Contents

Invited Talks

Track A: Algorithms, Complexity and Games

Track B: Automata, Logic, Semantics, and Theory of Programming

Preface

This volume contains the papers presented at the *47th International Colloquium on Automata, Languages and Programming (**ICALP 2020**)*, held *virtually*, hosted by the Saarland Informatics Campus in Saarbrücken, Germany, during July 8–11, 2020. ICALP is a series of annual conferences of the *European Association for Theoretical Computer Science (EATCS)*, which first took place in 1972. ICALP 2020 was co-located with the 35th Annual ACM/IEEE Symposium on Logic in Computer Science (LICS 2020).

The conference was affected by the outbreak of COVID-19, which had an enormous impact across the world and the ICALP community was no exception. The original plan had been to hold ICALP 2020, in conjunction with LICS 2020 at Peking University in Beijing, China. When it became clear that this would not be possible due to travel restrictions that were being imposed, and after intensive discussions between the ICALP and LICS steering committees, together with the PC chairs and conference chairs, it was decided to re-locate the conferences to Saarbrücken. Eventually, keeping the safety, health and well-being of ICALP participants as a top priority, it was decided to hold ICALP 2020 entirely online. We are very grateful to the organizers in Beijing and Saarbrücken and to all members of the theoretical computer science community for their flexibility and adaptability in this difficult situation. This first online ICALP is an experiment forced on us by the situation and will no doubt offer many lessons for the future.

For 15 years, the ICALP conference ran with three tracks. This has been the subject of much deliberation in the ICALP community in recent years and the decision was taken, with ICALP 2020, to return to a two-track format. Topics previously included in Track C have been incorporated into Track A. This year, the ICALP program consisted of the following two tracks:

- Track A: Algorithms, Complexity, and Games.
- Track B: Logic, Semantics, Automata and Theory of Programming.

In response to the call for papers, a total of 470 submissions were received: 347 for Track A and 123 for Track B. Each submission was assigned to at least three Program Committee members, aided by 857 external subreviewers. The committees decided to accept 138 papers for inclusion in the scientific program: 102 papers for Track A and 36 for Track B. The selection was made by the Program Committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high indeed, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper in each of the two tracks, selected by the Program Committees.
The **best paper awards** were given to the following papers:

Track A: Paweł Gawrychowski, Shay Mozes, and Oren Weimann. *Minimum cut in* $O(m \log^2 n)$ *time.*

Track B: David Barozzini, Lorenzo Clemente, Thomas Colcombet and Paweł Parys. *Cost automata, safe schemes, and downward closures.*

The **best student paper awards**, for papers that are solely authored by students, were given to the following papers:

Track A: Aditya Potukuchi. *A spectral bound on hypergraph discrepancy.*

Track B: Erik Paul. *Finite sequentiality of finitely ambiguous max-plus tree automata.*

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).
Editors: Artur Czumaj, Anuj Dawar, and Emanuela Merelli
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Apart from the contributed talks, ICALP 2020 included invited presentations by Stefan Kiefer (Oxford University), Robert Krauthgamer (The Weizmann Institute of Science) and Virginia Vassilevska Williams (MIT). There were also two invited talks joint with LICS 2020: by Jerôme Leroux (Bordeaux University) and Andrew Chi-Chih Yao (Tsinghua University). This volume contains all the contributed papers presented at the conference, papers that accompany the invited talks of Andrew Yao and Stefan Kiefer, and an abstract of the invited presentation of Robert Krauthgamer.

The program of ICALP 2020 also included presentations of the EATCS Award 2020 to Mihalis Yannakakis, the Gödel Prize 2020 to Robin A. Moser and Gábor Tardos, the Presburger Award 2020 to Dmitriy Zhuk, and the EATCS Distinguished Dissertation Awards to Josh Alman, Sándor Kisfaludi-Bak, and Jakub Tarnawski.

The following workshops were held as satellite events of ICALP and LICS 2020 on July 6–7, 2020:

- Algorithmic Aspects of Temporal Graphs (AATG),
- Fine-Grained and Parameterized Approximation Algorithms (FG-PAAW),
- Verification of Infinite-State Systems (INFINITY),
- Logic and Computational Complexity Workshop (LCC 2020),
- Logic Mentoring Workshop (LMW),
- Programming Research in Mainstream Languages (PRiML).

We wish to thank all authors who submitted extended abstracts for consideration, the Program Committees for their scholarly effort, and all the referees who assisted the Program Committees in the evaluation process. We are also grateful to the Conference Co-Chairs Xiaotie Deng and Holger Hermanns and all the support staff of the Organizing Committee for organizing ICALP 2020: to our colleagues in Peking University, led by Xiaotie Deng, for their organizational efforts in the originally planned location in Beijing, and to the colleagues from Saarbrücken, led by Holger Hermanns, who generously accepted the challenging task of organizing the conference at short notice, and who were then ready to run the conference online. Finally, we are grateful to all members of the TCS community who offered their support in this difficult situation.

We wish to thank CPEC — Center for Perspicuous Computing and Saarland University in Saarbrücken for their generous support for the conference.

We would like to thank Anca Muscholl, the Chair of the ICALP Steering Committee, for her continuous support and Paul Spirakis, the president of EATCS, for his generous advice on the organization of the conference.

An Incentive Analysis of Some Bitcoin Fee Designs

Abstract

In the Bitcoin system, miners are incentivized to join the system and validate transactions through fees paid by the users. A simple "pay your bid" auction has been employed to determine the transaction fees. Recently, Lavi, Sattath and Zohar [8] proposed an alternative fee design, called the *monopolistic price* (MP) mechanism, aimed at improving the revenue for the miners. Although MP is not strictly incentive compatible (IC), they studied how close to IC the mechanism is for iid distributions, and conjectured that it is nearly IC asymptotically based on extensive simulations and some analysis. In this paper, we prove that the MP mechanism is nearly incentive compatible for any iid distribution as the number of users grows large. This holds true with respect to other attacks such as splitting bids. We also prove a conjecture in [8] that MP dominates the RSOP auction in revenue (originally defined in Goldberg et al. [5] for digital goods). These results lend support to MP as a Bitcoin fee design candidate. Additionally, we explore some possible intrinsic correlations between incentive compatibility and revenue in general.

1 Introduction

Bitcoin, and more broadly *blockchain* systems, rely on the willingness of honest players to participate in the system. A good blockchain system should have simple, practical designs with suitable security guarantees against cheating. The *incentive compatibility* (IC) concept which seeks to incentivize the participants to be truthful is playing an increasingly central role in the design of distributed financial systems.

Recently, Lavi, Sattath and Zohar [8] started a study of the subject of *Bitcoin Fee Market* design. In this market, there are two kinds of players: the *users* who have transaction records that need to be certified and registered in the bitcoin system, and the *miners* who create new blocks to include the transactions and get them certified. Each user declares the maximal amount she is willing to pay for her transaction, and the miners use a mechanism to decide which transactions to include and how much fee to charge each user. A primary focus of their study is the *Monopolistic Price (MP)* mechanism, which is a natural and practical mechanism, although not IC in the strict sense (see Section 2 below). Their extensive simulations indicate that the mechanism does not deviate too much from being IC for most iii distributions, as the number of users n grows large. An analysis was given for the special case of discrete distributions of finite size. They suggest that MP might be a good alternative to the "pay your bid" auction, which is subject to low bids and revenue. It is posed as a conjecture that the MP mechanism is nearly-IC for general iid distributions.

We will prove that MP is nearly-IC for any iid distribution as n grows large, thus mathematically validating the strong simulation results obtained in [8]. Note that the standard IC criterion (in auction market) only addresses one kind of attack, namely, the reporting of an untruthful bid value. There are other possible attacks by Bitcoin users: for example, in the *multiple strategic bids* (MSB) attack discussed in [8], a user could gain advantage by splitting his transaction into several transactions and bidding separately. This strategy could even enable a losing transaction to be included in the block. We will also prove the nearly-IC conjecture for MP with respect to the MSB attack.

We consider another mechanism, called the RSOP (Random Sampling Optimal Price) auction, which was first defined by Goldberg et al. [5] in the digital goods context and shown to be truthful. We prove that the RSOP revenue is always dominated by the MP revenue, as conjectured in [8]. In fact, the revenue difference can be arbitrarily large for some distributions, prompting us to look more deeply into possible correlation between IC and revenue in general (Theorem 6-8).

The contributions of the present paper are two-fold. First, we prove the Monopolistic Price mechanism to be nearly-IC, confirming the previous strong experimental data. This holds true against the MSB attack as well. We also show MP to dominate the RSOP auction in revenue. These results lend support to MP as a Bitcoin fee design candidate. Secondly, the methodology used in our proofs involves sophisticated mathematical analysis. It demonstrates that theoretical computer science can provide powerful tools to complement system design for blockchains. Finally, we believe that the emerging area of incentive compatible blockchain design is an exciting research area with many intriguing problems to solve, for theorists and system designers alike.

Related Work. The basic model for Bitcoin fee market introduced in [8] in fact resembles the maximum revenue problem for *Digital Goods* as considered by Goldberg et al. [4][5]. The MP mechanism is similar to the optimal omniscient auction in [5]. However, The Bitcoin fee market differs from digital goods in its additional features: such as the auctioneer may delete or insert bids, or the users may split bids. This makes the Bitcoin fee design a rich and relevant new research subject for auction theory and mechanism design. Among those work closely related to the current subject include Babaioff et al. [1], Kroll et al. [7], Carlsten et al. [3], Bonneau [2], Huberman et al. [6]. To formulate meaningful incentive models, there is much research work in Bitcoin which provides important ingredients for consideration. A more complete survey of related work can be found in [8, Section 1.3].

2 Review of the Models and Known Results

For background, we first review some Bitcoin fee models and mechanisms previously considered. A *miner* acts as a monopolist who offers n users to include their transactions in the miner's next block for a fee. Each user i has one transaction that needs this service and is willing to pay a fee up to some value v_i. The miner's problem is to design a mechanism to extract good revenue. The standard Bitcoin mechanism in use is a pay-your-bid system, where the miner simply takes the highest bids to fill the capacity of the block. This mechanism may not receive good revenue, since some bidders may not reveal the true value of the fees they are willing to pay. In view of this, some alternative mechanisms are proposed in [8] and their security properties considered, which we will review below.

2.1 The Monopolistic Price (MP) Mechanism

Suppose user i bids v_i for $1 \leq i \leq n$. Sort $v_1, \cdots, v_n$ into a decreasing sequence $b_1 \geq b_2 \geq \cdots \geq b_n$. Consider the expression $k \cdot b_k$ and let $k^*(v)$ be the k maximizing $k \cdot b_k$ over all k (in case of ties, k^* is taken to be the maximal one). The miner will include all users with the highest bids $b_1, b_2, \cdots b_{k^*(v)}$ and simply charge each one of them the same fee $b_{k^*(v)}$. Call this the *monopolistic price* $p^{mono}(v) = b_{k^*(v)}$. This mechanism gives the miner revenue $MP(v) = k^* \cdot b_{k^*(v)}$, which is obviously the maximum revenue obtainable if all accepted bids must be charged a single price.

The above MP Mechanism is not truthful. To analyze how serious the non-truthfulness can be, consider the following model. For any user i with bid v_i and the vector of bids $v_{-i} = (v_1, \cdots, v_{i-1}, v_{i+1}, \cdots v_n)$ of the other users, let

$$p^{honest}(v_i, v_{-i}) = p^{mono}(v_i, v_{-i}), \text{ and}$$
$$p^{strategic}(v_{-i}) = \min\{v_i \,|p^{mono}(v_i, v_{-i}) \leq v_i\}.$$

The temptation for user i to *shade* her bids can be measured by the *discount ratio* δ_i defined as:

$$\delta_i(v_i, v_{-i}) = \begin{cases} 1 - \frac{p^{strategic}(v_{-i})}{p^{honest}(v_i, v_{-i})} & \text{if } v_i \geq p^{strategic}(v_{-i}), \\ 0 & \text{otherwise.} \end{cases}$$

This ratio captures the gain a user can obtain by bidding strategically (instead of truthfully). Assume all true values v_i are drawn iid from some distribution F on $[0, \infty)$. Two measures are defined: the worst-case measure and the average case one. For the former, let

$$\delta_{max}(v) = \max_i \delta_i(v_i, v_{-i}),$$
$$\Delta_n^{max} = E_{(v_1, \cdots, v_n) \sim F}[\delta_{max}(v)].$$

For the latter, let

$$\Delta_n^{average} = E_{(v_1, \cdots, v_n) \sim F}[\delta_1(v_1, v_{-1})].$$

Clearly, for every F and n, we have $\Delta_n^{max} \geq \Delta_n^{average}$, since $\delta_{max}(v) \geq \delta_i(v_i, v_{-i})$ for any v. For the special case of discrete distributions of finite size, the following is known.

▶ **Theorem A** ([8, Theorem 2.3]). *For any distribution F with a finite support size, $\lim_{n\to\infty} \Delta_n^{max}(F) = 0$. (This implies also $\lim_{n\to\infty} \Delta_n^{average}(F) = 0$ for such F.)*

Based on extensive simulations done for a variety of distributions, it was conjectured that MP is nearly IC for general iid distributions as n gets large.

Nearly IC Conjecture for MP

1. For any distribution F, $\lim_{n\to\infty} \Delta_n^{average}(F) = 0$. Specifically $\Delta_n^{average}(F) = O(\frac{1}{n})$.
2. If F has a bounded support, $\lim_{n\to\infty} \Delta_n^{max}(F) = 0$. Specifically $\Delta_n^{max}(F) = O(\frac{1}{n})$.
3. There exists a distribution F with an unbounded support such that $\lim_{n\to\infty} \Delta_n^{max}(F) > 0$.

In the O-notation above, the constants may depend on F. The main purpose of our paper is to settle the Nearly IC Conjecture for MP in the positive (see Theorem 1–3).

A stronger attack, called the **Multiple Strategic Bids** (MSB) attack was also raised in [8]. They observed that a user could gain advantage by splitting his bid into several transactions with separate bids; this strategy could enable a losing transaction to be included in the block. We note that, under this strategy,

$$p^{multi}(v_{-i}) = \min\left\{u \cdot v_i^{(u)} \,|\, v_i^{(1)} \geq \cdots \geq v_i^{(u)} \geq p^{mono}(v_i^{(1)}, \cdots, v_i^{(u)}, v_{-i})\right\},$$

$$\delta_i(v_i, v_{-i}) = \begin{cases} 1 - \frac{p^{multi}(v_{-i})}{p^{honest}(v_i, v_{-i})} & \text{if } \ v_i \geq p^{multi}(v_{-i}), \\ 0 & \text{otherwise.} \end{cases}$$

We show that the Nearly IC Conjecture for MP remains true under the MSB attack (see Theorem 4) as conjectured in [8].

2.2 The Random Sampling Optimal Price (RSOP) Auction

We consider another mechanism, called the RSOP (Random Sampling Optimal Price) auction, first defined by Goldberg et al. [5] in the digital goods context.

▶ **Definition** (RSOP auction). *Upon receiving n bids $v = (v_1, \cdots, v_n)$, the auctioneer randomly partitions the bids into two disjoint sets A and B, and computes the monopolistic price for each set: P_A^{mono}, P_B^{mono} (with the monopolistic price for an empty set being set to 0). Finally, the set of winning bids is $A' \cup B'$, where $A' = \{i \in A : v_i \geq P_B^{mono}\}$ and $B' = \{i \in B : v_i \geq P_A^{mono}\}$. The bidders in A' each pays P_B^{mono}, and the bidders in B' each pays P_A^{mono}.*

Note the revenue obtained in this auction is

$$RSOP(v) = |A'| \cdot P_B^{mono} + |B'| \cdot P_A^{mono}.$$

▶ **Theorem B** (Goldberg et al. [5]). *The RSOP auction is truthful. For any $v = (v_1, \cdots, v_n)$ with $v_i \in [1, D]$ (where D is a constant) for all i, we have*

$$\lim_{n\to\infty} \max_{v} \frac{MP(v)}{RSOP(v)} = 1.$$

In [8], several variants of RSOP were examined and simulation carried out which led to the following conjecture.

Dominance Conjecture of MP over RSOP. [8, Conjecture 5.4]
For any v and all choices of A and B, the RSOP revenue is at most the monopolistic price revenue. That is, $RSOP(v) \leq MP(v)$.

The MP Dominance Conjecture has relevance to the robustness of RSOP against adding false bids or deleting bids by the auctioneer (see discussions in [8]). In the present paper we prove the MP Dominance Conjecture to be true.

3 Main Results

In this paper we settle the Nearly-IC Conjecture (even allowing for the MSB attack) and the MP Dominance Conjecture mentioned above: the former in Theorem 1–4, and the latter in Theorem 5. Additionally, we investigate the possible correlation between incentive compatibility and revenue. In this regard, we demonstrate that distributions with unbounded support can exhibit different characteristics from the bounded ones, and these findings will be presented in Theorems 6–8.

3.1 Nearly Incentive Compatibility of MP

We prove the Nearly-IC Conjecture, part (1)-(3), in Theorems 1-3 respectively. Let the *Inverse* distribution *Inv* be defined as $Pr_{Inv}\{X > x\} = \frac{1}{x}$ for $x \in [1, \infty)$.

▶ **Theorem 1.** *For any distribution F on bounded support, $\lim_{n\to\infty} \Delta_n^{max}(F) = 0$.*

▶ **Theorem 2.** *For any distribution F, $\lim_{n\to\infty} \Delta_n^{average}(F) = 0$.*

▶ **Theorem 3.** *For $F = Inv$, $\lim_{n\to\infty} \Delta_n^{max}(F) > c$ for all n, where $c > 0$ is some absolute constant.*

▶ **Theorem 4.** *With respect to the MSB attack, the MP mechanism is nearly incentive compatible, i.e., Theorems 1-2 are still valid.*

▶ Remark. The proof of Theorem 4 uses similar techniques as Theorems 1-2 and will be omitted in this paper. We remark that Theorem 1 can be refined to show that $\Delta_n^{max}(F) = O(\frac{1}{n^\beta})$ where $\beta > 0$ is a constant independent of F, while the constant in the O-notation is F-dependent. Similarly, Theorem 2 can be strengthened to $\Delta_n^{average}(F) = O(\frac{1}{n^\beta})$ when F satisfies $\sup_x x(1 - F(x)) < \infty$. The analysis follows the same outline as the proofs for Theorems 1, 2 above but the details are more complicated. They will be left for a later version of the paper.

3.2 The Effect of IC on Revenue

The following theorem settles the Dominance Conjecture of MP over RSOP.

▶ **Theorem 5.** *For any v, $RSOP(v) \le MP(v)$.*

Theorem B of Goldberg et al. [5] says that, RSOP yields asymptotically the same revenue as the MP mechanism when the distribution F has a bounded support $[1, D]$. We point out that this is not always true when F has infinite support. For the distribution $F = Inv$, MP can extract infinite revenue versus a finite amount by RSOP.

▶ **Theorem 6.** *For $F = Inv$,*

$$\lim_{n\to\infty} \frac{1}{n} E_{v_1,\cdots,v_n\sim F}[MP(v)] = \infty, \text{ \textit{while}}$$
$$\lim_{n\to\infty} \frac{1}{n} E_{v_1,\cdots,v_n\sim F}[RSOP(v)] = 1.$$

One may ask, could the revenue gap between MP and RSOP be attributable to the fact that RSOP is IC while MP drastically deviates from IC (as demonstrated in Theorem 3)? In other words, could the property derived in Theorem 3, $\lim_{n\to\infty} \Delta_n^{max}(F) > c$, be a necessary condition for any mechanism to achieve infinite revenue on $F = Inv$? The following theorem shows that this is not the case.

Let $n \ge 1$ and M be a fee mechanism for n bidders. For a bid vector $v = (v_1, \cdots, v_n)$, let $\delta_{max}(M, v)$ be the maximum of $\delta_i(v_i, v_{-i})$ for any i when M is applied to v. Let $\Delta_n^{max}(M, F) = E_{v_1,\cdots,v_n\sim F}[\delta_{max}(M, v)]$. Also, let $M(v)$ denote the revenue collected by M.

▶ **Theorem 7.** *For any n and $\epsilon > 0$, there exists a fee mechanism M for n users such that $\Delta_n^{max}(M, Inv) \le \epsilon$ and $E_{v_1,\cdots,v_n\sim Inv}[M(v)] = \infty$.*

Note that δ_{max} and Δ_n^{max} are not the only ways to quantify a mechanism's closeness to being incentive compatible. Two standard ways to define being *ϵ-close* to IC (or more generally, to Nash equilibrium) are

(1) Additively ϵ-close: $p(v_i, v_{-i}) - p_i^*(v_{-i}) \leq \epsilon$,

(2) Multiplicatively ϵ-close: $p(v_i, v_{-i}) - p_i^*(v_{-i}) \leq \epsilon(v_i - p(v_i, v_{-i}))$,

where $p_i^*(v_{-i})$ is defined as the *minimum* bid value u for user i that would allow her to be among the winners when the bid vector is $v = (u, v_{-i})$.

We will show that, adopting the "multiplicatively ϵ-close" definition, one can obtain nearly IC mechanisms that derive infinite revenue under the distribution $F = Inv$.

Let M be any IC mechanism (such as RSOP). For any bid vector v, let $p_i(v)$ be the fee paid by user i (if i is a winner), and $u_i(v) = v_i - p_i(v)$ be the *utility.* For any $0 \leq \epsilon < 1$, let M_ϵ be the mechanism that uses the same allocation rule as M, with the fee modified to be $p_i'(v) = p_i(v) + \frac{\epsilon}{1+\epsilon} u_i(v)$. The following theorem is easy to prove.

▶ **Theorem 8.**

(a) *M_ϵ is multiplicatively ϵ-close to IC;*

(b) $\lim_{n\to\infty} \frac{1}{n} E_{v\sim F}[R_{M_\epsilon}(v)] = \lim_{n\to\infty} \frac{1}{n} E_{v\sim F}[R_M(v)] + \frac{\epsilon}{1+\epsilon} \lim_{n\to\infty} \frac{1}{n} E_{v\sim F}(\sum_i u_i(v))$.

Theorem 8 implies that RSOP can be easily modified to become a multiplicatively ϵ-close-to-IC mechanism such that, like MP, its revenue is infinite under $F = Inv$.

We will prove Theorems 1-3, 5 in the following sections. The proof for the Multiple Strategic Bids model of Theorem 4 is similar in essence to the basic model, and hence will be omitted. We also leave out the proofs of Theorem 6-8.

4 An Overview of the Proof for Theorem 1

Theorem 1 is the most difficult to prove. In this section we give some intuition and an overview of the proof.

Let F be a distribution over $[0, D]$. Let $v_1, \cdots, v_n$ be generated according to iid F, and denote by $b_1 \geq b_2 \geq \cdots \geq b_n$ the sorted list of the $v_i's$. By Claim A9 in [8], $\delta_{max}(b) = \delta_1(b_1, b_{-1})$, i.e. the maximum discount ratio is achieved by the user with the highest bid. This leads immediately to a necessary condition on w, the optimal strategic bid by the highest bidder, as we state below.

▶ **Lemma 1** (Optimal Strategic Bid (OSB) Condition). *Let $k^* = k^*(b)$. If $\delta_{max}(b) \geq \eta$, where $0 < \eta \leq 1$, then there exists $w \in [0, (1-\eta)b_{k^*}]$ such that $i_w \cdot w \geq k^* \cdot b_{k^*} - D$, where i_w is defined by $b_{i_w} \geq w > b_{i_w+1}$.*

Lemma 1 states that, in order to have a sizable η, there has to exist a w some distance away from b_{k^*} such that $i_w \cdot w$ is only a constant D smaller than the sampled maximum $R(b) = k^* \cdot b_{k^*}$. We will prove Theorem 1 by showing that a random b is stochastically unlikely to satisfy the OSB necessary condition.

As a start, we prove Theorem 1 when the distribution F has a unique $\alpha_0 > 0$ where $A = \sup_\alpha \alpha(1 - F(\alpha))$ is achieved. The law of large number implies that, for large n, every $w \leq \alpha_0(1 - \frac{1}{2}\eta)$ satisfies $i_w \cdot w < (A - \rho)n$ (where ρ is some fixed constant) with overwhelming probability. Coupled with the fact $b_{k^*} - \alpha_0 = O(\frac{1}{\sqrt{n}})$ and $k^* \cdot b_{k^*} = A \cdot n + O(\sqrt{n})$ probabilistically, we see that the OSB condition in Lemma 1 cannot hold. Hence we have shown Theorem 1 for the case when $\sup_\alpha \alpha(1 - F(\alpha))$ has a maximum achieved at a unique point $\alpha = \alpha_0$.

The above argument does not apply when $\sup_\alpha \alpha(1-F(\alpha))$ achieves maximum value at multiple points. As an extreme case, consider the Inverse distribution modified as follows:

$$Inv^{(D)}(x) = \begin{cases} 1-\frac{1}{x} & \text{for } 1 \leq x < D, \\ 1 & \text{for } x = D. \end{cases}$$

In this case, $x(1 - Inv^{(D)}(x)) = 1$ for all $1 \leq x < D$.

Hence the challenge is to prove that, even for extreme cases like the above, the OSB condition in Lemma 1 cannot be met except with vanishingly small probability. At the top level, we wish to show that, in any two subintervals $I, J \subseteq [0, D]$ separated by a non-negligible distance, the maximum values $A_I = \max\{j \cdot b_j \,| b_j \in I\}$ and $A_J = \max\{j \cdot b_j \,| b_j \in J\}$ cannot achieve perfect correlation to allow $|A_I - A_J| = O(1)$ except with negligible probability for large n. This claim takes a non-trivial proof since intervals A_I and A_J, being taken from the sorted version b of v, are correlated to a certain degree.

Before proving Theorem 1, we first recast Lemma 1 in an new form which does not reference the quantity w. The main advantage of Lemma 1A is that, the condition now refers only to the quantities $b_1, \cdots, b_n$, thus making it easier to analyze how likely the condition can be satisfied stochastically.

▶ **Lemma 1A** (Optimal Strategic Bid (OSB) Condition). *Let $k^* = k^*(b)$ and $0 < \eta < 1$. If $\delta_{max}(b) \geq \eta$, then there exists $b_j \in [0,\, b_{k^*}(1-\frac{1}{2}\eta)]$ such that $j \cdot b_j \geq k^* \cdot b_{k^*} - \frac{2D^2}{\eta \cdot b_{k^*}}$.*

Proof. Take the w as specified in Lemma 1. The following constraints are satisfied: write $i = i_w$ and $B = k^* \cdot b_{k^*}$, then

$$b_{k^*} - \eta \cdot b_{k^*} \geq w, \tag{1}$$

$$i \cdot w \geq B - D. \tag{2}$$

Let $\Delta_j = b_{k^*} - b_j$ for $j \in \{i, i+1\}$. Let $0 \leq \lambda < 1$ such that $w = \lambda b_i + \lambda' b_{i+1}$ where $\lambda' = 1 - \lambda$. It is easy to verify from Eq. (1), (2) that

$$\lambda \Delta_i + \lambda' \Delta_{i+1} \geq \eta \cdot b_{k^*}, \tag{3}$$

$$\lambda(i \cdot b_i) + \lambda'\left((i+1)b_{i+1}\right) \geq B - D. \tag{4}$$

Note that Eq. (4) implies

$$\max\{i \cdot b_i,\, (i+1)b_{i+1}\} \geq B - D. \tag{5}$$

We now prove Lemma 1A.

Case 1. If $\Delta_i > \frac{1}{2}\eta \cdot b_{k^*}$, then choose $j \in \{i,\, i+1\}$ depending on which gives the larger $j \cdot b_j$. This j satisfies Lemma 1A, as a consequence of Eq. (1) and (5).

Case 2. $\Delta_i \leq \frac{1}{2}\eta \cdot b_{k^*}$. Eq. (3) implies $\lambda' D \geq \frac{1}{2}\eta \cdot b_{k^*}$, and thus

$$\lambda' \geq \frac{\eta \cdot b_{k^*}}{2D}. \tag{6}$$

From Eq. (4) and the fact $i \cdot b_i \leq B$, we have

$$\lambda'\left((i+1)b_{i+1}\right) \geq \lambda' B - D.$$

Using Eq. (6), we obtin

$$(i+1)b_{i+1} \geq B - \frac{2D^2}{\eta \cdot b_{k^*}}.$$

Taking $j = i+1$ satisfies Lemma 1A. ◀

5 Proof of Theorem 1

For simplicity of presentation, we assume that F has support $[1, D]$. Without loss of generality, we can assume that $F(x) < F(D) = 1$ for any $x < D$. Some additional arguments are needed for the general case $[0, D]$; we omit them here.

We will demonstrate that for a random b, the condition stated in Lemma 1A occurs with probability at most $O(\frac{(\log n)^2}{\sqrt{n}})$. That is, stochastically, the pair (b_j, b_{k^*}) with the stated property rarely exists. First some notation. Let $H_F(x) = Pr_{z\sim F}\{z \geq x\} = 1 - F(x-)$. To start the proof, we pick a point $D_1 \in [1, D]$ with the following properties:

P1: $(D_1, D]$ is a forbidden zone for b_{k^*}. Precisely, for a random b, the probability of $b_{k^*} \in (D_1, D]$ is $e^{-\Omega(n)}$.

P2: $Pr_{x\sim F}\{x \in [D_1, D]\} > 0$.

▶ **Fact 1.** *D_1 exists.*

Proof. Let α_{max} be the maximal α achieving $\sup_\alpha\{\alpha \cdot H_F(\alpha)\}$.

Case 1. If $\alpha_{max} = D$, then $(D_1, D]$ is empty and $Pr_{x\sim F}\{x \in [D_1, D]\} = D \cdot H_F(D) \; > 0$.

Case 2. If $\alpha_{max} < D$, then choose any $D_1 \in (\alpha_{max}, D)$. Choose $\Delta = \frac{1}{2}(D_1 - \alpha_{max})$. Then for large n, the probability of $b_{k^*} \in [0, \alpha_{max} + \Delta]$ is $1 - e^{-\Omega(n)}$, satisfying **P1**. We also have $Pr_{x\sim F}\{x \in [D_1, D]\} \geq 1 - F(D_1) > 0$, thus satisfying **P2**. ◀

Divide $[1, D_1]$ into disjoint intervals of length ϵ, that is, write $[1, D_1] = \cup_{\ell=1}^{m} I_\ell$ where $I_\ell = [1 + (\ell - 1)\epsilon, \, 1 + \ell\epsilon)$ for $1 \leq \ell < m$, and $I_m = [1 + (m - 1)\epsilon, \, 1 + m\epsilon]$. Take a random b, which is the sorted list of iid $v_1, \cdots, v_n \sim F$. Let A_ℓ^{max} denote the random variable $\max\{i \cdot b_i | \, b_i \in I_\ell\}$. Let $A_{>\ell}^{max}$ be the random variable $\max\{i \cdot b_i \,|\, b_i \in I_{\ell+1} \cup \cdots \cup I_m\}$. Let W_ℓ denote the event that

$$A_{>(\ell+1)}^{max} - \frac{D^2}{\epsilon} \leq A_\ell^{max} \leq A_{>(\ell+1)}^{max}.$$

Now note that, for $\delta_{max}(b) > 2\epsilon$, the OSB condition for (B_j, b_{k^*}) in Lemma 1A can hold only if either 1) $b_j \in I_\ell$ and $b_{k^*} \in I_{\ell+2} \cup \cdots \cup I_m$ for some ℓ, or 2) $b_{k^*} \in (D_1, D]$.

▶ **Lemma 2.** *$Pr\{\delta_{max}(b) > 2\epsilon\} \leq \sum_{\ell=1}^{m-2} Pr\{W_\ell\} + e^{-\Omega(n)}$.*

Proof. Immediate from property **P1** and Lemma 1A. ◀

The rest of this section is devoted to the proof of the following lemma, which indicates that A_ℓ^{max} and $A_{>(\ell+1)}^{max}$ are not correlated to be nearly identical.

▶ **Lemma 3** (Weak Correlation Lemma). *For each $1 \leq \ell \leq m - 2$, $Pr\{W_\ell\} = O(\frac{(\log n)^2}{\sqrt{n}})$.*

There are two cases to consider.

Case 1. $Pr_{x\sim F}\{x \in I_{\ell+1}\} > 0$;

Case 2. $Pr_{x\sim F}\{x \in I_{\ell+1}\} = 0$.

We give the proof of Case 1. The proof for Case 2 uses the same general idea, and will only be sketched with details omitted here. Assume we have Case 1. Let G be the distribution (normalized) when F is restricted to the interval $L \equiv I_{\ell+1} \cup I_{\ell+2} \cup \cdots \cup I_m \cup [D_1, D]$. Let

$$\rho_0 = Pr_{x\sim G}\{x \in I_{\ell+1}\} > 0, \text{ and}$$
$$\rho_1 = Pr_{x\sim G}\{x \in [D_1, D]\} > 0.$$

Consider the generation of a random b in the following alternative (but equivalent) way.

Phase 1. Generate a random integer N so that

$$Pr\{N = s\} = \binom{n}{s} q^s (1-q)^{n-s}$$

for $0 \le s \le n$, where $q = Pr_{x \sim F}\{x \in L\}$.

Phase 2. Generate $n - N$ iid random numbers $v_1, \cdots, v_{N-n} \sim F|_{I_1 \cup \cdots \cup I_\ell}$, and sort them into decreasing order $b_{N+1}, b_{N+2}, \cdots, b_n$. (Note that A_ℓ^{max} is already determined after the completion of Phase 2.)

Phase 3. Generate $v_1, v_2, \cdots, v_N \sim G$ one number at a time. After step t, we sort the numbers $v_1, v_2, \cdots, v_t$ into decreasing order $b_1^{(t)} \ge b_2^{(t)} \ge \cdots \ge b_t^{(t)}$. Let

$$A^{(t)} = \max\{i \cdot b_i^{(t)} \mid b_i^{(t)} \in I_{\ell+2} \cup I_{\ell+3} \cup \cdots \cup I_m\}.$$

At time $t = N$, $A^{(N)}$ is exactly the same random variable as $A_{>(\ell+1)}^{max}$.

We prove two facts below, from which Lemma 3 follows immediately.

▶ **Fact 2.** *In Phase 1, $N \ge \frac{1}{2} q n$ with probability $1 - e^{-\Omega(n)}$.*

Proof. Chernoff's bound. ◀

After Phase 1 and 2, we have N and $K = A_\ell^{max}$ decided. To prove Lemma 3 we only need to show that, in Phase 3, there is enough randomness so that $A^{(N)}$ is unlikely to have a value within an additive constant $\frac{D^2}{\epsilon}$ to K.

Let us examine the evolution of $A^{(t)}$ as a random process of infinite length. The random sequence $A^{(t)}$ satisfies $A^{(0)} = 0$, and

$$A^{(t)} \begin{cases} = A^{(t-1)} & \text{with probability } \rho_0, \\ \ge A^{(t-1)} + 1 & \text{with probability } \rho_1, \\ \ge A^{(t-1)} & \text{otherwise,} \end{cases}$$

for $t \ge 1$.

▶ **Fact 3.** *At $t = N$, we have*

$$Pr\{|A^{(N)} - K| < \frac{D^2}{\epsilon}\} = O(\frac{(\log N)^2}{\sqrt{N}}) = O(\frac{(\log n)^2}{\sqrt{n}}).$$

Proof Sketch. Let s be the total number of times in the above process when either the second or third selection is made by $A^{(t)}$, for $1 \le t \le N$. Let $A^{(t_1)}, A^{(t_2)}, \cdots, A^{(t_s)}$ be the projected sequence. Note $E(s) = (1 - \rho_0)N$, $Var(s) = \Theta(N)$, and in fact $Pr\{s = u\} = O(\frac{1}{\sqrt{N}})$ for any u. Relabel $A^{(t_i)}$ as $B^{(i)}$, and consider the random sequence $B^{(1)}, B^{(2)}, \cdots$. Let $B^{(i)}, B^{(i+1)}, \cdots, B^{(i')}$ be the portion of the sequence in the range $[K - \frac{D^2}{\epsilon}, K + \frac{D^2}{\epsilon}]$. It is easy to verify that, for the random sequence $B^{(1)}, B^{(2)}, \cdots$,

$$Pr\{i' - i + 1 \ge \frac{D^2}{\epsilon} (\log N)^2\} = O(N^{-\log N}). \tag{7}$$

To see this, note that there is at least a constant $\phi = \frac{\rho_1}{1-\rho_0}$ probability to increase the next $B^{(j)}$ value by 1 (or more). Thus, to increase the value by $\frac{D^2}{\epsilon}$, it takes only $\frac{D^2}{\epsilon}\frac{1}{\phi}$ steps on average, rarely requiring a $(\log N)^2$ factor more steps.

As $Pr\{s = u\} = O(\frac{1}{\sqrt{N}})$ for any u, we conclude that $Pr\{B^{(s)} \in [K - \frac{D^2}{\epsilon}, K + \frac{D^2}{\epsilon}]\} \le O(\frac{(\log n)^2}{\sqrt{n}})$. This completes the proof of Case 1.

In Case 2, $Pr_{x\sim F}\{x \in I_{\ell+1}\} = 0$. We have lost the source of randomness critical for the above argument since $\rho_0 = 0$. Yet the source of randomness can be obtained by splitting I_ℓ into $I'_\ell \cup I''_\ell$ suitably, so that I''_ℓ does not contain any b_j with $j \cdot b_j$ anywhere close to the level of $A^{max}_{>(\ell+1)}$. (This will rely critically on the fact $Pr_{x\sim F}\{x \in I_{\ell+1}\} = 0$.) We omit here the details of implementing this plan, as well as the necessary handling of discontinuities in distribution F. This finishes the proof of Lemma 3 and thus Theorem 1. ◀

6 Proof of Theorem 2

Proof. For any $1 > \epsilon > 0$, we show that

$$\Delta_n^{average}(F) \le \epsilon \tag{8}$$

for all sufficiently large n. First pick $D > 0$ such that $F(D) > 1 - \epsilon/3$. Take n iid $v_i \sim F$ and let $q_{n,m}$ be the probability of exactly m of the $v_i' s$ falling into $[0, D]$. Let $\epsilon' = \epsilon/2$. By the law of large numbers, there exists N_1 such that for all $n \ge N_1$,

$$\sum_{m \le (1-\epsilon')n} q_{n,m} < \epsilon/6. \tag{9}$$

Consider the distribution G, obtained from restricting F to $[0, D]$. By Theorem 1, there exists $N_2 > 0$ such that

$$\Delta_m^{average}(G) < \epsilon/3 \tag{10}$$

for all $m > N_2$. We are now set for proving Theorem 2. By definition of $\Delta_n^{average}$, we have

$$\Delta_n^{average}(F) \le \sum_{m>(1-\epsilon')n} q_{n,m} \left[\frac{m}{n}\Delta_m^{average}(G) + \frac{n-m}{n}\right] + \sum_{m \le (1-\epsilon')n} q_{n,m}.$$

Using Eq. (9)-(10), we obtain for all $n > \max\{N_1, N_2\}$,

$$\Delta_n^{average}(F) \le (\frac{\epsilon}{3} + \epsilon') + \frac{\epsilon}{6} = \epsilon.$$

This proves Eq. (8) and Theorem 2. ◀

7 Proof of Theorem 3

Consider n iid random variables $v_1, \cdots, v_n$ distributed according to the Inverse distribution Inv, and let $b_1 \ge \cdots \ge b_n$ be their sorted sequence. Let $\lambda = 40$, $\lambda' = 1$, and let T_n be the event $(b_1 > \lambda n) \wedge (b_2 < \lambda' n)$. Let V_n be the event $(\max_{2 \le i \le n} i \cdot b_i \le \lambda n)$. Theorem 3 is an immediate consequence of the following two lemmas.

▶ **Lemma 4.** *If v satisfies event $T_n \wedge V_n$, then $\delta_{max}(v) \ge 1 - \frac{\lambda'}{\lambda}$.*

▶ **Lemma 5.**

$$Pr\{T_n \wedge V_n\} \ge \frac{1}{\lambda} e^{-\frac{2}{\lambda'}} - 4\,e^{-\frac{\lambda}{2}}.$$

Lemma 4 and 55 imply

$$\Delta_n^{max}(Inv) \ge c, \quad \textit{where}$$

$$c = (1 - \frac{\lambda'}{\lambda}) \cdot \left(\frac{1}{\lambda} e^{-\frac{2}{\lambda'}} - 4\,e^{-\frac{\lambda}{2}}\right) > 0.$$

This proves Theorem 3.

To prove Lemma 4, note that when $T_n \wedge V_n$ occurs, the highest bidder has a monopolistic price b_1 and a strategic price less than λn. Thus for the highest bidder i, we have $\delta_i(v) \geq 1 - \frac{\lambda n}{b_1} \geq 1 - \frac{\lambda'}{\lambda}$. This proves Lemma 4.

Lemma 5 follows from the following facts:

▶ **Fact 4.** $Pr\{T_n\} \geq \frac{1}{\lambda} e^{-\frac{2}{\lambda'}}$.

Proof.

$$\begin{aligned} Pr\{T_n\} &= \binom{n}{1} \frac{1}{\lambda n} \left(1 - \frac{1}{\lambda' n}\right)^{n-1} \\ &\geq \frac{1}{\lambda} e^{-\frac{2}{\lambda'}}. \end{aligned}$$ ◀

▶ **Fact 5.** $Pr\{V_n | T_n\} \leq 2\, e^{-\frac{\lambda}{2}}$.

Proof. Let $y_1, \cdots, y_n$ be iid distributed according to G, where for $t \in [1, n]$,

$$Pr_{z \sim G}\{z > t\} = \frac{1}{1 - \frac{1}{n}} \left(\frac{1}{t} - \frac{1}{n}\right).$$

Define $Y_n^{max} = \max_{1 \leq i \leq m}\{i \cdot b_i\}$, where $b_1 \geq \cdots \geq b_n$ is the sorted sequence of $y_1, \cdots, y_n$. Clearly,

$$Pr\{V_n | T_n\} \leq Pr\{Y_n^{max} \geq \lambda n\}.$$

To prove Fact 5, it suffices to prove:

$$Pr\{Y_n^{max} \geq \lambda n\} \leq 2\, e^{-\frac{\lambda}{2}}. \tag{11}$$

For any $t \geq 1$, let M_t be the number of y_i's satisfying $y_i \geq t$, and B_t be the event that $t \cdot M_t \geq \frac{\lambda}{2} n$. Let $t_k = \frac{1}{2^k} n$ for $1 \leq k \leq \lfloor \log_2 n \rfloor$. As the event $Y_n^{max} \geq \lambda n$ implies $\vee_{1 \leq k \leq \lfloor \log_2 n \rfloor} B_{t_k}$, we have

$$Pr\{Y_n^{max} \geq \lambda n\} \leq \sum_{i=1}^{\lfloor \log_2 n \rfloor} Pr\{B_{t_k}\}. \tag{12}$$

Observe that $E(M_t) = (1 - \frac{1}{n}) \frac{n}{t}$. Using Chernoff's bound, we have

$$Pr\{B_t\} \leq e^{-\frac{\lambda}{2} \frac{n}{t}}. \tag{13}$$

Equation (11) follows from (12) and (13) immediately. This completes the proof of Fact 5 and Theorem 3. ◀

8 Proof of Theorem 5

Without loss of generality, we assume that A, B are non-empty and that $p_A^{mono} \leq p_B^{mono}$. Let A consist of $y_1 \geq \cdots \geq y_m$ and B consist of $z_1 \geq \cdots \geq z_\ell$, with $y_s = p_A^{mono}$ and $z_t = p_B^{mono}$. Let $A' = \{y_1, y_2, \cdots, y_{s'}\}$ and $B' = \{z_1, z_2, \cdots, z_{t'}\}$ be the winners from A and B respectively. By definition of RSOP,

$$\begin{aligned} y_s &\leq z_{t'}, \\ t' z_{t'} &\leq t\, z_t. \end{aligned}$$

It follows that

$$\begin{aligned} RSOP(v) &= t' y_s + s' z_t \\ &\leq t' z_{t'} + s' z_t \\ &\leq t\, z_t + s' z_t. \end{aligned}$$

Now by definition $R(v) \geq (t + s')z_t$. Theorem 5 follows.

Sketching Graphs and Combinatorial Optimization

Robert Krauthgamer
Weizmann Institute of Science, Rehovot, Israel
robert.krauthgamer@weizmann.ac.il

Abstract

Graph-sketching algorithms summarize an input graph G in a manner that suffices to later answer (perhaps approximately) one or more optimization problems on G, like distances, cuts, and matchings. Two famous examples are the Gomory-Hu tree, which represents all the minimum *st*-cuts in a graph G using a tree on the same vertex set $V(G)$; and the cut-sparsifier of Benczúr and Karger, which is a sparse graph (often a reweighted subgraph) that approximates every cut in G within factor $1 \pm \varepsilon$. Another genre of these problems limits the queries to designated terminal vertices, denoted $T \subseteq V(G)$, and the sketch size depends on $|T|$ instead of $|V(G)|$.

The talk will survey this topic, particularly cut and flow problems such as the three examples above. Currently, most known sketches are based on a graph representation, often called edge and vertex sparsification, which leaves room for potential improvements like smaller storage by using another representation, and faster running time to answer a query. These algorithms employ a host of techniques, ranging from combinatorial methods, like graph partitioning and edge or vertex sampling, to standard tools in data-stream algorithms and in sparse recovery. There are also several lower bounds known, either combinatorial (for the graph representation) or based on communication complexity and information theory.

Many of the recent efforts focus on characterizing the tradeoff between accuracy and sketch size, yet many intriguing and very accessible problems are still open, and I will describe them in the talk.

Abstract

Markov decision processes (MDPs) are a standard model for dynamic systems that exhibit both stochastic and nondeterministic behavior. For MDPs with finite state space it is known that for a wide range of objectives there exist optimal strategies that are memoryless and deterministic. In contrast, if the state space is infinite, optimal strategies may not exist, and optimal or ε-optimal strategies may require (possibly infinite) memory. In this paper we consider qualitative objectives: reachability, safety, (co-)Büchi, and other parity objectives. We aim at giving an introduction to a collection of techniques that allow for the construction of strategies with little or no memory in countably infinite MDPs.

1 Introduction

Markov decision processes (MDPs) are a standard model for dynamic systems that exhibit both stochastic and controlled behavior [13]. MDPs play a prominent role in numerous domains, including artificial intelligence and machine learning [16, 15], control theory [3, 1], operations research and finance [4, 14], and formal verification [8, 2]. In an MDP, the system starts in the initial state and makes a sequence of transitions between states. Depending on the type of the current state, either the controller gets to choose an enabled transition (or a distribution over transitions), or the next transition is chosen randomly according to a defined distribution. By fixing a strategy for the controller, one obtains a probability space of runs of the MDP. The goal of the controller is to maximize the probability of a given objective (some set of desired runs), or, more generally, to optimize the expected value of a random variable (some real-valued function on runs).

The type of strategy needed to satisfy an objective optimally (or ε-optimally) is called the *strategy complexity* of the objective. There are different types of strategies, depending on whether one can take the whole history of the run into account (history-dependent; (H)), or whether one is limited to a finite amount of memory (finite memory; (F)) or whether decisions are based only on the current state (memoryless; (M)). Moreover, the strategy

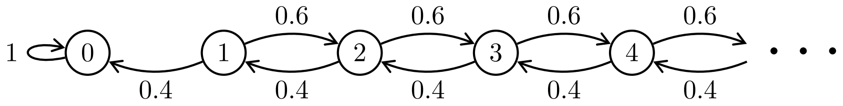
type depends on whether the controller can randomize (R) or is limited to deterministic choices (D). The simplest type MD refers to memoryless deterministic strategies. *Markov strategies* are strategies that base their decisions only on the current state and the number of steps in the history or the run. Thus they use infinite memory, but only in a very restricted form by maintaining an unbounded step counter.

For finite MDPs, there exist optimal MD-strategies for many (but not all) objectives [5, 6, 7, 13], but the picture is more complex for countably infinite MDPs [11, 12, 13]. For example, given some objective, consider the set of all states for which there exists a strategy that achieves the objective with positive probability. If the MDP is finite then this set is finite and thus there exists some minimal nonzero value, which can often be exploited for the construction of an optimal strategy. These methods do not carry over to infinite MDPs. Here it is possible, even for reachability objectives, that every state has a strategy that achieves the objective with positive probability, but no state, except the target itself, can achieve it almost surely. Such phenomena appear already in infinite-state Markov chains like the classic gambler's ruin problem with unfair coin tosses in the player's favor (0.6 win, 0.4 lose):



The probability of ruin is always positive, but less than 1 in every state except the ruin state itself; cf. [9, Chapter 14]. Another difference to finite MDPs is that optimal strategies need not exist, even for qualitative objectives like reachability or parity. Even if there is a sequence of strategies whose success probabilities converge to 1, there may not exist a strategy with success probability equal to 1. This motivates the investigation of ε-*optimal* strategies, which are those strategies such that no other strategy has a success probability that is more than ε higher.

In this paper we restrict ourselves to MDPs with *countable* state space. Certain theorems such as Theorem 3 are known to be false for MDPs with uncountably many states, see [12]. Uncountable MDPs in general have been studied less, and the underlying measure theory is more complicated.

We aim at providing an introduction to a toolkit for the construction of memoryless or "low-memory" optimal and ε-optimal strategies for certain qualitative objectives like reachability and safety. We will illustrate that these techniques can be combined to construct strategies for more general objectives.

2 Preliminaries

A *probability distribution* over a countable set S is a function $f : S \to [0,1]$ with $\sum_{s \in S} f(s) = 1$. We write $\mathcal{D}(S)$ for the set of all probability distributions over S.

Markov decision processes. In this paper we study Markov decision processes (MDPs) over *countably infinite* state spaces. Formally, an MDP $\mathcal{M} = (S, S_\Box, S_\bigcirc, {\longrightarrow}, P)$ consists of a countable set S of *states*, which is partitioned into a set $S_\Box$ of *controlled states* and a set $S_\bigcirc$ of *random states*, a *transition relation* ${\longrightarrow} \subseteq S \times S$, and a *probability function* $P : S_\bigcirc \to \mathcal{D}(S)$. If $(s, s') \in {\longrightarrow}$, we call s' a *successor* of s. We assume that every state has at least one successor. The probability function P assigns to each random state $s \in S_\bigcirc$ a probability distribution $P(s)$ over its set of successor states. A *sink* is a subset $T \subseteq S$ closed under the $\longrightarrow$ relation. An MDP is *acyclic* if the underlying directed graph $(S, \longrightarrow)$ is acyclic. It is *finitely branching* if every state has finitely many successors and *infinitely branching* otherwise. An MDP without controlled states ($S_\Box = \emptyset$) is a *Markov chain.*

Strategies and Probability Measures. A *run* ρ is an infinite sequence $s_0 s_1 \cdots$ of states such that $(s_i, s_{i+1}) \in \longrightarrow$ for all $i \in \mathbb{N}$. A *partial run* is a finite prefix of a run. A *strategy* is a function $\sigma : S^* S_\Box \to \mathcal{D}(S)$ that assigns to partial runs $\rho s \in S^* S_\Box$ a distribution over the successors of s.

A strategy σ and an initial state $s_0 \in S$ induce a standard probability measure on sets of infinite runs, see, e.g., [10]. Such measurable sets of infinite runs are called *events* or *objectives*. We write $\mathbb{P}^{\sigma}_{\mathcal{M},s_0}(E)$ for the probability of an event $E \subseteq s_0 S^\omega$ of runs starting from s_0. We may drop the subscript $\mathcal{M}$ when it is understood.

Objectives. Given a set $T \subseteq S$ of states, the *reachability* objective $\mathtt{Reach}(T)$ is the set of runs that visit T at least once; and the *safety objective* $\mathtt{Safety}(T)$ is the set of runs that never visit T. *Parity* objectives are defined via a *color function* $\mathit{Col} : S \to \mathbb{N}$ with finite range. The corresponding parity objective is the set of runs such that the largest color that occurs infinitely often along the run is even. We call a parity objective a $\mathcal{C}$-parity objective if $\mathit{Col}(S) \subseteq \mathcal{C}$, i.e., the set of colors is restricted to $\mathcal{C}$. *Büchi* and *co-Büchi* objectives are common names for $\{1,2\}$- and $\{0,1\}$-parity objectives, respectively.

Optimal and ε-optimal Strategies. Given an objective E, the *value* of state s in an MDP $\mathcal{M}$, denoted by $\mathtt{val}_{\mathcal{M},s}(E)$, is the supremum probability of achieving E, i.e., $\mathtt{val}_{\mathcal{M},s}(E) \overset{\text{def}}{=} \sup_{\sigma \in \Sigma} \mathbb{P}^{\sigma}_{\mathcal{M},s}(E)$ where Σ is the set of all strategies. We may drop the subscript $\mathcal{M}$ when it is understood. For $\varepsilon > 0$ and a state $s \in S$, we say that a strategy is *ε-optimal* if $\mathbb{P}^{\sigma}_{\mathcal{M},s}(E) \geq \mathtt{val}_{\mathcal{M},s}(E) - \varepsilon$. A 0-optimal strategy is called *optimal*. An optimal strategy is *almost surely winning* if $\mathtt{val}_{\mathcal{M},s}(E) = 1$.

Strategy Classes. Strategies $\sigma : S^* S_\Box \to \mathcal{D}(S)$ are in general *randomized* (R) in the sense that they take values in $\mathcal{D}(S)$. A strategy σ is *deterministic* (D) if $\sigma(\rho)$ is a Dirac distribution for all partial runs $\rho \in S^* S_\Box$. A strategy is called *memoryless* (M) or *positional* if it only depends on the current state; i.e., a memoryless strategy can be given by a function $\sigma : S_\Box \to \mathcal{D}(S)$. Thus, the simplest strategies are MD strategies, which are both memoryless and deterministic (and thus can be given by a function $\sigma : S_\Box \to S$).

We also consider strategies with memory, but we do not formalize this here. After each transition such a strategy updates its memory mode depending on the taken transition and the previous memory mode. To choose a successor of a controlled state, the strategy can use its memory and the current state but not the partial run that led to the current state. Every strategy can be viewed as a strategy with memory (by using partial runs as memory modes).

For example, k-bit strategies use (at most) k bits of memory; they have (at most) 2^k memory modes. *Markov* strategies use infinite memory but only as a step counter; such strategies depend only on the current state and the number of steps taken so far. A *k-bit Markov* strategy can use both k bits and an (unbounded) step counter.

3 Constructing MD Strategies

In this section we illustrate some techniques to construct MD strategies. We mostly focus on reachability objectives, which we use as a running example. But many ideas apply also to other objectives.

