that all these definitions are for analysis purposes only, and have no impact on the execution of the algorithm. Consider a pair of terminals t and t'. Let $P_{t,t'} = \{t = v_0, \dots, v_\gamma = t'\}$ be the shortest path from t to t' in G. We can assume that there are no terminals in $P_{t,t'}$ other than t, t'. This is because if we will prove the distortion guarantee for every pair of terminals t, t' such that $P_{t,t'} \cap K = \{t, t'\}$, then by the triangle inequality the distortion guarantee will hold for all terminal pairs.

Detours. The terminals t, t' are fixed. During the execution of the algorithm, for every terminal t_j we will maintain a *detour* $\mathcal{D}_{t_j}$ (or shortly $\mathcal{D}_j$). A detour is a consecutive subinterval $\{a_j, \dots, b_j\}$ of $P_{t,t'}$, where $a_j \in \mathcal{D}_j$ is the leftmost (i.e., with minimal index) vertex in the detour and b_j is the rightmost. Initially $\mathcal{D}_t = \{t\}$ and $\mathcal{D}_{t'} = \{t'\}$, while for every $t_j \notin \{t, t'\}$, $\mathcal{D}_j = \emptyset$. Every pair of detours $\mathcal{D}_j, \mathcal{D}_{j'}$ will be disjoint throughout the execution of the algorithm.

A vertex $v \in P_{t,t'}$ is *active* if and only if it does not belong to any detour. It will hold that every active vertex is necessarily unassigned (while there might be unassigned vertices which are inactive). Initially, t, t' are *inactive*, while all the other vertices of $P_{t,t'}$ are active. Consider the i'th iteration of the algorithm. We go over the terminals according to an arbitrary order $\{t_1, \dots, t_k\}$. Consider the terminal t_j with detour $\mathcal{D}_j = \{a_j, \dots, b_j\}$ (which might be empty). If no active vertices are assigned to t_j we do nothing. Otherwise, let $a'_j \in P_{t,t'}$ (resp. b'_j) be the leftmost (resp. rightmost) active vertex that was assigned to t_j during the i'th iteration. Set a_j to be vertex with minimal index between the former a_j and a'_j (a'_j if there was no a_j). Similarly b_j is the vertex with maximal index between the former b_j and b'_j. $\mathcal{D}_j$ is updated to be $\{a_j, \dots, b_j\}$. All the vertices in $\{a_j, \dots, b_j\} = \mathcal{D}_j$ become inactive. Note that a vertex might become inactive while remaining yet unassigned.

Consider an additional detour $\mathcal{D}_{j'}$. Before the updating of $\mathcal{D}_j$ at iteration i, $\mathcal{D}_j, \mathcal{D}_{j'}$ are disjoint. If a'_j, b'_j were active they cannot belong to $\mathcal{D}_{j'}$. Thus after the update, a_j, b_j did not belong to $\mathcal{D}_{j'}$ as well. However, it is possible that after the update $\mathcal{D}_j$ and $\mathcal{D}_{j'}$ are no longer disjoint. The only such possibility is when $\mathcal{D}_{j'} \subset \mathcal{D}_j$. In such a case, we set $\mathcal{D}_{j'} \leftarrow \emptyset$, maintaining the disjointness property (while not changing the (in)active status of any vertex).

After we nullify all the detours that were contained in $\mathcal{D}_j$, we will proceed to treat the next terminals in turn. Once we finish going over all the terminals, we proceed to the $i+1$ iteration. Eventually, all the vertices cease to be active, and in particular belong to some detour. In other words, all the vertices of $P_{t,t'}$ are partitioned to consecutive disjoint detours $\mathcal{D}_{\ell_1}, \dots, \mathcal{D}_{\ell_s}$.

Intervals. For an *interval* $Q=\{v_a,\dots,v_b\}\subseteq P_{t,t'}$, the *internal length* is $L(Q)=d_G(v_a,v_b)$, while the *external length* is $L^+(Q)=d_G(v_{a-1},v_{b+1})$.[16] We denote by $D(Q)=D(v_a)$ the distance from the leftmost vertex $v_a\in Q$ to its closest terminal. Set $c_{\text{int}}=\frac{1}{7}$ ("int" for interval). We partition the vertices in $P_{t,t'}$ into consecutive intervals $\mathcal{Q}$, such that for every $Q\in\mathcal{Q}$,

$$L(Q)\le c_{\text{int}}\cdot D(Q)\le L^+(Q)\ . \tag{3.1}$$

Such a partition could be obtained as follows: Sweep along the path $P_{t,t'}$ in a greedy manner, after partitioning the prefix $v_0,\dots,v_{h-1}$, to construct the next interval Q, simply pick the minimal index s such that $L^+(\{v_h,\dots,v_{h+s}\})\ge c_{\text{int}}\cdot D(v_h)$. By the minimality of s, $L(\{v_h,\dots,v_{h+s}\})\le L^+(\{v_h,\dots,v_{h+s-1}\})\le c_{\text{int}}\cdot D(v_h)$ (in the case $s=0$, trivially $L(\{v_h\})=0\le c_{\text{int}}\cdot D(v_h)$). Note that such s could always be found, as $L^+(\{v_h,\dots,v_\gamma=t'\})=d_G(v_{h-1},t')\ge d_G(v_h,t')\ge D(v_h)=D(Q)$.

Consider some interval $Q=\{v_a,\dots,v_b\}\in\mathcal{Q}$. For every vertex $v\in Q$, by triangle inequality it holds that $D(Q)-L(Q)\le D(v)\le D(Q)+L(Q)$. Therefore,

$$(1-c_{\text{int}})D(Q)\le D(v)\le(1+c_{\text{int}})D(Q)\ . \tag{3.2}$$

Note that the set $\mathcal{Q}$ of intervals is determined before the execution of the algorithm, and is never changed. In particular, it is independent from the set of detours (which evolves during the execution of the algorithm).
For an interval Q, we denote by i_Q the first iteration when some vertex v belonging to the interval Q is assigned.

▷ Claim 10. All Q vertices are assigned in either iteration i_Q or i_Q+1.

Proof. Let $u\in Q$ be some vertex which is assigned during iteration i_Q. Then u belongs to a cluster $C\in\mathcal{C}_{i_Q}$, containing a vertex $u'\in C$ such that $D(u')\le 2^{i_Q}$. As C has diameter at most 2^{i_Q-1}, it holds that $2^{i_Q}\ge D(u')\ge D(u)-d_G(u,u')\ge D(u)-2^{i_Q-1}$. Hence $D(u)\le\frac{3}{2}\cdot 2^{i_Q}$. It follows that

$$D(Q)\overset{(3.2)}{\le}\frac{1}{1-c_{\text{int}}}\cdot D(u)\le\frac{3}{2}\cdot\frac{1}{1-c_{\text{int}}}\cdot 2^{i_Q}\ . \tag{3.3}$$

For every vertex $v\in Q$ it holds that,

$$D(v)\le D(Q)+L(Q)\overset{(3.2)}{\le}(1+c_{\text{int}})\cdot D(Q\overset{(3.3)}{\le}\frac{3}{2}\cdot\frac{(1+c_{\text{int}})}{(1-c_{\text{int}})}\cdot 2^{i_Q}=2^{i_Q+1}\ .$$

Therefore, in the i_Q+1 iteration, all the (yet unassigned) vertices of Q will necessarily be assigned. ◁

▶ **Lemma 11.** *Consider an interval $Q\in\mathcal{Q}$. Then the vertices of Q are partitioned into at most $O(\tau^2)$ different detours.*

Proof. By definition, by the end of the i_Q-1'th iteration all the vertices of Q are unassigned. We first consider the case where by the end i_Q-1'th iteration some vertex $v\in Q$ is inactive. It holds that v belongs to some detour $\mathcal{D}_j$. As all the vertices of Q are unassigned, necessarily $Q\subset\mathcal{D}_j$. In particular, all the vertices of Q belong to a single detour. This property will not change till the end of the algorithm, thus the lemma follows.

[16] For ease of notation we will denote $v_{-1}=t$ and $v_{\gamma+1}=t'$.

Next, we consider the case where by the end of the $i_Q - 1$'th iteration all the vertices of Q are active. The algorithm at iteration i_Q creates an $\left(1, \tau, \Delta_{i_Q}\right)$-scattering partition $\mathcal{P}_{i_Q}$. The length of Q is bounded by

$$L(Q) \overset{(3.1)}{\leq} c_{\text{int}} \cdot D(Q) \overset{(3.3)}{\leq} c_{\text{int}} \cdot \frac{3}{2} \cdot \frac{1}{1 - c_{\text{int}}} \cdot 2^{i_Q} = \frac{1}{4} \cdot 2^{i_Q} < \Delta_{i_Q} \tag{3.4}$$

Hence Q is partitioned by $\mathcal{P}_{i_Q}$ to $\tau' \leq \tau$ clusters $C_1, \dots, C_{\tau'} \in \mathcal{P}_{i_Q}$. It follows that by the end of the i_Q'th iteration, the inactive vertices in Q are partitioned to at most τ detours. If all the vertices in Q become inactive, then we are done, as the number of detours covering Q can only decrease further in the algorithm (as a result of detour nullification). Hence we will assume that some of Q vertices remain active.

A *slice* is a maximal sub-interval $S \subseteq Q$ of active vertices. The active vertices in Q are partitioned to at most $\tau + 1$ slices $S_1, S_2, \dots, S_{\tau''}$.[17] By the end of the $i_Q + 1$ iteration, according to Claim 10 all Q vertices will be assigned, and in particular belong to some detour. The algorithm creates a $\left(\Delta_{i_Q+1}, \tau, 1\right)$-scattering partition $\mathcal{P}_{i_Q+1}$ of the unassigned vertices. By equation (3.4) the length of every slice S is bounded by $L(S) \leq L(Q) \leq \frac{1}{4} \cdot 2^{i_Q} \leq \Delta_{i_Q+1}$. Therefore the vertices S intersect at most τ clusters of $\mathcal{P}_{i_Q+1}$, and thus will be partitioned to at most τ detours. Some detours might get nullified, however in the worst case, by the end of the $i_Q + 1$ iteration, the vertices in $\cup_i S_i$ are partitioned to at most $\tau \cdot (\tau + 1)$ detours. In particular all the vertices in Q are partitioned to at most $O(\tau^2)$ detours. As the number of detours covering Q can only decrease further in the algorithm, the lemma follows. ◀

By the end of algorithm, we will *charge* the intervals for the detours. Consider the detour $\mathcal{D}_j = \{a_j, \dots, b_j\}$ of t_j. Let $Q_j \in \mathcal{Q}$ be the interval containing a_j. We will charge Q_j for the detour $\mathcal{D}_j$. Denote by $X(Q)$ the number of detours for which the interval Q is charged for. By Lemma 11, $X(Q) = O(\tau^2)$ for every interval $Q \in \mathcal{Q}$.

Recall that by the end of the algorithm, all the vertices of $P_{t,t'}$ are partitioned to consecutive disjoint detours $\mathcal{D}_{\ell_1}, \dots, \mathcal{D}_{\ell_s}$, where $\mathcal{D}_{\ell_j} = \{a_{\ell_j}, \dots, b_{\ell_j}\}$ and a_{ℓ_j}, b_{ℓ_j} belong to the cluster of t_{ℓ_j}. In particular $t_{\ell_1} = t$ and $t_{\ell_s} = t'$, as each terminal belongs to the cluster of itself. Moreover, for every $j < s$, there is an edge $\{b_{\ell_j}, a_{\ell_{j+1}}\}$ in G between the cluster of t_{ℓ_j} to that of $t_{\ell_{j+1}}$. Therefore, in the minor induced by the partition there is an edge between t_{ℓ_j} to $t_{\ell_{j+1}}$. We conclude

$$\begin{aligned} d_M(t, t') &\leq \sum_{j=1}^{s-1} d_G(t_{\ell_j}, t_{\ell_{j+1}}) \leq \sum_{j=1}^{s-1} \left[d_G(t_{\ell_j}, a_{\ell_j}) + d_G(a_{\ell_j}, a_{\ell_{j+1}}) + d_G(a_{\ell_{j+1}}, t_{\ell_{j+1}}) \right] \\ &\leq \sum_{j=1}^{s-1} d_G(a_{\ell_j}, a_{\ell_{j+1}}) + 2 \sum_{j=1}^{s} d_G(t_{\ell_j}, a_{\ell_j}) \ . \end{aligned}$$

Note that $\sum_{j=1}^{s-1} d_G(a_{\ell_j}, a_{\ell_{j+1}}) \leq d_G(t, t')$ as $P_{t,t'}$ is a shortest path. Denote by Q_{ℓ_j} the interval containing a_{ℓ_j}. By Corollary 8,

$$d_G(t_{\ell_j}, a_{\ell_j}) = d_G(a_{\ell_j}, f(a_{\ell_j})) \leq O(\tau) \cdot D(a_{\ell_j}) \overset{(3.2)}{=} O(\tau) \cdot D(Q_{\ell_j}) \overset{(3.1)}{=} O(\tau) \cdot L^+(Q_{\ell_j}) \ .$$

By changing the order of summation we get

$$\sum_{j=1}^{s} d_G(t_{\ell_j}, a_{\ell_j}) = O(\tau) \cdot \sum_{Q \in \mathcal{Q}} X(Q) \cdot L^+(Q) = O(\tau^3) \cdot \sum_{Q \in \mathcal{Q}} L^+(Q) \ .$$

Finally, note that $\sum_{Q \in \mathcal{Q}} L^+(Q) \leq 2 \cdot d_G(t, t')$ as every edge in $P_{t,t'}$ is counted at most twice. We conclude $d_M(t, t') \leq O(\tau^3) \cdot d_G(t, t')$. Theorem 2 now follows.

[17] Actually, as at least one Q vertex remained active, at the beginning of the $i_Q + 1$ iteration the inactive vertices of Q partitioned to at most $\tau - 1$ detours. Therefore the maximal number of slices is τ.

4 Discussion and Open Problems

In this paper we defined scattering partitions, and showed how to apply them in order to construct solutions to the SPR problem. We proved an equivalence between sparse partitions and sparse covers. Finally, we constructed many sparse and scattering partitions for different graph families (and lower bounds), implying new results for the SPR, UST, and UTSP problems. An additional contribution of this paper is a considerable list of (all but question (5)) new intriguing open questions and conjectures.

1. **Planar graphs:** The SPR problem is most fascinating and relevant for graph families which are closed under taking a minor. Note that already for planar graphs (or even treewidth 2 graphs), the best upper bound for the SPR problem is $O(\log k)$ (same as general graphs), while the only lower bound is 8. The most important open question coming out of this paper is the following conjecture:

   ▶ **Conjecture 1.** *Every graph family excluding a fixed minor is $(O(1), O(1))$-scatterable.*

   Note that proving this conjecture for a family $\mathcal{F}$, will imply a solution to the SPR problem with constant distortion. Proving the conjecture for planar graphs will be fascinating. However, it is already open for outerplanar graphs, and graphs with treewidth 2.

2. **Scattering Partitions for General Graphs:** While we provide almost tight upper and lower bounds for sparse partitions, for scattering partitions, the story is different.

   ▶ **Conjecture 2.** *Consider an n vertex weighted graph G such that between every pair of vertices there is a unique shortet path. Then G is $(1, O(\log n))$-scatterable. Furthermore, this is tight.*

   In the full version [31], we provide some evidence that Conjecture 2 cannot be pushed further. However, any nontrivial lower bound will be interesting. Furthermore, every lower bound larger than 8 for the general SPR problem will be intriguing.

3. **Doubling graphs:** While we constructed strong sparse partition for doubling graphs (which imply scattering), it has no implication for the SPR problem. This is due to the fact that Theorem 2 required scattering partition for every induced subgraph. As induced subgraphs of a doubling graph might have unbounded doubling dimension, the proof fails to follow through. We leave the required readjustments to future work.

4. **Sparse Covers:** We classify various graph families according to the type of partitions/-covers they admit. We currently lack any example of a graph family that admits weak sparse covers but does not admit strong sparse covers. It will be interesting to find such an example, or even more so to prove that every graph that admits weak sparse cover, also has strong sparse cover with (somewhat) similar parameters.

Abstract

In the $(1+\varepsilon, r)$-*approximate near-neighbor* problem for curves (ANNC) under some similarity measure δ, the goal is to construct a data structure for a given set $\mathcal{C}$ of curves that supports approximate near-neighbor queries: Given a query curve Q, if there exists a curve $C \in \mathcal{C}$ such that $\delta(Q,C) \le r$, then return a curve $C' \in \mathcal{C}$ with $\delta(Q,C') \le (1+\varepsilon)r$. There exists an efficient reduction from the $(1+\varepsilon)$-*approximate nearest-neighbor* problem to ANNC, where in the former problem the answer to a query is a curve $C \in \mathcal{C}$ with $\delta(Q,C) \le (1+\varepsilon)\cdot\delta(Q,C^*)$, where C^* is the curve of $\mathcal{C}$ most similar to Q.

Given a set $\mathcal{C}$ of n curves, each consisting of m points in d dimensions, we construct a data structure for ANNC that uses $n \cdot O(\frac{1}{\varepsilon})^{md}$ storage space and has $O(md)$ query time (for a query curve of length m), where the similarity measure between two curves is their discrete Fréchet or dynamic time warping distance. Our method is simple to implement, deterministic, and results in an exponential improvement in both query time and storage space compared to all previous bounds.

Further, we also consider the *asymmetric* version of ANNC, where the length of the query curves is $k \ll m$, and obtain essentially the same storage and query bounds as above, except that m is replaced by k. Finally, we apply our method to a version of approximate range counting for curves and achieve similar bounds.

1 Introduction

Nearest neighbor search is a fundamental and well-studied problem that has various applications in machine learning, data analysis, and classification. This important task also arises in applications where the recorded instances are trajectories or polygonal curves modeling, for example, epigenetic and surgical processes, market value fluctuations, population growth, the number of the requests per hour received at some web-page, and even the response of a football player in a given situation.

Let $\mathcal{C}$ be a set of n curves, each consisting of at most m points in d dimensions, and let δ be some distance measure for curves. In the *nearest-neighbor* problem for curves, the goal is to construct a data structure for $\mathcal{C}$ that supports nearest-neighbor queries, that is, given a query curve Q of length at most m, return the curve $C^* \in \mathcal{C}$ closest to Q (according to δ). The approximation version of this problem is the $(1+\varepsilon)$*-approximate nearest-neighbor* problem, where the answer to a query Q is a curve $C \in \mathcal{C}$ with $\delta(Q,C) \leq (1+\varepsilon)\delta(Q,C^*)$. We study a decision version of this approximation problem, which is called the $(1+\varepsilon,r)$*-approximate near-neighbor* problem for curves (ANNC). Here, if there exists a curve in $\mathcal{C}$ that lies within distance r of the query curve Q, one has to return a curve in $\mathcal{C}$ that lies within distance $(1+\varepsilon)r$ of Q. Note that there exists a reduction from the $(1+\varepsilon)$-approximate nearest-neighbor problem to the $(1+\varepsilon,r)$-approximate near-neighbor problem [14, 22, 13], at the cost of an additional logarithmic factor in the query time and an $O(\log^2 n)$ factor in the storage space.

In practice, it is often the case that the query curves are significantly shorter than the input curves (e.g., Google-search queries). Thus, we also study the *asymmetric setting* of $(1+\varepsilon,r)$-ANNC, where each of the input curves has complexity at most m, while each query curve has complexity at most $k \ll m$.

There are many methods that are used in real-world applications for comparing curves, and one of the most prevalent is the (discrete) *Fréchet* distance (DFD for short), which is often described by the following analogy. Two frogs are hopping from vertex to vertex along two polygonal curves. At each step, one of the frogs or both frogs may advance to the next vertex on its curve. The discrete Fréchet distance is defined as the smallest maximum distance between the frogs that can be achieved in such a joint sequence of hops. Another useful distance measure for curves or time series is the *dynamic time warping* distance (DTW for short), in which instead of taking the smallest maximum distance we take the smallest sum of distances.

In the last several years, a series of papers have been written investigating the approximate near-neighbor problem for curves (ANNC) and its variants under the Fréchet distance [15, 6, 10, 7, 1, 12, 2] (see Table 1), and several different approaches and sophisticated methods were utilized in order to provide efficient data structures. Up to now, all data structures for ANNC under DFD have either an exponential in m query time, or an infeasible storage space bound. In this paper, for the first time, we manage to remove the exponential factor from the query time, while also significantly reducing the space consumption. Our approach consists of a discretization of space based on the input curves, which allows us to prepare a small set of curves that captures all possible queries approximately.

Indyk [15] was the first to give a deterministic near-neighbor data structure for curves under DFD. The data structure achieves an approximation factor of $O((\log m + \log\log n)^{t-1})$ given some trade-off parameter $t > 1$. Its space consumption is very high, $O(m^2|X|)^{tm^{1/t}} \cdot n^{2t}$, where $|X|$ is the size of the domain on which the curves are defined, and the query time is $(m \log n)^{O(t)}$. In Table 1 we set $t = 1 + o(1)$ to obtain a constant approximation factor.

Later, Driemel and Silvestri [10] presented a locality-sensitive-hashing scheme for curves under DFD, improving the result of Indyk for short curves. Their data structure uses $O(2^{4md} n \log n)$ space and answers queries in $O(2^{4md} \log n)$ time with an approximation factor of $O(d^{3/2})$. They also provide a trade-off between approximation quality and computational performance: for $d = O(1)$, and given a parameter $k \in [m]$, a data structure of size $O(2^{2k} m^{k-1} n \log n + mn)$ is constructed that answers queries in $O(2^{2k} m^k \log n)$ time with an approximation factor of $O(m/k)$. They also show that this result can be applied to DTW, but only for the extreme of the trade-off which gives an $O(m)$ approximation.

Recently, Emiris and Psarros [12] presented near-neighbor data structures for curves under both DFD and DTW. Their algorithm provides an approximation factor of $(1+\varepsilon)$, at the expense of increased space usage and preprocessing time. They use the idea that for a fixed alignment between two curves (i.e., a given sequence of hops of the two frogs), the problem can be reduced to the near-neighbor problem for points in ℓ_∞ product of ℓ_2 spaces. Their basic idea is to construct a data structure for every possible alignment. Once a query is given, they query all these data structures and return the closest curve found. This approach is responsible for the 2^m factor in their query time. Furthermore, they generalize this approach using randomized projections of ℓ_p-products of Euclidean metrics (for any $p \geq 1$), and define the $\ell_{p,2}$-distance for curves (for $p \geq 1$), which is exactly DFD when $p = \infty$, and DTW when $p = 1$ (see Section 2). The space used by their data structure is $\tilde{O}(n) \cdot (2 + \frac{d}{\log m})^{O(m^{1+1/\varepsilon} \cdot d \log(1/\varepsilon))}$ with query $\tilde{O}(d m^{1+1/\varepsilon} \cdot 2^{4m} \log n)$ for DFD and $\tilde{O}(n) \cdot \frac{1}{\varepsilon}^{O(md)}$ space and $\tilde{O}(d \cdot 2^{4m} \log n)$ query for DTW.

Subsequent work. In a recent manuscript, Driemel, Psarros, and Schmidt [9], study the asymmetric setting of $(1+\varepsilon, r)$-ANNC under DFD. They follow our approach of preparing in advance the answers to all relevant queries on a discretization of the space, to construct a randomized data structure with space in $n \cdot O\left(\frac{kd^{3/2}}{\varepsilon}\right)^{dk}$ and query time in $O(dk)$. They also show how to derandomize their data structure, at the cost of increasing the space to $d^{3/2} n k \varepsilon^{-1} \cdot O\left(\frac{kd^{3/2}}{\varepsilon}\right)^{dk}$, and the query time to $O(d^{5/2} k^2 \varepsilon^{-1} (\log n + kd \log \frac{kd}{\varepsilon}))$. This provides additional evidence that our approach to ANNC, although quite simple and easy to implement, seems to produce more efficient data structures than those obtained using tools such as LSH and randomized projections. Moreover, in this version of our manuscript we show how to improve upon the results in [9] for the asymmetric setting.

Our results. We present a data structure for the $(1+\varepsilon, r)$-approximate near-neighbor problem using a bucketing method. We construct a relatively small set of curves $\mathcal{I}$ such that given a query curve Q, if there exists some curve in $\mathcal{C}$ within distance r of Q, then one of the curves in $\mathcal{I}$ must be very close to Q. The points of the curves in $\mathcal{I}$ are chosen from a simple discretization of space, thus, while it is not surprising that we get the best query time, it is surprising that we achieve a better space bound. Moreover, while the analysis of the space bounds is rather involved, the implementation of our data structures remain simple in practice.

See Table 1 for a summary of our results. In the table, we do not state our result for the general $\ell_{p,2}$-distance. Instead, we state our results for the two most important cases, i.e. DFD and DTW, and compare them with previous work. Note that our results substantially improve the current state of the art for any $p \geq 1$. In particular, we remove the exponential dependence on m in the query bounds and significantly improve the space bounds.

Our results for the asymmetric setting, where the query curve Q has complexity $k \ll m$, are summarized in Table 2. We show that in the asymmetric setting for DFD, our data structure can be slightly modified in order to achieve query time and storage space independent of m. Moreover, the storage space and query time matches those of the symmetric setting, by replacing m with k.

We also apply our methods to an approximation version of range counting for curves (for the general $\ell_{p,2}$ distance) and achieve bounds similar to those of our ANNC data structure. Moreover, at the cost of an additional $O(n)$-factor in the space bound, we can also answer the corresponding approximation version of range searching, thus answering a question of Afshani and Driemel [1], with respect to DFD.

We note that our approach with obvious modifications works also in a dynamic setting, that is, we can construct an efficient dynamic data structure for ANNC as well as for other related problems such as range counting and range reporting for curves.

Another significant advantage of our approach is that, unlike some of the previous solutions, our data structure always returns an answer, and never returns a curve at distance greater than $(1+\varepsilon)r$ from the query curve, i.e., there are no false positives. This is an important property of our solution, due to the fact that verifying the validity of the answer (i.e., computing the distance between two curves) cannot be done in strongly subquadratic time (assuming SETH, see [4]), which is already more than our query time (for $d < m$).

Table 1 Our approximate near-neighbor data structure under DFD and DTW compared to the previous results.

	Space	Query	Approx.	Comments
DFD	$O(m^2\|X\|)^{m^{1-o(1)}} \cdot n^{2+o(1)}$	$(m \log n)^{O(1)}$	$O(1)$	deterministic, [15]
	$O(2^{4md} n \log n)$	$O(2^{4md} \log n)$	$O(d^{3/2})$	randomized, using LSH [10]
	$\tilde{O}(n) \cdot (2 + \frac{d}{\log m})^{O(m^{1+1/\varepsilon} \cdot d \log(\frac{1}{\varepsilon}))}$	$\tilde{O}(dm^{1+1/\varepsilon} \cdot 2^{4m} \log n)$	$1+\varepsilon$	randomized, [12]
	$n \cdot O(\frac{1}{\varepsilon})^{md}$	$O(md)$	$1+\varepsilon$	deter. (rand. construction), Theorem 9
DTW	$O(n \log n + mn)$	$O(m \log n)$	$O(m)$	randomized, using LSH, $d = O(1)$, [10]
	$\tilde{O}(n) \cdot \frac{1}{\varepsilon}^{O(md)}$	$\tilde{O}(d \cdot 2^{4m} \log n)$	$1+\varepsilon$	randomized, [12]
	$n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$	$O(md)$	$1+\varepsilon$	deter. (rand. construction), Theorem 15

More related work. De Berg, Gudmundsson, and Mehrabi [7] described a dynamic data structure for approximate nearest neighbor for curves (which can also be used for other types of queries such as range reporting), under the (continuous) Fréchet distance. Their data structure uses $n \cdot O\left(\frac{1}{\varepsilon}\right)^{2m}$ space and has $O(m)$ query time, but with an additive error of $\varepsilon \cdot \mathit{reach}(Q)$, where $\mathit{reach}(Q)$ is the maximum distance between the start vertex of the query curve Q and any other vertex of Q. Furthermore, their query procedure might fail when the distance to the nearest neighbor is relatively large.

Afshani and Driemel [1] studied (exact) range searching under both the discrete and continuous Fréchet distance. In this problem, the goal is to preprocess $\mathcal{C}$ such that given a query curve Q of length m_q and a radius r, all the curves in $\mathcal{C}$ that are within distance r from

Table 2 Summary of previous and current results for the asymmetric approximate near-neighbor data structure for curves. All the results in the table are w.r.t. DFD. The approximation ratio is $1+\varepsilon$ for $\varepsilon \in (0,1)$, and our data structures always succeed. Historic note: [9] is a subsequent work to the first version of this paper arXiv:1902.07562. In this second version we also apply our counting techniques to the asymmetric cases.

Space	Query	Deterministic construction?	Reference
$n \cdot \left(O(\frac{kd^{3/2}}{\varepsilon})^{kd}\right)$	$O(kd)$	no	[9]
$n \cdot \left(O(\frac{kd^{3/2}}{\varepsilon})^{kd+1}\right)$	$O(\frac{k^2d^{5/2}}{\varepsilon}(\log n + kd\log(\frac{kd}{\varepsilon})))$	yes	[9]
$n \cdot O(\frac{1}{\varepsilon})^{kd}$	$O(kd)$	no	Theorem 11
$n \cdot O(\frac{1}{\varepsilon})^{kd}$	$O(kd\log(\frac{nkd}{\varepsilon}))$	yes	Theorem 18

Q can be found efficiently. For DFD, their data structure uses $O(n(\log\log n)^{m-1})$ space and has $O(n^{1-\frac{1}{d}} \cdot \log^{O(m)} n \cdot m_q^{O(d)})$ query time, where m_q is limited to $\log^{O(1)} n$. Additionally, they provide a lower bound in the pointer model, stating that every data structure with $Q(n)+O(k)$ query time, where k is the output size, has to use roughly $\Omega\left((n/Q(n))^2\right)$ space in the worst case (even for $m_q = 1$). Afshani and Driemel conclude their paper by asking whether more efficient data structures might be constructed if one allows approximation.

De Berg, Cook IV, and Gudmundsson [6], considered the following range counting problem under the continuous Fréchet distance. Given a polygonal curve C with m vertices, they show how to preprocess it into a data structure of size $O(k \cdot \text{polylog(m)})$, so that, given a query segment s, one can return a constant approximation of the number of subcurves of C that lie within distance r of s in $O(\frac{m}{\sqrt{k}} \cdot \text{polylog(m)})$ time, where k is a parameter between m and m^2.

Aronov et al. [2] managed to obtain practical bounds for two cases of the asymmetric $(1+\varepsilon, r)$-ANNC under DFD: (i) when Q is a line segment (i.e., $k=2$), or (ii) when $\mathcal{C}$ consists of line segments (i.e., $m=2$). The bounds on the size of the data structure and query time are nearly linear in the size of the input and query curve, respectively. Specifically, for the case where $k=2$, they achieve query time $O(\log^4(\frac{n}{\varepsilon}))$ and storage space $O(n\frac{1}{\varepsilon^4}\log^4(\frac{n}{\varepsilon}))$. They also provide efficient data structures for several other variants of the problem: the (exact) NNC where ℓ_∞ is used for interpoint distances, and the case where the location of the input curves is only fixed up to translation.

1.1 Technical ideas

We use a discretization of the space, by laying a d-dimensional uniform grid with edge length $\frac{\varepsilon r}{\sqrt{d}}$. The main ingredient in our data structure is then a relatively small set $\mathcal{I}$ of curves defined by grid points, which represents all possible queries. For each curve in $\mathcal{I}$ we store an index of a close enough curve from the input set $\mathcal{C}$. Given a query Q sufficiently close to some curve in $\mathcal{C}$, we find a representative Q' in $\mathcal{I}$ by simply rounding Q's vertices and return the index of the curve stored for Q'.

Given a point $x \in \mathbb{R}^d$, the number of grid points that are within distance $(1+\varepsilon)r$ from x is bounded by $O(\frac{1}{\varepsilon})^d$ (Corollary 7). Thus, given a curve C of length m, the total number of grid points that are within distance $(1+\varepsilon)r$ from one of its vertices is $m \cdot O(\frac{1}{\varepsilon})^d$. Naively, the number of curves needed to represent all possible queries of length m within distance

r of C is bounded by the number of ways to choose m points with repetitions from a set of grid points of size $m \cdot O(\frac{1}{\varepsilon})^d$, which is bounded by $m^m \cdot O(\frac{1}{\varepsilon})^{md}$. This infeasible bound on the storage space might be the reason why more sophisticated solutions for ANNC have been suggested throughout the years.

One of the main technical contributions of this paper is an analysis leading to a significantly better bound, if we store only candidate curves that are within distance $(1+\varepsilon)r$ from C. Actually, in Section 3 we show that for the case of DFD, it is sufficient to store a set of representative curves of size only $O(\frac{1}{\varepsilon})^{md}$ for each input curve. The basic idea is to bound the number of representatives that can be obtained by some fixed alignment between C and the candidate curve (see Claim 8).

For the general case of $\ell_{p,2}$-distance (including DTW), we are minimizing the sum of distances instead of the maximum distance (as in DFD). Thus, we have to use a more dense grid (with edge length $\frac{\varepsilon r}{(2m)^{1/p}\sqrt{d}}$), and the situation becomes more complicated. First, unlike DFD, the triangle inequality does not hold for $\ell_{p,2}$-distance in general (including DTW). Second, since DFD is a min-max measure, the choice of different vertices for a representative curve is "independent" in a sense, whereas for $\ell_{p,2}$-distance in general, the choice of different vertices depends on their sum of distances from the input curve. Using more careful counting arguments and analysis of the alignment between two curves, we are able to show that in this case the number of representative curves that our data structure has to store per input curve is bounded by $O(\frac{1}{\varepsilon})^{m(d+1)}$ (see Claim 13).

To store the set $\mathcal{I}$ we simply use a dictionary, which can be implemented using a hash table and guarantees a query time linear in the size of the query. To obtain a fully deterministic solution, one can use a search tree instead. However, a naive implementation using a binary search tree results in an additional factor of $O(\log|\mathcal{I}|) = O(md\log(\frac{n}{\varepsilon}))$ to the query time, i.e., in a query time of $O(m^2d^2\log(\frac{n}{\varepsilon}))$. We show how to implement the dictionary using a prefix tree, exploiting the fact that the vertices of the curves in $\mathcal{I}$ are from a relatively small set of grid points, which improves the query time to $O(md\log(\frac{nmd}{\varepsilon}))$.

For the asymmetric setting (where the length of a query is $k \ll m$), we use simplifications of the input curves in order to obtain bounds that are independent of m. Given a curve C of length m, a simplification Π of C is a curve of length $k \ll m$ that is relatively close to C. Simplifications were used in order to provide approximate solutions in several asymmetric versions of problems on curves, such as clustering [5], and distance oracles [8, 9].

By the triangle inequality for DFD, every query curve Q within distance r from an input curve C is at distance at most $2r$ from the simplification Π (where Π is within distance r from C). Thus, it is enough to prepare for query curves at distance at most $2r$ from Π, which follows from previous arguments. Note that the query time and storage space are independent of m.

2 Preliminaries

To simplify the presentation, we assume throughout the paper that all the input curves have exactly the same size, m, and all the query curves have exactly the same size, either m or k, depending on whether we are considering the standard or the asymmetric version. This assumption can be easily removed (see Remark 16 at the end of Section 5).

Let $\mathcal{C}$ be a set of n curves, each consisting of m points in d dimensions, and let δ be some distance measure for curves.

▶ **Problem 1** ($(1+\varepsilon)$-approximate nearest-neighbor for curves). *Given a parameter $0 < \varepsilon \leq 1$, preprocess $\mathcal{C}$ into a data structure that given a query curve Q, returns a curve $C' \in \mathcal{C}$, such that $\delta(Q, C') \leq (1+\varepsilon) \cdot \delta(Q, C)$, where C is the curve in $\mathcal{C}$ closest to Q.*

▶ **Problem 2** ($(1+\varepsilon, r)$-approximate near-neighbor for curves). *Given a parameter r and $0 < \varepsilon \leq 1$, preprocess $\mathcal{C}$ into a data structure that given a query curve Q, if there exists a curve $C_i \in \mathcal{C}$ such that $\delta(Q, C_i) \leq r$, returns a curve $C_j \in \mathcal{C}$ such that $\delta(Q, C_j) \leq (1+\varepsilon)r$.*

▶ **Problem 3** (Asymmetric $(1+\varepsilon, r)$-approximate near-neighbor for curves). *Given parameters r,k, and $0 < \varepsilon \leq 1$, preprocess $\mathcal{C}$ into a data structure that given a query curve Q of length k, if there exists a curve $C_i \in \mathcal{C}$ such that $\delta(Q, C_i) \leq r$, returns a curve $C_j \in \mathcal{C}$ such that $\delta(Q, C_j) \leq (1+\varepsilon)r$.*

Curve alignment. Given two integers m_1, m_2, let $\tau := \langle (i_1, j_1), \ldots, (i_t, j_t) \rangle$ be a sequence of pairs where $i_1 = j_1 = 1$, $i_t = m_1$,$j_t = m_2$, and for each $1 < k \leq t$, one of the following conditions holds:

(i) $i_k = i_{k-1} + 1$ and $j_k = j_{k-1}$,
(ii) $i_k = i_{k-1}$ and $j_k = j_{k-1} + 1$, or
(iii) $i_k = i_{k-1} + 1$ and $j_k = j_{k-1} + 1$.

We call such a sequence τ an *alignment* of two curves.

Let $P = (p_1, \ldots, p_{m_1})$ and $Q = (q_1, \ldots, q_{m_2})$ be two curves of lengths m_1 and m_2, respectively, in d dimensions. We say that an alignment τ w.r.t. P and Q matches p_i and p_j if $(i, j) \in \tau$.

Discrete Fréchet distance (DFD). The *Fréchet cost* of an alignment τ w.r.t. P and Q is $\sigma_{dF}(\tau(P, Q)) := \max_{(i,j)\in\tau} \|p_i - q_j\|_2$. The discrete Fréchet distance is defined over the set $\mathcal{T}$ of all alignments as

$$d_{dF}(P, Q) = \min_{\tau\in\mathcal{T}} \sigma_{dF}(\tau(P, Q)).$$

Dynamic time wrapping (DTW). The *time warping cost* of an alignment τ w.r.t. P and Q is $\sigma_{DTW}(\tau(P, Q)) := \sum_{(i,j)\in\tau} \|p_i - q_j\|_2$. The DTW distance is defined over the set $\mathcal{T}$ of all alignments as

$$d_{DTW}(P, Q) = \min_{\tau\in\mathcal{T}} \sigma_{DTW}(\tau(P, Q)).$$

$\ell_{p,2}$-distance for curves. The *$\ell_{p,2}$-cost* of an alignment τ w.r.t. P and Q is $\sigma_{p,2}(\tau(P, Q)) := \left(\sum_{(i,j)\in\tau} \|p_i - q_j\|_2^p\right)^{1/p}$. The $\ell_{p,2}$-distance between P and Q is defined over the set $\mathcal{T}$ of all alignments as

$$d_{p,2}(P, Q) = \min_{\tau\in\mathcal{T}} \sigma_{p,2}(\tau(P, Q)).$$

Notice that $\ell_{p,2}$-distance is a generalization of DFD and DTW, in the sense that $\sigma_{dF} = \sigma_{\infty,2}$ and $d_{dF} = d_{\infty,2}$, $\sigma_{DTW} = \sigma_{1,2}$ and $d_{DTW} = d_{1,2}$. Also note that DFD satisfies the triangle inequality, but DTW and $\ell_{p,2}$-distance (for $p \neq \infty$) do not (see Section 5 for details).

Emiris and Psarros [12] showed that the number of all possible alignments of two curves is in $O(m \cdot 2^{2m})$. We reduce this bound by counting only alignments that can determine the $\ell_{p,2}$-distance between two curves.[1] More formally, let τ be an alignment. If there

[1] Since our storage space is already in $O(\frac{1}{\varepsilon})^{md}$, and $m \cdot 2^{2m} \leq 3^{2m}$ is in $O(1)^{md}$, we could have used this larger upper bound. However, in Lemma 4 we show a tight upper bound on the number of relevant alignments, which may be useful for other applications.

exists an alignment τ' such that $\tau' \subset \tau$, then clearly $\sigma_{p,2}(\tau'(P,Q)) \leq \sigma_{p,2}(\tau(P,Q))$, for any $1 \leq p \leq \infty$ and for any two curves P and Q. In this case, we say that τ cannot determine the $\ell_{p,2}$-distance between two curves.

▶ **Lemma 4.** *The number of different alignments that can determine the $\ell_{p,2}$-distance between two m-curves (for any $1 \leq p \leq \infty$) is at most $O(\frac{2^{2m}}{\sqrt{m}})$.*

Proof. Let $\tau = \langle (i_1, j_1), \ldots, (i_t, j_t) \rangle$ be an alignment. Notice that $m \leq t \leq 2m-1$. By definition, τ has 3 types of (consecutive) subsequences of length two:

(i) $\langle (i_k, j_k), (i_k+1, j_k) \rangle$,
(ii) $\langle (i_k, j_k), (i_k, j_k+1) \rangle$, and
(iii) $\langle (i_k, j_k), (i_k+1, j_k+1) \rangle$.

Denote by $\mathcal{T}_1$ the set of all alignments that do not contain any subsequence of type (iii). Then, any $\tau_1 \in \mathcal{T}_1$ is of length exactly $2m-1$. Moreover, τ_1 contains exactly $2m-2$ subsequences of length two, of which $m-1$ are of type (i) and $m-1$ are of type (ii). Therefore, $|\mathcal{T}_1| = \binom{2m-2}{m-1} = O(\frac{2^{2m}}{\sqrt{m}})$.

Assume that an alignment τ contains a subsequence of the form $(i_k, j_k-1), (i_k, j_k), (i_k+1, j_k)$, for some $1 < k \leq t-1$. Notice that removing the pair (i_k, j_k) from τ results in a legal alignment τ', such that $\sigma_{p,2}(\tau'(P,Q)) \leq \sigma_{p,2}(\tau(P,Q))$, for any $1 \leq p \leq \infty$ and two curves P, Q. We call the pair (i_k, j_k) a *redundant pair.* Similarly, if τ contains a subsequence of the form $(i_k-1, j_k), (i_k, j_k), (i_k, j_k+1)$, for some $1 < k \leq t-1$, then the pair (i_k, j_k) is also a redundant pair. Therefore we only care about alignments that do not contain any redundant pairs. Denote by $\mathcal{T}_2$ the set of all alignments that do not contain any redundant pairs, then any $\tau_2 \in \mathcal{T}_2$ contains at least one subsequence of type (iii).

We claim that for any alignment $\tau_2 \in \mathcal{T}_2$, there exists a unique alignment $\tau_1 \in \mathcal{T}_1$. Indeed, if we add the redundant pair (i_l, j_l+1) between (i_l, j_l) and (i_l+1, j_l+1) for each subsequence of type (iii) in τ_2, we obtain an alignment $\tau_1 \in \mathcal{T}_1$. Moreover, since τ_2 does not contain any redundant pairs, the reverse operation on τ_1 results in τ_2. Thus we obtain $|\mathcal{T}_2| \leq |\mathcal{T}_1| = O(\frac{2^{2m}}{\sqrt{m}})$. ◀

Points and balls. Given a point $x \in \mathbb{R}^d$ and a real number $R > 0$, we denote by $B_p^d(x, R)$ the d-dimensional ball under the ℓ_p norm with center x and radius R, i.e., a point $y \in \mathbb{R}^d$ is in $B_p^d(x, R)$ if and only if $\|x - y\|_p \leq R$, where $\|x - y\|_p = \left(\sum_{i=1}^d |x_i - y_i|^p\right)^{1/p}$. Let $B_p^d(R) = B_p^d(\mathbf{0}, R)$, and let $V_p^d(R)$ be the volume (w.r.t. Lebesgue measure) of $B_p^d(R)$, then

$$V_p^d(R) = \frac{2^d \Gamma(1+1/p)^d}{\Gamma(1+d/p)} R^d,$$

where $\Gamma(\cdot)$ is Euler's Gamma function (an extension of the factorial function). For $p = 2$ and $p = 1$, we get

$$V_2^d(R) = \frac{\pi^{d/2}}{\Gamma(1+d/2)} R^d \quad \text{and} \quad V_1^d(R) = \frac{2^d}{d!} R^d.$$

Our approach consists of a discretization of the space using lattice points, i.e., points from $\mathbb{Z}^d$.

▶ **Lemma 5.** *The number of lattice points in the d-dimensional ball of radius R under the ℓ_p norm (i.e., in $B_p^d(R)$) is bounded by $V_p^d(R + d^{1/p})$.*

Proof. With each lattice point $z = (z_1, z_2, \ldots, z_d)$, $z_i \in \mathbb{Z}$, we match the d-dimensional lattice cube $C(z) = [z_1, z_1 + 1] \times [z_2, z_2 + 1] \times \cdots \times [z_d, z_d + 1]$. Notice that $z \in C(z)$, and the ℓ_p-diameter of a lattice cube is $d^{1/p}$. Therefore, the number of lattice points in the ℓ_p^d-ball of radius R is bounded by the number of lattice cubes that are contained in a ℓ_p^d-ball with radius $R + d^{1/p}$. This number is bounded by $V_p^d(R + d^{1/p})$ divided by the volume of a lattice cube, which is $1^d = 1$. ◀

▶ Remark 6. In general, in all our data structures we do not assume any bound on the dimension d. However, using dimension reduction techniques, we may assume that $d \le O(\frac{\log(nm)}{\varepsilon^2})$. See Section 9 for details.

3 Discrete Fréchet distance (DFD)

Consider the infinite d-dimensional grid with edge length $\frac{\varepsilon r}{\sqrt{d}}$. Given a point x in $\mathbb{R}^d$, by rounding one can find in $O(d)$ time the grid point x' closest to x, and $\|x - x'\|_2 \le \frac{\varepsilon r}{2}$. Let $G(x, R)$ denote the set of grid points that are contained in $B_2^d(x, R)$.

▶ **Corollary 7.** $|G(x, (1 + \varepsilon)r)| = O(\frac{1}{\varepsilon})^d$.

Proof. We scale our grid so that the edge length is 1, hence we are looking for the number of lattice points in $B_2^d(x, \frac{1+\varepsilon}{\varepsilon}\sqrt{d})$. By Lemma 5 we get that this number is bounded by the volume of the d-dimensional ball of radius $\frac{1+\varepsilon}{\varepsilon}\sqrt{d} + \sqrt{d} \le \frac{3\sqrt{d}}{\varepsilon}$. Using Stirling's formula we conclude that

$$V_2^d\left(\frac{3\sqrt{d}}{\varepsilon}\right) = \frac{\pi^{\frac{d}{2}}}{\Gamma(\frac{d}{2}+1)} \cdot \left(\frac{3\sqrt{d}}{\varepsilon}\right)^d \le \left(\frac{\alpha}{\varepsilon}\right)^d ,$$

where α is a constant. For example, if d is even, then

$$V_2^d\left(\frac{3\sqrt{d}}{\varepsilon}\right) = \frac{\pi^{\frac{d}{2}}}{(\frac{d}{2})!} \cdot \left(\frac{3\sqrt{d}}{\varepsilon}\right)^d \le \frac{\pi^{\frac{d}{2}}}{\sqrt{2\pi}(d/2)^{d/2+1/2}e^{-d/2}} \cdot \left(\frac{3\sqrt{d}}{\varepsilon}\right)^d \le \left(\frac{12.4}{\varepsilon}\right)^d = O\left(\frac{1}{\varepsilon}\right)^d .$$

◀

Denote by p_j^i the j'th point of C_i, and let $G_i = \bigcup_{1 \le j \le m} G(p_j^i, (1+\varepsilon)r)$ and $\mathcal{G} = \bigcup_{1 \le i \le n} G_i$, then by the above corollary we have $|G_i| = m \cdot O(\frac{1}{\varepsilon})^d$ and $|\mathcal{G}| = mn \cdot O(\frac{1}{\varepsilon})^d$. Let $\mathcal{I}_i$ be the set of all curves $\overline{Q} = (x_1, x_2, \ldots, x_m)$ with points from G_i, such that $d_{dF}(C_i, \overline{Q}) \le (1 + \frac{\varepsilon}{2})r$.

▷ Claim 8. $|\mathcal{I}_i| = O(\frac{1}{\varepsilon})^{md}$ and it can be computed in $O(\frac{1}{\varepsilon})^{md}$ time.

Proof. Let $\overline{Q} \in \mathcal{I}_i$ and let τ be an alignment with $\sigma_{dF}(\tau(C_i, \overline{Q})) \le (1 + \frac{\varepsilon}{2})r$. For each $1 \le k \le m$ let j_k be the smallest index such that $(j_k, k) \in \tau$. In other words, j_k is the smallest index that is matched to k by the alignment τ. Since $d_{dF}(C_i, \overline{Q}) \le (1 + \frac{\varepsilon}{2})r$, we have $x_k \in B_2^d(p_{j_k}^i, (1 + \frac{\varepsilon}{2})r)$, for $k = 1, \ldots, m$. This means that for any curve $\overline{Q} \in \mathcal{I}_i$ such that $\sigma_{dF}(\tau(C_i, \overline{Q})) \le (1 + \frac{\varepsilon}{2})r$, we have $x_k \in G(p_{j_k}^i, (1 + \frac{\varepsilon}{2})r)$, for $k = 1, \ldots, m$. By Corollary 7, the number of ways to choose a grid point x_k from $G(p_{j_k}^i, (1 + \frac{\varepsilon}{2})r)$ is bounded by $O(\frac{1}{\varepsilon})^d$.

We conclude that given an alignment τ, the number of curves $\overline{Q}$ with m points from G_i such that $\sigma_{dF}(\tau(C_i, \overline{Q})) \le (1 + \frac{\varepsilon}{2})r$ is bounded by $O(\frac{1}{\varepsilon})^{md}$. Finally, by Lemma 4, the total number of curves in $\mathcal{I}_i$ is bounded by $2^{2m} \cdot O(\frac{1}{\varepsilon})^{md} = O(\frac{1}{\varepsilon})^{md}$.

To construct $\mathcal{I}_i$ we compute, for each of the $O(\frac{1}{\varepsilon})^{md}$ candidates, its discrete Fréchet distance to C_i. Thus, we construct $\mathcal{I}_i$ in total time $O(\frac{1}{\varepsilon})^{md} \cdot O(m^2) = O(\frac{1}{\varepsilon})^{md}$. (The latter equality is true, since clearly $(\frac{\alpha}{\varepsilon})^{md} \cdot O(m^2) \le (\frac{c\alpha}{\varepsilon})^{md}$, i.e., $O(m^2) \le c^{md}$, where α is the constant from Corollary 7 and $c > 1$ is a sufficiently large constant.) ◁

The data structure. Denote $\mathcal{I} = \bigcup_{1\leq i\leq n} \mathcal{I}_i$, so $|\mathcal{I}| \leq n \cdot O(\frac{1}{\varepsilon})^{md}$ and we construct $\mathcal{I}$ in total time $n \cdot O(\frac{1}{\varepsilon})^{md}$. Next, we would like to store the set $\mathcal{I}$ in a dictionary (a hash table or a lookup table) $\mathcal{D}$, such that given a query curve Q, one can find Q in $\mathcal{D}$ (if it exists) in $O(md)$ time. We use Cuckoo Hashing [21] to construct a (dynamic) dictionary of linear space, constant worst-case query and deletion time, and constant expected amortized insertion time. We insert the curves of $\mathcal{I}$ into the dictionary $\mathcal{D}$ as follows. For each $1 \leq i \leq n$ and curve $\overline{Q} \in \mathcal{I}_i$, if $\overline{Q} \notin \mathcal{D}$, insert $\overline{Q}$ into $\mathcal{D}$, and set $C(\overline{Q}) \leftarrow C_i$. The storage space required for $\mathcal{D}$ is $O(|\mathcal{I}|)$, and to construct it we perform $|\mathcal{I}|$ insertions and look-up operations which take in total $O(|\mathcal{I}| \cdot md) = O(|\mathcal{I}|)$ expected time.

The query algorithm. Let $Q = (q_1, \ldots, q_m)$ be the query curve. The query algorithm is as follows: For each $1 \leq k \leq m$ find the grid point q'_k (not necessarily from $\mathcal{G}$) closest to q_k. This can be done in $O(md)$ time by rounding. Then, search for the curve $Q' = (q'_1, \ldots, q'_m)$ in the dictionary $\mathcal{D}$. If Q' is in $\mathcal{D}$, return $C(Q')$, otherwise, return NO. The total query time is then $O(md)$.

Correctness. Consider a query curve $Q = (q_1, \ldots, q_m)$. Assume that there exists a curve $C_i \in \mathcal{C}$ such that $d_{dF}(C_i, Q) \leq r$. We show that the query algorithm returns a curve C^* with $d_{dF}(C^*, Q) \leq (1+\varepsilon)r$.

Consider a point $q_k \in Q$. Denote by $q'_k \in \mathcal{G}$ the grid point closest to q_k, and let $Q' = (q'_1, \ldots, q'_m)$. We have $\|q_k - q'_k\|_2 \leq \frac{\varepsilon r}{2}$, so $d_{dF}(Q, Q') \leq \frac{\varepsilon r}{2}$. By the triangle inequality,

$$d_{dF}(C_i, Q') \leq d_{dF}(C_i, Q) + d_{dF}(Q, Q') \leq r + \frac{\varepsilon r}{2} = (1 + \frac{\varepsilon}{2})r,$$

so Q' is in $\mathcal{I}_i \subseteq \mathcal{I}$. This means that $\mathcal{D}$ contains Q' with a curve $C(Q') \in \mathcal{C}$ such that $d_{dF}(C(Q'), Q') \leq (1 + \frac{\varepsilon}{2})r$, and the query algorithm returns $C(Q')$. Now, again by the triangle inequality,

$$d_{dF}(C(Q'), Q) \leq d_{dF}(C(Q'), Q') + d_{dF}(Q', Q) \leq (1 + \frac{\varepsilon}{2})r + \frac{\varepsilon r}{2} = (1+\varepsilon)r.$$

We obtain the following theorem.

▶ **Theorem 9.** *There exists a data structure for the $(1+\varepsilon, r)$-ANNC under DFD, with $n \cdot O(\frac{1}{\varepsilon})^{md}$ space, $n \cdot O(\frac{1}{\varepsilon})^{md}$ expected preprocessing time, and $O(md)$ query time.*

4 The asymmetric setting under DFD

In this section, we show how to easily adapt our data structure to the asymmetric setting, by using simplifications of length at most k instead of the original input curves.

Bereg et al. [3] showed that given a curve C consisting of m points in 3D, and a parameter $r > 0$, there is an algorithm that runs in $O(m \log m)$ time and returns a simplification Π with minimum number of vertices such that $d_{dF}(C, \Pi) \leq r$. Their algorithm generalizes to higher dimensions, using an approximation algorithm for the minimum enclosing ball problem (see Kumar et al. [17]). In this section, we use the following generalization of their original approach ([3], Theorem 1). More details are given in Section 8.

▶ **Lemma 10.** *Let C be a curve consisting of m points in $\mathbb{R}^d$. Given parameters $k \leq m$, $r > 0$, and $\varepsilon \in (0, 1]$, there is an algorithm that runs in $O\left(\frac{d \cdot m \log m}{\varepsilon} + m \cdot \text{poly}\frac{1}{\varepsilon}\right)$ time that either returns a simplification Π consisting of k points such that $d_{dF}(C, \Pi) \leq (1+\varepsilon)r$, or declares that for every simplification Π with k points, it holds that $d_{dF}(C, \Pi) > r$.*

For each $C_i \in \mathcal{C}$, using Lemma 10 with parameter $\varepsilon = 1$, we find a curve Π_i of length k such that $d_{dF}(C_i, \Pi_i) \leq 2r$. If we fail to find such a curve, then we can ignore C_i, because it means that $d_{dF}(Q, C_i) > r$ for any curve Q of length k.

To reduce the space consumption of our data structure, we only store candidate curves of length k that are close enough to the simplifications Π_i. However, since the distance between the simplification Π_i and the input curve C_i could be up to $2r$, storing the answers for the set of candidate curves that are within distance $(1 + \frac{\varepsilon}{2})r$ from Π_i is not enough, because a query Q that is within distance $(1+\varepsilon)r$ from C_i might be as far as $(3+\varepsilon)r$ from Π_i. Thus, instead, we insert into our data structure all the curves that are within distance $4r$ from Π_i. This allows us to capture all query curves that are within distance r from C_i.

The data structure. We construct our data structure for the original (symmetric) version, with the following modifications. The set of input curves is $\mathcal{P} = \{\Pi_1, \ldots, \Pi_n\}$ (instead of $\mathcal{C}$), and the radius parameter is $4r$ (instead of r), but the grid edge length remains $\frac{\varepsilon r}{\sqrt{d}}$. In addition, we let $\mathcal{I}'_i$ be the set of all curves $\overline{Q}$ with k points from G_i, such that $d_{dF}(\overline{Q}, \Pi_i) \leq 4r$, and $\mathcal{I}_i$ will be the set of all curves $\overline{Q} \in \mathcal{I}'_i$ such that $d_{dF}(\overline{Q}, C_i) \leq (1 + \frac{\varepsilon}{2})r$. We insert the curves in $\mathcal{I}_i$ into the database $\mathcal{D}$ as before: For each $\overline{Q} \in \mathcal{I}_i$, if $\overline{Q} \notin \mathcal{D}$, insert $\overline{Q}$ into $\mathcal{D}$ and set $C(\overline{Q}) \leftarrow C_i$.

Notice that using $4r$ instead of r, increases the ratio between the radius and the grid edge length by only a factor of 4, and therefore the bound on $|\mathcal{I}'_i|$ does not change, except that m is replaced by k. Therefore, the bounds on the storage space and query time are similar to those of the original data structure, where m is replaced by k. Thus, the storage space is in $n \cdot O(\frac{1}{\varepsilon})^{kd}$ and the query time is in $O(kd)$. As for the preprocessing time, we get an additional term of $O(nmd \log m)$ for computing the simplifications $\Pi_1, \ldots, \Pi_n$. We also need to compute the distances $d_{dF}(C_i, \overline{Q})$ in the construction of $\mathcal{I}_i$, for $1 \leq i \leq n$, which takes $n \cdot O(\frac{1}{\varepsilon})^{kd} \cdot O(mkd) = nm \cdot O(\frac{1}{\varepsilon})^{kd}$ time in total (as $kd \leq 2^{kd}$). Thus the total expected preprocessing time is $O(nmd \log m) + nm \cdot O(\frac{1}{\varepsilon})^{kd} = nm \cdot \big(O(d \log m) + O(\frac{1}{\varepsilon})^{kd}\big)$.

Correctness. Consider a query curve Q, and assume that there exists a curve $C_i \in \mathcal{C}$ such that $d_{dF}(C_i, Q) \leq r$. Then, Π_i is a curve of length k and $d_{dF}(C_i, \Pi_i) \leq 2r$. As in the previous section, let Q' be the curve computed by the query algorithm, then $d_{dF}(Q', Q) \leq \frac{\varepsilon r}{2}$. By the triangle inequality, we have $d_{dF}(Q', C_i) \leq d_{dF}(Q', Q) + d_{dF}(Q, C_i) \leq (1 + \frac{\varepsilon}{2})r$, and

$$d_{dF}(Q', \Pi_i) \leq d_{dF}(Q', C_i) + d_{dF}(C_i, \Pi_i) \leq (1 + \frac{\varepsilon}{2})r + 2r \leq 4r.$$

Therefore our data structure contains Q', and the query algorithm returns $C(Q')$, where $d_{dF}(C(Q'),Q') \leq (1+\frac{\varepsilon}{2})r$. Finally, again by the triangle inequality, we have

$$d_{dF}(C(Q'),Q) \leq d_{dF}(C(Q'),Q') + d_{dF}(Q',Q) \leq (1+\frac{\varepsilon}{2})r + \frac{\varepsilon r}{2} = (1+\varepsilon)r.$$

We obtain the following theorem.

▶ **Theorem 11.** *There exists a data structure for the asymmetric $(1+\varepsilon, r)$-ANNC under DFD, with $n \cdot O(\frac{1}{\varepsilon})^{dk}$ space, $nm \cdot \big(O(d \log m) + O(\frac{1}{\varepsilon})^{kd}\big)$ expected preprocessing time, and $O(kd)$ query time.*

5 $\ell_{p,2}$-distance of polygonal curves

For the near-neighbor problem under the $\ell_{p,2}$-distance, we use the same basic approach as in Section 3, but with two small modifications. The first is that we set the grid's edge length to $\frac{\varepsilon r}{(2m)^{1/p}\sqrt{d}}$, and redefine $G(x,R)$, G_i, and $\mathcal{G}$, as in Section 3 but with respect to the new edge length of our grid. The second modification is that we redefine $\mathcal{I}_i$ to be the set of all curves $\overline{Q} = (x_1, x_2, \dots, x_m)$ with points from $\mathcal{G}$, such that $d_{p,2}(C_i, \overline{Q}) \leq (1+\frac{\varepsilon}{2})r$.

We assume without loss of generality from now and to the end of this section that $r = 1$ (we can simply scale the entire space by $1/r$), so the grid's edge length is $\frac{\varepsilon}{(2m)^{1/p}\sqrt{d}}$. The following corollary is respective to Corollary 7.

▶ **Corollary 12.** $|G(x,R)| = O\left(1 + \frac{m^{1/p}}{\varepsilon}R\right)^d$.

Proof. We scale our grid so that the edge length is 1, hence we are looking for the number of lattice points in $B_2^d(x, \frac{(2m)^{1/p}\sqrt{d}}{\varepsilon}R)$. By Lemma 5 we get that this number is bounded by the volume of the d-dimensional ball of radius $(1 + \frac{(2m)^{1/p}}{\varepsilon}R)\sqrt{d}$. Using Stirling's formula we conclude,

$$V_2^d\left(\left(1 + \frac{(2m)^{1/p}}{\varepsilon}R\right)\sqrt{d}\right) = \frac{\pi^{\frac{d}{2}}}{\Gamma(\frac{d}{2}+1)} \cdot \left(\left(1 + \frac{(2m)^{1/p}}{\varepsilon}R\right)\sqrt{d}\right)^d = \alpha^d \cdot \left(1 + \frac{m^{1/p}}{\varepsilon}R\right)^d$$

where α is a constant (approximately $4.13 \cdot 2^{1/p}$). ◀

In the following claim we bound the size of $\mathcal{I}_i$, which, surprisingly, is independent of p.

▷ Claim 13. $|\mathcal{I}_i| = O(\frac{1}{\varepsilon})^{m(d+1)}$ and it can be computed in $O(\frac{1}{\varepsilon})^{m(d+1)}$ time.

Proof. Let $\overline{Q} = (x_1, x_2, \dots, x_m) \in \mathcal{I}_i$, and let τ be an alignment with $\sigma_{p,2}(\tau(C_i, \overline{Q})) \leq (1+\frac{\varepsilon}{2})$. For each $1 \leq k \leq m$ let j_k be the smallest index such that $(j_k, k) \in \tau$. In other words, j_k is the smallest index that is matched to k by the alignment τ.

Set $R_k = \|x_k - p^i_{j_k}\|_2$, then we have $\|(R_1, \dots, R_m)\|_p \leq \sigma_{p,2}(\tau(C_i, \overline{Q})) \leq (1+\frac{\varepsilon}{2})$.

Let $\alpha_k = \left\lceil \frac{m^{1/p}}{\varepsilon} R_k \right\rceil$. By triangle inequality,

$$\begin{aligned} \|(\alpha_1, \alpha_2, \dots, \alpha_m)\|_p &\leq \frac{m^{1/p}}{\varepsilon}\|(R_1, R_2, \dots, R_m)\|_p + m^{1/p} \\ &\leq \frac{m^{1/p}}{\varepsilon}\left(1 + \frac{\varepsilon}{2}\right) + m^{1/p} < \left(2 + \frac{1}{\varepsilon}\right) m^{1/p}. \end{aligned}$$

Clearly, $x_k \in B_2^d(p^i_{j_k}, \alpha_k \frac{\varepsilon}{m^{1/p}})$.

We conclude that for each curve $\overline{Q} = (x_1, x_2, \ldots, x_m) \in \mathcal{I}_i$ there exists an alignment τ such that $\sigma_{p,2}(\tau(C_i, \overline{Q})) \leq 1 + \frac{\varepsilon}{2}$, and a sequence of integers $(\alpha_1, \ldots, \alpha_m)$ such that $\|(\alpha_1, \alpha_2, \ldots, \alpha_m)\|_p \leq (2 + \frac{1}{\varepsilon})m^{1/p}$ and $x_k \in B_2^d(p^i_{j_k}, \alpha_k \frac{\varepsilon}{m^{1/p}})$, for $k = 1, \ldots, m$. Therefore, the number of curves in $\mathcal{I}_i$ is bounded by the multiplication of three numbers:

1. The number of alignments that can determine the distance, which is at most 2^{2m} by Lemma 4.
2. The number of ways to choose a sequence of m positive integers $\alpha_1, \ldots, \alpha_m$ such that $\|(\alpha_1, \alpha_2, \ldots, \alpha_m)\|_p \leq (2 + \frac{1}{\varepsilon})m^{1/p}$, which is bounded by the number of lattice points in $B_p^m((2 + \frac{1}{\varepsilon})m^{1/p})$ (the m-dimensional ℓ_p-ball of radius $(2 + \frac{1}{\varepsilon})m^{1/p}$). By Lemma 5, this number is bounded by

$$V_p^m((2 + \frac{1}{\varepsilon})m^{1/p} + m^{1/p}) \leq V_p^m(\frac{4m^{1/p}}{\varepsilon}) = \frac{2^m \Gamma(1 + 1/p)^m}{\Gamma(1 + m/p)} \left(\frac{4m^{1/p}}{\varepsilon}\right)^m = O(\frac{1}{\varepsilon})^m \ ,$$

   where the last equality follows as $\frac{m^{m/p}}{\Gamma(1+m/p)} = O(1)^m$.
3. The number of ways to choose a curve $(x_1, x_2, \ldots, x_m)$, such that $x_k \in G(p^i_{j_k}, \alpha_k \frac{\varepsilon}{m^{1/p}})$, for $k = 1, \ldots, m$. By Corollary 12, the number of grid points in $G(p^i_{j_k}, \alpha_k \frac{\varepsilon}{m^{1/p}})$ is $O(1+\alpha_k)^d$, so the number of ways to choose $(x_1, x_2, \ldots, x_m)$ is at most $\Pi_{k=1}^m O(1+\alpha_k)^d = O(1)^{md} \left(\Pi_{k=1}^m (1 + \alpha_k)\right)^d$. By the inequality of arithmetic and geometric means we have

$$\begin{aligned}
(\Pi_{k=1}^m (1 + \alpha_k)^p)^{1/p} &\leq \left(\frac{\sum_{k=1}^m (1 + \alpha_k)^p}{m}\right)^{m/p} = \left(\frac{\|(1 + \alpha_1, \ldots, 1 + \alpha_m)\|_p}{m^{1/p}}\right)^m \\
&\leq \left(\frac{\|1\|_p + \|(\alpha_1, \ldots, \alpha_m)\|_p}{m^{1/p}}\right)^m \\
&\leq \left(\frac{m^{1/p} + (2 + \frac{1}{\varepsilon})m^{1/p}}{m^{1/p}}\right)^m = O(\frac{1}{\varepsilon})^m,
\end{aligned}$$

   so $\Pi_{k=1}^m O(1 + \alpha_k)^d = O(1)^{md} O(\frac{1}{\varepsilon})^{md} = O(\frac{1}{\varepsilon})^{md}$.

Finally, $|\mathcal{I}_i| \leq 2^{2m} \cdot O(\frac{1}{\varepsilon})^m \cdot O(\frac{1}{\varepsilon})^{md} \leq O(\frac{1}{\varepsilon})^{m(d+1)}$. ◁

The data structure and query algorithm are similar to those we described for DFD, and the size of $\mathcal{I}_i$ and $\mathcal{I}$ is roughly the same (here there is an additional $O(\frac{1}{\varepsilon})^m$ factor in the space bound). Therefore, the query time, storage space, and preprocessing time are roughly similar, but we still need to show that the algorithm is correct.

Correctness. Consider a query curve $Q = (q_1, \ldots, q_m)$. Assume that there exists a curve $C_i \in \mathcal{C}$ such that $d_{p,2}(C_i, Q) \leq 1$. We will show that the query algorithm returns a curve C^* with $d_{p,2}(C^*, Q) \leq 1 + \varepsilon$.

Consider a point $q_k \in Q$. Denote by $q'_k \in \mathcal{G}$ the grid point closest to q_k, and let $Q' = (q'_1, \ldots, q'_m)$. We have $\|q_k - q'_k\|_2 \leq \frac{\varepsilon}{2(2m)^{1/p}}$. Let τ be an alignment such that the $\ell_{p,2}$-cost of τ w.r.t. C_i and Q is at most 1. Unlike the Fréchet distance, $\ell_{p,2}$-distance for curves does not satisfy the triangle inequality. However, by the triangle inequality under ℓ_2 and ℓ_p, we get that the $\ell_{p,2}$-cost of τ w.r.t. C_i and Q' is

$$\sigma_{p,2}(\tau(C_i,Q')) = \left(\sum_{(j,t)\in\tau} \|p^i_j - q'_t\|_2^p\right)^{1/p} \leq \left(\sum_{(j,t)\in\tau} \left(\|p^i_j - q_t\|_2 + \|q_t - q'_t\|_2\right)^p\right)^{1/p}$$
$$\leq \left(\sum_{(j,t)\in\tau} \|p^i_j - q_t\|_2^p\right)^{1/p} + \left(\sum_{(j,t)\in\tau} \|q_t - q'_t\|_2^p\right)^{1/p}$$
$$\leq 1 + \left(2m\left(\frac{\varepsilon}{2(2m)^{1/p}}\right)^p\right)^{1/p} \leq 1 + \frac{\varepsilon}{2}.$$

So $d_{p,2}(C_i, Q') \leq 1 + \frac{\varepsilon}{2}$, and thus Q' is in $I_i \subseteq \mathcal{I}$. This means that $\mathcal{T}$ contains Q' with a curve $C(Q') \in \mathcal{C}$ such that $d_{p,2}(C(Q'), Q') \leq 1 + \frac{\varepsilon}{2}$, and the query algorithm returns $C(Q')$. Now, again by the same argument (using an alignment with $\ell_{p,2}$-cost at most $1 + \frac{\varepsilon}{2}$ w.r.t. $C(Q')$ and Q'), we get that $d_{p,2}(C(Q'), Q) \leq 1 + \frac{\varepsilon}{2} + \left(2m\left(\frac{\varepsilon}{2(2m)^{1/p}}\right)^p\right)^{1/p} = 1 + \varepsilon$.

We obtain the following theorem.

▶ **Theorem 14.** *There exists a data structure for the $(1+\varepsilon, r)$-ANNC under $\ell_{p,2}$-distance, with $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ space, $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ expected preprocessing time, and $O(md)$ query time.*

As mentioned in the preliminaries section, the DTW distance between two curves equals to their $\ell_{1,2}$-distance, and therefore we obtain the following theorem.

▶ **Theorem 15.** *There exists a data structure for the $(1+\varepsilon, r)$-ANNC under DTW, with $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ space, $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ expected preprocessing time, and $O(md)$ query time.*

▶ Remark 16 (Dealing with query curves and input curves of varying size). For the case of DFD, our assumption that all query curves are of length exactly k can be easily removed, by constructing k data structures $\mathcal{D}_1, \ldots, \mathcal{D}_k$, where $\mathcal{D}_i$ is our data structure constructed for query curves of length i (instead of k), for $1 \leq i \leq k$. Clearly, the query time does not change. The storage space is multiplied by k, so in the case of DFD we have storage space $nk \cdot O(\frac{1}{\varepsilon})^{kd}$, but $k < 2^{kd}$, so the storage space remains $n \cdot O(\frac{1}{\varepsilon})^{kd}$.

For the case of $d_{p,2}$ we can deal with queries of all sizes up to m. Our construction in Section 5 can be modified in a straightforward manner to deal with queries of size k, the space guarantee however will depend on m, upper bounded by $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$, as in Theorem 14. From here, we can use the same approach as above.

6 A deterministic construction using a prefix tree

When implementing the dictionary $\mathcal{D}$ as a hash table, the construction of the data structure is randomized and thus in the worst case we might get higher prepeocessing time. To avoid this, we can implement $\mathcal{D}$ as a prefix tree.

6.1 Discrete Fréchet distance

In this section we describe the implementation of $\mathcal{D}$ as a prefix tree in the case of ANNC under DFD.

We can construct a prefix tree $\mathcal{T}$ for the curves in $\mathcal{I}$, where any path in $\mathcal{T}$ from the root to a leaf corresponds to a curve that is stored in it. For each $1 \leq i \leq n$ and curve $\overline{Q} \in \mathcal{I}_i$, if $\overline{Q} \notin \mathcal{T}$, insert $\overline{Q}$ into $\mathcal{T}$, and set $C(\overline{Q}) \leftarrow C_i$.

Each node $v \in \mathcal{T}$ corresponds to a grid point from $\mathcal{G}$. Denote the set of v's children by $N(v)$. We store with v a multilevel search tree on $N(v)$, with a level for each coordinate. The points in $\mathcal{G}$ are the grid points contained in nm balls of radius $(1+\varepsilon)r$. Thus when projecting these points to a single dimension, the number of 1-dimensional points is at most $nm \cdot \frac{\sqrt{d}(1+\varepsilon)2r}{\varepsilon r} = O(\frac{nm\sqrt{d}}{\varepsilon})$. So in each level of the search tree on $N(v)$ we have $O(\frac{nm\sqrt{d}}{\varepsilon})$ 1-dimensional points, so the query time is $O(d\log(\frac{nmd}{\varepsilon}))$.

Inserting a curve of length m to the tree $\mathcal{T}$ takes $O(md\log(\frac{nmd}{\varepsilon}))$ time. Since $\mathcal{T}$ is a compact representation of $|\mathcal{I}| = n \cdot O(\frac{1}{\varepsilon})^{dm}$ curves of length m, the number of nodes in $\mathcal{T}$ is $m \cdot |\mathcal{I}| = nm \cdot O(\frac{1}{\varepsilon})^{dm}$. Each node $v \in \mathcal{T}$ contains a search tree for its children of size $O(d \cdot |N(v)|)$, and $\sum_{v\in\mathcal{T}} |N(v)| = nm \cdot O(\frac{1}{\varepsilon})^{dm}$ so the total space complexity is $O(nmd) \cdot O(\frac{1}{\varepsilon})^{md} = n \cdot O(\frac{1}{\varepsilon})^{md}$. Constructing $\mathcal{T}$ takes $O(|\mathcal{I}| \cdot md\log(\frac{nmd}{\varepsilon})) = n\log(\frac{nmd}{\varepsilon}) \cdot O(\frac{1}{\varepsilon})^{md}$ time.

▶ **Theorem 17.** *There exists a data structure for the* $(1+\varepsilon, r)$*-ANNC under DFD, with* $n \cdot O(\frac{1}{\varepsilon})^{dm}$ *space,* $n \cdot \log(\frac{n}{\varepsilon}) \cdot O(\frac{1}{\varepsilon})^{md}$ *preprocessing time, and* $O(md\log(\frac{nmd}{\varepsilon}))$ *query time.*

Similarly, for the asymmetric case we obtain the following theorem.

▶ **Theorem 18.** *There exists a data structure for the asymmetric* $(1+\varepsilon, r)$*-ANNC under DFD, with* $n \cdot O(\frac{1}{\varepsilon})^{dk}$ *space,* $nm\log(\frac{n}{\varepsilon}) \cdot \big(O(d\log m) + O(\frac{1}{\varepsilon})^{kd}\big)$ *preprocessing time, and* $O(kd\log(\frac{nkd}{\varepsilon}))$ *query time.*

6.2 $\ell_{p,2}$-distance

For the case of ANNC under $\ell_{p,2}$-distance, the total number of curves stored in the tree $\mathcal{T}$ is roughly the same as in the case of DFD. We only need to show that for a given node v of the tree $\mathcal{T}$, the upper bound on the size and query time of the search tree associated with it are similar.

The grid points corresponding to the nodes in $N(v)$ are from n sets of m balls with radius $(1+\varepsilon)$. When projecting the grid points in one of the balls to a single dimension, the number of 1-dimensional points is at most $\frac{m^{1/p}\sqrt{d}}{\varepsilon} \cdot (1+\varepsilon)$, so the total number of projected points is at most $\frac{nm^{1+\frac{1}{p}}\sqrt{d}}{\varepsilon} \cdot (1+\varepsilon)$.

Thus in each level of the search tree of v we have $O(\frac{nm^2\sqrt{d}}{\varepsilon})$ 1-dimensional points, so the query time is $O(d\log(\frac{nmd}{\varepsilon}))$, and inserting a curve of length m into the tree $\mathcal{T}$ takes $O(md\log(\frac{nmd}{\varepsilon}))$ time. Note that the size of the search tree of v remains $O(d \cdot |N(v)|)$.

We conclude that the total space complexity is $O(\frac{nm^2\sqrt{d}}{\varepsilon}) \cdot O(\frac{1}{\varepsilon})^{m(d+1)} = n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$, constructing $\mathcal{T}$ takes $O(|\mathcal{I}| \cdot md\log(nmd/\varepsilon)) = n\log(\frac{n}{\varepsilon}) \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ time, and the total query time is $O(md\log(\frac{nmd}{\varepsilon}))$.

▶ **Theorem 19.** *There exists a data structure for the* $(1+\varepsilon, r)$*-ANNC under* $\ell_{p,2}$*-distance, with* $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ *space,* $n \cdot \log(\frac{n}{\varepsilon}) \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ *preprocessing time, and* $O(md\log(\frac{nmd}{\varepsilon}))$ *query time.*

7 Approximate range counting

In the range counting problem for curves, we are given a set $\mathcal{C}$ of n curves, each consisting of m points in d dimensions, and a distance measure for curves δ. The goal is to preprocess $\mathcal{C}$ into a data structure that given a query curve Q and a threshold value r, returns the number of curves that are within distance r from Q.

In this section we consider the following approximation version of range counting for curves, in which r is part of the input (see Remark 22). Note that by storing pointers to curves instead of just counters, we can obtain a data structure for the approximate range searching problem (at the cost of an additional $O(n)$-factor to the storage space).

▶ **Problem 20** ($(1+\varepsilon, r)$-approximate range-counting for curves). *Given a parameter r and $0 < \varepsilon \le 1$, preprocess $\mathcal{C}$ into a data structure that given a query curve Q, returns the number of all the input curves whose distance to Q is at most r plus possibly additional input curves whose distance to Q is greater than r but at most $(1+\varepsilon)r$.*

We construct the dictionary $\mathcal{D}$ (implemented as a dynamic hash table, or a prefix tree) for the curves in $\mathcal{I}$ as in Section 5, as follows. For each $1 \le i \le n$ and curve $\overline{Q} \in \mathcal{I}_i$, if $\overline{Q}$ is not in $\mathcal{D}$, insert it into $\mathcal{D}$ and initialize $C(\overline{Q}) \leftarrow 1$. Otherwise, if $\overline{Q}$ is in $\mathcal{D}$, update $C(\overline{Q}) \leftarrow C(\overline{Q}) + 1$. Notice that $C(\overline{Q})$ holds the number of curves from $\mathcal{C}$ that are within distance $(1+\frac{\varepsilon}{2})r$ to $\overline{Q}$. Given a query curve Q, we compute Q' as in Section 5. If Q' is in $\mathcal{D}$, we return $C(Q')$, otherwise, we return 0.

Clearly, the storage space, preprocessing time, and query time are similar to those in Section 5. We claim that the query algorithm returns the number of curves from $\mathcal{C}$ that are within distance r to Q plus possibly additional input curves whose distance to Q is greater than r but at most $(1+\varepsilon)r$. Indeed, let C_i be a curve such that $d_{dF}(C_i, Q) \le r$. As shown in Section 5 we get $d_{p,2}(C_i, Q') \le (1+\frac{\varepsilon}{2})r$, so Q' is in $\mathcal{I}_i$ and C_i is counted in $C(Q')$. Now let C_i be a curve such that $d_{p,2}(C_i, Q) > (1+\varepsilon)r$. If $d_{p,2}(C_i, Q') \le (1+\frac{\varepsilon}{2})r$, then by a similar argument (switching the rolls of Q and Q') we get that $d_{p,2}(C_i, Q') \le (1+\varepsilon)r$, a contradiction. So $d_{p,2}(C_i, Q') > (1+\frac{\varepsilon}{2})r$, and thus C_i is not counted in $C(Q')$.

We obtain the following theorem.

▶ **Theorem 21.** *There exists a data structure for the $(1+\varepsilon, r)$-approximate range-counting for curves under $\ell_{p,2}$-distance, with $n \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ space, $n \log(\frac{n}{\varepsilon}) \cdot O(\frac{1}{\varepsilon})^{m(d+1)}$ preprocessing time, and $O(md \log(\frac{nmd}{\varepsilon}))$ query time. (Under DFD, the exponent in the bounds for the space and preprocessing time is md rather than $m(d+1)$.)*

▶ Remark 22. When the threshold parameter r is part of the query, we call the problem the $(1+\varepsilon)$-*approximate range-counting problem.* Note that the reduction from $(1+\varepsilon)$-approximate nearest-neighbor to $(1+\varepsilon, r)$-approximate near-neighbor can be easily adapted to a reduction from $(1+\varepsilon)$-approximate range-counting to $(1+\varepsilon, r)$-approximate range-counting, more details will be given in a full version of this paper.

8 Simplification in d-dimensions

The algorithm of Bereg et al. [3] receives as an input a curve C consisting of m points in $\mathbb{R}^3$, and a parameter $r > 0$. In $O(m \log m)$ time, it returns a curve Π such that $d_{dF}(C, \Pi) \le r$, and Π has the minimum number of vertices among all curves within distance r from C. The algorithm is operating in a greedy manner, by repeatedly executing Megiddo's [19] minimum enclosing ball (MEB) algorithm for points in $\mathbb{R}^3$, which takes linear time.

We generalize the algorithm of Bereg et al. for curves in $\mathbb{R}^d$, by using an algorithm presented by Kumar et al. [17] for approximated minimum enclosing ball (AMEB) in $\mathbb{R}^d$. Formally, given a set A of n points in $\mathbb{R}^d$ and a parameter $\varepsilon \in (0, 1]$, the goal is to find an enclosing ball of A with radius $r > 0$, where the minimum enclosing ball of A has radius at least $\frac{r}{1+\varepsilon}$. The algorithm of [17] can find an AMEB in $O(\frac{nd}{\varepsilon} + \varepsilon^{-4.5} \log \frac{1}{\varepsilon})$ time. In particular, given an additional parameter $r > 0$, this algorithm either returns an enclosing ball of A with radius $(1+\varepsilon)r$, or declares that the minimum enclosing ball of A has radius larger than r.

Next, we describe our modified algorithm. Consider a curve $C = (x_1, \ldots, x_m)$, and denote $C[i,j] = (x_i, \ldots, x_j)$. The following sub-procedure takes as an input a curve A and returns a point y and an index s, such that the ball with radius $(1+\varepsilon)r$ centered at y covers the prefix $A[1,s]$, and (if $s < |A|$) the minimum enclosing ball of $A[1,s+1]$ has radius larger than r.

1. By iterative probing, using an algorithm for AMEB, find some t such that $A[1,2^t]$ can be covered by a ball of radius $(1+\varepsilon)r$, while $A[1,2^{t+1}]$ cannot be covered by a ball of radius r. If all the points in A can be enclosed by a single ball of radius $(1+\varepsilon)r$ centered at y, simply return y and $|A|$.
2. By binary search, again using an algorithm for AMEB, find some $s \in [2^t, 2^{t+1})$ such that $A[1,s]$ can be covered by a ball of radius $(1+\varepsilon)r$, and $A[1,s+1]$ cannot be covered by a ball of radius r. Let $y \in \mathbb{R}^d$ be the center of this ball. Return y and s.

Starting from the input $A = C[1,m]$, repeat the above sub-procedure such that in each step the input is the suffix of C that was not yet covered by the previous steps (i.e. $A[s+1,m]$). Let $(y_1, \ldots, y_q)$ be the sequence of output points.

Lemma 10 is an easy corollary of the following lemma.

▶ **Lemma 23.** *Let C be a curve consisting of m points in $\mathbb{R}^d$. Given parameters $r > 0$, and $\varepsilon \in (0,1]$, the algorithm above runs in $O\left(\frac{d \cdot m \log m}{\varepsilon} + m \cdot \varepsilon^{-4.5} \log \frac{1}{\varepsilon}\right)$ time and returns a curve $\Pi = (y_1, \ldots, y_q)$ such that $d_{dF}(C, \Pi) \le (1+\varepsilon)r$. Furthermore, for every curve Π' with less than q points, it holds that $d_{dF}(C, \Pi') > r$.*

Proof sketch. We start by analyzing the running time for a single iteration of the sub-procedure, when using the algorithm of [17] to find an AMEB. The total time for the first step of the sub-procedure (finding t) is

$$\sum_{i=1}^{t+1} O(\frac{2^i \cdot d}{\varepsilon} + \varepsilon^{-4.5} \log \frac{1}{\varepsilon}) = O(\frac{2^t \cdot d}{\varepsilon} + t \cdot \varepsilon^{-4.5} \log \frac{1}{\varepsilon}).$$

In the second step, there are $O(t)$ executions of [17] on a set of size at most 2^{t+1}, so the total time for this step is $t \cdot O(\frac{2^t \cdot d}{\varepsilon} + \varepsilon^{-4.5} \log \frac{1}{\varepsilon})$.

Let m_i be the length of the subcurve covered by the point y_i that was found in the i'th iteration of the sub-procedure. The total time spent for finding y_i is therefore $\log m_i \cdot O(\frac{m_i \cdot d}{\varepsilon} + \varepsilon^{-4.5} \log \frac{1}{\varepsilon})$, and the total running time of the algorithm is

$$\sum_{i=1}^{q} \log m_i \cdot O\left(\frac{m_i \cdot d}{\varepsilon} + \varepsilon^{-4.5} \log \frac{1}{\varepsilon}\right) = O\left(\frac{d \cdot m \log m}{\varepsilon} + m \cdot \varepsilon^{-4.5} \log \frac{1}{\varepsilon}\right) ,$$

where we used the the concavity of the log function, and the fact $\sum_{i=1}^{q} m_i = m$.

Next we argue the correctness. Clearly, $d_{dF}(C, \Pi) \le (1+\varepsilon)r$. Let $s_0 = 0, s_1, \ldots, s_q = m$ be the sequence of indices (of vertices in C) found during the execution of the algorithm, such that the ball of radius $(1+\varepsilon)r$ around y_i covers $C[s_{i-1}+1, s_i]$. It follows by a straightforward induction that every curve Π' with less that i points will be at distance greater than r from $C[1, s_{i-1}+1]$. The lemma now follows. ◀

9 Remark on dimension reduction

In general, when the dimension d is large, i.e. $d \gg \log(nm)$, one can use dimension reduction (using the celebrated Johnson-Lindenstrauss lemma [16]) in order to achieve a better running time, at the cost of inserting randomness in the prepossessing and query procedure. However, such an approach can work only against an oblivious adversary, as it will necessarily fail for some curves. Recently Narayanan and Nelson [20] (improving [11, 18]) proved a terminal version of the JL-lemma. Given a set K of k points in $\mathbb{R}^d$ and $\varepsilon \in (0,1)$, there is a dimension reduction function $f : \mathbb{R}^d \to \mathbb{R}^{O(\frac{\log k}{\varepsilon^2})}$ such that for every $x \in K$ and $y \in \mathbb{R}^d$ it holds that $\|x-y\|_2 \leq \|f(x)-f(y)\|_2 \leq (1+\varepsilon)\cdot\|x-y\|_2$.

This version of dimension reduction can be used such that the query remains deterministic and always succeeds. The idea is to take all the nm points from all the input curves to be the terminals, and let f be the terminal dimension reduction. We transform each input curve $P = (p_1,\dots,p_m)$ into $f(P) = (f(p_1),\dots,f(p_m))$, a curve in $\mathbb{R}^{O(\frac{\log nm}{\varepsilon^2})}$. Given a query $Q = (q_1,\dots,q_m)$ we transform it to $f(Q) = (f(q_1),\dots,f(q_m))$. Since the pairwise distances between every query point to all input points are preserved, so is the distance between the curves. Specifically, the $d_{p,2}$ distance w.r.t. any alignment τ is preserved up to a $1+\varepsilon$ factor, and therefore we can reliably use the answer received using the transformed curves.

Abstract

We prove that the Hadwiger number of an n-vertex graph G (the maximum size of a clique minor in G) cannot be computed in time $n^{o(n)}$, unless the Exponential Time Hypothesis (ETH) fails. This resolves a well-known open question in the area of exact exponential algorithms. The technique developed for resolving the Hadwiger number problem has a wider applicability. We use it to rule out the existence of $n^{o(n)}$-time algorithms (up to ETH) for a large class of computational problems concerning edge contractions in graphs.

1 Introduction

The *Hadwiger number* $h(G)$ of a graph G is the largest number h for which the complete graph K_h is a minor of G. Equivalently, $h(G)$ is the maximum size of the largest complete graph that can be obtained from G by contracting edges. It is named after Hugo Hadwiger, who conjectured in 1943 that the Hadwiger number of G is always at least as large as its chromatic number. According to Bollobás, Catlin, and Erdős, this conjecture remains "one of the deepest unsolved problems in graph theory" [4].

The Hadwiger number of an n-vertex graph G can be easily computed in time $n^{\mathcal{O}(n)}$ by brute-forcing through all possible partitions of the vertex set of G into connected sets, contracting each set into one vertex and checking whether the resulting graph is a complete graph. The question whether the Hadwiger number of a graph can be computed in single-exponential $2^{\mathcal{O}(n)}$ time was previously asked in [1, 6, 13]. Our main result provides a negative answer to this open question.

▶ **Theorem 1.** *Unless the Exponential Time Hypothesis (ETH) is false, there does not exist an algorithm computing the Hadwiger number of an n-vertex graph in time $n^{o(n)}$.*

The interest in the complexity of the Hadwiger number is naturally explained by the recent developments in the area of exact exponential algorithms, that is, algorithms solving intractable problems significantly faster than the trivial exhaustive search, though still in exponential time [8]. Within the last decade, significant progress on upper and lower bounds of exponential algorithms has been achieved. Drastic improvements over brute-force algorithms were obtained for a number of fundamental problems like Graph Coloring [3] and Hamiltonicity [2]. On the other hand, by making use of the ETH, lower bounds could be obtained for 2-CSP [15] or for Subgraph Isomorphism and Graph Homomorphism [6].

Graph Minor (deciding whether a graph G contains a graph H as a minor) is a fundamental problem in graph theory and graph algorithms. Graph Minor could be seen as special case of a general graph embedding problem where one wants to embed a graph H into graph G. In what follows we will use n to denote the number of vertices in G and h to denote the number of vertices in H. By the theorem of Robertson and Seymour [14], there exists a computable function f and an algorithm that, for given graphs G and H, checks in time $f(h) \cdot n^3$ whether H is a minor of G. Thus the problem is fixed-parameter tractable (FPT) being parameterized by H. On the other hand, Cygan et al. [6] proved that unless the ETH fails, this problem cannot be solved in time $n^{o(n)}$ even in the case when $|V(G)| = |V(H)|$. Other interesting embedding problems that are strongly related to Graph Minor include the following problems.

- Subgraph Isomorphism: Given two graphs G and H, decide whether G contains a subgraph isomorphic to H. This problem cannot be solved in time $n^{o(n)}$ when $|V(G)| = |V(H)|$, unless the ETH fails [6]. In the special case called Clique, when H is a clique, a brute-force algorithm checking for every vertex subset of G whether it is a clique of size h solves the problem in time $n^{\mathcal{O}(h)}$. The same algorithm also runs in single-exponential time $\mathcal{O}(2^n n^2)$. It is also known that Clique is W[1]-hard parameterized by h and cannot be solved in time $f(h) \cdot n^{o(h)}$ for any function f unless the ETH fails [7, 5].
- Graph Homomorphism: Given two graphs G and H, decide whether there exists a homomorphism from G to H. (A *homomorphism* $G \to H$ from an undirected graph G to an undirected graph H is a mapping from the vertex set of G to that of H such that the image of every edge of G is an edge of H.) This problem is trivially solvable in time $h^{\mathcal{O}(n)}$, and an algorithm of running time $h^{o(n)}$ for this problem would yield the failure of

the ETH [6]. However, for the special case of H being a clique, Graph Homomorphism is equivalent to h-Coloring (deciding whether the chromatic number of G is at most h), and thus is solvable in single-exponential time $2^n \cdot n^{\mathcal{O}(1)}$ [3, 12]. When the graph G is a complete graph, the problem is equivalent to finding a clique of size n in H, and then is solvable in time $2^h \cdot h^{\mathcal{O}(1)}$.

- Topological Graph Minor: Given two graphs G and H, decide whether G contains H as a topological minor. (We say that a graph H is a subdivision of a graph G if G can be obtained from H by contracting only edges incident with at least one vertex of degree two. A graph H is called a *topological minor* of a graph G if a subdivision of H is isomorphic to a subgraph of G.) This problem is, perhaps, the closest "relative" of Graph Minor. Grohe et al. [11] gave an algorithm of running time $f(h) \cdot n^3$ for this problem for some computable function f. Similar to Graph Minor and Subgraph Isomorphism, this problem cannot be solved in time $n^{o(n)}$ when $|V(G)| = |V(H)|$, unless the ETH fails [6]. However for the special case of the problem with H being a complete graph, Lingas and Wahlen [13] gave a single-exponential algorithm solving the problem in time $2^{\mathcal{O}(n)}$.

Thus all the above graph embedding "relatives" of Graph Minor are solvable in single-exponential time when graph H is a clique. However, from the perspective of exact exponential algorithms, Theorem 1 implies that finding the largest clique minor is the most difficult problem out of them all. This is why we find the lower bound provided by Theorem 1 surprising. Moreover, from the perspective of parameterized complexity, finding a clique minor of size h, which is FPT, is actually easier than finding a clique (as a subgraph) of size h, which is W[1]-hard, as well as from finding an h-coloring of a graph, which is para-NP-hard.

Theorem 1 also answers another question of Cygan et al. [6], who asked whether deciding if a graph H can be obtained from a graph G only by edge contractions, could be resolved in single-exponential time. By Theorem 1, the existence of such an algorithm is highly unlikely even when the graph H is a complete graph. Moreover, the technique developed to prove Theorem 1, appears to be extremely useful to rule out the existence of $n^{o(n)}$-time algorithms for various contraction problems. We formalize our results with the following $\mathcal{F}$-Contraction problem. Let $\mathcal{F}$ be a graph class. Given a graph G and $t \in \mathbb{N}$, the task is to decide whether there exists a subset $F \subseteq E(G)$ of size at most t such that $G/F \in \mathcal{F}$ (where G/F is the graph obtained from G by contracting the edges in F). We prove that in each of the cases of $\mathcal{F}$-Contraction where $\mathcal{F}$ is the family of chordal graphs, interval graphs, proper interval graphs, threshold graphs, trivially perfect graphs, split graphs, complete split graphs and perfect graphs, unless the ETH fails, $\mathcal{F}$-Contraction is not solvable in time $n^{o(n)}$. For lack of space, some of these results are relegated to the full version of this paper (see [9]).

Technical Details. A summary of the reductions presented in this paper is given in Fig. 1. To prove our lower bounds, we first revisit the proof of Cygan et al. [6] for the ETH-hardness of a problem called List Subgraph Isomorphism. Informally, in this problem we are given two graphs G and H on the same number of vertices, as well as a list of vertices in H for each vertex in G, and we need to find a copy of G in H so that each vertex u in G is mapped to a vertex v in H that belongs to its list (i.e. v belongs to the list of u). We prove that the instances produced by the reduction (after some modification) of [6] have a very useful property that we crucially exploit later. Specifically, we construct a proper coloring of G as well as a proper coloring of H, and show that every vertex v in H that belongs to the list of some vertex u is, in fact, of the same color as u.

Figure 1 A summary of the problems considered in this paper, and the reductions between them.

Having proved the above, we turn to prove the ETH-hardness of a special case of Clique Contraction where the input graph is highly structured. To this end, we introduce an intermediate problem called Cross Matching. Informally, in this problem we are given a graph L with a partition (A, B) of its vertex set, and need to find a perfect matching between A and B whose contraction gives a clique. To see the connection between this problem and List Subgraph Isomorphism, think of the subgraph of L induced by one side of the partition – say, A – as a representation of the *complement* of G, and the subgraph of L induced by the other side of the partition as a representation of H. Then, the edges that go across A and B in a perfect matching can be thought of as a mapping of the vertices of G to the vertices of H. The crossing edges of L are easily defined such that necessarily a vertex of G can only be matched to a vertex in its list. In particular, we would like to enforce that every "non-edge" of the complement of G (which corresponds to an edge of G) would have to be mapped to an edge of H in order to obtain a clique. However, the troublesome part is that non-edges of the complement of G may also be "filled" (to eventually get a clique) using crossing edges rather than only edges of H. To argue that this critical issue does not arise, we crucially rely on the proper colorings of G and H.

Now, for the connection between Cross Matching and Clique Contraction, note that a solution to an instance of Cross Matching is clearly a solution to the instance of Clique Contraction defined by the same graph, but the other direction is not true. By adding certain vertices and edges to the graph of an instance of Cross Matching, we enforce all solutions to be perfect matchings between A and B. In particular, we construct the instances of Clique Contraction in a highly structured manner that allows us to derive not only the ETH-hardness of Clique Contraction itself, but to build upon them and further derive ETH-hardness for a wide variety of other contraction problems. In particular, we show that the addition of "noise" (that is, extra vertices and edges) to any structured instance of Clique Contraction has very limited effect. Roughly speaking, we show that the edges in the "noise" and the edges going across the "noise" and core of the graph (that is, the original vertices corresponding to the structured instance of Clique Contraction) are not "helpful" when trying to create a clique on the core (i.e. it is not helpful to try to use these edges in order to fill non-edges between vertices in the core). Depending on the contraction problem at hand, the noise is slightly different, but the proof technique stays the same – first showing that the core must yield a clique, and then using the argument above (in fact, in all cases but that of perfect graphs, we are able to invoke the argument as a black box) to show that the noise is, in a sense, irrelevant.

Preliminaries. As we only use standard notations, we present them only in the full version of this paper.

2 Lower Bound: Prop-Colored List Subgraph Isomorphism

In this section we build upon the work of Cygan et al. [6] and show a lower bound for a problem called Properly Colored List Subgraph Isomorphism (Prop-Col LSI). Intuitively, Prop-Col LSI is a variant of Spanning Subgraph Isomorphism where given two graphs G and H, we ask whether G is isomorphic to some spanning subgraph of H. The input to the variant consists also of proper colorings of G and H and an additional labeling of vertices in G by subsets of vertices in H of the same color, so that each vertex in G can be mapped only to vertices in H contained in its list. Formally, it is defined as follows.

Properly Colored List Subgraph Isomorphism (Prop-Col LSI)
Input: Graphs G and H with proper colorings $c_G : V(G) \to \{1, \dots, k\}$ and $c_H : V(H) \to \{1, \dots, k\}$ for some $k \in \mathbb{N}$, respectively, and a function $\ell : V(G) \to 2^{V(H)}$ such that for every $u \in V(G)$ and $v \in \ell(u)$, $c_G(u) = c_H(v)$.
Question: Does there exist a bijective function $\varphi : V(G) \to V(H)$ such that *(i)* for every $\{u, v\} \in E(G)$, $\{\varphi(u), \varphi(v)\} \in E(H)$, and *(ii)* for every $u \in V(G)$, $\varphi(u) \in \ell(u)$?

Notice that as the function φ above is bijective rather than only injective, we seek a spanning subgraph. Our objective is to prove the following statement.

▶ **Lemma 2.** *Unless the ETH is false, there does not exist an algorithm that solves Prop-Col LSI in time $n^{o(n)}$ where $n = |V(G)|$.*

In [6], the authors considered the two problems defined below. Intuitively, the second is defined as Prop-Col LSI when no proper colorings of H and G are given (and hence the labeling of vertices in G is not restricted accordingly); the first is defined as the second when we seek a homomorphism rather than an isomorphism (i.e., the sought function φ may not be injective) and also $|V(G)|$ may not be equal to $|V(H)|$ (thus φ may neither be onto).

List Subgraph Homomorphism (LSH)
Input: Graphs G and H, and a function $\ell : V(G) \to 2^{V(H)}$.
Question: Does there exist a function $\varphi : V(G) \to V(H)$ such that *(i)* for every $\{u, v\} \in E(G)$, $\{\varphi(u), \varphi(v)\} \in E(H)$, and *(ii)* for every $u \in V(G)$, $\varphi(u) \in \ell(u)$?

List Subgraph Isomorphism (LSI)
Input: Graphs G and H where $|V(G)| = |V(H)|$, and a function $\ell : V(G) \to 2^{V(H)}$.
Question: Does there exist a bijective function $\varphi : V(G) \to V(H)$ such that *(i)* for every $\{u, v\} \in E(G)$, $\{\varphi(u), \varphi(v)\} \in E(H)$, and *(ii)* for every $u \in V(G)$, $\varphi(u) \in \ell(u)$?

The proof of hardness of LSI consists of two parts:

- Showing ETH-hardness of LSH.
- Giving a fine-grained reduction from LSH to LSI.

We cannot use the hardness of LSI as a black box because Prop-Col LSI is a special case of LSI. Nevertheless, we will prove that the instances generated by the reduction (with a minor crucial modification) of Cygan et al. [6] have the additional properties required to make them instances of our special case.

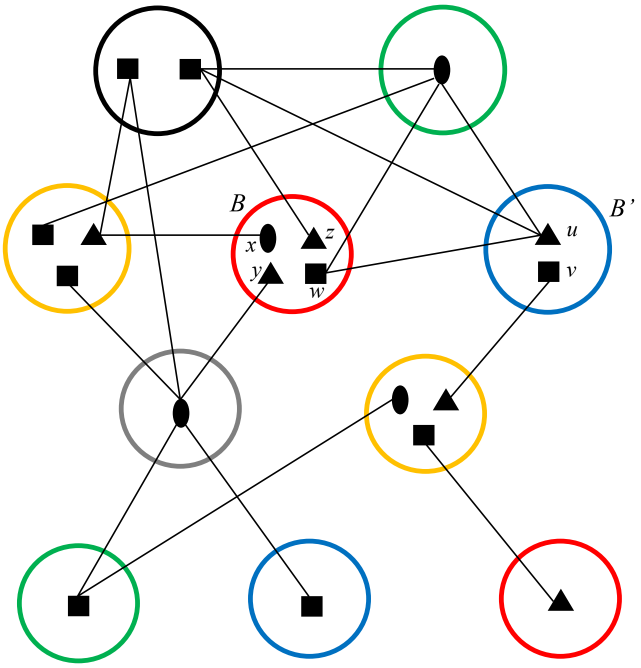

Figure 2 The reduction in Definition 4. The vertices of G are depicted by black shapes, where each distinct shape represents a different color (say, square is 1, rectangle is 2 and oval is 3), and the vertices of $\widetilde{G}$ are depicted by circles enclosing the vertex sets identifies with them, where the color of a vertex is the color of its circle (say, black is 1, green is 2, yellow is 3, red is 4, blue is 5 and grey is 6). Edges (of both graphs) are depicted by black lines. (The graph $\widetilde{H}$ is not shown). Then, the function ϕ_B is defined as follows: $\phi_B(1) = z, \phi_B(2) = \phi_B(5) = w, \phi_B(3) = x, \phi_B(4) = 0$, and $\phi_B(6) = y$. Moreover, the function $\phi_{B'}$ is defined as follows: $\phi_{B'}(1) = \phi_{B'}(2) = \phi_{B'}(4) = u, \phi_{B'}(3) = v$, and $\phi_{B'}(5) = \phi_{B'}(6) = 0$. With respect to B and B', the labeling ℓ is defined as follows: $\ell(B) = \{(R,4) : R[1] \neq 0, R[2] = R[5] \neq 0, R[3] \neq 0, R[4] = 0, R[6] \neq 0\}$, and $\ell(B') = \{(R,5) : R[1] = R[2] = R[4] \neq 0, R[3] \neq 0, R[5] = R[6] = 0\}$.

Lower Bound: Properly Colored Subgraph Homomorphism. Adapting the scheme of Cygan et al. [6] to our purpose, we will first show that finding a homomorphism remains hard if it has to preserve a given proper coloring:

> Properly Colored List Subgraph Homomorphism (Prop-Col LSH)
> **Input:** Graphs G and H with proper colorings $c_G : V(G) \to \{1,\dots,k\}$ and $c_H : V(H) \to \{1,\dots,k\}$ for some $k \in \mathbb{N}$, respectively, and a function $\ell : V(G) \to 2^{V(H)}$ such that for every $u \in V(G)$ and $v \in \ell(u)$, $c_G(u) = c_H(v)$.
> **Question:** Does there exist a function $\varphi : V(G) \to V(H)$ such that *(i)* for every $\{u,v\} \in E(G)$, $\{\varphi(u),\varphi(v)\} \in E(H)$, and *(ii)* for every $u \in V(G)$, $\varphi(u) \in \ell(u)$?

In [6], the authors gave a reduction from the 3-Coloring problem on n-vertex graphs of degree 4 (which is known not to be solvable in time $2^{o(n)}$ unless the ETH fails), which generates equivalent instances (G', H', ℓ) of LSH where both $|V(G')|$ and $|V(H')|$ are bounded by $\mathcal{O}(\frac{n}{\log n})$. This proves that LSH is not solvable in time $n^{o(n)}$ where $n = \max\{|V(G)|, |V(H)|\}$ unless the ETH fails. For their reduction, Cygan et al. [6] considered the notion of a *grouping* (also known as *quotient graph*) $\widetilde{G}$ of a graph G is a graph with vertex set $V(\widetilde{G}) = \{B_1, B_2, \dots, B_t\}$ where $(B_1, B_2, \dots, B_t)$ is a partition of $V(G)$ for some $t \in \mathbb{N}$ and for any distinct $i, j \in \{1,\dots,t\}$, the vertices B_i and B_j are adjacent in $\widetilde{G}$ if and only if there exist $u \in B_i$ and $v \in B_j$ that are adjacent in G. Specifically, they computed a grouping with a coloring having specific properties as stated in the following lemma (see also Fig. 2.).

▶ **Lemma 3** (Lemma 3.2 in [6]). *For any constant $d \geq 1$, there exist positive integers $\lambda = \lambda(d)$, $n_0 = n_0(d)$ and a polynomial time algorithm that for a given graph G on $n \geq n_0$ vertices of maximum degree d and a positive integer $r \leq \sqrt{\frac{n}{2\lambda}}$, finds a grouping $\widetilde{G}$ of G and a coloring $\widetilde{c} : V(\widetilde{G}) \to [\lambda r]$ with the following properties:*

1. $|V(\widetilde{G})| \leq |V(G)|/r$;
2. *The coloring $\widetilde{c}$ is a proper coloring of $\widetilde{G}^2$;*[1]
3. *Each vertex of $\widetilde{G}$ is an independent set in G;*
4. *For any edge $\{B_i, B_j\} \in E(\widetilde{G})$, there exists exactly one pair $(u, v) \in B_i \times B_j$ such that $\{u, v\} \in E(G)$.*

Now, we describe the reduction of [6]. Here, without loss of generality, it is assumed that G has no isolated vertices, else they can be removed. An explanation of the intuition behind this somewhat technical definition is given below it.

▶ **Definition 4.** *For any instance G of 3-Coloring where G has degree d and a positive integer $r = o(\sqrt{|V(G)|})$, the instance* `reduce`$(G) = (\widetilde{G}, \widetilde{H}, \ell)$ *of LSH is defined as follows.*

- ***The graph $\widetilde{G}$.*** *Let $\widetilde{G}$ and $\widetilde{c} : V(\widetilde{G}) \to \{1, 2, \ldots, L\}$ be the grouping and coloring given by Lemma 3 where $L = \lambda(d)r$. Additionally, for each $B \in V(\widetilde{G})$, define $\phi_B : \{1, 2, \ldots, L\} \to B \cup \{0\}$ as follows: for any $i \in \{1, 2, \ldots, L\}$, if there exists (u, v, B') such that $u \in B$ and $v \in B'$, $\{u, v\} \in E(G)$ and $\widetilde{c}(B') = i$, then $\phi_B(i) = u$, and otherwise $\phi_B(i) = 0$.*[2]
- ***The graph $\widetilde{H}$.*** *Let $V(\widetilde{H}) = \{(R, l) : R \in \{0, 1, 2, 3\}^L, l \in L\}$,*[3] *and $E(\widetilde{H}) = \{\{(R, l), (R', l')\} : R[l'] \neq R'[l]\}$.*
- ***The labeling ℓ.*** *For any $B \in V(\widetilde{G})$, let $\ell(B)$ contain all vertices $(R, l) \in V(\widetilde{H})$ such that $\widetilde{c}(B) = l$, and there exists $f : B \to \{1, 2, 3\}$ such that for all $i \in \{1, 2, \ldots, L\}$, either $\phi_B(i) = R[i] = 0$ or both $\phi_B(i) \neq 0$ and $f(\phi_B(i)) = R[i]$.*

Intuitively, for every vertex $B \in V(\widetilde{G})$, the function ϕ_B can be interpreted as follows. It is the assignment, for every possible color $i \in \{1, \ldots, L\}$, of the unique vertex u within the vertex set identified with B itself that is adjacent to some vertex in the vertex subset identified with some vertex $B' \in V(\widetilde{G})$ colored i, if such a vertex u exists (else the assignment is of 0). In a sense, B thus stores the information on the identity of each vertex within it that is adjacent (in G) to some vertex outside of it, where each such internal vertex is uniquely accessed by specifying the color of the vertex in $\widetilde{G}$ whose identified vertex set contains the *neighbor*. With respect to the graph $\widetilde{H}$ and labeling ℓ, we interpret each vertex $(R, l) \in V(\widetilde{H})$ as a "placeholder" (i.e. potential assignment of the sought function φ) for any vertex $B \in V(\widetilde{G})$ that "complies with the pattern encoded by the pair (R, l)" as follows. First and straightforwardly, B must be colored l. Here, we remind that the colors of vertices in $\widetilde{G}$ belong to $\{1, \ldots, L\}$, while vertices in G are colored 1, 2 or 3 only. Then, the second requirement is that we can recolor (by f) the vertices in B so that the color of each vertex in B that is adjacent (in G) to some vertex outside B is as encoded by the vector R – that is, for each color $i \in \{1, \ldots, L\}$, if the vertex $\phi_B(i)$ is defined (i.e., $\phi_B(i) \neq 0$), then its color (which is $1, 2$ or 3) must be equal to the i-th entry of R. (More intuition is given in Fig. 2.)

Now, we state the correctness of the reduction.

[1] The square G^2 of a graph G is the graph on vertex set $V(G)$ and edge set $\{\{u, v\} : \{u, v\} \in E(G)$ or there exists $w \in V(G)$ with $\{u, w\}, \{v, w\} \in E(G)\}$.

[2] The uniqueness of u (if it exists), and thus the validity of ϕ_B, follows from Properties 2 and 4 in Lemma 3.

[3] That is, R is a vector with L entries where each entry is 0, 1, 2 or 3.

▶ **Lemma 5** (Lemma 3.3 in [6]). *For any instance G of 3-Coloring where G is an n-vertex graph of degree d, and a positive integer $r = o(\sqrt{|V(G)|})$, the instance* $\texttt{reduce}(G) = (\widetilde{G}, \widetilde{H}, \ell)$ *is computable in time polynomial in the sizes of $G, \widetilde{G}$ and $\widetilde{H}$, and has the following properties.*

- *G is a Yes-instance of 3-Coloring if and only if $(\widetilde{G}, \widetilde{H}, \ell)$ is a Yes-instance of LSH.*
- *$|V(\widetilde{G})| \le n/r$, and $|V(\widetilde{H})| \le \gamma(d)^r$ where γ is some computable function of d.*

We next prove that we can add colorings to the instance $\texttt{reduce}(G) = (\widetilde{G}, \widetilde{H}, \ell)$ of LSH in order to cast it as an instance of Prop-Col LSH while making a minor mandatory modification to the graph $\widetilde{H}$.

▶ **Lemma 6.** *Given an instance* $\texttt{reduce}(G) = (\widetilde{G}, \widetilde{H}, \ell)$ *of LSH, an equivalent instance $(\widetilde{G}, \widetilde{H}', c_{\widetilde{G}}, c_{\widetilde{H}'}, \ell)$ of Prop-Col LSH, where $\widetilde{H}'$ is a subgraph of $\widetilde{H}$, is computable in polynomial time.*

Proof. Define $c_{\widetilde{G}} = \widetilde{c}$ where $\widetilde{c}$ is the coloring of $\widetilde{G}$ in Definition 4. Additionally, let $\widetilde{H}'$ be the subgraph of $\widetilde{H}$ induced by the vertex set $\{(R, l) \in V(\widetilde{H})$: there exists $B \in V(\widetilde{G})$ such that $(R, l) \in \ell(B)\}$. Then, define $c_{\widetilde{H}'} : V(\widetilde{H}') \to \{1, 2, \dots, L\}$ as follows: for any $(R, l) \in V(\widetilde{H}')$, define $c_{\widetilde{H}'}((R, l)) = l$. Notice that, by the definition of $V(\widetilde{H}')$, every set assigned by ℓ is subset of $V(\widetilde{H}')$.

First, we assert that $(\widetilde{G}, \widetilde{H}', c_{\widetilde{G}}, c_{\widetilde{H}'}, \ell)$ is an instance of Prop-Col LSH. To this end, we need to verify that the three following properties hold.

1. $c_{\widetilde{G}}$ is a proper coloring of $\widetilde{G}$.
2. $c_{\widetilde{H}'}$ is a proper coloring of $\widetilde{H}'$.
3. For every $B \in V(\widetilde{G})$ and $(R, l) \in \ell(B)$, it holds that $c_{\widetilde{G}}(B) = c_{\widetilde{H}'}((R, l))$.

By the definition of $c_{\widetilde{G}}$, it is a proper coloring of $\widetilde{G}^2$, which is a supergraph of $\widetilde{G}$. Thus, $c_{\widetilde{G}}$ is a proper coloring of $\widetilde{G}$.

Now, we argue that $c_{\widetilde{H}'}$ is a proper coloring of $\widetilde{H}'$. To this end, consider some edge $\{(R, l), (R', l')\} \in E(\widetilde{H}')$. We need to show that $c_{\widetilde{H}'}((R, l)) \neq c_{\widetilde{H}'}((R', l'))$. By the definition of $c_{\widetilde{H}'}$, we have that $c_{\widetilde{H}'}((R, l)) = l$ and $c_{\widetilde{H}'}((R', l')) = l'$, and therefore it suffices to show that $l \neq l'$. By the definition of $E(\widetilde{H})$ (which is a superset of $E(\widetilde{H}')$), we have that $R[l'] \neq R'[l]$. Thus, necessarily at least one among $R[l']$ and $R'[l]$ is not 0, and so we suppose w.l.o.g. that $R[l']$ is not 0. Furthermore, since $(R, l) \in V(\widetilde{H}')$, we have that there exists $B \in E(\widetilde{G})$ such that $(R, l) \in \ell(B)$. Thus,

- $\widetilde{c}(B) = l$.
- There exists $f : B \to \{1, 2, 3\}$ such that for all $i \in \{1, 2, \dots, L\}$, either $\phi_B(i) = R[i] = 0$ or both $\phi_B(i) \neq 0$ and $f(\phi_B(i)) = R[i]$.

From the second property, and because $R[l'] \neq 0$, we necessarily have that both $\phi_B(l') \neq 0$ and $f(\phi_B(l')) = R[l']$. In particular, by the definition of ϕ_B, having $\phi_B(l') \neq 0$ means that there exists (u, v, B') such that $u \in B$, $v \in B'$, $\{u, v\} \in E(G)$ and $\widetilde{c}(B') = l'$. By the definition of $\widetilde{G}$ as a grouping of G, having $u \in B$, $v \in B'$ and $\{u, v\} \in E(G)$ implies that $\{B, B'\} \in E(\widetilde{G})$. Because $\widetilde{c}$ is a proper coloring of $\widetilde{G}$, this means that $\widetilde{c}(B) \neq \widetilde{c}(B')$. Since $\widetilde{c}(B) = l$ and $\widetilde{c}(B') = l'$, we derive that $l \neq l'$. Hence, $c_{\widetilde{H}'}$ is indeed a proper coloring of $\widetilde{H}'$.

To conclude that $(\widetilde{G}, \widetilde{H}', c_{\widetilde{G}}, c_{\widetilde{H}'}, \ell)$ is indeed an instance of Prop-Col LSH, it remains to assert that for every $B \in V(\widetilde{G})$ and $(R, l) \in \ell(B)$, it holds that $c_{\widetilde{G}}(B) = c_{\widetilde{H}'}((R, l))$. To this end, consider some $B \in V(\widetilde{G})$ and $(R, l) \in \ell(B)$. By the definition of ℓ (recall Definition 4), $(R, l) \in \ell(B)$ implies that $\widetilde{c}(B) = l$. As $c_{\widetilde{G}} = \widetilde{c}$, we have that $c_{\widetilde{G}}(B) = l$. Moreover, the definition of $c_{\widetilde{H}'}$ directly implies that $c_{\widetilde{H}'}((R, l)) = l$. Thus, $c_{\widetilde{G}}(B) = c_{\widetilde{H}'}((R, l))$.

Finally, we argue that $(\widetilde{G}, \widetilde{H}, \ell)$ is a Yes-instance of LSH if and only if $(\widetilde{G}, \widetilde{H}', c_{\widetilde{G}}, c_{\widetilde{H}'}, \ell)$ is a Yes-instance of Prop-Col LSH. In one direction, because $\widetilde{H}'$ is a subgraph of $\widetilde{H}$, it is immediate that if $(\widetilde{G}, \widetilde{H}', c_{\widetilde{G}}, c_{\widetilde{H}'}, \ell)$ is a Yes-instance of Prop-Col LSH, then so is $(\widetilde{G}, \widetilde{H}, \ell)$. For the other direction, suppose that $(\widetilde{G}, \widetilde{H}, \ell)$ is a Yes-instance of LSH. Thus, there exists a function $\varphi : V(\widetilde{G}) \to V(\widetilde{H})$ such that *(i)* for every $\{B, B'\} \in E(\widetilde{G})$, $\{\varphi(B), \varphi(B')\} \in E(\widetilde{H})$, and *(ii)* for every $B \in V(\widetilde{G})$, $\varphi(B) \in \ell(B)$. In particular, directly by the definition of $V(\widetilde{H}')$, the second condition implies that for every $B \in V(\widetilde{G})$, it holds that $\varphi(B) \in V(\widetilde{H}')$. Thus, because $\widetilde{H}'$ is an induced subgraph of $\widetilde{H}$, it holds that for every $\{B, B'\} \in E(\widetilde{G})$, $\{\varphi(B), \varphi(B')\} \in E(\widetilde{H}')$. Therefore, φ witnesses that $(\widetilde{G}, \widetilde{H}', c_{\widetilde{G}}, c_{\widetilde{H}'}, \ell)$ is a Yes-instance of Prop-Col LSH. ◀

We are now ready to assert the hardness of Prop-Col LSH. The proof, based on Lemmas 3, 5 and 6, can be found in the full version of this paper.

▶ **Lemma 7.** *Unless the ETH is false, there does not exist an algorithm that solves* Prop-Col *LSH in time $n^{o(n)}$ where $n = \max(|V(G)|, |V(H)|)$.*

From Graph Homomorphism to Subgraph Isomorphism. In this part, we observe that the reduction of [6] from LSH to LSI can be essentially used as is to serve as a reduction from Prop-Col LSH to Prop-Col LSI. For the sake of completeness, we give the full details (and the conclusion of the proof of Lemma 2) in the full version of this paper.

3 Lower Bound for the Cross Matching Problem

In this section, towards the proof of a lower bound for Clique Contraction, we prove a lower bound for an intermediate problem called Cross Matching that somewhat resembles Clique Contraction, and which is defined as follows.

Cross Matching
Input: A graph G with a partition (A, B) of $V(G)$ where $|A| = |B|$.
Question: Does there exist a perfect matching M in G such that every edge in M has one endpoint in A and the other in B, and G/M is a clique?

Our objective is to prove the following statement.

▶ **Lemma 8.** *Unless the ETH is false, there does not exist an algorithm that solves* Cross Matching *in time $n^{o(n)}$ where $n = |A|$.*

Proof. Towards a contradiction, suppose that there exists an algorithm, denoted by MatchingAlg, that solves Cross Matching in time $n^{o(n)}$ where n is the number of vertices in the set A in the input. We will show that this implies the existence of an algorithm, denoted by LSIAlg, that solves Prop-Col LSI in time $n^{o(n)}$ where n is the number of vertices in the input graph G, thereby contradicting Lemma 2 and hence completing the proof.

We define the execution of LSIAlg as follows. Given an instance (G, H, c_G, c_H, ℓ) of Prop-Col LSI, LSIAlg constructs an instance (L, A, B) of Cross Matching as follows (see Fig. 3):

- $V(L) = V(\overline{G}) \cup V(H)$.
- $E(L) = E(\overline{G}) \cup E(H) \cup \{\{u, v\} : u \in V(G), v \in L(u)\}$.
- $A = V(\overline{G})$ and $B = V(H)$.

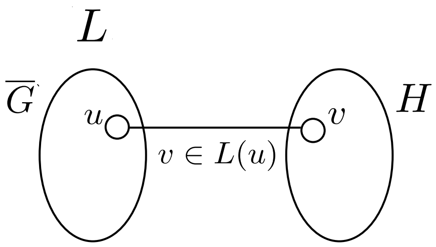

Figure 3 The construction of an instance of Cross Matching in the proof of Lemma 8.

Then, LSIAlg calls MatchingAlg with (L, A, B) as input, and returns the answer of this call.

Denote $n = |V(G)|$, and notice that $|A| = |B| = n$. Thus, because MatchingAlg runs in time $|A|^{o(|A|)} = n^{o(n)}$, so does LSIAlg.

For the correctness of the algorithm, first suppose that (G, H, c_G, c_H, ℓ) is a Yes-instance of Prop-Col LSI. This means that there exists a bijective function $\varphi : V(G) \to V(H)$ such that *(i)* for every $\{u, v\} \in E(G)$, $\{\varphi(u), \varphi(v)\} \in E(H)$, and *(ii)* for every $u \in V(G)$, $\varphi(u) \in L(u)$. Having φ at hand, we will show that (L, A, B) is a Yes-instance, which will imply that the call to MatchingAlg with (L, A, B) as input returns Yes, and hence LSIAlg returns Yes.

Based on φ, we define a subset $M \subseteq E(L)$ as follows: $M = \{\{u, \varphi(u)\} : u \in A\}$. Notice that the containment of M in $E(L)$ follows from the definition of $E(L)$ and Condition *(ii)* above. Moreover, by the definition of A, B and because φ is bijective, it further follows that M is a perfect matching in L such that every edge in M has one endpoint in A and the other in B. Thus, to conclude that (L, A, B) is a Yes-instance, it remains to argue that L/M is a clique. To this end, we consider two arbitrary vertices x and y of L/M, and prove that they are adjacent in L/M. Necessarily x is a vertex that replaced two vertices $u \in A$ and $u' \in B$ such that $\{u, u'\} \in M$, and y is a vertex that replaced two vertices $v \in A \setminus \{u\}$ and $v' \in B \setminus \{u'\}$ such that $\{v, v'\} \in M$. By the definition of contraction, to show that x and y are adjacent in L/M, it suffices to show that u and v are adjacent in L or u' and v' are adjacent in L (or both). To this end, suppose that u and v are not adjacent in L, else we are done. By the definition of $E(L)$, this means that $\{u, v\} \notin E(\overline{G})$ and hence $\{u, v\} \in E(G)$. By Condition *(i)* above, we derive that $\{\varphi(u), \varphi(v)\} \in E(H)$. By the definition of M, we know that $u' = \varphi(u)$ and $v' = \varphi(v)$, therefore $\{u', v'\} \in E(H)$. In turn, by the definition of $E(L)$, we get that $\{u', v'\} \in E(L)$. Thus, the proof of the forward direction is complete.

Now, suppose that LSIAlg returns Yes, which means that the call to MatchingAlg with (L, A, B) returns Yes. Thus, (L, A, B) is a Yes-instance, which means that there exists a perfect matching M in G such that every edge in M has one endpoint in A and the other in B, and G/M is a clique. We define a function $\varphi : A \to B$ as follows. For every $u \in V(G)$, let $\varphi(u) = v$ where v is the unique vertex in B such that $\{u, v\} \in M$; the existence and uniqueness of v follows from the supposition that M is a perfect matching such that every edge in M has one endpoint in A and the other in B. Furthermore, by the definition of A, B and the edges in $E(L)$ with one endpoint in A and the other in B, it directly follows that φ is a bijective mapping between $V(G)$ and $V(H)$ such that for every $u \in V(G)$, it holds that $\varphi(u) \in L(u)$. Thus, it remains to argue that for every edge $\{u, v\} \in E(G)$, it holds that $\{\varphi(u), \varphi(v)\} \in E(H)$. To this end, consider some arbitrary edge $\{u, v\} \in E(G)$, and denote $u' = \varphi(u)$ and $v' = \varphi(v)$. Because L/M is a clique and M is a matching that, by the definition of φ, necessarily contains both $\{u, u'\}$ and $\{v, v'\}$, we derive that at least one of the following four conditions must be satisfied: *(i)* $\{u, v\} \in E(L)$; *(ii)* $\{u', v'\} \in E(L)$; *(iii)*

$\{u,v'\} \in E(L)$; *(iv)* $\{v,u'\} \in E(L)$. Because $\{u,v\} \in E(G)$, we have that $\{u,v\} \notin E(\overline{G})$ and therefore $\{u,v\} \notin E(L)$. Thus, we are left with Conditions *(ii)*, *(iii)* and *(iv)*. Now, we will crucially rely on the proper colorings of G and H to rule out the satisfaction of Conditions *(iii)* and *(iv)*.

▷ Claim 9. For any two edges $\{x,x'\},\{y,y'\} \in E(L)$ such that $\{x,y\} \in E(G)$ and $x',y' \in V(H)$, it holds that neither $\{x,y'\}$ nor $\{y,x'\}$ belongs to $E(L)$.

Proof of Claim 9. Because c_G is a proper coloring of G and $\{x,y\} \in E(G)$, it holds that $c_G(x) \neq x_G(y)$. Because $\{x,x'\},\{y,y'\} \in E(L)$, $x,y \in V(G)$ and $x',y' \in V(H)$, and by the definition of $E(L)$, it holds that $x' \in L(x)$ and $y' \in L(y)$, and therefore $c_G(x) = c_H(x')$ and $c_G(y) = c_H(y')$. Thus, $c_G(x) \neq c_H(y')$ and $c_G(y) \neq c_H(x')$, implying that $y' \notin L(x)$ and $x' \notin L(y)$. In turn, by the definition of $E(L)$, this means that neither $\{x,y'\}$ nor $\{y,x'\}$ belongs to $E(L)$. This completes the proof of the claim. ◁

We now return to the proof of the lemma. By Claim 9, we are only left with Condition *(ii)*, that is, $\{u',v'\} \in E(L)$. However, by the definition of $E(L)$, this means that $\{u',v'\} \in E(H)$. As argued earlier, this completes the proof of the reverse direction. ◀

4 Lower Bounds: Clique Contraction and Hadwiger Number

In this section, we prove a lower bound for Clique Contraction and consequently for Hadwiger Number, defined as follows.

Clique Contraction
Input: A graph G and $t \in \mathbb{N}$.
Question: Is there a subset $F \subseteq E(G)$ of size at most t such that G/F is a clique?

Hadwiger Number
Input: A graph G and $h \in \mathbb{N}$.
Question: Is the Hadwiger number of G at least as large as h?

Our objective is to prove the following statement, where the analogous statement for Hadwiger Number (called Theorem 1 in the introduction) will follow as a corollary.

▶ **Theorem 10.** *Unless the ETH is false, there does not exist an algorithm that solves Clique Contraction in time $n^{o(n)}$ where $n = |V(G)|$.*

To make our approach adaptable to extract analogous statements for other contraction problems, we will first define a new problem called Noisy Structured Clique Contraction (which will arise in Section 5) along with a special case of it that is also a special case of Clique Contraction. Then, we will prove a crucial property of instances of Noisy Structured Clique Contraction, and afterwards we will use this property to prove Theorem 10 and its corollary. The definition of the new problem is as follows (see Fig. 4).

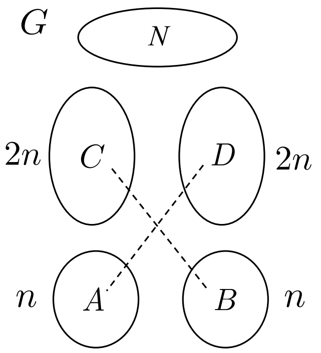

Figure 4 An instance of Noisy Structured Clique Contraction where dashed lines represent non-edges.