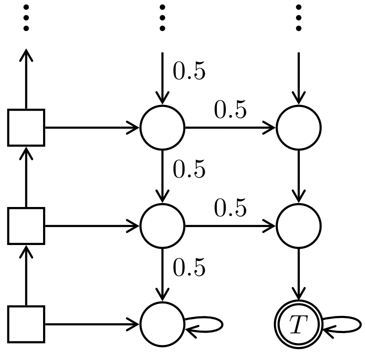


Figure 1 Optimal strategy for reachability may not exist. Here, as in all pictures, we depict controlled states as squares, and random states as circles.

3.1 Reduction to a Finite Case

Suppose we have a (countable) MDP $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$, and we are interested in the reachability objective $\texttt{Reach}(T)$, i.e., we would like to reach a target set $T \subseteq S$.

If S is finite, the situation is as good as it could be:

▶ **Lemma 1** (optimal MD strategies in finite MDPs). *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ be an MDP, and consider the reachability objective $\texttt{Reach}(T)$ for some $T \subseteq S$. If S is finite then there exists a single MD strategy σ that is optimal for every start state s at the same time; formally, $\mathbb{P}_s^\sigma(\texttt{Reach}(T)) = \texttt{val}_s(\texttt{Reach}(T))$ for all $s \in S$.*

Spelled out, Lemma 1 says that, if the state space is finite, we can fix for each controlled state an outgoing transition in a way that maximizes the probability of reaching the target for every state. The assumption of a finite state space is so powerful that Lemma 1 generalizes from reachability to parity objectives. In fact, even in finite parity *games*, where some controlled states are controlled by a player who wants to maximize the probability of achieving the parity objective, and the remaining controlled states are controlled by a player who wants to *minimize* the probability of achieving the parity objective, both players have optimal MD strategies for all states [17, Theorem 1].

Lemma 1 does not hold without the assumption of S being finite, as optimal strategies may not exist, let alone optimal MD strategies. Indeed, consider the MDP in Figure 1. The controlled states are those in the leftmost column. Suppose you start in the bottom-left state and you would like to reach the target T consisting only of the bottom-right state. The higher you climb the ladder of states in the left column, the bigger you can make the probability to reach T, but eventually you have to turn right and hope for the best. We have $\texttt{val}_s(\texttt{Reach}(T)) = 1$ for all controlled states s, i.e., we can get the probability of reaching T arbitrarily close to 1. But we cannot make that probability equal to 1: there is no strategy that reaches T with probability 1.

Recall that a strategy σ is called ε-optimal for s if $\mathbb{P}_s^\sigma(\texttt{Reach}(T)) \geq \texttt{val}_s(\texttt{Reach}(T)) - \varepsilon$. The following lemma says that every state has ε-optimal *MD* strategies:

▶ **Lemma 2** (non-uniform ε-optimal MD strategies). *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ be an MDP, and consider the reachability objective $\texttt{Reach}(T)$ for some $T \subseteq S$. For every $\varepsilon > 0$ and every $s \in S$ there exists an MD strategy σ that is ε-optimal for s; formally, $\mathbb{P}_s^\sigma(\texttt{Reach}(T)) \geq \texttt{val}_s(\texttt{Reach}(T)) - \varepsilon$.*

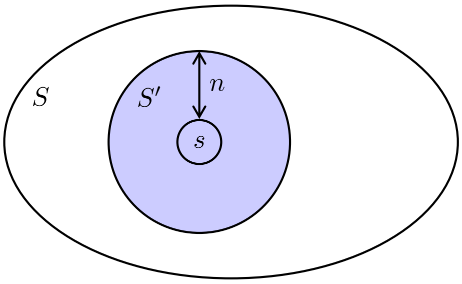

Figure 2 The set S' consists of those states that are reachable from s within at most n steps. Due to finite branching, S' is finite. For n large enough, S' probably suffices to reach the target.

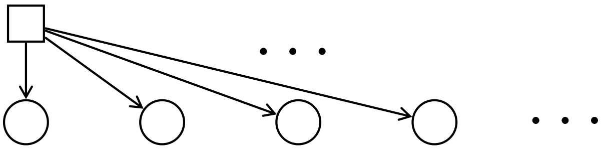
Proof. First assume that $\mathcal{M}$ is finitely branching. Fix $s \in S$ and $\varepsilon > 0$, and let τ be an arbitrary (i.e., not necessarily MD) strategy with $\mathbb{P}^{\tau}_{s}(\mathtt{Reach}(T)) \geq \mathtt{val}_s(\mathtt{Reach}(T)) - \frac{\varepsilon}{2}$. Define a modified reachability objective $\mathtt{Reach}_i(T)$ which means reaching T in exactly i steps. Then we have:

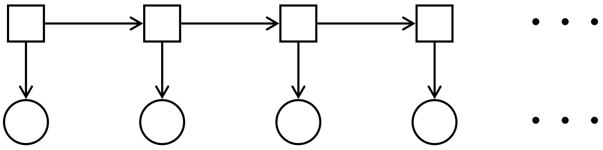
$$\sum_{i=0}^{\infty} \mathbb{P}^{\tau}_{s}(\mathtt{Reach}_i(T)) \;=\; \mathbb{P}^{\tau}_{s}(\mathtt{Reach}(T)) \;\geq\; \mathtt{val}_s(\mathtt{Reach}(T)) - \frac{\varepsilon}{2}$$

It follows that we can pick a number n large enough so that $\sum_{i=0}^{n} \mathbb{P}^{\tau}_{s}(\mathtt{Reach}_i(T)) \geq \mathtt{val}_s(\mathtt{Reach}(T)) - \varepsilon$. From state s, in at most n steps, strategy τ can only use a finite subset $S' \subseteq S$, as $\mathcal{M}$ is finitely branching; see Figure 2. That means, τ manages to reach T with probability at least $\mathtt{val}_s(\mathtt{Reach}(T)) - \varepsilon$ even when it is restricted to the sub-MDP with state space S' (think of leaving S' as losing). But by Lemma 1 this finite sub-MDP has an optimal MD strategy σ. We may extend the definition of σ outside of S' in an arbitrary way. Then, in $\mathcal{M}$, we have $\mathbb{P}^{\sigma}_{s}(\mathtt{Reach}(T)) \geq \mathtt{val}_s(\mathtt{Reach}(T)) - \varepsilon$, as desired.

The assumption that $\mathcal{M}$ is finitely branching can be satisfied using a simple construction: replace every infinitely branching controlled state



by



A similar construction works for random states. Then, construct an MD strategy, as above, from an arbitrary ε-optimal strategy in the new finitely branching MDP. Any MD strategy can be transferred back to the original infinitely branching MDP. ◀

3.2 Ornstein's Plastering Technique

Ornstein [12] proved in 1969 a uniform version of Lemma 2. That is, for every $\varepsilon > 0$ there exists a single MD strategy that is ε-optimal for all states:

▶ **Theorem 3** ([12], uniform ε-optimal MD strategies)**.** *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ be an MDP, and consider the reachability objective $\mathtt{Reach}(T)$ for some $T \subseteq S$. For every $\varepsilon > 0$ there exists a single MD strategy σ that is ε-optimal for every start state s at the same time; formally, $\mathcal{P}^\sigma_s(\mathtt{Reach}(T)) \geq \mathtt{val}_s(\mathtt{Reach}(T)) - \varepsilon$ for all $s \in S$.*

Ornstein actually proved a stronger statement with multiplicative instead of additive error; i.e., Theorem 3 also holds with $\mathtt{val}_s(\mathtt{Reach}(T)) - \varepsilon$ replaced by $\mathtt{val}_s(\mathtt{Reach}(T)) \cdot (1 - \varepsilon)$.

Proof of Theorem 3. We follow Ornstein's proof [12]. Without loss of generality, we assume that T is a sink. Recall that an MD strategy σ can be viewed as a function $\sigma : S_\Box \to S$ such that for all $s \in S_\Box$, the state $\sigma(s)$ is a successor state of s. Starting from the original MDP $\mathcal{M}$ we successively *fix* more and more controlled states, by which we mean select an outgoing transition and remove all others. While this is in general an infinite (but countable) process, it defines an MD strategy in the limit. Visually, we "plaster" the whole state space by the fixings.

Put the states in some order, i.e., $s_1, s_2, \ldots$ with $S = \{s_1, s_2, \ldots\}$. The plastering proceeds in *rounds*, one round for every state. Let $\mathcal{M}_i$ be the MDP obtained from $\mathcal{M}$ after the fixings of the first $i - 1$ rounds (with $\mathcal{M}_1 = \mathcal{M}$). In round i we fix controlled states in such a way that

(A) the probability, starting from s_i, of reaching the target T using only random and *fixed* controlled states is not much less than the value $\mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T))$; and

(B) for all states s, the value $\mathtt{val}_{\mathcal{M}_{i+1},s}(\mathtt{Reach}(T))$ is almost as high as $\mathtt{val}_{\mathcal{M}_i,s}(\mathtt{Reach}(T))$.

The purpose of goal (A) is to guarantee good progress towards the target when starting from s_i. The purpose of goal (B) is to avoid fixings that would cause damage to the values of other states.

Now we describe round i. Consider the MDP $\mathcal{M}_i$ after the fixings from the first $i-1$ rounds, and let $\varepsilon_i > 0$. Recall that we wish to fix a part of the state space so that s_i has a high probability of reaching T using only random and fixed controlled states. By Lemma 2 there is an MD strategy σ such that $\mathcal{P}^\sigma_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) \geq \mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) - \varepsilon_i^2$. Fixing σ everywhere would accomplish goal (A), but potentially compromise goal (B). So instead we are going to fix σ only for states where σ does well: define

$$G \overset{\text{def}}{=} \{s \in S \mid \mathcal{P}^\sigma_{\mathcal{M}_i,s}(\mathtt{Reach}(T)) \geq \mathtt{val}_{\mathcal{M}_i,s}(\mathtt{Reach}(T)) - \varepsilon_i\}$$

and obtain $\mathcal{M}_{i+1}$ from $\mathcal{M}_i$ by fixing σ on G. (Note that σ does not "contradict" earlier fixings, because in the MDP $\mathcal{M}_i$ the previously fixed states have only one outgoing transition left.) See Figure 3 for an illustration.

We have to check that with this fixing we accomplish the two goals above. Indeed, we accomplish goal (A): by its definition strategy σ is ε_i^2-optimal from s_i, so the probability of ever entering $S \setminus G$ (where σ is less than ε_i-optimal) cannot be large:

$$\mathcal{P}^\sigma_{\mathcal{M}_i,s_i}(\mathtt{Reach}(S \setminus G)) \;\leq\; \varepsilon_i \tag{1}$$

In slightly more detail, this inequality holds because the probability that the ε_i^2-optimal strategy σ enters a state whose value is underachieved by σ by at least ε_i can be at most ε_i. We give a detailed proof of (1) in Section 5.1. It follows from the ε_i^2-optimality of σ and from (1) that we have $\mathcal{P}^\sigma_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T) \wedge \neg\mathtt{Reach}(S \setminus G)) \geq \mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) - \varepsilon_i - \varepsilon_i^2$. So in $\mathcal{M}_{i+1}$ we obtain for *all* strategies σ':

$$\mathcal{P}^{\sigma'}_{\mathcal{M}_{i+1},s_i}(\mathtt{Reach}(T)) \;\geq\; \mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) - \varepsilon_i - \varepsilon_i^2 \tag{2}$$

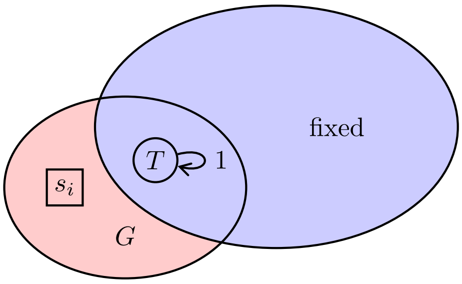


Figure 3 The blue area has been fixed in the first $i-1$ iterations. The smaller ellipse is the set G, where strategy σ does well. The red area will be fixed using σ. Under σ, a run that starts from s_i is likely to lead to the target T without ever leaving G.

We also accomplish goal (B): the difference between $\mathcal{M}_i$ and $\mathcal{M}_{i+1}$ is that σ is fixed on G, but σ performs well from G on. So we obtain for *all* states s:

$$\mathtt{val}_{\mathcal{M}_{i+1},s}(\mathtt{Reach}(T)) \;\geq\; \mathtt{val}_{\mathcal{M}_i,s}(\mathtt{Reach}(T)) - \varepsilon_i \tag{3}$$

In slightly more detail, this inequality holds because any strategy in $\mathcal{M}_i$ can be transformed into a strategy in $\mathcal{M}_{i+1}$, with the difference that once the newly fixed part G is entered, the strategy switches to the strategy σ, which (by the definition of $\mathcal{M}_{i+1}$) is consistent with the fixing and (by the definition of G) is ε_i-optimal from there. We give a detailed proof of (3) in Section 5.2. This completes the description of round i.

Let $\varepsilon \in (0,1)$, and for all $i \geq 1$, choose $\varepsilon_i \overset{\text{def}}{=} \frac{\varepsilon}{2} \cdot 2^{-i}$. Let σ be an arbitrary MD strategy that is compatible with all fixings. (This strategy σ is actually unique.) It follows that σ is playable in all $\mathcal{M}_i$. Consider an arbitrary state s_i. Then it follows from (3) that the value $\mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T))$ is not much lower than $\mathtt{val}_{\mathcal{M},s_i}(\mathtt{Reach}(T))$, and from (2) that σ realizes most of this value, implying for all $i \geq 1$:

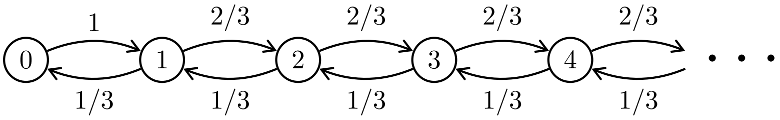
$$\mathbb{P}^{\sigma}_{\mathcal{M},s_i}(\mathtt{Reach}(T)) \;\geq\; \mathtt{val}_{\mathcal{M},s_i}(\mathtt{Reach}(T)) - \varepsilon \tag{4}$$

We give a detailed proof of (4) in Section 5.3. Thus, the MD strategy σ is ε-optimal for all states. ◀

▶ Remark 4. Instead of $\mathtt{Reach}(T)$ the proof above also works for many other objectives, including so-called *tail* events. See Section 3.3 for more discussion about tail events.

3.3 Lévy's Zero-One Law

Consider a Markov chain $\mathcal{M} = (S, \emptyset, S_{\bigcirc}, \longrightarrow, P)$, i.e., an MDP without controlled states. Recall that an event is a set of runs $s_0 s_1 \cdots$. For example, in the Markov chain



we may define an event E as the set of all runs that start in state 0 and revisit state 0 exactly once. Starting in state 1, the probability of ever visiting state 0 can be calculated to be $\frac{1}{2}$. It follows that, starting in state 0, the probability of E is $\frac{1}{2} \cdot (1 - \frac{1}{2}) = \frac{1}{4}$; formally, $\mathbb{P}_0(E) = \frac{1}{4}$. There are two ways of failing to satisfy E: one is to never revisit state 0, the other is to revisit

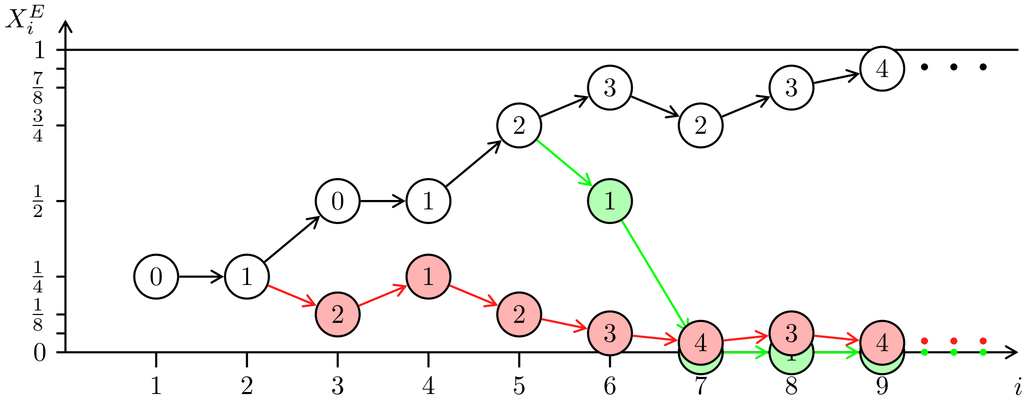


Figure 4 For the event E (exactly one revisit to state 0), three sample runs starting from state 0 are depicted, along with their values $X_1^E, \ldots, X_9^E$. The partially covered "green" run revisits state 0 for a second time, causing $0 = X_7^E = X_8^E = \ldots$ Lévy's zero-one law asserts that X_i^E almost surely converges to 0 or 1.

it more than once. It is because of the latter that for any given finite prefix of a run, we can never be sure that E will hold. For example, if the run starts with 010123, then we have already revisited state 0 and it is unlikely that we will ever do so again: the probability is only $\frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{8}$. So, given this prefix 010123, the probability of satisfying E is $\frac{7}{8}$. However, in this example, no matter what prefix is given, the probability of satisfying E cannot be 1.

Let us define a sequence of random variables, $X_1^E, X_2^E, \ldots$, so that each X_i^E maps a run ρ to the probability that event E will be satisfied, given the prefix of ρ of length i. For example, if $\rho = 010123234\cdots$, then we previously discussed that $X_1^E(\rho) = \frac{1}{4}$ and that $X_6^E(\rho) = \frac{7}{8}$. It is (a consequence of) Lévy's zero-one law that the sequence $X_1^E, X_2^E, \ldots$[1] converges to 0 or 1 almost surely (see also Figure 4):

▶ **Theorem 5** (Lévy's zero-one law for Markov chains)**.** *Let $\mathcal{M} = (S, \emptyset, S_\bigcirc, \longrightarrow, P)$ be a Markov chain, $s_0 \in S$, and E an event of runs starting in s_0. We have $\lim_{i\to\infty} X_i^E \in \{0,1\}$ (and hence this limit exists) almost surely; more formally:*

$$\mathbb{P}_{s_0}\left(\left\{\rho \;\middle|\; \lim_{i\to\infty} X_i^E(\rho) \in \{0,1\}\right\}\right) \;=\; 1\,.$$

Moreover, up to a null set of runs, the limit is 1 *for those runs satisfying E, and* 0 *for those runs not satisfying E.*

As a consequence, the probability of E is equal to the probability that the limit is 1.

For *tail* objectives E, Lévy's zero-one law becomes simpler and clearer. A tail objective is an objective whose occurrence is independent of any finite prefix. The objective E from the example above is not a tail objective because the number of revisits to state 0 may change if we cut off or add a finite prefix. For an example of a tail objective, suppose that the states of an arbitrary Markov chain are classified as accepting and non-accepting states. The *Büchi* objective consists of those runs that visit accepting states infinitely often. Büchi is a tail objective: for any run we can cut off or add any finite prefix without changing whether the run satisfies Büchi. We can also view reachability objectives as tail objectives, provided that the target is a sink, which is often a harmless assumption.

[1] It is conventional to write X_i^E for $X_i^E(\rho)$ if the run (such as a random run produced by $\mathcal{M}$) is understood.

For tail objectives E, the random variable X_i^E depends only on the ith visited state (and not also on the first $i-1$ states as in the general case), and for any run $s_1 s_2 s_3 \cdots$ we have $X_i^E = \mathbb{P}_{s_i}(E)$. For a tail objective E and any state s, a picture analogous to Figure 4 would show each occurrence of state s on the same height, independently of the partial run leading up to the occurrence. As a consequence of Lévy's zero-one law, for any tail objective E, the events

$$E \quad \text{and} \quad \left\{ s_1 s_2 \cdots \;\middle|\; \lim_{i\to\infty} \mathbb{P}_{s_i}(E) = 1 \right\} \quad \text{are equal up to a null set.} \tag{5}$$

This can be used, in conjunction with Ornstein's Theorem 3 about uniform ε-optimal MD strategies, to construct almost surely winning MD strategies:

▶ **Theorem 6** ([12], uniform almost surely winning MD strategies)**.** *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ be an MDP, and consider the reachability objective $\texttt{Reach}(T)$ for some $T \subseteq S$. Let $S_0 \subseteq S$ be the set of states from which there exists an almost surely winning strategy. Then there exists a single MD strategy σ that is almost surely winning for all $s \in S_0$ at the same time; formally, $\mathbb{P}_s^\sigma(\texttt{Reach}(T)) = 1$ for all $s \in S_0$.*

Proof. Obtain from $\mathcal{M}$ an MDP $\mathcal{M}_0$ by restricting the state space to S_0 and eliminating all transitions that leave S_0. In $\mathcal{M}_0$ all states have an almost surely winning strategy, as an almost surely winning strategy may never enter a state that does not have an almost surely winning strategy. By Theorem 3 there exists, for $\mathcal{M}_0$, a uniform $\frac{1}{2}$-optimal MD strategy σ. Then $\mathbb{P}^\sigma_{\mathcal{M}_0,s}(\texttt{Reach}(T)) \geq \frac{1}{2}$ holds for all states. For any run $s_0 s_1 \cdots$ in $\mathcal{M}_0$ we have $\mathbb{P}^\sigma_{\mathcal{M}_0,s_i}(\neg\texttt{Reach}(T)) \leq \frac{1}{2}$ for all i; in particular, the sequence $\left(\mathbb{P}^\sigma_{\mathcal{M}_0,s_i}(\neg\texttt{Reach}(T))\right)_i$ does not converge to 1. Using (5) for $E = \neg\texttt{Reach}(T)$, we obtain for all $s \in S_0$ that $\mathbb{P}_s^\sigma(E) = 0$, hence, $\mathbb{P}_s^\sigma(\texttt{Reach}(T)) = 1$. ◀

3.4 The Flag Construction

We now move from reachability to co-Büchi objectives: here, a subset of states are marked as "bad", and the goal is to visit bad states only finitely often. Co-Büchi is more general than both reachability and safety objectives: for reachability, make the target a sink and mark all other states as bad; for safety, make the states to be avoided a sink and mark them as bad.

In this section we focus on almost surely winning strategies, and we will argue that for co-Büchi objectives almost surely winning strategies can be chosen MD. However, this does not always hold for infinitely branching MDPs, as the example in Figure 5 shows. Therefore, we assume in the rest of the section that the MDP is finitely branching. We will show:

▶ **Theorem 7** ([11])**.** *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ be a finitely branching MDP, and consider a co-Büchi objective $\texttt{co-Büchi}(B)$ for some set $B \subseteq S$ of bad states. Let $S_0 \subseteq S$ be the set of states from which there exists an almost surely winning strategy. Then there exists a single MD strategy σ that is almost surely winning for all $s \in S_0$ at the same time; formally, $\mathbb{P}_s^\sigma(\texttt{co-Büchi}(B)) = 1$ for all $s \in S_0$.*

In order to prove Theorem 7, a *safety strategy* may appear promising: in each state minimize the probability of ever visiting a bad state again. The appeal of a safety strategy is twofold:

- If a safety strategy succeeds in never visiting a bad state again, then clearly it visits bad states only finitely often.
- A safety strategy can be chosen uniformly MD (in finitely branching MDPs): in every controlled state pick the successor with the best value.[2]

[2] Such an approach for constructing an optimal strategy does not work for reachability or more general objectives: intuitively, this approach cannot guarantee "progress" towards the goal.

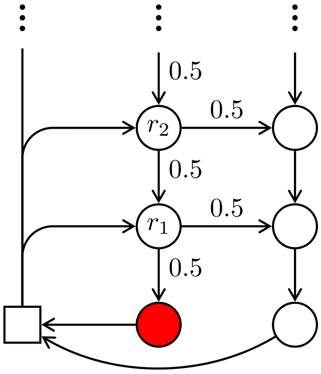

Figure 5 In infinitely branching MDPs with co-Büchi objectives, almost surely winning strategies cannot always be chosen MD. In the MDP above, the bad state is marked red. There exists an almost surely winning strategy, but it requires memory in order to choose r_i for ever higher i.

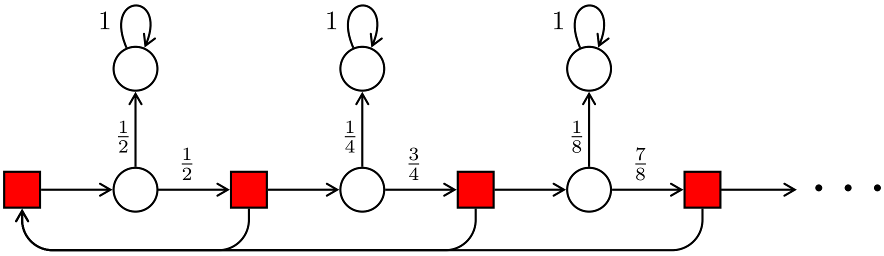

Figure 6 In this MDP (with bad states marked red), a safety strategy always chooses the right outgoing transition, chasing after the ever smaller chance of entering a safe sink state without re-entering any bad state. Starting from the leftmost state, the probability that this strategy achieves the co-Büchi objective is less than 0.72. The “opposite” strategy, which always returns to the leftmost state, succeeds almost surely.

But a safety strategy alone does not suffice for co-Büchi, as the example in Figure 6 shows. In the following proof we construct an almost surely winning MD strategy for co-Büchi by combining an MD strategy for safety with an MD strategy for reachability.

Proof sketch of Theorem 7. Similarly as in the proof of Theorem 6, we can assume without loss of generality that for all states there exists an almost surely winning strategy. We will show that there exists a single MD strategy that is almost surely winning for all states.

We have mentioned previously that there exists an MD uniformly optimal safety strategy σ_{safe}, i.e., for each state, σ_{safe} minimizes the probability of ever revisiting a bad state. For $x \in [0,1]$ define $\mathit{Safe}(x) \subseteq S$ as the set of states with *safety level* at least x. By safety level we mean the probability of never visiting another bad state, assuming σ_{safe} is played. See Figure 7 for an abstract visualization. We *fix* σ_{safe} in $\mathit{Safe}(\frac{1}{3})$, i.e., in the following we will only consider strategies that are compatible with σ_{safe} in $\mathit{Safe}(\frac{1}{3})$, see the right side of Figure 7.

After this fixing, every state still has an almost surely winning strategy. Indeed, consider any state and its almost surely winning strategy before the fixing. We modify the strategy as follows. First we play it as before, but if and when we reach $\mathit{Safe}(\frac{1}{3})$, we switch to σ_{safe}. Now the probability is at least $\frac{1}{3}$ that we never visit a bad state again and thus also achieve the co-Büchi objective. If we do visit a bad state again, we revert to a strategy that is almost surely winning from that bad state in the original MDP. We follow that strategy until we

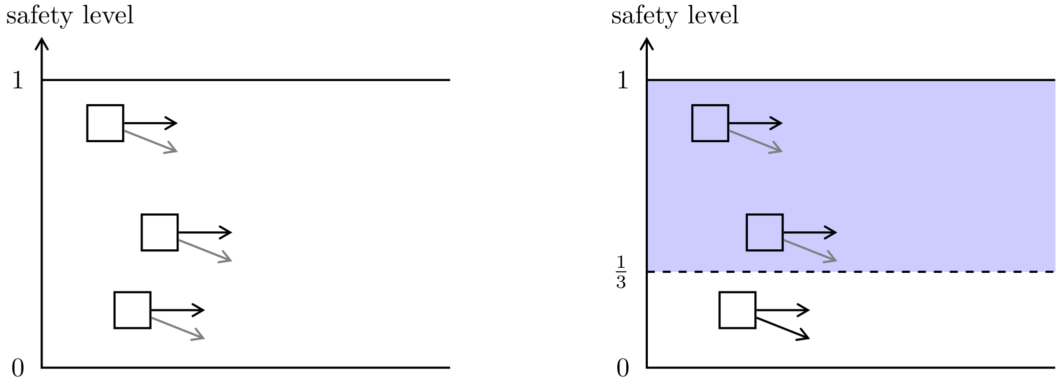

Figure 7 Left: In this diagram the controlled states are arranged according to their safety level. A safety strategy entails not to pick successor states with smaller safety level, so grey transitions are not used. Right: The optimal safety strategy σ_{safe} is fixed for the states with safety level at least $\frac{1}{3}$.

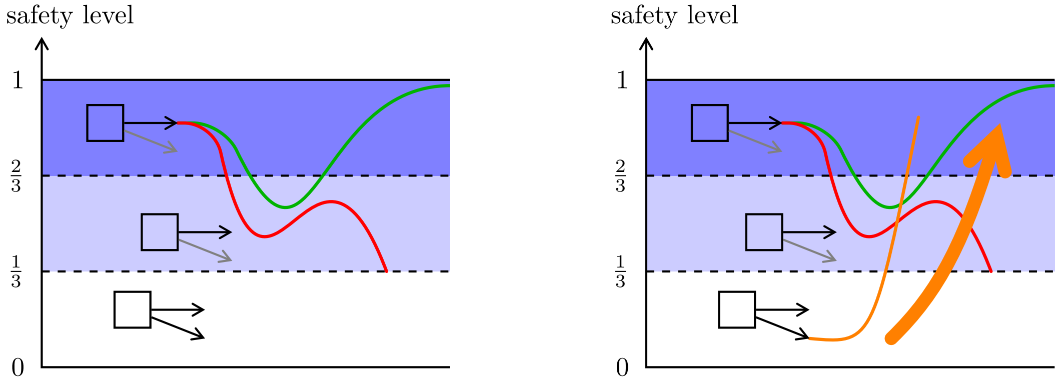

Figure 8 Left: Starting from a state with safety level at least $\frac{2}{3}$ the probability of keeping a safety level of at least $\frac{1}{3}$ forever is at least $\frac{1}{2}$. Right: For the states with safety level less than $\frac{1}{3}$ we aim at reaching safety level at least $\frac{2}{3}$.

possibly reach $Safe(\frac{1}{3})$ again. At this point we switch again to σ_{safe}, thus forever avoiding the bad states with a fresh chance of at least $\frac{1}{3}$. Continuing in this way, we win almost surely. Note that this strategy is not MD, as we have to remember in which phase we are: at any point we either follow a winning strategy of the original MDP, or follow σ_{safe}. We have merely argued here that having fixed σ_{safe} in $Safe(\frac{1}{3})$ has not done any harm.

Before we define an MD strategy for the rest of the state space, consider a state $s \in Safe(\frac{2}{3})$, i.e., s has an even higher safety level of at least $\frac{2}{3}$. Since $Safe(\frac{2}{3}) \subseteq Safe(\frac{1}{3})$, the MD strategy σ_{safe} has been fixed there. Two things might happen starting at s (see the left side of Figure 8): either the run remains in $Safe(\frac{1}{3})$ forever and never visits a bad state; or it eventually leaves $Safe(\frac{1}{3})$ (or even visits a bad state). The second case (leaving $Safe(\frac{1}{3})$ or visiting a bad state) cannot have a very large probability: after all, we start with safety level at least $\frac{2}{3}$, so if the safety level is very likely to drop below $\frac{1}{3}$, we were not very safe to start with. Doing the maths shows that the probability of the second case is at most $\frac{1}{2}$. So starting from $Safe(\frac{2}{3})$, the probability of avoiding bad states forever is at least $\frac{1}{2}$, no matter what strategy is played outside of $Safe(\frac{1}{3})$.

We still need to define an MD strategy for the part of the state space with safety level less than $\frac{1}{3}$. Our ambition is to define it so that from every state we reach almost surely $\mathit{Safe}(\frac{2}{3})$, see the right side of Figure 8. If we succeed in this goal, then we achieve the co-Büchi objective almost surely, because every time we reach $\mathit{Safe}(\frac{2}{3})$ we receive a fresh chance of $\frac{1}{2}$ to avoid bad states forever, as just argued.

First we argue that for each state there is *some* strategy to reach $\mathit{Safe}(\frac{2}{3})$ almost surely. Recall that we have shown above that after the fixing in $\mathit{Safe}(\frac{1}{3})$ every state s still has a strategy σ_s to achieve the co-Büchi objective almost surely. We argue that σ_s reaches $\mathit{Safe}(\frac{2}{3})$ almost surely. Indeed, whenever a run is outside of $\mathit{Safe}(\frac{2}{3})$ there is a risk of more than $\frac{1}{3}$ to visit a bad state. It follows that there is a risk of at least $\frac{1}{3}$ to visit a bad state within a finite time horizon. Since σ_s almost surely achieves the co-Büchi objective, it must avoid that this risk materializes infinitely often. Hence σ_s almost surely reaches $\mathit{Safe}(\frac{2}{3})$.

Using Theorem 6 it follows that, in the MDP after having fixed σ_{safe} in $\mathit{Safe}(\frac{1}{3})$, there is uniform almost surely winning MD strategy σ_{reach} for $\mathtt{Reach}(\mathit{Safe}(\frac{2}{3}))$. In summary, here is our almost surely winning MD strategy for co-Büchi: in $\mathit{Safe}(\frac{1}{3})$ play σ_{safe}, and elsewhere play σ_{reach}. The key point is that these two MD strategies are not conflicting. ◀

▶ Remark 8. Generalizations of Theorem 7 are also considered in [11]:

1. A similar proof shows a version of Theorem 7 for ε-optimal strategies.
2. Theorem 7 generalizes to $\{0, 1, 2\}$-parity objectives, which also encompass Büchi objectives. The theorem further generalizes from almost surely winning to *optimal* strategies as follows: The set $S_0 \subseteq S$ can be taken as the set of states from which there exists an optimal strategy (note that an almost surely winning strategy is optimal). Then there exists a single MD strategy that is optimal for all states in S_0.
3. Theorem 7 does not hold for $\{1, 2, 3\}$-parity objectives.

4 Markov Strategies and Generalizations

We describe a technique to prove the existence of ε-optimal Markov strategies (resp. Markov strategies with one extra bit of memory) for certain types of objectives, based on the work on Büchi objectives in [10].

Obtaining Markov strategies via acyclic MDPs. *Markov strategies* are strategies that base their decisions only on the current state and the number of steps in the history of the run from some initial state s_0. Thus they do use infinite memory, but only in a very restricted form by maintaining an unbounded step counter. Slightly more general are *1-bit Markov strategies* that use one extra bit of extra memory in addition to a step counter.

The existence of ε-optimal (1-bit) Markov strategies for some objective φ on countable MDPs can be proven by first studying the strategy complexity of φ on *acyclic* MDPs, i.e., MDPs where the underlying transition graph is a directed acyclic graph (DAG). Note that a DAG is more general than a tree. If the transition graph is a tree with root s_0 then there always exist ε-optimal positional strategies for any objective, since the entire history is implicit in the current state. This does not hold for a DAG, since the same state s could be reached via (possibly infinitely many) different paths from s_0.

However, for every countable MDP $\mathcal{M}$ with initial state s_0, there is a corresponding acyclic MDP $\mathcal{M}'$ that encodes the step counter into the states, i.e., the states of $\mathcal{M}'$ are of the form (s, i) where s is a state of $\mathcal{M}$ and $i \in \mathbb{N}$ counts the number of steps. Then for every ε-optimal positional strategy for φ in $\mathcal{M}'$ there is a corresponding ε-optimal Markov strategy for φ in $\mathcal{M}$, and vice-versa [10]. Thus, if ε-optimal positional strategies for φ exist in *all* acyclic MDPs then ε-optimal Markov strategies for φ exist in general countable MDPs. The reverse implication does not hold, however, since not all acyclic MDPs encode a step counter, e.g., if some state has infinite in-degree and can be reached from the initial state via paths of arbitrary length.

Acyclic and finitely branching MDPs have nice properties that make it easier to infer the existence of simpler ε-optimal strategies. In the following, we first observe the behavior of a general ε-optimal strategy, and then show how a 1-bit strategy can closely match it (for certain types of objectives).

Observing the behavior of an ε-optimal strategy. Consider an acyclic and finitely branching MDP with initial state s_0. (One could also have a finite set of initial states as in [10], but we use a single state to simplify the presentation.) Let σ be an arbitrary ε-optimal strategy from the initial state s_0. We now observe its behavior, i.e., the induced runs. Let $\mathsf{bubble}_k(\{s_0\})$ be the set of states that can be reached from the initial state s_0 within at most k steps. This set is finite for every finite k, since our MDP is finitely branching. Note that, by acyclicity, any given run can visit a given finite set of states X only finitely often (at most $|X|$ times). However, this does not imply that the probability of re-visiting X must eventually become zero. E.g., it is possible that in the i-th state of some run the probability of re-visiting X (in continuations of this run) is 2^{-i} (i.e., re-visiting X remains always possible, but does not happen almost surely).

Still, a weaker property does hold in acyclic and finitely branching MDPs. It follows from acyclicity [10, Lemma 10] that, after a sufficiently large number of steps, runs are arbitrarily unlikely to visit any given finite set of states again. In particular this holds for the finite set $\mathsf{bubble}_k(\{s_0\})$.

Formally, for every k and $\delta > 0$ there exists some l such that the probability of visiting $\mathsf{bubble}_k(\{s_0\})$ after step l is $\leq \delta$. By definition, states *outside* the set $\mathsf{bubble}_l(\{s_0\})$ are reachable only after a number of steps that is strictly larger than l. Therefore, it is unlikely (probability $\leq \delta$) to visit $\mathsf{bubble}_k(\{s_0\})$ again after some state $s \notin \mathsf{bubble}_l(\{s_0\})$ has been visited for the first time.

These observations allow to define a decreasing sequence $\delta_i \overset{\text{def}}{=} \varepsilon \cdot 2^{-i}$ of small errors and sufficiently large and increasing numbers k_i and l_i with $k_i < l_i < k_{i+1}$ for $i \geq 1$ such that for the finite sets $K_i \overset{\text{def}}{=} \mathsf{bubble}_{k_i}(\{s_0\})$ and $L_i \overset{\text{def}}{=} \mathsf{bubble}_{l_i}(\{s_0\})$ it is unlikely (probability $\leq \delta_i$) to visit K_i after leaving L_i (for the first time). I.e., runs like π_2 in Figure 9 are unlikely. However, the probability of leaving K_i and later returning to K_i (even multiple times) before leaving L_i may be large.

Note that we still have a lot of freedom to choose the numbers k_i and l_i. For the numbers k_i we just need $l_i < k_{i+1}$. The minimal required size of l_i depends on k_i, σ and δ_i, but l_i can be chosen arbitrarily larger than this minimal size.

Let now SEQ be the objective of never visiting a set K_i after leaving L_i (for the first time) for any $i \geq 1$. (I.e., SEQ depends on the chosen numbers k_i, l_i.)

The strategy σ is not only ε-optimal for the objective φ from state s_0, but also 2ε-optimal for the stronger objective $\varphi \wedge \mathsf{SEQ}$, since $\sum_{i\geq 1} \delta_i \leq \varepsilon$.

Constructing simpler strategies. For certain types of objectives φ (e.g., Büchi objectives), one can exploit this pattern of SEQ to construct simpler (1-bit) ε-optimal strategies for φ in acyclic and finitely branching MDPs. This then yields ε-optimal 1-bit Markov strategies in general finitely branching MDPs.

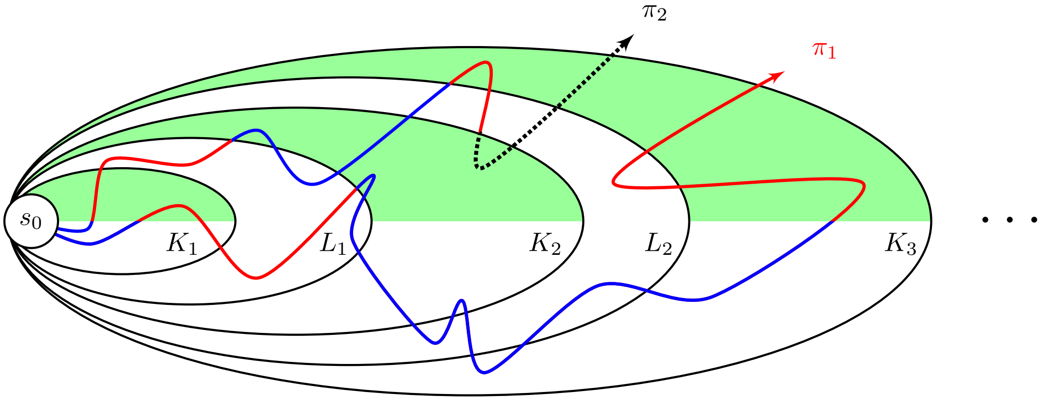

Figure 9 Updates of the extra mode bit along runs π_1, π_2, drawn in blue while the memory-bit is one and in red while the bit is zero. The run π_2 violates SEQ and is drawn as a dotted line once it does. Upon entering the green zone of $K_i \setminus K_{i-1}$, the runs attain the local objective φ_i and flip the mode bit.

Suppose that $\varphi \wedge \mathsf{SEQ}$ can be decomposed into an infinite sequence of local sub-objectives $\varphi_i \wedge \mathsf{SEQ}$ such that, with arbitrarily high probability, satisfying $\varphi_i \wedge \mathsf{SEQ}$ in each finite set $K_i \setminus K_{i-1}$ implies $\varphi \wedge \mathsf{SEQ}$ overall, and vice-versa. (E.g., if φ is a Büchi objective to visit a given set of states F infinitely often then φ_i is the objective to visit the subset of F inside $K_i \setminus K_{i-1}$ (i.e., to visit $F \cap (K_i \setminus K_{i-1})$); cf. [10].) Note that the "vice-versa" part often depends on the fact that the numbers k_i can be chosen sufficiently large to get a sufficiently high probability of satisfying φ_i inside $K_i \setminus K_{i-1}$.

Of course, not every objective φ can be decomposed in this way, e.g., in parity objectives, different runs can win by different colors and local conditions φ_i are insufficient.

Now suppose that in the MDP induced by the finite subspace K_i there exist ε-optimal positional strategies σ_i that attain a high probability of φ_i in $K_i \setminus K_{i-1}$, and additionally maintain a high value w.r.t. future objectives φ_j in $K_j \setminus K_{j-1}$ for all $j > i$. I.e., σ_i has a high attainment for the local sub-objective without compromising future sub-objectives.

One extra bit. The above suggests a scheme to construct an ε-optimal positional strategy σ' for $\varphi \wedge \mathsf{SEQ}$ by playing each local positional strategy σ_i inside $K_i \setminus K_{i-1}$.

However, this is not always sufficient. The problem is that, when playing in $K_i \setminus K_{i-1}$, a run might temporarily go back into the set K_{i-1} (though not into the states that this particular run has previously visited, due to acyclicity). If this run has never yet left L_{i-1}, then going back to K_{i-1} is allowed by SEQ and can be necessary (or even unavoidable). (In contrast, once one has left L_{i-1}, it is possible to henceforth avoid K_{i-1} and still attain φ with high probability, as witnessed by the strategy σ.) But back in K_{i-1} the strategy σ' would play σ_{i-1} towards objective φ_{i-1} (that had already been attained previously) instead of focusing on the current objective φ_i. Although the run will inevitably (by acyclicity) exit K_{i-1} again, it might re-visit K_{i-1} many times, and thus switch the focus back to φ_{i-1} many times. I.e., the strategy σ' might attempt to re-attain the previous objective φ_{i-1} many times over, instead of permanently switching the focus to φ_i once φ_{i-1} has been attained once. Switching the focus back to the previous objective φ_{i-1} too often is wasteful and might damage the ability to attain future objectives φ_j for the $j \geq i$ with high probability, e.g., due to a trade-off between current and future objectives. So this strategy σ' might not always succeed for objective φ (e.g., it cannot work for Büchi objectives [10]).

Instead we want the strategy to always focus on the next objective φ_i after it has completed the previous objective φ_{i-1}. To this end, we need one extra bit of memory, called the *mode bit*, to distinguish two modes of playing: current-mode and next-mode. The mode bit is used to remember whether one has already attained φ_i in $K_i \setminus K_{i-1}$. Upon attaining φ_i in $K_i \setminus K_{i-1}$, one switches from current-mode to next-mode.

One interprets the content of the mode bit (0 or 1) differently for even and odd numbers i, so that the next-mode for $K_i \setminus K_{i-1}$ is the current-mode for $K_{i+1} \setminus K_i$ (and vice-versa). This means that if the strategy plays in next-mode in $K_i \setminus K_{i-1}$ then upon entering $K_{i+1} \setminus K_i$ it automatically switches to current-mode. Dually, if it plays in current-mode in $K_{i+1} \setminus K_i$ and temporarily goes back into $K_i \setminus K_{i-1}$ then it automatically switches to next-mode; cf. Figure 9. The strategy pursues different local goals, depending on the mode bit.

- In current-mode, it continues to focus on attaining φ_i in K_i. Temporarily going back to K_{i-1} does not change the focus on φ_i, because current-mode for K_i is next-mode for K_{i-1}. By suitably choosing φ_i and k_i, one can ensure with high probability that φ_i is attained only in $K_i \setminus L_{i-1}$, i.e., *after* leaving L_{i-1}. So, since one has already left L_{i-1} before this success, it is possible with high probability to avoid K_{i-1} afterwards. In particular, after attaining φ_i in $K_i \setminus L_{i-1}$ the strategy switches the mode-bit to next-mode. The value of the mode bit is the same for next-mode in K_i and for current-mode in K_{i-1}. However, there is only a small danger of ever confusing these, since the probability of visiting K_{i-1} after leaving L_{i-1} is small.
- In next-mode, the focus is on leaving K_i to reach $K_{i+1} \setminus K_i$ and attaining the next objective φ_{i+1}. In particular, upon entering $K_{i+1} \setminus K_i$ the mode bit is interpreted as current mode for $K_{i+1} \setminus K_i$. Moreover, it is then not a problem if the run temporarily goes back from $L_i \setminus K_i$ into K_i, because the focus remains on φ_{i+1} (since current-mode in K_{i+1} is next-mode in K_i).

By combining the positional strategies for the local objectives φ_i with the extra mode bit, one obtains ε-optimal 1-bit strategies on all acyclic finitely branching MDPs. This yields 1-bit Markov strategies on general finitely branching MDPs by the argument above.

For Büchi objectives, one can encode infinite branching into finite branching by a gadget similar to the one used in the proof of Lemma 2. Moreover, the local strategies σ_i can be chosen MD. Thus one obtains deterministic 1-bit Markov ε-optimal strategies. There is also a matching lower bound.

▶ **Theorem 9** ([10], ε-optimal deterministic 1-bit Markov strategies for Büchi objectives). *Given a countable MDP and a Büchi objective, for every $\varepsilon > 0$ and initial state s_0, there exists an ε-optimal deterministic 1-bit Markov strategy. Moreover, neither randomized Markov strategies nor randomized finite-memory strategies are sufficient.*

▶ Remark 10. The whole argument can, of course, be generalized. If the strategies for the local objectives φ_i in acyclic MDPs are not positional but use finite memory, say m bits, then one obtains $(m + 1)$-bit Markov strategies in general MDPs.

5 Missing Proof Details

5.1 Proof of Equation (1)

Proof. For a state $s \in S \setminus G$, define the event L_s as the set of runs that leave G such that s is the first visited state in $S \setminus G$. Then we have:

$$\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\texttt{Reach}(S \setminus G)) \;=\; \sum_{s \in S \setminus G} \mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(L_s) \tag{6}$$

Since T is a sink and using the Markov property:

$$\begin{aligned}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\texttt{Reach}(T)) \;&=\; \mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\neg\texttt{Reach}(S\setminus G)\wedge\texttt{Reach}(T)) + \\ &\quad\sum_{s\in S\setminus G}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(L_s)\cdot\mathbb{P}^{\sigma}_{\mathcal{M}_i,s}(\texttt{Reach}(T))\end{aligned} \tag{7}$$

By the definition of G it follows:

$$\begin{aligned}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\texttt{Reach}(T)) \;&\le\; \mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\neg\texttt{Reach}(S\setminus G)\wedge\texttt{Reach}(T)) + \\ &\quad\sum_{s\in S\setminus G}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(L_s)\cdot(\texttt{val}_{\mathcal{M}_i,s}(\texttt{Reach}(T))-\varepsilon_i)\end{aligned} \tag{8}$$

On the other hand, σ is ε_i^2-optimal for s_i, hence:

$$\begin{aligned}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\texttt{Reach}(T)) \;&\ge\; -\varepsilon_i^2+\texttt{val}_{\mathcal{M}_i,s}(\texttt{Reach}(T)) \\ &\ge\; -\varepsilon_i^2+\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\texttt{Reach}(T)\wedge\neg\texttt{Reach}(S\setminus G)) + \\ &\quad\sum_{s\in S\setminus G}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(L_s)\cdot\texttt{val}_{\mathcal{M}_i,s}(\texttt{Reach}(T))\end{aligned} \tag{9}$$

By combining (8) and (9) we obtain:

$$\varepsilon_i^2 \;\ge\; \varepsilon_i\cdot\sum_{s\in S\setminus G}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(L_s) \;=\; \varepsilon_i\cdot\mathbb{P}^{\sigma}_{\mathcal{M}_i,s_i}(\texttt{Reach}(S\setminus G)) \qquad ◀$$

5.2 Proof of Equation (3)

Proof. For a state $s'\in G$, define the event $E_{s'}$ as the set of runs that enter G such that s' is the first visited state in G. Fix any state $s\in S$ and any strategy σ_i in $\mathcal{M}_i$. We transform σ_i into a strategy σ_{i+1} in $\mathcal{M}_{i+1}$ such that σ_{i+1} behaves like σ_i until G is entered, at which point σ_{i+1} switches to the MD strategy σ, which we recall is compatible with $\mathcal{M}_{i+1}$ and is ε_i-optimal from G in $\mathcal{M}_i$. To show (3) it suffices to show that $\mathbb{P}^{\sigma_{i+1}}_{\mathcal{M}_{i+1},s}(\texttt{Reach}(T)) \ge \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(\texttt{Reach}(T))-\varepsilon_i$. We have:

$$\begin{aligned}\mathbb{P}^{\sigma_{i+1}}_{\mathcal{M}_{i+1},s}(\texttt{Reach}(T)) \;&=\; \mathbb{P}^{\sigma_{i+1}}_{\mathcal{M}_{i+1},s}(\neg\texttt{Reach}(G)\wedge\texttt{Reach}(T)) + && \text{as } T \text{ is a sink}\\ &\quad\sum_{s'\in G}\mathbb{P}^{\sigma_{i+1}}_{\mathcal{M}_{i+1},s}(E_{s'})\cdot\mathbb{P}^{\sigma_{i+1}}_{\mathcal{M}_{i+1},s'}(\texttt{Reach}(T)) && \text{Markov property}\\ &=\; \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(\neg\texttt{Reach}(G)\wedge\texttt{Reach}(T)) + && \text{using def. of } \sigma_{i+1}\\ &\quad\sum_{s'\in G}\mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(E_{s'})\cdot\mathbb{P}^{\sigma}_{\mathcal{M}_i,s'}(\texttt{Reach}(T))\end{aligned}$$

Further we have for all $s'\in G$:

$$\begin{aligned}\mathbb{P}^{\sigma}_{\mathcal{M}_i,s'}(\texttt{Reach}(T)) \;&\ge\; \texttt{val}_{\mathcal{M}_i,s'}(\texttt{Reach}(T))-\varepsilon_i && \text{as } s'\in G\\ &\ge\; \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s'}(\texttt{Reach}(T))-\varepsilon_i\end{aligned}$$

Plugging this in above, we obtain:

$$\begin{aligned}
\mathbb{P}^{\sigma_{i+1}}_{\mathcal{M}_{i+1},s}(\mathtt{Reach}(T)) &\geq \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(\neg\mathtt{Reach}(G) \wedge \mathtt{Reach}(T)) + \\
&\qquad \sum_{s' \in G} \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(E_{s'}) \cdot (\mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s'}(\mathtt{Reach}(T)) - \varepsilon_i) \\
&\geq \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(\neg\mathtt{Reach}(G) \wedge \mathtt{Reach}(T)) + \\
&\qquad \Big(\sum_{s' \in G} \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(E_{s'}) \cdot \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s'}(\mathtt{Reach}(T))\Big) - \varepsilon_i \\
&= \mathbb{P}^{\sigma_i}_{\mathcal{M}_i,s}(\mathtt{Reach}(T)) - \varepsilon_i
\end{aligned}$$

◀

5.3 Proof of Equation (4)

Proof. For all $i \geq 1$ we have:

$$\begin{aligned}
\mathbb{P}^{\sigma}_{\mathcal{M},s_i}(\mathtt{Reach}(T)) &\geq \mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) - \varepsilon_i - \varepsilon_i^2 && \text{by (2)} \\
&\geq \mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) - 2\varepsilon_i && \text{as } \varepsilon_i < 1 \\
&\geq \mathtt{val}_{\mathcal{M}_i,s_i}(\mathtt{Reach}(T)) - \frac{\varepsilon}{2} && \text{choice of } \varepsilon_i \\
&\geq \mathtt{val}_{\mathcal{M},s_i}(\mathtt{Reach}(T)) - \sum_{j=1}^{i-1} \varepsilon_j - \frac{\varepsilon}{2} && \text{by (3)} \\
&\geq \mathtt{val}_{\mathcal{M},s_i}(\mathtt{Reach}(T)) - \varepsilon && \text{choice of } \varepsilon_j
\end{aligned}$$

Abstract

Given N instances $(X_1, t_1), \ldots, (X_N, t_N)$ of Subset Sum, the AND Subset Sum problem asks to determine whether all of these instances are yes-instances; that is, whether each set of integers X_i has a subset that sums up to the target integer t_i. We prove that this problem cannot be solved in time $\widetilde{O}((N \cdot t_{max})^{1-\varepsilon})$, for $t_{max} = \max_i t_i$ and any $\varepsilon > 0$, assuming the $\forall\exists$ Strong Exponential Time Hypothesis ($\forall\exists$-SETH). We then use this result to exclude $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithms for several scheduling problems on n jobs with maximum processing time P_{max}, assuming $\forall\exists$-SETH. These include classical problems such as $1||\sum w_j U_j$, the problem of minimizing the total weight of tardy jobs on a single machine, and $P_2||\sum U_j$, the problem of minimizing the number of tardy jobs on two identical parallel machines.

1 Introduction

The Subset Sum problem is one of the most fundamental problems in computer science and mathematics: Given n integers $X = \{x_1, \ldots, x_n\} \subset \mathbb{N}$, and a target value $t \in \mathbb{N}$, determine whether there is a subset of X that sums[1] to t. This problem appeared in Karp's initial list of 21 NP-complete problems [24], and entire books have been devoted to it and to its closely related variants [25, 30]. Most relevant to this paper is the particular role Subset Sum plays in showing hardness for various problems on integers, essentially being

[1] Note that we can ignore any numbers $x_i > t$, so we will assume throughout the paper that $\max(X) \leq t$.

the most basic such problem where hardness arises exclusively from the additive nature of the problem. In particular, in areas such as operations research, Subset Sum plays a similar role to that of 3-SAT, serving as the core problem used in the vast majority of reductions (see e.g. [9, 11, 15, 24, 28, 32]). Many important problems can be shown to be generalizations of Subset Sum (by easy reductions) including scheduling problems, Knapsack, and Bicriteria Shortest Path. The broad goal of this paper is to understand the fine-grained complexity of such important problems, and more specifically whether the complexity of such generalizations is the same as that of Subset Sum or higher.