Noisy Structured Clique Contraction

Input: A graph G on at least $6n$ vertices for some $n \in \mathbb{N}$, and a partition (A, B, C, D, N) of $V(G)$ such that $|A| = |B| = n$, $|C| = |D| = 2n$, no vertex in A is adjacent to any vertex in D, and no vertex in B is adjacent to any vertex in C.

Question: Does there exist a subset $F \subseteq E(G)$ of size at most n such that $G[A \cup B \cup C \cup D \cup X]/F$ is a clique,[a] where $X = \{u \in N :$ there exists a vertex $v \in A \cup B \cup C \cup D$ such that u and v belong to the same connected component of $G[F]\}$?

[a] Note that F might contain edges outside $G[A \cup B \cup C \cup D \cup X]$. Then, we slightly abuse notation so that $G[A \cup B \cup C \cup D \cup X]/F$ refers to $G[A \cup B \cup C \cup D \cup X]/(F \cap E(G[A \cup B \cup C \cup D \cup X]))$.

Intuitively, the vertex set X consists of the noise (represented by N) that "interacts" with non-noise (represented by $V(G) \setminus N$) through contracted edges (in F), i.e. the vertices in N that lie together with at least one vertex in $V(G) \setminus N$ in a component that will be contracted and thereby replaced by a single vertex. We refer to the special case of Noisy Structured Clique Contraction where $N = \emptyset$ as Structured Clique Contraction. Note that Structured Clique Contraction is also a special case of Clique Contraction.

Solutions to instances of Noisy Structured Clique Contraction exhibit the following property, which will be crucial in the proof of Theorem 10 as well as results in Section 5.

▶ **Lemma 11.** *Let F be a solution to an instance (G, A, B, C, D, N, n) of Noisy Structured Clique Contraction. Then, F is a matching of size n in G such that each edge in F has one endpoint in A and the other in B.*

Proof. We first argue that every vertex in $A \cup B$ is incident to at least one edge in F. Targeting a contradiction, suppose that there exists a vertex $u \in A \cup B$ that is not incident to any edge in F. Because $|A \cup B \cup C \cup D| = 6n$, $|F| \leq n$ and $G[A \cup B \cup C \cup D \cup X]/F$ is a clique (where the last two properties follow from the supposition that F is a solution), it holds that $G[A \cup B \cup C \cup D \cup X]/F$ is a clique on at least $5n + |X|$ vertices. Hence, the degree of every vertex in $G[A \cup B \cup C \cup D \cup X]/F$, and in particular of u, should be $5n - 1 + |X|$ in $G[A \cup B \cup C \cup D \cup X]/F$. However, because no vertex in A is adjacent to any vertex in D and no vertex in B is adjacent to any vertex in C, the degree of any vertex in $A \cup B$, and in particular of u, is at most $|A \cup B| - 1 + |C \cup D|/2 + |X| = 4n - 1 + |X|$ in $G[A \cup B \cup C \cup D \cup X]$. Because u is not incident to any edge in F, its degree in $G[A \cup B \cup C \cup D \cup X]/F$ is at most its degree in $G[A \cup B \cup C \cup D \cup X]$. This is a contradiction, thus we get that indeed every vertex in $A \cup B$ is incident to at least one edge in F. From this, because $|F| \leq n$ and $|A \cup B| = 2n$, we derive that F is a perfect matching in $G[A \cup B]$.

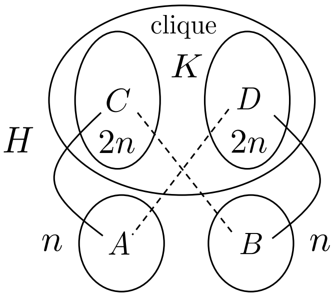

Figure 5 The construction of an instance of Structured Clique Contraction in the proof of Lemma 12 where dashed lines represent non-edges.

It remains to argue that every edge in F has one endpoint in A and the other in B. Targeting a contradiction, suppose that this is false. Because F is a perfect matching in $G[A \cup B]$, this means that there exist two vertices $a, a' \in A$ such that $\{a, a'\} \in F$. By the definition of Noisy Structured Clique Contraction, neither a nor a' is adjacent to any vertex in D. Moreover, note that $D \subseteq V(G[A \cup B \cup C \cup D \cup X]/F)$. In particular, the vertex of $G[A \cup B \cup C \cup D \cup X]/F$ yielded by the contraction of $\{a, a'\}$ is not adjacent to any vertex of D in $G[A \cup B \cup C \cup D \cup X]/F$. However, this is a contradiction because $G[A \cup B \cup C \cup D \cup X]/F$ is a clique. ◀

We now prove a lower bound for Structured Clique Contraction. Because it is a special case of Clique Contraction, this will directly yield the correctness of Theorem 10.

▶ **Lemma 12.** *Unless the ETH is false, there does not exist an algorithm that solves Structured Clique Contraction in time $n^{o(n)}$ where $n = |V(G)|$.*

Proof. Targeting a contradiction, suppose that there exists an algorithm, denoted by CliConAlg, that solves Structured Clique Contraction in time $n^{o(n)}$ where n is the number of vertices in the input graph. We will show that this implies the existence of an algorithm, denoted by MatchingAlg, that solves Cross Matching in time $n^{o(n)}$ where n is the size of the set A in the input, thereby contradicting Lemma 8 and hence completing the proof.

We define the execution of MatchingAlg as follows. Given an instance (G, A, B) of Cross Matching, MatchingAlg constructs an instance (H, A, B, C, D, n) of Structured Clique Contraction as follows (see Fig. 5):

- Let $n = |A|$, and K be a clique on $4n$ new vertices. Let (C, D) be a partition of $V(K)$ such that $|C| = |D|$.
- $V(H) = V(G) \cup V(K)$.
- $E(H) = E(G) \cup E(K) \cup \{\{a, c\} : a \in A, c \in C\} \cup \{\{b, d\} : b \in B, d \in D\}$.

Then, MatchingAlg calls CliConAlg with (H, A, B, C, D, n) as input, and returns the answer.

First, note that by construction, $|V(H)| = 6n$. Thus, because CliConAlg runs in time $|V(H)|^{o(|V(H)|)} \leq n^{o(n)}$, it follows that MatchingAlg runs in time $n^{o(n)}$.

For the correctness of the algorithm, first suppose that (G, A, B) is a Yes-instance of Cross Matching. This means that there exists a perfect matching M in G such that every edge in M has one endpoint in A and the other in B, and G/M is a clique. By the definition of $E(H)$, $M \subseteq E(H)$. We will show that H/M is a clique. As $|M| = n$, this will mean that (H, A, B, C, D, n) is a Yes-instance of Structured Clique Contraction, which will mean, in turn, that the call to CliConAlg with (H, A, B, C, D, n) as input returns Yes, and hence MatchingAlg returns Yes.

Note that $V(H/M) = V(K) \cup V(G/M)$. To show that H/M is a clique, we consider two arbitrary vertices $u, v \in V(H/M)$, and show that they are adjacent in H/M. If $u, v \in V(K)$, then because K is a clique, it is clear that $\{u, v\} \in E(H/M)$. Moreover, if $u, v \in G/M$, then because G/M is a clique, it is clear that $\{u, v\} \in E(H/M)$. Thus, one of the vertices u and v belongs to $V(G/M)$ and the other belongs to $V(K)$. We suppose w.l.o.g. that $u \notin V(K)$. Because M is a perfect matching in G such that every edge in M has one endpoint in A and the other in B, it follows that u resulted from the contraction of the edge between some $a \in A$ and some $b \in B$. If $v \in C$, then $\{a, v\} \in E(H)$, and otherwise $v \in D$ and so $\{b, v\} \in E(H)$. Thus, by the definition of contraction, we conclude that $\{u, v\} \in E(H/M)$. This completes the proof of the forward direction.

Now, suppose that MatchingAlg returns Yes, which means that the call to CliConAlg with (H, A, B, C, D, n) returns Yes. Thus, (H, A, B, C, D, n) is a Yes-instance, which means that there exists a subset $F \subseteq E(H)$ of size at most n such that H/F is a clique. We will show that F is a perfect matching in G such that every edge in F has one endpoint in A and the other in B. Because H/F is a clique, this will imply that G/F is a clique and thus that (G, A, B) is a Yes-instance of Cross Matching. To achieve this, notice that by Lemma 11, F is a matching of size n in H such that each edge in F has one endpoint in A and the other in B. Because $G = H[A \cup B]$, we have that F is a perfect matching in G. Thus, the proof of the reverse direction is complete. ◀

▶ **Corollary 13.** *Unless the ETH is false, there does not exist an algorithm that solves Hadwiger Number in time $n^{o(n)}$ where $n = |V(G)|$.*

Proof. Targeting a contradiction, suppose that there exists an algorithm, denoted by HadwigerAlg, that solves Hadwiger Number in time $n^{o(n)}$ where n is the number of vertices in the input graph. We will show that this implies the existence of an algorithm, denoted by CliConAlg, that solves Clique Contraction in time $n^{o(n)}$ where n is the number of vertices in the input graph, thereby contradicting Theorem 10 and hence completing the proof.

We define the execution of CliConAlg as follows. Given an instance (G, t) of Clique Contraction, if G is not connected, then CliConAlg returns No, and otherwise it returns Yes if and only if HadwigerAlg returns Yes when called with $(G, |V(G)| - t)$ as input. Because the call to HadwigerAlg with input $(G, |V(G)| - t)$ runs in time $n^{o(n)}$ where $n = |V(G)|$, we have that CliConAlg runs in time $n^{o(n)}$ as well.

For the correctness of the algorithm, first observe that if G is not connected, then no sequence of edge contractions can yield a clique, and hence it is correct to return No. Thus, now assume that G is connected. First, suppose that (G, t) is a Yes-instance of Clique Contraction. This means that there exists a sequence of at most t edge contractions that transforms G into a clique. In particular, this clique must have at least $|V(G)| - t$ vertices, and therefore the Hadwiger number of G is at least as large as $|V(G)| - t$. By the correctness of HadwigerAlg, its call with $(G, |V(G)| - t)$ returns Yes, and therefore CliConAlg returns Yes.

Now, suppose that CliConAlg returns Yes, which means that the call to HadwigerAlg with $(G, |V(G)| - t)$ returns Yes. By the correctness of HadwigerAlg, the clique K_h for $h = |V(G)| - t$ is a minor of G. This means that there is a sequence of vertex deletions, edge deletions and edge contractions that transforms G into K_h. In particular, this sequence can contain at most t vertex deletions and edge contractions in total. Furthermore, by replacing each vertex deletion for a vertex v by an edge contraction for some edge e incident to v (which exists because G is connected) and dropping all edge deletions, we obtain another sequence that transforms G into K_h. Because this sequence contains only edge contractions, and at most t of them, we conclude that (G, t) is a Yes-instance of Clique Contraction. ◀

5 Lower Bounds for Contraction to Graph Classes Problems

In this section, we prove lower bounds for several cases of the $\mathcal{F}$-CONTRACTION problem, defined as follows. Here, $\mathcal{F}$ is a (possibly infinite) family of graphs.

$\mathcal{F}$-CONTRACTION
Input: A graph G and $t \in \mathbb{N}$.
Question: Does there exist a subset $F \subseteq E(G)$ of size at most t such that $G/F \in \mathcal{F}$?

Notice that CLIQUE CONTRACTION is the case of $\mathcal{F}$-CONTRACTION where $\mathcal{F}$ is the family of cliques. In this section, we consider the cases of $\mathcal{F}$-CONTRACTION where $\mathcal{F}$ is the family of chordal graphs, interval graphs, proper interval graphs, threshold graphs, trivially perfect graphs, split graphs, complete split graphs and perfect graphs, also called CHORDAL CONTRACTION, INTERVAL CONTRACTION, PROPER INTERVAL CONTRACTION, THRESHOLD CONTRACTION, TRIVIALLY PERFECT CONTRACTION, SPLIT CONTRACTION, COMPLETE SPLIT CONTRACTION and PERFECT CONTRACTION, respectively. Before we define these classes formally, it will be more enlightening to first define only the class of chordal graphs as well as somewhat artificial classes of graphs that will help us prove lower bounds for many of the classes above in a unified manner.

▶ **Definition 14** (Chordal Graphs). *A graph is* chordal *if it does not contain C_ℓ for all $\ell \geq 4$ as an induced subgraph.*

Our first class of graphs is defined as follows (see Fig. 6).

▶ **Definition 15** (Two-Cliques Graphs). *A* two-cliques graph *is a graph G such that there exist $A, B \subseteq V(G)$ such that $A \cup B = V(G)$, $G[A]$ and $G[B]$ are cliques, and there do not exist vertices $a \in A \setminus B$ and $b \in B \setminus A$ such that $\{a, b\} \in E(G)$. The* two-cliques class *is the class of all two-cliques graphs.*

It should be clear that the two-cliques class is a subclass of the class of chordal graphs. Now, we further define a family of classes of graphs as follows.

▶ **Definition 16** (Non-Trivial Chordal Class). *We say that a class of graphs $\mathcal{F}$ is* non-trivial chordal *if it is a subclass of the class of chordal graphs, and a superclass of the two-cliques class.*

Clearly, the class of cliques is not a non-trivial chordal class, and the class of chordal graphs is a non-trivial chordal class. The rest of this section is divided as follows. First, in Section 5, we prove a lower bound for any non-trivial chordal class. Then, in Section 5, we prove a lower bound for some graph classes that are not non-trivial chordal.

Non-Trivial Chordal Graph Classes. Here, our objective is to prove the following theorem. Afterwards, we will derive lower bounds for several known graph classes as corollaries.

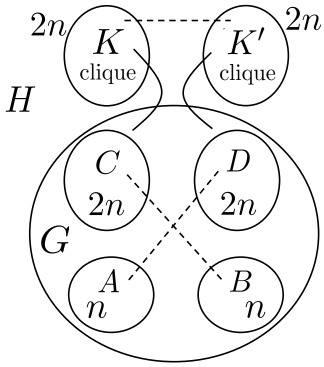

Figure 7 The construction of an instance of $\mathcal{F}$-Contraction in the proof of Theorem 17 where dashed lines represent non-edges.

▶ **Theorem 17.** *Let $\mathcal{F}$ be any non-trivial chordal graph class. Unless the ETH is false, there does not exist an algorithm that solves $\mathcal{F}$-Contraction in time $n^{o(n)}$ where $n = |V(G)|$.*

For the proof of this theorem, the following well-known property of chordal graphs will come in handy. This property is a direct consequence of the alternative characterization of the class of chordal graphs as the class of graphs that admit clique-tree decompositions, see [10].

▶ **Proposition 18.** *Let G be a chordal graph, and let u and v be two non-adjacent vertices in G. Then, $G[N(u) \cap N(v)]$ is a clique.*

We are now ready to prove Theorem 17.

Proof of Theorem 17. Targeting a contradiction, suppose that there exists an algorithm, denoted by NonTrivChordAlg, that solves $\mathcal{F}$-Contraction in time $n^{o(n)}$ where n is the number of vertices in the input graph. We will show that this implies the existence of an algorithm, denoted by CliConAlg, that solves Structured Clique Contraction in time $n^{o(n)}$ where n is the number of vertices in the input graph, thereby contradicting Lemma 12 and hence completing the proof.

We define the execution of CliConAlg as follows. Given an instance (G, A, B, C, D, n) of Structured Clique Contraction, CliConAlg constructs an instance (H, n) of $\mathcal{F}$-Contraction as follows (see Fig. 7):

- Let $n = |A|$. Moreover, let K and K' be two cliques, each on $2n$ new vertices.
- $V(H) = V(G) \cup V(K) \cup V(K')$.
- $E(H) = E(G) \cup E(K) \cup E(K') \cup \{\{u, v\} : u \in V(G), v \in V(K) \cup V(K')\}$.

Then, CliConAlg calls NonTrivChordAlg with (H, n) as input, and returns the answer of this call.

First, note that by construction, $|V(H)| = 10n$. Thus, because NonTrivChordAlg runs in time $|V(H)|^{o(|V(H)|)} \leq n^{o(n)}$, it follows that CliConAlg runs in time $n^{o(n)}$.

For the correctness of the algorithm, first suppose that (G, A, B, C, D, n) is a Yes-instance of Structured Clique Contraction. This means that there exists a subset $F \subseteq E(G)$ of size at most n such that G/F is a clique. By the definition of H, we directly derive that H/F is a two-cliques graphs, and therefore it belongs to $\mathcal{F}$. Thus, (H, n) is a Yes-instance of $\mathcal{F}$-Contraction, which means that the call to NonTrivChordAlg with (H, n) as input returns Yes, and hence CliConAlg returns Yes.

Now, suppose that CliConAlg returns Yes, which means that the call to NonTrivChordAlg with (H, n) returns Yes. Thus, (H, n) is a Yes-instance of $\mathcal{F}$-Contraction, which means that there exists a subset $F \subseteq E(H)$ of size at most n such that $H/F \in \mathcal{F}$. In particular, H/F

is a chordal graph. Based on Proposition 18, we will first show that $H[A \cup B \cup C \cup D \cup X]/F$ is a clique, where $X = \{u \in V(K) \cup V(K') :$ there exists a vertex $v \in A \cup B \cup C \cup D$ such that u and v belong to the same connected component of $H[F]\}$.

Targeting a contradiction, suppose that $H[A \cup B \cup C \cup D \cup X]/F$ is not a clique, and therefore there exist two non-adjacent vertices u and v in this graph. By the definition of X, $H[A \cup B \cup C \cup D \cup X]/F$ is equal to the subgraph of H/F induced by the set of vertices derived from connected components that contain at least one vertex from $A \cup B \cup C \cup D$. In particular, u and v are also non-adjacent vertices in H/F. By Proposition 18, this implies that $(H/F)[N_{H/F}(u) \cap N_{H/F}(v)]$ is a clique. Let $\mathcal{C}_1$ (resp. $\mathcal{C}_2$) be the set of connected components of $H[F]$ that contain at least one vertex from $V(K_1)$ (resp. $V(K_2)$). Because $|F| \leq n$ and $|V(K_1)| = |V(K_2)| = 2n$, there exists at least one component $C_1 \in \mathcal{C}_1$ (resp. $C_2 \in \mathcal{C}_2$) that does not contain any vertex from $A \cup B \cup C \cup D$. Let c_1 and c_2 be the vertices of H/F yielded by the replacement of C_1 and C_2, respectively. As all vertices in $V(K_1) \cup V(K_2)$ are adjacent to all vertices in $A \cup B \cup C \cup D$, we have that $c_1, c_2 \in N_{H/F}(u) \cap N_{H/F}(v)$. However, there do not exist a vertex in $V(K_1)$ and a vertex in $V(K_2)$ that are adjacent in H, and for every vertex in $V(K_1) \cup V(K_2)$, its neighborhood outside this set is contained in $A \cup B \cup C \cup D$. Thus, c_1 and c_2 must be non-adjacent in H/F. However, this is a contradiction to the argument that $(H/F)[N_{H/F}(u) \cap N_{H/F}(v)]$ is a clique. From this, we derive that $H[A \cup B \cup C \cup D \cup X]/F$ is indeed a clique.

Now, notice that (H, A, B, C, D, N, n) where $N = V(K_1) \cup V(K_2)$ is an instance of Noisy Structured Clique Contraction. Furthermore, since $|F| \leq n$ and we have already shown that $H[A \cup B \cup C \cup D \cup X]/F$ is a clique, we have that F is a solution to this instance. Therefore, by Lemma 11, F is a matching of size n in H such that each edge in F has one endpoint in A and the other in B. In particular, $F \subseteq E(G)$ and hence $X = \emptyset$. Because $G = H[A \cup B \cup C \cup D]$, we thus derive that G/F is a clique. Thus, we conclude that (G, A, B, C, D, n) is a Yes-instance of Structured Clique Contraction. This completes the proof of the reverse direction. ◀

Now, we give definitions for several classes of graphs for which lower bounds will follow from Theorem 18. First, a graph is an *interval graph* if there exists a set of intervals on the real line such that the vertices of the graph are in bijection with these intervals, and there exists edge between two vertices if and only if their intervals intersect. A graph is a *proper interval graph* if, in the former definition, we also add the constraint that all intervals must have the same length. A graph is a *threshold graph* if it can be constructed from a one-vertex graph by repeated applications of the following two operations: addition of a single isolated vertex to the graph; addition of a single vertex that is connected to all other vertices. A graph is *trivially perfect* if in each of its induced subgraphs, the maximum size of an independent set equals the number of maximal cliques.

It is well-known that every graph that is a (proper) interval graph, or a threshold graph, or a trivially perfect graph, is also a chordal graph (see [10]). Moreover, it is immediate to verify that the two-cliques class is a subclass of the classes of (proper) interval graphs, threshold graphs and trivially perfect graphs. Thus, these classes are non-trivial chordal graphs classes, and therefore Theorem 17 directly implies lower bounds for them:

▶ **Corollary 19.** *Unless the ETH is false, none of the following problems admits an algorithm that solves it in time $n^{o(n)}$ where $n = |V(G)|$: Chordal Contraction, Interval Contraction, Proper Interval Contraction, Threshold Contraction and Trivially Perfect Contraction.*

Other Graph Classes. In Section 4, we proved a lower bound for a class of graphs that is not non-trivial chordal, namely, the class of cliques. In the full version of this paper, we show that our approach can yield lower bounds also for other classes of graphs that are not non-trivially chordal, including the classes of Split Graphs, Complete Split Graphs and Perfect Graphs.

Abstract

In this work, we seek a more refined understanding of the complexity of local optimum computation for Max-Cut and pure Nash equilibrium (PNE) computation for congestion games with weighted players and linear latency functions. We show that computing a PNE of linear weighted congestion games is PLS-complete either for very restricted strategy spaces, namely when player strategies are paths on a series-parallel network with a single origin and destination, or for very restricted latency functions, namely when the latency on each resource is equal to the congestion. Our results reveal a remarkable gap regarding the complexity of PNE in congestion games with weighted and unweighted players, since in case of unweighted players, a PNE can be easily computed by either a simple greedy algorithm (for series-parallel networks) or any better response dynamics (when the latency is equal to the congestion). For the latter of the results above, we need to show first that computing a local optimum of a natural restriction of Max-Cut, which we call *Node-Max-Cut*, is PLS-complete. In Node-Max-Cut, the input graph is vertex-weighted and the weight of each edge is equal to the product of the weights of its endpoints. Due to the very restricted nature of Node-Max-Cut, the reduction requires a careful combination of new gadgets with ideas and techniques from previous work. We also show how to compute efficiently a $(1+\varepsilon)$-approximate equilibrium for Node-Max-Cut, if the number of different vertex weights is constant.

1 Introduction

Motivated by the remarkable success of local search in combinatorial optimization, Johnson et al. introduced [25] the complexity class Polynomial Local Search (PLS), consisting of local search problems with polynomially verifiable local optimality. PLS includes many natural complete problems (see e.g., [28, App. C]), with Circuit-Flip [25] and Max-Cut [33] among the best known ones, and lays the foundation for a principled study of the complexity of local optima computation. In the last 15 years, a significant volume of research on PLS-completeness was motivated by the problem of computing a pure Nash equilibrium of potential games (see e.g., [1, 34, 20] and the references therein), where any improving deviation by a single player decreases a potential function and its local optima correspond to pure Nash equilibria [29].

Computing a local optimum of Max-Cut under the flip neighborhood (a.k.a. Local-Max-Cut) has been one of the most widely studied problems in PLS. Given an edge-weighed graph, a cut is locally optimal if we cannot increase its weight by moving a vertex from one side of the cut to the other. Since its PLS-completeness proof by Schäffer and Yannakakis [33], researchers have shown that Local-Max-Cut remains PLS-complete for graphs with maximum degree five [9], is polynomially solvable for cubic graphs [31], and its smoothed complexity is either polynomial in complete [2] and sparse [9] graphs, or almost polynomial in general graphs [7, 10]. Moreover, due to its simplicity and versatility, Max-Cut has been widely used in PLS reductions (see e.g., [1, 20, 34]). Local-Max-Cut can also be cast as a game, where each vertex aims to maximize the total weight of its incident edges that cross the cut. Cut games are potential games (the value of the cut is the potential function), which has motivated research on efficient computation of approximate equilibria for Local-Max-Cut [3, 6]. To the best of our knowledge, apart from the work on the smoothed complexity of Local-Max-Cut (and may be that Local-Max-Cut is P-complete for unweighted graphs [33, Theorem 4.5]), there has not been any research on whether (and to which extent) additional structure on edge weights affects hardness of Local-Max-Cut.

A closely related research direction deals with the complexity of computing a pure Nash equilibrium (equilibrium or PNE, for brevity) of *congestion games* [32], a typical example of potential games [29] and among the most widely studied classes of games in Algorithmic Game Theory (see e.g., [15] for a brief account of previous work). In congestion games (or CGs, for brevity), a finite set of players compete over a finite set of resources. Strategies are resource subsets and players aim to minimize the total cost of the resources in their strategies. Each resource e is associated with a (non-negative and non-decreasing) latency function, which determines the cost of using e as a function of e’s *congestion* (i.e., the number of players including e in their strategy). Researchers have extensively studied the properties of special cases and variants of CGs. Most relevant to this work are *symmetric* (resp. *asymmetric*) CGs, where players share the same strategy set (resp. have different strategy sets), *network* CGs, where strategies correspond to paths in an underlying network, and *weighted* CGs, where player contribute to the congestion with a different weight.

Fabrikant et al. [12] proved that computing a PNE of asymmetric network CGs or symmetric CGs is PLS-complete, and that it reduces to min-cost-flow for symmetric network CGs. About the same time [17, 30] proved that weighted congestion games admit a (weighted) potential function, and thus a PNE, if the latency functions are either affine or exponential (and [23, 24] proved that in a certain sense, this restriction is necessary). Subsequently, Ackermann et al. [1] characterized the strategy sets of CGs that guarantee efficient equilibrium computation. They also used a variant of Local-Max-Cut, called *threshold games*, to simplify the PLS-completeness proof of [12] and to show that computing a PNE of asymmetric network CGs with (exponentially steep) linear latencies is PLS-complete.

On the other hand, the complexity of equilibrium computation for weighted CGs is not well understood. All the hardness results above carry over to weighted CGs, since they generalize standard CGs (where the players have unit weight). But on the positive side, we only know how to efficiently compute a PNE for weighted CGs on parallel links with general latencies [16] and for weighted CGs on parallel links with identity latency functions and asymmetric strategies [19]. Despite the significant interest in (exact or approximate) equilibrium computation for CGs (see e.g., [4, 5, 6, 27] and the references therein), we do not understand how (and to which extent) the complexity of equilibrium computation is affected by player weights. This is especially true for weighted CGs with linear latencies, which admit a potential function and their equilibrium computation is in PLS.

Contributions. We contribute to both research directions outlined above. In a nutshell, we show that equilibrium computation in linear weighted CGs is significantly harder than for standard CGs, in the sense that it is PLS-complete either for very restricted strategy spaces, namely when player strategies are paths on a series-parallel network with a single origin and destination, or for very restricted latency functions, namely when resource costs are equal to the congestion. Our main step towards proving the latter result is to show that computing a local optimum of Node-Max-Cut, a natural and interesting restriction of Max-Cut where the weight of each edge is the product of the weights of its endpoints, is PLS-complete.

More specifically, using a tight reduction from Local-Max-Cut, we first show, in Section 3.1, that equilibrium computation for linear weighted CGs on series-parallel networks with a single origin and destination is PLS-complete (Theorem 1). The reduction results in games where both the player weights and the latency slopes are exponential. Our result reveals a remarkable gap between weighted and standard CGs regarding the complexity of equilibrium computation, since for standard CGs on series-parallel networks with a single origin and destination, a PNE can be computed by a simple greedy algorithm [18].

Aiming at a deeper understanding of how different player weights affect the complexity of equilibrium computation in CGs, we show, in Section 3.2, that computing a PNE of weighted network CGs with asymmetric player strategies and identity latency functions is PLS-complete (Theorem 2). Again the gap to standard CGs is remarkable, since for standard CGs with identity latency functions, any better response dynamics converges to a PNE in polynomial time. In the reduction of Theorem 2, Node-Max-Cut plays a role similar to that of threshold games in [1, Sec. 4]. The choice of Node-Max-Cut seems necessary, in the sense that known PLS reductions, starting from Not-All-Equal Satisfiability [12] or Local-Max-Cut [1], show that equilibrium computation is hard due to the interaction of players on different resources (where latencies simulate the edge / clause weights), while in our setting, equilibrium computation is hard due to the player weights, which are the same for all resources in a player's strategy.

Node-Max-Cut is a natural restriction of Max-Cut and settling the complexity of its local optima computation may be of independent interest, both conceptually and technically. Node-Max-Cut coincides with the restriction of Max-Cut shown (weakly) NP-complete on complete graphs in the seminal paper of Karp [26], while a significant generalization of Node-Max-Cut with polynomial weights was shown P-complete in [33].

A major part of our technical effort concerns reducing Circuit-Flip to Node-Max-Cut, thus showing that computing a local optimum of Node-Max-Cut is PLS-complete (Section 5). Since Node-Max-Cut is a very restricted special case of Max-Cut, we have to start from a PLS-complete problem lying before Local-Max-Cut on the "reduction paths" of PLS. The reduction is technically involved, due to the very restricted nature of the problem. In Node-Max-Cut, every vertex contributes to the cut value of its neighbors with the same weight, and differentiation comes only as a result of the different total weight in the neighborhood of each vertex. To deal with this restriction, we combine some new carefully constructed gadgets with the gadgets used by Schäffer and Yannakakis [33], Elsässer and Tscheuschner [9]. and Gairing and Savani [20]. In general, as a very restricted special case of Max-Cut, Node-Max-Cut is a natural and convenient starting point for future PLS reductions, especially when one wants to show hardness of equilibrium computation for restricted classes of games that admit weighted potential functions (e.g., as that in [17]). So, our results may serve as a first step towards a better understanding of the complexity of (exact or approximate) equilibrium computation for weighted potential games.

We also show that a $(1+\varepsilon)$-approximate equilibrium for Node-Max-Cut, where no vertex can switch sides and increase the weight of its neighbors across the cut by a factor larger than $1+\varepsilon$, can be computed in time exponential in the number of different weights (Theorem 3). Thus, we can efficiently compute a $(1+\varepsilon)$-approximate equilibrium for Node-Max-Cut, for any $\varepsilon > 0$, if the number of different vertex weights is constant. Since similar results are not known for Max-Cut, Theorem 3 may indicate that approximate equilibrium computation for Node-Max-Cut may not be as hard as for Max-Cut. An interesting direction for further research is to investigate (i) the quality of efficiently computable approximate equilibria for Node-Max-Cut; and (ii) the smoothed complexity of its local optima.

Related Work. Existence and efficient computation of (exact or approximate) equilibria for weighted congestion games have received significant research attention. We briefly discuss here some of the most relevant previous work. There has been significant research interest in the convergence rate of best response dynamics for weighted congestion games (see e.g., [8, 4, 11, 13, 22]). Gairing et al. [19] presented a polynomial algorithm for computing a PNE for load balancing games on restricted parallel links. Caragiannis et al. [6] established existence and presented efficient algorithms for computing approximate PNE in weighted CGs with polynomial latencies (see also [14, 21]).

Bhalgat et al. [3] presented an efficient algorithm for computing a $(3+\varepsilon)$-approximate equilibrium in Max-Cut games, for any $\varepsilon > 0$. The approximation guarantee was improved to $2+\varepsilon$ in [6]. We highlight that the notion of approximate equilibrium in cut games is much stronger than the notion of approximate local optimum of Max-Cut, since the former requires that no vertex can significantly improve the total weight of its incidence edges that cross the cut (as e.g., in [3, 6]), while the latter simply requires that the total weight of the cut cannot be significantly improved (as e.g., in [6]).

Johnson et al. [25] introduced the complexity class PLS and proved that Circuit-Flip is PLS-complete. Subsequently, Schäffer and Yannakakis [33] proved that Max-Cut is PLS-complete. From a technical viewpoint, our work is close to previous work by Elsässer and

Tscheuschner [9] and Gairing and Savani [20], where they show that Local-Max-Cut in graphs of maximum degree five [9] and computing a PNE for hedonic games [20] are PLS-complete, and by Ackermann et al. [1], where they reduce Local-Max-Cut to computing a PNE in network congestion games.

2 Basic Definitions and Notation

Polynomial-Time Local Search (PLS). A *polynomial-time local search* (PLS) problem L [25, Sec. 2] is specified by a (polynomially recognizable) set of instances I_L, a set $S_L(x)$ of feasible solutions for each instance $x \in I_L$, with $|s| = O(\text{poly}(|x|)$ for every solution $s \in S_L(x)$, an objective function $f_L(s, x)$ that maps each solution $s \in S_L(x)$ to its value in instance x, and a *neighborhood* $N_L(s, x) \subseteq S_L(x)$ of feasible solutions for each $s \in S_L(x)$. Moreover, there are three polynomial-time algorithms that for any given instance $x \in I_L$: (i) the first generates an initial solution $s_0 \in S_L(x)$; (ii) the second determines whether a given s is a feasible solution and (if $s \in S_L(x)$) computes its objective value $f_L(s, x)$; and (iii) the third returns either that s is *locally optimal* or a feasible solution $s' \in N_L(s, x)$ with better objective value than s. If L is a maximization (resp. minimization) problem, a solution s is locally optimal if for all $s' \in N_L(s, x)$, $f_L(s, x) \geq f_L(s', x)$ (resp. $f_L(s, x) \leq f_L(s', x)$). If s is not locally optimal, the third algorithm returns a solution $s' \in N_L(s, x)$ with $f(s, x) < f(s', x)$ (resp. $f(s, x) > f(s', x)$). The complexity class PLS consists of all polynomial-time local search problems. By abusing the terminology, we always refer to polynomial-time local search problem simply as local search problems.

PLS Reductions and Completeness. A local search problem L is PLS-*reducible* to a local search problem L', if there are polynomial-time algorithms ϕ_1 and ϕ_2 such that (i) ϕ_1 maps any instance $x \in I_L$ of L to an instance $\phi_1(x) \in I_{L'}$ of L'; (ii) ϕ_2 maps any (solution s' of instance $\phi_1(x)$, instance x) pair, with $s' \in S_{L'}(\phi_1(x))$, to a solution $s \in S_L(x)$; and (iii) for every instance $x \in I_L$, if s' is locally optimal for $\phi_1(x)$, then $\phi_2(s', x)$ is locally optimal for x.

By definition, if a local search problem L is PLS-reducible to a local search problem L', a polynomial-time algorithm that computes a local optimum of L' implies a polynomial time algorithm that computes a local optimum of L. Moreover, a PLS-reduction is transitive. As usual, a local search problem Q is PLS-*complete*, if $Q \in$ PLS and any local search problem $L \in$ PLS is PLS-reducible to Q.

Max-Cut and Node-Max-Cut. An instance of Max-Cut consists of an undirected edge-weighted graph $G(V, E)$, where V is the set of vertices and E is the set of edges. Each edge e is associated with a positive weight w_e. A cut of G is a vertex partition $(S, V \setminus S)$, with $\emptyset \neq S \neq V$. We usually identify a cut with one of its sides (e.g., S). We denote $\delta(S) = \{\{u, v\} \in E : u \in S \wedge v \notin S\}$ the set of edges that cross the cut S. The weight (or the value) of a cut S, denoted $w(S)$, is $w(S) = \sum_{e \in \delta(S)} w_e$. In Max-Cut, the goal is to compute an optimal cut S^* of maximum value $w(S^*)$.

In Node-Max-Cut, each vertex v is associated with a positive weight w_v and the weight of each edge $e = \{u, v\}$ is $w_e = w_u w_v$, i.e. equal to the product of the weights of e's endpoints. Again the goal is to compute a cut S^* of maximum value $w(S^*)$. As optimization problems, both Max-Cut and Node-Max-Cut are NP-complete [26].

In this work, we study Max-Cut and Node-Max-Cut as local search problems under the flip neighborhood. Then, they are referred to as Local-Max-Cut and Local-Node-Max-Cut. The neighborhood $N(S)$ of a cut $(S, V \setminus S)$ consists of all cuts $(S', V \setminus S')$ where S and

S' differ by a single vertex. Namely, the cut S' is obtained from S by moving a vertex from one side of the cut to the other. A cut S is locally optimal if for all $S' \in N(S)$, $w(S) \geq w(S')$. In Local-Max-Cut (resp. Local-Node-Max-Cut), given an edge-weighted (resp. vertex-weighted) graph, the goal is to compute a locally optimal cut. Clearly, both Max-Cut and Node-Max-Cut belong to PLS. In the following, we abuse the terminology and refer to Local-Max-Cut and Local-Node-Max-Cut as Max-Cut and Node-Max-Cut, for brevity, unless we need to distinguish between the optimization and the local search problem.

Weighted Congestion Games. A *weighted congestion game* $\mathcal{G}$ consists of n players, where each player i is associated with a positive weight w_i, a set of resources E, where each resource e is associated with a non-decreasing latency function $\ell_e : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$, and a non-empty strategy set $\Sigma_i \subseteq 2^E$ for each player i. A game is linear if $\ell_e(x) = a_e x + b_e$, for some $a_e, b_e \geq 0$, for all $e \in E$. The identity latency function is $\ell(x) = x$. The player strategies are *symmetric*, if all players share the same strategy set Σ, and *asymmetric*, otherwise.

We focus on *network* weighted congestion games, where the resources E correspond to the edges of an underlying network $G(V, E)$ and the player strategies are paths on G. A network game is *single-commodity*, if G has an origin o and a destination d and the player strategies are all (simple) $o - d$ paths. A network game is *multi-commodity*, if G has an origin o_i and a destination d_i for each player i, and i's strategy set Σ_i consists of all (simple) $o_i - d_i$ paths. A single-commodity network $G(V, E)$ is *series-parallel*, if it either consists of a single edge (o, d) or can be obtained from two series-parallel networks composed either in series or in parallel (see e.g., [35] for details on composition and recognition of series-parallel networks).

A configuration $\vec{s} = (s_1, \dots, s_n)$ consists of a strategy $s_i \in \Sigma_i$ for each player i. The congestion s_e of resource e in configuration $\vec{s}$ is $s_e = \sum_{i:e \in s_i} w_i$. The cost of resource e in $\vec{s}$ is $\ell_e(s_e)$. The *individual cost* (or *cost*) $c_i(\vec{s})$ of player i in configuration $\vec{s}$ is the total cost for the resources in her strategy s_i, i.e., $c_i(\vec{s}) = \sum_{e \in s_i} \ell_e(s_e)$. A configuration $\vec{s}$ is a *pure Nash equilibrium* (equilibrium or PNE, for brevity), if for every player i and every strategy $s' \in \Sigma_i$, $c_i(\vec{s}) \leq c_i(\vec{s}_{-i}, s')$ (where $(\vec{s}_{-i}, s')$ denotes the configuration obtained from $\vec{s}$ by replacing s_i with s'). Namely, no player can improve her cost by unilaterally switching her strategy.

Equilibrium Computation and Local Search. [17] shows that for linear weighted congestion games, with latencies $\ell_e(x) = a_e x + b_e$, $\Phi(\vec{s}) = \sum_{e \in E}(a_e s_e^2 + b_e s_e) + \sum_i w_i \sum_{e \in s_i}(a_e w_i + b_e)$ changes by $2w_i(c_i(\vec{s}) - c_i(\vec{s}_{-i}, s'))$, when a player i switches from strategy s_i to strategy s' in $\vec{s}$. Hence, Φ is a weighted potential function, whose local optimal (wrt. single player deviations) correspond to PNE of the underlying game. Hence, equilibrium computation for linear weighted congestion games is in PLS. Specifically, configurations corresponds to solutions, the neighborhood $N(\vec{s})$ of a configuration $\vec{s}$ consists of all configurations $(\vec{s}_{-i}, s')$ with $s' \in \Sigma_i$, for some player i, and local optimality is defined wrt. the potential function Φ.

Max-Cut and Node-Max-Cut as Games. Local-Max-Cut and Local-Node-Max-Cut can be cast as cut games, where players correspond to vertices of $G(V, E)$, strategies $\Sigma = \{0, 1\}$ are symmetric, and configurations $\vec{s} \in \{0, 1\}^{|V|}$ correspond to cuts, e.g., $S(\vec{s}) = \{v \in V : s_v = 0\}$. Each player v aims to maximize $w_v(\vec{s}) = \sum_{e=\{u,v\} \in E: s_u \neq s_v} w_e$, that is the total weight of her incident edges that cross the cut. For Node-Max-Cut, this becomes $w_v(\vec{s}) = \sum_{u:\{u,v\} \in E \wedge s_u \neq s_v} w_u$, i.e., v aims to maximize the total weight of her neighbors across the cut. A cut $\vec{s}$ is a PNE if for all players v, $w_v(\vec{s}) \geq w_v(\vec{s}_{-i}, 1 - s_v)$. Equilibrium computation for cut games is equivalent to local optimum computation, and thus, is in PLS.

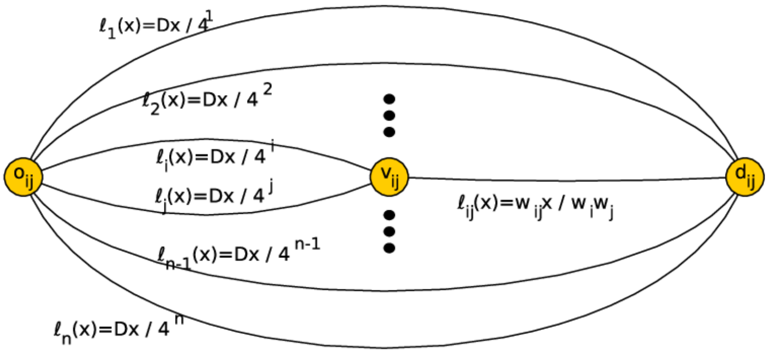

Figure 1 The series-parallel network F_{ij} that corresponds to edge $\{i, j\} \in A$.

A cut $\vec{s}$ is a $(1+\varepsilon)$-approximate equilibrium, for some $\varepsilon > 0$, if for all players v, $(1+\varepsilon)w_v(\vec{s}) \geq w_v(\vec{s}_{-i}, 1 - s_v)$. Note that the notion of $(1+\varepsilon)$-approximate equilibrium is stronger than the notion of $(1+\varepsilon)$-approximate local optimum, i.e., a cut S such that for all $S' \in N(S)$, $(1+\varepsilon)w(S) \geq w(S')$ (see also the discussion in [6]).

3 Hardness of Computing Equilibria in Weighted Congestion Games

We next show that computing a PNE in weighted congestion games with linear latencies is PLS-complete either for single-commodity series-parallel networks or for multi-commodity networks with identity latency functions.

3.1 Weighted Congestion Games on Series-Parallel Networks

▶ **Theorem 1.** *Computing a pure Nash equilibrium in weighted congestion games on single-commodity series-parallel networks with linear latency functions is PLS-complete.*

Proof sketch. Membership in PLS follows from the potential function argument of [17]. To show hardness, we present a reduction from Local-Max-Cut.

Let $H(V, A)$ be an instance of Local-Max-Cut with n vertices and m edges. Based on H, we construct a weighted congestion game on a single-commodity series-parallel network G with $3n$ players, where for every $i \in [n]$, there are three players with weight $w_i = 16^i$. Network G is a parallel composition of two identical copies of a simpler series-parallel network. We refer to these copies as G_1 and G_2. Each of G_1 and G_2 is a series composition of m simple series-parallel networks F_{ij}, each corresponding to an edge $\{i, j\} \in A$. Network F_{ij} is depicted in Figure 1, where D is assumed to be a constant chosen (polynomially) large enough. An example of the entire network G is shown in Figure 2.

In each of G_1 and G_2, there is a unique path that contains all edges with latency functions $\ell_i(x) = Dx/4^i$, for each $i \in [n]$. We refer to these paths as p_i^u for G_1 and p_i^l for G_2. In addition to the edges with latency $\ell_i(x)$, p_i^u and p_i^l include all edges with latencies $\ell_{ij}(x) = \frac{w_{ij}x}{w_i w_j} = \frac{w_{ij}x}{16^{i+j}}$, which correspond to the edges incident to vertex i in H.

Due to the choice of the player weights and the latency slopes, a player with weight w_i must choose either p_i^u or p_i^l in any PNE. We can prove this claim by induction on the player weights. The players with weight $w_n = 16^n$ have a dominant strategy to choose either p_n^u or p_n^l, since the slope of $\ell_n(x)$ is significantly smaller than the slope of any other latency $\ell_i(x)$. In fact, the slope of ℓ_n is so small that even if all other $3n - 1$ players choose one of p_n^u or p_n^l, a player with weight w_n would prefer either p_n^u or p_n^l over all other paths. Therefore, we

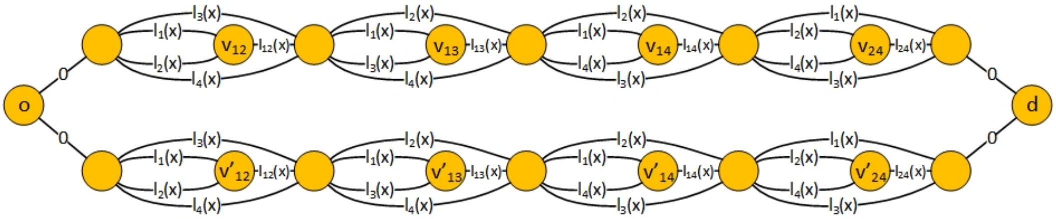

Figure 2 An example of the network G constructed in the proof of Theorem 1 for graph $H(V, A)$, with $V = \{1, 2, 3, 4\}$ and $A = \{\{1, 2\}, \{1, 3\}, \{1, 4\}, \{2, 4\}\}$. G is a parallel composition of two parts, each consisting of the smaller networks F_{12}, F_{13}, F_{14} and F_{24} (see also Figure 1) connected in series.

can assume that each of p^u_n and p^l_n are used by at least one player with weight w_n in any PNE, which would increase their latency so much that no player with smaller weight would prefer them any more. The inductive argument applies the same reasoning for players with weights w_{n-1}, who should choose either p^u_{n-1} or p^l_{n-1} in any PNE, and subsequently, for players with weights $w_{n-2}, \dots, w_1$. Hence, we conclude that for all $i \in [n]$, each of p^u_i and p^l_i is used by at least one player with weight w_i.

Moreover, we note that two players with different weights, say w_i and w_j, go through the same edge with latency $\ell_{ij}(x) = \frac{w_{ij}x}{w_i w_j}$ in G only if the corresponding edge $\{i, j\}$ is present in H. The correctness of the reduction follows the fact that a player with weight w_i aims to minimize her cost through edges with latencies ℓ_{ij} in G in the same way that in the Max-Cut instance, we want to minimize the weight of the edges incident to a vertex i and do not cross the cut. Formally, we next show that a cut S is locally optimal for the Max-Cut instance if and only if the configuration where for every $k \in S$, two players with weight w_k use p^u_k and for every $k \notin S$, two players with weight w_k use p^l_k is a PNE of the weighted congestion game on G.

Assume an equilibrium configuration and consider a player a of weight w_k that uses p^u_k together with another player of weight w_k (if this is not the case, vertex k is not included in S and we apply the symmetric argument for p^l_k). By the equilibrium condition, the cost of player a on p^u_k is at most her cost on p^l_k, which implies that

$$\sum_{k=1}^{m} \frac{2D16^k}{4^k} + \sum_{j:\{k,j\}\in A} \frac{w_{kj}(2 \cdot 16^k + x^u_j 16^j)}{16^{k+j}} \le \sum_{k=1}^{m} \frac{2D16^k}{4^k} + \sum_{j:\{k,j\}\in A} \frac{w_{kj}(2 \cdot 16^k + x^l_j 16^j)}{16^{k+j}} \,,$$

where x^u_j (resp. x^l_j) is either 1 or 2 (resp. 2 or 1) depending on whether, for each vertex j connected to vertex k in H, one or two players (of weight w_j) use p^u_j. Simplifying the inequality above, we obtain that:

$$\sum_{j:\{k,j\}\in A} w_{kj}(x^u_j - 1) \le \sum_{j:\{k,j\}\in A} w_{kj}(x^l_j - 1) \tag{1}$$

Let $S = \{i \in V : x^u_i = 2\}$. By hypothesis, $k \in S$ and the left-hand side of (1) corresponds to the total weight of the edges in H that are incident to k and do not cross the cut S. Similarly, the right-hand side of (1) corresponds to the total weights of the edges in H that are incident to k and cross the cut S. Therefore, (1) implies that we cannot increase the value of the cut S by moving vertex k from S to $V \setminus S$. Since this or its symmetric condition holds for any vertex k of H, the cut $(S, V \setminus S)$ is locally optimal. To conclude the proof, we argue along the same lines that any locally optimal cut of H corresponds to a PNE in the weighted congestion game on G. ◀

3.2 Weighted Congestion Games with Identity Latency Functions

We next prove that computing a PNE in weighted congestion games on multi-commodity networks with identity latency functions is PLS-complete. Compared to Theorem 1, we allow for a significantly more general strategy space, but we significantly restrict the latency functions, only allowing for the player weights to be exponentially large.

▶ **Theorem 2.** *Computing a pure Nash equilibrium in weighted congestion games on multi-commodity networks with identity latency functions is PLS-complete.*

Proof sketch. We use a reduction from Local-Node-Max-Cut, which as we show in Theorem 4, is PLS-complete. Our construction draws ideas from [1].

Let $H(V, A)$ be an instance of Node-Max-Cut. We construct a weighted congestion game on a multi-commodity network G with identity latency functions $\ell_e(x) = x$ such that equilibria of the congestion game correspond to locally optimal cuts of H.

At the conceptual level, each player i of the congestion game corresponds to vertex $i \in V$ and has weight w_i (i.e., equal to the weight of vertex i in H). The key step is to construct a network G such that for every player $i \in [n]$, there are two paths, say p_i^u and p_i^l, whose cost dominate the cost of any other path for player i. Therefore, in any equilibrium, player i selects either p_i^u or p_i^l (which corresponds to vertex i selecting one of the two sides of a cut). For every edge $\{i, j\} \in A$, paths p_i^u and p_j^u (resp. paths p_i^l and p_j^l) have an edge e_{ij}^u (resp. e_{ij}^l) in common. Intuitively, the cost of p_i^u (resp. p_i^l) for player i is determined by the set of players j, with j connected to i in H, that select path p_j^u (resp. p_j^l).

Let $\vec{s}$ be any equilibrium configuration of the weighted congestion game. Each player $i \in [n]$ selects either p_i^u or p_i^l in $\vec{s}$. Let $S = \{i \in [n] : \text{player } i \text{ selects } p_i^u \text{ in } \vec{s}\}$. Applying the equilibrium condition, we next show that S is a locally optimal cut.

We let $V_i = \{j : \{i, j\} \in A\}$ be the neighborhood of vertex i in H. By the construction of G, the individual cost of a player i on path p_i^u (resp. p_i^l) in $\vec{s}$ is equal to $K+|V_i|w_i+\sum_{j\in S\cap V_i} w_j$ (resp. $K + |V_i|w_i + \sum_{j\in V_i\setminus S} w_j$), where K is a large constant that depends on the network G only. Therefore, for any player $i \in S$, equilibrium condition for $\vec{s}$ implies that

$$K + |V_i|w_i + \sum_{j\in S\cap V_i} w_j \le K + |V_i|w_i + \sum_{j\in V_i\setminus S} w_j \Rightarrow \sum_{j\in S\cap V_i} w_j \le \sum_{j\in V_i\setminus S} w_j$$

Multiplying both sides by w_i, we get that the total weight of the edges that are incident to i and cross the cut S is no less than the total weight of the edges that are incident to i and do not cross the cut. By the same reasoning, we reach the same conclusion for any player $i \notin S$. Therefore, the cut $(S, V \setminus S)$ is locally optimal for the Node-Max-Cut instance $H(V, A)$.

To conclude the proof, we argue along the same lines that any locally optimal cut S for the Node-Max-Cut instance $H(V, A)$ corresponds to an equilibrium in the network G, by letting a player i select path p_i^u if and only if $i \in S$. ◀

4 Computing Approximate Equilibria for Node-Max-Cut

We complement our PLS-completeness proof for Node-Max-Cut, in Section 5, with an efficient algorithm computing $(1 + \varepsilon)$-approximate equilibria for Node-Max-Cut, when the number of different vertex weights is a constant. We note that similar results are not known (and a similar approach fails) for Max-Cut. Investigating if stronger approximation guarantees are possible for efficiently computable approximate equilibria for Node-Max-Cut is beyond the scope of this work and an intriguing direction for further research.

Given a vertex-weighted graph $G(V,E)$ with n vertices and m edges, our algorithm, called BridgeGaps, computes a $(1+\varepsilon)^3$-approximate equilibrium for a Node-Max-Cut, for any $\varepsilon > 0$, in $(m/\varepsilon)(n/\varepsilon)^{O(D_\varepsilon)}$ time, where D_ε is the number of different vertex weights in G, when the weights are rounded down to powers of $1+\varepsilon$. We next sketch the algorithm and the proof of Theorem 3.

For simplicity, we assume that n/ε is an integer and that vertices are indexed in nondecreasing order of weight, i.e., $w_1 \le w_2 \le \cdots \le w_n$. BridgeGaps first rounds down vertex weights to the closest power of $(1+\varepsilon)$. Namely, each weight w_i is replaced by weight $w'_i = (1+\varepsilon)^{\lfloor \log_{1+\varepsilon} w_i \rfloor}$. Clearly, an $(1+\varepsilon)^2$-approximate equilibrium for the new instance G' is an $(1+\varepsilon)^3$-approximate equilibrium for the original instance G. The number of different weights D_ε, used in the analysis, is defined wrt. the new instance G'.

Then, BridgeGaps partitions the vertices of G' into groups $g_1, g_2, \ldots$, so that the vertex weights in each group increase with the index of the group and the ratio of the maximum weight in group g_j to the minimum weight in group g_{j+1} is no less than n/ε. This can be performed by going through the vertices, in nondecreasing order of their weights, and assign vertex $i+1$ to the same group as vertex i, if $w'_{i+1}/w'_i \le n/\varepsilon$. Otherwise, vertex $i+1$ starts a new group. The idea is that for an $(1+\varepsilon)^2$-approximate equilibrium in G', we only need to enforce the $(1+\varepsilon)$-approximate equilibrium condition for each vertex i only for i's neighbors in the highest-indexed group (that includes some neighbor of i). To see this, let g_j be the highest-indexed group that includes some neighbor of i and let ℓ be the lowest indexed neighbor of i in g_j. Then, the total weight of i's neighbors in groups $g_1, \ldots, g_{j-1}$ is less than $\varepsilon w'_\ell$. This holds because i has at most $n-2$ neighbors in these groups and by definition, $w'_q \le (\varepsilon/n) w'_\ell$, for any i's neighbor q in groups $g_1, \ldots, g_{j-1}$. Therefore, we can ignore all neighbors of i in groups $g_1, \ldots, g_{j-1}$, at the expense of one more $1+\varepsilon$ factor in the approximate equilibrium condition.

Since for every vertex i, we need to enforce its (approximate) equilibrium condition only for i's neighbors in a single group, we can scale down vertex weights in the same group uniformly (i.e., dividing all the weights in each group by the same factor), as long as we maintain the key property in the definition of groups (i.e., that the ratio of the maximum weight in group g_j to the minimum weight in group g_{j+1} is no less than n/ε). Hence, we uniformly scale down the weights in each group so that (i) the minimum weight in group g_1 becomes 1; and (ii) for each $j \ge 2$, the ratio of the maximum weight in group g_{j-1} to the minimum weight in group g_j becomes exactly n/ε. This results in a new instance G'' where the minimum weight is 1 and the maximum weight is $(n/\varepsilon)^{D_\varepsilon}$. Therefore, a $(1+\varepsilon)$-approximate equilibrium in G'' can be computed, in a standard way, after at most $(m\varepsilon)(n/\varepsilon)^{2D_\varepsilon}$ ε-best response moves.

Putting everything together and using $\varepsilon' = \varepsilon/7$, so that $(1+\varepsilon')^3 \le 1+\varepsilon$, for all $\varepsilon \in (0,1]$, we obtain the following. We note that the running time of BridgeGaps is polynomial, if $D_\varepsilon = O(1)$ (and quasipolynomial if $D_\varepsilon = \text{poly}(\log n)$).

▶ **Theorem 3.** *For any vertex-weighted graph G with n vertices and m edges and any $\varepsilon > 0$, BridgeGaps computes a $(1+\varepsilon)$-approximate pure Nash equilibrium for Node-Max-Cut on G in $(m/\varepsilon)(n/\varepsilon)^{O(D_\varepsilon)}$ time, where D_ε denotes the number of different vertex weights in G, after rounding them down to the nearest power of $1+\varepsilon$.*

5 PLS-Completeness of Node-Max-Cut

In this section we sketch the proof of Theorem 4 and highlight the main differences of our reduction from known PLS reductions to Max-Cut [9, 20, 33].

▶ **Theorem 4.** *Local-Node-Max-Cut is PLS-complete.*

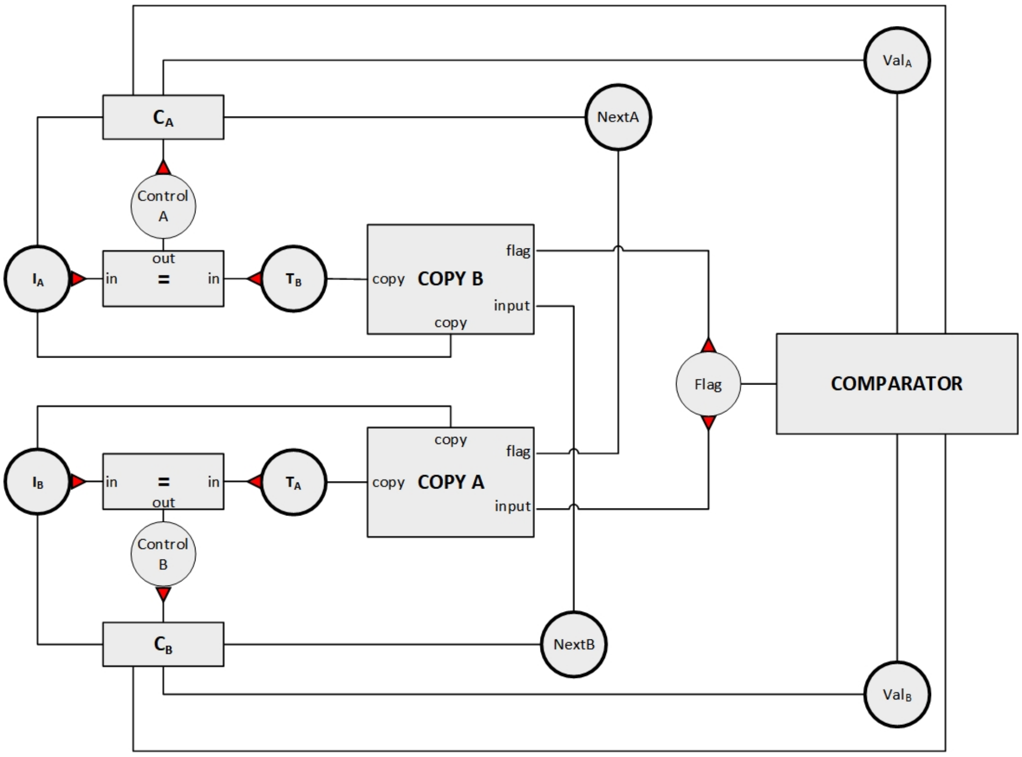

Figure 3 The general structure of the Node-Max-Cut instance constructed in the proof of Theorem 4. Rectangles denote the main gadgets, circles denote vertices that participate in multiple gadgets, and circles with bold border denote groups of n such vertices. The small red triangles are used to indicate the "information flow" through the instance.

As discussed in Section 2, the local search version of Node-Max-Cut is in PLS. To establish the PLS-hardness of Node-Max-Cut, we present a reduction from Circuit-Flip. We start with an outline of our construction and a brief discussion of its technical novelty. Then, in Section 5.1, we discuss our gadget constructions in more detail and present the key technical steps towards the proof of Theorem 4.

An Outline of the Construction. An instance of Circuit-Flip consists of a Boolean circuit C with n inputs and m outputs (and wlog. only NOR gates). The value $C(s)$ of an n-bit input string s is the integer corresponding to the m-bit output string. The neighborhood $N(s)$ of s consists of all n-bit strings s' at Hamming distance 1 to s (i.e., s' is obtained from s by flipping one bit of s). The goal is to find a locally optimal input string s, i.e., an s with $C(s) \geq C(s')$, for all $s' \in N(s)$. Circuit-Flip was the first problem shown to be PLS-complete in [25].

Given an instance C of Circuit-Flip, we construct a vertex-weighted undirected graph $G(V, E)$ so that from any locally optimum cut of G, we can recover, in polynomial time, a locally optimal input of C. The graph G consists of different gadgets (see Figure 3), which themselves might be regarded as smaller instances of Node-Max-Cut. Intuitively, each of these gadgets receives information from its "input" vertices, processes this information, while carrying it through its internal part, and outputs the results through its "output" vertices. Different gadgets are glued together through their "input" and "output" vertices.

Our construction follows the *flip-flop* architecture (Figure 3), previously used e.g., in [9, 20, 33], but requires more sophisticated implementations of several gadgets, so as to conform with the very restricted weight structure of Node-Max-Cut. Next, we outline the functionality of the main gadgets and how the entire construction works.

Given a circuit C, we construct two *Circuit Computing* gadgets C_ℓ (ℓ always stands for either A or B), which are instances of Node-Max-Cut that simulate circuit C in the following sense: Each C_ℓ has a set I_ℓ of n "input" vertices, whose (cut) values correspond to the input string of circuit C, and a set Val_ℓ of m "output" vertices, whose values correspond to the output string of C on input I_ℓ. There is also a set $Next\ell$ of n vertices whose values correspond to a n-bit string in the neighborhood of I_ℓ of circuit value larger than that of I_ℓ (if the values of Nextℓ coincide with the values of I_ℓ, I_ℓ is locally optimal). Lastly, there is a (set of) vertices $Control_\ell$ that control the behavior of the gadget.

The Circuit Computing gadgets operate in two different modes, determined by Control$_\ell$: the *write mode*, when Control$_\ell = 0$, and the *compute mode*, when Control$_\ell = 1$. If C_ℓ operates in write mode, the input values of I_ℓ can be updated to the values of the complementary Next set (i.e., I_A is updated to NextB, and vice versa). When, C_ℓ operates in the compute mode, C_ℓ simulates the computation of circuit C and the values of Nextℓ and Val$_\ell$ are updated to the corresponding values produced by C. Throughout the proof, we let Real-Val(I_ℓ) denote the output string of circuit C on input I_ℓ (i.e., the input of C takes the cut values of the vertices in I_ℓ), and let Real-Next(I_ℓ) denote a neighbor of I_ℓ with circuit value larger than the circuit value of I_ℓ. If I_ℓ is locally optimal, Real-Next(I_ℓ) $= I_\ell$.

Our Circuit Computing gadgets C_A and C_B are based on the gadgets of Schäffer and Yannakakis [33] (see also Figure 4 for an abstract description of them). Their detailed construction is described in the next section and their properties are summarized in Theorem 5.

The *Comparator* gadget compares Val$_A$ with Val$_B$, which are intended to be Real-Val(I_A) and Real-Val(I_B), respectively, and outputs 1, if Val$_A \leq$ Val$_B$, and 0, otherwise. The result of the Comparator is stored in the value of the *Flag* vertex. If Flag $= 1$, the Circuit Computing gadget C_A enters its write mode and the input values in I_A are updated to the neighboring solution of I_B, currently stored in NextB (everything operates symmetrically, if Flag $= 0$). Then, in the next "cycle", the input in I_A leads C_A to a Val$_A >$ Val$_B$ (and to a better neighboring solution at NextA), Flag becomes 0, and the values of I_B are updated to NextA. When we reach a local optimum, I_A and I_B are stabilized to the same values.

The workflow above is implemented by the *Copy* and the *Equality* gadgets. The *CopyB* (resp. *CopyA*) gadget updates the values of I_A (resp. I_B) to the values in NextB (resp. NextA), if Val$_A \leq$ Val$_B$ and Flag $= 1$ (resp. Val$_A >$ Val$_B$ and Flag $= 0$). When Flag $= 1$, the vertices in T_B take the values of the vertices in NextB. If the values of I_A and NextB are different, the Equality gadget sets the value of Control$_A$ to 0. Hence, the Circuit Computing gadget C_A enters its write mode and the vertices in I_A take the values of the vertices in NextB. Next, Control$_A$ becomes 1, because the values of I_A and NextB are now identical, and C_A enters its compute mode. As a result, the vertices in Val$_A$ and NextA take the values of Real-Val(I_A) and Real-Next(I_A), and we proceed to the next cycle.

A key notion used throughout the reduction is the *bias* that a vertex i experiences from a vertex subset. The bias of vertex i from (or wrt.) $V' \subseteq V$ is $\left|\sum_{j \in V_i^1 \cap V'} w_j - \sum_{j \in V_i^0 \cap V'} w_j\right|$, where V_i^1 (resp. V_i^0) denotes the set of i's neighbors on the 1 (resp. 0) side of the cut.

Technical Novelty. Next, we briefly discuss the points where our reduction needs to deviate substantially from known PLS reductions to Max-Cut. Our discussion is unavoidably technical and assumes familiarity with (at least one of) the reductions in [9, 20, 33].

Our Circuit Computing gadgets are based on similar gadgets used e.g., in [33]. A key difference is that our Circuit Computing gadgets are designed to operate with w_{Control} (i.e., weight of the Control_ℓ vertex) arbitrarily smaller than the weight of any other vertex in the Circuit Computing gadget. Hence, the Control vertex can achieve a very small bias wrt. the Circuit Computing gadget (see Theorem 5, Case 3), which in turn, allows us to carefully balance the weights in the Equality gadget. The latter weights should be large enough, so as to control the write and compute modes of C_ℓ, and at the same time, small enough, so as to avoid interference with the values of the input vertices I_ℓ. The second important reason for setting w_{Control} sufficiently small is that we need the Control vertex to follow the "output" of the Equality gadget, and not the other way around.

The discussion above highlights a key difference between Max-Cut and Node-Max-Cut. Previous reductions to Max-Cut (see e.g., the reduction in [33]) implement Control's functionality using different weights for its incident edges. More specifically, Control is connected with edges of appropriately large weight to the vertices of the circuit gadget, so that it can control the gadget's mode, and with edges of appropriately small weight to vertices outside the circuit gadget, so that its does not interfere with its other neighbors.

For Node-Max-Cut, we need to achieve the same desiderata with a single vertex weight. We manage to do so by introducing a *Leverage* gadget. Our *Leverage* gadget reduces the influence of a vertex with large weight to a vertex with small weight and is used internally in the Circuit Computing gadget. Hence, we achieve that Control has small bias wrt. the circuit gadget and weight comparable to the weights of the circuit gadget's internal vertices.

Another important difference concerns the implementation of the *red marks* (denoting the information flow) between Flag and the Copy gadgets, in Figure 3. They indicate that the value of Flag should agree with the output of the Comparator gadget. This part of the information flow is difficult to implement, because the Comparator gadget and the Copy gadgets receive input from NextA, NextB, Val_A and Val_B, where the vertex weights are comparable to the weights of the output vertices in the Circuit Computing gadgets. As a result, the weights of the vertices inside the Comparator gadget cannot become sufficiently larger than the weights of the vertices inside the Copy gadgets. [33, 20, 9] connect Flag to the Copy gadgets with edges of sufficiently small weight, which makes the bias of Flag from the Copy gadgets negligible compared against its bias from Comparator. Again, the *Leverage* gadget comes to our rescue. We use it internally in the Copy gadgets, in order to decrease the influence of the vertices inside the Copy gadgets to Flag. As a result, Flag's bias from the Copy gadgets becomes much smaller than its bias from Comparator (see Lemma 10).

Another key technical difference concerns the design of the Comparator gadget. As stated in Lemma 10 and explained below, the Comparator gadget manages to compute the result of the comparison $\text{Real-Val}(I_A) \leq \text{Real-Val}(I_B)$, even if some input vertices may have incosistent values. In previous work [33, 20, 9], the Comparator guarantees correctness of the values in both NextB and Val_B using appropriately chosen edge weights. With the correctness of the input values guaranteed, the comparison is not hard to implement. It is not clear if this decoupled architecture of the Comparator gadget can be implemented in Node-Max-Cut, due to the special structure of edge weights. Instead, we implement a new *all at once* Comparator, which ensures correctness to a subset of its input values enough to perform the comparison correctly (see also the discussion after Lemma 11 on this point).

5.1 A Technical Overview of the Proof of Theorem 4

In this section, we outline the gadget constructions and the key technical claims used in the proof of Theorem 4. As shown in Figure 3, our Node-Max-Cut instance consists of the following gadgets:

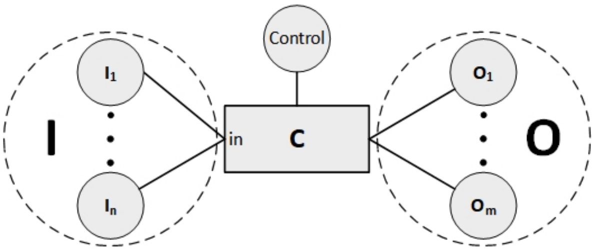

Figure 4 The Circuit Computing gadgets. The dashed circles, labeled I and O, represent all input and output vertices, respectively.

1. Two Circuit Computing gadgets that calculate the values and next neighbors of solutions.
2. Two Copy gadgets that transfer the solution of one circuit to the other, and vice versa.
3. Two Equality gadgets that determine the (write or compute) mode in which the Circuit Computing gadgets operate.
4. A Comparator gadget.

Unlike previous similar reductions in the literature (see e.g.,[33, 20, 9]), we introduce each gadget separately rather than through types of diminishing weight. This is because in NODE-MAX-CUT, weights are associated with vertices and each vertex may be part of multiple gadgets.

The Circuit Computing Gadgets. The Circuit Computing gadgets C_A and C_B are the basic primitives of our reduction. They are based on the gadgets introduced by Schäffer and Yannakakis [33] to establish PLS-completeness of MAX-CUT. This type of Circuit Computing gadgets can be constructed so as to simulate any Boolean circuit C.

The most important vertices are those corresponding to the input and the output of the simulated circuit C. Another important vertex is Control, which allows the gadget to switch between the write and the compute mode of operation. Figure 4 is an abstract depiction of the Circuit Computing gadgets. Theorem 5 describes the local optimum behavior of the input vertices I_ℓ and output vertices Nextℓ, Val$_\ell$ of the Circuit Computing gadgets C_ℓ.

▶ **Theorem 5.** *At any local optimum of the NODE-MAX-CUT instance in Figure 3, the following hold:*

1. *If Control$_\ell = 1$ and the vertices in Nextℓ, Val$_\ell$ experience 0 bias from any other gadget beyond C_ℓ, then Nextℓ = Real-Next(I_ℓ) and Val$_\ell$ = Real-Val(I_ℓ).*
2. *If Control$_\ell = 0$, then each vertex in I_ℓ experiences 0 bias from the internal vertices of C_ℓ.*
3. *Control$_\ell$ experiences w_{Control_ℓ} bias from the internal vertices of C_ℓ.*

Case 1 of Theorem 5 describes the *compute mode* of the Circuit Computing gadgets. At any local optimum with Control$_A = 1$ and with the output vertices of C_A being indifferent wrt. other gadgets, C_A computes its output correctly. Case 2 of Theorem 5 describes the *write mode.* If at a local optimum Control$_A = 0$, the vertices in I_A have 0 bias from the C_A gadget. As a result, their value is determined by the biases of the CopyB gadget and the Equality gadget. Case 3 of Theorem 5 bounds the bias that the Equality gadget poses to the Control vertices, so as to make the computing gadget flip from one mode to the other.

The Copy and Equality Gadgets. The Copy and Equality gadgets are responsible for transferring the output of one Circuit Computing gadget to the other. More specifically, the Equality gadget takes as input the nodes I_A, I_B, T_A, T_B and assures that the Control vertices always have the correct values. Recall that as shown in Theorem 5, Case 3, the bias that the Equality gadget exerts is enough to dominate the values of the Control nodes. Using that, we can prove the following lemma:

▶ **Lemma 6.** *For any local optimum of the* Node-Max-Cut *instance in Figure 3, we have that* $Control_A = (I_A = T_B)$ *and* $Control_B = (I_B = T_A)$.

The Copy gadget transfers the values of the NextB and NextA to I_A and I_B, respectively, when each gadget is in its *write mode*. This behavior is summarized by the following:

▶ **Lemma 7.** *At any local optimum point of the* Node-Max-Cut *instance in Figure 3, the following hold:*

1. *If* $Flag = 1$*, i.e.,* $NextB$ writes *on* I_A*, then (i)* $T_B = NextB$*, and (ii) if* $Control_A = 0$*, then* $I_A = T_B = NextB$.
2. *If* $Flag = 0$ *i.e.,* $NextA$ writes *on* I_B*, then (i)* $T_A = NextA$*, and (ii) if* $Control_B = 0$*, then* $I_B = T_A = NextA$.

Additionally, the Copy gadget has the property of leaving the NextB and NextA vertices unbiased, when Flag has certain values. This is necessary so that whenever a Circuit Computing gadget is about to compute, the second condition of Theorem 5, Case 1, can apply and allow the computation to take place.

▶ **Lemma 8.** *At any local optimum of the* Node-Max-Cut *instance in Figure 3:*

- *If* $Flag = 1$*, then any vertex in* $NextA$ *experiences* 0 *bias from the* $CopyA$ *gadget.*
- *If* $Flag = 0$*, then any vertex in* $NextB$ *experiences* 0 *bias from the* $CopyB$ *gadget.*

Having established the above properties of the Copy and Equality gadgets, we can show the following theorem which asserts that at an local optimum, one of the two circuits has taken the other's output as input.

▶ **Theorem 9.** *At any a local optimum of the* Node-Max-Cut *instance in Figure 3, the following hold:*

- *If* $Flag = 1$*, then* $I_A = NextB$.
- *If* $Flag = 0$*, then* $I_B = NextA$.

Proof of Theorem 9. Let a local optimum in which Flag $= 1$. Let us assume that $I_A \neq$ NextB. Then, by Case 1 of Lemma 7, $T_B =$ NextB. As a result, $I_A \neq T_B$, which implies that $Control_A = 0$, by Lemma 6. Now, by Lemma 7, Case 1.ii, we have that $I_A =$ NextB, which is a contradiction. The same analysis can be applied in case where Flag $= 0$. ◀

The Comparator Gadget. The last important gadget in our reduction is the Comparator, whose construction is technically involved. We first recall that Nextℓ and Val$_\ell$ denote the actual values that the corresponding vertices have in our construction, while Real-Next(I_ℓ) and Real-Val(I_ℓ) denote the values that these vertices are supposed to have, assuming that the Circuit Computing gadgets operate correctly. We also recall that when Flag $= 1$ (resp. Flag $= 0$), the Circuit Computing gadget C_A (resp. C_B) recomputes its output values, based on the (possibly incorrect) outputs of the other Circuit Computing gadget C_B (resp. C_A). The construction of the Comparator gadget and the following lemmas ensure that at any local optimum of the Node-Max-Cut instance in Figure 3, the actual values of the vertices in Nextℓ and Val$_\ell$ are identical to Real-Next(I_ℓ) and Real-Val(I_ℓ).

First, connecting certain internal vertices of the Circuit Computing gadgets with the vertices in NextA and NextB and in the Comparator, we obtain the following pair of lemmas.

▶ **Lemma 10.** *At any local optimum of the* Node-Max-Cut *instance in Figure 3, the following hold:*

- *If* $Flag = 1$*,* $NextA = Real\text{-}Next(I_A)$*,* $Val_A = Real\text{-}Val(I_A)$ *and* $NextB = Real\text{-}Next(I_B)$*, then* $Real\text{-}Val(I_A) \leq Real\text{-}Val(I_B)$*.*
- *If* $Flag = 0$*,* $NextB = Real\text{-}Next(I_B)$*,* $Val_B = Real\text{-}Val(I_B)$ *and* $NextA = Real\text{-}Next(I_A)$*, then* $Real\text{-}Val(I_B) \leq Real\text{-}Val(I_A)$*.*

▶ **Lemma 11.** *At any local optimum of the* Node-Max-Cut *instance in Figure 3:*

- *If* $Flag = 1$*, then* $NextB = Real\text{-}Next(I_B)$*.*
- *If* $Flag = 0$*, then* $NextA = Real\text{-}Next(I_A)$*.*

We should highlight that in the proofs of Lemma 10 and Lemma 11, in the first case where Flag = 1 (the case where Flag = 0 is symmetric), the correctness of values of the output vertices NextB (i.e., that NextB = Real-Next(I_B), in the first case of Lemma 11) is not guaranteed by Theorem 5 (as it happens with the correctness of the values of the output vertices NextA and Val$_A$ in the hypothesis of the first case in Lemma 10), but from the construction of the Comparator gadget. We should also highlight that Lemma 11 does not imply anything about the correctness of the Val$_B$ values, as this cannot be guaranteed in our construction. Hence, (the first case of) Lemma 10 does not assume anything about Val$_B$ (in particular, it does not assume that Val$_B$ = Real-Val(I_B), as one might have expected). However, the Comparator gadget manages to output the right outcome of the comparison Real-Val(I_A) ≤ Real-Val(I_B), even if Val$_B$ ≠ Real-Val(I_B). The connections from internal vertices of the Circuit Computing gadgets to the vertices in NextA and NextB and in the Comparator, in Figure 3, are crucial towards establishing this property. So, Lemma 10 ensures the robustness of the outcome of the Comparator, even with possibly inconsistent values in the output vertices Val$_B$. This property of the Comparator gadget is among the key technical steps (and novelties) in our reduction and is indicative of the difficulty of showing that Local-Node-Max-Cut is PLS-hard.

Furthermore, similarly to the Copy gadget, the Comparator gadget leaves the vertices of the Circuit Computing gadgets unbiased wrt. certain values of the Flag vertex.

▶ **Lemma 12.** *At any local optimum of the instance of* Node-Max-Cut *in Figure 3:*

- *If* $Flag = 1$*, then all vertices of* C_A *experience* 0 *bias from the Comparator gadget.*
- *If* $Flag = 0$*, then all vertices of* C_B *experience* 0 *bias from the Comparator gadget.*

Now using Lemma 8 and Lemma 12, we can prove the correctness of the output vertices NextA and Val$_A$, when Flag = 1, and of the output vertices NextB and Val$_B$, when Flag = 0.

▶ **Lemma 13.** *At any local optimum of the instance of* Node-Max-Cut *of Figure 3:*

- *If* $Flag = 1$*, then* $NextA = Real\text{-}Next(I_A)$ *and* $Val_A = Real\text{-}Val(I_A)$*.*
- *If* $Flag = 0$*, then* $NextB = Real\text{-}Next(I_B)$ *and* $Val_B = Real\text{-}Val(I_B)$*.*

Proof. We only consider the case where Flag = 1 (the same analysis applies to the case where Flag = 0). By Theorem 9, I_A = NextB, and by Lemma 7, T_B = NextB. As a result, $I_A = T_B$, and by Lemma 6, Control$_A$ = 1. Then, Lemmas 8 and 12 ensure that the vertices in NextA and Val$_A$ of the Computing Gadget C_A experience 0 bias from all the other gadgets. Therefore, since Control$_A$ = 1, we can apply Theorem 5, Case 1, and conclude that Val$_A$ = Real-Val(I_A) and that NextA = Real-Next(I_A). ◀

Concluding the Proof of Theorem 4. The technical lemmas above are summarized by the following key technical claim:

▶ **Theorem 14.** *At any local optimum of the instance of* NODE-MAX-CUT *of Figure 3:*

- *If Flag* $= 1$*, then (i) Real-Val*$(I_A) \leq$ *Real-Val*(I_B)*, and (ii) NextB* $=$ *Real-Next*(I_B)*.*
- *If Flag* $= 0$*, then (i) Real-Val*$(I_B) \leq$ *Real-Val*(I_A)*, and (ii) NextA* $=$ *Real-Next*(I_A)*.*

Proof of Theorem 14. We consider a local optimum of the instance in Figure 3 with Flag $= 1$ (the same argument applies when Flag $= 0$). By Lemma 11, NextB $=$ Real-Next(I_B), and thus, (ii) is established. Moreover by Lemma 13, NextA $=$ Real-Next(I_A) and Val$_A$ $=$ Real-Val(I_A). Consequently, by Lemma 10, we conclude Real-Val$(I_A) \leq$ Real-Val(I_B). ◀

With theorems 9 and 14 at hand, the PLS-completeness of LOCAL-NODE-MAX-CUT follows easily. For the sake of completeness, we show how we put everything together.

Proof of Theorem 4. For a given circuit C of CIRCUIT-FLIP, we construct in polynomial time the instance of NODE-MAX-CUT in Figure 3. We next consider any local optimum of this instance. Without loss of generality, we assume that Flag $= 1$. Then, by Theorem 9 and Theorem 14, $I_A =$ NextB, NextB $=$ Real-Next(I_B) and Real-Val$(I_A) \leq$ Real-Val(I_B). Hence, we obtain that

$$\text{Real-Val}(I_B) \geq \text{Real-Val}(I_A) = \text{Real-Val}(\text{NextB}) = \text{Real-Val}(\text{Real-Next}(I_B))\,.$$

If $I_B \neq$ Real-Next(I_B), then Real-Val$(I_B) >$ Real-Val(Real-Next(I_B)), which is a contradiction. Therefore, $I_B =$ Real-Next(I_B), meaning that the binary string defined by the values of I_B is a locally optimal solution for CIRCUIT-FLIP. ◀

6 Conclusions and Future Work

In this work, we showed that equilibrium computation in linear weighted congestion games is PLS-complete either on single-commodity series-parallel networks or on multi-commodity networks with identity latency functions, where computing an equibrium for (unweighted) congestion games is known to be easy. The key step for the latter reduction is to show that local optimum computation for NODE-MAX-CUT, a natural and significant restriction of MAX-CUT, is PLS-complete. The reductions in Section 3 are both *tight* [33], thus preserving the structure of the local search graph. In particular, for the first reduction, we have that (i) there are instances of linear weighted congestion games on single-commodity series-parallel networks such that any best response sequence has exponential length; and (ii) that the problem of computing the equilibrium reached from a given initial state is PSPACE-hard.

However, our reduction of CIRCUIT-FLIP to NODE-MAX-CUT is not tight. Specifically, our *Copy* and *Equality* gadgets allow that the *Circuit Computing* gadget might enter its *compute* mode, before the entire input has changed. Thus, we might “jump ahead” and reach an equilibrium before CIRCUIT-FLIP would allow, preventing the reduction from being tight.

Our work leaves several interesting directions for further research. A natural first step is to investigate the complexity of equilibrium computation for weighted congestion games on series-parallel (or extension-parallel) networks with identity latency functions. An intriguing research direction is to investigate whether our ideas (and gadgets) in the PLS-reduction for NODE-MAX-CUT could lead to PLS-hardness results for approximate equilibrium computation for standard and weighted congestion games (similarly to the results of Skopalik and Vöcking [34], but for latency functions with non-negative coefficients). Finally, it would be interesting to understand better the quality of efficiently computable approximate equilibria for NODE-MAX-CUT and the smoothed complexity of its local optima.

Abstract

We consider the online Min-Sum Set Cover (MSSC), a natural and intriguing generalization of the classical list update problem. In Online MSSC, the algorithm maintains a permutation on n elements based on subsets $S_1, S_2, \ldots$ arriving online. The algorithm serves each set S_t upon arrival, using its current permutation π_t, incurring an access cost equal to the position of the first element of S_t in π_t. Then, the algorithm may update its permutation to π_{t+1}, incurring a moving cost equal to the Kendall tau distance of π_t to π_{t+1}. The objective is to minimize the total access and moving cost for serving the entire sequence. We consider the r-uniform version, where each S_t has cardinality r. List update is the special case where $r = 1$.

We obtain tight bounds on the competitive ratio of deterministic online algorithms for MSSC against a static adversary, that serves the entire sequence by a single permutation. First, we show a lower bound of $(r+1)(1-\frac{r}{n+1})$ on the competitive ratio. Then, we consider several natural generalizations of successful list update algorithms and show that they fail to achieve any interesting competitive guarantee. On the positive side, we obtain a $O(r)$-competitive deterministic algorithm using ideas from online learning and the multiplicative weight updates (MWU) algorithm.

Furthermore, we consider efficient algorithms. We propose a memoryless online algorithm, called *Move-All-Equally*, which is inspired by the Double Coverage algorithm for the k-server problem. We show that its competitive ratio is $\Omega(r^2)$ and $2^{O(\sqrt{\log n \cdot \log r})}$, and conjecture that it is $f(r)$-competitive. We also compare Move-All-Equally against the dynamic optimal solution and obtain (almost) tight bounds by showing that it is $\Omega(r\sqrt{n})$ and $O(r^{3/2}\sqrt{n})$-competitive.

1 Introduction

In Min-Sum Set Cover (MSSC), we are given a universe U on n elements and a collection of subsets $\mathcal{S} = \{S_1, \dots, S_m\}$, with $S_t \subseteq U$, and the task is to construct a permutation (or list) π of elements of U. The cost $\pi(S_t)$ of covering a set S_t (a.k.a. the cover time of S_t) with a permutation π is the position of the first element of S_t in π, i.e., $\pi(S_t) = \min\{i \,|\, \pi(i) \in S_t\}$. The goal is to minimize the overall cost $\sum_t \pi(S_t)$ of covering all subsets of $\mathcal{S}$.

The MSSC problem generalizes various NP-hard problems such as Min-Sum Vertex Cover and Min-Sum Coloring and it is well-studied. Feige, Lovasz and Tetali [25] showed that the greedy algorithm, which picks in each position the element that covers the most uncovered sets, is a 4-approximation (this was also implicit in [11]) and that no $(4-\epsilon)$-approximation is possible, unless P = NP. Several generalizations have been considered over the years with applications in various areas (we discuss some of those problems and results in Section 1.2).

Online Min-Sum Set Cover. In this paper, we study the online version of Min-Sum Set Cover. Here, the sets arrive online; at time step t, the set S_t is revealed. An online algorithm is charged the *access cost* of its current permutation $\pi_t(S_t)$; then, it is allowed to change its permutation to π_{t+1} at a *moving cost* equal to the number of inversions between π_t and π_{t+1}, known as the Kendall tau distance $d_{\text{KT}}(\pi_t, \pi_{t+1})$. The goal is to minimize the total cost, i.e., $\sum_t \big(\pi_t(S_t) + d_{\text{KT}}(\pi_t, \pi_{t+1})\big)$. This is a significant generalization of the classic list update problem, which corresponds to the special case where $|S_t| = 1$ for all sets $S_t \in \mathcal{S}$.

Motivation. Consider a web search engine, such as Google. Each query asked might have many different meanings depending on the user. For example, the query "Python" might refer to an animal, a programming language or a movie. Given the pages related to "Python", a goal of the search engine algorithm is to rank them such that for each user, the pages of interest appear as high as possible in the ranking (see e.g., [23]). Similarly, news streams include articles covering different reader interests each. We want to rank the articles so that every reader finds an article of interest as high as possible. The MSSC problem serves as a theoretical model for practical problems of this type, where we want to aggregate disjunctive binary preferences (expressed by the input sets) into a total order. E.g., for a news stream, the universe U corresponds to the available articles and the sets S_t correspond to different user types. The cost of a ranking (i.e., permutation on U) for a user type is the location of the first article of interest. Clearly, in such applications, users arrive online and the algorithm might need to re-rank the stream (i.e., change the permutation) based on user preferences.

Benchmarks. For the most part, we evaluate the performance of online algorithms by comparing their cost against the cost of an optimal offline solution that knows the input in advance and chooses an optimal permutation π. Note that this solution is *static*, in the sense that it does not change permutations over time. This type of analysis, called *static optimality*, is typical in online optimization and online learning. It was initiated in the context of adaptive data structures by the landmark result of Sleator and Tarjan [44], who showed that *splay trees* are asymptotically as fast as any *static* tree. Since then, it has been an established benchmark for various problems in this area (see e.g. [13, 30]); it is also a standard benchmark for several other problems in online optimization (e.g., online facility location [26, 37], minimum metric matching [28, 33, 39], Steiner tree [38], etc.).

A much more general benchmark is the *dynamic Min-Sum Set Cover* problem, where the algorithm is compared against an optimal solution allowed to change permutations over time. This problem has not been studied even in the offline case. In this work, we define the problem formally and obtain first results for the online case.

We remark that the online dynamic MSSC problem belongs to a rich class of problems called *Metrical Task Systems* (MTS) [15]. MTS is a far-reaching generalization of several fundamental online problems and provides a unified framework for studying online problems (we discuss this in more detail in Section 1.2). Indeed, our results suggest that solving the online dynamic MSSC requires the development of powerful generic techniques for online problems, which might have further implications for the broader setting of MTS.

Throughout this paper, whenever we refer to online problems, like Min-Sum Set Cover or list update, we assume the static case, unless stated otherwise.

Previous Work on List Update. Prior to our work, the only version of online MSSC studied is the special case where $|S_t| = 1$ for all sets; this is the celebrated list update problem and it has been extensively studied (an excellent reference is [14]). It is known that the deterministic competitive ratio it least $2 - \frac{2}{n+1}$ and there are several 2-competitive algorithms known; most notably, the Move-to-Front (MTF) algorithm, which moves the (unique) element of S_t to the first position of the permutation, and the Frequency Count algorithm, which orders the elements in decreasing order according to their frequencies.

The dynamic list update problem has also been extensively studied. MTF is known to be 2-competitive [43] and there are several other 2-competitive algorithms [1, 24].

1.1 Our Results

In this work, we initiate a systematic study of the online Min-Sum Set Cover problem. We consider the r-uniform case, where all request sets have the same size $|S_t| = r$. This is without loss of generality, as we explain in Section 1.3.

The first of our main results is a tight bound on the deterministic competitive ratio of Online MSSC. We show that the competitive ratio of deterministic algorithms is $\Omega(r)$.

▶ **Theorem 1.** *Any deterministic online algorithm for the Online Min-Sum Set Cover problem has competitive ratio at least* $(r + 1)(1 - \frac{r}{n+1})$.

Note that for $r = 1$, this bound evaluates to $2 - \frac{2}{n+1}$, which is exactly the best known lower bound for the list update problem.

We complement this result by providing a matching (up to constant factors) upper bound.

▶ **Theorem 2.** *There exists a* $(5r + 2)$*-competitive deterministic online algorithm for the Online Min-Sum Set Cover problem.*

Interestingly, all prior work on the list update problem (case $r = 1$) does not seem to provide us with the right tools for obtaining an algorithm with such guarantees! As we discuss in Section 2, virtually all natural generalizations of successful list update algorithms (e.g., Move-to-Front, Frequency Count) end up with a competitive ratio way far from the desired bound. In fact, even for $r = 2$, most of them have a competitive ratio depending on n, such as $\Omega(\sqrt{n})$ or even $\Omega(n)$.

This suggests that online MSSC has a distinctive combinatorial structure, very different from that of list update, whose algorithmic understanding calls for significant new insights. The main reason has to do with the disjunctive nature of the definition of the access cost $\pi(S_t)$. In list update, where $r = 1$, the optimal solution is bound to serve a request S_t by its unique element. The only question is how fast an online algorithm should upgrade it (and the answer is "as fast as possible"). In MSSC, the hard (and crucial) part behind the design of any competitive algorithm is how to ensure that the algorithm learns fast enough about the element e_t used by the optimal solution to serve each request S_t. This is evident in the highly adaptive nature of the deceptively simple greedy algorithm of [25] and in the adversarial request sequences for generalizations of Move-to-Front, in Section 2.

To obtain the asymptotically optimal ratio of Theorem 2, we develop a rounding scheme and use it to derandomize the multiplicative weights update (MWU) algorithm. Our analysis bounds the algorithm's access cost in terms of the optimal cost, but it does not account for the algorithm's moving cost. We then refine our approach, by performing lazy updates to the algorithm's permutation, and obtain a competitive algorithm for online MSSC.

We also observe (in Section 1.3) that based on previous work of Blum and Burch [12], there exists a (computationally inefficient) randomized algorithm with competitive ratio $1 + \epsilon$, for any $\epsilon \in (0, 1/4)$. This implies that no lower bound is possible, if randomization is allowed, and gives a strong separation between deterministic and randomized algorithms.

Memoryless Algorithms. While the bounds of Theorems 1 and 2 are matching, our algorithm from Theorem 2 is computationally inefficient since it simulates the MWU algorithm, which in turn, maintains a probability distribution over all $n!$ permutations. This motivates the study of trade-offs between the competitive ratio and computational efficiency. To this end, we propose a memoryless algorithm, called *Move-All-Equally* (MAE), which moves all elements of set S_t towards the beginning of the permutation at the same speed until the first reaches the first position. This is inspired by the Double Coverage algorithm from k-server [20, 21]. We believe that MAE achieves the best guarantees among all memoryless algorithms. We show that this algorithm can not match the deterministic competitive ratio.

▶ **Theorem 3.** *The competitive ratio of the Move-All-Equally algorithm is* $\Omega(r^2)$.

Based on Theorem 3, we conjecture that an $O(r)$ guarantee cannot be achieved by a memoryless algorithms. We leave as an open question whether MAE has a competitive ratio $f(r)$, or a dependence on n is necessary. To this end, we show that the competitive ratio of MAE is at most $2^{O(\sqrt{\log n \cdot \log r})}$ (see Section 4 for details).

Dynamic Min-Sum Set Cover. We also consider the dynamic version of online MSSC. Dynamic MSSC is much more general and the techniques developed for the static case do not seem adequately powerful. This is not surprising, since the MWU algorithm is designed to perform well against the best static solution. We investigate the performance of the MAE algorithm. First, we obtain an upper bound on its competitive ratio.

▶ **Theorem 4.** *The competitive ratio of the Move-All-Equally algorithm for the dynamic online Min-Sum Set Cover problem is* $O(r^{3/2}\sqrt{n})$.

Although this guarantee is not very strong, we show that, rather surprisingly, it is essentially tight and no better guarantees can be shown for this algorithm.

▶ **Theorem 5.** *For any $r \geq 3$, the competitive ratio of the Move-All-Equally algorithm for the dynamic online Min-Sum Set Cover problem is $\Omega(r\sqrt{n})$.*

This lower bound is based on a carefully crafted adversarial instance; this construction reveals the rich structure of this problem and suggests that more powerful generic techniques are required in order to achieve any $f(r)$ guarantees. In fact, we conjecture that the lower bound of Theorem 1 is the best possible (ignoring constant factors) even for the dynamic problem and that using a work-function based approach such a bound can be obtained.

1.2 Further Related Work

Multiple Intents Re-ranking. This is a generalization of MSSC where for each set S_t, there is a *covering requirement* $K(S_t)$, and the cost of covering a set S_t is the position of the $K(S_t)$-th element of S_t in π. The MSSC problem is the special case where $K(S_t) = 1$ for all sets S_t. Another notable special case is the Min-Latency Set Cover problem, which corresponds to the other extreme case where $K(S_t) = |S_t|$ [29]. Multiple Intents Re-ranking was first studied by Azar et. al. [5], who presented a $O(\log r)$-approximation; later $O(1)$-approximation algorithms were obtained [10,32,42]. Further generalizations have been considered, such as the Submodular Ranking problem, studied by Azar and Gamzu [4], which generalizes both Set Cover and MSSC, and the Min-Latency Submodular Cover, studied by Im et.al [31].

Prediction from Expert Advice and Randomized MSSC. In prediction from expert advice, there are N experts and expert i incurs a cost c_i^t in each step. A learning algorithm decides which expert i_t to follow (before the cost vector $\mathbf{c}^t$ is revealed) and incurs a cost of $c_{i_t}^t$. The landmark technique for solving this problem is the multiplicative weights update (MWU - a.k.a. Hedge) algorithm. For an in-depth treatment of MWU, we refer to [3,27,35].

In the classic online learning setting, there is no cost for moving probability mass between experts. However, in a breakthrough result, Blum and Burch [12] showed that MWU is $(1+\epsilon)$-competitive against the best expert, even if there is a cost D for moving probability mass between experts. By adapting this result to online MSSC (regarding permutations as experts), we can get an (inefficient) randomized algorithm with competitive ratio $(1+\epsilon)$, for any constant $\epsilon \in (0, 1/4)$. A detailed description is deferred to the full version of this paper.

Metrical Task Systems and Online Dynamic MSSC. The online dynamic Min-Sum Set Cover problem belongs to a rich family of problems called Metrical Task Systems (MTS). In MTS, we are given a set of N states and a metric function d specifying the cost of moving between the states. At each step, a task arrives; the cost of serving the task at state i is c_i. An algorithm has to choose a state to process the task. If it switches from state i to state j and processes the task there, it incurs a cost $d(i,j) + c_j$. Given an initial state and a sequence of requests, the goal is to process all tasks at minimum cost.

It is easy to see that the online version of dynamic MSSC problem is a MTS, where the states correspond to permutations, thus $N = n!$, and the distance between two states is their Kendall tau distance. For a request set S_t, the request is a vector specifying the cost $\pi(S_t)$ for every permutation π.

Several other fundamental online problems (e.g., k-server, convex body chasing) are MTS. Although there has been a lot of work on understanding the structure of MTS problems [2,8,9,15,16,22,34,40,41], there is not a good grasp on how the structure relates to the hardness of MTS problems. Getting a better understanding on this area is a long-term goal, since it would lead to a systematic framework for solving online problems.

1.3 Preliminaries

Notation. Given a request sequence $\mathcal{S} = \{S_1, \dots, S_m\}$, for any algorithm ALG we denote Cost(ALG($\mathcal{S}$)) or simply Cost(ALG) the total cost of ALG on $\mathcal{S}$. Similarly we denote AccessCost(ALG) the total access cost of ALG and MovingCost(ALG) the total movement cost of ALG. For a particular time step t, an algorithm using permutation π_t incurs an access cost AccessCost(ALG(t)) $= \pi_t(S_t)$. We denote by $\pi_t[j]$ the position of element $j \in U$ in the permutation π_t.

Online Min-Sum Set Cover. We focus on the r-uniform case, i.e., when all sets S_t have size $r \ll n$. This is essentially without loss of generality, because we can always let $r = \max_t |S_t|$ and add the $r - |S_t|$ last unrequested elements in the algorithm's permutation to any set S_t with $|S_t| < r$. Assuming that $r \leq n/2$, this modification cannot increase the optimal cost and cannot decrease the online cost by more than a factor of 2.

2 Lower Bounds on the Deterministic Competitive Ratio

We start with a lower bound on the deterministic competitive ratio of online MSSC.

▶ **Theorem 1.** *Any deterministic online algorithm for the Online Min-Sum Set Cover problem has competitive ratio at least* $(r+1)(1 - \frac{r}{n+1})$.

For the proof, we employ an averaging argument, similar to those in lower bounds for list update and k-server [36, 43]. In each step, the adversary requests the last r elements in the algorithm's permutation. Hence, the algorithm's cost is at least $(n - r + 1)$. Using a counting argument, we show that for any fixed set S_t of size r and any $i \in [n - r + 1]$, the number of permutations π with access cost $\pi(S_t) = i$ is $\binom{n-i}{r-1} r!(n-r)!$. Summing up over all permutations and dividing by $n!$, we get that the average access cost for S_t is $\binom{n+1}{r+1}\frac{r!(n-r)!}{n!} = \frac{n+1}{r+1}$. Therefore, the cost of the optimal permutation is a most $\frac{(n+1)}{r+1}$, and the competitive ratio of the algorithm at least $\frac{(n-r+1)(r+1)}{n+1}$. The details can be found in the full version of this paper.

Lower Bounds for Generalizations of Move-to-Front. For list update, where $r = 1$, simple algorithms like Move-to-Front (MTF) and Frequency Count achieve an optimal competitive ratio. We next briefly describe several such generalizations of them and show that their competitive ratio depends on n, even for $r = 2$. Missing details can be found in the full version.

MTF$_{\text{first}}$: Move to the first position (of the algorithm's permutation) the element of S_t appearing first in π_t . This algorithm is $\Omega(n)$-competitive when each request S_t consists of the last two elements in π_t. Then, the last element in the algorithm's permutation never changes and is used by the optimal permutation to serve the entire sequence!

MTF$_{\text{last}}$: Move to the first position the element of S_t appearing last in π_t .

MTF$_{\text{all}}$: Move to the first r positions all elements of S_t (in the same order as in π_t).

MTF$_{\text{random}}$: Move to the first position an element of S_t selected uniformly at random.

MTF$_{\text{last}}$, MTF$_{\text{all}}$ and MTF$_{\text{random}}$ have a competitive ratio of $\Omega(n)$ when each request S_t consists of a fixed element e (always the same) and the last element in π_t, because they all incur an (expected for MTF$_{\text{random}}$) moving cost of $\Theta(n)$ per request.

The algorithms seen so far fail for the opposite reasons: MTF$_{\text{first}}$ cares only about the first element and ignores completely the second, and the others are very aggressive on using the second (rth) element. A natural attempt to balance those two extremes is the following.

$\text{MTF}_{\text{relative}}$: Let i be the position of the first element of S_t in π_t. Move to the first positions of the algorithm's permutation (keeping their relative order) all elements of S_t appearing up to the position $c \cdot i$ in π_t, for some constant c. The bad instance for this algorithm is when each request S_t consists of the last element and the element at position $\lfloor n/c \rfloor - 1$ in π_t; it never uses the nth element and the adversary serves all requests with it at a cost of 1.

All generalizations of MTF above are memoryless and they all fail to identify the element by which optimal serves S_t. The following algorithm tries to circumvent this by keeping memory and in particular the frequencies of reqested elements.

$\text{MTF}_{\text{count}}$: Move to the first position the most frequent element of S_t (i.e., the element of S_t appearing in most requested sets so far).

This algorithm behaves better in easy instances, however with some more work we can show a lower bound of $\Omega(\sqrt{n})$ on its competitive ratio. Let $e_1, \dots, e_n$ be the elements indexed according to the initial permutation π_0 and $b = \sqrt{n}$. The request sequence proceeds in m/n phases of length n each. The first $n - b$ requests of each phase are $\{e_1, e_2\}, \{e_1, e_3\}, \dots, \{e_1, e_{n-b}\}$, and the last b requests consist of e_{n-b+i} and the element at position $n - b$ at the current algorithm's permutation, for $i = 1, \dots, b$. An optimal solution can cover all the requests by the elements $e_1, e_{n-b+1}, \dots, e_n$ with total cost $\Theta(m + n\sqrt{n})$. The elements $e_{n-b+1}, \dots, e_n$ are never upgraded by $\text{MTF}_{\text{count}}$. Hence, the algorithm's cost is $\Theta(m\sqrt{n})$.

3 An Algorithm with Asymptotically Optimal Competitive Ratio

Next, we present algorithm Lazy-Rounding (Algorithm 2) and analyze its competitive ratio. The following is the main result of this section:

▶ **Theorem 2.** *Deterministic online algorithm* Lazy-Rounding*, presented in Algorithm 2, is* $(5r + 2)$*-competitive for the static version of the Online Min-Sum Set Cover problem.*

The remainder of this section is devoted to the proof of Theorem 2. At a high-level, our approach is summarized by the following three steps:

1. We use as black-box the multiplicative weights update (MWU) algorithm with learning rate $1/n^3$. Using standard results from learning theory, we show that its expected access cost is within a factor 5/4 of OPT, i.e., $\text{AccessCost(MWU)} \le \frac{5}{4}\,\text{Cost(OPT)}$ (Section 3.1).
2. We develop an online rounding scheme, which turns any randomized algorithm $\mathcal{A}$ into a deterministic one, denoted $\text{Derand}(\mathcal{A})$, with access cost at most $2r \cdot \mathbb{E}[\text{AccessCost}(\mathcal{A})]$ (Section 3.2). However, our rounding scheme does not provide any immediate guarantee on the moving cost of $\text{Derand}(\mathcal{A})$.
3. Lazy-Rounding is a lazy version of Derand(MWU) that updates its permutation only if MWU's distribution has changed a lot. A *phase* corresponds to a time interval that Lazy-Rounding does not change its permutation. We show that during a phase:
   - **(i)** The upper bound on the access cost increases, compared to Derand(MWU), by a factor of at most 2, i.e., $\text{AccessCost(Lazy-Rounding)} \le 4r \cdot \mathbb{E}[\text{AccessCost(MWU)}]$ (Lemma 11).
   - **(ii)** The (expected) access cost of MWU is at least n^2. Since our algorithm moves only once per phase, its movement cost is at most n^2. Thus we get that (Lemma 12):

$$\text{MovingCost(Lazy-Rounding)} \le \mathbb{E}[\text{AccessCost(MWU)}]\,.$$

For the upper bound on the moving cost above, we relate how much MWU's distribution changes during a phase, in terms of the total variation distance, to the cost of MWU and the cost of our algorithm.

Based on the above properties, we compare the access and the moving cost of Lazy-Rounding against the access cost of MWU and to get the desired competitive ratio:

$$\mathrm{Cost}(\text{Lazy-Rounding}) \leq (4r+1)\,\mathbb{E}[\mathrm{AccessCost}(\mathrm{MWU})] \leq (5r+2)\,\mathrm{Cost}(\mathrm{OPT})\,.$$

Throughout this section we denote by $d_{\mathrm{TV}}(\delta, \delta')$ the total variation distance of two discrete probability distributions $\delta, \delta' : [N] \to [0,1]$, defined as $d_{\mathrm{TV}}(\delta, \delta') = \sum_{i=1}^{N} \max\{0, \delta(i) - \delta'(i)\}$.

3.1 Using Multiplicative Weights Update in Online Min-Sum Set Cover

In this section, we explain how the well-known MWU algorithm [27,35] is used in our context.

The MWU Algorithm. Given $n!$ permutations of elements of U, the algorithm has a parameter $\beta \in [0,1]$ and a weight w_π for each permutation $\pi \in [n!]$, initialized at 1. At each time step the algorithm chooses a permutation according to distribution $\mathrm{P}^t_\pi = w^t_\pi / (\sum_{\pi \in [n!]} w^t_\pi)$. When request S_t arrives, MWU incurs an expected access cost of

$$\mathbb{E}[\mathrm{AccessCost}(\mathrm{MWU}(t))] = \sum_{\pi \in [n!]} \mathrm{P}^t_\pi \cdot \pi(S_t)$$

and updates its weights $w^{t+1}_\pi = w^t_\pi \cdot \beta^{\pi(S_t)}$, where $\beta = e^{-1/n^3}$; this is the so-called *learning rate* of our algorithm. Later on, we discuss the reasons behind choosing this value.

On the Access Cost of MWU. Using standard results from learning theory [27,35] and adapting them to our setting, we get that the (expected) access cost of MWU is bounded by Cost(OPT). This is formally stated in Lemma 6 (and is proven in the full version).

▶ **Lemma 6.** *For any request sequence $\sigma = (S_1, \ldots, S_m)$ we have that*

$$\mathbb{E}[\mathrm{AccessCost}(\mathrm{MWU})] \leq \frac{5}{4} \cdot \mathrm{Cost}(\mathrm{OPT}) + 2n^4 \ln n\,.$$

On the Distribution of MWU. We now relate the expected access cost of the MWU algorithm to the total variation distance among MWU's distributions. More precisely, we show that if the total variation distance between MWU's distributions at times t_1 and t_2 is large, then MWU has incurred a sufficiently large access cost. The proof of the following makes a careful use of MWU's properties and is deferred to the full version of this paper.

▶ **Lemma 7.** *Let P^t be the probability distribution of the MWU algorithm at time t. Then,*

$$d_{\mathrm{TV}}(\mathrm{P}^t, \mathrm{P}^{t+1}) \leq \frac{1}{n^3} \cdot \mathbb{E}[\mathrm{AccessCost}(\mathrm{MWU}(t))].$$

The following is useful for the analysis of Lazy-Rounding. Its proof follows from Lemma 7 and the the triangle inequality and is deferred to the full version of this paper.

▶ **Lemma 8.** *Let t_1 and t_2 two different time steps such that $d_{\mathrm{TV}}(\mathrm{P}^{t_1}, \mathrm{P}^{t_2}) \geq 1/n$. Then,*

$$\sum_{t=t_1}^{t_2-1} \mathbb{E}[\mathrm{AccessCost}(\mathrm{MWU}(t))] \geq n^2\,.$$

3.2 Rounding

Next, we present our rounding scheme. Given as input a probability distribution δ over permutations, it outputs a fixed permutation ρ such that for each possible request set S of size r, the cost of ρ on S is within a $O(r)$ factor of the expected cost of the distribution δ on S. For convenience, we assume that n/r is an integer. Otherwise, we use $\lceil n/r \rceil$.

Algorithm 1 Greedy-Rounding (derandomizing probability distributions over the permutations).

Input: A probability distribution δ over $[n!]$.
Output: A permutation $\rho \in [n!]$.

```
R ← $U$
for $i = 1$ to $n/r$ do
    $S^i \leftarrow \arg\min_{S \in \{R\}^r} \mathbb{E}_{\pi \sim \delta}[\pi(S)]$
    Place the elements of $S^i$ (arbitrarily) from positions $(i-1) \cdot r + 1$ to $i \cdot r$ of $\rho$.
    $R \leftarrow R \setminus S^i$
end for
return $\rho$
```

Our rounding algorithm is described in Algorithm 1. At each step, it finds the request S with minimum expected covering cost under the probability distribution δ and places the elements of S as close to the beginning of the permutation as possible. Then, it removes those elements from set R and iterates. The main claim is that the resulting permutation has the following property: *any request S of size r has covering cost at most $O(r)$ times of its expected covering cost under the probability distribution δ.*

▶ **Theorem 9.** *Let δ be a distribution over permutations and let ρ be the permutation output by Algorithm 1 on δ. Then, for any set S, with $|S| = r$,*

$$\rho(S) \leq 2r \cdot \mathop{\mathbb{E}}_{\pi \sim \delta}[\pi(S)]\,.$$

Proof Sketch. The key step is to show that if the element used by ρ to serve the request S was picked during the kth iteration of the rounding algorithm, then $\mathbb{E}_{\pi \sim \delta}[\pi(S)] \geq k/2$. Clearly, $\rho(S) \leq k \cdot r$ and the theorem follows. Full proof is in the full version. ◀

3.3 The Lazy Rounding Algorithm

Lazy-Rounding, presented in Algorithm 2, is essentially a lazy derandomization of MWU. At each step, it calculates the distribution on permutations maintained by MWU. At the beginning of each *phase*, it sets its permutation to that given by Algorithm 1. Then, it sticks to the same permutation for as long as the total variation distance of MWU's distribution at the beginning of the phase to the current MWU distribution is at most $1/n$. As soon as the total variation distance exceeds $1/n$, Lazy-Rounding starts a new phase.

The main intuition behind the design of our algorithm is the following. In Section 3.2 we showed that Algorithm 1 results in a deterministic algorithm with access cost no larger than $2r\,\mathbb{E}[\text{AccessCost(MWU)}]$. However, such an algorithm may incur an unbounded moving cost; even small changes in the distribution of MWU could lead to very different permutations after rounding. To deal with that, we update the permutation of Lazy-Rounding only if there are substantial changes in the distribution of MWU. Intuitively, small changes in MWU's distribution should not affect much the access cost (this is formalized in Lemma 10). Moreover, Lazy-Rounding switches to a different permutation only if it is really required, which we use to bounds Lazy-Rounding's moving cost.

Bounding the Access Cost. We first show that the access cost of Lazy-Rounding is within a factor of $4r$ from the expected access cost of MWU (Lemma 11). To this end, we first show that if the total variation distance between two distributions is small, then sampling from those distributions yields roughly the same expected access cost for any request S. The proof of the following is based on the optimal coupling lemma and can be found in the full version of this paper.

▶ **Lemma 10.** *Let δ and δ' be two probability distributions over permutations. If that $d_{\mathrm{TV}}(\delta, \delta') \leq 1/n$, for any request set S of size r, we have that*

$$\mathop{\mathbb{E}}_{\pi\sim\delta'}[\pi(S)] \leq 2 \cdot \mathop{\mathbb{E}}_{\pi\sim\delta}[\pi(S)].$$

We are now ready to upper bound the access cost of our algorithm.

▶ **Lemma 11.** $\mathrm{AccessCost(Lazy\text{-}Rounding)} \leq 4r \cdot \mathbb{E}[\mathrm{AccessCost(MWU)}]$.

Proof. Consider a phase of Lazy-Rounding starting at time t_1. We have that at any round $t \geq t_1$, $\pi_t = \mathrm{Greedy\text{-}Rounding}(\mathrm{P}^{t_1})$, as long as $\mathrm{d_{TV}}(\mathrm{P}^t, \mathrm{P}^{t_1}) \leq 1/n$. By Theorem 9 and Lemma 10, we have that,

$$\mathrm{AccessCost}(\mathrm{Lazy\text{-}Rounding}(t)) = \pi_t(S_t) \leq 2r \cdot \mathop{\mathbb{E}}_{\pi\sim\mathrm{P}^{t_1}}[\pi(S_t)] \leq 4r \mathop{\mathbb{E}}_{\pi\sim\mathrm{P}^{t}}[\pi(S_t)].$$

Overall we get, $\mathrm{AccessCost(Lazy\text{-}Rounding)} = \sum_{t=1}^{m} \pi_t(S_t) \leq 4r\, \mathbb{E}[\mathrm{AccessCost(MWU)}]$. ◀

Bounding the Moving Cost. We now show that the moving cost of Lazy-Rounding is upper bounded by the expected access cost of MWU.

▶ **Lemma 12.** $\mathrm{MovingCost(Lazy\text{-}Rounding)} \leq \mathbb{E}[\mathrm{AccessCost(MWU)}]$.

Proof. Lazy-Rounding moves at the end of a phase incurring a cost of at most n^2. Let t_1 and t_2 be the starting times of two consecutive phases. By the definition of Lazy-Rounding, $d_{\mathrm{TV}}(P^{t_1}, P^{t_2}) > 1/n$. By Lemma 8, we have that the access cost of MWU during t_1 and t_2 is at least n^2. We get that

$$\frac{\mathrm{MovingCost(ALG)}}{\mathbb{E}[\mathrm{AccessCost(MWU)}]} \leq \frac{n^2\#\text{ different phases}}{n^2\#\text{different phases}} = 1.$$ ◀

Theorem 2 follows from lemmas 11, 12 and 6. The details can be found in the full version.

Algorithm 2 Lazy Rounding.

Input: Sequence of requests $(S_1, \ldots, S_m)$ and the initial permutation $\pi_0 \in [n!]$.
Output: A permutation π_t at each round t, which serves request S_t.

```
start-phase ← 1
P^1 ← uniform distribution over permutations
for each round $t \geq 1$ do
    if $\mathrm{d_{tv}}(\mathrm{P}^t, \mathrm{P}^{\text{start-phase}}) \leq 1/n$ then
        $\pi_t \leftarrow \pi_{t-1}$
    else
        $\pi_t \leftarrow$ Greedy-Rounding($\mathrm{P}^t$)
        start-phase ← $t$
    end if
    Serve request $S_t$ using permutation $\pi_t$.
    $w_\pi^{t+1} = w_\pi^t \cdot e^{-\pi(S_t)/n^3}$, for all permutations $\pi \in [n!]$.
    $\mathrm{P}^{t+1} \leftarrow$ Distribution on permutations of MWU, $\mathrm{P}_\pi^{t+1} = w_\pi^t / (\sum_{\pi\in[n!]} w_\pi^t)$.
end for
```

Algorithm 3 Move-All-Equally.

```
Input: A request sequence $(S_1, \dots, S_m)$ and the initial permutation $\pi_0 \in [n!]$
Output: A permutation $\pi_t$ at each round $t$.
for each round $t \geq 1$ do
    $k_t \leftarrow \min\{i \,|\, \pi_{t-1}[i] \in S_t\}$
    Decrease the index of all elements of $S_t$ by $k_t - 1$.
end for
```

Remark. Note that to a large extent, our approach is generic and can be used to provide static optimality for a wide range of online problems. The only requirement is that there is a maximum access cost $\mathrm{C}_{\max}$ and a maximum moving cost D; then, we should use MWU with learning rate $1/(D \cdot \mathrm{C}_{\max})$ and move when $d_{\mathrm{TV}} \geq 1/\,\mathrm{C}_{\max}$. Here we used $D = n^2$ and $\mathrm{C}_{\max} = n$. The only problem-specific part is the rounding of Section 3.2. We believe it is an interesting direction to use this technique for generalizations of this problem, like multiple intents re-ranking or interpret known algorithms for other problems like the BST problem using our approach.

4 A Memoryless Algorithm

In this section we focus on memoryless algorithms. We present an algorithm, called Move-All-Equally (MAE), which seems to be the "right" memoryless algorithm for online MSSC. MAE decreases the index of all elements of the request S_t at the same speed until one of them reaches the first position of the permutation (see Algorithm 3). Note that MAE belongs to the *Move-to-Front* family, i.e., it is a generalization of the classic MTF algorithm for the list update problem. MAE admits two key properties that substantially differentiate it from the other algorithms in the Move-to-Front family presented in Section 2.

(i) Let e_t denote the element used by OPT to cover the request S_t. MAE always moves the element e_t towards the beginning of the permutation.

(ii) It balances moving and access costs: if the access cost at time t is k_t, then the moving cost of MAE is roughly $r \cdot k_t$ (see Algorithm 3). The basic idea is that the moving cost of MAE can be compensated by the decrease in the position of element e_t. This is why it is crucial all the elements to be moved with the same speed.

Lower Bound. First, we show that this algorithm, besides its nice properties, fails to achieve a tight bound for the online MSSC problem.

▶ **Theorem 3.** *The competitive ratio of the Move-All-Equally algorithm is $\Omega(r^2)$.*

In the lower bound instance, the adversary always requests the last r elements of the algorithm's permutation. Since MAE moves all elements to the beginning of the permutation, we end up in a request sequence where n/r disjoint sets are repeatedly requested. Thus the optimal solution incurs a cost of $\Theta(n/r)$ per request, while MAE incurs a cost of $\Omega(n \cdot r)$ per request (the details are in the full version) . Note that in such a sequence, MAE loses a factor of r by moving all elements, instead of one. However, this extra movement seems to be the reason that MAE outperforms all other memoryless algorithms and avoids poor performance in trivial instances, like other MTF-like algorithms.

Upper Bounds. Let $\mathcal{L}$ denote the set of elements used by the optimal permutation on a request sequence such that $|\mathcal{L}| = \ell$. That means, OPT has those ℓ elements in the beginning of its permutation, and it never uses the remaining $n - \ell$ elements. Consider a potential function $\Phi(t)$ being the number of inversions between elements of $\mathcal{L}$ and $U \setminus \mathcal{L}$ in the permutation of MAE (an inversion occurs when an element of $\mathcal{L}$ is behind an element of $U \setminus \mathcal{L}$). Consider the request S_t at time t and let k_t be the access cost of MAE.

Let e_t be the element used by OPT to serve S_t. Clearly, in the permutation of MAE, e_t passes (i.e., changes relative order w.r.t) $k_t - 1$ elements. Among them, let L be the set of elements of $\mathcal{L}$ and R the elements of $U \setminus \mathcal{L}$. Clearly, $|L| + |R| = k_t - 1$ and $|L| \leq |\mathcal{L}| = \ell$. We get that the move of e_t changes the potential by $-|R|$. The moves of all other elements increase the potential by at most $(r-1) \cdot \ell$. We get that

$$k_t + \Phi(t) - \Phi(t-1) \quad \leq \quad |L| + |R| - |R| + (r-1) \cdot \ell \leq |L| + (r-1) \cdot \ell \leq r \cdot \ell.$$

Since the cost of MAE at step t is no more than $(r+1) \cdot k_t$, we get that the amortized cost of MAE per request is $O(r^2 \cdot \ell)$. This implies that for all sequences such that OPT uses all elements of $\mathcal{L}$ with same frequencies (i.e, the OPT pays on average $\Omega(\ell)$ per request), MAE incurs a cost within $O(r^2)$ factor from the optimal. Recall that all other MTF-like algorithms are $\Omega(\sqrt{n})$ competitive even in instances where OPT uses only one element!

While this simple potential gives evidence that MAE is $O(r^2)$-competitive, it is not enough to provide satisfactory competitiveness guarantees. We generalize this approach and define the potential function $\Phi(t) = \sum_{j=1}^{n} \alpha_j \cdot \pi_t(j)$, where $\pi_t(j)$ is the position of element j at round t and α_j are some non-negative coefficients. The potential we described before is the special case where $\alpha_j = 1$ for all elements of $\mathcal{L}$ and $\alpha_j = 0$ for elements of $U \setminus \mathcal{L}$.

By refining further this approach and choosing coefficients α_j according to the frequency that OPT uses element j to serve requests (elements of high frequency are "more important" so they should have higher values α_j), we get an improved upper bound.

▶ **Theorem 14.** *The competitive ratio of* MAE *algorithm is at most* $2^{O(\sqrt{\log n \cdot \log r})}$.

Note that this guarantee is $o(n^\epsilon)$ and $\omega(\log n)$. The proof is based on the ideas sketched above but the analysis is quite involved and is deferred to the full version of this paper.

5 Dynamic Online Min-Sum Set Cover

In this section, we turn our attention to the dynamic version of online MSSC. In online dynamic MSSC, the optimal solution maintains a trajectory of permutations $\pi_0^*, \pi_1^*, \ldots, \pi_t^*, \ldots$ and use permutation π_t^* to serve each request S_t. The cost of the optimal dynamic solution is $\mathrm{OPT}_{\mathrm{dynamic}} = \sum_t (\pi_t^*(S_t) + d_{\mathrm{KT}}(\pi_{t-1}^*, \pi_t^*))$, where $\{\pi_t^*\}_t$ denotes the optimal permutation trajectory for the request sequence that minimizes the total access and moving cost.

We remark that the ratio between the optimal static solution and the optimal dynamic solution can be as high as $\Omega(n)$. For example, in the sequence of requests $\{1\}^b\{2\}^b \ldots \{n\}^b$, the optimal static solution pays $\Theta(n^2 b)$, whereas the optimal dynamic solution pays $\Theta(n^2 + n \cdot b)$ by moving the element that covers the next $n \cdot b$ requests to the first position and then incurring access cost 1. The above example also reveals that although Algorithm 2 is $\Theta(r)$-competitive against the optimal static solution, its worst-case ratio against a dynamic solution can be $\Omega(n)$.

MAE Algorithm. As a first study of the dynamic problem, we investigate the competitive ratio of *Move-All-Equally* (MAE) algorithm from Section 4. We begin with an upper bound.

▶ **Theorem 4.** *The competitive ratio of the Move-All-Equally algorithm for the dynamic online Min-Sum Set Cover problem is* $O(r^{3/2}\sqrt{n})$.

The approach for proving Theorem 4 is generalizing that exhibited in Section 4 for the static case. We use a generalized potential function $\Phi(t) = \sum_{j=1}^{n} \alpha_j^t \cdot \pi_t(j)$; i.e, the multipliers α_j may change over time so as to capture the moves of $\text{OPT}_{\text{dynamic}}$. To select coefficients α_j^t we apply a two-level approach. We observe that there is always a 2-approximate optimal solution that moves an element of S_t to the front (similar to classic MTF in list update). We call this MTF_{OPT} . We compare the permutation of the online algorithm with the permutation maintained by this algorithm; at each time, elements the beginning of the offline permutation are considered to be "important" and have higher coefficients α_j^t. The formal proof is in the full version.

Next, we show an almost matching lower bound.

▶ **Theorem 5.** *For any $r \geq 3$, the competitive ratio of the Move-All-Equally algorithm for the dynamic online Min-Sum Set Cover problem is $\Omega(r\sqrt{n})$.*

Sketch of the Construction. The lower bound is based on a complicated adversarial request sequence; we sketch the main ideas. Let k be an integer. During a *phase* we ensure that:

(i) There are $2k$ "important" elements used by OPT; we call them $e_1, \dots, e_{2k}$. In the beginning of the phase, those elements are ordered in the start of the optimal permutation π^*, i.e., $\pi^*[e_j] = j$. The phase contains k consecutive requests to each of them, in order; thus the total number of requests is $\approx 2k^2$. OPT brings each element e_j at the front and uses it for k consecutive requests; thus the access cost of OPT is $2k^2$ (1 per request) and the total movement cost of OPT of order $\Theta(k^2)$. Over a phase of $2k^2$ requests, OPT incurs an overall cost $\Theta(k^2)$, i.e., an average of $O(1)$ per request.

(ii) The first $k + r - 2$ positions of the online permutation will be always occupied by the same set of "not important" elements; at each step the $r - 2$ last of them will be part of the request set and MAE will move them to the front. Thus the access cost will always be $k + 1$ and the total cost more than $(r + 1) \cdot k$.

The two properties above are enough to provide a lower bound $\Omega(r \cdot k)$; the optimal cost is $O(1)$ per request and the online cost $\Omega(r \cdot k)$. The goal of an adversary is to construct a request sequence with those two properties for the largest value of k possible.

The surprising part is that although MAE moves all requested elements towards the beginning of the permutation, it never manages to bring any of the "important" elements in a position smaller than $r + k - 2$. While the full instance is complex and described in the full version, at a high-level, we make sure that whenever a subsequence of k consecutive requests including element e_j begins, e_j is at the end of the online permutation, i.e., $\pi_t[e_j] = n$. Thus, even after k consecutive requests where MAE moves it forward by distance k, it moves by k^2 positions; by making sure that $n - k^2 > r + k - 2$ (which is true for some $k = \Omega(\sqrt{n})$), we can make sure that e_j does not reach the first $r + k - 2$ positions of the online permutation.

6 Concluding Remarks

Our work leaves several intriguing open questions. For the (static version of) Online MSSC, it would be interesting to determine the precise competitive ratio of the MAE algorithm; particularly whether it depends only on r or some dependency on n is really necessary. More generally, it would be interesting to determine the best possible performance of memoryless algorithms and investigate trade-offs between competitiveness and computational efficiency.

For the online dynamic MSSC problem, the obvious question is whether a $f(r)$-competitive algorithm is possible. Here, we showed that techniques developed for the list update problem seem to be too problem-specific and are not helpful in this direction. This calls for the use of more powerful and systematic approaches. For example, the online primal-dual method [18] has been applied successfully for solving various fundamental problems [6,7,17,19]. Unfortunately, we are not aware of a primal-dual algorithm even for the special case of list update; the only attempt we are aware of is in [45], but this analysis basically recovers known (problem-specific) algorithms using dual-fitting. Our work gives further motivation for designing a primal-dual algorithm for list-update: this could be a starting point towards solving the online dynamic MSSC.

In a broader context, the online MSSC is the first among a family of poorly understood online problems such as the multiple intents re-ranking problem described in Section 1.2. In this problem, when a set S_t is requested, we need to cover it using $s \leq r$ elements; MSSC is the special case $s = 1$. It is natural to expect that the lower bound of Theorem 1 can be generalized to $\Omega(r/s)$, i.e., as s grows, we should be able to achieve a better competitive ratio. It will be interesting to investigate this and the applicability of our technique to obtain tight bounds for this problem.

Abstract

Let $M = (m_{ij})$ be a symmetric matrix of order n and let G be the graph with vertex set $\{1, \ldots, n\}$ such that distinct vertices i and j are adjacent if and only if $m_{ij} \neq 0$. We introduce a dynamic programming algorithm that finds a diagonal matrix that is congruent to M. If G is given with a tree decomposition $\mathcal{T}$ of width k, then this can be done in time $O(k|\mathcal{T}| + k^2 n)$, where $|\mathcal{T}|$ denotes the number of nodes in $\mathcal{T}$.

1 Introduction and main result

Two matrices M and N are said to be *congruent*, which is denoted $M \cong N$, if there exists a nonsingular matrix P for which $N = P^T MP$. Matrix congruence naturally appears when studying Gram matrices associated with a quadratic form on a finite-dimensional vector space; finding a diagonal matrix D that is congruent to a symmetric matrix M allows us to classify the quadratic form.

In a different direction, finding a diagonal matrix that is congruent to M allows us to determine the number of eigenvalues of M in a given real interval. Indeed, fix real numbers $c < d$. Let $D_c \cong N = M - cI$ and $D_d \cong M - dI$ be diagonal matrices. By Sylvester's Law of Inertia [16, p. 568], the number n_1 of eigenvalues of M greater than c equals the number positive entries in D_c. Moreover, the number of eigenvalues equal to c, or less than c, are given by the number of zero diagonal entries, or by the number of negative entries in D_c, respectively. As a consequence, if n_2 is the number of positive entries in D_d, then $n_1 - n_2$ is the number of eigenvalues of M in the interval $(c, d]$.

Given a symmetric matrix $M = (m_{ij})$ of order n, we may associate it with a graph G with vertex set $[n] = \{1, \ldots, n\}$ such that distinct vertices i and j are adjacent if and only if $m_{ij} \neq 0$. We say that G is the *underlying graph* of M. This allows us to employ structural decompositions of graph theory to deal with the nonzero entries of M in an efficient way.

One such decomposition is the tree decomposition, which has been extensively studied since the seminal paper of Robertson and Seymour [18]. The graph parameter associated with this decomposition is the *treewidth*.

A tree decomposition of a graph $G = (V, E)$ is a tree $\mathcal{T}$ with *nodes* $1, \dots, m$, where each node i is associated with a *bag* $B_i \subseteq V$, satisfying the following properties: (1) $\bigcup_{i=1}^{m} B_i = V$; (2) For every edge $\{v, w\} \in E$, there exists B_i containing v and w; (3) For any $v \in V$, the subgraph of $\mathcal{T}$ induced by the nodes that contain v is connected.

The *width* of the tree decomposition $\mathcal{T}$ is defined as $\max_i (|B_i| - 1)$ and the *treewidth* $tw(G)$ of graph G is the smallest k such that G has a tree decomposition of width k. Clearly, it is always the case that $tw(G) < |V|$, and for connected graphs, $tw(G) = 1$ if and only if G is a tree on two or more vertices. Even though computing the treewidth of a graph is hard, this is a widely studied parameter and tree decompositions with bounded width are known for several graph classes. Moreover, there is an extensive literature on approximation algorithms for this problem. For instance, Fomin et al. [9] devised an algorithm such that, given an n-vertex graph and an integer k, runs in time $O(k^7 n \log n)$ and either correctly reports that the treewidth of G is larger than k, or constructs a tree decomposition of G of width $O(k^2)$.

Often, graph widths have been used to design algorithms for NP-complete or even harder problems that are efficient on graphs of bounded width, by which we mean that their running time is equal to $O(f(k)n^c)$ for a constant c and an arbitrary computable function f, where k is the width of the graph. Problems that can be solved with such a running time are called fixed parameter tractable (FPT). For more information, interested readers are referred to [5, 7, 8, 17], and to the references therein.

On the other hand, graph widths may be quite useful for polynomial time solvable problems. Indeed, treewidth has a strong connection to the solution of sparse linear systems and Gaussian elimination. For a long time heuristics have been designed to maintain sparsity throughout Gaussian elimination. The goal is to minimize the *fill-in*, defined as the set of matrix positions that were initially 0, but have received nonzero values during the computation. Fill-in minimization has been analyzed as a graph problem in the case of symmetric [19] as well as asymmetric [20] matrices. As in our paper, a nonzero matrix entry a_{ij} is interpreted as an edge (or arc) from vertex i to vertex j. However, unlike here, it was assumed that the matrix was diagonally dominant, so that all the pivots could be chosen in the diagonal.

A major source of applications are symmetric positive definite matrices due to their prevalence. When the ith diagonal pivot is chosen in the symmetric case, then the fill-in consists of all missing edges between those neighbors of vertex i that have not yet been eliminated. The minimum k over all elimination orders of the maximal number of higher numbered neighbors is precisely the treewidth of the graph associated with a symmetric matrix [2]. When such an optimal elimination order or, equivalently, a tree decomposition of width k is given, then Gaussian elimination can trivially be done in time $O(k^2 n)$, if the pivot can always be chosen in the diagonal. This is clearly the case for symmetric positive definite matrices. On the other hand, it long seemed impossible to get an efficient algorithm when off-diagonal pivots have to be chosen. Note that, if the graph corresponding to a symmetric matrix has treewidth k, then you can always find a diagonal element with at most k off-diagonal nonzero elements in its row and column. But if this diagonal element is zero, and the pivot is chosen somewhere else in its row, then there can be an arbitrary number of nonzero elements in the pivot's column. The main contribution of this paper is an algorithm that deals with these diagonal elements.

The paper of Bodlaender et al. [2] is dedicated to the approximation of treewidth, pathwidth, and minimum elimination tree height. (Pathwidth is defined by tree decompositions where the tree is required to be a path.) In this context, they discuss the important matrix tasks of Cholesky factorization ($A = LL^T$) and Gaussian elimination for sparse matrices. These tasks have efficient FPT algorithms parameterized by treewidth or pathwidth, while their parallel complexity is determined by the minimum elimination tree height.

A recent paper of Fomin et al. [9] explores topics very similar to ours. For a matrix[1] with a given tree decomposition of width k, these authors present various efficient algorithms. In time $O(k^3 n)$ they solve systems of linear equations, compute the determinant and the rank of a matrix. These problems are also solved by our approach, in the case of symmetric matrices. They also solve various matching and flow problems and compute an $O(k^2)$ approximation to treewidth in $k^{O(1)} n \log^{O(1)} n$ time.

Here, we design a dynamic programming algorithm with running time $O(k^2 n)$ to find a diagonal matrix that is congruent to an input symmetric matrix M of order n, provided that a tree decomposition of width k for the underlying graph G is part of the input. In particular, for bounded treewidth, we find a linear-time solution to this problem. To achieve our goal, we were inspired by an algorithm with the same purpose for graphs with small clique-width (*clique-width* is defined based on another structural decomposition introduced by Courcelle and Olariu [4]). This algorithm was proposed by Jacobs and the current authors [12].

Astonishingly, the problem with the treewidth parameter turned out to be more challenging. This is somewhat counterintuitive and unusual, because graphs of bounded treewidth are also of bounded clique-width. Clearly, there is no direct implication. There are graphs whose clique-width is exponentially bigger than their treewidth [3]. However the implication of a running time of $2^{O(k)} n$ for a polynomially solvable problem is rather unimpressive and useless. The conclusion in the current paper is stronger. It is also much more useful, because practical examples of sparse matrices often have small treewidth, while a pattern of large minors with the same entry, typical of bounded clique-width matrices, is rather unusual.

As [9] and [12], the current paper fits into the recent trend "FPT within P", which investigates fundamental problems that are solvable in polynomial time, but for which a lower exponent may be achieved using an FPT algorithm that is also polynomial in terms of the parameter k (see [14]). For our problem, it does not seem that $O(poly(k)n)$ algorithms are possible for graphs of fusion-width or multi-clique-width k [10, 11]. For some problems, like the independent set problem, there are algorithms whose running time as a function of these parameters is not worse than as a function of the clique-width, even though the clique-width can be exponentially larger. An $O(k^2 n)$ algorithm for multi-clique-width k would imply the same time bound when k is the clique-width or the tree-width.

▶ **Theorem 1.** *Given a symmetric matrix M of order n and a tree decomposition $\mathcal{T}$ of width k for the underlying graph of M, algorithm* `CongruentDiagonal` *(see Sect. 3) produces a diagonal matrix D congruent to M in time $O(k|\mathcal{T}| + k^2 n)$.*

Naturally, we assume throughout this paper, that the input matrix M is given in a compact form because, in standard form, just reading M would already take quadratic time. A possible representation could be a list of triples (i, j, m_{ij}) containing all nonzero entries. For convenience, we assume the value m_{uv} for $u \neq v$ is just attached to the edge uv in the given tree decomposition. Likewise the value m_{uu} is attached to the vertex u. This representation could be obtained efficiently from the list representation. We will not discuss

[1] The matrices in [9] are not necessarily symmetric (in fact, not necessarily square), and they associate an $m \times n$-matrix with a bipartite graph whose partition classes have size m and n.

such a transformation even though it is not trivial. An interesting discussion by Bodlaender et al. [1] shows how a data structure of size $O(kn)$ enables an $O(k)$ test whether two given vertices are adjacent, a detail that had previously often been overlooked.

Our paper is organized as follows. In Section 2, we define the concept of an edge-explicit tree decomposition and state auxiliary results about it. We then describe our algorithm in Section 3 and justify why it works as claimed, ending with an example.

2 Edge-explicit tree decomposition

In this paper, we consider graph decompositions based on the concept of *nice tree decomposition*, introduced by Kloks [15]. The current variation is due to Fürer and Yu [13], and to distinguish it from the original version, we call it an *edge-explicit tree decomposition.* (Nice tree decompositions with explicit nodes to introduce edges have been considered by Cygan et al. [6] before.) A rooted tree decomposition $\mathcal{T}$ of a graph G whose nodes are associated with bags $B_1, \ldots, B_m$ is *edge-explicit* if each node i is of one of the following types:

(a) **(Leaf)** The node i is a leaf of $\mathcal{T}$;

(b) **(Introduce Vertex)** The node i introduces vertex v if it has a single child j, $v \notin B_j$ and $B_i = B_j \cup \{v\}$.

(c) **(Introduce Edges)** The node i introduces edges if it has a single child j and $|B_i| = |B_j|$. This node is labelled by a vertex $v \in B_i$ and inserts all edges $\{u, v\}$ of $E(G)$ such that $u \in B_i$.

(d) **(Forget)** The node i forgets vertex v if i has a single child j, $v \notin B_i$ and $B_j = B_i \cup \{v\}$;

(e) **(Join)** The node i is a join if it has two children j and ℓ, where $B_i = B_j = B_\ell$.

Unlike the other operations, the vertex v whose adjacencies are introduced by an Introduce Edges node must be given as part of the operation. We assume that every edge $uv \in E$ is introduced exactly once. In fact, for every edge uv, we will further suppose that, if j is the node that introduces the edge uv and it is labelled by vertex v, then the parent of j forgets v. Another assumption that will simplify our discussion is that $B_r = \emptyset$ for the root r of the tree, so that every vertex will be forgotten.

For constant k, Kloks [15] shows how to construct a nice tree decomposition of size at most $4n$ from a k-tree in time $O(n)$. We want to construct an edge-explicit tree decomposition from an arbitrary tree decomposition efficiently. With the help of the given tree decomposition of G of width k, we could embed G into a k-tree, apply the algorithm of Kloks, and finally add the Introduce Edges nodes. For our application, we want to analyze the dependence of the time on k precisely. For this purpose, we do a direct construction avoiding the k-trees.

▶ **Lemma 2.** *From a tree decomposition of width k and m nodes, an edge-explicit tree decomposition of the same width k with less than $5n$ nodes can be computed in time $O(k(m+n))$.*

Proof. We assume that all bags are given by a sorted list of their vertices. If these lists were unsorted, we could trivially sort them all in time $O((k \log k)m)$, or in a more sophisticated manner in time $O(km)$. As an additional preprocessing step, we produce a new node with empty bag and declare it to be the root. It is connected to an arbitrary node of the original tree decomposition.

Now we modify the tree decomposition in a sequence of depth-first tree traversals. Some of these traversals could be combined, but obviously without improving the asymptotic running time. During the first traversal, every node whose bag is contained in the bag of its parent is merged with the parent. Initially, the number of nodes m is not bounded by any function of the number of vertices n, because many subtrees could represent the same subgraph. From our argument below, it follows that the tree has a size less than $4n$ after this step.

In four more depth-first traversals, we produce an edge-explicit tree decomposition. In the second traversal, whenever the bag of a node has size less than the size of the bag of its parent, we add some nodes from the parent until both bags have the same size. This is a crucial step. Avoiding it, could increase the number of nodes in the fourth depth-first traversal to $\Omega(kn)$.

In the third traversal, all nodes with more than one child are replaced by binary trees with identical bags such that the original children appear as children of their leaves. In the fourth traversal, for any node i with a single child j, if necessary, some new nodes are inserted such that the bags only change by one vertex in each step. This is done from j to i by a sequence of nodes alternating between Forget nodes and Introduce Vertex nodes possibly followed by more Forget nodes. Now we have a nice tree decomposition, which we will show to have at most $4n$ nodes. Finally, in the fifth depth-first traversal, immediately below every Forget node of a vertex v, we insert an Introduce Edges node introducing the edges to v, to make the nice tree decomposition edge-explicit.

Now we count the nodes. Note that the root and the Leaf nodes are incident with a single edge, the Join nodes are incident with three edges and the other nodes are incident with two edges. As a consequence, there is one less Join node than Leaf node. Every vertex can be forgotten only once. Thus the number of Forget nodes is at most n. Between every Leaf node and the first Join node above it in the tree, there is at least one Forget node, otherwise, the the leaf would have been merged with its parent in the first traversal. Thus there are at most n Leaf nodes and at most $n-1$ Join nodes. The single child of every Introduce Vertex node is a Forget node. The same is true for the parent of every Introduce Edges node. Therefore, the number of Introduce Vertex nodes and and the number of Introduce Edges nodes are at most n each. ◀

▶ Remark 3. The somewhat wasteful second traversal could be avoided. Its effect is to push Introduce Vertex nodes down the tree in order to avoid some of them when the corresponding vertices are introduced in leaves. This guarantees a bound of $O(n)$ rather than $O(kn)$ on the number of Introduce Vertex nodes.

Without changing the asymptotic running time nor the treewidth, a tree decomposition with typically many smaller bags could be obtained by allowing Introduce Vertex nodes introducing many vertices at once. For our application, this would work, because handling a node introducing many vertices could still be done in time $O(k^2)$.

For later use, we state an auxiliary result that records facts about an edge-explicit tree decomposition. We do not include a proof, as it follows directly from the definition of this concept. Let $G = (V, E)$ be a graph with tree decomposition $\mathcal{T}$, whose bags are $B_1, \ldots, B_m$. For $v \in V$ and a node j of $\mathcal{T}$, let $\mathcal{T}(v)$ and $\mathcal{T}_j$ be the subtree of $\mathcal{T}$ induced by the nodes containing v and the branch of $\mathcal{T}$ rooted at j, respectively.

▶ **Lemma 4.** *In an edge-explicit tree decomposition $\mathcal{T}$ of a graph $G = (V, E)$, the following statements hold.*

(a) *Every $v \in V$ is forgotten exactly once in $\mathcal{T}$.*

(b) *Let $uv \in E$ and let i be the node that introduces the edge uv. If ℓ is an ancestor of i and ℓ is a join or a node that introduces a vertex, then $\{u, v\} \not\subseteq B_\ell$.*

(c) *For every $v \in V$, the subtree $\mathcal{T}(v)$ of $\mathcal{T}$ is rooted at the child of the node that forgets v. Moreover, the leaves of $\mathcal{T}(v)$ are precisely the leaves of $\mathcal{T}$ that contain v and the nodes of $\mathcal{T}$ that introduce v.*

(d) *Suppose i forgets vertex v and j is its child. If $w \notin B_i$ and $\mathcal{T}(v) \cap \mathcal{T}(w) \neq \emptyset$, then $\mathcal{T}(w)$ is a subtree of $\mathcal{T}_j$. In particular, $\mathcal{T}(v)$ is a subtree of $\mathcal{T}_j$.*

3 The Algorithm

We now describe our diagonalization algorithm, which we call `CongruentDiagonal`. Let M be a symmetric matrix of order n and let $G = (V, E)$ be the underlying graph with vertex set $V = [n]$ associated with it. We wish to find a diagonal matrix congruent to M. Let $\mathcal{T}$ be an edge-explicit tree decomposition of G of width k. The algorithm works bottom-up in the rooted tree $\mathcal{T}$, so we order the nodes $1, \ldots, m$ of $\mathcal{T}$ in post-order and operate on a node i after its children have been processed. It is well-known that two matrices are congruent if we can obtain one matrix from the other by a sequence of *pairs* of elementary operations, each pair consisting of a row operation followed by the *same* column operation. In our algorithm we only use congruence operations that permute rows and columns or add a multiple of a row and column to another row and column respectively. To achieve linear-time we must operate on a sparse representation of the graph associated with M, rather than on the matrix itself.

We start with a high-level description of the algorithm, which is summarized below. Each node i in the tree produces a pair of matrices $(N_i^{(1)}, N_i^{(2)})$, which may be combined into a symmetric matrix N_i of order at most $2(k+1)$. The algorithm traverses the tree decomposition from the leaves to the root so that, at node i, the algorithm either initializes a pair $(N_i^{(1)}, N_i^{(2)})$, or it produces $(N_i^{(1)}, N_i^{(2)})$ based on the matrices produced by its children, transmitting the pair to its parent. During this step, the algorithm may also produce diagonal elements of a matrix congruent to M. These diagonal elements are not transmitted by a node to its parent, but are appended to a global array as they are produced. At the end of the algorithm, the array consists of the diagonal elements of a diagonal matrix D that is congruent to M.

Algorithm 1 High level description of the algorithm `CongruentDiagonal`.

```
CongruentDiagonal(M)
input:  an edge-explicit tree decomposition $\mathcal{T}$ of the underlying
graph $G$ associated with $M$ of width $k$ and the nonzero entries of $M$
output:  diagonal entries in $D \cong M$
Order the nodes of $\mathcal{T}$ as $1, 2, \ldots, m$ in post order
for $i$ from  1 to $m$ do
    if is-Leaf($i$) then construct $(N_i^{(1)}, N_i^{(2)})$=LeafBox($B_i$)
    if is-IntroduceVertex($i$) then construct $(N_i^{(1)}, N_i^{(2)})$=IntroVertexBox($B_i$)
    if is-IntroduceEdge($i$) then construct $(N_i^{(1)}, N_i^{(2)})$=IntroEdgesBox($B_i$)
    if is-Join($i$) then construct $(N_i^{(1)}, N_i^{(2)})$=JoinBox($B_i$)
    if is-Forget($i$) then construct $(N_i^{(1)}, N_i^{(2)})$=ForgetBox($B_i$)
```

In the remainder, we shall describe each operation in detail and justify that the algorithm `CongruentDiagonal` yields the desired output. Step i of the algorithm refers to the ith iteration of the loop above, and we assume that Step i processes the node i. To describe the matrix produced by each node, we need the concept of a matrix $M = (m_{ij})$ in *row echelon form*. This means that $m_{ij} = 0$ for all $j < i$. Moreover, let the *pivot* of row i be the first j such that $m_{ij} \neq 0$, if such an element exists. We require that distinct rows have different pivots.

Each matrix N_i produced by a node on the tree has the form

$$N_i = \begin{array}{|c|c|} \hline N_i^{(0)} & N_i^{(1)} \\ \hline N_i^{(1)T} & N_i^{(2)} \\ \hline \end{array}, \qquad (1)$$

where $N_i^{(0)}$ is a matrix of dimension $k_i' \times k_i'$ whose entries are zero, $N_i^{(2)}$ is a symmetric matrix of dimension $k_i'' \times k_i''$ and $N_i^{(1)}$ is a $k_i' \times k_i''$ matrix in row echelon form. Moreover, $0 \leq k_i' \leq k_i'' \leq k+1$. Observe that k_1' can be zero, in which case we regard $N_i^{(0)}$ and $N_i^{(1)}$ as empty. An important fact about N_i is that each of its rows (and the corresponding column) is associated with a vertex of G (equivalently, a row of M). Let $V(N_i)$ denote the set of vertices of G associated with the rows of N_i. We say that the k_i' rows in $N_i^{(0)}$ have *type-i* and the k_i'' rows of $N_i^{(2)}$ have *type-ii*. This is represented by the partition $V(N_i) = V_1(N_i) \cup V_2(N_i)$, where $V_1(N_i)$ and $V_2(N_i)$ are the vertices of type-i and type-ii, respectively. As it turns out, the vertices of type-ii are precisely the vertices in B_i. When proving facts about the algorithm, we shall often refer to the matrix N_i as the result of processing B_i, even if the actual output is the pair $(N_i^{(1)}, N_i^{(2)})$.

The structure of the matrix N_i is described by the following lemma.

▶ **Lemma 5.** *For all $i \in [m]$, the matrix N_i defined in terms of the pair $(N_i^{(1)}, N_i^{(2)})$ produced by node i satisfies the following properties:*
(a) $0 \leq k_i' \leq k_i'' \leq k+1$.
(b) *$N_i^{(1)}$ is a matrix in row echelon form.*
(c) $V_2(N_i) = B_i$.

To give an intuition about how the algorithm works, consider that we are trying to apply the strategy for Gaussian elimination described in the introduction. Vertices of type-ii would represent the rows that have never been used to eliminate elements of other rows, while vertices of type-i would be the nonzero rows that have already been used to eliminate elements in other rows, but for which the basic strategy of using the diagonal element as a pivot failed because it was equal to 0. The algorithm keeps these rows in a temporary buffer, which is maintained in row echelon form to make sure that its size k' satisfies $k' \leq k+1$. In the process of maintaining row echelon form, some of these rows become diagonalised. In our algorithm, to preserve congruence, we perform the same Gaussian operations on rows and columns. Any row v of the input matrix M begins as a type-ii row. It can either be diagonalized during the application of ForgetBox to the node that forgets v, or it becomes a type-i row at this step, and finally becomes diagonalized in a later application of JoinBox or ForgetBox. Finally, we discuss the content of the boxes. Let $\tilde{M}(i)$ be the matrix that would be obtained by performing all row and column operations performed by the algorithm up to step i to the original matrix M. It turns out that, for a type-i row u in N_i and any row v in the matrix, the entries uv and vu in $\tilde{M}(i)$ and N_i coincide, if $v \in V(N_i)$, and the entries uv and vu in $\tilde{M}(i)$ are equal to 0, if $v \notin V(N_i)$. This is consistent with the intuition that rows of type-i have already been partially diagonalized and that their diagonal elements are 0. However, this connection does not hold in general for the entries of $\tilde{M}(i)$ and $N_i^{(2)}$, as $N_i^{(2)}$ can only capture changes the operations made for nodes in its branch of the tree decomposition, but vertices of type-ii could simultaneously lie in many different branches. This needs to be dealt with when looking at the effect of `JoinBox`.

To record the diagonal entries produced by the algorithm, let D_i be the set of all pairs (v, d_v), where v is a vertex of G (equivalently, a row of M) and d_v is the diagonal entry associated with it, produced up to the end of step i. Let $\pi_1(D_i)$ and $\pi_2(D_i)$ be the projections of D_i onto their first and second coordinates, respectively, so that $\pi_1(D_i)$ is the set of rows that have been diagonalized up to the end of step i and $\pi_2(D_i)$ is the (multi)set of diagonal elements found up to this step. Note that, if we only require the algorithm to produce the diagonal entries of a diagonal matrix that is congruent to the input matrix, it is not necessary to actually keep track of the particular pairs in D_i.

Let M_0 be the input matrix M. Let $\tilde{M}(i)$ be the matrix that is congruent to M obtained by performing the row and column operations performed by the algorithm up to step i. Let M_i be the matrix obtained from M by replacing by 0 any entry m_{uv} such that $u \neq v$ and the edge uv has not been introduced in $\mathcal{T}_i$, or such that $u = v$ and $\mathcal{T}(v) \cap \mathcal{T}_i = \emptyset$. Let $\tilde{M}_i$ be the matrix that is congruent to M_i produced by performing the row and column operations performed by the algorithm for all nodes in $\mathcal{T}_i$, in the order in which they have been performed. We only keep track of the matrices $\tilde{M}(i)$, M_i and $\tilde{M}_i$ to prove the correctness of the algorithm, they are not stored by the algorithm. In what follows, given $S \subset V$ and a matrix Q whose rows and columns are indexed by V, we write $Q[S]$ for the principal submatrix of M indexed by S. Moreover, if $u, v \in V$, $Q[u, v]$ denotes the entry uv in Q.

Our main technical lemmas control the relationship between N_i and the diagonal elements produced in step i with the matrices M_i, $\tilde{M}_i$ and $\tilde{M}(i)$. At the start of the algorithm, we set $\tilde{M}(-1) = \tilde{M}(0) = M$, $D_{-1} = D_0 = \emptyset$, $\mathcal{T}_0 = \emptyset$ and $V(N_0) = \emptyset$. The matrices N_0, M_0 and $\tilde{M}_0$ are empty.

▶ **Lemma 6.** *The following facts hold for all $i \in \{0, \ldots, m\}$.*

(a) *$\tilde{M}(i)$ and $\tilde{M}_i$ are symmetric matrices congruent to M and M_i, respectively.*

(b) *$D_{i-1} \subseteq D_i$.*

(c) *If a multiple of row (or column) v has been added to a row (or column) u in step i, then $v \in \pi_1(D_i \setminus D_{i-1}) \cup V_1(N_i)$ and $u \in \pi_1(D_i \setminus D_{i-1}) \cup V(N_i)$.*

The second lemma relates subtrees $\mathcal{T}(v)$ with the matrices produced by the algorithm.

▶ **Lemma 7.** *The following facts hold for all $i \in \{0, \ldots, m\}$.*

(a) *If $v \in \pi_1(D_i) \cup V_1(N_i)$ and $\mathcal{T}_i \cap \mathcal{T}(v) \neq \emptyset$, then $\mathcal{T}(v)$ is a subtree of $\mathcal{T}_i$.*

(b) *Let v be such that $\mathcal{T}(v) \cap \mathcal{T}_i \neq \emptyset$. Then $v \in V(N_i) \cup \pi_1(D_i)$.*

(c) *If $v \in \pi_1(D_i \setminus D_{i-1}) \cup V(N_i)$, then $\mathcal{T}_i \cap \mathcal{T}(v) \neq \emptyset$.*

The third result relates the entries of the matrices N_i and the set D produced by the algorithm with the entries of $\tilde{M}(i)$ and $\tilde{M}_i$.

▶ **Lemma 8.** *The following facts hold for all $i \in \{0, \ldots, m\}$.*

(a) *If $\mathcal{T}(v) \cap \mathcal{T}(w) = \emptyset$ and $\tilde{M}(i)[v, w] \neq 0$, then $v, w \in V(N_j)$, where $j \leq i$ is the largest index for which $\mathcal{T}(v) \cap \mathcal{T}_j \neq \emptyset$ or $\mathcal{T}(w) \cap \mathcal{T}_j \neq \emptyset$. For $\tilde{M}_i$, $\tilde{M}_i[v, w] \neq 0$ only if $v, w \in V(N_i)$.*

(b) *If $(v, d_v) \in D_i$, the row (and column) associated with v in $\tilde{M}(i)$, consists of zeros, with the possible exception of the vth entry, which is equal to d_v. If $\mathcal{T}_i \cap \mathcal{T}(v) \neq \emptyset$, then the row (and column) associated with v in $\tilde{M}_i$ satisfy the same property.*

(c) *If $v \in V_1(N_i)$, then the row (and column) associated with v in $\tilde{M}_i$ coincides with the row (and column) associated with v (restricted to the elements of $u \in V(N_i)$) in $\tilde{M}(i)$. The entries uv and vu are equal to 0 if $u \notin B_i$ and are equal to the corresponding entries in N_i if $u \in B_i$. Moreover, the entries uv and vu of $\tilde{M}(i)$ for $u \notin V(N_i)$ are equal to 0.*

(d) *Assume that $u, v \in B_i$. The entry uv of $\tilde{M}_i$ is equal to the entry uv of $N_i^{(2)}$.*

The proof of Lemmas 6, 7 and 8 is by induction on i. As $M_0 = M$, Lemma 6(a) is obviously true for $i = 0$, while Lemma 8(a) holds by definition of tree decomposition. The remaining items are vacuously true.

Before detailing each step of the algorithm, we show that, if the above lemmas hold for $i = m$, where m is the the number of nodes in the tree decomposition, then Algorithm `CongruentDiagonal` correctly computes a diagonal matrix congruent to M. To see why this is true, by Lemma 6(a), we know that M is congruent to $\tilde{M}(m)$. Moreover, by Lemma 8(b), if $(v, d_v) \in D_m$, then the row (and column) associated with v in $\tilde{M}(m)$ consists of zeros, with the possible exception of the vth entry, which is equal to d_v. It remains to prove that $\pi_1(D) = V$. To this end, let $v \in V$ and let i be the node that forgets v given by Lemma 4(a). Let j be its child. Since $v \in B_j$, we have $\mathcal{T}(v) \cap \mathcal{T}_i \neq \emptyset$, so that $v \in V_1(N_i) \cup \pi_1(D_i)$ by Lemma 7(b) (we are using that $v \notin B_i = V_2(N_i)$, a consequence of Lemma 5(c)). Then $\mathcal{T}(v) \subset \mathcal{T}_i$ by Lemma 7(a). If $v \in \pi_1(D_i)$ we are done, so assume that $v \in V_1(N_i)$. Let ℓ be the parent of i. By Lemma 7(b), $v \in V_1(N_\ell) \cup \pi_1(D_\ell)$. We would again be done if $v \in \pi_1(D_\ell)$, otherwise we repeat the argument to show that $v \in V(N_p)$, where p is the parent of ℓ. This argument may be repeated inductively. The result now follows from the fact that the root m of the tree satisfies $B_m = \emptyset$, which implies that $V_2(N_m) = \emptyset$ by Lemma 5(c). This implies that $V_1(N_m) = \emptyset$ by Lemma 5(a), as required.

We now describe each step of Algorithm `CongruentDiagonal`. When the node is a leaf corresponding to a bag B_i of size b_i, then we apply procedure `LeafBox`. This procedure only initializes a matrix N_i to be transmitted up the tree. The matrix N_i is such that $k' = 0$ and $k'' = b_i$, where $N_i^{(2)}$ is the diagonal matrix such that, for every $v \in B_i$, the entry vv is given by the element vv in M. Observe that no off-diagonal entries appear in this initialization, as the edges involving vertices in B_i have yet to be introduced.

```
LeafBox($B_i$)
input:  a set $B_i$ of size $b_i$
output:  a matrix $N_i = (N_i^{(1)}, N_i^{(2)})$
   Set $N_i^{(1)} = \emptyset$
   $N_i^{(2)}$ is a diagonal matrix of order $b_i$
   for each vertex $v \in B_i$ set entry $vv$ of $N_i^{(2)}$ as $m_{vv}$.
```

Figure 1 Procedure `LeafBox`.

By construction, the matrix N_i defined by `LeafBox` satisfies the properties of Lemma 5. It is not hard to show that, if Lemmas 6, 7 and 8 hold up to the end of step $i-1$ and step i processes a leaf B_i, the lemmas must also hold at the end of step i.

Next, we explain the procedures associated with nodes of type IntroduceVertex and IntroduceEdge. For vertices, the input is the set B_i, the vertex v that has been introduced and the matrix $N_j = (N_j^{(1)}, N_j^{(2)})$ obtained after processing the child B_j of B_i. The matrix N_i is obtained from N_j by adding a new type-ii row/column corresponding to vertex v (this becomes the last row/column of the matrix). This row is zero everywhere with the exception of the diagonal entry vv, which is equal to m_{vv}.

For edges, the input is the set B_i, a vertex $v \in B_i$, the set $\Gamma_{B_i}(v)$ of neighbors of v in B_i and the matrix $N_j = (N_j^{(1)}, N_j^{(2)})$ produced after processing the child B_j of B_i. The matrix N_i is obtained from N_j by replacing the entries uv and vu in $N_j^{(2)}$, which are equal to some value α, by $\alpha + \beta$, where β is the entry uv in M.

It is obvious that the matrices N_i produced by `IntroVertexBox` and `IntroEdgesBox` satisfy the properties of Lemma 5. In both cases, no row/column operation is performed, $\tilde{M}(i) = \tilde{M}(i-1)$ and $D_i = D_{i-1}$.

We now address the operation associated with nodes of type join. Let i be a node of type join and let N_j and N_ℓ be the matrices transmitted by its children, where $j < \ell < i$. By Lemma 5(c) and the definition of the join operation, we have $V_2(N_j) = V_2(N_\ell)$. By Lemma 7(a), we have $V_1(N_j) \cap V_1(N_\ell) = \emptyset$.

```
IntroVertexBox($B_i, v, N_j$)
input: a node $i$ with bag $B_i$, child $j$, $B_j = B_i - v$, and $N_j = (N_j^{(1)}, N_j^{(2)})$
output: a matrix $N_i = (N_i^{(1)}, N_i^{(2)})$
    $N_i^{(1)} = N_j^{(1)}$
    $N_i^{(2)} = N_j^{(2)}$
    Add zero row and zero column $v$ to $N_i^{(2)}$
    Add diagonal element $vv$ to $N_i^{(2)}$ as $m_{vv}$
    Add zero column $v$ to $N_i^{(1)}$
```

Figure 2 Procedure `IntroVertexBox`.

```
IntroEdgesBox($B_i, v, \Gamma_{B_i}(v), N_j$)
input: $v \in B_i$, $\Gamma_{B_i}(v)$ and a matrix $N_j = (N_j^{(1)}, N_j^{(2)})$
output: a matrix $N_i = (N_i^{(1)}, N_i^{(2)})$
    $N_i^{(1)} = N_j^{(1)}$
    $N_i^{(2)} = N_j^{(1)}$
    For all $u \in \Gamma_{B_i}(v)$, set entries $uv$ and $vu$ of $N_i^{(2)}$ as $N_i^{(2)}[uv] + m_{uv}$
```

Figure 3 Procedure `IntroEdgesBox`.

The `JoinBox` operation first creates a matrix N_i^* whose rows and columns are labelled by $V_1(N_j) \cup V_1(N_\ell) \cup V_2(N_j)$ with the structure below. Assume that $|V_1(N_j)| = r$, $|V_1(N_\ell)| = s$ and $|B_i| = t$.

$$N_i^* = \begin{array}{|c|c|c|}\hline \mathbf{0}_{r\times r} & \mathbf{0}_{r\times s} & N_j^{(1)} \\ \hline \mathbf{0}_{s\times r} & \mathbf{0}_{s\times s} & N_\ell^{(1)} \\ \hline N_j^{(1)T} & N_\ell^{(1)T} & N_i^{*(2)} \\ \hline \end{array}, \qquad (2)$$

where $N_i^{*(2)} = N_j^{(2)} + N_\ell^{(2)} - M_i[B_i]$. We observe that, at this point, $M_i[B_i]$ is a diagonal matrix, as no edges with both endpoints in B_i may have been introduced by Lemma 4(b).

Note that the matrix

$$N_i^{*(1)} = \begin{array}{|c|}\hline N_j^{(1)} \\ \hline N_\ell^{(1)} \\ \hline \end{array}$$

is an $(r+s) \times t$ matrix consisting of two matrices in row echelon form on top of each other. We perform row and column operations on N_i^* involving rows associated with $V_1(N_j)$ (the *left rows*) and $V_1(N_\ell)$ (the *right rows*) to turn N_i^* into a matrix $N_i^{*(1)}$ in row echelon form. To do this, we proceed by steps in which we always add a multiple of a left or right row (and the corresponding column) to a right row (and the corresponding column): to choose the next operation, at each step we look at the pivots of the right rows and select the leftmost such pivot that coincides with a pivot of a left row or with the pivot of another right row (say w and v are the right and left/right rows that satisfy this, and j is the pivot. At the first step, v is always a left row). If R_w and C_w are the row and column corresponding to w, while $\alpha_j = R_w(j) = C_w(j)$ and $\beta_j = R_v(j) = C_v(j)$, we define

$$R_w \leftarrow R_w - \frac{\alpha_j}{\beta_j} R_v, C_w \leftarrow C_w - \frac{\alpha_j}{\beta_j} C_v.$$

```
JoinBox($B_i, N_j, N_\ell$)
input:  a node $i$ with bag $B_i$ and matrices $N_j, N_\ell$ associated with its two children
output:  a matrix $N_i = (N_i^{(1)}, N_i^{(2)})$
   $N_i^{(2)} = N_j^{(2)} + N_\ell^{(2)}$
   For every $v \in B_i$, set the entry $vv$ of $N_i^{(2)}$ as $N_i^{(2)}[v,v] - m_{vv}$
   Construct $N_i^{(1)*} = \begin{bmatrix} N_j^{(1)} \\ N_\ell^{(1)} \end{bmatrix}$
   Do row and column operations on $N_i^{(1)*}$, putting it in row echelon form
   For each zero row of $N_i^{(1)*}$ (indexed by a vertex $u$), add $(u,0)$ to $D_i$
   $N_i^{(1)}$ is $N_i^{(1)*}$ with zero row/columns removed
```

Figure 4 Procedure `JoinBox`.

This eliminates the pivot of row w. Note that the entries in $N_j^{(2)}$ are not affected by these operations. Moreover, for all $u, v \in V_1(N_j) \cup V_1(N_\ell)$, the entry uv in N_i^* is equal to 0.

As we do this, we may create rows and columns (associated with the right rows) whose entries are all zero (for instance, this will certainly happen if $r + s > t$). If Z_i denotes the set of vertices associated with rows whose entries are all zero, where $|Z_i| = z$, we let $D_i = D_{i-1} \cup \{(v, 0) \colon v \in Z_i\}$, we remove the rows and columns associated with vertices in Z_i from $N_i^{*(1)}$ to produce the matrix

$$N_i = \begin{array}{|c|c|}\hline \mathbf{0}_{k' \times k'} & N_i^{(1)} \\ \hline N_i^{(1)T} & N_i^{(2)} \\ \hline \end{array}, \tag{3}$$

where $k' = r + s - z$, $k'' = t$ and $N_i^{(1)}$ is a matrix of dimension $k' \times k''$ in row echelon form and $N_i^{(2)} = N_i^{*(2)}$. We observe that N_i satisfies the properties of Lemma 5. Items (b) and (c) are satisfied by construction. For (a), the inequality $k' \leq k''$ is a consequence of the fact that $N_i^{(1)}$ is in row echelon form, while $k'' \leq k + 1$ follows from $k'' = |B_i|$. Proving that Lemmas 6, 7 and 8 hold after step i uses induction and the properties discussed above.

To conclude the description of the algorithm, we describe `ForgetBox`. Assume that i forgets vertex v and let j be its child, so that $B_i = B_j \setminus \{v\}$. By Lemma 4(c), we know that $\mathcal{T}(v)$ is a subtree of $\mathcal{T}_j$, and therefore all edges incident with v have been introduced. This procedure starts with $N_i^* = N_j$ and produces a new matrix N_i so that $v \in V_1(N_i)$ or $v \in \pi_1(D_i \setminus D_{i-1})$.

We look at N_i^* in the following way:

$$N_i^* = \begin{array}{|c|c|c|}\hline d_v & \mathbf{x}_v & \mathbf{y}_v \\ \hline \mathbf{x}_v^T & \mathbf{0}_{k' \times k'} & N_i^{*(1)} \\ \hline \mathbf{y}_v^T & N_i^{*(1)T} & N_i^{*(2)} \\ \hline \end{array}. \tag{4}$$

Here, the first row and column represent the row and column in N_j associated with v, while $N_i^{*(1)}$ and $N_i^{*(2)}$ are given by the submatrices of $N_j^{(1)}$ and $N_j^{(2)}$ obtained by removing the row and/or column associated with v. In particular $\mathbf{x}_v$ and $\mathbf{y}_v$ are row vectors of size k_j' and $k_j'' - 1$, respectively.

```
ForgetBox($B_i, v, N_j,$)
input:  a node $i$ with bag $B_i$, child $j$ with $B_i = B_j \setminus \{v\}$ and matrix $N_j$
output:  a matrix $N_i = (N_i^{(1)}, N_i^{(2)})$
   $N_i = N_j$
   Perform row/column exchange so that $N_i$ has the form of (4)
   if $\mathbf{x}_v$ is empty or 0 then
      if $\mathbf{y}_v$ is empty or 0 then
         add $(v, d_v)$ to $D$
         remove row $v$ from $N_i$
      else if $d_v \neq 0$ then // Here $\{\mathbf{y}_v \neq 0\}$.
         use $d_v$ to diagonalize row/column $v$
         add $(v, d_v)$ do $D$ and remove row $v$ form $N_i$
      else // Here $d_v = 0$.
         Set $u = \min\{w : y_w \neq 0\}$
         do row and column operations inserting row $v$ to $N_i^{(1)}$
         if a zero row is obtained add $(v, 0)$ to $D$ and remove row from $N_i$
   else // Here $\mathbf{x}_v \neq 0$.
      use operations as in (5) to diagonalize rows $u$ and $v$
      add $(v, d_v)$ and $(u, d_u)$ to $D$ and eliminate rows $v$ and $u$ from $N_i$.
```

Figure 5 Procedure ForgetBox.

Depending on the properties of the vectors $\mathbf{x}_v$ and $\mathbf{y}_v$, we proceed in different ways.

Case 1: $\mathbf{x}_v$ is empty or $\mathbf{x}_v = [0 \cdots 0]$. If $\mathbf{y}_v = [0 \cdots 0]$ (or $\mathbf{y}_v$ is empty), we add (v, d_v) to D_i and remove the row and column associated with v from N_i^* to produce N_i.

If $\mathbf{y}_v \neq [0 \cdots 0]$, there are again two options. If $d_v = 0$, the aim is to turn v into a row of type-i. To do this, we need to insert $\mathbf{y}_v$ into the matrix $N_i^{*(1)}$ in a way that the ensuing matrix is in row echelon form. Note that this may be done by only adding multiples of rows of $V(N_i^{*(1)})$ to the row associated with v. At each step, if the pivot α_j of the (current) row associated with v is in the same position of the pivot β_j of R_u, the row associated with vertex u already in $N_i^{*(1)}$, we use R_u to eliminate the pivot of R_v:

$$R_v \leftarrow R_v - \frac{\alpha_j}{\beta_j} R_u, C_v \leftarrow C_v - \frac{\alpha_j}{\beta_j} C_u.$$

This is done until the pivot of the row associated with v may not be cancelled by pivots of other rows, in which case the row associated with v may be inserted in the matrix (to produce the matrix $N_i^{(1)}$), or until the row associated with v becomes a zero row, in which case $(v, 0)$ is added to D_i and we remove the row and column associated with v from N_i^* to produce N_i. If $d_v \neq 0$, we use d_v to eliminate the nonzero entries in y_v and diagonalize the row corresponding to v. For each element $u \in B_i$ such that the component α_v of y_v associated with u is nonzero, we perform

$$R_u \leftarrow R_u - \frac{\alpha_v}{d_v} R_v, C_u \leftarrow C_u - \frac{\alpha_v}{d_v} C_v.$$

When all such entries have been eliminated, we add (d_v, v) to D_i and we let N_i be the remaining matrix. Observe that, in this case, $N_i^{(1)} = N_i^{*(1)}$, only the elements of $N_i^{*(2)}$ are modified to generate $N_i^{(2)}$.

Case 2: $\mathbf{x}_v$ *is nonempty and* $\mathbf{x}_v \neq [0 \cdots 0]$.

Let u be the vertex associated with the rightmost nonzero component of x_v. Let α_j be this component. We use this element to eliminate all the other nonzero entries in x_v, from right to left. Let w be the vertex associated with the entry α_ℓ. We perform

$$R_w \leftarrow R_w - \frac{\alpha_\ell}{\alpha_j} R_u, \quad C_w \leftarrow C_w - \frac{\alpha_\ell}{\alpha_j} C_u.$$

A crucial fact is that the entries corresponding to the matrix $N_i^{*(1)}$ in the matrix produced by these operations is still in row echelon form and has the same pivots as $N_i^{*(1)}$. If $d_v \neq 0$, we still use R_u to eliminate this element:

$$R_v \leftarrow R_v - \frac{d_v}{2\alpha_j} R_u, \quad C_v \leftarrow C_v - \frac{d_v}{2\alpha_j} C_u.$$

At this point, the only nonzero entries in the $(k'+1) \times (k'+1)$ left upper corner of the matrix obtained after performing these operations are in positions uv and vu (and are equal to α_j). We perform the operations

$$R_u \leftarrow R_u + \frac{1}{2} R_v, \quad C_u \leftarrow C_u + \frac{1}{2} C_v, R_v \leftarrow R_v - R_u, \quad C_v \leftarrow C_v - C_u$$

The relevant entries of the matrix are modified as follows:

$$\begin{pmatrix} 0 & \alpha_j \\ \alpha_j & 0 \end{pmatrix} \to \begin{pmatrix} 0 & \alpha_j \\ \alpha_j & \alpha_j \end{pmatrix} \to \begin{pmatrix} -\alpha_j & 0 \\ 0 & \alpha_j \end{pmatrix}. \tag{5}$$

We are now in the position to use the diagonal elements to diagonalize the rows associated with v and u, as was done in Case 1, when $x_v = [0, \ldots, 0]$ and $d_v \neq 0$. At the end of the step, we add $(v, -\alpha_j)$ and (u, α_j) to D_i.

Finally, it is time to analyze the complexity of Algorithm `CongruentDiagonal`, and prove Theorem 1.

Proof. The correctness of Algorithm `CongruentDiagonal` follows from the Lemmas and the justifications of every step of the algorithm as it is described throughout the paper. By Lemma 2, the time bound of $O(k|\mathcal{T}| + k^2 n)$ is sufficient to transform an arbitrary given tree decomposition into an edge-efficient tree decomposition.

For the running time of the main computation, we have to analyze the procedures done at each type of tree node. `LeafBox` initializes a matrix in $O(k^2)$ trivial steps. `IntroVertexBox` and `IntroEdgesBox` use only $O(k)$ steps. For the other procedures, the main cost comes from row and column operations. As the matrices have order at most $k+1$ each such operation costs $O(k)$. Regarding `ForgetBox`, when v is forgotten, either v is turned into a type-i vertex, or its row and column, and possibly the row and column of another vertex u, are diagonalized. The latter requires at most $O(k)$ row and column operations. If v is turned into a type-i vertex, then inserting it into the matrix $N_i^{(1)}$ in row echelon form takes at most $k+1$ row operations. `JoinBox` can be most time consuming. To insert just one row vector into a matrix of order k in row echelon form, and preserving this property by adding multiples of one vector to another, can require up to $k+1$ row operations. Each such operation can be done in time $O(k)$. To combine two matrices in row echelon form into one such matrix, up to $k+1$ row vectors are inserted. Thus the total time for this operation is $O(k^3)$. This immediately results in an upper bound of $O(k^3 n)$ for the whole computation.

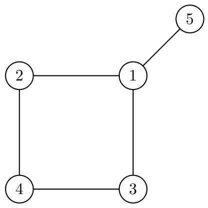

Figure 6 Graph with 5 labeled vertices.

To obtain an $O(k|\mathcal{T}| + k^2n)$ bound for the whole computation, we have to employ a different accounting scheme for the time spent to merge two matrices in row echelon form into one during the `JoinBox` procedure. We notice that every row operation in any $N_i^{(1)}$ creates at least one 0 entry in some row, meaning that its pivot moves at least one position to the right or creates a zero row. For every vertex v, its row is added at most once to some $N_i^{(1)}$, namely when v is forgotten. Its pivot can move at most k times and disappear at most once. Thus for all n vertices together, at most $(k+1)n$ row operations can occur in all $N_i^{(1)}$ together. This only uses time $O(k^2n)$. Thus, while during a single join procedure, $\Omega(k^2)$ row operations might be needed, the average is $O(k)$ such operations per join procedure. ◀

4 Example

In this section, we illustrate how the algorithm acts on a concrete example. To this end, we consider the graph in Figure 6. An edge-explicit tree decomposition representing this graph may be seen in Figure 7.

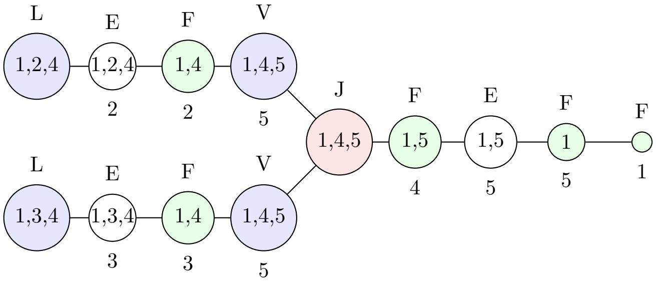

Figure 7 An edge-explicit tree representing the graph, where the root is on the right. A label above describes the type of node, a label below indicates which vertices or edges are introduced or forgotten.

Note that G is the underlying graph of the symmetric matrix

$$M = \begin{pmatrix} 1 & 1 & 1 & 0 & -1 \\ 1 & 0 & 0 & 2 & 0 \\ 1 & 0 & 1 & -1 & 0 \\ 0 & 2 & -1 & 1 & 0 \\ -1 & 0 & 0 & 0 & -1 \end{pmatrix}.$$

Suppose that we want to find the number of eigenvalues greater than 0 (and equal to and less than 0). We apply our algorithm with $c = 0$, that is, originally $M - cI = M$.

Assume that we have ordered the nodes of the tree in Figure 7 in post order so that the first five nodes are in the upper branch of Figure 7, followed by the five nodes on the lower branch and by the five nodes starting from the node of type join. When we start, the node

Leaf calls the LeafBox with bag of vertices $\{1,3,4\}$ producing the matrix $N_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$, whereas the node Introduce Edges labelled by vertex 3 introduces edges 13 and 34, leading to the matrix

$$N_3 = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & -1 \\ 0 & -1 & 1 \end{pmatrix}.$$

The node Forget Vertex $F3$ receives the matrix N_3 and, after exchanging rows and columns 1 and 2 (so that vertex 3 corresponds to first row), processes the matrix

$$\left(\begin{array}{r|rr} 1 & 1 & -1 \\ \hline 1 & 1 & 0 \\ -1 & 0 & 1 \end{array}\right).$$

According to our description, we are in Case 1 of Procedure ForgetBox, with $\mathbf{x}_v$ empty and $\mathbf{y}_v = [1,-1] \neq [0,0]$. Since $d_v = 1$, the algorithm diagonalizes the row/columns corresponding to v. To this end, we perform the operations $R_2 \leftarrow R_2 - R_1$, followed by $C_1 \leftarrow C_1 - C_2$, producing the matrix

$$N_3 = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 1 \\ -1 & 1 & 1 \end{pmatrix},$$

followed by the operations $R_3 \leftarrow R_3 + R_1$, followed by $C_3 \leftarrow C_3 + C_1$, giving

$$\left(\begin{array}{c|cc} 1 & 0 & 0 \\ \hline 0 & 0 & 1 \\ 0 & 1 & 0 \end{array}\right).$$

We have diagonalized row 1, corresponding to vertex 3. Hence, the node $F3$ sets the diagonal vector $D = (v, d_v) = (3,1)$ and transmits the matrix $N_4 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, whose rows are indexed by vertices 1 and 4, respectively, to its parent. The node $V5$ introduces vertex 5, producing the matrix

$$N_5 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix},$$

indexed by the vertices $1,4$ and 5, respectively. We notice that this matrix N is such that $N_5^{(1)}$ is empty and $N_5^{(2)} = N$.

Working on the lower branch of the tree of Figure 7 in a similar way, we arrive at node $F2$, after exchanging the rows/columns, with the matrix

$$N_9^* = \left(\begin{array}{c|cc} 0 & 1 & 2 \\ \hline 1 & 1 & 0 \\ 2 & 0 & 1 \end{array}\right),$$

indexing vertices 2, 1 and 4, respectively. This corresponds to Case 1 of Procedure ForgetBox, with empty $\mathbf{x}_v$ and $\mathbf{y}_v = [1,2]$, but $d_v = 0$. We notice that, in this particular case, the matrix $N_9^{(1)} = [1,2]$ is already in row echelon form, so that $N_9 = (N_9^{(1)}, N_9^{(2)})$, $N_9^{(2)} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, is transmitted by F_2 to its parent.

Now the Introduce Vertex node $V5$ processes the matrix N_9 and produces matrix

$$N_{10} = \left(\begin{array}{c:ccc} 0 & 1 & 2 & 0 \\ \hdashline 1 & 1 & 0 & 0 \\ 2 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{array}\right),$$

where the rows are indexed by the vertices 2, 1, 4 and 5, respectively.

Now the JoinBox procedure will process the matrices N_5 and N_{10}. We first do the operation $N_{11}^{(2)} = N_{10}^{(2)} + N_5^{(2)} - M_D[1,4,5]$, where $M_D[1,4,5]$ is the diagonal matrix whose rows and columns are indexed by 1, 4 and 5 such that each entry ii is given by m_{ii}. We then merge $N_{10}^{(1)}$ on top of $N_5^{(1)}$. Since $N_5^{(1)}$ is empty, these operation produce the matrix

$$N_{11} = \left(\begin{array}{c:ccc} 0 & 1 & 2 & 0 \\ \hdashline 1 & 0 & 1 & 0 \\ 2 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{array}\right),$$

whose rows index the vertices 2, 1, 4 and 5, respectively.

We now process node $F4$ of the tree, where the vertex 4 is forgotten. We first exchange rows and columns so that the first row is indexed by 4. The matrix becomes

$$N_{12}^{*} = \left(\begin{array}{c:c:cc} 0 & 2 & 1 & 0 \\ \hdashline 2 & 0 & 1 & 0 \\ \hdashline 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{array}\right),$$

whose rows index the vertices 4, 2, 1 and 5, respectively. We look at this matrix as in equation (4). We are in case 2 of Procedure ForgetBox with $d_v = 0, \mathbf{x}_v = [2], \mathbf{y}_v = [1,0], N_{12}^{*(1)} = [1,0]$ and $N_{12}^{*(2)} = \begin{pmatrix} 0 & 0 \\ 0 & -1 \end{pmatrix}$. Since $\mathbf{x}_v = [2]$, there is no operation to perform in order to put $\mathbf{x}_v$ in row echelon form. The goal now is to transform the left upper corner of the above matrix $\begin{pmatrix} 0 & 2 \\ 2 & 0 \end{pmatrix}$ into a diagonal matrix. We perform the operations $R_2 \leftarrow R_2 + 1/2R_1, C_2 \leftarrow C_2 + 1/2C_1$ followed by $R_1 \leftarrow R_1 - R_2$ and $C_1 \leftarrow C_1 - C_2$, obtaining the matrix

$$N_{12}^{*} = \begin{pmatrix} -2 & 0 & -1/2 & 0 \\ 0 & 2 & 3/2 & 0 \\ -1/2 & 2 & 2 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}.$$

We now use the nonzero pivots obtained in order to diagonalize rows 1 and 2. To achieve this, we perform the operations $R_3 \leftarrow R_3 - 1/4R_1, C_3 \leftarrow C_3 - 1/4C_1$, followed by $R_3 \leftarrow R_3 - 3/4R_2, C_3 \leftarrow C_3 - 3/4C_2$. This produces the matrix

$$N_{12}^{*} = \begin{pmatrix} -2 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}.$$

At this point, the first two rows are diagonalized, corresponding to vertices 4 and 2. To the diagonal vector $D = (v, d_v)$ we added the components $(4,-2)$ and $(2,2)$. Node $F4$ transmits the matrix $N_{12} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$, corresponding the edges 1 and 5. The Introduce Edges node

$E5$ puts the edge 15, and the matrix returned by IntroduceEdgesBox is $N_{13} = \left(\begin{array}{c:c} -1 & -1 \\ \hdashline -1 & -1 \end{array}\right)$ in the form the Forget node $F5$ receives it. We see that $\mathbf{x}_v$ is empty and $\mathbf{y}_v = [-1]$ and $d_v = -1$, meaning that we are in case 2. Using d_v as pivot we arrive at $N^*_{14} = \begin{pmatrix} -1 & 0 \\ 0 & 0 \end{pmatrix}$, adding to the diagonal vector D the component $(v, d_v) = (5, -1)$, and returning the matrix $N_{14} = [0]$. The final node $F1$ forgets the vertex 1. Since the matrix received is $[0]$ already in diagonal form, it adds to D the component $(v, d_v) = (1, 0)$. The diagonal vector D returned by the algorithm is

$$\begin{pmatrix} v \\ d_v \end{pmatrix} = \begin{pmatrix} 3 & 4 & 2 & 5 & 1 \\ 1 & -2 & 2 & -1 & 0 \end{pmatrix},$$

meaning that M has 2 positive eigenvalues, 2 negative eigenvalues and 0 is an eigenvalue with multiplicity 1.

Abstract

We give the first efficient algorithm to approximately count the number of solutions in the random k-SAT model when the density of the formula scales exponentially with k. The best previous counting algorithm was due to Montanari and Shah and was based on the correlation decay method, which works up to densities $(1+o_k(1))\frac{2\log k}{k}$, the Gibbs uniqueness threshold for the model. Instead, our algorithm harnesses a recent technique by Moitra to work for random formulas with much higher densities. The main challenge in our setting is to account for the presence of high-degree variables whose marginal distributions are hard to control and which cause significant correlations within the formula.

1 Introduction

Let $\Phi = \Phi(k,n,m)$ be a k-CNF formula on n Boolean variables with m clauses chosen uniformly at random where each clause has size $k \geq 3$. The random formula Φ shows an interesting threshold behaviour, where the asymptotic probability that Φ is satisfiable drops dramatically from 1 to 0 when the density $\alpha := m/n$ crosses a certain threshold $\alpha_\star$. There has been tremendous progress on establishing this phase transition and pinpointing the

threshold $\alpha_\star$ [25, 19, 3, 4, 12, 15] guided by elaborate but non-rigorous methods in physics [28, 27]. The exact value of the threshold $\alpha_\star$ is established in [15] for sufficiently large k; it is known that $\alpha_\star = 2^k \ln 2 - \frac{1}{2}(1 + \ln 2) + o_k(1)$ as $k \to \infty$.

In contrast, the "average case" computational complexity of random k-CNF formulas remains elusive. It is a notoriously hard problem to design algorithms that succeed in finding a satisfying assignment when the density of the formula Φ is close to (but smaller than) the satisfiability threshold $\alpha_\star$. The best polynomial-time algorithm to find a satisfying assignment of Φ is due to Coja-Oghlan [8], which succeeds if $\alpha < (1 - o_k(1)) \cdot 2^k \ln k/k$. It is known that beyond this density bound $2^k \ln k/k$ the solution space of the formula undergoes a phase transition and becomes severely more complicated [2], so local algorithms are bound to fail to find a satisfying assignment in polynomial time (see for example [24, 9, 11]).

It is also a natural question to determine the number of satisfying assignments to Φ, denoted by $Z(\Phi)$, when the density is below the satisfying threshold. It has been shown that $\frac{1}{n} \log Z(\Phi)$ is concentrated around its expectation [1, 13] for $\alpha < (1 - o_k(1)) \cdot 2^k \ln k/k$. However, for the k-SAT model, there is no known formula for the expectation $\mathbb{E}\, \frac{1}{n} \log Z(\Phi)$ (though see [35, 14] for progress along these lines for more symmetric models of random formulas). Regarding the algorithmic question, Montanari and Shah [31] have given an efficient algorithm to approximate $\log Z(\Phi)$ if $\alpha \le \frac{2 \log k}{k}(1 + o_k(1))$, based on the correlation decay method and the uniqueness threshold of the Gibbs distribution. Note that this only gives an approximation to $Z(\Phi)$ within an exponential factor. Also, the threshold for α is exponentially lower than the satisfiability threshold. No efficient algorithm was known to give a more precise approximation.

In this paper, we address the algorithmic counting problem by giving the first *fully polynomial-time approximation scheme* (FPTAS) for the number of satisfying assignments to random k-CNF formulas, if the density α is less than 2^{rk}, for sufficiently large k and some constant $r > 0$. Our bound is exponential in k and goes well beyond the uniqueness threshold of $\frac{2 \log k}{k}(1 + o_k(1))$ which is required by the correlation decay method.

Our result is related to other algorithmic counting results on random graphs such as counting colourings, independent sets, and other structures [33, 37, 16, 26] in random graphs. However, previous methods, such as Markov Chain Monte Carlo and Barvinok's method, appear to be difficult to apply to random formulas. Instead, our algorithm is the first adaptation of Moitra's method [30] to the random instance setting. We give a high level overview of the techniques in Section 1.2.

1.1 The model and the main result

For $k \ge 3$, let $\Phi = \Phi(k, n, m)$ denote a k-SAT formula chosen uniformly at random from the set of all k-SAT formulas with n variables and m clauses. Specifically, Φ has n variables $v_1, v_2, \ldots, v_n$ and m clauses $c_1, c_2, \ldots, c_m$. Each clause c_i has k literals $\ell_{i,1}, \ell_{i,2}, \ldots, \ell_{i,k}$ and each literal $\ell_{i,j}$ is chosen uniformly at random from $2n$ literals $\{v_1, v_2, \ldots, v_n, \neg v_1, \neg v_2, \ldots, \neg v_n\}$. Note that each clause has exactly k literals (repetitions allowed), so there are $(2n)^{km}$ possible formulas; we use $\Pr(\cdot)$ to denote the uniform distribution on the set of all such formulas. Throughout, we will assume that $m = \lfloor n\alpha \rfloor$, where $\alpha > 0$ is the density of the formula. We say that an event $\mathcal{E}$ holds *w.h.p.* if $\Pr(\mathcal{E}) = 1 - o(1)$ as $n \to \infty$.

For a k-SAT formula Φ, we let $\Omega = \Omega(\Phi)$ denote the set of satisfying assignments of Φ.

▶ **Theorem 1.** *There is a polynomial-time algorithm $\mathcal{A}$ and there are two constants $r > 0$ and $k_0 \ge 3$ such that, for all $k \ge k_0$ and all $\alpha < 2^{rk}$, the following holds w.h.p. over the choice of the random k-SAT formula $\Phi = \Phi(k, n, \lfloor \alpha n \rfloor)$. The algorithm $\mathcal{A}$, given as input the formula Φ and a rational $\varepsilon > 0$, outputs in time poly$(n, 1/\varepsilon)$ a number Z that satisfies $e^{-\varepsilon}|\Omega(\Phi)| \le Z \le e^{\varepsilon}|\Omega(\Phi)|$.*

Throughout this paper, we will assume that $k \geq k_0$ where k_0 is a sufficiently large constant. We will also assume that the density α of the formula Φ satisfies $\alpha < 2^{k/300}/k^3$, so r can be taken to be $1/301$ in Theorem 1. The constant 300 here is not optimised, but we do not expect to be able to use the current techniques to improve it substantially. Our main point is that for a density which is exponential in k, an FPTAS exists for random k-CNF formulas. Finally, we assume that $k^2\alpha \geq 1$, otherwise it is well-known (see, e.g., Theorem 3.6 in [34]) that w.h.p. every connected component of Φ, viewed as a hypergraph where variables correspond to vertices and clauses correspond to hyperedges, is of size $O(\log n)$. In this case we can count the number of satisfying assignments by brute force.

1.2 Algorithm overview

We give a high-level overview of our algorithm here before giving the details. Approximately counting the satisfying assignments of a k-CNF formula has been a challenging problem using traditional algorithmic techniques, since the solution space (the set of satisfying assignments) is complicated and it is not connected, using the transitions of commonly-studied Markov chains. Recently some new approaches were introduced [30, 20]. Most notably, the breakthrough work of Moitra [30] gives the first (and so far the only) efficient deterministic algorithm that can approximately count the satisfying assignments of k-CNF formulas in which each variable appears in at most d clauses, if, roughly, $d \lesssim 2^{k/60}$. Inspired by this, Feng et al. [18] have also given a MCMC algorithm which applies when $d \lesssim 2^{k/20}$.

As our goal is to count satisfying assignments of sparse random k-CNF formulas, where these degree bounds do not hold, but average degrees are small, it is natural to also choose Moitra's method in the random instance setting. However, the first difficulty is that Moitra's method relies on the fact that the marginal probability of each variable (the probability that the variable is true in a uniformly-chosen satisfying assignment) is nearly 1/2. This is necessary because Moitra's method involves solving a certain linear program (LP) and the size of this LP is polynomially-bounded only if a certain process couples quickly. The proof that the process couples quickly relies on the fact that the marginals are nearly 1/2 (and certainly on the fact that they are bounded away from 0 and 1). In contrast, for a random k-CNF formula, although the *average* degree of variables is low, w.h.p. there are variables with degrees as high as $\Omega(\log n/\log\log n)$. In the presence of these high-degree variables, the marginal probabilities of the variables can be arbitrarily near 0 or 1, instead of 1/2.

Our solution to this issue is to separate out high-degree variables, as well as those that are heavily influenced by high-degree variables. To do this, we define a process to recursively label "bad" variables. At the start, all high-degree variables are bad. Then, all clauses containing more than $k/10$ bad variables are labelled bad, as are all variables that they contain. We run this process until no more bad clauses are found. We call the remaining variables and clauses of the formula "good". A key property is that all good variables have an upper bound on their degree and all good clauses contain at least $9k/10$ good variables; this allows us to show that the marginal probabilities of good variables are close to 1/2.

The next step is to attempt to apply Moitra's method. The goal of Moitra's method is to compute more precise estimates for the marginal probabilities of the variables; given accurate estimates on the marginal probabilities, it is then relatively easy to approximate the number of satisfying assignments using refined self-reducibility techniques.

Of course, we need to modify the method to deal with the bad variables, which still appear in the formula. We first explain Moitra's method and then proceed with our modifications. The first step is to mark variables, so that every clause contains a good fraction of marked variables and a good fraction of unmarked variables. Then, for a particular marked variable

v, we set up an LP. As noted earlier, the variables of the LP correspond to the states of a certain coupling process which couples two distributions on satisfying assignments using the marked variables – the first distribution over satisfying assignments in which v is true, and the second distribution over satisfying assignments in which v is false. Solving the LP recovers the transition probabilities of the coupling process and yields enough information to approximate the marginal probability of v.

In order to guarantee that the size of the LP is bounded by a polynomial in the size of the original CNF formula, we have to restrict the coupling process. The process can be viewed as a tree and it suffices to truncate this tree at a suitable level.

Thus, a crucial part of the proof (both in Moitra's case and in ours) is to show that the error caused by the truncation is sufficiently small. The reason that the error caused by the truncation is small is that, with high probability, branches of the coupling tree "die out" before reaching a large level. The reason for this is that the marginals of marked variables stay near $1/2$, even when conditioning on partial assignments.

In our case where Φ is a random formula, the marginals are not all near $1/2$, even without any conditioning. But the good variables do have marginals near $1/2$. So we only mark/unmark good variables and we "give up" on bad variables. Given that we don't have any control over the bad variables, we have to modify the coupling process. Thus, whenever we meet a bad variable in the coupling process, we have to assume the worst case and treat this variable and all bad variables connected to it as if they all have failed the coupling, meaning that the disagreement spreads quickly over bad components.

The most important part of our analysis is to upper bound the size of connected bad components and how often we encounter them during the coupling processs. Given these upper bounds, we are able to show that the coupling still dies out sufficiently quickly, so the error caused by the truncation is not too large. Solving the LP then allows us to estimate the marginals of the good variables. Given that the bad components have small size, this turns out to be enough information to estimate the number of satisfying assignments of the original formula (containing both good and bad clauses).

We conclude this summary by discussing the prospects for improving our work. Although we have given an efficient algorithm which works for densities that are exponentially large in k, the densities that we can handle are still small compared to the satisfiability threshold or to the threshold under which efficient search algorithms exist. Perhaps a modest start towards obtaining comparable thresholds for approximate counting algorithms would be to consider models whose state spaces are connected. For example, for monotone k-CNF formulas where each variable appears in at most d clauses, Hermon et al. [23] showed that efficient randomised algorithms exist if $d \le c2^{k/2}$ for some constant $c > 0$, which is optimal up to the constant c due to complementing hardness results [6]. They also showed that the same algorithm works for *random regular* monotone k-CNF formulas, if the degree $d \le c2^k/k$ for some $c > 0$. It remains open whether an average case bound of the same order can be achieved for random monotone k-CNF formulas.

2 The coupling tree

2.1 Identifying bad variables

We start by identifying bad variables; the method that we use is inspired by [12].

▶ **Definition 2.** *Let Φ be a k-SAT formula. We say that a variable v of Φ is* high-degree *if Φ contains at least $\Delta := 2^{k/300}$ occurrences of literals involving the variable v.*

The reason that high-degree variables are harmful is that their marginal probabilities (when we sample uniformly from satisfying assignments) are not bounded away from 0 and 1. Also, any variable that shares clauses with high-degree variables may also have biased marginals. In our algorithm, we will not be able to control these high degree variables or other variables that are affected by them. This variables contribute to the "bad" part of the formula Φ. Formally, denote the set of clauses of Φ by $\mathcal{C}$ and the set of variables by $\mathcal{V}$. For each $c \in \mathcal{C}$, let $\mathsf{var}(c)$ denote the set of variables in c. For each subset C of $\mathcal{C}$, let $\mathsf{var}(C) := \cup_{c \in C}\mathsf{var}(c)$. The *bad variables* and *bad clauses* of Φ are identified as follows:

1. $\mathcal{V}_0$ (the initial bad variables) $\leftarrow$ the set of high-degree variables;
2. $\mathcal{C}_0 \leftarrow$ the set of clauses with at least $k/10$ variables in $\mathcal{V}_0$;
3. $i \leftarrow 0$;
4. Do the following until $\mathcal{V}_i = \mathcal{V}_{i-1}$:
   - $i \leftarrow i+1$;
   - $\mathcal{V}_i \leftarrow \mathcal{V}_{i-1} \cup \mathsf{var}(\mathcal{C}_{i-1})$;
   - $\mathcal{C}_i \leftarrow \{c \in \mathcal{C} \mid \mathsf{var}(c) \cap \mathcal{V}_i \geq k/10\}$;
5. $\mathcal{C}_{\text{bad}} \leftarrow \mathcal{C}_i$ and $\mathcal{V}_{\text{bad}} \leftarrow \mathcal{V}_i$;
6. $\mathcal{C}_{\text{good}} \leftarrow \mathcal{C} \setminus \mathcal{C}_i$ and $\mathcal{V}_{\text{good}} \leftarrow \mathcal{V} \setminus \mathcal{V}_i$.

▶ **Observation 3.** *$\forall c \in \mathcal{C}_{good}$, $|\mathsf{var}(c) \cap \mathcal{V}_{bad}| < k/10$. $\forall c \in \mathcal{C}_{bad}$, $|\mathsf{var}(c) \cap \mathcal{V}_{good}| = 0$.*

2.2 Marking good variables and identifying a satisfying assignment

Apart from the fact that we only mark variables in $\mathcal{V}_{\text{good}}$, our marking follows the approach of Moitra [30]. Formally, a "marking" is an assignment from $\mathcal{V}_{\text{good}}$ to $\{\text{marked}, \text{unmarked}\}$. Using Observation 3 and applying the asymmetric version of the Lovász local lemma [17, 36, 22] and the algorithmic version of the local lemma by Moser and Tardos [32] it is easy to prove the following lemma.

▶ **Lemma 8.** *There exists a marking on $\mathcal{V}_{good}$ such that every good clause has at least $3k/10$ marked variables and at least $k/4$ unmarked good variables. It has the property that there is a partial assignment of bad variables that satisfies all bad clauses. Furthermore, such a marking can be found in deterministic polynomial time.*

We also use the Lovász local lemma to identify a partial assignment Λ^* that we will use to apply self-reducibility.

▶ **Lemma 10.** *Let $\Phi = \Phi(k, n, m)$ and let $v_1, v_2, \ldots, v_n$ be the variables of Φ. In each clause, order the literals in the order induced by the indices of their variables. Then there is a partial assignment Λ^* of truth values to some subset of $\mathcal{V}_{\mathsf{marked}}$ with the property that every clause $c \in \mathcal{C}_{good}$ is satisfied by its first $k/20$ literals corresponding to marked variables. Moreover, Λ^* can be found in deterministic polynomial time.*

2.3 The coupling tree

Fix a prefix Λ of the assignment Λ^* from Lemma 10. Let Φ^Λ be the formula produced by simplifying Φ under Λ (remove clauses that are satisfied under Λ and remove all false literals). $\mathcal{C}^\Lambda$ denotes the clauses of Φ^Λ and $\mathcal{V}^\Lambda$ denotes the variables. We also define $\mathcal{V}^\Lambda_{\text{good}} = \mathcal{V}_{\text{good}} \cap \mathcal{V}^\Lambda$ and $\mathcal{C}^\Lambda_{\text{good}} = \mathcal{C}_{\text{good}} \cap \mathcal{C}^\Lambda$. Ω^Λ denotes the set of satisfying assignments of Φ^Λ.

For a variable $v^* \in \mathcal{V}^\Lambda$, let Ω^Λ_1 be the set of assignments in Ω^Λ in which v^* is true, and let Ω^Λ_2 be the set of assignments in Ω^Λ in which v^* is false. The algorithm estimates the marginal probability that v^* is true by solving a certain LP which allows it to estimate the ratio $|\Omega_1^\Lambda|/|\Omega_2^\Lambda|$. The variables of the LP correspond to the states of a coupling process. The process couples the uniform distribution on Ω_1^Λ with the uniform distribution on Ω_2^Λ. We can now describe process via its "coupling tree" $\mathbb{T}^\Lambda$.

For each node ρ there is a partial assignment $\mathcal{A}_1(\rho) \in \Omega_1^\Lambda$ and a partial assignment $\mathcal{A}_2(\rho) \in \Omega_2^\Lambda$. The variables set in these partial assignments are $\Lambda \cup V_{\mathrm{set}}(\rho)$. The set $V_I(\rho)$ contains "problematic" variables. The details will be clear later. Roughly, these include variables in $V_{\mathrm{set}}(\rho)$ on which $\mathcal{A}_1(\rho)$ and $\mathcal{A}_2(\rho)$ disagree, variables contained in clauses that are not satisfied in some $\mathcal{A}_i(\rho)$, even though all marked variables have already been set, and variables "affected" by bad variables during the coupling process. $\mathcal{C}_{\mathrm{rem}}(\rho)$ is the set of remaining clauses to consider at descendants of ρ in the coupling.

The root of the coupling tree is the node ρ^* with $V_{\mathrm{set}}(\rho^*) = V_I(\rho^*) = \{v^*\}$. The assignment $\mathcal{A}_1(\rho^*)$ sets v^* to T and the assignment $\mathcal{A}_2(\rho^*)$ sets v^* to F. $\mathcal{C}_{\mathrm{rem}}(\rho^*) = \mathcal{C}^\Lambda$. Let $n = |\mathcal{V}|$. In order to ensure that the size of the LP is bounded by a polynomial in n we need to ensure that the size of the coupling tree is also bounded by a polynomial in n. To do this, we choose truncation depth $L := C_0(3k^2\Delta)\lceil\log(n/\varepsilon)\rceil$ where C_0 is a sufficiently large constant. We then truncate the tree as follows.

▶ **Definition 12.** *A node ρ of the coupling tree is* a leaf *if $|V_I(\rho)| \le L$ and every $c \in \mathcal{C}_{rem}(\rho)$ has the property that $\mathsf{var}(c) \subseteq V_I(\rho) \cup V_{set}(\rho)$ or $\mathsf{var}(c) \subseteq \mathcal{V}^\Lambda \setminus (V_I(\rho) \cup V_{set}(\rho))$. If $|V_I(\rho)| > L$, then ρ is* a truncating node. *We denote the set of leaves by $\mathcal{L}$, the set of truncating nodes by $\mathcal{T}$, and their union by $\mathcal{L}^* := \mathcal{L} \cup \mathcal{T}$.*

If ρ is not in $\mathcal{L}^*$ then we define its four children as follows. The "first clause" of ρ is the first good clause c with a variable in $V_I(\rho)$ and a variable in $\mathcal{V}^\Lambda \setminus V_I(\rho)$. (The definitions imply that such a clause exists.) The "first variable" u of ρ is the first (good) variable in $\mathsf{marked}(c) \setminus V_{\mathrm{set}}(\rho)$. For each of the four pairs (τ_1, τ_2) where τ_1 and τ_2 are assignments from $\{u\}$ to $\{\mathsf{T}, \mathsf{F}\}$, we create a child ρ_{τ_1,τ_2} of ρ using the following algorithm.

Algorithm 1 Constructing the child ρ_{τ_1,τ_2} of a non-truncating node ρ of the coupling tree, where τ_1, τ_2 are assignments from $\{u\}$ to $\{\mathsf{T}, \mathsf{F}\}$, and u is the first variable of ρ.

```
$V_{\mathrm{set}}(\rho_{\tau_1,\tau_2}) \leftarrow V_{\mathrm{set}}(\rho) \cup \{u\}$;
$\mathcal{A}_1(\rho_{\tau_1,\tau_2}) \leftarrow$ combine $\mathcal{A}_1(\rho)$ with $\tau_1$;
$\mathcal{A}_2(\rho_{\tau_1,\tau_2}) \leftarrow$ combine $\mathcal{A}_2(\rho)$ with $\tau_2$;
$(V_I, \mathcal{C}_{\mathrm{rem}}) \leftarrow (V_I(\rho), \mathcal{C}_{\mathrm{rem}}(\rho))$;
if $\tau_1(u) \neq \tau_2(u)$ then
    $V_I \leftarrow V_I \cup \{u\}$;
end if
for $c' \in \mathcal{C}_{\mathrm{rem}}$ s.t. $c'$ is satisfied by both $\mathcal{A}_1(\rho_{\tau_1,\tau_2})$ and $\mathcal{A}_2(\rho_{\tau_1,\tau_2})$ do
    $\mathcal{C}_{\mathrm{rem}} \leftarrow \mathcal{C}_{\mathrm{rem}} \setminus \{c'\}$;
end for
while $\exists c' \in \mathcal{C}_{\mathrm{rem}}$ with $\mathsf{var}(c') \cap V_I \neq \emptyset$, $\mathsf{var}(c') \cap (\mathcal{V}^\Lambda \setminus V_I) \neq \emptyset$, and $\mathsf{marked}(c') \setminus V_{\mathrm{set}}(\rho_{\tau_1,\tau_2}) = \emptyset$ do
    $V_I \leftarrow V_I \cup (\mathsf{var}(c') \setminus V_{\mathrm{set}}(\rho_{\tau_1,\tau_2}))$;
    $\mathcal{C}_{\mathrm{rem}} \leftarrow \mathcal{C}_{\mathrm{rem}} \setminus \{c'\}$;
end while
while $\exists c' \in \mathcal{C}_{\mathrm{rem}} \cap \mathcal{C}_{\mathrm{bad}}$ with $\mathsf{var}(c') \cap V_I \neq \emptyset$ do
    $V_I \leftarrow V_I \cup (\mathsf{var}(c') \setminus V_{\mathrm{set}}(\rho_{\tau_1,\tau_2}))$;
    $\mathcal{C}_{\mathrm{rem}} \leftarrow \mathcal{C}_{\mathrm{rem}} \setminus \{c'\}$;
end while
$(V_I(\rho_{\tau_1,\tau_2}), \mathcal{C}_{\mathrm{rem}}(\rho_{\tau_1,\tau_2})) \leftarrow (V_I, \mathcal{C}_{\mathrm{rem}})$;
```

2.4 Key property of the coupling tree for a random formula

Recall that the variables of the LP which is used to estimate the marginal of the variable v^* of Φ^Λ correspond to the states of the coupling on the coupling tree $\mathbb{T}^\Lambda$. We will define two LP variables $P_{1,\rho}$ and $P_{2,\rho}$ for each node ρ of $\mathbb{T}^\Lambda$. In order to efficiently solve the LP, we need its size to be bounded by a polynomial in n, so we need the number of nodes of $\mathbb{T}^\Lambda$ to be bounded by a polynomial in n. For a random formula, this follows from the following key lemma, which is a main technical contribution of our work.

▶ **Lemma 14.** *W.h.p. over the choice of Φ, for every prefix Λ of Λ^*, every node ρ in $\mathbb{T}^\Lambda$ has the property that $|V_{set}(\rho)| \leq 3k^3\alpha L + 1$.*

To see that Lemma 14 implies that the size of the coupling tree is at most a polynomial in n, note that the depth of the tree does not exceed $\max_{\rho\in\mathbb{T}^\Lambda} |V_{\text{set}}(\rho)| \leq 3k^3\alpha L + 1 = O(\log \frac{n}{\varepsilon})$. Also, each node has at most 4 children.

In the rest of this section, we sketch the proof of Lemma 14. We start by defining some graphs associated with Φ. The formula Φ naturally corresponds to a bipartite "factor graph" where one side is variables and the other clauses (a variable has an edge to a clause in the factor graph if one its literals is contained in the clause). We also use the following two graphs.

▶ **Definition 3.** *Let G_Φ be the graph with vertex set $\mathcal{C}$ (the clauses of Φ) in which two clauses c and c' are adjacent if and only if $\mathsf{var}(c) \cap \mathsf{var}(c') \neq \emptyset$. We say that a set $C \subseteq \mathcal{C}$ of clauses is connected if the induced subgraph $G_\Phi[C]$ is connected.*

▶ **Definition 4.** *Let H_Φ be the graph with vertex set $\mathcal{V}$ (the variables of Φ) in which two variables v and v' are adjacent if and only if there exists a clause $c \in \mathcal{C}$ such that $v, v' \in \mathsf{var}(c)$. We say that a set $V \subseteq \mathcal{V}$ of variables is connected if the induced subgraph $H_\Phi[V]$ is connected. Let $H_{\Phi,bad}$ be the graph with vertex set $\mathcal{V}_{bad}$ in which two variables v and v' are adjacent if and only if there exists a bad clause $c \in \mathcal{C}_{bad}$ such that $v, v' \in \mathsf{var}(c)$. We say that a set $V \subseteq \mathcal{V}$ of variables is a* bad component *if V is a connected component in $H_{\Phi,bad}$.*

For $V \subseteq \mathcal{V}$, let $\Gamma_{H_\Phi}(V) = \cup_{v\in V}\Gamma_{H_\Phi}(v)$ be the neighbourhood of V in H_Φ. Let $\Gamma^+_{H_\Phi}(V) = V \cup \Gamma_{H_\Phi}(V)$ be the extended neighbourhood. The proof of Lemma 14 relies on the following rather abstract fact about random formulas.[1]

▶ **Lemma 41.** *W.h.p. over the choice of Φ, there do not exist sets Y', Z of clauses and a set V of variables such that $|Y'| \geq \log n$, $|V| \geq |Y'|$, $|Z| \geq 2k^2\alpha|V|$, $Y' \cap Z = \emptyset$, $G_\Phi[Y']$ is connected, $V \subseteq \mathsf{var}(Y')$, and every clause in Z contains at least one variable from V.*

The lemma says that if you take any "large" set of clauses Y' that are connected in G_Φ and any large set V of the variables of Y' then there aren't many clauses outside of Y' that contain variables in V. (There isn't a large set Z of such clauses.) Obviously, the lemma doesn't apply to every Φ, but is highly dependent on the random way in which Φ is chosen. The proof of Lemma 41 relies crucially on upper-bounding the probability that a set of clauses Y' is connected in G_Φ. To do this, we sum over possible trees connecting the clauses in Y'. We use the bound from Lemma 39 of the full version, which shows that the probability that any particular tree T is connected in G_Φ is at most $(k^2/n)^{|V(T)|-1}$.

[1] We need a more general version in the full paper, but this suffices here. The variable names here are chosen to make the (single) application in this short version easy.

Proof of Lemma 14. Let Λ be a prefix of Λ^* and let ρ be a node in $\mathbb{T}^\Lambda$. Our goal is to prove $|V_{\text{set}}(\rho)| \leq 3k^3\alpha L + 1$. We first consider the case in which ρ is not a truncating node, so $|V_I(\rho)| \leq L$ and we show $|V_{\text{set}}(\rho)| \leq 3k^3\alpha L$. The proof has two parts.

Part 1. $V_{\text{set}}(\rho) \subseteq \Gamma^+_{H_\Phi}(V_I(\rho))$.

To prove Part 1, we consider any $u \in V_{\text{set}}(\rho) \setminus V_I(\rho)$ and show that there is a clause c containing u and containing a variable in $V_I(\rho)$.

We first rule out the case that $u = v^*$ by noting (from the construction of the coupling tree) that $v^* \in V_I(\rho) \cap V_{\text{set}}(\rho)$.

So consider $u \in V_{\text{set}}(\rho) \setminus V_I(\rho)$ and let ρ' be the ancestor of ρ in the coupling tree such that u is the first variable of ρ'. The definition of the coupling tree guarantees that ρ' is uniquely defined and that it is a proper ancestor of ρ – the definition of "first variable" guarantees that $u \notin V_{\text{set}}(\rho')$, but for all proper descendants ρ''' of ρ', $u \in V_{\text{set}}(\rho''')$.

Let ρ'' be the child of ρ' on the path to ρ. We will show that there is a clause c containing u and containing a variable in $V_I(\rho')$. Part 1 then follows from the fact that $V_I(\rho)$ contains $V_I(\rho')$. The existence of such a clause c is immediate from the definition of "first variable" – indeed c is the "first clause" of ρ'.

Part 2. W.h.p., the random formula Φ is such that $\forall \rho, |\Gamma^+_{H_\Phi}(V_I(\rho))| \leq 3k^3\alpha L$.

For Part 2, it is important that the set $V_I(\rho)$ is connected in H_Φ – this follows from the construction of the coupling tree. We show (this is Lemma 51) that, w.h.p. over the choice of Φ, *every* connected set of variables $V \subseteq \mathcal{V}$ satisfies

$$|\Gamma^+_{H_\Phi}(V)| \leq 3k^3\alpha \max\{|V|, k \log n\}, \tag{1}$$

which establishes Part 2 since $|V_I(\rho)| \leq L$.

The proof of (1) is as follows. Let V be a connected of variables and let Y be the set of neighbours of V in the factor graph of Φ, i.e., $Y = \{c \in \mathcal{C} \mid \mathsf{var}(c) \cap V \neq \emptyset\}$. Clearly $|\Gamma^+_{H_\Phi}(V)| \leq k|Y|$ and hence it suffices to show that $|Y| \leq 3k^2\alpha \max\{|V|, k \log n\}$. There are two cases depending on the size of V.

- $|V| \geq k \log n$. Since V is a connected set of variables, there exists a set $Y' \subseteq Y$ such that $|V|/k \leq |Y'| \leq |V|$ and $V \cup Y'$ is connected in the factor graph of Φ. Hence, Y' is a connected set of clauses and $|Y'| \geq \log n$. Let $Z = Y \setminus Y'$. If $|Z| \geq 2k^2\alpha |V|$ then we obtain a contradiction to Lemma 41, which holds w.h.p. Thus, w.h.p., $|Z| \leq 2k^2\alpha |V|$ which implies $|Y| = |Y'| + |Z| \leq 3k^2\alpha |V|$, as required.
- Otherwise $|V| < k \log n$. If $|\Gamma^+_{H_\Phi}(V)| < \lceil k \log n \rceil$ then we are finished. Otherwise, consider an arbitrary connected $V' \supset V$ such that $|V'| = \lceil k \log n \rceil$. By the argument of the previous case, the set of neighbours of V' in the factor graph, denoted Y'', satisfies that $|Y''| \leq 3k^2\alpha |V'| \leq 3k^3\alpha \log n$. Thus, $|Y| \leq |Y''| \leq 3k^3\alpha \log n$.

This completes the proof of (1), and hence Part 2.

To finish, we consider the case where ρ is a truncating node. Let ρ' be the parent of ρ. Parts 1 and 2 imply that $|V_{\text{set}}(\rho')| \leq 3k^3\alpha L$. The result follows since $|V_{\text{set}}(\rho)| = |V_{\text{set}}(\rho')| + 1$. ◀

3 The linear program

Here we briefly list the constraints in the LP so that we can discuss its analysis. For a node ρ of the coupling tree, let $\mathcal{C}_I(\rho)$ be the set of clauses $c \in \mathcal{C}^\Lambda$ such that $\mathsf{var}(c) \subseteq V_I(\rho) \cup V_{\text{set}}(\rho)$. For $i \in \{1, 2\}$, let $N_i(\rho)$ be the number of assignments τ to $V_I(\rho) \setminus V_{\text{set}}(\rho)$ such that every clause in $\mathcal{C}_I(\rho)$ is satisfied by $\tau \cup \mathcal{A}_i(\rho)$. It turns out (see Lemma 15) that $N_i(\rho) \neq 0$ for $i \in \{1, 2\}$, so we define $r(\rho) = N_1(\rho)/N_2(\rho)$.

The LP relies on two constants r_{lower} and r_{upper}. The algorithm that uses the LP will move these closer and closer together by binary search. For each node ρ of the coupling tree, we introduce two variables $P_{1,\rho}$ and $P_{2,\rho}$. The constraints are as follows. **Constraint Set 0**: For every node ρ of the coupling tree and every $i \in \{1,2\}$ we add the constraint $0 \leq P_{i,\rho} \leq 1$. **Constraint Set 1**: If $\rho \in \mathcal{L}$ then we add the constraint $r_{\mathsf{lower}}\, P_{2,\rho} \leq P_{1,\rho}\, r(\rho)$ and the constraint $P_{1,\rho}\, r(\rho) \leq r_{\mathsf{upper}}\, P_{2,\rho}$. **Constraint Set 2**: For the root ρ^* of the coupling tree, we add the constraints $P_{1,\rho^*} = 1$ and $P_{2,\rho^*} = 1$. For every node ρ of the coupling tree that is not in $\mathcal{L}^*$, let u be the first variable of ρ. For each $X \in \{\mathsf{T},\mathsf{F}\}$ add the constraints $P_{1,\rho} = P_{1,\rho_{u\to X, u\to \mathsf{T}}} + P_{1,\rho_{u\to X, u\to \mathsf{F}}}$ and $P_{2,\rho} = P_{2,\rho_{u\to \mathsf{T}, u\to X}} + P_{2,\rho_{u\to \mathsf{F}, u\to X}}$. **Constraint Set 3**: For every node ρ of the coupling tree that is not in $\mathcal{L}^*$, every $X \in \{\mathsf{T},\mathsf{F}\}$, and every $i \in \{1,2\}$, let u be the first variable of ρ and add the constraint $P_{i,\rho_{u\to X, u\to\neg X}} \leq \frac{1}{s} P_{i,\rho}$.

4 Analysis of the linear program for a random formula and how it enables us to conclude Theorem 1

The key lemmas demonstrating the purpose of the linear program are as follows.

▶ **Lemma 24.** *Suppose $r_{\mathsf{lower}} \leq |\Omega_1^\Lambda|/|\Omega_2^\Lambda| \leq r_{\mathsf{upper}}$. There is a set of variables $\mathbf{P} = \{P_{i,\rho}\}$ that satisfies all constraints of the LP.*

▶ **Lemma 34.** *Fix $r_{\mathsf{lower}} \leq r_{\mathsf{upper}}$. W.h.p. over the choice of Φ, the following holds. If the LP has a solution $\mathbf{P}$ using r_{lower} and r_{upper}, then $e^{-\varepsilon/(3n)} r_{\mathsf{lower}} \leq |\Omega_1^\Lambda|/|\Omega_2^\Lambda| \leq e^{\varepsilon/(3n)} r_{\mathsf{upper}}$.*

The full version proves Theorem 1 using these two lemmas. Here we just give the main idea. First, consider the sub-goal of estimating $|\Omega_1^\Lambda|/|\Omega_2^\Lambda|$ given Φ and a partial assignment Λ of Λ^*. We can do this with accuracy $\exp(\pm\varepsilon/n)$ using the linear program. The proof of Lemma 57 in the full version uses the Lovász local lemma to establish values for r_{lower} and r_{upper} that meet the conditions in Lemma 24. Then, by binary search we bring r_{lower} and r_{upper} closer together until we achieve the desired accuracy (by Lemma 34). The initial values of r_{lower} and r_{upper} guarantee (see the proof of Lemma 57 for details) that the LP is run at most $O(\log(n/\varepsilon))$ times. Since we have already shown that the size of the LP is bounded by a polynomial in n/ε the algorithm runs in polynomial time.

Now consider the proof of Theorem 1. Using standard self-reducibility, we can use the estimates that we have just established to obtain an accurate estimate (within $\exp(\pm\varepsilon)$) of $|\Omega^{\Lambda^*}|/|\Omega|$, which is the probability that a random satisfying assignment is consistent with Λ^*.

To finish we need one last key ingredient – we need a method to estimate $|\Omega^{\Lambda^*}|$. Since all good clauses are satisfied by Λ^*, the set $\mathcal{C}^{\Lambda^*}$ of clauses of Φ^{Λ^*} consists only of bad clauses. Now we need one more key lemma.

▶ **Lemma 48.** *W.h.p. over the choice of Φ, every bad component S has size at most $21600k\log n$.*

Lemma 48 implies that $\mathcal{C}^{\Lambda^*}$ can be divided into disjoint subsets where each subset of clauses contains $O(\log n)$ variables. The algorithm can then compute the number of satisfying assignments of each subset by brute force in time *poly*(n). Then $|\Omega^{\Lambda^*}|$ is the product of these numbers.

This concludes the sketch of the proof of Theorem 1 – the details are in the full version. In the rest of this short version, we briefly discuss the proof of the remaining key lemmas, Lemmas 48, 34, and 24.

We start with the proof of Lemma 48. This lemma, which bounds the size of bad components, is one of the main technical achievements allowing us to extend Moitra's method to random CNFs with high density. Here we only have room for a very rough sketch. Recall that a bad component is a set S of variables that is connected in $H_{\Phi,\text{bad}}$. Let $\mathsf{HD}(S) = \mathcal{V}_0 \cap S$ be the set of high-degree variables in S. We wish to show that w.h.p., over the choice of Φ, every bad component S has size at most $21600k \log n$. This follows from the following two lemmas, which give a contradiction for large bad components S.

▶ **Lemma 42.** *W.h.p. over the choice of Φ, every connected set U of variables with size at least $21600k \log n$ satisfies that $|\mathsf{HD}(U)| \leq \frac{|U|}{21600}$.*

▶ **Lemma 47.** *W.h.p. over the choice of Φ, for any bad component S, $|S| \leq 60\,|\mathsf{HD}(S)|$.*

The proof of Lemma 42 is deferred to the full version. It uses Lemma 41 and studies trees in the factor graph of Φ. The following proof sketch concludes the proof of Lemma 48.

Proof Sketch of Lemma 47. Consider the following process P which we will use to work with bad compoments. The process, for every set S of variables, defines a set of variables $\mathsf{BC}(S)$.

```
1. Let $\mathsf{BC}(S) = S$.
2. While there is a clause $c$ such that $|\mathsf{var}(c) \cap \mathsf{BC}(S)| \geq k/10$ and $\mathsf{BC}(S) \setminus \mathsf{var}(c) \neq \emptyset$
     $\mathsf{BC}(S) := \mathsf{BC}(S) \cup \mathsf{var}(c)$
```

Note that $\mathcal{V}_{\text{bad}} = \mathsf{BC}(\mathcal{V}_0)$, where $\mathcal{V}_0$ is the set of high-degree variables. We show (Lemma 43) that for every bad component S, we have $S = \mathsf{BC}(\mathsf{HD}(S))$. Thus, the process P can be viewed as a "local" process for identifying bad components.

Let S be a bad component. If S contains only an isolated variable, it must be a high-degree variable and hence $\mathsf{HD}(S) = S$ (so we are finished). Otherwise, since a bad component is a connected component of variables in $H_{\Phi,\text{bad}}$, the definition of $H_{\Phi,\text{bad}}$ ensures that the bad component has at least $k/10$ high-degree variables.

Note that $|\mathsf{HD}(S)| \leq |\mathcal{V}_0|$. In Lemma 35 of the full version we use Poisson estimates for the degrees of the variables to show that, w.h.p., $|\mathcal{V}_0| \leq n/2^{k^{10}}$.

The next step is to apply a counting argument to show that, w.h.p., for *every* set of variables Y such that $2 \leq |Y| \leq n/2^k$, the number of clauses that contain at least $k/10$ variables from Y is at most $\frac{30}{k}|Y|$. This is Corollary 38 of the full version. We apply the corollary with $Y = \mathsf{HD}(S)$, so we find that there are at most $\frac{30}{k}\,|\mathsf{HD}(S)|$ clauses that contain at least $k/10$ variables from $\mathsf{HD}(S)$.

Now, we run the process P starting with $\mathsf{HD}(S)$. Take Z to be the set of clauses that contain at least $k/10$ variables from $\mathsf{HD}(S)$ (so, from above, we have $|Z| \leq \frac{30}{k}\,|\mathsf{HD}(S)| \leq \frac{30}{k}\frac{n}{2^{k^{10}}}$).

The next step is to show that, w.h.p., the number of clauses c such that $\mathsf{var}(c) \subseteq \mathsf{BC}(\mathsf{HD}(S))$ is at most $2|Z|$ (which we have already shown to be at most $60\,|\mathsf{HD}(S)|\,/k$). This analysis is contained in Corollary 45. It is essentially an analysis of the process P which follows easily from a lemma of Coja-Oghlan and Frieze [10, Lemma 2.4]. The high-probability guarantees are universal over Z (hence universal over S).

Since $S = \mathsf{BC}(\mathsf{HD}(S))$ and each variable in S is contained in some bad clause, we have

$$|S| \leq \left| \bigcup_{c \in \mathcal{C}_{\text{bad}}:\ \mathsf{var}(c) \cap S \neq \emptyset} \mathsf{var}(c) \right| \leq 60\,|\mathsf{HD}(S)|\,, \text{ as required.}$$ ◀

We now turn to the proof of Lemma 34. There are two kinds of errors which cause solutions of the LP to differ from the ratio $\left|\Omega_1^\Lambda\right|/\left|\Omega_2^\Lambda\right|$. The first kind comes from so-called "ℓ-wrong assignments" and the second kind comes from the truncation of the coupling tree. To define these more precisely, we need some graph-theoretic notation.

▶ **Definition 25.** *Given a graph G and any positive integer k, let $G^{\leq k}$ be the graph with vertex set $V(G)$ in which vertices u and v are connected iff there is a path from u to v in G of length at most k.*

The main combinatorial structure that we use is a set $\mathcal{D}(G_\Phi)$, which is based on Alon's "2,3-tree" [5]. Similar structures were subsequently used in [30, 21]. The main difference between our definition and previous ones is that we take into account whether clauses are connected via good variables.

▶ **Definition 26.** *Given G_Φ, let $\mathcal{D}(G_\Phi)$ be the set of subsets $T \subseteq V(G_\Phi)$ such that (1) For any $c_1, c_2 \in T$, $\mathsf{var}(c_1) \cap \mathsf{var}(c_2) \cap \mathcal{V}_{good} = \emptyset$; and (2) The graph $G_\Phi^{\leq 4}[T]$, which is the subgraph of $G_\Phi^{\leq 4}$ induced by T, is connected.*

▶ **Definition 29.** *An assignment $\sigma \in \Omega_i^\Lambda$ is ℓ-wrong if $\exists$ a size-ℓ set $T \in \mathcal{D}(G_\Phi)$ such that $c^* \in T$, $|T \cap \mathcal{C}_{good}^\Lambda| \geq 2\,|T|/3$, and there is a size $\lceil \ell/2 \rceil$ subset S of $T \cap \mathcal{C}_{good}^\Lambda$ such that the restriction of σ to marked variables in clauses in S does not satisfy any clause in S. Otherwise σ is ℓ-correct.*

Proof Sketch of Lemma 34. The constraints in **Constraint Set 2** guarantee (see Lemma 18 of the full version) that, for any $i \in \{1,2\}$ and $\sigma \in \Omega_i^\Lambda$, $\sum_{\rho \in \mathcal{L}^*:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho} = 1$. Thus, $|\Omega_i^\Lambda| = \sum_{\sigma\in\Omega_i^\Lambda} 1 = \sum_{\sigma\in\Omega_i^\Lambda} \sum_{\rho\in\mathcal{L}^*:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho}$. Let $\ell = L/(3k^2\Delta)$. We start by defining Z_i, Z_i' and Z_i'' as follows for $i \in \{1,2\}$.

$$Z_i = \sum_{\sigma\in\Omega_i^\Lambda} \sum_{\rho\in\mathcal{L}:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho},$$

$$Z_i' = \sum_{\sigma\in\Omega_i^\Lambda,\ \sigma \text{ is } \ell\text{-wrong}} \sum_{\rho\in\mathcal{L}^*:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho},$$

$$Z_i'' = \sum_{\sigma\in\Omega_i^\Lambda,\ \sigma \text{ is } \ell\text{-correct}} \sum_{\rho\in\mathcal{T}:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho}.$$

Thus $Z_i \leq \left|\Omega_i^\Lambda\right| \leq Z_i + Z_i' + Z_i''$. The full version proves

$$r_{\mathsf{lower}} \leq Z_1/Z_2 \leq r_{\mathsf{upper}}. \tag{2}$$

$$Z_i'/|\Omega_i^\Lambda| \leq (1-e^{-\varepsilon/(3n)})/2 \text{ for } i \in \{1,2\}. \tag{3}$$

$$Z_i''/|\Omega_i^\Lambda| \leq (1-e^{-\varepsilon/(3n)})/2 \text{ for } i \in \{1,2\}. \tag{4}$$

The lemma follows easily from these. Combining (3) and (4) with the fact that $Z_i \leq \left|\Omega_i^\Lambda\right| \leq Z_i + Z_i' + Z_i''$, we get $e^{-\varepsilon/(3n)} \leq \frac{Z_i}{|\Omega_i^\Lambda|} \leq 1$. Plugging in (2) we obtain the result.

To prove (2) we exchange the order of summation in the definition of Z_i to get

$$Z_i = \sum_{\rho\in\mathcal{L}} \sum_{\sigma\in\Omega_i^\Lambda:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho} = \sum_{\rho\in\mathcal{L}} P_{i,\rho} \cdot |\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}|.$$

Since $\rho \in \mathcal{L}$, we prove (see Lemma 17) that $r(\rho) = |\Omega^{\mathcal{A}_1(\rho)\cup\Lambda}|/|\Omega^{\mathcal{A}_2(\rho)\cup\Lambda}|$ (this is actually the point of $r(\rho)$). **Constraint Set 1** then guarantees that

$$r_{\mathsf{lower}} \leq \frac{P_{1,\rho} \cdot \left|\Omega^{\mathcal{A}_1(\rho)\cup\Lambda}\right|}{P_{2,\rho} \cdot \left|\Omega^{\mathcal{A}_2(\rho)\cup\Lambda}\right|} = \frac{P_{1,\rho} \cdot r(\rho)}{P_{2,\rho}\cdot} \leq r_{\mathsf{upper}}, \text{which suffices.}$$

The main ingredient in the proof of (3) is Lemma 30, which shows that the fraction of assignments in Ω_i^Λ that are ℓ-wrong is at most $(k\Delta)^{-9\ell}$. The main ingredient in the proof of (4) is showing that, w.h.p., for every ℓ-correct $\sigma \in \Omega_i^\Lambda$, $\sum_{\rho\in\mathcal{T}:\sigma\in\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}} P_{i,\rho} \le (k\Delta)^{-8\ell}$. This is handled in Lemmas 32 and 33.

To prove these lemmas (say for $i=1$) we consider a sampling procedure for choosing a node $\rho \in \mathcal{L}^*$ conditioned on some $\sigma \in \Omega_1^\Lambda$. The probability that it reaches any node $\rho \in \mathcal{L}^*$ with $\sigma \in \Omega^{\mathcal{A}_1(\rho)\cup\Lambda}$ is designed to be $P_{1,\rho}$ so the goal is to bound the probability that it reaches the set $\Upsilon_\sigma = \{\rho \in \mathcal{T} \mid \sigma \in \Omega^{\mathcal{A}_1(\rho)\cup\Lambda}\}$. This is where the combinatorial structures that we have defined come in. We use $\mathcal{F}(\rho)$ to denote the set of clauses that "fail" in the coupling process, contributing variables to $V_I(\rho)$. Lemma 28 shows that w.h.p., for every node $\rho \in \Upsilon_\sigma$, there is a set $T \subseteq \mathcal{F}(\rho)$ containing the first clause c^* such that $T \in \mathcal{D}(G_\Phi)$, $|T| = \ell$ and $|T \cap \mathcal{C}_{\text{bad}}| \le |T|/3$. This implies that $|T \cap C_{\text{good}}^\Lambda| \ge 2|T|/3$. We therefore need to upper bound the probability that such a T is contained in $\mathcal{F}(\rho)$ when ρ is chosen from the sampling procedure. T has size ℓ and contains c^* and contains enough good clauses. So it turns out that, since σ is ℓ-correct, a lot of these failed clauses in $\mathcal{F}(\rho)$ must have failed due to disagreements in the coupling. Since $T \in \mathcal{D}(G_\Phi)$ these clauses do not share good variables. The constraints in **Constraint Set 3** then imply that the probability of all of these simultaneous disagreements is unlikely.

That concludes the proof, apart from proving the key Lemma 28. This again relies on properties about bad components - in particular on Lemma 50, which says that, w.h.p., for every connected set of clauses Y such that $|\mathsf{var}(Y)| \ge 21600k\log n$, it holds that $|Y \cap \mathcal{C}_{\text{bad}}| \le |Y|/12$. This is somewhat similar to the issues that we discussed regarding the proof of Lemma 48 – we defer the details to the full version. ◀

Proof Sketch of Lemma 24. Suppose $r_{\mathsf{lower}} \le |\Omega_1^\Lambda|/|\Omega_2^\Lambda| \le r_{\mathsf{upper}}$. Our goal is to show that there is a set of variables $\mathbf{P} = \{P_{i,\rho}\}$ that satisfies all constraints of the LP. Here is a suitable assignment. Let ρ be a node of the coupling tree with first variable u. For $X \in \{\mathsf{T}, \mathsf{F}\}$, we use the notation $\psi_{\rho,X,1} := |\Omega^{\mathcal{A}_1(\rho_{u\to X,u\to X})\cup\Lambda}|/|\Omega^{\mathcal{A}_1(\rho)\cup\Lambda}| = |\Omega^{\mathcal{A}_1(\rho_{u\to X,u\to\neg X})\cup\Lambda}|/|\Omega^{\mathcal{A}_1(\rho)\cup\Lambda}|$. This is well-defined since $\mathcal{A}_1(\rho_{u\to X,u\to X}) = \mathcal{A}_1(\rho_{u\to X,u\to\neg X})$. In other words, $\psi_{\rho,X,1}$ is the probability that u is assigned value X under the uniform distribution on $\Omega^{\mathcal{A}_1(\rho)\cup\Lambda}$. We similarly define $\psi_{\rho,X,2} := |\Omega^{\mathcal{A}_2(\rho_{u\to X,u\to X})\cup\Lambda}|/|\Omega^{\mathcal{A}_2(\rho)\cup\Lambda}| = |\Omega^{\mathcal{A}_2(\rho_{u\to\neg X,u\to X})\cup\Lambda}|/|\Omega^{\mathcal{A}_2(\rho)\cup\Lambda}|$.

We will next give an inductive definition of a function Q from nodes of the coupling tree to real numbers in $[0,1]$. The way to think about this is as follows – we will implicitly define a probability distribution over paths from the root of the coupling tree to $\mathcal{L}^*$. For each node ρ, $Q(\rho)$ will be the probability that ρ is included in a path drawn from this distribution.

Any such path starts at the root, so we define $Q(\rho^*) = 1$. Once we have defined $Q(\rho)$ for a node ρ that is not in $\mathcal{L}^*$ we can define $Q(\cdot)$ on the children of ρ as follows. Let u be the first variable of ρ and consider the four children $\rho_{u\to\mathsf{T},u\to\mathsf{T}}, \rho_{u\to\mathsf{T},u\to\mathsf{F}}, \rho_{u\to\mathsf{F},u\to\mathsf{T}}, \rho_{u\to\mathsf{F},u\to\mathsf{F}}$. Define the values of Q as follows: $Q(\rho_{u\to\mathsf{T},u\to\mathsf{T}}) := Q(\rho)\min\{\psi_{\rho,\mathsf{T},1}, \psi_{\rho,\mathsf{T},2}\}$, $Q(\rho_{u\to\mathsf{T},u\to\mathsf{F}}) := Q(\rho)(\psi_{\rho,\mathsf{T},1} - \min\{\psi_{\rho,\mathsf{T},1}, \psi_{\rho,\mathsf{T},2}\})$, $Q(\rho_{u\to\mathsf{F},u\to\mathsf{F}}) := Q(\rho)\min\{1-\psi_{\rho,\mathsf{T},1}, 1-\psi_{\rho,\mathsf{T},2}\}$, and $Q(\rho_{u\to\mathsf{F},u\to\mathsf{T}}) := Q(\rho)((1-\psi_{\rho,\mathsf{T},1}) - \min\{1-\psi_{\rho,\mathsf{T},1}, 1-\psi_{\rho,\mathsf{T},2}\})$. Finally, we define $P_{i,\rho} := Q(\rho)|\Omega_i^\Lambda|/|\Omega^{\mathcal{A}_i(\rho)\cup\Lambda}|$. In the full version, we prove that this assignment satisfies the constraints of the LP. Mostly, the LP is designed to make this true, though for example to establish the constraint $P_{i,\rho_{u\to X,u\to\neg X}} \le \frac{1}{s} P_{i,\rho}$ (Lemma 23) we need to prove that $\psi_{\rho,X,i}$ is around $1/2$. Like Moitra, we prove this using the Lovász local lemma, so this is why it is essential that we restrict the LP to good variables. ◀

Abstract

Robust optimization is a widely studied area in operations research, where the algorithm takes as input a range of values and outputs a single solution that performs well for the entire range. Specifically, a robust algorithm aims to minimize *regret*, defined as the maximum difference between the solution's cost and that of an optimal solution in hindsight once the input has been realized. For graph problems in **P**, such as shortest path and minimum spanning tree, robust polynomial-time algorithms that obtain a constant approximation on regret are known. In this paper, we study robust algorithms for minimizing regret in **NP**-hard graph optimization problems, and give constant approximations on regret for the classical traveling salesman and Steiner tree problems.

1 Introduction

In many graph optimization problems, the inputs are not known precisely and the algorithm is desired to perform well over a range of inputs. For instance, consider the following situations. Suppose we are planning the delivery route of a vehicle that must deliver goods to n locations. Due to varying traffic conditions, the exact travel times between locations are not known precisely, but a range of possible travel times is available from historical data. Can we design a tour that is nearly optimal for *all* travel times in the given ranges? Consider another situation where we are designing a telecommunication network to connect a set of locations. We are given cost estimates on connecting every two locations in the network but these estimates might be off due to unexpected construction problems. Can we design the network in a way that is nearly optimal for *all* realized construction costs?

These questions have led to the field of *robust* graph algorithms. Given a range of weights $[\ell_e, u_e]$ for every edge e, the goal is to find a solution that minimizes *regret*, defined as the maximum difference between the algorithm's cost and the optimal cost for any edge weights.

In other words, the goal is to obtain: $\min_{\text{SOL}} \max_{\mathbf{I}}(\text{SOL}(\mathbf{I}) - \text{OPT}(\mathbf{I}))$, where $\text{SOL}(\mathbf{I})$ (resp. $\text{OPT}(\mathbf{I})$) denotes the cost of SOL (resp. the optimal solution) in instance $\mathbf{I}$, SOL ranges over all feasible solutions, and $\mathbf{I}$ ranges over all realizable inputs. We emphasize that SOL is a fixed solution (independent of $\mathbf{I}$) whereas the solution determining $\text{OPT}(\mathbf{I})$ is dependent on the input $\mathbf{I}$. The solution that achieves this minimum is called the *minimum regret solution* (MRS), and its regret is the *minimum regret* (MR). In many cases, however, minimizing regret turns out to be **NP**-hard, in which case one seeks an approximation guarantee. Namely, a β-approximation algorithm satisfies, for all input realizations $\mathbf{I}$, $\text{SOL}(\mathbf{I}) - \text{OPT}(\mathbf{I}) \leq \beta \cdot \text{MR}$, i.e., $\text{SOL}(\mathbf{I}) \leq \text{OPT}(\mathbf{I}) + \beta \cdot \text{MR}$.

It is known that minimizing regret is **NP**-hard for shortest path [34] and minimum cut [1] problems, and using a general theorem for converting exact algorithms to robust ones, 2-approximations are known for these problems [12, 23]. In some cases, better results are known for special classes of graphs, e.g., [24]. Robust minimum spanning tree (MST) has also been studied, although in the context of making exponential-time exact algorithms more practical [33]. Moreover, robust optimization has been extensively researched for other (non-graph) problem domains in the operations research community, and has led to results in clustering [5, 3, 6, 27], linear programming [21, 28], and other areas [4, 23]. More details can be found in the book by Kouvelis and Yu [26] and the survey by Aissi *et al.* [2].

To the best of our knowledge, all previous work in polynomial-time algorithms for minimizing regret in robust graph optimization focused on problems in **P**. In this paper, we study robust graph algorithms for minimizing regret in **NP**-hard optimization problems. In particular, we study robust algorithms for the classical traveling salesman (TSP) and Steiner tree (STT) problems, that model e.g. the two scenarios described at the beginning of the paper. As a consequence of the **NP**-hardness, we cannot hope to show guarantees of the form: $\text{SOL}(\mathbf{I}) \leq \text{OPT}(\mathbf{I}) + \beta \cdot \text{MR}$, since for $\ell_e = u_e$ (i.e., $\text{MR} = 0$), this would imply an exact algorithm for an **NP**-hard optimization problem. Instead, we give guarantees: $\text{SOL}(\mathbf{I}) \leq \alpha \cdot \text{OPT}(\mathbf{I}) + \beta \cdot \text{MR}$, where α is (necessarily) at least as large as the best approximation guarantee for the optimization problem. We call such an algorithm an (α, β)-robust algorithm. If both α and β are constants, we call it a constant-approximation to the robust problem. In this paper, our main results are constant approximation algorithms for the robust traveling salesman and Steiner tree problems. We hope that our work will lead to further research in the field of robust approximation algorithms, particularly for other **NP**-hard optimization problems in graph algorithms as well as in other domains.

1.1 Problem Definition and Results

We first define the Steiner tree (STT) and traveling salesman problems (TSP). In both problems, the input is an undirected graph $G = (V, E)$ with non-negative edge costs. In Steiner tree, we are also given a subset of vertices called *terminals* and the goal is to obtain a minimum cost connected subgraph of G that spans all the terminals. In traveling salesman, the goal is to obtain a minimum cost tour that visits every vertex in V[1]. In the robust versions of these problems, the edge costs are ranges $[\ell_e, u_e]$ from which any cost may realize.

Our main results are the following:

▶ **Theorem 1** (Robust Approximations). *There exist constant approximation algorithms for the robust traveling salesman and Steiner tree problems.*

[1] There are two common and equivalent assumptions made in the TSP literature in order to achieve reasonable approximations. In the first assumption, the algorithms can visit vertices multiple times in the tour, while in the latter, the edges satisfy the metric property. We use the former in this paper.

▶ Remark. The constants we are able to obtain for the two problems are very different: $(4.5, 3.75)$ for TSP (in Section 3) and $(2755, 64)$ for STT (in Section 4). While we did not attempt to optimize the precise constants, obtaining small constants for STT comparable to the TSP result requires new ideas beyond our work and is an interesting open problem.

We complement our algorithmic results with lower bounds. Note that if $\ell_e = u_e$, we have $\textsc{mr} = 0$ and thus an (α, β)-robust algorithm gives an α-approximation for precise inputs. So, hardness of approximation results yield corresponding lower bounds on α. More interestingly, we show that hardness of approximation results also yield lower bounds on the value of β (see Section 5 for details):

▶ **Theorem 2** (APX-hardness). *A hardness of approximation of ρ for TSP (resp., STT) under $\mathbf{P} \neq \mathbf{NP}$ implies that it is $\mathbf{NP}$-hard to obtain $\alpha \leq \rho$ (irrespective of β) and $\beta \leq \rho$ (irrespective of α) for robust TSP (resp., robust STT).*

1.2 Our Techniques

We now give a sketch of our techniques. Before doing so, we note that for problems in $\mathbf{P}$ with linear objectives, it is known that running an exact algorithm using weights $\frac{\ell_e + u_e}{2}$ gives a $(1, 2)$-robust solution [12, 23]. One might hope that a similar result can be obtained for $\mathbf{NP}$-hard problems by replacing the exact algorithm with an approximation algorithm in the above framework. Unfortunately, there exists robust TSP instances where using a 2-approximation for TSP with weights $\frac{\ell_e + u_e}{2}$ gives a solution that is **not** (α, β)-robust for *any* $\alpha = o(n), \beta = o(n)$. More generally, a black-box approximation run on a fixed realization could output a solution including edges that have small weight relative to OPT for that realization (so including these edges does not violate the approximation guarantee), but these edges could have large weight relative to MR and OPT in other realizations, ruining the robustness guarantee. This establishes a qualitative difference between robust approximations for problems in $\mathbf{P}$ considered earlier and $\mathbf{NP}$-hard problems being considered in this paper, and demonstrates the need to develop new techniques for the latter class of problems.

LP relaxation. We denote the input graph $G = (V, E)$. For each edge $e \in E$, the input is a range $[\ell_e, u_e]$ where the actual edge weight d_e can realize to any value in this range. The robust version of a graph optimization problem is is then described by the LP

$$\min\{r : \mathbf{x} \in P; \sum_{e \in E} d_e x_e \leq \textsc{opt}(\mathbf{d}) + r, \ \forall \mathbf{d}\},$$

where P is the standard polytope for the optimization problem, and $\textsc{opt}(\mathbf{d})$ denotes the cost of an optimal solution when the edge weights are $\mathbf{d} = \{d_e : e \in E\}$. That is, this is the standard LP for the problem, but with the additional constraint that the fractional solution $\mathbf{x}$ must have regret at most r for any realization of edge weights. We call the additional constraints the *regret constraint set*. Note that setting $\mathbf{x}$ to be the indicator vector of MRS and r to MR gives a feasible solution to the LP; thus, the LP optimum is at most MR.

Solving the LP. We assume that the constraints in P are separable in polynomial time (e.g., this is true for most standard optimization problems including STT and TSP). So, designing the separation oracle comes down to separating the regret constraint set, which requires checking that:

$$\max_{\mathbf{d}} \left[\sum_{e \in E} d_e x_e - \textsc{opt}(\mathbf{d})\right] =$$

$$\max_{\mathbf{d}} \max_{\textsc{sol}} \left[\sum_{e \in E} d_e x_e - \textsc{sol}(\mathbf{d})\right] = \max_{\textsc{sol}} \max_{\mathbf{d}} \left[\sum_{e \in E} d_e x_e - \textsc{sol}(\mathbf{d})\right] \leq r.$$

Thus, given a fractional solution $\mathbf{x}$, we need to find an integer solution $\textsc{sol}$ and a weight vector $\mathbf{d}$ that maximizes the regret of $\mathbf{x}$ given by $\sum_{e \in E} d_e x_e - \textsc{sol}(\mathbf{d})$. Once $\textsc{sol}$ is fixed, finding $\mathbf{d}$ that maximizes the regret is simple: If $\textsc{sol}$ does not include an edge e, then to maximize $\sum_{e \in E} d_e x_e - \textsc{sol}(\mathbf{d})$, we set $d_e = u_e$; else if $\textsc{sol}$ includes e, we set $d_e = \ell_e$. Note that in these two cases, edge e contributes $u_e x_e$ and $\ell_e x_e - \ell_e$ respectively to the regret. The above maximization thus becomes:

$$\max_{\textsc{sol}} \left[\sum_{e \notin \textsc{sol}} u_e x_e + \sum_{e \in \textsc{sol}} (\ell_e x_e - \ell_e) \right] = \sum_{e \in E} u_e x_e - \min_{\textsc{sol}} \sum_{e \in \textsc{sol}} (u_e x_e - \ell_e x_e + \ell_e). \tag{1}$$

Thus, $\textsc{sol}$ is exactly the optimal solution with edge weights $a_e := u_e x_e - \ell_e x_e + \ell_e$. (For reference, we define the *derived* instance of the problem as one with edge weights a_e.)

Now, if we were solving a problem in $\mathbf{P}$, we would simply need to solve the problem on the derived instance. Indeed, we will show later that this yields an alternative technique for obtaining robust algorithms for problems in $\mathbf{P}$, and recover existing results in [23]. However, we cannot hope to find an optimal solution to an $\mathbf{NP}$-hard problem. Our first compromise is that we settle for an *approximate* separation oracle. More precisely, our goal is to show that there exists some fixed constants $\alpha', \beta' \geq 1$ such that if $\sum_e d_e x_e > \alpha' \cdot \textsc{opt}(\mathbf{d}) + \beta' \cdot r$ for some $\mathbf{d}$, then we can find $\textsc{sol}, \mathbf{d}'$ such that $\sum_e d'_e x_e > \textsc{sol}(\mathbf{d}') + r$. Since the LP optimum is at most $\textsc{mr}$, we can then obtain an (α', β')-robust *fractional* solution using the standard ellipsoid algorithm.

For $\textsc{tsp}$, we show that the above guarantee can be achieved by the classic $\textsc{mst}$-based 2-approximation on the derived instance. The details appear in Section 3 and the full paper. Although $\textsc{stt}$ also admits a 2-approximation based on the $\textsc{mst}$ solution, this turns out to be insufficient for the above guarantee. Instead, we use a different approach here. We note that the regret of the fractional solution against any fixed solution $\textsc{sol}$ (i.e., the argument over which Eq. (1) maximizes) can be expressed as the following difference:

$$\sum_{e \notin \textsc{sol}} (u_e x_e - \ell_e x_e + \ell_e) - \sum_{e \in E} (\ell_e - \ell_e x_e) = \sum_{e \notin \textsc{sol}} a_e - \sum_{e \in E} b_e, \text{ where } b_e := \ell_e - \ell_e x_e.$$

The first term is the weight of edges in the derived instance that are *not* in $\textsc{sol}$. The second term corresponds to a new $\textsc{stt}$ instance with different edge weights b_e. It turns out that the overall problem now reduces to showing the following approximation guarantees on these two $\textsc{stt}$ instances (c_1 and c_2 are constants):

$$\text{(i)} \sum_{e \in \textsc{alg} \setminus \textsc{sol}} a_e \leq c_1 \cdot \sum_{e \in \textsc{sol} \setminus \textsc{alg}} a_e \qquad \text{and} \qquad \text{(ii)} \sum_{e \in \textsc{alg}} b_e \leq c_2 \cdot \sum_{e \in \textsc{sol}} b_e.$$

Note that guarantee (i) on the derived instance is an unusual "difference approximation" that is stronger than usual approximation guarantees. Moreover, we need these approximation bounds to *simultaneously* hold, i.e., hold for the same $\textsc{alg}$. Obtaining these dual approximation bounds simultaneously forms the most technically challenging part of our work; a high level overview is given in Section 4 and technical details are deferred to the full paper.

Rounding the fractional solution. After applying our approximate separation oracles, we have a fractional solution $\mathbf{x}$ such that for all edge weights $\mathbf{d}$, we have $\sum_e d_e x_e \leq \alpha' \cdot \textsc{opt}(\mathbf{d}) + \beta' \cdot \textsc{mr}$. Suppose that, ignoring the regret constraint set, the LP we are using has integrality gap at most δ for precise inputs. Then a natural rounding approach is to search for an integer solution $\textsc{alg}$ that has minimum regret with respect to the specific solution $\delta\mathbf{x}$, i.e., $\textsc{alg}$ satisfies:

$$\textsc{alg} = \operatorname*{argmin}_{\textsc{sol}} \max_{\mathbf{d}} \left[\textsc{sol}(\mathbf{d}) - \delta \sum_{e \in E} d_e x_e \right]. \tag{2}$$

Since the integrality gap is at most δ, we have $\delta \cdot \sum_{e\in E} d_e x_e \geq \textsc{opt}(\mathbf{d})$ for any $\mathbf{d}$. This implies that:

$$\textsc{mrs}(\mathbf{d}) - \delta \cdot \sum_{e\in E} d_e x_e \leq \textsc{mrs}(\mathbf{d}) - \textsc{opt}(\mathbf{d}) \leq \textsc{mr}.$$

Hence, the regret of $\textsc{mrs}$ with respect to δx is at most $\textsc{mr}$. Since $\textsc{alg}$ has minimum regret with respect to $\delta\mathbf{x}$, $\textsc{alg}$'s regret is also at most $\textsc{mr}$. Note that $\delta\mathbf{x}$ is a $(\delta\alpha', \delta\beta')$-robust solution. Hence, $\textsc{alg}$ is a $(\delta\alpha', \delta\beta' + 1)$-robust solution.

If we are solving a problem in **P**, finding $\textsc{alg}$ that satisfies Eq. (2) is easy. So, using an integral LP formulation (i.e., integrality gap of 1), we get a $(1, 2)$-robust algorithm overall for these problems. This exactly matches the results in [23], although we are using a different set of techniques. Of course, for **NP**-hard problems, finding a solution $\textsc{alg}$ that satisfies Eq. (2) is **NP**-hard as well. It turns out, however, that we can design a generic rounding algorithm that gives the following guarantee:

▶ **Theorem 3.** *There exists a rounding algorithm that takes as input an (α, β)-robust fractional solution to $\textsc{stt}$ (resp. $\textsc{tsp}$) and outputs a $(\gamma\delta\alpha, \gamma\delta\beta + \gamma)$-robust integral solution, where γ and δ are respectively the best approximation factor and integrality gap for (classical) $\textsc{stt}$ (resp., $\textsc{tsp}$).*

We remark that while we stated this rounding theorem for $\textsc{stt}$ and $\textsc{tsp}$ here, we actually give a more general version (Theorem 4) in Section 2 that applies to a broader class of covering problems including set cover, survivable network design, etc. and might be useful in future research in this domain.

1.3 Related Work

We have already discussed the existing literature in robust optimization for minimizing regret. Other robust variants of graph optimization have also been studied in the literature. In the *robust combinatorial optimization* model proposed by Bertsimas and Sim [7], edge costs are given as ranges as in this paper, but instead of optimizing for all realizations of costs within the ranges, the authors consider a model where at most k edge costs can be set to their maximum value and the remaining are set to their minimum value. The objective is to minimize the maximum cost over all realizations. In this setting, there is no notion of regret and an approximation algorithm for the standard problem translates to an approximation algorithm for the robust problem with the same approximation factor.

In the *data-robust model* [13], the input includes a polynomial number of explicitly defined "scenarios" for edge costs, with the goal of finding a solution that is approximately optimal for all given scenarios. That is, in the input one receives a graph and a polynomial number of scenarios $\mathbf{d}^{(1)}, \mathbf{d}^{(2)} \ldots \mathbf{d}^{(k)}$ and the goal is to find $\textsc{alg}$ whose maximum cost across all scenarios is at most some approximation factor times $\min_{\textsc{sol}} \max_{i\in[k]} \sum_{e\in\textsc{sol}} d_e^{(i)}$. In contrast, in this paper, we have exponentially many scenarios and look at the maximum of $\textsc{alg}(\mathbf{d}) - \textsc{opt}(\mathbf{d})$ rather than $\textsc{alg}(\mathbf{d})$. A variation of this is the *recoverable robust model* [9], where after seeing the chosen scenario, the algorithm is allowed to "recover" by making a small set of changes to its original solution.

Dhamdhere *et al.* [13] also studies the *demand-robust model*, where edge costs are fixed but the different scenarios specify different connectivity requirements of the problem. The algorithm now operates in two phases: In the first phase, the algorithm builds a partial solution T' and then one of the scenarios (sets of terminals) T_i is revealed to the algorithm. In the second phase, the algorithm then adds edges to T' to build a solution T, but must pay a multiplicative cost of σ_k on edges added in the second phase. The demand-robust model was inspired by a two-stage stochastic optimization model studied in, e.g., [30, 29, 31, 13, 14, 25, 18, 19, 20, 8] where the scenario is chosen according to a distribution rather than an adversary.

Another related setting to the data-robust model is that of *robust network design*, introduced to model uncertainty in the demand matrix of network design problems (see the survey by Chekuri [10]). This included the well-known VPN conjecture (see, e.g., [17]), which was eventually settled in [15]. In all these settings, however, the objective is to minimize the maximum cost over all realizations, whereas in this paper, our goal is to minimize the maximum *regret* against the optimal solution.

2 Generalized Rounding Algorithm

We start by giving the rounding algorithm of Theorem 3, which is a corollary of the following, more general theorem:

▶ **Theorem 4.** *Let $\mathcal{P}$ be an optimization problem defined on a set system $\mathcal{S} \subseteq 2^E$ that seeks to find the set $S \in \mathcal{S}$ that minimizes $\sum_{e \in S} d_e$, i.e., the sum of the weights of elements in S. In the robust version of this optimization problem, we have $d_e \in [\ell_e, u_e]$ for all $e \in E$.*

Consider an LP formulation of $\mathcal{P}$ (called $\mathcal{P}$-LP) given by: $\{\min \sum_{e \in E} d_e x_e : \boldsymbol{x} \in X, \boldsymbol{x} \in [0,1]^E\}$, where X is a polytope containing the indicator vector χ_S of all $S \in \mathcal{S}$ and not containing χ_S for any $S \notin \mathcal{S}$. The corresponding LP formulation for the robust version (called $\mathcal{P}_{\text{robust}}$-LP) is given by: $\{\min r : \boldsymbol{x} \in X, \boldsymbol{x} \in [0,1]^E, \sum_{e \in E} d_e x_e \leq \text{OPT}(\boldsymbol{d}) + r \ \forall \boldsymbol{d}\}$.

Now, suppose we have the following properties:

- *There is a γ-approximation algorithm for $\mathcal{P}$.*
- *The integrality gap of $\mathcal{P}$-LP is at most δ.*
- *There is a feasible solution $\boldsymbol{x}^*$ to $\mathcal{P}$-LP that satisfies: $\forall \boldsymbol{d} : \sum_{e \in E} d_e x_e^* \leq \alpha \cdot \text{OPT}(\boldsymbol{d}) + \beta \cdot \text{MR}$.*

Then, there exists an algorithm that outputs an integer solution SOL *for $\mathcal{P}$ that satisfies:*

$$\forall \boldsymbol{d} : \text{SOL}(\boldsymbol{d}) \leq (\gamma\delta\alpha) \cdot \text{OPT}(\boldsymbol{d}) + (\gamma\delta\beta + \gamma) \cdot \text{MR}.$$

Proof. The algorithm is as follows: Construct an instance of $\mathcal{P}$ which uses the same set system $\mathcal{S}$ and where element e has weight $\max\{u_e(1 - \delta x_e^*), \ell_e(1 - \delta x_e^*)\} + \delta \ell_e x_e^*$. Then, use the γ-approximation algorithm for $\mathcal{P}$ on this instance to find an integral solution S, and output it.