While Subset Sum (and its generalizations) is NP-hard, it is well-known that it can be solved in pseudo-polynomial time $O(t \cdot n)$ with the classical dynamic programming algorithm of Bellman [6]. Much more recently, this upper bound was improved to $\widetilde{O}(t + n)$ [7, 23, 27]; this is a significant improvement in the dense regime of the problem, e.g. if $t = O(n^2)$ the new algorithms achieve quadratic as opposed to cubic time. Most recently, in the dense regime the fine-grained complexity of Subset Sum was essentially resolved under the Strong Exponential Time Hypothesis (SETH) by the authors of this paper [1] (the same lower bound was previously known under the incomparable Set Cover Conjecture [12]). SETH [21, 22] postulates that there is no $O(2^{(1-\varepsilon)n})$-time algorithm for deciding the satisfiability of a k-CNF formula, for some $\varepsilon > 0$ independent of k.

▶ **Theorem 1.1** (Hardness of Subset Sum [1]). *Assuming SETH, there is no $\varepsilon > 0$ and $\delta < 1$ such that Subset Sum on n numbers and target t can be solved in time $O(t^{1-\varepsilon} \cdot 2^{\delta n})$.*

The lower bound given by Theorem 1.1 translates directly to several generalizations of Subset Sum, but does this yield tight lower bounds for the generalizations? Or can we prove higher lower bound for them? To answer this kind of question, the OR Subset Sum problem was introduced in [1]: Given N instances $(X_1, t_1), \dots, (X_N, t_N)$ of Subset Sum, determine whether at least one of these instances is a yes-instance; that is, whether there exists an $i \in \{1, \dots, N\}$ such that X_i contains a subset that sums up to t_i. While it seems natural to assume that no algorithm can solve this problem faster than solving each of the N Subset Sum instances independently, it is not clear how to prove this. In fact, an $O(N^{1/10} \cdot \max_i t_i)$ time algorithm for this problem does not directly break the lower bound for Subset Sum. Nevertheless, one can still show a tight lower bound by taking a somewhat indirect route: SAT does have a reduction to its OR variant, and then Theorem 1.1 allows us to reduce OR SAT to OR Subset Sum.

▶ **Theorem 1.2** (Hardness of OR Subset Sum [1]). *Assuming SETH, there are no $\varepsilon, \delta > 0$ such that there is an $O(N^{1+\delta-\varepsilon})$ time algorithm for the following problem: Given N Subset Sum instances, each with $O_{\delta,\varepsilon}(\lg N)$ integers and target $O(N^{\delta})$, determine whether one of these instances is a yes-instances.*

Thus, while Subset Sum admits[2] $\widetilde{O}(n + t)$-time algorithms [7, 23, 27], SETH rules time $\widetilde{O}(N + t)$ for OR Subset Sum. For example, when $N = O(n)$ and $t = O(n^2)$, Subset Sum can be solved in time $O(n^2)$, but OR Subset Sum has a cubic lower bound according to the above theorem. This distinction was used in [1] to show a higher lower bound for a generalization of Subset Sum that is a particularly prominent problem in the operations research community, the Bicriteria Shortest Path problem [19, 41]: Given a graph G with edge lengths and edge costs, two vertices s and t, and a budget B, determine whether there is an s, t-path of total length at most B and total cost at most B. While Theorem 1.1 immediately rules out time

[2] The term $\widetilde{O}()$ is used here and throughout the paper to suppress logarithmic factors.

$B^{1-\varepsilon} \cdot 2^{o(n)}$, it leaves open the possibility of an $\widetilde{O}(B+n)$ algorithm (as is known to exist for Subset Sum). As it turns out, Bicriteria Shortest Path can not only encode a *single* Subset Sum instance, but even *several* instances, and thus Theorem 1.2 yields an $\Omega(n + Bn^{1-\varepsilon})$ lower bound under SETH.

1.1 An Analogue of Theorem 1.2 for AND Subset Sum

While the OR variant in Theorem 1.2 is perfectly suited for showing lower bounds for Bicriteria Shortest Path and other problems of a similar type, there are others, such as the scheduling problems discussed below, whose type can only capture an AND variant: Given N instances of Subset Sum, determine whether *all* are yes-instances. It is natural to wonder whether there is a fine-grained reduction from SAT to AND Subset Sum (either directly or indirectly, by first reducing to AND SAT). Intuitively, the issue is that SAT, Subset Sum, and their OR variants have an $\exists$ quantifier type, while AND SAT and AND Subset Sum have a $\forall\exists$ quantifier type. Reducing one type to another seems very challenging, but fortunately, a morally similar challenge had been encountered before in fine-grained complexity and resolved to some extent as follows.

First, we can observe that the reduction we are looking for is impossible under the Nondeterministic Strong Exponential Time Hypothesis (NSETH) [10] which states that no non-deterministic $O(2^{(1-\varepsilon)n})$-time algorithm can decide whether a given k-CNF is unsatisfiable, for an $\varepsilon > 0$ independent of k. This hypothesis was introduced to show non-reducibility results. Intuitively, NSETH says that even though SAT is easy for nondeterministic algorithms its complement is not. Therefore, if for a certain problem both it and its complement are easy for nondeterministic algorithms then a reduction from SAT is impossible. Note that AND SAT, AND Subset Sum, and their complements admit efficient nondeterministic algorithms: to prove that the AND is "yes" we can guess a solution in each instance, and (for the complement) to prove that the AND is "no" we can guess the index of the instances that is "no". (Notice that the latter is not possible for the OR variants.)

There are already conjectures in fine-grained complexity that can capture problems with a $\forall\exists$ type. In the "n^2 regime", where SAT is faithfully represented by the Orthogonal Vectors (OV) problem[3] which has an $\exists$ type, Abboud, Vassilevska Williams and Wang [2] introduced a hardness hypothesis about the Hitting Set (HS) problem[4] which is the natural $\forall\exists$ type variant of OV. This hypothesis was used to derive lower bounds that cannot (under NSETH) be based on OV or SETH, e.g. for graph median and radius [2, 3, 13] and for Earth Mover Distance [35], and was also studied in the context of model checking problems [18]. Going back to the "2^n regime", the analogous hypothesis, which implies the HS hypothesis, is the following.

▶ **Hypothesis** ($\forall\exists$-SETH). *There is no $0 < \alpha < 1$ and $\varepsilon > 0$ such that for all $k \geq 3$ we can decide in time $O(2^{(1-\varepsilon)n})$, given a k-CNF formula ϕ on n variables $x_1, \dots, x_n$, whether for all assignments to $x_1, \dots, x_{\lceil \alpha \cdot n \rceil}$ there exists an assignment to the rest of the variables that satisfies ϕ, that is, whether:*

$$\forall x_1, \dots, x_{\lceil \alpha \cdot n \rceil} \exists x_{\lceil \alpha \cdot n \rceil + 1}, \dots, x_n : \phi(x_1, \dots, x_n) = \mathit{true}.$$

[3] Given two sets of n binary vectors of dimension $O(\log n)$, decide whether there is a vector in the first set and a vector of the second set that are orthogonal. SETH implies that this problem cannot be solved in time $O(n^{2-\varepsilon})$ [40], and essentially all SETH-based n^2 lower bounds go through this problem.

[4] Given two sets of n binary vectors of dimension $O(\log n)$, decide whether for all vectors in the first set there is an orthogonal vector in the second set. The Hitting Set Hypothesis states that this problem cannot be solved in time $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$.

Note that this hypothesis may also be thought of as the Π_2-SETH, where Π_2 is the second level of the polynomial hierarchy, and one can also think of higher levels of the polynomial hierarchy. Indeed, Bringmann and Chaudhury [8] recently proposed such a version, called Quantified-SETH, in which we can have any constant number $q \geq 1$ of alternating quantifier blocks, with a constant fraction of the variables in each block[5]. Non-trivial algorithms for Quantified-SAT exist [37], but none of them can refute even the stronger of these hypotheses.

It is important to note that while ∀∃-SAT is a strictly harder problem than SAT (as adding more quantifiers can only make the problem harder), in the restricted setting of ∀∃-SETH, where there is a constant fraction of the variables in each quantifier block, the situation is the opposite! A faster algorithm for SAT does imply a faster algorithm for ∀∃-SAT: exhaustively search over all assignments to the universally quantified αn variables and for each assignment solve SAT on $(1-\alpha)n$ variables. A reduction in the other direction is impossible under NSETH[6]. Therefore, ∀∃-SETH is a stronger assumption than SETH, which explains why it is helpful for proving more lower bounds, yet it seems equally plausible (to us). In particular, it gives us a tight lower bound for AND Subset Sum which we will use to show higher lower bounds for scheduling problems.

▶ **Theorem 1.3** (Hardness of AND Subset Sum). *Assuming ∀∃-SETH, there are no $\varepsilon, \delta > 0$ such that the following problem can be solved in time $O(N^{1+\delta-\varepsilon})$: Given N Subset Sum instances, each with $O(N^\varepsilon)$ integers and target $O(N^\delta)$, determine whether all of these instances are yes-instances.*

Note that in comparison with the OR Subset Sum case (Theorem 1.2), the size of our instances is polynomial $O(N^\varepsilon)$ instead of logarithmic $O_{\delta,\varepsilon}(\log N)$. We leave it as an open problem whether this is inherent or Theorem 1.3 can be improved.

It follows from Theorem 1.3 that AND Subset Sum on N instances, each on at most s integers and with target at most t, cannot be solved in time $\widetilde{O}(Ns + t(Ns)^{1-\varepsilon})$. We show that the same holds for the Partition problem, which is the special case of Subset Sum where the target is half of the total input sum. This is the starting point for our reductions in the next section.

▶ **Corollary 1.4.** *Assuming ∀∃-SETH, there is no $\varepsilon > 0$ such that the following problem can be solved in time $\widetilde{O}(Ns + t(Ns)^{1-\varepsilon})$: Given N Partition instances, each with at most s integers and target at most t, determine whether all of these instances are yes-instances.*

1.2 Scheduling lower bounds

To exemplify the power of Theorem 1.3, we use it to show strong lower bounds for several non-preemptive scheduling problems that generalize Subset Sum. These problems include some of the most basic ones such as minimizing the total weight of tardy jobs on a single machine, or minimizing the number of tardy jobs on two parallel machines. Theorem 1.5 below lists all of these problems; they are formally defined in Section 3 and each requires a different reduction. To describe the significance of our new lower bounds more clearly, let us focus on only one of these problems, $P_2||\sum U_j$, for the rest of this section. The input to this problem is a set of n jobs, where each job J_j has a processing time p_j and a due

[5] However, we remark that for the purposes of their paper as well as ours ∀∃-SETH is sufficient; Quantified-SETH is merely mentioned for inspiration. They were motivated by understanding the complexity of the polyline simplification problem from geometry (which turns out to have a ∀∀∃ type).

[6] This is analogous to the "n^2 regime" where HS implies OV but not the other way, assuming NSETH.

date d_j, and the goal is to schedule all jobs on two parallel machines so that the number of jobs exceeding their due dates is minimal. Let $P = \sum_j p_j$ and $P_{max} = \max_j p_j$ denote the sum of processing times and maximum processing time of the input jobs. Observe that $P \leq P_{max} \cdot n$.

The standard dynamic programming algorithm for this problem runs in $O(P \cdot n) = O(P_{max} \cdot n^2)$ time [29], and it is not known whether this running time is the best possible. Nevertheless, there is a well-known easy reduction from Subset Sum on numbers $x_1, \ldots, x_n$ to $P_2||\sum U_j$ that generates an instance with total processing time $P = \sum x_i = O(n \cdot t)$ and $P_{max} = \max x_i = O(t)$. Thus, using Theorem 1.1, we can rule out $P^{1-\varepsilon} \cdot 2^{o(n)}$-time and $P_{max}^{1-\varepsilon} \cdot 2^{o(n)}$-time algorithms for $P_2||\sum U_j$. However, this leaves open the possibility of $\widetilde{O}(P_{max} + n)$-time algorithms, which would be near-linear as opposed to the currently known cubic algorithm in a setting where $P_{max} = \Theta(n)$ and $P = \Theta(n^2)$. One approach for excluding such an upper bound is to first prove the impossibility of an algorithm for Subset Sum with running time $\widetilde{O}(\max_{x \in X} x + n)$. However, such a result has been elusive and is perhaps the most interesting open question in this context [4, 16, 17, 27, 33]. Instead, taking an indirect route, we are able to exclude such algorithms with an $\Omega(n + P_{max} n^{1-\varepsilon})$ lower bound under ∀∃-SETH by showing that $P_2||\sum U_j$ can actually encode the AND of several Subset Sum instances. In particular, in the above regime we improve the lower bound from linear to quadratic.

▶ **Theorem 1.5.** *Assuming ∀∃-SETH, for all $\varepsilon > 0$, none of the following problems have $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithms:*

- $1||\sum w_j U_j$, $1|Rej \leq R|\sum U_j$, $1|Rej \leq R|T_{max}$, *and* $1|r_j \geq 0, Rej \leq R|C_{max}$.
- $P_2||T_{max}$, $P_2||\sum U_j$, $P_2|r_j|C_{max}$, *and* $P_2|\textit{level-order}|C_{max}$.

All problems listed in this theorem are direct generalizations of Subset Sum, and each one admits a $O(P \cdot n) = O(P_{max} \cdot n^2)$-time algorithm via dynamic programming [29, 36, 38].

We note that the distinction between running times depending on P versus P_{max} and n relates to instances with low or high variance in their job processing times. In several experimental studies, it has been reported by researchers that the ability of scheduling algorithms to solve NP-hard problems deteriorates when the variance in job processing time increases (see e.g. [26, 31, 34]). Our results provide theoretical evidence for this claim by showing tighter lower bounds on the time complexity of several scheduling problems based on the maximum processing time P_{max}.

2 Quantified SETH Hardness of AND Subset Sum

In the following we provide a proof for Theorem 1.3, the main technical result of the paper. For this, we present a reduction from Quantified k-SAT to AND Subset Sum which consists of two main steps. The first step uses a tool presented in [1] which takes a (non-quantified) k-SAT instance and reduces it to subexponentially many Subset Sum instances that have relatively small targets. The second step is a new tool, which we develop in Section 2.2, that takes many Subset Sum instances and reduces them to a single instance with only a relatively small increase of the output target.

2.1 Main construction

The following two theorems formally state the two main tools that are used in our construction. Note that for our purpose, the important property here is the manageable increase of the output target in both theorems. The proof of Theorem 2.1 can be found in [1], while the proof of Theorem 2.2 is given in Section 2.2.

▶ **Theorem 2.1** ([1]). *For any $\varepsilon > 0$ and $k \geq 3$, given a k-SAT formula ϕ on n variables, we can in time $2^{\varepsilon n} \cdot n^{O(1)}$ construct $2^{\varepsilon n}$ Subset Sum instances, each with $O(n)$ integers and target at most $2^{(1+\varepsilon)n}$, such that ϕ is satisfiable if and only if at least one of the Subset Sum instances is a yes-instance.*

▶ **Theorem 2.2.** *Given Subset Sum instances $(X_1, t_1), \ldots, (X_N, t_N)$, denoting $n = \max_i |X_i|$ and $t = \max_i t_i$, we can construct in time $(nN \log t)^{O(1)}$ a single Subset Sum instance (X_0, t_0), with $|X_0| = O(nN)$ and $t_0 = t \cdot (nN)^{O(1)}$, such that (X_0, t_0) is a yes-instance if and only if (X_i, t_i) is a yes-instance for some $i \in \{1, \ldots, N\}$.*

Using the two results above, the proof of Theorem 1.3 follows by combining both constructions given by the theorems:

Proof of Theorem 1.3. Let ϕ be a k-SAT formula on n variables and let $0 < \alpha < 1$. We write $n_1 = \lfloor \alpha \cdot n \rfloor$ and $n_2 = n - n_1$, so that $n_1 \leq \alpha n$ and $n_2 \leq (1-\alpha)n + 1$. Our goal is to determine whether $\forall x_1, \ldots, x_{n_1} \exists x_{n_1+1}, \ldots, x_n \colon \phi(x_1, \ldots, x_n)$ is true.

We enumerate all assignments ∂ of the variables $x_1, \ldots, x_{n_1}$, and let ϕ_∂ be the resulting k-SAT formula on n_2 variables after applying ∂. Note that there are 2^{n_1} formulas ϕ_∂.

For each formula ϕ_∂, we run the reduction from Theorem 2.1 with parameter ε_0, resulting in a set $\mathcal{I}_\partial$ of at most $2^{\varepsilon_0 n_2}$ Subset Sum instances such that ϕ_∂ is satisfiable if and only if at least one of the instances in $\mathcal{I}_\partial$ is a yes-instance. Note that each Subset Sum instance in $\mathcal{I}_\partial$ consists of $O(n_2) = O(n)$ integers and has target at most $t = 2^{(1+\varepsilon_0)n_2}$. Moreover, running this reduction for all formulas ϕ_∂ takes time $2^{n_1 + \varepsilon_0 n_2} n^{O(1)}$.

Next, using Theorem 2.2, we reduce $\mathcal{I}_\partial$ to a single Subset Sum instance (X_∂, t_∂) such that (X_∂, t_∂) is yes-instance if and only if ϕ_∂ is a yes-instance, and so ϕ is a yes-instance if and only if *all* (X_∂, t_∂) are yes-instances. Note that we have $|X_\partial| = O(n \cdot 2^{\varepsilon_0 n_2})$ and $t_\partial = O(2^{(1+\varepsilon_0)n_2} \cdot (n \cdot 2^{\varepsilon_0 n_2})^\gamma)$ for some constant $\gamma > 0$ that replaces a hidden constant in Theorem 2.2. Moreover, running this step for all formulas ϕ_∂ takes time $O(2^{n_1} \cdot (n 2^{\varepsilon_0 n_2})^\gamma)$, where again $\gamma > 0$ replaces a hidden constant in Theorem 2.2.

Finally, we assume that for some $\varepsilon', \delta > 0$ we can solve AND Subset Sum on N instances, each with $O(N^{\varepsilon'})$ integers and target $O(N^\delta)$, in time $O(N^{1+\delta-\varepsilon'})$. Set $\varepsilon := \varepsilon'/(1+\delta)$ and note that then we can in particular solve AND Subset Sum on N instances, each with $O(N^\varepsilon)$ integers and target $O(N^\delta)$, in time $O(N^{(1+\delta)(1-\varepsilon)})$; for convenience we use this formulation in the following. Clearly, we can assume $\varepsilon < 1$. Set

$$N := 2^{(1+\varepsilon)n_1} = \Theta(2^{(1+\varepsilon)\alpha n}),$$

and note that the number of instances (X_∂, t_∂) is $2^{n_1} \leq N$. In order to apply the assumed algorithm to the instances (X_∂, t_∂), we need to verify that $|X_\partial| = O(N^\varepsilon)$ and $t_\partial = O(N^\delta)$. To this end, we set $\alpha := 1/(1+\delta)$ and $\varepsilon_0 := \min\{\varepsilon\alpha, \varepsilon/(1+2\gamma)\}$, and check that

$$\begin{aligned} |X_\partial| &= O(n \cdot 2^{\varepsilon_0 n_2}) = O(2^{\varepsilon_0 n}) = O(N^\varepsilon), \\ t_\partial &= O(2^{(1+\varepsilon_0)n_2} \cdot (n \cdot 2^{\varepsilon_0 n_2})^\gamma) = O(2^{(1+\varepsilon_0(1+2\gamma))n_2}). \end{aligned}$$

Using $\varepsilon_0 \leq \varepsilon/(1+2\gamma)$ and $n_2 \leq (1-\alpha)n + 1$, we further simplify this to $t = O(2^{(1+\varepsilon)(1-\alpha)n})$. From our setting of $\alpha = 1/(1+\delta)$ it now follows that $t = O(2^{(1+\varepsilon)\delta\alpha n}) = O(N^\delta)$. Hence, we showed that the assumed algorithm for AND Subset Sum is applicable to the at most N instances (X_∂, t_∂). This algorithm runs in time

$$O(N^{(1+\delta)(1-\varepsilon)}) = O(2^{(1+\delta)(1-\varepsilon)(1+\varepsilon)\alpha n}) = O(2^{(1-\varepsilon^2)n}).$$

Additionally, as analyzed above, the running time incurred by the reduction is bounded by

$$O\big(2^{n_1+\varepsilon_0 n_2} n^{O(1)} + 2^{n_1} \cdot (n 2^{\varepsilon_0 n_2})^{\gamma}\big) = O(2^{n_1+\varepsilon_0(1+2\gamma)n_2}) = O(2^{\alpha n+\varepsilon(1-\alpha)n}) \\ = O(2^{(1-(1-\varepsilon)(1-\alpha))n}).$$

Hence, we can solve the quantified k-CNF formula ϕ in time $O(2^{(1-\min\{\varepsilon^2,(1-\varepsilon)(1-\alpha)\})n})$, which for sufficiently large k violates ∀∃-SETH. ◀

Next, we infer Corollary 1.4 from Theorem 1.3.

Proof of Corollary 1.4. Fix any $\delta > 0$, and let $\varepsilon > 0$ to be chosen later. For given Subset Sum instances $(X_1, t_1), \ldots, (X_N, t_N)$, each with $O(N^{\varepsilon})$ integers and target $O(N^{\delta})$, our goal is to determine whether all of these instances are yes-instances.

For each i, we construct a Partition instance (X_i^*, t_i^*) by setting

$$X_i^* := X_i \cup \Big\{\Big(\sum_{x\in X_i} x\Big) + t_i, 2\cdot\Big(\sum_{x\in X_i} x\Big) - t_i\Big\} \qquad \text{and} \qquad t_i^* := \frac{1}{2}\sum_{x\in X_i^*} x.$$

It is easy to see that the Partition instance (X_i^*, t_i^*) is equivalent to the Subset Sum instance (X_i, t_i). Indeed, the two additional items cannot be put on the same side of the partition, as their sum is too large. Putting them on different sides of the partition, it remains to split X_i into a subset $Y_i \subseteq X_i$ summing to t_i and the remainder $X_i \setminus Y_i$ summing to $(\sum_{x\in X_i} x) - t_i$, to obtain a balanced partition.

Observe that $|X_i^*| = O(|X_i|) = O(N^{\varepsilon})$ and $t_i^* = O(|X_i| \cdot t_i) = O(N^{\delta+\varepsilon})$.

Now assume that we can solve AND Partition on N instances, each with at most s integers and target at most t, in time $O(Ns + t(Ns)^{1-\varepsilon_0})$ for some $\varepsilon_0 > 0$. On the instances $(X_1^*, t_1^*), \ldots, (X_n^*, t_N^*)$, this algorithm would run in time

$$\widetilde{O}(Ns + t(Ns)^{1-\varepsilon_0}) = \widetilde{O}(N^{1+\varepsilon} + N^{\delta+\varepsilon+(1+\varepsilon)(1-\varepsilon_0)}) = \widetilde{O}(N^{1+\varepsilon} + N^{1+\delta+2\varepsilon-\varepsilon_0}).$$

Finally, we pick $\varepsilon := \min\{\delta/2, \varepsilon_0/3\}$ to bound this running time by $O(N^{1+\delta-\varepsilon})$. This violates Theorem 1.3. ◀

2.2 From OR Subset Sum to Subset Sum

We next provide a proof of Theorem 2.2, the second tool used in our reduction from Quantified k-SAT to Subset Sum. We will use the notion of average-free sets.

▶ **Definition 2.3** (m-average-free set). *A set of integers S is called m-average-free if for all (not necessarily distinct) integers $s_1, \ldots, s_{m+1} \in S$ we have:*

$$s_1 + \cdots + s_m = m \cdot s_{m+1} \quad \textit{implies that} \quad s_1 = \cdots = s_{m+1}.$$

▶ **Lemma 2.4** ([5]). *Given $m \geq 2$, $M \geq 1$, and $0 < \varepsilon < 1$, an m-average-free set S of size M with $S \subseteq [0, m^{O(1/\varepsilon)} M^{1+\varepsilon}]$ can be constructed in $M^{O(1)}$ time.*

Proof of Theorem 2.2. Let $(X_1, t_1), \ldots, (X_N, t_N)$ be N given Subset Sum instances, and write $t = \max_i t_i$ and $n = \max_i |X_i|$. We begin by slightly modifying these instances. First, let $t^* = (n+1)t$, and add to each X_i the integer $t^* - t_i$. Clearly, there is a subset of X_i which sums up to t_i if and only if there is a subset of $X_i \cup \{t^* - t_i\}$ that sums up to t^*. Next, we add at most $2(n+1)$ copies of 0 to each instance, ensuring that all instances have the same number of integers $2(n+1)$, and that any instance which has a solution also has one which includes exactly $n+1$ integers. Note that these modifications only change n by a constant factor, and t by a factor $O(n)$, which are negligible for the theorem statement.

Therefore, with slight abuse of notation, henceforth we assume that we are given N Subset Sum instances $(X_1, t_1), \ldots, (X_N, t_N)$ with $t_1 = \ldots = t_N = t$ and $|X_1| = \ldots = |X_N| = 2n$. Moreover, for any i if there exists a subset $Y_i \subseteq X_i$ that sums up to t then we can assume without loss of generality that $|Y_i| = n$.

We construct an n-average-free set $S = \{s_1, \ldots, s_N\}$, with $S \subseteq [0, N^2 \cdot n^{O(1)}]$, using Lemma 2.4. Let $S_{\max} = \max_{s \in S} s$.

We are now ready to describe our construction of (X_0, t_0). It will be convenient to view the integers in (X_0, t_0) as binary encoded numbers, or binary strings, and to describe how they are constructed in terms of *blocks* of consecutive bits. Each integer will consist of seven blocks of fixed sizes. Starting with the least significant bit, the first block has $\lceil \lg t \rceil$ bits and is referred to as the *encoding block*, the third block has $\lceil \lg n \rceil$ bits and is referred to as the *counting block*, the fifth block has $\lceil \log(n \cdot S_{\max}) \rceil = O(\log(nN))$ bits and is referred to as the *verification block*, and the last block consists of a single bit. In between these blocks are blocks containing $\lceil \log(2nN) \rceil$ bits of value 0, whose sole purpose is to avoid overflows.

For each integer $x_{i,j} \in X_i$, we construct a corresponding integer $x^0_{i,j} \in X_0$ as follows (here the "|"-characters are used only to differentiate between blocks, and have no other meaning):

$$x^0_{i,j} \;=\; 0 \;|\; 0\cdots0 \;|\; s_i \;|\; 0\cdots0 \;|\; 0\cdots01 \;|\; 0\cdots0 \;|\; x_{i,j},$$

Additionally, for each $i \in \{1, \ldots, N\}$ we construct an integer $x^0_i \in X_0$ associated with the instance (X_i, t_i) as

$$x^0_i \;=\; 1 \;|\; 0\cdots0 \;|\; n \cdot (S_{\max} - s_i) \;|\; 0\cdots0 \;|\; 0\cdots0 \;|\; 0\cdots0 \;|\; 0.$$

The two sets of integers described above constitute X_0. To complete the construction of the output instance, we construct the target integer t_0 as

$$t_0 \;=\; 1 \;|\; 0\cdots0 \;|\; n \cdot S_{\max} \;|\; 0\cdots0 \;|\; n \;|\; 0\cdots0 \;|\; t^*.$$

Note that $|X_0| = O(\sum_i |X_i|) = O(nN)$ and $t_0 = t \cdot (nN)^{O(1)}$, as required by the theorem statement. Furthermore, the time required to construct (X_0, t_0) is $(nN \log t)^{O(1)}$.

We next argue that (X_0, t_0) is a yes-instance if and only if (X_i, t_i) is a yes-instance for some $i \in \{1, \ldots, N\}$. Suppose that there exists some $i \in \{1, \ldots, N\}$ and some $Y_i \subseteq X_i$ for which $\sum_{x_{i,j} \in Y_i} x_{i,j} = t$. By the discussion at the beginning of this proof, we can assume that $|Y_i| = n$. It is not difficult to verify that all integers in $Y_0 := \{x^0_{i,j} : x_{i,j} \in Y_i\} \cup \{x^0_i\}$ sum up to t_0. Indeed, by construction, the bits in the encoding block of these integers sum up to $\sum_{x_{i,j} \in Y_i} x_{i,j} = t$, the bits in the counting block sum up to n, the bits in the verification block sum up to $n \cdot S_{\max}$, and the last bit sums up to 1.

Conversely, assume that there is some subset $Y_0 \subseteq X_0$ with $\Sigma(Y_0) = \sum_{x \in Y_0} x = t_0$. Let $y_1, \ldots, y_m \in Y_0$ denote all integers of the form $x^0_{i,j}$ in Y_0, and let $x_{i_1,j_1}, \ldots, x_{i_m,j_m} \in X_1 \cup \cdots \cup X_M$ denote the integers that appear in the encoding blocks of $y_1, \ldots, y_m$. Observe that as $m \leq 2nM$, by our construction the highest bit in each overflow block of $\Sigma(Y_0)$ must be 0. It follows that we can argue in each of the encoding block, counting block, verification block, and last block separately. This yields:

- $\sum_\ell x_{i_\ell,j_\ell} = t$, since if this sum is greater than t then the second block of $\Sigma(Y_0)$ would not be all zeros, and if $\sum_\ell x_{i_\ell,j_\ell} < t$ then the encoding block of $\Sigma(Y_0)$ would not be t.
- $m = n$, by a similar argument in the counting block.

- There is exactly one integer of the form $x^0_{i^*}$ in Y_0, for some $i^* \in \{1, \ldots, N\}$, as otherwise the most significant bit of $\Sigma(Y_0)$ would not be 1.
- $i^* = i_1 = \cdots = i_n$: Note that $x^0_{i^*}$ contributes $n \cdot (S_{\max} - s_{i^*})$ to the verification block of $\Sigma(Y_0)$, and so the remaining n integers in Y_0 need to contribute together exactly $n \cdot s_{i^*}$ to this block, since the value of this block is $n \cdot S_{\max}$ in t_0. Since S is an n-average-free set, the only way for this to occur is if all of these integers have s_{i^*} encoded in their verification blocks, implying that $i^* = i_1 = \cdots = i_n$.

Let $i = i^*$ be the index in the last point above. Then $\sum_\ell x_{i,j_\ell} = t$ by the first point above, and so the subset $\{x_{i,j_1}, \ldots, x_{i,j_n}\}$ is a solution for the instance (X_i, t_i). ◀

3 Scheduling Lower Bounds

We next show how to apply Corollary 1.4 to obtain $\Omega(n + P_{max} \cdot n^{1-\varepsilon})$ lower bounds for several scheduling problems. In particular, we provide a complete proof of Theorem 1.5 in a sequence of lemmas below, each exhibiting a reduction from AND Subset Sum (or rather AND Partition) to the scheduling problem at hand.

In each reduction, we start with N Partition instances $(X_1, t_1), \ldots, (X_N, t_N)$; these are Subset Sum instances with $t_i = \frac{1}{2} \sum_{x \in X_i} x$. We write $s = \max_i |X_i|$ and $t = \max_i t_i$. We present reductions that transform these given instances into an instance $\mathcal{I}$ of a certain scheduling problem, such that $\mathcal{I}$ is a yes-instance if and only if (X_i, t_i) is a yes-instance for all i. The constructed instance $\mathcal{I}$ will consist of $n = O(Ns)$ jobs with maximum processing time $P_{max} = O(t)$. Since Corollary 1.4 rules out time $\widetilde{O}(Ns + t(Ns)^{1-\varepsilon})$ for AND Partition, it follows that the scheduling problem is not in time $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$, for any $\varepsilon > 0$ assuming ∀∃-SETH.

For an instance (X_i, t_i), we let $x_{i,j}$ denote the j-th integer in X_i.

3.1 Scheduling Notation and Terminology

In all scheduling problems considered in this paper, we are given a set of jobs $J_1, \ldots, J_n$ to be scheduled non-preemptively on one or two identical parallel machines. Each job J_j has a *processing time* p_j, and according to the specific problem at hand, it may also have a *due date* d_j, a *release date* r_j, and a *weight* w_j. We always use the same subscript for the job and its parameters. A *schedule* consists of assigning each job J_j a machine $M(J_j)$ and a *starting time* $S_j \in \mathbb{N}^{\geq 0}$. The *completion time* of job j in a given schedule is $C_j = S_j + p_j$, and the *makespan* of the schedule is its maximum completion time $C_{max} = \max_j C_j$. A schedule is *feasible* if no two distinct jobs *overlap* on the same machine; that is, for any pair of distinct jobs J_j and J_k with $M(J_j) = M(J_k)$ and $S_j \leq S_k$ we have $S_k \notin [S_j, C_j)$. Furthermore, when release dates are present, we require that $S_j \geq r_j$ for each job J_j.

A job J_j is said to be tardy in a given schedule if $C_j > d_j$, and otherwise it is said to be early. For each job J_j, we let $U_j \in \{0, 1\}$ denote a Boolean variable with $U_j = 1$ if J_j is tardy and otherwise $U_j = 0$. In this way, $\sum U_j$ denotes the number of tardy jobs in a given schedule, and $\sum w_j U_j$ denote their total weight. We let T_j denote the *tardiness* of a job J_j defined by $T_j = \max\{0, C_j - d_j\}$, and we let $T_{max} = \max_j T_j$ denote the *maximum tardiness* of the schedule. Below we use the standard three field notation $\alpha|\beta|\gamma$ introduced by Graham et al. [20] to denote the various problems, where α denotes the machine model, β denotes the constrains on the problem, and γ is the objective function. Readers unfamiliar with the area of scheduling are also referred to [32] for additional background.

3.2 Problems on Two Machines

We begin by considering scheduling problems on two parallel identical machines, as here our reductions are simpler to describe. Recall that in this setting, a schedule consists of assigning a starting-time S_j and a machine $M(J_j)$ to each input job J_j.

3.2.1 $P_2|$*level-order*$|C_{max}$

Perhaps the easiest application of Theorem 1.3 is makespan minimization on two parallel machines when level-order precedence constraints are present [14, 39]. In this problem, jobs only have processing-times, and they are partitioned into classes $\mathcal{J}_1, \ldots, \mathcal{J}_k$ such that all jobs in any class $\mathcal{J}_i$ must be scheduled after all jobs in $\mathcal{J}_{i-1}$ are completed. The goal is to find a feasible schedule with minimum makespan $C_{max} = \max_j C_j$.

▶ **Lemma 3.1.** *$P_2|$level-order$|C_{max}$ has no $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithm, for any $\varepsilon > 0$, unless $\forall\exists$-SETH is false.*

Proof. First recall that a single Partition instance (X, t) easily reduces to an instance of $P_2||C_{max}$ (*i.e.* without precedence constraints on the jobs) by creating a job with processing time x for each $x \in X$, and then setting the required makespan C to be $C = t$. For reducing multiple Partition instances we can use the precedence constraints: For each instance (X_i, t_i) of Partition, we create a class of jobs $\mathcal{J}_i$ which includes a job $J_{i,j}$ for each $x_{i,j} \in X_i$ with processing time $p_{i,j} = x_{i,j}$. Then since all jobs in class $\mathcal{J}_i$ must be processed after all jobs in $\mathcal{J}_1, \ldots, \mathcal{J}_{i-1}$ are completed, it is easy to see that the $P_2|$*level-order*$|C_{max}$ instance has a feasible schedule with makespan at most $C = \sum_i t_i$ if and only if each Partition instance is a yes-instance.

Indeed, if each X_i has a subset $Y_i \subset X_i$ which sums up to $t_i = \frac{1}{2} \cdot \sum_j x_{i,j}$, then we can schedule all jobs $J_{i,j}$ associated with elements $x_{i,j} \in Y_i$ on the first machine (following all jobs associated with elements in $Y_1, \ldots, Y_{i-1}$), and all jobs $J_{i,j}$ associated with elements $x_{i,j} \notin Y_i$ on the second machine. This gives a feasible schedule with makespan at most C. Conversely, a schedule with makespan at most C must have the last job in $\mathcal{J}_i$ complete no later than $\sum_{i_0 \leq i} t_{i_0}$, for each $i \in \{1, \ldots, N\}$. This in turn can only be done if each X_i can be partitioned into two sets that sum up to t_i, which implies that each (X_i, t_i) is a yes-instance.

Starting from N Partition instances $(X_1, t_1), \ldots, (X_N, t_N)$, each with at most s integers and target at most t, our reduction constructs $n \leq Ns$ jobs with maximum processing time $P_{max} \leq t$. Therefore, any $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithm for $P_2|$*level-order*$|C_{max}$ would yield an $\widetilde{O}(Ns + t(Ns)^{1-\varepsilon})$-time algorithm for AND Partition, which contradicts Corollary 1.4, assuming $\forall\exists$-SETH. ◀

3.2.2 $P_2||T_{max}$ and $P_2||\sum U_j$

We next consider the $P_2||T_{max}$ and $P_2||\sum U_j$ problems, where jobs also have due dates, and the goal is to minimize the maximum tardiness and the total number of tardy jobs, respectively. The reduction here is very similar to the previous reduction. We create for each $i \in \{1, \ldots, N\}$, and each $x_{i,j} \in X_i$, a job $J_{i,j}$ with processing time $p_{i,j} = x_{i,j}$ and due date

$$d_{i,j} = d_i = \sum_{\ell=1}^{i} t_\ell = \frac{1}{2} \cdot \sum_{\ell=0}^{i} \sum_{j} x_{\ell,j}.$$

Observe that for each $i \in \{1, \ldots, N\}$, all jobs $J_{i,j}$ can be scheduled early if and only if X_i can be partitioned into two sets summing up to t_i. Thus, all jobs can be scheduled early if and only if all Partition instances are yes-instances. Note that this corresponds to both objective functions T_{max} and $\sum U_j$ at value 0. Thus, using Corollary 1.4 we obtain:

▶ **Lemma 3.2.** *Both $P_2||T_{max}$ and $P_2||\sum U_j$ have no $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithms, for any $\varepsilon > 0$, assuming ∀∃-SETH.*

3.2.3 $P_2|r_j \geq 0|C_{max}$

Our final dual machine example is the problem of minimizing makespan when release dates are present, the classical $P_2|r_j \geq 0|C_{max}$ problem.

▶ **Lemma 3.3.** *$P_2|r_j \geq 0|C_{max}$ has no $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithm, for any $\varepsilon > 0$, unless ∀∃-SETH is false.*

Proof. Let $(X_1, t_1), \dots, (X_N, t_N)$ be N instances of Partition. For each element $x_{i,j} \in X_i$ we create a job $J_{i,j}$ with processing time $p_{i,j} = x_{i,j}$ and release date $r_{i,j} = \sum_{\ell<i} t_\ell$. Note that there is a schedule for this instance with makespan $\sum_{i=1}^{N} t_i$, where each job is scheduled no earlier than its release date, if and only if each Partition instance is a yes-instance. Also note that the resulting instance has maximum processing time $P_{max} = \max_i t_i$ and total number of jobs $n \leq N \cdot \max_i |X_i|$. As before, using Corollary 1.4 we can now rule out time $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$, assuming ∀∃-SETH. ◀

3.3 Problems on One Machine

We next consider single machine problems. Obviously, a schedule in this case only needs to specify a starting time S_j for each job J_j, and in case there are no release dates, a schedule can be simply thought of as a permutation of the jobs.

3.3.1 $1||\sum w_j U_j$

One of the most classical single-machine scheduling problems which already appeared in Karp's initial list of 21 NP-complete problems [24] is the problem of minimizing the total weight of tardy jobs. Here each job J_j has a due date d_j and weight w_j, and the goal is to minimize $\sum w_j U_j$.

▶ **Lemma 3.4.** *Assuming ∀∃-SETH, there is no $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithm for $1||\sum w_j U_j$, for any $\varepsilon > 0$.*

Proof. Let $(X_1, t_1), \dots, (X_N, t_N)$ be N instances of Partition. For each $i \in \{1, \dots, N\}$, and for each $x_{i,j} \in X_i$, we create a job $J_{i,j}$ with the following parameters:

- processing time $p_{i,j} = x_{i,j}$,
- weight $w_{i,j} = (N - i + 1) \cdot x_{i,j}$,
- and due date $d_{i,j} = d_i = \sum_{\ell=1}^{i} t_\ell$.

We argue that there is a schedule for all jobs $J_{i,j}$ with total weight of tardy jobs at most $W = \sum_{i=1}^{N} (N - i + 1) \cdot t_i$ if and only if each Partition instance (X_i, t_i) is a yes-instance.

Suppose that each X_i has a subset $Y_i \subseteq X_i$ which sums up to t_i. Let $\mathcal{E}_i = \{J_{i,j} : x_{i,j} \in Y_i\}$ and $\mathcal{T}_i = \{J_{i,j} : x_{i,j} \notin Y_i\}$ for $i \in \{1, \dots, N\}$, and let $\mathcal{E} = \bigcup_i \mathcal{E}_i$ and $\mathcal{T} = \bigcup_i \mathcal{T}_i$. Then any schedule of the form $\mathcal{E}_1, \dots, \mathcal{E}_N, \mathcal{T}$, where the order inside each subset of jobs is arbitrary, schedules all jobs in $\mathcal{E}$ early, and so the total weight of tardy jobs of such a schedule is at most the total weight of $\mathcal{T}$ which is $w(\mathcal{T}) = \sum_i w(\mathcal{T}_i) = \sum_{i=1}^{N} (N - i + 1) \cdot t_i = W$.

Conversely, suppose there is a schedule for the jobs $J_{i,j}$ where the total weight of tardy jobs is at most W. Let $\mathcal{E}_i$ denote the set of early jobs in the schedule with due date d_i, for $i = \{1, \dots, N\}$, and let $\mathcal{E} = \bigcup \mathcal{E}_i$. Then as the total weight of all jobs is $2W$, we have $w(\mathcal{E}) \geq W = \sum_i (N - i + 1) \cdot t_i$. By our construction, this can only happen if we have

$w(\mathcal{E}_i) \geq (N-i+1) \cdot t_i$ for each $i \in \{1,\dots,N\}$, which in turn can only happen if $p(\mathcal{E}_i) \geq t_i$. Since all jobs in each $\mathcal{E}_i$ are early, we have $p(\mathcal{E}_i) \leq t_i$, and so $p(\mathcal{E}_i) = t_i$. It follows that for each $i \in \{1,\dots,N\}$, the set $Y_i = \{x_{i,j} : J_{i,j} \in \mathcal{E}_i\} = \{p_{i,j} : J_{i,j} \in \mathcal{E}_i\}$ sums up to t_i. Thus we have found a solution for each Subset Sum instance (X_i, t_i), and so the lemma follows. ◀

3.3.2 $1|Rej \leq R|\sum U_j$ and $1|Rej \leq R|T_{max}$

In scheduling with rejection problems [38], jobs J_j are allowed not to be scheduled (*i.e.* rejected) at the cost of w_j. Here we consider the case where the total cost of rejected jobs cannot exceed some prespecified bound R. Under this constraint, the $1|Rej \leq R|\sum U_j$ and $1|Rej \leq R|T_{max}$ problems focus on minimizing the number of tardy jobs $\sum U_j$ and the maximum tardiness of any job T_{max}, respectively.

Note that there is a direct reduction from the $1||\sum w_j U_j$ problem to the $1|Rej \leq R|\sum U_j$ and $1|Rej \leq R|T_{max}$ problems: An instance of $1||\sum w_j U_j$ has a schedule with total weight at most W if and only if there are jobs of total weight $R = W$ that can be rejected so that all remaining jobs can be scheduled early. Thus, the lemma below immediately follows from Lemma 3.4 above.

▶ **Lemma 3.5.** *Assuming ∀∃-SETH, both $1|Rej \leq R|\sum U_j$ and $1|Rej \leq R|T_{max}$ have no $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithms, for any $\varepsilon > 0$.*

3.3.3 $1|r_j \geq 0, Rej \leq R|C_{max}$

In this problem, each job J_j has a processing time p_j, a release date r_j, and a weight w_j, and the goal is to find a schedule that rejects jobs with total weight at most R and minimizes the makespan of the remaining non-rejected jobs.

▶ **Lemma 3.6.** *There is no $\widetilde{O}(n + P_{max} \cdot n^{1-\varepsilon})$-time algorithm for $1|r_j \geq 0, Rej \leq R|C_{max}$, for any $\varepsilon > 0$, unless ∀∃-SETH is false.*

Proof. Let $(X_1, t_1), \dots, (X_N, t_N)$ be N instances of Partition. For each $i \in \{1,\dots,N\}$, and for each $x_{i,j} \in X_i$, we create a job $J_{i,j}$ with:

- processing time $p_{i,j} = x_{i,j}$,
- weight $w_{i,j} = i \cdot x_{i,j}$,
- and release date $r_{i,j} = r_i = \sum_{\ell=1}^{i-1} t_\ell$.

We argue that there is a schedule for all jobs $J_{i,j}$ with makespan at most $C = \sum_i t_i$ that rejects jobs with cost at most $R = \sum_i i \cdot t_i$ if and only if each Partition instance (X_i, t_i) is a yes-instance.

Suppose that each X_i has a subset $Y_i \subseteq X_i$ which sums up to t_i. Let $\mathcal{E}_i = \{J_{i,j} : x_{i,j} \in Y_i\}$ and $\mathcal{T}_i = \{J_{i,j} : x_{i,j} \notin Y_i\}$ for $i \in \{1,\dots,N\}$, and let $\mathcal{E} = \bigcup_i \mathcal{E}_i$ and $\mathcal{T} = \bigcup_i \mathcal{T}_i$. Then any schedule of the form $\mathcal{E}_1, \dots, \mathcal{E}_N$, where the jobs in $\mathcal{T}$ are rejected, respects all release dates of jobs in $\mathcal{E}$, and has makespan $C_{max} = \sum_i t_i = C$. Moreover, the total cost of the rejected jobs is $w(\mathcal{T}) = \sum_i w(\mathcal{T}_i) = \sum_{i=1}^N i \cdot t_i = R$.

Conversely, suppose there is schedule for the jobs $J_{i,j}$ that respects all release dates, rejects jobs with weight at most R, and has makespan at most C. Let $\mathcal{E}_i$ denote the set of non-rejected jobs with release date r_i, for $i = \{1,\dots,N\}$, and let $\mathcal{E} = \bigcup \mathcal{E}_i$. Then as the total weight of all jobs is $2R$, we have $w(\mathcal{E}) \leq R = \sum_i i \cdot t_i$. By our construction, this can only happen if we have $w(\mathcal{E}_i) \geq i \cdot t_i$ for each $i \in \{1,\dots,N\}$, which in turn can only happen if $p(\mathcal{E}_i) \geq t_i$. On the other hand, the release date r_{i+1} of jobs in $\mathcal{E}_{i+1}$ can be respected only if $p(\mathcal{E}_i) \leq r_{i+1} = \sum_{\ell=1}^{i} t_\ell$, and so $p(\mathcal{E}_i) = t_i$. It follows that for each $i \in \{1,\dots,N\}$, the set $Y_i = \{x_{i,j} : J_{i,j} \in \mathcal{E}_i\} = \{p_{i,j} : J_{i,j} \in \mathcal{E}_i\}$ sums up to t_i. Thus, we have found a solution for each Subset Sum instance (X_i, t_i), and so the lemma follows. ◀

4 Conclusion

In this paper we considered the AND Subset Sum problem: Given N instances of Subset Sum, determine whether all instances are yes-instances. We showed that the problem is essentially as hard as solving N Subset Sum instances independently, and then used this result to strengthen existing lower bounds for several scheduling problems. Our research is closely related to the question of whether Subset Sum on input (X, t) can be solved in time $\widetilde{O}(\max_{x \in X} x + |X|)$, which is currently a central open problem in the area [4, 16, 17, 27, 33]. Our results answer this question in the negative for several generalizations of Subset Sum. We believe that the line of thought in this paper can provide other results in a similar vein.

Observe that almost all scheduling problems considered in this paper do not have a matching upper-bound of $\widetilde{O}(P_{max} \cdot n)$ to the lower bound constructed in Section 3. The exception is $P_2|\text{level-order}|C_{max}$ which can be solved in time $O(P_{max} \cdot n)$ by using the known $O(P_{max} \cdot n)$-time Subset Sum algorithm [33] (or the faster algorithms given in [7, 27]) on each class of jobs $\mathcal{J}_i$ separately. It would be very interesting to close the gap for other problems listed in Theorem 1.5. This could be done by either devising an $\widetilde{O}(P_{max} \cdot n)$-time algorithm for the problem, or by strengthening our lower bound mechanism.

Abstract

We consider the *parity* variants of basic problems studied in fine-grained complexity. We show that finding the exact solution is just as hard as finding its parity (i.e. if the solution is even or odd) for a large number of classical problems, including All-Pairs Shortest Paths (APSP), Diameter, Radius, Median, Second Shortest Path, Maximum Consecutive Subsums, Min-Plus Convolution, and 0/1-Knapsack.

A direct reduction from a problem to its parity version is often difficult to design. Instead, we revisit the existing hardness reductions and tailor them in a problem-specific way to the parity version. Nearly all reductions from APSP in the literature proceed via the (subcubic-equivalent but simpler) Negative Weight Triangle (NWT) problem. Our new modified reductions also start from NWT or a non-standard parity variant of it. We are not able to establish a subcubic-equivalence with the more natural *parity counting* variant of NWT, where we ask if the number of negative triangles is even or odd. Perhaps surprisingly, we justify this by designing a reduction from the seemingly-harder Zero Weight Triangle problem, showing that parity is (conditionally) strictly harder than decision for NWT.

1 Introduction

The blossoming field of fine-grained complexity is concerned with understanding the time complexity of basic computational problems in a precise way. The main approach is to hypothesize the hardness of a few core problems and then reduce them to a large number of other problems, establishing tight conditional lower bounds for them. A cornerstone finding in this field is that there is a class of more than ten problems that are all *subcubic equivalent* to the All-Pairs Shortest Paths (APSP) problem, in the sense that if any of them can be solved in truly subcubic $O(n^{3-\varepsilon})$ time (for some $\varepsilon > 0$) then all of them can. Most of the problems in this "APSP-class" are related to distance computations in graphs such as computing the radius of the graph or deciding if the graph contains a negative weight triangle (NWT). In this work, we investigate the fine-grained complexity of the natural

parity versions of such problems: are they easier, harder, or do they have the same time complexity? Depending on the problem, the natural parity version could have a different type; let us consider the two main types that will appear in this paper and illustrate them with examples.

- **Parity Computation:** The Radius-Parity problem asks whether the radius of the graph is even or odd. Similarly, the APSP-Parity problem asks to compute, for each pair of nodes, whether the distance between them is even or odd. This type is often natural for optimization problems.
- **Parity Counting:** The NWT-Parity problem asks if the number of negative triangles in the graph is even or odd, or equivalently, it asks to count the number of negative triangles modulo 2. Similarly, SAT-Parity asks if the number of satisfying assignments to a given formula is even or odd. This type is often natural for decision problems where we are looking for a solution satisfying a certain property[1].

The parity computation versions are clearly no harder than the original problem: If we know the radius exactly we also know its parity (if it is even or odd). In fact, sometimes knowing the parity can be much easier than computing the entire answer. For instance, while computing the maximum number of nodes in a matching requires super-linear time, knowing the parity is trivial (it is always 0). On the other hand, parity counting versions can make the problem much harder. A famous example is 2-SAT: the decision version takes linear time but the parity version is probably not in P [42]. Thus, in general, the natural parity version could be easier or harder than the original problem.

Various questions related to parity arose naturally in different contexts in computer science throughout the years. For instance, the SAT-Parity problem played a key role in the proof of Toda's theorem [40], which is one of the earliest and most fundamental results in the large body of works on counting complexity [23]. There, parity counting problems are extensively studied, being of intermediate complexity between the decision problems and the counting problems (see e.g. [5, 8, 34, 41–44]). The first type of problems are less studied in terms of worst-case complexity but are morally related to hard-core predicates in cryptography [45] where it is desirable that the parity (least significant bit) of a function is hard to guess. The motivation for our work is twofold: (1) many of the parity versions are interesting on their own and we would like to know their complexity, and (2) this investigation could lead to a deeper understanding of the structure among the original (non-parity) versions.

1.1 Our Results

1.1.1 The APSP Class

Our first set of results concern the APSP equivalence class. We have gone through the problems in this class from the works of [3, 20, 51] and tried to classify the complexity of their parity versions. Our first theorem shows that, with the notable exception of Negative Weight Triangle (NWT), all the parity versions are subcubic-equivalent to APSP and therefore also to the original (non-parity) problems. These problems and their parity versions are listed and defined in Table 1 together with our results for each of them and where they appear in the paper.

[1] The parity counting version could be viewed simply as the parity computation version of the counting version of the problem, so the first type could be considered the "real" parity version. However, parity counting is widely referred to as the parity version in the literature.

Table 1 The APSP class: problem definitions, known results, and our results (in bold). We denote subcubic equivalent as SE and as SER when it is under a randomized reduction. The first seven problems output a single value and their parity version computes the parity of this value. The next three problems output multiple values and their parity version computes the parity of every value. The last two problems are the only parity counting problems, in which we distinguish between the parity version (asking for the parity of the number of such triangles) and the vertex parity version (asking for the parity of the number of vertices that belong to such triangles).