Given a feasible solution S to $\mathcal{P}$, note that:

$$\max_{\mathbf{d}}[\sum_{e \in S} d_e - \delta \sum_{e \in E} d_e x_e^*] = \sum_{e \in S} \max\{u_e(1 - \delta x_e^*), \ell_e(1 - \delta x_e^*)\} - \sum_{e \notin S} \delta \ell_e x_e^*$$

$$= \sum_{e \in S}[\max\{u_e(1 - \delta x_e^*), \ell_e(1 - \delta x_e^*)\} + \delta \ell_e x_e^*] - \sum_{e \in E} \delta \ell_e x_e^*.$$

Now, note that since S was output by a γ-approximation algorithm, for any feasible solution S':

$$\sum_{e \in S}[\max\{u_e(1-\delta x_e^*), \ell_e(1-\delta x_e^*)\}+\delta \ell_e x_e^*] \leq \gamma \sum_{e \in S'}[\max\{u_e(1-\delta x_e^*), \ell_e(1-\delta x_e^*)\}+\delta \ell_e x_e^*] \implies$$

$$\sum_{e \in S}[\max\{u_e(1 - \delta x_e^*), \ell_e(1 - \delta x_e^*)\} + \delta \ell_e x_e^*] - \gamma \sum_{e \in E} \delta \ell_e x_e^*$$

$$\leq \gamma[\sum_{e \in S'}[\max\{u_e(1-\delta x_e^*), \ell_e(1-\delta x_e^*)\} + \delta \ell_e x_e^*] - \sum_{e \in E} \delta \ell_e x_e^*]$$

$$= \gamma \max_{\mathbf{d}}[\sum_{e \in S'} d_e - \delta \sum_{e \in E} d_e x_e^*].$$

Since $\mathcal{P}$-LP has integrality gap δ, for any fractional solution $\mathbf{x}$, $\forall \mathbf{d} : \textsc{opt}(\mathbf{d}) \leq \delta \sum_{e \in E} d_e x_e$. Fixing S' to be the set of elements used in the minimum regret solution then gives:

$$\max_{\mathbf{d}}[\sum_{e \in S'} d_e - \delta \sum_{e \in E} d_e x_e^*] \leq \max_{\mathbf{d}}[\textsc{mrs}(\mathbf{d}) - \textsc{opt}(\mathbf{d})] = \textsc{mr}.$$

Combined with the previous inequality, this gives:

$$\sum_{e \in S}[\max\{u_e(1-\delta x_e^*), \ell_e(1-\delta x_e^*)\} + \delta \ell_e x_e^*] - \gamma \sum_{e \in E} \delta \ell_e x_e^* \leq \gamma \textsc{mr} \implies$$

$$\sum_{e \in S}[\max\{u_e(1-\delta x_e^*), \ell_e(1-\delta x_e^*)\} + \delta \ell_e x_e^*] - \sum_{e \in E} \delta \ell_e x_e^* \leq \gamma \textsc{mr} + (\gamma - 1) \sum_{e \in E} \delta \ell_e x_e^* \implies$$

$$\max_{\mathbf{d}}[\sum_{e \in S} d_e - \delta \sum_{e \in E} d_e x_e^*] \leq \gamma \textsc{mr} + (\gamma - 1) \sum_{e \in E} \delta \ell_e x_e^*.$$

This implies:

$$\forall \mathbf{d} : \textsc{sol}(\mathbf{d}) = \sum_{e \in S} d_e \leq \delta \sum_{e \in E} d_e x_e^* + \gamma \textsc{mr} + (\gamma - 1) \sum_{e \in E} \delta \ell_e x_e^*$$

$$\leq \delta \sum_{e \in E} d_e x_e^* + \gamma \textsc{mr} + (\gamma - 1) \sum_{e \in E} \delta d_e x_e^*$$

$$= \gamma\delta \sum_{e \in E} d_e x_e^* + \gamma \textsc{mr} \leq \gamma\delta[\alpha \textsc{opt}(\mathbf{d}) + \beta \textsc{mr}] + \gamma \textsc{mr} = \gamma\delta\alpha \cdot \textsc{opt}(\mathbf{d}) + (\gamma\delta\beta + \gamma) \cdot \textsc{mr}. \blacktriangleleft$$

3 Algorithm for the Robust Traveling Salesman Problem

In this section, we give a robust algorithm for the traveling salesman problem:

▶ **Theorem 5.** *There exists a* $(4.5, 3.75)$*-robust algorithm for the traveling salesman problem.*

Recall that we consider the version of the problem where we are allowed to use edges multiple times in TSP. We present a high level sketch of our ideas here, the details are deferred to the full paper. We recall that any TSP tour must contain a spanning tree, and an Eulerian walk on a doubled MST is a 2-approximation algorithm for TSP (known as the "double-tree algorithm"). One might hope that since we have a $(1, 2)$-robust algorithm for robust MST, one could take its output and apply the double-tree algorithm to get a $(2, 4)$-robust solution to robust TSP. Unfortunately, this algorithm is not (α, β)-robust for any $\alpha = o(n), \beta = o(n)$. Nevertheless, we are able to leverage the connection to MST to arrive at a $(4.5, 3.75)$-robust algorithm for TSP.

$$\textbf{Minimize } \ r \textbf{ subject to}$$

$$\begin{array}{ll}
\forall \emptyset \neq S \subset V: & \sum_{u \in S, v \in V \setminus S} y_{uv} \geq 2 \\
\forall u \in V: & \sum_{v \neq u} y_{uv} = 2 \\
\forall \emptyset \neq S \subset V, u \in S, v \in V \setminus S: & \sum_{e \in \delta(S)} x_{e,u,v} \geq y_{uv} \\
\forall \mathbf{d}: & \sum_{e \in E} d_e x_e \leq \textsc{opt}(\mathbf{d}) + r \\
\forall u, v \in V, u \neq v: & 0 \leq y_{uv} \leq 1 \\
\forall e \in E, u, v \in V, v \neq u: & 0 \leq x_{e,u,v} \leq 1 \\
\forall e \in E: & x_e \leq 2
\end{array} \tag{3}$$

Figure 1 The Robust TSP Polytope.

3.1 Approximate Separation Oracle

We use the LP relaxation of robust traveling salesman in Figure 1. This is the standard subtour LP (see e.g. [32]), but augmented with variables specifying the edges used to visit each new vertex, as well as with the regret constraint set. Integrally, y_{uv} is 1 if splitting the tour into subpaths at each point where a vertex is visited for the first time, there is a subpath from u to v (or vice-versa). That is, y_{uv} is 1 if between the first time u is visited and the first time v is visited, the tour only goes through vertices that were already visited before visiting u. $x_{e,u,v}$ is 1 if on this subpath, the edge e is used. We use x_e to denote $\sum_{u,v \in V} x_{e,u,v}$ for brevity. A discussion of why the constraints other than the regret constraint set in (3) are identical to the standard TSP polytope is included in the full paper.

We now describe the separation oracle RRTSP-Oracle used to separate (3). All constraints except the regret constraint set can be separated in polynomial time by solving a min-cut problem. Recall that exactly separating the regret constraint set involves finding an "adversary" SOL that maximizes $\max_{\mathbf{d}}[\sum_{e \in E} d_e x_e - \textsc{sol}(\mathbf{d})]$, and seeing if this quantity exceeds r. However, since TSP is **NP**-hard, finding this solution in general is **NP**-hard. Instead, we will only consider a solution SOL if it is a walk on some spanning tree T, and find the one that maximizes $\max_{\mathbf{d}}[\sum_{e \in E} d_e x_e - \textsc{sol}(\mathbf{d})]$.

Fix any SOL that is a walk on some spanning tree T. For any e, if e is not in T, the regret of $\mathbf{x}, \mathbf{y}$ against SOL is maximized by setting e's length to u_e. If e is in T, then SOL is paying $2d_e$ for that edge whereas the fractional solution pays $d_e x_e \leq 2d_e$, so to maximize the fractional solution's regret, d_e should be set to ℓ_e. This gives that the regret of fractional solution $\mathbf{x}$ against any SOL that is a spanning tree walk on T is

$$\sum_{e \in T} (\ell_e x_e - 2\ell_e) + \sum_{e \notin T} u_e x_e = \sum_{e \in E} u_e x_e - \sum_{e \in T} (u_e x_e - (\ell_e x_e - 2\ell_e)).$$

The quantity $\sum_{e \in E} u_e x_e$ is fixed with respect to T, so finding the spanning tree T that maximizes this quantity is equivalent to finding T that minimizes $\sum_{e \in T}(u_e x_e - (\ell_e x_e - 2\ell_e))$. But this is just an instance of the minimum spanning tree problem where edge e has weight $u_e x_e - (\ell_e x_e - 2\ell_e)$, and thus we can find T in polynomial time. After finding this spanning tree, RRTSP-Oracle checks if the regret of $\mathbf{x}, \mathbf{y}$ against the walk on T is at least r, and if so outputs this as a violated inequality. If there is some $\textsc{sol}, \mathbf{d}$ such that $\sum_{e \in E} d_e x_e > 2 \cdot \textsc{sol}(\mathbf{d}) + r$, then the regret of the fractional solution against a walk on a spanning tree contained in SOL (which has cost at most $2 \cdot \textsc{sol}(\mathbf{d})$ in realization $\mathbf{d}$) must be at least r, and thus its regret against T must also be at least r. This gives the following lemma:

$$\textbf{Minimize} \quad r \textbf{ subject to}$$

$$\forall S \subset V \text{ such that } \emptyset \subset S \cap T \subset T: \quad \textstyle\sum_{e \in \delta(S)} x_e \geq 1 \tag{4}$$

$$\forall \mathbf{d} \text{ such that } d_e \in [\ell_e, u_e]: \quad \textstyle\sum_{e \in E} d_e x_e \leq \text{OPT}(\mathbf{d}) + r \tag{5}$$

$$\forall e \in E: \quad x_e \in [0,1] \tag{6}$$

Figure 2 The Robust Steiner Tree Polytope.

▶ **Lemma 6.** *For any instance of robust traveling salesman there exists an algorithm RRTSP-Oracle that given a solution* $(\boldsymbol{x}, \boldsymbol{y}, r)$ *to* (3) *either:*

- *Outputs a separating hyperplane for* (3)*, or*
- *Outputs "Feasible", in which case* $(\boldsymbol{x}, \boldsymbol{y})$ *is feasible for the (non-robust) TSP LP and* $\forall \boldsymbol{d}: \sum_{e \in E} d_e x_e \leq 2 \cdot \text{OPT}(\boldsymbol{d}) + r$*.*

The formal description of RRTSP-Oracle and the proof of Lemma 6 are given in the full paper. By using the ellipsoid method with separation oracle RRTSP-Oracle and the fact that (3) has optimum at most MR, we get a $(2, 1)$-robust fractional solution. Applying Theorem 3 as well as the fact that the TSP polytope has integrality gap $3/2$ (see e.g. [32]) and the TSP problem has a $3/2$-approximation gives Theorem 5.

4 Algorithm for the Robust Steiner Tree Problem

In this section, our goal is to find a fractional solution to the LP in Fig. 2 for robust Steiner tree. By Theorem 3 and known approximation/integrality gap results for Steiner Tree, this gives the following theorem:

▶ **Theorem 7.** *There exists a* $(2755, 64)$*-robust algorithm for the Steiner tree problem.*

It is well-known that the standard Steiner tree polytope admits an exact separation oracle (by solving the s, t-min-cut problem using edge weights x_e for all $s, t \in T$) so it is sufficient to find an approximate separation oracle for the regret constraint set. Unlike TSP, we do not know how to leverage the approximation for STT via solving an instance of MST, since this approximation uses information about shortest paths in the STT distance which are not well-defined when the weights are unknown. In turn, a more nuanced separation oracle and analysis is required. We present the main ideas of the separation oracle here, and defer the details to the full paper.

First, we create the derived instance of the Steiner tree problem which is a copy G' of the input graph G with edge weights $u_e x_e + \ell_e - \ell_e x_e$. As noted earlier, the optimal Steiner tree T^* on the derived instance maximizes the regret of the fractional solution $\mathbf{x}$. However, since Steiner tree is **NP**-hard, we cannot hope to exactly find T^*. We need a Steiner tree $\hat{T}$ such that the regret caused by it can be bounded against that caused by T^*. The difficulty is that the regret corresponds to the total weight of edges *not* in the Steiner tree (plus an offset that we will address later), whereas standard Steiner tree approximations give guarantees in terms of the total weight of edges in the Steiner tree. We overcome this difficulty by requiring a stricter notion of "difference approximation" – that the weight of edges $\hat{T} \setminus T^*$ be bounded against those in $T^* \setminus \hat{T}$. Note that this condition ensures that not only is the weight of edges in $\hat{T}$ bounded against those in T^*, but also that the weight of edges *not in* $\hat{T}$ is bounded against that of edges *not in* T^*. We show the following lemma to obtain the difference approximation:

▶ **Lemma 8.** *For any $\epsilon > 0$, there exists a polynomial-time algorithm for the Steiner tree problem such that if $\textsc{opt}$ denotes the set of edges in the optimal solution and $c(S)$ denotes the total weight of edges in S, then for any input instance of Steiner tree, the output solution $\textsc{alg}$ satisfies $c(\textsc{alg} \setminus \textsc{opt}) \leq (4+\epsilon) \cdot c(\textsc{opt} \setminus \textsc{alg})$.*

The algorithm proving Lemma 8 is a local search procedure proposed by [16] (who considered the more general Steiner forest) that considers local moves of the following form: For the current solution $\textsc{alg}$, a local move consists of adding any path f whose endpoints are vertices in $\textsc{alg}$ and whose intermediate vertices are not in $\textsc{alg}$, and then deleting from $\textsc{alg}$ a subpath a in the resulting cycle such that $\textsc{alg} \cup f \setminus a$ remains feasible. We extend the results in [16] by showing that such an algorithm is 4-approximate for Steiner tree. We can further extend this argument to show that such an algorithm, in fact, satisfies the stricter difference approximation requirement in Lemma 8 (see the full paper for details).

Recall that the regret caused by T is not exactly the weight of edges not in T, but includes a fixed offset of $\sum_{e \in E}(\ell_e - \ell_e x_e)$. If $\ell_e = 0$ for all edges, i.e., the offset is 0, then we can recover a robust algorithm from Lemma 8 alone with much better constants than in Theorem 7 (we defer the discussion/proof of this result to the full paper). In general though, the approximation guarantee given in Lemma 8 alone does not suffice because of the offset. We instead rely on a stronger notion of approximation formalized in the next lemma that provides simultaneous approximation guarantees on two sets of edge weights: $c_e = u_e x_e - \ell_e x_e + \ell_e$ and $c'_e = \ell_e - \ell_e x_e$. The guarantee on $\ell_e - \ell_e x_e$ can then be used to handle the offset.

▶ **Lemma 9.** *Let G be a graph with terminals T and two sets of edge weights c and c'. Let $\textsc{sol}$ be any Steiner tree connecting T. Let $\Gamma' > 1$, $\kappa > 0$, and $0 < \epsilon < \frac{4}{35}$ be fixed constants. Then there exists a constant Γ (depending on $\Gamma', \kappa, \epsilon$) and an algorithm that obtains a collection of Steiner trees $\textsc{alg}$, at least one of which (let us call it $\textsc{alg}_i$) satisfies:*

- *$c(\textsc{alg}_i \setminus \textsc{sol}) \leq 4\Gamma \cdot c(\textsc{sol} \setminus \textsc{alg}_i)$, and*
- *$c'(\textsc{alg}_i) \leq (4\Gamma' + \kappa + 1 + \epsilon) \cdot c'(\textsc{sol})$.*

The fact that Lemma 9 generates multiple solutions (but only polynomially many) is fine because as long as we can show that one of these solutions causes sufficient regret, our separation oracle can just iterate over all solutions until it finds one that causes sufficient regret.

We give a high level sketch of the proof of Lemma 9 here, and defer details to the full paper. The algorithm uses the idea of *alternate minimization*, alternating between a "forward phase" and a "backward phase". The goal of each forward phase/backward phase pair is to keep $c'(\textsc{alg})$ approximately fixed while obtaining a net decrease in $c(\textsc{alg})$. In the forward phase, the algorithm greedily uses local search, choosing swaps that decrease c and increase c' at the best "rate of exchange" between the two costs (i.e., the maximum ratio of decrease in c to increase in c'), until $c'(\textsc{alg})$ has increased past some upper threshold. Then, in the backward phase, the algorithm greedily chooses swaps that decrease c' while increasing c at the best rate of exchange, until $c'(\textsc{alg})$ reaches some lower threshold, at which point we start a new forward phase.

We guess the value of $c'(\textsc{sol})$ (we can run many instances of this algorithm and generate different solutions based on different guesses for this purpose) and set the upper threshold for $c'(\textsc{alg})$ appropriately so that we satisfy the approximation guarantee for c'. For c we show that as long as $\textsc{alg}$ is not a 4Γ-difference approximation with respect to c then a forward/backward phase pair reduces $c(\textsc{alg})$ by a non-negligible amount (of course, if $\textsc{alg}$ is a 4Γ-difference approximation then we are done). This implies that after enough iterations,

$\textsc{alg}$ must be a 4Γ-difference approximation as $c(\textsc{alg})$ can only decrease by a bounded amount. To show this, we claim that while $\textsc{alg}$ is not a 4Γ-difference approximation, for sufficiently large Γ the following bounds on rates of exchange hold:

- For each swap in the forward phase, the ratio of decrease in $c(\textsc{alg})$ to increase in $c'(\textsc{alg})$ is at least some constant k_1 times $\frac{c(\textsc{alg} \setminus \textsc{sol})}{c'(\textsc{sol} \setminus \textsc{alg})}$.
- For each swap in the backward phase, the ratio of increase in $c(\textsc{alg})$ to decrease in $c'(\textsc{alg})$ is at most some constant k_2 times $\frac{c(\textsc{sol} \setminus \textsc{alg})}{c'(\textsc{alg} \setminus \textsc{sol})}$.

Before we discuss how to prove this claim, let us see why this claim implies that a forward phase/backward phase pair results in a net decrease in $c(\textsc{alg})$. If this claim holds, suppose we set the lower threshold for $c'(\textsc{alg})$ to be, say, $101c'(\textsc{sol})$. That is, throughout the backward phase, we have $c'(\textsc{alg}) > 101c'(\textsc{sol})$. This lower threshold lets us rewrite our upper bound on the rate of exchange in the backward phase in terms of the lower bound on rate of exchange for the forward phase:

$$k_2 \frac{c(\textsc{sol} \setminus \textsc{alg})}{c'(\textsc{alg} \setminus \textsc{sol})} \leq k_2 \frac{c(\textsc{sol} \setminus \textsc{alg})}{c'(\textsc{alg}) - c'(\textsc{sol})} \leq k_2 \frac{c(\textsc{sol} \setminus \textsc{alg})}{100c'(\textsc{sol})} \leq k_2 \frac{c(\textsc{sol} \setminus \textsc{alg})}{100c'(\textsc{sol} \setminus \textsc{alg})}$$

$$\leq k_2 \frac{1}{4\Gamma} \frac{c(\textsc{alg} \setminus \textsc{sol})}{100c'(\textsc{sol} \setminus \textsc{alg})} = \frac{k_2}{400\Gamma k_1} \cdot k_1 \frac{c(\textsc{alg} \setminus \textsc{sol})}{c'(\textsc{sol} \setminus \textsc{alg})}.$$

In other words, the bound in the claim for the rate of exchange in the forward phase is larger than the bound for the backward phase by a multiplicative factor of $\Omega(1) \cdot \Gamma$. While these bounds depend on $\textsc{alg}$ and thus will change with every swap, let us make the simplifying assumption that through one forward phase/backward phase pair these bounds remain constant. Then, the change in $c(\textsc{alg})$ in one phase is just the rate of exchange for that phase times the change in $c'(\textsc{alg})$, which by definition of the algorithm is roughly equal in absolute value for the forward and backward phase. So this implies that the decrease in $c(\textsc{alg})$ in the forward phase is $\Omega(1) \cdot \Gamma$ times the increase in $c(\textsc{alg})$ in the backward phase, i.e., the net change across the phases is a non-negligible decrease in $c(\textsc{alg})$ if Γ is sufficiently large. Without the simplifying assumption, we can still show that the decrease in $c(\textsc{alg})$ in the forward phase is larger than the increase in $c(\textsc{alg})$ in the backward phase for large enough Γ using a much more technical analysis. In particular, our analysis will show there is a net decrease as long as:

$$\min\left\{\frac{4\Gamma - 1}{8\Gamma}, \frac{(4\Gamma - 1)(\sqrt{\Gamma} - 1)(\sqrt{\Gamma} - 1 - \epsilon)\kappa}{16(1+\epsilon)\Gamma^2}\right\} - (e^{\zeta'(4\Gamma' + \kappa + 1 + \epsilon)} - 1) > 0, \tag{7}$$

where

$$\zeta' = \frac{4(1+\epsilon)\Gamma'}{(\sqrt{\Gamma'} - 1)(\sqrt{\Gamma'} - 1 - \epsilon)(4\Gamma' - 1)(4\Gamma - 1)}.$$

Note that for any positive $\epsilon, \kappa, \Gamma'$, there exists a sufficiently large value of Γ for (7) to hold, since as $\Gamma \to \infty$, we have $\zeta' \to 0$, so that

$$(e^{\zeta'(4\Gamma' + \kappa + 1 + \epsilon)} - 1) \to 0 \text{ and}$$

$$\min\left\{\frac{4\Gamma - 1}{8\Gamma}, \frac{(4\Gamma - 1)(\sqrt{\Gamma} - 1)(\sqrt{\Gamma} - 1 - \epsilon)\kappa}{16(1+\epsilon)\Gamma^2}\right\} \to \min\{1/2, \kappa/(4 + 4\epsilon)\}.$$

So, the same intuition holds: as long as we are willing to lose a large enough Γ value, we can make the increase in $c(\textsc{alg})$ due to the backward phase negligible compared to the decrease in the forward phase, giving us a net decrease.

It remains to argue that the claimed bounds on rates of exchange hold. Let us argue the claim for $\Gamma = 4$, although the ideas easily generalize to other choices of Γ. We do this by generalizing the analysis of the local search algorithm. This analysis shows that if $\textsc{alg}$ is a locally optimal solution, then

$$c(\textsc{alg} \setminus \textsc{sol}) \leq 4 \cdot c(\textsc{sol} \setminus \textsc{alg}),$$

i.e., $\textsc{alg}$ is a 4-difference approximation of $\textsc{sol}$. The contrapositive of this statement is that if $\textsc{alg}$ is not a 4-difference approximation, then there is at least one swap that will improve it by some amount. We modify the approach of [16] by weakening the notion of locally optimal. In particular, suppose we define a solution $\textsc{alg}$ to be "approximately" locally optimal if at least half of the (weighted) swaps between paths a in $\textsc{alg} \setminus \textsc{sol}$ and paths f in $\textsc{sol} \setminus \textsc{alg}$ satisfy $c(a) \leq 2c(f)$ (as opposed to $c(a) \leq c(f)$ in a locally optimal solution; the choice of 2 for both constants here implies $\Gamma = 4$). Then a modification of the analysis of the local search algorithm, losing an additional factor of 4, shows that if $\textsc{alg}$ is approximately locally optimal, then

$$c(\textsc{alg} \setminus \textsc{sol}) \leq 16 \cdot c(\textsc{sol} \setminus \textsc{alg}).$$

The contrapositive of this statement, however, has a stronger consequence than before: if $\textsc{alg}$ is not a 16-difference approximation, then a weighted half of the swaps satisfy $c(a) > 2c(f)$, i.e. reduce $c(\textsc{alg})$ by at least

$$c(a) - c(f) > c(a) - c(a)/2 = c(a)/2.$$

The decrease in $c(\textsc{alg})$ due to all of these swaps together is at least $c(\textsc{alg} \setminus \textsc{sol})$ times some constant. In addition, since a swap between a and f increases $c'(\textsc{alg})$ by at most $c'(f)$, the total increase in c' due to these swaps is at most $c'(\textsc{sol} \setminus \textsc{alg})$ times some other constant. An averaging argument then gives the rate of exchange bound for the forward phase in the claim, as desired. The rate of exchange bound for the backward phase follows analogously.

This completes the algorithm and proof summary, although more detail is needed to formalize these arguments. Moreover, we also need to show that the algorithm runs in polynomial time. These details are given in the full paper.

We now formally define our separation oracle RRST-Oracle in Fig. 3 and prove that it is an approximate separation oracle in the lemma below:

▶ **Lemma 10.** *Fix any $\Gamma' > 1, \kappa > 0, 0 < \epsilon < 4/35$ and let Γ be the constant given in Lemma 9. Let $\alpha = (4\Gamma' + \kappa + 2 + \epsilon)4\Gamma + 1$ and $\beta = 4\Gamma$. Then there exists an algorithm RRST-Oracle that given a solution $(\boldsymbol{x}, r)$ to the LP in Fig. 2 either:*

- *Outputs a separating hyperplane for the LP in Fig. 2, or*
- *Outputs "Feasible", in which case $\boldsymbol{x}$ is feasible for the (non-robust) Steiner tree LP and*

$$\forall \boldsymbol{d} : \sum_{e \in E} d_e x_e \leq \alpha \cdot \textsc{opt}(\boldsymbol{d}) + \beta \cdot r.$$

Proof. It suffices to show that if there exists $\mathbf{d}, \textsc{sol}$ such that

$$\sum_{e \in E} d_e x_e > \alpha \cdot \textsc{sol}(\mathbf{d}) + \beta \cdot r, \text{ i.e., } \sum_{e \in E} d_e x_e - \alpha \cdot \textsc{sol}(\mathbf{d}) > \beta \cdot r$$

then RRST-Oracle outputs a violated inequality on line 6, i.e., the algorithm finds a Steiner tree T' such that

$$\sum_{e \notin T'} u_e x_e + \sum_{e \in T'} \ell_e x_e - \sum_{e \in T'} \ell_e > r.$$

```
RRST-Oracle($G(V,E)$, $\{[\ell_e, u_e]\}_{e\in E}$, $(\mathbf{x}, r)$)
   Data: Undirected graph $G(V,E)$, lower and upper bounds on edge lengths
         $\{[\ell_e, u_e]\}_{e\in E}$, solution $(\mathbf{x} = \{x_e\}_{e\in E}, r)$ to the LP in Fig. 2
   Check all constraints of the LP in Fig. 2 except regret constraint set, return any
     violated constraint that is found;
   $G' \leftarrow$ copy of $G$ where $c_e = u_e x_e - \ell_e x_e + \ell_e$, $c'_e = \ell_e - \ell_e x_e$;
   $\textsc{alg} \leftarrow$ output of algorithm from Lemma 9 on $G'$;
   for $\textsc{alg}_i \in \textsc{alg}$ do
      if $\sum_{e\notin \textsc{alg}_i} u_e x_e + \sum_{e\in \textsc{alg}_i} \ell_e x_e - \sum_{e\in \textsc{alg}_i} \ell_e > r$ then
         return $\sum_{e\notin \textsc{alg}_i} u_e x_e + \sum_{e\in \textsc{alg}_i} \ell_e x_e - \sum_{e\in \textsc{alg}_i} \ell_e \le r$;
      end
   end
   return "Feasible";
```

Figure 3 Separation Oracle for LP in Fig. 2.

Notice that in the inequality

$$\sum_{e\in E} d_e x_e - \alpha \cdot \textsc{sol}(\mathbf{d}) > \beta \cdot r,$$

replacing $\mathbf{d}$ with $\mathbf{d}'$ where $d'_e = \ell_e$ when $e \in \textsc{sol}$ and $d'_e = u_e$ when $e \notin \textsc{sol}$ can only increase the left hand side. So replacing $\mathbf{d}$ with $\mathbf{d}'$ and rearranging terms, we have

$$\sum_{e\in\textsc{sol}} \ell_e x_e + \sum_{e\notin\textsc{sol}} u_e x_e > \alpha \sum_{e\in\textsc{sol}} \ell_e + \beta\cdot r = \sum_{e\in\textsc{sol}} \ell_e + \left[(\alpha-1)\sum_{e\in\textsc{sol}} \ell_e + \beta\cdot r\right].$$

In particular, the regret of the fractional solution against $\textsc{sol}$ is at least $(\alpha-1)\sum_{e\in\textsc{sol}} \ell_e + \beta\cdot r$.

Let T' be the Steiner tree satisfying the conditions of Lemma 9 with $c_e = u_e x_e - \ell_e x_e + \ell_e$ and $c'_e = \ell_e - \ell_e x_e$. Let $E_0 = E \setminus (\textsc{sol} \cup T')$, $E_S = \textsc{sol} \setminus T'$, and $E_T = T' \setminus \textsc{sol}$. Let $c(E')$ for $E' = E_0, E_S, E_T$ denote $\sum_{e\in E'}(u_e x_e - \ell_e x_e + \ell_e)$, i.e., the total weight of the edges E' in G'. Now, note that the regret of the fractional solution against a solution using edges E' is:

$$\sum_{e\notin E'} u_e x_e + \sum_{e\in E'} \ell_e x_e - \sum_{e\in E'} \ell_e = \sum_{e\notin E'} (u_e x_e - \ell_e x_e + \ell_e) - \sum_{e\in E} (\ell_e - \ell_e x_e)$$

$$= c(E \setminus E') - \sum_{e\in E} (\ell_e - \ell_e x_e).$$

Plugging in $E' = \textsc{sol}$, we then get that:

$$c(E_0) + c(E_T) - \sum_{e\in E} (\ell_e - \ell_e x_e) > (\alpha-1)\sum_{e\in\textsc{sol}} \ell_e + \beta\cdot r.$$

Isolating $c(E_T)$ then gives:

$$c(E_T) > (\alpha-1)\sum_{e\in\textsc{sol}} \ell_e + \beta\cdot r - \sum_{e\in E_0} (u_e x_e - \ell_e x_e + \ell_e) + \sum_{e\in E} (\ell_e - \ell_e x_e)$$

$$= (\alpha-1)\sum_{e\in\textsc{sol}} \ell_e + \beta\cdot r - \sum_{e\in E_0} u_e x_e + \sum_{e\notin E_0} (\ell_e - \ell_e x_e).$$

Since $\beta = 4\Gamma$, Lemma 9 along with an appropriate choice of ϵ gives that $c(E_T) \leq \beta c(E_S)$, and thus:

$$c(E_S) > \frac{1}{\beta}\left[(\alpha-1)\sum_{e\in\text{SOL}} \ell_e + \beta\cdot r - \sum_{e\in E_0} u_e x_e + \sum_{e\notin E_0}(\ell_e - \ell_e x_e)\right].$$

Recall that our goal is to show that $c(E_0) + c(E_S) - \sum_{e\in E}(\ell_e - \ell_e x_e) > r$, i.e., that the regret of the fractional solution against T' is at least r. Adding $c(E_0) - \sum_{e\in E}(\ell_e - \ell_e x_e)$ to both sides of the previous inequality, we can lower bound $c(E_0) + c(E_S) - \sum_{e\in E}(\ell_e - \ell_e x_e)$ as follows:

$$\begin{aligned}
&c(E_0) + c(E_S) - \sum_{e\in E}(\ell_e - \ell_e x_e)\\
&> \frac{1}{\beta}\left[(\alpha-1)\sum_{e\in\text{SOL}} \ell_e + \beta\cdot r - \sum_{e\in E_0} u_e x_e + \sum_{e\notin E_0}(\ell_e - \ell_e x_e)\right]\\
&+ \sum_{e\in E_0}(u_e x_e - \ell_e x_e + \ell_e) - \sum_{e\in E}(\ell_e - \ell_e x_e)\\
&= r + \frac{\alpha-1}{\beta}\sum_{e\in\text{SOL}} \ell_e + \frac{1}{\beta}\sum_{e\notin E_0}(\ell_e - \ell_e x_e) + \frac{\beta-1}{\beta}\sum_{e\in E_0} u_e x_e - \sum_{e\notin E_0}(\ell_e - \ell_e x_e)\\
&\geq r + \frac{\alpha-1-\beta}{\beta}\sum_{e\in\text{SOL}} \ell_e + \frac{1}{\beta}\sum_{e\notin E_0}(\ell_e - \ell_e x_e) + \frac{\beta-1}{\beta}\sum_{e\in E_0} u_e x_e - \sum_{e\in E_T}(\ell_e - \ell_e x_e) \geq r.
\end{aligned}$$

Here, the last inequality holds because by our setting of α, we have

$$\frac{\alpha-1-\beta}{\beta} = 4\Gamma' + \kappa + 1 + \epsilon,$$

and thus Lemma 9 gives that

$$\sum_{e\in E_T}(\ell_e - \ell_e x_e) \leq \frac{\alpha-1-\beta}{\beta}\sum_{e\in\text{SOL}}(\ell_e - \ell_e x_e) \leq \frac{\alpha-1-\beta}{\beta}\sum_{e\in\text{SOL}} \ell_e. \qquad ◀$$

By using Lemma 10 with the ellipsoid method and the fact that the LP optimum is at most MR, we get an (α,β)-robust fractional solution. Then, Theorem 3 and known approximation/integrality gap results give us the following theorem, which with appropriate choice of constants gives Theorem 7:

▶ **Theorem 11.** *Fix any $\Gamma' > 1, \kappa > 0, 0 < \epsilon < 4/35$ and let Γ be the constant given in Lemma 9. Let $\alpha = (4\Gamma' + \kappa + 2 + \epsilon)4\Gamma + 1$ and $\beta = 4\Gamma$. Then there exists a polynomial-time $(2\alpha\ln 4 + \epsilon, 2\beta\ln 4 + \ln 4 + \epsilon)$-robust algorithm for the Steiner tree problem.*

5 Lower Bounds

To contextualize our approximation guarantees, we give the following generalized hardness result for a family of problems which includes many graph optimization problems:

▶ **Theorem 12.** *Let $\mathcal{P}$ be any robust covering problem whose input includes a weighted graph G where the lengths d_e of the edges are given as ranges $[\ell_e, u_e]$ and for which the non-robust version of the problem, $\mathcal{P}'$, has the following properties:*

- *A solution to an instance of $\mathcal{P}'$ can be written as a (multi-)set S of edges in G, and has cost $\sum_{e \in S} d_e$.*
- *Given an input including G to $\mathcal{P}'$, there is a polynomial-time approximation-preserving reduction from solving $\mathcal{P}'$ on this input to solving $\mathcal{P}'$ on some input including G', where G' is the graph formed by taking G, adding a new vertex v^*, and adding a single edge from v^* to some $v \in V$ of weight 0.*
- *For any input including G to $\mathcal{P}'$, given any spanning tree T of G, there exists a feasible solution only including edges from T.*

Then, if there exists a polynomial time (α, β)-robust algorithm for $\mathcal{P}$, there exists a polynomial-time β-approximation algorithm for $\mathcal{P}$.

Before proving Theorem 12, we note that robust traveling salesman and robust Steiner tree are examples of problems that Theorem 12 implicitly gives lower bounds for. For both problems, the first property clearly holds.

For traveling salesman, given any input G, any solution to the problem on input G' as described in Theorem 12 can be turned into a solution of the same cost on input G by removing the new vertex v^* (since v^* was distance 0 from v, removing v^* does not affect the length of any tour), giving the second property. For any spanning tree of G, a walk on the spanning tree gives a valid TSP tour, giving the third property.

For Steiner tree, for the input with graph G' and the same terminal set, for any solution containing the edge (v, v^*) we can remove this edge and get a solution for the input with graph G that is feasible and of the same cost. Otherwise, the solution is already a solution for the input with graph G that is feasible and of the same cost, so the second property holds. Any spanning tree is a feasible Steiner tree, giving the third property.

We now give the proof of Theorem 12.

Proof of Theorem 12. Suppose there exists a polynomial time (α, β)-robust algorithm A for $\mathcal{P}$. The β-approximation algorithm for $\mathcal{P}'$ is as follows:

1. From the input instance $\mathcal{I}$ of $\mathcal{P}$ where the graph is G, use the approximation-preserving reduction (that must exist by the second property of the theorem) to construct instance $\mathcal{I}'$ of $\mathcal{P}'$ where the graph is G'.
2. Construct an instance $\mathcal{I}''$ of $\mathcal{P}$ from $\mathcal{I}'$ as follows: For all edges in G', their length is fixed to their length in $\mathcal{I}'$. In addition, we add a "special" edge from v^* to all vertices besides v with length range $[0, \infty]$[2].
3. Run A on $\mathcal{I}''$ to get a solution $\textsc{sol}$. Treat this solution as a solution to $\mathcal{I}'$ (we will show it only uses edges that appear in $\mathcal{I}$). Use the approximation-preserving reduction to convert $\textsc{sol}$ into a solution for $\mathcal{I}$ and output this solution.

Let O denote the cost of the optimal solution to $\mathcal{I}'$. Then, $\textsc{mr} \leq O$. To see why, note that the optimal solution to $\mathcal{I}'$ has cost O in all realizations of demands since it only uses edges of fixed cost, and thus its regret is at most O. This also implies that for all $\mathbf{d}$, $\textsc{opt}(\mathbf{d})$ is finite. Then for all $\mathbf{d}$, $\textsc{sol}(\mathbf{d}) \leq \alpha \cdot \textsc{opt}(\mathbf{d}) + \beta \cdot \textsc{mr}$, i.e. $\textsc{sol}(\mathbf{d})$ is finite in all realizations of demands, so $\textsc{sol}$ does not include any special edges, as any solution with a special edge has infinite cost in some realization of demands.

Now consider the realization of demands $\mathbf{d}$ where all special edges have length 0. The special edges and the edge (v, v^*) span G', so by the third property of $\mathcal{P}'$ in the theorem statement there is a solution using only cost 0 edges in this realization, i.e. $\textsc{opt}(\mathbf{d}) = 0$.

[2] We use ∞ to simplify the proof, but it can be replaced with a sufficiently large finite number. For example, the total weight of all edges in G suffices and has small bit complexity.

Then in this realization, $\textsc{sol}(\mathbf{d}) \leq \alpha \cdot \textsc{opt}(\mathbf{d}) + \beta \cdot \textsc{mr} \leq \beta \cdot O$. But since $\textsc{sol}$ does not include any special edges, and all edges besides special edges have fixed cost and their cost is the same in $\mathcal{I}''$ as in $\mathcal{I}'$, $\textsc{sol}(\mathbf{d})$ also is the cost of $\textsc{sol}$ in instance $\mathcal{I}'$, i.e. $\textsc{sol}(\mathbf{d})$ is a β-approximation for $\mathcal{I}'$. Since the reduction from $\mathcal{I}$ to $\mathcal{I}'$ is approximation-preserving, we also get a β-approximation for $\mathcal{I}$. ◀

From [11, 22] we then get the following hardness results:

▶ **Corollary 13.** *Finding an (α, β)-robust solution for Steiner tree where $\beta < 96/95$ is NP-hard.*

▶ **Corollary 14.** *Finding an (α, β)-robust solution for TSP where $\beta < 121/120$ is NP-hard.*

6 Conclusion

In this paper, we designed constant approximation algorithms for the robust Steiner tree and traveling salesman problems. To the best of our knowledge, this is the first instance of robust polynomial-time algorithms being developed for **NP**-complete graph problems. While our approximation bounds for TSP are small constants, that for STT are very large constants. A natural question is whether these constants can be made smaller, e.g. of the same scale as classic approximation bounds for STT. While we did not seek to optimize our constants, obtaining truly small constants for STT appears to be beyond our techniques, and is an interesting open question. More generally, robust algorithms are a key component in the area of optimization under uncertainty that is of much practical and theoretical significance. We hope that our work will lead to more research in robust algorithms for other fundamental problems in combinatorial optimization, particularly in graph algorithms.

Abstract

We study interactive proof systems (IPSes) in a strong adversarial setting where the machines of *honest parties* might be corrupted and under control of the adversary. Our aim is to answer the following, seemingly paradoxical, questions:

- Can Peggy convince Vic of the veracity of an NP statement, without leaking any information about the witness even in case Vic is malicious and Peggy does not trust her computer?
- Can we avoid that Peggy fools Vic into accepting false statements, even if Peggy is malicious and Vic does not trust her computer?

At EUROCRYPT 2015, Mironov and Stephens-Davidowitz introduced cryptographic reverse firewalls (RFs) as an attractive approach to tackling such questions. Intuitively, a RF for Peggy/Vic is an external party that sits between Peggy/Vic and the outside world and whose scope is to sanitize Peggy's/Vic's incoming and outgoing messages in the face of subversion of her/his computer, e.g. in order to destroy subliminal channels.

In this paper, we put forward several natural security properties for RFs in the concrete setting of IPSes. As our main contribution, we construct efficient RFs for different IPSes derived from a large class of Sigma protocols that we call *malleable*.

A nice feature of our design is that it is completely transparent, in the sense that our RFs can be directly applied to already deployed IPSes, without the need to re-implement them.

1 Introduction

An interactive proof system (IPS) $\Pi = (\mathsf{P}, \mathsf{V})$ allows a prover P to convince a verifier V about the veracity of a public statement $x \in \mathcal{L}$, where $\mathcal{L}$ is an NP language and where both P and V are modeled as interactive PPT machines. The prover is facilitated by possessing a witness w to the fact that, indeed, $x \in \mathcal{L}$, and the interaction with the verifier may consist of several rounds of communication, at the end of which the verifier outputs a verdict on the membership of x in $\mathcal{L}$.

In order to be useful, an IPS should satisfy the following properties:

- *Completeness:* If $x \in \mathcal{L}$, the honest prover (almost) always convinces the honest verifier.
- *Soundness:* If $x \notin \mathcal{L}$, no (computationally bounded) malicious prover can convince the honest verifier that $x \in \mathcal{L}$. An even stronger guarantee, known as *knowledge soundness* [9], is to require that the only way a prover can convince the honest verifier that $x \in \mathcal{L}$ is to "know" a valid witness w corresponding to x. Such proofs[1] are called *proofs of knowledge* (PoKs).
- *Zero Knowledge (ZK):* A valid proof reveals nothing beyond the fact that $x \in \mathcal{L}$, and thus in particular it leaks no information about the witness w, even in case the proof is conducted in the presence of a (computationally bounded) malicious verifier [36]. A weaker guarantee, known as *witness indistinguishability* (WI) [24], is that, whenever there are multiple witnesses attesting that $x \in \mathcal{L}$, no (computationally bounded) malicious verifier can distinguish whether a proof is conducted using either of two witnesses.

One of the motivations for studying IPSes with the above properties is that they are ubiquitous in cryptography, with applications ranging from identification protocols [24], blind digital signatures [42], and electronic voting [16], to general-purpose maliciously secure multi-party computation [35].

1.1 Sigma Protocols

While WI/ZK PoKs exist for all of NP, based on minimal cryptographic assumptions [23, 34, 33], efficiency is a different story. Fortunately, it is possible to design practical interactive proofs for specific languages, typically in the form of so-called Sigma protocols. Briefly, a Sigma protocol is a special type of IPS consisting of just three rounds, where the prover sends a first message α (the commitment), the verifier sends a random string β (the challenge), and finally the prover forwards a last message γ (the response). Sigma protocols satisfy two main properties: The first one, known as *special soundness*, is a strong form of knowledge soundness; the second one, known as *honest-verifier zero knowledge* (HVZK), is a weak form of the zero knowledge property that only holds against honest-but-curious verifiers.

The applications of Sigma protocols to cryptographic constructions are countless (see, e.g., [25, 17, 48, 22, 43]). These results are perhaps surprising, as Sigma protocols only satisfy HVZK and thus guarantee no security in the presence of malicious verifiers. In some cases, the solution to this apparent paradox is due to a beautiful technique put forward by Cramer, Damgård, and Schoenmakers [15], which allows to add WI to any Sigma protocol. Moreover, it is relatively easy to transform any Sigma protocol into an interactive ZK PoK at the cost of adding a single round of interaction [33].

1.2 Our Question

The standard definitions of security for IPSes (implicitly) rely on the assumption that honest parties can fully trust their machines. In practice, however, such an assumption may just be too optimistic, as witnessed by the revelations of Edward Snowden about subversion of cryptographic standards [45, 7], and in light of the numerous (seemingly accidental) bugs in widespread pieces of cryptographic software [38, 1, 2].

[1] Sometimes, the term "proof" is used to refer to statistically sound IPSes, while computationally sound IPSes are typically called "arguments".

Motivated by the above incidents, we ask the following question which constitutes the main source of inspiration for this work:

> *Can we design practical interactive proofs that remain secure even if the machines of the honest parties running them have been tampered with?*

In order to see why the above question is well motivated and not trivial, let us analyze the dramatic consequences of subverting the prover of ZK IPSes. Clearly, the problem of subversion-resistant interactive zero knowledge is just impossible in its utmost generality, as a subverted prover could just reveal the witness to the verifier. However, one may argue that these kind of attacks are easily detectable, and thus can be avoided.

The problem becomes more interesting if we restrict the subversion to be *undetectable*, as suggested by Bellare, Paterson, and Rogaway [11] in their seminal work on subversion of symmetric encryption, where the authors show how to subvert any sufficiently randomized cipher in an undetectable manner, using rejection sampling. A moment of reflection shows that their attack can be adapted to the case of IPSes.[2] The solution proposed by [11] is to rely on deterministic symmetric encryption. Unfortunately, this approach is not viable for the case of IPSes, as it is well-known that interactive proofs with deterministic provers can be zero knowledge only for trivial languages [32, §4.5].

Reverse firewalls

The above described undetectable attacks show that the problem of designing IPSes that remain secure even when run on untrusted machines is simply impossible if we are not willing to make any further assumption. In this paper, we study how to tackle subversion attacks against interactive proofs in the framework of "cryptographic reverse firewalls (RFs)", introduced by Mironov and Stephens-Davidowitz [40]. In such a setting, both the prover and the verifier are equipped with their own RF W, also modeled as an interactive PPT machine, whose scope is solely to sanitize the parties' incoming and outgoing messages in the face of subversion.

Importantly, neither the prover nor the verifier put any trust in the RF, meaning that they are not allowed to share secrets with the firewall itself. The hope is that an uncorrupted[3] RF can provide meaningful security guarantees even in case the honest prover's and/or verifier's machines have been tampered with. Note that a RF can never "create security", as it does not even know the inputs to the protocol, but at best can preserve the security guarantees satisfied by the initial IPS. At the same time, the RF should not ruin the functionality of the underlying IPS, in the sense that the sanitized IPS should still work in case no subversion takes place.

Mironov and Stephens-Davidowitz construct general-purpose RFs that can be used in order to preserve both functionality and security of any two-party protocol. It is important to note that since ZK/WI IPSes are a special case of secure two-party computation, their RF constructions already seem to solve our problem.[4] However, the solutions in [40] are not

[2] In particular, a subverted prover with a hardwired secret key k for a pseudorandom function $F_k(\cdot)$, could sample the random coins $r^{(i)}$ needed to generate the honest prover's message $m^{(i)}$ (for round $i \in \mathbb{N}$) multiple times, until $F_k(m^{(i)})$ leaks one bit of the witness. This attack works provided that at least one of the prover's messages has high-enough min-entropy.

[3] Clearly, if both the machine of the honest party and the firewall are corrupted, there is no hope for security. On the other hand, in case the machine is honest and the firewall is corrupt, the underlying protocol is still secure, since we can simply think of the RF as being part of the adversary [21].

[4] At least to some extent, since, strictly speaking, their results for IPSes are incomparable to ours. We refer the reader to §5.1 for more details.

practical. In particular, one of their RFs increases the round complexity of the initial IPS, and, more importantly, it requires to carry out the underlying IPS in the encrypted domain, thus requiring to completely change the original protocol. In contrast, we seek constructions of RFs that can be applied directly to existing IPSes, without adding any overhead, and without the need to re-implement them.

2 Reverse Firewalls for Interactive Proofs

In this section, we give security definitions for RFs applied to IPSes. Our notions can be seen as special cases of the generic framework by Mironov and Stephens-Davidowitz [40], who defined security of RFs for the more general case of arbitrary two-party protocols.

Let $\Pi = (\mathsf{P}, \mathsf{V})$ be an IPS for a relation $\mathcal{R}$. A cryptographic reverse firewall is an external party W that can be attached either to the prover P or to the verifier V, whose scope is to sanitize incoming and outgoing messages in the face of parties' subversion. Importantly, the RF is allowed to keep its own state but cannot share state with any of the parties. Similarly to [40], we model an interactive Turing machine M as a triple of algorithms $\mathsf{M} := (\mathsf{M}_{\mathsf{nxt}}, \mathsf{M}_{\mathsf{rec}}, \mathsf{M}_{\mathsf{out}})$ specified as follows: (i) Algorithm $\mathsf{M}_{\mathsf{nxt}}$ takes as input the current state and outputs the next message to be sent; (ii) Algorithm $\mathsf{M}_{\mathsf{rec}}$ takes as input an incoming message, and updates the state; (iii) Algorithm $\mathsf{M}_{\mathsf{out}}$ takes as input the final state at the completion of the protocol, and returns a bit.

▶ **Definition 1** (RF for IPSes). *Let $\Pi = (\mathsf{P}, \mathsf{V})$ be an IPS for a relation $\mathcal{R}$. A cryptographic reverse firewall (RF) for Π is a stateful algorithm W that takes as input a message, its state, and outputs a sanitized message, together with an updated state. For an interactive Turing machine $\mathsf{M} = (\mathsf{M}_{\mathsf{nxt}}, \mathsf{M}_{\mathsf{rec}}, \mathsf{M}_{\mathsf{out}}) \in \{\mathsf{P}, \mathsf{V}\}$, and RF W, the sanitized machine $\mathsf{W} \circ \mathsf{M} := \widehat{\mathsf{M}} = (\widehat{\mathsf{M}}_{\mathsf{nxt}}, \widehat{\mathsf{M}}_{\mathsf{rec}}, \widehat{\mathsf{M}}_{\mathsf{out}})$ is specified as follows:*

$$\begin{aligned}\widehat{\mathsf{M}}_{\mathsf{nxt}}(\sigma) &:= \mathsf{W}(\mathsf{M}_{\mathsf{nxt}}(\sigma))\\ \widehat{\mathsf{M}}_{\mathsf{rec}}(\sigma, m) &:= \mathsf{M}_{\mathsf{rec}}(\sigma, \mathsf{W}(m))\\ \widehat{\mathsf{M}}_{\mathsf{out}}(\sigma) &:= \mathsf{M}_{\mathsf{out}}(\sigma).\end{aligned}$$

As our first contribution, we put forward several natural properties that a RF for an IPS might satisfy. In particular, we consider the following notions (see the full version [29] for more formal definitions).

- *Completeness preservation:* The sanitized IPS (i.e., the IPS obtained by sanitizing both the honest prover's and the honest verifier's messages) still satisfies completeness.
- *Strong soundness preservation:* Whenever $x \notin \mathcal{L}$, no malicious prover can convince the verifier that $x \in \mathcal{L}$, even if the verifier's implementation has been arbitrarily subverted.
- *Strong ZK preservation:* A valid proof reveals nothing beyond the fact that $x \in \mathcal{L}$, even in case the proof is conducted in the presence of a malicious verifier talking to a prover whose implementation has been arbitrarily subverted.
- *Strong WI preservation:* Whenever there are multiple witnesses attesting that $x \in \mathcal{L}$, no malicious verifier talking to a prover whose implementation has been arbitrarily subverted can distinguish whether a proof is conducted using either of two witnesses.
- *Strong exfiltration resistance for the prover (resp. verifier):* Transcripts produced by running the sanitized IPS in the presence of a malicious verifier (resp. prover) talking to a prover (resp. verifier) whose implementation has been arbitrarily subverted are indistinguishable to transcripts produced by running the sanitized IPS in the presence of a malicious verifier (resp. prover) talking to the honest prover (resp. verifier).

For each of the above properties (except for completeness), we also consider a weak variant which only holds w.r.t. *functionality-maintaining* provers/verifiers. Intuitively, a prover is functionality maintaining if, upon input a valid statement/witness pair, it still convinces the honest verifier with overwhelming probability. Similarly, a verifier is functionality maintaining if, upon input a valid statement, it still accepts with overwhelming probability in a protocol run with the honest prover.

What is possible and what is impossible

A moment of reflection shows that soundness preservation is impossible to achieve. In fact, an arbitrarily subverted verifier might always[5] output one, thus automatically accepting both true and false statements. Such a verifier is still functionality maintaining,[6] and thus this simple attack even rules out *weak* soundness preservation. One way to circumvent this impossibility would be to only consider *partial subversion*, i.e. split the verifier into two components, one for computing the next messages in the protocol, and the other one for determining the final verdict on the veracity of a statement; hence, assume the latter component to be untamperable.

Turning to subversion of the prover, consider the subverted prover that always outputs the all-zero string. The soundness property of the underlying IPS implies that, for any RF and for any *false* statement $x \notin \mathcal{L}$, a sanitized transcript in this case can never be accepting. Moreover, assuming the language $\mathcal{L}$ is non-trivial, the latter holds true even in case x is a *true* statement, which in turn rules out strong exfiltration resistance. For similar reasons, strong ZK/WI preservation are also impossible to achieve.

3 Firewall Constructions from Malleable Sigma Protocols

As our second contribution, we formalize a class of Sigma protocols which admit simple, and very efficient, RFs for the prover. (See the full version [29] for similar constructions dealing with functionality-maintaining subversion of the verifier.) The main idea is to use the RF to re-randomize the prover's messages, in order to destroy any potential subliminal channel signaling information about the witness. The difficulty, though, is that such re-randomization must be carried out without knowing a witness, and while at the same time preserving the completeness property of the underlying IPS.

For the sake of concreteness, let us describe our firewall applied to the classical Sigma protocol for proving knowledge of a discrete logarithm [49]. Here, the statement consists of a description of a cyclic group $\mathbb{G}$ with generator g and prime order q, together with a value $x \in \mathbb{G}$ such that $x = g^w$ for some $w \in \mathbb{Z}_q$. The prover's first message is a random group element $\alpha = g^a \in \mathbb{G}$. Finally, the prover's last message is $\gamma = a - w \cdot \beta$, where $\beta \in \mathbb{Z}_q$ is the verifier's challenge; the verifier accepts (α, β, γ) if and only if $g^\gamma = \alpha \cdot x^{-\beta}$. Our RF sanitizes the messages α and γ from a possibly subverted implementation of the prover as follows:

$$\begin{aligned} \widehat{\alpha} &= \alpha \cdot g^\sigma \\ \widehat{\gamma} &= \gamma + \sigma, \end{aligned}$$

for random $\sigma \in \mathbb{Z}_q$. Note that $g^{\widehat{\gamma}} = g^a \cdot g^\sigma \cdot x^{-\beta} = \widehat{\alpha} \cdot x^{-\beta}$, and thus the RF preserves completeness.

[5] If one insists on undetectability, the subverted verifier may output 1 upon some hard-wired, randomly chosen, false statement $\overline{x} \notin \mathcal{L}$.

[6] The latter is because completeness is a guarantee that only concerns true statements.

$\widehat{\gamma}$
$\mathsf{V}(x, (\widehat{\alpha}, \beta, \widehat{\gamma})) \overset{?}{=} 1$

Figure 1 Cryptographic reverse firewall for a malleable Sigma protocol.

We now sketch the proof of weak HVZK preservation. Observe that for any $\widetilde{\alpha} = g^{\widetilde{a}}$ sent by a functionality-maintaining subverted prover, the distribution of $\widehat{\alpha} = g^{\widetilde{a}+\sigma}$ is uniform over $\mathbb{G}$ and independent of $\widetilde{\alpha}, \widetilde{a}$, and in fact it is identical to the distribution of α in an honest run of the original Sigma protocol (without the firewall). As for $\widehat{\gamma}$, note that if there would be two possible values γ, γ' which make both $\tau = (\alpha, \beta, \gamma)$ and $\tau' = (\alpha, \beta, \gamma')$ valid transcripts, the choice of which response to pick could be used by a functionality-maintaining subverted prover as a subliminal channel signaling information about the witness. Hence, we exploit the fact that for any prefix α, β, there exists a unique response γ such that the verifier accepts upon input x and (α, β, γ).

It follows that the distribution of $\widehat{\gamma}$ is identical to that of γ in an honest run of the original Sigma protocol (without the firewall). Putting it all together, we have shown that the distribution of a sanitized transcript $\widehat{\tau} = (\widehat{\alpha}, \beta, \widehat{\gamma})$ is identical to the distribution of an honest transcript $\tau = (\alpha, \beta, \gamma)$. Thus, weak HVZK preservation follows by the fact that Schnorr's Sigma protocol is HVZK.

3.1 HVZK Preservation

Let us now explain how to generalize the above idea to a large class of Sigma protocols that we call *malleable*. In what follows, given a Sigma protocol $\Sigma = (\mathsf{P}, \mathsf{V})$, we denote by P_1 and P_2 the algorithms that compute, respectively, the first prover's message α, and the last prover's message (response) γ. The challenge space is represented[7] as $\{0,1\}^\ell$, so that there are 2^ℓ possible challenges, and we write V for the algorithm that the verifier runs upon statement x and transcript τ to make its final decision. Let $\mathcal{A}$ be the space of all possible prover's first messages; we assume that membership in $\mathcal{A}$ can be tested efficiently, so that V always outputs $\perp$ whenever $\alpha \notin \mathcal{A}$.

As for the case of Schnorr's Sigma protocol, an additional requirement that we need is that the prover's responses are unique, meaning that for all $x \in \mathcal{L}$, and for any $\alpha \in \mathcal{A}$ and $\beta \in \{0,1\}^\ell$, there exists at most one[8] value γ such that $\mathsf{V}(x, (\alpha, \beta, \gamma)) = 1$.

Intuitively, a Sigma protocol is malleable if there exists an efficient algorithm Maul for randomizing the prover's first message α into a value $\widehat{\alpha}$ which is distributed identically to the first message of an honest prover. Moreover, for any challenge β, given the coins used to randomize α and any response γ yielding a valid transcript $\tau = (\alpha, \beta, \gamma)$, there exists an

[7] In the case of Schnorr's Sigma protocol, the challenge space is a cyclic group. However, we can embed such group in $\{0,1\}^\ell$ for some $\ell \in \mathbb{N}$.

[8] This property is met by many natural Sigma protocols, and was already considered in several previous works [26, 22, 51].

Figure 2 Sigma protocol compiled with standard techniques to obtain full zero knowledge.

efficient algorithm Bal for computing a balanced response $\widehat{\gamma}$ such that $(\widehat{\alpha}, \beta, \widehat{\gamma})$ is also valid. As we show in the full version [29], many natural Sigma protocols are already malleable. In particular, the latter holds true for Maurer's unifying protocol [39], which includes the protocols by Fiat-Shamir [25], Guillou-Quisquater [37], Schnorr [49], Okamoto [41], and many others as special cases.

Our RF construction is depicted in Fig. 1. Intuitively, the firewall uses the malleability property of the underlying Sigma protocol in order to re-randomize the prover's first and last messages, in such a way that a functionality-maintaining subverted prover cannot signal information about the witness through them. The theorem below, whose proof appears in the full version [29], establishes its security.

▶ **Theorem 2.** *Let $\Sigma = (\mathsf{P} = (\mathsf{P}_1, \mathsf{P}_2), \mathsf{V})$ be a malleable Sigma protocol with unique responses, for a relation $\mathcal{R}$. The RF W of Fig. 1 preserves completeness, and is weakly HVZK preserving for the prover.*

3.2 ZK Preservation

As Sigma protocols are not in general zero knowledge, there is no hope to prove that the above firewall weakly preserves ZK. However, a standard trick [33] allows to transform any Sigma protocol into a 5-round IPS satisfying ZK. The idea is to let the prover send the public key pk of a commitment scheme $(\mathsf{Gen}, \mathsf{Com}, \mathsf{Open})$ during the first round. Then, during the second round, the verifier forwards to the prover a commitment c to the challenge β. Finally, the Sigma protocol is executed as before with the difference that the verifier also needs to open the commitment, with the prover aborting if the opening is invalid. We depict such a modified protocol in Fig. 2.

In order to build a RF for this IPS, we need to sanitize the additional messages from the (possibly subverted, but functionality-maintaining) prover.[9] We do so by relying on a special type of *key-malleable* commitment, which intuitively allows to maul any public key pk (via an algorithm $\mathsf{MaulKey}$) into a uniformly random public key $\widehat{pk}$, in such a way that, given a commitment c with opening d w.r.t. $\widehat{pk}$, it is possible to map (c, d) into a commitment

[9] The other messages are sanitized as before, i.e. we still exploit the fact that the underlying Sigma protocol is malleable.

	$\xrightarrow{\gamma}$			
		$\beta = \mathsf{Open}(pk,\widehat{c},\widehat{d})$ If $\beta = \perp$, then $\widehat{\gamma} = \perp$ Else, $\widehat{\gamma} = \mathsf{Bal}(\gamma,\sigma)$		
			$\xrightarrow{\widehat{\gamma}}$	
				$\mathsf{V}(x,(\widehat{\alpha},\beta,\widehat{\gamma})) \overset{?}{=} 1$

Figure 3 Prover's RF for the protocol in Fig. 2.

$\widehat{c}$ with opening $\widehat{d}$ w.r.t. pk, without changing the message inside the commitment. We denote by $\mathsf{MaulCom}$ and $\mathsf{BalOpen}$, respectively, the algorithms for mauling the commitment c and the opening d, and additionally require that the distribution of mauled public keys and commitments is identical, respectively, to that of honestly computed public keys and commitments. As we show in the full version [29], the standard Pedersen's commitment [44] is easily seen to be key malleable, thus yielding a concrete instantiation under the Discrete Logarithm assumption.

Our RF for the protocol of Fig. 2 is depicted in Fig. 3. The theorem below, whose proof appears in the full version [29], establishes its security.

▶ **Theorem 3.** *Let $\Sigma = (\mathsf{P} = (\mathsf{P}_1, \mathsf{P}_2), \mathsf{V})$ be a malleable Sigma protocol with unique responses, for a relation $\mathcal{R}$. Let $\Gamma = (\mathsf{Gen}, \mathsf{Com}, \mathsf{Open})$ be a key-malleable commitment scheme with message space $\{0,1\}^\ell$. The RF W of Fig. 3 preserves completeness, and moreover is weakly exfiltration resistant and weakly zero-knowledge preserving for the prover.*

▶ Remark 4 (On knowledge soundness). The IPS of Fig. 2 satisfies soundness, but is not in general a proof of knowledge. However, we would like to note that the prover's firewall still works for the standard transformation of a Sigma protocol into a zero-knowledge proof of knowledge. In such a transformation, a *trapdoor* commitment scheme is used to commit to the verifier's challenge. Then, after the verifier decommits, the prover sends the trapdoor to the verifier. This allows an extractor to learn the trapdoor, rewind the prover, and open the commitment to a different challenge, thus learning the response for two different challenges, which allows it to obtain a witness using special soundness.

The prover's RF for this protocol stays the same, except that it additionally needs to provide a trapdoor for the mauled public key $\widehat{pk}$ given a trapdoor for the original public key pk. This is possible, for instance, using Pedersen's commitment, where given a public key $pk = (g, h = g^k)$ with trapdoor k, we can maul the key to $(\widehat{g} = g^{t_1}, \widehat{h} = h^{t_2})$ for random t_1, t_2. Given the trapdoor k for the key pk, the trapdoor for the mauled key $\widehat{pk}$ can be computed as $t_2 t_1^{-1} k$.

4 Firewalls for Proving Compound Statements

In this section, we show how to construct firewalls for Sigma protocols that prove compound statements.

Given two Sigma protocols Σ_0 and Σ_1 for NP languages $\mathcal{L}_0$ and $\mathcal{L}_1$, it is easy to obtain a Sigma protocol Σ_{AND} for the NP language $\mathcal{L}_{\mathsf{AND}} = \{(x_0, x_1) : \ x_0 \in \mathcal{L}_0 \wedge x_1 \in \mathcal{L}_1\}$ by simply running Σ_0 and Σ_1 in parallel, with the verifier sending a single challenge. In a similar vein, the OR technique by Cramer, Damgård, and Schoenmakers [15] allows to obtain a Sigma protocol Σ_{OR} for the NP language $\mathcal{L}_{\mathsf{OR}} = \{(x_0, x_1) : \ x_0 \in \mathcal{L}_0 \vee x_1 \in \mathcal{L}_1\}$. Importantly, if Σ_0 and Σ_1 are both perfect HVZK, Σ_{OR} satisfies perfect WI. On the other hand, Garay et al. [30] showed that if Σ_0 and Σ_1 are computational HVZK, Σ_{OR} satisfies computational WI, although the latter holds only in case both statements x_0, x_1 in the definition of language $\mathcal{L}_{\mathsf{OR}}$ are true (but the prover knows either a witness for x_0 or for x_1).

As long as Σ_0 and Σ_1 are malleable, it is easy to build RFs for Σ_{AND} and Σ_{OR} using our techniques. The RF for Σ_{AND} weakly preserves HVZK, whereas the RF for Σ_{OR} weakly preserves both HVZK and WI.

4.1 AND Composition

Given x_0, x_1, a prover wishes to prove to a verifier that $x_0 \in \mathcal{L}_0$ and $x_1 \in \mathcal{L}_1$. More precisely, consider the derived relation:

$$\mathcal{R}_{\mathsf{AND}} = \{((x_0, x_1), (w_0, w_1)) : \ (x_0, w_0) \in \mathcal{R}_0 \wedge (x_1, w_1) \in \mathcal{R}_1\}.$$

Let $\Sigma_0 = ((\mathsf{P}_1^0, \mathsf{P}_2^0), \mathsf{V}^0)$ (resp. $\Sigma_1 = ((\mathsf{P}_1^1, \mathsf{P}_2^1), \mathsf{V}^1)$) be a Sigma protocol for language $\mathcal{L}_0$ (resp. $\mathcal{L}_1$). A Sigma protocol Σ_{AND} for the relation $\mathcal{R}_{\mathsf{AND}}$ can be obtained by running the two provers of Σ_0 and Σ_1 in parallel, with the verifier sending a single challenge for both executions. Fig. 4 shows a RF for the prover of Σ_{AND}, assuming that both Σ_0 and Σ_1 are malleable. We prove the following result, whose proof appears in the full version [29].

The RF* W *of Fig. 4 preserves completeness, and is weakly HVZK preserving for the prover of the Sigma protocol* Σ_{AND} *for relation* $\mathcal{R}_{\mathsf{AND}}$*.*

4.2 OR Composition

Given x_0, x_1, a prover wishes to prove to a verifier that either $x_0 \in \mathcal{L}_0$ or $x_1 \in \mathcal{L}_1$ (without revealing which one is the case). More precisely, consider the derived relation

$$\mathcal{R}_{\mathsf{OR}} = \{((x_0, x_1), w) : \ (x_0, w) \in \mathcal{R}_0 \vee (x_1, w) \in \mathcal{R}_1\}.$$

Let $\Sigma_0 = ((\mathsf{P}_1^0, \mathsf{P}_2^0), \mathsf{V}^0)$ (resp. $\Sigma_1 = ((\mathsf{P}_1^1, \mathsf{P}_2^1), \mathsf{V}^1)$) be a Sigma protocol for language $\mathcal{L}_0$ (resp. $\mathcal{L}_1$); we denote by S^0 (resp. S^1) the HVZK simulator for Σ_0 (resp. Σ_1). A Sigma protocol Σ_{OR} for the relation $\mathcal{R}_{\mathsf{OR}}$ has been constructed for the first time in [15], where the authors showed that Σ_{OR} satisfies both (perfect) special HVZK and (perfect) WI. We describe the protocol Σ_{OR} in Fig. 5, and depict our RF for the prover in Fig. 6.

Prover$((x_0, x_1), w)$		**Verifier**(x_0, x_1)
$\alpha_b = \mathsf{P}_1^b(x_b, w; a)$ $(\alpha_{1-b}, \beta_{1-b}, \gamma_{1-b}) \leftarrow\$ \mathsf{S}^{1-b}(x_{1-b})$		
	$\xrightarrow{\alpha_0, \alpha_1}$	
		$\beta \leftarrow\$ \{0,1\}^\ell$
	$\xleftarrow{\beta}$	
$\beta_b = \beta \oplus \beta_{1-b}$ $\gamma_b = \mathsf{P}_2^b(x_b, w, \beta_b, a)$		
	$\xrightarrow{\beta_0, \beta_1, \gamma_0, \gamma_1}$	
		$\beta \overset{?}{=} \beta_0 \oplus \beta_1$ $\mathsf{V}^0(x_0, (\alpha_0, \beta_0, \gamma_0)) \overset{?}{=} 1$ $\mathsf{V}^1(x_1, (\alpha_1, \beta_1, \gamma_1)) \overset{?}{=} 1$

Figure 5 OR composition of Sigma protocols, where $b \in \{0,1\}$ is s.t. $(x_b, w) \in \mathcal{R}_b$.

As in the case of AND composition, we still rely on the fact that the input Sigma protocols Σ_0, Σ_1 are malleable. An additional difficulty, however, stems from the fact that a functionality maintaining prover could now try to change the distribution of the challenges β_0, β_1 in such a way that, even if $\beta_0 \oplus \beta_1 = \beta$, the pair (β_0, β_1) signals some information about the witness w or about the hidden bit b. Intuitively, the RF in Fig. 6 tackles this attack by randomizing the challenges β, β_0, β_1. The latter requires a different form of malleability from the underlying Sigma protocols, which we dub *instance-dependent malleability*, where it should be possible to maul the prover's first message in such a way that we can later balance the prover's last message as well as the verifier's challenge.

For the RF in Fig. 6, we prove the following result, whose proof appears in the full version [29] of this paper.

▶ **Theorem 6.** *Let* $\Sigma_0 = (\mathsf{P}^0 = (\mathsf{P}_1^0, \mathsf{P}_2^0), \mathsf{V}^0)$ *and* $\Sigma_1 = (\mathsf{P}^1 = (\mathsf{P}_1^1, \mathsf{P}_2^1), \mathsf{V}^1)$ *be instance-dependent malleable Sigma protocols with unique responses, for relations* $\mathcal{R}_0$ *and* $\mathcal{R}_1$*. The RF* W *of Fig. 6 preserves completeness, and is weakly HVZK/WI preserving for the prover of the Sigma protocol* Σ_{OR} *for relation* $\mathcal{R}_{\mathsf{OR}}$*.*

5 Previous Work

5.1 Comparison with Mironov and Stephens-Davidowitz

In their original paper, Mironov and Stephens-Davidowitz [40] build RFs for arbitrary two-party protocols. While their results are related to ours, since IPSes are just a special case of two-party computation, there are some crucial differences which we highlight below.

The first RF construction sanitizes a specific combination of re-randomizable garbled circuits and oblivious transfer, for obtaining general-purpose private function evaluation. The second RF construction sanitizes any two-party protocol, at the price of encrypting the full transcript under public keys that are broadcast at the beginning of the protocol. Both constructions can be instantiated based on (variants of) the DDH assumption. When cast to IPSes, their results yield:

(i) A RF for the prover that weakly preserves ZK. This is comparable to our RF achieving weak ZK preservation using malleable Sigma protocols and key-malleable commitments. However, our constructions have the advantage that we do not need to change the initial IPS, and thus our RF can be applied directly to already existing implementations in a fully transparent manner (and without introducing any overhead).

(ii) A RF for the prover satisfying a property called strong exfiltration resistance *against an eavesdropper*, which means that exfiltration resistance holds w.r.t. an arbitrarily subverted prover talking to the *honest verifier*. Note that the latter does not contradict our impossibility result ruling out strong ZK preservation, as our attacks crucially rely on the fact that the distinguisher can (passively) corrupt the verifier.

(iii) A RF for the verifier satisfying both strong exfiltration resistance and the following weak guarantee: No malicious prover can find statements x_0, x_1 such that it can distinguish transcripts obtained by talking to an arbitrarily subverted verifier holding either input x_0 or input x_1. Note that the latter does not contradict our impossibility result that rules out weak soundness preservation, since none of the above guarantees imply soundness preservation.

We observe that the above results have at least one of the following drawbacks: (i) The RF is not transparent, i.e. it cannot be applied to the initial protocol as is; (ii) The resulting sanitized protocol is not efficient, as we first need to encode the function being computed as a circuit.

Our techniques allow to overcome these limitations in the concrete case of IPSes, as our RFs are both transparent (i.e. they can be applied directly to already deployed protocols) and efficient (i.e. the sanitized IPSes have exactly the same efficiency as the original, both in terms of round and communication complexity). We see this as the main novelty of our work.

5.2 Additional Related Works

Besides the already mentioned constructions, RFs have also been realized in other settings including digital signatures [5], secure message transmission and key exchange [21, 12], and oblivious transfer [40, 12].

Moreover, a few other lines of research recently[10] emerged to tackle the challenge of protecting cryptographic algorithms against (different forms of) subversion. We review the main ones below.

Algorithm substitution attacks

Bellare, Patterson, and Rogaway [11] studied subversion of symmetric encryption schemes in the form of algorithm substitution attacks (ASAs). In particular, they show that *undetectable* subversion of the encryption algorithm is possible, and may lead to severe security breaches; moreover, they prove that deterministic, stateful, ciphers are secure against the same type of ASAs. Follow-up works improved the original paper in several aspects [18, 10], and explored the power of ASAs in other contexts, e.g. digital signatures [5], secret sharing [31], and message authentication codes [3].

Backdoors

Another form of subversion consists of all those attacks that surreptitiously generate public parameters (primes, curves, etc.) together with secret backdoors that allow to bypass security. The study of this type of subversion is motivated by the DUAL_EC_DRBG PRG incident.

A formal study of parameters subversion has been considered for several primitives, including pseudorandom generators [20, 19], hash functions [27], non-interactive zero knowledge [8], and public-key encryption [6].

Cliptography

Russell et al. [46] (see also [47, 4]) consider a different approach to the immunization of cryptosystems against complete subversion (i.e., when all algorithms can be subverted by the attacker): offline/online black-box testing. This amounts to introducing an external entity, called the watchdog, whose goal is to test, either in an online or in an offline fashion, whether a given cryptographic implementation is compliant with its specification.

[10] All these research directions have their roots in the seminal works of Young and Yung [52] and Simmons [50], in the settings of kleptography and subliminal channels.

Hence, a cryptosystem is deemed secure against complete subversion if there exists a universal watchdog such that, for every attacker subverting all algorithms, either the watchdog detects subversion with high probability, or the cryptoscheme remains secure even when using its subverted implementation.

Self-guarding

Yet another approach towards thwarting subversion is that of self-guarding [28]. The idea here is to assume a trusted initialization phase in which the honest parties possess a genuine implementation of the cryptosystem, before subversion takes place. This phase is used in order to generate samples that will be exploited later, together with additional simple operations that need to be implemented from scratch, to prevent leakage in the face of subversion attacks.

6 Conclusion

We showed how to design cryptographic reverse firewalls allowing to preserve security of interactive proof systems in the face of subversion. Our firewalls apply to a large class of Sigma protocols meeting a natural malleability property, and can be extended to cover classical applications of Sigma protocols for designing zero-knowledge proofs and for proving compound statements.

We leave it as an intriguing open problem to design a reverse firewall for the OR composition of Sigma protocols that are delayed input, as considered in [13, 14].

Abstract

In this paper, we study streaming and online algorithms in the context of randomness in the input. For several problems, a random order of the input sequence – as opposed to the worst-case order – appears to be a necessary evil in order to prove satisfying guarantees. However, algorithmic techniques that work under this assumption tend to be vulnerable to even small changes in the distribution. For this reason, we propose a new *adversarial injections* model, in which the input is ordered randomly, but an adversary may inject misleading elements at arbitrary positions. We believe that studying algorithms under this much weaker assumption can lead to new insights and, in particular, more robust algorithms. We investigate two classical combinatorial-optimization problems in this model: Maximum matching and cardinality constrained monotone submodular function maximization. Our main technical contribution is a novel streaming algorithm for the latter that computes a 0.55-approximation. While the algorithm itself is clean and simple, an involved analysis shows that it emulates a subdivision of the input stream which can be used to greatly limit the power of the adversary.

1 Introduction

In the streaming model, an algorithm reads the input sequentially from the input stream while using limited memory. In particular, the algorithm is expected to use memory that is much smaller than the input size, ideally, linear in the size of a solution. We consider the most fundamental setting in which the algorithm is further restricted to only read the input stream once. In this case, the algorithm cannot remember much of the input along the way, and part of the input is irrevocably lost. Something similar happens for online algorithms: Here, the input is given to the algorithm one element at a time and the algorithm has to decide whether to take it into its solution or to discard it. This decision is irrevocable.

The most common approach to analyze the quality of an algorithm in these models is worst-case analysis. Here, an adversary has full knowledge of the algorithm's strategy and presents a carefully crafted instance to it, trying to make the ratio between the value of the algorithm's solution and that of an optimum solution (the approximation ratio; for online algorithms called the competitive ratio) as small as possible[1]. While worst-case analysis gives very robust guarantees, it is also well-known that such an analysis is often very pessimistic. Not only are good guarantees not possible for many problems, but in many cases worst-case instances appear quite artificial. Hence, the worst-case approximation/competitive ratio does not necessarily represent the quantity that we want to optimize.

One way to remedy this is to weaken the power of the adversary and a popular model to achieve that is the random-order model. Here, an adversary may pick the instance as before, but it is presented in a uniformly-random order to the algorithm. This often allows for significantly better provable guarantees. A prime example is the secretary problem: For the worst-case order it is impossible to get a bounded competitive ratio whereas for the random-order a very simple stopping rule achieves a competitive ratio of $1/e$. Unfortunately, in this model, algorithms tend to overfit and the assumption of a uniformly-random permutation of the input is a strong one. To illustrate this point, it is instructive to consider two examples of techniques that break apart when the random-order assumption is slightly weakened:

Several algorithms in the random-order model first read a small fraction of the input, say, the first 1% of the input. Such an algorithm relies on the assumption that around 1% of the elements from an optimum solution are contained in this first chunk. It computes some statistics, summaries, or initial solutions using this chunk in order to estimate certain properties of the optimum solution. Then in the remaining 99% of the input it uses this knowledge to build a good solution for the problem. For examples of such streaming algorithms, see Norouzi-Fard et al. [29] who study submodular maximization and Gamlath et al. [13] who study maximum matching. Also Guruganesh and Singla's [16] online algorithm for maximum matching for bipartite graphs is of this kind. Note that these algorithms are very sensitive to noise at the beginning of the stream.

Another common technique is to split the input into fixed parts and exploit that with high probability the elements of the optimum solution are distributed evenly among these parts, e.g., each part has at most one optimum element. These methods critically rely on the assumption that each part is representative for the whole input or that the parts are in some way homogeneous (properties of the parts are the same in expectation). Examples of such algorithms include the streaming algorithm for maximum matching [23], and the streaming algorithm for submodular maximization [1] that achieves the tight competitive ratio $1 - 1/e$ in the random-order model.

The motivation of this work is to understand whether the strong assumption of uniformly-random order is necessary to allow for better algorithms. More specifically, we are motivated by the following question:

> Can we achieve the same guarantees as in the uniform-random order but by algorithms that are more robust against some distortions in the input?

In the next subsection, we describe our proposed model that is defined so as to avoid overfitting to the random-order model, and, by working in this model, our algorithms for submodular maximization and maximum matching are more robust while maintaining good guarantees.

[1] We assume that the problem is a maximization problem.

1.1 The Adversarial Injections Model

Our model – that we call the *adversarial-injections* model – lies in between the two extremes of random-order and adversarial-order. In this model, the input elements are divided into two sets E_{NOISE} and E_{GOOD}. An adversary first picks all elements, puts each element in either E_{NOISE} or E_{GOOD}, and chooses the input order. Then the elements belonging to E_{GOOD} are permuted uniformly at random among themselves. The algorithm does not know if an element is good or noise. We judge the quality of the solution produced by an algorithm by comparing it to the best solution in E_{GOOD}.

An equivalent description of the model is as follows. First, a set of elements is picked by the adversary and is permuted randomly. Then, the adversary injects more elements at positions of his choice without knowing the random permutation of the original stream[2]. Comparing with the previous definition, the elements injected by the adversary correspond to E_{NOISE} and the elements of the original stream correspond to E_{GOOD}.

We denote by $E_{\text{OPT}} \subseteq E_{\text{GOOD}}$ the elements of a fixed optimum solution of the elements in E_{GOOD}. We can assume without loss of generality that $E_{\text{GOOD}} = E_{\text{OPT}}$, because otherwise elements in $E_{\text{GOOD}} \setminus E_{\text{OPT}}$ can be treated as those belonging to E_{NOISE} (which only strengthens the power of the adversary).

1.2 Related Models

With a similar motivation, Kesselheim, Kleinberg, Niazadeh [21] studied the robustness of algorithms for the secretary problem from a slightly different perspective: They considered the case when the order of the elements is not guaranteed to be uniformly-at-random but still contains "enough" randomness with respect to different notions such as entropy. Recently, Esfandiari, Korula, Mirrokni [8] introduced a model where the input is a combination of stochastic input that is picked from a distribution and adversarially ordered input. Our model is different in the sense that the input is a combination of randomly ordered (instead of stochastic input) and adversarially ordered elements.

Two models that are more similar to ours in the sense that the input is initially ordered in a uniformly-random order and then scrambled by an adversary in a limited way are [15] and [3]. First, in the streaming model, Guha and McGregor [15] introduced the notion of a t-bounded adversary that can disturb a uniformly-random stream but has memory to remember and delay at most t input elements at a time. Second, Bradac et al. [3] very recently introduced a new model that they used to obtain robust online algorithms for the secretary problem. Their model, called the *Byzantine* model, is very related to ours: the input is split into two sets which exactly correspond to E_{GOOD} and E_{NOISE} in the adversarial-injections model. The adversary gets to pick the elements in both of them, but an algorithm will be compared against only E_{GOOD}. Then – this is where our models differ – the adversary chooses an arrival time in $[0, 1]$ for each element in E_{NOISE}. He has no control over the arrival times of the elements in E_{GOOD}, which are chosen independently and uniformly at random in $[0, 1]$. The algorithm does not know to which set an element belongs, but it knows the timestamp of each element, as the element arrives. While the Byzantine model prevents certain kinds of

[2] We remark that the assumption that the adversary does not know the order of the elements is important. Otherwise, the model is equivalent to the adversarial order model for "symmetric" problems such as the matching problem. To see this, let E_{OPT} correspond to an optimum matching in any hard instance under the adversarial order. Since a matching is symmetric, the adversary can inject appropriately renamed edges depending on the order of the edges (which he without this assumption knows) and obtain exactly the hard instance.

overfitting (e.g., of the classical algorithm for the secretary problem), it does not tackle the issues of the two algorithmic techniques we discussed earlier: Indeed, by time $t = 0.01$, we will see around 1% of the elements from E_{OPT}. Hence, we can still compute some estimates based on them, but do not lose a lot when dismissing them. Likewise, we may partition the timeline, and thereby the input, into parts such that in each part at most one element of E_{OPT} appears.

Hence, even if our model appears very similar to the Byzantine model, there is this subtle, yet crucial, difference. The adversarial-injections model does not add the additional dimension of time, and hence, does not allow for the kind of overfitting that we discussed earlier. To further emphasize this difference, we now describe why it is strictly harder to devise algorithms in the adversarial-injections model compared to the Byzantine model. It is at least as hard as the Byzantine model, because any algorithm for the former also works for the latter. This holds because the adversarial-injections model can be thought of as the Byzantine model with additional power to the adversary and reduced power for the algorithm: The adversary gets the additional power of setting the timestamps of elements in E_{GOOD}, but not their identities, whereas the algorithm is not allowed to see the timestamp of any element.

To show that it is strictly harder, consider online bipartite matching. We show that one cannot beat 1/2 in the adversarial-injections model (for further details, see Section 2.2) whereas we observe that the $(1/2 + \delta)$-approximation algorithm [16] for bipartite graphs and its analysis generalizes to the Byzantine model as well. This turns out to be the case because the algorithm in [16] runs a greedy algorithm on the first small fraction, say 1% of the input and "augments" this solution using the remaining 99% of the input. The analysis crucially uses the fact that 99% of the optimum elements are yet to arrive in the augmentation phase. This can be simulated in the Byzantine model using timestamps in the online setting as one sees 1% of E_{OPT} in expectation.

1.3 Our Results

We consider two benchmark problems in combinatorial optimization under the adversarial-injections model in both the streaming and the online settings, namely maximum matching and monotone submodular maximization subject to a cardinality constraint. As we explain next, the study of these classic problems in our new model gives interesting insights: for many settings we can achieve more robust algorithms with similar guarantees as in the random-order model but, perhaps surprisingly, there are also natural settings where the adversarial-injection model turns out to be as hard as the adversarial order model.

The maximum matching problem. We first discuss the (unweighted) *maximum matching* problem. Given a graph $G = (V, E)$, a matching M is a subset of edges such that every vertex has at most one incident edge in M. A matching of maximum cardinality is called a maximum matching, whereas a *maximal* matching is one in which no edge can be added without breaking the property of it being a matching. The goal in the maximum matching problem is to compute a matching of maximum cardinality. Note that a maximal matching is 1/2-approximate. Work on maximum matching has led to several important concepts and new techniques in theoretical computer science [26, 24, 6, 19]. The combination of streaming and random-order model was first studied by Konrad, Magniez and Mathieu [23], where edges of the input graph arrive in the stream. We allow a streaming algorithm to have memory $O(n \operatorname{polylog}(n))$, which is called the semi-streaming setting. This is usually significantly less than the input size, which can be as large as $O(n^2)$. This memory usage is justified, because even storing a solution can take $\Omega(n \log(n))$ space ($\Omega(\log(n))$ for each edge identity). The question that Konrad et al. answered affirmatively was whether the trivial 1/2-approximation algorithm that computes a maximal matching can be improved in the random-order model. Since then, there has been some work on improving the constant [14, 9]. The state-of-the-art is an approximation ratio of $6/11 \approx 0.545$ proved by Farhadi, Hajiaghayi, Mah, Rao, and Rossi [9]. We show that beating the ratio of 1/2 is possible also in the adversarial-injections model by building on the techniques developed for the random-order model.

▶ **Theorem 1.** *There exists an absolute constant $\gamma > 0$ such that there is a semi-streaming algorithm for maximum matching under adversarial-injections with an approximation ratio of $1/2 + \gamma$ in expectation.*

We note that beating 1/2 in adversarial-order streams is a major open problem. In this regard, our algorithm can be viewed as a natural first step towards understanding this question.

Now we move our attention to the online setting, where the maximum matching problem was first studied in the seminal work of Karp, Vazirani, and Vazirani [20]. They gave a tight $(1 - 1/e)$-competitive algorithm for the so-called one-sided vertex arrival model which is an important special case of the edge-arrival model considered here. Since then, the online matching problem has received significant attention (see e.g. [4, 7, 11, 17, 14]). Unlike the adversarial streaming setting, there is a recent hardness result due to [14] in the adversarial online setting that the trivial ratio of 1/2 cannot be improved. We also know by [16] that one can beat 1/2 for bipartite graphs in the random-order online setting. Hence, one might hope at least for bipartite graphs to use existing techniques to beat 1/2 in the online adversarial-injections setting and get a result analogous to Theorem 1. But surprisingly so, this is not the case. We observe that the construction used in proving Theorem 3 in [14] also implies that there does not exist an algorithm with a competitive ratio of $1/2 + \varepsilon$ for any $\varepsilon > 0$ in the adversarial-injections model.

Maximizing a monotone submodular function subject to a cardinality constraint. In this problem, we are given a ground set E of n elements and a monotone submodular set function $f : 2^E \to \mathbb{R}_{\geqslant 0}$. A function is said to be submodular, if for any $S, T \subseteq E$ it holds that $f(S) + f(T) \geqslant f(S \cup T) + f(S \cap T)$. It is monotone if $f(S) \leqslant f(T)$ for all $S \subseteq T \subseteq E$. The problem we consider is to find a set $S \subseteq E$ with $|S| \leqslant k$ that maximizes $f(S)$. We assume that access to f is via an oracle.

In the offline setting, a simple greedy algorithm that iteratively picks the element with the largest marginal contribution to f with respect to the current solution is $(1 - 1/e)$-approximate [28]. This is tight: Any algorithm that achieves an approximation ratio of better than $(1 - 1/e)$ must make $\Omega(n^k)$ oracle calls [27], which is enough to brute-force over all k-size subsets. Even for maximum coverage (which is a special family of monotone submodular functions), it is NP-hard to get an approximation algorithm with ratio better than $1 - 1/e$ [10].

In the random-order online setting, this problem is called the *submodular secretary* problem, and an exponential time $1/e$-approximation and polynomial-time $(1 - 1/e)/e$-approximation algorithms are the state-of-the-art [22]. In the adversarial online setting, it is impossible to get any bounded approximation ratio for even the very special case of picking a maximum weight element. In this case, $|E_{\text{OPT}}| = 1$ and adversarial and adversarial-injections models coincide; hence the same hardness holds. In light of this negative result, we focus on adversarial-injections in the streaming setting. Note that to store a solution we only need the space for k element identities. We think of k to be much smaller than n. Hence, it is natural to ask, whether the number of elements in memory can be independent of n.

Table 1 : Comparison of different models for the two studied problems. Here, $\gamma > 0$ is a fixed absolute constant and $\varepsilon > 0$ is any constant.

Maximum matching

	Random order	Adversarial Injections	Adversarial order
Streaming	$\geqslant 6/11$ [9]	$\geqslant 1/2 + \gamma$	$\leqslant 1 - 1/e + \varepsilon$ [18]
Online	$\geqslant 1/2$ (folklore)	$\leqslant 1/2$	$\leqslant 1/2$ [14]

Submodular function maximization

	Random order	Adversarial Injections	Adversarial order
Streaming	$\geqslant 1 - 1/e - \varepsilon$ [1] $\leqslant 1 - 1/e + \varepsilon$ [25]	$\geqslant 0.55$	$\geqslant 1/2 - \varepsilon$ [2] $\leqslant 1/2$ [12]

For streaming algorithms in the adversarial order setting, the problem was first studied by Chakrabarti and Kale [5] where they gave a 1/4-approximation algorithm. This was subsequently improved to $1/2 - \varepsilon$ by Badanidiyuru et al. [2]. Later, Norouzi-Fard et al. [29] observed that in the random-order model this ratio can be improved to beyond 1/2. Finally, Agrawal et al. [1] obtained a tight $(1 - 1/e)$-approximation guarantee in the random-order model.

The algorithm of Agrawal et al. [1] involves as a crucial step a partitioning the stream in order to isolate the elements of the optimum solution. As discussed earlier, this approach does not work under adversarial-injections. However, we note that the algorithm and analysis by Norouzi-Fard et al. [29] can be easily modified to work under adversarial-injections as well. Their algorithm, however, has an approximation ratio of $1/2 + 8 \cdot 10^{-14}$. In this paper, we remedy this weak guarantee.

▶ **Theorem 2.** *There exists a* 0.55*-approximation algorithm that stores a number of elements that is independent of n for maximizing a monotone submodular function with a cardinality constraint k under adversarial-injections in the streaming setting.*

We summarize and compare our results with random-order and adversarial-order models for the problems we study in Table 1. It is interesting to see that in terms of beating 1/2, our model in the streaming setting agrees with the random-order model and in the online setting agrees with the adversarial-order model.

2 Matching

In this section, we consider the problem of maximum unweighted matching under adversarial injections in both streaming and online settings where the edges of the input graph arrive one after another.

2.1 Streaming Setting

We show that the trivial approximation ratio of 1/2 can be improved upon. We provide a robust version of existing techniques and prove a statement about robustness of the greedy algorithm to achieve this.

First, let us introduce some notation which we will use throughout this section. We denote the input graph by $G = (V, E)$, and let M^* be a maximum matching. For any matching M, the union $M \cup M^*$ is a collection of vertex-disjoint paths and cycles. When M is clear from the context, a path of length $i \geqslant 3$ in $M \cup M^*$ which starts and ends with an edge of M^* is called an i-augmenting path. Notice that an i-augmenting path alternates between edges of M^* and M and that we can increase the size of M by one by taking all edges from M^* and removing all edges from M along this path. We say that an edge in M is 3-augmentable if it belongs to some 3-augmenting path. Otherwise, we say it is non-3-augmentable. Also, let $M^* = E_{\text{OPT}}$; as described in the introduction, this is without loss of generality.

As a subroutine for our algorithm we need the following procedure.

▶ **Lemma 3** (Lemma 3.1 in [13]). *There exists a streaming algorithm 3-Aug-Paths with the following properties:*

1. *The algorithm is initialized with a matching M and a parameter $\beta > 0$. Then a set E of edges is given to the algorithm one edge at a time.*
2. *If $M \cup E$ contains at least $\beta|M|$ vertex disjoint 3-augmenting paths, the algorithm returns a set A of at least $(\beta^2/32)|M|$ vertex disjoint 3-augmenting paths. The algorithm uses space $O(|M|)$.*

2.1.1 The Algorithm

We now describe our algorithm Match. It runs two algorithms in parallel and selects the better of the two outputs. The first algorithm simply constructs a maximal matching greedily by updating the variable M_1. The second algorithm also constructs a matching $M_2^{(1)}$ greedily, but it stops once $M_2^{(1)}$ has $|M^*|(1/2 - \varepsilon)$ edges. We call this Phase 1. Then, it finds 3-augmentations using the 3-Aug-Paths algorithm given by Lemma 3. Finally, it augments the paths found to obtain a matching M_2. The constant β used in 3-Aug-Paths is optimized for the analysis and will be specified there.

Notice that here we assumed that the algorithm knows $|M^*|$. This assumption can be removed using geometric guessing at a loss of an arbitrary small factor in the approximation ratio. We refer the reader to the full version for details.

2.1.2 Overview of the Analysis

We discuss only the intuition here and refer the reader to the full version for a formal proof. Consider the first portion of the stream until we have seen a small constant fraction of the elements in E_{OPT}. If the greedy matching up to this point is already close to a 1/2-approximation, this is good for the second algorithm as we are able to augment the matching using the remaining edges of M^*. The other case is good for the first algorithm: We will show that the greedy matching formed so far must contain a significant fraction of the edges in M^* which we have seen so far. If this happens, the first algorithm outputs a matching of size a constant fraction more than $|M^*|/2$.

A technical challenge and novelty comes from the fact that the two events above are not independent of the random order of E_{OPT}. Hence, when conditioning on one event, we can no longer assume that the order of E_{OPT} is uniformly at random. We get around this by showing that the greedy algorithm is robust to small changes in streams. The intuition is that in the first part of the stream the greedy solution either is large for all permutations of E_{OPT} or it is small for all permutations. Hence, these are not random events depending on the order, but two cases in which we can assume a uniform distribution.

2.2 Online Setting

Since we can improve 1/2 for the streaming setting, it is natural to hope that the existing techniques (e.g., the approach of the previous subsection) can be applied in the online setting as well. Surprisingly, this is not the case. In other words, the competitive ratio of 1/2 is optimal even for bipartite graphs. The technique from the previous subsection breaks apart, because the algorithm constructs several candidate solutions in parallel by guessing $|M^*|$. This is not a problem for a streaming algorithm, however, an online algorithm can only build one solution.

For a formal proof, we rely on the bipartite construction used in the proof of Theorem 3 from [14]. The authors show that there is no (randomized) algorithm with a competitive ratio of $1/2 + \varepsilon$ for any $\varepsilon > 0$. More precisely, they show that not even a good fractional matching can be constructed online. For fractional matchings, randomization does not help and therefore we can assume the algorithm is deterministic. The original proof is with respect to adversarial order, but it is not hard to see that it transfers to adversarial injections.

The authors construct a bipartite instance that arrives in (up to) N rounds. In round i, a matching of size i arrives. The algorithm does not know whether the current round is the last one or not. Hence, it has to maintain a good approximation after each round. This forces the algorithm to take edges that do not belong to the optimal matching and eventually leads to a competitive ratio of $1/2$. The same construction works in our model: The edges from the optimal matching arrive in the last round and their internal order does not affect the proof. In fact, the construction works for any order of the elements within a round. Thus, an algorithm cannot exploit the fact that their order is randomized and therefore also cannot do better than $1/2$.

3 Submodular Maximization

In this section, we consider the problem of submodular maximization subject to a cardinality constraint. The algorithm has query access to a monotone, submodular function $f : 2^E \to \mathbb{R}$ over a ground set E. Moreover, f is normalized with $f(\emptyset) = 0$. The goal is to compute a set S of size at most k that maximizes $f(S)$. We present a 0.55-approximate streaming algorithm in the adversarial-injections model which only needs the memory to store $(O(k))^k$ many elements. In particular, this number is independent of the length of the stream.

3.1 Notation

For $e \in E$ and $S \subseteq E$ we write $S + e$ for the set $S \cup \{e\}$ and $f(e \mid S)$ for $f(S + e) - f(S)$. Similarly, for $A, B \subseteq E$ let $f(A \mid B) := f(A \cup B) - f(B)$. An equivalent definition of submodularity to the one given in the introduction states that for any two sets $S \subseteq T \subseteq E$, and $e \in E \setminus T$ it holds that $f(e \mid S) \geqslant f(e \mid T)$.

We denote by σ the stream of elements E, by $-\infty$ and ∞ the start and end of the stream. For elements a and b, we write $\sigma[a, b]$ for the interval including a and b and $\sigma(a, b)$ for the interval excluding them. Moreover, we may assume that $f(\emptyset) = 0$, since otherwise, we may replace the submodular function by $f' : 2^E \to \mathbb{R}_{\geqslant 0}, T \mapsto f(T) - f(\emptyset)$.

Denote the permutation of E_{OPT} by π. Let o_i^π be the i'th element of E_{OPT} in the stream according to the order given by π. Let $O_0^\pi = \emptyset$ and $O_i^\pi = \{o_1^\pi, \dots, o_i^\pi\}$ for all i; hence, $E_{\text{OPT}} = O_k^\pi$ for any π. Finally, let $\text{OPT} = f(O_k^\pi)$.

3.2 The Algorithm

For simplicity we present an algorithm with the assumption that it knows the value OPT. Moreover, for the set of increases in f, that is $I = \{f(e \mid S) : e \in E, S \subseteq E\}$, we assume that $|I| \leqslant O(k)$. These two assumptions can be made at a marginal cost in the approximation ratio and an insignificant increase in memory. This follows from standard techniques. We refer the reader to the full version for details.

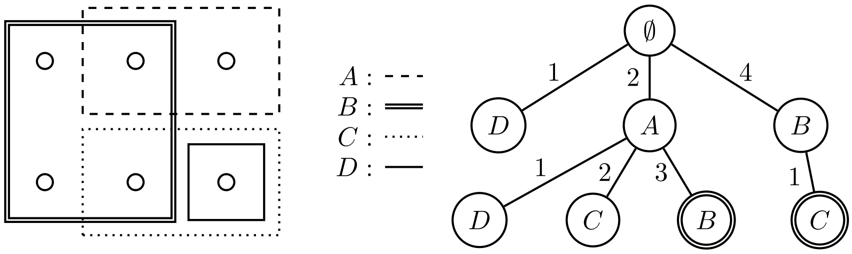

Figure 1 In this example, function f counts the dots covered by a set of rectangles. On the right, the tree for stream $\sigma = (A, B, C, D)$ and $k = 2$ is depicted. The labels on the edges correspond to the increase in f. The maximal leaves are highlighted.

As a central data-structure, the algorithm maintains a rooted tree T of height at most k. Every node except for the root stores a single element from E. The structure resembles a prefix tree: Each node is associated with the solution, where the elements on the path from the root to it is selected. The nodes can have at most $|I|$ children, that is, one for each increase. The basic idea is that for some partial solution $S \subseteq E$ (corresponding to a node) and two elements e, e' with $f(e \mid S) = f(e' \mid S)$ we only consider one of the solutions $S \cup \{e\}$ and $S \cup \{e'\}$. More precisely, the algorithm starts with a tree consisting only of the root. When it reads an element e from the stream, it adds e as a child to every node where (1) the distance of the node to the root is smaller than k and (2) the node does not have a child with increase $f(e \mid S)$, where S is the partial solution corresponding to this particular node.

Because of (1), the solutions are always of cardinality at most k. When the stream is read completely, the algorithm selects the best solution among all leaves. An example of the algorithm's behavior is given in Figure 1.

3.3 Overview of the Analysis

For analyzing the algorithm, we will use a sophisticated strategy to select one of the leaves and only compare this leaf to the optimum. We emphasize that this selection does not have to be computed by the algorithm. In particular, it does not need to be computable by a streaming algorithm and it can rely on knowledge of E_{OPT} and E_{NOISE}, which the algorithm does not have. Since the algorithm always takes the best leaf, we only need to give a lower bound for one of them. Before we describe this strategy, we analyze the tree algorithm in two educational corner cases.

The first one shows that by a careful selection of a leaf the algorithm appears to take elements based on the location of the E_{OPT}, although it does not know them. Let $r_i^\pi = \text{argmax}_{e \in \sigma(-\infty, o_1^\pi]} f(e)$, that is, the most valuable element until the arrival of the first element from E_{OPT}. Here argmax breaks ties in favor of the first element in σ. We do not know when o_1^π arrives, but we know that the algorithm will have created a node (with the root as its parent) for r_1^π by then. We define iteratively $R_i^\pi = \{r_1^\pi, \dots, r_i^\pi\}$ and $r_{i+1}^\pi = \text{argmax}_{e \in \sigma(r_i^\pi, o_{i+1}^\pi]} f(e \mid R_i^\pi)$ for all i. Again, we can be sure that r_{i+1}^π, which yields the best increase for R_i^π until the arrival of o_{i+1}^π, is a appended to the path $r_1^\pi \to \cdots \to r_i^\pi$.

This selection is inspired by the following idea. Suppose we could partition the stream into k intervals such that in each exactly one elements from E_{OPT} appears. Then a sensible approach would be to start with an empty solution and greedily add the element that yields the maximal increase to our partial solution in each interval. Clearly one such partition would be $\sigma(o_i^\pi, o_{i+1}^\pi]$, $i = 1, \dots, k$. We note that while the selection above is similar, it does not completely capture this. Although r_{i+1}^π is an element that arrives before o_{i+1}^π, we cannot be certain that it arrives after o_i^π. We only know that it arrives after r_i^π.

Next, we prove that the solution R_k^π is a 1/2-approximation. This already shows that the tree algorithm is 1/2-approximate even in the adversarial order model. By definition of R_i^π and r_i^π, we have

$$\begin{aligned} f(R_k^\pi) = \sum_{i=1}^{k} f(r_i^\pi \mid R_{i-1}^\pi) \geqslant \sum_{i=1}^{k} f(o_i^\pi \mid R_{i-1}^\pi) \\ = \sum_{i=1}^{k} [f(o_i^\pi \mid R_{i-1}^\pi) - f(o_i^\pi \mid R_k^\pi)] + \sum_{i=1}^{k} f(o_i^\pi \mid R_k^\pi). \end{aligned}$$

Notice that due to submodularity the term $f(o_i^\pi \mid R_{i-1}^\pi) - f(o_i^\pi \mid R_k^\pi)$ is always non-negative. Moreover, if $o_i^\pi = r_i^\pi \in R_k^\pi$, it collapses to $f(o_i^\pi \mid R_{i-1}^\pi)$. Thus, we can bound the right term of the equation and thereby $f(R_k^\pi)$ with

$$f(R_k^\pi) \geqslant \sum_{\substack{i=1 \\ r_i^\pi = o_i^\pi}}^{k} f(o_i^\pi \mid R_{i-1}^\pi) + \sum_{i=1}^{k} f(o_i^\pi \mid R_k^\pi).$$

From submodularity and monotonicity of f it follows that

$$\sum_{i=1}^{k} f(o_i^\pi \mid R_k^\pi) \geqslant f(O_k^\pi \mid R_k^\pi) = f(O_k^\pi \cup R_k^\pi) - f(R_k^\pi) \geqslant f(O_k^\pi) - f(R_k^\pi).$$

Hence, we conclude that

$$2f(R_k^\pi) \geqslant f(O_k^\pi) + \sum_{\substack{i=1 \\ r_i^\pi = o_i^\pi}}^{k} f(o_i^\pi \mid R_{i-1}^\pi).$$

This shows that R_k^π is 1/2-approximate, because $O_k^\pi = E_{\text{OPT}}$. Indeed, if a significant value of the elements in E_{OPT} are taken, then R_k^π is even better than 1/2-approximate.

Recall that the elements E_{OPT} are ordered randomly in the adversarial-injections model. Hence, the worst-case in the analysis above is that R_k^π is disjoint from E_{OPT} for all realizations of π. However, by a different analysis we can see that this case is in fact well-behaved. This is because the algorithm would select the same elements $r_1^\pi, \dots, r_k^\pi$ for every realization of π. Hence, we can safely drop the superscript π in R_i^π and r_i^π. Since for every element $o \in E_{\text{OPT}}$ there is some realization of π where $o_i^\pi = o$, yet the algorithm does not pick o_i^π, we can bound the increase of each r_i by

$$f(r_i \mid R_{i-1}) \geqslant \max_{o \in E_{\text{OPT}}} f(o \mid R_{i-1}) \geqslant \frac{1}{k} \sum_{o \in E_{\text{OPT}}} f(o \mid R_{i-1}).$$

By submodularity and monotonicity we get

$$\frac{1}{k} \sum_{o \in E_{\text{OPT}}} f(o \mid R_{i-1}) \geqslant \frac{1}{k} f(E_{\text{OPT}} \mid R_{i-1}) \geqslant \frac{1}{k}(\text{OPT} - f(R_{i-1})).$$

This is the same recurrence formula as in the classic greedy algorithm and by simple calculations we get the closed form

$$f(R_k) \geqslant \left(1 - \left(1 - \frac{1}{k}\right)^k\right) \text{OPT} \geqslant \left(1 - \frac{1}{e}\right) \text{OPT}.$$

In other words, the algorithm is even $(1 - 1/e)$-approximate in this case. In our main proof we will use a more involved strategy for selecting a leaf. This is to be able to combine the two approaches discussed above.

3.4 Analysis

Let us first define the selection of the leaf we are going to analyze. The elements on the path to this leaf will be denoted by $s_1^\pi, \dots, s_k^\pi$ and we write S_i^π for $\{s_1^\pi, \dots s_i^\pi\}$. The elements are defined inductively, but as opposed to the previous section we need in addition indices $n_1, \dots, n_k$. Recall, previously we defined the $(i+1)$'th element r_{i+1}^π as the best increase in $\sigma(r_i^\pi, o_{i+1}^\pi]$. Here, we use n_{i+1} to describe the index of the element from E_{OPT} which constitutes the end of this interval. It is not necessarily o_{i+1}^π anymore. We always start with $n_1 = 1$, but based on different cases we either set $n_{i+1} = n_i + 1$ or $n_{i+1} = n_i$. We underline that n_i is independent of the realization of π. In the following, $t \in [0,1]$ denotes a parameter that we will specify later.

The element s_i^π will be chosen from two candidates u_i^π and v_i^π. The former is the best increase of elements excluding $o_{n_i}^\pi$, that is,

$$u_i^\pi = \begin{cases} \operatorname{argmax}_{e \in \sigma(-\infty, o_{n_1}^\pi)} f(e) & \text{if } i = 1, \\ \operatorname{argmax}_{e \in \sigma(s_i^\pi, o_{n_i}^\pi)} f(e \mid S_{i-1}^\pi) & \text{otherwise.} \end{cases}$$

The latter is defined in the same way, except it includes $o_{n_i}^\pi$ in the choices, that is,

$$v_i^\pi = \begin{cases} \operatorname{argmax}_{e \in \sigma(-\infty, o_{n_1}^\pi]} f(e) & \text{if } i = 1, \\ \operatorname{argmax}_{e \in \sigma(s_{i-1}^\pi, o_{n_i}^\pi]} f(e \mid S_{i-1}^\pi) & \text{otherwise.} \end{cases}$$

We now define the choice of s_i^π and n_{i+1} based on the following two cases. Note that the cases are independent from the realization of π.

Case 1: $\mathbb{E}_\pi\, f(u_i^\pi \mid S_{i-1}^\pi) \geqslant t \cdot \mathbb{E}_\pi\, f(o_{n_i}^\pi \mid S_{i-1}^\pi)$. In this case, we set $s_i^\pi = u_i^\pi$ and $n_{i+1} = n_i$. Notice that this means s_i^π is chosen independently from $o_{n_i}^\pi$. In other words, we did not see $o_{n_i}^\pi$, yet. The element $o_{n_i}^\pi$ is still each of the remaining elements in E_{OPT} with equal probability. In the analysis this is beneficial, because the distribution of $o_{n_i}^\pi, \dots, o_k^\pi$ remains unchanged. This is similar to the second case in the previous section.

Case 2: $\mathbb{E}_\pi\, f(u_i^\pi \mid S_{i-1}^\pi) < t \cdot \mathbb{E}_\pi\, f(o_{n_i}^\pi \mid S_{i-1}^\pi)$. Here, set $s_i^\pi = v_i^\pi$ and $n_{i+1} = n_i + 1$. Now the distribution of $o_i^\pi, \dots, o_k^\pi$ can change. However, a considerable value of s_i^π over different π comes from taking $o_{n_i}^\pi$. As indicated by the first case in the previous section this will improve the guarantee of the algorithm.

The solution S_k^π corresponds to a leaf in the tree algorithm. Clearly, u_1^π and v_1^π are children of the root. Hence, s_1^π is also a child. Then for induction we assume s_i^π is a node, which implies u_{i+1}^π and v_{i+1}^π are also nodes: The elements u_{i+1}^π and v_{i+1}^π are the first elements after s_i^π with the respective gains $(f(u_{i+1}^\pi \mid S_i^\pi)$ and $f(v_{i+1}^\pi \mid S_i^\pi))$. Hence, s_{i+1}^π is a child of s_i^π.

In order to bound $\mathbb{E}_\pi\, f(S_k^\pi)$, we will study more broadly all values of $\mathbb{E}_\pi\, f(S_h^\pi)$ where $h \leqslant k$. To this end, we define a recursive formula $R(k,h)$ and prove that it bounds $\mathbb{E}_\pi\, f(S_h^\pi)/\operatorname{OPT}$ from below. Then using basic calculus we will show that $R(k,k) \geqslant 0.5506$ for all k. Initialize $R(k,0) = 0$ for all k. Then let $R(k,h)$, $h \leqslant k$, be defined by

$$R(k,h) = \min\left\{ \frac{t}{k} + \left(1 - \frac{t}{k}\right) R(k, h-1)\,,\ \frac{1}{k} + \left(1 - \frac{1+t}{k}\right) R(k-1, h-1)\,,\ \frac{1}{1+t} \right\}.$$

▶ **Lemma 4.** *For all instances of the problem and $h \leqslant k$, the solution S_h^π as defined above satisfies $\mathbb{E}_\pi\, f(S_h^\pi) \geqslant R(k,h)\operatorname{OPT}$.*

Proof. The proof is by induction over h. For $h = 0$, the statement holds as $R(k, 0)\,\mathrm{OPT} = 0 = \mathbb{E}_\pi\, f(S_0^\pi)$. Let $h > 0$ and suppose the statement of the lemma holds with $h - 1$ for all instances of the problem. Suppose we are given an instance with $k \geqslant h$. We distinguish the two cases $s_1^\pi = u_1^\pi$ and $s_1^\pi = v_1^\pi$.

First, consider $\mathbb{E}_\pi\, f(u_1^\pi) \geqslant t \cdot \mathbb{E}_\pi\, f(o_1^\pi)$, which implies that $s_1^\pi = u_1^\pi$. Note that u_1^π is the best element in $\sigma(-\infty, o_1^\pi)$, consequently, its choice is independent from the realization of π. Let us drop the superscript in u_1^π and s_1^π for clarity. We construct a new instance mimicking the subtree of s_1. Formally, our new instance still has the same k elements E_{OPT}, i.e., $k' = k$. The stream is $\sigma' = \sigma(s_1^\pi, \infty)$ and, the submodular function $f' : 2^U \to \mathbb{R}$, $f'(T) \mapsto f(T \mid s_1)$. In this instance we have $\mathrm{OPT}' = f'(E_{\mathrm{OPT}}) = f(E_{\mathrm{OPT}} \mid s_1) \geqslant \mathrm{OPT} - f(s_1)$. It is easy to see that the elements $s_1'^\pi, \ldots, s_{h-1}'^\pi$ chosen in the new instance correspond exactly to the elements $s_2^\pi, \ldots, s_h^\pi$. Hence, with the induction hypothesis we get

$$\mathbb{E}_\pi\, f(S_h^\pi) = f(s_1) + \mathbb{E}_\pi\, f(S_h^\pi \mid s_1) = f(s_1) + \mathbb{E}_\pi\, f'(S_{h-1}'^\pi) \geqslant f(s_1) + R(k, h-1)(\mathrm{OPT} - f(s_1)).$$

By assumption we have $f(s_1) \geqslant t \cdot \mathbb{E}_\pi\, f(o_i^\pi) \geqslant t \cdot \mathrm{OPT}/k$. Together with $R(k, h-1) \leqslant 1/(1+t) \leqslant 1$ we calculate

$$f(s_1) + R(k, h-1)(\mathrm{OPT} - f(s_1)) \geqslant \frac{t}{k}\,\mathrm{OPT} + R(k, h-1)\left(1 - \frac{t}{k}\right)\mathrm{OPT}\,.$$

The right-hand side is by definition at least $R(k, h)\,\mathrm{OPT}$.

Now we turn to the case $\mathbb{E}_\pi\, f(u_1^\pi) < t \cdot \mathbb{E}_\pi\, f(o_1^\pi)$, which means $s_1^\pi = v_1^\pi$ is chosen. Similar to the previous case, we construct a new instance. After taking s_1^π, our new instance has $k' = k - 1$ elements $E'_{\mathrm{OPT}} = E_{\mathrm{OPT}} \setminus \{o_1^\pi\}$, stream $\sigma' = \sigma(s_1, \infty)$, and submodular function $f' : 2^E \to \mathbb{R}$, $f(T) \mapsto f(T \mid s_1^\pi)$. Thus, $\mathrm{OPT}' = f'(E'_{\mathrm{OPT}}) = f(E_{\mathrm{OPT}} \setminus \{o_1^\pi\} \mid s_1^\pi) \geqslant \mathrm{OPT} - f(s_1^\pi \cup o_1^\pi)$. We remove o_1^π from E_{OPT}, because $s_1^\pi = v_1^\pi$ depends on it. The distribution of $o_2^\pi, \ldots, o_k^\pi$ when conditioning on the value of o_1^π (and thereby the choice of s_1^π) is still a uniformly random permutation of E'_{OPT}. Like in the previous case, we can see that $S_{h-1}'^\pi = S_h^\pi \setminus \{s_1^\pi\}$ and we can apply the induction hypothesis. First, however, let us examine $\mathbb{E}_\pi\, f(s_1^\pi \cup o_1^\pi)$. Since we know that whenever $s_1^\pi \neq o_1^\pi$ we have $s_1^\pi = u_1^\pi$, it follows that

$$\mathbb{P}_\pi[s_1^\pi \neq o_1^\pi] \cdot \mathbb{E}_\pi[f(s_1) \mid s_1^\pi \neq o_1^\pi] \leqslant \mathbb{E}_\pi\, f(u_1^\pi) < t \cdot \mathbb{E}_\pi\, f(o_1^\pi) \leqslant t \cdot \mathbb{E}_\pi\, f(s_1^\pi).$$

Hence, we deduce

$$\mathbb{E}_\pi\, f(s_1^\pi \cup o_1^\pi) \leqslant \mathbb{E}_\pi\, f(o_1^\pi) + \mathbb{P}_\pi[s_1^\pi \neq o_1^\pi] \cdot \mathbb{E}_\pi[f(s_1) \mid s_1^\pi \neq o_1^\pi] \leqslant \mathbb{E}_\pi\, f(o_1^\pi) + t \cdot \mathbb{E}_\pi\, f(s_1^\pi).$$

We are ready to prove the bound on $\mathbb{E}_\pi\, f(S_h^\pi)$. By induction hypothesis, we get

$$\begin{aligned}\mathbb{E}_\pi\, f(S_h^\pi) &= \mathbb{E}_\pi\, f(s_1^\pi) + \mathbb{E}_\pi\, f'(S_{h-1}'^\pi)\\ &\geqslant \mathbb{E}_\pi\, f(s_1^\pi) + R(k-1, h-1)(\mathrm{OPT} - \mathbb{E}_\pi\, f(s_1^\pi \cup o_1^\pi)).\end{aligned}$$

Inserting the bound on $\mathbb{E}_\pi\, f(s_1^\pi \cup o_1^\pi)$ we know that the right-hand side is at least

$$\mathbb{E}_\pi\, f(s_1^\pi) + R(k-1, h-1)(\mathrm{OPT} - \mathbb{E}_\pi\, f(o_1^\pi) - t \cdot \mathbb{E}_\pi\, f(s_1^\pi)).$$

Using that $f(s_1^\pi) \geqslant f(o_1^\pi)$ for all π and $R(k-1, h-1) \cdot t \leqslant t/(1+t) \leqslant 1$ we bound the previous term from below by

$$\mathbb{E}_\pi\, f(o_1^\pi) + R(k-1, h-1)(\mathrm{OPT} - (1+t)\,\mathbb{E}_\pi\, f(o_1^\pi)).$$

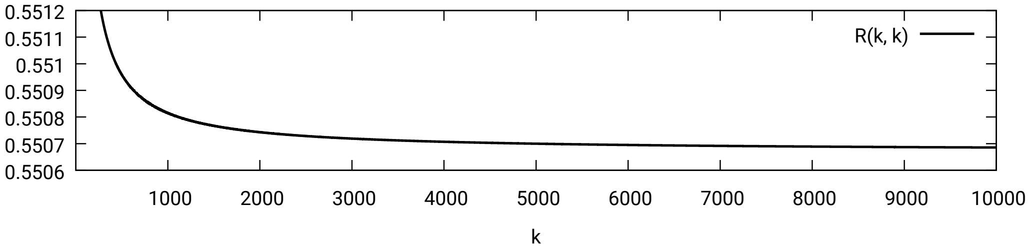

Figure 2 Values of the recurrence formula for $t = 0.8$.

Finally, we use that $\mathbb{E}_\pi f(o_1^\pi) \geqslant \mathrm{OPT}/k$ and $R(k-1, h-1)(1+t) \leqslant 1$ to arrive at

$$\frac{1}{k}\,\mathrm{OPT} + R(k-1,h-1)\left(\mathrm{OPT} - \frac{1+t}{k}\,\mathrm{OPT}\right) \geqslant R(k,h)\,\mathrm{OPT},$$

which concludes the proof. ◀

With $t = 0.8$ we are able to show that for sufficiently large k the minimum in the definition of $R(k,k)$ is always attained by the first term. Then, after calculating a lower bound on $R(k,k)$ for small values, we can easily derive a general bound.

▶ **Lemma 5.** *With $t = 0.8$ for all positive integers k it holds that $R(k,k) \geqslant 0.5506$.*

Figure 2 contains a diagram (generated by computer calculation), which shows that the formula tends to a value between 0.5506 and 0.5507 for $k \in \{0, \ldots, 10000\}$. The proof requires tedious and mechanical calculations and hence is omitted here. We refer the reader to the full version for complete details.

4 Conclusion and Open Problems

In this paper, we introduced a semi-random model called adversarial-injections with the motivation of eliminating algorithms that overfit to random-order streams while still being easier than adversarial-order streams. We studied two classical problems in combinatorial optimization in this model.

For unweighted matching, we could beat 1/2 in the streaming setting whereas we observed from [14] that we could not beat 1/2 in the online setting. This also makes our model non-trivial as there is a separation between the online and streaming setting.

For monotone submodular maximization with cardinality constraint k, we obtained a 0.55 approximation algorithm albeit with a huge memory footprint but importantly independent of n (universe size). The obvious open question is whether one can design a $(1-1/e)$-approximation algorithm which stores number of elements that is independent of n. Does our algorithm have an approximation ratio of $1-1/e$? We observed that the algorithm in [29] is a $1/2+\varepsilon$ approximation for a very small $\varepsilon > 0$. The algorithm stores $\mathrm{poly}(k)$ elements. Can one design an algorithm that stores only $\mathrm{poly}(k)$ elements and beats 1/2 by a significant constant or, even better, gets $1-1/e$?

Abstract

We give a randomized algorithm that finds a minimum cut in an undirected weighted m-edge n-vertex graph G with high probability in $O(m \log^2 n)$ time. This is the first improvement to Karger's celebrated $O(m \log^3 n)$ time algorithm from 1996. Our main technical contribution is a deterministic $O(m \log n)$ time algorithm that, given a spanning tree T of G, finds a minimum cut of G that 2-respects (cuts two edges of) T.

1 Introduction

The minimum cut problem is one of the most fundamental and well-studied optimization problems in theoretical computer science. Given an undirected edge-weighted graph $G = (V, E)$, the problem asks to find a subset of vertices S such that the total weight of all edges between S and $V \setminus S$ is minimized. The vast literature on the minimum cut problem can be classified into three main approaches:

The maximum-flow approach. The minimum cut problem was originally solved by computing the maximum st-flow [3] for all pairs of vertices s and t. In 1961, Gomory and Hu [10] showed that only $O(n)$ maximum st-flow computations are required, and in 1994 Hao and Orlin [11] showed that in fact a single maximum st-flow computation suffices. A maximum st-flow can be found in $O(mn \log(n^2/m))$ time using the Goldberg-Tarjan algorithm [9], and the fastest algorithm to date takes $O(mn)$ time [33, 22]. Faster (though not near-linear time) algorithms are known (see e.g [8, 25, 27] and references within) when the graph is unweighted or when the maximum edge weight W is not extremely large.

The edge-contraction approach. An alternative method is edge contraction. If we can identify an edge that does not cross the minimum cut, then we can contract this edge without affecting the minimum cut. Nagamochi and Ibaraki [30, 31] showed how to deterministically find a contractible edge in $O(m)$ time, leading to an $O(mn + n^2 \log n)$-time minimum cut algorithm. Karger [14] showed that randomly choosing the edge to contract works well with high probability. In particular, Karger and Stein [20] showed that this leads to an improved $O(n^2 \log^3 n)$ Monte Carlo algorithm.

The tree-packing approach. In 1961, Nash-Williams [32] proved that, in unweighted graphs, any graph with minimum cut c contains a set of $c/2$ edge-disjoint spanning trees. Gabow's algorithm [4] can be used to find such a tree-packing with $c/2$ trees in $O(mc \log n)$ time. Karger [18] observed that the c edges of a minimum cut must be partitioned among these $c/2$ spanning trees, hence the minimum cut *1-* or *2-respects* some tree in the packing. That is, one of the trees is such that at most two of its edges cross the minimum cut (these edges are said to *determine* the cut). We can therefore find the minimum cut by examining each tree and finding the minimum cut that 1- or 2-respects it.

Several obstacles need be overcome in order to translate this idea into an efficient minimum cut algorithm for weighted graphs: (1) we need a weighted version of tree-packing, (2) finding the packing (even in unweighted graphs) takes time proportional to c (and c may be large), (3) checking all trees takes time proportional to c, and (4) one needs an efficient algorithm that, given a spanning tree T of G, finds the minimum cut in G that 2-respects T (finding a minimum cut that 1-respects T can be easily done in $O(m+n)$ time, see e.g [18, Lemma 5.1]).

In a seminal work, Karger [18] overcame all four obstacles: First, he converts G into an unweighted graph by conceptually replacing an edge of weight w by w parallel edges. Then, he uses his random sampling from [16, 14] combined with Gabow's algorithm [4] to reduce the packing time to $O(m + n \log^3 n)$ and the number of trees in the packing to $O(\log n)$. Finally, he designs a deterministic $O(m \log^2 n)$ time algorithm that given a spanning tree T of G finds the minimum cut in G that 2-respects T. Together, this gives an $O(m \log^3 n)$ time randomized algorithm for minimum cut. Until the present work, this was the fastest known algorithm for undirected weighted graphs.

Karger's $O(m \log^2 n)$ algorithm for the 2-respecting problem finds, for each edge $e \in T$, the edge $e' \in T$ that minimizes the cut determined by $\{e, e'\}$. He used link-cut trees [35] to efficiently keep track of the sizes of cuts as the candidate edges e of T are processed in a certain order (bough decomposition), consisting of $O(\log n)$ iterations, and guarantees that the number of dynamic tree operations is $O(m)$ per iteration. Since each link-cut tree operation takes $O(\log n)$ time, the total running time for solving the 2-respecting problem is $O(m \log^2 n)$.

In a very recent paper, Lovett and Sandlund [26] proposed a simplified version of Karger's algorithm. Their algorithm has the same $O(m \log^3 n)$ running time as Karger's. To solve the 2-respecting problem they use top trees [1] rather than link-cut trees, and use heavy path decomposition [12, 35] to guide the order in which edges of T are processed. A property of heavy path decomposition is that, for every edge $(u, v) \notin T$, the u-to-v path in T intersects $O(\log n)$ paths of the decomposition. This property implies that the contribution of each non-tree edge to the cut changes $O(\log n)$ times along the the entire process. See also [6] who use the fact that the bough decomposition, implicitly used by Karger, also satisfies the above property. The idea of traversing a tree according to a heavy path decomposition, i.e., by first processing a smaller subtree and then processing the larger subtree has been used quite a few times in similar problems on trees. See e.g., [2]. While the ideas of Lovett and Sandlund [26] do not improve on Karger's bound, their paper has drawn our attention to this problem.

1.1 Our result and techniques

In this paper, we present a deterministic $O(m \log n)$ time algorithm that, given a spanning tree T of G, finds the minimum cut in G that 2-respects T. Using Karger's framework, this implies an $O(m \log^2 n)$ time randomized algorithm for minimum cut in weighted graphs.

Like prior algorithms for this problem, our algorithm finds, for each edge $e \in T$ the edge $e' \in T$ that minimizes the cut determined by $\{e, e'\}$. The difficult case to handle is when e and e' are such that neither of them is an ancestor of the other. In Karger's solution, handling each edge $e = (u, v) \in T$ was done using amortized $O(d \log n)$ operations on Sleator and Tarjan's link-cut trees [35] where d is the number of non-tree edges incident to u. Since operations on link-cut trees require $O(\log n)$ amortized time, the time to handle all edges is $O(m \log^2 n)$ (implying an $O(m \log^3 n)$ time algorithm for the minimum cut problem). As an open problem, Karger [18] asked (more than 20 years ago) whether the required link-cut tree operations can be done in constant amortized time per operation (implying an $O(m \log^2 n)$ time algorithm for the minimum cut problem). Karger even pointed out why one could perhaps achieve this: "*We are not using the full power of dynamic trees (in particular, the tree we are operating on is static, and the sequence of operations is known in advance).*" In this paper, we manage to achieve exactly that. We show how to order the link cut tree operations so that they can be handled efficiently in batches. We call such a batch a *bipartite problem* (see Definition 9).

Perhaps a reason that the running time of Karger's algorithm has not been improved in more than two decades is that it is not at all apparent that these bipartite problems can indeed be solved more efficiently. Coming up with an efficient solution to the bipartite problem requires a combination of several additional ideas. Like [26], we use heavy path decomposition, but in a different way. We develop a new decomposition of a tree that combines heavy path decomposition with biased divide and conquer, and use this decomposition in conjunction with a compact representation which we call topologically induced subtrees (see Definition 4). This compact representation turns out to be crucial not only for solving the bipartite problem, but also to the reduction from the original problem to a collection of bipartite problems.

1.2 Application to unweighted graphs

Karger's method is inherently randomized and obtaining a deterministic (or at least Las Vegas) near-linear time algorithm for the minimum cut in undirected weighted graphs is an interesting open problem. For unweighted graphs, such a deterministic algorithm was provided by Kawarabayashi and Thorup [21]. Later, Henzinger, Rao, and Wang [13] designed a faster $O(m \log^2 n (\log \log n)^2)$ time algorithm. Very recently Ghaffari, Nowicki and Thorup [7] introduced a new technique of random 2-out contractions and applied it to design an $O(\min\{m + n \log^3 n, m \log n\})$ time randomized algorithm that finds a minimum cut with high probability. We stress that the faster algorithms of Henzinger et al. and Ghaffari et al. work only for unweighted graphs, that is, for edge connectivity. Interestingly, the latter uses Karger's $O(m \log^3 n)$ time algorithm as a black box, and by plugging in our faster method one immediately obtains an improved running time of $O(\min\{m + n \log^2 n, m \log n\})$ for unweighted graphs.

1.3 Independent work

Independently to our work[1], Mukhopadhyay and Nanongkai [29] came up with an $O(m \log n + n \log^4 n)$ time algorithm for finding a minimal 2-respecting cut. While this improves Karger's bound for sufficiently dense graphs, it does not improve it for all graphs, and is randomized. Our algorithm uses a different (deterministic and simple) approach and strictly dominates both Karger's and Mukhopadhyay and Nanongkai's running time for all graphs. There are however benefits to the approach of [29] in other settings. Namely, they use it to obtain an algorithm that requires $\tilde{O}(n)$ cut queries to compute the min-cut, and a streaming algorithm that requires $\tilde{O}(n)$ space and $O(\log n)$ passes to compute the min-cut.

2 Preliminaries

2.1 Karger's algorithm

At a high level, Karger's algorithm [18] has two main steps. The input is a weighted undirected graph G. The first step produces a set $\{T_1, \ldots, T_s\}$ of $s = O(\log n)$ spanning trees such that, with high probability, the minimum cut of G 2-respects at least one of them. The second step deterministically computes for each T_i the minimum cut in G that 2-respects T_i. The minimum cut in G is the minimum among the cuts found in the second step.