Problem	Definition	Complexity
Median	$\min_u \sum_v d(u,v)$	SE to APSP [3], **Parity is SE to APSP (Sec. 2)**
Wiener Index	$\sum_u \sum_v d(u,v)$	SE to APSP [20], **Parity is SER to APSP (Sec. 3.2, 3.3)**
Radius	$\min_u \max_v d(u,v)$	SE to APSP [3], **Parity is SE to APSP (Sec. 8)**
Sum of Eccentricities	$\sum_u \max_v d(u,v)$	**SE to APSP, (Sec. 7),** **Parity is SER to APSP (Sec. 3.4)**
Integer Betweenness Centrality	find the number of vertices pairs with a shortest path passing through a given vertex x	SE to APSP [3], $(1+\varepsilon)$-approx. is SER to Diameter [3] **Parity is SER to APSP (Sec. 3.5, 3.6)**
Second Shortest Path	given vertices s,t, find the length of the second shortest s-to-t path	SE to APSP [51], **Parity is SE to APSP (Full version)**
Maximum Subarray	given a matrix, find the maximum total value in a submatrix	SE to APSP [6, 39], **Parity is SE to APSP (Full version)**
APSP	Compute all distances $d(u,v)$	**Parity is SE to APSP (Sec. 4)**
Min-Plus Matrix Multiplication	given $n \times n$ matrices A and B, compute the matrix C where $C[i,j] = \min_k\{A[i,k] + B[k,j]\}$	SE to APSP (folklore), **Parity is SE to APSP (Sec. 4)**
Replacement Paths	for every edge e on a shortest s-to-t path, find the length of the shortest s-to-t path that avoids e	SE to APSP [51], **Parity is SE to APSP (Full version)**
Negative Weight Triangle	determine if there is a triangle of total negative weight	SE to APSP [51], $(1+\epsilon)$-approx. Counting is SER to APSP [19]. **Randomized reductions from APSP and 3SUM to Parity and Counting (Sec. 5.1, 5.2), Vertex Parity is SER to APSP (Sec. 3.1)**
Zero Weight Triangle	determine if there is a triangle of total zero weight	Reduction from APSP and 3SUM [50], **Randomized reduction to Parity and Vertex Parity (Sec. 3.1, 5.2)**

▶ **Theorem 1.** *The following problems are subcubic-equivalent:*

- *All-Pairs Shortest Paths and its parity computation,*
- *Min-Plus Matrix Multiplication and its parity computation,*
- *Radius and its parity computation,*
- *Median and its parity computation,*
- *Wiener Index and its parity computation,*
- *Replacement Paths and its parity computation,*
- *Second Shortest Path and its parity computation,*
- *Vertex in Negative Weight Triangle and its parity computation,*

- *Integer Betweenness Centrality and its parity computation,*
- *Maximum Subarray and its parity computation,*
- *Sum of Eccentricities*[2] *and its parity computation.*

This adds more than ten natural problems to the APSP-equivalence class. For all problems in Theorem 1, the reduction from the parity version to the original problem is straightforward (since they are parity computation rather than parity counting problems), while the reduction in the other direction is not. For instance, it is not at all clear how to establish the hardness of Median-Parity by reducing from Median to it. Instead, we find it much more convenient to start from NWT which is the canonical APSP-complete problem and the starting point for nearly all APSP-hardness reductions.

Some of our results take the known reductions from NWT and modify them to establish the hardness of the parity versions, e.g. for Median-Parity. Notably, reductions of this kind are deterministic. For other parity problems such as Wiener-Index it is more convenient to reduce from a parity version of NWT. However, (the most natural) NWT-Parity is a parity counting problem which makes it seem harder than NWT and therefore inappropriate as a starting point for reductions. Instead, we identify a different variant that we call NWT-Vertex-Parity (asking if the number of vertices that belong to a negative triangle is even or odd) which turns out to be subcubic-equivalent to NWT and a very useful intermediate problem. Reductions of this kind seem to require randomization.

Finally, we investigate the intriguing NWT-Parity problem. This is the modulo 2 version of the NWT-counting problem (asking for the number of negative triangles) that was recently studied by Dell and Lapinskas [19] in their work on the fine-grained complexity of approximate counting. With standard subsampling techniques, one can show that NWT reduces to NWT-Parity. But are they subcubic-equivalent? We show that such an equivalence would imply breakthroughs in fine-grained complexity, therefore suggesting that the parity version is strictly harder. Our next theorem shows that NWT-Parity can solve a problem that is considered strictly harder than APSP: the problem of deciding whether a graph has a Zero Weight Triangle (ZWT). As discussed below, if the same reduction can be shown between the original (non-parity) problems it would be a major breakthrough.

▶ **Theorem 2.** *There is a deterministic subcubic-reduction from the Zero Weight Triangle Parity problem to the Negative Weight Triangle Parity problem.*

The ZWT problem is considered one of the "hardest" n^3-problems since a subcubic algorithm for it would refute *two* of the main conjectures in fine-grained complexity: it would give a subcubic algorithm for APSP and a subquadratic algorithm for 3SUM [35, 50, 51]. The 3SUM Conjecture states that we cannot decide in truly subquadratic $O(n^{2-\varepsilon})$ time if among a set of n numbers there are three that sum to zero. The class of problems that are 3SUM-hard contains dozens of problems mostly from computational geometry (see [24, 28] for a partial list), but also in other domains, e.g. [4, 29, 35]. One of the central open questions in the field is whether the APSP class and the 3SUM class can be unified; in particular, whether APSP is 3SUM-hard. One way to prove this is to reduce ZWT to APSP, and our result shows that NWT-Parity to NWT suffices:

▶ **Corollary 3.** *If the Negative Weight Triangle Parity problem is subcubic-equivalent to the Negative Weight Triangle problem, then APSP is 3SUM-hard.*

[2] This natural problem was not considered before to our knowledge, but it is closely related to Median, Radius, and the other distance computation problems.

A more quantitative reason for supposing that ZWT is harder than NWT is that their current upper bounds, while all mildly-subcubic, are significantly far apart. All the problems in the APSP equivalence class can be solved in $n^3/2^{\Omega(\sqrt{\log n})}$ time [47], which is faster than $O(n^3/\log^c n)$ for all $c > 0$. For ZWT, on the other hand, nothing better than $O(n^3/\log^c n)$ is known for a small $c \leq 2$, and even small improvements would lead to a faster mildly subquadratic algorithm for 3SUM beating the current fastest $O(n^2(\log\log n)^2/\log n)$ [26]. Dell and Lapinskas [19] achieve an $n^3/2^{\Omega(\sqrt{\log n})}$ upper bound for the approximate counting version of NWT but not for exact counting. We show that even for the parity version such a result has breakthrough consequences for 3SUM. For NWT, this (conditionally) separates the counting and parity versions from the decision and approximate counting versions.

Table 2 The other (non-APSP) problems. We denote subcubic (subquadratic) equivalent as SE (SQE) and as SER (SQER) when it is under a randomized reduction. As before, the parity version of problems that output a single (multiple) value(s) computes the parity of this value (all these values). The last problems is the only parity counting problem, in which the parity version asks for the parity of the number of vertices that do not belong to any negative triangle.

Problem	**Definition**	**Complexity**
Diameter	$\max_u \max_v d(u,v)$	**Parity is SE to Diameter (Sec. 8)**
Maximum Row Sum	$\max_u \sum_v d(u,v)$	**Reduction from Co-Negative Triangle to Parity (Full version)**
Reach Centrality	compute the maximum distance between a given vertex x and the closest endpoint of any shortest path passing through x	SE to Diameter [3], **Parity is SE to Diameter (Full version)**
0/1-Knapsack	given items (w_i, v_i) and a weight t, find a subset I that maximizes $\sum_{i\in I} v_i$ subject to $\sum_{i\in I} w_i \leq t$	SQER to Min-Plus Convolution, variants are SQE to Min-Plus Convolution [17,30], **Parity is SQER to Min-Plus Convolution, variants are SQE to Min-Plus Convolution (Sec. 6)**
Tree Sparsity	given a node-weighted tree, find the maximum weight of a subtree of size k	SQE to Min-Plus Convolution [7,17], **Parity is SQE to Min-Plus Convolution (Full version)**
Min-Plus Convolution	given n-length vectors A and B, compute the vector C where $C[k] = \min_{i+j=k}\{A[i]+B[j]\}$	Reduction to APSP and 3SUM [13,17], **SQE to Parity (Sec. 4.2)**
Maximum Consecutive Subsums	given an n-length vector A, compute the vector B where $B[k] = \max_i\{\sum_{j=0}^{k-1} A[i+j]\}$	SQE to Min-Plus Convolution [17,31], **Parity is SQE to Min-Plus Convolution (Sec. 4.3)**
Co-Negative Triangle	find a vertex that does not belong to any negative triangle	Reduction to Diameter [10], **Reduction to Maximum Row Sum Parity (Full version)**

1.1.2 Other Classes

In our second set of results we ask whether parity computation problems are as hard also for problems that are outside the APSP class. We have gone through other fine-grained complexity results from the works of [7,17,30,31] and tried to establish the same results for the parity versions. All problems we consider are defined in Table 2 together with our results and where they appear in the paper. The general message is that, in all cases we considered, the same hardness reductions (if modified carefully) can establish the hardness of the (seemingly easier) parity version as well. We mention a few concrete examples.

In the context of distance computations in graphs, the central open question is whether the Diameter problem is subcubic equivalent to APSP. Meanwhile, Diameter has its own (smaller) equivalence class which includes problems such as Reach Centrality [3]. We prove that Diameter-Parity and Reach Centrality-Parity are subcubic equivalent to Diameter.

Another interesting problem in fine-grained complexity whose importance is rapidly increasing is the Min-Plus Convolution problem [17]. The naïve algorithm for this problem runs in $O(n^2)$ time, and a truly subquadratic $O(n^{2-\varepsilon})$ algorithm is conjectured to be impossible. This problem is one of the easiest n^2 problems since it can be reduced to both APSP (i.e. a subcubic algorithm for APSP yields a subquadratic algorithm for Min-Plus Convolution) and to 3SUM (an opposing situation to that of ZWT). This means that all of the APSP and 3SUM lower bounds can be based on this conjecture, but also that Min-Plus Convolution is unlikely to be equivalent to either of them (as it would imply a unification of the classes). Recently, a few other problems have been shown to be harder, e.g. [2], or subquadratic-equivalent to it, e.g. Maximum consecutive subsums [17, 31], 0/1-Knapsack [17, 30], and a $(1+\varepsilon)$-approximation for Subset Sum [14]. We prove that these equivalences hold for the parity versions as well (except the latter problem for which we did not find a natural parity version). Our reduction from the Maximum consecutive subsums problem to its parity version in Section 4.3 is quite involved and it uses specific properties of the addition operator. One can obtain such a reduction indirectly and more easily via Min-Plus Convolution, however, we believe that our reduction gives more insight into the problem and into the usage of the addition operator.

▶ **Theorem 4.** *The following problems are subquadratic-equivalent:*
- *Min-Plus Convolution and its parity computation,*
- *Maximum Consecutive Subsums and its parity computation,*
- 0/1-*Knapsack and its parity computation,*
- *Tree Sparsity and its parity computation.*

1.2 Related Work

While parity counting problems are extensively studied in classical complexity theory, the parity computation problems seem to have received less attention. In many cases, the standard NP-hardness reduction from SAT gives instances in which the solution is always either k or $k-1$, which directly implies the NP-hardness of the parity version as well. Some of the results in fine-grained complexity also have this property. For example, the quadratic hardness result for Diameter in sparse graphs [36] shows that it is hard to distinguish diameter 2 from 3 and immediately gives the same lower bound for parity. However, for many other problems, such as the ones we consider, this is not the case and a careful problem-specific treatment is required.

Theorem 2 and its corollaries conditionally separate NWT from its parity and counting versions. Such separations are famously known in classical complexity, e.g. for 2-SAT [42]. In fine-grained complexity, a (conditional) separation for a variant of the Orthogonal Vectors problem between near-linear time decision [48] and quadratic time exact counting [46] was recently achieved. Notably, the approximate counting version is also in near-linear time [19] and the parity version is open.

The parity counting version of the Strong Exponential Time Hypothesis was studied in a seminal paper on the fine-grained complexity of NP-hard problems [16]. The central question left open in that paper (and is still wide open, see [1]) is whether SAT can be reduced to Set-Cover in a fine-grained way; interestingly, the authors have shown such a reduction for the parity counting versions.

Exact and approximate counting problems have received a lot of attention in parameterized [15, 22] and fine-grained complexity [18]. In a recent development, the k-Clique counting problem was shown to have worst-case to average-case reductions [9, 25]. It is likely that our result for NWT-Parity can be extended to Negative Weight k Clique Parity showing that it is as hard as Zero Weight k Clique. The decision version of the latter problem was used as the basis for public-key cryptography schemes [32].

Due to the large amount of works on APSP-hardness and equivalences we did not manage to exhaustively enumerate all of them and investigate the complexity of the parity versions, e.g. for problems on stochastic context-free grammars [38] or dynamic graphs [4, 37]. Still, we expect that the ideas in this work can be extended to show the hardness of those parity computation problems as well.

Besides parity computation and parity counting, there is a third natural type of parity problems where we take a problem and replace one of the operations (e.g. summation) with a parity. For example, the 3XOR problem is a variant of 3SUM where we are given a set of n binary vectors of size $O(\log n)$ and are asked if there is a triple whose bit-wise XOR is all zero. 3XOR is the subject of study of several papers [11, 12, 21] and it seems just as hard as 3SUM but a reduction in either direction has been elusive [27].

1.3 Preliminaries

In all graph problems we assume that the graphs have n nodes and $O(n^2)$ edges. In all the weighted problems we consider, we assume the weights are integers in $[-M, M]$ (and generally it is assumed that $M = poly(n)$).

Intuitively, a fine-grained reduction [49, 51] from problem A with current upper bound $O(n^a)$ to problem B with current upper bound $O(n^b)$ is a Turing-reduction proving that if B is solvable in time $O(n^{b-\varepsilon})$, for some $\varepsilon > 0$, then A is solvable in time $O(n^{a-\varepsilon'})$, for some $\varepsilon' > 0$. More formally, an (a, b)-fine-grained reduction from A to B is a (possibly randomized) algorithm solving A on instances of size n using t calls to an oracle for B on instances of sizes $n_1, \dots, n_t$, such that for all $\varepsilon > 0$: $\sum_{i=1}^{t} (n_i)^{b-\varepsilon} \leq n^{a-\varepsilon'}$ for some $\varepsilon' > 0$. In this paper, unless otherwise stated, we assume that the reduction is randomized. A $(3, 3)$-fine-grained reduction is called a subcubic-reduction and two problems are called subcubic-equivalent if there are subcubic-reductions in both ways. Similarly, two problems are subquadratic-equivalent if there are $(2, 2)$-fine-grained reductions between them in both ways.

2 APSP to Median Parity

In this section, we show a subcubic reduction from the Negative Weight Triangle problem (hence also from APSP [51]) on a directed graph G with integral edge weights in $[-M, M]$ to Median Parity. We first describe the reduction of [3] from Negative Weight Triangle to Median and then modify it to become a reduction to Median Parity.

2.1 Negative Weight Triangle to Median [3]

The instance G' to the Median problem (illustrated in Figure 1) is an undirected graph constructed as follows. First, for any two (not necessarily different) vertices u, v if there is no edge (u, v) in G then we add an edge (u, v) of weight $w(u, v) = 4M$ to G (this will not form a new negative triangle). Each vertex u of G has five copies in G' denoted $u_A, u_B, u_{B'}, u_C, u_{C'}$. Let H be a sufficiently large number (say $H = 100M$). For any two (not necessarily different) vertices u, v of G we add the following edges to G': (u_A, v_B) of weight $3H + w(u,v)$, $(u_A, v_{B'})$ of weight $3H - w(u,v)$, (u_A, v_C) of weight $6H - w(v,u)$[3], $(u_A, v_{C'})$ of weight $3H + w(v,u)$[3], (u_A, v_A) of weight H, and (u_B, v_C) of weight $3H + w(u,v)$.

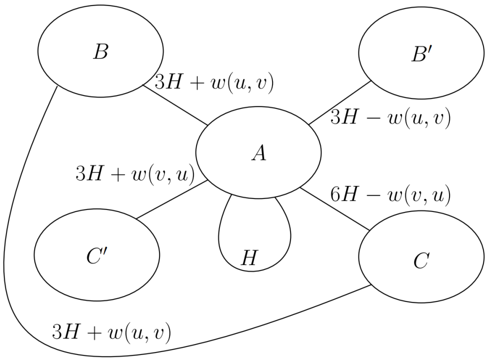

Figure 1 The graph G' in the reduction from Negative Weight Triangle to Median.

▶ **Lemma 5** ([3]). *G does not contain a negative triangle iff the median of G' is $(16n-1)H$.*

Proof. Consider first a vertex u_X with $X \neq A$. We claim that the sum of distances $\sum_{v \in V(G')} d_{G'}(u_X, v)$ is at least $(19n - 5)H$. To see this, first observe that the sum is minimized when $X = B$. This is because shortest paths from vertices in B' and C' go through A, and because every C-to-A distance is larger than any B-to-A distance by at least H. We therefore focus on $X = B$: The distance from u_B to u_B is zero and the distance from u_B to v_B (for $v \neq u$) is at least $5H$ (since H is large enough, $3H + w(u,t) + 3H + w(t,v) > 5H$), so the sum of distances from u_B to all vertices of B is $5H(n-1)$. Similarly, for every vertex v of G, the distances from u_B to $v_A, v_{B'}, v_C, v_{C'}$ are at least $2H, 5H, 2H, 5H$ respectively. Overall, the sum of distances from u_B is at least $(5n-5)H + 2nH + 5nH + 2nH + 5nH = (19n-5)H$.

Next consider a vertex u_A. Let $F(u,v) = \min\{0, \min_{t \in V(G)}\{w(v,u) + w(u,t) + w(t,v)\}\}$. Observe that $F(u,v) = 0$ if the edge (v,u) is not part of any negative triangle in G, and $F(u,v) < 0$ otherwise. We claim that the sum of distances $\sum_{v \in V(G')} d_{G'}(u_A, v)$ is exactly $(16n-1)H + \sum_{v \in V(G)} F(u,v)$. To see this, consider the distances from u_A. Distances to v_A, v_B, and $v_{B'}$ are H (for $v \neq u$), $3H + w(u,v)$, and $3H - w(u,v)$ respectively. Over all such vertices the sum of the distances is therefore $(n-1)H + 6nH = (7n-1)H$. The distance to $v_{C'}$ is $3H + w(v,u)$ and the distance to v_C is the minimum between $6H - w(v,u)$ (using a single edge) and $3H + w(u,t) + 3H + w(t,v)$ for some vertex t (using two edges, through some t_B). Summing those two distances together, we get $9H + w(v,u) + \min_{t \in V(G)}\{-w(v,u), w(u,t) + w(t,v)\} = 9H + F(u,v)$. Overall, we get that $\sum_{v \in V(G')} d_{G'}(u_A, v) = (16n-1)H + \sum_{v \in V(G)} F(u,v)$ as claimed. This implies that the median vertex must come from A and that the median value is $(16n-1)H$ iff every $F(u,v) = 0$ (i.e. G does not contain a negative triangle). ◀

2.2 Negative Weight Triangle to Median Parity

We now modify the above reduction so that it reduces to MEDIAN PARITY instead of MEDIAN. We assume n is odd (otherwise add an isolated vertex to G). Let *Med* be the value of the median of G'. We multiply all the edge weights of G' by $4n$ (notice that this multiplies the

[3] Notice the different order of the vertices.

median value Med by $4n$). We do this in order to make sure that small changes in edge weights would not change any shortest path, and also to make sure that subtracting n from distance sums would not change the median vertex.

We show how to find the median of G' using $O(\log n)$ executions of Median Parity: Given a set of vertices $T \subseteq A$ (initialized to be A), pick an arbitrary subset S of T of half of its size. Temporarily (i.e restore weights at the end of the iteration) subtract 1 from all the S-to-B and S-to-C edges and add 1 to all the S-to-B' edges. Now solve Median Parity on G'. If the median value is odd, set $T \leftarrow S$. If the median value is even, set $T \leftarrow T/S$. We continue recursively for $O(\log n)$ steps until T contains a single vertex. We then check if this vertex participates in a negative triangle in G.

For the correctness of the above procedure, inductively assume that T contains the median vertex of G'. Notice that the temporary changes to the edge weights do not change the identity of shortest paths in G', only their value. In particular, the sum of distances from every vertex $u_A \in S$ decreases exactly by n, and for any vertex $u_A \in A \backslash S$ the sum remains the same. To see this, consider first a vertex $u_A \in S$. The sum of its distances to any v_B and $v_{B'}$ remains the same (one is larger by 1 and one is smaller by 1) and its distance to v_C is decreased by 1 (recall that the shortest path is either the direct edge (u_A, v_C) or two edges $(u_A, t_B), (t_B, v_C)$). Therefore, the sum of distances from $u_A \in S$ to all vertices of G' decreases by exactly n. As for vertices in $u_A \in A \backslash S$, we do not change weights of edges in their shortest paths so their sum of distances is unchanged.

If the median is from S, then its sum of distances in G' was originally Med. Since we multiplied the edge weights by $4n$ and subtracted n from its sum, the median value is now $4n \cdot Med - n$. This value is odd and indeed we set $T \leftarrow S$. If on the other hand the median is not from S, then the sum of distances from any vertex of S was originally at least $Med + 1$, and is therefore now at least $4n \cdot (Med + 1) - n$. This value is strictly bigger than the value $4n \cdot Med$ of the median. The value $4n \cdot Med$ is even and indeed we set $T \leftarrow T/S$.

3 Negative Triangle Vertex Parity

In this section, we show that Negative Triangle Vertex Parity (finding if the number of vertices that belong to a negative triangle is odd or even) is subcubic equivalent to APSP under randomized reductions. We then use Negative Triangle Vertex Parity in order to establish a subcubic equivalence with the Parity versions of Wiener Index, Sum of Eccentricities, and Integer Betweenness Centrality.

3.1 APSP to Negative Triangle Vertex Parity

We now show a probabilistic (one side error) reduction from Negative Weight Triangle (NWT) to Negative Triangle Vertex Parity (NTVP). We assume without loss of generality that the NWT instance G is undirected (otherwise, we turn G into an undirected tripartite graph (by adding vertices v_1, v_2, v_3 for every v in $V(G)$ and edges $(u_1, v_2), (u_2, v_3), (u_3, v_1)$ for every (u, v) in $E(G)$) with the property that there is a negative triangle in G iff there is a negative triangle in the tripartite graph). The NTVP instance G' is also undirected and is created as follows: Choose $V_1 \subseteq V(G)$ uniformly, and let $\overline{V} = V(G) \backslash V_1$. For every $u_1 \in V_1$ we add a vertex u_2, and let the union of all u_2 vertices be V_2. For every edge (u_1, v_1) in $V_1 \times V_1$ we add the edge (u_2, v_2) and for every edge (u_1, v) in $V_1 \times \overline{V}$ we add the edge (u_2, v). Notice that the graph induced by $\overline{V} \cup V_2$ is G, and the same for $\overline{V} \cup V_1$.

Since there are no edges between V_1 and V_2, every triangle is either in $\overline{V} \cup V_1$ or in $\overline{V} \cup V_2$. Furthermore, for every vertex $u_1 \in V_1$, if u_1 belongs to a negative triangle in G then both u_1 and u_2 belong to negative triangles in G', thus contributing 2 (even) to the parity NTVP(G')

of the number of vertices that belong to a negative triangle in G'. Therefore, vertices in V_1 do not affect the parity NTVP(G'). In other words, NTVP(G') is the parity of vertices in $\overline{V}$ with a negative triangle. If G contains a negative triangle, then the probability of odd NTVP(G') is exactly $1/2$ (since each vertex with a negative triangle is chosen to be in $\overline{V}$ with probability $1/2$). If G does not contain a negative triangle, then the probability of even NTVP(G') is exactly 1. By repeating this process $O(\log n)$ times we can amplify the probability of success to $1 - 1/n^c$ for any constant c.

We remark that the above reduction can also be used to reduce Zero Weight Triangle to its vertex parity version.

3.2 Negative Triangle Vertex Parity to Wiener Index Parity (Directed)

We handle the directed case here and the undirected case in Section 3.3. Assume n is even by adding a vertex with no negative triangles, if needed. The reduction graph G' is constructed as in [3, 51] (see Figure 2): Each vertex u of G has five copies in G' denoted u_S, u_A, u_B, u_C, u_D. Let H be a sufficiently large *even* number (say $H = 100M$). For every $(X, Y) \in \{(A, B), (B, C), (C, D)\}$ and $u, v \in V(G)$, add the edge (u_X, v_Y) with weight $2H + 2w(u, v)$. For every $u \neq v \in V(G)$, add an edge (u_A, v_D) with weight $5H$. For every $u \in V(G)$, we add the edge (u_S, u_A) with weight $H + 1$ and the edge (u_S, u_D) with weight $7H$. Turn G' into a clique by replacing any missing edge with an edge of weight $16H$.

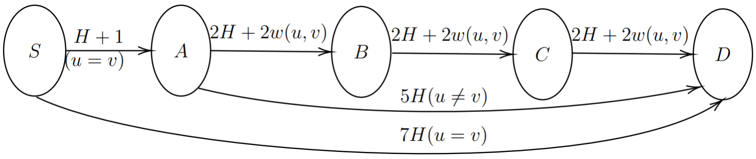

Figure 2 The graph G' in the reduction from Negative Triangle Vertex Parity to Wiener Index Parity. Edges of weight $16H$ are absent.

We now show that the Negative Triangle Vertex Parity of G (NTVP(G)) is equal to the Wiener Index Parity of G' (WIP(G')). Since H is an even number, the only edges in G' that have an odd length are the (u_S, u_A) edges of length $H + 1$. Therefore, the parity WIP(G') is determined by the S to $A \cup B \cup C \cup D$ distances.

First observe that the sum of distances from S to $A \cup B \cup C$ is even. This is because for any vertex u_S in S the following shortest paths consist of a single edge of weight $H + 1$: the u_S-to-v_A (for $v = u$) path, the u_S-to-v_B (for $v = u$ or $v \neq u$) paths, and the u_S-to-v_C (for $v = u$ or $v \neq u$) paths. Thus, the total number of odd edges in the sum of distances from S to $A \cup B \cup C$ is $n(2n + 1)$, which is even since n is even.

It remains to consider the distances from S to D. For $u \neq v$, $d_{G'}(u_S, v_D) = 6H + 1$, and the sum of such distances is $n(n - 1)(6H + 1)$ (even). We are left with the sum of distances $d_{G'}(u_S, u_D)$. If u belongs to a negative triangle in G and k is the minimal weight of such cycle then $d_{G'}(u_S, u_D) = 7H + 2k + 1$ (odd). If u does not belong to any negative triangle then $d_{G'}(u_S, u_D) = 7H$ (even). Therefore the sum of distances is odd iff there is an odd number of vertices belonging to a negative triangle.

3.3 Negative Triangle Vertex Parity to Wiener Index Parity (Undirected)

In undirected graphs, to avoid a trivial Wiener Index Parity of 0, the Wiener Index is defined as the sum of $d(u, v)$ over every unordered (rather than ordered) pair $\{u, v\}$.

We assume that every triangle has odd length by multiplying every edge-weight by 4 and adding 1 (this preserves the sign of negative and non-negative triangles). We construct a graph G' similarly to [3, 51] and to Section 3.2 but the approach differs in the analysis of correctness: Each vertex u of G has four copies in G' denoted u_A, u_B, u_C, u_D. Let $H = 100M$ (sufficiently large *even* number). For every $(X, Y) \in \{(A, B), (B, C), (C, D)\}$ and $u, v \in V(G)$, add the edge (u_X, v_Y) of weight $2H + w(u, v)$. For every $u \neq v \in V(G)$, add an edge (u_A, v_D) of weight $5H$. For every $u = v \in V(G)$, add an edge (u_A, u_D) of weight $6H$.

Let m be the number of edges in G and let W be the sum of edge weights in G. We claim that $\mathrm{WIP}(G') - W$ is odd iff $\mathrm{NTVP}(G)$ is odd: The sum of A-to-B distances is $W + 2H \cdot m$. This sum has the same parity as W, which we cancel out by subtracting W from $\mathrm{WIP}(G')$. Notice that the sum of B-to-C (A-to-C) distances and the sum of C-to-D (B-to-D) distances are equal thus by adding both sums the parity of $\mathrm{WIP}(G')$ does not change. Similarly, the sum of the X-to-X distances for every $X \in \{A, B, C, D\}$ is the same and $\mathrm{WIP}(G')$ is not changed. We are left with the A-to-D distances. The sum of u_A-to-v_D distances for $u \neq v$ is $5H \cdot n(n-1)$ (even). If u is not in a negative triangle, then $d(u_A, u_D) = 6H$ (even) by using the direct edge (u_A, u_D). If u is in a negative triangle, the u_A-to-u_D distance is $6H$ plus the weight of the minimum weight triangle of u (odd). Therefore $\mathrm{WIP}(G') - W$ is odd iff there is an odd number of vertices with a negative triangle.

3.4 Negative Triangle Vertex Parity to Sum of Eccentricities Parity

The reduction is obtained by tweaking the reduction of Section 3.3. We add to G' an additional vertex y. For every $u \in V(G)$, we add the edge (y, u_D) of weight $7H$ and the edges $(y, u_A), (y, u_B)$ and (y, u_C) each of weight $5H$.

Notice that these changes to G' do not affect the distances between vertices of $V(G')\backslash\{y\}$ since every path that goes through y has weight of at least $10H$. Recall that H is an even number. The *eccentricity* of a vertex u is defined as $\max_v d(u, v)$. The eccentricity of vertices in $B \cup C$ is $5H$ (even), since their distance to y is $5H$ and their distance to any other vertex is bounded by $4H + 2M$ (i.e. smaller than $5H$). The eccentricity of vertices in D is $7H$ (even), since their distance to y is $7H$ and their distance to any other vertex is bounded by $6H$ (maximized by a vertex in A). The eccentricity of y is $7H$ (even). Finally, the eccentricity of a vertex u_A in A is $d(u_A, u_D)$, since the u_A-to-u_D distance is at least $6H - 3M$ and any other distance is bounded by $5H$ (maximized by y and some v_D). This means that, as shown in Section 3.3, the parity of $\sum_u d(u_A, u_D)$ equals $\mathrm{NTVP}(G)$.

3.5 Negative Triangle Vertex Parity to Integer Betweenness Centrality Parity

The reduction is deterministic and uses a similar graph G' to the one used in the reduction of [3] from Negative Weight Triangle to Betweenness Centrality: Each vertex u of G has four copies in G' denoted u_A, u_B, u_C, u_D. Let $H = 100M$ (sufficiently large number). For every $(X, Y) \in \{(A, B), (B, C), (C, D)\}$ and $u, v \in V(G)$, add the edge (u_X, v_Y) with weight $2H + w(u, v)$. Add a single vertex x and for every vertex $v \in V(G)$, add the edges $(u_A, x), (x, v_D)$ with weight $3H$. Add two sets of vertices Z, O each of size $\lceil \log n \rceil$. Let $z_i \in Z, o_i \in O$ be the i'th vertex of the sets. If the i'th bit in u's binary representation is 0, add an edge (u_A, z_i) with weight $2H$ and an edge (o_i, u_D) with weight $3H$. Otherwise, add an edge (u_A, o_i) with weight $2H$ and an edge (z_i, u_D) with weight $3H$. This dependency on the binary representation assures that every u_A and v_D are connected with a path (of weight $5H$) through O or through Z except for the case where $u = v$. See Figure 3.

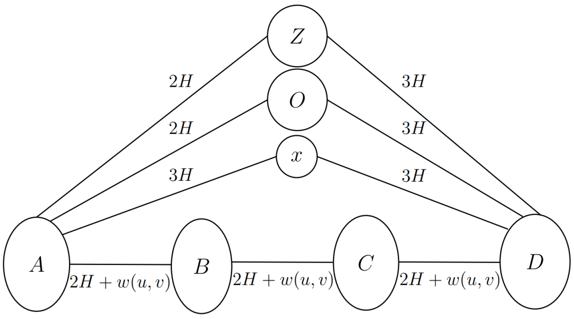

Figure 3 A representation of G' in the reduction from Negative Weight Triangle to Integer Betweenness Centrality Parity.

Consider the Integer Betweenness Centrality Parity of the vertex x in G'. Assume n is even (otherwise add a vertex to G with no negative triangle). Notice that the only pairs with a shortest path through x can be of the form (u_A, u_D) (pairs (u_A, v_D) with $v \neq u$ have shorter paths of weight $5H$ through Z or O). Furthermore, there is a shortest u_A-to-u_D path through x iff u is not in a negative triangle. This is because the distance between u_A and u_D is the minimum between $6H$ (going through x) and $6H + w(u,v) + w(v,t) + w(t,u)$ for some $v, t \in V(G)$. Therefore, the number of pairs (u_A, u_D) with shortest paths through x is n minus the number of vertices in a negative triangle, hence the parity of the number of paths going through x in G' is the same as the parity of the number of vertices in G with a negative triangle.

3.6 APSP to Integer Betweenness Centrality Parity

We provide a probabilistic (one sided error) reduction from Negative Weight Triangle that does not go through Negative Triangle Vertex Parity. We continue from where we stopped in Section 3.5. Recall that the number of pairs that have a shortest path through x is n minus the number of vertices in a negative triangle. If there is an odd number of pairs then we return that a negative triangle exists. Otherwise, there is an even number of vertices with a negative triangle. We then choose a set $S \subseteq V(G)$ uniformly, and limit A, D to the vertices in S (B, C remain the same). If the number of paths going through x is odd we report that there is a negative triangle, otherwise we report that there is none. If a negative triangle exists, S has an odd number of vertices with a negative triangle with probability $1/2$, and we detect an odd number of pairs. Otherwise, S always has 0 (even) vertices with a negative triangle, and we succeed with probability 1. We can repeat the process $O(\log n)$ times and amplify the probability of success to $1 - 1/n^c$ for any constant c.

4 APSP to Min-Plus Matrix Multiplication Parity

4.1 Min-Plus Multiplication to Min-Plus Multiplication Parity

Given two $n \times n$ matrices A and B we wish to compute $C = A \otimes B$ where $C[i,j] = \min_k\{A[i,k] + B[k,j]\}$. First assume that for every i, j the value $C[i,j]$ is obtained by a unique index k. Let K be the $n \times n$ matrix such that $K[i,j]$ is the unique index k of $C[i,j]$. We show how to compute K by using Min-Plus Matrix Multiplication Parity.

Define $\hat{A} = 2A$, and for any $t \in [\log n]$ define k_t as the t'th bit of k and $\hat{B}_t$ to be the matrix such that $\hat{B}_t[k,j] = 2B[k,j] + k_t$. We compute the parity of $\hat{C}_t = \hat{A} \otimes \hat{B}_t$ for every $t \in [\log n]$. We claim that the parity of $\hat{C}_t[i,j]$ is the t'th bit of $K[i,j]$. This is because

$\hat{C}_t[i,j] = \min_k\{2A[i,k] + 2B[k,j] + k_t\}$. The parity of this value is 0 if the unique index k that minimizes $A[i,k] + B[k,j]$ has $k_t = 0$ and is 1 otherwise. Therefore, from this parity we can recover the t'th bit of $K[i,j]$.

To remove the assumption on the uniqueness of k, we define matrices A' and B' as $A'[i,k] = (n+1) \cdot A[i,k] + k$ and $B'[k,j] = (n+1) \cdot B[k,j]$. Observe that A' and B' have the uniqueness of k property. This is because if $A'[i,k_1] + B'[k_1,j] = A'[i,k_2] + B'[k_2,j]$ for some k_1, k_2 then $(n+1) \cdot (A[i,k_1] + B[k_1,j]) + k_1 = (n+1) \cdot (A[i,k_2] + B[k_2,j]) + k_2$ and, since k_1 and k_2 are smaller than $n+1$, it follows that $k_1 = k_2$. Furthermore, in order to compute $A \otimes B$ it suffices to compute $C' = A' \otimes B'$. Because if $A'[i,k_1] + B'[k_1,j] \leq A'[i,k_2] + B'[k_2,j]$ then (since k_1 and k_2 are smaller than $n+1$) $A[i,k_1] + B[k_1,j] \leq A[i,k_2] + B[k_2,j]$.

As a corollary, we get that APSP is subcubic equivalent to APSP Parity (i.e. the problem of deciding the parity of every pairwise distance in the graph): Let M be a bound on the absolute values in A and B. Create a graph consisting of vertices a_i, b_i, c_i for every $i \in [n]$ and the edges $(a_i, b_j), (b_i, c_j)$ with weights $A[i,j] + 3M$ and $B[i,j] + 3M$ respectively for every i, j. The distance $d(a_i, c_j) = 6M + \min_k\{A[i,k] + B[k,j]\}$ and therefore has the same parity as $(A \otimes B)[i,j]$. Notice that the reduction can be modified (with a folklore trick) to show that even computing $A \otimes A$ Parity is hard. Let D be the $n \times n$ matrix with every element equals to $3M$. Let E be the $2n \times 2n$ matrix $\begin{bmatrix} A & B \\ D & D \end{bmatrix}$. Then $E \otimes E$ equals $\begin{bmatrix} X & Y \\ Z & W \end{bmatrix}$ where $Y = A \otimes B$ since $Y[i,j] = \min\{(A \otimes B)[i,j], (B \otimes D)[i,j]\} = (A \otimes B)[i,j]$.

4.2 Min-Plus Convolution to Min-Plus Convolution Parity

Given vectors A and B each of length n, we wish to compute their convolution C where $C[i] = \min_{i=j+k}\{A[j] + B[k]\}$. The approach is the same as in Section 4.1. We assume each value $C[i]$ is obtained by a unique index k, otherwise we multiply A and B by $n+1$ and add to each $B[k]$ the value k (as in Section 4.1). Let K be the vector such that $K[i]$ is the unique index k of $C[i]$. Define $\hat{A} = 2A$, and for any $t \in [\log n]$ define k_t is the t'th bit of k and $\hat{B}_t$ to be the vector such that $\hat{B}_t[k] = 2B[k] + k_t$. Let $\hat{C}_t[i]$ be the convolution of $\hat{A}$ and $\hat{B}_t$. Then the t'th bit of $K[i]$ is the same as the parity of $\hat{C}_t[i]$. This is because $\hat{C}_t[i] = \min_{i=j+k}\{2A[j] + 2B[k] + k_t\}$.

4.3 Maximum Consecutive Subsums to Maximum Consecutive Subsums Parity

Given a vector X of length n, the maximum consecutive subsums problem asks to compute $\max_i \sum_{j=1}^{k} X[i+j]$ for every $k \in [n]$. To achieve this, we first compute (in linear time) the vector A where $A[k] = \sum_{j=1}^{k} X[j]$. The problem then reduces to computing Diff(A) where Diff$(A)[k] = \max_i\{A[k+i] - A[i]\}$. In fact, since $X[k] = A[k] - A[k-1]$, there is also a reduction in the opposite direction and so the two problems are equivalent (and their parity versions are equivalent). In this section, we show that given the parity of Diff(A) (i.e. the parity of every element in Diff(A)) we can compute Diff(A) itself.

Given a vector A, we wish to compute Diff(A). We assume that for every k, the value Diff$(A)[k] = \max_i\{A[k+i] - A[i]\}$ is obtained by a unique index i. Otherwise, we multiply every $A[k]$ by (n^2+1) and add k^2 (similarly to Section 4.1). Let I be the vector of such unique indices, and let J be the vector where $J[k] = I[k] + k$. By definition, Diff$(A)[k] = A[J[k]] - A[I[k]]$. We define A_t to be the vector such that $A_t[k] = 4 \cdot A[k] + k_t$ (where k_t is the t'th bit of k). Notice that $A_t[j] - A_t[i] = 4 \cdot (A[j] - A[i]) + (j_t - i_t)$ where $(j_t - i_t) \in \{-1, 0, 1\}$. Thus, for every k, Diff$(A)[k]$ is maximized when $j = J[k]$ and $i = I[k]$

(regardless of the values of j_t and i_t). This is because for every $i \neq I[k]$ and $j = k + i$ it holds that $4\cdot(A[j]-A[i])+(j_t-i_t) \leq 4\cdot(A[J[k]]-A[I[k]]-1)+1 < 4\cdot(A[J[k]]-A[I[k]])+(J[k]_t-I[k]_t)$. Observe that that the parity of $A_t[j] - A_t[i]$ is $j_t \oplus i_t$, where $\oplus$ is the bitwise XOR operation.

For every $t \in [\log n]$ we compute the parity of $\mathsf{Diff}(A_t)$. The computed parity of $\mathsf{Diff}(A_t)[k]$ is $J[k]_t \oplus I[k]_t$. Given $J[k]_1 \oplus I[k]_1, \ldots, J[k]_{\log n} \oplus I[k]_{\log n}$, we want to compute $J[k]$ and $I[k]$. Recall that $J[k] = k + I[k]$. Let $c_1, \ldots, c_{\log n}$ be the carry bits in the binary addition of $I[k]$ and k. We know that $I[k]_t \oplus k_t \oplus c_t = J[k]_t$ so by substituting $J[k]_t \oplus I[k]_t$ we compute every $c_t = J[k]_t \oplus I[k]_t \oplus k_t$. Given c_t, c_{t+1}, k_t, and $J[k]_t \oplus I[k]_t$ we wish to compute $J[k]_t$ and $I[k]_t$. However, this can only be done when $J[k]_t \oplus I[k]_t = 1$. In this case $I[k]_t = \neg J[k]_t = c_{t+1}$. This is because $k_t \oplus c_t = J[k]_t \oplus I[k]_t = 1$ so $k_t + c_t = 1$ and therefore $c_{t+1} = 1$ iff $I[k]_t + k_t + c_t \geq 2$ iff $I[k]_t = 1$. We are left with the bits where $J[k]_t = I[k]_t$. Let $A_{t,p}$ be the vector such that $A_{t,p}[k] = 4 \cdot A[k] + (k_t \to k_p)$ (compared to A_t, we replace k_t with k_t implies k_p). For every $(t,p) \in [\log n]^2$ we compute the parity of $\mathsf{Diff}(A_{t,p})$. The parity of $\mathsf{Diff}(A_{t,p})[k]$ is $(J[k]_t \to J[k]_p) \oplus (I[k]_t \to I[k]_p)$ and is denoted as $b_{t,p}$. Given that $J[k]_t$ and $I[k]_t$ have not been computed yet, we know that $J[k]_t = I[k]_t$, hence for every p it holds that $b_{t,p} = (I[k]_t \to J[k]_p) \oplus (I[k]_t \to I[k]_p)$. Notice that $J[k] > I[k]$ therefore there must be an index p' where $I[k]_{p'} \neq J[k]_{p'}$ (which we previously found) thus $b_{t,p'} = (I[k]_t \to \neg I[k]_{p'}) \oplus (I[k]_t \to I[k]_{p'})$. Observe that $I[k]_t = 0$ iff $b_{t,p'} = 0$. Overall, we find $I[k]$ for every k using $O(\log^2 n)$ Diff parity computations and $\tilde{O}(n)$ reduction time.

5 Zero Weight Triangle Counting to Negative Triangle Counting

In this section we show a simple but surprising reduction from counting zero weight triangles to counting negative triangles. We show a deterministic reduction from Zero Weight Triangle to Negative Triangle Counting and a randomized reduction from Zero Weight Triangle to Negative Triangle Parity.

5.1 Zero Weight Triangle Counting (Parity) to Negative Triangle Counting (Parity)

We want to count the number of triangles with weight zero in G. Let Δ be the number of triangles in G. We can compute Δ in matrix-multiplication $O(n^\omega)$ time[4]. Let $\Delta^0, \Delta^+, \Delta^-$ be the number of zero, positive, and negative weight triangles in G' respectively. Given a subcubic algorithm for Negative Triangle Counting, we can compute Δ^-. By negating weights in G we can compute Δ^+ as well. We then compute $\Delta^0 = \Delta - \Delta^+ - \Delta^-$. This simple reduction also reduces Zero Weight Triangle Parity to Negative Triangle Parity.

5.2 Zero Weight Triangle to Zero Weight Triangle Parity

Given a graph G, we want to find whether there is a zero weight triangle. We create a graph G' as follows: For every vertex $u \in V(G)$, we create three copies u_A, u_B, u_C in G', and for every edge $(u,v) \in E(G)$ we add the edges (u_A, v_B),(u_B, v_C), (u_C, v_A) to G' (with the same weight as (u,v)). Notice that there is a zero weight triangle in G iff there is a zero weight triangle in G'. We now create a graph G'' by removing from G' each edge (u_B, v_C) with probability $\frac{1}{2}$, and removing from G' each vertex u_A with probability $\frac{1}{2}$. We report that a zero weight triangle exists in G iff there is an odd number of zero weight triangles in G''. We now show that this reduction works with probability at least $\frac{1}{4}$.

[4] We can also compute Δ with Negative Triangle Counting by changing every weight in G to -1.

If there is no zero weight triangle in G', we succeed with probability 1. If there is a zero weight triangle in G', then let u_A be a vertex of G' that participates in some zero weight triangle. Since we removed each edge (v_B, t_C) with probability $\frac{1}{2}$ then, with probability $\frac{1}{2}$, the vertex u_A participates in an odd number of zero weight triangles in G''. Let $\Delta^0_{v_A}$ be the number of zero weight triangles in G'' that v_A participates in. The total number of zero weight triangles in G'' is $\sum_{v\in V(G)} \Delta^0_{v_A} = \sum_{v\in V(G)\setminus\{u\}} \Delta^0_{v_A} + \Delta^0_{u_A}$. If $\Delta^0_{u_A}$ is odd then, with probability $\frac{1}{2}$, our decision whether to remove u_A leads to an odd number of zero weight triangles in G''. Overall, the probability of success is therefore at least $\frac{1}{4}$.

6 Min-Plus Convolution to Knapsack Parity

In the KNAPSACK problem, given a set of n items (w_i, v_i) and a target weight t, we wish to pick a multiset of items I that maximizes $\sum_{i\in I} v_i$ subject to $\sum_{i\in I} w_i \leq t$. When I is required to be a set (and not a multiset) the problem is called 0/1-KNAPSACK. In the INDEXED KNAPSACK problem, we have $w_i = i$ and $t = n$. Finally, the COIN CHANGE problem [30, 33] is the same as INDEXED KNAPSACK but with the additional restriction $\sum_{i\in I} i = n$.

The KNAPSACK and the 0/1-KNAPSACK problems are equivalent to Min-plus Convolution under randomized reductions [17]. The INDEXED KNAPSACK and the COIN CHANGE problem are equivalent to Min-plus Convolution under deterministic reductions [30]. In this section, we show that the parity versions of all the above problems are equivalent to Min-plus Convolution.

6.1 Super-Additivity Testing to Knapsack [17]

Given a vector $A[0], \ldots, A[n-1]$, the SUPER-ADDITIVITY TESTING problem asks whether $A[i] + A[j] \leq A[i+j]$ for every i, j. The problem is subquadratic equivalent to Min-plus Convolution under deterministic reductions [17]. We now give a brief description of the reduction in [17] from SUPER-ADDITIVITY TESTING to KNAPSACK.

First, it is shown in [17] that we can assume without loss of generality that $0 = A[0] < A[1] < \cdots < A[n-1] = M$. Let $D = Mn + 1$, the instance of KNAPSACK consists of two types of items: Type-A items are $(i, A[i])$ and Type-B items are $(2n-1-i, D-A[i])$. It remains to show that, when setting $t = 2n-1$, the optimal sum of values $\sum_{i\in I} v_i$ equals D iff A is super-additive. Since $D > \sum_i A[i]$, the optimal solution must take at least one Type-B item, and it cannot take more than one because the weight would exceeds t. If A is not super-additive, then for some i, j it holds that $A[i] + A[j] > A[i+j]$ and therefore the three items $\{(i, A[i]), (j, A[j]), (2n-1-i-j, D-A[i+j])\}$ constitute a valid solution whose value is larger than D. If A is super-additive, then every two Type-A items $(i, A[i]), (j, A[j])$ can be replaced by $(i+j, A[i+j])$ without changing the total weight. Thus, for any i, the solution $\{(i, A[i]), (2n-1-i, D-A[i])\}$ is optimal and its value is exactly D.

6.2 Super-Additivity Testing to Knapsack Parity

We now modify the above the reduction to obtain a reduction to KNAPSACK PARITY. We first remove the item $(0, A[0])$ (since $A[0] = 0$ it does not contribute any value). We then replace every Type-A item $(i, A[i])$ by $(i, 2A[i])$, every Type-B item $(2n-1-i, D-A[i])$ (with $i \neq 1$) by $(2n-1-i, 2(D-A[i]))$, and the Type-B item $(2n-1-1, D-A[1])$ by $(2n-1-1, 2(D-A[1])+1)$. We show that A is super-additive iff the value of the optimal solution is odd.

Once again, every optimal solution must consist of exactly one Type-B item since if there are no Type-B items then the value does not exceed $2D$ as $2D > \sum_i 2A[i]$, and with more than one Type-B items the weight exceeds $t = 2n-1$. If A is not super-additive, then there are i, j such that $k = i + j \geq 2$ and $A[i] + A[j] > A[k]$ therefore the items $\{(i, 2A[i]), (j, 2A[j]), (2n - 1 - i - j, 2D - 2A[k])\}$ constitute a valid solution whose value is larger than $2D + 1$. Notice that $k \geq 2$ since if $k = 0$ then the total value is $2D$ (thus not optimal), and if $k = 1$ then we include the item $(2n - 1 - 1, 2(D - A[1]) + 1)$ and since $t = 2n - 1$ we can only add the item $(1, 2A[1])$ leading to a non-optimal solution with value $2D + 1$. Therefore, the optimal solution does not use the item $(2n - 1 - 1, 2(D - A[1]) + 1)$ and hence it has an even value. On the other hand, if A is super-additive, then the solution $\{(1, 2A[1]), (2n - 1 - 1, 2(D - A[1]) + 1)\}$ is optimal and has value exactly $2D + 1$ (odd). This is because among the solutions that include a Type-B item $(2n - 1 - i - j, 2D - 2A[k])$ with $k \neq 1$, once again by super-additivity, $\{(k, 2A[k]), (2n - 1 - k, 2D - 2A[k])\}$ has the maximal value of $2D$ (i.e. smaller than $2D + 1$).

6.3 Super-Additivity Testing to 0/1-knapsack Parity

We now show how to modify the above reductions to be reductions to 0/1-KNAPSACK and 0/1-KNAPSACK PARITY. In the above reductions, when A is super-additive the optimal solution does not use any item more than once, and its total value V is either D or $2D + 1$. When A is not super-additive, there is a solution with a higher value than V. There is only one case where this solution may use the same item more than once. This happens when A is not super-additive in the following way: $A[i] + A[j] \leq A[i + j]$ for every $i \neq j$ but $A[i] + A[j] > A[i + j]$ for some $i = j$. Therefore, in $O(n)$ time we can check for every i whether $2A[i] \leq A[2i]$ and only if the answer is yes we apply the reduction.

Note that the above reductions also apply to the INDEXED KNAPSACK PARITY problem. This is because the target weight t equals the total number of items $2n-1$, and each item has a unique weight in $[2n - 1]$. The reductions also apply to COIN CHANGE PARITY: When A is super-additive, the optimal solution for COIN CHANGE (which is also an optimal solution for KNAPSACK) has weight $2n - 1$ (equal to the number of items) and an odd value $(2D + 1)$. When A is not super-additive, the optimal solution for COIN CHANGE (which is possibly not an optimal solution for KNAPSACK) has weight $2n - 1$ (equal to the number of items) and an even value (larger than $2D + 1$).

7 APSP to Sum of Eccentricities

In this section, we show a subcubic reduction from RADIUS (hence also from APSP) on a graph G to SUM OF ECCENTRICITIES on a graph G'. Let R be the radius of G. In order to compute R it suffices to find whether $R \geq k$ for any given $k \in [Mn]$ (since then we can binary search for R). The constructed graph G' is similar to the one in the reduction of [3] from DIAMETER to POSITIVE BETWEENESS CENTRALITY: We create G' by multiplying the edge weights of G by 2 and then adding a vertex x and the edges (x, u) and (u, x) each of weight k for every $u \in V(G)$.

▶ **Lemma 6.** *$R \geq k$ iff the sum of eccentricities of G' is $\sum_u \max_v d_{G'}(u, v) = 2kn + k$.*

Proof. This is the same as claiming that $R \geq k$ iff $\sum_{u \neq x} \max_v d_{G'}(u, v) = 2kn$. If $R \geq k$, then every vertex $u \neq x$ can use x to get to its furthest vertex with a path of length $2k \leq 2R$. Observe that any other path would be of length at least $2R$ (because we have multiplied all edge weights by 2). Therefore, $\sum_{u \neq x} \max_v d_{G'}(u, v) = 2kn$. If on the other hand $R < k$, then the distance in G' from the radius vertex of G to any other vertex is at most $\max\{2R, k\} < 2k$ so this vertex adds less than $2k$ to the sum. All the other vertices add at most $2k$ to the sum, and thus $\sum_{u \neq x} \max_v d_{G'}(u, v) \neq 2kn$. ◀

8 Radius to Radius Parity and Diameter to Diameter Parity

In this section, we show that computing the Radius R (resp. Diameter D) of a graph G subcubicaly reduces to computing the parity of R (resp. D). As usual, to compute R, D it suffices to find whether $R, D \geq k'$ for $k' \in [Mn]$. Let $k' = (k+1)/2$ for some odd $k \geq 1$. We create a reduction graph G' similarly to [3] and to Section 7: We multiply the edge weights of G by 2 and add a vertex x with (v,x),(x,v) edges of weight k for every $v \in V(G)$.

Consider first the radius of G'. If the radius vertex of G' is x then its value is k. Otherwise, its value is either $\max\{2R, k\}$ (by using the edge to x and the same path as in G to all other vertices) or $2k$ (by using a path through x). Therefore, the radius of G' has value $\min\{k, 2R\}$. If $2R \geq k+1$ (i.e $R \geq k'$), the radius is k (odd). Otherwise $2R < k+1$ (i.e $R < k'$) and the radius is $2R$ (even). Next consider the diameter of G'. If x is an endpoint of the diameter of G' then the diameter value is k. Otherwise, the diameter value is either $2D$ (by taking the same path as in G) or $2k$ (by using a path through x). Therefore the diameter of G' has value $\max\{k, \min\{2D, 2k\}\}$. If $2D \leq k$ (i.e. $D < k'$), then the diameter is k (odd). Otherwise $2D \geq k+1$ (i.e. $D \geq k'$), and the diameter is either $2D$ or $2k$ (even in both cases).

Abstract

We study the problem of maximizing a *non-monotone* submodular function subject to a cardinality constraint in the streaming model. Our main contributions are two single-pass (semi-)streaming algorithms that use $\tilde{O}(k) \cdot \text{poly}(1/\varepsilon)$ memory, where k is the size constraint. At the end of the stream, both our algorithms post-process their data structures using *any offline algorithm* for submodular maximization, and obtain a solution whose approximation guarantee is $\frac{\alpha}{1+\alpha} - \varepsilon$, where α is the approximation of the offline algorithm. If we use an exact (exponential time) post-processing algorithm, this leads to $\frac{1}{2} - \varepsilon$ approximation (which is nearly optimal). If we post-process with the algorithm of [5], that achieves the state-of-the-art offline approximation guarantee of $\alpha = 0.385$, we obtain 0.2779-approximation in polynomial time, improving over the previously best polynomial-time approximation of 0.1715 due to [17]. One of our algorithms is combinatorial and enjoys fast update and overall running times. Our other algorithm is based on the multilinear extension, enjoys an improved space complexity, and can be made deterministic in some settings of interest.

1 Introduction

In this paper, we study the problem of maximizing a *non-monotone* submodular function subject to a cardinality (size) constraint in the streaming model. This problem captures problems of interest in a wide-range of domains, such as machine learning, data mining, combinatorial optimization, algorithmic game theory, social networks, and many others. A representative application is data summarization, where the goal is to select a small subset of the data that captures the salient features of the overall dataset [2]. One can model these problems as submodular maximization with a cardinality constraint: the submodular objective captures how informative the summary is, as well as other considerations such as how diverse the summary is, and the cardinality constraint ensures that the summary is small. Obtaining such a summary is very beneficial when working with massive data sets, that may not even fit into memory, since it makes it possible to analyze the data using algorithms that would be prohibitive to run on the entire dataset.

There have been two main approaches to deal with the large size of modern data sets: the *distributed* computation approach partitions the data across many machines and uses local computation on the machines and communication across the machines in order to perform the analysis, and the *streaming* computation approach processes the data in a stream using only a small amount of memory and (ideally) only a single pass over the data. Classical algorithms for submodular maximization, such as the Greedy algorithm, are not suitable in these settings since they are centralized and require many passes over the data. Motivated by the applications as well as theoretical considerations, there has been a significant interest in studying submodular maximization problems both in the distributed and the streaming setting, leading to many new results and insights [22, 29, 2, 9, 11, 26, 4, 28, 3, 14, 27, 17, 31, 1].

Despite this significant progress, several fundamental questions remain open both in the streaming and distributed setting. In the streaming setting, which is the main focus of this paper, submodular maximization is fairly well understood when the objective function is additionally *monotone* – i.e., we have $f(A) \leq f(B)$ whenever $A \subseteq B$. For example, the Greedy approach, which obtains an optimal $(1 - 1/e)$-approximation in the centralized setting when the function is monotone [30], can be adapted to the streaming model [22, 2]. This yields the single-threshold Greedy algorithm: make a single pass over the data and select an item if its marginal gain exceeds a suitably chosen threshold. If the threshold is chosen to be $\frac{1}{2}\frac{f(\mathrm{OPT})}{k}$, where $f(\mathrm{OPT})$ is the value of the optimal solution and k is the cardinality constraint, then the single-threshold Greedy algorithm is guaranteed to achieve $\frac{1}{2}$-approximation. Although the value of the optimal solution is unknown, it can be estimated based on the largest singleton value even in the streaming setting [2]. Remarkably, this approximation guarantee is optimal in the streaming model even if we allow unbounded computational power: Feldman et al. [19] showed that any algorithm for monotone submodular maximization that achieves an approximation better than $\frac{1}{2}$ requires $\Omega\left(\frac{n}{k^3}\right)$ memory, where n is the length of the stream. Additionally, the single-threshold Greedy algorithm enjoys a fast update time of $O(\varepsilon^{-1} \log k)$ marginal value computations per item, and it uses $O(\varepsilon^{-1} k \log k)$ space.

In contrast, the general problem with a *non-monotone* objective has proved to be considerably more challenging. Even in the centralized setting, the Greedy algorithm fails to achieve any approximation guarantee when the objective is non-monotone. Thus, several approaches have been developed for handling non-monotone objectives in this setting, including local search [15, 24, 23], continuous optimization [18, 13, 5] and sampling [6, 16]. The currently best approximation guarantee is 0.385 [5], and the strongest inapproximability is 0.491 [20], and it remains a long-standing open problem to settle the approximability of submodular maximization subject to a cardinality constraint.

Adapting the above techniques to the streaming setting is challenging, and the approximation guarantees are weaker. The main approach for non-monotone maximization in the streaming setting has been to extend the local search algorithm of Chakrabarti and Kale [9] from monotone to non-monotone objectives. This approach was employed in a sequence of works [11, 17, 27], leading to the currently best approximation of $\frac{1}{3+2\sqrt{2}} \approx 0.1715$.[1] This naturally leads to the following questions.

- *What is the optimal approximation ratio achievable for submodular maximization in the streaming model? Is it possible to achieve $\frac{1}{2} - \varepsilon$ approximation using an algorithm that uses only* $\mathrm{poly}(k, 1/\varepsilon)$ *space?*
- *Is there a good streaming algorithm for non-monotone functions based on the single-threshold Greedy algorithm that works so well for monotone functions?*
- *Can we exploit existing heuristics for the offline problem in the streaming setting?*

Our contributions. In this work, we give an affirmative answer to all of the above questions. Specifically, we give streaming algorithms[2] that perform a single pass over the stream and output a set of size $k \cdot \mathrm{poly}(1/\varepsilon)$ that can be post-processed using *any offline algorithm* for submodular maximization. The post-processing is itself quite straightforward: we simply run the offline algorithm on the output set to obtain a solution of size at most k. We show that, if the offline algorithm achieves α-approximation, then we obtain $\left(\frac{\alpha}{1+\alpha} - \varepsilon\right)$-approximation.

Our main result implies that if we post-process using an exact (exponential time) algorithm, we obtain $(\frac{1}{2} - \varepsilon)$-approximation. This matches the inapproximability result proven by [19] for the special case of a monotone function. Furthermore, we show that in the non-monotone case any streaming algorithm guaranteeing $(\frac{1}{2} + \varepsilon)$-approximation for some positive constant ε must use in fact $\Omega(n)$ space.[3] Thus, we essentially settle the approximability of the problem if exponential-time computation is allowed.

The best (polynomial-time) approximation guarantee that is currently known in the offline setting is $\alpha = 0.385$ [5]. If we post-process using this algorithm, we obtain 0.2779-approximation in polynomial time, improving over the previously best polynomial-time approximation of 0.1715 due to [17]. The offline algorithm of [5] is based on the multilinear extension, and thus is quite slow. One can obtain a more efficient overall algorithm by using the combinatorial random Greedy algorithm of [6] that achieves $\frac{1}{e}$-approximation. Furthermore, any existing heuristic for the offline problem can be used for post-processing, exploiting their effectiveness beyond the worst case.

Our techniques. The two streaming algorithms that we present enjoy the same approximation guarantee, but differ in other properties. Our first algorithm (StreamProcess) is a combinatorial algorithm that achieves very fast update time and overall running time. StreamProcess takes inspiration both from the single-threshold Greedy algorithm for *monotone* maximization and distributed algorithms that randomly partition the data [26, 4, 3]: it randomly partitions the elements into $1/\varepsilon$ parts as they arrive in the stream and runs

[1] Chekuri et al. [11] claimed an improved approximation ratio of $\frac{1}{2+e} - \varepsilon$ for a cardinality constraint, but an error was later found in the proof of this improved ratio [10]. We defer the details to the full version.

[2] Formally, our algorithms are semi-streaming algorithms, i.e., their space complexity is nearly linear in k. Since this is unavoidable for algorithms designed to output an approximate solution (as opposed to just estimating the value of the optimal solution), we ignore the difference between streaming and semi-streaming algorithms in this paper and use the two terms interchangably.

[3] This result is a simple adaptation of a result due to Buchbinder et al. [7]. For completeness, we include the proof in the full version of the paper.

the single-threshold Greedy algorithm on each part; this process is repeated independently and in parallel $O(\ln(1/\varepsilon)/\varepsilon)$ times. Since the main engine behind our algorithm is the very efficient and practical single-threshold Greedy algorithm, our StreamProcess algorithm inherits its very efficient update time and practical potential. Compared to the optimal streaming algorithm for monotone maximization discussed above, our algorithm is quite similar: the monotone algorithm runs $O(\log k/\varepsilon)$ instances of single-threshold Greedy, each of which processes all n items; StreamProcess runs $O(\ln(1/\varepsilon)/\varepsilon^2) \cdot O(\log k/\varepsilon)$ instances of single-threshold Greedy, each of which processes $O(\varepsilon \cdot n)$ items with high probability.

Our second algorithm (StreamProcessExtension) is based on the multilinear extension of the submodular function. This algorithm is similar to the single-threshold Greedy algorithm, but adds fractions of elements rather than whole elements to the solution it maintains. The extension based approach of this algorithm allows us to save on the space usage. Furthermore, when the multilinear extension can be evaluated deterministically, this approach leads to a deterministic algorithm. However, the time complexity of this approach depends on the complexity of evaluating the multilinear extension, which is quite high if we are only given value oracle access to f. Thus, given such restricted access, this approach leads to higher update and overall running time.

We note that combining the single-threshold Greedy with randomization is difficult because it requires delicate care of the event that the single-threshold Greedy algorithm fills up the budget. In particular, this was the source of the subtle error mentioned above in one of the results of [11]. Our approach here for handling this issue is simple in retrospect. In our combinatorial algorithm, we consider two cases depending on the probability that the budget is filled up in a run (this is a good event since the resulting solution has good value). If this probability is sufficiently large (at least ε), we repeat the basic algorithm $O(\ln(1/\varepsilon)/\varepsilon)$ times to boost the probability of this good event to $1 - \varepsilon$. Otherwise, the probability that the budget is not filled up in a run is at least $1 - \varepsilon$, and conditioning on this event changes the probabilities by only a $1 - \varepsilon$ factor.

In our extension based algorithm, the decisions of the algorithm are based on the values taken by derivatives of the extension, which are values of expectations over appropriately chosen distributions. On the one hand, this allows our algorithm to include a random component, which is a component that appears (at least implicitly) in all of the known algorithms for non-monotone submodular maximization. On the other hand, since expectations have deterministic values, the algorithm we get is deterministic enough that it suffices for us to consider at each time only one of two possible cases: the case in which the budget fills up, and the case in which it does not.

Paper structure. In Section 2, defines the notation that we use and presents some known lemmata. Section 3 presents and analyzes our combinatorial algorithm (StreamProcess). Finally, in Section 4, we present and analyze our extension based algorithm.

2 Preliminaries

Basic notation. Let V denote a finite ground set of size $n := |V|$. We occasionally assume without loss of generality that $V = \{1, 2, \dots, n\}$, and use, e.g., $x = (x_1, x_2, \dots, x_n)$ to denote a vector in $\mathbb{R}^V$. For two vectors $x, y \in \mathbb{R}^V$, we let $x \vee y$ and $x \wedge y$ be the vectors such that $(x \vee y)_e = \max\{x_e, y_e\}$ and $(x \wedge y)_e = \min\{x_e, y_e\}$ for all $e \in V$. For a set $S \subseteq V$, we let $\mathbf{1}_S$ denote the indicator vector of S, i.e., the vector that has 1 in every coordinate $e \in S$ and 0 in every coordinate $e \in V \setminus S$. Given an element $e \in V$, we use $\mathbf{1}_e$ as a shorthand for $\mathbf{1}_{\{e\}}$. Furthermore, if S is a random subset of V, we use $\mathbb{E}[\mathbf{1}_S]$ to denote the vector p such that $p_e = \Pr[e \in S]$ for all $e \in V$ (i.e., the expectation is applied coordinate-wise).

Submodular functions. In this paper, we consider the problem of maximizing a non-negative submodular function subject to a cardinality constraint. A set function $f\colon 2^V \to \mathbb{R}$ is submodular if $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$ for all subsets $A, B \subseteq V$.

Continuous extensions. We make use of two standard continuous extensions of submodular functions. The first of these extensions is known as the *multilinear extension*. To define this extension, we first need to define the random set $\mathtt{R}(x)$. For every vector $x \in [0,1]^V$, $\mathtt{R}(x)$ is defined as a random subset of V that includes every element $e \in V$ with probability x_e, independently. The multilinear extension F of f is now defined for every $x \in [0,1]^V$ by

$$F(x) = \mathbb{E}\big[f\big(\mathtt{R}(x)\big)\big] = \sum_{A \subseteq V} f(A) \cdot \Pr[\mathtt{R}(x) = A] = \sum_{A \subseteq V} \left(f(A) \cdot \prod_{e \in A} x_e \cdot \prod_{e \notin A} (1 - x_e) \right) .$$

One can observe from the definition that F is indeed a multilinear function of the coordinates of x, as suggested by its name. Thus, if we use the shorthand $\partial_e F(x)$ for the first partial derivative $\frac{\partial F(x)}{\partial x_e}$ of the multilinear extension F, then $\partial_e F(x) = F(x \vee \mathbf{1}_e) - F\big(x \wedge \mathbf{1}_{V \setminus \{e\}}\big)$.

In the analysis of our extension based algorithm, we need an upper bound on the possible increase in the value of $F(x)$ when some of the indices of x are zeroed. Corollary 2 provides such an upper bound. It readily follows from the following known lemma by Buchbinder et al. [6].

▶ **Lemma 1** (Lemma 2.2 from [6]). *Let $f\colon 2^V \to \mathbb{R}_{\geq 0}$ be a non-negative submodular function. Denote by $A(p)$ a random subset of $A \subseteq V$ where each element appears with probability at most p (not necessarily independently). Then, $\mathbb{E}[f(A(p))] \geq (1-p) \cdot f(\varnothing)$.*

In the statement of Corollary 2, and in the rest of the paper, we denote by $\operatorname{supp}(x)$ the support of vector x, i.e., the set $\{e \in V \mid x_e > 0\}$.

▶ **Corollary 2.** *Let $f\colon 2^V \to \mathbb{R}_{\geq 0}$ be a non-negative submodular function, let p be a number in the range $[0,1]$ and let $x, y \in [0,1]^V$ be two vectors such that $\operatorname{supp}(x) \cap \operatorname{supp}(y) = \varnothing$ and $y_e \leq p$ for every $e \in V$. Then, the multilinear extension F of f obeys $F(x+y) \geq (1-p) \cdot F(x)$.*

The analyses of both our algorithms make use of the *Lovász extension* $\hat{f}$ of f. The Lovász extension $\hat{f}\colon [0,1]^V \to \mathbb{R}$ is defined as follows. For every $x \in [0,1]^V$, $\hat{f}(x) = \mathbb{E}_{\theta \sim [0,1]}[f(\{e \in V\colon x_e \geq \theta\})]$, where we use the notation $\theta \sim [0,1]$ to denote a value chosen uniformly at random from the interval $[0,1]$. The Lovász extension $\hat{f}$ of a non-negative submodular function has the following properties: (1) convexity: $c\hat{f}(x) + (1-c)\hat{f}(y) \geq \hat{f}(cx + (1-c)y)$ for all $x, y \in [0,1]^V$ and all $c \in [0,1]$ [25]; (2) restricted scale invariance: $\hat{f}(cx) \geq c\hat{f}(x)$ for all $x \in [0,1]^V$ and all $c \in [0,1]$; (3) it lower bounds the multilinear extension, i.e., $F(x) \geq \hat{f}(x)$ for every $x \in [0,1]^V$ [32, Lemma A.4].

3 Combinatorial Algorithm

Our combinatorial streaming algorithm is shown in Algorithm 1. For simplicity, we describe the algorithm assuming the knowledge of an estimate of the value of the optimal solution, $f(\mathrm{OPT})$. To remove this assumption, we use the standard technique introduced by [2]. The basic idea is to use the maximum singleton value $v = \max_e f(\{e\})$ as a k-approximation of $f(\mathrm{OPT})$. Given this approximation, one can guess a $1+\varepsilon$ approximation of $f(\mathrm{OPT})$ from a set of $O(\log(k/\alpha)/\varepsilon)$ values ranging from v to kv/α (α is the approximation guarantee of the offline algorithm OfflineAlg that we use in the post-processing step). The final streaming algorithm is simply $O(\log(k/\alpha)/\varepsilon)$ copies of the basic algorithm running in parallel with different guesses. As new elements appear in the stream, the value $v = \max_e f(\{e\})$ also increases over time and thus, existing copies of the basic algorithm with small guesses are dropped and new copies with higher guesses are added. An important observation is that when we introduce a new copy with a large guess, starting it from mid-stream has exactly the same outcome as if we started it from the beginning of the stream: all previous elements have marginal gain much smaller than the guess and smaller than the threshold so they would have been rejected anyway. We refer to [2] for the full details.

▶ **Theorem 3.** *There is a streaming algorithm* StreamProcess *for non-negative, non-monotone submodular maximization with the following properties ($\varepsilon > 0$ is any desired accuracy and it is given as input to the algorithm):*

- *The algorithm makes a single pass over the stream.*
- *The algorithm uses $O\left(\frac{k \log(k/\alpha)\log(1/\varepsilon)}{\varepsilon^3}\right)$ space.*
- *The update time per item is $O\left(\frac{\log(k/\alpha)\log(1/\varepsilon)}{\varepsilon^2}\right)$ marginal gain computations.*

At the end of the stream, we post-process the output of StreamProcess *using any offline algorithm* OfflineAlg *for submodular maximization. The resulting solution is a $\frac{\alpha}{1+\alpha} - \varepsilon$ approximation, where α is the approximation of* OfflineAlg*.*

Algorithm 1 Streaming algorithm for $\max_{|S| \le k} f(S)$. PostProcess uses any offline algorithm OfflineAlg with approximation α. Lines shown in blue are comments. The algorithm does **not** store the sets $V_{i,j}$, they are defined for analysis purposes only.

```
StreamProcess($f, k, \varepsilon, \kappa$)
$r \leftarrow \Theta(\ln(1/\varepsilon)/\varepsilon)$
$m \leftarrow 1/\varepsilon$
$S_{i,j} \leftarrow \varnothing$ for all $i \in [r], j \in [m]$
$V_{i,j} \leftarrow \varnothing$ for all $i \in [r], j \in [m]$ // not stored, defined for analysis purposes only
for each arriving element $e$ do
    for $i = 1$ to $r$ do
        choose an index $j \in [m]$ uniformly and independently at random
        $V_{i,j} \leftarrow V_{i,j} \cup \{e\}$ // not stored, defined for analysis purposes only
        if $f(S_{i,j} \cup \{e\}) - f(S_{i,j}) \ge \kappa$ and $|S_{i,j}| < k$ then
            $S_{i,j} \leftarrow S_{i,j} \cup \{e\}$
return $\{S_{i,j} : i \in [r], j \in [m]\}$

PostProcess($f, k, \varepsilon$)
$\kappa \leftarrow \frac{\alpha}{1+\alpha} \cdot \frac{1}{k} \cdot f(\mathrm{OPT})$ // threshold
$\{S_{i,j}\} \leftarrow$ StreamProcess($f, k, \varepsilon, \kappa$)
if $|S_{i,j}| = k$ for some $i$ and $j$ then
    return $S_{i,j}$
else
    $U \leftarrow \bigcup_{i,j} S_{i,j}$
    $T \leftarrow$ OfflineAlg($f, k, U$)
    return $\arg\max\{f(S_{1,1}), f(T)\}$
```

Algorithm 2 Single threshold Greedy algorithm. The algorithm processes the elements in the order in which they arrive in the stream, and it uses the same threshold κ as StreamProcess.

```
STGreedy($f, N, k, \kappa$):
$S \leftarrow \varnothing$
for each $e \in N$ in the stream order do
    if $f(S \cup \{e\}) - f(S) \geq \kappa$ and $|S| < k$ then
        $S \leftarrow S \cup \{e\}$
return $S$
```

In the remainder of this section, we analyze Algorithm 1 and show that it achieves a $\frac{\alpha}{1+\alpha} - \varepsilon$ approximation, where α is the approximation guarantee of the offline algorithm OfflineAlg.

We divide the analysis into two cases, depending on the probability of the event that a set $S_{i,1}$ (for some $i \in [r]$) constructed by StreamProcess has size k. For every $i \in [r]$, let $\mathcal{F}_i$ be the event that $|S_{i,1}| = k$. Since each of the r repetitions (iterations of the for loop of StreamProcess) use independent randomness to partition V, the events $\mathcal{F}_1, \dots, \mathcal{F}_r$ are independent. Additionally, the events $\mathcal{F}_1, \dots, \mathcal{F}_r$ have the same probability. We divide the analysis into two cases, depending on whether $\Pr[\mathcal{F}_1] \geq \varepsilon$ or $\Pr[\mathcal{F}_1] < \varepsilon$. In the first case, since we are repeating $r = \Theta(\ln(1/\varepsilon)/\varepsilon)$ times, the probability that there is a set $S_{i,j}$ of size k is at least $1 - \varepsilon$, and we obtain the desired approximation since $f(S_{i,j}) \geq \kappa\,|S_{i,j}| = \kappa k = \frac{\alpha}{1+\alpha} f(\mathrm{OPT})$. In the second case, we have $\Pr\left[\,\overline{\mathcal{F}_1}\,\right] \geq 1 - \varepsilon$ and we argue that $\bigcup_{i,j} S_{i,j}$ contains a good solution. We now give the formal argument for each of the cases.

The case $\Pr[\mathcal{F}_1] \geq \varepsilon$

As noted earlier, the events $\mathcal{F}_1, \dots, \mathcal{F}_r$ are independent and have the same probability. Thus,

$$\Pr\left[\,\overline{\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_r}\,\right] \leq (1-\varepsilon)^r \leq \exp(-\varepsilon r) \leq \varepsilon$$

since $r = \Theta(\ln(1/\varepsilon)/\varepsilon)$. Thus $\Pr[\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_r] \geq 1 - \varepsilon$.

Conditioned on the event $\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_r$, we obtain the desired approximation due to the following lemma. The lemma follows from the fact that the marginal gain of each selected element is at least κ.

▶ **Lemma 4.** *We have $f(S_{i,j}) \geq \kappa\,|S_{i,j}|$ for all $i \in [r]$, $j \in [m]$.*

We can combine the two facts and obtain the desired approximation as follows. Let $\mathcal{S}$ be the random variable equal to the solution returned by PostProcess. We have

$$\mathbb{E}[f(\mathcal{S})] \geq \mathbb{E}[f(\mathcal{S})|\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_r]\Pr[\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_r] \geq (1-\varepsilon)\kappa k = (1-\varepsilon)\frac{\alpha}{1+\alpha} f(\mathrm{OPT})$$

The case $\Pr[\mathcal{F}_1] < \varepsilon$

In this case, we show that the solution $\arg\max\{f(T), f(S_{1,1})\}$ returned on the last line of PostProcess has good value in expectation. Our analysis borrows ideas and techniques from the work of Barbosa et al. [3]: the probabilities p_e defined below are analogous to the probabilities used in that work; the division of OPT into two sets based on these probabilities is analogous to the division employed in Section 7.3 in that work; Lemma 6 shows a consistency property for the single threshold greedy algorithm that is analogous to the consistency property shown for the standard greedy algorithm and other algorithms by Barbosa *et al.* Barbosa *et al.* use these concepts in a different context (specifically, *monotone* maximization in the *distributed* setting). When applied to our context – *non-monotone* maximization in the *streaming* setting – the framework of Barbosa *et al.* requires $\Omega(\sqrt{nk})$ memory if used with a single pass (alternatively, they use $\Omega(\min\{k, 1/\varepsilon\})$ passes) and achieves worse approximation guarantees.

Notation and definitions. For analysis purposes only, we make use of the Lovasz extension $\hat{f}$. We fix an optimal solution $\mathrm{OPT} \in \arg\max\{f(A) \colon A \subseteq V, |A| \leq k\}$. Let $\mathcal{V}(1/m)$ be the distribution of $1/m$-samples of V, where a $1/m$-sample of V includes each element of V independently at random with probability $1/m$. Note that $V_{i,j} \sim \mathcal{V}(1/m)$ for every $i \in [r]$, $j \in [m]$ (see StreamProcess). Additionally, for each $i \in [r]$, $V_{i,1}, \ldots, V_{i,m}$ is a partition of V into $1/m$-samples.

For a subset $N \subseteq V$, we let STGreedy(N) be the output of the single threshold greedy algorithm when run as follows (see also Algorithm 2 for a formal description of the algorithm): the algorithm processes the elements of N *in the order in which they arrive in the stream* and it uses the same threshold κ as StreamProcess; starting with the empty solution and continuing until the size constraint of k is reached, the algorithm adds an element to the current solution if its marginal gain is above the threshold. Note that $S_{i,j} = \mathrm{STGreedy}(V_{i,j})$ for all $i \in [r], j \in [m]$. For analysis purposes only, we also consider STGreedy(N) for sets N that do not correspond to any set $V_{i,j}$.

For each $e \in V$, we define

$$p_e = \begin{cases} \Pr_{X \sim \mathcal{V}(1/m)}\left[e \in \mathrm{STGreedy}(X \cup \{e\})\right] & \text{if } e \in \mathrm{OPT} \\ 0 & \text{otherwise} \end{cases}$$

We partition OPT into two sets:

$$O_1 = \{e \in \mathrm{OPT} \colon p_e \geq \varepsilon\} \quad O_2 = \mathrm{OPT} \setminus O_1$$

We also define the following subset of O_2:

$$O_2' = \{e \in O_2 \colon e \notin \mathrm{STGreedy}\left(V_{1,1} \cup \{e\}\right)\}.$$

Note that (O_1, O_2) is a deterministic partition of OPT, whereas O_2' is a random subset of O_2. The role of the sets O_1, O_2, O_2' will become clearer in the analysis. The intuition is that, using the repetition, we can ensure that each element of O_1 ends up in the collected set $U = \bigcup_{i,j} S_{i,j}$ with good probability: each iteration $i \in [r]$ ensures that an element $e \in O_1$ is in $S_{i,1} \cup \cdots \cup S_{i,m}$ with probability $p_e \geq \varepsilon$ and, since we repeat $r = \Theta(\ln(1/\varepsilon)/\varepsilon)$ times, we will ensure that $\mathbb{E}[\mathbf{1}_{O_1 \cap U}] \geq (1-\varepsilon)\mathbf{1}_{O_1}$. We also have that $\mathbb{E}\left[\mathbf{1}_{O_2'}\right] \geq (1-\varepsilon)\mathbf{1}_{O_2}$: an element $e \in O_2 \setminus O_2'$ ends up being picked by STGreedy when run on input $V_{1,1} \cup \{e\}$, which is a low probability event for the elements in O_2; more precisely, the probability of this event is equal to p_e (since $V_{1,1} \sim \mathcal{V}(1/m)$) and $p_e \leq \varepsilon$ (since $e \in O_2$). Thus $\mathbb{E}\left[\mathbf{1}_{(O_1 \cap U) \cup O_2'}\right] \geq (1-\varepsilon)\mathbf{1}_{\mathrm{OPT}}$, which implies that the expected value of $(O_1 \cap U) \cup O_2'$ is at least $(1-\varepsilon)f(\mathrm{OPT})$. However, whereas $O_1 \cap U$ is available in the post-processing phase, elements of O_2' may not be available and they may account for most of the value of O_2. The key insight is to show that $S_{1,1}$ makes up for the lost value from these elements.

We start the analysis with two helper lemmas, which follow from standard arguments that have been used in previous works. The first of these lemmas follows from an argument based on the Lovasz extension and its properties.

▶ **Lemma 5.** *Let* $0 \leq u \leq v \leq 1$*. Let* $S \subseteq V \setminus \mathrm{OPT}$ *and* $O \subseteq \mathrm{OPT}$ *be random sets such that* $\mathbb{E}[\mathbf{1}_S] \leq u\mathbf{1}_{V\setminus\mathrm{OPT}}$ *and* $\mathbb{E}[\mathbf{1}_O] \geq v\mathbf{1}_{\mathrm{OPT}}$*. Then* $\mathbb{E}[f(S \cup O)] \geq (v-u)f(\mathrm{OPT})$*.*

The following lemma establishes a consistency property for the STGreedy algorithm, analogous to the consistency property shown and used by Barbosa et al. for algorithms such as the standard Greedy algorithm. The proof is also very similar to the proof shown by Barbosa et al.

▶ **Lemma 6.** *Conditioned on the event* $|S_{1,1}| < k$*, we have* $\textit{STGreedy}(V_{1,1} \cup O_2') = \textit{STGreedy}(V_{1,1}) = S_{1,1}$*.*

We now proceed with the main analysis. Recall that PostProcess runs the algorithm OfflineAlg on U to obtain a solution T, and returns the better of the two solutions $S_{1,1}$ and T. In the following lemma, we show that the value of this solution is proportional to $f(S_{1,1} \cup (O_1 \cap U))$. Note that $S_{1,1} \cup (O_1 \cap U)$ may not be feasible, since we could have $|S_{1,1}| > |O_2|$, and hence the scaling based on $\frac{|O_2|}{k}$.

▶ **Lemma 7.** *We have* $\max\{f(S_{1,1}), f(T)\} \geq \frac{\alpha}{1+\alpha\left(1-\frac{|O_2|}{k}\right)} f(S_{1,1} \cup (O_1 \cap U))$*.*

Proof. To simplify notation, we let $S_1 = S_{1,1}$. Let $b = |O_2|$. First, we analyze $f(T)$. Let $X \subseteq S_1$ be a random subset of S_1 such that $|X| \leq b$ and $\mathbb{E}[\mathbf{1}_X] = \frac{b}{k}\mathbf{1}_{S_1}$. We can select such a subset as follows: we first choose a permutation of S_1 uniformly at random, and let $\tilde{X}$ be the first $s := \min\{b, |S_1|\}$ elements in the permutation. For each element of $\tilde{X}$, we add it to X with probability $p := |S_1|b/(sk)$. For each $e \in S_1$, we have

$$\Pr[e \in X] = \Pr\left[e \in X | e \in \tilde{X}\right] \Pr\left[e \in \tilde{X}\right] = p\frac{s}{|S_1|} = \frac{b}{k}$$

For each $e \notin S_1$, we have $\Pr[e \in X] = 0$. Thus $\mathbb{E}[\mathbf{1}_X] = \frac{b}{k}\mathbf{1}_{S_1}$.

Since $X \cup ((O_1 \cap U) \setminus S_1)$ is a feasible solution contained in U and OfflineAlg achieves an α-approximation, we have

$$f(T) \geq \alpha f(X \cup ((O_1 \cap U) \setminus S_1))$$

By taking expectation over X only (more precisely, the random sampling that we used to select X) and using that $\hat{f}$ is a convex extension, we obtain:

$$\begin{aligned} f(T) &\geq \alpha\mathbb{E}_X\left[f(X \cup ((O_1 \cap U) \setminus S_1))\right] = \alpha\mathbb{E}_X\left[\hat{f}\left(\mathbf{1}_{X\cup((O_1\cap U)\setminus S_1)}\right)\right] \\ &\geq \alpha\hat{f}\left(\mathbb{E}_X\left[\mathbf{1}_{X\cup((O_1\cap U)\setminus S_1)}\right]\right) = \alpha\hat{f}\left(\frac{b}{k}\mathbf{1}_{S_1} + \mathbf{1}_{(O_1\cap U)\setminus S_1}\right) \end{aligned}$$

Next, we lower bound $\max\{f(S_1), f(T)\}$ using a convex combination $(1-\theta)f(S_1) + \theta f(T)$ with coefficient $\theta = 1/(1+\alpha\left(1-\frac{b}{k}\right))$. Note that $1-\theta = \theta\alpha\left(1-\frac{b}{k}\right)$. By taking this convex combination, using the previous inequality lower bounding $f(T)$, and the convexity and restricted scale invariance of $\hat{f}$, we obtain:

$$\begin{aligned}
&\max\{f(S_1), f(T)\} \geq (1-\theta)f(S_1) + \theta f(T) = \theta\alpha\left(1-\frac{b}{k}\right)f(S_1) + \theta f(T) \\
&\geq \theta\alpha\left(1-\frac{b}{k}\right)\hat{f}\left(\mathbf{1}_{S_1}\right) + \theta\alpha\hat{f}\left(\frac{b}{k}\mathbf{1}_{S_1} + \mathbf{1}_{(O_1\cap U)\setminus S_1}\right) \\
&= \theta\alpha\left(2-\frac{b}{k}\right)\left(\frac{1-\frac{b}{k}}{2-\frac{b}{k}}\hat{f}\left(\mathbf{1}_{S_1}\right) + \frac{1}{2-\frac{b}{k}}\hat{f}\left(\frac{b}{k}\mathbf{1}_{S_1} + \mathbf{1}_{(O_1\cap U)\setminus S_1}\right)\right) \\
&\geq \theta\alpha\left(2-\frac{b}{k}\right)\hat{f}\left(\frac{1-\frac{b}{k}}{2-\frac{b}{k}}\mathbf{1}_{S_1} + \frac{1}{2-\frac{b}{k}}\left(\frac{b}{k}\mathbf{1}_{S_1} + \mathbf{1}_{(O_1\cap U)\setminus S_1}\right)\right) \\
&= \theta\alpha\left(2-\frac{b}{k}\right)\hat{f}\left(\frac{1}{2-\frac{b}{k}}\mathbf{1}_{S_1\cup(O_1\cap U)}\right) \geq \frac{\alpha}{1+\alpha\left(1-\frac{b}{k}\right)}f(S_1\cup(O_1\cap U)). \qquad \blacktriangleleft
\end{aligned}$$

(We note that we chose θ to make the coefficients of $\mathbf{1}_{S_1}$ and $\mathbf{1}_{(O_1\cap U)\setminus S_1}$ equal, and this allowed us to relate the value of the final solution to $f(S_1\cup(O_1\cap U))$.)

Next, we analyze the expected value of $f(S_{1,1}\cup(O_1\cap U))$. We do so in two steps: first we analyze the marginal gain of O_2' on top of $S_{1,1}$ and show that it is suitably small, and then we analyze $f(S_{1,1}\cup(O_1\cap U)\cup O_2')$ and show that its expected value is proportional to $f(\mathrm{OPT})$. We use the notation $f(A|B)$ to denote the marginal gain of A on top of B, i.e., $f(A|B) = f(A\cup B) - f(B)$.

▶ **Lemma 8.** *We have* $\mathbb{E}[f\left(O_2'|S_{1,1}\right)] \leq \kappa b + \varepsilon f(\mathrm{OPT})$.

Proof. As before, to simplify notation, we let $S_1 = S_{1,1}$ and $V_1 = V_{1,1}$. We break down the expectation using the law of total expectation as follows:

$$\begin{aligned}
\mathbb{E}[f\left(O_2'|S_1\right)] &= \mathbb{E}[f\left(O_2'|S_1\right)\,|\,|S_1|<k]\cdot\underbrace{\Pr[|S_1|<k]}_{\leq 1} + \underbrace{\mathbb{E}[f\left(O_2'|S_1\right)\,|\,|S_1|=k]}_{\leq f(\mathrm{OPT})}\cdot\underbrace{\Pr[|S_1|=k]}_{\leq\varepsilon} \\
&\leq \mathbb{E}[f\left(O_2'|S_1\right)\,|\,|S_1|<k] + \varepsilon f(\mathrm{OPT})
\end{aligned}$$

Above, we have used that $f(O_2'|S_1) \leq f(O_2') \leq f(\mathrm{OPT})$, where the first inequality follows by submodularity. We have also used that $\Pr[|S_1| = k] = \Pr[\mathcal{F}_1] \leq \varepsilon$. Thus it only remains to show that $\mathbb{E}[f\left(O_2'|S_1\right)\,|\,|S_1|<k] \leq \kappa b$.

We condition on the event $|S_1| < k$ for the remainder of the proof. By Lemma 6, we have $\textsc{STGreedy}(V_1\cup O_2') = S_1$. Since $|S_1| < k$, each element of $O_2'\setminus S_1$ was rejected because its marginal gain was below the threshold when it arrived in the stream. This, together with submodularity, implies that $f\left(O_2'|S_1\right) \leq \kappa\,|O_2'| \leq \kappa b$. ◀

▶ **Lemma 9.** *We have* $\mathbb{E}[f(S_{1,1}\cup(O_1\cap U)\cup O_2')] \geq (1-2\varepsilon)f(\mathrm{OPT})$.

Proof. We apply Lemma 5 to the following sets:

$$\begin{aligned}
&S = S_{1,1}\setminus\mathrm{OPT} \\
&O = (S_{1,1}\cap\mathrm{OPT})\cup(O_1\cap U)\cup O_2'
\end{aligned}$$

We show below that $\mathbb{E}[\mathbf{1}_O] \leq \varepsilon\mathbf{1}_{V\setminus\mathrm{OPT}}$ and $\mathbb{E}[\mathbf{1}_O] \geq (1-\varepsilon)\mathbf{1}_{\mathrm{OPT}}$. Assuming these bounds, we can take $u = \varepsilon$ and $v = 1-\varepsilon$ in Lemma 5, which gives the desired result.

Since $S \subseteq S_{1,1} \subseteq V_{1,1}$ and $V_{1,1}$ is a $(1/m)$-sample of V, we have $\mathbb{E}[\mathbf{1}_S] \leq \frac{1}{m}\mathbf{1}_{V\setminus\mathrm{OPT}} = \varepsilon\mathbf{1}_{V\setminus\mathrm{OPT}}$. Thus it only remains to show that, for each $e\in\mathrm{OPT}$, we have $\Pr[e\in O] \geq 1-\varepsilon$. Since $(O_1\cap U)\cup O_2' \subseteq O$, it suffices to show that $\Pr[e\in(O_1\cap U)\cup O_2'] \geq 1-\varepsilon$, or equivalently that $\Pr[e\in(O_1\setminus U)\cup(O_2\setminus O_2')] \leq \varepsilon$.

Recall that (O_1, O_2) is a deterministic partition of OPT. Thus e belongs to exactly one of O_1 and O_2 and we consider each of these cases in turn.

Suppose that $e \in O_1$. A single iteration of the for loop of StreamProcess ensures that e is in $S_{i,1} \cup \cdots \cup S_{i,m}$ with probability $p_e \geq \varepsilon$. Since we perform $r = \Theta(\ln(1/\varepsilon)/\varepsilon)$ independent iterations, we have $\Pr[e \notin U] \leq (1-\varepsilon)^r \leq \exp(-\varepsilon r) \leq \varepsilon$.

Suppose that $e \in O_2$. We have

$$\Pr[e \in O_2 \setminus O_2'] = \Pr[e \in \text{STGreedy}\,(V_{1,1} \cup \{e\})] = p_e \leq \varepsilon$$

where the first equality follows from the definition of O_2', the second equality follows from the definition of p_e and the fact that $V_{1,1} \sim \mathcal{V}(1/m)$, and the inequality follows from the definition of O_2. ◀

Lemmas 8 and 9 immediately imply the following:

▶ **Lemma 10.** *We have* $\mathbb{E}[f\,(S_{1,1} \cup (O_1 \cap U))] \geq (1-3\varepsilon)f(\text{OPT}) - \kappa b$.

Finally, Lemmas 7 and 10 give the approximation guarantee:

▶ **Lemma 11.** *We have* $\mathbb{E}[\max\{f(S_{1,1}), f(T)\}] \geq \left(\frac{\alpha}{1+\alpha} - 3\varepsilon\right) f(\text{OPT})$.

4 Extension based algorithm

Using our extension based algorithm, we prove the following theorem.

▶ **Theorem 12.** *Assume there exists an α-approximation offline algorithm OfflineAlg for maximizing a non-negative submodular function subject to cardinality constraint whose space complexity is nearly linear in the size of the ground set. Then, for every constant $\varepsilon \in (0,1]$, there exists an $(\frac{\alpha}{1+\alpha} - \varepsilon)$-approximation semi-streaming algorithm for maximizing a non-negative submodular function subject to a cardinality constraint. The algorithm stores at most $O(k\varepsilon^{-2})$ elements.*[4]

In this section, we introduce a simplified version of the algorithm used to prove Theorem 12. This simplified version (given as Algorithm 3) captures our main new ideas, but makes two simplifying assumptions that can be avoided using standard techniques.

- The first assumption is that Algorithm 3 has access to an estimate τ of $f(\text{OPT})$ obeying $(1-\varepsilon/8) \cdot f(\text{OPT}) \leq \tau \leq f(\text{OPT})$. Such an estimate can be produced using well-known techniques, at the cost of a slight increase in the space complexity of the algorithm. In the full version of this paper we formally show that one such technique due to [21] can be used for that purpose, and that it increases the space complexity of the algorithm only by a factor of $O(\varepsilon^{-1} \log \alpha^{-1})$.
- The second assumption is that Algorithm 3 has value oracle access to the multilinear extension F. If the time complexity of Algorithm 3 is not important, then this assumption is of no consequence since a value oracle query to F can be emulated using an exponential number of value oracle queries to f. However, the assumption becomes problematic when we would like to keep the time complexity of the algorithm polynomial and we only have value oracle access to f. Thus, we explain in the full version of this paper how to drop this

[4] Formally, the number of elements stored by the algorithm also depends on $\log \alpha^{-1}$. Since α is typically a positive constant, or at least lower bounded by a positive constant, we omit this dependence from the statement of the theorem.

assumption via sampling. Interestingly, the rounding step and this sampling technique are the only parts of the extension based algorithm that employ randomness. Since the rounding can be made deterministic given either exponential time or value oracle access to F, we get the following observation.

▶ **Observation 13.** *If* OfflineAlg *is deterministic, then the algorithm whose existence is guaranteed by Theorem 12 is also* deterministic *when it is allowed either exponential computation time or value oracle access to F.*

Algorithm 3 has two constant parameters $p \in (0, 1)$ and $c > 0$ and maintains a fractional solution $x \in [0, 1]^V$. This fractional solution starts empty, and the algorithm adds to it fractions of elements as they arrive. Specifically, when an element e arrives, the algorithm considers its marginal contribution with respect to the current fractional solution x. If this marginal contribution exceeds the threshold of $c\tau/k$, then the algorithm tries to add to x a p-fraction of e, but might end up adding a smaller fraction of e if adding a full p-fraction of e to x will make x an infeasible solution, i.e., make $\|x\|_1 > k$ (note that $\|x\|_1$ is the sum of the coordinates of x).

After viewing all of the elements, Algorithm 3 uses the fractional solution x to generate two sets S_1 and S_2 that are feasible (integral) solutions. The set S_1 is generated by rounding the fractional solution x. Two rounding procedures, named Pipage Rounding and Swap Rounding, were suggested for this task in the literature [8, 12]. Both procedures run in polynomial time and guarantee that the output set S_1 of the rounding is always feasible, and that its expected value with respect to f is at least the value $F(x)$ of the fractional solution x. The set S_2 is generated by applying OfflineAlg to the support of the vector x, which produces a feasible solution that (approximately) maximizes f among all subsets of the support whose size is at most k. After computing the two feasible solutions S_1 and S_2, Algorithm 3 simply returns the better one of them.

Algorithm 3 StreamProcessExtension (simplified) (p, c).

```
Let $x \leftarrow \mathbf{1}_\varnothing$.
for each arriving element $e$ do
    if $\partial_e F(x) \geq \frac{c\tau}{k}$ then $x \leftarrow x + \min\{p, k - \|x\|_1\} \cdot \mathbf{1}_e$.
Round the vector $x$ to yield a feasible solution $S_1$ such that $\mathbb{E}[f(S_1)] \geq F(x)$.
Find another feasible solution $S_2 \subseteq \mathrm{supp}(x)$ by running OfflineAlg with $\mathrm{supp}(x)$
  as the ground set.
return the better solution among $S_1$ and $S_2$.
```

Let us denote by $\hat{x}$ the final value of the fractional solution x (i.e., its value when the stream ends). We begin the analysis of Algorithm 3 with the following useful observation.

▶ **Observation 14.** *If $\|\hat{x}\|_1 < k$, then $\hat{x}_e = p$ for every $e \in \mathrm{supp}(\hat{x})$. Otherwise (when $\|\hat{x}\|_1 = k$), this is still true for every element $e \in \mathrm{supp}(\hat{x})$ except for maybe a single element.*

Proof. For every element e added to the support of x by Algorithm 3, the algorithm sets x_e to p unless this will make $\|x\|_1$ exceed k, in which case the algorithm set x_e to be the value that will make $\|x\|_1$ equal to k. Thus, after a single coordinate of x is set to a value other than p (or the initial 0), $\|x\|_1$ becomes k and Algorithm 3 stops changing x. ◀

Using the last observation we can now bound the space complexity of Algorithm 3, and show (in particular) that it is a semi-streaming algorithm for a constant p when the space complexity of OfflineAlg is nearly linear.

▶ **Observation 15.** *Algorithm 3 can be implemented so that it stores at most $O(k/p)$ elements.*

Proof. To calculate the sets S_1 and S_2, Algorithm 3 needs access only to the elements of V that appear in the support of x. Thus, the number of elements it needs to store is $O(|\operatorname{supp}(\hat{x})|) = O(k/p)$, where the equality follows from Observation 14. ◀

We now divert our attention to analyzing the approximation ratio of Algorithm 3. The first step in this analysis is lower bounding the value of $F(\hat{x})$, which we do by considering two cases, one when $\|\hat{x}\|_1 = k$, and the other when $\|\hat{x}\|_1 < k$. The following lemma bounds the value of $F(\hat{x})$ in the first of these cases. Intuitively, this lemma holds since $\operatorname{supp}(\hat{x})$ contains many elements, and each one of these elements must have increased the value of $F(x)$ significantly when added (otherwise, Algorithm 3 would not have added this element to the support of x).

▶ **Lemma 16.** *If $\|\hat{x}\|_1 = k$, then $F(\hat{x}) \geq c\tau$.*

Proof. Denote by $e_1, e_2, \ldots, e_\ell$ the elements in the support of $\hat{x}$, in the order of their arrival. Using this notation, the value of $F(\hat{x})$ can be written as follows.

$$\begin{aligned} F(\hat{x}) &= F(\mathbf{1}_\varnothing) + \sum_{i=1}^{\ell} \left(F\big(\hat{x} \wedge \mathbf{1}_{\{e_1, e_2, \ldots, e_i\}}\big) - F\big(\hat{x} \wedge \mathbf{1}_{\{e_1, e_2, \ldots, e_{i-1}\}}\big) \right) \\ &= F(\mathbf{1}_\varnothing) + \sum_{i=1}^{\ell} \left(\hat{x}_{e_i} \cdot \partial_{e_i} F\big(\hat{x} \wedge \mathbf{1}_{\{e_1, e_2, \ldots, e_{i-1}\}}\big) \right) \\ &\geq F(\mathbf{1}_\varnothing) + \frac{c\tau}{k} \cdot \sum_{i=1}^{\ell} \hat{x}_{e_i} = F(\mathbf{1}_\varnothing) + \frac{c\tau}{k} \cdot \|\hat{x}\|_1 \geq c\tau \enspace , \end{aligned}$$

where the second equality follows from the multilinearity of F, and the first inequality holds since Algorithm 3 selects an element e_i only when $\partial_{e_i} F\big(\hat{x} \wedge \mathbf{1}_{\{e_1, e_2, \ldots, e_{i-1}\}}\big) \geq \frac{c\tau}{k}$. The last inequality holds since f (and thus, also F) is non-negative and $\|\hat{x}\|_1 = k$ by the assumption of the lemma. ◀

Consider now the case in which $\|\hat{x}\|_1 < k$. Recall that our objective is to lower bound $F(\hat{x})$ in this case as well. Towards this goal, we bound the expression $F(\hat{x} + \mathbf{1}_{\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})})$ from below and above in the following two lemmata.

▶ **Lemma 17.** *If $\|\hat{x}\|_1 < k$, then $F\big(\hat{x} + \mathbf{1}_{\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})}\big) \geq (1-p) \cdot \big[p \cdot f(\mathrm{OPT}) + (1-p) \cdot f\big(\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})\big)\big]$.*

Proof. Since $\|\hat{x}\|_1 < k$, Observation 14 guarantees that $\hat{x}_e = p$ for every $e \in \operatorname{supp}(\hat{x})$. Thus $\hat{x} = p \cdot \mathbf{1}_{\mathrm{OPT} \cap \operatorname{supp}(\hat{x})} + p \cdot \mathbf{1}_{\operatorname{supp}(\hat{x}) \setminus \mathrm{OPT}}$, and therefore,

$$\begin{aligned} F\big(\hat{x} + \mathbf{1}_{\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})}\big) &= F\big(p \cdot \mathbf{1}_{\mathrm{OPT} \cap \operatorname{supp}(\hat{x})} + p \cdot \mathbf{1}_{\operatorname{supp}(\hat{x}) \setminus \mathrm{OPT}} + \mathbf{1}_{\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})}\big) \\ &\geq (1-p) \cdot F\big(p \cdot \mathbf{1}_{\mathrm{OPT} \cap \operatorname{supp}(\hat{x})} + \mathbf{1}_{\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})}\big) \\ &\geq (1-p) \cdot \hat{f}\big(p \cdot \mathbf{1}_{\mathrm{OPT} \cap \operatorname{supp}(\hat{x})} + \mathbf{1}_{\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})}\big) \\ &= (1-p) \cdot \Big[p \cdot f(\mathrm{OPT}) + (1-p) \cdot f\big(\mathrm{OPT} \setminus \operatorname{supp}(\hat{x})\big)\Big] \enspace , \end{aligned}$$

where the first inequality follows from Corollary 2, the second inequality holds since the Lovász extension lower bounds the multilinear extension, and the last equality follows from the definition of the Lovász extension. ◀

In the following lemma, and the rest of the section, we use the notation $b = k^{-1} \cdot |\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})|$. Intuitively, the lemma holds since the fact that the elements of $\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})$ where not added to the support of x implies that their marginal contribution is small.

▶ **Lemma 18.** *If $\|\hat{x}\|_1 < k$, then $F\big(\hat{x} + \mathbf{1}_{\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})}\big) \leq F(\hat{x}) + bc\tau$.*

Proof. The elements in $\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})$ were rejected by Algorithm 3, which means that their marginal contribution with respect to the fractional solution x at the time of their arrival was smaller than $c\tau/k$. Since the fractional solution x only increases during the execution of the algorithm, the submodularity of f guarantees that this is true also with respect to $\hat{x}$. More formally, we get

$$\partial_e F(\hat{x}) < \frac{c\tau}{k} \quad \forall\, e \in \mathrm{OPT} \setminus \mathrm{supp}(\hat{x}) \ .$$

Using the submodularity of f again, this implies

$$F\big(\hat{x} + \mathbf{1}_{\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})}\big) \leq F(\hat{x}) + \sum_{e \in \mathrm{OPT} \setminus \mathrm{supp}(\hat{x})} \partial_e F(\hat{x}) \leq F(\hat{x}) + |\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})| \cdot \frac{c\tau}{k} = F(\hat{x}) + bc\tau. \blacktriangleleft$$

Combining the last two lemmata immediately yields the promised lower bound on $F(\hat{x})$. To understand the second inequality in the following corollary, recall that $\tau \leq f(\mathrm{OPT})$.

▶ **Corollary 19.** *If $\|\hat{x}\|_1 < k$, then $F(\hat{x}) \geq (1-p) \cdot \Big[p \cdot f(\mathrm{OPT}) + (1-p) \cdot f\big(\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})\big)\Big] - bc\tau \geq [p(1-p) - bc]\tau + (1-p)^2 \cdot f\big(\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})\big)$.*

Our next step is to get a lower bound on the expected value of $f(S_2)$. One easy way to get such a lower bound is to observe that $\mathrm{OPT} \cap \mathrm{supp}(\hat{x})$ is a subset of the support of $\hat{x}$ of size at most k, and thus, is a candidate to be OPT; which implies $\mathbb{E}[f(S_2)] \geq \alpha \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x}))$ since the algorithm OfflineAlg used to find S_2 is an α-approximation algorithm. The following lemma proves a more involved lower bound by considering the vector $(b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}$ as a fractional candidate to be OPT (using the rounding methods discussed above it, it can be converted into an integral candidate of at least the same value). The proof of the lemma lower bounds the value of the vector $(b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}$ using the concavity of the function $F((t \cdot \hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$ as well as ideas used in the proofs of the previous claims.

▶ **Lemma 20.** *If $\|\hat{x}\|_1 < k$, then $\mathbb{E}[f(S_2)] \geq \alpha b(1 - p - cb)\tau + \alpha(1-b) \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x}))$.*

Proof. Consider the vector $(b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}$. Clearly,

$$\begin{aligned}\big\|(b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}\big\|_1 &\leq b \cdot \|\hat{x}\|_1 + \big\|\mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}\big\|_1 \\ &\leq |\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})| + |\mathrm{OPT} \cap \mathrm{supp}(\hat{x})| = |\mathrm{OPT}| \leq k \ ,\end{aligned}$$

where the second inequality holds by the definition of b since $\|\hat{x}\|_1 < k$. Thus, due to the existence of the rounding methods discussed in Section 4, there must exist a set S of size at most k obeying $f(S) \geq F((b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$. Since S_2 is produced by OfflineAlg, whose approximation ratio is α, this implies $\mathbb{E}[f(S_2)] \geq \alpha \cdot F((b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$. Thus, to prove the lemma it suffices to show that $F((b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$ is always at least $b(1 - p - cb)\tau + (1-b) \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x}))$.

The first step towards proving the last inequality is getting a lower bound on $F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$. Recall that we already showed in the proof of Lemma 18 that

$$\partial_e F(\hat{x}) < \frac{c\tau}{k} \quad \forall\, e \in \mathrm{OPT} \setminus \mathrm{supp}(\hat{x}) \enspace .$$

Thus, the submodularity of f implies

$$\begin{aligned} F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT}}) &\leq F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}) + \sum_{e \in \mathrm{OPT} \setminus \mathrm{supp}(\hat{x})} \partial_e F(\hat{x}) \\ &\leq F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}) + \frac{c\tau \cdot |\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})|}{k} = F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}) + cb\tau \enspace . \end{aligned}$$

Rearranging this inequality yields

$$F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}) \geq F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT}}) - cb\tau \geq (1-p) \cdot f(\mathrm{OPT}) - cb\tau \geq (1-p-cb)\tau \enspace ,$$

where the second inequality holds by Corollary 2 since Observation 14 guarantees that every coordinate of $\hat{x}$ is either 0 or p. This gives us the promised lower bound on $F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$.

We now note that the submodularity of f implies that $F((t \cdot \hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})})$ is a concave function of t within the range $[0, 1]$. Since b is inside this range,

$$\begin{aligned} F((b\hat{x}) \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}) &\geq b \cdot F(\hat{x} \vee \mathbf{1}_{\mathrm{OPT} \cap \mathrm{supp}(\hat{x})}) + (1-b) \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x})) \\ &\geq b(1-p-cb)\tau + (1-b) \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x})) \enspace , \end{aligned}$$

which completes the proof of the lemma. ◀

Using the last two claims we can now obtain a lower bound on the value of the solution of Algorithm 3 in the case of $\|\hat{x}\|_1 < k$ which is a function of α, τ and p alone. We note that both the guarantees of Corollary 19 and Lemma 20 are lower bounds on the expected value of the output of the algorithm in this case since $\mathbb{E}[f(S_1)] \geq F(\hat{x})$. Thus, any convex combination of these guarantees is also such a lower bound, and the proof of the following corollary basically proves a lower bound for one such convex combination – for the specific value of c stated in the corollary.

▶ **Corollary 21.** *If $\|\hat{x}\|_1 < k$ and c is set to $\frac{\alpha(1-p)}{\alpha+1}$, then $\mathbb{E}[\max\{f(S_1), f(S_2)\}] \geq \frac{(1-p)\alpha\tau}{\alpha+1}$.*

Proof. The corollary follows immediately from the non-negativity of f when $p = 1$. Thus, we may assume $p < 1$ in the rest of the proof.