Karger shows [18, Theorem 4.1] that producing the trees $\{T_1, \ldots, T_s\}$ in the first step can be done in $O(m + n \log^3 n)$ time, and that finding the minimum 2-respecting cut for all the T_i's in the second step can be done in $O(m \log^3 n)$ time. We will show that each of the steps can be implemented in $O(m \log^2 n)$ time. Showing this for the second step is the main result of the paper, and is presented in Section 3. For the first step, we essentially use Karger's proof. Since the first step was not the bottleneck in Karger's paper, proving a bound of $O(m + n \log^3 n)$ was sufficient for his purposes. Karger's concluding remarks suggest that he knew that the first step could be implemented in $O(m \log^2 n)$ time. For completeness, we prove the $O(m \log^2 n)$ bound by slightly modifying Karger's arguments and addressing a few issues that were not important in his proof. Readers proficient with Karger's algorithm can safely skip the proof.

▶ **Definition 1** (2-respecting and 2-constraining). *Given a spanning tree T and a cut $(S, \bar{S})$, we say that the cut 2-respects T and that T 2-constrains the cut if at most 2 edges of T cross the cut.*

▶ **Definition 2** (weighted tree packing). *Let G be an unweighted undirected graph. Let $\mathcal{T}$ be a set of spanning trees of G, where each tree $T \in \mathcal{T}$ is assigned a weight $w(T)$. We say that the* load *of an edge e of G (w.r.t. $\mathcal{T}$) is $\ell(e) = \sum_{T \in \mathcal{T} : e \in T} w(T)$. We say that $\mathcal{T}$ is a* weighted tree packing *if no edge has load exceeding 1. The* weight *of the packing $\mathcal{T}$ is $\tau = \sum_{T \in \mathcal{T}} w(T)$.*

▶ **Theorem 3.** *Given a weighted undirected graph G, in $O(m \log^2 n)$ time, we can construct a set $\mathcal{T}$ of $O(\log n)$ spanning trees such that, with high probability, the minimum cut 2-respects at least one of the trees in $\mathcal{T}$.*

Before proving the above theorem, we first describe how to precompute (in $O(m \log^2 n)$ time using Matula's algorithm [28]) a constant factor approximation of the weight c of the minimum cut in G.

[1] To be accurate, their work appeared on arXiv one day after ours.

Matula's algorithm [28]. Matula gave an $O(m/\epsilon)$ time algorithm that finds a $(2+\epsilon)$ approximation of the minimum cut in an unweighted graph G. The algorithm proceeds in iterations, where each iteration takes $O(m)$ time, and either finds a $(2+\epsilon)$ approximate cut, or produces a subgraph G' that contains the minimum cut of G, but has only a constant fraction of the edges of G. Hence there are $O(\log n)$ iterations, and the total running time is $O(m)$ for any fixed ϵ.

Matula's algorithm can be easily extended to the weighted setting. Each iteration can be implemented in $O(m \log n)$ time (cf. [15]), and produces a subgraph G' with a constant factor of the total edge weight of G. Thus, the algorithm produces a $(2+\epsilon)$ approximation of the minimum cut in a weighted graph G in $O(m \log n \log W)$ time, where W is the sum of edge weights in G.

The running time can be decreased to $O(m \log^2 n)$ at the expense of a worse constant factor approximation as follows. Let G be a weighted graph. Let c denote the weight of the minimum cut in G. Compute a maximum spanning tree T of G, and let w^* be the minimum weight of an edge in T. It is easy to see [17] that $w^* \leq c \leq n^2 w^*$. Contract all edges e with $w(e) > n^2 w^*$. Clearly, this does not affect the minimum cut. If $w^* \leq n^3$, then all edge weights are now bounded by n^5, and we can run Matula's algorithm in $O(m \log^2 n)$ time, and obtain a $(2+\epsilon)$-approximate minimum cut. Otherwise, set $\tilde{w}(e) \leftarrow \lfloor w(e)/\frac{w^*}{n^3} \rfloor$, and delete all edges with $\tilde{w} = 0$. Call the resulting graph $\tilde{G}$. Observe that $\tilde{G}$ has integer edge weights bounded by n^5, so we can find a $(2+\epsilon)$-approximate minimum cut in $\tilde{G}$ in $O(m \log^2 n)$ time. Now scale up the edge weights in $\tilde{G}$ by $\frac{w^*}{n^3}$. The weight of each edge in $\tilde{G}$ is now off from its original weight in G by at most $\frac{w^*}{n^3} \leq \frac{c}{n^3}$. Thus, the weights of any cut in $\tilde{G}$ and in G differ by at most c/n. Hence, an $(2+\epsilon)$-approximate minimum cut in $\tilde{G}$ is an $O(1)$-approximate minimum cut in G.

Proof of Theorem 3. Let $(S, \bar{S})$ be the partition of the vertices of G that forms a minimum cut. We assume that all weights are integers, each fitting in a single memory word. Since edges with weight greater than c never cross the minimum cut, we contract all edges with weight greater than our estimate for c, so that now the total weight of edges of G is $O(mc)$.

For the sake of presentation we think of an unweighted graph $\tilde{G}$, obtained from G by replacing an edge of weight w by w parallel edges. We stress that $\tilde{G}$ is never actually constructed by the algorithm. Let $\tilde{m}$ denote the number of edges of $\tilde{G}$. By the argument above, $\tilde{m} = O(mc)$. Let $p = \Theta(\log n/c)$. Let H be the unweighted multigraph obtained by sampling $\lceil p\tilde{m} \rceil$ edges of $\tilde{G}$ ($H = \tilde{G}$ if $c < \log n$). Clearly, the expected value of every cut in H is p times the value of the same cut in G. By [16, Lemma 5.1], choosing the appropriate constants in the sampling probability p guarantees that, with high probability, the value of every cut in H is at least $64/65$ times its expected value, and no more than $66/65$ times its expected value. It follows that, with high probability, (i) the minimum cut in H has value $c' = \Theta(\log n)$, and that (ii) the value of the cut in H defined by $(S, \bar{S})$ is at most $33c'/32$.

The conceptual process for constructing H can be carried out by randomly selecting $\lceil p\tilde{m} \rceil$ edges of G (with replacement) with probability proportional to their weights. Since the total edge weight of G is $O(mc)$, each selection can be easily performed in $O(\log(mc))$ time. Using a standard technique [24], each selection can actually be done with high probability in $O(\log m)$ time. Thus, the time to construct H is $O(p\tilde{m} \log m) = O(m \log^2 n)$. We emphasize that H is an unweighted multigraph with $m' = O(m \log n)$ edges, and note that we can assume no edge of H has multiplicity greater than c' (we can just delete extra copies).

Next, we apply the following specialized instantiation [36, Theorem 2] of Young's variant [38] of the Lagrangian packing technique of Plotkin, Shmoys, and Tardos [34]. It is shown [36, 38] that for an unweighted graph H with m' edges and minimum cut of size c', the following algorithm finds a weighted tree packing of weight $3c'/8 \leq \tau \leq c'$.

```
$\ell(e) := 0$ for all $e \in E(H)$
while there is no $e$ with $\ell(e) \geq 1$ do
    find a minimum spanning tree $T$ w.r.t. $\ell(\cdot)$
    $w(T) = w(T) + 1/(96 \ln m')$
    $\ell(e) = \ell(e) + 1/(96 \ln m')$ for all $e \in T$
end while
```

Karger [18, Lemma 2.3] proves that for a graph H with minimum cut c', any tree packing of weight at least $3c'/8$, and any cut $(S, \bar{S})$ of H of value at most $33c'/32$, at least a $1/8$ fraction of the trees (by weight) 2-constrain the cut $(S, \bar{S})$. Thus, a tree chosen at random from the packing according to the weights 2-constrains the cut $(S, \bar{S})$ with probability at least $1/8$. Choosing $O(\log n)$ trees guarantees that, with high probability, one of them 2-constrains the cut $(S, \bar{S})$, which is the minimum cut in G.

It remains to bound the running time of the packing algorithm. Observe that the algorithm increases the weight of some tree by $1/(96 \ln m')$ at each iteration. Since the weight τ of the resulting packing is bounded by c', there are at most $96c' \ln m' = O(\log^2 n)$ iterations. The bottleneck in each iteration is the time to compute a minimum spanning tree in H. We argue that this can be done in $O(m)$ time even though $m' = O(n \log n)$. To see this, first note that since H is a subgraph of G, H has at most m edges (ignoring multiplicities of parallel edges). Next note that it suffices to invoke the MST algorithm on a subgraph of H that includes just the edge with minimum load among any set of parallel edges. Since the algorithm always increases the load of edges by a fixed amount, the edge with minimum load in each set of parallel edges can be easily maintained in $O(1)$ time per load increase by maintaining a cyclic ordered list of each set of parallel edges and moving to choose the next element in this cyclic list whenever the load of the current element is incremented. Hence, we can invoke the randomized linear time MST algorithm [19] on a simple subgraph of H of size $O(m)$. It follows that the running time of the packing algorithm, and hence of the entire procedure, is $O(m \log^2 n)$. ◀

2.2 Link-cut trees

In our algorithm we will repeatedly use a structure that maintains a rooted tree T with costs on the edges under the following operations:

1. T.ADD(u, Δ) adds Δ to the cost of every edge on the path from u to the root,
2. T.PATH(u) finds the minimum cost of an edge on the path from u to the root,
3. T.SUBTREE(u) finds the minimum cost of an edge in the subtree rooted at u.

All three operations can be supported with a link-cut tree [35] in amortized $O(\log |T|)$ time.[2] We note that we only require these three operations and do not actually use the link and cut functionality of link-cut trees. Other data structures might also be suitable. See, e.g., the use of top-trees in [26].

[2] The original paper [35] did not include the third operation. However, as shown in [23, Appendix 17], it is not difficult to add it.

2.3 Topologically induced subtrees

For a rooted tree T and a node v we denote by T_v the subtree of T rooted at v. For an edge e of T we denote by T_e the subtree of T rooted at the lower endpoint of e.

Let T be a binary tree with edge-costs and n nodes, equipped with a data structure that can answer lowest common ancestor (LCA) queries on T in constant time [12]. Let $\Lambda = \{w_1, w_2, \ldots, w_s\}$ be a subset of nodes of T. We define a smaller tree T^Λ that is equivalent to T in the following sense:

▶ **Definition 4** (topologically induced tree). *We say that a tree T^Λ is topologically induced on T by Λ if for every $S \subseteq \Lambda$, the minimum cost edge $f \in T^\Lambda$ with $T^\Lambda_f \cap \Lambda = S$ has the same cost as the minimum cost edge $e \in T$ with $T_e \cap \Lambda = S$.*

To be clear, the above definition implies that, for any $S \subseteq \Lambda$, there is an edge $e \in T$ with $T_e \cap \Lambda = S$, if and only if there is an edge $f \in T^\Lambda$ with $T^\Lambda_f \cap \Lambda = S$. The term *topologically induced tree* will be justified by the construction in the following lemma.

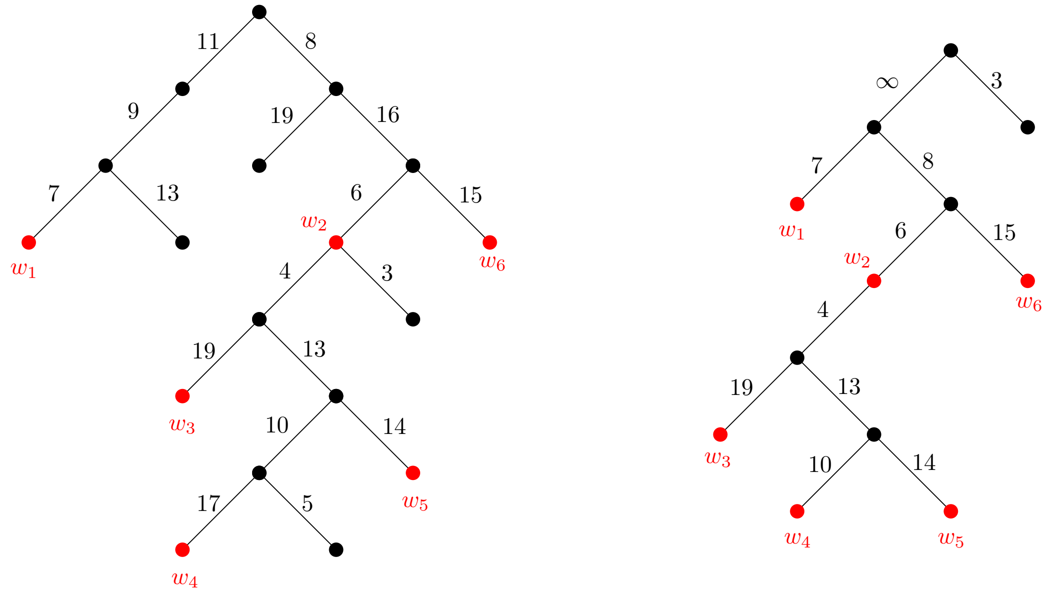

Figure 1 On the left: a tree and (in red) a set $\Lambda = \{w_1, w_2, \ldots, w_6\}$ sorted according to their preorder numbers. On the right: the corresponding topologically induced tree.

▶ **Lemma 5.** *There exists an algorithm that, given a binary tree T with edge costs, equipped with a link-cut data structure, and a list $\Lambda = \{w_1, w_2, \ldots, w_s\}$ of nodes of T, ordered according to their visit time in a preorder traversal of T, constructs in $O(\min\{|T|, s \log |T|\})$ time, a tree T^Λ of size $O(s)$ that is topologically induced on T by Λ.*

Proof. We define the tree T^Λ to be a tree over all nodes $w_i \in \Lambda$, together with the root and the lowest common ancestor in T of every pair of nodes w_i and w_j. For any two nodes $u, v \in T^\Lambda$, u is an ancestor of v in T^Λ if and only if u is an ancestor of v in T. Thus, each edge (u, v) of T^Λ corresponds to the u-to-v path in T. The edges on this path in T are exactly the edges e of T with $T_e \cap \Lambda = T^\Lambda_{(u,v)} \cap \Lambda$. Hence, the paths of T corresponding to distinct edges of T^Λ are edge disjoint. We define the cost of the edge (u, v) of T^Λ to be the minimum cost of an edge on the corresponding path in T. It follows that for every $\emptyset \neq S \subseteq \Lambda$, the minimum cost edge $f \in T^\Lambda$ with $T^\Lambda_f \cap \Lambda = S$ has the same cost as the minimum cost edge $e \in T$ with $T_e \cap \Lambda = S$. To guarantee that this condition holds for $S = \emptyset$ as well, we choose the edge e of T with the minimum cost such that $T_e \cap \Lambda = \emptyset$ and proceed as follows if such an edge exists. We create a new node v and change the root of T^Λ to v by making the old root of T^Λ a child of v via an edge with infinite cost. We then add a new edge incident to v, whose cost is set to the cost of e. This transformation does not change $T_e \cap \Lambda$ for any edge e of T^Λ, but now that condition with $S = \emptyset$ is satisfied for the new edge incident to the root.

We now turn to proving the construction time. We first prove that T^Λ consists of at most $2s$ nodes. This is because T^Λ consists only of the root, the nodes w_i and $\text{LCA}(w_i, w_{i+1})$. To see this, consider two nodes w_i and w_j with $i < j$ such that their lowest common ancestor u is different than w_i and w_j. Let u_ℓ (u_r) be the left (right) child of u. Then, w_i is a descendant of u_ℓ and w_j a descendant of u_r. Let i' be the largest index such that $w_{i'}$ is in the subtree rooted at u_ℓ. Then $u =$LCA$(w_{i'}, w_{i'+1})$.

We next prove that T^Λ can be constructed in $O(s)$ time. We use a method similar to constructing the Cartesian tree [37, 5] of a sequence: we scan $w_1, w_2, \ldots, w_s$ from the left to right while maintaining the subtree of T^Λ induced by $w_0 = \text{LCA}(w_1, w_s)$, and $w_1, w_2, \ldots, w_i$. initially, the subtree of T^Λ induced by w_0 and w_1 is just a single edge (w_0, w_1). We keep the rightmost path of the subtree of T^Λ induced by $w_0, w_1, \ldots, w_i$ on a stack, with the bottommost edge on the top. To process w_{i+1}, we first find $x = \text{LCA}(w_i, w_{i+1})$. Then, we pop from the stack all edges (u, v) such that u and v are both below (or equal to) x in T. Finally, we possibly split the edge on the top of the stack into two and push a new edge onto the stack. The amortized complexity of every step is constant, so the total time is $O(s)$.

Once T^Λ is constructed, we set the cost of every edge (u, v) in T^Λ to be the minimum cost of an edge on the u-to-v path in T. This can be done in $O(\log|T|)$ time per edge of T^Λ by first calling $T.\textsc{add}(u)(\infty)$, then $T.\textsc{path}(v)$ to retrieve the answer, and finally $T.\textsc{add}(u)(-\infty)$, for a total of $O(s \log|T|)$ time. Alternatively, we can explicitly go over the edges of the corresponding paths of T for every edge of T^Λ. We had argued above that these paths are disjoint so this takes $O(|T|)$ in total.

We also need to compute the cost of the edge e of T with minimum cost such that $T_e \cap \Lambda = \emptyset$. To this end, for each $v \in \Lambda$ we add ∞ to the cost of all edges on the path from v to the root of T. This takes $O(\min(|T|, s \log|T|)$ by either a bottom up computation on T, or using $T.\textsc{add}(u, \infty)$ for every $v \in \Lambda$. We then retrieve the edge with minimum cost in the entire tree in $O(\log|T|)$ time by a call to SUBTREE for the root of T, and then subtract ∞ from the cost of all edges on the path from v to the root of T for every $v \in \Lambda$. ◀

We will use the fact that the operation of taking the topologically induced subtree is composable in the following sense.

▶ **Proposition 6.** *Let T be a binary tree with edge-costs. Let $\Lambda_2 \subseteq \Lambda_1$ be subsets of nodes of T. Let T_1 be topologically induced on T by Λ_1 and T_2 be topologically induced on T_1 by Λ_2. Then T_2 is topologically induced on T_1 by Λ_2.*

3 Finding a Minimum 2-respecting Cut

Given a graph G and a spanning tree T of G, a cut in G is said to *2-respect* the tree T if at most two edges e, e' of T cross the cut (these edges are said to *determine* the cut). In this section we prove the main theorem of this paper:

▶ **Theorem 7.** *Given an edge-weighted graph G with n vertices and m edges and a spanning tree T, the minimum (weighted) cut in G that 2-respects T can be found in $O(m \log n)$ time.*

The minimum cut determined by every single edge can be easily found in $O(m+n)$ time [18, Lemma 5.1]. We therefore focus on finding the minimum cut determined by two edges. Observe that the cut determined by $\{e, e'\}$ is unique and consists of all edges $(u, v) \in G$ such that the u-to-v path in T contains exactly one of $\{e, e'\}$.

We begin by transforming T (in linear time) into a binary tree. This is standard and is done by replacing every node of degree d with a binary tree of size $O(d)$ where internal edges have weight ∞ and edges incident to leaves have their original weight. We also add an artificial root to T and connect it to the original root with an edge of weight ∞. From now we will be working with binary trees only.

3.1 Descendant edges

We first describe an $O(m \log n)$ time algorithm for finding the minimum cut determined by all pairs of edges $\{e, e'\}$ where e' is a descendant of e in T (i.e. e' is in the subtree of T rooted at the lower endpoint of e). To this end we shall efficiently find, for each edge e of T, the descendant edge e' that minimizes the weight of the cut determined by $\{e, e'\}$, and return the pair minimizing the weight of the cut.

For a given edge e of T, let T_e denote the subtree of T rooted at the lower endpoint of e. We associate with every node x a list of all edges (u, v) such that x is the lowest common ancestor of u and v. Note that all these lists can be computed in linear time, and form a partition of the edges of G. We also compute in $O(m)$ time, for every edge e of T, the total weight $A(e)$ of all edges with exactly one endpoint in T_e (in fact, this is the information computed by Karger's algorithm for the 1-respecting case). Note that $A(e)$ includes the weight of e.

Using a link-cut tree we maintain a *score* for every edge e of T. All scores are first initialized to zero. Then, for every edge (u, v) of G, we increase the score of all edges on the u-to-v path in T by the weight $w(u, v)$ of (u, v). This takes $O(\log n)$ time per edge (u, v) by calling $T.\textsc{add}(u, w(u, v))$, $T.\textsc{add}(v, (u, w(u, v))$ and $T.\textsc{add}(\mathrm{LCA}(u, v), -2(u, w(u, v))$. This initialization takes $O(m \log n)$ time. We then perform an Euler tour of T. When the tour first descends below a node x, for every edge (u, v) in the list of x, we decrease the score of all edges on the u-to-v path in T by $2w(u, v)$. Note that, at any point during this traversal, each edge (u, v) either contributes $w(u, v)$ or $-w(u, v)$ to the score of every edge on the u-to-v path in T, depending on whether the tour is yet to descend below $\mathrm{LCA}(u, v)$ or has already done so. As above, each update can be implemented in $O(\log n)$ time. Since every edge appears in exactly one list, the total time to perform all the updates is $O(m \log n)$.

▶ **Lemma 8.** *Consider the point in time when the Euler tour had just encountered an edge e for the first time. At that time, for every descendant edge e' of e, the weight of the cut determined by $\{e, e'\}$ is $A(e)$ plus the score of e'.*

Proof. Observe that the weight of the cut determined by $\{e, e'\}$ is the sum of weights of all edges with (1) one endpoint in $T_e - T_{e'}$ and the other not in T_e, or (2) one endpoint in $T_e - T_{e'}$ and the other in $T_{e'}$. Note that the edges satisfying (1) have exactly one endpoint in T_e, and hence their weight is accounted for in $A(e)$. However, $A(e)$ also counts the weight of edges (u, v) with one endpoint in $T_{e'}$ and the other not in T_e. Such edges do not cross the cut. Note that for such edges both e and e' are on the u-to-v path in T. The fact that e is on the u-to-v path implies that the traversal has already descended below $\mathrm{LCA}(u, v)$. Hence, (u, v) currently contributes $-w(u, v)$ to the score of e', offseting its contribution to

$A(e)$. Next note that the edges satisfying (2) are edges (u, v) with both u and v in T_e, which means that they are not accounted for in $A(e)$, and that the traversal did not yet descend below $\mathrm{LCA}(u, v)$. Hence the contribution of such an edge (u, v) to the score of e' is indeed the weight of (u, v). ◀

By the lemma, the descendant edge e' of e that minimizes the weight of the cut determined by $\{e, e'\}$ is the edge with minimum score in the subtree of e at that time. The score of this edge e' can be found in $O(\log n)$ time by calling $T.\textsc{subtree}(x)$, where x is the lower endpoint of e.

3.2 Independent edges

We now describe an $O(m \log n)$ time algorithm for finding the minimum cut determined by all pairs of edges $\{e, e'\}$ where e is *independent* of e' in T (i.e. e is not a descendant of e' and e' is not a descendant of e). We begin by showing that the problem can be reduced to the following *bipartite* problem:

▶ **Definition 9** (The bipartite problem). *Given two trees T_1 and T_2 with costs on the edges and a list of non-tree edges $L = \{(u, v) : u \in T_1, v \in T_2\}$ where each non-tree edge has a cost, find a pair of edges $e \in T_1$ and $e' \in T_2$ that minimize the sum of costs of e, of e', and of all non-tree edges $(u, v) \in L$ where u is in ${T_1}_e$, and v is in ${T_2}_{e'}$. The size of such a problem is defined as the number of non-tree edges in L plus the sizes of T_1 and T_2.*

▶ **Lemma 10.** *Given an edge-weighted graph G with n vertices and m edges and a spanning tree T, finding the minimum cut among those determined by a pair of independent edges $\{e, e'\}$ can be reduced in $O(m \log n)$ time to multiple instances of the bipartite problem of total size $O(m)$.*

Proof. Recall that every node w of T has at most two children. We create a separate bipartite problem for every node w of T that has exactly two children (x and y). This bipartite problem will be responsible for finding the minimum cut determined by all pairs of independent edges $\{e, e'\}$ where e is in T_x and e' is in T_y.

Throughout our description, note the distinction between edge weights and edge costs. The input graph G has edge weights, and the goal is to find the cut with minimum weight. The bipartite problems we define have edge costs, which are derived from the weights of edges in the input graph.

We initialize the cost of every edge of G to be zero. Then, for every edge $f = (u, v)$ of G, we add the weight of f to the cost of every edge on the u-to-v path. We maintain the costs in a link-cut tree so each f is handled in $O(\log n)$ time. Now consider any node w with exactly two children x and y, and any pair of independent edges $\{e, e'\}$ where e is in T_x and e' is in T_y. Observe that the edges crossing the cut determined by $\{e, e'\}$ are exactly the edges $f = (u, v)$ with one endpoint in T_e or in $T_{e'}$, and the other endpoint not in T_e nor in $T_{e'}$. Hence, the weight of the cut determined by $\{e, e'\}$ equals the sum of the cost of e plus the cost of e' minus twice the total weight of all non-tree edges $f = (u, v)$ such that u is in T_e and v is in $T_{e'}$.

We therefore define the bipartite problem for w as follows: (1) T_1 is composed of the edge (w, x) and the subtree rooted at x with costs as described above, (2) T_2 is composed of the edge (w, y) and the subtree rooted at y with the costs as described above, and (3) for every non-tree edge $f = (u, v)$ with weight c such that $\mathrm{LCA}(u, v) = w$ the list of non-tree edges L includes (u, v) with cost $-2c$. By construction, the solution to this bipartite problem is the pair of independent edges e, e' with $e \in T_x$ and $e' \in T_y$ that minimize the weight of the cut in G defined by e and e'.

The only issue with the above bipartite problem is that the overall size of all bipartite problems (over all nodes w) might not be $O(m)$. This is because the edges of T might appear in the bipartite problems defined for more than a single node w. In order to guarantee that the overall size of all bipartite problems is $O(m)$, we construct a compact bipartite problem using the topologically induced trees of Lemma 5.

We construct in $O(m)$ time a constant-time LCA data structure [12] for T. In overall $O(m \log n)$ time, we construct, for each node $w \in T$ with exactly two children x and y:

1. A list L_w of all non-tree edges (u, v) with $\mathrm{LCA}(u, v) = w$.
2. A list $\Lambda_x = \{w, x\} \cup \{u : (u, v) \in L_w \text{ and } u \in T_x\}$, sorted according to their visit time in a preorder traversal of T.
3. A list $\Lambda_y = \{w, y\} \cup \{v : (u, v) \in L_w \text{ and } v \in T_y\}$, sorted according to their visit time in a preorder traversal of T.

These lists require $O(m)$ space and can be easily computed in $O(m \log n)$ time by going over the non-tree edges, because each non-tree edge is in the list L_w of a unique node w.

The list L for the compact bipartite problem is identical to the list L for the non-compact problem. The tree T_1° (T_2°) for the compact bipartite problem of w is the topologically tree induced on $(w, x) \cup T_x$ ($(w, y) \cup T_y$) by Λ_x (Λ_y). This is done in $O(|\Lambda_x| \log n)$ ($O(|\Lambda_y| \log n)$) time by invoking Lemma 5. It follows that the total time for constructing all compact bipartite problems is $O(m \log n)$ and the their total space is $O(m)$.

It remains to argue that the solution to the compact bipartite problem is identical to the solution to the non-compact one. Observe that the cost of a solution e, e' for the non-compact bipartite problem is the cost of e plus the cost of e' plus the cost of all edges in L with one endpoint in ${T_1}_e \cap \Lambda$ and the other endpoint in ${T_2}_{e'} \cap \Lambda$.

Consider now any pair of edges e and e' for the non-compact bipartite problem. By definition of topologically induced trees, the minimum cost edge $f \in T_1^\circ$ with ${T_1^\circ}_f \cap \Lambda = {T_1}_e \cap \Lambda$, has cost not exceeding that of e. An analogous argument holds for e' and an edge f' of T_2°. Hence, the cost of the optimal solution for the compact problem is not greater than that of the non-compact problem. Conversely, for any edge f in T_1°, there exists an edge e in T_1 with cost not exceeding that of f and ${T_1^\circ}_f \cap \Lambda = {T_1}_e \cap \Lambda$. Hence, the cost of the optimal solution for the compact problem is not less than that of the non-compact problem. It follows that the two solutions are the same. ◀

The proof of Theorem 7 follows from the above reduction and the following solution to the bipartite problem:

▶ **Lemma 11.** *A bipartite problem of size m can be solved in $O(m \log m)$ time.*

Proof. Recall that in the bipartite problem we are given two trees T_1 and T_2 with edge-costs and a list of non-tree edges $L = \{(u, v) : u \in T_1, v \in T_2\}$ where each non-tree edge has a cost. To prove the lemma, we describe a recursive $O(m \log m)$ time algorithm that finds, for every edge $e \in T_1$, the best edge $e' \in T_2$ (i.e. the edge e' that minimizes the sum of costs of e' and of all non-tree edges $(u, v) \in L$ where u in ${T_1}_e$ and $v \in {T_2}_{e'}$).

We begin by applying a standard heavy path decomposition [12] to T_1, guided by the number of non-tree edges: The *heavy* edge of a node of T_1 is the edge leading to the child whose subtree has the largest number of incident non-tree edges in L (breaking ties arbitrarily). The other edges are called *light*. The maximal sets of connected heavy edges define a decomposition of the nodes into *heavy paths*.

We define a *fragment* of the tree T_1 to be a subtree of T_1 formed by a contiguous subpath $u_1 - u_2 - \cdots - u_k$ of some heavy path of T_1, together with all subtrees hanging from this subpath via light edges. Given a fragment f, let $L(f) = \{(x_1, y_1), (x_2, y_2) \ldots, (x_\ell, y_\ell)\}$ be the set of edges (x, y) of L with $x \in f$. We define the induced subtree $T_2(f)$ to be the tree topologically induced on T_2 by the root of T_2 and $\{y_1, y_2, \ldots, y_\ell\}$. The size of $T_2(f)$ is $|T_2(f)| = O(|L(f)|)$. We also define a modified induced subtree $T'_2(f)$ as follows. Let $L_\downarrow(f)$ be the set of edges $(x, y) \in L$ with x in the subtree rooted at the heavy child of the last node u_k of the fragment f (if such a heavy child exists). Consider the tree T_2, where the cost of each edge e' of T_2 is increased by the total cost of all edges $(x, y) \in L_\downarrow(f)$, where y is in $T_{2e'}$. The modified induced subtree $T'_2(f)$ is defined as the tree topologically induced by the root of T_2 and $\{y_1, y_2, \ldots, y_\ell\}$ on this modified T_2.

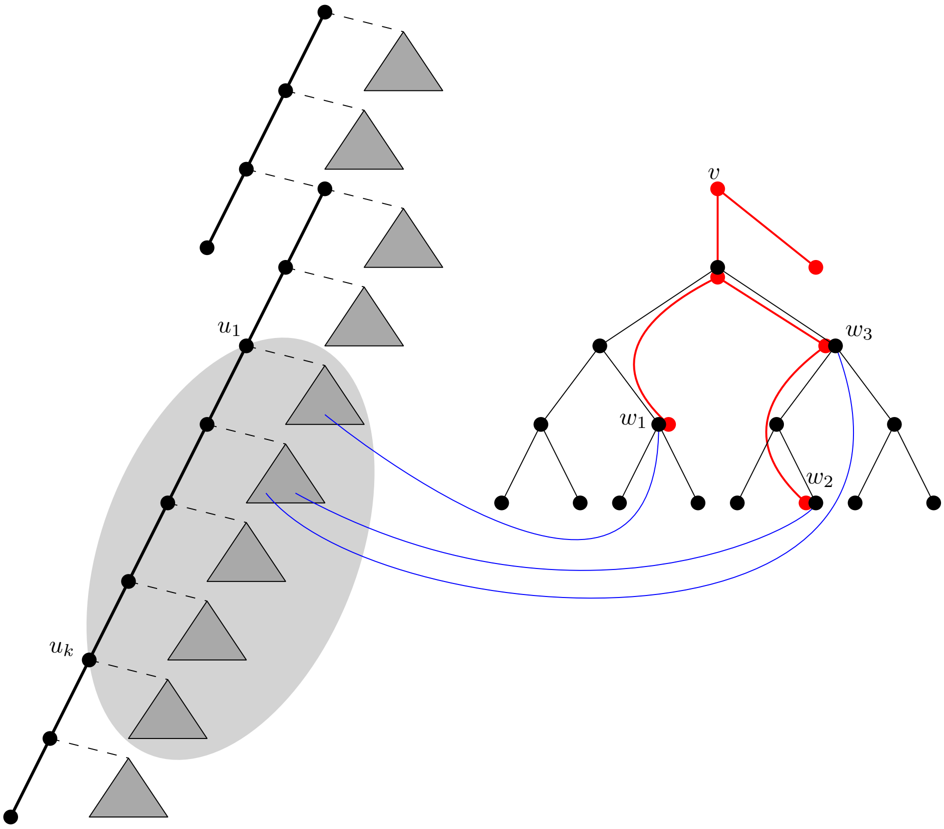

Figure 2 On the left: A fragment (in light gray) in the tree T_1, defined by the top node u_1 and the bottom node u_k, both laying on the same heavy path (solid edges). The triangles (in dark gray) are the subtrees hanging from the heavy paths via light edges (dashed). On the right: The tree T_2 (black) connected to the fragment via three non-tree edges (blue). The endpoints w_1, w_2, w_3 of these edges define the topologically induced tree (in red).

We are now ready to describe the recursion. The input to a recursive call is a fragment f of T_1 and the list $(x_1, y_1), (x_2, y_2), \ldots, (x_\ell, y_\ell)$ of all non-tree edges in L with x_i in f, together with $T_2(f)$ and $T'_2(f)$. A fragment f is specified by the *top* node (u_1) and the *bottom* node (u_k) of the corresponding subpath of a heavy path of T_1. In the first call, f is specified by the root of T_1 and the leaf ending the heavy path of T_1 that contains the root. That is, in the first call f is the entire tree T_1. The list of non-tree edges for the first call is the entire list L. The recursion works by selecting the *middle* node of the subpath, defined as follows: We define the *light size* s_i of node u_i as the number of non-tree edges $(x, y) \in L$ where either $x = u_i$ or x is in the subtree rooted at the light child of u_i. Note that $s_1 + s_2 + \ldots + s_k = |L(f)|$. If

$s_1 > |L(f)|/2$ then the middle node is defined as u_1. Otherwise, the middle node is defined as the node u_i such that $s_1 + \ldots + s_{i-1} \leq |L(f)|/2$ but $s_1 + \ldots + s_i > |L(f)|/2$. We keep, for every heavy path P of T_1 a list of the nodes of P with non-zero light size, ordered according to their order on P. We find the middle node u_i in $O(|L(f)|)$ time by going over the nodes in this list one after the other until we encounter the middle node.

After identifying the middle node u_i we apply recursion on the following three fragments: the fragment defined by subpath $u_1 - \cdots - u_{i-1}$, the fragment defined by subpath $u_{i+1} - \cdots - u_k$, and the fragment consisting of the entire subtree rooted at the light child of u_i. Before a recursive call to fragment g, we construct the appropriate $T_2(g)$ and $T_2'(g)$. The induced tree $T_2(g)$ can be computed from $T_2(f)$ in $O(|T_2(f)|) = O(|L(f)|)$ time by invoking Lemma 5 on $T_2(f)$ with $\Lambda_g = r \cup \{y : (x, y) \in L(g)\}$, where r is the root of T_2. Note that we had defined $T_2(g)$ as the topologically induced tree on T_2 by Λ_g, not on $T_2(f)$ by Λ_g. However, since $\Lambda_g \subseteq \Lambda_f$, by Proposition 6, the two definitions are equivalent.

For constructing $T_2'(g)$ from $T_2'(f)$, we first need to increase the cost of each edge $\tilde{e}$ of $T_2'(f)$ by the total cost of edges in $L_\downarrow(g) \setminus L_\downarrow(f)$ that are incident to $T_2'(f)_{\tilde{e}}$. This can be done in a single bottom up traversal of $T_2'(f)$ in $O(|T_2'(f)|)$ time. Then, we invoke Lemma 5 on $T_2'(f)$ with Λ_g to obtain $T_2'(g)$. To summarize, constructing the trees $T_2(g)$ and $T_2'(g)$ for all three recursive subproblems takes $O(|L(f)|)$ time.

The three recursive calls will take care of finding the best edge $e' \in T_2$ for every edge $e \in T_1$ included in one of the recursive problems. It only remains to handle the three edges that do not belong to any of the recursive problems; the edge between u_i and its light child, the edge (u_{i-1}, u_i), and the edge (u_i, u_{i+1}). For each such edge e we describe a procedure that finds its best $e' \in T_2(f)$ in time $O(|T_2(f)|)$.

Recall that, by definition of the bipartite problem, the best edge e' for e is the edge e' of T_2 minimizing the cost of e' plus the cost of all non-tree edges $(x, y) \in L$ with $x \in T_{1e}$, and $y \in T_{2e'}$. For the case where e is the edge between u_i and its light child, $T_{1e} = T_1(f)_e$. We therefore mark all non-tree edges $(x, y) \in L(f)$, where x is in $T_1(f)_e$. A non-efficient solution would work directly on T_2 by propagating, in a bottom up traversal of T_2, the cost of all marked edges so that, after the propagation, the cost of every edge e' in T_2 has been increased by the total cost of all non-tree edges $(x, y) \in L$ with $x \in T_1(f)_e$, and with $y \in T_{2e'}$. Then we can take the edge $e' \in T_2$ with minimum cost. However, this would take $O(|T_2|) = O(m)$, which is too slow. Instead, we perform the propagation in $T_2(f)$. Namely, in a bottom up traversal of $T_2(f)$, we propagate the cost of all marked edges so that, after the propagation, the cost of every edge e' in $T_2(f)$ has been increased by the total cost of all non-tree edges $(x, y) \in L(f)$ with $x \in T_1(f)_e$, and with $y \in T_2(f)_{e'}$. This takes $O(|T_2(f)|) = O(|L(f)|)$ time. Since the propagation process affects all the edges $\tilde{e}$ with the same $T_{2\tilde{e}} \cap \Lambda_f$ in the same way, the definition of topologically induced tree guarantees that the edges with minimum cost in T_2 and in $T_2(f)$ have the same cost, so using $T_2(f)$ instead of T_2 is correct.

The procedure for the cases where e is the edge (u_{i-1}, u_i) or (u_i, u_{i+1}) is identical, except that we apply it with $T_2'(f)$ instead of $T_2(f)$. This difference stems from the fact that applying the above procedure on $T_2(f)$ only considers the costs of the non-tree edges in $L(f)$, but not the costs of the non-tree edges in $L_\downarrow(f)$, which might also cross cuts involving the edges (u_{i-1}, u_i) or (u_i, u_{i+1}). The definition of the costs of edges in $T_2'(f)$ takes into account the contribution of costs of non-tree edges in $L_\downarrow(f)$. The rest of the propagation procedure and the proof of its correctness remain unchanged.

To analyze the overall running time, let $T(m)$ be the time to handle a fragment f corresponding to a whole heavy path, and $T'(m)$ be the time to handle a fragment f corresponding to a proper subpath of some heavy path, where $m = |L(f)|$. Then $T(m) =$

$T'(m_1)+T(m_2)+T'(m_3)$ for some m_1, m_2, m_3, where $m_1+m_2+m_3=m$ since the subproblems are disjoint, $m_1, m_3 \le m/2$ by the choice of the middle node, and $m_2 \le m/2$ by the definition of a heavy path. This is since the light child of u_i does not have more incident non-tree edges in its subtree than the number of non-tree edges incident to the subtree of the heavy child u_{i+1}. When f corresponds to a whole heavy path the number of non-tree edges incident to the subtree of u_{i+1} is exactly m_3. Similarly, for the case where f does not correspond to a whole heavy path, $T'(m)=T'(m_1)+T(m_2)+T'(m_3)$ for some m_1, m_2, m_3, where $m_1+m_2+m_3=m$ and $m_1, m_3 \le m/2$ (but now we cannot guarantee that $m_2 \le m/2$). Considering the tree describing the recursive calls, on any path from the root (corresponding to the fragment consisting of the whole T_1) to a leaf, we have the property that the value of m decreases by at least a factor of 2 every two steps. Hence, the depth of the recursion is $O(\log m)$. It follows that the total time to handle a bipartite problem of size m is $O(m\log m)$. ◀

Abstract

In this paper we consider the following *sparse recovery* problem. We have query access to a vector $\mathbf{x} \in \mathbb{R}^N$ such that $\hat{\mathbf{x}} = \mathbf{F}\mathbf{x}$ is k-sparse (or nearly k-sparse) for some orthogonal transform $\mathbf{F}$. The goal is to output an approximation (in an ℓ_2 sense) to $\hat{\mathbf{x}}$ in sublinear time. This problem has been well-studied in the special case that $\mathbf{F}$ is the Discrete Fourier Transform (DFT), and a long line of work has resulted in sparse Fast Fourier Transforms that run in time $O(k \cdot \text{polylog} N)$. However, for transforms $\mathbf{F}$ other than the DFT (or closely related transforms like the Discrete Cosine Transform), the question is much less settled.

In this paper we give sublinear-time algorithms – running in time $\text{poly}(k \log(N))$ – for solving the sparse recovery problem for orthogonal transforms $\mathbf{F}$ that arise from *orthogonal polynomials*. More precisely, our algorithm works for any $\mathbf{F}$ that is an orthogonal polynomial transform derived from *Jacobi polynomials*. The Jacobi polynomials are a large class of classical orthogonal polynomials (and include *Chebyshev* and *Legendre* polynomials as special cases), and show up extensively in applications like numerical analysis and signal processing. One caveat of our work is that we require an assumption on the sparsity structure of the sparse vector, although we note that vectors with random support have this property with high probability.

Our approach is to give a very general reduction from the k-sparse sparse recovery problem to the 1-sparse sparse recovery problem that holds for any flat orthogonal polynomial transform; then we solve this one-sparse recovery problem for transforms derived from Jacobi polynomials. Frequently, sparse FFT algorithms are described as implementing such a reduction; however, the technical details of such works are quite specific to the Fourier transform and moreover the actual implementations of these algorithms do not use the 1-sparse algorithm as a black box. In this work we give a reduction that works for a broad class of orthogonal polynomial families, and which uses any 1-sparse recovery algorithm as a black box.

Acknowledgements We would like to thank Mark Iwen for useful conversations. Thanks also to Stefan Steinerberger for showing us the proof of a number theory lemma we used in the 1-sparse Jacobi solver and graciously allowing us to use it, and to Clément Canonne for helpful comments on our manuscript. We also thank Eric Winsor for pointing out an error in a lemma in an earlier version of this paper. Thanks also to anonymous reviewers who pointed out some missing references and whose comments improved the presentation of the paper.

1 Introduction

In this paper, we consider the following *sparse recovery* problem. Suppose that we have query access to a vector $\mathbf{x} \in \mathbb{R}^N$, which has the property that for a fixed *orthogonal transform matrix* $\mathbf{F}$, $\hat{\mathbf{x}} = \mathbf{F}\mathbf{x}$ is k-sparse (or approximately k-sparse, in the sense that $\hat{\mathbf{x}}$ is close in ℓ_2 distance to a k-sparse vector). The goal is to recover an approximation $\hat{\mathbf{z}}$ to $\hat{\mathbf{x}}$, so that $\|\hat{\mathbf{x}} - \hat{\mathbf{z}}\|_2$ is small with high probability, as quickly as possible.

Variants of this problem have been studied extensively over several decades – we refer the reader to the book [16] for many examples and references. One particularly well-studied example is the *sparse Fast Fourier Transform* (sFFT) – see the survey [18] and the references therein. In this case, the matrix $\mathbf{F}$ is taken to be the Discrete Fourier Transform (DFT) and a long line of work has produced near-optimal results: algorithms with running time $O(k \operatorname{polylog}(N))$ and sample complexity $O(k \log N)$ [8, 9, 19, 23–27]– though not all of these works achieve both the claimed sample complexity and runtime at the same time.

We study the sparse recovery problem for a more general class of transforms $\mathbf{F}$ called *orthogonal polynomial transforms,* and in particular those that arise from *Jacobi polynomials,* a broad class of orthogonal polynomials (OPs). Jacobi polynomials include as special cases many familiar families of OPs, including Gegenbauer and in particular Chebyshev, Legendre, and Zernike[1] polynomials, and the corresponding OP transforms appear throughout numerical analysis and signal processing.

Despite the progress on the sFFT described above, much remains unknown for general orthogonal polynomial transforms. As discussed more in Section 1.2 below, the *sample complexity* of the sparse recovery problem is well understood, and the "correct" answer

[1] To be more precise the *radial* component of a Zernike polynomial is a Gegenbauer and hence, a Jacobi polynomial.

is known to be $\Theta(k\,\mathrm{polylog}(N))$ queries to $\mathbf{x}$. However, the algorithmic results that go along with these sample complexity bounds result in $\mathrm{poly}(N)$ time algorithms. Our goal in this work will be *sublinear* time algorithms as well as sublinear sample complexity. There are sublinear-time algorithms available for the special cases of Chebyshev and Legendre polynomials that work by essentially reducing to the Fourier case [21]. For general Jacobi polynomials, such reductions are not available. We elaborate in the full version of the paper why reducing general Jacobi polynomials to the Fourier case does not seem easy. There are also algorithms based on Prony's method, some of which work for quite general families of OPs [29]. However these general results require exact sparsity; to the best of our knowledge versions of Prony's method that are provably robust to noise are restricted to classes of OPs similar to the Fourier transform.

Results

In this work, we give the first (to the best of our knowledge) sublinear-time algorithms with provable guarantees for the (approximately-)sparse recovery problem for general orthogonal transforms derived from Jacobi polynomials. We discuss our results in more detail in Section 3 and briefly summarize them here. Our algorithms run in time $\mathrm{poly}(k\log(N))$ and given query access to $\mathbf{v} = \mathbf{F}^{-1}\hat{\mathbf{v}}$, can find approximations to $\hat{\mathbf{v}}$ when $\hat{\mathbf{v}}$ is approximately k-sparse of an appropriate form. More precisely, we can handle vectors $\hat{\mathbf{v}} = \hat{\mathbf{x}} + \hat{\mathbf{w}}$ where $\hat{\mathbf{x}}$ is k-sparse with a "spread-out" support (made precise in Definition 2.3), and $\hat{\mathbf{w}}$ is an adversarial noise vector with sufficiently small ℓ_2 norm. We obtain guarantees of the following flavor: for any such vector $\mathbf{v}$, we can find $\hat{\mathbf{z}}$ such that $\|\hat{\mathbf{z}} - \hat{\mathbf{x}}\|_2 \leq 0.01\|\hat{\mathbf{x}}\|_2$ with high probability.

We note that these results are weaker than the results for the sFFT: our sample complexity and running time are polynomially larger, and we need stronger assumptions on the sparse signals. However, we also note that the decade or so of work on the sFFT culminating in the results above began with similar results (see [17], for example, in which the dependence on k is an unspecified polynomial) and we hope that this work will similarly be a first step towards near-optimal algorithms for general orthogonal polynomial transforms.

Techniques

Our techniques follow the outline of existing algorithms for the sFFT, although as we elaborate on in Section 1.3, the situation for general Jacobi polynomials is substantially more complicated. More precisely, we first give a very general reduction, which reduces the k-sparse case to the 1-sparse case. The idea of such a reduction was implicit in the sFFT literature, but previous work has relied heavily on the structure of the DFT. Our reduction applies to a broad class of OPs including Jacobi polynomials. Next, we show how to solve the 1-sparse recovery problem for general Jacobi polynomials. The basic idea is to use known approximations of Jacobi polynomial evaluations by certain cosine evaluations [35] in order to iteratively narrow down the support of the unknown 1-sparse vector. We give a more detailed overview of our techniques in Section 1.3.

Organization

For the rest of the introduction, we briefly introduce orthogonal polynomial transforms, discuss previous work, and give a high-level overview of our approach. After that we introduce the formal notation and definitions we need in Section 2, after which we state our results more formally in Section 3.

Due to space constraints, proofs of our main results are in the full version of the paper, including the reduction from k to 1-sparse recovery, the 1-sparse recovery algorithm for Jacobi polynomials, and the resulting k-sparse recovery algorithm for Jacobi polynomials.

1.1 Orthogonal Polynomial Transforms

Orthogonal polynomials (OPs) play an important role in classical applied mathematics, mathematical physics, and the numerical analysis necessary to simulate solutions to such problems. We give more precise definitions in Section 2; briefly, a family of orthogonal polynomials $p_0(X), p_1(X), \ldots$ is a collection of polynomials defined on an interval $\mathcal{D}$ of $\mathbb{R}$, that are pairwise orthogonal with respect to a (non-negative) weight function w.

Orthogonal polynomials naturally give rise to (discrete) orthogonal polynomial transforms. In particular, we define the transform as follows– $\mathbf{F}$ is an $N \times N$ matrix, with each column corresponding to an orthogonal polynomial $p_0, \ldots, p_{N-1}$ and each row an evaluation point $\lambda_0, \ldots, \lambda_{N-1}$ in a suitable domain and suitably normalized so that it is an orthogonal matrix (Definition 2.1). A familiar example might be the DFT: in this language, the DFT matrix is defined by the polynomials $1, X, X^2, \ldots, X^{N-1}$, evaluated at points $\lambda_j = \omega^j$ where ω is the Nth root of unity.[2] Like the Fourier Transform, it is known that all OP transforms admit "fast" versions, allowing matrix-vector multiplication in time $O(N \log^2(N))$ [15].[3] Thus, our problem of sparse recovery for OP transforms is a natural extension of the sFFT problem, with applications to several areas mentioned below.

In this work we study *Jacobi polynomials* (defined formally in Section 2), which are a very general class of orthogonal polynomials. These include Chebyshev polynomials, Legendre polynomials, Zernike polynomials and more generally Gegenbauer polynomials. These OP families show up in many places. For example, Zernike polynomials are a family of orthogonal polynomials on the unit disk that permit an analytic expression of the 2D Fourier transform on the disk. They are used in optics and interferometry [36]. They can be utilized to extract features from images that describe the shape characteristics of an object and were recently used for improved cancer imaging [39]. Different families of orthogonal polynomials give rise to different quadrature rules for numerical integration [12, 33]. Specifically, Chebyshev polynomials are used for numerical stability (see e.g. the ChebFun package [3]) as well as approximation theory (see e.g. Chebyshev approximation [1]). Chebyshev polynomials also have certain optimal *extremal* properties, which has resulted in many uses in theoretical computer science, including in learning theory, quantum complexity theory, linear systems solvers, eigenvector computation, optimization, and more [28]. Further, Jacobi polynomials form solutions of certain differential equations [2].

More recently, orthogonal polynomials and orthogonal polynomial transforms have found applications in various facets of machine learning. For example, Dao et al. [13] leverage the connection between orthogonal polynomials and quadrature to derive rules for computing

[2] We note that in this work we consider a setting slightly different than this example, where $\mathcal{D} = [-1, 1]$ rather than $\mathbf{S}^1$.

[3] We note that even though the work of [15] has in some sense solved the problem of computing any OP transform in near-linear time, many practical issues still remain to be resolved and the problem of computing OP transforms in near-linear time has seen a lot of research activity recently. We just mention two recent works [6, 7] that present near-linear time algorithms for the Jacobi polynomial transforms (and indeed their notion of *uniform Jacobi transform* corresponds exactly to the Jacobi polynomial transform that we study in this paper). However, these algorithms inherently seem to require at least linear-time and it is not clear how to convert them into sub-linear algorithms, which is the focus of our work.

kernel features in machine learning. The Legendre Memory Unit [38] augments recurrent neural networks by orthogonalizing the history of features on a sliding Legendre basis; mathematically, this is essentially an online update of the discrete Legendre Transform. More directly, Thomas et al. [37] apply parametrized families of structured matrices directly inspired by orthogonal polynomial transforms (De Sa et al. [14]) as layers in neural networks. In this context, *any* form of structured matrix that admits fast operations is valuable, such as those considered in this work. Although not directly applied yet, all of these applications have a natural way of incorporating *sparsity* if the appropriate sparse transforms exist, which is a particular focus of modern ML in the face of sharply increasing trends in computation.

1.2 Related Work

As previously described, there has been a great deal of work on the sFFT; we refer the reader to the survey [18] for an overview. There has also been work on non-Fourier OP transforms. We break up our discussion below into discussion on the *sample complexity* (which as mentioned above is largely settled) and the *algorithmic complexity* (which remains largely open).

Sample complexity

The sample complexity of OP transforms $\mathbf{F}$ has been largely pinned down by the *compressed sensing* literature. For example, suppose that $\mathbf{F} \in \mathbb{R}^{N \times N}$ is any orthogonal and sufficiently flat matrix, in the sense that none of the entries of $\mathbf{F}$ are too large. Then a result of Haviv and Regev (sharpening of results by Bourgain, and Rudelson and Vershynin) shows that $m = O(k \log^2 k \log N)$ samples suffice to establish that the matrix $\Phi \in \mathbb{R}^{m \times N}$ (which is made up of m sampled rows from $\mathbf{F}^T$) has the *Restricted Isometry Property* (RIP) [5,20,34]. Finding $\hat{\mathbf{x}} = \mathbf{F}\mathbf{x}$ from samples of $\mathbf{F}$ of corresponds to the problem of finding an (approximately) k-sparse vector $\hat{\mathbf{x}}$ from the linear measurements $\Phi\hat{\mathbf{x}}$, which is precisely the compressed sensing problem. It is known that if Φ satisfies the RIP, then this can be solved (for example with ℓ_1 minimization) in time $N^{O(1)}$. On the other hand, recent results by Błasiok et al. show that this is essentially tight when $\mathbf{F}$ are certain Fourier matrices over constant sized prime finite fields, such as the Hadamard matrix, in that $O(k \log k \log N)$ queries (for a certain range of k) to $\mathbf{x}$ are needed to compute a k-sparse approximation of $\mathbf{F}\mathbf{x}$ [4].

Foucart and Rauhut [16] show that if the orthogonal polynomials satisfy a Bounded Orthogonal System (BOS) that are suitably flat, then if the m evaluation points λ_j are chosen uniformly at random proportional to the weight function w, then the $m \times N$ matrix Φ defined by normalizing $\mathbf{P}_N[i,j] = p_j(\lambda_i)$ appropriately satisfies the RIP with high probability provided that m has an appropriate dependence on N, k, ϵ, and the flatness of the matrix, and this again gives an $N^{O(1)}$-time algorithm to solve the sparse recovery problem.

Rauhut and Ward [32] show that for Jacobi polynomial transforms if the evaluation points were picked according to the *Chebyshev measure*, then with $O(k\,\mathrm{polylog} N)$ random measurements, the corresponding matrix has the RIP (note that the Foucart and Rauhut sample the evaluation points according to the measure of orthogonality for the Jacobi polynomials, which in general is *not* the Chebyshev measure). This result again does not give a sub-linear time algorithm but was used in the result of [21] which we describe below.

While these approaches can give near-optimal sample complexity, they do not give sublinear-time algorithms. In fact, it is faster to compute $\hat{\mathbf{x}}$ exactly by computing $\mathbf{F}\mathbf{x}$, if we care only about the running time and not about sample complexity [15]. Thus, we turn our attention to sublinear-time algorithms.

Sublinear-time algorithms for OP transforms

There have been several works generalizing and building on the sFFT results mentioned above. One direction is to the multi-dimensional DFT (for example in [23,27]). Another direction is to apply the sFFT framework to orthogonal polynomials with similar structure. One example is Chebyshev polynomials and the Discrete Cosine Transform (DCT). It was observed in [21] that this can be reduced to sFFT in a black box manner, solving the sparse recovery problem for Chebyshev polynomials and the DCT. A second example of OP transforms which can essentially be reduced to the sFFT is *Legendre polynomials.* Hu et al. [21] seek to recover an unknown k-term Legendre polynomial (with highest magnitude degree limited to be $N/2$), defined on $[-1,1]$, from samples. They give a sublinear two-phase algorithm: in the first phase, they reduce k-sparse-Legendre to sFFT to identify a set of candidate Legendre polynomials. The second phase uses the RIP result for BOS to produce a matrix that is used to estimate the coefficients of the candidate Legendre polynomials. We note that in this work the setting is naturally continuous, while ours is discrete.

Choi et al. [10,11] study higher dimensions and obtain sublinear-time algorithms for more general harmonic expansions in multiple dimensions. These results complement our work. More precisely, that work shows how to use any algorithm for a univariate polynomial transform (the work in [11] needs these algorithms to have certain specific properties) to design an algorithm for a multi-variate polynomial transform where the multi-variate polynomials are products of univariate polynomials in the individual variables. Thus our improvements for univariate polynomial transforms can (potentially) be used with [10,11].

Finally, there are sparse OP transforms based on Prony's method. The work [29] extends Prony's method to a very general setting, including Jacobi polynomials, and gives an algorithm that requires only $O(k)$ queries to recover exactly k-sparse polynomials. However, these general results work only for exact sparsity and are in general not robust to noise. There has been work extending and modifying these techniques to settings with noise (for example, [22,30]), but to the best of our knowledge the only provable results for noise are for either the sFFT or closely related polynomial families. We note that [31] presents a Prony-like algorithm for Legendre and Gegenbauer polynomials and demonstrates empirically that this algorithm is robust to noise, although they do not address the question theoretically.

1.3 Technical overview

Our technical results have two main parts. First, inspired by existing approaches to the sFFT, we provide a general reduction from the k-sparse recovery problem to the 1-sparse recovery algorithm, which works for any family of OPs that is sufficiently "flat": that is, no entry of the matrix $\mathbf{F}$ is too large. Second, we provide a 1-sparse recovery algorithm for Jacobi polynomials. We give an overview of both parts below.

For what follows, let $\mathbf{F}$ be an orthogonal matrix. For simplicity in this overview we will assume that there is no noise. That is, we want to compute the exactly k-sparse $\hat{\mathbf{x}} = \mathbf{F}\mathbf{x}$ given query access to $\mathbf{x}$. However, we note that our final results do work for approximately k-sparse vectors $\hat{\mathbf{v}} = \hat{\mathbf{x}} + \hat{\mathbf{w}}$ provided that $\|\hat{\mathbf{w}}\|_2$ is sufficiently small.

1.3.1 Reduction to one-sparse recovery

We give a general reduction from the k-sparse recovery problem to the one-sparse recovery problem, which works for a broad class of OP families defined on a finite interval.[4] At a high level, the idea is as follows. Suppose that $\hat{\mathbf{x}} = \mathbf{Fx}$ is k-sparse and $\mathbf{b} \in \mathbb{R}^N$ is a "filter": at this stage it is helpful to think of it like a boxcar filter, so $\mathbf{b}$ is 1 on some interval I and zero outside of that interval. If we choose this interval randomly, we might hope to isolate a single "spike" of $\hat{\mathbf{x}}$ with $\mathbf{b}$: that is, we might hope that $\mathbf{D_b}\hat{\mathbf{x}}$ is one-sparse, where $\mathbf{D_b}$ is the diagonal matrix with $\mathbf{b}$ on the diagonal. Suppose that this occurs, so $\mathbf{y} = \mathbf{D_b}\hat{\mathbf{x}}$ is one sparse. In order to take advantage of this with a black-box solution to the one-sparse recovery problem $\hat{\mathbf{y}} = \mathbf{Fy}$, we would need query access to the vector $\mathbf{y} = \mathbf{F}^{-1}\mathbf{D_b}\hat{\mathbf{x}} = \mathbf{F}^{-1}\mathbf{D_b}\mathbf{Fx}$, while what we have is query access to $\mathbf{x}$. Thus, we would like to design $\mathbf{b}$ so that $\mathbf{F}^{-1}\mathbf{D_b}\mathbf{F}$ is *row-sparse*. This would allow us to query a position of $\mathbf{y} = \mathbf{F}^{-1}\mathbf{D_b}\hat{\mathbf{x}}$ using only a few queries from $\mathbf{x}$.

One of our main technical contributions is showing how to design such a vector $\mathbf{b}$, so that $\mathbf{b}$ approximates a boxcar filter and so that $\mathbf{F}^{-1}\mathbf{D_b}\mathbf{F}$ is row-sparse for *any* OP transform $\mathbf{F}$.

Then, given this filter, we can iteratively identify and subtract off "spikes" in $\hat{\mathbf{x}}$ until we have recovered the whole thing. Of course, the actual details are much more complicated than the sketch above. First, the one-sparse solver might have a bit of error, which will get propagated through the algorithm. Second, in our analysis the vector $\hat{\mathbf{x}}$ need not be exactly k-sparse. Third, $\mathbf{b}$ will only approximate a boxcar filter, and this is an additional source of error that needs to be dealt with. Complete details are in the full version of the paper.

For the reader familiar with the sFFT, this approach might look familiar: most sFFT algorithms work by using some sort of filter to isolate single spikes in an approximately sparse signal. Below, we highlight some of the challenges in extending this idea beyond the Fourier transform. Some of these challenges we have overcome, and one we have not (yet) overcome. We mention this last open challenge both because it explains the assumption we have to make on the sparsity structure of $\hat{\mathbf{x}}$, and also because we hope it will inspire future work.

Challenge 1: Choice of filter

One key difficulty in extending sFFT algorithms to general orthogonal polynomials is that the filters used in the sFFT approach are very specific to the Fourier transform. Indeed, much of the progress that has been made on that problem has been due to identifying better and better choices of filter specialized to the Fourier transform. In order to find filters that work for *any* OP family, we take a different approach and construct a filter out of low-degree Chebyshev polynomials. Then we use the orthogonality properties of the OP family to guarantee that $\mathbf{F}^{-1}\mathbf{D_b}\mathbf{F}$ has the desired sparsity properties.

Challenge 2: Explicit black-box reduction

Because our goal is generality (to as broad a class of OPs as possible), we give an explicit reduction that uses a 1-sparse solution as a black box. To the best of our knowledge, existing work on the sFFT does not explicitly do this: a reduction of this flavor is certainly implicit in many of these works, and even explicitly given as intuition, but we are not aware of an sFFT algorithm which actually uses a 1-sparse recovery algorithm as a black box.

[4] We note that our results do not (yet) work for the case when the orthogonality is defined over an infinite interval. In particular, our reduction does not work for the Hermite and Laguerre polynomials.

Challenge 3: Equi-spaced evaluation points

The evaluations points in DFT and the DCT are equispaced (in the angular space). This fact is crucially exploited in sFFT algorithms (as well as the reduction of DCT to DFT – see the full version of this paper for more details on the reduction). Unfortunately, the roots of Jacobi polynomials are no longer equally spaced. However, it is known that the roots of Jacobi polynomials are "spread out" (in a sense made below precise in Definition 2.2), and we show that this property is enough for our reduction. In fact, our reduction from k-sparse recovery to 1-sparse recovery works generally for any "flat" OP family with "spread out" roots.

(Open) Challenge 4: Permuting the coordinates of $\hat{\mathbf{x}}$

In the approach described above, we hoped that an interval I would "isolate" a single spike. In the sFFT setting, this can be achieved through a permutation of the coordinates of $\hat{\mathbf{x}}$. In our language, in the sFFT setting it is possible to define a random (enough) permutation matrix $\mathbf{P}$ so that $\mathbf{P}\hat{\mathbf{x}}$ has permuted coordinates, and so that $\mathbf{F}^{-1}\mathbf{D_b}\mathbf{P}\mathbf{F}$ is row-sparse – this argument crucially exploits the fact that the roots of unity are equispaced in the angle space. This means that not only can we sample from the one-sparse vector $\mathbf{D_b}\hat{\mathbf{x}}$, but also we can sample from $\mathbf{D_b}\mathbf{P}\hat{\mathbf{x}}$, and then there is some decent probability that any given spike in $\hat{\mathbf{x}}$ is isolated by $\mathbf{b}$. However, we have not been able to come up with (an approximation to) such a $\mathbf{P}$ that works in the general OP setting. This explains why we require the assumption that the support of $\hat{\mathbf{x}}$ be reasonably "spread out," so that we can hope to isolate the spikes by $\mathbf{b}$. This assumption is made precise in Definition 2.3. We note that if such a $\mathbf{P}$ were found in future work, this would immediately lead to an improved k-sparse recovery result for Jacobi polynomials, which would work for arbitrary sparse signals $\hat{\mathbf{x}}$.

1.3.2 A one-sparse recovery algorithm for Jacobi polynomials

With the reduction complete, to obtain a k-sparse recovery algorithm for general Jacobi polynomials we need to solve the one-sparse case. We give an overview of the basic idea here, with full details in the full version of the paper. First, we note that via well-known approximations of Jacobi polynomials [35], one can approximate the evaluation of any Jacobi polynomial at a point in $(-1, 1)$ by evaluating the cosine function at an appropriate angle. Using some standard local error-correcting techniques (for example, computing $\cos(A)$ via $\cos A = \frac{\cos(A+B)+\cos(A-B)}{2\cos B}$ for a random B), we reduce the 1-sparse recovery problem to computing some unknown value θ, corresponding to the index of the spike, from noisy values of $\cos(w\theta)$ for some integers $w \geq 1$, corresponding to evaluations of the Jacobi polynomials for this index. Since the reduction is approximate, some care has to be taken to handle some corner cases where the approximation does not hold. In particular, we have to figure out for which real numbers $y \in [0, N)$ does its orbit $\langle xy \rangle$ for $x \in \mathbb{Z}_N$ have small order. We give a result to handle this, which to the best of our knowledge (and somewhat surprisingly) seems to be new.[5] With this out of the way, our algorithm to compute the value of θ from the evaluations $\cos(w\theta)$ is based on the following idea. Assuming we already know $\cos(\theta)$ up to $\pm\epsilon$, we get a noisy estimate of θ (which lives in the range $\arccos(\cos(\theta) \pm \epsilon)$) and then use the evaluations at $w > 1$ to "dilate" the range where we know θ lies, reducing ϵ. We

[5] We thank Stefan Steinerberger for showing us a much simpler proof than our original more complicated proof, which also gave worse parameters.

proceed iteratively until the region of uncertainty is small enough that there are only $O(1)$ possibilities remaining, which we then prune out using the fact that $\mathbf{F}$ is orthogonal and flat, in the sense that none of its entries are too large. (We note that proving $\mathbf{F}$ is flat needs a bit of care. In particular, we need a sharper bound on Jacobi polynomials (than the cosine approximation mentioned above) in terms of Bessel functions to prove that *all* entries of $\mathbf{F}$ are small.) Similar ideas have been used for 1-sparse recovery for the DFT (for example, in [19]), although our situation is more complicated than the DFT because working with cosines instead of complex exponentials means that we lose sign information about θ along the way (though it is similar in spirit to the one-sparse recovery algorithm for DFT in [19]).

2 Background and Preliminaries

2.1 Notation

We use bold lower-case letters $(\mathbf{x}, \mathbf{y})$ for vectors and bold upper-case letters $(\mathbf{P}, \mathbf{F})$ for matrices. Non-bold notation x, y, U is used for scalars in $\mathbb{R}$. In general, if there is a given transform $\mathbf{F}$ we are considering, then the notation $\hat{\mathbf{x}} \in \mathbb{R}^N$ indicates $\mathbf{F} \cdot \mathbf{x}$. We use the notation $\mathbf{x}[i]$ or $\mathbf{X}[i,j]$ to index into a vector or matrix, respectively. All of our vectors and matrices are 0-indexed, i.e. the entries of a vector $\mathbf{x} \in \mathbb{R}^N$ are $\mathbf{x}[0], \dots, \mathbf{x}[N-1]$. We use $[N]$ to denote the set $\{0, \dots, N-1\}$. Given a subset $S \subset [N]$, we will denote the complement set (i.e. $[N] \setminus S$) by S^c.

Given a vector $\mathbf{x} \in \mathbb{R}^N$ and an integer $1 \leq s \leq N$, we define $\textsc{large}(s, \mathbf{x})$ to be the magnitude of the sth largest value in $\mathbf{x}$ (by absolute value).

For any vector $\mathbf{u} \in \mathbb{R}^N$, we define $\mathbf{D}_\mathbf{u} \in \mathbb{R}^{N \times N}$ as the diagonal matrix with $\mathbf{u}$ on its diagonal. For a diagonal matrix $\mathbf{D}$, and any real α we denote $\mathbf{D}^\alpha$ to denote the diagonal matrix with the (i,i) entry being $(\mathbf{D}[i,i])^\alpha$. Given a vector $\mathbf{x} \in \mathbb{R}^N$ and set $S \subseteq [N]$, $\mathbf{x}_S$ denotes the vector $\mathbf{x}$ where all entries out of S are masked to 0. For $\mathbf{x} \in \mathbb{R}^N$, $\mathrm{supp}(\mathbf{x}) \subseteq [N]$ denotes the support (i.e. the set of non-zero positions) of $\mathbf{x}$.

We use $x \pm h$ to refer to either the interval $[x-h, x+h]$ or a point in this interval, whichever is clear from context. Similarly, if S is an interval $[a,b]$ then $S \pm h$ is the interval $[a-h, b+h]$.

When stating algorithms, we use superscript notation to denote query access. That is $\mathcal{A}^{(\mathbf{x})}(\mathbf{z})$ takes input $\mathbf{z}$ and has query access to $\mathbf{x}$.

We use the notation $f(n) \lesssim g(n)$ to mean that there is some constant C so that, for sufficiently large $n \geq n_0$, $f(n) \leq Cg(n)$.

The notation $\mathcal{J}_\square$ means $\mathcal{J}_j$ for all indices j.

2.2 Orthogonal Polynomials

For the remainder of this paper, we consider polynomials $p_0(X), p_1(X), \dots$ that form a normalized orthogonal polynomial family with respect to some compactly supported measure $w(X)$. By suitably scaling and translating X, we can ensure that the orthogonality is on $[-1,1]$.[6] In particular $\deg(p_i) = i$ and for any $i, j \geq 0$,

$$\int_{-1}^{1} p_i(X) p_j(X) w(X) dX = \delta_{i,j}, \tag{1}$$

where $\delta_{i,j} = 1$ if $i = j$ and 0 otherwise.

[6] See footnote 4.

Then for given N evaluation points $\lambda_0, \dots \lambda_{N-1}$, define the orthogonal polynomial transform $\mathbf{P}_N$ as follows. For any $0 \le i, j < N$, we have

$$\mathbf{P}_N[i, j] = p_j(\lambda_i).$$

In other words, the rows of $\mathbf{P}_N$ are indexed by the evaluation points and the columns are indexed by the polynomials.

For the rest of the paper, assume $\lambda_0 \le \lambda_1 \le \cdots \le \lambda_{N-1}$ are the roots of $p_N(X)$. Then it is well-known (see e.g. [35]) that

- The roots lie in the support of the measure (i.e. $\lambda_i \in [-1, 1]$) and are distinct (i.e. $\lambda_0 < \lambda_1 < \cdots < \lambda_{N-1}$).
- There exists Gaussian quadrature weights $w_\ell = \frac{1}{\sum_{j=0}^{N-1} p_j(\lambda_\ell)^2}, i = 0, \dots, N-1$ such that for any polynomial $f(X)$ of degree at most $2N-1$,

$$\int_{-1}^{1} f(X)w(X)dX = \sum_{\ell=0}^{N-1} f(\lambda_\ell) \cdot w_\ell. \tag{2}$$

We are now ready to define the orthogonal matrix corresponding to $\mathbf{P}_N$ that we deal with in this paper:

▶ **Definition 2.1.** *Let $p_0(X), \dots, p_{N-1}(X), \dots$ be an orthogonal polynomial family, $\lambda_0, \dots,$ λ_{N-1} be the roots of $p_N(X)$, and $w_0, \dots, w_{N-1}$ be the Gaussian quadrature weights. Define $\mathbf{D_w}$ to be the diagonal matrix with $w_0, \dots, w_{N-1}$ on its diagonal, and*

$$\mathbf{F}_N = \mathbf{D}_{\mathbf{w}}^{\frac{1}{2}} \mathbf{P}_N.$$

Note that by (1) and (2),

$$\mathbf{F}_N^T \mathbf{F}_N = \mathbf{P}_N^T \mathbf{D_w} \mathbf{P}_N = \mathbf{I}_N,$$

so $\mathbf{F}_N$ is an orthogonal matrix. In particular,

$$\mathbf{P}_N^T \mathbf{D_w} \mathbf{P}_N[i, j] = \sum_{k=0}^{N-1} p_i(\lambda_k) w_k p_j(\lambda_k) = \int_{-1}^{1} p_i(X) p_j(X) w(X) \, dX = \delta_{i,j}.$$

Note that since $\mathbf{F}_N$ is orthogonal, by definition we have

$$\mathbf{F}_N^{-1} = \mathbf{F}_N^T.$$

2.2.1 Jacobi Polynomials and Special Cases

In this section we define Jacobi Polynomials, our main object of interest, and point out a few special cases. We note that families of named orthogonal polynomials $\{p_i(X)\}$ are sometimes defined through different means, hence are normalized differently up to constants. The corresponding discrete orthogonal polynomial transform (e.g. Discrete Legendre Transform) frequently refers to multiplication by $\mathbf{P}$ instead of $\mathbf{F}$. In these cases, the transform satisfies $\mathbf{P}_N^T \mathbf{D_w} \mathbf{P}_N = \mathbf{D}$ for a diagonal matrix $\mathbf{D}$ corresponding to the normalization. The transform $\mathbf{F}_N = \mathbf{D}_{\mathbf{w}}^{\frac{1}{2}} \mathbf{P} \mathbf{D}^{-\frac{1}{2}}$ we consider (note that this matrix is indeed orthogonal) is thus equivalent up to diagonal multiplication.

Jacobi polynomials

Jacobi polynomials are indexed by two parameters $\alpha, \beta > -1$ and these are polynomials $\left\{P_j^{(\alpha,\beta)}\right\}_{j\geq 0}$ that are orthogonal with respect to the measure

$$w^{(\alpha,\beta)}(X) = (1-X)^{\alpha} \cdot (1+X)^{\beta}$$

in the range $[-1,1]$. This definition is not normalized, in the sense that we have $\mathbf{P}_N^T \mathbf{D}_{\mathbf{w}} \mathbf{P}_N = \mathbf{D}$, where

$$\mathbf{D}[j,j] = \frac{2^{\alpha+\beta+1}}{2j+\alpha+\beta+1} \cdot \frac{\Gamma(j+\alpha+1)\Gamma(j+\beta+1)}{\Gamma(j+1)\Gamma(j+\alpha+\beta+1)}$$

(see [35, Pg. 68, (4.3.3)]).

We record three well-known special cases: Chebyshev polynomials (of the first kind) are special case of $\alpha = \beta = -\frac{1}{2}$ and Legendre polynomials are the special case of $\alpha = \beta = 0$ (up to potentially a multiplicative factor that could depend on the degree j). Another notable special case of Jacobi polynomials are the *Gegenbauer* or *ultraspherical polynomials* ($\alpha = \beta$). Our results hold for all Jacobi polynomials with $\alpha, \beta \geq -\frac{1}{2}$, which include essentially all named special cases of Jacobi polynomials used in practice.

Chebyshev polynomials of the 1st kind

The Chebyshev polynomials of the 1st kind are orthogonal with respect to the weight measure $w(X) = (1-X^2)^{-\frac{1}{2}}$.

The normalized transform $\mathbf{F}_N$ has the closed form

$$\mathbf{F}_N[i,j] = \begin{cases} \sqrt{\frac{1}{N}} & j = 0 \\ \sqrt{\frac{2}{N}} \cdot \cos\left[\frac{\pi}{N} j \left(i + \frac{1}{2}\right)\right] & j = 1, \ldots, N-1. \end{cases}$$

This is a variant of the Discrete Cosine Transform (DCT-III, or the inverse DCT). It is well-known that the DCT-III can be “embedded” into a DFT of twice the dimension, and we work out some of the details of how to use the sparse FFT to compute a sparse DCT in the full version of the paper.

Legendre polynomials

Legendre polynomials are orthogonal with respect to the uniform measure i.e. $w(X) = 1$ and play a critical role in multipole expansions of potential functions (whether electrical or gravitational) in spherical coordinates. They are also important for solving Laplace’s equation in spherical coordinates.

2.2.2 Roots of Orthogonal Polynomials

Since $\lambda_i \in [-1,1]$ for all i, there is a unique $\theta_i \in [0,\pi]$ such that $\lambda_i = \cos\theta_i$. Our reduction holds for orthogonal polynomials that have roots that are “well-separated” in this angle space:

▶ **Definition 2.2.** *Let $0 < C_0 < C_1$. A family of orthogonal polynomials $p_0(X), p_1(X), \dots$ is* (C_0, C_1, γ_0)-dense *if for all large enough d, the following holds.*

Let $\lambda_0, \dots, \lambda_{d-1}$ be the roots of p_d, and $\theta_i = \arccos \lambda_i$. Then for any $i \in [d]$, for any $\gamma \geq \gamma_0/d$:

$$C_0 \gamma d \leq \left| \{\theta_0, \dots, \theta_{d-1}\} \cap \left[\theta_i - \frac{\gamma}{2}, \theta_i + \frac{\gamma}{2}\right] \right| \leq C_1 \gamma d.$$

It turns out that any family of Jacobi polynomials has the required property: their roots are spaced out such that θ_ℓ is close to $\ell\pi/N$.

2.3 Sparse Recovery Problem

We will consider approximately k-sparse vectors $\hat{\mathbf{v}} = \hat{\mathbf{x}} + \hat{\mathbf{w}}$, where $\hat{\mathbf{x}}$ is k-sparse and $\|\hat{\mathbf{w}}\|_2$ is sufficiently small. We will require that $\hat{\mathbf{x}}$ has a "spread out" support, defined as follows.

▶ **Definition 2.3.** *Let $k \in [N]$ and $0 \leq \sigma < 1$. We say that a vector $\mathbf{x} \in \mathbb{R}^N$ is* (k, σ)-sparsely separated *if there are k non-zero locations in $\mathbf{x}$ and any two non-zero locations are more than σN indices apart.*

It is not hard to see that a vector $\mathbf{x}$ with random support of size k is, with constant probability, $\left(k, \Omega\left(\frac{1}{k^2}\right)\right)$-sparsely separated.

In our reduction, we will reduce the k-sparse recovery problem to the special case of $k = 1$. Next, we define some notation for the 1-sparse case.

▶ **Definition 2.4.** *We say that the matrix $\mathbf{F}_N$ has an $(N, \epsilon, \delta, \mu)$ one-sparse recovery algorithm with query complexity $Q(N, \epsilon, \delta, \mu)$ and time complexity $T(N, \epsilon, \delta, \mu)$ if there exists an algorithm $\mathcal{A}$ with the properties below:*

For all $\mathbf{y}$ so that $\hat{\mathbf{y}} = \mathbf{F}_N \mathbf{y}$ can be decomposed as

$$\hat{\mathbf{y}} = \tilde{\mathbf{y}} + \mathbf{w},$$

where $\tilde{\mathbf{y}} = v \cdot \mathbf{e}_h$ is 1-sparse and

$$\|\mathbf{w}\|_2 \leq \epsilon \, |v| \, ,$$

we have:

1. *$\mathcal{A}$ makes at most $Q(N, \epsilon, \delta, \mu)$ queries into $\mathbf{y} = \mathbf{F}_N^{-1}(v \cdot \mathbf{e}_h + \mathbf{w})$.*
2. *With probability at least $1 - \mu$, $\mathcal{A}$ outputs $\tilde{v} \cdot \mathbf{e}_h$ with $|v - \tilde{v}| \leq \delta \, |v|$ in time $T(N, \epsilon, \delta, \mu)$.*

Pre-processing time

Our algorithm requires some pre-processing of $\mathbf{F}_N$. Our pre-processing step involves computing the roots $\lambda_1, \dots, \lambda_N$ of p_N and storing them in an appropriate data structure, and additionally forming and storing some matrices that we will use in our algorithm. Finding the roots and creating the data structure can be done in time poly(N), and the rest of the pre-processing step also takes time poly(N). We note that this is an up-front cost that needs to be only paid once.

Precision

We note that we need to make certain assumptions on size of the entries in $\hat{\mathbf{v}}$ since otherwise we would not even be able to read coefficients that are either too large or too small and need $\Omega(\log N)$ bits to represent. Towards this end we will make the standard assumption that $\|\hat{\mathbf{v}}\|_2 = 1$. In particular, this allows us to ignore any coefficients that are smaller than say $\frac{1}{N}$

since their contribution to $\|\hat{\mathbf{v}}\|_2$ is at most $\frac{1}{\sqrt{N}}$, which will be too small for our purposes.[7] In particular, this implies that we only have to deal with numbers that need $O(\log N)$ bits and as is standard in the RAM model, basic arithmetic operations on such numbers can be done in $O(1)$ time. We will implicitly assume this for the rest of the paper (except in the proof of one lemma, where we will explicitly make use of this assumption).

3 Results

In this section we state our main results. These results follow from more detailed versions which are stated in the full version of the paper.

We start off with our main result for Jacobi polynomials. We state an informal version here, and refer the reader to the full version of the paper for the formal result.

▶ **Theorem 3.1** (General Sparse Recovery for Jacobi Polynomial Transform, Informal). *Fix arbitrary parameters $\alpha, \beta \geq -\frac{1}{2}$ for Jacobi polynomials and let $\mathbf{J}_N^{(\alpha,\beta)}$ be the $N \times N$ orthogonal matrix that arises from it as in Definition 2.1. Then there is an algorithm* Recover *that does the following. Let $\mathbf{v} = \mathbf{x} + \mathbf{w}$ where $\hat{\mathbf{x}} = \mathbf{J}_N^{(\alpha,\beta)}\mathbf{x}$ is $(k, C_1/k^2)$-sparsely separated, and suppose that $\|\hat{\mathbf{w}}\|_2 \lesssim \delta \min_{h \in \mathrm{supp}(\hat{\mathbf{x}})} |\hat{\mathbf{x}}[h]|$. Then with probability at least 0.99,* Recover *outputs $\hat{\mathbf{z}}$ such that*

$$\|\hat{\mathbf{x}} - \hat{\mathbf{z}}\|_2 \lesssim \delta \|\hat{\mathbf{x}}\|_2,$$

with $\mathrm{poly}\left(\frac{k \log N}{\delta}\right)$ *queries and running time* $\mathrm{poly}\left(\frac{k \log N}{\delta}\right)$.

▶ Remark 3.2. The requirement on the noise term might be bad if one entry of $\hat{\mathbf{x}}$ is extremely small compared to the rest. However in this case we can decrease k and add the very small entries of $\hat{\mathbf{x}}$ to the noise term $\hat{\mathbf{w}}$ resulting in a potentially better guarantee. We note that our algorithm iteratively finds the large components of $\hat{\mathbf{x}}$ and in fact has a mechanism for stopping early when all of the "large-enough" entries have been found.

▶ Remark 3.3. The $(k, O(1/k^2))$-sparsely separated requirement is chosen to reflect the separation of a random k-sparse vector (c.f. comment below Definition 2.3). Smaller amounts of sparse separation are acceptable, which translate accordingly into the query and time complexity. The full dependence is in the complete result in the full version of the paper.

To prove the above result, we first reduce the k-sparse recovery problem to 1-sparse recovery problem, in the presence of a small amount of noise. Next, we present an informal statement of our reduction.

▶ **Theorem 3.4** (Main Reduction, Informal). *Let $p_1, \ldots, p_N$ be a (C_0, C_1, γ_0)-dense orthogonal polynomial family, and let $\mathbf{F}_N$ be the $N \times N$ orthogonal matrix that arises from it as in Definition 2.1. Suppose that $|\mathbf{F}_N^{-1}[i,j]| \lesssim 1/\sqrt{N}$ for all $i, j \in [N]$. Suppose that for some sufficiently small $\delta > 0$, $\mathbf{F}_N$ has a $\left(N, O(\delta), \delta, O(C_0/k^2)\right)$ one-sparse recovery algorithm with query complexity Q and running time T.*

Then there is an algorithm Recover *that does the following. Let $\mathbf{v} = \mathbf{x} + \mathbf{w}$ where $\hat{\mathbf{x}} = \mathbf{F}_N\mathbf{x}$ is $(k, C_1/k^2)$-sparsely separated, and suppose that $\|\hat{\mathbf{w}}\|_2 \lesssim \delta \min_{h \in \mathrm{supp}(\hat{\mathbf{x}})} |\hat{\mathbf{x}}[h]|$. Then with probability at least 0.99,* Recover *outputs $\hat{\mathbf{z}}$ so that*

$$\|\hat{\mathbf{x}} - \hat{\mathbf{z}}\|_2 \lesssim \delta \|\hat{\mathbf{x}}\|_2,$$

with $\mathrm{poly}(k/\delta C_0)Q$ *queries and running time* $\mathrm{poly}(k/\delta C_0)T$.

[7] More generally, we can ignore smaller coefficients as long as they are polynomial sized in N.

The final algorithmic piece missing from the result above is the algorithm for 1-sparse recovery. We provide this missing piece for Jacobi polynomials:

▶ **Theorem 3.5** (1-Sparse Recovery for Jacobi Transform, Informal)**.** *There exists a universal constant C such that the following holds. Consider the Jacobi transform for any fixed parameters $\alpha, \beta \geq -\frac{1}{2}$. There exists an $(N, \epsilon, C \cdot \epsilon, \gamma)$ 1-sparse recovery algorithm for the Jacobi transform that makes* $\text{poly}\left(\log\left(\frac{N}{\gamma}\right) \cdot \frac{1}{\epsilon}\right)$ *queries and takes time* $\text{poly}\left(\log\left(\frac{N}{\gamma}\right) \cdot \frac{1}{\epsilon}\right)$.

4 Open Questions

To conclude, we list a few questions left open by our work.

1. First, it is natural to try and improve our k-sparse recovery algorithm to work for arbitrary k-sparse support, rather than "well-separated" supports. One natural way to do this is to address the fourth (open) challenge in Section 1.3 for a general class of OPs.
2. Second, we could hope to handle a more general class of noise $\hat{\mathbf{w}}$ than we currently do. One could hope to handle *any* vector $\mathbf{v}$, with an error guarantee that degrades smoothly with the ℓ_2 norm of the "tail" of $\mathbf{v}$. There is a long list of work on "de-noising" the contribution of the "head" to the "tail" in the sFFT literature that could potentially be useful here [23–27].
3. Third, we would like to extend our results to hold for OPs defined over infinite intervals (e.g. Hermite and Laguerre polynomials).
4. Fourth, we would like to solve the sparse recovery for $\mathbf{F}^T$ (where $\mathbf{F}$ is as in Definition 2.1): i.e. given query access to $\mathbf{x}$ figure out a good k-sparse approximation to $\mathbf{F}^T\mathbf{x}$ (recall that $\mathbf{F}^{-1} = \mathbf{F}^T$). (Note that this problem can be equivalently stated as follows: given query access to $\mathbf{F}\mathbf{y}$, compute a good k-sparse approximation to $\mathbf{y}$.) Currently our results do not solve this problem since we cannot show that the existence of a filter $\mathbf{b}$ such that $\mathbf{F}\mathbf{D}_\mathbf{b}\mathbf{F}^T$ is row-sparse. Note that this is not an issue for DFT since it is symmetric.
5. Finally, we would like to reduce the exponent on k in our final runtime. In particular, for the case of random k-sparse support, the dependence on k in the runtime for Jacobi transform is k^8. We note that we have not tried too hard to optimize the constants though we believe even getting a quadratic dependence on k with our framework would be challenging. We would like to stress that the majority of the work in the sFFT literature has been to make the dependence on k be linear and for such results, it seems very unlikely that a generic reduction from k-sparse recovery to 1-sparse recovery would work. In other words, using the knowledge about the 1-sparse recovery algorithm for DFT seems necessary to get a overall k-sparse FFT with running time $k\text{poly}(\log n)$.

Abstract

In the Directed Long Cycle Hitting Set problem we are given a directed graph G, and the task is to find a set S of at most k vertices/arcs such that $G - S$ has no cycle of length longer than ℓ. We show that the problem can be solved in time $2^{\mathcal{O}(\ell^6+\ell k^3 \log k+k^5 \log k \log \ell)} \cdot n^{\mathcal{O}(1)}$, that is, it is fixed-parameter tractable (FPT) parameterized by k and ℓ. This algorithm can be seen as a far-reaching generalization of the fixed-parameter tractability of Mixed Graph Feedback Vertex Set [Bonsma and Lokshtanov WADS 2011], which is already a common generalization of the fixed-parameter tractability of (undirected) Feedback Vertex Set and the Directed Feedback Vertex Set problems, two classic results in parameterized algorithms. The algorithm requires significant insights into the structure of graphs without directed cycles of length longer than ℓ and can be seen as an exact version of the approximation algorithm following from the Erdős-Pósa property for long cycles in directed graphs proved by Kreutzer and Kawarabayashi [STOC 2015].

1 Introduction

Feedback Vertex Set (FVS) and its directed variant Directed FVS (DFVS) are among the most classical problems in algorithmic graph theory: given a (directed) graph G the task is to find a minimum-size set $S \subseteq V(G)$ of vertices such that $G - S$ contains no (directed) cycles. Interestingly, the directed version is *not* a generalization of the undirected one. There is no obvious reduction from FVS to DFVS (replacing each undirected edge with two arcs of opposite directions does not work, as this would create directed cycles of length 2).

Both problems received significant amount of attention from the perspective of parameterized complexity. The main parameter of interest there is the optimal solution size $k = |S|$. Both problems can easily be solved in time $n^{\mathcal{O}(k)}$ by enumerating all size-k vertex subsets $S \subseteq V(G)$ and then checking whether $G - S$ is acyclic. The interesting question is thus whether the problems are *fixed-parameter tractable* with respect to k, i.e. whether there is an algorithm with run time $f(k) \cdot n^{\mathcal{O}(1)}$ for some computable function f depending only on k. FVS is one of the most studied problems in parameterized complexity: starting in the early 1990's, a long series of improved fixed-parameter algorithms [5, 6, 10, 13, 18, 25] lead to the currently fastest (randomized) algorithm from 2020 with run time $2.7^k \cdot n^{\mathcal{O}(1)}$ [20]. The DFVS problem has also received a significant amount of attention from the perspective of parameterized complexity. It was a long-standing open problem whether DFVS admits such an algorithm; the question was finally resolved by Chen et al. who gave a $4^k k! k^4 \cdot \mathcal{O}(nm)$-time algorithm for graphs with n vertices and m edges. Recently, an algorithm for DFVS with run time $4^k k! k^5 \cdot \mathcal{O}(n+m)$ was given by Lokshtanov et al. [22]. A fruitful research direction is trying to extend the algorithm to more general problems than DFVS. On the one hand, Chitnis et al. [8] generalized the result by giving a fixed-parameter algorithm for Directed Subset FVS: here we are given a subset U of arcs and only require the k-vertex set S to hit every cycle that contains an arc of U. On the other hand, Lokshtanov et al. [21] showed that the Directed Odd Cycle Transversal problem, where only the directed cycles of odd length needed to be hit, is W[1]-hard parameterized by solution size.

It is worth noting that very different algorithmic tools form the basis of the fixed-parameter tractability of FVS and DFVS: the undirected version behaves more like a hitting set-type problem, whereas the directed version has a more cut-like flavor. These differences motivated Bonsma and Lokshtanov [4] to consider Mixed FVS, the common generalization of FVS and DFVS where the input graph contains both directed and undirected edges. In such *mixed graphs*, cycles can contain directed arcs and undirected edges, but in particular the walk visiting an undirected edge twice is not a cycle. They obtained an algorithm for Mixed FVS with run time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ for k the size of the smallest feedback vertex set.

In this paper we study the following generalization of DFVS: We want to find a minimum size vertex set S such that all cycles of $G - S$ to have length at most ℓ. For $\ell = 1$ this is DFVS in loopless graphs. For $\ell = 2$ this is Mixed FVS in mixed graphs. The length of a longest cycle in a (directed) graph is also known as (directed) circumference of a graph. The parameterized version of our problem thus reads:

Directed Long Cycle Hitting Set	*Parameter:* $k + \ell$.
Input: A directed multigraph G and integers $k, \ell \in \mathbb{N}$.	
Task: Find a set S of at most k vertices such that $G - S$ has circumference at most ℓ.	

Note that Directed Long Cycle Hitting Set for $\ell = 2$ generalizes Mixed FVS (and hence both FVS and DFVS): to see this, subdivide anti-parallel arcs to make all cycles have length at least three and then replace undirected edges by anti-parallel arcs.

In contrast to FVS and DFVS, even checking feasibility of a given solution is a non-trivial task. It amounts to checking, for a digraph G and integer ℓ, whether G contains a cycle of length more than ℓ. This is also known as the Long Directed Cycle problem, which is obviously NP-hard since it contains the Directed Hamiltonian Cycle problem for $\ell = |V(G)| - 1$. However, Long Directed Cycle is fixed-parameter tractable parameterized by ℓ [29], hence *verifying* the solution of Directed Long Cycle Hitting Set is fixed-parameter tractable in ℓ.

Our contributions. Our main result is a fixed-parameter algorithm for Directed Long Cycle Hitting Set.

▶ **Theorem 1.** *There is an algorithm that solves* Directed Long Cycle Hitting Set *in time* $2^{\mathcal{O}(\ell^6 + \ell k^3 \log k + k^5 \log k \log \ell)} \cdot n^{\mathcal{O}(1)}$ *for n-vertex digraphs G and parameters $k, \ell \in \mathbb{N}$.*

The result also extends to the arc deletion variant of the problem, as we show both of them to be equivalent in a parameter preserving way.

The run time in Theorem 1 depends on two parameters, k and ℓ. This is necessary for the following reason. For $\ell = 1$, Directed Long Cycle Hitting Set corresponds to the DFVS problem, which is NP-hard. Moreover, the problem is also NP-hard for $k = 0$, as it contains the Directed Hamiltonian Cycle problem. This also shows that the run time cannot be polynomial in k or ℓ (unless P = NP). Assuming ETH, it is even necessary that the run time depends *exponentially* on both k and ℓ. Our algorithm achieves a run time that is single-exponential in both parameters k and ℓ. It is, in this sense, optimal.

Our algorithm is based on an elaborate combination algorithmic techniques, some of them used previously, some of them new.

- We use the standard opening step of iterative compression, which allows to assume that each directed cycle of length more than ℓ goes through a small number of exceptional vertices.
- We do not want to deal with the situation when there are two exceptional vertices x and y that are in the same strong component of the solution $G - S$. If we guess that this happens in the solution, then a way to avoid this problem is to guess a directed cycle C containing both x and y, and to contract this cycle. In order to guess this cycle, we essentially need a **representative set** of $x \to y$ paths, that is, a collection of paths such that if an (unknown) set S of at most k vertices does not disconnect y from x, then there is at least one $x \to y$ path disjoint from S in our collection. As an interesting self-contained result, we construct such a collection of size $\ell^{\mathcal{O}(k^2 \log k)} \cdot \log n$ on directed graphs without cycles of length greater than ℓ.
- If we can assume that the exceptional vertices are in different strong components of the solution, then this defines a separation problem on the exceptional vertices and makes the **directed shadow removal** technique of Chitnis et al. [8] relevant to simplify the structure of the instance. In particular, a major structural goal that we want to achieve is to ensure that every arc of the input graph lies in a directed cycle of length at most ℓ.
- Removing the exceptional vertices breaks the graph into some number of strong components with no cycle of length longer than ℓ in any of them. We call **portal vertices** the endpoints of the arcs connecting these strong components with each other and with the exceptional vertices. We show that the portal vertices can be partitioned into **clusters**: portals in each cluster are close to each other, while the distance between any two clusters is large. Furthermore, every solution has to separate the clusters from each other, defining another directed multiway cut problem.
- In the final step of the algorithm, we would like to use the technique of **important separators** to solve the directed multiway cut problem defined above: these are separators that are maximally "pushed" towards the target of the separations. However, the exact notion of importance is difficult to define due to the additional constraints of the problem being solved. Ergo, we perform a detailed analysis of the instance structure to identify **outlet vertices** that allows us to represent the additional constraints as separation, and to formally reduce the problem to branching on the choice of an important separator.

Related work. The structure of long cycles in directed graphs has been of interest for long time. For instance, Lewin [19] analyzed the density of such graphs, and Kintali [16] analyzes the directed treewidth of such directed graphs. Algorithmically, though, it was only recently shown by Kawarabayashi and Kreutzer [15] that the vertex version of the Erdős-Posa property holds for long directed cycles: namely, they show that any digraph G

either contains a set of $k+1$ vertex-disjoint directed cycles of length at least ℓ or some set S of at most $f(k,\ell)$ vertices that intersects all directed cycles of G with length at least ℓ. The corresponding questions for directed cycles without length restrictions have also been well-investigated [2, 26].

Note that an algorithmic proof of the Erdős-Pósa property can be a useful opening step for a fixed-parameter algorithm: we either find a set of $k+1$ arc- or vertex-disjoint cycles of length at least ℓ (and thus can reject the instance (G,k,ℓ) as "no"-instance) or obtain a set S which can serve as a feasible approximate solution. Such an opening step was also discussed in the well-known fixed-parameter algorithm for DFVS by Chen et al. [7, Remark 5.3], where the function $f(k,1)$ is known to be near-linear. In our case though, the function $f(k,\ell)$ from the Kawarabayashi-Kreutzer result is too large for us to obtain an algorithm for Directed Long Cycle Hitting Set with run time $2^{\mathrm{poly}(k,\ell)} \cdot n^{\mathcal{O}(1)}$.

Further, directed circumference can be seen as an intermediate step towards a general algorithmic framework for graph optimization problems related to *directed treewidth*. In undirected graphs, treewidth as a graph measure has enjoyed unprecedented success as a tool towards efficient approximation algorithms and fixed-parameter algorithms. For instance, as part of their Graph Minors series, Robertson and Seymour [28] showed that the k-linkage problem is fixed-parameter tractable, heavily relying on the reduction of the problem to graphs of bounded treewidth. In directed graphs, the situation is again much more complicated: Johnson et al. [14] introduced the notion of directed treewidth for digraphs. Yet, for digraphs the k-linkage problem is NP-hard already for $k=2$, and no fixed-parameter algorithm is known which recognizes digraphs of nearly-bounded directed treewidth. On the positive side, though, digraphs of bounded directed circumference are nicely squeezed between acyclic digraphs and digraphs of bounded directed treewidth [16]. Also, the arc version of the k-linkage problem is fixed-parameter tractable on digraphs of directed circumference 2 [3]; the question remains open for digraphs of larger directed circumference.

Returning to the original motivation of studying generalizations of DFVS, Neogi et al. [24] gave a fixed-parameter algorithm for the problem of finding a set S of size at most k in a given digraph G such that every strong component of $G-S$ excludes graphs in a fixed finite family $\mathcal{H}$ as (not necessarily induced) subgraphs, when $\mathcal{H}$ contains only rooted graphs, or contains at least one directed path. Göke et al. [12] considered the problem of finding a set S of size at most k in a given digraph G such that every strong component of $G-S$ has size at most s; they gave a fixed-parameter algorithm for parameter $k+s$.

2 Definitions and Notations

In this paper, we mainly consider finite loop-less directed graphs (or digraphs) G with vertex set $V(G)$ and arc set $A(G)$. We allow multiple arcs and arcs in both directions between the same pairs of vertices. A *walk* is a sequence of vertices $(v_1,\ldots,v_\ell)$ with corresponding arcs (v_i,v_{i+1}) for $i=1,\ldots,\ell-1$ which forms a subgraph of G; the *length* of a walk is its number of arcs. A walk is *closed* if $v_1=v_\ell$; otherwise, it is *open*. A *path* in G is an open walk where all vertices are visited at most once. A *cycle* in G is a closed walk in which every vertex is visited at most once, except for $x_1=x_\ell$ which is visited twice. (Throughout this entire paper, by "cycle" we always mean directed cycle.) We call G *acyclic* if G does not contain any cycle. For two vertices x_i,x_j of a walk W with $i\leq j$ we denote by $W[x_i,x_j]$ the subwalk of W starting at x_i and ending in x_j. For a walk W ending in a vertex x and a second walk R starting in x, $W\circ R$ is the walk resulting when concatenating W and R.

For each vertex $v \in V(G)$, its *out-degree* in G is the number $d^+_G(v)$ of arcs of the form (v, w) for some $w \in V(G) \setminus \{v\}$, and its *in-degree* in G is the number $d^-_G(v)$ of arcs of the form (w, v) for some $w \in V(G) \setminus \{v\}$. For each subset $V' \subseteq V(G)$, the subgraph induced by V' is the graph $G[V']$ with vertex set V' and arc set $\{(u, v) \in A(G) \mid u, v \in V'\}$. For a set X of vertices or arcs, let $G - X$ denote the subgraph of G obtained by deleting the elements in X from G. For a subgraph G' and an integer d we denote by $R^+_{G'}(X)$ the set of vertices that are reachable from X in G'.

A digraph G is *strong* if either G consists of a single vertex (then G is called *trivial*), or for any distinct $u, v \in V(G)$ there is a (directed) path from u to v. A *strong component* of G is an inclusion-wise maximal induced subgraph of G that is strong. The *(directed) circumference* of a digraph G is the length $\mathsf{cf}(G)$ of a longest cycle of G; if G is acyclic, then define $\mathsf{cf}(G) = 0$.

3 Directed Long Cycle Hitting Set Algorithm

The goal of this section is to devise an algorithm for Directed Long Cycle Hitting Set and thereby proof Theorem 1. We will only consider the vertex deletion variant. This will suffice, as the arc deletion version can be reduced to the vertex deletion version in a parameter-preserving way, as we show in the full version.

The algorithm performs a sequence of reductions to special cases of the original Bounded Cycle Length Vertex Deletion. All these sections are modular and just need the problem formulation and theorem at the end of the previous section.

Compression. Recall that in the Directed Long Cycle Hitting Set problem we are given a digraph G and integers k and ℓ. The task then is to find a set of at most k vertices such that $G - S$ contains no cycles of length more than ℓ.

As already stated in the introduction, checking a solution for correctness is an non-trivial task. For this we use a fixed-parameter algorithm by Zehavi [29].

▶ **Theorem 2.** *There is an algorithm that decides in time $2^{\mathcal{O}(\ell)} \cdot n^{\mathcal{O}(1)}$ whether an n-vertex digraph G contains a cycle of length more than ℓ.*

This already solves the case for $k = 0$. We now want to design an algorithm for general k.

The goal of this subsection is to get an existing solution T for which we have to find a disjoint solution S of size less than $|T|$. For this we use the standard techniques of iterative compression and disjoint solution.

We start our algorithm by applying the iterative compression technique introduced by Reed, Smith and Vetta [27]. This technique was also used by Chen et al. [7] to show the fixed parameter tractability of DFVS. We choose an arbitrary enumeration $v_1, \ldots, v_n$ of the vertices of G. By G_i we denote the digraph $G[v_1, \ldots, v_i]$. We want to iteratively construct solutions S_{i+1} to (G_{i+1}, k, ℓ) by using the solution S_i of (G_i, k, ℓ). We start with the empty digraph G_0 and the empty solution $S_0 = \emptyset$. This solution is feasible for every choice of G, k and ℓ as the empty digraph contains no cycles.

Now, if S_i hits all cycles of length more than ℓ in G_i, then $T_{i+1} = S_{i+1} \cup \{v_{i+1}\}$ does the same for G_{i+1} (as $G_i - S_i = G_{i+1} - T_{i-1}$). The only problem now is that T_{i+1} may be to large. Therefore, we consider the compression version of our problem: given an instance (G_i, k, ℓ) with a solution T_i of size $k + 1$, find a solution S_i of size at most k. If we can solve this problem, by above procedure we get a solution S_n for the digraph $G_n = G$ and hence have solved the original problem. This adds a factor of n to the run-time, preserving fixed-parameter tractability.

The compression problem can be modified further in two useful ways. The first modification is to get disjointness of solutions T_i and S_i. This can be achieved by guessing the intersection $U_i = T_i \cap S_i$ by taking all possible subsets of T_i. For every choice we can then solve the disjoint compression problem $(G_i - U_i, k - |U_i|, \ell)$ with starting solution $T_i \setminus U_i$. If the non-disjoint instance has a solution, then the instance where we guessed the intersection correctly has a solution. Otherwise, none of the disjoint instances has a solution. This adds a factor of $2^{|T_i|} = 2^{k+1}$ to the run-time, also preserving fixed-parameter tractability.

The other useful modification is about not solving the problem exactly but instead to guess a set $\mathcal{S}$ of bounded size intersecting S_i in at least one vertex. If we have a routine that for an instance (G', k', ℓ', T') of the disjoint compression problem returns us a set $\mathcal{S}$ that is guaranteed to intersect some solution (if a non-empty solution exists), we can branch as follows. First we check whether the empty solution already solves the problem by Theorem 2. This solves the the problem for $k = 0$. Otherwise we call our routine on the instance obtaining a set $\mathcal{S}$. For every $v \in \mathcal{S}$ we recurse on the instance $(G' - v, k' - 1, \ell, T')$. This adds a factor of $f(k', \ell', n')^{k'}$ to the run-time where $f(k', \ell', n')$ is an upper bound on the size of $\mathcal{S}$ on an instance (G', k', ℓ', T') with $n' = |G'|$. This preserves fixed-parameter tractability if we can write $f(k', \ell', n')^{k'}$ as $g(k', \ell') \cdot \mathrm{poly}(n')$ for some appropiate function g. Note that this is the case even if $f(k', \ell', n') = h_1(k', \ell') \cdot \log^{h_2(k', \ell')}(n')$.

After all these reductions we are left with the following problem:

INTERSECTING DIRECTED LONG CYCLE HITTING SET *Parameter:* $k + \ell$.
Input: A directed multigraph G, $T \subseteq V(G)$ and integers $k, \ell \in \mathbb{N}$.
Properties: $\mathsf{cf}(G - T) \leq \ell$
Task: Find a set $\mathcal{S} \subseteq V(G) \setminus T$ that intersects a set $S \subseteq V(G) \setminus T$ of size at most k with $\mathsf{cf}(G - S) \leq \ell$ if such a set exists.

The set $\mathcal{S}$ will often help us to argue about solutions S disjoint from it. This is often described as branching steps throughout the algorithm but we decided to collect all the branching here to be more precise about the assumptions needed in the theorems.

Contraction. In the last section we reduced the original DIRECTED LONG CYCLE HITTING SET problem to a variant where we are already given a solution T and now want to find a set $\mathcal{S}$ intersecting every solution S disjoint from T. Except for the intersection step, such reductions have been used by Chen et al. [7] in their algorithm for DFVS. The next key observation in their algorithm for DFVS is that every vertex of T must lie in their own strong component of $G - S$. The reason is that for every directed feedback vertex set S of G, each strong component of $G - S$ is a single vertex. For DIRECTED LONG CYCLE HITTING SET, the situation is way more complicated, as strong components of $G - S$ contain cycles of length up to ℓ. Moreover, those cycles can concatenate to arbitrarily large strong components. So it is possible that $G - S$ contains strong components with more than one vertex of T. In this section, we want to contract (parts of) such components to a single vertex such that eventually, after contraction, every strong component of $G - S$ contains at most one vertex of T. A structural result allowing the contraction is the following lemma:

▶ **Lemma 3.** *Let G be a digraph and let $X \subseteq V(G)$ be such that $G[X]$ is strong and $\mathsf{cf}(G[X]) \leq \ell$. Suppose that the following two properties hold:*

1. *Every cycle of G has length at most ℓ or length at least ℓ^2.*
2. *For any $a, b \in X$ there cannot be both*
   a. *an $a \to b$-path P_{ab} of length at least ℓ in $G[X]$*
   b. *a $b \to a$-path P_{ba} of length at most ℓ in $G - (X \setminus \{a, b\})$*

Let G/X be the digraph obtained by contracting X to a single vertex x.

- *If $\mathsf{cf}(G-S) \leq \ell$ for some $S \subseteq V(G) \setminus X$, then $\mathsf{cf}(G/X - S) \leq \ell$.*
- *If $\mathsf{cf}(G/X - S') \leq \ell$ for some $S' \subseteq V(G/X) \setminus \{x\}$, then $\mathsf{cf}(G - S') \leq \ell$.*

To algorithmically use this result we have to make sure its requirements are fulfilled. This is easy if G has a cycle C with $\ell < |C| < \ell^2$. We can can detect these cycles in time $2^{\mathcal{O}(\ell^2)} \cdot n^{\mathcal{O}(1)}$ by using color coding (see Alon et al. [1]). If there exists such an cycle, any long cycle hitting set has to intersect it. Also it's length is bounded, so we can return it as set $\mathcal{S}$.

To find a set X fulfilling the remaining properties is more difficult. For this we build on a tool called "k-representative set of paths".

▶ **Definition 4.** *Let G be a digraph, $x, y \in V(G)$ and $k \in \mathbb{Z}_{\geq 0}$. A set $\mathcal{P}$ of $x \to y$-paths is a* k-representative set of $x \to y$-paths, *if for every set $S \subseteq V(G)$ of size at most k it holds: If there is an $x \to y$-path in $G - S$ there is an $x \to y$-path $P \in \mathcal{P}$ that is disjoint from S.*

In our case such a k-representative set of paths will be useful for constructing a closed walk visting several vertices of T to use as our set X. Later on the reversed property of k-representative sets of paths will also be handy: if you hit all paths of $\mathcal{P}$ with a set S of size at most k, then there exist no $x \to y$-paths in $G - S$.

Alas, we were not able to find k-representative sets of paths of small size in general graphs. In the case of strong digraphs of bounded circumference, however, we obtain the following:

▶ **Theorem 5.** *Let G be a strong digraph, $x, y \in V(G)$ and $k \in \mathbb{Z}_{\geq 0}$. Then a k-representative set of $x \to y$-paths having size $\mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \cdot \log n$ can be found in time $\mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$.*

We need to generalize this tool a bit further as our graph G neither has bounded circumference nor does it need to be strong. However, we have a set T of small size such that $\mathsf{cf}(G - T) \leq \ell$ and we are only interested in the strong components of the graph. This leads us to the following specialized lemma:

▶ **Lemma 6.** *Let G be a strong digraph, $T \subseteq V(G)$ and $k, \ell \in \mathbb{Z}_{\geq 0}$ with $\mathsf{cf}(G - T) \leq \ell$. Then in time $2^{\mathcal{O}(k\ell + k^2 \log k \log \ell)} n^{\mathcal{O}(1)}$, we can find a set $\mathcal{Q}$ of $|T|^2 2^{\mathcal{O}(k\ell + k^2 \log k \log \ell)} \log^2 n$ closed walks with the following property: If there is a set $S \subseteq V(G)$ of size at most k with $\mathsf{cf}(G - S) \leq \ell$ and there are two vertices of T in the same strong component of $G - S$ then there is*

- *a closed walk in $Q \in \mathcal{Q}$ containing two vertices of T that is disjoint from S or*
- *a simple cycle of length at most ℓ containing two vertices of T.*

The lemma allows for a branching procedure that creates several instances. For each instance we assume that there is a solution S such that no two vertices of T lie in the same strong component of $G - S$. We call such a solution *isolating* long cycle hitting set. The instances are created in the following way: We keep our original instance just in case it has an isolating long cycle hitting set. Then we search for a simple cycle C of length at most ℓ in G visiting at least two vertices of T. Such a cycle can be found by color coding in time $2^{\mathcal{O}(\ell)} \cdot n^{\mathcal{O}(1)}$. If such a cycle exists, we branch into two instances: In the first instance, we assume that S intersects C and we can just return $\mathcal{S} = V(C)$ as solution to our intersection problem. In the second instance, C is disjoint from S and we have a candidate X for contraction with Lemma 3. If no such cycle exists we get our candidate applying Lemma 6 by branching on which closed walk of $\mathcal{Q}$ is disjoint from S and take that as a candidate X.

We now have to check whether our candidate X fulfills the assumptions of Lemma 3. If $\mathsf{cf}(G[X]) > \ell$ then X cannot be disjoint from S in contradiction to our branching assumption and we give up on this branch. Then we check for every pair $a, b \in X$, if paths P_{ab} and P_{ba}

as in Lemma 3 exist. If they do we cannot contract X, but $P_{ab} \circ P_{ba}$ forms a cycle of length more than ℓ, so it has to be intersected by S. By branching assumption $V(P_{ab}) \subseteq X$ is disjoint from S and therefore P_{ba} has to intersect S. Luckily, $|V(P_{ba})| \leq \ell + 1$ and we can return $\mathcal{S} = V(P_{ba})$ as set intersecting S. If these paths do not exist we can contract X to a single vertex to obtain a new instance (G', k, ℓ, T'). We continue our branching procedure with this new instance until we guess that our instance has an isolating long cycle hitting separator. As the cardinality of T is decreased in each branching step this is the case at the latest when $|T| = 1$. Note that this may lead to the strange case that we are indeed searching for a solution S that is larger than our set T.

The remaining problem can be stated as:

Isolating Long Cycle Hitting Set Intersection	*Parameter:* $k + \ell + |T|$.
Input:	A directed multigraph G, integers $k, \ell \in \mathbb{N}$ and a set $T \subseteq V(G)$
Properties:	$\mathsf{cf}(G - T) \leq \ell$
Task:	Find a set $\mathcal{S}$ intersecting some isolating long cycle hitting set S of size at most k with respect to T if such a set exists.

The above procedure (and the result of this section) can be summarized as follows.

▶ **Theorem 7.** *Instances (G, k, ℓ) of* Directed Long Cycle Hitting Set *can be solved in time $2^{\mathcal{O}(\ell^2+\ell k^3 \log k)} \cdot (f_{ii}(k, \ell))^k \cdot n^{\mathcal{O}(1)}$ by at most $2^{\mathcal{O}(\ell k^3 \log k)} \cdot (f_{ii}(k, \ell))^k \cdot n^2 \log^{2k+2}(n)$ calls to an algorithm A_{ii} solving the* Isolating Long Cycle Hitting Set Intersection *problem, where $f_{ii}(k, \ell)$ is a size bound on the set produced by A_{ii}.*

Reducing to Important Hitting Separator. In the previous section we reduced the Directed Long Cycle Hitting Set problem to the Isolating Long Cycle Hitting Set Intersection problem, a variant where we are already given a solution T and search for a solution S disjoint from T of size at most k. Additionally, we know that T has at most one vertex in each strong component of $G - S$. For the remainder of this subsection, assume that there is such a solution S of size at most k.

Intuitively, we did the reduction to the isolating variant in order to apply something like Skewed Multiway Cut. This was done by Chen et al. [7] in their algorithm for Directed FVS. They guessed a topological ordering of the vertices of T in $G - S$ and used Skewed Multiway Cut to cut away the backward paths. This also implied that each strong component consisted of a single vertex. In our case, though, we still have cycles left, and a direct construction to Skewed Multiway Cut gives us no control over their length.

We instead guess only a last vertex $t \in T$ in some topological ordering of the strong components of $G - S$. From here our approach differs significantly from that of Chen et al. [7] for Directed FVS. Instead of finding all cuts at once, we focus on the $t \to T \setminus \{t\}$-cuts while still hitting long cycles. This is we want to find the strong component of t in $G - S$.

For this it is useful to see, that two types of arcs may not lie in the strong component of t in $G - S$. The first kind of arcs are simply the arcs having their endpoint in $T \setminus \{t\}$, i.e. arcs in $\delta^-(T \setminus \{t\})$. This is because S is isolating. The other kind of arcs are the arcs that lie only on long cycles, i.e. arcs $a = (v, w) \in A(G)$ with $\mathrm{dist}_{G-a}(w, v) \geq \ell$. This follows from the fact that S hits all long cycles. Therefore, the strong component of t in $G - S$ must be a subset of the connected component of t in G after above arcs are removed. We call the later component $C_t^\star$. We want to focus our search onto that component.

However, there may also be other arcs and vertices which do not lie in the strong component of t in $G - S$ which are still in $C_t^\star$. To make it easier to argue about these, we use the shadow-covering technique introduced by Chitnis et al. [9] to solve the Directed Multiway Cut problem. For this we need to define what the shadow of our solution S with respect to the set T is:

▶ **Definition 8** (shadow). *Let G be a digraph and let $T, S \subseteq V(G)$. A vertex $v \in V(G)$ is* in the forward shadow $f_{G,T}(S)$ of S (with respect to T) *if S is a $T \to v$-separator in G, and v is* in the reverse shadow $r_{G,T}(S)$ of S (with respect to T) *if S is a $v \to T$-separator in G. All vertices of G which are either in the forward shadow or in the reverse shadow of S (with respect to T) are said to be* in the shadow of S (with respect to T)*.*

Note that S itself is not in its own shadow. The most useful property of the shadow for our purposes is that every vertex that is not in the shadow of S with respect to T is reachable from a vertex of T and can reach some (maybe different) vertex of T. In particular, if a vertex v is not in the shadow of S and reachable from t (our last vertex) in $G - S$ then it has to lie in the strong component of t in $G - S$. This is because v can also reach a vertex of T but there is no $T \to T \setminus \{t\}$-walk in $G - S$.

We use the deterministic algorithm for shadow covering by Chitnis et al. [8]. The following corollary follows from their paper:

▶ **Corollary 9.** *Let (G, k, ℓ, T) be an instance of* Isolating Long Cycle Hitting Set Intersection*. One can construct, in time $2^{\mathcal{O}(k^2)} \cdot n^{\mathcal{O}(1)}$, sets $Z_1, \dots, Z_p$ with $p \leq 2^{\mathcal{O}(k^2)} \log^2 n$ such that if there is an isolating long cycle hitting set of size at most k, there is isolating long cycle hitting set S of size at most k and an $i \in \{1, \dots, p\}$ such that $Z_i \cap (S \cup T) = \emptyset$ and Z_i includes the shadow of S with respect to T.*

By branching on the possible choices of Z_i we can assume that we have a set Z that covers (read: includes) the shadow of S with respect to T and is disjoint from S and T. Now every vertex outside of Z is reachable from a vertex of T and can also reach a vertex of T.

Consider now the set $V_{\mathsf{out}} \subseteq V(G) \setminus Z$ defined as follows. For every $v \in V_{\mathsf{out}}$ there is a $v \to w$-path P with $w \in V(G) \setminus Z$ whose inner vertices are inside Z and one of the following properties holds. The endpoint w is contained in $T \setminus \{t\}$ or P contains an arc $a = (x, y) \in A(G)$ that only lies on long cycles (i.e. $\mathrm{dist}_{G-a}(y, x) \geq \ell$). The set of these vertices may not be reached from t in $G - S$ if the other endpoint w is not in S. Because then w reaches a vertex of T and that gives us either a $t \to T \setminus \{t\}$ path in $G - S$ or a closed walk in $G - S$ containing an arc that only lies on long cycles (which therefore contains itself a long cycle).

To get rid of the condition that the other endpoint of the path P we apply the tool of critical vertices also used by Chitnis et al. [8]. For this we use an auxiliary graph (called torso) which is created by taking all vertices of $V(G) \setminus Z$ and shrinking paths with interior points in Z to arcs. By remembering the paths which contained arcs only on long cycle we get a set U_t^{long} of dangerous arcs that must not be traversable from t. In case they are not traversable only by the endpoint w lying in S these vertices are called k-critical with respect to U_t^{long}. Now, we can use the following theorem by Chitnis et al. [8].

▶ **Proposition 10** ([8]). *Given a digraph G, a subset U of its arcs, and some $t \in V(G)$, in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ we can find a set F_{critical} of size $2^{\mathcal{O}(k)}$ that contains all k-critical vertices.*

We apply Proposition 10 to $G, U_t^{\mathsf{long}}, t$ and k, and add the resulting set F_{critical} to our solution $\mathcal{S}$. If our solution S is still disjoint from $\mathcal{S}$, it cannot contain a k-critical vertex. This implies that t cannot reach a vertex of V_{out} in $G - S$. So S is a $t \to V_{\mathsf{out}}$-separator in the strong component $C_t^\star$.

But $S \cap C_t^\star$ may also have other properties like hitting long cycles that intersect or lie within $C_t^\star$. To cover these we introduce the notation of important hitting $t \to V_{\mathsf{out}}$-separators. These are $t \to V_{\mathsf{out}}$-separators U that hit all long cycles in a digraph and are backward-range minimal in the sense that there is no other $t \to V_{\mathsf{out}}$-separators U' hitting all cycles with $|U'| \leq |U|$ and $R^-_{G-U'}(V_{\mathsf{out}}) \subsetneq R^-_{G-U}(V_{\mathsf{out}})$.

The main result of this section is that it is enough to find a set $\mathcal{S}$ intersecting one important hitting $t \to V_{\mathsf{out}}$-separator U for every backward range $R^-_{G-U}(V_{\mathsf{out}})$ in a strong digraph (read $G[C_t^\star]$). We call the remaining problem Important Hitting Separator in Strong Digraphs which reads as follows:

Important Hitting Separator in Strong Digraphs *Parameter:* $k + \ell$.

Input: A strong digraph G, integers $k, \ell \in \mathbb{N}$, $t \in V(G)$ and $V_{\mathsf{out}} \subseteq V(G)$.

Properties: $\mathsf{cf}(G - t) \leq \ell$, every arc of G lies on a cycle of length at most ℓ.

Task: Find a set $\mathcal{S}_{\mathsf{hs}}$ intersecting a important hitting $t \to V_{\mathsf{out}}$-separator of size at most k in every range equivalence class.

Portals and Clusters. In the previous section we reduced Isolating Long Cycle Hitting Set Intersection to Important Hitting Separator in Strong Digraphs. In an intuitive way we replaced the constraint on S of hitting all cycles going through $T \setminus \{t\}$ by a constraint that S needs to be a backward-range minimal $t \to V_{\mathsf{out}}$-separator. Also we simplified our graph to be strongly connected and that every arc lies on a short cycle. We now want to also break the long cycles going only through t into cut constraints. For this we consider the strong components of $G - t$. Let $\mathcal{C}$ the set of all such components. Our main interest are now portal vertices.

▶ **Definition 11.** *Let G be a digraph and let $C \subset V(G)$. A vertex $v \in C$ is a* portal vertex *of C, if $\Delta_G(v) > \Delta_{G[C]}(v)$, where $\Delta_H(v)$ is the number of incident arcs (both in-coming and out-going) of v in a graph H. We denote by X_C the set of all portal vertices of C.*

As all arcs of G lie on a short cycles the arcs going between clusters must cycle back to t.

▶ **Lemma 12.** *Let $C \in \mathcal{C}$ and $v \in X_C$. There is a cycle O_v with $v, t \in V(O_v)$ and $|O_v| \leq \ell$.*

These cycles allow us to transform paths between portal vertices of the same strong component into closed walks. Like in the first part of our algorithm we can eliminate cycles of length between $\ell + 1$ and $2\ell^6$ by detecting them and returning them as set $\mathcal{S}_{\mathsf{hs}}$ as any hitting separator has to intersect these. This gap between small and large cycles however allows us to get a similar gap for the distance between portal vertices.

▶ **Lemma 13.** *For any $v_1, v_2 \in X_C$, either $\mathsf{dist}_{G[C]}(v_1, v_2) \leq 2\ell^2$ or $\mathsf{dist}_{G[C]}(v_1, v_2) \geq 2\ell^6 - 2\ell$.*

This in turn allows us to cluster the portal vertices of every component. For $\ell_{\max} = 2\ell^2$ we put all portal vertices at distance at most $\ell_{\max}$ from a portal vertex v into the set X_v. This defines a partition into clusters:

▶ **Lemma 14.** *For any $C \in \mathcal{C}$ and $v_1, v_2 \in X_C$, sets X_{v_1} and X_{v_2} are either disjoint or equal.*

Consider now a long cycle O in G. Assume it contains for each strong component $C \in \mathcal{C}$ it visits only portal vertices of one of the clusters of C. In strong digraphs of circumference at most ℓ (like $G[C]$) the length of a path can at most be ℓ^2 times the distance between its endpoints. Therefore the length of O inside a single component C can be at most $2\ell^4$. We already made sure that long cycles in G have length more than $2\ell^6$. But we can shortcut O after the visit of C to a cycle with length between $\ell+1$ and $2\ell^6$ – a contradiction. Therefore every long cycle has a path between different clusters of some strong component of $G-t$.

By carefully analyzing the structure of the strong components and guessing vertices of S (by including them into $\mathcal{S}_{\mathsf{hs}}$) we make sure there are neither too many strong components with more than one cluster nor do these have to many clusters themselves. Moreover, we were able to restrict $t \to V_{\mathsf{out}}$-paths to a single strong component.

This means that our sought after solution S forms in each strong component C a multiway cut between the different cluster X_i of C and additionally cuts all $X_i \to V_{\mathsf{out}}$-paths in backward-range minimal way. This structure of S we call important cluster separators:

▶ **Definition 15.** *Let G be a digraph and let $X_1, \ldots, X_t, Y \subseteq V(G)$ be pairwise disjoint vertex sets. We call a vertex set $U \subseteq V \setminus (X_1 \cup \ldots \cup X_t \cup Y)$ a* cluster separator *if $G-U$ contains*

- *no path from X_i to X_j for $i \neq j$ and*
- *no path from X_i to Y for $i = 1, \ldots, t$.*

A cluster separator U is important *if there is no cluster separator U' with $|U'| \leq |U|$ and $R^-_{G-U'}(Y) \subsetneq R^-_{G-U}(Y)$.*

If $V_{\mathsf{out}} = \emptyset$ this boils down to the Directed Multiway Cut problem, which we solve by the algorithm of Chitnis et al. [9]. It thus remains to solve the case where $V_{\mathsf{out}} \neq \emptyset$.

Important Cluster Separator in Strong Digraphs of Bounded Circumference — *Parameter:* $k+\ell$.

Input: A strong digraph G, integers $k, \ell \in \mathbb{N}$ and sets $X_1, \ldots, X_p, V_{\mathsf{out}} \subseteq V(G)$.

Properties: $\mathsf{cf}(G) \leq \ell$, $X_i, V_{\mathsf{out}} \neq \emptyset$, $2 \leq p \leq k(k+1)+1$,
$\mathrm{dist}(v,w) \leq 2\ell^2 \quad \forall v, w \in X_i, i \in \{1, \ldots, p\}$.

Task: Find a vertex set $\mathcal{S}_{\mathsf{cluster}}$ intersecting any important cluster separator with respect to $X_1, \ldots, X_\ell, V_{\mathsf{out}}$ of size at most k.

Finding Important Cluster Separators. In this section we want to solve the Important Cluster Separator in Strong Digraphs of Bounded Circumference problem. This problem is strongly related to the Directed Multiway Cut Problem. By adding an additional vertex $v^\star$ that has an incoming arc from ever vertex of V_{out} we see that cluster separator are indeed multiway cuts in this modified graph. The difficulty lies in the notion of importance we introduced (and needed). That is, we want to intersect all cluster separators S where $R^-_{G-S}(V_{\mathsf{out}})$ is minimal for their size.

We introduce two definitions to handle this. The first is the concept of the *frontier* F of a cluster separator S. These are the vertices that define the backward range from V_{out}, i.e. the vertices of S that can reach V_{out} without going through another vertex of S. The other concept is that of an *outlet*. Given an $X_i \to X_j$-path P and two integers $\alpha, \beta \in \mathbb{Z}_{\geq 0}$, an (α, β)-outlet of P is a vertex ω of P with the following property: there is a $\omega \to V_{\mathsf{out}}$-path R_ω such that every vertex on P except for the α-many preceding and following vertices of ω on P have distance at least β from R_ω. These outlets are in some sense key positions where $X_i \to X_j$-paths start to significantly differ from $X_i \to V_{\mathsf{out}}$-paths.

For outlets we differentiate between "open" and "closed" outlets. *Open* outlets are outlets that lie in $R^-_{G-S}(V_{\mathsf{out}})$, i.e. behind the frontier; the other outlets *closed.* The frontier F is therefore separates $\mathcal{X} = \bigcup_{i=1}^t X_i$ from the open outlets. The rest of our efforts now focuses on finding a set V_Ω such that the frontier F is an important $\mathcal{X} \to (V_{\mathsf{out}} \cup V_\Omega)$-separator. This set V_Ω contains (a subset of) the open outlets for some $X_i \to X_j$-paths. As set of paths tho search on we take for every ordered pair of distinct X_i, X_j an arbitrary $X_i \to X_j$-path $P_{i,j}$.

The main property we use for finding the set V_Ω is some kind of locality argument. As our graph G is strong and has bounded circumference, the length of any path cannot differ too much from the distance of its endpoints. So if we know that a path is hit by S not to far from an outlet, we can guess these vertices. This is done with the help of k-representative sets of paths: if we know that an $\omega \to V_{\mathsf{out}}$-path is hit near ω, we construct a k-representative set of $\omega \to V_{\mathsf{out}}$-paths. We can argue that also one of the paths in this set has to be hit near ω. So we can guess all the vertices near ω on the paths of the k-representative set for their intersection with S.

By carefully guessing such potential intersections, and choosing α, β properly, we obtain:

- If a path $P_{i,j}$ has more than $\gamma = \mathrm{poly}(k, \ell)$ outlets, one of them is open.
- If there is a $X_i \to X_j$-path in $G - F$ then $P_{i,j}$ has an open outlet.

The last step is now to get rid of the $X_i \to X_j$-paths in $G - F$. We achieve this by guessing that a so called *landing strip* in front of an open outlet of $P_{i,j}$ (which exists by the second property) is disjoint from S. This landing strip has the task that that if there is a $X_i \to X_j$-path in $G - F$ than also the open outlet would be reachable. This again works by the locality of our strong graphs of bounded circumference.

After all these guessing we obtain (for the right guess) a set V_Ω such that F is an important $\mathcal{X} \to (V_{\mathsf{out}} \cup V_\Omega)$-separator. These we can enumerate by a result of Chitnis et al. [9].

▶ **Proposition 16** ([9]). *Let G be a digraph and let $X, Y \subseteq V(G)$ be disjoint non-empty vertex sets. For every $p \geq 0$ there are at most 4^p important $X - Y$-separators of size at most p, and all these separators can be enumerated in time $\mathcal{O}(4^p \cdot p(n + m))$.*

Putting Everything Together. Finally, we are able to prove our main result. By combining the reductions of the previous sections, we get an overall algorithm solving Directed Long Cycle Hitting Set:

▶ **Theorem 1.** *There is an algorithm that solves* Directed Long Cycle Hitting Set *in time $2^{\mathcal{O}(\ell^6 + \ell k^3 \log k + k^5 \log k \log \ell)} \cdot n^{\mathcal{O}(1)}$ for n-vertex digraphs G and parameters $k, \ell \in \mathbb{N}$.*

4 k-Representative Sets of Paths

In this section, we show how to obtain a k-representative set of paths of small size in strong digraphs of bounded circumference. Let us briefly recall the definition.

▶ **Definition 4.** *Let G be a digraph, $x, y \in V(G)$ and $k \in \mathbb{Z}_{\geq 0}$. A set $\mathcal{P}$ of $x \to y$-paths is a* k-representative set of $x \to y$-paths, *if for every set $S \subseteq V(G)$ of size at most k it holds: If there is an $x \to y$-path in $G - S$ there is an $x \to y$-path $P \in \mathcal{P}$ that is disjoint from S.*

Our goal is to prove the following:

▶ **Theorem 5.** *Let G be a strong digraph, $x, y \in V(G)$ and $k \in \mathbb{Z}_{\geq 0}$. Then a k-representative set of $x \to y$-paths having size $\mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \cdot \log n$ can be found in time $\mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$.*

If all $x \to y$-paths are short we can use the following result of Monien [23]:

▶ **Proposition 17** ([23]). *Let G be a digraph, let $x, y \in V(G)$ and let $k \in \mathbb{N}$. If every $x \to y$-path in G has length at most ℓ, then a k-representative set containing at most ℓ^k many $x \to y$-paths can be found in time $\ell^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.*

Recently, Fomin et al. [11] improved the computation of representative sets of paths, both in terms of the size of the set and the run time, but Proposition 17 will be sufficient for our purposes.

A motivational example. Before we give our construction for k-representative sets of paths in strong digraphs of bounded circumference, we want to consider graphs of treewidth two and a special example of treewidth three. Strong digraphs of treewidth two are trees with bidirected arcs. In this case we have that for every pair $x, y \in V(G)$ there is an unique $x \to y$-path P. Thus, $\{P\}$ is a feasible k-representative set of paths.

The situation is significantly different even for $\mathsf{cf}(G) = 3$. Consider the strong digraph in Figure 1.

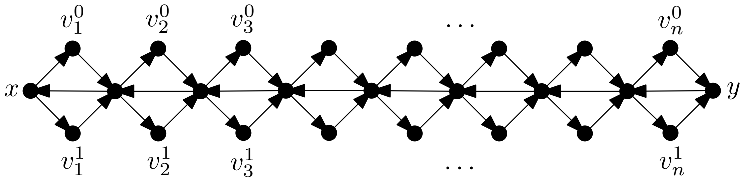

Figure 1 A digraph G with $\mathsf{cf}(G) = 3$ where every k-representative set of $x \to y$-paths has size $2^{\Omega(k)} \log n$.

There are exactly 2^n different $x \to y$-paths in G; each such path corresponds to a $0-1$ vector of length n. Thus, if we remove a vertex v_i^0 or v_i^1, then only those paths survive that have 1 or 0 at the i-th coordinate, respectively. Therefore, a collection of paths in this graph is k-representative only if no matter how we fix the values of k arbitrary coordinates, there is a vector in the collection satisfying these constraints. Such collections of vectors are also known as binary covering arrays. Kleitman and Spencer [17] proved that every collection of vectors of length n satisfying this property has size $2^{\Omega(k)} \cdot \log n$ (more precisely, they gave a lower bound on the dual question of k-independent families, but it can be easily rephrased into this lower bound).

We will now construct a k-representative set of paths for this graph G by using so called k-perfect families of hash functions.

▶ **Definition 18.** *Let $\mathcal{F}$ be a family of functions $f : U \to \{1, \ldots, k\}$ on the universe U. We say that $\mathcal{F}$ is a* k-perfect family of hash functions *if for every $X \subseteq U$ of size at most k, there is an $f \in \mathcal{F}$ that is injective on X, i.e. $f(x) \neq f(x')$ for any two distinct $x, x' \in X$.*

We use the following result by Alon et al. [1] for our construction.

▶ **Proposition 19** ([1]). *Let U be a universe and $k \in \mathbb{N}$. Then there exists a k-perfect family $\mathcal{F}$ of size $2^{\mathcal{O}(k)} \log |U|$ that can be constructed in time $2^{\mathcal{O}(k)}|U|^{\mathcal{O}(1)}$.*

Before considering arbitrary strong digraphs of bounded circumference, let us explain how k-perfect families of hash functions can be used for the construction in the case of the digraph G of Figure 1. Let $\mathcal{F}$ be a k-perfect family of hash functions over the universe $U = \{1, \ldots, n\}$ as in Proposition 19. Moreover, let $\mathcal{H}$ be the set of all functions $h : \{1, \ldots, k\} \to \{0, 1\}$. For $(f, h) \in \mathcal{F} \times \mathcal{H}$ denote by $P_{f,h}$ the $x \to y$-path in G that uses the vertices $v_i^{h(f(i))}$ for $i = 1, \ldots, n$. Then we add for every pair $(f, h) \in \mathcal{F} \times \mathcal{H}$ the path $P_{f,h}$ to our set $\mathcal{P}$.

Now consider a deletion set $S \subseteq V(G)$ of size at most k such that there is still an $x \to y$-path in G. Then S contains only vertices of type v_i^j and at most one of v_i^0 and v_i^1 for every $i \in \{1, \ldots, n\}$. In other words, for some $X \subseteq U$ of size at most k and function $g : X \to \{0, 1\}$, the vertices $v_i^{g(i)}$ form the set S. As $\mathcal{F}$ is a k-perfect family of hash functions, there is an $f \in \mathcal{F}$ that is injective on X. Now consider the function h defined as follows.

For every $i \in X$, let $h(f(i)) = 1 - g(i)$; as f is injective on X, this is well-defined and gives a function $h : f(X) \to \{0,1\}$. Complete, h to a function $h : \{1,\dots,k\} \to \{0,1\}$ by choosing the remaining values arbitrarily. We claim that the path $P_{f,h}$ introduced for this choice of f and h is disjoint from S. For $i \notin X$, it does not matter if $P_{f,h}$ uses v_i^0 or v_i^1. For $i \in X$, set S contains $v_i^{g(i)}$. By our definition of h, we have $h(f(i)) = 1 - g(i)$, hence $P_{f,h}$ uses $v_i^{1-g(i)}$, avoiding S. Thus $P_{f,h}$ is indeed disjoint from S.

Our proof of Theorem 5 generalizes this construction to arbitrary strong digraphs of bounded circumference: we construct the path by concatenating a series of fairly independent "short jumps." For each of these short jumps, we construct a k-representative set of paths by Proposition 17. The choice of which short path to select is determined by a k-perfect family of hash functions, similarly to the argument in the previous paragraph.

Strong digraphs with bounded circumference. Before we formally start proving Theorem 5, we establish some structural properties of strong digraphs with bounded circumference.

▶ **Lemma 20.** *Let G be a digraph and let $x, y \in V(G)$. If P_1 is an $x \to y$-path and P_2 is a $y \to x$-path, then $|P_1| \le (\mathsf{cf}(G) - 1)|P_2|$ holds. Consequently, we have $\mathsf{dist}_G(x,y) \le (\mathsf{cf}(G) - 1)\mathsf{dist}_G(y,x)$.*

Proof. Suppose, for sake of contradiction, that $|P_1| > (\mathsf{cf}(G) - 1)|P_2|$. By $x, y \in V(P_1) \cap V(P_2)$, we can split P_1 into $|P_2|$ pairwise disjoint subpaths whose internal vertices are disjoint from $V(P_2)$. Note that there are $|V(P_1)| - |V(P_2)| = (|P_1| + 1) - (|P_2| + 1) = |P_1| - |P_2|$ of these internal vertices. By pigeonhole principle, at least one of the subpaths has at least $\left\lceil \frac{|P_1|-|P_2|}{|P_2|} \right\rceil = \left\lceil \frac{|P_1|}{|P_2|} \right\rceil - 1$ internal vertices. By our assumption, these are at least $\mathsf{cf}(G) - 1$ many. But than the whole subpath has at least $\mathsf{cf}(G) + 1$ vertices. Since $P_1 \circ P_2$ is a closed walk, our segment is contained in a closed walk. Moreover, P_1 is acyclic and our segment is internally disjoint from P_2. Thus, the segment is even contained in a cycle. But this cycle then has length at least $\mathsf{cf}(G) + 1$, contradicting the definition of circumference. ◀

By using that there is always a backward path in strong digraphs, applying above result twice yields:

▶ **Lemma 21.** *Let G be a strong digraph and $x, y \in V(G)$. Then $|P| \le (\mathsf{cf}(G) - 1)^2 \mathsf{dist}_G(x,y)$ for every $x \to y$-path P.*

Proof. Let W be a shortest $x \to y$-path in G. As G is strong, there is also a $y \to x$-path Q in G. By Lemma 20 we then have

$$|P| \le (\mathsf{cf}(G) - 1)|Q| \le (\mathsf{cf}(G) - 1)^2|W| = (\mathsf{cf}(G) - 1)^2 \mathsf{dist}_G(x,y). \quad ◀$$

Similarly to the length, we can also argue about the distance between two paths.

▶ **Lemma 22.** *Let G be a strong digraph, $x, y \in V(G)$ be two vertices, and P_1, P_2 be two $x \to y$-paths. For every vertex v of P_1, we have $\mathsf{dist}_G(P_2, v) \le 2(\mathsf{cf}(G) - 2)$ and $\mathsf{dist}_G(v, P_2) \le 2(\mathsf{cf}(G) - 2)$.*

Proof. As G is strong, there is a $y \to x$-path Q.

▷ Claim 23. For $i \in \{1,2\}$, we have that

(i) $\mathsf{dist}_G(Q, v) \le \mathsf{cf}(G) - 2$ and $\mathsf{dist}_G(v, Q) \le \mathsf{cf}(G) - 2$ for every $v \in P_i$, and

(ii) $\mathsf{dist}_G(P_i, v) \le \mathsf{cf}(G) - 2$ and $\mathsf{dist}_G(v, P_i) \le \mathsf{cf}(G) - 2$ for every $v \in Q$.

Proof. Let $v \in P_i$. As P_i is acyclic (it is a path), but $P_i \circ Q$ is a closed walk in G, v has to lie on a cycle O in $P_i \circ Q$. This cycle has length at most $\mathsf{cf}(G)$. Furthermore, O has at least two vertices in $V(Q)$, as it contains an arc of Q. So there is a path in O from v to a vertex of Q of length at most $|O| - 2 \leq \mathsf{cf}(G) - 2$, showing $\mathsf{dist}_G(v, Q) \leq \mathsf{cf}(G) - 2$. On the other hand there is also a $V(Q) \to v$-path (from another vertex of $V(Q) \cap V(O)$) in O of length at most $|O| - 2 \leq \mathsf{cf}(G) - 2$, showing $\mathsf{dist}_G(Q, v) \leq \mathsf{cf}(G) - 2$. This shows Statement (i). Statement (ii) can be seen analogously by switching the roles of P_i and Q. ◁

Now fix a $v \in V(P_1)$. By Claim 23, we have that there is a $w \in V(Q)$ such that $\mathsf{dist}_G(w, v) = \mathsf{dist}_G(Q, v) \leq \mathsf{cf}(G) - 2$. Applying Claim 23 another time and using triangle inequality we get

$$\mathsf{dist}_G(P_2, v) \leq \mathsf{dist}_G(P_2, w) + \mathsf{dist}_G(w, v) \leq 2(\mathsf{cf}(G) - 2).$$

Similarly, we get from Claim 23 that there is an $u \in V(Q)$ with $\mathsf{dist}_G(v, u) = \mathsf{dist}_G(v, Q) \leq \mathsf{cf}(G) - 2$. Another application of Claim 23 and the triangle inequality yields

$$\mathsf{dist}_G(v, P_2) \leq \mathsf{dist}_G(v, u) + \mathsf{dist}_G(u, P_2) \leq 2(\mathsf{cf}(G) - 2),$$

concluding the proof. ◀

We are now ready to prove Theorem 5.

▶ **Theorem 5.** *Let G be a strong digraph, $x, y \in V(G)$ and $k \in \mathbb{Z}_{\geq 0}$. Then a k-representative set of $x \to y$-paths having size $\mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \cdot \log n$ can be found in time $\mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$.*

Proof. Let us fix an arbitrary $x \to y$-path R (which exists as G is strong) to guide our construction. Denote by r the length of R and by $v_0 = x, v_1, \ldots, v_{r-1}, v_r = y$ its vertices. We only consider a subset of vertices z_i at distance $d = 2\mathsf{cf}(G)^4$ from each other or more formally $z_i = v_{i \cdot d}$. These z_i will be the anchor vertices for our short jumps. We divide then z_i further into $k+1$ subsets Z^o by taking every $(k+1)$st vertex starting at offset o. Formally we define $z_i^o = z_{i(k+1)+o}$ and $Z^o = \{z_i^o\}$. These subsets have the advantage that one of these is far away from a deletion set S of size at most k. For this we fix a set S of size at most k such that an $x \to y$-path in $G - S$ exists.

▷ Claim 24. There is some $o_S \in \{0, \ldots, k\}$ such that

- $\mathsf{dist}_G(Z^{o_S}, S) > 2(\mathsf{cf}(G) - 2)$ and
- $\mathsf{dist}_G(S, Z^{o_S}) > 2(\mathsf{cf}(G) - 2)$.

Proof. We claim that for every $s \in S$ there is at most one value $o \in \{0, \ldots, k\}$ such that $\mathsf{dist}_G(Z^o, s) \leq 2\mathsf{cf}(G)^2$. Suppose that $\mathsf{dist}_G(w_1, s), \mathsf{dist}(w_2, s) \leq 2\mathsf{cf}(G)^2$ for some $w_1 \in Z^{o_1}$ and $w_2 \in Z^{o_2}$ with $o_1 \neq o_2$. Assume, without loss of generality, that w_1 is before w_2 on R; then $R[w_1, w_2]$ has length at least d (as different z_i have distance at least d). By Lemma 20, we have $\mathsf{dist}_G(s, w_1) \leq (\mathsf{cf}(G) - 1)\mathsf{dist}_G(w_1, s) \leq (\mathsf{cf}(G) - 1) \cdot 2\mathsf{cf}(G)^2$, thus $\mathsf{dist}_G(w_2, w_1) \leq \mathsf{dist}_G(w_2, s) + \mathsf{dist}_G(s, w_1) \leq 2\mathsf{cf}(G)^3$. Again by Lemma 20, we have $d \leq |R[w_1, w_2]| \leq (\mathsf{cf}(G) - 1)\mathsf{dist}_G(w_2, w_1) < 2\mathsf{cf}(G)^4$, a contradiction. Thus, we have proven that for each of the k vertices $s \in S$ there is at most one value $o \in \{0, \ldots, k\}$ such that s is at distance at most $2\mathsf{cf}(G)^2$ from Z^o. Therefore, by the pigeon-hole principle there is an $o_S \in \{0, \ldots, k\}$ such that $\mathsf{dist}_G(Z^{o_S}, S) > 2\mathsf{cf}(G)^2$. By Lemma 20 this also implies $\mathsf{dist}_G(S, Z^{o_S}) > 2\mathsf{cf}(G)^2 / (\mathsf{cf}(G) - 1) > 2(\mathsf{cf}(G) - 2)$. This completes the proof of Claim 24. ◁

Thus we know that a small surrounding of one of the Z^o's will be disjoint from S. Furthermore, Lemma 21 gives a bound on the length of a path P between two consecutive vertices z_i^o and z_{i+1}^o of Z^o, by $|P| \leq (\mathsf{cf}(G)-1)^2|R[z_i^o, z_{i+1}^o]| = \mathcal{O}(\mathsf{cf}(G)^7 k)$. This allows us to introduce sets $\mathcal{P}_i^o$ of k-representative $z_i^o \to z_{i+1}^o$-paths using the algorithm of Proposition 17 and have their size bounded by some $B = \mathcal{O}(\mathsf{cf}(G)^7 k)^k = \mathsf{cf}(G)^{\mathcal{O}(k \log k)}$ (using $k = 2^{\log k}$ and $\mathsf{cf}(G) \geq 2$). By duplicating paths as necessary we can assume that every P_i^o has size exactly B.

To make sure that our path collections with offset are connected to x and y, we construct additional sets $\mathcal{P}_x^o$ and $\mathcal{P}_y^o$ as follows: Let z_x^o be the first vertex in Z^o *after* x and z_y^o the last vertex *before* y. Then compute, using the algorithm of Proposition 17, $\mathcal{P}_x^o$ as a k-representative set of $x \to z_x^o$-paths and $\mathcal{P}_y^o$ as a k-representative set of $z_y^o \to y$-paths. As the distances between these pairs of vertices are bounded by the distance of neighboring vertices in Z^o we can analogously get a size bound of B for $\mathcal{P}_x^o$ and $\mathcal{P}_y^o$. Note that for some offsets o either $\mathcal{P}_x^o$ or $\mathcal{P}_y^o$ may align with some $\mathcal{P}_i^o$; then we leave out this $\mathcal{P}_i^o$ as we do not need it anymore. For each o, let $\mathcal{P}^o := \{\mathcal{P}_x^o, \mathcal{P}_y^o\} \cup \{\mathcal{P}_i^o\}_i$ be the set of these relevant sets.

▷ Claim 25. Every $\mathcal{P}_T^{o_S} \in \mathcal{P}^{o_S}$ contains a path disjoint from S.

Proof. Consider a set $\mathcal{P}_T^{o_S}$ with $T \in \{x, y, i\}$ such that the paths in $\mathcal{P}_T^{o_S}$ are $x_T \to y_T$-paths. As above sets are k-representative sets of paths, we must only show that there is any $x_T \to y_T$-path in $G - S$. By assumption there is a $x \to y$ path Q in $G - S$. By Lemma 22 we can find a $q_x \in V(Q)$ such that $\mathsf{dist}(x_T, q_x) \leq 2(\mathsf{cf}(G) - 2)$ and a $x_T \to q_x$-path Q_x in G achieving this distance. By Claim 24 we know that Q_x is disjoint from S and therefore, $Q_x \circ Q[q_x, y]$ is a $q_x \to y$ walk disjoint from S. Let $\hat{Q}_x$ be a $q_x \to y$-path contained in this walk. Another application of Lemma 22 yields a vertex $q_y \in V(\hat{Q})$ with $\mathsf{dist}(q_y, y_T) \leq 2(\mathsf{cf}(G) - 2)$ and a $q_y \to y_T$-path Q_y in G achieving this distance. Again, by Claim 24, Q_y is disjoint from S. Then $\hat{Q}_x[x_T, q_y] \circ Q_y$ contains a $x_T \to y_T$-path as proposed. This completes the proof of Claim 25. ◁

Of course, enumerating all possible tuples of paths would construct too many candidates, as the size of $\mathcal{P}^{o_S}$ can be $\Omega(m)$. Therefore, we want to use a $f(k)$-perfect family of hash functions. This is possible if we can bound the number of intersections with the sets $\mathcal{P}^{o_S}$ by $f(k)$.

▷ Claim 26. The set S intersects at most $2k$ sets of $\mathcal{P}^{o_S}$.

Proof. We show that $s \in S$ can intersect for at most two sets that share an endpoint, thus achieving the claimed size bound. Suppose for contradiction that s intersects two paths Q_1 and Q_2 out of sets in $\mathcal{P}^{o_S}$ that do not share an endpoint. Let each Q_i be a $x_i \to y_i$-path, then we can assume without loss on generality that the order the endpoints appear on R is x_1, y_1, x_2, y_2 and $|R[y_1, x_2] \geq 2\mathsf{cf}(G)^5$ (by the distance of the z_i. On the other hand $R[x_i, y_i]$ and Q_i connect the same endpoints, hence Lemma 22 implies that there is a $t_1 \in V(R[x_1, y_1])$ with $\mathsf{dist}(t_1, s) \leq 2(\mathsf{cf}(G) - 2)$ and a $t_2 \in V(R[x_2, y_2])$ with $\mathsf{dist}(s, t_2) \leq 2(\mathsf{cf}(G) - 2)$ as $s \in Q_1 \cap Q_2$. This implies that $\mathsf{dist}(t_1, t_2) \leq \mathsf{dist}(t_1, s) + \mathsf{dist}(s, t_2) \leq 4(\mathsf{cf}(G) - 2)$. If we now consider $R[t_1, t_2]$, we get $|R[t_1, t_2]| \geq |R[y_1, x_2] \geq 2\mathsf{cf}(G)^5 > (\mathsf{cf}(G) - 1)^2 \cdot \mathsf{dist}(t_1, t_2)$ in contradiction to Lemma 21. This completes the proof of Claim 26. ◁

We can now construct a $2k$-perfect family Ψ^o of hash functions over the universe $\mathcal{P}^o$ for each o. For o_S this family contains an element ψ which gives every set of $\mathcal{P}^{o_S}$ that is intersected by S a different number in $\{1, \ldots, 2k\}$ (by Claim 26). Further, there is a map π_{free} that maps the numbers of $\{1, \ldots, 2k\}$ to a number of $\{1, \ldots, B\}$, such that for every $\mathcal{P} \in \mathcal{P}^{o_S}$ which has a path intersected by S, we have that the $\psi \circ \pi_{\mathsf{free}}(\mathcal{P})$th path of $\mathcal{P}$ is not intersected by S. There is such a path by Claim 25. Denote by $Q_{\psi,\pi_{\mathsf{free}}}(\mathcal{P})$ this path. As we cannot know π_{free} in advance we create a set Π of all possible functions from $\{1,\dots,2k\}$ to $\{1,\dots,B\}$.

We know that for the specific choices of o_S, ψ and π_{free} we get a that the union of paths in $\{Q_{\psi,\pi_{\mathsf{free}}}(\mathcal{P}) | \mathcal{P} \in \mathcal{P}^{o_S}\}$ forms a $x \to y$ walk W in $G - S$. Every $x \to y$-path within W is also disjoint from S. Therefore, the set $\mathcal{P}_{x,y,k}$ created as follows contains a path disjoint from S: For every $o \in \{1,\dots,k+1\}$, every $\psi \in \Psi$ and every $\pi \in \Pi$ consider the $x \to y$-walk $\bigcup_{\mathcal{P} \in \mathcal{P}^o} Q_{\psi,\pi}(\mathcal{P})$ and introduce an arbitrary $x \to y$-path contained in it into $\mathcal{P}_{x,y,k}$.

The size bound on $\mathcal{P}_{x,y,k}$ is proven by multiplying the possibilities for each choice:

$$\underbrace{(k+1)}_{\text{choice of } o} \cdot \underbrace{2^{\mathcal{O}(k)} \log m}_{|\Psi|} \cdot \underbrace{B^{2k}}_{|\Pi|} = \mathsf{cf}(G)^{\mathcal{O}(k^2 \log k)} \log n.$$

The run time follows similarly. ◀

We think that k-representative sets of paths could prove a useful tool in many vertex deletion problems. Together with iterative compression, it allows one to argue about connectivity structure of the old solution. In our case it led to contraction argument strengthening the solution structure (Lemma 3) and a focused guessing of solution vertices (subsection about finding important cluster separators).

There may be other use cases as well. Therefore, we decided to present our result on k-representative sets of paths in a self-contained way. We hope that this helps other researchers and improves our understanding of vertex-deletion problems in directed graphs.

Abstract

The *central levels problem* asserts that the subgraph of the $(2m+1)$-dimensional hypercube induced by all bitstrings with at least $m+1-\ell$ many 1s and at most $m+\ell$ many 1s, i.e., the vertices in the middle 2ℓ levels, has a Hamilton cycle for any $m \geq 1$ and $1 \leq \ell \leq m+1$. This problem was raised independently by Savage, by Gregor and Škrekovski, and by Shen and Williams, and it is a common generalization of the well-known *middle levels problem*, namely the case $\ell = 1$, and classical binary Gray codes, namely the case $\ell = m+1$. In this paper we present a general constructive solution of the central levels problem. Our results also imply the existence of optimal cycles through any sequence of ℓ consecutive levels in the n-dimensional hypercube for any $n \geq 1$ and $1 \leq \ell \leq n+1$. Moreover, extending an earlier construction by Streib and Trotter, we construct a Hamilton cycle through the n-dimensional hypercube, $n \geq 2$, that contains the symmetric chain decomposition constructed by Greene and Kleitman in the 1970s, and we provide a loopless algorithm for computing the corresponding Gray code.

1 Introduction

The *n-dimensional hypercube*, or *n-cube* for short, is the graph Q_n formed by all $\{0,1\}$-strings of length n, with an edge between any two bitstrings that differ in exactly one bit. This family of graphs has numerous applications in computer science and discrete mathematics, many of which are tied to famous problems and conjectures, such as the sensitivity conjecture of Nisan and Szegedy [29], recently proved by Huang [23]; Erdős and Guys' crossing number problem [8] (see [9]); Füredi's conjecture [13] on equal-size chain partitions (see [41]); Shearer and Kleitman's conjecture [37] on orthogonal symmetric chain decompositions (see [39]); the Ruskey-Savage problem [32] on matching extendability (see [11, 12]), and the conjectures of Norine, and Feder and Subi on edge-antipodal colorings [10, 30], to name just a few.

The focus of this paper are Hamilton cycles in the n-cube and its subgraphs. A Hamilton cycle in a graph is a cycle that visits every vertex exactly once, and in the context of the n-cube, such a cycle is often referred to as a *Gray code.* Gray codes have found applications in signal processing, circuit testing, hashing, data compression, experimental design, and in solving puzzles like the Towers of Hanoi or the Chinese rings; see Savage's survey [35]. They are also fundamental for efficient exhaustive generation algorithms, a topic that is covered in depth in the most recent volume of Knuth's *'The Art of Computer Programming'* [25].

To start with, it is an easy exercise to show that the n-cube has a Hamilton cycle for any $n \geq 2$. One such cycle is given by the classical *binary reflected Gray code* Γ_n [14], defined inductively by $\Gamma_1 := 0, 1$ and $\Gamma_{n+1} := 0\Gamma_n, 1\Gamma_n^R$, where Γ^R denotes the reversal of the sequence Γ, and 0Γ or 1Γ means prefixing all strings in the sequence Γ by 0 or 1, respectively. For instance, this construction gives $\Gamma_2 = 00, 01, 11, 10$ and $\Gamma_3 = 000, 001, 011, 010, 110, 111, 101, 100$. The problem of finding a Hamilton cycle becomes considerably harder when we restrict our attention to subgraphs of the cube induced by a sequence of consecutive levels, where the *k-th level* of Q_n, $0 \leq k \leq n$, is the set of all bitstrings with exactly k many 1s in them. One such instance is the famous *middle levels problem*, raised in the 1980s by Havel [22] and independently by Buck and Wiedemann [4], which asks for a Hamilton cycle in the subgraph of the $(2m + 1)$-cube induced by levels m and $m + 1$. This problem received considerable attention in the literature, and a construction of such a cycle for all $m \geq 1$ was provided only recently by Mütze [27]. A much simpler construction was described subsequently by Gregor, Mütze, and Nummenpalo [19].

1.1 Our results

In this paper we consider the *central levels problem*, a broad generalization of the middle levels problem: Does the subgraph of the $(2m + 1)$-cube induced by the middle 2ℓ levels, i.e., by levels $m + 1 - \ell, \ldots, m + \ell$, have a Hamilton cycle for any $m \geq 1$ and $1 \leq \ell \leq m + 1$? This problem was raised independently by Savage [34], Gregor and Škrekovski [20], and by Shen and Williams [38]. Clearly, the case $\ell = 1$ of the central levels problem is the aforementioned middle levels problem (solved in [27]). Moreover, the case $\ell = 2$ was solved affirmatively in a paper by Gregor, Jäger, Mütze, Sawada, and Wille [16] presented at ICALP 2018. Also, the case $\ell = m + 1$ is established by the binary reflected Gray code Γ_{2m+1}. Furthermore, the case $\ell = m$ was solved by El-Hashash and Hassan [7], and in a more general setting by Locke and Stong [26], and the case $\ell = m - 1$ was settled in [20].

The main contribution of this paper is to solve the central levels problem affirmatively in full generality; see Figure 1 (a)–(d).

▶ **Theorem 1.** *For any $m \geq 1$ and $1 \leq \ell \leq m + 1$, the subgraph of the $(2m + 1)$-cube induced by the middle 2ℓ levels has a Hamilton cycle.*

The most general question in this context is to ask for a Hamilton cycle in Q_n that visits all vertices in *any* sequence of ℓ consecutive levels, i.e., the levels need not be symmetric around the middle, and the dimension n needs not be odd. These graphs are all bipartite, and to circumvent the imbalances that prevent the existence of a Hamilton cycle for general n and ℓ, we have to slightly generalize the notion of Hamilton cycles: Firstly, a *saturating cycle* in a bipartite graph is a cycle that visits all vertices in the smaller partition class (if it has size 1, then a single edge is considered to be a cycle). Secondly, a *tight enumeration* in a (bipartite) subgraph of the cube is a cyclic listing of all its vertices where the total number of bits flipped is exactly the number of vertices plus the difference in size between the two partition classes. Clearly, if both partition classes have the same size, these two notions are equal to a Hamilton cycle. In fact, all cases of this more general problem, except the central levels problem, were solved already in [18], some of them conditional on a "yes" answer to the central levels problem. Combining Theorem 1 with these previous results, we now also obtain an unconditional result for this more general question.

▶ **Corollary 2.** *For any $n \geq 1$ and $1 \leq \ell \leq n+1$, the subgraph of the n-cube induced by any sequence of ℓ consecutive levels has both a saturating cycle and a tight enumeration.*

An essential tool in our proof of Theorem 1 are symmetric chain decompositions. This is a well-known concept from the theory of posets, which we now define specifically for the n-cube using graph-theoretic language. A *symmetric chain* in Q_n is a path $(x_k, x_{k+1}, \ldots, x_{n-k})$ in the n-cube where x_i is from level i for all $k \leq i \leq n-k$, and a *symmetric chain decomposition*, or SCD for short, is a partition of the vertices of Q_n into symmetric chains. It is well-known that the n-cube has an SCD for all $n \geq 1$, and the simplest explicit construction was given by Greene and Kleitman [15] (see Section 2.2 below). Streib and Trotter [40] first investigated the interplay between SCDs and Hamilton cycles in the n-cube, and they described an SCD in Q_n that can be extended to a Hamilton cycle; see Figure 1 (e). Their SCD, however, is different from the aforementioned Greene-Kleitman SCD. In this paper, we extend Streib and Trotter's result as follows; see Figure 1 (f).

▶ **Theorem 3.** *For any $n \geq 2$, the Greene-Kleitman SCD can be extended to a Hamilton cycle in Q_n.*

The Greene-Kleitman SCD has found a large number of applications in the literature, e.g., to construct symmetric Venn diagrams [21, 33], to solve the Littlewood-Offord problem [3, Chap. 4], or to learn monotone Boolean functions [25, Sec. 7.2.1.6] (see also [1, 6, 31, 37, 42]). Knowing that this SCD extends to a Hamilton cycle and that it is a crucial ingredient for solving the general central levels problem adds to this list of interesting properties and applications. Observe also that a Hamilton cycle that extends an SCD has the intriguing property that it minimizes the number of changes of direction from moving up to moving down, or vice versa, between consecutive levels in the cube. For comparison, the monotone paths constructed by Savage and Winkler [36] maximize these changes.

Motivated by these results and by the aforementioned conjecture of Ruskey and Savage [32] that every matching in Q_n extends to a Hamilton cycle, we raise the following conjecture:

▶ **Conjecture 4.** *Every SCD can be extended to a Hamilton cycle in Q_n.*

Although every SCD of Q_n is the union of two matchings, there are matchings in Q_n that do not extend to an SCD; take for example the two edges obtained by starting at the vertices 0^n and 1^n and flipping the same bit. Consequently, an affirmative answer to Conjecture 4 would cover only some cases of the Ruskey-Savage conjecture.

1.2 Efficient algorithms

Our proof of Theorem 1 is constructive and translates directly into an algorithm for computing the Hamilton cycle in time and space that are polynomial in the size of the graph (the middle 2ℓ levels of Q_n, $n := 2m+1$), which is exponential in n. Often, it is desirable to have

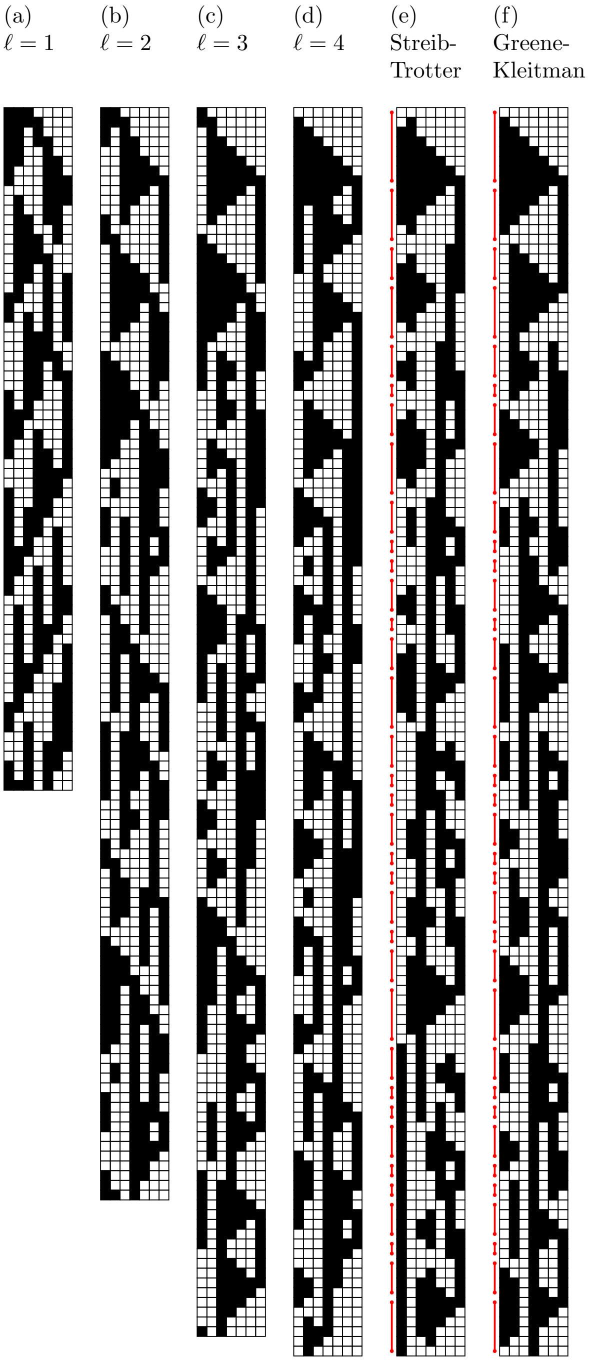

Figure 1 (a)–(d) The Hamilton cycles in $Q_{7,\ell}$ for $\ell = 1, 2, 3, 4$ constructed as in our proof of Theorem 1. (e) The Hamilton cycle in Q_7 containing an SCD obtained from the Streib-Trotter construction, with symmetric chains highlighted on the side. (f) The Hamilton cycle in Q_7 containing the Greene-Kleitman SCD obtained from our proof of Theorem 3. In this figure, 1-bits are drawn as black squares, 0-bits as white squares.

a "local" algorithm that uses only time and space that are polynomial in n. Ideally, one might hope for $\mathcal{O}(n)$ space to store the current bitstring and some additional data structures, and $\mathcal{O}(1)$ time to compute the next bitstring on the cycle. Such algorithms are known for the binary reflected Gray code Γ_n [2], and for the middle levels problem [28], i.e., for the extreme cases $\ell = m+1$ and $\ell = 1$ of the central levels problem. There are fundamental obstacles that prevent us to obtain such a local algorithm from our proof, and it remains a challenging open problem to find such an algorithm. Our Theorem 3 on the other hand, can be translated into a simple algorithm that uses only $\mathcal{O}(n)$ space and $\mathcal{O}(1)$ time in every iteration to compute the next bitstring along the Hamilton cycle. A pseudocode description of this algorithm is available in [17]. We also implemented it in C++, available for download and for demonstration on the Combinatorial Object Server [5].

1.3 Proof ideas

We first describe the ideas for proving Theorem 1. For any $m \geq 1$ we define $n := 2m+1$, and for $1 \leq \ell \leq m+1$ we let $Q_{n,\ell}$ denote the subgraph of Q_n induced by the middle 2ℓ levels. To prove that $Q_{n,\ell}$ has a Hamilton cycle for general m and ℓ, we combine and generalize the tools and techniques developed for the cases $\ell = 1$ and $\ell = 2$ in [19] and [16], respectively. Our proof proceeds in two steps: In a first step, we construct a *cycle factor* in $Q_{n,\ell}$, i.e., a collection of disjoint cycles which together visit all vertices of $Q_{n,\ell}$. In a second step, we use local modifications to join the cycles in the factor to a single Hamilton cycle. Essentially, this technique reduces the Hamiltonicity problem in $Q_{n,\ell}$ to proving that a suitably defined auxiliary graph is connected, which is much easier.

In fact, the predecessor paper [16] already proved the existence of a cycle factor in $Q_{n,\ell}$, but this construction does not seem to yield a factor that would be amenable to analysis. In this paper, we therefore construct another cycle factor in $Q_{n,\ell}$, based on modifying the aforementioned Greene-Kleitman SCD of Q_n by the lexical matchings introduced by Kierstead and Trotter [24]. The resulting cycle factor in $Q_{n,\ell}$ has a rich structure, in particular the number of cycles and their lengths can be described combinatorially.

The simplest way to join two cycles C and C' from this factor to a single cycle is to consider a 4-cycle F that shares exactly one edge with each of the cycles C and C' (the other two edges of F must then go between C and C'), and to take the symmetric difference of the edge sets of $C \cup C'$ and of F, yielding a single cycle $(C \cup C') \bigtriangleup F$ on the same vertex set as $C \cup C'$. We refer to such a cycle F as a *flipping* 4*-cycle*. For example, if we interpret the binary reflected Gray code Γ_n as a cycle in Q_n, we see that $\Gamma_{n+1} = (0\Gamma_n \cup 1\Gamma_n^R) \bigtriangleup F$ where F is the 4-cycle $F = 0^{n+1}, 010^{n-1}, 110^{n-1}, 10^n$. In addition to flipping 4-cycles, we also use flipping 6-cycles, which intersect with the two cycles to be joined in a slightly more complicated way, albeit with the same effect of joining them to a single cycle. The most technical aspect of this part of the proof is to ensure that all flipping cycles used are edge-disjoint, so that the joining operations do not interfere with each other.

To prove Theorem 3, we proceed by induction from dimension n to $n+2$, treating the cases of even and odd n separately. We first specify a particular ordering of all chains of the Greene-Kleitman SCD, and then show that this ordering admits a matching that alternatingly joins the bottom or top vertices of any two consecutive chains in our ordering. In fact, there is a close relation between our proofs of Theorem 1 and 3: The aforementioned construction of a cycle factor in $Q_{n,\ell}$ is particularly nice for $\ell = m+1$, i.e., for the case where we consider the entire cube. Specifically, in this case our cycle factor contains *all* chains from the Greene-Kleitman SCD. These cycles can be joined to a single Hamilton cycle in such a way, so as to give exactly the aforementioned Hamilton cycle constructed for proving Theorem 3.

1.4 Outline of this paper

In Section 2 we discuss the Greene-Kleitman SCD and lexical matchings, and collect some other preliminaries. In Section 3 we describe our construction of a cycle factor in $Q_{n,\ell}$. Due to space constraints, in this extended abstract we are unable to provide the full details of the analysis of this cycle factor, and how to join its cycles to a Hamilton cycle. We rather give an informal high-level sketch of these steps in Section 4. In Section 5 we present our proof of Theorem 3. The omitted proof details, together with the pseudocode description of the corresponding loopless algorithm can be found in [17].

2 Preliminaries

For the reader's convenience, important notations that are introduced in the following and used repeatedly in the paper are summarized in Table 1 at the end of this paper.

2.1 Bitstrings and lattice paths

For any string x and any integer $k \geq 0$, we let x^k denote the concatenation of k copies of x. We often interpret a bitstring x as a path in the integer lattice $\mathbb{Z}^2$ starting at the origin $(0,0)$, where every 0-bit is interpreted as a $\diagdown$-step that changes the current coordinate by $(+1,-1)$ and every 1-bit is interpreted as an $\diagup$-step that changes the current coordinate by $(+1,+1)$; see Figure 2.

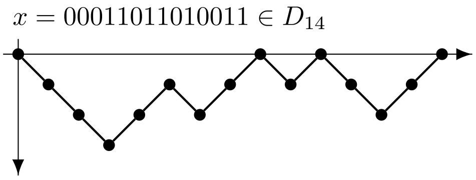

Figure 2 The correspondence between bitstrings (top) and lattice paths (bottom).

Let D_{2k} denote the set of bitstrings with exactly k many 1s and k many 0s, such that in every prefix, the number of 0s is at least as large as the number of 1s. We also define $D := \bigcup_{k\geq 0} D_{2k}$. Note that $D_0 = \{\varepsilon\}$, where ε denotes the empty bitstring. In terms of lattice paths, D corresponds to so-called *Dyck paths* that never move above the line $y = 0$ and end on this line. If a lattice path x contains a substring $u \in D$, then we refer to this substring u as a *valley* in x.

2.2 The Greene-Kleitman SCD

We now describe Greene and Kleitman's [15] construction of an SCD in the n-cube; see Figure 3. For any vertex x of the n-cube, we interpret the 0s in x as opening brackets and the 1s as closing brackets. By matching closest pairs of opening and closing brackets in the natural way, the chain containing x is obtained by flipping the leftmost unmatched 0 to ascend the chain, or the rightmost unmatched 1 to descend the chain, until no more unmatched bits can be flipped. It is easy to see that this indeed yields an SCD of the n-cube for any $n \geq 1$. We always work with this SCD due to Greene and Kleitman, and whenever referring to a chain, we mean a chain from this decomposition.

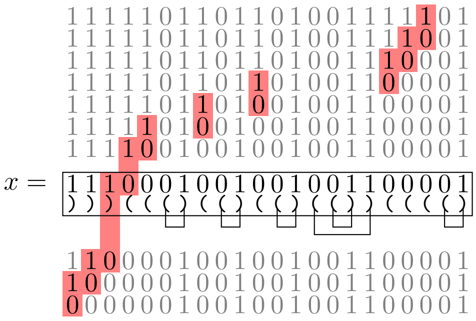

Figure 3 Construction of the Greene-Kleitman SCD containing a bitstring x via parenthesis matching. The highlighted bits are the leftmost unmatched 0 and the rightmost unmatched 1 in each bitstring.

Each chain C of length h in Q_n can be encoded compactly as a string of length n over the alphabet $\{0, 1, *\}$ in the form

$$C = u_0 * u_1 * \cdots * u_{h-1} * u_h, \tag{1}$$

where $u_0, \ldots, u_h \in D$. The symbols $*$ represent unmatched positions, and the vertices along the chain are obtained by replacing the $*$s by 1s followed by 0s in all possible ways; see (2). For example, the chain shown in Figure 3 is $C = *****01*01*010011***01$, so we have $u_0 = u_1 = u_2 = u_3 = u_4 = u_8 = u_9 = \varepsilon$, $u_5 = u_6 = u_{10} = 01$, and $u_7 = 010011$.

We distinguish four types of chains depending on whether u_0 and u_h, i.e., the first and last valleys in (1), are empty or not. These chain types are denoted by $[--]$, $[+-]$, $[++]$, and $[-+]$, where the first symbol is $-$ if $u_0 = \varepsilon$ and $+$ otherwise, and the second symbol is $-$ if $u_h = \varepsilon$ and $+$ otherwise. For example, the chain in Figure 3 is a $[-+]$-chain. We also use the symbol ? in these type specifications if we do not know whether a valley is empty or not. Note that there is no $[--]$-chain in Q_n of length $h = 1$ unless $n = 1$.

Given a chain C of length h as in (1), the ith vertex of C from the bottom is

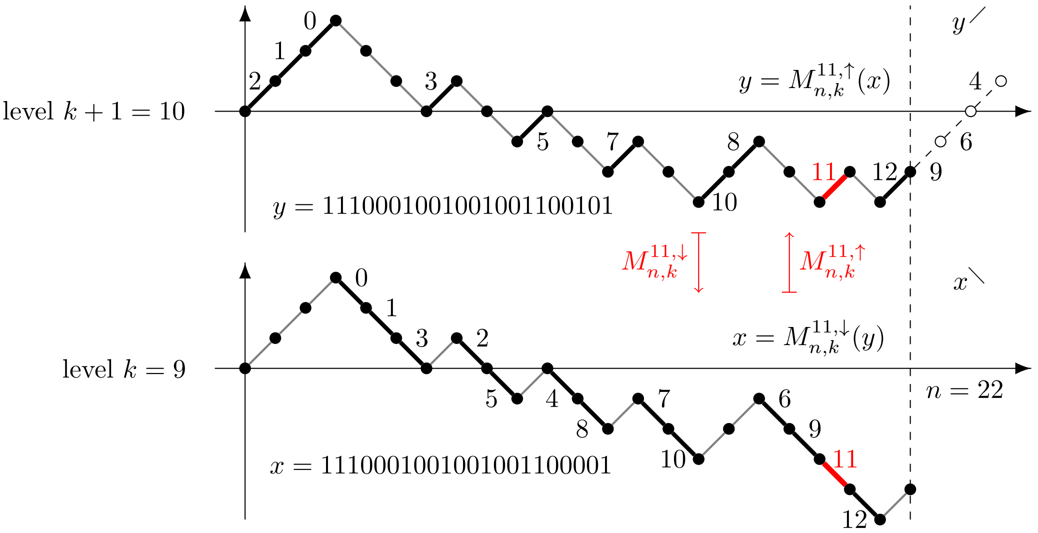
$$x = u_0\, 1 \cdots u_{i-1}\, 1\, u_i\, 0\, u_{i+1} \cdots 0\, u_h \tag{2}$$

where $i = 0, \ldots, h$, and this vertex belongs to level $k = \frac{n-h}{2} + i$. Note that every vertex x of Q_n can be written uniquely in the form (2), and we refer to this as the *chain factorization of* x. For the following arguments, it will be crucial to consider the lattice path representation of x, with the valleys $u_0, \ldots, u_h$ that are separated by i many $\nearrow$-steps, followed by $h - i$ many $\searrow$-steps, i.e., the valley u_i is the highest one on the lattice path.

We use $C_{h,i}$, $0 \leq i \leq h$, to denote the set of the ith vertices in all chains of length h. Moreover, we partition $C_{h,i}$ into two sets $C^-_{h,i}$ and $C^+_{h,i}$, depending on whether the valley u_i in (2) is empty or nonempty, respectively. Clearly, $C^+_{h,h}$ are exactly the top vertices of [?+]-chains of length h and $C^+_{h,0}$ are exactly the bottom vertices of [+?]-chains of length h, and similarly with $-$ instead of $+$. Note that the sets $C_{h,i}$ are empty if n is odd and h is even, or vice versa.

2.3 Lexical matchings

Lexical matchings in Q_n were introduced by Kierstead and Trotter [24], and they are parametrized by some integer $p \in \{0, 1, \ldots, n-1\}$. These matchings are defined as follows; see Figure 4. We interpret a bitstring x as a lattice path, and we let $x^{\searrow}$ denote the lattice



$y^{\diagup}$
$y = M_{n,k}^{11,\uparrow}(x)$
level $k+1 = 10$
0
1
2

12
$y = 1110001001001001100101$
$M_{n,k}^{11,\downarrow}$
$M_{n,k}^{11,\uparrow}$
$x^{\diagdown}$
$x = M_{n,k}^{11,\downarrow}(y)$
level $k = 9$
$n = 22$
$x = 1110001001001001100001$

Figure 4 Definition of p-lexical matchings between levels 9 and 10 of Q_{22}, where steps flipped along the p-lexical edge are marked with p. Between those two levels, the vertex x is incident with p-lexical edges for each $p \in \{0, 1, \ldots, 12\}$, and the vertex y is incident with p-lexical edges for each $p \in \{0, 1, \ldots, 12\} \setminus \{4, 6, 9\}$.

path that is obtained by appending $\diagdown$-steps to x until the resulting path ends at height -1. If x ends at a height less than -1, then $x^{\diagdown} := x$. Similarly, we let $x^{\diagup}$ denote the lattice path obtained by appending $\diagup$-steps to x until the resulting path ends at height $+1$. If x ends at a height more than $+1$, then $x^{\diagup} := x$. We let $L_{n,k}$ denote the set of all vertices on level k of Q_n, and we define a matching by two partial mappings $M_{n,k}^{p,\uparrow}\colon L_{n,k} \to L_{n,k+1}$ and $M_{n,k}^{p,\downarrow}\colon L_{n,k+1} \to L_{n,k}$ defined as follows: For any $x \in L_{n,k}$ we consider the lattice path $x^{\diagdown}$ and scan it row-wise from top to bottom, and from right to left in each row. The partial mapping $M_{n,k}^{p,\uparrow}(x)$ is obtained by flipping the pth $\diagdown$-step encountered in this fashion, where counting starts with $0, 1, \ldots$, if this $\diagdown$-step is part of the subpath x of $x^{\diagdown}$; otherwise x is left unmatched. Similarly, for any $x \in L_{n,k+1}$ we consider the lattice path $x^{\diagup}$ and scan it row-wise from top to bottom, and from left to right in each row. The partial mapping $M_{n,k}^{p,\downarrow}(x)$ is obtained by flipping the pth $\diagup$-step encountered in this fashion if this $\diagup$-step is part of the subpath x of $x^{\diagup}$; otherwise x is left unmatched. It is straightforward to verify that these two partial mappings are inverse to each other, so they indeed define a matching between levels k and $k+1$ of Q_n, called the *p-lexical matching*, which we denote by $M_{n,k}^{p}$. We also define $M_n^p := \bigcup_{0 \le k < n} M_{n,k}^p$, where we omit the index n whenever it is clear from the context. In the following, we will only ever use p-lexical edges for $p = 0, 1, 2$. For instance, it is

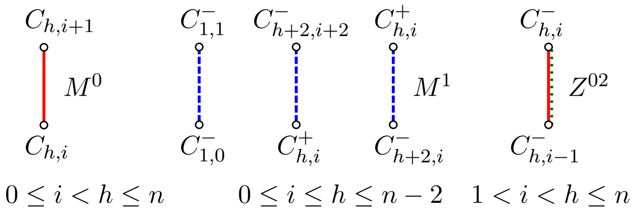

Figure 5 Perfect matchings described by Lemma 5. The $\{0, 1, 2\}$-lexical edges are drawn solid, dashed, and dotted, respectively.

well-known that taking the union of all 0-lexical edges, i.e., the set M^0, yields exactly the Greene-Kleitman SCD [24]. This property is captured by the following lemma, together with several other explicit perfect matchings, consisting of $\{0,1,2\}$-lexical edges between certain sets of vertices from our SCD; see Figure 5.

To state the lemma, for a set M of edges of Q_n and disjoint sets X, Y of vertices, we let $M[X,Y]$ denote the set of all edges of M between X and Y. Moreover, for any vertex $x \in C^-_{h,i}$, $1 < i < h \leq n$, we consider the chain factorization $x = u_0\,1 \cdots u_{i-2}\,1\,u_{i-1}\,1\,0\,u_{i+1} \cdots 0\,u_h$ with $u_0, \ldots, u_h \in D$, and we define a neighbor $z(x)$ on the level below by

$$z(x) := \begin{cases} u_0\,1 \cdots u_{i-2}\,1\,0\,0\,u_{i+1} \cdots 0\,u_h & \text{if } u_{i-1} = \varepsilon, \\ u_0\,1 \cdots u_{i-2}\,1\,0\,v\,0\,w\,1\,0\,u_{i+1} \cdots 0\,u_h & \text{if } u_{i-1} = 0\,v\,1\,w \text{ with } v, w \in D. \end{cases} \tag{3}$$

Note that $(x, z(x))$ is a 0-lexical or 2-lexical edge in the first or second case, respectively.

▶ **Lemma 5.** *For every $n \geq 3$, the following sets of edges $M[X,Y]$ are perfect matchings in Q_n between the vertex sets X and Y.*

(i) $M^0[C_{h,i}, C_{h,i+1}]$ *for every* $0 \leq i < h \leq n$*;*

(ii) $M^1[C^-_{1,0}, C^-_{1,1}]$*,* $M^1[C^+_{h,i}, C^-_{h+2,i+2}]$*, and* $M^1[C^+_{h,i}, C^-_{h+2,i}]$ *for every* $0 \leq i \leq h \leq n-2$*;*

(iii) $Z^{02}[C^-_{h,i-1}, C^-_{h,i}]$ *for every* $1 < i < h \leq n$*, where* $Z^{02} := \{(x, z(x)) \mid x \in C^-_{h,i}\}$*.*

The proof of Lemma 5 can be found in [17].

3 Cycle factor construction

We now construct a cycle factor $\mathcal{C}_{n,\ell}$ in the graph $Q_{n,\ell}$, $n = 2m+1$, i.e., in the subgraph of the n-cube induced by the middle 2ℓ levels. Throughout this section we consider fixed $m \geq 1$ and $2 \leq \ell \leq m+1$. We construct the cycle factor incrementally, starting with chains from the Greene-Kleitman SCD and adding $\{0,1,2\}$-lexical edges between certain sets of vertices, see Figure 6. In the following, when referring to a subgraph given by a set of edges, we mean the subgraph of $Q_{n,\ell}$ induced by those edges. Moreover, we say that a chain is *short* if its length is at most $2\ell-3$, i.e., if it does not span all levels of $Q_{n,\ell}$.

Our construction starts by taking all those short chains, formally

$$X^0 := \bigcup_{0 \leq i < h \leq 2\ell-3} M^0[C_{h,i}, C_{h,i+1}]; \tag{4a}$$

recall Lemma 5 (i). From Lemma 5 (ii) we know that 1-lexical edges perfectly match all bottom vertices of $[-+]$-chains of length 1 with all top vertices of $[+-]$-chains of length 1 along the edges

$$X^1_{\mathtt{m}} := M^1[C^-_{1,0}, C^-_{1,1}]. \tag{4b}$$

Furthermore, for $1 \leq h \leq 2\ell-5$, 1-lexical edges perfectly match all top vertices of $[?+]$-chains of length h with all top vertices of $[?-]$-chains of length $h+2$, and all bottom vertices of $[+?]$-chains of length h with all bottom vertices of $[-?]$-chains of length $h+2$ along the edges

$$X^1_{\mathtt{t}} := \bigcup_{1 \leq h \leq 2\ell-5} M^1[C^+_{h,h}, C^-_{h+2,h+2}], \quad X^1_{\mathtt{b}} := \bigcup_{1 \leq h \leq 2\ell-5} M^1[C^+_{h,0}, C^-_{h+2,0}], \tag{4c}$$

respectively. Note that the only vertices of short chains that have degree 1 in the set

$$X := X^0 \cup X^1_{\mathtt{m}} \cup X^1_{\mathtt{t}} \cup X^1_{\mathtt{b}} \tag{4d}$$

are exactly the vertices of $C^+_{2\ell-3,2\ell-3}$ and $C^+_{2\ell-3,0}$; that is, the top vertices of $[?+]$-chains of length $2\ell-3$ and the bottom vertices of $[+?]$-chains of length $2\ell-3$.

Next, between every pair of consecutive levels of $Q_{n,\ell}$ we take all 0-lexical and 1-lexical edges that are not incident to a degree-2 vertex in X. Specifically, between these pairs of levels we take all 0-lexical edges from chains that are not short and all 1-lexical edges between chains that are not short. In addition, between the top two levels we take all 1-lexical edges between top vertices of [?+]-chains of length $2\ell-3$ and top vertices of [?−]-chains of length $2\ell-1$, and symmetrically, between the bottom two levels we take all 1-lexical edges between bottom vertices of [+?]-chains of length $2\ell-3$ and bottom vertices of [−?]-chains of length $2\ell-1$. Formally, these sets of edges are

$$Y_1 := Y_1' \cup M^1[C^+_{2\ell-3,0}, C^-_{2\ell-1,0}], \quad Y_\ell := Y_\ell' \cup M^1[C^+_{2\ell-3,2\ell-3}, C^-_{2\ell-1,2\ell-1}], \quad Y_k := Y_k' \tag{5a}$$

for $1 < k < \ell$ where

$$Y_k' := \bigcup_{\substack{h\geq 2\ell-1\\ i:=(h-(2\ell-1))/2+2(k-1)}} M^0[C_{h,i}, C_{h,i+1}] \cup M^1[C^+_{h,i}, C^-_{h+2,i+2}] \cup M^1[C^+_{h,i+1}, C^-_{h+2,i+1}] \tag{5b}$$

for $1 \leq k \leq \ell$. Note that Y_1 and Y_ℓ contain all $\{0,1\}$-lexical edges between the bottom two levels or the top two levels of $Q_{n,\ell}$, respectively. We also define

$$Y := \bigcup_{1\leq k\leq \ell} Y_k. \tag{5c}$$

As a consequence of these definitions and Lemma 5 (i) and (ii), the only vertices of $Q_{n,\ell}$ that have degree 1 in the set $X \cup Y$ are exactly the vertices of $C^-_{2\ell-1,i}$ for $1 \leq i \leq 2\ell-2$. We thus add the edges

$$Z := \bigcup_{i=1,3,5,\ldots,2\ell-3} Z^{02}[C^-_{2\ell-1,i}, C^-_{2\ell-1,i+1}] \tag{6}$$

defined in part (iii) of Lemma 5, which makes

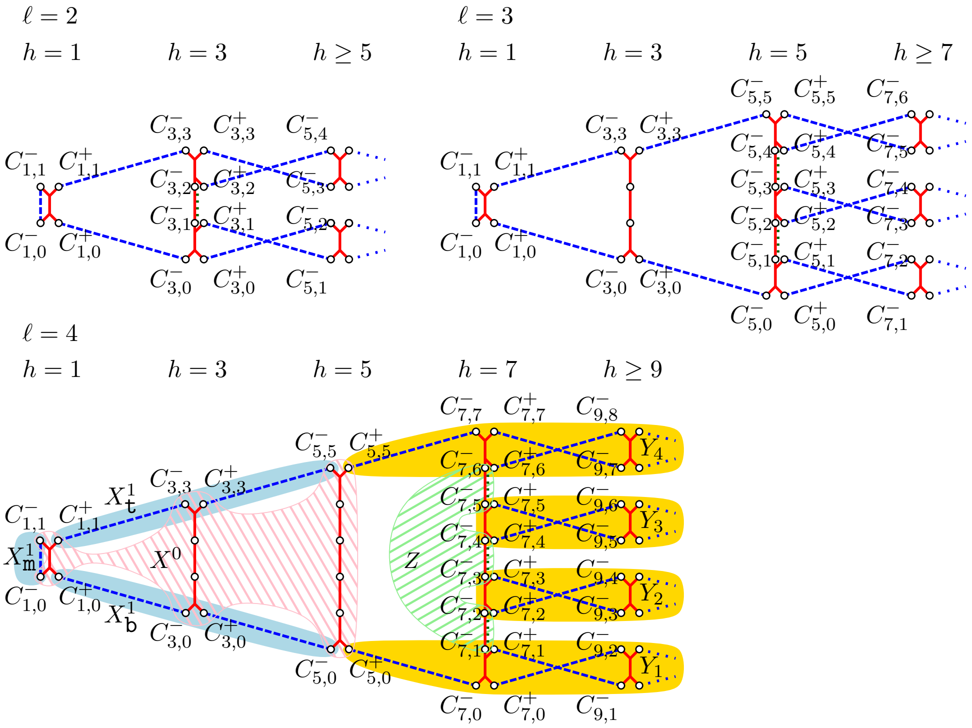
$$\mathcal{C}_{n,\ell} := X \cup Y \cup Z \tag{7}$$

a cycle factor in the graph $Q_{n,\ell}$.

3.1 Comparison with previous constructions

Our cycle factor construction generalizes the construction for $\ell = 1$ presented in [19, 27], which simply consisted in taking the union of all 0-lexical and 1-lexical edges between the middle two levels. It also generalizes the construction for $\ell = 2$ presented in [16], which also only used $\{0,1,2\}$-lexical matchings. In fact, all these earlier papers actually used $\{m, m-1, m-2\}$-lexical matching edges, but these are isomorphic to $\{0,1,2\}$-lexical edges by reversing bitstrings. The earlier construction for $\ell = 2$ seemed rather arbitrary at the time, but now nicely fits into the general picture shown in Figure 6[1].

[1] As the picture of this construction resembles a rocket, with the tip on the left and the boosters on the right, one might be tempted to consider this rocket science.



$\ell = 2$
$h = 1$
$h = 3$
$h \geq 5$
$\ell = 3$
$h = 5$
$h \geq 7$
$\ell = 4$
$h = 7$
$h \geq 9$

Figure 6 Illustration of the cycle factor $\mathcal{C}_{n,\ell}$ for $\ell = 2, 3, 4$. Each bullet represents an entire set of vertices, as specified in the figure, lines between them specify perfect matchings between these sets. The $\{0, 1, 2\}$-lexical edges are drawn with solid, dashed, and dotted lines, respectively. In the bottom part, various sets of matching edges are highlighted.

4 Sketch of the remaining proof steps

It turns out that each cycle from the factor $\mathcal{C}_{n,\ell}$ defined in (7) visits vertices from an interval of $2r$ levels, where $2 \leq r \leq \ell$, around the middle. We refer to the number $2r$ as the *range* of the cycle, and we say the cycle is *short* if $2 \leq r < \ell$, and *long* if $r = \ell$. One can show that any short cycle with range r has length $8(r-1)$, contains exactly one $[--]$-chain of length $2r-1$, one $[-+]$- and one $[+-]$-chain of length $2r-3$ each, and one $[++]$-chain of length $2r-5$ (the latter only if $r \geq 3$), i.e., short cycles are in bijection with short $[--]$-chains. For long cycles, on the other hand, we are lacking such a detailed understanding of their structure. However, we are able to identify certain vertices on them, and to describe the operation of moving along one cycle from one such special vertex to the next one in terms of certain *rotation operations* on ordered rooted trees. Consequently, long cycles are obtained as equivalence classes of ordered rooted trees under such rotations.

As outlined in Section 1.3, to join the cycles in our factor to a Hamilton cycle, we explicitly construct flipping 4-cycles and 6-cycles. The 4-cycles are used to join short cycles among each other and to long cycles, in such a way that every short cycle is joined to some long cycle, possibly via other short cycles. For this we exploit the fact that certain pairs of short chains from the Greene-Kleitman SCD are connected by many 4-cycles. Specifically, consider any short chain C of length $h \geq 3$, and any chain C' of length $h-2$ obtained from C by replacing two consecutive *s at positions a and b by 0 and 1, respectively. Using the definition of Greene-Kleitman chains, it is easy to check that C and C' are connected by $h-2$ many 4-cycles, each using a distinct edge of C and C', except the two consecutive edges of C that flip the coordinates a and b. The Greene-Kleitman SCD has an abundance of such pairs of heavily connected pairs of chains, and as our cycle factor contains all these short chains, we can exploit this to join short cycles to each other and to some long cycle in a tree-like fashion, by considering the short cycles by increasing range. Particular care must be taken to ensure that all selected flipping 4-cycles are edge-disjoint from each other, so that they do not interfere with each other in the joining process.

The remaining task is to join long cycles to each other, and for this we use flipping 6-cycles between the topmost two levels of $Q_{n,\ell}$, ensuring that they are edge-disjoint from any flipping 4-cycles, which all live in the levels below. Such a flipping 6-cycle can be used to connect two long cycles with each other, and this operation can again be interpreted in terms of an operation on ordered rooted trees, which we call a *pull operation*. These 6-cycles have been described and used heavily already in the predecessor papers [16, 19], where it was shown that they are all edge-disjoint. To complete the proof of Theorem 1, we show that all long cycles can be joined to each other by flipping 6-cycles, by showing that all equivalence classes of ordered rooted trees under the aforementioned rotations (which correspond to long cycles) can be transformed into each other by pull operations (which correspond to flipping 6-cycles). This step of the proof reduces the Hamiltonicity problem in $Q_{n,\ell}$ to proving that a suitably defined auxiliary graph is connected, which turns out to be much easier.

5 Proof of Theorem 3

In this section, we prove Theorem 3. All lemmas stated below follow from straightforward calculations; see [17] for details. For any chain C, we let $|C|$ denotes its length, i.e., the number of $*$s in C. For any chain C with $|C| \geq 2$, we let $f(C)$ and $\ell(C)$, respectively, denote the chains obtained by replacing the first two $*$s or the last two $*$s in C by 0 and 1. Note that if $|C| \geq 2$, then we have $f(\ell(*C*)) = \ell(f(*C*))$.

Our goal is to order the chains of the Greene-Kleitman SCD in Q_n, $n \geq 2$, so that any consecutive pair of chains is joined at their top end vertices or bottom end vertices alternatingly, with the exception of any two consecutive chains of length 1 that are connected from the bottom end of one of them to the top end of the other, so as to form a Hamilton cycle. We call such an ordering of chains a *cycle ordering*. The following simple but powerful lemma, valid for arbitrary SCDs, shows that the direction in which each chain is traversed along the Hamilton cycle (upwards or downwards) is determined only by the chain length.

▶ **Lemma 6.** *Let Λ_n be a cycle ordering of chains of an SCD in Q_n, $n \geq 2$. In this Hamilton cycle, any two chains C and C' with $|C| \equiv |C'| \pmod 4$ are traversed in the same direction.*

We now define a cycle ordering Λ_n, $n \geq 2$, for the Greene-Kleitman SCD. The corresponding Hamilton cycle is oriented so that it traverses the longest chain $*^n$, which will be the first in the ordering Λ_n, from bottom to top. Our construction works inductively, and the induction step goes from n to $n+2$, with separate rules for even and odd n. The base cases are $n = 0$ and $n = 1$, for which the entire cube consists only of a single vertex and a single edge, respectively, so for these cases the notion of a cycle ordering is not defined.

For even n, we define $\Lambda_0 := \varepsilon$, and for $n \geq 0$ and given $\Lambda_n =: C_1, \ldots, C_N$ we define $\Lambda_{n+2} := \rho(\Lambda_n) = \rho(C_1), \ldots, \rho(C_N)$ with

$$\rho(C) := \begin{cases} \lambda(C) & \text{if } |C| \equiv n \pmod 4, \\ \lambda(C)^R & \text{if } |C| \not\equiv n \pmod 4, \end{cases} \tag{8}$$

and

$$\lambda(C) := \begin{cases} *C*, f(*C*), f(\ell(*C*)), \ell(*C*) & \text{if } |C| \geq 2, \\ *C*, 0C1 & \text{if } |C| = 0. \end{cases} \tag{9}$$

We call the chains of $\lambda(C)$ arising from C the *descendants of* C. This rule replaces each chain C in Λ_n by its descendants $\lambda(C)$, where the order of descendants can be reversed, indicated by the superscript R, depending on the length of C modulo 4.

For odd n, we define $\Lambda_1 := *$, and for $n \geq 1$ and given Λ_n we define $\Lambda_{n+2} := \rho(\Lambda_n)$, where ρ is as before and

$$\lambda(C) := \begin{cases} *C*, \ell(*C*), \ell(f(*C*)), f(*C*) & \text{if } |C| \geq 3, \\ *C*, \ell(*C*), f(*C*) & \text{if } |C| = 1. \end{cases} \tag{10}$$

▶ **Lemma 7.** Λ_n *contains every chain of the Greene-Kleitman SCD exactly once.*

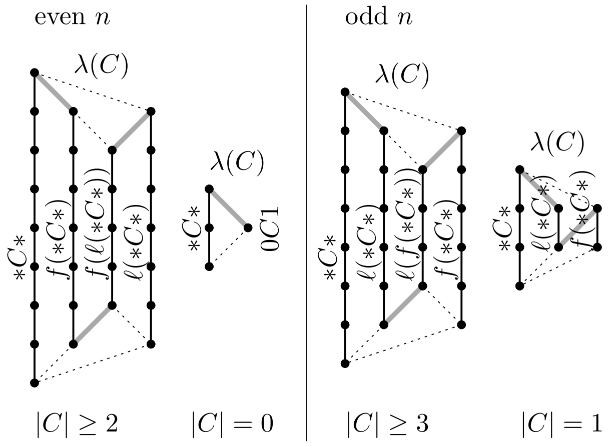

Figure 7 Connections between top and bottom ends of the descendants $\lambda(C)$ of a chain C, as guaranteed by Lemma 8. Bold gray edges are used along the Hamilton cycle. Dotted edges are present but not used.

To complete the proof of Theorem 3, it remains to show that any two consecutive chains in Λ_n can be joined by an edge between their top ends or bottom ends alternatingly. For this we need the following simple lemmas that guarantee these connecting edges.

▶ **Lemma 8.** *For any* $n \geq 2$ *and any chain* C *with* $|C| \geq 2$*, the chains* C *and* $f(C)$*, and the chains* C *and* $\ell(C)$ *are connected both at their top and bottom ends in* Q_n.

All connecting edges between top and bottom ends among the descendants of a chain guaranteed by Lemma 8 are shown in Figure 7. The next two lemmas are illustrated in Figure 8.

▶ **Lemma 9.** *For any* $n \geq 2$ *and any two chains* C, C' *connected at their bottom ends in* Q_n*, we have that* $*C*$ *and* $*C'*$ *are connected at their bottom ends in* Q_{n+2}.

▶ **Lemma 10.** *For any* $n \geq 2$ *and any chain* C *with* $|C| \geq 2$ *in* Q_n*, we have that* $\ell(*C*)$ *and* $\ell(*f(C)*)$ *are connected at their bottom ends in* Q_{n+2}.

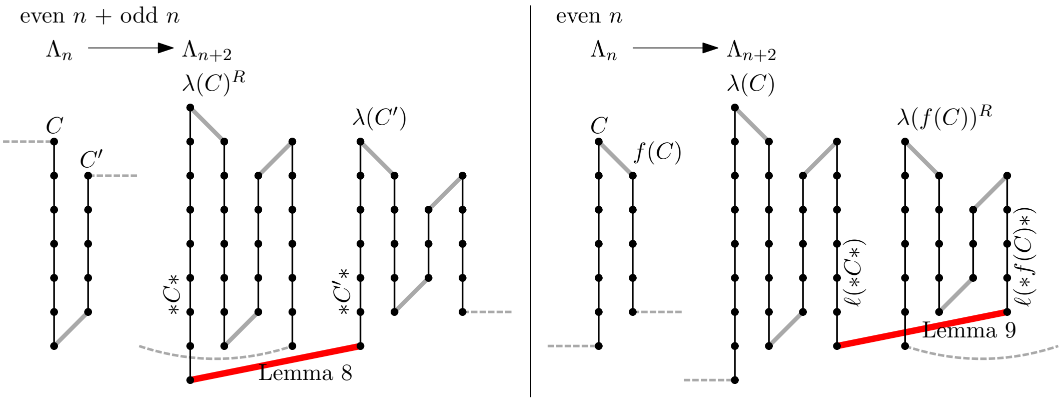

Figure 8 Joining of the descendants of two consecutive chain from Λ_n in the induction step $n \to n+2$, via the thick edges guaranteed by Lemmas 9 and 10. The dashed edges are connections to preceding and subsequent chains on the Hamilton cycle.

Proof of Theorem 3 (even n). We show that Λ_n, $n \geq 2$ even, defined in (9) is a cycle ordering of the Greene-Kleitman chains, by proving that any consecutive pair of chains is connected at their top or bottom ends alternatingly, starting with the first chain $*^n$ of length n that is traversed from bottom to top. We will also establish the following additional property P: For any two consecutive chains C and C' connected at their top ends, we either have $C = f(C')$ or $f(C) = C'$. These invariants can easily be checked for the induction base case $n = 2$, which is given by $\Lambda_2 = **, 01$.

For the induction step consider $n \geq 2$ to be even, and assume that Λ_n is a cycle ordering satisfying property P. By Lemma 8, the descendants $\lambda(C)$ for any chain C from Λ_n can be joined as shown on the left hand side of Figure 7, so we only need to check the connections between the first and last chains among consecutive groups of descendants. Indeed, if C and C' are consecutive in Λ_n and joined at their bottom ends, then C is traversed from top to bottom and C' from bottom to top in the Hamilton cycle; see the left part of Figure 8. Consequently, by Lemma 6, we have $|C| \not\equiv |*^n| = n \pmod 4$ and $|C'| \equiv n \pmod 4$, i.e., by (8) the sequence Λ_{n+2} contains $\lambda(C)^R$ and $\lambda(C')$, and indeed, the bottom vertex of the last chain of $\lambda(C)^R$, namely $*C*$, is connected to the bottom vertex of the first chain of $\lambda(C')$, namely $*C'*$, by Lemma 9. Similarly, if C and C' are consecutive in Λ_n and joined at their top ends, then C is traversed from bottom to top and C' from top to bottom in the Hamilton cycle; see the right part of Figure 8. Consequently, by Lemma 6, we have $|C| \equiv n \pmod 4$ and $|C'| \not\equiv n \pmod 4$, i.e., by (8) the sequence Λ_{n+2} contains $\lambda(C)$ and $\lambda(C')^R$, and indeed, the bottom vertex of the last chain of $\lambda(C)$, namely $\ell(*C*)$, is connected to the bottom vertex of the first chain of $\lambda(C')^R$, namely $\ell(*C'*)$, using that by property P we have either $C = f(C')$ or $f(C) = C'$, so we can invoke Lemma 10. Moreover, property P still holds for Λ_{n+2} by the definition (9) (note that if $|C| = 0$, then we have $0C1 = f(*C*)$). ◀

The proof of Theorem 3 for odd n is very similar. In [17] we provide all details and a loopless algorithm for computing this Gray code. An implementation of this algorithm in C++ is available for download and for demonstration [5].

Table 1 A glossary for notation used in the paper.

Q_n	$n \geq 1$	the n-dimensional hypercube
$Q_{n,\ell}$	$1 \leq \ell \leq m+1$ $n = 2m+1$, $m \geq 1$	the subgraph of Q_n induced by the middle 2ℓ levels
D_{2k}	$k \geq 0$	the set of all Dyck paths (bitstrings) of length $2k$
D		the set of all Dyck paths
C		a chain $C = u_0 * u_1 * \cdots * u_{h-1} * u_h$ of length $h \geq 0$ in the Greene-Kleitman decomposition, $u_i \in D$ for every i
$C_{h,i}$	$0 \leq i \leq h$	the set of the ith vertices in all chains of length h
$C^-_{h,i}$	$0 \leq i \leq h$	as above but only in chains with $u_i = \varepsilon$
$C^+_{h,i}$	$0 \leq i \leq h$	as above but only in chains with $u_i \neq \varepsilon$
$L_{n,k}$	$0 \leq k \leq n$	the set of vertices on level k in Q_n
$M^p_{n,k}$	$0 \leq k < n$, $0 \leq p < n$	the p-lexical matching between $L_{n,k}$ and $L_{n,k+1}$
M^p_n, M^p	$0 \leq p < n$	the set of all p-lexical edges in Q_n
$\|C\|$		the length of a chain C, i.e., $\|C\| = h$ for C as above
$f(C)$	$\|C\| \geq 2$	the chain $f(C) = u_0\,0\,u_1\,1\,u_2 * \cdots * u_h$ for C as above
$l(C)$	$\|C\| \geq 2$	the chain $l(C) = u_0 * \cdots * u_{h-2}\,0\,u_{h-1}\,1\,u_h$ for C as above
$\lambda(C)$		a sequence of descendant chains for a chain C, see (9), (10)

Abstract

A set function $f\colon 2^E \to \mathbb{R}$ on the subsets of a set E is called submodular if it satisfies a natural diminishing returns property: for any $S \subseteq E$ and $x, y \notin S$, we have $f(S \cup \{x, y\}) - f(S \cup \{y\}) \leq f(S \cup \{x\}) - f(S)$. Submodular minimization problem asks for finding the minimum value a given submodular function takes. We give an algebraic algorithm for this problem for a special class of submodular functions that are "linearly representable". It is known that every submodular function f can be decomposed into a sum of two monotone submodular functions, i.e., there exist two non-decreasing submodular functions f_1, f_2 such that $f(S) = f_1(S) + f_2(E \setminus S)$ for each $S \subseteq E$. Our class consists of those submodular functions f, for which each of f_1 and f_2 is a sum of k rank functions on families of subspaces of $\mathbb{F}^n$, for some field $\mathbb{F}$.

Our algebraic algorithm for this class of functions can be parallelized, and thus, puts the problem of finding the minimizing set in the complexity class randomized NC. Further, we derandomize our algorithm so that it needs only $O(\log^2(kn|E|))$ many random bits.

We also give reductions from two combinatorial optimization problems to linearly representable submodular minimization, and thus, get such parallel algorithms for these problems. These problems are (i) covering a directed graph by k a-arborescences and (ii) packing k branchings with given root sets in a directed graph.

1 Introduction

Submodular functions have been studied in a wide variety of contexts like combinatorics, electrical networks, game theory, and machine learning. For a set E, a submodular function is a set function $f\colon 2^E \to \mathbb{R}$ that satisfies a natural diminishing returns property: for any $T \subseteq S \subseteq E$ and $x \in E \setminus S$, we have

$$f(S \cup \{x\}) - f(S) \leq f(T \cup \{x\}) - f(T).$$

That is, the marginal value of an element with respect to a set decreases as the set grows. Another equivalent way to describe submodularity is: for any $S, T \subseteq E$, we have $f(S)+f(T) \geq f(S \cup T) + f(S \cap T)$. Submodular functions appear in a diverse set of areas. To give a few

examples, a linear function, maximum number in the given subset, the rank function on a set of vectors or subspaces, the cut function on the set of vertices of a graph, entropy on a set of random variables, the coverage function on a collection of subsets, are all submodular.

There are various natural optimization problems involving submodular functions: *Submodular Minimization* asks for the set that minimizes a given submodular function among all subsets of the ground set. Similarly, *Submodular Maximization* asks for the maximizing set. Note that the these two questions are interesting only for non-monotone submodular functions like graph cut. There are also constrained versions of minimization and maximization, for example, optimizing a submodular function over subsets of a given size. The submodular function might be given by an explicit representation, for example, a given graph can represent the corresponding cut function. However, not all submodular functions are succinctly representable, as their number grows as doubly-exponential in the ground set size [27]. In the most general framework, the function is given via a value oracle, i.e., given any subset $S \subseteq E$, the oracle will provide the function value on S.

Submodular minimization is in some sense a discrete version of convex minimization [20], and thus, admits polynomial time algorithms (even with just the value oracle). The initial algorithms for it were based on the ellipsoid algorithm [11, 12], but later on combinatorial algorithms were also obtained [6, 15, 28]. Submodular maximization, on the other hand, is known to be hard: Max-cut [16] and maximum facility location [5] are instances of submodular maximization which are NP-hard. Moreover, in the oracle model, there is an exponential lower bound known on the number of queries required [9].

When we put cardinality constraints, then in fact, both minimization and maximization problems become hard even for monotone submodular functions. Examples of such maximization problems that are NP-hard include max-k-cover (set-cover, which is NP-hard [16], reduces to it) and sparse approximation [7] (for a set E of vectors and fixed vector v, the function $f_v(S) = \|proj_{span(S)}(v)\|_2$ for $S \subseteq E$ is submodular). Similarly, min-k-vertex-cover is an example of an NP-hard minimization question (see [13]). Moreover, in the oracle model, cardinality constrained submodular minimization has a sub-exponential lower bound on the number of queries (follows from [31]).

Parallel complexity of submodular minimization. In this paper, we investigate the question of parallel complexity of unconstrained submodular minimization. In the oracle model, the parallel complexity question can be phrased as follows: if one is allowed to simultaneously make polynomially many function value queries in one round, how many rounds are required to find the minimum value (and the minimizing set). The number of rounds required is also known the *adaptivity* (see [1]). To the best of our knowledge, the best upper bound on the adaptivity of submodular minimization is $O(n \log(nM))$ [19], where M is the largest absolute value the function takes (they use a separation oracle that can be implemented with one round of n parallel queries to the value oracle). While on the lower bound side, there is a known impossibility result for one round [2], and $\tilde{\Omega}(n^2/k^5)$ query lower bound for k rounds [1]. Very recently, it was shown that there are no adaptive algorithms that run in $o(\frac{\log n}{\log \log n})$ rounds with poly(n) queries per round [3]. In particular, it is not clear whether the adaptivity of submodular minimization can be sublinear.

On the other hand, if we consider explicitly given submodular functions, there are instances for which the minimization problem admits parallel algorithms. Such special cases of submodular minimization include (s, t)-min-cut (small capacities), maximum bipartite matching[1], and its generalization linear matroid intersection. These problems have algebraic algorithms, which just involve randomized reductions to matrix rank computation and thus, fall into the class randomized NC (RNC) [17, 21, 23, 24]. In recent years, these algorithms have also been partially derandomized [10, 14], i.e., they can work with only $O(\log^2 n)$ random bits. A natural question arises: what is the most general class of submodular functions for which such algebraic algorithms can work. One would expect such algebraic algorithms for submodular functions that are linear algebraic in some sense. Towards this, we define a class of *linearly representable* submodular functions.

Linearly representable (LR) submodular functions. Suppose we have a family of subspaces $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e\in E}$, for some field F. Recall that the rank function of the family $\mathcal{V}$ given by $r(S) = \dim(\sum_{e\in S} V_e)$ for $S \subseteq E$ is submodular. The rank function is non-decreasing, and hence, the minimization question for it is not interesting. One can try to consider the difference of two rank functions, but that is not submodular. Interestingly, there is a way to construct a non-increasing submodular function from a non-decreasing submodular function: if a function $f(S)$ is submodular then so is $g(S) := f(E\setminus S)$. So, if we have two non-decreasing submodular functions $f_1(S)$ and $f_2(S)$, we can get a non-monotone submodular function by considering $f_1(S)+f_2(E\setminus S)$ (since the sum of two submodular functions is also submodular). In fact, using this way one can arrive at any submodular function. It is known (see [6]) that every submodular function f can be decomposed into two non-decreasing submodular functions f_1 and f_2 such that for any $S \subseteq E$, $f(S) = f_1(S) + f_2(E \setminus S)$.

Our contributions

The above facts motivate us to define the following natural class of linear algebraic submodular functions that are not necessarily monotone. For a ground set E, let $\bar{S} := E \setminus S$.

▶ **Definition 1** (Linearly representable (LR) submodular functions). *We call a submodular function $f: 2^E \to \mathbb{Z}$ linearly representable (LR) by k families of subspaces $\mathcal{V}_j = \{V_{j,e} \subseteq \mathbb{F}^n\}_{e\in E}$ for $1 \le j \le k$ and a number $\ell \le k$ if*

$$f(S) = \sum_{j=1}^{\ell} r_j(S) + \sum_{j=\ell+1}^{k} r_j(\bar{S}),$$

where $r_j: 2^E \to \mathbb{Z}$ is the rank function for family $\mathcal{V}_j$.

This class includes many interesting submodular functions like directed graph cut, hypergraph cut, coverage function, integral linear function (up to additive normalization), and more interestingly, any combination of them in the above form. Our main results are a randomized algebraic algorithm for minimizing LR submodular functions that puts the minimization problem in RNC, and an almost complete derandomization of the algorithm; see Section 3.

▶ **Theorem 2** (Linearly representable submodular minimization). *Given an LR submodular function $f: 2^E \to \mathbb{Z}$ via families of subspaces $\mathcal{V}_j = \{V_{j,e} \subseteq \mathbb{F}^n\}_{e\in E}$ for $1 \le j \le k$ and a number $\ell \le k$ (Definition 1), we can find a set minimizing $f(S)$ in RNC. Further, the randomized algorithm can be almost completely derandomized so that it uses only $O(\log^2(kn|E|))$ random bits.*

[1] For a bipartite graph $G(V_1 \cup V_2, E)$, the maximum matching size is equal to $|V_1| + \min_{S\subseteq V_1}(|N(S)| - |S|)$ (Hall's theorem), where $N(S) \subseteq V_2$ is the set of neighbor of S. The function $|N(S)| - |S|$ is submodular.

Another way to put the derandomization result is that minimizing an LR submodular function is in quasi-NC (see [10, 14] for the details of class quasi-NC). Our results also imply a randomized parallel algorithm and its almost deterministic version for a problem called linear polymatroid intersection, generalizing the corresponding results for linear matroid intersection [24, 14].

In the *linear polymatroid intersection* problem, we are given two families of subspaces, $\mathcal{V}_j = \{V_{j,e} \subseteq \mathbb{F}^n\}_{e \in E}$ for $j = 1, 2$, with their rank functions r_1, r_2, respectively. And the goal is to find

$$\max\{\sum_{e \in E} x_e \mid x_e \geq 0 \; \forall e \in E, \text{ and } \sum_{e \in S} x_e \leq r_1(S), \sum_{e \in S} x_e \leq r_2(S) \text{ for each } S \subseteq E\}.$$

Min-max relation. It is known that this maximum value is equal to $\min_{S \subseteq E} r_1(S) + r_2(\bar{S})$ (see [29, Corollary 46.1c]). Thus, the maximization problem is captured by LR submodular minimization.

▶ **Corollary 3.** *Linear polymatroid intersection has a randomized* NC *algorithm that uses only $O(\log^2(n|E|))$ random bits.*

Linear matroid intersection is the special case of linear polymatroid intersection when each of the above subspaces $V_{j,e}$ is of dimension 1. Thus, the above min-max relation with a LR submodular function also holds for linear matroid intersection. Our parallel algorithm has a crucial difference from the known parallel algorithms [24, 14] for linear matroid intersection. They give the minimum value of the corresponding LR submodular function, but they do not lead to a minimizing set, while our algorithm also finds a minimizing set.

Further applications

As mentioned above, LR submodular minimization captures linear matroid intersection and thus, several other combinatorial optimization problems that reduce to linear matroid intersection, like bipartite matching, packing spanning trees, finding arborescences (see [29]), packing a-arborescences [29, Theorem 53.10], and hypergraph min-cut [18]. Since linear matroid intersection already has parallel algorithms [24, 14], so do these problems.

However, there are also combinatorial problems that reduce to submodular minimization but are not captured by linear matroid intersection. We show that two such problems, in fact, reduce to LR submodular minimization (see Section 4.2 for definitions and reductions).

- **Covering by a-arborescences.** For a given directed graph and a number k, decide whether the edge set is covered by k a-arborescences.
- **Packing of branchings.** For a given directed graph and given subsets $R_1, R_2, \ldots, R_k$ of vertices, decide whether there exist k edge-disjoint branchings that are rooted at $R_1, R_2, \ldots, R_k$, respectively.

To the best of our knowledge, there is no straightforward reduction known from these problems to linear matroid intersection. Using Theorem 2, we get the following.

▶ **Theorem 4.** *Covering by a-arborescences and packing of branchings can be solved in* RNC *using only $O(\log^2 n)$ random bits, n being the size of the input graph.*

Variants

Furthermore, we list out two problems, one of which is an extension of LR submodular minimization and the other one is equivalent to it (see Section 4.1).

1. **Minimization with containment constraints**: There is a variant of submodular minimization that appears frequently in combinatorial optimization. Given two subsets $S_0 \subseteq S_1 \subseteq E$, the goal is to minimize the given submodular function $f(S)$ subject to $S_0 \subseteq S \subseteq S_1$. We can extend our algorithm to LR submodular minimization with this kind of constraints. This is a generalization of the minimum $(S_0, \bar{S}_1)$ cut problem in a graph $G(V,E)$ with two given disjoint subsets $S_0, \bar{S}_1 \subseteq V$.
2. **Separation oracle for a linear polymatroid**: Given a family $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e \in E}$ of subspaces with its rank function $r \colon 2^E \to \mathbb{Z}$, the corresponding polymatroid is a polytope $P_r \subseteq \mathbb{R}^E$ defined as

$$P_r = \{x \in \mathbb{R}^E \mid x \geq 0, \sum_{e \in S} x_e \leq r(S) \ \forall S \subseteq E\}.$$

Given a rational point $\beta \in \mathbb{R}^E$, one needs to decide if β lies in P_r, and if not then find a violating constraint from the above set. We reduce this problem to LR submodular minimization assuming the coordinates in β are rational numbers with a polynomially bounded common denominator.

2 Preliminaries

Complexity Class NC. NC represents the class of problems that can be solved by polynomially many parallel processors in poly-logartihmic time. RNC, i.e., randomized NC, represents problems that can be solved with the same resources, but with the use of randomness.

2.1 Submodular functions

For a set E, a *submodular* function is a set function $f \colon 2^E \to \mathbb{R}$ for any $S, T \subseteq E$, we have $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$. If f satisfies this with equality then it is called *modular*. There are various properties of submodular functions that are useful for us and are easy to verify. For $S \subseteq E$, $\bar{S}$ will denote $E \setminus S$.

- If f_1 and f_2 are submodular then so is $f_1 + f_2$.
- If f is submodular then so is $g(S) = f(\bar{S})$.

For a set E and a family of subspaces $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e \in E}$, its corresponding rank function $r \colon 2^E \to \mathbb{Z}$ is defined to be as $r(S) = \dim(\sum_{e \in S} V_e)$ for $S \subseteq E$. It is not hard to verify that the rank function is submodular for any family of subspaces.

2.2 Polynomial identity testing

To design our randomized algorithm, we will need a fundamental result about zeros of polynomials, which says that if a polynomial is nonzero then at a random point, its evaluation is nonzero with high probability (see, for example, [25, 30, 33, 8]).

▶ **Lemma 5.** *Let there be an n-variate degree-d nonzero polynomial $P(z_1, z_2, \ldots, z_n)$. If for each $1 \leq i \leq n$, the variable x_i is substituted with a random number R_i chosen uniformly and independently from a set of size D then*

$$\Pr\{P(R_1, R_2, \ldots, R_n) = 0\} \leq d/D.$$

Note that D should be at least as large as the degree. Throughout the paper, we will assume that the underlying field is large enough. This lemma gives a simple algorithm to test if a given polynomial is nonzero: just evaluate it at a random point and output nonzero if and only if the evaluation is nonzero. To derandomize our submodular minimization algorithm, we will need to derandomize this test of nonzeroness of a polynomial. For general polynomials, there is no non-trivial derandomization known. However, we will need the derandomization result only for polynomials that have certain special structure.

Let U be a square matrix whose entries are all linear polynomials (degree-1). The polynomials of interest in our setting will be determinants of such symbolic matrices, where any particular variable appears in at most one column of the matrix. For this class of polynomials, an almost complete derandomization of nonzero testing is known. A way to do deterministic nonzero testing is to obtain a small hitting-set – a set of points such that any nonzero polynomial in the class of our interest gives a nonzero evaluation on at least one of the points.

The work of [14] gave a quasi-polynomial size hitting-set for polynomials of the following form which subsume the above case: $P(\mathbf{z}) = \det(\sum_{i=1}^{n} A_i z_i)$, where each A_i is a rank-1 matrix. The result of [14] can be easily modified to generate a slightly stronger notion of a hitting-set, though it is not explicitly stated there.

▶ **Lemma 6** ([14]). *There is an NC-computable hitting-set generator, that is, a function $h\colon \{0,1\}^t \to \mathbb{F}^n$, $t = O(\log^2 mn)$, with the following property: for any nonzero polynomial $P(\mathbf{z}) = \det(\sum_{i=1}^{n} A_i z_i)$ where each $A_i \in \mathbb{F}^{m\times m}$ is a rank-1 matrix*

$$\Pr_{R\in\{0,1\}^t}\{P(h(R)) = 0\} \le 1/poly(mn).$$

3 Parallel algorithm for linearly representable submodular minimization

Our first step towards the parallel algorithm is to consider one of the special cases of LR submodular minimization. We give an algebraic algorithm for this special case. The algorithm is essentially a reduction to basic linear algebraic operations like computing rank and inverse of a matrix, which are doable in NC. The reduction is randomized and thus, puts the special case in RNC. Finally, we reduce the LR submodular minimization problem to this special case. We start with describing the special case and a solution for it.

3.1 LR submodular minimization for a special case

The special case we first consider is when the submodular function is the difference of a rank function and a positive linear function. Let $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e\in E}$ be a family of subspaces for a ground set E and a field $\mathbb{F}$, and $r\colon 2^E \to \mathbb{Z}$ be the corresponding rank function. Let $w \in \mathbb{Z}_+^E$ be a positive integer vector and define a modular function $w(S) := \sum_{e\in S} w_e$ for any $S \subseteq E$. Consider the function defined as $f(S) = r(S) - w(S)$ for $S \subseteq E$. Note that since w is modular, so is $-w$, and hence, f is submodular because both r and $-w$ are. We show that there is a randomized algebraic algorithm to find a minimizing set for $f(S)$ over $S \subseteq E$.

▶ **Lemma 7.** *Given a family of subspaces $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e\in E}$ with rank function r and a vector $w \in \mathbb{Z}_+^E$, there is an RNC algorithm to find the minimizing set $S^* \subseteq E$ for $f(S) = r(S) - w(S)$ that uses only $O(\log^2(nw(E)))$ random bits.*

To prove the Lemma 7, we work with a random/generic vectors that belong to any subspace V_e. Let us first build some terminology towards that. Let $B_e \subseteq \mathbb{F}^n$ be a basis for V_e for $e \in E$. For any set $S \subseteq E$, let us define $S_w = \{(e,i) \mid e \in S,\ 1 \le i \le w_e\}$. Clearly, $|S_w| = w(S)$. We will construct a matrix U whose columns will consist of w_e many generic vectors from the subspace V_e for $e \in E$. Formally, consider a tuple of indeterminates $\boldsymbol{\alpha} = (\alpha_{e,i,v} \mid (e,i) \in E_w,\ v \in B_e)$. Now, construct an $n \times E_w$ matrix U over $\mathbb{F}[\boldsymbol{\alpha}]$ whose columns are as follows:

$$u_{(e,i)} = \sum_{v \in B_e} \alpha_{e,i,v} v \text{ for } (e,i) \in E_w. \tag{1}$$

All notions of rank and linear independence for columns of U will be over the field of fractions $\mathbb{F}(\boldsymbol{\alpha})$. For any set $T \subseteq E_w$, let U_T denote the set of columns of U indexed by elements in T. Our first step is to show a lower bound on $\min_S f(S)$ in terms of rank of U.

▷ Claim 8. For any set $S \subseteq E$,

$$f(S) = r(S) - w(S) \geq \text{rank}(U) - |E_w| = \text{rank}(U) - w(E). \tag{2}$$

Proof. Consider the sets $S_w \subseteq E_w$ and $\bar{S}_w := E_w \setminus S_w$. One can write

$$\text{rank}(U) \leq \text{rank}(U_{S_w}) + \text{rank}(U_{\bar{S}_w}) \leq r(S) + |\bar{S}_w|.$$

The first inequality is from basic linear algebra. The second inequality holds because every column in S_w is in the space $\sum_{e \in S} V_e$ and rank of $U_{\bar{S}_w}$ can be at most its cardinality. Writing $|\bar{S}_w| = |E_w| - |S_w| = w(E) - w(S)$ and rearranging the above inequality will give us the claim. ◁

Once we obtain this lower bound, a natural approach to find $\min_S f(S)$ is to find a set $S^* \subseteq E$ which satisfies (2) with equality. We describe a construction of such a set. First let us define $T^* \subseteq E_w$ to be the set of elements (e,i) such that the column $u_{(e,i)}$ participates non-trivially in some linear dependency among the columns of U. Equivalently,

$$T^* := \{(e,i) \in E_w \mid \text{rank}(U) = \text{rank}(U_{E_w \setminus (e,i)})\}.$$

Then define

$$S^* = \{e \in E \mid (e,i) \in T^* \text{ for some } i\}.$$

▶ **Lemma 9.** *S^* is a set minimizing $f(S)$ over all subsets $S \subseteq E$.*

Proof. As mentioned above, the strategy is to show that S^* satisfies (2) with equality. Towards this we will first prove that

$$\text{rank}(U_{T^*}) = r(S^*). \tag{3}$$

Recall that the columns U_{T^*} are contained in $\sum_{e \in S^*} V_e$. What we need to show for (3) is that $\sum_{e \in S^*} V_e$ is in the linear span of U_{T^*}. We show this for each $V_{\tilde{e}}$, $\tilde{e} \in S^*$.

▷ Claim 10. For each $\tilde{e} \in S^*$, the subspace $V_{\tilde{e}}$ is in the linear span of columns in U_{T^*}.

Proof. By definition of S^*, there must be some $1 \leq \tilde{i} \leq w_{\tilde{e}}$ so that $(\tilde{e}, \tilde{i}) \in T^*$. By definition of T^*, the column $u_{(\tilde{e},\tilde{i})}$ non-trivially participates in some linear dependency among the columns of U_{T^*}. So, there exists a set $J \subseteq T^* \setminus \{(\tilde{e},\tilde{i})\}$ and a vector $\Gamma \in \mathbb{F}[\boldsymbol{\alpha}]^J$ such that

$$u_{(\tilde{e},\tilde{i})} = U_J \Gamma. \tag{4}$$

Now, recall that $u_{(\tilde{e},\tilde{i})}$ is a generic vector in $V_{\tilde{e}}$, and thus, can be used to express any vector in $V_{\tilde{e}}$. Hence, Equation (4) implies that every vector in $V_{\tilde{e}}$ is in the linear span of the columns in U_J. Below, we argue this point more formally.

Recall (1) that gives $u_{(\tilde{e},\tilde{i})}$ as $\sum_{v \in B_{\tilde{e}}} \alpha_{\tilde{e},\tilde{i},v} v$. One can invert (4) to write the vector Γ as a function of indeterminates $\{\alpha_{\tilde{e},\tilde{i},v}\}_v$ as follows. By basic linear algebra, there is an invertible submatrix $\hat{U}_J$ of U_J and a truncation $\hat{u}_{(\tilde{e},\tilde{i})}$ of $u_{(\tilde{e},\tilde{i})}$ such that

$$\Gamma = \hat{U}_J^{-1} \hat{u}_{(\tilde{e},\tilde{i})}. \tag{5}$$

Consider any vector $v' \in V_{\tilde{e}}$. Suppose v' can be expressed using the basis $B_{\tilde{e}}$ as $\sum_{v \in B_{\tilde{e}}} \delta_v v$. We can substitute $(\alpha_{\tilde{e},\tilde{i},v})_v = (\delta_v)_v$ in the right-hand side of (5) to obtain a vector Γ'. Note that since the matrix U_J is free of indeterminates $\{\alpha_{\tilde{e},\tilde{i},v}\}_v$, this substitution in (5) does not create any issues like division by zero. It will follow that

$$v' = U_J \Gamma'.$$

To conclude, every vector $v' \in V_{\tilde{e}}$ is in the linear span of columns in U_{T^*}. ◁

Claim 10 proves Equation (3). Now, we come back to proving that S^* satisfies (2) with equality. From (3), we have

$$f(S^*) = r(S^*) - w(S^*) = \text{rank}(U_{T^*}) - w(S^*) \leq \text{rank}(U_{T^*}) - |T^*|.$$

The inequality holds because $w(S^*) = |S^*_w| \geq |T^*|$ by the definition of S^*. By construction of T^*, the columns in $U_{E_w \setminus T^*}$ do not participate in any column dependency. Thus, we have $\text{rank}(U) - \text{rank}(U_{T^*}) = |E_w \setminus T^*| = |E_w| - |T^*|$. Putting this in the above inequality, we get

$$f(S^*) = r(S^*) - w(S^*) \leq \text{rank}(U) - |E_w|.$$

This together with (2) implies that S^* is a set that minimizes $f(S)$ over $S \subseteq E$. ◀

Proof of Lemma 7: the parallel algorithm

Let us review the construction of the minimizing set S^* from the previous subsection.

- Construct a matrix U, whose columns are generic vectors from the given subspaces. To be precise U has exactly w_e generic vectors from V_e for each $e \in E$.
- Construct the set $T^* := \{(e,i) \in E_w \mid \text{rank}(U) = \text{rank}(U_{E_w \setminus (e,i)})\}$.
- Construct the set $S^* \subseteq E$ that contains all those elements e such that T^* contains (e,i) for some $1 \leq i \leq w_e$.

The rank computations in the second step can all be done in parallel. Importantly, rank computation for any matrix over the base field $\mathbb{F}$ can be done in NC. However, this computation is not efficient for U (or its submatrices) as it is a matrix with indeterminates $\boldsymbol{\alpha}$. To overcome this, we plan to substitute all the indeterminates with field constants. Observe that as long as our substitution preserves the ranks of all column subsets of U, one can safely run the above procedure on the substituted matrix and expect to get the correct answer.

How do we find the right substitution? We argue that a random substitution from a large enough set of field elements does the job. It is known that the rank of a subset of columns remains the same with high probability if each indeterminate is replaced with a field element randomly chosen from a set of size poly(size(U)) = poly($n \times w(E)$). One can see this by applying Lemma 5 on the largest nonzero minor. But, note that we need one substitution that preserves ranks for U and each submatrix $U_{E_w \setminus (e,i)}$ simultaneously. One can use union bound to argue that with high probability, all the desired submatrices preserve their rank. Note that this algorithm needs to use polynomially many random bits. Next we show how to reduce this number of random bits.

Derandomization

To reduce the number of random bits, we use results from deterministic polynomial identity testing. Recall Lemma 6 that gives a pseudorandom substitution that preserves nonzeroness of polynomials of the form $\det(\sum_{i=1}^{n} A_i z_i)$ for $\operatorname{rank}(A_i) = 1$, with high probability. Note that any minor of U is also a polynomial of this form because any variable $\alpha_{e,i,u}$ appears in exactly one column of U. Again, one can use union bound to argue that with high probability, the substitution preserves nonzeroness for all the desired minors of U and each $U_{E_w \setminus (e,i)}$ simultaneously.

To conclude, the pseudorandom substitution from Lemma 6 uses $O(\log^2(nw(E)))$ random bits and with that substitution our algorithm will give the correct minimizing set S^* with high probability.

3.2 Reduction to the special case

Recall Definition 1 which defines LR submodular functions to be those which can be written as a sum of a collection of rank functions together with another collection of rank functions applied on the complement set. We will first argue that the same class of functions is also captured by just taking sum of a rank function and another rank function applied on the complement.

▶ **Observation 11.** *Let $f\colon 2^E \to \mathbb{Z}$ be an LR submodular function given as*

$$f(S) = \sum_{j=1}^{\ell} r_j(S) + \sum_{j=\ell+1}^{k} r_j(\bar{S}),$$

for some $\ell \leq k$, where r_j is the rank function for a family of subspaces $\mathcal{V}_j = \{V_{j,e} \subseteq \mathbb{F}^n\}_{e\in E}$ for $1 \leq j \leq k$. Then f can also be written as

$$f(S) = r'_1(S) + r'_2(\bar{S}),$$

where r'_1 and r'_2 are the rank functions of the families $\mathcal{V}'_1 = \{\oplus_{j=1}^{\ell} V_{j,e} \subseteq \mathbb{F}^{\ell n}\}_{e\in E}$ and $\mathcal{V}'_2 = \{\oplus_{j=\ell+1}^{k} V_{j,e} \subseteq \mathbb{F}^{(k-\ell)n}\}_{e\in E}$, respectively.

Next, we show that we can, in fact, take one of the rank functions to be modular. That is, any LR submodular function can be written as a sum of a rank function and a modular function. In context of general submodular functions, this is a known fact and was used in the first pseudo-polynomial time submodular minimization [6, Lemma 2.1]. Here, we show a more specific result for LR submodular functions that says that the new rank function is also linearly representable and the corresponding family of subspaces can be constructed efficiently.

▶ **Lemma 12.** *Given an LR submodular function $f(S)$ by k families of subspaces of $\mathbb{F}^n$ as in Definition 1, one can compute in NC a family of subspaces $\mathcal{V} = \{V_e \subseteq \mathbb{F}^{kn|E|}\}_{e\in E}$ with rank function r, a vector $w \in \{1, 2, \ldots, kn\}^E$, and a constant C such that for each $S \subseteq E$,*

$$f(S) = r(S) - w(S) + C.$$

To prove Lemma 12, the first step is to use Observation 11 to get the LR submodular function in the form $r'_1(S) + r'_2(\bar{S})$. Then the next step is to write $r'_2(\bar{S})$ as a sum of a rank function on S and a modular function, which is what the following lemma does. Final step is to combine the new rank function with $r'_1(S)$ to get a single rank function, again using Observation 11.

▶ **Lemma 13.** *Let $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e\in E}$ be a family of subspaces with its rank function $r\colon 2^E \to \mathbb{Z}$. Then one can construct in* NC *another family of subspaces $\mathcal{V}^* = \{V_e^* \subseteq \mathbb{F}^{n'}\}_{e\in E}$ with rank function r^* for some $n' \leq n|E|$, and a vector $b \in \{1, 2, \dots, n\}^E$ such that for each $S \subseteq E$,*

$$r(\bar{S}) = r^*(S) - b(S) + r(E).$$

Proof. For each $e \in E$, let b_e be the dimension of the subspace V_e and $B_e = \{u_{e,i} \mid 1 \leq i \leq b_e\}$ be a basis for it. Let $E' = \{(e, i) \mid e \in E,\ 1 \leq i \leq b_e\}$ be a new ground set. Note that since $b_e \leq n$, we have $|E'| \leq n|E|$. Consider an $n \times |E'|$ matrix M whose set of columns is $\{u_{e,i}\}_{e,i}$. Without loss of generality, we can assume that M has full row-rank, i.e., $n = r(E)$ (otherwise we could drop some rows). Let M^* be a $(|E'| - n) \times |E'|$ matrix whose row-space is the orthogonal complement of the row-space of M (for a construction in NC, see [4, 22]). The following claim is well known in matroid theory and is used for representation of a dual matroid (see [26, 2.1.9 and 2.2.8]). For any $T \subseteq E'$ and matrix M, let M_T stand for the set of columns of M corresponding to the set of indices T.

▷ Claim 14. For any set $T \subseteq E'$,

$$\mathrm{rank}(M_{E'\setminus T}) = \mathrm{rank}(M^*_T) - |T| + n.$$

Let $\{u^*_{e,i}\}_{e,i}$ be the set of columns of M^*. Consider the family of subspaces $\mathcal{V}^* = \{V_e^* \subseteq \mathbb{F}^{|E'|-n}\}_{e\in E}$, where $V_e^* = \mathrm{span}\{u^*_{e,i} \mid 1 \leq i \leq b_e\}$. Let $r^*\colon 2^E \to \mathbb{Z}$ be the rank function of $\mathcal{V}^*$. Then for any $S \subseteq E$, take $T = \{(e, i) \mid e \in S,\ 1 \leq i \leq b_e\}$ in Claim 14, and we get

$$r(E \setminus S) = r^*(S) - b(S) + n. \qquad ◀$$

Proof of Theorem 2. Lemma 12 gives an NC-reduction from LR submodular minimization to minimizing functions of the form $f(S) = r(S) - w(S) + C$. To minimize $f(S)$, it is sufficient to minimize $r(S) - w(S)$, which is what Lemma 7 does. This concludes the RNC algorithm for LR submodular functions as claimed in Theorem 2. ◀

4 Variants and Applications

In this section, we first consider two variants of submodular minimization which can be reduced to submodular minimization. Here we basically show that this kind of reductions can also made to work in the setting of LR submodular functions. Later on, we also show reductions from two combinatorial problems to LR submodular minimization.

4.1 Variants

Submodular minimization with containment constraints. We first consider an extension of submodular minimization that asks for a minimizing set with containment constraints. Given a submodular function $f\colon 2^E \to \mathbb{R}$ and two sets $S_0 \subseteq S_1 \subseteq E$, suppose the goal is to minimize $f(S)$ subject to $S_0 \subseteq S \subseteq S_1$. It is known that there is a submodular function g on the ground set $S_1 \setminus S_0$ such that for any $S_0 \subseteq S \subseteq S_1$, $f(S) = g(S \setminus S_0) + C'$ for some constant C'. If f is linearly representable then we would like to come up with such a function g that is also linearly representable. Towards this, we will need the following claim.

▷ Claim 15. Let $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e\in E}$ be a family of subspaces and r be the corresponding rank function. Let there be two sets $S_0 \subseteq S_1 \subseteq E$. Then we can construct a family of subspaces $\mathcal{V}' = \{V'_e\}_{e\in S_1\setminus S_0}$ with rank function r' such that for each $S_0 \subseteq S \subseteq S_1$

$$r(S) - r(S_0) = r'(S \setminus S_0).$$

Proof. Let V_{S_0} be the subspace $\sum_{e \in S_0} V_e$. For each $e \in S_1 \setminus S_0$, we define V'_e to be the quotient space $V'_e = V_e / V_{S_0}$. Now, for any $S_0 \subseteq S \subseteq S_1$, we have

$$r'(S \setminus S_0) = \dim(\sum_{e \in S \setminus S_0} V'_e) = \dim \left((\sum_{e \in S \setminus S_0} V_e)/V_{S_0} \right) = \dim(V_S/V_{S_0}) = r(S) - r(S_0).$$

◁

From Lemma 12, any linearly representable submodular function can be given as $f(S) = r(S) - w(S) + C$, for a rank functions $r(S)$ on a family of subspaces $\mathcal{V}$, a modular function $w(S)$ and a constant C. For given two sets $S_0 \subseteq S_1 \subseteq E$, let r' be the function constructed in Claim 15 from r. For any $T \subseteq S_1 \setminus S_0$ define $g(T) = r'(T) - w(T) + C$. Using Claim 15, one can verify that for any $S_0 \subseteq S \subseteq S_1$,

$$g(S \setminus S_0) = r'(S \setminus S_0) - w(S \setminus S_0) + C = r(S) - r(S_0) - w(S) + w(S_0) + C = f(S) - f(S_0) + C.$$

Choose $C' = C - f(S_0)$ and we get the desired relation. Now, to minimize f under containment constraints, one can just minimize g on the smaller ground set.

Submodular minimization over non-empty sets. In applications, one often needs to minimize a submodular function over non-empty sets, for example, min-cut in an undirected graph. To do this, one can go over all elements $e \in E$ and minimize $f(S)$ with the containment constraint $\{e\} \subseteq S$ (as discussed above). This will give us a minimum value for each choice of e. The minimum among these values will be the minimum over non-empty subsets.

Separation oracle for a linear polymatroid. Given a family of subspaces $\mathcal{V} = \{V_e \subseteq \mathbb{F}^n\}_{e \in E}$ with its rank function $r \colon 2^E \to \mathbb{Z}$, the corresponding polymatroid is a polytope $P_r \subseteq \mathbb{R}^E$ defined as

$$P_r = \{x \in \mathbb{R}^E \mid x \geq 0, \sum_{e \in S} x_e \leq r(S) \ \forall S \subseteq E.\}$$

Given a rational point $\beta \in \mathbb{R}^E$, one needs to decide if β lies in P_r, and if not then find a violating constriant. The non-negativity constraints are easy to check. The other rank constraints are equivalent to

$$\min_{S \subseteq E} (r(S) - x(S)) \geq 0.$$

Thus, to check if β satisfies the rank constraints, it suffices to minimize the function $f(S) = r(S) - \beta(S)$. Moreover, if there is a violating constraint, then the set S^* minimizing $f(S)$ will give a violating constraint. If β is an integer vector, we have already seen how to find S^* in Lemma 7. When β has rational coordinates, then one can assume them to have a common denominator q, i.e., $\beta_e = p_e/q$ for integers p_e, q. Now, the minimization function becomes $q \times r(S) - p(S)$. Now, $p(S)$ is an integral function. To get the multiplicative factor q in the rank, for each subspace V_e in the family, one can take the direct sum with its copies as $\oplus_{j=1}^{q} V_e$. Note that this is efficient as long as the number q is polynomially bounded.

4.2 Applications

In this section, we show that the two combinatorial problems mentioned in Section 1 reduce to LR submodular minimization. To the best of our knowledge, these problems do not have any known reduction to linear matroid intersection. We start with defining the necessary terminology. Branchings and arborescences are directed analogues of forests and spanning trees.

▶ **Definition 16** (Branching and Arborescence). *For a directed graph $G(V, E)$, a subset $B \subseteq E$ of edges is a branching if it contains no undirected cycles (i.e, there are no cycles induced by B if edges in B are considered to be undirected) and for every vertex v, there is at most one edge in B that is incoming to v. A vertex is a root of B if it has no incoming edges in B. An arborescence is a branching with exactly one root, that is, it is a rooted tree. If the root vertex of an arborescence is a, then we call it an a-arborescence.*

Covering by a-arborescences

A directed graph $G(V, E)$ is said to be covered by k a-arborescences if there exists subsets $B_1, B_2, \ldots, B_k \subseteq E$, each of which is an a-arborescence and $E = B_1 \cup B_2 \cup \cdots \cup B_k$. Vidyasankar [32] gave the following characterization for the graph to covered by k a-arborescences. For any set of vertices $S \subseteq V$, let $H[S] := \{u \in S \mid \exists v \in V \setminus S,\ (v, u) \in E\}$ and let $\delta^{in}(S) := \{(v, u) \in E \mid \exists v \in V \setminus S,\ u \in S\}$ be the set of incoming edges in S. Let $\deg^{\text{in}}(v)$ be the number of incoming edges to v.

▶ **Theorem 17** ([32]). *For a vertex $a \in V$ and a positive number k, the directed graph $G(V, E)$ is be covered by k a-arborescences if and only if*

- $\deg^{\text{in}}(a) = 0$ *and* $\deg^{\text{in}}(v) \le k$ *for each* $v \in V$ *and*
- $\sum_{v \in H[S]}(k - \deg^{\text{in}}(v)) \ge k - |\delta^{in}(S)|$, *for each non-empty subset S of $V \setminus \{a\}$.*

Reduction to submodular minimization. We show that testing the conditions required in Theorem 17 can be reduced to LR submodular minimization. Testing the first condition is trivial. We come to the second one. Let us define a function $f \colon 2^{V \setminus \{a\}} \to \mathbb{Z}$ as follows:

$$f(S) = \sum_{v \in H[S]} (k - \deg^{\text{in}}(v)) + |\delta^{in}(S)|.$$

We will just show that $f(S)$ is a linearly representable submodular function. Clearly, one can check the required condition by finding $\min_{S \subseteq V \setminus \{a\}} f(S)$ and verifying that it is at least k.

For any vertex $u \in V$, let $\chi_u \in \{0, 1\}^V$ be the characteristic vector of v. Let us define two families of subspaces $\mathcal{L}_1$ and $\mathcal{L}_2$ with rank functions r_1 and r_2.

- $\mathcal{L}_1 = \{L_{1,u} \subseteq \mathbb{R}^{k \times |V|}\}_{u \in V}$, where $L_{1,u} = \sum\limits_{\substack{v=u \text{ or} \\ (u,v) \in E}} \oplus_{j=1}^{k - \deg^{\text{in}}(v)} \operatorname{span}(\chi_v)$ and
- $\mathcal{L}_2 = \{L_{2,u} \subseteq \mathbb{R}^{k \times |V|}\}_{u \in V}$, where $L_{2,u} = \oplus_{j=1}^{k - \deg^{\text{in}}(u)} \operatorname{span}(\chi_u)$

One can observe that for any set $S \subseteq V$, $r_1(S)$ is just the sum of the quantity $k - \deg^{\text{in}}(v)$ over all vertices v that are either in S or out-neighbors of S, and $r_2(S)$ is sum of the same quantity over all the vertices of S. Thus, we can write

$$r_1(S) - r_2(S) = \sum_{v \in H[\bar{S}]} (k - \deg^{\text{in}}(v)), \tag{6}$$

where $\bar{S} = V \setminus S$. Note that $-r_2(S)$ is same as $r_2(\bar{S}) - r_2(V)$. Thus,

$$\sum_{v \in H[S]} (k - \deg^{\text{in}}(v)) = r_1(\bar{S}) + r_2(S) - r_2(V). \tag{7}$$

Now, we will express the second part of $f(S)$, that is $|\delta^{in}(S)|$, as a LR submodular function. For any edge $e \in E$, let $\chi_e \in \{0, 1\}^E$ be the characteristic vector of e. Let us define three families of subspaces $\mathcal{L}_3$, $\mathcal{L}_4$ and $\mathcal{L}_5$ with rank functions r_3, r_4 and r_5, respectively.

- $\mathcal{L}_3 = \{L_{3,u} \subseteq \mathbb{R}^E\}_{u \in V}$, where $L_{3,u} = \text{span}\{\chi_e \mid e = (u,v) \text{ for some } v \in V\}$.
- $\mathcal{L}_4 = \{L_{4,u} \subseteq \mathbb{R}^E\}_{u \in V}$, where $L_{4,u} = \text{span}\{\chi_e \mid e = (v,u) \text{ for some } v \in V\}$.
- $\mathcal{L}_5 = \{L_{5,u} \subseteq \mathbb{R}^E\}_{u \in V}$, where $L_{5,u} = \text{span}\{\chi_e \mid e = (u,v) \text{ or } e = (v,u) \text{ for some } v \in V\}$.

One can observe that for any set $S \subseteq V$, $r_3(S)$ is the total number of edges which are outgoing from some vertex in S, $r_4(S)$ is the total number of edges which are incoming to some vertex in S, and $r_5(S)$ is the total number of edges that are incident (outgoing or incoming) to some vertex in S. Thus, one can write

$$2|\delta^{in}(S)| = r_3(\bar{S}) + r_4(S) + r_5(S) + r_5(\bar{S}) - 2|E|. \tag{8}$$

Together with (7) and (8), we can write,

$$2f(S) = 2 \times (r_1(\bar{S}) + r_2(S) - r_2(V)) + r_3(\bar{S}) + r_4(S) + r_5(S) + r_5(\bar{S}) - 2|E|.$$

The terms $r_2(V)$ and $2|E|$ are constants here. The other terms give us a linearly representable submodular function.

Recall that we have to minimize the function $f(S)$ over subsets S that do not contain the vertex a. We had reduced such a constrained minimization to general minimization in the previous subsection.

Packing of branchings

For a given directed graph and given subsets $R_1, R_2, \ldots, R_k$ of vertices, we need to decide if there exist k edge-disjoint branchings that are rooted at $R_1, R_2, \ldots, R_k$, respectively. Edmonds (see [29, Theorem 53.1]) gave the following characterization.

▶ **Theorem 18.** *Let $G = (V, E)$ be a directed graph with $R_1, R_2, \ldots, R_k$ being subsets of V. Then there exist disjoint branchings $B_1, B_2, \ldots, B_k$ such that B_i has root set R_i for $1 \leq i \leq k$ if and only if $|\delta^{in}(S)| \geq |i : R_i \cap S = \emptyset|$ for each non-empty subset S of V.*

Let $f(S) = |\delta^{in}(S)| - |i : R_i \cap S = \emptyset|$. To check the condition in the theorem, it is sufficient to minimize $f(S)$ over non-empty subsets of V. We have already expressed $|\delta^{in}(S)|$ as a linearly representable submodular function in (8). We need to now express the other part of the function. Let us define

$$g_i(S) := \begin{cases} 1 & \text{if } S \cap R_i \neq \emptyset \\ 0 & \text{otherwise.} \end{cases}$$

One can verify that g_i is the rank function of the following family of subspaces: $\mathcal{L}_i = \{L_{i,u} \subseteq \mathbb{R}\}_{u \in V}$, where $L_{i,u} = \{1\}$ if $u \in R_i$ and $L_{i,u} = \{0\}$ otherwise. Now, one can express the desired function in terms of g_i's.

$$-|i : R_i \cap S = \emptyset| = \sum_{i=1}^{k} g_i(S) - k.$$

Together with (8), this gives us a linear representation for $f(S)$ (up to additive constants).

5 Discussion

We have given a parallel algorithm for submodular minimization in the special case of linearly representable submodular functions. It would be interesting to know if there are other classes of submodular functions that admit parallel algorithms. More generally, it is not clear if there can be an efficient parallel algorithm for submodular minimization in the oracle model.

We have given two examples of combinatorial problems that are captured by LR submodular minimization, but are not known to be reducible to linear matroid intersection. One needs to investigate what are other examples of such problems.

Abstract

The d-to-1 conjecture of Khot asserts that it is NP-hard to satisfy an ϵ fraction of constraints of a satisfiable d-to-1 Label Cover instance, for arbitrarily small $\epsilon > 0$. We prove that the d-to-1 conjecture for any fixed d implies the hardness of coloring a 3-colorable graph with C colors for arbitrarily large integers C.

Earlier, the hardness of $O(1)$-coloring a 4-colorable graphs is known under the 2-to-1 conjecture, which is the strongest in the family of d-to-1 conjectures, and the hardness for 3-colorable graphs is known under a certain "fish-shaped" variant of the 2-to-1 conjecture.

1 Introduction

Determining if a graph is 3-colorable is one of the classic NP-complete problems. Thus, given a 3-colorable graph it is NP-hard to color it with 3 colors. The best known polynomial time algorithms for coloring 3-colorable graphs use about $n^{0.2}$ colors, where n is the number of vertices in the graph [9]. On the other hand, on the hardness front, we only know that 5-coloring 3-colorable graphs is NP-hard [3].

This embarrassingly large gap between the hardness and algorithmic results has prompted the quest for conditional hardness results for approximate graph coloring. The canonical starting point for most strong inapproximability results is the Label Cover problem. Label Cover refers to constraint satisfaction problems of arity two over a large (but fixed) domain whose constraint relations are *functions*. Label Cover is known to be very hard to approximate even on satisfiable instances.

The Unique Games Conjecture of Khot [10], which asserts strong inapproximability of Label Cover when the constraint maps are bijections, has formed the basis of numerous tight hardness results for problems which have defied NP-hardness proofs. However, the imperfect completeness inherent in the Unique Games Conjecture makes it unsuitable as the basis for hardness results for graph coloring, where we want *all* edges to be properly colored under the coloring.

In [10], along with the Unique Games Conjecture, Khot introduced the d-to-1 conjecture. The d-to-1 conjecture says that given a Label Cover instance whose constraint relations are d-to-1 functions, it is NP-hard to decide if there exists a labelling that satisfies all the constraints or no labelling can satisfy even an ϵ fraction of constraints, for arbitrarily small $\epsilon > 0$. (The key is that d can be held fixed and achieve soundness $\epsilon \to 0$.) Constraints similar to 2-to-1 also played an implicit role in the beautiful work of Dinur and Safra on inapproximability of vertex cover [8].

Based on the 2-to-1 conjecture, Dinur, Mossel and Regev [7], extending the invariance principle based techniques of [11,15], proved the hardness of coloring graphs that are promised to be 4-colorable with any constant number of colors. Furthermore, they prove the same for 3-colorable graphs under a certain "fish shaped" variant of the 2-to-1 conjecture. In this paper, we prove that the same result can be proved under the weaker assumption of d-to-1 conjecture[1], for some (arbitrarily large) constant d.

▶ **Theorem 1.** *Assume that d-to-1 conjecture is true for some constant d. Then, for every positive integer $t \geq 3$, it is NP-hard to color a 3-colorable graph G with t colors.*

We stress that the d-to-1 conjecture insists on perfect completeness (i.e., hardness on satisfiable instances), and this important feature seems necessary for its implications for coloring problems, where we seek to properly color all edges. The variant of the 2-to-1 conjecture where one settles for near-perfect completeness was recently established in a striking sequence of works [5,6,12,13].

The result of [7] in fact shows hardness of finding an independent set of density ϵ in a 3-colorable graph for arbitrary $\epsilon > 0$ (which immediately implies the hardness of finding a coloring with $1/\epsilon$ colors). Our result in Theorem 1 above does *not* get this stronger hardness for finding independent sets. But it is conditioned on the d-to-1 conjecture for arbitrary d rather than the specific 2-to-1 conjecture. We note that proving the d-to-1 conjecture for some large d could be significantly easier than the 2-to-1 conjecture, so Theorem 1 perhaps provides an avenue for resolving a longstanding challenge concerning the complexity of approximate graph coloring.

Our proof of Theorem 1 is a simple combination of two results. First, following the methodology of [7], we prove that the d-to-1 conjecture implies that coloring a $2d$-colorable graph with $O(1)$ colors is NP-hard. The result of [7] is the $d = 2$ case of this claim. In fact, they state in a future work section that the d-to-1 conjecture should imply hardness of $O(1)$-coloring q-colorable graphs for some large enough $q = q(d)$. However, they did not specify the details of the reduction or an explicit value of q, and mention determining the dependence of q on d as an interesting question. Here we show the conditional hardness based on d-to-1 conjecture holds for $q = 2d$ (achieving $q < 2d$ seems unlikely with the general reduction approach of [7]).

The key technical ingredient necessary for such a reduction is a symmetric Markov chain on $[q]^d$ where transitions are allowed only between disjoint tuples and which has spectral radius bounded away from 1. We show the existence of such a symmetric Markov chain for $q = 2d$. We do so via a connection to matrix scaling, which enables us to deduce the necessary chain at a conceptual level without messy calculations. Specifically, we use the result [4], which follows from the Sinkhorn-Knopp iterative matrix scaling algorithm [19],

[1] For d-to-1 Label Cover, there are two definitions possible, one where the constraint maps are *at most* d-to-1 with each element in the range having at most d pre-images, and one where the constraint maps are *exactly* d-to-1. In this paper, we stick with the exact variant.

that if a non-negative symmetric matrix A has *total support* then there is a symmetric doubly stochastic matrix supported on the non-zero entries of A. When A is the adjacency matrix of a graph G, the total support condition is equivalent to every edge of G belonging to a cycle cover. We describe a graph on $[q]^d$ whose edges connect disjoint tuples and where every edge belongs to a cycle cover.

Our second ingredient is a remarkable yet simple reduction due to Krokhin, Opršal, Wrochna and Živný [14], which exploits the relation between the arc-chromatic number and chromatic number of a digraph [17]. Let $b : \mathbb{N} \to \mathbb{N}$ be defined by $b(n) := \binom{n}{\lfloor n/2 \rfloor}$. Their result then is that $b(t)$-coloring $b(c)$-colorable graphs is polynomial time (in fact logspace) reducible to t-coloring c-colorable graphs. Since $b(n)$ is increasing and $b(n) > n$ for all $n \geq 4$, it follows that a NP-hardness result for $O(1)$-coloring q-colorable graphs also implies NP-hardness of $O(1)$-coloring 4-colorable graphs. Furthermore, the NP hardness of $O(1)$-coloring of 3-colorable graphs follows from the above by applying the arc graph reduction twice to K_4.

Overview

In Section 2, we define the Label Cover problem, and state the d-to-1 conjecture formally. We also introduce low degree influences that we need later. In Section 3, we first prove the existence of the Markov chain with required properties, and then describe the reduction from Label Cover to Approximate Coloring. We note that the reduction is in fact exactly the same one used in [7], the difference being in using a different Markov Chain. We present the reduction and the preliminaries required in this paper for the sake of completeness.

2 Preliminaries

We first formally define the Label Cover problem and then state the hardness conjectures.

2.1 Label Cover

▶ **Definition 2** (Label Cover). *In the Label Cover instance, we are given a tuple $G = ((V, E), R, \Psi)$ where*

1. *(V, E) is a graph on vertex set V with edge set E.*
2. *Each vertex in V has to be assigned a label from the set $\Sigma = [R] = \{1, 2, \dots, R\}$.*
3. *For every edge $e = (u, v) \in E$, there is an associated relation $\Psi_e \subseteq \Sigma \times \Sigma$. This corresponds to a constraint between u and v.*

A labeling $\sigma : V \to \Sigma$ satisfies a constraint associated with the edge $e = (u, v)$ if and only if $(\sigma(u), \sigma(v)) \in \Psi_e$. Given such an instance, the goal is to distinguish if there is a labeling that can satisfy all the constraints or no labeling can satisfy a significant fraction of constraints.

We now state the d-to-1 conjecture. As is the case with [7], we will state and use the *exact* d-to-1 variant where the constraint maps have exactly d pre-images for each element in the range. Khot's original formulation only required that there are at most d pre-images for each element in the range. The d-to-1 conjecture becomes stronger for smaller d (so that the 2-to-1 is the strongest form of the conjecture) – this is obvious for the variant where the maps are at most d-to-1. For the exact variant, if we allow the Label cover graph to have multiple edges, we can reduce d-to-1 conjecture to $(d + 1)$-to-1 conjecture using a simple argument. We present this reduction in Section 4. On that note, we remark without details that our reduction indeed works with the multigraph variant of d-to-1 conjecture.