By the definition of S_1, $\mathbb{E}[f(S_1)] \geq F(\hat{x})$. Thus, by Corollary 19 and Lemma 20,

$$\begin{aligned} \mathbb{E}[\max\{f(S_1), f(S_2)\}] &\geq \max\{\mathbb{E}[f(S_1)], \mathbb{E}[f(S_2)]\} \\ &\geq \max\{[p(1-p) - bc]\tau + (1-p)^2 \cdot f\big(\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})\big), \\ &\qquad \alpha b(1-p-cb)\tau + \alpha(1-b) \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x}))\} \\ &\geq \frac{\alpha(1-b)}{\alpha(1-b) + (1-p)^2} \cdot \big[[p(1-p) - bc]\tau + (1-p)^2 \cdot f\big(\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})\big)\big] \\ &\quad + \frac{(1-p)^2}{\alpha(1-b) + (1-p)^2} \cdot [\alpha b(1-p-cb)\tau + \alpha(1-b) \cdot f(\mathrm{OPT} \cap \mathrm{supp}(\hat{x}))] \enspace . \end{aligned}$$

To keep the following calculations short, it will be useful to define $q = 1-p$ and $d = 1-b$. Using this notation and the fact that the submodularity and non-negativity of f guarantee together $f\big(\mathrm{OPT} \setminus \mathrm{supp}(\hat{x})\big) + f\big(\mathrm{OPT} \cap \mathrm{supp}(\hat{x})\big) \geq f(\mathrm{OPT}) \geq \tau$, the previous inequality implies

$$\begin{aligned}\frac{\mathbb{E}[\max\{f(S_1),f(S_2)\}]}{\alpha\tau} &\geq \frac{(1-b)[p(1-p)-bc]+b(1-p)^2(1-p-bc)+(1-b)(1-p)^2}{\alpha(1-b)+(1-p)^2}\\ &= \frac{d[q(1-q)-(1-d)c]+q^2(1-d)[q-(1-d)c]+dq^2}{\alpha d+q^2}\\ &= \frac{d[q-(1-d)c]+q^2(1-d)[q-(1-d)c]}{\alpha d+q^2} = \frac{[d+q^2(1-d)][q-(1-d)c]}{\alpha d+q^2}\\ &= \frac{q[d+q^2(1-d)](d\alpha+1)}{(\alpha+1)(d\alpha+q^2)} = \frac{d^2\alpha+d\alpha q^2-d^2\alpha q^2+d+q^2-dq^2}{d\alpha+q^2}\cdot\frac{q}{\alpha+1}\ , \end{aligned} \tag{1}$$

where the fourth equality holds by plugging in the value we assume for c.

The second fraction in the last expression is independent of the value of d, and the derivative of the first fraction in this expression as a function of d is

$$\begin{aligned}&\frac{(2d\alpha+\alpha q^2-2d\alpha q^2+1-q^2)[d\alpha+q^2]-\alpha(d^2\alpha+d\alpha q^2-d^2\alpha q^2+d+q^2-dq^2)}{[d\alpha+q^2]^2}\\ &\qquad\qquad\qquad\qquad = \frac{1-q^2}{[d\alpha+q^2]^2}\cdot[q^2(1-\alpha)+d\alpha(d\alpha+2q^2)]\ ,\end{aligned}$$

which is always non-negative since both q and α are numbers between 0 and 1. Thus, we get that the minimal value of the expression (1) is obtained for $d=0$ for any choice of q and α. Plugging this value into d yields

$$\mathbb{E}[\max\{f(S_1),f(S_2)\}] \geq \frac{q\alpha\tau}{\alpha+1} = \frac{(1-p)\alpha\tau}{\alpha+1}\ . \qquad ◀$$

Note that Lemma 16 and Corollary 21 prove the same lower bound on the expectation $\mathbb{E}[\max\{f(S_1),f(S_2)\}]$ when c is set to the value it is set to in Corollary 21 (because $\mathbb{E}[\max\{f(S_1),f(S_2)\}] \geq \mathbb{E}[f(S_1)] \geq F(\hat{x})$). Thus, we can summarize the results we have proved so far using the following proposition.

▶ **Proposition 22.** *Algorithm 3 is a semi-streaming algorithm storing $O(k/p)$ elements. Moreover, for the value of the parameter c given in Corollary 21, the output set produced by this algorithm has an expected value of at least $\frac{\alpha\tau(1-p)}{\alpha+1}$.*

Using the last proposition, we can now prove the following theorem. As discussed at the beginning of the section, in the full version of this paper we explain how the assumption that τ is known can be dropped at the cost of increasing of a slight increase in the number of of elements stored by the algorithm, which yields Theorem 12.

▶ **Theorem 23.** *For every constant $\varepsilon \in (0,1]$, there exists a semi-streaming algorithm that assumes access to an estimate τ of $f(\mathrm{OPT})$ obeying $(1-\varepsilon/8)\cdot f(\mathrm{OPT}) \leq \tau \leq f(\mathrm{OPT})$ and provides $(\frac{\alpha}{1+\alpha}-\varepsilon)$-approximation for the problem of maximizing a non-negative submodular function subject to cardinality constraint. This algorithm stores at most $O(k\varepsilon^{-1})$ elements.*

Proof. Consider the algorithm obtained from Algorithm 3 by setting $p=\varepsilon/2$ and c as is set in Corollary 21. By Proposition 22, this algorithm stores only $O(k/p)=O(k\varepsilon^{-1})$ elements, and the expected value of its output set is at least

$$\frac{\alpha\tau(1-p)}{\alpha+1} \geq \frac{\alpha(1-\varepsilon/8)(1-\varepsilon/2)}{\alpha+1}\cdot f(\mathrm{OPT}) \geq \frac{\alpha(1-\varepsilon)}{\alpha+1}\cdot f(\mathrm{OPT}) \geq \left(\frac{\alpha}{\alpha+1}-\varepsilon\right)\cdot f(\mathrm{OPT})\ ,$$

where the first inequality holds since τ obeys, by assumption, $\tau \geq (1-\varepsilon/8)\cdot f(\mathrm{OPT})$. ◀

Further discussion. Before concluding, let us discuss in more detail the value that should be assigned to the parameter p of Algorithm 3. In the proof of Theorem 23, we chose p to be very small. This makes sense whenever α is independent of p since the formula given by Proposition 22 for the guaranteed value of the output is non-increasing in p. However, for some choices of OfflineAlg the value of α might depend on p, and thus, it might be beneficial to choose a value for p which is not very small. To see why α might depend on p, note that the input passed to OfflineAlg by Algorithm 3 is of size at most $\lceil k/p \rceil$ due to Observation 14; and therefore, the ratio between the size of the ground set and k in this input is roughly $1/p$. Hence, α depends on p if the approximation ratio of OfflineAlg depends on the above ratio; which is the case, e.g., for one of the algorithms described in [6].

As a corollary of the above discussion, we get that for some offline algorithms a smart choice of p can yield a better approximation guarantee than the one stated in Theorem 23. At the current point this corollary is not very useful since the state-of-the-art offline approximation algorithm has an approximation ratio which is independent of p; however, this might change in the future.

Dynamic Averaging Load Balancing on Cycles

Abstract

We consider the following dynamic load-balancing process: given an underlying graph G with n nodes, in each step $t \geq 0$, one unit of load is created, and placed at a randomly chosen graph node. In the same step, the chosen node picks a random neighbor, and the two nodes *balance* their loads by averaging them. We are interested in the expected gap between the minimum and maximum loads at nodes as the process progresses, and its dependence on n and on the graph structure.

Variants of the above graphical balanced allocation process have been studied previously by Peres, Talwar, and Wieder [10], and by Sauerwald and Sun [12]. These authors left as open the question of characterizing the gap in the case of *cycle graphs* in the *dynamic* case, where weights are created during the algorithm's execution. For this case, the only known upper bound is of $\mathcal{O}(n \log n)$, following from a majorization argument due to [10], which analyzes a related graphical allocation process.

In this paper, we provide an upper bound of $\mathcal{O}(\sqrt{n} \log n)$ on the expected gap of the above process for cycles of length n. We introduce a new potential analysis technique, which enables us to bound the difference in load between k-hop neighbors on the cycle, for any $k \leq n/2$. We complement this with a "gap covering" argument, which bounds the maximum value of the gap by bounding its value across all possible subsets of a certain structure, and recursively bounding the gaps within each subset. We provide analytical and experimental evidence that our upper bound on the gap is tight up to a logarithmic factor.

1 Introduction

We consider balls-into-bins processes where a sequence of m weights are placed into n bins via some randomized procedure, with the goal of minimizing the load imbalance between the most loaded and the least loaded bin. This family of processes has been used to model several practical allocation problems, such as load-balancing [3, 7, 11], hashing [5], or even relaxed data structures [2, 1].

One way to put our results into context is to view them as a variation of the well-known d-choice process, in which, in each step, a new weight is generated, and is placed in the least loaded of d uniform random choices. If $d = 1$, then we have the uniform random choice scheme, whose properties are well understood. In particular, if we place $m = n$ unit weights into the bins, then it is known that the most loaded bin will have expected $\Theta(\log n/\log\log n)$ load, whereas if $m = \Omega(n \log n)$ we have that the expected maximum load is $m/n + \Theta(\sqrt{m \log n/n})$. Seminal work by Azar, Broder, Karlin, and Upfal [3] showed that, if we place n unit weights into n bins by the d-choice process with $d \geq 2$, then, surprisingly, the maximum load is reduced to $\Theta(\log\log n/\log d)$. A technical tour-de-force by Berenbrink, Czumaj, Steger, and Vöcking [4] extended this result to the "heavily-loaded" case where $m \gg n$, showing that in this case the maximum load is $m/n + \log\log n/\log d + O(1)$ with failure probability at most $1/\text{poly } n$. An elegant alternative proof for a slightly weaker version of this result was later provided by Talwar and Wieder [13].

More recently, Peres, Talwar, and Wieder [10] analyzed the *graphical* version of this process, where the bins are the vertices of a graph, an *edge* is chosen at every step, and the weight is placed at the less loaded endpoint of the edge, breaking ties arbitrarily. (The classic 2-choice process corresponds to the case where the graph is a clique.) The authors focus on the evolution of the gap between the highest and lowest loaded bins, showing that, for graphs of β-edge-expansion [10], this gap is $O(\log n/\beta)$, with probability $1 - 1/\text{poly } n$.

An alternative way to frame our results is to consider *static load-balancing*, where each node starts with an arbitrary initial load, and the endpoints *average* their initial loads whenever the edge is chosen. Then, the balancing process can be mapped to a Markov chain, whose convergence is well-understood in terms of the spectral gap of the underlying graph [12]. Sauerwald and Sun [12] considered this static case in the *discrete* setting, where the fixed initial load can only be divided to *integer* tokens upon each averaging step, for which they gave strong upper bounds for a wide range of graph families.

By contrast to this previous work, in this paper we consider the less complex *continuous averaging case*, where exact averaging of the weights is possible, but in the more challenging *dynamic* scenario, where weights arrive in each step rather than being initially allocated, which is closer to the setting of the d-choice process discussed above.

One question left open by previous work concerns the evolution of the gap in the dynamic case on graphs of low expansion, such as cycles. In particular, for cycles, the only known upper bound on the expected gap in the dynamic case is of $O(n \log n)$, following from [10], whereas the only lower bound is the immediate $\Omega(\log n)$ gap lower bound for the clique. Closing this gap for cycle graphs is known to be a challenging open problem [9]. As suggested in [10], to deal with the cycle case, there is a need for a new approach, which takes the structure of the load balancing graph into account.

Contribution. In this paper, we address this question for the case where averaging is performed on a cycle graph. Let $Gap(t)$ be a difference between highest and lowest loads of the nodes at time step t. We provide the upper bound on the gap in the dynamic, heavily-loaded case, via a new potential argument. More formally, for any $t > 0$, we show that for a cycle graph with n vertices:

$$\mathbb{E}[Gap(t)] = O(\sqrt{n}\log(n)). \tag{1}$$

We complement this result with a lower bound of $\Omega(n)$ on the $\mathbb{E}[Gap(t)^2]$, as well as additional experimental evidence suggesting that our upper bound is tight within a logarithmic factor. Our results extend to *weighted* input. That is, we can allow our input to come from any distribution W, such that $\mathbb{E}[W^2] \leq M^2$, for some $M > 0$.

Technical Argument. Our upper bound result is based on two main ideas. The first introduces a new parametrized hop-potential function, which measures the squared difference in load between any k-hop neighbors on the graph, where $k \geq 1$ is a fixed hop parameter. Let $G = (V, E)$ be our input graph, where $V = \{1, 2, ..., n\}$. Throughout the paper, for any $1 \leq i \leq n$ we assume that the nodes $i + n$ and $i - n$ are the same as the node i. Let $x_i(t)$ be the load of node i node at step t. Then, we define the k-hop potential as:

$$\phi_k(t) = \sum_{i=1}^{n} (x_i(t) - x_{i+k}(t))^2.$$

The first technical step in the proof is to understand the expected ("steady-state") value of the k-hop potential. We show that, in expectation, the k-hop potential has a recursive structure on regular graphs. While the expected values of k-hop potentials cannot be computed precisely, we can isolate upper and lower bounds on their values for cycles. In particular, for the k-hop potential on an n-cycle, we prove the following bound:

$$\mathbb{E}[\phi_k(t)] \leq k(n-k) - 1, \forall k \geq 1. \tag{2}$$

In the second technical step, we shift gears, aiming to bound the *maximum possible value* of the gap between any two nodes, leveraging the fact that we understand the hop potential for any $k \geq 1$. We achieve this via a "gap covering" technique, which characterizes the maximum value of the gap across all possible subsets of a certain type.

More precisely, in the case of a cycle of length $n = 2^m$, for each node i and hop count k, we define the set family A_k^i to be formed of nodes $\{i, i + 2^k, i + 2 \times 2^k, i + 3 \times 2^k, \dots\}$. (Since we are on a cycle, $i = i + 2^{m-k} 2^k$.) Then for any $1 \leq i \leq n$ and $k > 0$, we will have

$$\sum_{i=1}^{n} Gap_{A_{k-1}^i}(t) \leq \sum_{i=1}^{n} Gap_{A_k^i}(t) + \frac{n}{\sqrt{2^{k-1}}} \sqrt{\phi_{2^{k-1}}(t)}, \tag{3}$$

where $Gap_X(t)$ is the maximal gap inside the set X at time t. Intuitively, this result allows us recursively characterize the gap value at various "resolutions" across the graph.

Finally, we notice that we can "cover" the gap across between *any* two nodes by carefully unwinding the recursion in the above inequality, considering all possible subsets of a well-chosen structure, and recursively bounding the gaps within each subset. (This step is particularly delicate in the case where n is not a power of two, see Section 5.) We obtain that

$$\mathbb{E}[Gap(t)] = O(\sqrt{n} \log(n)), \tag{4}$$

as claimed. The logarithmic slack is caused by the second term on the right-hand-side of (2). We note that this technique extends to the case where inserted items are *weighted*, where the weights are coming from some distribution of bounded second moment.

Lower Bound. It is interesting to ask whether this upper bound is tight. To examine this question, we revisit the recursive structure of the k-hop potential, which we used to obtain the lower bound in Equation 2. We can leverage this structure to obtain a *lower bound* on the expected k-hop potential as well. Starting from this lower bound, we can turn the upper bound argument "inside out," to obtain a linear lower bound on the *expected squared gap*:

$$\mathbb{E}[Gap(t)^2] = \Omega(n). \tag{5}$$

This second moment bound strongly suggests that our above analysis is tight within logarithmic factors. We conjecture that the bound is also tight with regards to the expected gap, and examine this claim empirically in Section 6.

Extensions and Overview. The analysis template we described above is general, and could be extended to other graph families, such as regular expanders. In particular, we note that the recursive structure of the k-hop potentials is preserved for such graphs. The main technical steps in analyzing a new graph family are to (1) identify the right upper bound on the k-hop potential (the analogue of (1)); and (2) identify the right set family for the gap covering argument, and its recursive structure (the analogue of (2)). Obtaining tight bounds for these quantities is not straightforward, since they do not seem to be immediately linked to well-studied graph properties. Here, we focus on obtaining tight bounds on the gap for cycles, which is technically non-trivial, and leave the extensions for other graph families as future work. To substantiate our generality claim, we exhibit an application of our analysis technique to Harary graphs [6] in a full version of the paper.

We discuss the relation between our results and bounds for the graphical power-of-two process on a cycle [10] in Section 7.

Related Work. As we have already discussed broad background, we will now mainly focus on the technical differences from previous work. As stated, we are the first to specifically consider the *dynamic* case for *continuous averaging* on cycles. In the *static* case with *discrete averaging*, the problem has been considered by Sauerwald and Sun [12]. However, their techniques would not apply in our case, since we consider that weights would be introduced *dynamically*, during the processes' execution.

To our knowledge, the only non-trivial upper bound on the gap of the process we consider which would follow from previous work is of $\mathcal{O}(n \log n)$, by the potential analysis of [10]: they consider 2-choice load balancing, and one can re-do their potential analysis for (continuous) averaging load balancing, yielding the same bounds. However, as our bounds show, the resulting analysis is quite loose in the case of cycles, yielding an $\Omega(\sqrt{n})$ gap. This is a consequence of the majorization technique used, which links dynamic averaging on the cycle and a very weak form of averaging on the clique.

Our potential analysis is substantially different from that of [10], as they track a sum of exponential potentials across the entire graph. By contrast, our analysis tracks the squared load differences between k-hop neighbors, establishing recurrences between these potentials. We notice that this is also different from the usual square potentials used for analyzing averaging load balancing, e.g. [8], which usually compare against the *global mean*, as opposed to pairwise potential differences. Our approach is also different from the classic analyses of e.g. [3], which perform probabilistic induction on the number of bins at a given load, assuming a clique.

Generally, our technique can be seen as performing the induction needed to bound the gap not on the bin loads, as is common in previous work, e.g. [3], but *over the topology of the graph*. This approach is natural, since we wish to obtain tight, topology-specific bounds, but we believe we are the first to propose and analyze it successfully.

2 Averaging on the Cycle: Upper Bounding the Gap

Preliminaries. We consider a cycle graph $G = (V, E)$ where $V = \{1, 2, ..., n\}$, such that each node i is connected to its left and right neighbors, $i - 1$ and $i + 1$ (recall that for any $1 \leq i \leq n$ the nodes $i + n$ and $i - n$ are the same as the node i).

We consider a stochastic process following real time $t \geq 0$, in which, in each step, a weight $w(t)$ is generated from a same distribution W. We associate a real-valued *load* value $x_i(t)$ with each node i. In step t, an edge $(i, i + 1)$ is chosen uniformly at random, and the two endpoints nodes update their weights as follows:

$$x_i(t+1) = x_{i+1}(t+1) = \frac{x_i(t) + x_{i+1}(t) + w(t)}{2}.$$

We will assume that the second moment of the distribution W is bounded. That is: $E[W^2] \leq M^2$, for some $M > 0$. For simplicity, we will assume that weights are normalized by M. This gives us that $\mathbb{E}[W^2] \leq 1$.

Let $X(t) = (x_1(t), x_2(t), ..., x_n(t))$ be the vector of the bin weights after t balls have been thrown. First, we define the following potential functions:

$$\forall k \in \{1, 2, \dots, n-1\} : \phi_k(t) := \sum_{i=1}^{n} (x_i(t) - x_{i+k}(t))^2.$$

Notice that for every $1 \leq i \leq n$, we have that $\phi_i(t) = \phi_{n-i}(t)$. We want to analyze what is the value of these functions in expectation after an additional ball is thrown, for a given load vector $X(t)$.

We start with $\phi_1(t+1)$:

$$\begin{aligned}\mathbb{E}[\phi_1(t+1)|X(t), w(t)] &= \sum_{i=1}^{n} \frac{1}{n}\Bigg(\Big(\frac{x_i(t) + x_{i+1}(t) + w(t)}{2} - x_{i+2}(t)\Big)^2 \\ &\quad + \Big(\frac{x_i(t) + x_{i+1}(t) + w(t)}{2} - x_{i-1}(t)\Big)^2 \\ &\quad + \sum_{j \neq i-1, i, i+1} (x_j(t) - x_{j+1}(t))^2\Bigg) \\ &= \frac{n-3}{n}\phi_1(t) + \frac{1}{2} + \frac{1}{2n}(\phi_1(t) + 2\phi_2(t)) \\ &= \frac{n-2}{n}\phi_1(t) + \frac{1}{2}(w(t)^2 - \frac{\phi_1(t)}{n}) + \frac{1}{n}\phi_2(t).\end{aligned}$$

Now, we proceed with calculating the expected value of $\phi_k(t+1)$, for $2 \leq k \leq \lfloor n/2 \rfloor$:

$$\begin{aligned}\mathbb{E}[\phi_k(t+1)|X_t, w(t)] &= \sum_{i=1}^{n} \frac{1}{n}\Bigg(\Big(\frac{x_i(t) + x_{i+1}(t) + w(t)}{2} - x_{i-k}(t)\Big)^2 \\ &\quad + \Big(\frac{x_i(t) + x_{i+1}(t) + w(t)}{2} - x_{i+1-k}(t)\Big)^2 \\ &\quad + \Big(\frac{x_i(t) + x_{i+1}(t) + w(t)}{2} - x_{i+k}(t)\Big)^2 \\ &\quad + \Big(\frac{x_i(t) + x_{i+1}(t) + w(t)}{2} - x_{i+1+k}(t)\Big)^2 \\ &\quad + \sum_{j \neq i-k, i+1-k, i+k, i+1+k} (x_j(t) - x_{j+k}(t))^2\Bigg) \\ &= \frac{n-2}{n}\phi_k(t) + (w(t)^2 - \frac{\phi_1(t)}{n}) + \frac{\phi_{k+1}(t)}{n} + \frac{\phi_{k-1}(t)}{n}.\end{aligned}$$

Note that in the above calculations for $\phi_1(t+1)$ and $\phi_k(t+1)$, for $k > 1$ the terms which contain $w(t)$ as linear multiplicative term disappear because we can assume that loads $x_1(t), x_2(t), ..., x_n(t)$ are normalized (this will not change our potentials) and we have:

$$\sum_{i=1}^{n} w(t)x_i(t) = 0. \tag{6}$$

If we remove conditioning on $w(t)$ and express these equations for $k = 1, 2, \dots, n-1$, we get:

$$\begin{cases} \mathbb{E}[\phi_1(t+1)|X(t)] = (\frac{n-2}{n})\phi_1(t) + \frac{1}{2}(\mathbb{E}[W^2] - \frac{\phi_1(t)}{n}) + \frac{\phi_2(t)}{n}. \\ \mathbb{E}[\phi_2(t+1)|X(t)] = (\frac{n-2}{n})\phi_2(t) + (\mathbb{E}[W^2] - \frac{\phi_1(t)}{n}) + \frac{\phi_1(t)}{n} + \frac{\phi_3(t)}{n}. \\ \dots \\ \mathbb{E}[\phi_{\lfloor \frac{n}{2} \rfloor}(t+1)|X(t)] = (\frac{n-2}{n})\phi_{\lfloor \frac{n}{2} \rfloor}(t) + (\mathbb{E}[W^2] - \frac{\phi_1(t)}{n}) \\ \qquad + \frac{\phi_{\lfloor \frac{n}{2} \rfloor - 1}(t)}{n} + \frac{\phi_{\lfloor \frac{n}{2} \rfloor + 1}(t)}{n}. \\ \dots \\ \mathbb{E}[\phi_{n-2}(t+1)|X(t)] = (\frac{n-2}{n})\phi_{n-2}(t) \\ \qquad + (\mathbb{E}[W^2] - \frac{\phi_1(t)}{n}) + \frac{\phi_{n-3}(t)}{n} + \frac{\phi_{n-1}(t)}{n}. \\ \mathbb{E}[\phi_{n-1}(t+1)|X(t)] = (\frac{n-2}{n})\phi_{n-1}(t) + \frac{1}{2}(\mathbb{E}[W^2] - \frac{\phi_1(t)}{n}) + \frac{\phi_{n-2}(t)}{n}. \end{cases}$$

Using the above equations we can prove the following:

▶ **Lemma 1.** *For every $t \geq 0$ and $1 \leq k \leq n-1$, we have that*

$$\mathbb{E}[\phi_k(t)] \leq (k(n-k)-1)\mathbb{E}[W^2] \leq k(n-k)-1. \tag{7}$$

Proof. Let $\Phi(t) = (\phi_1(t), \phi_2(t), ..., \phi_{n-1}(t))$ be the vector of values of our potentials at time step t and let $Y = (y_1, y_2, ..., y_{n-1})$, be the vector containing our desired upper bounds for each potential. That is: for each $1 \leq i \leq n-1$, we have that $y_i = (i(n-i)-1)\mathbb{E}[W^2]$. An interesting and easily checkable thing about the vector Y is that

$$\mathbb{E}[\Phi(t+1)|\Phi(t) = Y] = Y. \tag{8}$$

Next, consider the vector $Z(t) = (z_1(t), z_2(t), ...z_{n-1}(t)) = Y - \Phi(t)$. Our goal is to show that for every step t and coordinate i, $\mathbb{E}[z_i(t)] \geq 0$. we have that

$$\begin{aligned} \mathbb{E}[z_1(t+1)|X(t)] &= y_1 - \mathbb{E}[\phi_1(t+1)|X(t)] \\ &= (\frac{n-2}{n})y_1 + \frac{1}{2}(\mathbb{E}[W^2] - \frac{y_1}{n}) + \frac{y_2}{n} - \left((\frac{n-2}{n})\phi_1(t) + \frac{1}{2}(\mathbb{E}[W^2] - \frac{\phi_1(t)}{n}) + \frac{\phi_2(t)}{n} \right) \\ &= (\frac{n-2}{n})z_1(t) - \frac{z_1(t)}{2n} + \frac{z_2(t)}{n}. \end{aligned}$$

and for $2 \leq i \leq \lfloor \frac{n}{2} \rfloor$, we have that

$$\mathbb{E}[z_i(t+1)|X(t)] = (\frac{n-2}{n})z_i(t) - \frac{z_1(t)}{n} + \frac{z_{i-1}(t)}{n} + \frac{z_{i-1}(t)}{n}.$$

Hence we get the following equations(recall that $z_i(t) = z_{n-i}(t)$):

$$\begin{cases} n \times \mathbb{E}[z_1(t+1)|X(t)] = (n-2-\frac{1}{2})z_1(t) + z_2(t). \\ n \times \mathbb{E}[z_2(t+1)|X(t)] = -z_1(t) + z_1(t) + (n-2)z_2(t) + z_3(t). \\ n \times \mathbb{E}[z_3(t+1)|X(t)] = -z_1(t) + z_2(t) + (n-2)z_3(t) + z_4(t). \\ \dots \\ n \times \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+1)|X(t)] = -z_1(t) + z_{\lfloor \frac{n}{2} \rfloor - 1}(t) + (n-2)z_{\lfloor \frac{n}{2} \rfloor}(t) + z_{\lfloor \frac{n}{2} \rfloor + 1}(t). \end{cases} \tag{9}$$

Next, using induction on t, we show that for every $t \geq 0$

$$0 \leq \mathbb{E}[z_1(t)] \leq \mathbb{E}[z_2(t)] \leq ... \leq \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t)]. \tag{10}$$

The base case holds trivially since $Z(0) = Y$. For the induction step, assume that $0 \leq \mathbb{E}[z_1(t)] \leq \mathbb{E}[z_2(t)] \leq ... \leq \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t)]$. First, we have that

$$n\mathbb{E}[z_1(t+1)] = n\mathbb{E}_{X(t)}[\mathbb{E}[z_1(t+1)|X(t)]] = (n-2-\frac{1}{2})\mathbb{E}[z_1(t)] + \mathbb{E}[z_2(t)] \geq 0.$$

Additionally, we have that:

$$\begin{aligned} n\mathbb{E}[z_1(t+1)] &= (n-2-\frac{1}{2})\mathbb{E}[z_1(t)] + \mathbb{E}[z_2(t)] \leq (n-2)\mathbb{E}[z_1(t)] + \mathbb{E}[z_2(t)] \\ &\leq (n-2)\mathbb{E}[z_2(t)] + \mathbb{E}[z_3(t)] = n\mathbb{E}[z_2(t+1)]. \end{aligned}$$

For $2 \leq i \leq \lfloor \frac{n}{2} \rfloor - 2$, we have that

$$\begin{aligned} n\mathbb{E}[z_i(t+1)] &= -\mathbb{E}[z_1(t)] + \mathbb{E}[z_{i-1}(t)] + (n-2)\mathbb{E}[z_i(t)] + \mathbb{E}[z_{i+1}(t)] \\ &\leq -\mathbb{E}[z_1(t)] + \mathbb{E}[z_i(t)] + (n-2)\mathbb{E}[z_{i+1}(t)] + \mathbb{E}[z_{i+2}(t)] \\ &= n\mathbb{E}[z_{i+1}(t+1)]. \end{aligned}$$

Next, observe that by our assumption:
$\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor+1}(t)] = \mathbb{E}[z_{\lceil \frac{n}{2} \rceil-1}(t)] \geq \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-2}(t)]$. Finally, by using this observation we get that

$$\begin{aligned} &n\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-1}(t+1)] = -\mathbb{E}[z_1(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-2}(t)] + (n-2)\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-1}(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t)] \\ &\quad \leq -\mathbb{E}[z_1(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor+1}(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-1}(t)] + (n-3)\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-1}(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t)] \\ &\quad \leq -\mathbb{E}[z_1(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor+1}(t)] + \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor-1}(t)] + (n-2)\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t)] \\ &\quad = n\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+1)]. \end{aligned}$$

This completes the proof of the theorem. ◀

3 Upper Bound on the Gap for $n = 2^m$

In this section we upper bound a gap in expectation for $n = 2^m$ case. The proof for the general case is quite technical but not necessarily more interesting, and is provided in the Section 5.

We begin with some definitions. For a set $A \subseteq \{1, 2, \ldots, n\}$, let

$$Gap_A(t) = \max_{i \in A}(x_i(t)) - \min_{i \in A}(x_i(t)).$$

Also, let A_k^i be $\{i, i+2^k, i+2 \times 2^k, i+3 \times 2^k, \ldots\}$ (Notice that $i = i + 2^{m-k}2^k$). Our proof works as follows: for each $1 \leq i \leq n$ and $0 < k \leq m$, we look at the vertices given by the sets A_k^i and $A_k^{i+2^{k-1}}$ and try to characterise the gap after we merge those sets (Note that this will give us the gap for the set $A_{k-1}^i = A_k^i \cup A_k^{i+2^{k-1}}$). Using this result, we are able to show that $\sum_{i=1}^n Gap_{A_{k-1}^i}(t)$ is upper bounded by $\sum_{i=1}^n Gap_{A_k^i}(t)$ plus n times maximum load difference between vertices at hop distance 2^{k-1}. Next, we use 2^{k-1} hop distance potential $\phi_{2^{k-1}}(t)$ to upper bound maximum load between the vertices at hop distance 2^{k-1}. Using induction on k, we are able to upper bound $\sum_{i=1}^n Gap_{A_0^i}(t)$ in terms of $\sum_{i=1}^n Gap_{A_m^i}(t)$ and $\sum_{k=1}^m \phi_{2^{k-1}}(t)$. Notice that by our definitions, for each i, $Gap_{A_m^i}(t) = 0$ (A_i^m contains only vertex i) and $Gap_{A_0^i}(t) = Gap(t)$ (A_0^i contains all vertices). Hence, what is left is to use the upper bounds for the hop distance potentials, which we derived in the previous section.

We start by proving the following useful lemma.

▶ **Lemma 2.** *For any $1 \leq i \leq n$ and $k > 0$, we have that*

$$2Gap_{A^i_{k-1}}(t) \leq 2 \max_{j \in A^i_{k-1}} |x_j(t) - x_{j+2^{k-1}}(t)| + Gap_{A^{i+2^{k-1}}_k}(t) + Gap_{A^i_k}(t). \tag{11}$$

Proof. Fix vertex i. Note that $A^i_{k-1} = A^i_k \cup A^{i+2^{k-1}}_k$. Let $u = \arg\max_{j \in A^i_{k-1}} x_j(t)$ and let $v = \arg\min_{j \in A^i_{k-1}} x_j(t)$. We consider several cases on the membership of nodes u and v, and bound the gap in each one:

Case 1. $u \in A^i_k$ and $v \in A^i_k$. Then $Gap_{A^i_{k-1}}(t) = Gap_{A^i_k}(t)$ and we have that

$$\begin{aligned} Gap_{A^i_k}(t) &= |x_u(t) - x_v(t)| \\ &\leq |x_{u+2^{k-1}}(t) - x_u(t)| + |x_{v+2^{k-1}}(t) - x_v(t)| + |x_{u+2^{k-1}}(t) - x_{v+2^{k-1}}(t)| \\ &\leq |x_{u+2^{k-1}}(t) - x_u(t)| + |x_{v+2^{k-1}}(t) - x_v(t)| + Gap_{A^{i+2^{k-1}}_k}(t) \\ &\leq 2 \max_{j \in A^i_{k-1}} |x_j(t) - x_{j+2^{k-1}}(t)| + Gap_{A^{i+2^{k-1}}_k}(t). \end{aligned}$$

Where we used the fact that both $u + 2^{k-1}$ and $v + 2^{k-1}$ belong to $A^{i+2^{k-1}}_k$. This gives us that

$$2Gap_{A^i_{k-1}}(t) \leq 2 \max_{j \in A^i_{k-1}} |x_j(t) - x_{j+2^{k-1}}(t)| + Gap_{A^{i+2^{k-1}}_k}(t) + Gap_{A^i_k}(t). \tag{12}$$

Case 2. $u \in A^i_k$ and $v \in A^{i+2^{k-1}}_k$. Then we have that:

$$\begin{aligned} Gap_{A^i_{k-1}}(t) &= |x_u(t) - x_v(t)| \leq |x_u(t) - x_{v+2^{k-1}}(t)| + |x_{v+2^{k-1}}(t) - x_v(t)| \\ &\leq Gap_{A^i_k}(t) + \max_{j \in A^i_{k-1}} (|x_j(t) - x_{j+2^{k-1}}(t)|) \end{aligned}$$

and

$$\begin{aligned} Gap_{A^i_{k-1}}(t) &= |x_u(t) - x_v(t)| \leq |x_u(t) - x_{u+2^{k-1}}(t)| + |x_{u+2^{k-1}}(t) - x_v(t)| \\ &\leq Gap_{A^{i+2^{k-1}}_k}(t) + \max_{j \in A^i_{k-1}} (|x_j(t) - x_{j+2^{k-1}}(t)|) \end{aligned}$$

Where we used $v + 2^{k-1} \in A^k_i$ and $u + 2^{k-1} \in A^{i+2^{k-1}}_k$. Hence, we again get that

$$2Gap_{A^i_{k-1}}(t) \leq 2 \max_{j \in A^i_{k-1}} |x_j(t) - x_{j+2^{k-1}}(t)| + Gap_{A^{i+2^{k-1}}_k}(t) + Gap_{A^i_k}(t). \tag{13}$$

Case 3. $u \in A^{i+2^{k-1}}_k$ and $v \in A^{i+2^{k-1}}_k$, is similar to Case 1.

Case 4. $v \in A^i_k$ and $u \in A^{i+2^{k-1}}_k$, is similar to Case 2. ◀

Next, we upper bound the quantity $\sum_{i=1}^n \max_{j \in A^i_k} |x_j(t) - x_{j+2^k}(t)|$.

▶ **Lemma 3.**

$$\sum_{i=1}^{n} \max_{j \in A^i_k} |x_j(t) - x_{j+2^k}(t)| \leq \frac{n}{\sqrt{2^k}} \sqrt{\phi_{2^k}(t)}. \tag{14}$$

Proof. Notice that for any i and $i' \in A_k^i$, we have that $A_k^i = A_k^{i'}$, hence $\max_{j \in A_k^i} |x_j(t) - x_{j+2^k}(t)| = \max_{j \in A_k^i} |x_j(t) - x_{j+2^k}(t)|$ and this means that

$$\sum_{i=1}^{n} \max_{j \in A_k^i} |x_j(t) - x_{j+2^k}(t)| = \frac{n}{2^k} \sum_{i=1}^{2^k} \max_{j \in A_k^i} |x_j(t) - x_{j+2^k}(t)|$$
$$\leq \frac{n}{2^k} \sqrt{2^k} \sqrt{\sum_{i=1}^{2^k} \max_{j \in A_k^i} |x_j(t) - x_{j+2^k}(t)|^2}$$
$$\leq \frac{n}{2^k} \sqrt{2^k} \sqrt{\sum_{j=1}^{n} |x_j(t) - x_{j+2^k}(t)|^2} = \frac{n}{\sqrt{2^k}} \sqrt{\phi_{2^k}(t)}$$

Where we used a fact that sets $A_k^1, A_k^2, ..., A_k^{2^k}$ are disjoint. ◀

Finally, using the two Lemmas above and Theorem 1 we can upper bound the expected gap at step t:

▶ **Theorem 4.** *For every $t \geq 0$, we have that*

$$\mathbb{E}[Gap(t)] = O(\sqrt{n} \log(n)).$$

Proof. From Lemma 2 we have that

$$\sum_{i=1}^{n} 2Gap_{A_{k-1}^i(t)} \leq \sum_{i=1}^{n} Gap_{A_k^i}(t) + \sum_{i=1}^{n} Gap_{A_k^{i+2^{k-1}}}(t)$$
$$+ \sum_{i=1}^{n} 2 \max_{j \in A_{k-1}^i} |x_j(t) - x_{j+2^{k-1}}(t)|$$
$$= 2\sum_{i=1}^{n} Gap_{A_k^i}(t) + 2\sum_{i=1}^{n} \max_{j \in A_{k-1}^i} |x_j(t) - x_{j+2^{k-1}}(t)|.$$

After dividing the above inequality by 2 and applying Lemma 3 we get that:

$$\sum_{i=1}^{n} Gap_{A_{k-1}^i}(t) \leq \sum_{i=1}^{n} Gap_{A_k^i}(t) + \frac{n}{\sqrt{2^{k-1}}} \sqrt{\phi_{2^{k-1}}(t)}.$$

Notice that $\sum_{i=1}^{n} Gap_0^i(t) = nGap(t)$ and we also have that

$$\sum_{i=1}^{n} Gap_{\frac{n}{2}}^i(t) = \sum_{i=1}^{n} |x_i(t) - x_{i+\frac{n}{2}}(t)| \leq \sqrt{n} \sqrt{\sum_{i=1}^{n} |x_i(t) - x_{i+\frac{n}{2}}(t)|^2} = \sqrt{n} \sqrt{\phi_{\frac{n}{2}}(t)}$$

Hence, we get that

$$nGap(t) = \sum_{i=1}^{n} Gap_0^i(t) \leq \sum_{i=1}^{n} Gap_{\frac{n}{2}}^i(t) + \sum_{k=1}^{m-1} \frac{n}{\sqrt{2^{k-1}}} \sqrt{\phi_{2^{k-1}}(t)}$$
$$\leq \sqrt{n} \sqrt{\phi_{\frac{n}{2}}(t)} + \sum_{k=1}^{m-1} \frac{n}{\sqrt{2^{k-1}}} \sqrt{\phi_{2^{k-1}}(t)}.$$

Next, we apply Jensen and Theorem 1:

$$\begin{aligned}
n\mathbb{E}[Gap(t)] &\leq \sqrt{n}\mathbb{E}\sqrt{\phi_{\frac{n}{2}}(t)} + \sum_{k=1}^{m-1} \frac{n}{\sqrt{2^{k-1}}}\mathbb{E}\sqrt{\phi_{2^{k-1}}(t)} \\
&\leq \sqrt{n}\sqrt{\mathbb{E}[\phi_{\frac{n}{2}}(t)]} + \sum_{k=1}^{m-1} \frac{n}{\sqrt{2^{k-1}}}\sqrt{\mathbb{E}[\phi_{2^{k-1}}(t)]} \\
&\leq \sqrt{n}\sqrt{\left(\frac{n}{2}\right)^2} + \sum_{k=1}^{m-1} \frac{n}{\sqrt{2^{k-1}}}\sqrt{2^{k-1}(n-2^{k-1})} \\
&\leq mn\sqrt{n} = n(\log n)\sqrt{n}.
\end{aligned}$$

This gives us the proof of the theorem. ◀

4 Gap Lower Bound

Next we prove the following theorem, which provides strong evidence that our bound on the gap is tight within a logarithmic factor.

▶ **Theorem 5.** *The following limit holds:*

$$\lim_{t\to\infty} \mathbb{E}[Gap(t)^2] = \Omega(n\mathbb{E}[W^2])).$$

Proof. In this case we want to prove that not only does vector $Z(t)$ have positive coordinates in expectation, but also $\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}]$ converges to 0 . This will give us that $\phi_{\lfloor\frac{n}{2}\rfloor}$ approaches it's upper bound $(\lfloor\frac{n}{2}\rfloor\lceil\frac{n}{2}\rceil - 1)\mathbb{E}[W^2]$ in expectation. Then, we can show that there exist two nodes(At distance $\lfloor\frac{n}{2}\rfloor$) such that the expected square of difference between their loads is $\Omega(n\mathbb{E}[w^2])$.

Recall from Equations 9 that

$$n\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor(t+1)}] = -\mathbb{E}[z_1(t)] + \mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor+1}(t)] + \mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor-1}(t)] + (n-2)\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}(t)].$$

We also know that Inequalities 10 hold for every t, hence we get that

$$\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor(t+1)}] \leq \mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor(t)}] - \frac{\mathbb{E}[z_1(t)]}{n}.$$

The above inequality in combination with Inequalities 10 means that

$$\begin{aligned}
\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}(t+\lfloor\frac{n}{2}\rfloor+1)] &\leq \mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}(t+1)] - \sum_{i=t}^{t+\lfloor\frac{n}{2}\rfloor}\frac{\mathbb{E}[z_1(i)]}{n} &\quad (15)\\
&\leq \mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}(t+1)] - \frac{\mathbb{E}[z_1(t+\lfloor\frac{n}{2}\rfloor)]}{n} &\quad (16)
\end{aligned}$$

Again by using Equations 9 and Inequalities 10, we can show that for every $1 \leq i \leq \lfloor\frac{n}{2}\rfloor - 1$:

$$\mathbb{E}[z_i(t+1)] \geq \frac{\mathbb{E}[z_{i+1}(t)]}{n}.$$

This gives us that:

$$\begin{aligned}
\mathbb{E}[z_1(t+\lfloor\frac{n}{2}\rfloor)] &\geq \left(\frac{1}{n}\right)\mathbb{E}[z_2(t+\lfloor\frac{n}{2}\rfloor-1)] \geq \left(\frac{1}{n}\right)^2\mathbb{E}[z_3(t+\lfloor\frac{n}{2}\rfloor-2)] \\
&\geq \dots \\
&\geq \left(\frac{1}{n}\right)^{\lfloor\frac{n}{2}\rfloor-1}\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}(t+\lfloor\frac{n}{2}\rfloor-(\lfloor\frac{n}{2}\rfloor-1))] = \left(\frac{1}{n}\right)^{\lfloor\frac{n}{2}\rfloor-1}\mathbb{E}[z_{\lfloor\frac{n}{2}\rfloor}(t+1)].
\end{aligned}$$

By plugging the above inequality in inequality 15 we get that

$$\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+\lfloor \frac{n}{2} \rfloor+1)] \le \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+1)] - \frac{\mathbb{E}[z_1(t+\lfloor \frac{n}{2} \rfloor)]}{n}$$

$$\le \mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+1)] - \left(\frac{1}{n}\right)^{\lfloor \frac{n}{2} \rfloor-1}\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+1)] = \left(1-\left(\frac{1}{n}\right)^{\lfloor \frac{n}{2} \rfloor-1}\right)\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t+1)]$$

Because $\left(1-\left(\frac{1}{n}\right)^{\lfloor \frac{n}{2} \rfloor-1}\right) < 1$ and does not depend on t, we get that $\lim_{t\to\infty}\mathbb{E}[z_{\lfloor \frac{n}{2} \rfloor}(t)] = 0$..
This means that $\lim_{t\to\infty}\mathbb{E}[\phi_{\lfloor \frac{n}{2} \rfloor}(t)] = \Omega(n^2\mathbb{E}[W^2])$.
Let $Gap_{\lfloor \frac{n}{2} \rfloor}(t) = \max_{1\le i\le n}|x_i(t) - x_{i+\lfloor \frac{n}{2} \rfloor}(t)|$. Note that:
$Gap(t)^2 \ge Gap_{\lfloor \frac{n}{2} \rfloor}(t)^2 \ge \frac{\phi_{\lfloor \frac{n}{2} \rfloor}(t)}{n}$. Hence $\lim_{t\to\infty}\mathbb{E}[Gap(t)^2] = \Omega(n\mathbb{E}[W^2])$.

Unfortunately we are not able to obtain the lower bound on the gap, since our approach uses the fact that the upper bounds on k-hop potentials are 'tight'. Since our potentials are quadratic, we are not able to derive any kind of lower on for the gap itself. Intuitively, this will be an issue with any argument which uses convex potential. ◀

5 Upper Bound on the Gap, General Case

To prove the Theorem 4 for the general case, we need to redefine our sets A_i^k. In order to do this, for each k we define 2^k dimensional vector $\Delta_k = (\delta_k^1, \delta_k^2, ..., \delta_k^{2^k})$. For $k = 0$, we have that $\Delta_k = (n)$. For $\lfloor \log n \rfloor \ge k > 0$ we set $\Delta_k = (\alpha_k, \delta_{k-1}^1 - \alpha_k, \alpha_k, \delta_{k-1}^2 - \alpha_k, ..., \alpha_k, \delta_{k-1}^{2^{k-1}} - \alpha_k)$.

Where,

$$\alpha_k = \begin{cases} \lfloor \frac{n}{2^{k-1}} \rfloor/2, & \text{if } \lfloor \frac{n}{2^{k-1}} \rfloor \text{ is even.} \\ \left\lfloor \lceil \frac{n}{2^{k-1}} \rceil/2 \right\rfloor, & \text{otherwise.} \end{cases}$$

First we prove the following lemma:

▶ **Lemma 6.** *For any $\lfloor \log n \rfloor \ge k > 0$, we have that*
(1) $\sum_{i=1}^{2^k} \delta_k^i = n$.
(2) *For any $1 \le i \le 2^k$, $\delta_k^i \in \{\lceil \frac{n}{2^k} \rceil \lfloor \frac{n}{2^k} \rfloor\}$ (Notice that this means $\alpha_k = \lfloor \frac{n}{2^k} \rfloor$ or $\alpha_k = \lceil \frac{n}{2^k} \rceil$).*

Proof. We prove the lemma using induction on k. Base case $k = 0$ holds trivially. For the induction step, assume that Properties 1 and 2 hold for $k-1$, we aim to prove that they hold for k as well. We have that $\sum_{i=1}^{2^k} \delta_k^i = \sum_{i=1}^{2^{k-1}} (\alpha_k + \delta_{k-1}^i - \alpha_k) = \sum_{i=1}^{2^{k-1}} \delta_{k-1}^i = n$. To prove Property 2 we consider several cases:

Case 1. $\frac{n}{2^{k-1}} = 2q$, for some integer q.
We have that $\alpha_k = q$, and hence for any $1 \le i \le 2^{k-1}$, $\delta_{k-1}^i - \alpha_k = q$. Since $\lfloor \frac{n}{2^k} \rfloor = q$, Property 2 holds.

Case 2. $\frac{n}{2^{k-1}} = 2q + 1$, for some integer q.
We have that $\alpha_k = q$, and hence for any $1 \le i \le 2^{k-1}$, $\delta_{k-1}^i - \alpha_k = q + 1$. Since $\lfloor \frac{n}{2^k} \rfloor = q$ and $\lceil \frac{n}{2^k} \rceil = q + 1$, Property 2 holds.

Case 3. $\frac{n}{2^{k-1}} = 2q + \epsilon$, for some integer q and $0 < \epsilon < 1$.
We have that $\lfloor \frac{n}{2^{k-1}} \rfloor = 2q$ and $\lceil \frac{n}{2^{k-1}} \rceil = 2q + 1$. Additionally, $\alpha_k = q$, and hence for any $1 \le i \le 2^{k-1}$, $(\delta_{k-1}^i - \alpha_k) \in \{q, q+1\}$. Since $\lfloor \frac{n}{2^k} \rfloor = q$ and $\lceil \frac{n}{2^k} \rceil = q + 1$, Property 2 holds.

Case 4. $\frac{n}{2^{k-1}} = 2q + 1 + \epsilon$, for some integer q and $0 < \epsilon < 1$.
We have that $\lfloor \frac{n}{2^{k-1}} \rfloor = 2q + 1$ and $\lceil \frac{n}{2^{k-1}} \rceil = 2q + 2$. Additionally, $\alpha_k = q + 1$, and hence for any $1 \le i \le 2^{k-1}$, $(\delta_{k-1}^i - \alpha_k) \in \{q, q+1\}$. Since $\lfloor \frac{n}{2^k} \rfloor = q$ and $\lceil \frac{n}{2^k} \rceil = q + 1$, Property 2 holds. ◀

Next, for $\lfloor \log n \rfloor \geq k > 0$ we set

$$A_i^k = \{i, i + \delta_k^1, i + \delta_k^1 + \delta_k^2, ..., i + \sum_{j=1}^{2^k - 1} \delta_k^j\}.$$

It is easy to see that for any $\lfloor \log n \rfloor \geq k > 0$ and i, we have that $|A_k^i| = 2^k$, $A_k^i = A_{k-1}^i \cup A_{k-1}^{i+\alpha_k}$ and $A_{k-1}^i \cap A_{k-1}^{i+\alpha_k} = \emptyset$. Also notice that for any $u \in A_{k-1}^i$, there exists $v \in A_{k-1}^{i+\alpha_k}$, such that $u + \alpha_k = v$ or $v + \alpha_k = u$ (For any $u \in A_{k-1}^{i+\alpha_k}$ there exists $v \in A_{k-1}^i$ with the same property).

Next we prove the lemma which is similar to the lemma for $n = 2^m$ case:

▶ **Lemma 7.** *For any $1 \leq i \leq n$ and $\lfloor \log n \rfloor \geq k > 0$, we have that*

$$2Gap_{A_k^i}(t) \leq 2 \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| + Gap_{A_{k-1}^{i+\alpha_k}}(t) + Gap_{A_{k-1}^i}(t). \tag{17}$$

Proof. Let $u = \arg\max_{j \in A_{k-1}^i} x_j(t)$ and let $v = \arg\min_{j \in A_{k-1}^i} x_j(t)$. We consider several cases:

Case 1. $u \in A_{k-1}^i$ and $v \in A_{k-1}^i$. Notice that in this case $Gap_{A_{k-1}^i}(t) = Gap_{A_k^i}(t)$. Let $u' \in A_{k-1}^{i+\alpha_k}$ be the vertex such that $u + \alpha_k = u'$ or $u' + \alpha_k = u$ and let $v' \in A_{k-1}^{i+\alpha_k}$ be the vertex such that $v + \alpha_k = v'$ or $v' + \alpha_k = v$. We have that

$$\begin{aligned} Gap_{A_k^i}(t) &= |x_u(t) - x_v(t)| \\ &\leq |x_{u'}(t) - x_u(t)| + |x_{v'}(t) - x_v(t)| + |x_{u'}(t) - x_{v'}(t)| \\ &\leq |x_{u'}(t) - x_u(t)| + |x_{v'} - x_v(t)| + Gap_{A_{k-1}^{i+\alpha_k}}(t) \\ &\leq 2 \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| + Gap_{A_{k-1}^{i+2^{k-1}}}(t). \end{aligned}$$

This gives us that

$$2Gap_{A_k^i}(t) \leq 2 \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| + Gap_{A_{k-1}^{i+\alpha_k}}(t) + Gap_{A_{k-1}^i}(t). \tag{18}$$

Case 2. $u \in A_{k-1}^i$ and $v \in A_{k-1}^{i+\alpha_k}$. Let $u' \in A_{k-1}^{i+\alpha_k}$ be the vertex such that $u + \alpha_k = u'$ or $u' + \alpha_k = u$ and let $v' \in A_{k-1}^i$ be the vertex such that $v + \alpha_k = v'$ or $v' + \alpha_k = v$. We have that:

$$\begin{aligned} Gap_{A_k^i}(t) = |x_u(t) - x_v(t)| &\leq |x_u(t) - x_{v'}(t)| + |x_{v'}(t) - x_v(t)| \\ &\leq Gap_{A_{k-1}^i}(t) + \max_{j \in A_k^i}(|x_j(t) - x_{j+\alpha_k}(t)|) \end{aligned}$$

and

$$\begin{aligned} Gap_{A_k^i}(t) = |x_u(t) - x_v(t)| &\leq |x_u(t) - x_{u'}(t)| + |x_{u'}(t) - x_v(t)| \\ &\leq Gap_{A_{k-1}^{i+\alpha_k}}(t) + \max_{j \in A_k^i}(|x_j(t) - x_{j+\alpha_k}(t)|) \end{aligned}$$

Hence, we again get that

$$2Gap_{A_k^i}(t) \leq 2 \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| + Gap_{A_{k-1}^{i+\alpha_k}}(t) + Gap_{A_{k-1}^i}(t). \tag{19}$$

Case 3. $u \in A_{k-1}^{i+\alpha_k}$ and $v \in A_{k-1}^{i+\alpha_k}$, is similar to Case 1.

Case 4. $v \in A_{k-1}^i$ and $u \in A_{k-1}^{i+\alpha_k}$, is similar to Case 2. ◀

Next, we upper bound $\sum_{i=1}^{n} \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)|$.

▶ **Lemma 8.**

$$\sum_{i=1}^{n} \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| \leq \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\phi_{\alpha_k}(t)} \tag{20}$$

Proof. Notice that for any $1 \leq u \leq n$ and sets $A_k^u, A_k^{u+1}, ..., A_k^{u+\lfloor \frac{n}{2^k} \rfloor - 1}$ are disjoint, because for any $1 \leq j \leq 2^k$, $\delta_k^j \geq \lfloor \frac{n}{2^k} \rfloor$ (This means that for any $1 \leq i \leq n$, distances between consecutive vertices in A_k^i are at least $\lfloor \frac{n}{2^k} \rfloor$). Using this fact and Cauchy-Schwarz inequality we get that

$$\begin{aligned}
&\sum_{i=u}^{u+\lfloor \frac{n}{2^k} \rfloor - 1} \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| \\
&\leq \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\sum_{i=u}^{u+\lfloor \frac{n}{2^k} \rfloor - 1} \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)|^2} \\
&\leq \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\sum_{j=1}^{n} |x_j(t) - x_{j+\alpha_k}(t)|^2} = \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\phi_{\alpha_k}(t)}
\end{aligned}$$

Since the above inequality holds for any u we can write that:

$$\sum_{i=1}^{n} \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| \leq \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\phi_{\alpha_k}(t)} \tag{21}$$

◀

With the above lemmas in place, we are ready to prove Theorem 4 for general n.