▶ **Conjecture 3** ((Exact) d-to-1 Conjecture). *For every $\epsilon > 0$, given a bipartite Label Cover instance $G = ((V = X \cup Y, E), (dR, R), \Psi)$ satisfying the following constraints:*

(i) *We refer to X as the vertices on the left, and Y as the set of vertices on the right. The vertices belonging to X are to be assigned labels from $[dR]$ while the vertices in Y are to be assigned labels from $[R]$.*

(ii) *The constraints are d-to-1 i.e. for every $b \in [R]$, there are precisely d values $a \in [dR]$ such that $(a, b) \in \Psi_e$ for every relation Ψ_e in the instance.*

It is NP-hard to distinguish between the following cases:

1. *There is a labeling that satisfies all the constraints in G.*
2. *No labeling can satisfy more than ϵ fraction of constraints in G.*

Similar to the d-to-1 constraints, one can consider d-to-d constraints in the Label Cover. In order to do so, we define the relation $d \leftrightarrow d$ on $[dR] \times [dR]$:

$$d \leftrightarrow d = \{(di - p + 1, di - q + 1) \ \mid \ 1 \le i \le R, \ \ 1 \le p, q \le d\} \ .$$

A constraint $\psi \subseteq [dR] \times [dR]$ is said to be d-to-d if there exist permutations π_1 and π_2 on $[dR]$ such that $(a, b) \in \psi$ iff $(\pi_1^{-1}(a), \pi_2^{-1}(b)) \in d \leftrightarrow d$.

In [7], it is proved that Conjecture 3 implies the following conjecture.

▶ **Conjecture 4** (d-to-d conjecture). *For every $\epsilon > 0$ and every $t \in \mathbb{N}$, there exists $R \in \mathbb{N}$ such that given a Label Cover instance $G = ((V, E), dR, \Psi)$ where all the constraints are d-to-d, it is NP-hard to distinguish between the following cases:*

(i) $sat(G) = 1$*, or*

(ii) $isat_t(G) < \epsilon$

Here, $sat(G)$ denotes the maximum fraction of constraints satisfied by any labeling. Similarly, $isat(G)$ denotes the size of the largest set $S \subseteq V$ such that there exists a labeling that satisfies all the constraints induced on S. The value $isat_t(G)$ denotes the size of largest set $S \subseteq V$ such that there exists a labeling that assigns at most t labels to each vertex that satisfies all the constraints induced on S. A constraint between u, v is said to be satisfied by labeling assigning multiple labels to u and v if and only if there exists at least one pair of labels to u and v among the multiple labels that satisfy the constraint.

2.2 Low degree influences

Next, we define the low degree influences that we need later. We refer the reader to [7] for a comprehensive treatment of the same.

Let $\alpha_0 = \mathbf{1}, \alpha_1, \dots, \alpha_{q-1}$ be an orthonormal basis of $\mathbb{R}^q$. We can define the set of functions $\alpha_x : [q]^n \to \mathbb{R}, x \in [q]^n$ as $\alpha_x(y) = (\alpha_{x_1}(y_1), \alpha_{x_2}(y_2), \dots, \alpha_{x_n}(y_n))$. Observe that these functions form a basis for the functions from $[q]^n$ to $\mathbb{R}$. Let $\hat{f}(\alpha_x) = \langle f, \alpha_x \rangle$, where we define the inner product between functions $f, g : [q]^n \to \mathbb{R}$ as $\langle f, g \rangle = q^{-n} \sum_{x \in [q]^n} f(x) g(x)$. We define the low degree influence of f as follows:

▶ **Definition 5.** *For a function $f : [q]^n \to \mathbb{R}$, the degree k influence of the coordinate i is defined as follows:*

$$I_i^{\le k}(f) = \sum_{x : x_i \neq 0, |x| \le k} \hat{f}^2(\alpha_x)$$

Note that the above definition is independent of the basis $\alpha_0, \alpha_1, \ldots, \alpha_{q-1}$ that we start with, as long as $\alpha_0 = \mathbf{1}$. From the above definition, we can infer that for functions $f : [q]^n \to [0,1]$, the sum of low degree influences is bounded by

$$\sum_i I_i^{\le k}(f) \le k$$

For a vector $x \in [q]^{dR}$, let $\overline{x} \in [q^d]^R$ be the corresponding element in $[q^d]^R$ i.e.

$$\overline{x} = ((x_1, x_2, \ldots, x_d), (x_{d+1}, x_{d+2}, \ldots, x_{2d}), \ldots, (x_{dR-d+1}, x_{dR-d+2}, \ldots, x_{dR}))$$

Similarly, for $y \in [q^d]^R$, let $\underline{y}$ denote the inverse of above operation. We can extend this notion to functions as well: For a function $f : [q]^{dR} \to \mathbb{R}$, let the function $\overline{f} : [q^d]^R \to \mathbb{R}$ be defined naturally by

$$\overline{f}(y) = f(\underline{y})$$

Similarly, for a function $f : [q^d]^R \to \mathbb{R}$, let $\underline{f} : [q]^{dR} \to \mathbb{R}$ be defined as $\underline{f}(x) = f(\overline{x})$.

We need the following lemma:

▶ **Lemma 6.** *For any function $f : [q]^{dR} \to \mathbb{R}$ and any $k \in \mathbb{N}$ and $i \in [R]$,*

$$I_i^{\le k}(\overline{f}) \le \sum_{j=1}^{d} I_{di-d+j}^{\le dk}(f)$$

Proof. Fix a basis α_x of functions from $[q]^{dR} \to \mathbb{R}$ as above. The functions $\alpha_{\overline{x}}$ form a basis for functions from $[q^d]^R \to \mathbb{R}$, where $\alpha_{\overline{x}}(\overline{y}) = \alpha_x(y)$. Note that $\hat{\overline{f}}(\alpha_{\overline{x}}) = \hat{f}(\alpha_x)$. Thus we get

$$\begin{aligned}
\sum_i I_i^{\le k}(\overline{f}) &= \sum_{\overline{x}:\overline{x}_i \neq (0,0,\ldots,0), |\overline{x}| \le k} \hat{\overline{f}}^2(\alpha_{\overline{x}}) = \sum_{\overline{x}:\overline{x}_i \neq (0,0,\ldots,0), |\overline{x}| \le k} \hat{f}^2(\alpha_x) \\
&\le \sum_{x:\overline{x}_i \neq (0,0,\ldots,0), |x| \le dk} \hat{f}^2(\alpha_x) \\
&\le \sum_{j=1}^{d} \sum_{x:x_{di-d+j} \neq 0, |x| \le dk} \hat{f}^2(\alpha_x) \\
&= \sum_{j=1}^{d} I_{di-d+j}^{\le dk}(f)
\end{aligned}$$

◀

Using the invariance principle and Borell's inequality, [7] prove the following:

▶ **Theorem 7.** *Let q be a fixed integer, and T be a symmetric Markov chain on $[q]$ with $r(T) < 1$. Then for every $\epsilon > 0$, there exists a $\delta > 0$ and a positive integer k such that the following holds: For every $f, g : [q]^n \to [0,1]$ if $\mathbb{E}[f] > \epsilon, \mathbb{E}[g] > \epsilon$ and $\langle f, Tg \rangle = 0$, then*

$$\exists i \in [n] : I_i^{\le k}(f) \ge \delta, I_i^{\le k}(g) \ge \delta$$

where $r(T)$ denotes the second largest eigenvalue (in absolute value) of T.

3 *d*-to-1 hardness for 3-colorable graphs

In this section, we will prove Theorem 1.

3.1 Reducing chromatic number to 3

The following lemma is present in [14] based on a beautiful result concerning the arc-chromatic numbers of digraphs from [17].

▶ **Lemma 8** (Theorem 1.8 of [14]). *Suppose there exists $q \in \mathbb{N}$ such that $O(1)$ coloring q-colorable graphs is NP-hard. Then, $O(1)$ coloring 3-colorable graphs is NP hard.*

Let Graph-Coloring(t, c) denote the promise problem of distinguishing if a graph can be colored with c colors, or cannot even be colored with t colors. The statement is proved by presenting a reduction from Graph-Coloring$(b(t), b(c))$ to Graph-Coloring(t, c) in polynomial time, for the function $b(n) := \binom{n}{\lfloor n/2 \rfloor}$. The reduction works by constructing the arc-graph of the underlying graphs, and using the property of arc graphs that the chromatic number of the arc graph can be bounded precisely using the chromatic number of the original graph. Since b is an increasing function and $b(n) > n$ for all $n \geq 4$, setting $c = 4$ and t large enough proves the statement claimed in the lemma. The reduction from 4-colorable graphs to 3-colorable graphs is achieved by applying the arc graph construction twice recursively.

Thanks to Lemma 8, we can restrict ourselves to the weaker goal of proving that $O(1)$ coloring q-colorable graphs is NP-hard for some fixed constant q assuming Conjecture 3. In fact, following [7], we prove a stronger statement showing hardness of finding independent sets of ϵ fraction of vertices for any $\epsilon > 0$. Combined with Lemma 8, this immediately gives us Theorem 1.

▶ **Theorem 9.** *Suppose that Conjecture 4 is true for a constant d. Then, there exists a constant $q = q(d)$ such that for every $\epsilon > 0$, given a graph G, it is NP-hard to distinguish the following cases:*

1. *G can be colored with q colors.*
2. *G does not have any independent set of relative size ϵ.*

In fact, we can take $q = 2d$.

In the remainder of the section, we will prove Theorem 9. We next develop the main technical ingredient that we will plug into the reduction framework of [7] to establish Theorem 9.

3.2 A symmetric Markov chain supported on disjoint tuples

A Markov chain T defined on a state space Ω is said to be symmetric if the transition matrix of T is symmetric, namely for all pairs of states $x, y \in \Omega$, the probability of transition from x to y is equal to the probability of transition from y to x. Symmetry of the Markov chain ensures that the uniform distribution is stationary which is essential when we compose the Label Cover-Long Code reduction with the Markov chain. We define the spectral radius $r(T)$ of a symmetric Markov chain as the second largest eigenvalue in absolute value of its transition probability matrix, i.e., if $1 = \lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_q$ are the eigenvalues, then $r(T) = \max(|\lambda_2|, |\lambda_q|)$.

We now show the existence of a symmetric Markov Chain T on $[q]^d$ with $r(T) < 1$ if $d \geq 2, q \geq 2d$. Furthermore, there is a nonzero transition probability between two elements $x, y \in [q]^d$ only if the support of x and y are disjoint. In [7], such a Markov Chain is shown to exist for the values $(q, d) = (3, 1), (4, 2)$.

▶ **Lemma 10.** *Suppose that $q, d \in \mathbb{N}, q \geq 2d, d \geq 2$. There exists a symmetric Markov chain T on $[q]^d$ such that $r(T) < 1$. Furthermore, if the transition $\{x_1, x_2, \ldots, x_d\} \leftrightarrow \{y_1, y_2, \ldots, y_d\}$ has positive probability in T, then $\{x_1, x_2, \ldots, x_d\} \cap \{y_1, y_2, \ldots, y_d\} = \phi$.*

Proof. We first construct an undirected graph G on $[q]^d$ such that there is an edge between $x, y \in [q]^d$ only if the support of x and y are disjoint. We then use a matrix scaling algorithm to obtain a symmetric Markov chain T from the adjacency matrix of G. For the resulting Markov chain to have $r(T) < 1$, we need that the underlying graph G is connected, and is not bipartite. Furthermore, for the scaling algorithm to produce a valid Markov chain, we need that every edge of G is present in a cycle cover, where a cycle cover of a graph is a disjoint union of cycles that covers every vertex in the graph. Note that we allow trivial 2-cycles in a cycle cover, where we just take an edge twice.

We say that two multisets $x = (x_1, x_2, \ldots, x_d), y = (y_1, y_2, \ldots, y_d) \in [q]^d$ are of the same *type* if the following condition holds: for all pairs of indices $i, j \in [d]$, $x_i = x_j$ if and only if $y_i = y_j$ and $(x_i - x_j)(y_i - y_j) \geq 0$. Note that this is an equivalence relation, and thus each element $x \in [q]^d$ uniquely determines its type.

Consider the graph $G = (V, E)$ where the vertex set is $V = [q]^d$. We add two kinds of edges in this graph. We add an edge between every pair of $x, y \in [q]^d$ that are of the same type, and have disjoint support. Let the subset of $[q]^d$ of elements that are supported on single element be denoted by S, i.e.,

$$S = \{(1, 1, \ldots, 1), (2, 2, \ldots, 2), \ldots, (q, q, \ldots, q)\} .$$

We also add edges between x and y if their support is disjoint, and at least one of x and y belongs to S.

First, we claim that G is connected. This follows from the fact that the set of nodes in S are connected to each other, and every vertex in V is adjacent to at least one vertex in S. As $q \geq 4$, the graph is not bipartite (indeed S induces a q-clique). We will now prove that every edge in this graph is part of a cycle cover. Given an undirected graph on vertex set V, a cycle cover of it is a function $\sigma : V \to V$ that is bijective, and $\sigma(u) = v$ only when u and v are adjacent in the underlying graph.

Towards this, we first prove that for every edge in G between multisets of the same type, there is a cycle cover that uses that edge. For each type, consider the graph obtained by taking the vertices as multisets of that type, and with edges between two multisets of the same type if they are disjoint. Note that for every type, this graph is isomorphic to a Kneser graph $KG(q, k)$ (for some $k \leq d$), whose vertex set corresponds to k-element subsets of $[q]$ and there is an edge between two subsets if they are disjoint.

By symmetry across the subsets, we can infer that the Kneser graphs are regular. Note that every regular graph contains a cycle cover: For a regular graph H, consider a bipartite graph H' which contains a copy of H on both the left side L, and right side R. There is an edge between $x \in L, y \in R$ of H' if and only if x, y are adjacent in H. As H is a regular graph, H' is a regular bipartite graph, and thus, contains a perfect matching. This perfect matching in H' directly gives a cycle cover of H. Furthermore, as Kneser graphs are also vertex-transitive, every edge in these graphs is part of a cycle cover.

Next, we consider edges of G that are between multisets of different types i.e. edges between multisets x, y where exactly one of x and y is in S. Consider an edge between $s \in S$ and $x \in V \setminus S$. As $q \geq 2d$, every multiset in G is adjacent to at least one multiset of the same type. Let y be a multiset that is adjacent to x in G and is of the same type as x. Let $s' \in S$ be chosen such that it is adjacent to y in G. As S is a complete subgraph of G, s and s' are adjacent in G. From the previous argument about edges between multisets of the same type, we can infer that there is a cycle cover of G where y is mapped to x, and s is mapped to s'. We can modify this cycle cover by transforming it as follows - $(s \to x)$ can be made part of cycle cover by transforming $(s \to s'), (y \to x)$ to $(s \to x), (y \to s')$ and keeping rest of the cycle cover intact. Thus, we have proved that every edge of G is part of a cycle cover.

Let A denote the adjacency matrix of the above graph G. Using the Sinkhorn Knopp iterative algorithm, it is proved in [4] that if a non-negative symmetric matrix A has total support, then there exists a diagonal matrix D such that DAD is a doubly stochastic matrix. A square matrix $A = (a_{ij})$ of order n is said to have total support if $A \neq 0$, and for every nonzero entry a_{ij} of A, there exists a permutation σ of $[n]$ such that $\sigma(i) = j$ and for all $e \in [n], a_{e,\sigma(e)} \neq 0$. When the matrix A is an adjacency matrix of a graph G, the total support condition translates to the requirement that every edge in G is part of a cycle cover, a property we have already shown to hold for the graph G.

Thus, we can apply the above scaling result, and view the resulting matrix $B = DAD$ as the transition matrix of a Markov chain T. As A and D are symmetric, B is symmetric, i.e., T is symmetric. As A is connected and no principal diagonal element of D is zero, T is connected as well. Note that every nonzero element of A stays nonzero in T, and A is not bipartite. The above two facts combined ensure that the spectral radius $r(T)$ of T is strictly less than 1. We conclude that there exists a symmetric Markov chain T on state space $[q]^d$ that has both the properties: (i) $r(T) < 1$, and (ii) there is nonzero probability of transition between two multisets only when their support is disjoint. ◀

3.3 Proof of Theorem 9

Let d be the constant for which Conjecture 3 is true. Thus, Conjecture 4 is true for the same value d as well. Choose q, T from Lemma 10 such that T is a symmetric Markov chain on $[q]^d$ such that $r(T) < 1$.

We now reduce the given d-to-d Label Cover instance to the problem of finding independent sets in q-colorable graphs. To be precise, given a Label Cover instance $G = ((V, E), dR, \Psi)$, we output a graph $G' = (V', E')$ such that

1. Completeness: If G is satisfiable, G' can be colored with q colors.
2. Soundness: If $isat_t(G) < \epsilon'$, then G' does not have any independent set of size ϵ.

The parameters t and ϵ' will be set later.

Reduction

Our reduction follows the standard Label Cover Long Code paradigm, and in particular closely mirrors [7]. We replace each vertex $w \in V$ of the Label Cover with a set f_w of $[q]^{dR}$ nodes, each corresponding to a vertex in G'. Consider an edge $e = (u, v)$ where Ψ_e is an associated constraint with permutations π_1, π_2 on $[dR]$ such that $(a, b) \in \Psi_e$ if and only if $(\pi_1^{-1}(a), \pi_2^{-1}(b)) \in d \leftrightarrow d$.

We add an edge between $(x_1, x_2, \ldots, x_{dR}) \in f_u$ and $(y_1, y_2, \ldots, y_{dR}) \in f_v$ to E' if and only if

$$\forall i \in [R], T((x_{\pi_1(di-d+1)}, x_{\pi_1(di-d+2)}, \ldots, x_{\pi_1(di)}) \leftrightarrow (y_{\pi_2(di-d+1)}, y_{\pi_2(di-d+2)}, \ldots, y_{\pi_2(di)})) > 0.$$

Completeness

Suppose $\sigma : V \to [dR]$ be a labeling satisfying all the constraints of the Label Cover instance G. We color the node $(x_1, x_2, \ldots, x_{dR}) \in f_w$ with $x_{\sigma(w)} \in [q]$. We claim that this is a legit q-coloring of G'. Suppose that we added an edge between $x \in f_u$ and $y \in f_v$. Let x be colored with x_a and y be colored with y_b. As $(a, b) \in \Psi_{(u,v)}$, we have $(\pi_1^{-1}(a), \pi_2^{-1}(b)) \in d \leftrightarrow d$. Thus, there exist $i \in [R], 1 \le p, q \le d$ such that $a = \pi_1(di - d + p)$ and $b = \pi_2(di - d + q)$.

As we have added an edge between $x \in f_u$ and $y \in f_v$, $x_a \neq y_b$ as the Markov chain T has nonzero probability only between two elements of $[q]^d$ with disjoint support. Thus, there exists a q-coloring of G' when G is satisfiable.

Soundness

We prove the contrapositive that if G' has an independent set of relative size ϵ, then there exists a labeling of G with $isat_t(G) \geq \epsilon'$. Let $S \subseteq V'$ be the largest independent set of G'. We know that $|S| \geq \epsilon|V'|$. This implies that in at least $\epsilon' = \frac{\epsilon}{2}$ fraction of the long code blocks, at least $\frac{\epsilon}{2}$ fraction of nodes belong to S. Let this subset of V be denoted by Z. Our goal is to show that there exists a small set of labels $\tau : Z \to 2^{[dR]}$ to which we can decode the vertices in Z such that all the constraints induced in Z are satisfied by τ.

For every vertex $w \in Z$, we define functions $g_w : [q]^{dR} \to \{0,1\}$ to be the indicator functions of set S inside the long code blocks corresponding to w i.e. $g_w(x) = 1$ if and only if $x \in S$. Consider an edge $e = (u,v)$ corresponding to the constraint Ψ_e induced in Z. Let the functions $f : [q]^{dR} \to \{0,1\}$ and $g : [q]^{dR} \to \{0,1\}$ be defined such that $f(x^{\pi_1}) = g_u(x)$ and $g(y^{\pi_2}) = g_v(y)$, where π_1 and π_2 are the permutations underlying the relation Ψ_e i.e. $(a,b) \in \Psi_e$ if and only if $(\pi_1^{-1}(a), \pi_2^{-1}(b)) \in d \leftrightarrow d$.

We note that $\langle f, Tg \rangle$ is equal to zero. In other words, suppose that $x, y \in [q]^{dR}, x \in f_u, y \in f_v$ are such that

$$\forall i \in [R], T((x_{di-d+1}, x_{di-d+2}, \ldots, x_{di}) \leftrightarrow (y_{di-d+1}, y_{di-d+2}, \ldots, y_{di})) > 0. \tag{1}$$

Then, $f(x)g(y) = 0$. Suppose for contradiction that there exist $x, y \in [q]^{dR}$ satisfying the above condition, and $f(x) = g(y) = 1$. Let $x' \in f_u, y' \in f_v$ be such that $(x')^{\pi_1} = x, (y')^{\pi_2} = y$. We have $g_u(x') = g_v(y') = 1$. That is, both $x' \in f_u, y' \in f_v$ are in the independent set S. However, Equation (1) can be rewritten as the following:

$$\forall i \in [R], T((x'_{\pi_1(di-d+1)}), (x'_{\pi_1(di-d+2)}), \ldots, x'_{\pi_1(di)}) \leftrightarrow (y'_{\pi_2(di-d+1)}, y'_{\pi_2(di-d+2)}, \ldots, y'_{\pi_2(di)})) > 0. \tag{2}$$

Note that this is precisely the condition for adding edges in G'. Thus, Equation (2) implies that $x' \in f_u$ and $y' \in f_v$ are adjacent in E', and thus cannot both be part of the independent set S. This completes the proof that $\langle f, Tg \rangle = 0$.

Thus, $\langle \overline{f}, T\overline{g} \rangle$ is also equal to zero, where $\overline{f} : [q^d]^R \to \{0,1\}$ and $\overline{g} : [q^d]^R \to \{0,1\}$ are the corresponding functions in $[q^d]^R$ of f, g. From the definition of Z, $\mathbb{E}(\overline{f}) \geq \frac{\epsilon}{2}$ and $\mathbb{E}(\overline{g}) \geq \frac{\epsilon}{2}$. We apply Theorem 7 to $\overline{f}$ and $\overline{g}$ to deduce that there exists $i \in [R]$, a positive integer $k = k(\epsilon)$ and $\delta = \delta(\epsilon)$ such that $I_i^{\leq k}(\overline{f}) \geq \delta$ and $I_i^{\leq k}(\overline{g}) \geq \delta$. This motivates us to define the label set of vertex $w \in Z$, $L(w)$ as the following -

$$L(w) := \{i \in [dR] : I_i^{\leq dk}(g_w) \geq \frac{\delta}{d}\}$$

As the sum of k degree influences of all variables is at most k, the size of $L(w)$ is upper bounded by $\frac{kd}{\delta}$ for every v. Thus, we set the parameter t to be $\frac{kd}{\delta}$.

The final step is to prove that the labeling L is indeed a valid labeling inside edges induced in Z. Consider an edge $e = (u,v)$ induced in Z with the constraint relation being Ψ_e such that $(a,b) \in \Psi_e$ if and only if $(\pi_1(a), \pi_2(b)) \in d \leftrightarrow d$. Our goal is to show that there exist indices $\sigma_1, \sigma_2 \in [dR]$ such that $\sigma_1 \in L(u), \sigma_2 \in L(v)$ and $(\sigma_1, \sigma_2) \in \Psi_e$. Using Theorem 7, we can deduce that there exists $i \in [R]$ such that $I_i^{\leq k}(\overline{f}) \geq \delta$ and $I_i^{\geq k}(\overline{g}) \geq \delta$. Using Lemma 6, we can conclude that there exist $i_1, i_2 \in [dR]$ such that $I_{i_1}^{\leq dk}(f) \geq \frac{\delta}{d}$ and $I_{i_2}^{\leq dk}(g) \geq \frac{\delta}{d}$ such that $(i_1, i_2) \in d \leftrightarrow d$. Let $\sigma_1, \sigma_2 \in [dR]$ be such that $i_1 = \pi_1(\sigma_1), i_2 \in \sigma_2$. As $f(x^{\pi_1}) = g_u(x)$, $I^{\leq dk}_{\pi_1^{-1}(i_1)}(g_u) \geq \frac{\delta}{d}$. And thus, $\sigma_1 \in L(u)$, and similarly $\sigma_2 \in L(v)$. As $(i_1, i_2) \in d \leftrightarrow d$, $(\sigma_1, \sigma_2) \in \Psi_e$, which completes the proof.

4 Reducing multigraph (exact) d-to-1 to $(d + 1)$-to-1 conjecture

For the version of d-to-1 conjecture where we only require the constraint maps to be at most d-to-1, the d-to-1 conjecture trivially implies the $(d + 1)$-to-1 conjecture. O'Donnell and Wu [16] remark that no such reduction appears to be known for the exact d-to-1 conjecture. Here we prove that the exact d-to-1 conjecture implies the exact $(d+1)$-to-1 conjecture when the underlying Label Cover instances are allowed to have parallel edges. We remark that multigraph version of exact d-to-1 conjecture, which is implied by the simple graph version, also suffices for our reduction to graph coloring (and indeed all known reductions from d-to-1 Label Cover).

Let $G = ((V = X \cup Y, E), (dR, R), \Psi)$ be a Label Cover instance such that every constraint is of d-to-1 structure. We reduce it to $G' = ((V = X \cup Y, E'), ((d + 1)R, R), \Psi')$ such that

1. If G is satisfiable, G' is satisfiable as well.
2. If every labeling violates at least ϵ fraction of constraints in G, then every labeling violates at least $\epsilon' = 2\epsilon$ fraction of constraints in G'.

Reduction

We first change the label set of X from $[dR]$ to $[(d + 1)R]$. For every constraint ψ in G between nodes $u \in X$ and $v \in Y$, we replace it with R constraints $\psi_1, \psi_2, \ldots, \psi_R$ between u and v in the following way: the relation between old labels is the same as ψ i.e. when $x \leq dR$, $(x, y) \in \psi_j$ for $j = 1, 2, \ldots, R$ if and only if $(x, y) \in \psi$. When $x > dR$, $(x, y) \in \psi_j$ if and only if R divides $(x + j - y)$. This ensures that each new label is mapped to a different label in each of the R new constraints. The constraints are clearly of $(d + 1) - to - 1$ form.

Completeness

If there is a labeling satisfying all the constraints of G, the same labeling satisfies all the constraints in G' as well.

Soundness

Suppose that there is no labeling satisfying at least ϵ fraction of constraints in G. Note that this implies that R is at least $\frac{1}{\epsilon}$ as there is always a labeling satisfying at least $\frac{1}{R}$ fraction of constraints: fix a labeling to the vertices on the left, and assign a label to the vertices in R uniformly at random from $[R]$. We claim that there is no labeling satisfying more than 2ϵ fraction of constraints in G'. Consider an arbitrary labeling of G, $\sigma : V \to [(d + 1)R]$. We can divide the set of edges E' of G' into two parts: the edges (u, v) such that $\sigma(u) \leq dR$ and the edges (u, v) such that $\sigma(u) > dR$. Let the set of first type of edges where the left vertex is assigned the new label be denoted by E_1, and the set of second type of edges be denoted by E_2. In E_1, the fraction of constraints that can be satisfied by σ is at most $\frac{1}{R} \leq \epsilon$. Note that we can get a labeling σ' of G by replacing labels of vertices in X with label greater than dR with an arbitrary label in $[dR]$, and keeping rest of the labels intact. For the edges in E_2, the labelings σ and σ' coincide. As σ' can satisfy at most ϵ fraction of constraints of G, σ can only satisfy at most ϵ fraction of overall edges in E'. Thus, overall σ satisfies at most $\epsilon + \frac{1}{R} \leq 2\epsilon$ fraction of constraints in E', which proves the required soundness claim.

5 Conclusion

In this paper, we prove that the d-to-1 conjecture, for arbitrarily large d, implies the NP-hardness of the longstanding and elusive problem of coloring 3-colorable graphs with constantly many colors. Note that the d-to-1 conjecture requires the soundness parameter to be arbitrarily small, independent of d. Currently, the best NP-hardness of d-to-1 Label Cover achieves a soundness of $d^{-\Omega(1)}$. This follows from the PCP Theorem [1, 2] combined with Raz's parallel repetition [18]. However, this does not yield any explicit constant in the exponent, obtaining which is an interesting open question. One can also investigate whether improving the soundness of d-to-1 Label Cover to something quantitatively much stronger, say inverse exponential in d, would have some implications for inapproximability of graph coloring.

Feasible Interpolation for Polynomial Calculus and Sums-Of-Squares

Tuomas Hakoniemi
Universitat Politècnica de Catalunya, Barcelona, Spain

Abstract

We prove that both Polynomial Calculus and Sums-of-Squares proof systems admit a strong form of feasible interpolation property for sets of polynomial equality constraints. Precisely, given two sets $P(x, z)$ and $Q(y, z)$ of equality constraints, a refutation Π of $P(x, z) \cup Q(y, z)$, and any assignment a to the variables z, one can find a refutation of $P(x, a)$ or a refutation of $Q(y, a)$ in time polynomial in the length of the bit-string encoding the refutation Π. For Sums-of-Squares we rely on the use of Boolean axioms, but for Polynomial Calculus we do not assume their presence.

1 Introduction

In this paper we consider the proof systems Polynomial Calculus (PC) and Sums-of-Squares (SOS). PC is a proof system that is used to derive polynomial equalities from a set of polynomial equality constraints in a step-by-step fashion similar to traditional logical proof systems. A PC proof is a compact certificate that the proved polynomial is in the ideal generated by the constraints. PC was introduced by Clegg et al. [4].

Sums-of-Squares proof system on the other hand is a proof system used to derive polynomial inequalities from a set of polynomial constraints. As a proof system Sums-of-Squares was first investigated by Grigoriev and Vorobjov in [6], but it has its roots in semialgebraic geometry and combinatorial optimization. We refer the reader to [10] for a thorough presentation of these connections.

Feasible interpolation was introduced by Krajíček in [9] as a framework to prove lengths-of-proofs lower bounds for propositional proof system from lower bounds on Boolean circuits or other computational models. The feasible interpolation has been applied to prove lower bounds for example for Resolution [9] and Cutting Planes [12] from lower bounds on monotone Boolean and real circuits, respectively. On the negative side Krajíček and Pudlák showed in [8] that Extended Frege does not admit feasible interpolation with respect to Boolean circuits unless RSA is not secure against P/poly. This was later extended to Frege in [3] and to bounded depth Frege in [2] under other cryptographic assumptions.

We will prove here feasible interpolation for both PC and SOS for equality constrains $P(x, y)$ and $Q(y, z)$ in disjoint sequences x, y and z of variables. We show that for both proof systems given a refutation Π of $P(x, z) \cup Q(y, z)$ and an assignment a to the variables z, one can in polynomial time in the bit-complexity of Π find a refutation of $P(x, a)$ or a refutation of $Q(y, a)$. Previously, a form of feasible interpolation for PC was proven for degree bounded PC-refutations by Pudlák and Sgall [13]. We know of no previous results on feasible interpolation for Sums-of-Squares proofs.

From [4] we know that PC is degree-automatable: any degree d proof can be found in time $n^{O(d)}$. The same is not true in general for SOS, since the coefficients in a small degree proof might be exceedingly large. This was first noted by O'Donnell in [11]. O'Donnell demonstrated a simple system of polynomial constraints that admit a degree 2 proofs of non-negativity, so that every degree 2 proof necessarily has coefficients of exponential bit-complexity. Later the example of [11] was strengthened by Raghavendra and Weitz in [14] by giving a system of constraints over the Boolean cube that have proofs of non-negativity of degree 2, but any proof of degree less than $O(\sqrt{n})$ must have exponential bit-complexity.

In view of these issues on the bit-complexity of SOS, the question arises whether doubly exponential coefficients can pose a problem for feasible interpolation. However we show that we can use the given refutation of $P(x, z) \cup Q(y, z)$ to bound the coefficients appearing in a refutation of $P(x, a)$ or a refutation of $Q(y, a)$.

Our proofs rely on a 'semantic' characterizations of refutations with bounded resources. A standard way to prove lower bounds in proof complexity is to exhibit a 'semantic' object whose existence is in contradiction with the existence of refutations with bounded resources. These include the reduction operators first used in [15] against low-degree PC-refutations, the d-designs first used in [1] against low-degree Nullstellensatz refutations and pseudoexpectations first used in [6] against low-degree Sums-of-Squares refutations. In many cases these objects actually characterize the associated classes of refutations, and thus they, from a logical point of view, give soundness and completeness theorems for resource bounded refutations. If soundness of these characterizations can be used to prove lower bounds, the completeness properties are useful in establishing upper bounds on proofs as exemplified by the proofs of Theorems 3 and 9 below.

Main results. Let $P(x, z)$ and $Q(y, z)$ be sets of polynomial equations, where x, y and z are disjoint sequences of variables. Our main results are as follows:

- For any finite field $\mathbb{F}$ there is a polynomial time algorithm that given a PC-refutation of $P(x, z) \cup Q(y, z)$, and an assignment a to the variables z, outputs a PC-refutation of $P(x, a)$ or a PC-refutation of $Q(y, a)$. (Theorem 5)
- There is a polynomial time algorithm that given an SOS-refutation of $P(x, z) \cup Q(y, z)$ over the Boolean hypercube and a Boolean assignment a to the variables z outputs an SOS-refutation of $P(x, a)$ over the Boolean hypercube or an SOS-refutation of $Q(y, a)$ over the Boolean hypercube. (Theorem 14)

Proof methods. We study the two systems in two separate parts. Each part follows the same outline. First we define a suitable class of proofs and its semantic counterpart. We define proofs over some fixed set of monomials. The idea is to shift the focus from trying to obtain size-of-proof upper bounds directly to proving the existence of proofs that use only monomials from some small set S. The corresponding semantic operators are then defined on the vector space of all polynomials which are linear combinations of elements of S.

Secondly we prove a feasible disjunction property for the system using the obtained semantic characterizations. Given a refutation of $P(x) \cup Q(y)$, where x and y are disjoint sequences of variables, we can define sets S_x and S_y whose size are polynomial in the size of the given refutation, such that either $P(x)$ has a refutation over S_x or $Q(y)$ has a refutation over S_y.

Finally we argue that the refutations whose existence is guaranteed by the feasible disjunction property can be found in time polynomial in the size of the underlying set of monomials. For PC we give a simple proof search algorithm, and for SOS we use the ellipsoid algorithm to search for a proof after meeting sufficient conditions for polynomial run-time.

2 Preliminaries

2.1 Polynomials and the Boolean Ideal

A monomial is a product of variables. A term over a field $\mathbb{F}$ is a product of a non-zero element of $\mathbb{F}$, called the coefficient of the term, and a monomial. A polynomial is a finite sum of terms, i.e. a finite linear combination of monomials. We write $\mathbb{F}[x]$ for the set of all polynomials over a field $\mathbb{F}$. In particular $\mathbb{R}[x]$ denotes the set of all monomials with real coefficients. For any set S of monomials we denote by $\mathbb{F}[S]$ the set of all linear combinations of monomials from S. For any $p \in \mathbb{R}[x]$ we denote by $\|p\|$ the largest absolute value of a coefficient that appears in p.

For SOS we consider polynomials over n pairs of twin variables $x_1, \dots, x_n, \bar{x}_1, \dots, \bar{x}_n$. The intended meaning is that the variables range over Boolean values $\{0,1\}$ and that a pair of twin variables assumes opposite values. Accordingly we define the Boolean ideal I_n to be the ideal generated by the Boolean axioms $\{x_i^2 - x_i, x_i + \bar{x}_i - 1 : i \in [n]\}$. We write $p \equiv q \mod I_n$ if $p - q \in I_n$.

The Boolean axioms form a Gröbner basis for the Boolean ideal. This is readily seen using the Buchberger's criterion. The important consequence of this for our purposes is that the multivariate division algorithm with respect to the Boolean axioms leaves a unique remainder, and in particular the remainder is 0 if and only if $p \in I_n$. For more information on multivariate division and Gröbner bases, we refer the reader to [5].

2.2 Polynomial Calculus and Sums-of-Squares proofs

Let Q be a set of polynomials over an arbitrary field $\mathbb{F}$. We think of elements of Q as equality constraints $q = 0$. Let p be another polynomial. A PC-proof of p from Q is a sequence $p_1, \dots, p_\ell$ of polynomials such that $p_\ell = p$ and for each $i \in [\ell]$ one of the following hold:

(i) $p_i \in Q$;
(ii) there are $j, k < i$ and $a, b \in \mathbb{F}$ such that $p_i = ap_j + bp_k$;
(iii) there is $j < i$ and a variable x such that $p_i = xp_j$.

A PC-proof of p from Q is a certificate that p is in the ideal generated by Q. A PC-refutation of Q is a PC-proof of 1 from Q.

Let now Q be a set of real polynomials over n pairs of Boolean variables. A Sums-of-Squares proof of non-negativity of p from Q over the Boolean hypercube is a polynomial equality of the form

$$p = \sum_{i \in [k]} r_i^2 + \sum_{q \in Q} t_q q + \sum_{i \in [n]} \left(u_i \left(x_i^2 - x_i \right) + v_i \left(x_i + \bar{x}_i - 1 \right) \right), \tag{1}$$

where r_i, t_q, u_i and v_i are arbitrary real polynomials. An SOS refutation of Q over the Boolean hypercube is a proof of non-negativity of -1. Usually we will simply write the SOS proof (1) as

$$p \equiv \sum_{i\in[k]} r_i^2 + \sum_{q\in Q} t_q q \mod I_n$$

and omit the explicit lifts of the Boolean axioms.

3 Feasible interpolation for Polynomial Calculus

3.1 PC proofs over a set of monomials

Let Q be a set of polynomials over field $\mathbb{F}$ and let S be a set of monomials containing all the monomials in Q and the empty monomial 1. Let $\hat{S} = S \cup xS$, where $xS = \{xm : m \in S \text{ and } x \text{ is a variable}\}$. A PC-proof of p from Q over S is a PC-proof of p from Q, where only monomials from the set $\hat{S}$ appear, and the inference rule p/xp is only applied when $p \in \mathbb{F}[S]$. Denote by $\mathrm{PC}_S(Q)$ the set of all p such that there exists a PC-proof of p from Q over S.

Let now $<$ be a total order on $\hat{S}$ satisfying the following two conditions:

(i) $1 \leq m$ for any $m \in \hat{S}$;

(ii) if $m \in S$ and $m' \in \hat{S} \setminus S$, then $m < m'$.

The leading monomial of a polynomial $p \in \mathbb{F}[\hat{S}]$, denoted $\mathrm{LM}(p)$, is the largest monomial with respect to $<$ that appears in p with a non-zero coefficient. The leading term of a polynomial $p \in \mathbb{F}[\hat{S}]$, denoted $\mathrm{LT}(p)$ is the term, whose underlying monomial is the leading monomial of p.

We say that a term $t \in \mathbb{F}[\hat{S}]$ is S-reducible modulo Q if there is $p \in \mathrm{PC}_S(Q)$ such that $t = \mathrm{LT}(p)$. Otherwise the term is S-irreducible modulo Q. The following lemma shows that any polynomial in $\mathbb{F}[\hat{S}]$ can be uniquely factorized into a provable and an S-irreducible component.

▶ **Lemma 1.** *For any polynomial $p \in \mathbb{F}[\hat{S}]$ there are unique $q \in \mathbb{F}[\hat{S}]$ and $r \in \mathbb{F}[\hat{S}]$ such that*

- *$p = q + r$;*
- *$q \in \mathrm{PC}_S(Q)$;*
- *r is a sum of S-irreducible terms modulo Q.*

Moreover $\mathrm{LT}(p) \geq t$ for each term t in r.

Proof. To prove the existence of such q and r, we construct sequences p_i, q_i, r_i such that

- $p = p_i + q_i + r_i$;
- $q_i \in \mathrm{PC}_S(Q)$;
- r_i is a sum of S-irreducible terms.
- $p_m = 0$ for some m.

Let $p_1 = p$ and $q_1 = r_1 = 0$. For step i, let $\mathrm{LT}(p_i) = t_i$. If t_i is S-reducible as witnessed by $q \in \mathrm{PC}_S(Q)$ let $p_{i+1} = p_i - q$, $q_{i+1} = q_i + q$ and $r_{i+1} = r_i$. On the other hand, if t_i is S-irreducible, let $p_{i+1} = p_i - t_i$, $q_{i+1} = q_i$ and $r_{i+1} = r_i + t_i$.

Now $p_m = 0$ for some m, since the rank of the leading term of p_i decreases at each step. By construction, q_m and r_m satisfy the conditions of the lemma.

To prove the uniqueness of q and r, suppose $p = q + r$ and $p = q' + r'$, i.e. $q - q' = r' - r$. Now $q - q' \in \mathrm{PC}_S(Q)$ and so $r' - r \in \mathrm{PC}_S(Q)$, Hence $\mathrm{LT}(r' - r)$ is not S-irreducible. However, since both r and r' are sums of S-irreducible terms, it follows that $\mathrm{LT}(r' - r) = 0$ and so $r = r'$. Hence also $q = q'$. ◀

Consider now the mapping $R^Q_S \colon \mathbb{F}[\hat{S}] \to \mathbb{F}[\hat{S}]$ that maps each p to the unique sum r of S-irreducible terms modulo Q such that $p - r \in \mathrm{PC}_S(Q)$. The following lemma gathers four basic properties of the mapping.

▶ **Lemma 2.** *The following hold.*

(i) *If there is no refutation of Q over S, then $R^Q_S(1) = 1$;*
(ii) *R^Q_S is a linear function;*
(iii) *$R^Q_S(R^Q_S(p)) = R^Q_S(p)$ for any polynomial $p \in \mathbb{F}[\hat{S}]$;*
(iv) *$R^Q_S(xm) = R^Q_S(xR^Q_S(m))$ for any $m \in S$ and any variable x.*

Proof. (i) If there is no refutation of Q over S, then, by part (i) of the definition of $<$, the constant polynomial 1 is S-irreducible modulo Q. On the other hand $0 \in \mathrm{PC}_S(Q)$ and so, by the uniqueness of the factorization, $R^Q_S(1) = 1$.

(ii) Firstly, we have that $p - R^Q_S(p), q - R^Q_S(q) \in \mathrm{PC}_S(Q)$, and so $p + q - (R^Q_S(p) + R^Q_S(q)) \in \mathrm{PC}_S(Q)$. Now $R^Q_S(p) + R^Q_S(q)$ is a sum of S-irreducible terms modulo Q and so, by the uniqueness of the factorization, $R^Q_S(p+q) = R^Q_S(p) + R^Q_S(q)$. Similarly $ap - aR^Q_S(p) \in \mathrm{PC}_S(Q)$ and so $R^Q_S(ap) = aR^Q_S(p)$.

(iii) We have that $p - R^Q_S(p), R^Q_S(p) - R^Q_S(R^Q_S(p)) \in \mathrm{PC}_S(Q)$ and so also $p - R^Q_S(R^Q_S(p)) \in \mathrm{PC}_S(Q)$, where $R^Q_S(R^Q_S(p))$ is a sum of S-irreducible terms modulo Q. Hence, again by the uniqueness of the factorization, $R^Q_S(p) = R^Q_S(R^Q_S(p))$.

(iv) Again, we have that $m - R^Q_S(m) \in \mathrm{PC}_S(Q)$. Now, by Lemma 1, each term t in $R^Q_S(m)$ satisfies $t \leq m$. Hence, by part (ii) of the definition of $<$, each t in $R^Q_S(m)$ is in S, and so $R^Q_S(m) \in \mathbb{F}[S]$. Hence also $xm - xR^Q_S(m) \in \mathrm{PC}_S(Q)$. It follows that $R^Q_S(xm) = R^Q_S(xR^Q_S(m))$. ◀

3.2 Feasible disjunction for PC

In this section we prove a feasible disjunction property for Polynomial Calculus using the machinery developed in the previous section. Below $P(x)$ and $Q(y)$ are set of polynomials in disjoint sequences x and y of variables.

For a set of monomials S, and a sequence x of variables, we denote by S_x the projection of S onto the variables x, i.e. $m \in S_x$, if only variables from x appear in m, there is some m', where no variables from x appear and $mm' \in S$.

▶ **Theorem 3.** *Let Π be a PC-refutation of $P(x) \cup Q(y)$, and let S be the set of all monomials appearing in the refutation Π. Then there is a PC-refutation of $P(x)$ over S_x or a PC-refutation of $Q(y)$ over S_y.*

Proof. Suppose towards a contradiction that the conclusion does not hold, and consider the reduction operators $R^{P(x)}_{S_x}$ and $R^{Q(y)}_{S_y}$. Let $S' := \{m_x m_y : m_x \in S_x \text{ and } m_y \in S_y\}$, and define a linear function $R \colon \mathbb{F}[S'] \to \mathbb{F}[S']$ with

$$R(m_x m_y) = R^{P(x)}_{S_x}(m_x) R^{Q(y)}_{S_y}(m_y)$$

for any $m_x m_y \in S'$ and extend linearly.

We claim now that R has the following properties:

(i) $R(1) = 1$;
(ii) $R(p(x,a)) = 0$ for any $p(x,a) \in P(x,a)$;
(iii) $R(q(y,a)) = 0$ for any $q(y,a) \in Q(y,a)$;
(iv) $R(x_i m) = R(x_i R(m))$ if $m \in S$;
(v) $R(y_i m) = R(y_i R(m))$ if $m \in S$.

The item (i) holds, since by Lemma 2(i), $R_{S_x}^{P(x)}(1) = R_{S_y}^{Q(y)}(1) = 1$. It is clear that both (ii) and (iii) hold.

Finally (iv) holds, by Lemma 2, since

$$\begin{aligned} R(x_i m) &= R_{S_x}(x_i m_x) R_{S_y}(m_y) \\ &= R_{S_x}(x_i R_{S_x}(m_x)) R_{S_y}(R_{S_y}(m_y)) \\ &= R(x_i R_{S_x}(m_x) R_{S_y}(m_y)) \\ &= R(x_i R(m)) \end{aligned}$$

The case (v) is proved similarly.

Now the existence of such R is in contradiction with the assumption that in Π there appears only monomials from S. Firstly R is defined for all the polynomial appearing in Π. Secondly, by (ii) and (iii), R maps each axiom in $P(x) \cup Q(y)$ to zero, and, by linearity and (iv) and (v), respects the inference rules in the sense that R maps the consequent of a rule to zero whenever it maps the premises to zero. Hence, by induction on the structure of the refutation, $R(1) = 0$, against (i). ◀

3.3 Proof search over S

In this section we show how to find proofs over a given set S of monomials in time polynomial in $|S|$. We make this claim only for proofs over a finite field $\mathbb{F}$. In order to avoid pathological counterexamples we tacitly assume that the size of S is at least the number of distinct variables in S.

We begin by constructing a basis B for $\mathrm{PC}_S(Q)$. The construction is given by the following algorithm, which is a modification of an algorithm from [4].

Algorithm 1 Proof search over S.

```
Initially $A = Q$ and $B = \emptyset$;
while $A \neq \emptyset$ do
    Pick $p \in A$ and remove it from $A$;
    while $\mathrm{LM}(p) \in \mathrm{LM}(B)$ do
        Let $q \in B$ be such that $\mathrm{LM}(q) = \mathrm{LM}(p)$;
        Let $p \leftarrow p - aq$, where $a$ is such that $\mathrm{LT}(p) = a\mathrm{LT}(q)$;
    end
    If $p \neq 0$, add $p$ to $B$;
    If $p \in \mathbb{F}[S]$, add $xp$ to $A$ for every variable $x$;
end
Output $B$;
```

Now B is a linearly independent set of polynomials, since all elements of B have distinct leading monomials. As all elements of B have distinct leading monomials there is never more than $|S|^3$ elements in A and thus the algorithm halts after polynomially many steps in $|S|$. Hence for any finite field the above algorithm will halt in time polynomial in $|S|$. In the following we prove that B is actually a basis for $\mathrm{PC}_S(Q)$.

▶ **Lemma 4.** *At the end of the above algorithm* $\mathrm{span}(B) = \mathrm{PC}_S(Q)$.

Proof. Clearly each $q \in B$ has a proof from Q over S, and so $\mathrm{span}(B) \subseteq \mathrm{PC}_S(Q)$.

Now suppose $p \in \mathrm{PC}_S(Q)$ and let $p_1, \ldots, p_\ell$ be a PCR proof of p from Q over S. We show by induction on the structure of the proof that $p_i \in \mathrm{span}(B)$ for any $i \in [\ell]$. To see that each axiom is in B, note that $\mathrm{span}(A \cup B)$ can only increase at each stage of the algorithm. Hence, as the algorithm halts with $A = \emptyset$, at the end each axiom is in $\mathrm{span}(B)$. If $p_i = ap_j + bp_k$ for some $j, k < i$, and $p_j, p_k \in \mathrm{span}(B)$, then clearly $p_i \in \mathrm{span}(B)$.

Finally, suppose that $p_i = xp_j$ for some $j < i$ and some variable x. Now $p_j \in \mathbb{F}[S]$, and by induction assumption, $p_j \in \mathrm{span}(B)$. Write $p_j = \sum a_k q_k$ for some $a_k \in \mathbb{F}$ and $q_k \in B$. We claim that $q_k \in \mathbb{F}[S]$ for each k with non-zero a_k. To see this, let m be the maximal monomial that appears in any q_k with a non-zero coefficient. Now m appears in only one of the q_k's, since they all have distinct leading monomials, and so the monomial m has a non-zero coefficient in p_j. Hence $m \in S$, and so $q_k \in \mathbb{F}[S]$ for every k. Now for any k, q_k was added to B and xq_k was added to A at some stage of the algorithm. Now, at that stage $xq_k \in \mathrm{span}(A \cup B)$. However, since the span only increases during the execution of the algorithm, $xq_k \in \mathrm{span}(B)$ at the end of the algorithm. Hence $xp_j \in \mathrm{span}(B)$ at the end of the algorithm. ◀

Now to check whether there is a PC proof of p from Q over S one simply needs to reduce the polynomial p with respect to the basis B. This is easy to do, since all the elements of B have distinct leading monomials. In order to construct the proof, one needs proofs for the basis elements. The construction of these proofs is easily incorporable into the algorithm above.

3.4 Feasible interpolation

Finally as a consequence of Theorem 3 and Section 3.3 we obtain the feasible interpolation property for PC over any finite field. Below $P(x, z)$ and $Q(y, z)$ are two sets of polynomials, where x, y and z are disjoint sequences of variables.

▶ **Theorem 5.** *For any finite field $\mathbb{F}$, there is a polynomial time algorithm that given a PC-refutation of $P(x, z) \cup Q(y, z)$, and an assignment a to the variables z, outputs a PC-refutation of $P(x, a)$ or a PC-refutation of $Q(y, a)$.*

4 Feasible interpolation for Sums-of-Squares

4.1 Bounded SOS proofs over a set of monomials

Let Q be a set of polynomials and let S be a set of monomials that includes all the monomials appearing in Q and the empty monomial 1.

Denote by S^2 the set of all monomials m such that $m = m_1 m_2$, where $m_1, m_2 \in S$. An SOS proof of non-negativity of some $p \in \mathbb{R}[S^2]$ from Q over S is a polynomial equality of the form

$$p \equiv \sum_{i \in [k]} r_i^2 + \sum_{q \in Q} t_q q \mod I_n$$

where $r_i, t_q \in \mathbb{R}[S]$. We write $Q \vdash_S p \geq q$ if there is a proof of non-negativity of $p - q$ from Q over S. The proof is R-bounded if $\|t_q\| \leq R$ for each $q \in Q$. We need to consider explicitly bounded proofs in order to later be able to give a polynomial time proof search algorithm.

We prove first the important fact that every polynomial in $\mathbb{R}[S^2]$ has provable upper bounds over S modulo the Boolean ideal.

▶ **Lemma 6.** *For any $p \in \mathbb{R}[S^2]$ there is $r \in \mathbb{R}_+$ such that*

$$\emptyset \vdash_S r \geq p.$$

Proof. Let first $m \in S$, and let $a \in \mathbb{R}$. We want to show that there is some $b \in \mathbb{R}_+$ such that $Q \vdash_S b \geq am$. If $a < 0$, then $-am \equiv (\sqrt{-a}m)^2 \mod I_n$ and so $Q \vdash_S 0 \geq am$. On the other hand if $a > 0$, then $a - am \equiv (\sqrt{a} - \sqrt{a}m)^2 \mod I_n$, and so $Q \vdash_S a \geq am$.

Let then $m_1, m_2 \in S$ and $a \in \mathbb{R}$. We show again that there is some $b \in \mathbb{R}_+$ such that $Q \vdash_S b \geq am_1m_2$. If $a < 0$, then $-am_1 - 2am_1m_2 - am_2 \equiv (\sqrt{-a}m_1 + \sqrt{-a}m_2)^2 \mod I_n$. On the other hand, by the above paragraph, there are $b_1, b_2 \in \mathbb{R}_+$ such that $Q \vdash_S b_1 \geq -am_1$ and $Q \vdash_S b_2 \geq -am_2$. Hence $Q \vdash_S (b_1 + b_2)/2 \geq am_1m_2$. If $a > 0$, then $am_1 - 2am_1m_2 + am_2 \equiv (\sqrt{a}m_1 - \sqrt{a}m_2)^2 \mod I_n$. Again there are $b_1, b_2 \in \mathbb{R}_+$ such that $Q \vdash_S b_1 \geq am_1$ and $Q \vdash_S b_2 \geq am_2$, and so $Q \vdash_S (b_1 + b_2)/2 \geq am_1m_2$. ◀

Now we define the objects that we consider to be the semantic counterparts of bounded refutations over a set of monomials. Let $\varepsilon > 0$. A linear functional $E \colon \mathbb{R}[S^2] \to \mathbb{R}$ is an ε-pseudoexpectation for Q over S if the following properties hold:

(i) $E(1) = 1$;
(ii) $E(p) = E(q)$ if $p \equiv q \mod I_n$;
(iii) $E(p^2) \geq 0$ for any $p \in \mathbb{R}[S]$;
(iv) $|E(mq)| \leq \varepsilon$ for any $m \in S$ and any $q \in Q$.

The following two lemmas show connections between ε-pseudoexpectations and proofs with bounded coefficients.

▶ **Lemma 7.** *If there is an ε-pseudoexpectation for Q over S, then there is no R-bounded refutation of Q over S for R less than $1/\varepsilon|S||Q|$.*

Proof. Let E be an ε-pseudoexpectation for Q over S, and suppose that

$$-1 \equiv \sum_{i \in [k]} r_i^2 + \sum_{q \in Q} t_q q \mod I_n$$

is a refutation over S with $\|t_q\| < 1/\varepsilon|S||Q|$ for any $q \in Q$. Now $|E(amq)| \leq |a|\varepsilon$ for each $m \in S$, $q \in Q$ and $a \in \mathbb{R}$. Hence $|E(t_q q)| < 1/|Q|$ for each $q \in Q$, and so $|E(\sum_{q \in Q} t_q q)| < 1$. Now applying E to both sides of the refutation we obtain that $-1 \geq \sum_{q \in Q} E(t_q q) > -1$. ◀

▶ **Lemma 8.** *If there is no R-bounded refutation of Q over S, then there is a $(1/R)$-pseudoexpectation for Q over S.*

Proof. Suppose there is no R-bounded refutation of Q over S, and consider the following two sets

$$A := \{p \in \mathbb{R}[S^2] : \emptyset \vdash_S p \geq 0\}$$

and

$$B := \{-1 + \sum_{q \in Q} t_q q : t_q \in \mathbb{R}[S] \text{ and } \|t_q\| \leq R \text{ for every } q \in Q\}.$$

Now, by assumption, A and B are disjoint, A is a convex cone and B is a convex set. Hence, by the hyperplane separation theorem, there is a non-trivial linear functional $L \colon \mathbb{R}[S^2] \to \mathbb{R}$ such that $L(p) \geq 0$ for every $p \in A$, and $L(p') \leq 0$ for every $p' \in B$.

We want to first argue that $L(1) \neq 0$. So suppose towards a contradiction that $L(1) = 0$. By Lemma 6, for any $p \in \mathbb{R}[S^2]$ there is some $R \in \mathbb{R}_+$ such that $\emptyset \vdash_S R \geq p \geq -R$. It follows that $L(R) \geq L(p) \geq L(-R)$, and so $L(p) = 0$ for every $p \in \mathbb{R}[S^2]$ against the non-triviality of L.

Now define $E(p) = L(p)/L(1)$ for any $p \in \mathbb{R}[S^2]$. We claim that E has the desired properties. We prove the last case. By definition, $-1 \pm Rmq \in B$, and so $E(-1 \pm Rmq) \leq 0$ for any $m \in S$ and $q \in Q$. Hence $|E(mq)| \leq 1/R$. ◀

4.2 Feasible disjunction for SOS

In this section we prove a feasible disjunction property for SOS. For a refutation

$$-1 = \sum_{i \in [k]} r_i^2 + \sum_{q \in Q} t_q q + \sum_{i \in [n]} \left(u_i\left(x_i^2 - x_i\right) + v_i\left(x_i + \bar{x}_i - 1\right)\right)$$

the explicit monomials of the refutation are all the monomials appearing in the polynomials r_i, t_q, q, u_i, v_i, $x_i^2 - x_i$ and $x_i + \bar{x}_i - 1$, i.e. the explicit monomials are the monomials that appear in an explicit representation of the refutation.

▶ **Theorem 9.** *Let*

$$\begin{aligned} -1 = \sum_{i \in [k]} r_i^2 + \sum_{p(x) \in P(x)} t_p p(x) + \sum_{q(y) \in Q(y)} t_q q(y) + \\ \sum_{i \in [n]} \left(u_i\left(x_i^2 - x_i\right) + v_i\left(x_i + \bar{x}_i - 1\right)\right) \sum_{i \in [n']} \left(u_i'\left(y_i^2 - y_i\right) + v_i'\left(y_i + \bar{y}_i - 1\right)\right) \end{aligned}$$

be an SOS refutation of $P(x) \cup Q(y)$ with $\|t_p\|, \|t_q\| \leq R$ for every $p(x) \in P(x)$ and $q(y) \in Q(y)$, let S be the set of explicit monomials appearing in the refutation, and let $R' = 2R|P(x) \cup Q(y)||S|$. Then there is a R'-bounded refutation of $P(x)$ over S_x or a R'-bounded refutation of $Q(y)$ over S_y.

Proof. Suppose towards a contradiction that the conclusion does not hold. Then, by Lemma 8, there are $1/R'$-pseudoexpectations for $P(x)$ over S_x and $Q(y)$ over S_y. Now define a linear functional $E\colon \mathbb{R}[S^2] \to \mathbb{R}$ with

$$E(m) = E_x(m_x)E_y(m_y),$$

for $m \in S^2$ and extend linearly. Here m_x and m_y are the projections of the monomial m to variables x and y, respectively. We claim that E has the following properties.

(i) $E(1) = 1$;
(ii) $E(m(x_i^2 - x_i)) = 0$ for any $m \in S$ and any variable x_i;
(iii) $E(m(x_i + \bar{x}_i - 1)) = 0$ for any $m \in S$ and any variable x;
(iv) $E(m(y_i^2 - y_i)) = 0$ for any $m \in S$ and any variable y_i;
(v) $E(m(y_i + \bar{y}_i - 1)) = 0$ for any $m \in S$ and any variable y_i;
(vi) $E(p^2) \geq 0$ for any $p \in \mathbb{R}[S]$;
(vii) $|E(m(p(x))| \leq 1/R'$ for any $m \in S$ and any $p(x) \in P(x)$;
(viii) $|E(m(q(y))| \leq 1/R'$ for any $m \in S$ and any $q(y) \in Q(y)$.

The cases (i)-(v) are easy to see. For (vi), write $p = \sum_{m \in S} a_m m$. Now the matrix $(E_y(m_y m'_y))_{m,m' \in S}$ is positive semidefinite and so there are vectors u su ch that $E_y(m_y m'_y) = \sum_u u_m u_{m'}$. Now we have

$$\begin{aligned} E(p^2) &= \sum_{m,m'} a_m a_{m'} E_x(m_x m'_x) E_y(m_y m'_y) \\ &= \sum_{m,m'} \sum_u a_m u_m a_{m'} u_{m'} E_x(m_x m'_x) \\ &= E_x((\sum_m \sum_u a_m u_m m_x)^2) \geq 0 \end{aligned}$$

Finally (vii) holds, since

$$|E(m(p(x))| = |E_x(m_x(p(x))||E_y(m_y)| \leq 1/R',$$

where the last inequality holds since E_x is an $1/R'$-pseudoexpectation for $P(x)$ over S_x and $|E_y(m_y)| \leq 1$ for all $m \in S$. Case (viii) is proved similarly.

Now the existence of such E is in contradiction with the assumptions about the given refutation of $P(x) \cup Q(y)$. Although the mapping E does not necessarily fulfill the condition (ii) of an ε-pseudoexpectation, as E is defined for all the summands in the given refutation, we reach a contradiction by a similar argument as in Lemma 7. ◀

4.3 Proof search over S with bounded coefficients

In this section we show how to find the bounded refutation, whose existence is guaranteed by Theorem 9, in time polynomial in the size of S and $\log R$. Again we tacitly assume that the size of S is at least the number of distinct variables appearing in S. For proof search we use the ellipsoid algorithm. Before we can apply the algorithm we need to show that we can bound the other coefficients appearing in the proof using the bound on the t_q polynomials.

As a first step we show that we can bound the coefficients appearing in the sum of squares part of a given refutation. The next lemma is a simple special case of the main theorem of [14].

▶ **Lemma 10.** *Let $p \in \mathbb{R}[S^2]$. If there is a proof of non-negativity of p from $\emptyset$ over S, then there are $r_i \in \mathbb{R}[S]$ such that*

$$p \equiv \sum_{i \in [k]} r_i^2 \mod I_n$$

and $\|r_i\|$ is at most polynomial in $2^{\text{poly}(|S|)}$ and $\|p\|$ for any $i \in [k]$.

Proof. The proof is practically the same as the proof of the main theorem of [14] with only small differences. We'll sketch the proof for completeness.

Let $\mathbf{v}_S$ be a vector of all the monomials in S, and let C be a PSD matrix such that $p \equiv \langle C, \mathbf{v}_S \mathbf{v}_S^T \rangle \mod I_n$. Now denote by M_S the averaged matrix $\mathbb{E}_{\alpha \in \{0,1\}^n} \mathbf{v}_S(\alpha) \mathbf{v}_S^T(\alpha)$ over all Boolean assignments. Now, by Lemma 6 of [14], the smallest non-zero eigenvalue δ of M_S is at least $1/2^{\text{poly}(|S|)}$.

Let now $P = \sum uu^T$ be a projection to the zero eigenspace of M_S. Now, for each u, $u^T \mathbf{v}_S$ is zero on all Boolean assignments, and thus $u^T \mathbf{v}_S \equiv 0 \mod I_n$. Hence

$$\begin{aligned} \langle C, \mathbf{v}_S \mathbf{v}_S^T \rangle &\equiv \langle C, (P + P^\perp) \mathbf{v}_S \mathbf{v}_S^T (P + P^\perp) \rangle \mod I_n \\ &\equiv \langle C, P^\perp \mathbf{v}_S \mathbf{v}_S^T P^\perp \rangle \mod I_n \\ &\equiv \langle P^\perp C P^\perp, \mathbf{v}_S \mathbf{v}_S^T \rangle \mod I_n \end{aligned}$$

Let $C' = P^\perp C P^\perp$, so that $p \equiv \langle C', \mathbf{v}_S \mathbf{v}_S^T \rangle$. Now, by taking averages on both sides, we obtain that

$$\mathbb{E}_{\alpha \in \{0,1\}^n}[p(\alpha)] = \langle C', M_S \rangle.$$

Now the left hand side is at most polynomial in $\|p\|$ and $|S|$. On the other hand the right hand side is at least $\delta \mathrm{Tr}(C')$, since every non-zero eigenvalue of M_S is at least δ and the zero eigenspace of C' is included in the zero-eigenspace of M_S. Since the Frobenius norm of C' is bounded by $\mathrm{Tr}(C')$ we have that each entry of C' is at most polynomial in $2^{\mathrm{poly}(|S|)}$ and $\|p\|$. Now let $r_i, i \in [k]$ be such that $\sum_{i \in [k]} r_i^2 = \langle C', \mathbf{v}_S \mathbf{v}_S^T \rangle$. Now each coefficient of r_i is bounded by a polynomial in $2^{\mathrm{poly}(|S|)}$ and $\|p\|$. ◀

▶ **Corollary 11.** *Let $p \in \mathbb{R}[S^2]$. If there is an R-bounded proof of p from Q over S, then there are $r_i \in \mathbb{R}[S]$ such that*

$$p = \sum_{i \in [k']} r_i^2 + \sum_{q \in Q} t_q q \mod I_n,$$

and the absolute value of all the coefficients appearing in each r_i is at most polynomial in $2^{\mathrm{poly}(|S|)}$, R and $\|p\|$.

Proof. If $p \equiv \sum_{i \in [k]} r_i^2 + \sum_{q \in Q} t_q q \mod I_n$, then $p - \sum_{q \in Q} t_q q \equiv \sum_{i \in [k]} r_i^2 \mod I_n$, and the result follows from the previous lemma. ◀

Secondly we need to restrict the search space for the lifts of the Boolean axioms. In our definition of a proof over a set of monomials, we worked over the Boolean ideal, and thus did not restrict the lifts of the Boolean axioms in any way. However since the Boolean axioms form a Gröbner basis for the Boolean ideal, we can show that there is a well-behaved set $\bar{S}$ of monomials computable from S in time polynomial in $|S|$ such that for any $p \in \mathbb{R}[S^2]$ with $p \equiv 0 \mod I_n$ there are $u_i, v_i \in \mathbb{R}[\bar{S}]$ such that

$$p = u_i(x_i^2 - x_i) + v_i(x_i + \bar{x}_i - 1)$$

To see this consider any monomial ordering $<$ such that B_n forms a Gröbner basis for I_n with respect to $<$, and define the set S_m for any monomial m with the following algorithm.

Algorithm 2 Construction of the set S_m.

```
Initially $I = \{m\}$ and $S_m = \emptyset$;
while leading monomial of some Boolean axiom divides $\mathrm{LM}(I)$ do
    Let $p$ be the first Boolean axiom such that $\mathrm{LM}(p)$ divides $\mathrm{LM}(I)$;
    Let $m'$ be such that $\mathrm{LM}(I) = m'\mathrm{LM}(p)$;
    Let $p' = m - m'p$;
    Add $m'$ to $S_m$;
    Add all the monomials in $p'$ to $I$;
end
Output $S_m$;
```

The runtime of the above algorithm is polynomial in the degree of m. Now define $\bar{S} = \bigcup_{m \in S^2} S_m$. Now, if S is a set of multilinear monomials, set $\bar{S}$ can be computed in time polynomial in $|S|$.

▶ **Lemma 12.** *For each $p \in \mathbb{R}[S^2]$ such that $p \equiv 0 \mod I_n$ there are $u_i, v_i \in \mathbb{R}[\bar{S}]$ such that*

$$p = \sum_{i \in [n]} (u_i(x_i^2 - x_i) + v_i(x_i + \bar{x}_i - 1)).$$

Moreover the absolute value of the coefficients in u_i and v_i is bounded by a polynomial in $\|p\|$, $|S|$ and the degree of p.

Proof. The proof follows since, as the Boolean axioms form a Gröbner basis for I_n with respect to $<$, we have that $p \equiv 0 \mod I_n$ if and only if p reduces to 0 with the multivariate division algorithm with respect to the monomial ordering $<$. The multivariate division algorithm will construct u_i and v_i that are linear combinations of monomials from $\bar{S}$. The last part follows from the fact that the algorithm halts after polynomially many steps in the degree of p and $|S|$. ◀

Now as a corollary to Corollary 11 and Lemma 12 we have the following

▶ **Corollary 13.** *Let $p \in \mathbb{R}[S^2]$. If there is an R-bounded proof of p from Q over S, then there are $r_i \in \mathbb{R}[S]$ and $u_i, v_i \in \mathbb{R}[\bar{S}]$ such that*

$$p = \sum_{i \in [k']} r_i^2 + \sum_{q \in Q} t_q q + \sum_{i \in [n]} \left(u_i \left(x_i^2 - x_i \right) + v_i \left(x_i + \bar{x}_i - 1 \right) \right),$$

and the absolute value of all the coefficients appearing in each s_i, u_i and v_i is at most polynomial in $2^{\mathrm{poly}(|S|)}$, R and $\|p\|$.

Now the existence of a proof given by Corollary 13 can be expressed as feasibility of a set of linear and semidefinite constraints over explicitly bounded variables and so we can find an approximate solution to the set of constraints in polynomial time using the ellipsoid algorithm. We will sketch some details below. For details on ellipsoid algorithm see [7].

For each $q \in Q$, let $\bar{q} \in \mathbb{R}^S$ such that $\bar{q}^T \mathbf{v}_S = q$, and introduce a vector x_q of variables. Similarly for each $m, m' \in S$, introduce a variable $x_{m,m'}$. In addition, introduce variables y_{m,x_i^2}, y_{m,x_i} for each i and $m \in \bar{S}$ and variables $z_{m,x_i}, z_{m,\bar{x}_i}, z_{m,i}$ for each $i \in [n]$ and $m \in \bar{S}$ Now let $p = \sum_{k \in S^2} a_k k$ and introduce for every $k \in S^2$ a constraint $C_k = a_k$, where

$$C_k = \sum_{\substack{m,m' \in S \\ mm' = k}} (x_{m,m'} + \sum_{q \in Q} \bar{q}_m x_{q,m'}) \\ + \sum_{i \in [n]} (\sum_{\substack{m, \in \bar{S} \\ mx_i^2 = k}} y_{m,x_i^2} + \sum_{\substack{m \in \bar{S} \\ mx_i = k}} (z_{m,x_i} - y_{m,x_i}) + \sum_{\substack{m \in \bar{S} \\ m\bar{x}_i = k}} z_{m,\bar{x}_i} - \sum_{\substack{m \in \bar{S} \\ m = k}} z_{m,i}).$$

Let X be the matrix $X_{m,m'} = x_{m,m'}$, and add the constraint $X \succeq 0$. Finally add the bounding constraints $-R' \leq x \leq R'$ for each variable for R' of magnitude polynomial in $2^{\mathrm{poly}(|S|)}$, R and $\|p\|$. Now any feasible solution gives a proof of p from Q with all coefficients bounded by R' and vice versa.

For $\varepsilon > 0$, an ε-relaxation of the above constraints is the set of constraints $|C_k - a_k| \leq \varepsilon$, $X \succeq 0$ and $-R' - \varepsilon \leq x \leq R' + \varepsilon$ for every variable x. Now if there is a feasible solution for the original set of constraints, the set of solutions of the ε-relaxation has volume at least $1/2^{\mathrm{poly}(\log(1/\varepsilon),|S|)}$.

Choose now $\varepsilon = 1/2^{\mathrm{poly}(|S|)}$. Now the ellipsoid method can find a feasible solution to the ε-relaxation in time polynomial in $|S|$, $\log R$ and $\log \|p\|$. Any such solution translates into a polynomial $p + q$, where $\|q\| \leq \varepsilon$. Now for each am that appears in q, define q_m as follows: if $a > 0$ let $q_m = a(1-m)^2$, and if $a < 0$ let $q_m = -a(m)^2$. Now adding all q_m to $p + q$ gives Sums-of-Squares proof of $p - \varepsilon'$ for some $\varepsilon' = 1/2^{\mathrm{poly}(|S|)}$.

4.4 Feasible interpolation

Finally we obtain the feasible interpolation property for SOS as a corollary to Theorem 9 and section 4.3. For the theorem below $P(x,z)$ and $Q(y,z)$ are sets of multilinear polynomials over Boolean variables, where x, y and z are disjoint sequences of variables.

▶ **Theorem 14.** *Let $P(x,z)$ and $Q(y,z)$ be sets of multilinear polynomials. There is a polynomial time algorithm that given an SOS-refutation of $P(x,z) \cup Q(y,z)$ and an assignment a to the variables z outputs an SOS-refutation of $P(x,a)$ or an SOS-refutation of $Q(y,a)$.*

5 Concluding remarks

We have seen that both Polynomial Calculus and Sums-of-Squares admit a strong form of feasible interpolation. Using similar methods we can also prove that Sherali-Adams proof system admits equally strong feasible interpolation property. The proof can be obtained by a simple modification of the proof for Sums-of-Squares. The proof is actually considerably simpler since the problem of too large coefficients does not appear with Sherali-Adams proofs.

Sums-of-Squares proofs cannot admit monotone feasible interpolation, since the Clique-Coloring formulas have small Sums-of-Squares refutations. Pudlák and Sgall prove in [13] that degree bounded Polynomial Calculus admits monotone feasible interpolation with respect to monotone polynomial programs. An interesting open question is whether one can prove monotone feasible interpolation for Polynomial Calculus with respect to monotone circuits.

We only prove feasible interpolation for SOS for sets of equality constraints. If there are inequality constraints, we can only prove a feasible disjunction property with respect to monomial size: if there is a refutation of $P(x,z) \cup Q(y,z)$ of monomial size s, then for any a there is a refutation of $P(x,a)$ or a refutation of $Q(y,a)$ of monomial size $O(s)$. The problem is that we don't have nice counterparts of the ε-pseudoexpectations when we add inequality constraints.

Finally we want to emphasize that although we proved the feasible interpolation for Sums-of-Squares only over the $\{0,1\}$-values, importantly the argument works also for Boolean values over the ± 1 basis.

Abstract

Consider a set $P \subseteq \mathbb{R}^d$ of n points, and a convex body C provided via a separation oracle. The task at hand is to decide for each point of P if it is in C using the fewest number of oracle queries. We show that one can solve this problem in two and three dimensions using $O(\hexagon_P \log n)$ queries, where $\hexagon_P$ is the largest subset of points of P in convex position. In 2D, we provide an algorithm which efficiently generates these adaptive queries.

Furthermore, we show that in two dimensions one can solve this problem using $O(\circledcirc(P, C) \log^2 n)$ oracle queries, where $\circledcirc(P, C)$ is a lower bound on the minimum number of queries that any algorithm for this specific instance requires. Finally, we consider other variations on the problem, such as using the fewest number of queries to decide if C contains all points of P.

As an application of the above, we show that the discrete geometric median of a point set P in $\mathbb{R}^2$ can be computed in $O(n \log^2 n (\log n \log\log n + \hexagon_P))$ expected time.

1 Introduction

1.1 Background

Active learning

Active learning is a subfield of machine learning, in which at any time, the learning algorithm is able to query an oracle for the label of a particular data point. One model for active learning is the membership query synthesis model [2]. Here, the learner wants to minimize the number of oracle queries, as such queries are expensive – they usually correspond to either consulting with a specialist, or performing an expensive computation. In this setting, the learning algorithm is allowed to query the oracle for the label of any data point in the instance space. See [21] for a more in-depth survey on the various active learning models.

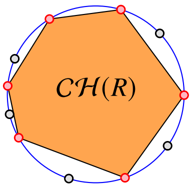
PAC learning

A classical approach for learning is using random sampling, where one gets labels for the samples (i.e., in the above setting, the oracle is asked for the labels of all items in the random sample). PAC learning studies the size of the sample needed. For example, consider the problem of learning a halfplane for n points $P \subset \mathbb{R}^2$, given a parameter $\varepsilon \in (0, 1)$. The first stage is to take a labeled random sample $R \subseteq P$. The algorithm computes any halfplane that classifies the sample correctly (i.e., the hypothesis). The misclassified points lie in the symmetric difference between the learned halfplane, and the (unknown) true halfplane, see Figure 1.1. In this case, the error region is a double wedge, and it is well known that its VC-dimension [22] is a constant (at most eight). As such, by the ε-net Theorem [13], a sample of size $O(\varepsilon^{-1} \log \varepsilon^{-1})$ is an ε-net for double wedges, which implies that this random sampling algorithm has at most εn error.

A classical example of a hypothesis class that cannot be learned is the set of convex regions (even in the plane). Indeed, given a set of points P in the plane, any sample $R \subseteq P$ cannot distinguish between the true region being $\mathcal{CH}(R)$ or $\mathcal{CH}(P)$. Intuitively, this is because the hypothesis space in this case grows exponentially in the size of the sample (instead of polynomially).



We stress that the above argument does not necessarily imply these types of hypothesis classes are unlearnable in practice. In general, there are other ways for learning algorithms to handle hypothesis classes with high (or even infinite) VC-dimension (for example, using regularization or assuming there is a large margin around the decision boundary).

Weak ε-nets

Because ε-nets for convex ranges do not exist, an interesting direction to overcome this problem is to define weak ε-nets [13]. A set of points R in the plane, not necessarily a subset of P, is a *weak ε-net* for P if for any convex body C containing at least εn points of P, it also contains a point of R. Matoušek and Wagner [16] gave a weak ε-net construction of size $O(\varepsilon^{-d}(\log \varepsilon^{-1})^{O(d^2 \log d)})$, which is doubly exponential in the dimension. The state of the art is the recent result of Rubin [20], that shows a weak ε-net construction in the plane of size (roughly) $O(1/\varepsilon^{3/2})$. However, these weak ε-nets cannot be used for learning such concepts. Indeed, the analysis above required an ε-net for the symmetric difference of two convex bodies of finite complexity, see Figure 1.1.

PAC learning with additional parameters

If one assumes the input instance obeys some additional structural properties, then random sampling can be used. For example, suppose that the point set P has at most k points in convex position. For an arbitrary convex body C, the convex hull $\mathcal{CH}(P \cap C)$ has complexity at most k. Let $R \subseteq P$ be a random sample, and C' be the learned classifier for R. The region of error is the symmetric difference between C and C'. In particular, since k-vertex polytopes in $\mathbb{R}^d$ have VC-dimension bounded by $O(d^2 k \log k)$ [15], this implies that the error region also has VC-dimension at most $O(d^2 k \log k)$. Hence if R is a random sample of size $O(d^2 k \log k \varepsilon^{-1} \log \varepsilon^{-1})$, the ε-net Theorem [13] implies that this sampling algorithm has error at most εn. However, even for a set of n points chosen uniformly at random from the unit square $[0,1]^2$, the expected number of points in convex position is $O(n^{1/3})$ [1]. Since we want $|R| < n$, this random sampling technique is only useful when ε is larger than $\log^2 n / n^{2/3}$ (ignoring constants).

To summarize the above discussions, random sampling on its own does not seem powerful enough to learn arbitrary convex bodies, even if one allows some error to be made. In this paper we focus on developing algorithms for learning convex bodies in low dimensions, where the algorithms are deterministic and do not make any errors.

1.2 Problem and motivation

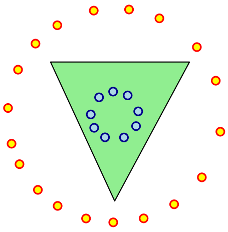
The problem

In this paper, we consider a variation on the active learning problem, in the membership query synthesis model. Suppose that the learner is trying to learn an unknown convex body C in $\mathbb{R}^d$. Specifically, the learner is provided with a set P of n unlabelled points in $\mathbb{R}^d$, and the task is to label each point as either inside or outside C, see Figure 1.2. For a query $q \in \mathbb{R}^d$, the oracle either reports that $q \in C$, or returns a hyperplane separating q and C (as a proof that $q \notin C$). Note that if the query is outside the body, the oracle answer is significantly more informative than just the label of the point. The problem is to minimize the overall number of queries performed.

Hard and easy instances

Note that in the worst case, an algorithm may have to query the oracle for all input points – such a scenario happens when the input points are in convex position, and any possible subset of the points can be the points in the (appropriate) convex body. As such, the purpose here is to develop algorithms that are *instance sensitive* – if the given instance is easy, they work well. If the given instance is hard, they might deteriorate to the naive algorithm that queries all points.

Natural inputs where one can hope to do better, are when relatively few points are in convex position. Such inputs are grid points, or random point sets, among others. However, there are natural instances of the problem that are easy, despite the input having many points in convex position. For example, consider when the convex body is a triangle, with the input point set being $n/2$ points spread uniformly on a tiny circle centered at the origin, while the remaining $n/2$ points are outside the convex body, spread uniformly on a circle of radius 10 centered at the origin. Clearly, such a point set can be fully classified using a sequence of a constant number of oracle queries. See Figure 3.1 for some related examples.



1.3 Additional motivation & previous work

Separation oracles

The use of separation oracles is a common tool in optimization (e.g., solving exponentially large linear programs) and operations research. It is natural to ask what other problems can be solved efficiently when given access to this specific type of oracle. For example, Bárány and Füredi [3] study the problem of computing the volume of a convex body in $\mathbb{R}^d$ given access to a separation oracle.

Other types of oracles

Various models of computation utilizing oracles have been previously studied within the community. Examples of other models include nearest-neighbor oracles (i.e., black-box access to nearest neighbor queries over a point set P) [11], proximity probes (which given a convex polygon C and a query q, returns the distance from q to C) [18], and linear queries. Recently, Ezra and Sharir [7] gave an improved algorithm for the problem of point location in an arrangement of hyperplanes. Here, a *linear query* consists of a point x and a hyperplane h, and outputs either that x lies on h, or else which side of h contains x. Alternatively, their problem can be interpreted as querying whether or not a given point lies in a halfspace h^+. Here, we study the more general problem as the convex body can be the intersection of many halfspaces.

Furthermore, other types of active learning models (in addition membership query model) have also been studied within the learning community, see, for example, [2].

Active learning

As discussed, the problem at hand can be interpreted as active learning a convex body in relation to a set of points P that need to be classified (as either inside or outside the body), where the queries are via a separation oracle. We are unaware of any work directly on this problem in the theory community, while there is some work in the machine learning community that studies related active learning classification problems [6, 9, 21, 14].

For example, Kane et al. [14] study the problem of actively learning halfspaces with access to *comparison queries*. Given a halfspace h^+ to learn, the model has two types of queries: (i) label queries (given $x \in \mathbb{R}^d$, is $x \in h^+$?), and (ii) comparison queries (given $x_1, x_2 \in \mathbb{R}^d$, is x_1 closer to the boundary of h^+ than x_2?). For example, they show that in the plane, one can classify all points using $O(\log n)$ comparison/label queries in expectation.

1.4 Our results

Due to space constraints, not all of the results listed below are included in this version. We refer the reader to the full version of the paper [12] for proofs of missing results.

(A) We develop a greedy algorithm, for points in the plane, which solves the problem using $O(\hexagon_P \log n)$ oracle queries, where $\hexagon_P$ is the largest subset of points of P in convex position. See Theorem 8. It is known that for a random set of n points in the unit square, $\mathbf{E}[\hexagon_P] = \Theta(n^{1/3})$ [1], which readily implies that classifying these points can be solved using $O(n^{1/3} \log n)$ oracle queries. A similar bound holds for the $\sqrt{n} \times \sqrt{n}$ grid. An animation of this algorithm is on YouTube [10]. We also show that this algorithm can be implemented efficiently, using dynamic segment trees, see Lemma 9.
We remark that Kane et al. [14] develop a framework and randomized algorithm for learning a concept C, where the expected number of queries depends near-linearly on a parameter they define as the *inference dimension* [14, Definition III.1] of the concept class. For our problem, one can show that the inference dimension is $O(\hexagon_P)$. As a corollary of their framework, one can obtain a randomized algorithm which solves our problem where the expected number of queries is $O(\hexagon_P \log \hexagon_P \log n)$. Our algorithm shaves a logarithmic factor in the number of queries and is deterministic.

(B) The above algorithm naturally extends to three dimensions, also using $O(\hexagon_P \log n)$ oracle queries. While the proof idea is similar to that of the algorithm in 2D, we believe the analysis in three dimensions is also technically interesting. See Theorem 10.

(C) For a given point set P and convex body C, we define the separation price $\circledcirc(P, C)$ of an instance (P, C), and show that any algorithm classifying the points of P in relation to C must make at least $\circledcirc(P, C)$ oracle queries (Lemma 11).
As an aside, we show in [12] that when P is a set of n points chosen uniformly at random from the unit square and C is a (fixed) smooth convex body, $\mathbf{E}[\circledcirc(P, C)] = O(n^{1/3})$, and this bound is tight when C is a disk (our result also generalizes to higher dimensions). For randomly chosen points, the separation price is related to the expected size of the convex hull of $P \cap C$, which is also known to be $\Theta(n^{1/3})$ [23]. We believe this result may be of independent interest/

(D) In Section 3 we present an improved algorithm for the 2D case, and show that the number of queries made is $O(\circledcirc(P, C) \log^2 n)$. This result is $O(\log^2 n)$ approximation to the optimal solution, see Theorem 12.

(E) We consider the extreme scenarios of the problem: Verifying that all points are either inside or outside of C. For each problem we present a $O(\log n)$ approximation algorithm to the optimal strategy. The results are presented in the full version of the paper [12].

(F) Section 4 presents an application of the above results, we consider the problem of minimizing a *convex* function $f : \mathbb{R}^2 \to \mathbb{R}$ over a point set P. Specifically, the goal is to compute $\arg\min_{p \in P} f(p)$. If f and its derivative can be efficiently evaluated at a given query point, then f can be minimized over P using $O(\varhexagon_P \log^2 n)$ queries to f (or its derivative) in expectation. We refer the reader to Lemma 17.

Given a set of n points P in $\mathbb{R}^d$, the discrete geometric median of P is a point $p \in P$ minimizing the function $\sum_{q \in P} \|p - q\|_2$. As a corollary of Lemma 17, we obtain an algorithm for computing the discrete geometric median for n points in the plane. The algorithm runs in $O(n \log^2 n \cdot (\log n \log\log n + \varhexagon_P))$ expected time. See Lemma 18. In particular, if P is a set of n points chosen uniformly at random from the unit square, it is known $\mathbf{E}[\varhexagon_P] = \Theta(n^{1/3})$ [1] and hence the discrete geometric median can be computed in $O(n^{4/3} \log^2 n)$ expected time.

While there has been ample work on approximating the geometric median (recently, Cohen et al. [5] gave a $(1+\varepsilon)$-approximation algorithm to the geometric median in $O(dn \log^3(1/\varepsilon))$ time), we are unaware of any *exact* sub-quadratic algorithm for the discrete case even in the plane.

▶ Remark. Throughout this paper, the model of computation we have assumed is unit-cost real RAM.

2 The greedy algorithm in two and three dimensions

2.1 Preliminaries

For a set of points $P \subseteq \mathbb{R}^2$, let $\mathcal{CH}(P)$ denote the convex hull of P. Given a convex body $C \subseteq \mathbb{R}^d$, two points $p, x \in \mathbb{R}^d \setminus \mathrm{int}(C)$ are **mutually visible**, if the segment px does not intersect $\mathrm{int}(C)$, where $\mathrm{int}(C)$ is the interior of C. We also use the notation $P \cap C = \{p \in P \mid p \in C\}$.

For a point set $P \subseteq \mathbb{R}^d$, a **centerpoint** of P is a point $¢ \in \mathbb{R}^d$, such that for any closed halfspace h^+ containing $¢$, we have $|h^+ \cap P| \geq |P|/(d+1)$. A centerpoint always exists, and it can be computed exactly in $O(n^{d-1} + n \log n)$ time [4].

Let C be a convex body in $\mathbb{R}^d$ and $q \in \mathbb{R}^d$ be a point such that q lies outside C. A hyperplane h **separates** q from C if q lies in the *closed* halfspace h^+ bounded by h, and C is contained in the *open* halfspace h^- bounded by h. This definition allows the separating hyperplane to contain the point q, and will simplify the descriptions of the algorithms.

2.2 The greedy algorithm in 2D

2.2.1 Operations

Initially, the algorithm copies P into a set U of unclassified points. The algorithm is going to maintain an inner approximation $B \subseteq C$. There are two types of updates (Figure 2.1 illustrates the two operations):

(A) `expand`(p): Given a point $p \in C \setminus B$, the algorithm is going to:
  - **(i)** Update the inner approximation: $B \leftarrow \mathcal{CH}(B \cup \{p\})$.
  - **(ii)** Remove (and mark) newly covered points: $U \leftarrow U \setminus B$.

(B) `remove`(ℓ): Given a closed halfplane ℓ^+ such that $\mathrm{int}(C) \cap \ell^+ = \emptyset$, the algorithm marks all the points of $U_\ell = U \cap \mathrm{int}(\ell^+)$ as being outside C, and sets $U \leftarrow U \setminus U_\ell$.

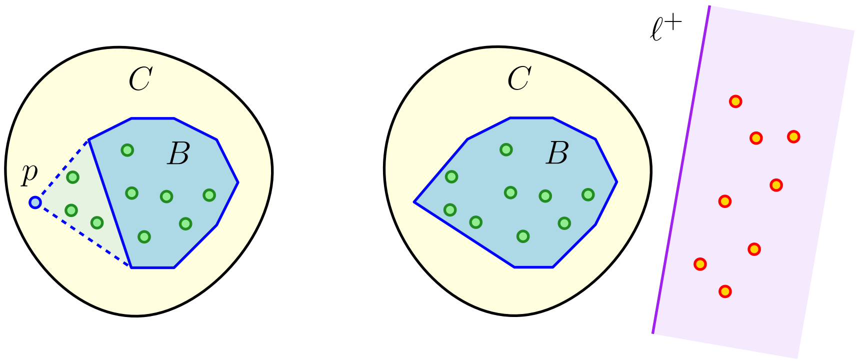


Figure 2.1 (I) Performing `expand`(p), and marking points inside C. (II) Performing `remove`(ℓ), and marking points outside C.

2.2.2 The algorithm

The algorithm repeatedly performs rounds, as described next, until the set of unclassified points is empty.

At every round, if the inner approximation B is empty, then the algorithm sets $U^+ = U$. Otherwise, the algorithm picks a line ℓ that is tangent to B with the largest number of points of U on the other side of ℓ than B. Let ℓ^- and ℓ^+ be the two closed halfspace bounded by ℓ, where $B \subseteq \ell^-$. The algorithm computes the point set $U^+ = U \cap \ell^+$. We have two cases:

(A) Suppose $|U^+|$ is of constant size. The algorithm queries the oracle for the status of each of these points. For every point $p \in U^+$, such that $p \in C$, the algorithm performs `expand`(p). Otherwise, the oracle returned a separating line ℓ, and the algorithm calls `remove`(ℓ^+).

(B) Otherwise, $|U+|$ does not have constant size. The algorithm computes a centerpoint $c \in \mathbb{R}^2$ for U^+, and asks the oracle for the status of c. There are two possibilities:
  - **(i)** If $c \in C$, then the algorithm performs `expand`(c).
  - **(ii)** If $c \notin C$, then the oracle returned a separating line $\hbar$, and the algorithm performs `remove`$(\hbar)$.

2.2.3 Analysis

Let B_i be the inner approximation at the start of the ith iteration, and let z be the first index where B_z is not an empty set. Similarly, let U_i be the set of unclassified points at the start of the ith iteration, where initially $U_1 = U$.

▶ **Lemma 1.** *The number of (initial) iterations in which the inner approximation is empty is $z = O(\log n)$.*

Proof. As soon as the oracle returns a point that is in C, the inner approximation is no longer empty. As such, we need to bound the initial number of iterations where the oracle returns that the query point is outside C. Let $f_i = |U_i|$, and note that $U_1 = P$ and $f_1 = |P| = n$. Let c_i be the centerpoint of U_i, which is the query point in the ith iteration (c_i is outside C). As such, the line separating c_i from C, returned by the oracle, has at least $f_i/3$ points of U_i on the same side as c_i, by the centerpoint property. All of these points get labeled in this iteration, and it follows that $f_{i+1} \leq (2/3)f_i$, which readily implies the claim, since $f_z < 1$, for $z = \lceil \log_{3/2} n \rceil + 1$. ◀

▶ **Definition 2** (Visibility graph)**.** *Consider the graph G_i over U_i, where two points $p, r \in U_i$ are connected $\iff$ the segment pr does not intersect the interior of B_i.*

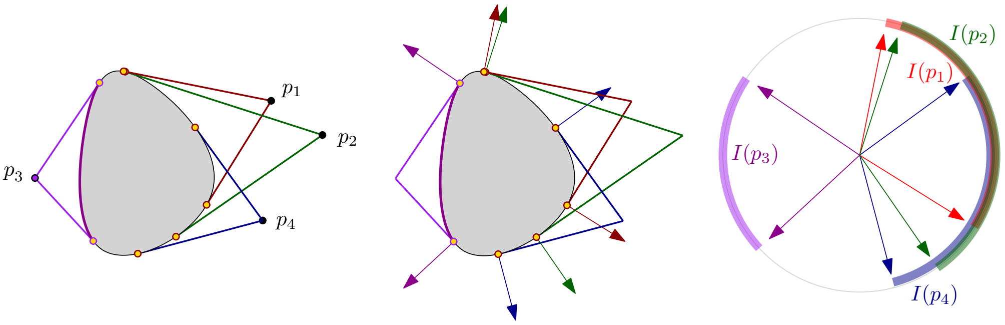

Figure 2.2 Four points and a convex body with their associated circular intervals.

The visibility graph as an interval graph

For a point $p \in U_i$, let $I_i(p)$ be the set of all directions v (i.e., vectors of length 1) such that there is a line perpendicular to v that separates p from B_i. Formally, a line ℓ separates p from B_i, if the interior of B_i is on one side of ℓ and p is on the (closed) other side of ℓ (if $p \in \ell$, the line is still considered to separate the two). Clearly, $I_i(p)$ is a circular interval on the unit circle. See Figure 2.2. The resulting set of intervals is $\mathcal{V}_i = \{I_i(p) \mid p \in U_i\}$. It is easy to verify that the intersection graph of $\mathcal{V}_i$ is G_i. Throughout the execution of the algorithm, the inner approximation B_i grows monotonically, this in turn implies that the visibility intervals shrink over time; that is, $I_i(p) \subseteq I_{i-1}(p)$, for all $p \in P$ and i. Intuitively, in each round, either many edges from G_i are removed (because intervals had shrunk and they no longer intersect), or many vertices are removed (i.e., the associated points are classified).

▶ **Definition 3.** *Given a set $\mathcal{V}$ of objects (e.g., intervals) in a domain D (e.g., unit circle), the* ***depth*** *of a point $p \in D$, is the number of objects in $\mathcal{V}$ that contain p. Let $\operatorname{depth}(\mathcal{V})$ be the maximum depth of any point in D.*

When it is clear, we use $\operatorname{depth}(G)$ to denote $\operatorname{depth}(\mathcal{V})$, where $G = (\mathcal{V}, E)$ is the intersection graph in Definition 2.

First, we bound the number of edges in this visibility graph G and then argue that in each iteration, either many edges of G are discarded or vertices are removed (as they are classified).

▶ **Lemma 4.** *Let $\mathcal{V}$ be a set of n intervals on the unit circle, and let $G = (\mathcal{V}, E)$ be the associated intersection graph. Then $|E| = O(\alpha\omega^2)$, where $\omega = \operatorname{depth}(\mathcal{V})$ and $\alpha = \alpha(G)$ is the size of the largest independent set in G. Furthermore, the upper bound on $|E|$ is tight.*

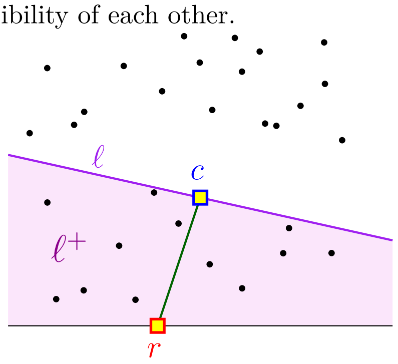
Proof. Let J be the largest independent set of intervals in G. The intervals of J divide the circle into $2|J|$ (atomic) circular arcs. Consider such an arc γ, and let $K(\gamma)$ be the set of all intervals of $\mathcal{V}$ that are fully contained in γ. All the intervals of $K(\gamma)$ are pairwise intersecting, as otherwise one could increase the size of the independent set. As such, all the intervals of $K(\gamma)$ must contain a common intersection point. It follows that $|K(\gamma)| \leq \omega$.

Let $K'(\gamma)$ be the set of all intervals intersecting γ. This set might contain up to 2ω additional intervals (that are not contained in γ), as each such additional interval must contain at least one of the endpoints of γ. Namely, $|K'(\gamma)| \leq 3\omega$. In particular, any two intervals intersecting inside γ both belong to $K'(\gamma)$. As such, the total number of edges contributed by $K'(\gamma)$ to G is at most $\binom{3\omega}{2} = O(\omega^2)$. Since there are $\leq 2\alpha$ arcs under consideration, the total number of edges in G is bounded by $O(\alpha\omega^2)$, which implies the claim.

The lower bound is easy to see by taking an independent set of intervals of size α, and replicating every interval ω times. ◀

▶ **Lemma 5.** *Let P be a set of n points in the plane lying above the x-axis, c be a centerpoint of P, and $S = \binom{P}{2}$ be set of all segments induced by P. Next, consider any point r on the x-axis. Then, the segment cr intersects at least $n^2/36$ segments of S.*

Proof. If the segment cr intersects the segment p_1p_2, for $p_1, p_2 \in P$, then we consider p_1 and p_2 to no longer be mutually visible. It suffices to lower bound the number of pairs of points which lose mutual visibility of each other.



Consider a line ℓ passing through the point c. Let ℓ^+ be the closed halfspace bounded by ℓ containing r. Note that $|P \cap \ell^+| \geq n/3$, since c is a centerpoint of P, and $c \in \ell$. Rotate ℓ around c until there are $\geq n/6$ points on each side of rc in the halfspace ℓ^+. To see why this rotation of ℓ exists, observe that the two halfspaces bounded by the line spanning rc, have zero points on one side, and at least $n/3$ points on the other side – a continuous rotation of ℓ between these two extremes, implies the desired property.

Observe that points in ℓ^+ and on opposite sides of the segment cr cannot see each other, as the segment connecting them must intersect cr. Consequently, the number of induced segments that cr intersects is at least $n^2/36$. ◀

▶ **Lemma 6.** *Let G_i be the intersection graph, in the beginning of the ith iteration, and let $m_i = |E(G_i)|$. After the ith iteration of the greedy algorithm, we have $m_{i+1} \leq m_i - \omega^2/36$, where $\omega = \mathrm{depth}(G_i)$.*

Proof. Recall that in the algorithm $U^+ = U_i \cap \ell^+$ is the current set of unclassified points and ℓ is the line tangent to B_i, where ℓ^+ is the closed halfspace that avoids the interior of B_i and contains the largest number of unlabeled points of U_i. We have that $\omega = |U^+|$.

If a `remove` operation was performed in the ith iteration, then the number of points of U^+ which are discarded is at least $\omega/3$. In this case, the oracle returned a separating line $\hbar$ between a centerpoint c of U^+ and the inner approximation. For the halfspace $\hbar^+$ containing c, we have $t_i = |U^+ \cap \hbar^+| \geq |U^+|/3 \geq \omega/3$. Furthermore, all the points of U^+ are pairwise mutually visible (in relation to the inner approximation B_i). Namely, $m_{i+1} = |E(G_i - (U^+ \cap \hbar^+))| \leq m_i - \binom{t_i}{2} \leq m_i - \omega^2/36$.

If an `expand` operation was performed, the centerpoint c of U^+ is added to the current inner approximation B_i. Let r be a point in $\ell \cap B_i$, and let c_i be the center point of U_i computed by the algorithm. By Lemma 5 applied to r, c and U^+, we have that at least $\omega^2/36$ pairs of points of U^+ are no longer mutually visible to each other in relation to B_{i+1}. We conclude, that at least $\omega^2/36$ edges of G_i are no longer present in G_{i+1}. ◀

▶ **Definition 7.** *A subset of points $X \subseteq P \subseteq \mathbb{R}^2$ are in **convex position**, if all the points of X are vertices of $\mathcal{CH}(X)$ (note that a point in the middle of an edge is not considered to be a vertex). The **index** of P, denoted by $\hexagon_P$, is the cardinality of the largest subset of P of points which are in convex position.*

▶ **Theorem 8.** *Let C be a convex body provided via a separation oracle, and let P be a set of n points in the plane. The greedy classification algorithm performs $O\big((\hexagon_P + 1)\log n\big)$ oracle queries. The algorithm correctly identifies all points in $P \cap C$ and $P \setminus C$.*

Proof. By Lemma 1, the number of iterations (and also queries) in which the inner approximation is empty is $O(\log n)$, and let $z = O(\log n)$ be the first iteration such that the inner approximation is not empty. It suffices to bound the number of queries made by the algorithm after the inner approximation becomes non-empty.

For $i \geq z$, let $G_i = (U_i, E_i)$ denote the visibility graph of the remaining unclassified points U_i in the beginning of the ith iteration. Any independent set in G_i corresponds to a set of points $X \subseteq P$ that do not see each other due to the presence of the inner approximation B_i. That is, X is in convex position, and furthermore $|X| \leq \hexagon_P$.

For $0 \leq t \leq n$, let $s(t)$ be the first iteration i, such that $\mathrm{depth}(G_i) \leq t$. Since the depth of G_i is a monotone decreasing function, this quantity is well defined. An **epoch** is a range of iterations between $s(t)$ and $s(t/2)$, for any parameter t. We claim that an epoch lasts $O(\hexagon_P)$ iterations (and every iteration issues only one oracle query). Since there are only $O(\log n)$ (non-overlapping) epochs till the algorithm terminates, as the depth becomes zero, this implies the claim.

So consider such an epoch starting at $i = s(t)$. We have $m = m_i = |E(G_i)| = O(\hexagon_P t^2)$, by Lemma 4, since $\hexagon_P$ is an upper bound on the size of the largest independent set in G_i. By Lemma 6, as long as the depth of the intervals is at least $t/2$, the number of edges removed from the graph at each iteration, during this epoch, is at least $\Omega(t^2)$. As such, the algorithm performs at most $O(m_i/t^2) = O(\hexagon_P)$ iterations in this epoch, till the maximum depth drops to $t/2$. ◀

2.2.4 Implementing the greedy algorithm

With the use of dynamic segment trees [17] we show that the greedy classification algorithm can be implemented efficiently.

▶ **Lemma 9.** *Let C be a convex body provided via a separation oracle, and let P be a set of n points in the plane. If an oracle query costs time T, then the greedy algorithm can be implemented in $O\big(n \log^2 n \log\log n + T \cdot \hexagon_P \log n\big)$ expected time.*

Proof. The algorithm follows the proof of Theorem 8. We focus on efficiently implementing the algorithm once inner approximation is no longer empty. Let $U \subseteq P$ be the subset of unclassified points. By binary searching on the vertices of the inner approximation B, we can compute the collection of visibility intervals $\mathcal{V}$ for all points in U in $O(|U| \log m) = O(n \log n)$ time (recall that $\mathcal{V}$ is a collection of circular intervals on the unit circle). We store these intervals in a dynamic segment tree $\mathcal{T}$ with the modification that each node v in $\mathcal{T}$ stores the maximum depth over all intervals contained in the subtree rooted at v. Note that $\mathcal{T}$ can be made fully dynamic to support updates in $O(\log n \log\log n)$ time [17].

An iteration of the greedy algorithm proceeds as follows. Start by collecting all points $U^+ \subseteq U$ realizing the maximum depth using $\mathcal{T}$. When $t = |U^+|$, this step can be done in $O(\log n + t)$ time by traversing $\mathcal{T}$. We compute the centerpoint of U^+ in $O(t \log t)$ expected time [4] and query the oracle using this centerpoint. Either points of U are classified (and we delete their associated intervals from $\mathcal{T}$) or we improve the inner approximation. The inner approximation (which is the convex hull of query points inside the convex body C) can be maintained in an online fashion with insert time $O(\log n)$ [19, Chapter 3]. When the inner approximation expands, the points of U^+ have their intervals shrink. As such, we recompute $I(p)$ for each $p \in U^+$ and reinsert $I(p)$ into $\mathcal{T}$.

As defined in the proof of Theorem 8, an epoch is the subset of iterations in which the maximum depth is in the range $[t/2, t]$, for some integer t. During such an epoch, we make two claims:

1. there are $\sigma = O(n)$ updates to $\mathcal{T}$, and
2. the greedy algorithm performs $O(n/t)$ centerpoint calculations on sets of size $O(t)$.

Both of these claims imply that a single epoch of the greedy algorithm can be implemented in expected time $O(\sigma \log n \log\log n + n \log n + T \cdot \bigcirc_P)$. As there are $O(\log n)$ epochs, the algorithm can be implemented in expected time $O(n \log^2 n \log\log n + T \cdot \bigcirc_P \log n)$.

We now prove the first claim. Recall that we have a collection of intervals $\mathcal{V}$ lying on the circle of directions. Partition the circle into k atomic arcs, where each arc contains $t/10$ endpoints of intervals in $\mathcal{V}$. Note that $k = 20n/t = O(n/t)$. For each circular arc γ, let $\mathcal{V}_\gamma \subseteq \mathcal{V}$ be the set of intervals intersecting γ. As the maximum depth is bounded by t, we have that $|\mathcal{V}_\gamma| \leq t + t/10 = 1.1t$. In particular, if $G[\mathcal{V}_\gamma]$ is the induced subgraph of the intersection graph G, then $G[\mathcal{V}_\gamma]$ has at most $\binom{|\mathcal{V}_\gamma|}{2} = O(t^2)$ edges.

In each iteration, the greedy algorithm chooses a point in an arc γ (we say that γ is *hit*) and edges are only deleted from $G[\mathcal{V}_\gamma]$. The key observation is that an arc γ can only be hit $O(1)$ times before all points of γ have depth below $t/2$, implying that it will not be hit again until the next epoch. Indeed, each time γ is hit, the number of edges in the induced subgraph $G[\mathcal{V}_\gamma]$ drops by a constant factor (Lemma 6). Additionally, when $G[\mathcal{V}_\gamma]$ has less than $\binom{t/2}{2}$ edges then any point on γ has depth less than $t/2$. These two facts imply that an arc is hit $O(1)$ times.

When an arc is hit, we must reinsert $|\mathcal{V}_\gamma| = O(t)$ intervals into $\mathcal{T}$. In particular, over a single epoch, the total number of hits over all arcs is bounded by $O(k)$. As such, $\sigma = O(kt) = O(n)$.

For the second claim, each time an arc is hit, a single centerpoint calculation is performed. Since each arc has depth at most t and is hit a constant number of times, there are $O(k) = O(n/t)$ such centerpoint calculations in a single epoch, each costing expected time $O(t \log t)$. ◀

In Section 4 we present an application of the greedy classification algorithm. Namely, we present an efficient algorithm for computing the discrete geometric median of a point set (Lemma 18).

2.3 The greedy algorithm in 3D

Consider the 3D variant of the 2D problem: Given a set of points P in $\mathbb{R}^3$ and a convex body C specified via a separation oracle, the task at hand is to classify, for all the points of P, whether or not they are in C, using the fewest oracle queries possible.

The greedy algorithm naturally extends, where at each iteration i a plane e_i is chosen that is tangent to the current inner approximation B_i, such that it's closed halfspace (which avoids the interior of B_i) contains the largest number of unclassified points from the set U_i.

If the queried centerpoint is outside, the oracle returns a separating plane and as such points can be discarded by the `remove` operation. Similarly, if the centerpoint is reported inside, then the algorithm calls the `expand` and updates the 3D inner approximation B_i.

The idea behind the analysis is similar to Theorem 8. The challenge in analyzing the greedy algorithm in 3D is that mutual visibility between pairs of points is not necessarily lost as the inner approximation grows. Thus we have to analyze mutual visibility between *triples* of points. The analysis considers both the intersection graph G_i between pairs of points, and a new hypergraph H_i, where there is an edge $\{p, q, r\}$ in H_i if the triangle in $\mathbb{R}^3$ formed by the points p, q, r avoids the inner approximation B_i. The main technical ingredient involves bounding the number of edges in H_i by the maximum depth and size of the largest independent set in G_i. Finally, we argue that in each iteration a constant number of edges are deleted from H_i by the centerpoint property. The full details are presented in [12]. We obtain the following result.

▶ **Theorem 10** (Proof in [12]). *Let $C \subseteq \mathbb{R}^3$ be a convex body provided via a separation oracle, and let P be a set of n points in $\mathbb{R}^3$. The greedy classification algorithm performs $O\big((\hexagon_P + 1)\log n\big)$ oracle queries. The algorithm correctly identifies all points in $P \cap C$ and $P \setminus C$.*

3 An instance-optimal approximation in two dimensions

Before discussing the improved algorithm, we present a lower bound on the number of oracle queries performed by any algorithm that classifies all the given points. We then present the the improved algorithm, which matches the lower bound up to a factor of $O(\log^2 n)$.

3.1 A lower bound

Given a set P of points in the plane, and a convex body C, the **outer fence** of P is a closed convex polygon F_{out} with minimum number of vertices, such that $C \subseteq F_{\text{out}}$ and $C \cap P = F_{\text{out}} \cap P$. Similarly, the **inner fence** is a closed convex polygon F_{in} with minimum number of vertices, such that $F_{\text{in}} \subseteq C$ and $C \cap P = F_{\text{in}} \cap P$. Intuitively, the outer fence separates $P \setminus C$ from ∂C, while the inner fence separates $P \cap C$ from ∂C. The **separation price** of P and C is

$$\circledcirc(P, C) = |F_{\text{in}}| + |F_{\text{out}}|,$$

where $|F|$ denotes the number of vertices of a polygon F. See Figure 3.1 for an example.

▶ **Lemma 11.** *Given a point set P and a convex body C in the plane, any algorithm that classifies the points of P in relation to C, must perform at least $\circledcirc(P, C)$ separation oracle queries.*

Proof. Consider the set Q of queries performed by the optimal algorithm (for this input), and split it, into the points inside and outside C. The set of points inside, $Q_{\text{in}} = Q \cap C$ has the property that $Q_{\text{in}} \subseteq C$, and furthermore $\mathcal{CH}(Q_{\text{in}}) \cap P = C \cap P$ – otherwise, there would be a point of $C \cap P$ that is not classified. Namely, the vertices of $\mathcal{CH}(Q_{\text{in}})$ are vertices of a fence that separates the points of P inside C from the boundary of C. As such, we have that $|Q_{\text{in}}| \geq |\mathcal{CH}(Q_{\text{in}})| \geq |F_{\text{in}}|$.

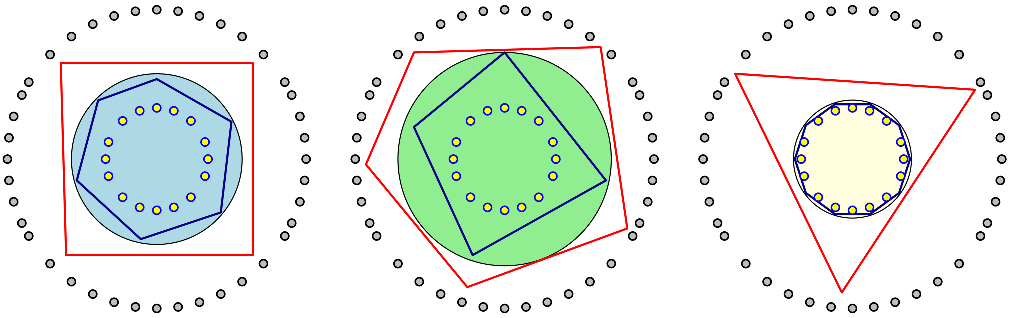


Figure 3.1 The separation price, for the same point set, is different depending on how "tight" the body is in relation to the inner and outer point set.

Similarly, each query in $Q_{\text{out}} = Q \setminus Q_{\text{in}}$ gives rise to a separating halfplane. The intersection of the corresponding halfplanes is a convex polygon H which contains C, and furthermore contains no point of $P \setminus C$. Namely, the boundary of H behaves like an outer fence. As such, we have $|Q_{\text{out}}| \geq |H| \geq |F_{\text{out}}|$.

Combining, we have that $|Q| = |Q_{\text{in}}| + |Q_{\text{out}}| \geq |F_{\text{in}}| + |F_{\text{out}}| = ⊚(P, C)$, as claimed. ◀

▶ Remarks.

1. Naturally the separation price, and thus the proof of the lower bound, generalizes to higher dimensions. See [12].
2. The lower bound only holds for $d \geq 2$. In 1D, the problem can be solved using $O(\log n)$ queries with binary search. The above would predict that any algorithm needs $\Omega(1)$ queries. However it is not hard to argue a stronger lower bound of $\Omega(\log n)$.
3. In [12], we show that when P is a set of n points chosen uniformly at random from a square and C is a smooth convex body, $\mathbf{E}[⊚(P, C)] = O(n^{1/3})$. Thus, when the points are randomly chosen, one can think of $⊚(P, C)$ as growing sublinearly in n.

3.2 A sketch of the improved algorithm

We refer to reader to [12] for a complete description of the improved algorithm in 2D. The idea of the algorithm is conceptually the same as the greedy algorithm of Section 2: at all times a current inner approximation $B \subseteq C$ and the set of unclassified points $U \subseteq P$ are maintained. We define a *pocket* to be a connected region of $\mathcal{CH}(U \cup B) \setminus B$ (see Figure 3.2). The algorithm will repeatedly choose points inside a pocket, and attempt to classify them, while simultaneously dividing the pocket into two smaller pockets. In this way, we improve the inner approximation B every time a pocket is handled. The algorithm continues in this fashion until all points are classified. The analysis involves a careful charging argument. Roughly speaking, whenever a pocket contains a vertex of F_{in} or F_{out}, we can charge the work of creating and splitting the pocket to such a vertex. Otherwise, a pocket contains no vertex from either fence. For such a pocket, we prove that when this pocket was created by the algorithm, all of the points contained in the pocket must lie outside C. When all points inside a pocket are outside C, we argue that they can all be classified as outside after $O(\log n)$ queries by using centerpoints as the oracle queries.

▶ **Theorem 12** (Proof in [12]). *Let C be a convex body provided via a separation oracle, and let P be a set of n points in the plane. The improved classification algorithm performs $O\big(\big[1 + ⊚(P, C)\big] \log^2 n\big)$ oracle queries. The algorithm correctly identifies all points in $P \cap C$ and $P \setminus C$.*

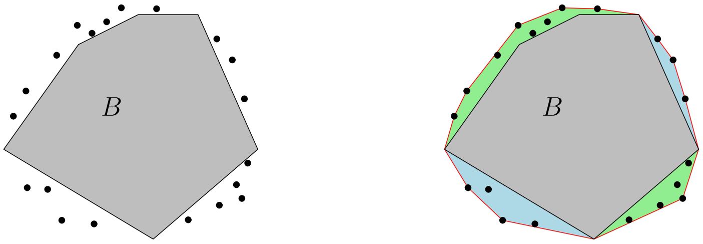

Figure 3.2 Unclassified points and their pockets.

4 Application: Minimizing a convex function

Suppose we are given a set of n points P in the plane and a convex function $f : \mathbb{R}^2 \to \mathbb{R}$. Our goal is to compute the point in P minimizing $\min_{p\in P} f(p)$. Given a point $p \in \mathbb{R}^2$, assuming that we can evaluate f and the derivative of f at p efficiently, we show that the point in P minimizing f can be computed using $O(\hexagon_P \log^2 n)$ evaluations to f or its derivative.

▶ **Definition 13.** *Let $f : \mathbb{R}^d \to \mathbb{R}$ be a convex function. For a number $c \in \mathbb{R}$, define the **level set of** f as $\mathcal{L}_f(c) = \left\{p \in \mathbb{R}^d \;\middle|\; f(p) \le c\right\}$. If f is a convex function, then $\mathcal{L}_f(c)$ is a convex set for all $c \in \mathbb{R}$.*

▶ **Definition 14.** *Let $f : \mathbb{R}^d \to \mathbb{R}$ be a convex (and possibly non-differentiable) function. For a point $p \in \mathbb{R}^d$, a vector $v \in \mathbb{R}^d$ is a **subgradient** of f at p if for all $q \in \mathbb{R}^d$, $f(q) \ge f(p) + \langle v, q - p\rangle$. The **subdifferential** of f at $p \in \mathbb{R}^d$, denoted by $\partial f(p)$, is the set of all subgradients $v \in \mathbb{R}^d$ of f at p.*

It is well known that when the domain for f is $\mathbb{R}^d$ and f is a convex function, then $\partial f(p)$ is a non-empty set of all $p \in \mathbb{R}^d$ (for example, see [8, Chapter 3]).

Let $\alpha = \min_{p\in P} f(p)$. We have that $\mathcal{L}_f(\alpha) \cap P = \{p \in P \mid f(p) = \alpha\}$ and $\mathcal{L}_f(\alpha') \cap P = \varnothing$ for all $\alpha' < \alpha$. Hence, the problem is reduced to determining the smallest value r such that $\mathcal{L}_f(r) \cap P$ is non-empty.

▶ **Lemma 15.** *Let P be a collection of n points in the plane. For a given value r, let $C_r = \mathcal{L}_f(r)$. The set $C_r \cap P$ can be computed using $O(\hexagon_P \log n)$ evaluations to f or its derivative. If T is the time needed to evaluate f or its derivative, the algorithm can be implemented in $O(n \log^2 n \log\log n + T \cdot \hexagon_P \log n)$ expected time.*

Proof. The Lemma follows by applying Theorem 8. Indeed, let $C_r = \mathcal{L}_f(r)$ be the convex body of interest. It remains to design a separation oracle for C_r.

Given a query point $q \in \mathbb{R}^2$, first compute $c = f(q)$. If $c \le r$, then report that $q \in C_r$. Otherwise, $c > r$. In this case, compute some gradient vector v in $\partial f(q)$. Using the vector v, we can obtain a line ℓ tangent to the boundary of $\mathcal{L}_f(c)$ at q. As $\mathcal{L}_f(r) \subseteq \mathcal{L}_f(c)$, ℓ is a separating line for q and C_r, as desired. As such, the number of separation oracle queries needed to determine $C_r \cap P$ is bounded by $O(\hexagon_P \log n)$ by Theorem 8.

The implementation details of Theorem 8 are given in Lemma 9. ◀

The algorithm

Let $\alpha = \min_{p\in P} f(p)$. For a given number $r \ge 0$, set $P_r = \mathcal{L}_f(r) \cap P$. We develop a randomized algorithm to compute α.

Set $P_0 = P$. In the ith iteration, the algorithm chooses a random point $p_i \in P_{i-1}$ and computes $r_i = f(p_i)$. Next, we determine P_{r_i} using Lemma 15. In doing so, we modify the separation oracle of Lemma 15 to store the collection of queries $S_i \subseteq P$ which satisfy $f(s) = r_i$ for all $s \in S_i$. We set $P_{i+1} = P_{r_i} \setminus S_i$. Observe that all points $p \in P_{i+1}$ have $f(p) < r_i$. The algorithm continues in this fashion until we reach an iteration j in which $|P_{j+1}| \leq 1$. If $P_{j+1} = \{q\}$ for some $q \in P$, output q as the desired point minimizing the geometric median. Otherwise $P_{j+1} = \varnothing$, implying that $P_{r_j} = S_j$, and the algorithm outputs any point in the set S_j.

Analysis

We analyze the running time of the algorithm. To do so, we argue that the algorithm invokes the algorithm in Lemma 15 only a logarithmic number of times.

▶ **Lemma 16.** *In expectation, the above algorithm terminates after $O(\log n)$ iterations.*

Proof. Let $V = \{f(p) \mid p \in P\}$ and $N = |V|$. For a number r, define $V_r = \{i \in V \mid i \leq r\}$. Notice that we can reinterpret the algorithm described above as the following random process. Initially set $r_0 = \max_{i \in V} i$. In the ith iteration, choose a random number $r_i \in V_{r_{i-1}}$. This process continues until we reach an iteration j in which $\left|V_{r_j}\right| \leq 1$.

We can assume without loss of generality that $V = \{1, 2, \ldots, N\}$. For an integer $i \leq N$, let $T(i)$ be the expected number of iterations needed for the random process to terminate on the set $\{1, \ldots, i\}$. We have that $T(i) = 1 + \frac{1}{i-1} \sum_{j=1}^{i-1} T(i-j)$, with $T(1) = 0$. This recurrence solves to $T(i) = O(\log i)$. As such, the algorithm repeats this random process $O(\log N) = O(\log n)$ times in expectation. ◀

▶ **Lemma 17.** *Let P be a set of n points in $\mathbb{R}^2$ and let $f : \mathbb{R}^2 \to \mathbb{R}$ be a convex function. The point in P minimizing f can be computed using $O(\hexagon_P \log^2 n)$ evaluations to f or its derivative. The bound on the number of evaluations holds in expectation. If T is the time needed to evaluate f or its derivative, the algorithm can be implemented in $O(n \log^3 n \log\log n + T \cdot \hexagon_P \log^2 n)$ expected time.*

Proof. The result follows by combining Lemma 15 and Lemma 16. ◀

4.1 The discrete geometric median

Let P be a set of n points in $\mathbb{R}^d$. For all $x \in \mathbb{R}^d$, define the function $f(x) = \sum_{q \in P-x} \|x - q\|_2$. The **discrete geometric median** is defined as the point in P minimizing the quantity $\min_{p \in P} f(p)$.

Note that f is convex, as it is the sum of convex functions. Furthermore, given a point p, we can compute $f(p)$ and the derivative of f at p in $O(n)$ time. As such, by Lemma 17, we obtain the following.

▶ **Lemma 18.** *Let P be a set of points in $\mathbb{R}^2$. Then the discrete geometric median of P can be computed in $O(n \log^2 n \cdot (\log n \log\log n + \hexagon_P))$ expected time.*

▶ Remark. For a set of n points P chosen uniformly at random from the unit square, it is known that in expectation $\hexagon_P = \Theta(n^{1/3})$ [1]. As such, the discrete geometric median for such a random set P can be computed in $O(n^{4/3} \log^2 n)$ expected time.

5 Conclusion and open problems

In this paper we have presented various algorithms for classifying points with oracle access to an unknown convex body. As far as the authors are aware, this problem has not been studied within the community previously. However we believe that this is an interesting and natural problem. We now pose some open problems.

(A) Develop a more natural instance-optimal algorithm in 2D which improves upon the $O(\log^2 n)$ approximation. Alternatively, develop algorithms in which the number of queries is parameterized by different functions of the input instance.

(B) An algorithm in 3D which is instance-optimal up to some additional factors (see [12] for the definition of the separation price in higher dimensions).

(C) Any results beyond three dimensions is unknown. The greedy algorithm (Theorem 8 and Theorem 10) easily extends to $\mathbb{R}^d$. However the analysis in higher dimensions will most likely reveal that the algorithm makes (ignoring logarithmic factors) of the order of $\hexagon_P{}^{O(d)}$ queries, which is only interesting when $\hexagon_P$ is much smaller than n.

Abstract

The *terminal backup problems* [Anshelevich and Karagiozova, 2011] form a class of network design problems: Given an undirected graph with a requirement on terminals, the goal is to find a minimum cost subgraph satisfying the connectivity requirement. The *node-connectivity terminal backup problem* requires a terminal to connect other terminals with a number of node-disjoint paths. This problem is not known whether is NP-hard or tractable. Fukunaga (2016) gave a 4/3-approximation algorithm based on LP-rounding scheme using a general LP-solver.

In this paper, we develop a combinatorial algorithm for the relaxed LP to find a half-integral optimal solution in $O(m\log(mUA)\cdot \mathrm{MF}(kn, m+k^2n))$ time, where m is the number of edges, k is the number of terminals, A is the maximum edge-cost, U is the maximum edge-capacity, and $\mathrm{MF}(n', m')$ is the time complexity of a max-flow algorithm in a network with n' nodes and m' edges. The algorithm implies that the 4/3-approximation algorithm for the node-connectivity terminal backup problem is also efficiently implemented. For the design of algorithm, we explore a connection between the node-connectivity terminal backup problem and a new type of a multiflow, called a *separately-capacitated multiflow*. We show a min-max theorem which extends Lovász–Cherkassky theorem to the node-capacity setting. Our results build on discrete convex analysis for the node-connectivity terminal backup problem.

1 Introduction

Network design problems are central problems in combinatorial optimization. A large number of basic combinatorial optimization problems are network design problems. Examples are spanning tree, matching, TSP, and Steiner networks. They admit a typical formulation of a network design problem: Find a minimum-cost network satisfying given connectivity requirements. The present paper addresses a relatively new class of network design problems,

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

called *terminal backup problems*. The problem is to find a cheapest subnetwork in which each terminal can send a specified amount of flows to other terminals, i.e., the data in each terminal can be backed up, possibly in a distributed manner, in other terminals.

A mathematical formulation of the terminal backup problem is given as follows. Let $((V,E),S,u,c,a,r)$ be an undirected network, where (V,E) is a simple undirected graph, $S \subseteq V$ ($|S| \geq 3$) is a set of *terminals*, $u : E \to \mathbb{Z}_+$ is a nonnegative edge-capacity function, $c : V \setminus S \to \mathbb{Z}_+$ is a nonnegative node-capacity function, $a : E \to \mathbb{Z}_+$ is a nonnegative edge-cost function, and $r : S \to \mathbb{Z}_+$ is a nonnegative requirement function on terminals. The goal is to find a feasible edge-capacity function x of minimum cost $\sum_{e \in E} a(e)x(e)$. Here an edge-capacity function x is said to be *feasible* if $0 \leq x \leq u$ and each terminal $s \in S$ has a flow from s to $S \setminus \{s\}$, an $\{s\}$–$(S \setminus \{s\})$ flow, of total flow-value $r(s)$ in the network $((V,E),S,x,c)$ capacitated by the edge-capacity x and the node-capacity c.

The original formulation, due to Anshelevich and Karagiozova [1], is uncapacitated (i.e., u, c are infinity), requires x to be integer-valued, and assumes $r(s) = 1$ for all $s \in S$. They showed that an optimal solution can be obtained in polynomial time. Bernáth et al. [2] extended this polynomial time solvability to an arbitrary integer-valued requirement r. For the setting of general edge-capacity (and infinite node-capacity), which we call the *edge-connectivity terminal backup problem (ETB)*, it is unknown whether ETB is NP-hard or tractable.

Fukunaga [8] considered the above setting including both edge-capacity and node-capacity, which we call the *node-connectivity terminal backup problem (NTB)*, and explored intriguing features of its fractional relaxation. The *fractional ETB (FETB)* and *fractional NTB (FNTB)* are LP-relaxations obtained from ETB and NTB, respectively, by relaxing solution x to be real-valued. Fukunaga showed the half-integrality property of FNTB, that is, there always exists an optimal solution that is half-integer-valued. Based on this property, he developed a 4/3-approximation algorithm for NTB by rounding a half-integral (extreme) optimal solution. Moreover, he noticed a useful relationship between FETB and *multicommodity flow (multiflow)*. In fact, a solution of FETB is precisely the edge-support of a multiflow consisting of the $r(s)$ amount of $\{s\}$–$(S \setminus \{s\})$ flow for each $s \in S$. This is a consequence of Lovász–Cherkassky theorem [5, 21] in multiflow theory. In particular, FETB is equivalent to a minimum-cost multiflow problem, which is a variant of the one studied by Karzanov [19, 20] and Goldberg and Karzanov [10].

Utilizing this connection, Hirai [12] developed a combinatorial polynomial time algorithm for FETB and the corresponding multiflow problem. This algorithm uses a max-flow algorithm as a subroutine, and brings a combinatorial implementation of Fukunaga's 4/3-approximation algorithm for ETB, where he used a generic LP-solver (e.g., the ellipsoid method) to obtain a half-integral extreme optimal solution.

Our first contribution is the extension of this result to the NTB setting, implying that the 4/3-approximation algorithm for NTB is also efficiently implemented.

▶ **Theorem 1.** *A half-integral optimal solution of FNTB can be obtained in* $O(m \log(mUA) \cdot \mathrm{MF}(kn, m + k^2 n))$ *time.*

Here $n := |V|$, $m := |E|$, $k := |S|$, $U := \max_{e \in E} u(e)$, and $A := \max_{e \in E} a(e)$, and $\mathrm{MF}(n', m')$ is the time complexity of an algorithm for solving the max-flow problem in the network with n' nodes and m' edges.

As in the ETB case, we explore and utilize a new connection between NTB and a multiflow problem. We introduce a new notion of a *free multiflow with separate node-capacity constraints* or simply a *separately-capacitated multiflow*. Instead of the usual node-capacity constraints, this multiflow should satisfy the separate node-capacity constraints: For each terminal $s \in S$ and each node $i \in V$, the total flow-value of flows connecting s to the other terminals and flowing into i is at most the node capacity $c(i)$.

Our second contribution is a min-max theorem for separately-capacitated multiflows, which extends Lovász–Cherkassky theorem to the node-capacitated setting and implies that a solution of FNTB is precisely the edge-support of a separately-capacitated multiflow. This answers Fukunaga's comment: *how the computation should proceed in the node capacitated setting remains elusive* [8, p. 799].

▶ **Theorem 2.** *The maximum flow-value of a separately-capacitated multiflow is equal to* $(1/2)\sum_{s \in S} \nu_s$*, where* ν_s *is the minimum capacity of an* $\{s\}$*–*$(S \setminus \{s\})$ *cut. Moreover, a half-integral maximum multiflow exists, and it can be found in* $O(n \cdot \mathrm{MF}(kn, m + k^2 n))$ *time.*

Here, a T–T' *cut* is a union of an edge-subset $F \subseteq E$ and a node-subset $X \subseteq V \setminus (T \cup T')$ such that removing those subsets disconnects T and T', and its capacity is defined as $u(F) + c(X)$.

Our algorithm for Theorem 1 builds on the ideas of *Discrete Convex Analysis (DCA) beyond* $\mathbb{Z}^n$ – a theory of discrete convex functions on special graph structures generalizing $\mathbb{Z}^n$ (the grid graph), which has been recently differentiated from the original DCA [23] and has been successfully applied to algorithm design for well-behaved classes of multiflow and related network design problems [12, 13, 14, 16]. Indeed, the algorithm in [12] for FETB was designed as: Formulate the dual of FETB as a minimization of an *L-convex function* on the (Cartesian) product of trees, apply the framework of the *steepest descent algorithm (SDA)*, and show that it is implemented by using a max-flow algorithm as a subroutine.

We formulate the dual of FNTB as an optimization problem on the product of the spaces of all subtrees of a fixed tree (Section 2.1). We develop a simple cut-descent algorithm for this optimization problem (Sections 2.2 and 2.3). Then we prove that this coincides with SDA for an L-convex function defined on the graph structure on the space of all subtrees (Section 3). Then the number of descents is estimated by a general theory of SDA, and the cost-scaling method is naturally incorporated to derive the time complexity (Section 2.4). Theorem 2 is obtained as a byproduct of these arguments. Due to the space limitation, we omit most of technical proofs, which are given in the full version.

Related work

ETB is a *survivable network design problem (SND)* with a special skew-supermodular function, and NTB is a node connectivity version (NSND) with a special skew-supermodular biset function. In his influential paper [18], Jain devised the iterative rounding method, and obtains a 2-approximation algorithm for SND, provided that an extreme optimal solution of the LP-relaxation of SND (with modified skew-supermodular functions) is available. Fleischer, Jain, and Williamson [7] and Cheriyan, Vempala, and Vetta [4] extended this iterative rounding 2-approximation algorithm to some classes of NSND. One of important open problems in the literature is a design of a combinatorial 2-approximation algorithm for (V)SND with the skew-supermodular (biset) function associated with connectivity requirements. One approach is to devise a combinatorial polynomial time algorithm to find an extreme optimal solution of its LP-relaxation; the currently known only polynomial time algorithm is a general LP-solver (e.g., the ellipsoid method). Our algorithm for FNTB, though it is the LP-relaxation of a very special NSND, may give an insight on such a research direction. On this direction, Feldmann, Könemann, Pashkovich, and Sanità [6] gave a $(2+\epsilon)$-approximation algorithm for SND with a proper function by solving the LP-relaxation approximately via the multiplicative weights method [9].

The notion of a separately-capacitated multiflow, introduced in this paper, is a new variation of S-paths packing. As seen in [24, Chapter 73], S-paths packing is one of the well-studied subjects in combinatorial optimization. Recent work [17] developed a fast algorithm for half-integral *nonzero S-paths packing problem on a group-valued graph* (with unit-capacity). Our derivation of Theorem 2 is different with flow-augmenting arguments such as Cherkassky's T-operation or those in [17]. It is a future research to develop such an algorithm for a separately-capacitated multiflow. Also, exploring an integer version of Theorem 2, an analogue of Mader's theorem [22], is an interesting future direction.

Notations

Let $\mathbb{Z}, \mathbb{Z}_+, \mathbb{R}, \mathbb{R}_+$ be the set of integers, nonnegative integers, reals, and nonnegative reals, respectively. Let $\mathbb{Z}^*, \mathbb{Z}^*_+$ be the set of half-integers and nonnegative half-integers, respectively, i.e., $\mathbb{Z}^* := \mathbb{Z}/2$. Let $\overline{\mathbb{R}} := \mathbb{R} \cup \{+\infty\}$ and $\underline{\mathbb{R}} := \mathbb{R} \cup \{-\infty\}$. Let denote $(a)^+ := \max\{a, 0\}$ for $a \in \mathbb{R}$. For a finite set V, we often identify a function on V with a vector in $\mathbb{R}^V$. For $i \in V$, its characteristic function $\chi_i : V \to \mathbb{R}$ is defined by $\chi_i(j) = 1$ if $j = i$ and $\chi_i(j) = 0$ otherwise. For a function f on V and a subset $U \subseteq V$, we denote $f(U) := \sum_{i \in U} f(i)$.

In this paper, all graphs are simple and connected unless otherwise specified. For an undirected graph on nodes V, the set of edges connecting U_1 and U_2 ($U_1, U_2 \subseteq V$) is denoted by $\delta(U_1, U_2)$. If $U_2 = V \setminus U_1$, we simply denote it by δU_1. If U_1 is a singleton, i.e., $U_1 = \{i\}$, then we denote $\delta\{i\}$ by δi. An edge connecting i and j is denoted by ij.

2 Node-Connectivity Terminal Backup Problem

Let $((V, E), S, u, c, a, r)$ be a network. Assume that $S = \{1, \ldots, k\} \subseteq V = \{1, \ldots, n\}$. By a perturbation technique, we may assume that a is positive; see Remark 3.

A sufficient and necessity condition for the feasibility of NTB is easily derived from the Menger's theorem as follows. A *biset* is a pair of node subsets $X, X^+ \subseteq V$ with $X \subseteq X^+$. We write $\hat{X} = (X, X^+)$ for a biset. Let $\Gamma(\hat{X}) := X^+ \setminus X$, and let $\delta(\hat{X}) := \delta(X, V \setminus X^+)$. For $s \in S$, define a family $\mathcal{C}_s$ of bisets by

$$\mathcal{C}_s := \{(X, X^+) \mid \{s\} \subseteq X \subseteq X^+ \subseteq V \setminus (S \setminus \{s\})\}.$$

Let $\mathcal{C} := \bigcup_{s \in S} \mathcal{C}_s$. Then an edge-capacity $x : E \to \mathbb{Z}_+$ is feasible if and only if

$$x(\delta(\hat{X})) + c(\Gamma(\hat{X})) \geq r(s) \quad (\hat{X} \in \mathcal{C}_s,\ s \in S). \tag{1}$$

We assume that u satisfies (1) throughout the paper (otherwise NTB is infeasible).

Fukunaga [8] developed an approximation algorithm for NTB via the following relaxation problem FNTB:

$$\begin{aligned} \text{(FNTB)} \quad \text{Minimize} \quad & \sum_{e \in E} a(e)x(e) \\ \text{subject to} \quad & x(\delta\hat{X}) + c(\Gamma(\hat{X})) \geq r(s) \quad (s \in S,\ \hat{X} \in \mathcal{C}_s), && (2) \\ & 0 \leq x(e) \leq u(e) \quad (e \in E). && (3) \end{aligned}$$

From the assumption, the polytope defined by (2) and (3) is nonempty. Also, it is known [8, Corollary 3.3] that the polytope is half-integral. Thus FNTB has a half-integral optimal solution. This can be obtained by a general LP solver [8, Lemma 4.4].

▶ Remark 3. If $Z := \{e \in E \mid a(e) = 0\}$ is nonempty, then we use the following perturbation technique based on [10, 20]. Recall that U is the maximum edge capacity. Define a positive edge-cost a' by $a'(e) := 1$ for $e \in Z$ and $a'(e) := (2U|Z| + 1)a(e)$ for $e \notin Z$. Let x^* be a half-integral optimal solution of FNTB under the edge-cost a' (it exists by the half-integrality). We prove that x^* is also optimal under the original edge-cost a. It suffices to show that $\sum_{e\in E} a(e)x^*(e) \leq \sum_{e\in E} a(e)x(e)$ for any feasible half-integral edge-capacity x. It holds that $(2U|Z| + 1)(\sum_{e\in E} a(e)x^*(e) - \sum_{e\in E} a(e)x(e)) = \sum_{e\in E} a'(e)x^*(e) - \sum_{e\in E} a'(e)x(e) - x^*(Z) + x(Z) \leq U|Z|$ and thus $\sum_{e\in E} a(e)x^*(e) - \sum_{e\in E} a(e)x(e) \leq U|Z|/(2U|Z| + 1) < 1/2$. By the half-integrality, we obtain $\sum_{e\in E} a(e)x^*(e) - \sum_{e\in E} a(e)x(e) \leq 0$.

2.1 Combinatorial Duality for FNTB

We introduce a combinatorial duality theory for FNTB. For each $s \in S$, consider an infinite path graph P_s with one endpoint. Glue those $k\,(= |S|)$ endpoints, and denote the resulting graph by $\mathbb{T}$. We denote the set of nodes of P_s and $\mathbb{T}$ also by P_s and $\mathbb{T}$, respectively. We give length $1/2$ for each edge in $\mathbb{T}$. The glued endpoint is denoted by 0, and the point in P_s $(s \in S)$ having the distance l from 0 is denoted by (l, s). We denote the set of all subtrees of $\mathbb{T}$ by $\mathbb{S} = \mathbb{S}(\mathbb{T})$. If a subtree T does not contain 0, then it is contained in some P_s. Such a subtree T is said to be of *s-type* and is denoted by $[l, l']_s$, where (l, s) and (l', s) are the closest and farthest nodes from 0 in T, respectively. If a subtree T contains 0, then it is said to be of *0-type* and is denoted by $[l_1, l_2, \ldots, l_k] = [l_s]_{s\in S}$, where (l_s, s) is the node in $T \cap P_s$ farthest from 0 for each $s \in S$. We identify a node on $\mathbb{T}$ with a subtree consisting of this node only.

For a 0-type subtree $T = [l_s]_{s\in S} \in \mathbb{S}$, let $\mathrm{size}_s(T) := l_s$ for $s \in S$, and $\mathrm{size}(T) := \sum_{s=1}^{k} \mathrm{size}_s(T)$. For an s-type subtree $T = [l, l']_s \in \mathbb{S}$, let $\mathrm{size}(T) := l' - l$. For two subtrees $T, T' \in \mathbb{S}$, we denote the minimum distance between T and T' on $\mathbb{T}$ by $\mathrm{dist}(T, T')$, i.e., $\mathrm{dist}(T, T') := \min\{d_{\mathbb{T}}(v, v') \mid v \in T,\ v' \in T'\}$, where $d_{\mathbb{T}}$ is the shortest distance on $\mathbb{T}$.

We formulate a dual of FNTB as a problem of assigning a subtree for each node $i \in V$. That is, subtrees are viewed as node-potentials. So we use p_i and $p : V \to \mathbb{S}$ for denoting a subtree assigned for node $i \in V$ and a potential function, respectively. Formally, let us consider the following maximization problem DTB.

$$\begin{aligned}
\text{(DTB)}\quad \text{Maximize}\quad & \sum_{s\in S} r_s \,\mathrm{dist}(0, p_s) - \sum_{i\in V\setminus S} c_i \,\mathrm{size}(p_i) - \sum_{ij\in E} u_{ij}(\mathrm{dist}(p_i, p_j) - a_{ij})^+ \\
\text{subject to}\quad & p : V \to \mathbb{S}, \\
& p_s \in P_s \quad (s \in S). \qquad\qquad (4)
\end{aligned}$$

It turns out in the proof of Proposition 4 below that this seemingly strange formulation of DTB is essentially the LP-dual of FTB. If $p : V \to \mathbb{S}$ satisfies (4), then it is called a *potential.* See Figure 1 for an intuition for a subtree-valued potential p. A potential p is said to be *proper* if any p_i for $i \in V$ is contained in the minimal subtree that contains all p_s $(s \in S)$.

▶ **Proposition 4.** *The optimum value of FNTB is at least that of DTB. Moreover, there exists a proper optimal potential for DTB.*

Proof. Let $p : V \to \mathbb{S}$ be any potential (not necessarily proper). For each $s \in S$, suppose that p_s is written as $p_s = (M_s, s)$ for $M_s \in \mathbb{Z}^*_+$. Define a new proper potential $p' : V \to \mathbb{S}$ by

$$p'_i := \begin{cases} [\min\{l, M_s\}, \min\{l', M_s\}]_s & \text{if } p_i = [l, l']_s, \\ [\min\{l_1, M_1\}, \ldots, \min\{l_k, M_k\}] & \text{if } p_i = [l_1, \ldots, l_k]. \end{cases}$$

Then the objective function value of p' does not decrease. This implies the latter part of the statement.

P_3
$((V,E),S,u,c,a,r)$

Figure 1 A subtree-valued potential p.

We next show the former part, i.e., the weak duality. The LP dual of FNTB is written as

$$\begin{aligned}&\text{Maximize} \quad \sum_{s\in S}\sum_{\hat{X}\in\mathcal{C}_s}(r_s - c(\Gamma(\hat{X})))\pi(\hat{X}) - \sum_{e\in E} u_e\left(\sum_{\hat{X}\in\mathcal{C}:e\in\delta\hat{X}}\pi(\hat{X}) - a_e\right)^+\\ &\text{subject to} \quad \pi : \mathcal{C}\to\mathbb{R}_+.\end{aligned}$$

We show that for any proper potential $p : V \to \mathbb{S}$, we can construct $\pi : \mathcal{C} \to \mathbb{R}_+$ such that

$$\sum_{\hat{X}\in\mathcal{C}_s}\pi(\hat{X}) = \mathrm{dist}(0, p_s) \quad (s \in S), \tag{5}$$

$$\sum_{\hat{X}\in\mathcal{C}:i\in\Gamma(\hat{X})}\pi(\hat{X}) = \mathrm{size}(p_i) \quad (i \in V \setminus S), \tag{6}$$

$$\sum_{\hat{X}\in\mathcal{C}:e\in\delta\hat{X}}\pi(\hat{X}) = \mathrm{dist}(p_i, p_j) \quad (ij \in E). \tag{7}$$

Then by $\sum_{\hat{X}\in\mathcal{C}} c(\Gamma(\hat{X}))\pi(\hat{X}) = \sum_{\hat{X}\in\mathcal{C}}\sum_{i\in\Gamma(\hat{X})} c_i\pi(\hat{X}) = \sum_{i\in V\setminus S} c_i \sum_{\hat{X}\in\mathcal{C}:i\in\Gamma(\hat{X})}\pi(\hat{X})$, the weak duality follows.

Let e be an edge in $\mathbb{T}$. We define a biset (X_e, X_e^+) as follows. When we remove e from $\mathbb{T}$, there appear two connected components. Let T_e be the component which does not contain $0\,(\in \mathbb{T})$. Define $X_e, X_e^+ \subseteq V$ by

$$X_e := \{i \in V \mid p_i \text{ is contained in } T_e\}, \quad X_e^+ := X_e \cup \{i \in V \mid p_i \text{ contains } e\}.$$

Observe that if e is an edge in P_s and $X_e \neq \emptyset$, then $(X_e, X_e^+) \in \mathcal{C}_s$. Then a potential function $\pi : \mathcal{C} \to \mathbb{R}_+$ defined by

$$\pi(\hat{X}) := \frac{1}{2}|\{e \mid \hat{X} = (X_e, X_e^+)\}| \quad (\hat{X} \in \mathcal{C})$$

satisfies (5)–(7). ◀

We remark that the technique used in the above proof is based on a tree representation of a laminar biset family; see also [11] for the relating argument that maps to each node a subtree as a potential. We also note that our algorithm below will give an algorithmic proof of the strong duality.

We next derive from Proposition 4 the complementary slackness condition. Let $p : V \to \mathbb{S}$ be a proper potential. By p, we decompose V into $S \cup V_0 \cup \bigcup_{s \in S} V_s$, where

$$V_0 := \{i \in V \setminus S \mid p_i \text{ is of 0-type}\},$$
$$V_s := \{i \in V \setminus S \mid p_i \text{ is of } s\text{-type}\} \quad (s \in S).$$

In the next lemma, we see that it is sufficient to only consider edges $ij \in E$ with $\mathrm{dist}(p_i, p_j) \geq a_{ij}$. Let denote the set of such edges by

$$E^* := \{ij \in E \mid \mathrm{dist}(p_i, p_j) \geq a_{ij}\}.$$

For $i \in V_0$ and $s \in S$, we denote a set of edges in E^* connecting i and V_s by

$$E^{i,s} := \{ij \in E^* \mid j \in V_s\} \quad (i \in V_0,\ s \in S).$$

By the positivity of a, we see that $(E^{i,1}, E^{i,2}, \ldots, E^{i,k})$ is a partition of $E^* \cap \delta i$. For $i \in V_s$ $(s \in S)$, there appear two connected components when we remove p_i from $\mathbb{T}$. Let $T_{i,0}$ be the component which includes $0\,(\in \mathbb{T})$, and let $T_{i,+}$ be the other component. Then we define the sets of edges $E^{i,0}$ and $E^{i,+}$ by

$$E^{i,0} := \{ij \in E^* \mid p_j \text{ is contained in } T_{i,0}\},$$
$$E^{i,+} := \{ij \in E^* \mid p_j \text{ is contained in } T_{i,+}\}.$$

By the positivity of a, we see that $(E^{i,0}, E^{i,+})$ is a partition of $E^* \cap \delta i$.

▶ **Lemma 5.** *Let $x : E \to \mathbb{R}_+$ be an edge-capacity function with $0 \leq x \leq u$, and let $p : V \to \mathbb{S}$ be a proper potential. If x and p satisfy the following conditions (A1–5), then x and p are optimal solutions for FNTB and DTB, respectively:*

(A1) *For each $ij \in E$, if $\mathrm{dist}(p_i, p_j) > a_{ij}$, then $x_{ij} = u_{ij}$.*
(A2) *For each $ij \in E$, if $\mathrm{dist}(p_i, p_j) < a_{ij}$, then $x_{ij} = 0$.*
(A3) *For each $i \in \bigcup_{s \in S} V_s$, it holds $x(E^{i,0}) = x(E^{i,+}) \leq c_i$. If $\mathrm{size}(p_i) > 0$, then $x(E^{i,0}) = x(E^{i,+}) = c_i$.*
(A4) *For each $i \in V_0$ and $s \in S$, it holds $x(E^{i,s}) \leq c_i$ and $x(E^{i,s}) \leq \sum_{s' \neq s} x(E^{i,s'})$. If $\mathrm{size}_s(p_i) > 0$, then $x(E^{i,s}) = c_i$.*
(A5) *For each $s \in S$, it holds $x(\delta s) \geq r_s$. If $\mathrm{dist}(0, p_s) > 0$, then $x(\delta s) = r_s$.*

Proof. Let x and p satisfy (A1–5). For the feasibility of x, it is sufficient to show that, for each $s \in S$, there exists a flow satisfying the capacities x and c that connects s and $S \setminus \{s\}$ with flow-value r_s. To prove this, we decompose x into a separately-capacitated multiflow. An *S-path* is a path connecting distinct terminals. Consider the following algorithm, which takes x as an input and outputs a function $\lambda : \mathcal{P} \to \mathbb{R}_+$, where $\mathcal{P}$ is a set of S-paths:

0. Let $\mathcal{P} = \emptyset$.
1. Take $s \in S$ and an edge sj satisfying $x(sj) > 0$. If such a pair does not exist, then stop the algorithm; output $(\mathcal{P}, \lambda)$. Otherwise, let $j_0 \leftarrow s,\ j_1 \leftarrow j,\ \mu \leftarrow x(sj),\ t \leftarrow 1$.
2. If j_t is a terminal, then add $P = (j_0, j_1, \ldots, j_t)$ to $\mathcal{P}$ and let $\lambda(P) := \mu > 0$. Update $x(e) \leftarrow x(e) - \mu$ on each edge e in P, and return to Step 1. Otherwise go to Step 3.
3. If $j_t \in \bigcup_{s \in S} V_s$, then $j_{t-1}j_t \in E^{j_t,+}$ or $j_{t-1}j_t \in E^{j_t,0}$ by (A2) and $x(j_{t-1}j_t) > 0$. In the former case, take $j_t j_{t+1} \in E^{j_t,0}$ with $x(j_t j_{t+1}) > 0$. Such an edge exists by the former part of (A3). In the latter case, take $j_t j_{t+1} \in E^{j_t,+}$ with $x(j_t j_{t+1}) > 0$. Update $\mu \leftarrow \min\{\mu, x(j_t j_{t+1})\},\ t \leftarrow t + 1$, and return to Step 2.

If $j_t \in V_0$, then $j_{t-1}j_t \in E^{j_t,s}$ (as we will show). Take $s' \neq s$ with maximum $x(E^{j_t,s'})$ ($>$ 0), and take $j_tj_{t+1} \in E^{j_t,s'}$ with $x(j_tj_{t+1}) > 0$. Such an edge exists by $x(j_{t-1}j_t) > 0$ and the former part of (A4). Update

$$\mu \leftarrow \min\left\{\mu, x(j_tj_{t+1}), \frac{\min\left\{\sum_{s'''\neq s''} x(E^{j_t,s'''}) - x(E^{j_t,s''}) \mid s'' \neq s, s'\right\}}{2}\right\},$$

and $t \leftarrow t+1$. Note that $\mu > 0$ by the maximality of $x(E^{j_t,s'})$. Return to Step 2.

Suppose that we add $(j_0, j_1, \ldots, j_\ell)$ to $\mathcal{P}$ in Step 2. Observe that j_{t+1} is at a side opposite to j_{t-1} based on j_t for each $t = 1, \ldots, \ell-1$. By the positivity of a and (A2), $\{j_{t-1}, j_t, j_{t+1}\}$ are distinct and

$$\mathrm{dist}(p_{j_{t-1}}, p_{j_{t+1}}) = \mathrm{dist}(p_{j_{t-1}}, p_{j_t}) + \mathrm{size}(p_{j_t}) + \mathrm{dist}(p_{j_t}, p_{j_{t+1}})$$

if $j_t \in \bigcup_{s\in S} V_s$, and

$$\mathrm{dist}(p_{j_{t-1}}, p_{j_{t+1}}) = \mathrm{dist}(p_{j_{t-1}}, p_{j_t}) + \mathrm{size}_s(p_{j_t}) + \mathrm{size}_{s'}(p_{j_t}) + \mathrm{dist}(p_{j_t}, p_{j_{t+1}})$$

if $j_t \in V_0$, where $j_{t-1} \in V_s$ and $j_{t+1} \in V_{s'}$ $(s \neq s')$. Since $\mathbb{T}$ is a tree, we can show

$$\mathrm{dist}(p_{j_0}, p_{j_\ell}) = \sum_{t=0}^{\ell-1} \mathrm{dist}(p_{j_t}, p_{j_{t+1}}) + \sum_{1\leq t\leq \ell-1,\ t\neq t'} \mathrm{size}(p_{j_t}) + \mathrm{size}_{j_0}(p_{j_{t'}}) + \mathrm{size}_{j_\ell}(p_{j_{t'}}) \quad (8)$$

by an induction, where $j_{t'} \in V_0$ (if exists); see also [12, Lemma 3.9]. Hence $(j_0, j_1, \ldots, j_\ell)$ is a "shortest path on $\mathbb{T}$" from j_0 to j_ℓ, and $j_0, \ldots, j_\ell$ are distinct.

Thus after $|V|$ executions of Step 3, the algorithm adds a path P to $\mathcal{P}$ in Step 2. Also the algorithm keeps (A2) and the former parts of (A3–4). To see it for (A4), suppose that the algorithm adds a path $(j_0, j_1, \ldots, j_t, \ldots, j_\ell)$ to $\mathcal{P}$ in Step 2, where $j_0 = s \in S$, $j_t \in V_0$ and $j_\ell = s' \in S$. By the above argument, such t is uniquely determined (if exists). Then for all $s'' \neq s, s'$, we have $\sum_{s'''\neq s''} x(E^{j_t,s'''}) - x(E^{j_t,s''}) \geq 2\mu$. Thus after the decrease of the value of x along with P, it satisfies that $\sum_{s'''\neq s''} x(E^{j_t,s'''}) - x(E^{j_t,s''}) \geq 0$.

After the decrease of the value of x along with a path, it becomes $x(e) = 0$ for at least one edge $e \in E$, or becomes $\sum_{s'\neq s} x(E^{i,s'}) - x(E^{i,s}) = 0$ for at least one pair of $i \in V_0$ and $s \in S$. The algorithm keeps those values to be zero in the remaining execution, implying that it terminates after adding at most $O(m + kn)$ paths to $\mathcal{P}$. To see it, suppose that after the decrease of the value of x along with a path, it becomes $\sum_{s'\neq s} x(E^{i,s'}) - x(E^{i,s}) = 0$ for $i \in V_0$ and $s \in S$. If the algorithm chooses a path $(j_0, \ldots, j_t = i, \ldots, j_\ell)$ for adding to $\mathcal{P}$ in the remaining execution, then by the maximality of $x(E^{i,s})$, it should satisfy that $j_{t-1}j_t \in E^{i,s}$ or $j_tj_{t+1} \in E^{i,s}$. Thus $\sum_{s'\neq s} x(E^{i,s'}) - x(E^{i,s})$ does not change by the decrease of the value of x along with $(j_0, \ldots, j_\ell)$.

We have shown the algorithm always terminates in finite steps. For the output $f = (\mathcal{P}, \lambda)$, let $f(e) := \sum_{P\in\mathcal{P}:e\in P} \lambda(P)$ for $e \in E$, and let $f(i) := \sum_{P\in\mathcal{P}:i\in P} \lambda(P)$ for $i \in V$. Also let $\mathcal{P}_s \subseteq \mathcal{P}$ be the subset of paths connecting s to other terminals, and let $f_s = (\mathcal{P}_s, \lambda_s)$ for $s \in S$. Clearly, it holds that $f(e) \leq x(e) \leq u(e)$ for $e \in E$. For $i \in V_s$ $(s \in S)$, if a path $P \in \mathcal{P}$ goes through i, then P must be contained in $\mathcal{P}_s$. Thus by the former part of (A3), $f_s(i) = f(i) \leq x(E^{i,0})$ $(= x(E^{i,+})) \leq c(i)$. Also, $f_{s'}(i) \leq f_s(i) \leq c(i)$ for any $s' \neq s$. On the other hand, for $i \in V_0$, if a path in $\mathcal{P}_s$ $(s \in S)$ goes through i, then it must include an edge contained in $E^{i,s}$. Thus by the former part of (A4), we have $f_s(i) \leq x(E^{i,s}) \leq c(i)$. Therefore f is a separately-capacitated multiflow. Moreover, f_s satisfies the requirement r by the former part of (A5). Thus x is a feasible solution of FNTB.

We next show the optimality of x and p. First observe that when the algorithm terminates, all edges $e \in E$ satisfy $x(e) = 0$. In fact, if there exists an edge $e \in E$ with $x(e) > 0$, then we can construct an S-path with edges having positive x-values by repeating to apply the former parts of (A3–4). Thus $f(e) = x(e)$ $(e \in E)$ for the original input x. We see that

$$\begin{aligned}
&\sum_{ij\in E} a_{ij}x_{ij} - \sum_{s\in S} r_s \operatorname{dist}(0,p_s) + \sum_{i\in V\setminus S} c_i \operatorname{size}(p_i) + \sum_{ij\in E} u_{ij}(\operatorname{dist}(p_i,p_j) - a_{ij})^+ \\
&= \sum_{ij\in E}(\operatorname{dist}(p_i,p_j) - a_{ij})^+(u_{ij} - x_{ij}) + \sum_{ij\in E}(a_{ij} - \operatorname{dist}(p_i,p_j))^+ x_{ij} + \sum_{ij\in E} x_{ij}\operatorname{dist}(p_i,p_j) \\
&\quad + \sum_{i\in V\setminus S} c_i \operatorname{size}(p_i) - \sum_{s\in S} r_s \operatorname{dist}(0,p_s) \\
&= \sum_{ij\in E}(\operatorname{dist}(p_i,p_j) - a_{ij})^+(u_{ij} - x_{ij}) + \sum_{ij\in E}(a_{ij} - \operatorname{dist}(p_i,p_j))^+ x_{ij} \\
&\quad + \sum_{s\in S}\sum_{i\in V_s}(c_i - f(i))\operatorname{size}(p_i) + \sum_{i\in V_0}\sum_{s\in S}(c_i - f_s(i))\operatorname{size}_s(p_i) + \sum_{s\in S}(f(s) - r_s)\operatorname{dist}(0,p_s), \qquad (9)
\end{aligned}$$

where we use $a + (d-a)^+ = d + (a-d)^+$ for $a, d \in \mathbb{R}$ and

$$\begin{aligned}
&\sum_{ij\in E} f(ij)\operatorname{dist}(p_i,p_j) + \sum_{s\in S}\sum_{i\in V_s} f(i)\operatorname{size}(p_i) + \sum_{i\in V_0}\sum_{s\in S} f_s(i)\operatorname{size}_s(p_i) \\
&= \sum_{ij\in E}\sum_{P\in\mathcal{P}, ij\in E(P)} \lambda(P)\operatorname{dist}(p_i,p_j) \\
&\qquad + \sum_{s\in S}\sum_{i\in V_s}\sum_{P\in\mathcal{P}, i\in V(P)} \lambda(P)\operatorname{size}(p_i) + \sum_{i\in V_0}\sum_{s\in S}\sum_{P\in\mathcal{P}_s, i\in V(P)} \lambda_s(P)\operatorname{size}_s(p_i) \\
&= \sum_{st}\sum_{P\in\mathcal{P}: P \text{ connects } st} \lambda(P)\operatorname{dist}(p_s,p_t) = \sum_{s\in S} f(s)\operatorname{dist}(0,p_s)
\end{aligned}$$

by (8). We see $f(i) = x(E^{i,0})$ $(= x(E^{i,+}))$ for $i \in \bigcup_{s\in S} V_s$, and $f_s(i) = x(E^{i,s})$ for $i \in V_0$ and $s \in S$. Also $f(s) = x(\delta s)$ for $s \in S$. Then (9) is zero by (A1–2) and the latter parts of (A3–5). By Proposition 4, we conclude that x and p are both optimal. ◀

▶ Remark 6. Suppose the input edge-capacity x satisfies $x(\delta i) \in \mathbb{Z}_+$ for any $i \in V$. Then μ is always half-integral, and the integrality of $x(\delta i)$ is also kept in the execution of the algorithm. Thus the output multiflow is half-integer-valued. This argument will be used for proving a min-max theorem (Theorem 2) for a separately-capacitated multiflow later.

The decomposition algorithm is based on [11, Lemma 4.5]; see also [14, Lemma 3.3].

The existence of an edge-capacity x satisfying (A1–5) can be checked by solving the *undirected circulation problem.* This fact leads a simple descent algorithm for DTB and FNTB. Notice that a potential $p : V \to \mathbb{S}$ can be identified with a vector in $\mathbb{S}^n$. For brevity we write $p \in \mathbb{S}^n$ below. Let $h_a = h : \mathbb{S}^n \to \overline{\mathbb{R}}$ be a function defined by

$$h(p) := -\sum_{s\in S} r_s \operatorname{dist}(0,p_s) + \sum_{i\in V\setminus S} c_i \operatorname{size}(p_i) + \sum_{ij\in E} u_{ij}(\operatorname{dist}(p_i,p_j) - a_{ij})^+ \qquad (10)$$

if $p \in \mathbb{S}^n$ is a potential and $h(p) := \infty$ otherwise. Then DTB is precisely a minimization of h over $\mathbb{S}^n$. Consider the following algorithm DESCENT:

Algorithm 1 DESCENT.

```
0. Initialize $p \equiv 0$ (i.e., $p(i) = 0$ for any $i \in V$).
1. Check the sufficiency of the optimality of $p$ by searching $x$ satisfying (A1–5).
2. If $x$ is found, then $x$ and $p$ are optimal; stop.
3. Otherwise find $q \in \mathbb{S}^n$ with $h(q) < h(p)$; update $p$ by $q$ and go to Step 1.
```

We give more details of DESCENT in Section 2.3. As for Step 1, we can also do Step 3 by the undirected circulation problem; q is computed by the certificate of the nonexistence of x. In the following subsections, we introduce the undirected circulation problem and discuss how to find x or q in each case.

2.2 Checking the Optimality

Let (U, F) be an undirected graph, and let $\underline{b} : F \to \underline{\mathbb{R}}$ and $\overline{b} : F \to \overline{\mathbb{R}}$ be lower and upper capacity functions satisfying $\underline{b}(e) \leq \overline{b}(e)$ for each $e \in F$. The graph (U, F) may contain self-loops but no multiedges. The *circulation problem* on $((U, F), \underline{b}, \overline{b})$ is the problem of finding an edge-weight $y : F \to \mathbb{R}$ satisfying $\underline{b}(e) \leq y(e) \leq \overline{b}(e)$ for each $e \in F$ and $\sum_{ij \in F} y(ij) = 0$ for each $i \in U$. Such a y is called a *circulation*.

Let 3^U denote the set of pairs (Y, Z) of two subsets $Y, Z \subseteq U$ with $Y \cap Z = \emptyset$. For $(Y, Z) \in 3^U$, let $\chi_{Y,Z} := \sum_{i \in Y} \chi_i - \sum_{i \in Z} \chi_i \in \mathbb{R}^U$. Define the *cut function* $\kappa : 3^U \to \underline{\mathbb{R}}$ by

$$\kappa(Y, Z) := \sum_{ij \in F} \{(\chi_{Y,Z}(\{i, j\}))^+ \underline{b}(ij) - (\chi_{Z,Y}(\{i, j\}))^+ \overline{b}(ij)\} \quad ((Y, Z) \in 3^U).$$

It is well-known that the feasibility of the circulation problem is characterized via the cut function. We can show it by reducing to Hoffman's circulation theorem. A cut $(Y, Z) \in 3^U$ with $\kappa(Y, Z) > 0$ is called *violating*, and is called *maximum violating* if it attains the maximum $\kappa(Y, Z)$ among all violating cuts.

▶ **Lemma 7** (see, e.g., [16, Theorems 2.4, 2.7]). *Let $((U, F), \underline{b}, \overline{b})$ be an undirected network.*

(1) *The circulation problem is feasible if and only if $\kappa(Y, Z) \leq 0$ for any $(Y, Z) \in 3^U$.*

(2) *If $\underline{b}$ and $\overline{b}$ are integer-valued, then there exists a feasible half-integer-valued circulation $y : E \to \mathbb{Z}^*_+$.*

(3) *Under the same assumption, we can obtain a feasible half-integer-valued circulation or a maximum violating cut in $O(\mathrm{MF}(|U|, |F|))$ time.*

Let us return to our problem. For a given proper potential $p \in \mathbb{S}^n$, the existence of $x : E \to \mathbb{R}_+$ satisfying (A1–5) reduces to the undirected circulation problem on the following network $\mathcal{N}_p := ((U, F), \underline{c}, \overline{c})$. See Figure 2 for the following construction.

For each $i \in \bigcup_{s \in S} V_s$, divide i into two nodes $U_i := \{i^0, i^+\}$, and connect nodes by an edge $i^0 i^+$. For representing (A3), let $\underline{c}(i^0 i^+) := -c_i$, and let $\overline{c}(i^0 i^+) := 0$ if $\mathrm{size}(p_i) = 0$ and $\overline{c}(i^0 i^+) := -c_i$ if $\mathrm{size}(p_i) > 0$. For each $i \in V_0$, divide i into $2k$ nodes $U_i := U_i^0 \cup U_i^+$, where $U_i^0 := \{i^{1,0}, i^{2,0}, \ldots, i^{k,0}\}$ and $U_i^+ := \{i^{1,+}, i^{2,+}, \ldots, i^{k,+}\}$, and connect them by edges $i^{s,0} i^{s,+}$ for $s \in S$ and $i^{s,0} i^{s',0}$ for distinct $s, s' \in S$. For representing (A4), let $\underline{c}(i^{s,0} i^{s,+}) := -c_i$, and let $\overline{c}(i^{s,0} i^{s,+}) := 0$ if $\mathrm{size}_s(p_i) = 0$ and $\overline{c}(i^{s,0} i^{s,+}) := -c_i$ if $\mathrm{size}_s(p_i) > 0$. Also let $\underline{c}(i^{s,0} i^{s',0}) := 0$ and $\overline{c}(i^{s,0} i^{s',0}) := \infty$. For each $s \in S$, let $s^0 := s$ and $U_s := \{s^0\}$, and add a self-loop $s^0 s^0$. For representing (A5), let $\underline{c}(s^0 s^0) := -\infty$ if $\mathrm{dist}(0, p_s) = 0$ and $\underline{c}(s^0 s^0) := -r_s$ if $\mathrm{dist}(0, p_s) > 0$, and let $\overline{c}(s^0 s^0) := -r_s$.

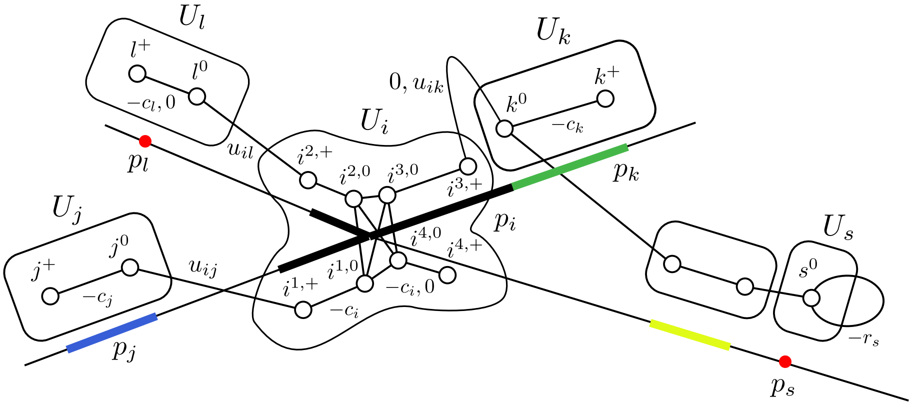

Figure 2 The undirected network $\mathcal{N}_p$.

For each edge $ij \in E$, if $\mathrm{dist}(p_i, p_j) < a_{ij}$, then $x_{ij} = 0$ by (A2). Thus we remove those edges. Let $E_>$ be the set of edges $ij \in E$ with $\mathrm{dist}(p_i, p_j) > a_{ij}$, and let $E_=$ be the set of edges $ij \in E$ with $\mathrm{dist}(p_i, p_j) = a_{ij}$. We replace endpoints of each edge $ij \in E_> \cup E_=$. If $i \in V_0$ and $j \in V_s$, then replace ij with $i^{s,+}j^0$. If $i \in V_s$ and $j \in V_{s'}$ $(s \neq s')$, then replace ij with $i^0 j^0$. If $i, j \in V_s$ and p_i is closer to 0 than p_j, i.e., $\mathrm{dist}(0, p_i) < \mathrm{dist}(0, p_j)$, then replace ij with $i^+ j^0$. We identify those replaced edges with the original edges. Let $\underline{c}(ij) := 0$ if $ij \in E_=$ and $\underline{c}(ij) := u_{ij}$ if $ij \in E_>$, and let $\overline{c}(ij) := u_{ij}$. U and F are defined as the union of all nodes and edges in the above, respectively.

▶ **Theorem 8.** *Let $\mathcal{N}_p = ((U, F), \underline{c}, \overline{c})$ be the undirected network constructed from a proper potential $p \in \mathbb{S}^n$. If it has a (half-integer-valued) circulation $y : F \to \mathbb{R}$, then an edge-capacity function $x : E \to \mathbb{R}_+$ defined by*

$$x(e) := \begin{cases} y(e) & \text{if } e \in E_> \cup E_=, \\ 0 & \text{otherwise } (e = ij \text{ with } \mathrm{dist}(p_i, p_j) < a_{ij}) \end{cases}$$

satisfies (A1–5).

Proof. We can obtain (A1–5) from definitions immediately. For example, the former part of (A4) follows from $x(E^{i,s}) = -y(i^{s,0} i^{s,+}) \leq -\underline{c}(i^{s,0} i^{s,+}) = c_i$ and

$$x(E^{i,s}) = -y(i^{s,0} i^{s,+}) = \sum_{s' \neq s} y(i^{s,0} i^{s',0}) \leq \sum_{s' \neq s} -y(i^{s',0} i^{s',+}) = \sum_{s' \neq s} x(E^{i,s'}),$$

and the latter part of (A4) follows from $-y(i^{s,0} i^{s,+}) \geq -\overline{c}(i^{s,0} i^{s,+}) = c_i$ for $i \in V_0$ and $s \in S$ with $\mathrm{size}_s(p_i) > 0$. ◀

2.3 Finding a Descent Direction

If the algorithm in Lemma 7 outputs a circulation in $\mathcal{N}_p$, then an optimal edge-capacity is computed from the circulation, and p is optimal by Lemma 5 and Theorem 8. Otherwise the algorithm outputs a maximum violating cut. We show that we can find $q \in \mathbb{S}^n$ with $h(q) < h(p)$ using the maximum violating cut. A basic idea is to modify each subtree p_i, according to the intersection pattern of the maximum violating cut with U_i, so that the objective function h decreases. This implies the necessity of Lemma 5 and the strong duality of Proposition 4.

We begin with introducing the notion of *basic moves* for a subtree. For an s-type subtree $T = [l, l']_s$, we denote its endpoints by $v_0(T) := (l, s) \in \mathbb{T}$ and $v_+(T) := (l', s) \in \mathbb{T}$. When we remove T from $\mathbb{T}$, there appear two connected components. Let T'_0 be the component containing $0\,(\in \mathbb{T})$, and T'_+ be the other. We can expand the subtree T by adding a node next to T. There are two nodes next to T, one is contained in T'_0 and the other is contained in T'_+. The 0-*expansion* is the operation to add that node contained in $T_{i,0}$ to T, and the $+$-*expansion* is the operation to add that node contained in $T_{i,+}$ to T. If T satisfies $\mathrm{size}(T) > 0$, then we can shrink T by removing $v_0(T)$ or $v_+(T)$ from T. The 0-*shrinkage* is the operation to remove $v_0(T)$ from T, and the $+$-*shrinkage* is the operation to remove $v_+(T)$ from T.

For a 0-type subtree $T = [l_s]_{s\in S}$, we denote its endpoints by $v_s(T) := (l_s, s) \in \mathbb{T}$ for $s \in S$. When we remove T from $\mathbb{T}$, there appear k $(= |S|)$ connected components. For $s \in S$, let T'_s be the component which is contained in P_s. As above, we can expand the subtree T by adding a node next to T. There are k nodes next to T, and each T'_s $(s \in S)$ contains exactly one such a node. The $(s, +)$-*expansion* for $s \in S$ is the operation to add that node contained in T'_s to T. If T satisfies $\mathrm{size}_s(T) > 0$ for $s \in S$, then we can shrink T by removing $v_s(T)$ from T. The $(s, +)$-*shrinkage* for $s \in S$ with $\mathrm{size}_s(T) > 0$ is the operation to remove $v_s(T)$ from T. For $s \in S$, if $\mathrm{size}_{s'}(T) = 0$ for any other $s' \in S$, then we can shrink T by removing $0\,(\in \mathbb{T})$ from T. The $(s, 0)$-*shrinkage* for such $s \in S$ is the operation to remove 0 from T. We call these expansion and shrinkages *basic moves*.

Let $(Y, Z) \in 3^U$ be a cut. From (Y, Z), the modification $p^{Y,Z}$ of p is defined as follows. For $s \in S$, do:

- If $s^0 \in Y$, then 0-expand and $+$-shrink p_s.
- If $s^0 \in Z$, then $+$-expand and 0-shrink p_s.

For $i \in \bigcup_{s\in S} V_s$, do:

- If $i^0 \in Y$, then 0-expand p_i. If $i^0 \in Z$, then 0-shrink p_i.
- If $i^+ \in Y$, then $+$-expand p_i. If $i^+ \in Z$, then $+$-shrink p_i.

For $i \in V_0$, do:

- If $U_i^0 \cap (Y \cup Z) = \emptyset$, then we do the following for each $s \in S$:
  - If $i^{s,+} \in Y$, then $(s, +)$-expand p_i. If $i^{s,+} \in Z$, then $(s, +)$-shrink p_i.
- If $i^{s,0} \in Z$ for some $s \in S$, then $(s, 0)$-shrink p_i. Also do the following:
  - If $i^{s,+} \in Y$, then $(s, +)$-expand p_i. If $i^{s,+} \in Z$, then $(s, +)$-shrink p_i.

There may exists $i \in V$ that such a move cannot be defined, e.g., $i \in \bigcup_{s\in S} V_s$ with $\mathrm{size}(p_i) \le 1/2$ and $\{i^0, i^+\} \subseteq Z$, or $j \in V_0$ with $\{j^{s,0}, j^{s',0}\} \subseteq Z$. If the moves can be defined for all $i \in V$, then the cut (Y, Z) is called *movable*. For a movable cut $(Y, Z) \in 3^U$, we denote the modified potential by $p^{Y,Z}$.

We cal a node $(l, s) \in \mathbb{T}$ *even* if the number of edges between (l, s) and 0 is even, and *odd* otherwise. A basic move is said to be *upward* if the added node is even or the removed node is odd. A basic move is said to be *downward* if the added node is odd or the removed node is even. A movable cut $(Y, Z) \in 3^U$ is *upward-movable* (resp. *downward-movable*) if all basic moves occurring in the modification from p to $p^{Y,Z}$ are basic upward moves (resp. basic downward moves). Let denote the sets of all upward-movable cuts and downward-movable cuts by $\mathcal{M}^\uparrow$ and $\mathcal{M}^\downarrow$, respectively.

▶ **Lemma 9.** *For $(Y, Z) \in \mathcal{M}^\uparrow \cup \mathcal{M}^\downarrow$, it holds $h(p^{Y,Z}) - h(p) = -\kappa(Y, Z)/2$.*

Thus we are motivated to obtain an upward- or downward-movable cut (Y, Z) with a positive $\kappa(Y, Z)$ value. The following lemma says that we can do this efficiently given a maximum violating cut.

▶ **Lemma 10.** *Given a maximum violating cut, we can obtain an upward-movable cut* $(Y, Z) \in \mathcal{M}^{\uparrow}$ *and a downward-movable cut* $(Y', Z') \in \mathcal{M}^{\downarrow}$ *satisfying*

$$\kappa(Y, Z) = \max_{(Y'', Z'') \in \mathcal{M}^{\uparrow}} \kappa(Y'', Z''), \quad \kappa(Y', Z') = \max_{(Y'', Z'') \in \mathcal{M}^{\downarrow}} \kappa(Y'', Z'') \tag{11}$$

in $O(kn)$ *time. Moreover, at least one of* $\kappa(Y, Z)$ *and* $\kappa(Y', Z')$ *is positive.*

▶ **Theorem 11.** *Let* $\mathcal{N}_p := ((U, F), \underline{c}, \overline{c})$ *be the undirected network constructed from a proper potential* $p \in \mathbb{S}^n$*. Suppose that the instance is infeasible. Given a maximum violating cut, we can obtain a proper potential* $q \in \mathbb{S}^n$ *with* $h(q) < h(p)$ *in* $O(kn)$ *time.*

Proof. By Lemma 10, we can obtain an upward-movable cut $(Y, Z) \in \mathcal{M}^{\uparrow}$ and a downward-movable cut $(Y', Z') \in \mathcal{M}^{\downarrow}$ satisfying (11) in $O(kn)$ time. Let (Y'', Z'') be the cut that attains maximum κ-value among $\{(Y, Z), (Y', Z')\}$, and let $q := p^{Y'', Z''}$. Then $h(q) < h(p)$ by Lemmas 9 and 10. We can make q proper by the procedure given in the first part of the proof of Proposition 4. ◀

Now we are ready to present the details of DESCENT. First construct $\mathcal{N}_p$ from the current proper potential $p \in \mathbb{S}^n$, and run the algorithm given in Lemma 7 to solve the circulation problem; this corresponds to Step 1 given in the procedure at the end of Section 2.1. If a feasible half-integer-valued circulation is obtained, then a half-integral optimal edge-capacity x is computed by Theorem 8; this corresponds to Step 2. Otherwise a maximum violating cut is obtained, and then a proper potential $q \in \mathbb{S}^n$ with $h(q) < h(p)$ is computed by Theorem 11; this corresponds to Step 3. One iteration of this algorithm can be done in $O(\mathrm{MF}(kn, m + k^2 n))$ time.

The value $-h(p)$ is at most mUA (by Proposition 4) and $-h(p) \in \mathbb{Z}^*_+$. Thus the number of iterations is at most $O(mUA)$. Actually, this analysis of the time complexity is not tight. In fact, the number of iterations can be evaluated as $O(nA)$.

If a potential $q \in \mathbb{S}^n$ is obtained from a potential p by a modification defined by a movable cut on $\mathcal{N}_p$, then we say that q is a *neighbor* of p, that is, there exists a movable cut $(Y', Z') \in 3^U$ such that $q = p^{Y', Z'}$. For $p, q \in \mathbb{S}^n$, define a distance $\tilde{d}_{\mathbb{S}^n}(p, q)$ by the minimum length of a sequence $(p = p_0, p_1, \dots, p_\ell = q)$ such that p_t is a neighbor of p_{t-1} for all $t = 1, \dots, \ell$. Let $\mathrm{opt}(h)$ denote the set of minimizers of h, and let $\tilde{d}_{\mathbb{S}^n}(p, \mathrm{opt}(h)) := \min_{q \in \mathrm{opt}(h)} \tilde{d}_{\mathbb{S}^n}(p, q)$.

▶ **Lemma 12.** *Starting with an initial potential* $p_0 \in \mathbb{S}^n$*, DESCENT finds an optimal potential at most* $\tilde{d}_{\mathbb{S}^n}(p_0, \mathrm{opt}(h)) + 2$ *iterations.*

Lemma 12 can be shown by using *DCA beyond* $\mathbb{Z}^n$. We will discuss it in Section 3.

▶ **Lemma 13.** *There exists an optimal potential* $p \in \mathrm{opt}(h)$ *satisfying that for any* $i \in V$*,* p_i *is contained in* $(2nA, 2nA, \dots, 2nA) \in \mathbb{S}$.

▶ **Theorem 14.** *DESCENT solves FNTB in* $O(nA \cdot \mathrm{MF}(kn, m + k^2 n))$ *time.*

Proof. We can only consider the potentials satisfying the condition in Lemma 13. Any pair of such potentials $p, q \in \mathbb{S}$ satisfies $\tilde{d}_{\mathbb{S}^n}(p, q) = O(nA)$. Then the statement follows from Lemma 12. ◀

We note that Theorem 14 is shown under the positivity assumption of the edge-cost a. We prove Theorem 2 using Theorem 14.

Proof of Theorem 2. Let $f = (\mathcal{P}, \lambda)$ be a separately-capacitated multiflow. Recall that $f_s = (\mathcal{P}_s, \lambda|_{\mathcal{P}_s})$, where $\mathcal{P}_s \subseteq \mathcal{P}$ is a subset of paths connecting s to other terminals. Let $\operatorname{val} f := \sum_{P \in \mathcal{P}} \lambda(P)$ and $\operatorname{val} f_s := \sum_{P \in \mathcal{P}_s} \lambda(P)$ for $s \in S$. Then $\operatorname{val} f_s$ is at most the capacity of any $\{s\}$–$(S \setminus \{s\})$ cut. Thus $\operatorname{val} f = (1/2) \sum_{s \in S} \operatorname{val} f_s \leq (1/2) \sum_{s \in S} \nu_s$.

Consider an instance $((V,E), S, u, c, a, r)$ of FNTB, where $a \equiv 1$ and $r_s := \nu_s$ for each $s \in S$. Since u clearly satisfies (1), this instance is feasible. Then DESCENT outputs a half-integral optimal edge-capacity x and an optimal potential p. Since x and p satisfy the conditions (A1–5), we can apply the decomposition algorithm in the proof of Lemma 5 for x, and obtain a separately-capacitated multiflow f. Then $\operatorname{val} f = (1/2) \sum_{s \in S} f(s) \geq (1/2) \sum_{s \in S} r_s = (1/2) \sum_{s \in S} \nu_s$. Moreover, since x comes from a half-integral circulation (Theorem 8), x satisfies $x(\delta i) \in \mathbb{Z}_+$ for any $i \in V \setminus S$. In fact, for $i \in \bigcup_{s \in S} V_s$, it is observed from $x(\delta i) = -2y(i^0 i^+)$, and for $i \in V_0$, it is observed from $x(\delta i) = \sum_{s \in S} -y(i^{s,0} i^{s,+}) = 2 \sum_{s < s'} y(i^{s,0}, i^{s',0})$. Then by Remark 6, the decomposition algorithm outputs a half-integer-valued multiflow.

The time complexity result follows from that FNTB can be solved in $O(n \cdot \mathrm{MF}(kn, m + k^2 n))$ time by Theorem 14, and the decomposition algorithm runs in $O((m + kn)n)$ time. ◀

2.4 Scaling Algorithm

The time complexity of DESCENT is pseudo-polynomial. We improve it by combining with a (cost-)scaling method.

Let $\gamma \in \mathbb{Z}_+$ be an integer such that $2^\gamma \geq A$. The scaling algorithm consists of $\gamma + 1$ phases. In t-th phase, solve DTB with an edge-cost $a_t : E \to \mathbb{Z}_+$ defined by $a_t(e) := \lceil a(e)/2^t \rceil$ $(e \in E)$, i.e., minimize h_{a_t}. (Recall h_a is defined by (10).) Here $\lceil \cdot \rceil$ is the round-up operator. Note that all $a_t(e)$ are positive. Begin with $t = \mu$, and decrease t one-by-one. Then, when $t = 0$, the problem coincides with the original DTB. In each t-phase, we use DESCENT to minimize h_{a_t}. At the initial phase $t = \mu$, we run DESCENT with the starting point $p_0 \in \mathbb{S}^n$, where $(p_0)_i = 0$ for all $i \in V$. For t-phase with $t \leq \mu - 1$, the starting point is determined from the obtained optimal potential in the previous phase. Let $2[l, l']_s := [2l, 2l']_s$ and $2[l_s]_{s \in S} := [2l_s]_{s \in S}$. For a potential $p \in \mathbb{S}^n$, define a new potential $2p \in \mathbb{S}^n$ by $(2p)_i := 2p_i$ for $i \in V$.

▶ **Lemma 15.** *Let $p \in \mathbb{S}^n$ be an optimal potential for t-phase ($t = 1, \ldots, \mu$). Then the potential $2p \in \mathbb{S}^n$ is optimal for DTB with an edge-cost $2a_t$.*

Proof. By the strong duality of Proposition 4, there exists a solution $x : E \to \mathbb{R}$ for FNTB, such that $\sum_{e \in E} a_t(e) x(e) = -h_{a_t}(p)$. Then $\sum_{e \in E} 2a_t(e) x(e) = -h_{2a_t}(2p)$ holds, which implies the optimality of $2p$ by (the weak duality of) Proposition 4. ◀

Observe that $a_{t-1} = 2a_t - \sum_{e \in F} \chi_e$, where $F := \{e \in E \mid a_{t-1}(e) \text{ is odd}\}$. The key property is the following sensitivity result.

▶ **Lemma 16.** *Let $a : E \to \mathbb{Z}_+$ be a positive edge-cost. Let $e \in E$ be an edge satisfying $a(e) \geq 2$, and $a' := a - \chi_e$. Let $p \in \operatorname{opt}(h_a)$. Then $\tilde{d}_{\mathbb{S}^n}(p, \operatorname{opt}(h_{a'})) \leq 2$.*

We prove Lemma 16 in Section 3.3 using the notion of discrete convexity.

Proof of Theorem 1. For the initial phase $t = \mu$, an optimal potential can be obtained in $O(n)$ iterations of DESCENT by Lemmas 12 and 13. For each remaining phase, an optimal potential can be obtained in $O(m)$ iterations of DESCENT by Lemmas 12, 15 and 16. Thus $O(n + m \log A) = O(m \log A)$ iterations of DESCENT are sufficient. Recall that we assume the positivity of the edge-cost a. When a is not positive, the perturbation (Remark 3) is needed. Thus the maximum of edge-costs is $O(mUA)$. Then the theorem follows. ◀

3 Discrete Convex Analysis for Node-Connectivity Terminal Backup

The theory of DCA beyond $\mathbb{Z}^n$ gives an algorithm, called the steepest descent algorithm (SDA), for minimizing L-convex functions on certain graph structures. We first introduce the L-convexity and SDA, and next show that DESCENT is precisely SDA for an L-convex function. Then Lemma 12 immediately follows. Finally, we discuss a sensitivity argument, which shows Lemma 16.

3.1 A General Theory

In this subsection, we briefly introduce a theory of discrete convexity on graph structures specialized to median graphs. See [15] for further details.

We use basic terminologies of poset and lattice. Let $\mathcal{L}$ be a poset (partially ordered set) with a partial order $\preceq$. The *principal filter* $\mathcal{F}_x$ and the *principal ideal* $\mathcal{I}_x$ of $x \in \mathcal{L}$ are defined as $\{y \in \mathcal{L} \mid y \succeq x\}$ and $\{y \in \mathcal{L} \mid y \preceq x\}$, respectively. For $x, y \in \mathcal{L}$ with $x \preceq y$, the *interval* $[x, y]$ is defined as the set of $z \in \mathcal{L}$ satisfying $x \preceq z \preceq y$. We consider a (meet-)semilattice having the minimum element. A *median semilattice* $\mathcal{L}$ is a semilattice that every principal ideal is a distributive lattice and for any $x, y, z \in \mathcal{L}$, the join $x \vee y \vee z$ exists if $x \vee y$, $y \vee z$, and $z \vee x$ exist. A *Boolean semilattice* is a median semilattice that every principal ideal is a Boolean lattice.

Let G be a (possibly infinite) undirected graph. We denote the set of nodes also by G. Let $d = d_G$ be the shortest path metric on G. The *(metric) interval* $I(u, v)$ of $u, v \in G$ is the set of $w \in G$ satisfying $d(u, v) = d(u, w) + d(w, v)$. A *median* graph G is a graph that for any $u, v, w \in G$, $I(u, v) \cap I(v, w) \cap I(w, u)$ is a singleton.

We consider an *orientation* on edges of a median graph G, that takes $u \searrow v$ or $u \swarrow v$ on each edge uv. An orientation is *admissible* if for any 4-cycle (u_1, u_2, u_3, u_4), $u_1 \searrow u_2$ implies $u_4 \searrow u_3$. It is known [13, Lemma 2.4] that an admissible orientation on a median graph is acyclic. Thus we can define a poset on G by the admissible orientation, i.e., if an edge uv is oriented as $u \swarrow v$, then $u \preceq v$. G with an admissible orientation is *well-oriented* if $[u, v]$ is a Boolean lattice for any u, v with $u \preceq v$. In a well-oriented median graph G, it is known [15, Proposition 2] that every principal filter of G is a Boolean semilattice, and every principal ideal of G is a Boolean semilattice with the reversed order.

We can define an L-convex function on a well-oriented median graph G. For a function $f : G \to \overline{\mathbb{R}}$, define the *effective domain* of f as $\{u \in G \mid f(u) < \infty\}$ and denote by $\operatorname{dom} f$. If a sequence of nodes $(u = u_0, u_1, \ldots, u_\ell = v)$ satisfies that for any $i = 1, \ldots, \ell$, there exist $u', v' \in G$ with $u' \preceq v'$ such that $\{u_{i-1}, u_i\} \subseteq [u', v']$, then the sequence is said to be a Δ-*path* connecting u and v. A subset $X \subseteq G$ is Δ-*connected* if for any $u, v \in X$, there exists a Δ-path in X connecting u and v. A function $f : G \to \overline{\mathbb{R}}$ is called *L-convex* if $\operatorname{dom} f$ is Δ-connected and the restrictions of f to every principal filter and ideal are submodular. Here the *submodularity* on a median semilattice is a rather complicated notion; we give a formal definition in the full version.

The global optimality of an L-convex function f can be characterized by a *local* condition; $u \in \operatorname{dom} f$ is a minimizer of f if and only if u is a minimizer of f restricted to $\mathcal{F}_u \cup \mathcal{I}_u$. This induces a natural minimization algorithm, called the *steepest descent algorithm* (SDA):

Algorithm 2 SDA.

```
0. Initialize $u \in G$ with $f(u) < \infty$.
1. Find a local minimizer $v \in \mathcal{F}_u \cup \mathcal{I}_u$ of $f$.
2. If $f(v) = f(u)$, then stop; output $u$. Otherwise update $u$ by $v$ and go to Step 1.
```

The number of iterations of SDA is bounded by the Δ-distance from the initial point u and minimizers of f. Here the *Δ-distance* $d^{\Delta}(u,v)$ of $u,v \in G$ is the minimum length of a Δ-path connecting u to v. Let $\mathrm{opt}(f)$ denote the set of minimizers of f, and let $d^{\Delta}(u, \mathrm{opt}(f)) := \min_{v \in \mathrm{opt}(f)} d^{\Delta}(u,v)$.

▶ **Theorem 17** ([15, Theorem 4.3]). *The number of iterations of SDA with the initial point $u \in G$ is at most $d^{\Delta}(u, \mathrm{opt}(f)) + 2$.*

3.2 Discrete Convexity in Node-Connectivity Terminal Backup

We show that the dual objective function h defined in (10) is actually an L-convex function, and the algorithm DESCENT is precisely SDA. Define a graph on $\mathbb{S}$ by connecting two nodes (subtrees) $T, T' \in \mathbb{S}$ such that T and T' can transform to each other by a basic move. If we can move T to T' by a basic downward-move (equivalently, we can move T' to T by a basic upward-move), we give an orientation $T \searrow T'$. The graph $\mathbb{S}$ is a median graph, but not well-oriented. To make the graph well-oriented, we add a virtual subtree connecting to nodes (l,s) and $(l+1/2, s)$ for each $l \in \mathbb{Z}_+^*$ and $s \in S$. We denote such a virtual subtree by $[l+1/2, l]_s$. Give a natural orientation to each added edge. Let $\overline{\mathbb{S}} := \mathbb{S} \cup \{[l+1/2,l]_s \mid l \in \mathbb{Z}_+^*, s \in S\}$. Extend h to be a function on $\overline{\mathbb{S}}^n$ by $h(p) := \infty$ if there exists $i \in V$ such that $p_i \in \overline{\mathbb{S}} \setminus \mathbb{S}$.

▶ **Proposition 18.**

(1) *$\overline{\mathbb{S}}$ is a well-oriented median graph, and so is $\overline{\mathbb{S}}^n$.*

(2) *h is an L-convex function on $\overline{\mathbb{S}}^n$.*

(3) *For $p, q \in \mathbb{S}^n$, $\tilde{d}_{\mathbb{S}^n}(p,q) = d^{\Delta}(p,q)$.*

(4) *The map $(Y,Z) \mapsto p^{Y,Z}$ is a bijection between $\mathcal{M}^{\uparrow}$ and $\mathcal{F}_p \cap \mathrm{dom}\, h$, and $\mathcal{M}^{\downarrow}$ and $\mathcal{I}_p \cap \mathrm{dom}\, h$.*

Proof of Lemma 12. By Lemma 9 and Proposition 18 (4), the cuts (Y,Z) and (Y',Z') in Lemma 10 are minimizers of h on $\mathcal{F}_p$ and $\mathcal{I}_p$, respectively. Therefore DESCENT is precisely SDA for h. Thus the number of iterations can be evaluated by Theorem 17, and the statement follows from Proposition 18 (3). ◀

3.3 Sensitivity

To prove Lemma 16, we transform the instance $((V,E), S, u, c, a, r)$ of FNTB to an edge-uncapacitated one by a standard technique: Divide each edge $e \in E$ into two edges e_1, e_2, and add a new node v_e into the middle of these two edges. Let the edge-costs of e_1 and e_2 be the same as the original edge-cost of e, and let the edge-capacities of e_1 and e_2 be ∞. Let the node-capacity of the added node be $u(e)$. The number of vertices in the new instance is $|V| + |E| = n + m$, and the number of edges is $2|E| = 2m$. We denote the new instance by $((\bar{V}, \bar{E}), S, \bar{u}, \bar{c}, \bar{a}, r)$.

We consider the dual problem DTB for the edge-uncapacitated instance. In this case, we say that $\bar{p} \in \mathbb{S}^{n+m}$ is a *potential* for an edge-cost $\bar{a}$ if it satisfies (4) and $\mathrm{dist}(\bar{p}_i, \bar{p}_j) \leq \bar{a}_{ij}$ for any $ij \in \bar{E}$. Then DTB is a minimization of a function $h_a : \mathbb{S}^n \to \overline{\mathbb{R}}$ defined by

$$\bar{h}_{\bar{a}}(\bar{p}) := -\sum_{s \in S} r_s \,\mathrm{dist}(0, \bar{p}_s) + \sum_{i \in \bar{V} \setminus S} \bar{c}_i \,\mathrm{size}(\bar{p}_i) \tag{12}$$

if $\bar{p}$ is a potential for $\bar{a}$ and $\bar{h}_{\bar{a}}(\bar{p}) := \infty$ otherwise.

Let $p \in \mathbb{S}^n$ be a potential for the original instance. We can extend p to a potential $\bar{p}$ for the edge-uncapacitated instance as follows: For $v = i \in V$, let $\bar{p}_v := 2p_i$. For $v = v_{ij}$ ($ij \in E$), we have two cases $\mathrm{dist}(p_i, p_j) \leq a_{ij}$ and $\mathrm{dist}(p_i, p_j) > a_{ij}$. For the former case, let $\bar{p}_v$ be any point in $\mathbb{T}$ (i.e., $\mathrm{size}(\bar{p}_v) = 0$) satisfying $\mathrm{dist}(\bar{p}_i, \bar{p}_v) \leq a_{ij}$ and $\mathrm{dist}(\bar{p}_v, \bar{p}_j) \leq a_{ij}$. For the latter case, let $\bar{p}_v$ satisfy $\mathrm{dist}(\bar{p}_i, \bar{p}_v) = a_{ij}$, $\mathrm{dist}(\bar{p}_v, \bar{p}_j) = a_{ij}$ and $\mathrm{size}(\bar{p}_v) = 2(\mathrm{dist}(\bar{p}_v, \bar{p}_j) - a_{ij}) > 0$.

▶ **Proposition 19.** *Let $p \in \mathbb{S}^n$ be an optimal potential for the original instance. Then the extended potential $\bar{p} \in \mathbb{S}^{n+m}$ defined above is optimal for the edge-uncapacitated instance.*

We first show Lemma 16 for an edge-uncapacitated instance. For brevity, we assume that the original instance $((V, E), S, u, c, a, r)$ is already an edge-capacitated instance. By Proposition 18 (3), the following is equivalent to Lemma 16.

▶ **Lemma 20.** *Let $a : E \to \mathbb{Z}_+$ be a positive edge-cost. Let $ij \in E$ be an edge satisfying $a(ij) \geq 2$, and $a' := a - \chi_{ij}$. Then for any $p \in \mathrm{opt}(h_a)$, it holds $d^\Delta(p, \mathrm{opt}(h_{a'})) \leq 2$.*

We prove Lemma 20 via the notion of *normal Δ-paths*. Let G be an oriented median graph. For nodes $u, v \in G$ with $d^\Delta(u, v) = 1$, let $\langle\langle u, v\rangle\rangle$ be the minimum interval $[u', v']$ such that $\{u, v\} \subseteq [u', v']$. A Δ-path $(u = u_0, u_1, \ldots, u_\ell = v)$ is the *normal Δ-path* from u to v if for any $t = 1, \ldots, \ell - 1$ and any interval $[u', v']$ with $\{u_{t-1}, u_t\} \subseteq [u', v']$ it holds $[u', v'] \cap \langle\langle u_t, u_{t+1}\rangle\rangle = \{u_t\}$. The normal Δ-path from u to v is uniquely determined, and the length ℓ equals to ${d_G}^\Delta(u, v)$ [3, Theorem 6.24]. Let $u \to v$ denote u_1, and let $u \twoheadrightarrow v$ denote $u_{\ell-1}$. Also Let $u \to^t v$ denote u_t for $t = 0, \ldots, \ell$.

▶ **Lemma 21.** *Let $p, q \in \mathrm{dom}\, h_a$. Then*

$$h_a(p) + h_a(q) \geq h_a(p \to q) + h_a(q \to p), \tag{13}$$

$$h_a(p) + h_a(q) \geq h_a(p \twoheadrightarrow q) + h_a(q \twoheadrightarrow p). \tag{14}$$

▶ **Lemma 22.** *Let $p, q \in \overline{\mathbb{S}}^n$ and $i, j \in V$. Suppose that $\mathrm{dist}(q_i, q_j) < \mathrm{dist}((q \to p)_i, (q \to p)_j)$ and $\mathrm{dist}(q_i, q_j) < \mathrm{dist}((p \twoheadrightarrow q)_i, (p \twoheadrightarrow q)_j)$. Then for any $t = 1, \ldots, d^\Delta(p, q)$, it holds $\mathrm{dist}((p \to^t q)_i, (p \to^t q)_j) + 1/2 \leq \mathrm{dist}((p \to^{t-1} q)_i, (p \to^{t-1} q)_j)$.*

Proof of Lemma 20. If p is a potential for a', then $p \in \mathrm{opt}(h_{a'})$. Suppose that p is not a potential for a'. Take $q \in \mathrm{opt}(h_{a'})$ having the minimum Δ-distance from p. Then $q \in \mathrm{dom}\, h_a$. Thus by (13) and $p \in \mathrm{opt}(h_a)$, we have $h_a(q) \geq h_a(q \to p)$. If $(q \to p) \in \mathrm{dom}\, h_{a'}$, then $h_{a'}(q \to p) = h_a(q \to p) \leq h_a(q) = h_{a'}(q)$ and thus $(q \to p) \in \mathrm{opt}(h_{a'})$; a contradiction to the minimality of q. Hence $(q \to p) \notin \mathrm{dom}\, h_{a'}$, and $\mathrm{dist}((q \to p)_i, (q \to p)_j) \geq a'_{ij} + 1/2 > a'_{ij} \geq \mathrm{dist}(q_i, q_j)$ (by the half-integrality of $\mathrm{dist}(\cdot, \cdot)$). Similarly we have $\mathrm{dist}((p \twoheadrightarrow q)_i, (p \twoheadrightarrow q)_j) > \mathrm{dist}(q_i, q_j)$. Then we can apply Lemma 22 and obtain

$$\begin{aligned} \mathrm{dist}(p_i, p_j) &\geq \mathrm{dist}((p \to q)_i, (p \to q)_j) + 1/2 \\ &\geq \mathrm{dist}((p \to^2 q)_i, (p \to^2 q)_j) + 2/2 \\ &\geq \cdots \geq \mathrm{dist}((p \twoheadrightarrow q)_i, (p \twoheadrightarrow q)_j) + (d^\Delta(p, q) - 1)/2. \end{aligned}$$

By $\mathrm{dist}(p_i, p_j) \leq a_{ij}$ and $\mathrm{dist}((p \twoheadrightarrow q)_i, (p \twoheadrightarrow q)_j) \geq a'_{ij} + 1/2 = a_{ij} - 1/2$, we have

$$d^\Delta(p, q) \leq 1 + 2(\mathrm{dist}(p_i, p_j) - \mathrm{dist}((p \twoheadrightarrow q)_i, (p \twoheadrightarrow q)_j)) \leq 2. \qquad ◀$$

We give a sketch of a proof of Lemma 16 for an edge-capacitated instance. First construct the edge-uncapacitated instance $((\bar{V}, \bar{E}), S, \bar{u}, \bar{c}, \bar{a}, r)$ as above. Then an optimal potential $\bar{p} \in \mathbb{S}^{n+m}$ is obtained from p by Proposition 19, and $e \in E$ is divided into two edges

$e_1, e_2 \in \bar{E}$. By Lemma 20 for e_1 and e_2, there exists an optimal potential $\bar{p}'$ for the edge-uncapacitated instance with $d^{\Delta}(\bar{p}, \bar{p}') \leq 4$. By halving $\bar{p}'$, a "quarter-integral" optimal potential $p' \in \mathrm{opt}(h_{a'})$ is obtained. Lemma 16 is then shown by rounding quarter-integral components to half-integral.

Abstract

We consider the complexity of counting weighted graph homomorphisms defined by a symmetric matrix A. Each symmetric matrix A defines a graph homomorphism function $Z_A(\cdot)$, also known as the partition function. Dyer and Greenhill [10] established a complexity dichotomy of $Z_A(\cdot)$ for symmetric $\{0,1\}$-matrices A, and they further proved that its #P-hardness part also holds for bounded degree graphs. Bulatov and Grohe [4] extended the Dyer-Greenhill dichotomy to nonnegative symmetric matrices A. However, their hardness proof requires graphs of arbitrarily large degree, and whether the bounded degree part of the Dyer-Greenhill dichotomy can be extended has been an open problem for 15 years. We resolve this open problem and prove that for nonnegative symmetric A, either $Z_A(G)$ is in polynomial time for all graphs G, or it is #P-hard for bounded degree (and simple) graphs G. We further extend the complexity dichotomy to include nonnegative vertex weights. Additionally, we prove that the #P-hardness part of the dichotomy by Goldberg et al. [12] for $Z_A(\cdot)$ also holds for simple graphs, where A is any real symmetric matrix.

1 Introduction

The modern study of graph homomorphisms originates from the work by Lovász and others several decades ago and has been a very active area [18, 14]. If G and H are two graphs, a graph homomorphism (GH) is a mapping $f\colon V(G) \to V(H)$ that preserves vertex adjacency, i.e., whenever (u, v) is an edge in G, $(f(u), f(v))$ is also an edge in H. Many combinatorial problems on graphs can be expressed as graph homomorphism problems. Well-known examples include the problems of finding a proper vertex coloring, vertex cover, independent

set and clique. For example, if $V(H) = \{0,1\}$ with an edge between 0 and 1 and a loop at 0, then $f\colon V(G) \to \{0,1\}$ is a graph homomorphism iff $f^{-1}(1)$ is an independent set in G; similarly, proper vertex colorings on G using at most m colors correspond to homomorphisms from G to $H = K_m$ (with no loops).

More generally, one can consider weighted graphs H and aggregate all homomorphisms from G to H into a weighted sum. This is a powerful graph invariant which can express many graph properties. Formally, for a symmetric $m \times m$ matrix A, the *graph homomorphism function* on a graph $G = (V, E)$ is defined as follows:

$$Z_A(G) = \sum_{\xi: V \to [m]} \prod_{(u,v) \in E} A_{\xi(u),\xi(v)}.$$

Note that if H is unweighted, and A is its $\{0,1\}$-adjacency matrix, then each product $\prod_{(u,v)\in E} A_{\xi(u),\xi(v)}$ is 0 or 1, and is 1 iff ξ is a graph homomorphism. Thus in this case $Z_A(G)$ counts the number of homomorphisms from G to H. One can further allow H to have vertex weights. In this case, we can similarly define the function $Z_{A,D}(\cdot)$ (see Definition 4).

These sum-of-product functions $Z_A(\cdot)$ and $Z_{A,D}(\cdot)$ are referred to as the *partition functions* in statistical physics [3]. Various special cases of GH have been studied there extensively, which include the Ising, Potts, hardcore gas, Beach, Widom-Rowlinsom models, etc. [3].

The computational complexity of $Z_A(\cdot)$ has been studied systematically. Dyer and Greenhill [10, 11] proved that, for a symmetric $\{0,1\}$-matrix A, $Z_A(\cdot)$ is either in polynomial time or #P-complete, and they gave a succinct condition for this complexity dichotomy: if A satisfies the condition then $Z_A(\cdot)$ is computable in polynomial time (we also call it *tractable*), otherwise it is #P-complete. Bulatov and Grohe [4] (see also [22, 13]) generalized the Dyer-Greenhill dichotomy to $Z_A(\cdot)$ for nonnegative symmetric matrices A. It was further extended by Goldberg et al. [12] to arbitrary real symmetric matrices, and finally by Cai, Chen and Lu [7] to arbitrary complex symmetric matrices. In the last two dichotomies, the tractability criteria are not trivial to state. Nevertheless, both tractability criteria are decidable in polynomial time (in the size of A).

The definition of the partition function $Z_A(\cdot)$ can be easily extended to directed graphs G and arbitrary (not necessarily symmetric) matrices A corresponding to directed edge weighted graphs H. Concerning the complexity of counting directed GH, we currently have the *decidable* dichotomies by Dyer, Goldberg and Paterson [9] for $\{0,1\}$-matrices corresponding to (unweighted) simple acyclic graphs H, and by Cai and Chen [6] for all nonnegative matrices A.

Dyer and Greenhill in the same paper [10] proved a stronger statement that if a $\{0,1\}$-matrix A fails the tractability condition then $Z_A(G)$ is #P-complete even when restricted to bounded degree graphs G. We note that the complexity of GH for bounded degree graphs is particularly interesting as much work has been done on the approximate complexity of GH focused on bounded degree graphs and approximate algorithms are achieved for them [8, 25, 21, 20, 17, 1, 2, 19, 15]. However, for fifteen years the worst case complexity for bounded degree graphs in the Bulatov-Grohe dichotomy was open. Since this dichotomy is used essentially in almost all subsequent work, e.g., [12, 7], this has been a stumbling block.

Our main contribution in this paper is to resolve this 15-year-old open problem. We prove that the #P-hardness part of the Bulatov-Grohe dichotomy still holds for *bounded degree graphs*. It can be further strengthened to apply to bounded degree *simple* graphs. We actually prove a broader dichotomy for $Z_{A,D}(\cdot)$, where in addition to the nonnegative symmetric edge weight matrix A there is also a nonnegative diagonal vertex weight matrix D. We will give an explicit tractability condition such that, if (A, D) satisfies the condition then $Z_{A,D}(G)$ is computable in polynomial time for all G, and if it fails the condition then $Z_{A,D}(G)$ is #P-hard even restricted to *bounded degree simple graphs* G. $Z_A(G)$ is the special case of $Z_{A,D}(G)$ when D is the identity matrix. Additionally, we prove that the #P-hardness part of the dichotomy by Goldberg et al. [12] for all real symmetric edge weight matrices A still holds for *simple graphs*. (Although in this case, whether under the same condition on A the #P-hardness still holds for bounded degree graphs is not resolved in the present paper.)

In order to prove the dichotomy theorem on bounded degree graphs, we have to introduce a nontrivial extension of the well-developed interpolation method [24]. We use some of the well-established techniques in this area of research such as stretchings and thickenings. But the main innovation is an overall design of the interpolation for a more abstract target polynomial than $Z_{A,D}$. To carry out the proof there is an initial condensation step where we combine vertices that have proportionately the same neighboring edge weights (technically defined by pairwise linear dependence) into a super vertex with a combined vertex weight. Note that this creates vertex weights even when initially all vertex weights are 1. When vertex weights are present, an approach in interpolation proof is to arrange things well so that in the end one can redistribute vertex weights to edge weights. However, when edge weights are not 0-1, any gadget design must deal with a quantity at each vertex that cannot be directly *redistributed*. This dependence has the form $\sum_{j=1}^{m_{\zeta(w)}} \alpha_{\zeta(w)j}\mu_{\zeta(w)j}^{\deg(w)}$, resulting from combining pairwise linearly dependent rows and columns, that depends on the vertex degree $\deg(w)$ in a complicated way. (We note that in the 0-1 case all $\mu_{\zeta(w)j} \in \{0, 1\}$, making it in fact degree *independent*.)

We overcome this difficulty by essentially introducing a virtual level of interpolation – an interpolation to realize some "virtual gadget" that cannot be physically realized, and yet its "virtual" vertex weights are suitable for redistribution. Technically we have to define an auxiliary graph G', and express the partition function in an extended framework, called $Z_{\mathscr{A},\mathscr{D}}$ on G' (see Definition 6). In a typical interpolation proof, there is a polynomial with coefficients that have a clear combinatorial meaning defined in terms of G, usually consisting of certain sums of exponentially many terms in some target partition function. Here, we will define a target polynomial with certain coefficients; however these coefficients do not have a direct combinatorial meaning in terms of $Z_{A,D}(G)$, but rather they only have a direct combinatorial meaning in terms of $Z_{\mathscr{A},\mathscr{D}}$ on G'. In a suitable "limiting" sense, a certain aggregate of these coefficients forms some useful quantity in the final result. This introduces a concomitant "virtual" vertex weight which depends on the vertex degree that is "just-right" so that it can be redistributed to become part of the incident edge weight, thus effectively killing the vertex weight. This leads to a reduction from $Z_C(\cdot)$ (without vertex weight) to $Z_{A,D}(\cdot)$, for some C that inherits the hardness condition of A, thus proving the #P-hardness of the latter. This high level description will be made clearer in Section 4. The nature of the degree dependent vertex weight introduces a substantial difficulty; in particular a direct adaptation of the proof in [10] does not work.

Our extended vertex-weighted version of the Bulatov-Grohe dichotomy can be used to correct a crucial gap in the proof by Thurley [23] for a dichotomy for $Z_A(\cdot)$ with Hermitian edge weight matrices A, where this degree dependence was also at the root of the difficulty. [2]

[2] In [23], the proof of Lemma 4.22 uses Lemma 4.24. In Lemma 4.24, A is assumed to have pairwise linearly independent rows while Lemma 4.22 does not assume this, and the author appeals to a twin reduction step in [10]. However, unlike in the 0-1 case [10], such a step incurs degree dependent vertex weights. This gap is fixed by our Theorem 8.

2 Preliminaries

In order to state all our complexity results in the strict notion of Turing computability, we adopt the standard model [16] of computation for partition functions, and require that all numbers be from an arbitrary but fixed algebraic extension of $\mathbb{Q}$. We use $\mathbb{R}$ and $\mathbb{C}$ to denote the sets of real and complex algebraic numbers. Many statements remain true in other fields or rings if arithmetic operations can be carried out efficiently in a model of computation (see [5] for more discussions on this issue).

For a positive integer n, we use $[n]$ to denote the set $\{1, \dots, n\}$. When $n = 0$, $[0] = \emptyset$. We use $[m : n]$, where $m \le n$, to denote $\{m, m + 1, \dots, n\}$.

In this paper, we consider undirected graphs unless stated otherwise. Following standard definitions, the graph G is allowed to have multiple edges but no loops. (However, we will touch on this issue a few times when G is allowed to have loops.) The graph H can have multiple edges and loops, or more generally, edge weights. For the graph H, we treat its loops as edges.

An edge-weighted graph H on m vertices can be identified with a symmetric $m \times m$ matrix A in the obvious way. We write this correspondence by $H = H_A$ and $A = A_H$.

▶ **Definition 1.** *Let $A \in \mathbb{C}^{m\times m}$ be a symmetric matrix. The problem* EVAL(A) *is defined as follows: Given an undirected graph $G = (V, E)$, compute*

$$Z_A(G) = \sum_{\xi: V \to [m]} \prod_{(u,v)\in E} A_{\xi(u),\xi(v)}.$$

The function $Z_A(\cdot)$ is called a *graph homomorphism function* or a *partition function*. When A is a symmetric $\{0, 1\}$-matrix, i.e., when the graph $H = H_A$ is unweighted, $Z_A(G)$ counts the number of homomorphisms from G to H. In this case, we denote EVAL(H) = EVAL(A_H), and this problem is also known as the #H-coloring problem.

▶ **Theorem 2** (Dyer and Greenhill [10]). *Let H be a fixed undirected graph. Then* EVAL(H) *is in polynomial time if every connected component of H is either (1) an isolated vertex, or (2) a complete graph with all loops present, or (3) a complete bipartite graph with no loops present. Otherwise, the problem* EVAL(H) *is #P-complete.*

Bulatov and Grohe [4] extended Theorem 2 to EVAL(A) where A is a symmetric matrix with nonnegative entries. In order to state their result, we need to define a few notions first.

We say a nonnegative symmetric $m \times m$ matrix A is rectangular if there are pairwise disjoint nonempty subsets of $[m]$: $T_1, \dots, T_r, P_1, \dots, P_s, Q_1, \dots, Q_s$, for some $r, s \ge 0$, such that $A_{i,j} > 0$ iff

$$(i, j) \in \bigcup_{k\in[r]} (T_k \times T_k) \cup \bigcup_{l\in[s]} [(P_l \times Q_l) \cup (Q_l \times P_l)].$$

We refer to $T_k \times T_k, P_l \times Q_l$ and $Q_l \times P_l$ as blocks of A. Further, we say a nonnegative symmetric matrix A is *block-rank-*1 if A is rectangular and every block of A has rank one.

▶ **Theorem 3** (Bulatov and Grohe [4]). *Let A be a symmetric matrix with nonnegative entries. Then* EVAL(A) *is in polynomial time if A is block-rank-*1*, and is #P-hard otherwise.*

There is a natural extension of EVAL(A) involving the use of vertex weights. Both papers [10, 4] use them in their proofs. A graph H on m vertices with vertex and edge weights is identified with a symmetric $m \times m$ edge weight matrix A and a diagonal $m \times m$ vertex weight matrix $D = \text{diag}(D_1, \dots, D_m)$ in a natural way. Then the problem EVAL(A) can be generalized to EVAL(A, D) for vertex-edge-weighted graphs.

▶ **Definition 4.** *Let $A \in \mathbb{C}^{m\times m}$ be a symmetric matrix and $D \in \mathbb{C}^{m\times m}$ a diagonal matrix. The problem* EVAL(A, D) *is defined as follows: Given an undirected graph $G = (V, E)$, compute*

$$Z_{A,D}(G) = \sum_{\xi:V\to[m]} \prod_{w\in V} D_{\xi(w)} \prod_{(u,v)\in E} A_{\xi(u),\xi(v)}.$$

Note that EVAL(A) is the special case EVAL(A, I_m). We also need to define another EVAL problem where the vertex weights are specified by the degree.

▶ **Definition 5.** *Let $A \in \mathbb{C}^{m\times m}$ be a symmetric matrix and $\mathfrak{D} = \{D^{[\![i]\!]}\}_{i=0}^{\infty}$ a sequence of diagonal matrices in $\mathbb{C}^{m\times m}$. The problem* EVAL$(A, \mathfrak{D})$ *is defined as follows: Given an undirected graph $G = (V, E)$, compute*

$$Z_{A,\mathfrak{D}}(G) = \sum_{\xi:V\to[m]} \prod_{w\in V} D^{[\![\deg(w)]\!]}_{\xi(w)} \prod_{(u,v)\in E} A_{\xi(u),\xi(v)}.$$

Finally, we need to define a general EVAL problem, where the vertices and edges can individually take specific weights. Let $\mathscr{A}$ be a set of (edge weight) $m \times m$ matrices and $\mathscr{D}$ a set of diagonal (vertex weight) $m \times m$ matrices. A GH-grid $\Omega = (G, \rho)$ consists of a graph $G = (V, E)$ with possibly both directed and undirected edges, and loops, and ρ assigns to each edge $e \in E$ or loop an $A^{(e)} \in \mathscr{A}$ and to each vertex $v \in V$ a $D^{(v)} \in \mathscr{D}$. (A loop is just an edge of the form (v, v).) If $e \in E$ is a directed edge then the tail and head correspond to rows and columns of $A^{(e)}$, respectively; if $e \in E$ is an undirected edge then $A^{(e)}$ must be symmetric.

▶ **Definition 6.** *The problem* EVAL$(\mathscr{A}, \mathscr{D})$ *is defined as follows: Given a GH-grid $\Omega = \Omega(G)$, compute*

$$Z_{\mathscr{A},\mathscr{D}}(\Omega) = \sum_{\xi\colon V\to[m]} \prod_{w\in V} D^{(w)}_{\xi(w)} \prod_{e=(u,v)\in E} A^{(e)}_{\xi(u),\xi(v)}$$

We remark that $Z_{\mathscr{A},\mathscr{D}}$ is introduced only as a tool to express a certain quantity in a "virtual" interpolation; the dichotomy theorems do not apply to this. Definitions 5 and 6 are carefully crafted in order to carry out the #P-hardness part of the proof of Theorem 8. Notice that the problem EVAL$(\mathscr{A}, \mathscr{D})$ generalizes both problems EVAL(A) and EVAL(A, D), by taking $\mathscr{A}$ to be a single symmetric matrix, and by taking $\mathscr{D}$ to be a single diagonal matrix. But EVAL$(A, \mathfrak{D})$ is not naturally expressible as EVAL$(\mathscr{A}, \mathscr{D})$ because the latter does not force the vertex-weight matrix on a vertex according to its degree.

We refer to $[m]$ as the domain of the corresponding EVAL problem. If $\mathscr{A} = \{A\}$ or $\mathscr{D} = \{D\}$, then we simply write $Z_{A,\mathscr{D}}(\cdot)$ or $Z_{\mathscr{A},D}(\cdot)$, respectively.

We use a superscript (Δ) and/or a subscript simp to denote the restriction of a corresponding EVAL problem to degree-Δ bounded graphs and/or simple graphs. E.g., EVAL$^{(\Delta)}(A)$ denotes the problem EVAL(A) restricted to degree-Δ bounded graphs, EVAL$_{\text{simp}}(A, \mathfrak{D})$ denotes the problem EVAL$(A, \mathfrak{D})$ restricted to simple graphs, and both restrictions apply in EVAL$^{(\Delta)}_{\text{simp}}(A, \mathfrak{D})$.

Working within the framework of EVAL(A, D), we define an edge gadget to be a graph with two distinguished vertices, called u^* and v^*. An edge gadget $G = (V, E)$ has a signature (edge weight matrix) expressed by an $m \times m$ matrix F, where

$$F_{ij} = \sum_{\substack{\xi\colon V\to[m] \\ \xi(u^*)=i,\, \xi(v^*)=j}} \prod_{z\in V\setminus\{u^*,v^*\}} D_{\xi(z)} \prod_{(x,y)\in E} A_{\xi(x),\xi(y)}$$

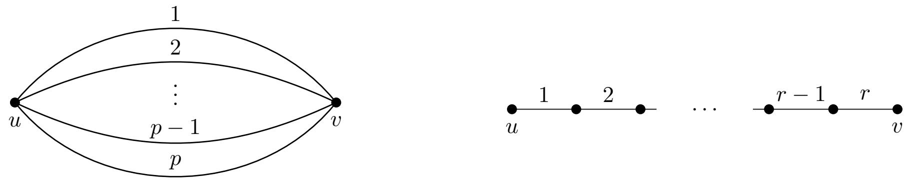

Figure 1 The thickening T_pe and the stretching S_re of an edge $e = (u, v)$.

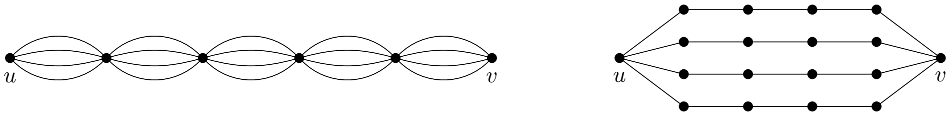

Figure 2 The graphs T_4S_5e (on the left) and S_5T_4e (on the right) where $e = (u, v)$.

for $1 \le i, j \le m$. When this gadget is placed in a graph identifying u^* and v^* with two vertices u and v in that graph, then F is the signature matrix for the pair (u, v). Note that the vertex weights corresponding to u and v are excluded from the product in the definition of F. Similar definitions can be introduced for $\mathrm{EVAL}(A)$, $\mathrm{EVAL}(A, \mathfrak{D})$ and $\mathrm{EVAL}(\mathscr{A}, \mathscr{D})$.

We use $\le_{\mathrm{T}}^{\mathrm{P}}$ (and $\equiv_{\mathrm{T}}^{\mathrm{P}}$) to denote polynomial-time Turing reductions (and equivalences, respectively).

Two simple operations are known as *thickening* and *stretching*. Let $p, r \ge 1$ be integers. A *p-thickening* of an edge replaces it by p parallel edges, and a *r-stretching* replaces it by a path of length r. In both cases we retain the endpoints u, v. The *p-thickening* or *r-stretching* of G with respect to $F \subseteq E(G)$, denoted respectively by $T_p^{(F)}(G)$ and $S_r^{(F)}(G)$, are obtained by *p-thickening* or *r-stretching* each edge from F, respectively. Other edges, if any, are unchanged in both cases. When $F = E(G)$, we call them the *p-thickening* and *r-stretching* of G and denote them by $T_p(G)$ and $S_r(G)$, respectively. T_pe and S_re are the special cases when the graph consists of a single edge e. See Figure 1 for an illustration. Thickenings and stretchings can be combined in any order. Examples are shown in Figure 2.

For a matrix A, we denote by $A^{\odot p}$ the matrix obtained by replacing each entry of A with its pth power. Clearly, $Z_A(T_pG) = Z_{A^{\odot p}}(G)$ and $Z_A(S_rG) = Z_{A^r}(G)$. More generally, for the vertex-weighted case, we have $Z_{A,D}(T_pG) = Z_{A^{\odot p},D}(G)$ and $Z_{A,D}(S_rG) = Z_{A(DA)^{r-1},D}(G)$. Here $(DA)^0 = I_m$ if A and D are $m \times m$.

3 Dichotomy for bounded degree graphs

In addition to the Dyer-Greenhill dichotomy (Theorem 2), in the same paper [10] they also proved that the #P-hardness part of their dichotomy holds for bounded degree graphs. The bounded degree case of the Bulatov-Grohe dichotomy (Theorem 3) was left open, and all known proofs [4, 22, 13] of its #P-hardness part require unbounded degree graphs. All subsequent dichotomies that use the Bulatov-Grohe dichotomy, e.g., [12, 7] also explicitly or implicitly (because of their dependence on the Bulatov-Grohe dichotomy) require unbounded degree graphs. In this paper, we extend the #P-hardness part of the Bulatov-Grohe dichotomy to bounded degree graphs.

▶ **Theorem 7.** *Let A be a symmetric nonnegative matrix. If A is not block-rank-1, then for some $\Delta > 0$, the problem $\mathrm{EVAL}^{(\Delta)}(A)$ is #P-hard.*

The degree bound Δ proved in Theorem 7 depends on A, as is the case in Theorem 2. The authors of [10] conjectured that a universal bound $\Delta = 3$ works for Theorem 2; whether a universal bound exists for both Theorems 2 and 7 is open. For general symmetric real or complex A, it is open whether bounded degree versions of the dichotomies in [12] and [7] hold. Xia [26] proved that a universal bound does not exist for complex symmetric matrices A, assuming #P does not collapse to P.

We prove a broader dichotomy than Theorem 7, which also includes arbitrary nonnegative vertex weights.

▶ **Theorem 8.** *Let A and D be $m \times m$ nonnegative matrices, where A is symmetric, and D is diagonal. Let A' be the matrix obtained from A by striking out rows and columns that correspond to 0 entries of D on the diagonal. If A' is block-rank-1, then the problem $\mathrm{EVAL}(A, D)$ is in polynomial time. Otherwise, for some $\Delta > 0$, the problem $\mathrm{EVAL}^{(\Delta)}_{\mathrm{simp}}(A, D)$ is #P-hard.*

Every 0 entry of D on the diagonal effectively nullifies the corresponding domain element in $[m]$, so the problem becomes an equivalent problem on the reduced domain. Thus, for a nonnegative diagonal D, without loss of generality, we may assume the domain has already been reduced so that D is positive diagonal. In what follows, we will make this assumption.

In Section 5, we will prove the tractability part of Theorem 8. This follows easily from known results. In Section 6, we will present two technical lemmas, Lemma 9 and Lemma 10 to be used in Section 4. Finally, in Section 7 we prove Theorem 11, showing that the #P-hardness part of the dichotomy for counting GH by Goldberg et al. [12] for real symmetric matrix (with mixed signs) is also valid for simple graphs.

4 Hardness proof

We proceed to prove the #P-hardness part of Theorem 8. Let A and D be $m \times m$ matrices, where A is nonnegative symmetric but not block-rank-1, and D is positive diagonal. The first step is to eliminate pairwise linearly dependent rows and columns of A. (We will see that this step will naturally create nontrivial vertex weights even if we initially start with the vertex unweighted case $D = I_m$.)

If A has a zero row or column i, then for any connected input graph G other than a single isolated vertex, no map $\xi : V(G) \to [m]$ having a nonzero contribution to $Z_{A,D}(G)$ can map any vertex of G to i. So, by crossing out all zero rows and columns (they have the same index set since A is symmetric) we may assume that A has no zero rows or columns. We then delete the same set of rows and columns from D, thereby expressing the problem $\mathrm{EVAL}^{(\Delta)}_{\mathrm{simp}}(A, D)$ for $\Delta \geq 0$ on a smaller domain. Also permuting the rows and columns of both A and D simultaneously by the same permutation does not change the value of $Z_{A,D}(\cdot)$, and so it does not change the complexity of $\mathrm{EVAL}^{(\Delta)}_{\mathrm{simp}}(A, D)$ for $\Delta \geq 0$ either. Having no zero rows and columns implies that pairwise linear dependence is an equivalence relation, and so we may assume that the pairwise linearly dependent rows and columns of A are contiguously arranged. Then, after renaming the indices, the entries of A are of the following form: $A_{(i,j),(i',j')} = \mu_{ij}\mu_{i'j'}A'_{i,i'}$, where A' is a nonnegative symmetric $s \times s$ matrix with all columns nonzero and pairwise linearly independent, $1 \leq i, i' \leq s$, $1 \leq j \leq m_i$, $1 \leq j' \leq m_{i'}$, $\sum_{i=1}^{s} m_i = m$, and all $\mu_{ij} > 0$. We also rename the indices of the matrix D so that the diagonal entries of D are of the following form: $D_{(i,j),(i,j)} = \alpha_{ij} > 0$ for $1 \leq i \leq s$ and $1 \leq j \leq m_i$. As $m \geq 1$ we get $s \geq 1$.

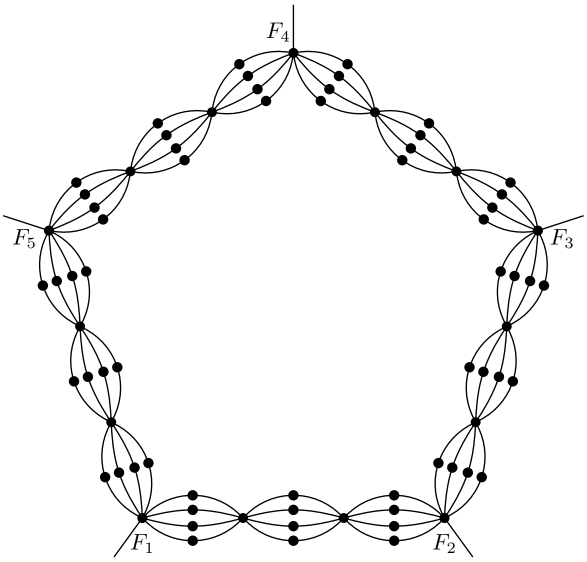

Figure 3 The gadget $\mathcal{R}_{5,3,4}$.

Then the partition function $Z_{A,D}(\cdot)$ can be written in a compressed form

$$Z_{A,D}(G) = \sum_{\zeta:V(G)\to[s]} \left(\prod_{w\in V(G)} \sum_{j=1}^{m_{\zeta(w)}} \alpha_{\zeta(w)j}\mu_{\zeta(w)j}^{\deg(w)} \right) \prod_{(u,v)\in E(G)} A'_{\zeta(u),\zeta(v)} = Z_{A',\mathfrak{D}}(G)$$

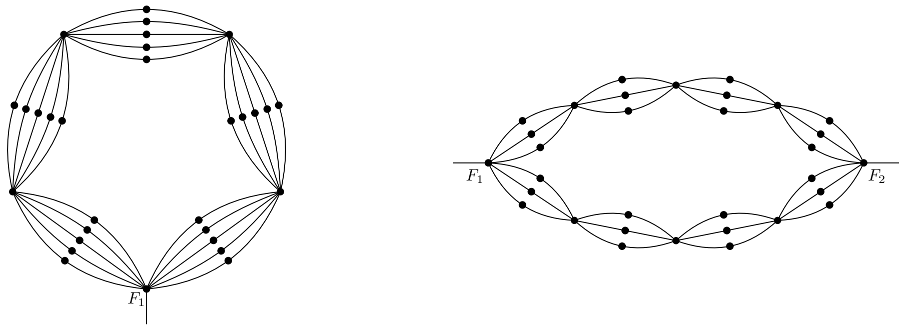
where $\mathfrak{D} = \{D^{[\![k]\!]}\}_{k=0}^{\infty}$ with $D_i^{[\![k]\!]} = \sum_{j=1}^{m_i} \alpha_{ij}\mu_{ij}^k > 0$ for $k \ge 0$ and $1 \le i \le s$. Then all matrices in $\mathfrak{D}$ are positive diagonal. Note the dependence on the vertex degree $\deg(w)$ for $w \in V(G)$. Since the underlying graph G remains unchanged, this way we obtain the equivalence $\text{EVAL}_{\text{simp}}^{(\Delta)}(A, D) \equiv_{\text{T}}^{\text{P}} \text{EVAL}_{\text{simp}}^{(\Delta)}(A', \mathfrak{D})$ for any $\Delta \ge 0$. Here the subscript simp can be included or excluded, and the same is true for the superscript (Δ), the statement remains true in all cases. We also point out that the entries of the matrices $D^{[\![k]\!]} \in \mathfrak{D}$ are computable in polynomial time in the input size of (A, D) as well as in k.

4.1 Gadgets $\mathcal{P}_{n,p}$ and $\mathcal{R}_{d,n,p}$

We first introduce the *edge gadget* $\mathcal{P}_{n,p}$, for all $p, n \ge 1$. It is obtained by replacing each edge of a path of length n by the gadget in Figure 5 from Lemma 10. More succinctly $\mathcal{P}_{n,p}$ is $S_2T_pS_ne$, where e is an edge.

To define the gadget $\mathcal{R}_{d,n,p}$, for all $d, p, n \ge 1$, we start with a cycle on d vertices $F_1, \dots, F_d$ (call it a d-cycle), replace every edge of the d-cycle by a copy of $\mathcal{P}_{n,p}$, and append a dangling edge at each vertex F_i of the d-cycle. To be specific, a 2-cycle has two vertices with 2 parallel edges between them, and a 1-cycle is a loop on one vertex. The gadget $\mathcal{R}_{d,n,p}$ always has d dangling edges. Note that all $\mathcal{R}_{d,n,p}$ are loopless simple graphs (i.e., without parallel edges or loops), for $d, n, p \ge 1$. An example of a gadget $\mathcal{R}_{d,n,p}$ is shown in Figure 3. For the special cases $d = 1, 2$, examples of gadgets $\mathcal{R}_{d,n,p}$ can be seen in Figure 4.

We note that vertices in $\mathcal{P}_{n,p}$ have degrees at most $2p$, and vertices in $\mathcal{R}_{d,n,p}$ have degrees at most $2p + 1$, taking into account the dangling edges. Clearly $|V(\mathcal{R}_{d,n,p})| = dn(p + 1)$ and $|E(\mathcal{R}_{d,n,p})| = (2np + 1)d$, including the dangling edges.



(a) $\mathcal{R}_{1,5,5}$

(b) $\mathcal{R}_{2,4,3}$

Figure 4 Examples of gadgets $\mathcal{R}_{d,n,p}$ for $d = 1, 2$.

By Lemma 10, we can fix some $p \geq 1$ such that $B = (A' D^{[\![2]\!]} A')^{\odot p}$ is nondegenerate, where the superscript $[\![2]\!]$ is from the stretching operator S_2 which creates those degree 2 vertices, and the superscript $\odot p$ is from the thickening operator T_p, followed by S_2, which creates those parallel paths of length 2. The edge gadget $\mathcal{P}_{n,p}$ has the edge weight matrix

$$L^{(n)} = \underbrace{BD^{[\![2p]\!]}B \dots BD^{[\![2p]\!]}B}_{D^{[\![2p]\!]} \text{ appears } n-1 \,\geq\, 0 \text{ times}} = B(D^{[\![2p]\!]}B)^{n-1} \tag{1}$$

$$= (D^{[\![2p]\!]})^{-1/2}((D^{[\![2p]\!]})^{1/2}B(D^{[\![2p]\!]})^{1/2})^{n}(D^{[\![2p]\!]})^{-1/2}, \tag{2}$$

where in the notation $L^{(n)}$ we suppress the index p. The $n-1$ occurrences of $D^{[\![2p]\!]}$ in (1) are due to those $n-1$ vertices of degree $2p$. Here $(D^{[\![2p]\!]})^{1/2}$ is a diagonal matrix with the positive square roots of the corresponding entries of $D^{[\![2p]\!]}$ on the main diagonal, and $(D^{[\![2p]\!]})^{-1/2}$ is its inverse. The vertices F_i are of degree $2p+1$ each, but the contributions by its vertex weights are not included in $L^{(n)}$.

The constraint function induced by $\mathcal{R}_{d,n,p}$ is more complicated to write down. When it is placed as a part of a graph, for any given assignment to the d vertices F_i, we can express the contribution of the gadget $\mathcal{R}_{d,n,p}$ in terms of d copies of $L^{(n)}$, *together with* the vertex weights incurred at the d vertices F_i which will depend on their degrees.

4.2 Interpolation using $\mathcal{R}_{d,n,p}$

Assume for now that G does not contain isolated vertices. We will replace every vertex $u \in V(G)$ of degree $d = d_u = \deg(u) \geq 1$ by a copy of $\mathcal{R}_{d,n,p}$, for all $n, p \geq 1$. The replacement operation can be described in two steps: In step one, each $u \in V(G)$ is replaced by a d-cycle on vertices $F_1, \dots, F_d$, each having a dangling edge attached. The d dangling edges will be identified one-to-one with the d incident edges at u. If u and v are adjacent vertices in G, then the edge (u, v) in G will be replaced by merging a pair of dangling edges, one from the d_u-cycle and one from the d_v-cycle. Thus in step one we obtain a graph G', which basically replaces every vertex $u \in V(G)$ by a cycle of $\deg(u)$ vertices. Then in step two, for every cycle in G' that corresponds to some $u \in V(G)$ we replace each edge on the cycle by a copy of the edge gadget $\mathcal{P}_{n,p}$.

Let $G_{n,p}$ denote the graph obtained from G by the replacement procedure above. Since all gadgets $\mathcal{R}_{d,n,p}$ are loopless simple graphs, so are $G_{n,p}$ for all $n, p \geq 1$, even if G has multiple edges (or had multiloops, if we view a loop as adding degree 2 to the incident vertex). As a technical remark, if G contains vertices of degree 1, then the intermediate graph G' has loops but all graphs $G_{n,p}$ $(n, p \geq 1)$ do not. Also note that all vertices in $G_{n,p}$ have degree at most $2p+1$, which is independent of n.

Next, it is not hard to see that

$$|V(G_{n,p})| = \sum_{u \in V(G)} d_u n(p+1) = 2n(p+1)|E(G)|,$$
$$|E(G_{n,p})| = |E(G)| + \sum_{u \in V(G)} 2npd_u = (4np+1)|E(G)|.$$

Hence the size of the graphs $G_{n,p}$ is polynomially bounded in the size of G, n and p.

Since we chose a fixed p, and will choose n to be bounded by a polynomial in the size of G, whenever something is computable in polynomial time in n, it is also computable in polynomial time in the size of G (we will simply say in polynomial time).

We consider $Z_{A',\mathfrak{D}}(G)$, and substitute G by $G_{n,p}$. We will make use of the edge weight matrix $L^{(n)}$ of $\mathcal{P}_{n,p}$ in (2). The vertices F_i are of degree $2p+1$ each in $G_{n,p}$, so will each contribute a vertex weight according to the diagonal matrix $D^{[\![2p+1]\!]}$ to the partition function, which are not included in $L^{(n)}$, but now must be accounted for in $Z_{A',\mathfrak{D}}(G_{n,p})$.

Since B is real symmetric and $D^{[\![2p]\!]}$ is positive diagonal, the matrix

$$\widetilde{B} = (D^{[\![2p]\!]})^{1/2} B (D^{[\![2p]\!]})^{1/2}$$

is real symmetric. Then $\widetilde{B}$ is orthogonally diagonalizable over $\mathbb{R}$, i.e., there exist a real orthogonal matrix S and a real diagonal matrix $J = \operatorname{diag}(\lambda_i)_{i=1}^{s}$ such that $\widetilde{B} = S^T J S$. Then $\widetilde{B}^n = S^T J^n S$ so the edge weight matrix for $\mathcal{P}_{n,p}$ becomes

$$L^{(n)} = (D^{[\![2p]\!]})^{-1/2} \widetilde{B}^n (D^{[\![2p]\!]})^{-1/2} = (D^{[\![2p]\!]})^{-1/2} S^T J^n S (D^{[\![2p]\!]})^{-1/2}.$$

Note that $L^{(n)}$ as a matrix is defined for any $n \geq 0$, and $L^{(0)} = (D^{[\![2p]\!]})^{-1}$, even though there is no physical gadget $\mathcal{P}_{0,p}$ that corresponds to it. However, it is precisely this "virtual" gadget we wish to "realize" by interpolation.

Clearly, $\widetilde{B}$ is nondegenerate as B and $(D^{[\![2p]\!]})^{1/2}$ both are, and so is J. Then all $\lambda_i \neq 0$. We can also write $L_{ij}^{(n)} = \sum_{\ell=1}^{s} a_{ij\ell} \lambda_\ell^n$ for every $n \geq 0$ and some real $a_{ij\ell}$'s which depend on S, $D^{[\![2p]\!]}$, but not on J and n, for all $1 \leq i, j, \ell \leq s$. By the formal expansion of the symmetric matrix $L^{(n)}$ above, we have $a_{ij\ell} = a_{ji\ell}$. Note that for all $n, p \geq 1$, the gadget $\mathcal{R}_{d_v,n,p}$ for $v \in V(G)$ employs exactly d_v copies of $\mathcal{P}_{n,p}$. Let $t = \sum_{v \in V(G)} d_v = 2|E(G)|$; this is precisely the number of edge gadgets $\mathcal{P}_{n,p}$ in $G_{n,p}$.

In the evaluation of the partition function $Z_{A',\mathfrak{D}}(G_{n,p})$, we stratify the vertex assignments in $G_{n,p}$ as follows. Denote by $\kappa = (k_{ij})_{1 \leq i \leq j \leq s}$ a tuple of nonnegative integers, where the indexing is over all $s(s+1)/2$ ordered pairs (i,j). There are a total of $\binom{t+s(s+1)/2-1}{s(s+1)/2-1}$ such tuples that satisfy $\sum_{1 \leq i \leq j \leq s} k_{ij} = t$. For a fixed s, this is a polynomial in t, and thus a polynomial in the size of G. Denote by $\mathcal{K}$ the set of all such tuples κ. We will stratify all vertex assignments in $G_{n,p}$ by $\kappa \in \mathcal{K}$, namely all assignments such that there are exactly k_{ij} many constituent edge gadgets $\mathcal{P}_{n,p}$ with the two end points (in either order of the end points) assigned i and j respectively.

For each $\kappa \in \mathcal{K}$, the edge gadgets $\mathcal{P}_{n,p}$ in total contribute $\prod_{1 \leq i \leq j \leq s} (L_{ij}^{(n)})^{k_{ij}}$ to the partition function $Z_{A',\mathfrak{D}}(G_{n,p})$. If we factor this product out for each $\kappa \in \mathcal{K}$, we can express $Z_{A',\mathfrak{D}}(G_{n,p})$ as a linear combination of these products over all $\kappa \in \mathcal{K}$, with polynomially many coefficient values c_κ that are independent of all edge gadgets $\mathcal{P}_{n,p}$. Another way to define these coefficients c_κ is to think in terms of G': For any $\kappa = (k_{ij})_{1 \leq i \leq j \leq s} \in \mathcal{K}$, we say a vertex assignment on G' is consistent with κ if it assigns exactly k_{ij} many cycle edges of G' (i.e., those that belong to the cycles that replaced vertices in G) as ordered pairs of vertices to the values (i,j) or (j,i). (For any loop in G', as a cycle of length 1 that came from a degree 1 vertex of G, it can only be assigned (i,i) for some $1 \le i \le s$.) Let L' be any symmetric edge signature to be assigned on each of these cycle edges in G', and keep the edge signature A' on the merged dangling edges between any two such cycles, and the suitable vertex weights specified by $\mathfrak{D}$, namely each vertex receives its vertex weight according to $D^{[\![2p+1]\!]}$. Then c_κ is the sum, over all assignments consistent with κ, of the products of all edge weights and vertex weights *other than* the contributions by L', in the evaluation of the partition function on G'. In other words, for each $\kappa \in \mathcal{K}$,

$$c_\kappa = \sum_{\substack{\zeta\colon V(G') \to [s] \\ \zeta \text{ is consistent with } \kappa}} \prod_{w \in V(G')} D^{[\![2p+1]\!]}_{\zeta(w)} \prod_{(u,v) \in \widetilde{E}} A'_{\zeta(u),\zeta(v)},$$

where $\widetilde{E} \subseteq E(G')$ are the non-cycle edges of G' that are in 1-1 correspondence with $E(G)$.

In particular, the values c_κ are independent of n. Thus for some polynomially many values c_κ, where $\kappa \in \mathcal{K}$, we have for all $n \ge 1$,

$$Z_{A',\mathfrak{D}}(G_{n,p}) = \sum_{\kappa \in \mathcal{K}} c_\kappa \prod_{1 \le i \le j \le s} (L_{ij}^{(n)})^{k_{ij}} = \sum_{\kappa \in \mathcal{K}} c_\kappa \prod_{1 \le i \le j \le s} (\sum_{\ell=1}^{s} a_{ij\ell} \lambda_\ell^n)^{k_{ij}}. \tag{3}$$

Expanding out the last sum and rearranging the terms, for some values $b_{i_1,\ldots,i_s}$ independent of n, we get

$$Z_{A',\mathfrak{D}}(G_{n,p}) = \sum_{\substack{i_1+\ldots+i_s=t \\ i_1,\ldots,i_s \ge 0}} b_{i_1,\ldots,i_s} (\prod_{j=1}^{s} \lambda_j^{i_j})^n$$

for all $n \ge 1$.

This represents a linear system with the unknowns $b_{i_1,\ldots,i_s}$ with the rows indexed by n. The number of unknowns is clearly $\binom{t+s-1}{s-1}$ which is polynomial in the size of the input graph G since s is a constant. The values $\prod_{j=1}^{s} \lambda_j^{i_j}$ can be clearly computed in polynomial time. We show how to compute the value

$$\sum_{\substack{i_1+\ldots+i_s=t \\ i_1,\ldots,i_s \ge 0}} b_{i_1,\ldots,i_s}$$

from the values $Z_{A',\mathfrak{D}}(G_{n,p})$, $n \ge 1$ in polynomial time. The coefficient matrix of this system is a Vandermonde matrix. However, it can have repeating columns so it might not be of full rank because the coefficients $\prod_{j=1}^{s} \lambda_j^{i_j}$ do not have to be pairwise distinct. However, when they are equal, say, $\prod_{j=1}^{s} \lambda_j^{i_j} = \prod_{j=1}^{s} \lambda_j^{i'_j}$, we replace the corresponding unknowns $b_{i_1,\ldots,i_s}$ and $b_{i'_1,\ldots,i'_s}$ with their sum as a new variable. Since all $\lambda_i \ne 0$, we have a Vandermonde system of full rank after all such combinations. Therefore we can solve this linear system in polynomial time and find the desired value $\sum_{\substack{i_1+\ldots+i_s=t \\ i_1,\ldots,i_s \ge 0}} b_{i_1,\ldots,i_s}$.

Now we will consider a problem in the framework of $Z_{\mathscr{A},\mathscr{D}}$ according to Definition 6. Let $G_{0,p}$ be the (undirected) GH-grid, with the underlying graph G', and every edge of the cycle in G' corresponding to a vertex in $V(G)$ is assigned the edge weight matrix $(D^{[\![2p]\!]})^{-1}$, and we keep the vertex-weight matrices $D^{[\![2p+1]\!]}$ at all vertices F_i. The other edges, i.e., the original edges of G, each keep the assignment of the edge weight matrix A'. (So in the specification of $Z_{\mathscr{A},\mathscr{D}}$, we have $\mathscr{A} = \{(D^{[\![2p]\!]})^{-1}, A'\}$, and $\mathscr{D} = \{D^{[\![2p+1]\!]}\}$. We note that G' may have loops, and Definition 6 specifically allows this.) Then

$$Z_{\{(D^{[\![2p]\!]})^{-1},A'\},D^{[\![2p+1]\!]}}(G_{0,p}) = \sum_{\substack{i_1+\ldots+i_s=t \\ i_1,\ldots,i_s \ge 0}} b_{i_1,\ldots,i_s} (\prod_{j=1}^{s} \lambda_j^{i_j})^0 = \sum_{\substack{i_1+\ldots+i_s=t \\ i_1,\ldots,i_s \ge 0}} b_{i_1,\ldots,i_s}$$

and we have just computed this value in polynomial time in the size of G from the values $Z_{A',\mathfrak{D}}(G_{n,p})$, for $n \geq 1$. In other words, we have achieved it by querying the oracle $\mathrm{EVAL}(A', \mathfrak{D})$ on the instances $G_{n,p}$, for $n \geq 1$, in polynomial time.

Equivalently, we have shown that we can simulate a virtual "gadget" $\mathcal{R}_{d,0,p}$ replacing every occurrence of $\mathcal{R}_{d,n,p}$ in $G_{n,p}$ in polynomial time. The virtual gadget $\mathcal{R}_{d,0,p}$ has the edge signature $(D^{\llbracket 2p \rrbracket})^{-1}$ in place of $(D^{\llbracket 2p \rrbracket})^{-1/2}\widetilde{B}^n(D^{\llbracket 2p \rrbracket})^{-1/2}$ in each $\mathcal{P}_{n,p}$, since

$$(D^{\llbracket 2p \rrbracket})^{-1/2}\widetilde{B}^0(D^{\llbracket 2p \rrbracket})^{-1/2} = (D^{\llbracket 2p \rrbracket})^{-1/2} I_s (D^{\llbracket 2p \rrbracket})^{-1/2} = (D^{\llbracket 2p \rrbracket})^{-1}.$$

Additionally, each F_i retains the vertex-weight contribution with the matrix $D^{\llbracket 2p+1 \rrbracket}$ in $\mathcal{R}_{d,0,p}$. We view it as having "virtual" degree $2p+1$. This precisely results in the GH-grid $G_{0,p}$.

However, even though $G_{0,p}$ still retains the cycles, since $(D^{\llbracket 2p \rrbracket})^{-1}$ is a diagonal matrix, each vertex F_i in a cycle is forced to receive the same vertex assignment value in the domain set $[s]$; all other vertex assignments contribute zero in the evaluation of $Z_{\{(D^{\llbracket 2p \rrbracket})^{-1}, A'\}, D^{\llbracket 2p+1 \rrbracket}}(G_{0,p})$. This can be easily seen by traversing the vertices $F_1, \ldots, F_d$ in a cycle. Hence we can view each cycle employing the virtual gadget $\mathcal{R}_{d,0,p}$ as a single vertex that contributes only a diagonal matrix of positive vertex weights $P^{\llbracket d \rrbracket} = (D^{\llbracket 2p+1 \rrbracket}(D^{\llbracket 2p \rrbracket})^{-1})^d$, where d is the vertex degree in G. Contracting all the cycles to a single vertex each, we arrive at the original graph G. Let $\mathfrak{P} = \{P^{\llbracket i \rrbracket}\}_{i=0}^{\infty}$, where we let $P^{\llbracket 0 \rrbracket} = I_s$, and for $i > 0$, we have $P_j^{\llbracket i \rrbracket} = w_j^i$ where $w_j = \sum_{k=1}^{m_j} \alpha_{jk}\mu_{jk}^{2p+1} / \sum_{k=1}^{m_j} \alpha_{jk}\mu_{jk}^{2p} > 0$ for $1 \leq j \leq s$. This shows that we now can interpolate the value $Z_{A',\mathfrak{P}}(G)$ using the values $Z_{A',\mathfrak{D}}(G_{n,p})$ in polynomial time in the size of G. The graph G is arbitrary but without isolated vertices here. We show next how to deal with the case when G has isolated vertices.

Given an arbitrary graph G, assume it has $h \geq 0$ isolated vertices. Let G^* denote the graph obtained from G by their removal. Then G^* is of size not larger than G and $h \leq |V(G)|$. Obviously, $Z_{A',\mathfrak{P}}(G) = (\sum_{i=1}^{s} P_i^{\llbracket 0 \rrbracket})^h Z_{A',\mathfrak{P}}(G^*) = s^h Z_{A',\mathfrak{P}}(G^*)$. Here the integer s is a constant, so the factor $s^h > 0$ can be easily computed in polynomial time. Thus, knowing the value $Z_{A',\mathfrak{P}}(G^*)$ we can compute the value $Z_{A',\mathfrak{P}}(G)$ in polynomial time. Further, since we only use the graphs $G_{n,p}, n \geq 1$ during the interpolation, each being simple of degree at most $2p+1$, combining it with the possible isolated vertex removal step, we conclude $\mathrm{EVAL}(A', \mathfrak{P}) \leq_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}_{\mathrm{simp}}^{(2p+1)}(A', \mathfrak{D})$.

Next, it is easy to see that for an arbitrary graph G

$$\begin{aligned}
Z_{A',\mathfrak{P}}(G) &= \sum_{\zeta: V(G) \to [s]} \prod_{z \in V(G)} P_{\zeta(z)}^{\llbracket \deg(z) \rrbracket} \prod_{(u,v) \in E(G)} A'_{\zeta(u),\zeta(v)} \\
&= \sum_{\zeta: V(G) \to [s]} \prod_{z \in V(G)} w_{\zeta(z)}^{\deg(z)} \prod_{(u,v) \in E(G)} A'_{\zeta(u),\zeta(v)} \\
&= \sum_{\zeta: V(G) \to [s]} \prod_{(u,v) \in E(G)} w_{\zeta(u)} w_{\zeta(v)} A'_{\zeta(u),\zeta(v)} \\
&= \sum_{\zeta: V(G) \to [s]} \prod_{(u,v) \in E(G)} C_{\zeta(u),\zeta(v)} = Z_C(G).
\end{aligned}$$

Here C is an $s \times s$ matrix with the entries $C_{ij} = A'_{ij} w_i w_j$ where $1 \leq i, j \leq s$. Clearly, C is a nonnegative symmetric matrix. In the above chain of equalities, we were able to *redistribute the weights w_i and w_j into the edge weights A'_{ij}* which resulted in the edge weights C_{ij}, so that precisely each edge (u, v) in G gets two factors $w_{\zeta(u)}$ and $w_{\zeta(v)}$ since the vertex weights at u and v were $w_{\zeta(u)}^{\deg(u)}$ and $w_{\zeta(v)}^{\deg(v)}$ respectively. (This is a crucial step in our proof.)

Because the underlying graph G is arbitrary, it follows that $\mathrm{EVAL}(A', \mathfrak{P}) \equiv_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}(C)$. Combining this with the previous EVAL-reductions and equivalences, we obtain

$$\mathrm{EVAL}(C) \equiv_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}(A', \mathfrak{P}) \leq_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}_{\mathrm{simp}}^{(2p+1)}(A', \mathfrak{D}) \equiv_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}_{\mathrm{simp}}^{(2p+1)}(A, D),$$

so that $\mathrm{EVAL}(C) \leq_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}_{\mathrm{simp}}^{(\Delta)}(A, D)$, by taking $\Delta = 2p + 1$.

Remembering that our goal is to prove the #P-hardness for the matrices A, D not satisfying the tractability conditions of Theorem 8, we finally use the assumption that A is not block-rank-1. Next, noticing that all $\mu_{ij} > 0$, by construction A' is not block-rank-1 either. Finally, because all $w_i > 0$ nor is C block-rank-1 implying that $\mathrm{EVAL}(C)$ is #P-hard by Theorem 3. Hence $\mathrm{EVAL}_{\mathrm{simp}}^{(2p+1)}(A, D)$ is also #P-hard. This completes the proof of the #P-hardness part of Theorem 8.

We remark that one important step in our interpolation proof happened at the stratification step before (3). In the proof we have the goal of redistributing vertex weights to edge weights; but this redistribution is sensitive to the degree of the vertices. This led us to define the auxiliary graph G' and the coefficients c_κ. Usually in an interpolation proof there are some coefficients that have a clear combinatorial meaning in terms of the original problem instance. Here these values c_κ do not have a clear combinatorial meaning in terms of $Z_{A',\mathfrak{D}}(G)$, rather they are defined in terms of an intermediate problem instance G', which is neither G nor the actual constructed graphs $G_{n,p}$. It is only in a "limiting" sense that a certain combination of these values c_κ allows us to compute $Z_{A',\mathfrak{D}}(G)$.

5 Tractability part

The tractability part of Theorem 8 follows easily from known results. For completeness we outline a proof here. Let A and D be $m \times m$ matrices, where A is nonnegative symmetric block-rank-1 and D is positive diagonal.

First, $Z_{A,D}(G)$ can be reduced to the connected components $G_1, \dots, G_t$ of G,

$$Z_{A,D}(G) = \prod_{i=1}^{t} Z_{A,D}(G_i),$$

so we may as well assume G is connected. We permute the rows and columns of A, D by the same permutation and then cross out zero rows and columns of A. This does not change $Z_{A,D}$. We may assume that $A = \mathrm{diag}(A_i)_{i=1}^{k}$ is block diagonal with nonzero blocks $A_1, \dots, A_k$, where each block A_i is either a symmetric matrix of rank 1 with no zero entries, or a symmetric bipartite matrix of the form $\left(\begin{smallmatrix} 0 & B \\ B^T & 0 \end{smallmatrix}\right)$ where B has rank 1 and no zero entries. Then we can write $D = \mathrm{diag}(D_i)_{i=1}^{k}$ where each D_i is positive diagonal of the corresponding size. As A is block diagonal and G is connected,

$$Z_{A,D}(G) = \sum_{i=1}^{k} Z_{A_i,D_i}(G).$$

So we may as well assume that A is one of these blocks. Also let $D = \mathrm{diag}(\alpha_i)_{i=1}^{m}$.

1) A is a symmetric matrix of rank 1 with no zero entries. We can write $A = x^T x$ for some positive row vector $x = (x_i)_{i=1}^{m}$. Then

$$Z_{A,D}(G) = \prod_{u \in V(G)} \sum_{i=1}^{m} \alpha_i x_i^{\deg(u)}.$$

2) $A = \left(\begin{smallmatrix} 0 & B \\ B^T & 0 \end{smallmatrix}\right)$, where B is $\ell \times (m-\ell)$ (for some $1 \le \ell < m$) has rank 1 and no zero entries. We can write $B = x^T y$ for some positive row vectors $x = (x_i)_{i=1}^{\ell}$ and $y = (y_j)_{j=\ell+1}^{m}$. Since G is connected, $Z_{A,D}(G) = 0$ unless G is bipartite. If G is bipartite with a vertex bipartization $V_1 \cup V_2$, then we only need to consider maps $\xi\colon G \to [m]$ such that either $\xi(V_1) \subseteq [\ell]$, $\xi(V_2) \subseteq [\ell+1:m]$ or $\xi(V_1) \subseteq [\ell+1:m]$, $\xi(V_2) \subseteq [\ell]$, with all other maps contribute zero to $Z_{A,D}(G)$. Then

$$\begin{aligned} Z_{A,D}(G) = &\left(\prod_{u \in V_1} \sum_{i=1}^{\ell} \alpha_i x_i^{\deg(u)}\right)\left(\prod_{v \in V_2} \sum_{j=\ell+1}^{m} \alpha_j y_j^{\deg(v)}\right) \\ &+ \left(\prod_{u \in V_1} \sum_{j=\ell+1}^{m} \alpha_j y_j^{\deg(u)}\right)\left(\prod_{v \in V_2} \sum_{i=1}^{\ell} \alpha_i x_i^{\deg(v)}\right). \end{aligned}$$

6 Two technical lemmas

We need two technical lemmas. The following lemma is from [10] (Lemma 3.6); for the convenience of readers we give a proof here.

▶ **Lemma 9.** *Let A and D be $m \times m$ matrices, where A is real symmetric with all columns nonzero and pairwise linearly independent, and D is positive diagonal. Then all columns of ADA are nonzero and pairwise linearly independent.*

Proof. The case $m = 1$ is trivial. Assume $m \ge 2$. Let $D = \operatorname{diag}(\alpha_i)_{i=1}^m$, and $\Pi = \operatorname{diag}(\sqrt{\alpha_i})_{i=1}^m$. Then $\Pi^2 = D$. We have $ADA = Q^T Q$, where $Q = \Pi A$. Let q_i denote the ith column of Q. Then Q has pairwise linearly independent columns. By the Cauchy-Schwartz inequality,

$$q_i^T q_j < \left((q_i^T q_i)(q_j^T q_j)\right)^{1/2},$$

whenever $i \ne j$. Then for any $1 \le i < j \le m$, the ith and jth columns of ADA contain a submatrix

$$\begin{bmatrix} q_i^T q_i & q_i^T q_j \\ q_i^T q_j & q_j^T q_j \end{bmatrix},$$

so they are linearly independent. ◀

The following is also adapted from [10] (Theorem 3.1).

▶ **Lemma 10.** *Let A and D be $m \times m$ matrices, where A is real symmetric with all columns nonzero and pairwise linearly independent, and D is positive diagonal. Then for all sufficiently large positive integers p, the matrix $B = (ADA)^{\odot p}$ corresponding to the edge gadget in Figure 5 is nondegenerate.*

Proof. If $m = 1$, then any $p \ge 1$ works. Let $m \ge 2$. Following the proof of Lemma 9, we have $q_i^T q_j < \sqrt{(q_i^T q_i)(q_j^T q_j)}$, for all $1 \le i < j \le m$. Let

$$\gamma = \max_{1 \le i < j \le m} \frac{q_i^T q_j}{\sqrt{(q_i^T q_i)(q_j^T q_j)}} < 1.$$

Let $A' = ADA = Q^T Q$ so $A'_{ij} = q_i^T q_j$. Then $A'_{ij} \le \gamma \sqrt{A'_{ii} A'_{jj}}$ for all $i \ne j$. Consider the determinant of A'. Each term of $\det(A')$ has the form

$$\pm \prod_{i=1}^{m} A'_{i\sigma(i)},$$