From Lemma 7 we have that

$$\begin{aligned}
\sum_{i=1}^{n} 2Gap_{A_k^i(t)} \leq \sum_{i=1}^{n} Gap_{A_{k-1}^i}(t) + \sum_{i=1}^{n} Gap_{A_{k-1}^{i+\alpha_k}}(t) \\
+ \sum_{i=1}^{n} 2 \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)| \\
= 2\sum_{i=1}^{n} Gap_{A_{k-1}^i}(t) + 2\sum_{i=1}^{n} \max_{j \in A_k^i} |x_j(t) - x_{j+\alpha_k}(t)|.
\end{aligned}$$

After dividing the above inequality by 2 and applying Lemma 8: we get that:

$$\sum_{i=1}^{n} Gap_{A_k^i}(t) \leq \sum_{i=1}^{n} Gap_{A_{k-1}^i}(t) + \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\phi_{\alpha_k}(t)}.$$

Notice that for any i, $Gap_0^i(t) = 0$. Hence, we get that

$$\sum_{i=1}^{n} Gap_{A_{\lfloor \log n \rfloor}^i}(t) \leq \sum_{k=1}^{\lfloor \log n \rfloor} \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\phi_{\alpha_k}(t)}.$$

Let $i' = \arg\min_i Gap_{A^i_{\lfloor \log n \rfloor}}(t)$. Notice that consecutive vertices in $A^{i'}_{\lfloor \log n \rfloor}$ are 1 or 2 edges apart, hence for any $1 \le i \le n$, either $i \in A^{i'}_{\lfloor \log n \rfloor}$ or $i + 1 \in A^{i'}_{\lfloor \log n \rfloor}$. This gives us that

$$\begin{aligned} Gap(t) &\le Gap_{A^{i'}_{\lfloor \log n \rfloor}}(t) + \max_i |x_i(t) - x_{i+1}(t)| \\ &= Gap_{A^{i'}_{\lfloor \log n \rfloor}}(t) + \sqrt{\max_i |x_i(t) - x_{i+1}(t)|^2} \le Gap_{A^{i'}_{\lfloor \log n \rfloor}}(t) + \sqrt{\phi_1(t)}. \end{aligned}$$

By combining the above two inequalities we get that

$$\begin{aligned} nGap(t) &\le nGap_{A^{i'}_{\lfloor \log n \rfloor}}(t) + n\sqrt{\phi_1(t)} \le \sum_{i=1}^{n} Gap_{A^{i}_{\lfloor \log n \rfloor}}(t) + n\sqrt{\phi_1(t)} \\ &\le \sum_{k=1}^{\lfloor \log n \rfloor} \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\phi_{\alpha_k}(t)} + n\sqrt{\phi_1(t)}. \end{aligned}$$

Next, we apply Jensen's inequality and Lemma 1 (We are going to use a looser upper bound: $\mathbb{E}[\phi_i(t)] \le i(n-i) - 1 \le in$)

$$\begin{aligned} n\mathbb{E}[Gap(t)] &\le n\mathbb{E}\sqrt{[\phi_1(t)]} + \sum_{k=1}^{\lfloor \log n \rfloor} \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \mathbb{E}\sqrt{\phi_{\alpha_k}(t)} \\ &\le n\sqrt{\mathbb{E}[\phi_1(t)]} + \sum_{k=1}^{\lfloor \log n \rfloor} \left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\mathbb{E}[\phi_{\alpha_k}(t)]} \\ &\le n\sqrt{n} + \sum_{k=1}^{\lfloor \log n \rfloor} \Bigg(\left\lceil \frac{n}{\lfloor \frac{n}{2^k} \rfloor} \right\rceil \sqrt{\lfloor \frac{n}{2^k} \rfloor} \sqrt{\alpha_k n} = O(n\sqrt{n}\log n). \end{aligned}$$

This completes the proof.

6 Experimental Validation

On the practical side, we implemented our load balancing algorithm with unit weight increments on a cycle. The results confirm our hypothesis that the gap is of order $\Theta(\sqrt{n})$. In Figure 1 we ran our experiment 100 times and calculated average gap over the all runs. x-axis shows number of balls thrown(which is the same as the number of increments) and y-axis is current average gap divided by $\sqrt{n}$. The experiment shows that once the number of thrown balls is large enough, the gap stays between $\sqrt{n}$ and $1.4\sqrt{n}$.

7 Discussion and Future Work

We have shown that in the case of dynamic averaging on a cycle the gap between highest and lowest loaded bins is upper bounded by $O(\sqrt{n}\log n)$ in expectation. Additionally we showed that the expected square of the gap is lower bounded by $\Omega(n)$. It the future, it would be interesting to further tighten our results, matching our experimental analysis. We conjecture that the "correct" bound on the expected gap is of $\Theta(\sqrt{n})$. As already discussed, we also plan to extend our results to more general graph families, in particular grid graphs.

Comparison of two-choice and averaging load balancing. Finally, it is interesting to ask if it possible to extend our gap bounds in the case of the classic two-choice load balancing process. In particular, it is possible to show that the gap in the case of averaging process is

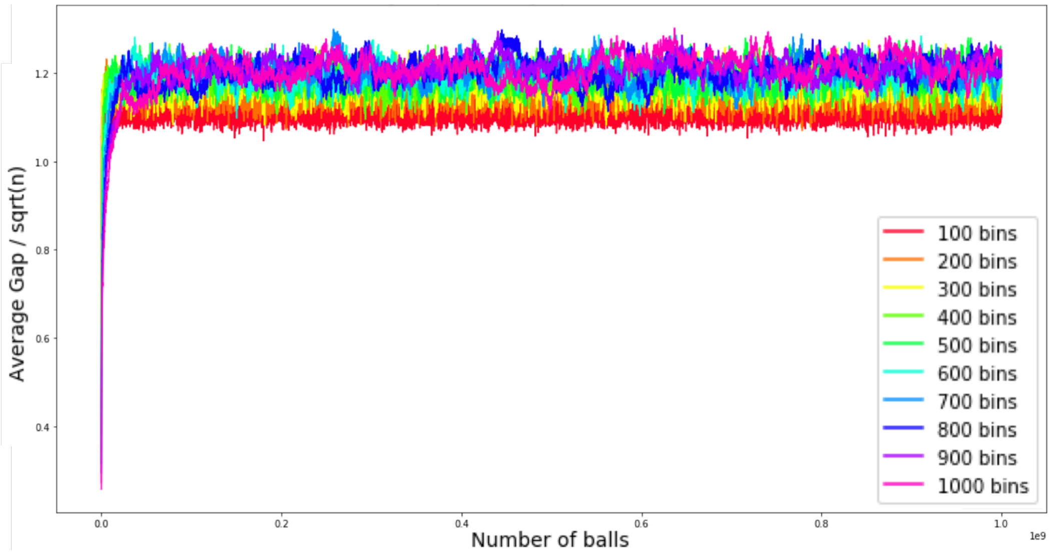

Figure 1 The evolution of average gap divided by square root of n, where n is the number of bins.

always smaller in expectation than the gap in the case of two choice process? Intuitively this should be the case, since the load balancing operation in the case of averaging can be viewed as picking up a random edge, incrementing the load of the less loaded endpoint, and then averaging the values. The extra averaging step should not make the gap larger. Indeed, the exponential potential used to analyse the gap in [10] can be used to upper bound the gap for averaging, since the exponential function is convex and averaging values does not increase it (by Jensen's inequality).

Unfortunately, it is not clear if averaging helps to actually *decrease* the exponential potential. Additionally, this argument shows that averaging does not make the gap worse if applied to the particular technique of upper bounding the gap, and it is not clear if the gap itself is actually smaller, if we use averaging on top of the two-choice process. We conjecture that there exists a majorization argument which is based on *how often* the process performs the averaging step. More precisely, we consider the setting where after the increment step (using two choice), we perform averaging with probability β. The gap should decrease in expectation as we increase β. Note that the only result which lower bounds the gap for the two-choice process on the cycle is the straightforward $\Omega(\log n)$ lower bound which can be shown for the clique [10]; so what makes the existence of the majorization argument interesting is that it would allow us to show that the lower bound we derived on the second moment of the gap while always performing averaging step on the cycle ($\beta = 1$) can be automatically used as the lower bound on the gap for two choice on the cycle ($\beta = 0$). We plan to investigate this connection in future work.

Abstract

We study information aggregation in networks where agents make binary decisions (labeled incorrect or correct). Agents initially form independent private beliefs about the better decision, which is correct with probability $1/2 + \delta$. The dynamics we consider are asynchronous (each round, a single agent updates their announced decision) and non-Bayesian (agents simply copy the majority announcements among their neighbors, tie-breaking in favor of their private signal).

Our main result proves that when the network is a tree formed according to the preferential attachment model [5], with high probability, the process stabilizes in a correct majority within $O(n \log n / \log \log n)$ rounds. We extend our results to other tree structures, including balanced M-ary trees for any M.

1 Introduction

Individuals form opinions about the world both through private investigation and through discussion with one-another. A citizen, trying to decide which candidate's economic policies will lead to more jobs, might form an initial belief based on her own employment history. However, her stated opinion might be swayed by the opinions of her friends. The dynamics of this process, together with the social network structure of the individuals, can result in a variety of societal outcomes. Even if individuals are well-informed, i.e., are more likely to have correct than incorrect initial beliefs, certain dynamics and/or network structures can cause large portions of the population to form mistaken opinions.

A substantial body of work exists modeling these dynamics mathematically, which we overview in Section 1.2. This paper focuses on the model of *asynchronous majority dynamics*. Initially, individuals have private beliefs over a binary state of the world, but no publicly stated opinion. Initial beliefs are independent: Correct with probability $1/2 + \delta$, and Incorrect with probability $1/2 - \delta$. In each time step, a random individual is selected to announce a public opinion. Each time an individual announces a public opinion, they simply copy the majority of their neighbors' announcements, tie-breaking in favor of their private belief. This is clearly naive: a true Bayesian would reason about the redundancy of information among the opinions of her friends, for example. Majority (or other non-Bayesian) dynamics are generally considered a more faithful model of agents with bounded rationality (e.g. voters), whereas Bayesian dynamics are generally considered a more faithful model of fully rational actors (e.g. financial traders). We consider asynchronous announcements[1] which are a more faithful model of human decisions (e.g. citizens deciding which candidate is better).

It's initially tempting to conjecture that these dynamics in a connected network should result in a Correct consensus; after all, the majority is initially Correct (with high probability) by assumption. Nonetheless, it's well-understood that individuals can fail miserably to learn. Suppose for instance that the individuals form a complete graph. Then in asynchronous majority dynamics, whichever individual is selected to announce first will have their opinion copied by the entire network. As this opinion is Incorrect with constant probability, there's a good chance that the entire network makes the wrong decision (this is known as an *information cascade*, and is not unique to asynchonous majority dynamics [4, 7]). So the overarching goal in these works is to understand in *which* graphs the dynamics stabilize in correctness with high probability.

For most previously studied dynamics (discussed in Section 1.2), "correctness" means a Correct consensus. This is because the models terminate in a consensus with probability 1, and the only question is whether this consensus is correct or not. With majority dynamics, it is certainly possible that the process stabilizes without a consensus. To see this, suppose individuals form a line graph. In this case, two adjacent individuals with the same initial belief are likely to form a "road block" (if both announce before their other neighbors), sticking to their initial beliefs throughout the process. In this case, with high probability a constant fraction of individuals terminate with a Correct opinion, but also a constant fraction terminate with an Incorrect opinion. As consensus is no longer guaranteed, we're instead interested in understanding network structures for which the dynamics converge, with high probability, to a *majority* of nodes having the Correct opinion (i.e., if a majority vote were to be taken, would it be correct w.h.p.?).

Prior work shows that, to reach a Correct consensus, it's sufficient for the social network to be sparse (every individual has only a constant number of neighbors) and expansive (every group of individuals have many friends outside the group) [12], and the tools developed indeed make strong use of both assumptions. Many networks of interest, however, like the hierarchy of employees in a corporation, are neither sparse nor expansive. Therefore, the focus of this paper is to push beyond these assumptions and develop tools for more general graphs.

[1] Unlike synchronous models where all agents announce simultaneously.

1.1 Our Results and Techniques

We focus our attention on trees, the simplest graphs outside the reach of prior techniques. In addition to modeling certain types of social networks (including hierarchical ones, or communication networks in which redundancy is expensive), and forming the backbone of many more, trees already present a number of technical challenges whose absence enabled the prior results. We study preferential attachment trees, which are well-studied graphs with rich structure[2]. Our main result is the following:

▶ **Theorem 1.** *Let G be a tree. Then with probability $1 - o(1)$*[3]*, asynchronous majority dynamics in G stabilizes in a* Correct *majority if:*

- *G is formed according to the preferential attachment model.*[4]
- *G is a balanced, M-ary tree of any degree.*[5]

Beyond Prior Tools

In prior work [12], the authors have two key ideas. Without yet getting into full details, one key idea crucially invokes sparsity to claim that most pairs of nodes u, v have distance $d(u, v) = \Omega(\ln n/\ln \ln n)$, which allows them to conclude that after $O(n \ln n/\ln \ln n)$ steps, most nodes are announcing a Correct opinion.

Still, just the fact that the dynamics hit a Correct majority along the way does not imply that the Correct majority will hold thru termination. To wrap up, they crucially invoke expansiveness (building off an argument of [24]) to claim that once there is a Correct majority, it spreads to a Correct consensus with high probability.

Both properties are necessary for prior work, and both properties fail in trees. For instance, the star graph is a tree, but $d(u, v) \leq 2$ for all u, v (precluding their "majority at $O(n \ln n/\ln \ln n)$" argument). Additionally, trees are not expansive. In particular, the line graph discussed earlier is a tree which hits a Correct majority at some point (as this tree happens to be sparse), but does not converge to consensus, so there is no hope for an argument like this. However, we believe that the process stabilizes in a correct majority in all trees.

▶ **Conjecture.** *Let G be any tree. Then the asynchronous majority dynamics stabilizes in a* Correct *majority with probability $1 - o(1)$.*

New Tools

Our main technical innovation is an approach to reason about majority without going through consensus. Specifically, we show in Sections 5 and 6 for preferential attachment trees, or balanced M-ary trees, that with probability $1 - o(1)$, a $1 - o(1)$ fraction of nodes have *finalized* after $O(n \ln n/\ln \ln n)$ steps. That is, after $O(n \ln n/\ln \ln n)$ steps, most (but not all) of the network has stabilized. The main barrier to extending our results to general trees is Section 5, as we require additional structure on the graphs to prove that the process stabilizes quickly. We postpone further details to Section 5, but just wish to highlight this approach as a fairly significant deviation from prior work.

[2] The more general preferential attachment graphs are a popular model of real networks.

[3] As $n \to \infty$ the probability converges to 1, where n is the number of nodes in G.

[4] That is, G is created by adding nodes one at a time. When a node is added, it attaches a single edge to a random previous node, selected proportional to its degree.

[5] That is, G can be rooted at some node v. All non-leaf nodes have M children, and all leaves have the same distance to v.

From here, our task is now reduced to showing that a Correct majority exists w.h.p. after $O(n \ln n / \ln \ln n)$ steps. Our main insight here is that most nodes with $d(u,v) = O(\ln n / \ln \ln n)$ must have some high-degree nodes along the path from u to v. We prove that such nodes act like a "road block," causing announcements on either side to be independent with high probability (and all nodes with $d(u,v) = \Omega(\ln n / \ln \ln n)$ can be handled with similar arguments to prior work).

1.2 Related Work

Information aggregation in social networks is an enormous field, and we will not come close to overviewing it in its entirety. Below, we'll briefly summarize the most related literature, restricting attention to works that consider two states of the world and independent initial beliefs are independently Correct with probability $1/2 + \delta$.

Bayesian Dynamics

In Bayesian models, agents are fully rational and sequentially perform Bayesian updates to their public opinion based on the public opinions of their neighbors. Seminal works of Banerjee [4] and Bikchandani, Hirshleifer, and Welch [7] first identified the potential of information cascades in this model. Subsequent works consider numerous variations, aiming to understand what assumptions on the underlying network or information structure results in Correct consensus [28, 3, 2]. Many other works studied repeated interactions of Bayesian agents in Social Networks [13, 27, 20, 26, 25, 23]. While the high-level goals of these works align with ours, technically they are mostly unrelated as we consider non-Bayesian dynamics.

Voter and DeGroot Dynamics

Prior work also considered other non-Bayesian dynamics. In voter dynamics, individuals update by copying a random neighbor [10, 18]. Similar dynamics (such as 3-majority, or k-majority) are analyzed from a distributed computing perspective with an emphasis on the rate of convergence to consensus [6, 15, 14]. In the DeGroot model, individuals announce an opinion in $[0,1]$ (as opposed to $\{0,1\}$), and update by averaging their neighbors [11, 16]. The biggest difference between these works and ours is that consensus is reached with probability 1 in these models on any connected graph, which doesn't hold for majority dynamics.

Majority Dynamics

The works most related to ours consider majority dynamics. Even synchronous majority dynamics may not result in a consensus (consider again the line graph). These works, like ours, therefore seek to understand what graph structures result in a Correct majority. Mossel, Neeman, and Tamuz study synchronous majority dynamics and prove that a Correct majority arises as long as the underlying graph is sufficiently symmetric, or sufficiently expansive (in the latter case, they prove that the network further reaches consensus) [24]. Feldman et al. study asynchronous majority dynamics and prove that a Correct consensus arises when the underlying graph is sparse and expansive [12]. Work of [29] further studies "retention of information," which asks whether *any* recovery procedure (not necessarily a majority vote) at stabilization can recover the ground truth with high probability. In connection to these, our work simply pushes the boundary beyond what classes of graphs are understood in prior work.

The key difference between the synchronous and asynchronous models is captured by the complete graph. In asynchronous dynamics, a Correct majority occurs only with probability $1/2 + \delta$, whereas in synchronous dynamics a Correct consensus occurs with probability $1 - \exp(-\Omega(n))$. This is because in step one, every node simply announces their private belief, and in step two everyone updates to the majority, which is Correct with probability $1 - \exp(-\Omega(n))$. So while the models bear some similarity, and some tools are indeed transferable (e.g. the expansiveness lemma of [24] used in [12]), much of the anlayses will necessarily diverge.

Preferential Attachment and Balanced M-ary Trees

There is also substantial prior work studying aggregation dynamics in trees. Here, the most related work is [19, 22], which studies synchronous majority dynamics in balanced M-ary trees. Less related are works which study "bottom-up" dynamics in balanced M-ary trees [21, 31, 30], k-majority dynamics in preferential attachment trees [1], or model cascades themselves as a preferential attachment tree [17]. While these works provide ample motivation for restricting attention to preferential attachment trees, or balanced M-ary trees, they bear no technical similarity to ours.

2 Model and Preliminaries

We consider an undirected tree $G = (V, E)$ with $|V(G)| = n$ and $|E(G)| = m$. We denote by $\deg(v)$ the degree of a node $v \in V(G)$, $N(v)$ to be its neighbors $\{u, (u, v) \in E\}$, and $d(u, v)$ to be the length of the unique path between u and v, and let $P(u, v)$ denote the ordered list of vertices on this path (i.e. starting with u and ending with v). We'll also denote by $D(G) = \max_{u,v}\{d(u, v)\}$ the diameter of G.

Individuals initially have one of two private beliefs, which we'll refer to as Correct (or 1) and Incorrect (or 0). That is, each $v \in V(G)$ receives an independent private signal $X(v) \in \{0, 1\}$, and $\Pr[X(v) = 1] = 1/2 + \delta$, for some constant $0 < \delta < 1/2$.

Individuals also have a *publicly announced* opinion (which we will simply refer to as an announcement). We define $C^t(v) \in \{\perp, 0, 1\}$ to be the public announcement of $v \in V(G)$ at time t. Initially, no announcements have been made, *i.e.* $C^0(v) = \perp$ for all v. In each subsequent step, a *single node* v^t is chosen uniformly at random from $V(G)$ and updates her announcement (announcements of all other nodes stay the same)[6]. v^t updates her announcement using *majority dynamics*. That is, if $N_1^t(v)$ denotes the number of v's neighbors with a Correct announcement at time t, and $N_0^t(v)$ denotes the number of v's neighbors with an Incorrect announcement, then:

$$C^t(v) = \begin{cases} 1 & \text{if } N_1^{t-1}(v) > N_0^{t-1}(v), \text{ and } v = v^t, \\ 0 & \text{if } N_1^{t-1}(v) < N_0^{t-1}(v), \text{ and } v = v^t, \\ X(v) & \text{if } N_1^{t-1}(v) = N_0^{t-1}(v), \text{ and } v = v^t, \\ C^{t-1}(v) & \text{if } v \neq v^t. \end{cases}$$

Note that we will treat δ as an absolute constant. Therefore, the only variable taken inside Big-Oh notation is n, the number of nodes (and, for instance, when we write $o(1)$ we mean any function of n that approaches 0 as n approaches ∞).

[6] This makes the process *asynchronous*.

As shown in [12], it is easy to see that in any network this process stabilizes with high probability in $O(n^2)$ steps. That is, the network reaches a state where no node will want to change its announcement and thus the process terminates.

2.1 Concentration Bounds and Tools from Prior Work

Our work indeed makes use of some tools from prior work to get started, which we state below. The concept of a *critical time*, defined below, is implicit in [12].

▶ **Definition 2.** *The* critical time[7] *from u to u, $T(u,u)$, is the first time that node u announces. The critical time from u to v, $T(u,v)$, is recursively defined as the first time that v announces* after *the critical time from u to x, where x is the neighbor of v in $P(u,v)$. We further denote the* critical chain *from u to v as the ordered list of critical times from u to x for all x on $P(u,v)$.*

The following lemma is a formal statement of ideas from prior work (a proof appears in Appendix A of the full version). To parse it, it will be helpful to think of the process as first drawing a countably infinite sequence S of nodes to announce, which then allows each $C^t(v)$ to be written as a deterministic function of the random variables $\{X(u), u \in V\}$. Lemma 3 below states that in fact, for early enough t, initial beliefs for only a proper subset of V suffice.

▶ **Lemma 3** ([12]). *For all t, and all v, $C^t(v)$ can be expressed as a function of the subset of signals $\{X(u), T(u,v) \leq t\}$.*

The final theorem we take from prior work is due to Mossel et al., and is used to claim that at minimum the *expected* number of CORRECT nodes at termination is at least $(1/2+\delta)n$.

▶ **Theorem 4** ([24]). *Let f be an odd, monotone Boolean function. Let $X_1, \ldots, X_n$ be input bits, each sampled i.i.d. from a distribution that is 1 with probability $p \geqslant 1/2$ and 0 otherwise. Then $\mathbb{E}[f(X_1, \ldots, X_n)] \geqslant p$.*

Note that, as long as v has announced at least once by t, $C^t(v)$ is an odd, monotone, Boolean function in variables $\{X(u), u \in V\}$,[8] and therefore $\Pr[C^t(v) = 1] \geq 1/2 + \delta$ for all v and $t \geq T(v,v)$.

Finally, we'll make use of the following concentration bound on $T(u,v)$ repeatedly. Its proof is a simple application of a Chernoff bound and appears in Appendix A of the full version.

▶ **Lemma 5.** *For all $0 < \beta < 1$:*

- $\Pr[T(u,v) > 8 \cdot \max\{\ln(1/\beta), d(u,v)+1\} \cdot n] \leq \beta^2$.
- $\Pr[T(u,v) < (d(u,v)+1) \cdot \beta \cdot n] \leq e^{-\beta d(u,v)(1-\beta)^2/3}$.
- $\Pr[T(u,v) < (d(u,v)+1) \cdot \beta \cdot n] \leq (e\beta)^{d(u,v)} = e^{(1+\ln\beta) \cdot d(u,v)}$.

[7] This definition can be naturally extended to any general graph.

[8] That is, flipping all $X(v)$ simultaneously to $1 - X(v)$ would cause $C^t(v)$ to flip (odd), and changing any subset of initial beliefs from 0 to 1 cannot change $C^t(v)$ from 1 to 0 (monotone).

3 Key Concepts

Before getting into our proofs, we elaborate some key concepts that will be used throughout. In Proposition 7 below, we analyze the connection between critical chains and switches in announcements. Intuitively, Proposition 7 is claiming that every fresh announcement can cause other nodes to switch a previous announcement along critical chains, but that these are the *only* switches that can occur.

▶ **Definition 6.** *Let v change her announcement at t, and her previous announcement be made at $t' > 0$. We say that node u is a* cause *of v changing her announcement at t if $C^t(u) = C^t(v)$, and $C^{t'}(u) \neq C^t(v)$. Observe that every such change in announcement has a cause.*

▶ **Proposition 7.** *If $C^t(v) \neq C^{t-1}(v)$, then there exists a node u such that:*

- *$t = T(u, v)$ (i.e. the influence of u just reaches v at time t).*
- *$C^{T(u,u)}(u) = C^t(v)$ (i.e. v is updating to match u's initial announcement).*
- *Denote $u = x_0, x_1, \ldots, x_{d(u,v)} = v$ the path $P(u, v)$. Then* every *x_i, $i > 0$, has $C^{T(u,x_i)-1}(x_i) = C^{t-1}(v)$ and $C^{T(u,x_i)}(x_i) = C^t(v)$, and x_{i-1} caused this change (i.e.* every *node along the path from u to v* changed *to match u's initial announcement).*

Proof. The proof proceeds by induction on t. Consider $t = 1$ as a base case. If $C^1(v) \neq C^0(v) = \perp$, then it must be because v announced at time 1, meaning that $1 = T(v, v)$ as desired.

Now assume that for all v and all $t' < t$ the claim holds, and consider time t. If v does not announce at time t then the claim vacuously holds. If v announces at time t but does *not* change their announcement, then again the claim vacuously holds. If v announces at time t for the first time, then v itself is the desired u and the claim holds. The remaining case is if v changes their previous announcement that was made at time $t' < t$ (and v did not announce between t' and t).

Let's consider the state of affairs at time t', when v announced some opinion A. This means that, at time t', a majority (tie-breaking for $X(v)$) of v's neighbors were announcing A. Yet, at time t, a majority (tie-breaking for $X(v)$) of v's neighbors were announcing $B = 1 - A$. Therefore, *some* node adjacent to v must have switched its announcement to B at some $t'' \in (t', t)$, and stays B till time t (and caused the change). Call this node x. We now wish to invoke the inductive hypothesis for x at t''.

The inductive hypothesis claims there there is some u (maybe $u = x$) such that u made B as its first announcement, and then every node y along the critical chain from u to x switched from A to B at $T(u, y)$ (caused by its predecessor), and that $t'' = T(u, x)$. Let's first consider the case that v is not on the path from u to x (and therefore x is on the path from u to v, since they are adjacent). Then as $T(u, x) = t'' \in (t', t)$, and v does not announce in (t', t), we see that $T(u, v) = t$ (immediately by definition of critical times). Moreover, as $P(u, v)$ is simply $P(u, x)$ concatenated with v, the inductive hypothesis already guarantees that u announced B at $T(u, u)$, and that every node y on $P(u, v)$ switched from A to B at $T(u, y)$. So the last step is to show that in fact v *must* not be on the path from u to x, and then the inductive step will be complete.

Finally, we show that we cannot have v on the path from u to x, completing the inductive step. Assume for contradiction that v were on the path from u to x. Then as $t'' = T(u, x)$, we would necessarily have $t' \geq T(u, v)$ (immediately from definition of critical times). However, by hypothesis, $C^{t''}(v) = C^{t'}(v) = A$ (the first equality is simply because v does not announce in $(t', t'']$), contradicting the inductive hypothesis that v caused x to change (because of u), which would imply instead that $C^{T(u,v)}(v) = C^{t''}(v) = B$. So v cannot be on the path from u to x. ◀

Below, we make use of Proposition 7 to prove that, in any tree[9], the process terminates quickly (proof in Appendix B of the full version). Note that [12] already proves that the process on trees terminates with probability $1 - o(1)$ after $O(n^2)$ steps, so Corollary 8 is a strict improvement when the diameter $D(G) = o(n)$.

▶ **Corollary 8.** *Let T_{stable} denote the last time that a node changes its announcement. Then with probability $1 - o(1)$, $T_{stable} \leq 8 \cdot \max\{2\ln(n), D(G) + 1\} \cdot n$.*

Finally, we prove one last proposition which will be used in future sections regarding the probability that a single node announces Correct throughout the process (the proof appears in Appendix B of the full version). Beginning with v's first announcement, because the graph is a tree, prior to v's first announcement all of v's neighbors' announcements are independent. Therefore, it initially seems like we should expect v's initial announcement to be Correct except with probability exponentially small in $\deg(v)$ – indeed, this would hold if the dynamics were synchronous. However, since the dynamics are *asynchronous*, there's a good chance that v announces before any of its neighbors and simply announces $X(v)$. That is, the probability that v's initial announcement is Incorrect is at least $\frac{1/2-\delta}{\deg(v)}$, so we cannot hope for such strong guarantees. This observation highlights one (of several) crucial differences between synchronous and asynchronous dynamics. Still, the proposition below shows roughly that the only bad event is v announcing before many of its neighbors. Below for a set S, we'll use $C_S^t(v)$ to denote the following modified dynamics: First, set $C_S^t(v) = $ Incorrect for all $v \in S$, and all t. Then, run the asynchronous majority dynamics as normal. In other words, the modified dynamics hard-code an Incorrect announcement for all nodes in S and otherwise run asynchronous majority dynamics as usual (this extension will be necessary for a later argument).

▶ **Definition 9.** *We say that a node v is* safe thru T *if $C^t(v) \in \{\perp, 1\}$ for all $t \leq T$. We further say that a node v is* safe thru T, even against S *if $C_S^t(v) \in \{\perp, 1\}$ for all $t \leq T$.*

▶ **Proposition 10.** *For all a, there exist constants[10] b, c such that for any S with $|S| = a$, $v \notin S$ and $T \leq n \cdot e^{b\deg(v)}$, v is safe thru T, even against S, with probability at least $1 - c/\deg(v)$.*

4 Forming an Initial Majority

In this section, we prove that in any tree, a Correct majority forms after a near-linear number of steps (but may later fade). The main idea is to show that the announcements of most pairs of nodes are independent with probability $1 - o(1)$, and use Chebyshev's inequality to show that the number of Correct announcements therefore concentrates around its expectation. The independence argument is the crux of the proof. To show it, we consider three cases depending on the length and degree sequence of the path between a pair of nodes. If the path is long, then, similar to prior work, there is simply not enough time for the pair to influence each other. If the path is short, but (some of) the intermediate nodes have high degrees, then these effectively block influence because the announcements of these high-degree nodes is effectively independent of what's happening on the path. Finally, if the path is short and the intermediate nodes have low degrees, then the pair certainly may influence each other. However, a counting argument shows there can only be a vanishingly small fraction of such pairs. The main result of this section is the following:

[9] Proposition 7 and Corollary 8 hold for any general graph. Since we are only interested in trees, we restrict our proofs to just trees for brevity.

[10] does not depend on n, but may depend on δ.

▶ **Theorem 11** (Majority in trees). *For sufficiently large n, any tree on n nodes and any $T \leq \frac{n \ln n}{32 \ln \ln n}$, after T steps, with probability at least $1 - O(e^{-\ln n/(24 \ln \ln n)})$, the announcements of at least $(\frac{1}{2} + \frac{\delta}{2} - e^{-T/n}) \cdot n$ nodes are* Correct *.*

Further, for all constants $\gamma > 0$, there exists a constant $\alpha > 0$ such that for sufficiently large n, when $T \leq \frac{n \ln^{1-\gamma} n}{\ln \ln n}$, after T steps, with probability at least $1 - n^{-\alpha}$, the announcements of at least $(\frac{1}{2} + \frac{\delta}{2} - e^{-T/n}) \cdot n$ nodes are Correct *.*

First, we analyze the expected number of Correct nodes using Theorem 4 (proof in Appendix C of the full version). Note that, the probability that a node v has announced by T is at least $(1 - e^{-T/n})$[11].

▶ **Lemma 12.** *At any time T, the expected number of nodes v with $C^T(v) =$ Correct is at least $(1/2 + \delta - e^{-T/n})n$.*

From here, we now need to show that the number of Correct announcements concentrates around its expectation. To this end, we'll show that most pairs of nodes can be written as functions of disjoint initial beliefs, and are therefore independent. Ideas from [12] formally show that this suffices:

▶ **Definition 13.** *We say that two nodes u, v are ε-disjoint at t if there exist random variables X_u, X_v, written as functions of disjoint sets of initial beliefs (and therefore independent), such that $\Pr[C^t(u) = X_u] \geq 1 - \varepsilon$ and $\Pr[C^t(v) = X_v] \geq 1 - \varepsilon$.*

▶ **Lemma 14** (Inspired by [12]). *Let ε^t_{uv} be such that u, v are ε^t_{uv}-disjoint at t. Then if $\sum_{u,v} \varepsilon^t_{uv} = D$, the number of* Correct *nodes at time t is within $\delta n/2$ of its expectation with probability $1 - \frac{4n+16D}{\delta^2 n^2}$.*

So our remaining task is to upper bound $\sum_{u,v} \varepsilon^t_{uv}$, and this is the point where we diverge from prior work. For a given pair u, v, there are three possible cases. Below, case one is most similar to prior work, and cases two/three are fairly distinct.

Case One: Long Paths

One possibility is that $d(u, v) \geq f(n)$, for some $f(n)$ to be decided later. The following proposition implies that at any time T, the announcements of pairs of nodes at a large enough distance are almost independent. The proof is provided in Appendix C of the full version.

▶ **Proposition 15.** *Let $d(u, v) \geq \max\{kT, f(n)\}$ for $k \geq 4$. Then $\varepsilon^T_{uv} \leq 2e^{-f(n)/24}$, and $\varepsilon^T_{uv} \leq 2e^{(1-\ln k)\cdot f(n)}$.*

Case Two: Short Paths A

Another possibility is that $d(u, v) < f(n)$. Here, there will be two subcases. First, maybe it's the case that $d(u, v)$ is small *and* the product of degrees on the path from u to v is small. In this case, it very well could be that ε^t_{uv} is large, which is bad. However, we prove that there cannot be many such pairs (and so in total they contribute $o(n^2)$ to the sum). The following lemma shows in fact that even if we remove the restriction that $d(u, v) = O(T)$, there simply cannot be many pairs of nodes such that the product of degrees on $P(u, v)$ is small (proof in Appendix C of the full version).

[11] The probability that v wasn't chosen in all T rounds is $\left(1 - \left(1 - \frac{1}{n}\right)^T\right)$.

▶ **Lemma 16.** *Let K be the set of pairs of nodes (u, v) such that $\prod_{w \in P(u,v)} \deg(w) \leq X$. Then $|K| \leq Xn/2$.*

Case Three: Short Paths B

The final possibility is that $d(u, v) < f(n)$, and also that $\prod_{w \in P(u,v)} \deg(w)$ is large. In this case, we will prove that with probability $1 - o(1)$ there is some block in $P(u, v)$ causing u's and v's announcemnts to be independent (proof in Appendix C of the full version).

▶ **Definition 17.** *We say that a node $x \in P(u, v)$* cuts *u from v thru T if some node y in $P(u, x)$ is safe thru T even against S_y, where S_y are y's (at most) two neighbors in $P(u, v)$.*

▶ **Lemma 18.** *Let T be any time and p_x be the probability that x cuts u from v thru T* and also *cuts v from u thru T. Then u and v are p_x-disjoint at T.*

Next, we wish to show that with good probability there is indeed a node on $P(u, v)$ that cuts u from v and also v from u (proofs in Appendix C of the full version).

▶ **Lemma 19.** *There exist absolute constants b, d such that for any pairs of nodes $u, v \in V$ with $\prod_{w \in P(u,v)} \deg(w) = X$, $d(u, v) \leq \frac{\ln(X)}{d}$, and $T \leq ne^{bX^{1/(4d(u,v))}}$, there exists an x such that that with probability $1 - X^{-1/8}$, x cuts u from v thru T and also v from u thru T.*

▶ **Corollary 20.** *There exist absolute constants b, d such that for pairs of nodes any $u, v \in V$ with $\prod_{w \in P(u,v)} \deg(w) = X$, $d(u, v) \leq \frac{\ln(X)}{d}$, and $T \leq ne^{bX^{1/(4d(u,v))}}$), u and v are $X^{-1/8}$-disjoint at T.*

Now, we'll put together case one, Lemma 18 and Corollary 20 together to prove Theorem 11, which is mostly a matter of setting parameters straight (and appears in Appendix C of the full version).

To conclude, at this point we have proven that a majority takes hold after $n\frac{\ln n}{32 \ln \ln n}$ steps for any tree. The remaining work is to prove that it does not disappear.

5 Stabilizing Quickly

In this section, we identify properties of a tree which cause it to stabilize quickly. Our main theorem will then follow by proving that both balanced M-ary trees and preferential attachment trees have this property. The main idea is to consider nodes that are "close" to leaves in the following formal sense:

▶ **Definition 21.** *We say that a node v is an (X, Y)-leaf in G if there exists a rooting of G such that v has $\leq X$ descendants, and the longest path from v to one of its descendants is at most Y. Note that leaves are $(0, 0)$-leaves. When we refer to a node's parent, children, or descendants, it will be with respect to this rooting.*

▶ **Definition 22.** *We say that a node v is:*

- finalized *at T, if $C^t(v) = C^T(v)$ for all $t \geq T$.*
- nearly-finalized *at T with respect to u if there exists a $t' \geq T$ such that v is finalized at t' and for all $t \in (T, t')$ when v announces, it either updates $C^t(v) = C^t(u)$, if $C^t(u) \neq \perp$, or $C^t(v) = C^{t-1}(v)$, if $C^t(u) = \perp$.*

Intuitively, a node is finalized if it is done changing its announcement. A node v is nearly-finalized with respect to u if v is not quite finalized, but changes in u are the only reason why v would change its announcement (and moreover, v will copy u every announcement until v finalizes).

The main result of this section is as follows:

▶ **Theorem 23.** *Let v be an (X, Y)-leaf. Then with probability $1 - Xe^{-T/nY}$, v is nearly-finalized at T with respect to its parent.*

The main insight for the proof of Theorem 23 will be the following lemmas. Below, Lemma 24 asserts that once all of v's children are nearly-finalized with respect to v, any changes in v's opinion are to copy its parent, and Lemma 25 builds off this to claim that we can relate the time until v nearly-finalizes to its critical times. Importantly, Lemma 25 does *not* require *all* critical paths to hit v, but only those from its descendents.

▶ **Lemma 24.** *Let all of v's children be nearly-finalized with respect to v at T, and let u be v's parent. Let also $t > t' \geq T$ be two timesteps during which v announced. Then if $C^t(v) \neq C^{t-1}(v)$, we must have $C^t(v) = C^t(u)$.*

▶ **Lemma 25.** *Let $T_v := \max\{T(x, v), x$ is a descendant of $v\}$. Then v is nearly-finalized at T_v with respect to its parent.*

These above lemmas suffice to prove Theorem 23. The proofs of these lemmas and Theorem 23 appear in Appendix D of the full version.

We will also need the following implications of Theorem 23. Below, Lemma 26 will be helpful in proving Corollary 27. Corollary 27 lets us claim that while nearly-finalized nodes are not themselves finalized, their existence implies the existence of other finalized nodes. This will be helpful in wrapping up in the following section, since the process only terminates once nodes are finalized. The proofs of Lemma 26 and Corollary 27 appear in Appendix D of the full version.

▶ **Lemma 26.** *For any $t > T_v$, if a child of v changes their announcement at t, v becomes finalized at t.*

▶ **Corollary 27.** *For any T, with probability $1 - e^{-T/n}$, v has $\lfloor(\deg(v) - 1)/2\rfloor$ children who are finalized at $T_v + T$.*

Moreover, if v is an (X, Y)-leaf and finalized at $t \geq T_v$, then with probability $1 - Xe^{-T/nY}$, all of v's descendants are finalized at $t + T$.

6 Wrapping Up: Preferential Attachment and Balanced *M*-ary Trees

In this section, we show how to make use of Theorem 23 to conclude that a $1 - o(1)$ fraction of nodes are finalized by $\frac{n \ln n}{32 \ln \ln n}$. Proofs for the two cases follow different paths, but both get most of their mileage from the developments in Section 5.

6.1 Preferential Attachment Trees Stabilize Quickly

Let's first be clear what we mean by a preferential attachment tree.[12]

[12] Note that this is the standard definition of preferential attachment used for heuristic arguments, e.g. [5]. Most prior rigorous work uses a slightly modified definition that produces a forest instead of a tree in order to rigorously analyze (say) the degree distribution [9, 8]. As we are only interested in (fairly loose) bounds on the degrees, our results are rigorous in the standard model.

▶ **Definition 28** (Preferential Attachment Tree). *n nodes arrive sequentially, attaching a single edge to a pre-existing node at random proportional to its degree. Specifically:*

- *Let v_i denote the i^{th} node to arrive.*
- *Let $\deg_t(v_i)$ denote the degree of node v_i after a total of t nodes have arrived.*
- *There is a special node v_0, which only v_1 connects to upon arrival, and no future nodes.*
- *When v_{i+1} arrives, v_{i+1} attaches a single edge to a previous node, choosing node v_j, $j \in [1, i]$, with probability $\frac{\deg_i(v_j)}{2i-1}$.*

Our main argument for preferential attachment trees is that most nodes are in a "good" subtree, defined below. All subsequent proofs are in Appendix E of the full version. At a high level the plan is as follows: first, we prove that because most nodes are (X, Y)-leaves for small X, Y, these nodes quickly become nearly-finalized. Next, we prove that most such nodes are part of a small subtree whose parent is likely to be safe thru the entire process. Therefore, the parent of this subtree is finalized early, and once the subtree becomes nearly-finalized, it finalizes quickly as well.

▶ **Definition 29.** *Say that a subtree rooted at v is* good *if:*

- *v is a (X, Y)-leaf, for $X = \ln^{O(1)} n$ and $Y = O(\ln \ln n)$.*
- *v's parent has degree at least $\ln^{\Omega(1)} n$.*

▶ **Proposition 30.** *Let the subtree rooted at v be good, and let the diameter of the entire graph be $O(\ln n)$. Then with probability $1 - o(1)$, the entire subtree rooted at v is finalized by $n \frac{\ln n}{32 \ln \ln n}$.*

▶ **Proposition 31.** *For a tree built according to the preferential attachment model, the following simultaneously hold with probability $1 - o(1)$.*

- *$n - o(n)$ nodes are in good subtrees.*
- *The diameter of the entire graph is $O(\ln n)$.*

▶ **Theorem 32.** *A tree built according to the preferential attachment model stabilizes in a* Correct *majority with probability $1 - o(1)$.*

The proofs for Proposition 30, Proposition 31, and Theorem 32 appear in Appendix E of the full version.

6.2 Balanced *M*-ary Trees Stablize Quickly

Let's first be clear what we mean by a balanced M-ary tree.

▶ **Definition 33.** *We say a tree is a balanced M-ary tree if there is a root v such that all non-leaf nodes have exactly M children, and all root-leaf paths have the same length.*

Our plan of attack is as follows (all proofs are in Appendix E of the full version). First, the case for large M (say, $M > \ln n$) is actually fairly straight-forward as a result of Proposition 10. This is because every pair of nodes has a high-degree block on their path, meaning that the "Case Three" argument used in Section 4 actually applies all the way until the process terminates. The $M \leq \ln n$ case is more interesting, and requires the tools developed in Section 5.

Here, the plan is as follows. Corollary 27 roughly lets us claim that all nearly-finalized nodes must have a decent number of finalized children, and moreover that all these finalized children have finalized descendents. Iterating this counting inductively through children, we see that actually most descendents of nearly-finalized nodes of sufficient height must themselves be finalized.

Formally, the approach is to first get a bound on the height for which we can claim that nodes are indeed nearly-finalized with high probability (Corollary 34, immediately from Theorem 23). $\ln\ln n$ turns out to be a good choice.

▶ **Corollary 34.** *Let v be distance h from a leaf. Then v is an $(2M^h, h)$-leaf, and therefore v is nearly-finalized with respect to its parent at $\frac{n\ln n}{64\ln\ln n}$ with probability $1 - 2M^h \cdot e^{-\frac{\ln n}{64h\ln\ln n}} = 1 - e^{-\frac{\ln n}{64h\ln\ln n} + h\ln(2M)}$.*

In particular, if $h = o(\sqrt{\frac{\ln n}{\ln\ln n \cdot \ln M}})$, then v is nearly-finalized with respect to its parent at $\frac{n\ln n}{64\ln\ln n}$ with probability $1 - o(1)$.

▶ **Proposition 35.** *Let v have height $h = \ln\ln n$ in a balanced M-ary tree for $M \leq \ln n$. Then with probability $1 - o(1)$, at most $2M^h \cdot (2/3)^h = o(M^h)$ descendents of v are not finalized by $\frac{n\ln n}{32\ln\ln n}$.*

▶ **Theorem 36.** *Any M-ary tree stablizes in a* Correct *majority with probability $1 - o(1)$.*

The proofs of Proposition 35 and Theorem 36 appear in Appendix E of the full version.

Abstract

The randomized query complexity $\mathsf{R}(f)$ of a boolean function $f\colon \{0,1\}^n \to \{0,1\}$ is famously characterized (via Yao's minimax) by the least number of queries needed to distinguish a distribution $\mathcal{D}_0$ over 0-inputs from a distribution $\mathcal{D}_1$ over 1-inputs, maximized over all pairs $(\mathcal{D}_0, \mathcal{D}_1)$. We ask: Does this task become easier if we allow query access to infinitely many samples from either $\mathcal{D}_0$ or $\mathcal{D}_1$? We show the answer is *no*: There exists a hard pair $(\mathcal{D}_0, \mathcal{D}_1)$ such that distinguishing $\mathcal{D}_0^\infty$ from $\mathcal{D}_1^\infty$ requires $\Theta(\mathsf{R}(f))$ many queries. As an application, we show that for any composed function $f \circ g$ we have $\mathsf{R}(f \circ g) \geq \Omega(\mathsf{fbs}(f)\mathsf{R}(g))$ where fbs denotes fractional block sensitivity.

1 Introduction

Randomized query complexity (see [8] for a classic survey) is often studied using Yao's minimax principle [20]. The principle states that for every boolean function $f\colon \{0,1\}^n \to \{0,1\}$

$$\textbf{Yao's minimax:} \qquad \mathsf{R}_\epsilon(f) \;=\; \max\nolimits_{\mathcal{D}} \mathsf{D}_\epsilon(f,\mathcal{D}).$$

- Here $\mathsf{R}_\epsilon(f)$ is the randomized ϵ-error query complexity of f. More precisely, $\mathsf{R}_\epsilon(f)$ equals the least number of queries a randomized algorithm (decision tree) must make to the input bits $x_i \in \{0,1\}$ of an unknown input $x \in \{0,1\}^n$ in order to output $f(x)$ with probability at least $1-\epsilon$ (where the probability is over the coin tosses of the algorithm). We often set $\epsilon = 1/3$ and omit ϵ from notation, as it is well known that this choice only affects constant factors in query complexity.
- $\mathcal{D}$ is a distribution over the inputs $\{0,1\}^n$. We may assume wlog that $\mathcal{D}$ is *balanced*: $\mathcal{D} = \frac{1}{2}\mathcal{D}_0 + \frac{1}{2}\mathcal{D}_1$ where $\mathcal{D}_b$ is a distribution over $f^{-1}(b)$.
- $\mathsf{D}_\epsilon(f,\mathcal{D})$ is the *distributional* ϵ-error query complexity of f relative to $\mathcal{D}$. More precisely, $\mathsf{D}_\epsilon(f,\mathcal{D})$ equals the least number of queries a *deterministic* algorithm must make to an input $x \sim \mathcal{D}$ in order to output $f(x)$ with probability at least $1-\epsilon$ (where the probability is over $x \sim \mathcal{D}$).

1.1 Correlated samples problem

One way to think about the distributional complexity of f relative to $\mathcal{D} = \frac{1}{2}\mathcal{D}_0 + \frac{1}{2}\mathcal{D}_1$ is as the following task: A deterministic algorithm is given query access to a sample from either $\mathcal{D}_0$ or $\mathcal{D}_1$ and it needs to decide which is the case. In this work, we ask: Does this task become easier if we allow query access to an unlimited number of independent samples from either $\mathcal{D}_0$ or $\mathcal{D}_1$? In short,

Is it easier to distinguish $\mathcal{D}_0^\infty$ from $\mathcal{D}_1^\infty$ than it is to distinguish $\mathcal{D}_0$ from $\mathcal{D}_1$?

More formally, we define the *correlated samples problem* for f relative to $\mathcal{D} = \frac{1}{2}\mathcal{D}_0 + \frac{1}{2}\mathcal{D}_1$ by

$$\mathsf{Corr}_\epsilon(f,\mathcal{D}) \;\coloneqq\; \min_{k\geq 1} \mathsf{D}_\epsilon(f^k, \tfrac{1}{2}\mathcal{D}_0^k + \tfrac{1}{2}\mathcal{D}_1^k).$$

Here $f^k\colon (\{0,1\}^n)^k \to \{0,1\}^k$ is the function that evaluates k copies of f on disjoint inputs. We also use the notation $\mathcal{D}^k \coloneqq \mathcal{D} \times \cdots \times \mathcal{D}$ (k times) for the k-fold product distribution. In particular, under $\frac{1}{2}\mathcal{D}_0^k + \frac{1}{2}\mathcal{D}_1^k$, the function f^k outputs either 0^k or 1^k; the correlated samples problem is to decide which is the case. We note that the expression to be minimized on the right side is a non-increasing function of k (access to more samples is only going to help). We may also assume wlog that $k \leq n$ (when an algorithm queries a sample for the first time, we may assume it is the first unqueried sample so far).

Shaltiel examples. It is not hard to give examples of input distributions where access to multiple correlated samples *does* help. Such examples were already discussed by Shaltiel [18] in the context of direct product theorems. For instance, consider the n-bit $\textsc{Xor}_n$ function. It is well known that $\mathsf{R}_\epsilon(\textsc{Xor}_n) = n$ for all $\epsilon > 0$. Define a balanced input distribution (here $\mathcal{U}$ is a uniform random bit in $\{0,1\}$)

$$\mathcal{D} \;\coloneqq\; \begin{cases} 0\,\mathcal{U}^{n-1} & \text{with probability } 99\%, \\ 1\,\mathcal{U}\,0^{n-2} & \text{with probability } 1\%. \end{cases}$$

This distribution is hard 99% of the time: if the first bit is 0, an algorithm has to compute $\textsc{Xor}_{n-1}$ relative to $\mathcal{U}^{n-1}$, which requires $n-1$ queries. For the remaining 1%, the distribution is easy: if the first bit is 1, the output can be deduced from the second bit. Here multiple correlated samples help a lot (for $\epsilon = 1/3$):

$$\begin{aligned} \mathsf{D}(\textsc{Xor}_n, \mathcal{D}) &= \Omega(n), \\ \mathsf{Corr}(\textsc{Xor}_n, \mathcal{D}) &= O(1). \end{aligned}$$

Indeed, given a single sample from $\mathcal{D}$, an algorithm is likely to have to solve the hard case of the distribution. By contrast, given multiple correlated samples, we can query the first bit for a large constant number of samples. This will give us a high chance to encounter at least one easy sample.

Error reduction. An important fact (which fails in the single-sample setting!) is that we can amplify the success probability of any algorithm for correlated samples. This is achieved by a variant of the usual trick: repeatedly run the algorithm on fresh samples to gain more confidence about the output.[1]

▶ **Fact 1.1.** $\mathsf{Corr}_\epsilon(f, \mathcal{D}) \leq O(\log(1/\epsilon)/\delta^2) \cdot \mathsf{Corr}_{1/2-\delta}(f, \mathcal{D})$ *for every* $(f, \mathcal{D})$.

The aforementioned Shaltiel example $(\textsc{Xor}_n, \mathcal{D})$ can alternatively be computed as follows: By querying the first two bits of a single sample $x \sim \mathcal{D}$ one can predict $\textsc{Xor}_n(x)$ to within error 49.5%. Now apply Fact 1.1 to reduce the error below 1/3 at the cost of a constant-factor blowup in query cost.

1.2 Main result

We study whether Shaltiel examples can be avoided if we restrict our attention to the hardest possible input distribution. Namely, we define a distribution-free complexity measure by

$$\mathsf{Corr}_\epsilon(f) \;:=\; \max_{\mathcal{D}} \mathsf{Corr}_\epsilon(f, \mathcal{D}).$$

Our main result is that multiple correlated samples do not help for the hardest distribution.

▶ **Theorem 1.2.** $\mathsf{Corr}(f) = \Theta(\mathsf{R}(f))$ *for any (partial) boolean function* f.

The main challenge in proving Theorem 1.2 is precisely the existence of Shaltiel examples: How to construct hard distributions that do not contain any hidden easy parts? We resolve it by building decision trees that can exploit the easy parts not only in its own input distribution, but in various other distributions as well.

1.3 Application 1: Selection problem

Next we describe a consequence of our main result to a natural query task that we dub the *selection problem*. A similar problem, called *choose*, was studied by [4] in communication complexity.

[1] In more detail: An algorithm T with error $1/2 - \delta$ has $|p_0 - p_1| \geq 2\delta$ where $p_i := \Pr[T(x_i) = 1]$ for $x_i \sim \mathcal{D}_i^k$. Reducing error below $\epsilon > 0$ boils down to distinguishing two random coins with heads-probabilities p_0 and p_1. Given multiple samples from one of the coins, Chernoff bounds state that $O(\log(1/\epsilon)/\delta^2)$ samples are enough to tell which coin the samples came from.

Fix an n-bit function f together with an input distribution $\mathcal{D}$. In the *k-selection problem* for $(f, \mathcal{D})$ the input is a random kn-bit string $x = (x^1, \ldots, x^k) \sim \mathcal{D}^k$, and the goal is to output $(i, f(x^i))$ for some $i \in [k]$. That is, the algorithm gets access to k independent samples from $\mathcal{D}$ and it selects one of them to solve. We define

$$\begin{aligned} k\text{-}\mathsf{Sel}_\epsilon(f, \mathcal{D}) &:= \epsilon\text{-error query complexity of } k\text{-selection for } (f, \mathcal{D}), \\ \mathsf{Sel}_\epsilon(f, \mathcal{D}) &:= \min\nolimits_{k \geq 1} k\text{-}\mathsf{Sel}_\epsilon(f, \mathcal{D}), \\ \mathsf{Sel}_\epsilon(f) &:= \max\nolimits_{\mathcal{D}} \mathsf{Sel}_\epsilon(f, \mathcal{D}). \end{aligned}$$

The selection problem is interesting because it, too, is subject to Shaltiel examples: for $(\textsc{Xor}_n, \mathcal{D})$ as described in Subsection 1.1, we have $\mathsf{Sel}(\textsc{Xor}_n, \mathcal{D}) = O(1)$ using the same idea of searching for an easy sample.

The following relates selection to correlated samples; see Section 5 for the proof.

▶ **Theorem 1.3.** *The correlated samples problem is easier than selection:*

1. $\mathsf{Corr}(f, \mathcal{D}) \leq O(\mathsf{Sel}(f, \mathcal{D}))$ *for every* $(f, \mathcal{D})$.
2. *There exists an n-bit $(f, \mathcal{D})$ such that* $\mathsf{Sel}(f, \mathcal{D}) = \Omega(n)$ *but* $\mathsf{Corr}(f, \mathcal{D}) = O(1)$.
3. *Selection does not admit efficient error reduction (as in Fact 1.1).*

Combining the first item of Theorem 1.3 with our main result (Theorem 1.2) we conclude that multiple samples do not help in the selection problem for the hardest distribution.

▶ **Corollary 1.4.** $\mathsf{Sel}(f) = \Theta(\mathsf{R}(f))$ *for any (partial) boolean function f.*

1.4 Application 2: Randomized composition

We give another application of our main result to the *randomized composition conjecture* studied in [7, 3, 9, 6]. In fact, this application is what originally motivated our research project!

For an n-bit function f and an m-bit function g we define their composition

$$f \circ g \colon (\{0,1\}^m)^n \to \{0,1\} \qquad \text{such that} \qquad (f \circ g)(x^1, \ldots, x^n) := f(g(x^1), \ldots, g(x^n)).$$

A *composition theorem* aims to understand the query complexity of $f \circ g$ in terms of f and g. Such theorems are known for deterministic query complexity, $\mathsf{D}(f \circ g) = \mathsf{D}(f)\mathsf{D}(g)$ [17, 19, 14], and quantum query complexity, $\mathsf{Q}(f \circ g) = \Theta(\mathsf{Q}(f)\mathsf{Q}(g))$ [12, 16]. The conjecture in the randomized case is:

▶ **Conjecture 1.5.** $\mathsf{R}(f \circ g) \geq \Omega(\mathsf{R}(f)\mathsf{R}(g))$ *for all boolean functions f and g.*

Gavinsky et al. [9] have shown that the conjecture fails if f is allowed to be a *relation*. They also show $\mathsf{R}(f \circ g) \geq \Omega(\mathsf{R}(f)\mathsf{R}(g)^{1/2})$ for any relation f and partial function g. In a very recent work (concurrent to ours) Ben-David and Blais [5, 6] have found a counterexample to the randomized conjecture for partial f and g, albeit with a tiny query complexity compared to input length; see also Subsection 1.5. The conjecture is still open for total functions.

Fractional block sensitivity. We show a new composition theorem in terms of *fractional block sensitivity* $\mathsf{fbs}(f)$, introduced by [19, 10]; see also [13, 2]. This measure is at most randomized query complexity, $\mathsf{fbs}(f) \leq O(\mathsf{R}(f))$, and it is equivalent to *randomized certificate complexity* [1].

Let us define $\mathsf{fbs}(f)$ for an n-bit f. We say that a block $B \subseteq [n]$ is *sensitive* on input x iff $f(x) \neq f(x^B)$ where x^B is x but with bits in B flipped. Fix an input x and introduce a real weight $w_B \in [0,1]$ for each sensitive block B of x. Define $\mathsf{fbs}(f,x)$ as the optimum value of the following linear program

$$\begin{array}{rll} \max & \sum_B w_B & \\ \textit{subject to} & \sum_{B \ni i} w_B \leq 1, & \forall i \in [n], \\ & w_B \geq 0, & \forall B. \end{array}$$

Finally, define $\mathsf{fbs}(f) := \max_x \mathsf{fbs}(f,x)$. For comparison, the more usual *block sensitivity* $\mathsf{bs}(f)$ [15] is defined the same way except with the integral constraint $w_B \in \{0,1\}$. In particular $\mathsf{bs}(f) \leq \mathsf{fbs}(f)$, and moreover a polynomial gap (power 1.5) between the two is known for a total function [10].

We make progress towards the composition conjecture; see Section 6 for the proof.

▶ **Theorem 1.6.** $\mathsf{R}(f \circ g) \geq \Omega(\mathsf{fbs}(f)\mathsf{R}(g))$ *for any (partial) boolean functions f and g.*

The previous best comparable composition theorem was $\mathsf{R}(f \circ g) \geq \Omega(\mathsf{bs}(f)\mathsf{R}(g))$, a proof of which is virtually the same as for the result that $\mathsf{R}(\textsc{And}_n \circ g) \geq \Omega(n\mathsf{R}(g))$; see [11, §5.1]. In fact, we were originally motivated to consider the correlated samples problem when trying to strengthen this composition result from block sensitivity to fractional block sensitivity.

1.5 Independent work by Ben-David and Blais

In an independent and concurrent work, Ben-David and Blais [5, 6] have also studied the randomized composition conjecture and ways of circumventing Shaltiel examples via improved minimax theorems. They develop a powerful framework for constructing hard *Shaltiel-free* distributions, which is general enough to apply not only to query complexity but also, for instance, to communication complexity. In particular, their framework is able to give an alternative proof of our main result (Theorem 1.2) as well as our fbs-based composition theorem (Theorem 1.6). Their proof techniques involve information theory and analysis; by contrast, our techniques are more elementary and directly tailored to the correlated samples problem (which does not explicitly appear in their work).

1.6 Roadmap

We will prove our main theorem (Theorem 1.2) in Section 3 and Section 4. Before that, we introduce our basic notions regarding decision trees in Section 2. In Section 3, we characterize decision trees as *likelihood boosters*, emphasizing that a good query algorithm must make significant progress in terms of boosting the likelihood of one of the outputs (0 or 1) to much higher than the other, and vice versa. This characterization frees us from considering inputs from both $\mathcal{D}_0$ and $\mathcal{D}_1$ simultaneously: if an algorithm is certain about the output on $\mathcal{D}_1$, then it must also make few errors on $\mathcal{D}_0$. We thus reduce the proof of Theorem 1.2 to bootstrapping decision trees that can make *overall* progress across multiple samples to a decision tree that makes uniform progress. In Section 4, we build such a bootstrapping algorithm and show that it makes satisfactory progress with a careful analysis. Proofs for our two applications are in Section 5 and Section 6.

2 Preliminaries

Let $f : \Sigma^n \to \{0, 1, *\}$ be a partial function for some alphabet Σ (typically $\Sigma = \{0, 1\}$). Let $\mathcal{D}_0, \mathcal{D}_1$ be distributions supported on $f^{-1}(0)$, $f^{-1}(1)$ respectively. For each $x \in \Sigma^n$, let $\mathcal{D}_0(x)$ (resp. $\mathcal{D}_1(x)$) denote the probability mass on x in distribution $\mathcal{D}_0$ (resp. $\mathcal{D}_1$). For a subset $S \subseteq \Sigma^n$, we define $\mathcal{D}_b(S) = \sum_{x\in S} \mathcal{D}_b(x)$ for $b = 0, 1$. If $\mathcal{D}_b(S) > 0$, we define the conditional distribution $\mathcal{D}_b|_S$ by $\mathcal{D}_b|_S(x) = \frac{\mathcal{D}_b(x)}{\mathcal{D}_b(S)}$ when $x \in S$, and $\mathcal{D}_b|_S(x) = 0$ when $x \notin S$. We define the *likelihood-ratio* of S as

$$\mathsf{LR}(S) := \frac{\mathcal{D}_1(S)}{\mathcal{D}_0(S)}.$$

Let T be a deterministic decision tree that takes as input a sample $x \in \Sigma^n$ drawn from either $\mathcal{D}_0$ or $\mathcal{D}_1$. For every vertex v in T, we use $\mathsf{Input}(v) \subseteq \Sigma^n$ to denote the set of strings that can reach v, or equivalently, the set of strings that agree with all the queries made so far. Typically, every non-leaf vertex in T corresponds to a query to a certain position in the sample, but we will allow non-leaf vertices v in T that do not make any query, each of them having only a single child v' with $\mathsf{Input}(v') = \mathsf{Input}(v)$. We abuse notation slightly and use v as a shorthand for $\mathsf{Input}(v)$, so we have $\mathcal{D}_0(v) = \sum_{x\in v} \mathcal{D}_0(x)$, $\mathcal{D}_1(v) = \sum_{x\in v} \mathcal{D}_1(x)$ and

$$\mathsf{LR}(v) = \frac{\mathcal{D}_1(v)}{\mathcal{D}_0(v)}.$$

Note that the likelihood-ratio $\mathsf{LR}(v)$ is non-negative, but could be zero or infinite. We can eliminate the undefined case ($\mathcal{D}_0(v) = \mathcal{D}_1(v) = 0$) by trimming the unreachable parts of the decision tree.

Now if the decision tree T takes as input k samples from Σ^n, it is not hard to see that $\mathsf{Input}(v)$ can be written as a Cartesian product $\mathsf{Input}(v) = \mathsf{Input}_1(v) \times \cdots \times \mathsf{Input}_k(v)$, where $\mathsf{Input}_j(v) \subseteq \Sigma^n$ is the set of strings that agree with all the queries made to the j-th sample so far. Again, we abuse notation slightly and use v_j as a shorthand for $\mathsf{Input}_j(v)$, so we will often write $v = v_1 \times \cdots \times v_k$. We define the *overall likelihood ratio* of v as the product

$$\mathsf{OLR}(v) := \mathsf{LR}(v_1) \cdots \mathsf{LR}(v_k) = \frac{\mathcal{D}_1(v_1)}{\mathcal{D}_0(v_1)} \cdots \frac{\mathcal{D}_1(v_k)}{\mathcal{D}_0(v_k)}.$$

It is often more convenient to consider the logarithm of likelihood ratios. We will use natural logarithm throughout the paper, i.e. $\log(\cdot) = \ln(\cdot)$.

3 Query Algorithms as Likelihood Boosters

Our overarching goal (Theorem 1.2) is to construct an efficient deterministic query algorithm that distinguishes $\mathcal{D}_0$ from $\mathcal{D}_1$, assuming the existence of one that distinguishes $\mathcal{D}_0^k$ from $\mathcal{D}_1^k$. As the starting point, we introduce the notion of *likelihood boosters* as a way of measuring the progress made by a query algorithm T in distinguishing $\mathcal{D}_0$ from $\mathcal{D}_1$. The key idea is that, as more queries are being made, the algorithm narrows down the possibilities of the unknown input, driving the likelihood of one of the output (0 or 1) much higher than the other. In fact, we show that T can distinguish $\mathcal{D}_0$ from $\mathcal{D}_1$ well if and only if a sample drawn from $\mathcal{D}_1$ has a high probability of arriving at a leaf of T where most of the remaining possibilities produce output 1. (Lemma 3.4 and Lemma 3.5).

In the multiple-sample setting, we use the notions of *overall likelihood boosters* and *uniform likelihood boosters*, which have different levels of guarantees, to measure the progress of a query algorithm on simultaneously classifying each of the samples in the input. We show that an efficient query algorithm that distinguishes $\mathcal{D}_0^k$ from $\mathcal{D}_1^k$ is an efficient overall likelihood booster (Corollary 3.6). Moreover, we show that an efficient uniform likelihood booster on multiple samples induces an efficient likelihood booster on a single sample (Lemma 3.7), which in turn implies an efficient query algorithm that distinguishes $\mathcal{D}_0$ from $\mathcal{D}_1$ (Lemma 3.4). These results will enable us to reduce proving Theorem 1.2 to relating overall likelihood boosters to uniform likelihood boosters, which is the focus of Section 4 (see Theorem 4.1).

We now formally define the three types of likelihood boosters mentioned above:

▶ **Definition 3.1.** *We say a deterministic decision tree T is a (δ, M)-*likelihood booster *for $\mathcal{D}_0, \mathcal{D}_1$ if, with probability at least $1 - \delta$, an input sample drawn from $\mathcal{D}_1$ reaches a leaf ℓ of T with likelihood ratio $\mathsf{LR}(\ell) \geq M$.*

▶ **Definition 3.2.** *We say a deterministic decision tree T is a (δ, M)-*overall likelihood booster *for $\mathcal{D}_0^k, \mathcal{D}_1^k$ if, with probability at least $1 - \delta$, an input drawn from $\mathcal{D}_1^k$ consisting of k samples reaches a leaf ℓ of T with* overall *likelihood ratio $\mathsf{OLR}(\ell) \geq M$.*

▶ **Definition 3.3.** *We say a deterministic decision tree T is a (δ, ε, M)-*uniform likelihood booster *for $\mathcal{D}_0^k$ and $\mathcal{D}_1^k$ if, with probability at least $1 - \delta$, an input x drawn from $\mathcal{D}_1^k$ consisting of k samples reaches a leaf $\ell = \ell_1 \times \cdots \times \ell_k$ of T with the property that at least $(1 - \varepsilon)k$ different samples $j \in \{1, \cdots, k\}$ satisfy $\mathsf{LR}(\ell_j) \geq M$.*

Note that the above definitions do not depend on the actual output of the decision tree T. We now show in the following two lemmas that likelihood boosters are in some sense equivalent to query algorithms that distinguish $\mathcal{D}_0$ from $\mathcal{D}_1$.

▶ **Lemma 3.4.** *Suppose T is a (δ, M)-likelihood booster for $\mathcal{D}_0, \mathcal{D}_1$. Consider the deterministic decision tree T' that makes exactly the same queries as T and accepts if and only if a leaf ℓ with $\mathsf{LR}(\ell) \geq M$ is reached. Then T' distinguishes $\mathcal{D}_0$ from $\mathcal{D}_1$ with the following guarantees:*

1. *(Completeness) T' accepts $x \sim \mathcal{D}_1$ with probability at* least *$1 - \delta$.*
2. *(Soundness) T' accepts $x \sim \mathcal{D}_0$ with probability at* most *$1/M$.*

Proof. Completeness follows directly from the definition of likelihood booster. To prove soundness, consider the set U of leaves ℓ with $\mathsf{LR}(\ell) \geq M$. For all $\ell \in U$, we have $\mathcal{D}_0(\ell) \leq \frac{1}{M}\mathcal{D}_1(\ell)$. Therefore, $\sum_{\ell \in U} \mathcal{D}_0(\ell) \leq \frac{1}{M} \sum_{\ell \in U} \mathcal{D}_1(\ell) \leq \frac{1}{M}$. This means that a sample from $\mathcal{D}_0$ reaches leaves in U with probability at most $\frac{1}{M}$, which is exactly the desired soundness. ◀

▶ **Lemma 3.5.** *Suppose a deterministic decision tree T can distinguish $\mathcal{D}_0$ from $\mathcal{D}_1$ with the following guarantees: T accepts $x \sim \mathcal{D}_0$ with probability at most δ_0, and accepts $x \sim \mathcal{D}_1$ with probability at least $1 - \delta_1$. Then T is a $(M\delta_0 + \delta_1, M)$-likelihood booster for any $M > 0$.*

Proof. Let U denote the set of leaves ℓ with $\mathsf{LR}(\ell) < M$. We can partition U as $U = U_0 \cup U_1$, where U_1 corresponds to the leaves at which T accepts. Since T accepts with probability at most δ_0 on $\mathcal{D}_0$, we have $\sum_{\ell \in U_1} \mathcal{D}_0(\ell) \leq \delta_0$. Similarly, we have $\sum_{\ell \in U_0} \mathcal{D}_1(\ell) \leq \delta_1$. Therefore,

$$\sum_{\ell \in U} \mathcal{D}_1(\ell) = \sum_{\ell \in U_0} \mathcal{D}_1(\ell) + \sum_{\ell \in U_1} \mathcal{D}_1(\ell) \leq \sum_{\ell \in U_0} \mathcal{D}_1(\ell) + M \sum_{\ell \in U_1} \mathcal{D}_0(\ell) = \delta_1 + M\delta_0.$$

In other words, a sample from $\mathcal{D}_1$ has probability at most $M\delta_0 + \delta_1$ of reaching a leaf in U, which means that T is a $(M\delta_0 + \delta_1, M)$-likelihood booster. ◀

In the multiple-sample setting, if we view the pair $\mathcal{D}_0^k$ and $\mathcal{D}_1^k$ as $\mathcal{D}_0'$ and $\mathcal{D}_1'$ in the single-sample setting with input length multiplied by k, the definition of overall likelihood ratio coincides with the definition of likelihood ratio in the single-sample setting. Therefore, we have the following corollary of Lemma 3.5, which essentially shows that an efficient query algorithm for the correlated samples problem is an efficient overall likelihood booster:

▶ **Corollary 3.6.** *Suppose a deterministic decision tree T can distinguish $\mathcal{D}_0^k$ from $\mathcal{D}_1^k$ in that T accepts $x \sim \mathcal{D}_0^k$ with probability at most δ_0, and T accepts $x \sim \mathcal{D}_1^k$ with probability at least $1 - \delta_1$. Then T is a $(M\delta_0 + \delta_1, M)$-overall likelihood booster for any $M > 0$.*

To conclude this section, we show that an efficient uniform likelihood booster in the multiple-sample setting implies an efficient likelihood booster in the single-sample setting.

▶ **Lemma 3.7.** *For any* (δ, ε, M)-uniform likelihood booster *T for $\mathcal{D}_0^k$ and $\mathcal{D}_1^k$ and any $C > 0$, there is a $(\delta + \varepsilon + \frac{1}{C}, M)$-likelihood booster T' for $\mathcal{D}_0$ and $\mathcal{D}_1$ with* $\mathrm{depth}(T') \leq C \cdot \frac{\mathrm{depth}(T)}{k}$.

Proof. Define $Q = C \cdot \frac{\mathrm{depth}(T)}{k}$. We first build a randomized query algorithm $\mathcal{A}'$ for $\mathcal{D}_0$ and $\mathcal{D}_1$, and later derandomize it as T'. On input $x_{\mathcal{A}'}$, $\mathcal{A}'$ generates k random samples $(x_1, \dots, x_k) \sim \mathcal{D}_1^k$, selects a uniformly random index j, replaces x_j with $\mathcal{A}'$'s own input $x_{\mathcal{A}'}$, and finally simulates T on the modified k samples $(x_1, \dots, x_{\mathcal{A}'}, \dots, x_k)$. If T attempts to make the $(\lfloor Q \rfloor + 1)$-th query to the j-th (modified) sample, $\mathcal{A}'$ halts.

It is easy to see that the maximum number of queries made by $\mathcal{A}'$ is at most Q. Moreover, by Markov's inequality, if the input $x_{\mathcal{A}'}$ to $\mathcal{A}'$ is drawn from $\mathcal{D}_1$, the probability that $\mathcal{A}'$ halts early because of T making more than Q queries to the j-th sample is at most $\frac{1}{C}$, since the average number of queries T makes to the j-th sample for a uniformly random j is at most $\frac{\mathrm{depth}(T)}{k}$.

We now show that with probability at least $1-(\delta+\varepsilon+\frac{1}{C})$, $\mathcal{A}'$ reaches a leaf $\ell = \ell_1 \times \cdots \times \ell_k$ of T with $\mathsf{LR}(\ell_j) \geq M$ when its own input $x_{\mathcal{A}'}$ is drawn from $\mathcal{D}_1$. By a union bound, we only need to show that this holds with probability at least $1 - (\delta + \varepsilon)$ for the extended version of $\mathcal{A}'$ that doesn't halt early. If we switch the order of randomness so that j is chosen after a leaf of T is reached, this follows easily from the definition of uniform likelihood boosters (Definition 3.3).

Finally, we derandomize $\mathcal{A}'$. Note that the randomness in $\mathcal{A}'$ only comes from the randomness in j and in all the generated samples x_i except the j-th sample. We can simply fix them so that the probability of reaching a leaf ℓ of T with $\mathsf{LR}(\ell_j) \geq M$ is maximized, assuming that the j-th sample is from $\mathcal{D}_1$. Since j and all generated samples other than the j-th sample have been fixed, the decision tree T now "shrinks" to a decision tree T' with only the first $\lfloor Q \rfloor$ queries to the j-th sample remaining, and every leaf ℓ of T that is reachable when we run $\mathcal{A}'$ now becomes a leaf ℓ' of T'. Shrinking the tree doesn't affect the computation history regarding the j-th sample, so we have $\ell' = \mathsf{Input}(\ell') = \mathsf{Input}_j(\ell) = \ell_j$ and $\mathsf{LR}(\ell') = \mathsf{LR}(\ell_j)$. This proves that T' is a $(\delta + \varepsilon + \frac{1}{C}, M)$-likelihood booster. ◀

4 Bootstrapping Overall Booster to Uniform Booster

The results from the previous section (Section 3) reduce proving our main result (Theorem 1.2) to proving relations between overall likelihood boosters and uniform likelihood boosters. In this section, we complete this step with the following result:

▶ **Theorem 4.1.** *Assume that there is a depth-L* $(0.1, 25)$*-overall likelihood booster for* every *distribution pair $\mathcal{D}_0^k, \mathcal{D}_1^k$. Then there is a depth-$O(KL)$* $(0.1, 0.1, 100)$*-uniform likelihood booster for every distribution pair $\mathcal{D}_0^K, \mathcal{D}_1^K$ whenever $K \geq 1000k(|\Sigma| + 1)^n$.*

We first show how to derive Theorem 1.2 from Theorem 4.1:

Proof of Theorem 1.2. We prove the inequality $\mathsf{R}(f) \leq O(\mathsf{Corr}(f))$ (the converse inequality is trivial). Suppose we have a depth-L deterministic decision tree that solves the correlated samples problem on $\frac{1}{2}\mathcal{D}_0^k + \frac{1}{2}\mathcal{D}_1^k$ with success probability at least 0.999 (recall that the success probability can be amplified by Fact 1.1). That is, the decision tree accepts inputs drawn from $\mathcal{D}_1^k$ with probability at *least* 0.998 and accepts inputs drawn from $\mathcal{D}_0^k$ with probability at *most* 0.002. By Corollary 3.6, it is a $(0.1, 25)$-overall likelihood booster for $\mathcal{D}_0^k$ and $\mathcal{D}_1^k$.

By Theorem 4.1, for any pair of distributions $\mathcal{D}_0^K, \mathcal{D}_1^K$, there is a $(0.1, 0.1, 100)$-uniform likelihood booster with depth $O(KL)$. Then by Lemma 3.7, there is a $(1/3, 100)$-likelihood booster with depth $O(L)$ for $\mathcal{D}_0$ and $\mathcal{D}_1$, which by Lemma 3.4 implies a query algorithm for $\mathcal{D}_0$ and $\mathcal{D}_1$ with success probability at least 1/3. By the arbitrariness of $\mathcal{D}_0$ and $\mathcal{D}_1$, we have $\mathsf{R}_{1/3}(f) = O(L)$ via Yao's minimax, as desired. ◀

The rest of this section is dedicated to proving Theorem 4.1. We construct the desired uniform likelihood booster $T_{\text{bootstrap}}$, described in Subsection 4.1, by applying different overall likelihood boosters to appropriate sets of samples at different phases of computation. To quantify the progress made by $T_{\text{bootstrap}}$, we design a measure based on a "truncated" log likelihood ratio which handles samples that $T_{\text{bootstrap}}$ is confident about with special care. As the technical core of the proof, we show that under our carefully constructed measure, $T_{\text{bootstrap}}$ in expectation makes *positive* and *constant* progress during each phase of computation (Lemmas 4.2 and 4.3). Therefore, $T_{\text{bootstrap}}$ is able to achieve the desired guarantees after sufficiently many phases.

4.1 Bootstrapping algorithm

We describe our depth-$O(KL)$ $(0.1, 0.1, 100)$-uniform likelihood booster $T_{\text{bootstrap}}$ taking $K \geq 1000k(|\Sigma| + 1)^n$ samples. Recall that each vertex v of $T_{\text{bootstrap}}$ can be written as a Cartesian product $v = v_1 \times \cdots \times v_K$, where $v_j \subseteq \Sigma^n$ is the set of strings that are consistent with the queries made to the j-th sample so far. We say that the j-th sample is *settled* at v if

$$\mathsf{LR}(v_j) = \frac{\mathcal{D}_1(v_j)}{\mathcal{D}_0(v_j)} \notin [e^{-100}, e^{100}].$$

Note that it is possible for a sample to be settled in the wrong direction (e.g. $\mathsf{LR}(v_j) < e^{-100}$ on input drawn from $\mathcal{D}_1^K$), but we will show that this is not a serious issue.

The query algorithm $T_{\text{bootstrap}}$ proceeds in at most $C \cdot K$ phases (for some large constant $C > 0$). Each phase consists of at most L queries and is described as follows:

Phase $s = 1, \cdots, C \cdot K$:

1. If fewer than $k(|\Sigma| + 1)^n$ out of the K samples are unsettled, halt.
2. Else, since each v_j is determined by a string v_* in $(\Sigma \cup \{*\})^n$ recording the queries made so far to the j-th sample, by the Pigeonhole Principle there exist k unsettled samples $j_1, \cdots, j_k$ with $v_{j_1} = \cdots = v_{j_k} = v_*$.
3. Run the depth-L $(0.1, 25)$-overall likelihood booster $A^{(v_*)}$, assumed in Theorem 4.1 to exist, relative to the input-distribution pair

$$(\mathcal{D}_0|_{v_*})^k \ , \quad (\mathcal{D}_1|_{v_*})^k$$

on the samples

$$(x^{j_1}, \ldots, x^{j_k}) \ .$$

If any query causes one of these samples to become settled (i.e. $\mathsf{LR}(v_{j_i}) \notin [e^{-100}, e^{100}]$ for some $i \in \{1, \cdots, k\}$), halt $A^{(v_*)}$ and go to the next Phase. Otherwise we proceed to the next Phase after $A^{(v_*)}$ terminates. If fewer than L queries are made in the current phase, insert dummy vertices that do not make any query (see Section 2) to $T_{\text{bootstrap}}$ so that each phase corresponds to a path in $T_{\text{bootstrap}}$ with length exactly L.

4.2 Sub-martingale property of progress measure

It's not hard to see that the overall likelihood ratio (OLR) is *not* an effective measure of progress for $T_{\text{bootstrap}}$: OLR can rocket to infinity even when there is only one settled sample. In this subsection, we introduce a better progress measure: *overall truncated log likelihood ratio* (OTLLR), and show that it is a sub-martingale along the computation path of *any* decision tree (Lemma 4.2). In other words, $T_{\text{bootstrap}}$ always makes *non-negative* progress in expectation. We will show that each phase of $T_{\text{bootstrap}}$ makes *positive* expected progress in the next subsection (Subsection 4.3).

Let T be a deterministic decision tree that takes as input K samples. For every vertex $v = v_1 \times \cdots \times v_K$ of T, we define the *truncated log likelihood ratio* of v_j as

$$\mathsf{TLLR}(v_j) := \begin{cases} \log(\mathsf{LR}(v_j)), & \text{if } |\log(\mathsf{LR}(v_j))| \le 100, \\ 500, & \text{otherwise.} \end{cases}$$

Note that if $\log(\mathsf{LR}(v_j))$ slightly exceeds the upper threshold 100, we set TLLR to a much higher value 500. Also, when $\log(\mathsf{LR}(v_j))$ drops below the lower threshold -100, we also set TLLR to 500. Thus, the j-th sample is *settled* at v if and only if $\mathsf{TLLR}(v_j) = 500$.

We define the *overall truncated log-likelihood-ratio* of v as the sum

$$\mathsf{OTLLR}(v) := \sum_{j=1}^{K} \mathsf{TLLR}(v_j).$$

The input x to T determines a computation path from the root of T to a leaf: $v^0 \to v^1 \to \cdots \to v^q$. The randomness in x transfers to the randomness in the path, so the path is a stochastic process. We now show that $\mathsf{OTLLR}(v^t)$ along the path is a sub-martingale when x is drawn from $\mathcal{D}_1^K$:

▶ **Lemma 4.2.** *Assume that T never queries a settled sample. Assume that the input x to T is drawn from $\mathcal{D}_1^K$, v is a non-leaf vertex with distance t from the root, and v is reachable (i.e.* $\Pr[v^t = v] > 0$ *on $\mathcal{D}_1^K$). Define $\Delta^t := \mathsf{OTLLR}(v^{t+1}) - \mathsf{OTLLR}(v^t)$. Then we have*

$$\mathbb{E}[\Delta^t | v^t = v] \ge 0.001 \cdot \mathbb{E}[(\Delta^t)^2 | v^t = v] \ge 0.$$

Proof. Let us condition on $v^t = v$ in the whole proof. If v is a dummy vertex that does not make any query, then $\Delta^t = 0$ deterministically and the lemma holds trivially. We assume that v is not a dummy vertex henceforth.

Suppose sample j is queried at vertex v. We have $\mathsf{OTLLR}(v^{t+1}) - \mathsf{OTLLR}(v^t) = \mathsf{TLLR}(v_j^{t+1}) - \mathsf{TLLR}(v_j^t)$. Since T never queries a settled sample, we know $\mathsf{TLLR}(v_j^t) = \log \frac{\mathcal{D}_1(v_j^t)}{\mathcal{D}_0(v_j^t)} \in [-100, 100]$.

Let $\sigma \in \Sigma$ denote the random outcome of the query, and let $p_0(\sigma), p_1(\sigma)$ denote the probability that the outcome to the query is σ under $\mathcal{D}_0|_{v_j^t}, \mathcal{D}_1|_{v_j^t}$, respectively. Let $H \subseteq \Sigma$ denote the set of $\sigma \in \Sigma$ with $|\mathsf{TLLR}(v_j^t) + \log \frac{p_1(\sigma)}{p_0(\sigma)}| > 100$. Note that $\mathcal{D}_0(v_j^{t+1}) = \mathcal{D}_0(v_j^t) p_0(\sigma)$ and $\mathcal{D}_1(v_j^{t+1}) = \mathcal{D}_1(v_j^t) p_1(\sigma)$, so

$$\mathsf{TLLR}(v_j^{t+1}) = \begin{cases} \mathsf{TLLR}(v_j^t) + \log \frac{p_1(\sigma)}{p_0(\sigma)}, & \sigma \notin H, \\ 500, & \sigma \in H. \end{cases}$$

Thus, H is precisely the set of outcomes $\sigma \in \Sigma$ that make sample j settled at v^{t+1}. Let $W = W(\sigma)$ denote the difference $\mathsf{TLLR}(v_j^{t+1}) - \mathsf{TLLR}(v_j^t)$. Our goal is to prove $\mathbb{E}[W] \ge 0.001 \cdot \mathbb{E}[W^2]$.

Note that $W(\sigma) \in [400, 600]$ when $\sigma \in H$ and $W(\sigma) = \log \frac{p_1(\sigma)}{p_0(\sigma)} \in [-200, 200]$ when $\sigma \notin H$. We have

$$\begin{aligned}\mathbb{E}[W] \geq& 400 \sum_{\sigma\in H} p_1(\sigma) + \sum_{\sigma\notin H} p_1(\sigma) \log \frac{p_1(\sigma)}{p_0(\sigma)}\\ =& 400 \sum_{\sigma\in H} p_1(\sigma) + \sum_{\sigma\notin H} p_0(\sigma) \cdot \frac{p_1(\sigma)}{p_0(\sigma)} \log \frac{p_1(\sigma)}{p_0(\sigma)}. \qquad (1)\end{aligned}$$

By a helper lemma (Lemma 4.4) proved in Subsection 4.4, we know that

$$\frac{p_1(\sigma)}{p_0(\sigma)} \log \frac{p_1(\sigma)}{p_0(\sigma)} \geq \left(\frac{p_1(\sigma)}{p_0(\sigma)} - 1\right) + \frac{1}{400} \cdot \frac{p_1(\sigma)}{p_0(\sigma)} \left(\log \frac{p_1(\sigma)}{p_0(\sigma)}\right)^2.$$

Plugging this into (1), we have

$$\begin{aligned}\mathbb{E}[W] \geq& 400 \sum_{\sigma\in H} p_1(\sigma) + \sum_{\sigma\notin H} p_1(\sigma) - \sum_{\sigma\notin H} p_0(\sigma) + \frac{1}{400} \sum_{\sigma\notin H} p_1(\sigma) \left(\log \frac{p_1(\sigma)}{p_0(\sigma)}\right)^2\\ \geq& 400 \sum_{\sigma\in H} p_1(\sigma) + \left(\sum_{\sigma\notin H} p_1(\sigma) - 1\right) + \frac{1}{400} \sum_{\sigma\notin H} p_1(\sigma) \left(\log \frac{p_1(\sigma)}{p_0(\sigma)}\right)^2\\ =& 400 \sum_{\sigma\in H} p_1(\sigma) - \sum_{\sigma\in H} p_1(\sigma) + \frac{1}{400} \sum_{\sigma\notin H} p_1(\sigma) \left(\log \frac{p_1(\sigma)}{p_0(\sigma)}\right)^2\\ =& 399 \sum_{\sigma\in H} p_1(\sigma) + \frac{1}{400} \sum_{\sigma\notin H} p_1(\sigma) \left(\log \frac{p_1(\sigma)}{p_0(\sigma)}\right)^2\\ =& 399 \sum_{\sigma\in H} p_1(\sigma) + \frac{1}{400} \sum_{\sigma\notin H} p_1(\sigma)(W(\sigma))^2\\ \geq& \frac{1}{1000} \sum_{\sigma\in H} p_1(\sigma)(W(\sigma))^2 + \frac{1}{400} \sum_{\sigma\notin H} p_1(\sigma)(W(\sigma))^2\\ \geq& \frac{1}{1000}\mathbb{E}[W^2].\end{aligned}$$

◀

4.3 Bounding the conditional expectation of progress

In the previous subsection, we showed that OTLLR, as a progress measure, is a sub-martingale. Now we refine our progress measure to also include the natural measure *number of settled samples*, and show that each phase of $T_{\text{bootstrap}}$ makes *positive* progress in expectation.

Recall that we inserted dummy vertices in $T_{\text{bootstrap}}$ to ensure that each phase corresponds to a computation path of length exactly L. Therefore, an entire computation path of $T_{\text{bootstrap}}$ must have length divisible by L: $v^0 \to \cdots \to v^{qL}$. The sub-path $v^{tL} \to \cdots \to v^{(t+1)L}$ is the computation path of the $(t+1)$-th phase.

Define $\mathsf{S}(v)$ as the number of settled samples at vertex v. Our new measure of progress is

$$\mathsf{P}(v^t) := \mathsf{S}(v^t) + \mathsf{OTLLR}(v^t).$$

▶ **Lemma 4.3.** *Assume that the input x to $T_{\text{bootstrap}}$ is drawn from $\mathcal{D}_1^K$, v is a non-leaf vertex with distance tL from the root, and v is reachable (i.e.* $\Pr[v^{tL} = v] > 0$ *on $\mathcal{D}_1^K$). Then we have*

$$\mathbb{E}[\mathsf{P}(v^{(t+1)L}) - \mathsf{P}(v^{tL}) | v^{tL} = v] \geq 0.001.$$

Before proving the lemma, we first show how it implies Theorem 4.1.

Proof of Theorem 4.1. We consider an extended version of $T_{\text{bootstrap}}$ that always halts after exactly $C \cdot K$ phases: whenever it would halt at line 1, it instead enters dummy phases and increases its total progress P by 0.001 per phase (so that now $\mathsf{P} = \mathsf{S} + \mathsf{OTLLR} + 0.001 \cdot$ number of dummy phases). By Lemma 4.3, the extended algorithm finishes with expected total progress $\mathbb{E}[\mathsf{P}] \geq 0.001C \cdot K$ on input drawn from $\mathcal{D}_1^K$. However, P can never grow too large: before any dummy phase, P is at most $501K$, and there are at most $C \cdot K$ dummy phases, so $\mathsf{P} \leq 501K + 0.001C \cdot K$. By Markov's inequality on the non-negative random variable $(501K + 0.001C \cdot K) - \mathsf{P}$, we have $\Pr[\mathsf{P} \leq 501K] \leq \frac{501K}{0.001C \cdot K} = \frac{501}{0.001C}$. If we choose a large enough C, we know that with probability at least 0.99, the total progress exceeds $501K$, which means that the extended algorithm enters dummy phases before halting, and the original algorithm halts at line 1 with all but 0.001 fraction of the samples settled.

It now suffices to show that the fraction of samples settled in the wrong direction (i.e., the likelihood ratio drops below e^{-100}) is at most 0.01 with probability at least 0.99. We first fix j and show that the probability that the j-th sample is settled in the wrong direction is at most e^{-100}, and then use the linearity of expectation and Markov's inequality to bound the overall wrong settlement.

Conditioning on all but the j-th sample, $T_{\text{bootstrap}}$ becomes a deterministic decision tree T' on a single sample. Let U denote the set of leaves ℓ of T' with $\mathsf{LR}(\ell) \leq e^{-100}$. We have $\sum_{\ell \in U} \mathcal{D}_1(\ell) \leq e^{-100} \sum_{\ell \in U} \mathcal{D}_0(\ell) \leq e^{-100}$. This means that the probability that a sample from $\mathcal{D}_1$ reaches leaves in U is at most e^{-100}. Thus the probability of wrong settlement for sample j in $T_{\text{bootstrap}}$ is at most e^{-100}.

By the linearity of expectation, the expected fraction of samples settled in the wrong direction is at most e^{-100}. Then by Markov's inequality, with probability at least 0.99, the fraction of wrong settlement is at most 0.01. ◀

Proof of Lemma 4.3. $\mathsf{S}(v^{(t+1)L}) - \mathsf{S}(v^{tL})$ is either 0 or 1, depending on whether or not a sample becomes settled in phase $t + 1$.

In the case where $\Pr[\mathsf{S}(v^{(t+1)L}) - \mathsf{S}(v^{tL}) = 1 | v^{tL} = v] \geq 0.001$, we have $\mathbb{E}[\mathsf{S}(v^{(t+1)L}) - \mathsf{S}(v^{tL}) | v^{tL} = v] \geq 0.001$, and by Lemma 4.2 we have $\mathbb{E}[\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL}) | v^{tL} = v] \geq 0$. Summing these two inequalities up proves the lemma.

From now on, we consider the harder case where $\Pr[\mathsf{S}(v^{(t+1)L}) - \mathsf{S}(v^{tL}) = 1 | v^{tL} = v] < 0.001$. We first prove that

$$\Pr[\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL}) \geq 3 | v^{tL} = v] \geq 0.8. \tag{2}$$

Recall that in this phase $T_{\text{bootstrap}}$ runs the $(0.1, 25)$-overall likelihood booster $A^{(v_*)}$ for $(\mathcal{D}_0|_{v_*})^k$ and $(\mathcal{D}_1|_{v_*})^k$ on the samples $j_1, \ldots, j_k$. If $\mathsf{S}(v^{(t+1)L}) - \mathsf{S}(v^{tL}) = 0$, i.e. no sample becomes settled in this phase, then

$$\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL}) = \sum_{s=1}^{k} \left(\log \frac{\mathcal{D}_1(v_{j_s}^{(t+1)L})}{\mathcal{D}_0(v_{j_s}^{(t+1)L})} - \log \frac{\mathcal{D}_1(v_{j_s}^{tL})}{\mathcal{D}_0(v_{j_s}^{tL})} \right).$$

Conditioning on $v^{tL} = v$, we have $v_{j_s}^{tL} = v_*$, since $v_{j_1} = \cdots = v_{j_k} = v_*$. From $\frac{\mathcal{D}_b(v_{j_s}^{(t+1)L})}{\mathcal{D}_b(v_*)} = \mathcal{D}_b|_{v_*}(v_{j_s}^{(t+1)L})$, we see that

$$\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL}) = \log \prod_{s=1}^{k} \frac{\mathcal{D}_1|_{v_*}(v_{j_s}^{(t+1)L})}{\mathcal{D}_0|_{v_*}(v_{j_s}^{(t+1)L})}.$$

Recall that $A^{(v_*)}$ halts early only when a new sample becomes settled, which happens with probability < 0.001. Therefore, in order to prove (2) by a union bound, we only need to prove that the extended version of phase $t+1$ where $A^{(v_*)}$ gets to run without early halting achieves $\prod_{s=1}^{k} \frac{\mathcal{D}_1|_{v_*}(v_{j_s}^{(t+1)L})}{\mathcal{D}_0|_{v_*}(v_{j_s}^{(t+1)L})} \geq e^3$ with probability at least 0.9. This is indeed true because $A^{(v_*)}$ is a $(0.1, 25)$-overall likelihood booster for $(\mathcal{D}_0|_{v_*})^k$ and $(\mathcal{D}_1|_{v_*})^k$.

We now prove $\mathbb{E}[\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL})|v^{tL} = v] \geq 0.001$. We prove it by contradiction. Suppose $\mathbb{E}[\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL})|v^{tL} = v] < 0.001$. For $tL \leq s < (t+1)L$, define $\Delta(v^s)$ as the conditional expectation $\mathbb{E}[\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s)|v^s]$ and $\Delta_2(v^s)$ as the conditional variance $\mathbb{E}[(\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s) - \Delta(v^s))^2|v^s]$. Note that

$$\begin{aligned}\Delta_2(v^s) &= \mathbb{E}[((\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s))^2|v^s] - (\Delta(v^s))^2\\ &\leq \mathbb{E}[((\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s))^2|v^s].\end{aligned}$$

Thus by Lemma 4.2, we know that $\Delta(v^s) \geq 0.001 \cdot \Delta_2(v^s) \geq 0$. Now we have

$$\begin{aligned}0.001 >&\mathbb{E}[\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL})|v^{tL} = v]\\ =& \sum_{tL \leq s < (t+1)L} \mathbb{E}[\Delta(v^s)|v^{tL} = v].\end{aligned}$$

By Markov's inequality, we have $\Pr\left[\sum_{tL \leq s<(t+1)L} \Delta(v^s) \geq 1|v^{tL} = v\right] \leq 0.001$. Now by a union bound with (2), we have

$$\begin{aligned}&\mathbb{E}\left[\left(\sum_{tL\leq s<(t+1)L} (\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s) - \Delta(v^s))\right)^2 \middle| v^{tL} = v\right]\\ =&\mathbb{E}\left[\left((\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL})) - \sum_{tL\leq s<(t+1)L} \Delta(v^s)\right)^2 \middle| v^{tL} = v\right]\\ \geq&(0.8 - 0.001) \times (3-1)^2\\ >&3. \end{aligned} \tag{3}$$

Since $\mathbb{E}\left[\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s) - \Delta(v^s)|v^s\right] = 0$, we have

$$\begin{aligned}&\mathbb{E}\big[(\mathsf{OTLLR}(v^{s_1+1}) - \mathsf{OTLLR}(v^{s_1}) - \Delta(v^{s_1}))\cdot\\ &\quad(\mathsf{OTLLR}(v^{s_2+1}) - \mathsf{OTLLR}(v^{s_2}) - \Delta(v^{s_2}))|v^{tL} = v\big] = 0\end{aligned}$$

whenever $s_1 < s_2$ by further conditioning on v^{s_2}. Thus expanding (3) we have

$$\begin{aligned}&\sum_{tL\leq s<(t+1)L} \mathbb{E}[\Delta_2(v^s)|v^{tL} = v]\\ =&\mathbb{E}\left[\sum_{tL\leq s<(t+1)L} (\mathsf{OTLLR}(v^{s+1}) - \mathsf{OTLLR}(v^s) - \Delta(v^s))^2 \middle| v^{tL} = v\right] \geq 3.\end{aligned}$$

Since $\Delta(v^s) \geq 0.001 \cdot \Delta_2(v^s)$, we have

$$0.001 > \sum_{tL\leq s<(t+1)L} \mathbb{E}[\Delta(v^s)|v^{tL} = v] \geq 0.001 \cdot \sum_{tL\leq s<(t+1)L} \mathbb{E}[\Delta_2(v^s)|v^{tL} = v] \geq 0.001 \times 3,$$

a contradiction.

Now we have shown $\mathbb{E}[\mathsf{OTLLR}(v^{(t+1)L}) - \mathsf{OTLLR}(v^{tL})|v^{tL} = v] \geq 0.001$. Adding it to the trivial inequality $\mathbb{E}[\mathsf{S}(v^{(t+1)L}) - \mathsf{S}(v^{tL})|v^{tL} = v] \geq 0$ proves the lemma. ◀

4.4 A helper inequality

▶ **Lemma 4.4.** *For all $M \geq 0, t \in (0, e^M]$, we have*

$$t \ln t - (t-1) \geq \frac{1}{M+2} \cdot t \ln^2 t.$$

Proof. Define function $h(t) = t \ln t - (t-1) - \frac{1}{M+2} \cdot t \ln^2 t$ on the interval $t \in (0, e^M]$. Our goal is to show $h(t) \geq 0$. Note that $h(1) = 0$, so we only need to show $h'(t) \geq 0$ for $t \geq 1$ and $h'(t) \leq 0$ for $t \leq 1$. We prove this by calculating $h'(t)$:

$$h'(t) = \ln t - \frac{1}{M+2} \cdot \ln^2 t - \frac{2}{M+2} \cdot \ln t = \left(1 - \frac{(\ln t) + 2}{M+2}\right) \ln t.$$

Note that $1 - \frac{(\ln t)+2}{M+2} \geq 0$ because $\ln t \leq M$. Therefore $h'(t) \geq 0$ when $t \geq 1$ and $h'(t) \leq 0$ when $t \leq 1$, as desired. ◀

5 Application 1: Selection Problem

5.1 Bi-correlated samples

To establish a relationship between correlated samples and selection, we first define an intermediate problem. The *bi-correlated samples problem* is defined by (here $\mathcal{D}_{ab} := \mathcal{D}_a \times \mathcal{D}_b$):

$$\begin{aligned} \mathsf{biCorr}_\epsilon(f, \mathcal{D}) &:= \min\nolimits_{k \geq 1} \mathsf{D}_\epsilon(f^{2k}, \tfrac{1}{2}\mathcal{D}_{01}^k + \tfrac{1}{2}\mathcal{D}_{10}^k), \\ \mathsf{biCorr}_\epsilon(f) &:= \max\nolimits_{\mathcal{D}} \mathsf{biCorr}_\epsilon(f, \mathcal{D}). \end{aligned}$$

That is, the task is to decide whether f^{2k} outputs $(01)^k$ or $(10)^k$ as $k \to \infty$. We show this is as hard as correlated samples:

▶ **Lemma 5.1.** $\mathsf{Corr}(f, \mathcal{D}) = \Theta(\mathsf{biCorr}(f, \mathcal{D}))$.

Proof. It is obvious that $\mathsf{biCorr}(f, \mathcal{D}) \leq \mathsf{Corr}(f, \mathcal{D})$, so we focus on the converse, $\mathsf{Corr}(f, \mathcal{D}) \leq O(\mathsf{biCorr}(f, \mathcal{D}))$. The proof is via a hybrid argument. Let $T\colon (\{0,1\}^n)^{2k} \to \{0,1\}$ be an optimal algorithm for $\mathsf{biCorr}_{1/3}(f, \mathcal{D})$ that uses k sample pairs. Letting $d(-,-)$ denote the statistical distance between two distributions, the fact that T achieves error $\epsilon := 1/3$ can be written as

$$d(T(\mathcal{D}_{01}^k), T(\mathcal{D}_{10}^k)) \;\geq\; 1 - 2\epsilon.$$

By the triangle inequality,

$$d(T(\mathcal{D}_{01}^k), T(\mathcal{D}_{00}^k)) \;+\; d(T(\mathcal{D}_{00}^k), T(\mathcal{D}_{10}^k)) \;\geq\; 1 - 2\epsilon.$$

Either the first or the second term is $\geq (1-2\epsilon)/2$. Say the first (second case is similar):

$$d(T(\mathcal{D}_{01}^k), T(\mathcal{D}_{00}^k)) \;\geq\; (1-2\epsilon)/2 \;=\; 1 - 2\epsilon' \qquad \text{where } \epsilon' := 1/4 + \epsilon/2 = 5/12.$$

This means we can turn T into an 5/12-error algorithm for the correlated k-samples problem: the odd numbered input samples of T the algorithm can generate from $\mathcal{D}_0$ on its own; the even numbered input samples of T are taken from the input to the correlated k-samples problem. Finally, the error can be reduced to 1/3 via Fact 1.1. ◀

5.2 Proof of Theorem 1.3

First item. The following claim together with Lemma 5.1 implies the first item.

▷ Claim 5.2. $\mathsf{biCorr}_\epsilon(f,\mathcal{D}) \le \mathsf{Sel}_\epsilon(f,\mathcal{D})$.

Proof. Let T_{Sel} be an optimal algorithm for $\mathsf{Sel}_\epsilon(f,\mathcal{D})$ using k samples. We describe an algorithm T_{biCorr} for bi-correlated k-samples with the same error and query cost. Let $x = (x_{ij})$ for $(i,j) \in [k] \times [2]$ be the random input to T_{biCorr}, that is, either *(i)* $x \sim \mathcal{D}_{01}^k$ or *(ii)* $x \sim \mathcal{D}_{10}^k$. The algorithm T_{biCorr} chooses a random string $z \in [2]^k$ and runs T_{Sel} on input $y \coloneqq (x_{iz_i})_{i\in[k]}$. Note that y is distributed as $\mathcal{D}^k$ in both cases *(i)* and *(ii)*. Suppose T_{Sel} outputs some $(i, f(x_{iz_i}))$. Assuming this output is correct for selection, and remembering our choice of z_i, we can deduce which case, *(i)* or *(ii)*, the input x came from, and let T_{biCorr} guess accordingly. Hence algorithm T_{biCorr} is correct every time T_{Sel} is, and so the error parameter is unaffected. ◁

Second and third item. For separating correlated samples from selection, we again consider the n-bit $\textsc{Xor}_n$ function. Define $x \sim \mathcal{D}$ by the following process:

1. Sample z uniformly from $\{0,1\}^{n-2}$ and let $a \coloneqq \textsc{Xor}_{n-2}(z)$.
2. Sample b uniformly from $\{0,1\}$.
3. With probability $\epsilon \coloneqq 1\%$, output $x \coloneqq aaz$; with probability $1-\epsilon = 99\%$, output $x \coloneqq bbz$.

Note that the first two bits of $x \sim \mathcal{D}$ are identical and hence $\textsc{Xor}_n(x) = \textsc{Xor}_{n-2}(z)$. Moreover, the first bit is ϵ-correlated with the function value $\textsc{Xor}_n(x)$. This makes $(\textsc{Xor}_n,\mathcal{D})$ easy for the correlated samples problem: The 1-query algorithm that guesses the function value based on the first bit of the first sample has error $\le 1/2 - \epsilon/2$, and this error can be reduced to $1/3$ via Fact 1.1. This shows that $\mathsf{Corr}(\textsc{Xor}_n,\mathcal{D}) = O(1)$.

Next we prove the lower bound $\mathsf{Sel}(\textsc{Xor}_n,\mathcal{D}) = \Omega(n)$, which also proves the third item. Suppose for contradiction that T is a height-$(n-3)$ deterministic decision tree for k-selection for $(\textsc{Xor}_n,\mathcal{D})$. Consider any leaf ℓ that claims the i-th sample evaluates to $b \in \{0,1\}$. If we condition $\mathcal{D}^k$ by the $\le n-3$ queries made by ℓ, we note that the function value is still only slightly biased away from $1/2$, that is, $\mathbb{E}_{x\sim\mathcal{D}^k|\ell}[\textsc{Xor}_n(x_i)] \in 1/2 \pm \epsilon$. Hence no leaf of T can compute selection to within error $\le 1/3$. This concludes the proof of Theorem 1.3.

6 Application 2: Randomized Composition

Goal. In this section we prove Theorem 1.6, namely $\mathsf{R}(f\circ g) \ge \Omega(\mathsf{fbs}(f)\mathsf{R}(g))$. By Theorem 1.2 and Lemma 5.1 (from Subsection 5.1) it suffices to show

$$\mathsf{biCorr}(g) \;\le\; O(\mathsf{R}(f\circ g)/\mathsf{fbs}(f)).$$

Let T be an optimal $1/10$-error algorithm for $f\circ g$ making $q \coloneqq O(\mathsf{R}(f\circ g))$ queries. Our goal is, given any balanced input distribution $\mathcal{D} \coloneqq \frac{1}{2}\mathcal{D}_0 + \frac{1}{2}\mathcal{D}_1$ to the inner function g, to build a bounded-error algorithm T' solving the bi-correlated samples problem for $(g,\mathcal{D})$.

Rarely queried block. By the definition of $\mathsf{fbs}(f)$, there is an input $y \in \{0,1\}^n$ to f (say, $f(y) = 0$) with sensitive blocks $B_1,\cdots,B_N \subseteq [n]$ and weights $w_1,\cdots,w_N \in [0,1]$ such that

$$\textstyle\sum_{j\in[N]} w_j \;=\; \mathsf{fbs}(f), \tag{4}$$

$$\textstyle\sum_{j:B_j\ni i} w_j \;\le\; 1, \qquad \forall i \in [n]. \tag{5}$$

For any $z \in \{0,1\}^n$, define $\mathcal{D}_z$ as the distribution over $(x_1, \cdots, x_n) \in (\{0,1\}^m)^n$ where each x_i is drawn independently from $\mathcal{D}_{z_i}$. Hence we have $g^n(x) = z$ for $x \sim \mathcal{D}_z$. We define

$$q_j \;\coloneqq\; \text{expected \# of queries } T \text{ makes to block } B_j \text{ on input } \mathcal{D}_y.$$

That is, if we denote by $i_t \in [n]$ the block that T queries at time t, then q_j is the expected number of time steps t with $i_t \in B_j$. By linearity of expectation and (5), we have

$$\textstyle\sum_{j\in[N]} w_j q_j \;=\; \mathbb{E}\Big[\sum_{j\in[N]} w_j \sum_{t:i_t\in B_j} 1\Big] \;=\; \mathbb{E}\Big[\sum_{t\in[q]} \sum_{j:B_j\ni i_t} w_j\Big] \;\le\; \mathbb{E}\Big[\sum_{t\in[q]} 1\Big] \;\le\; q.$$

Combining this with (4), we know there exists $j \in [N]$, say $j = 1$ for simplicity, such that

$$q_1 \;\le\; \frac{q}{\mathsf{fbs}(f)}.$$

Truncated *T*. Next we modify T so that it makes at most $5q_1$ queries to block B_1 for *every* input (not just on average over $\mathcal{D}_y$). Namely, if T makes more than $5q_1$ queries to block B_1, we simply let T halt and output 1; otherwise its behavior is unchanged. We denote this "truncated" algorithm by T^{tr}. We claim that T^{tr} still computes $f \circ g$ correctly on average over both $\mathcal{D}_y$ and $\mathcal{D}_{y^{B_1}}$ (recall that y^{B_1} is y but with the block B_1 flipped; note that $f(y^{B_1}) = 1$ and hence $(f \circ g)(x) = 1$ for each $x \sim \mathcal{D}_{y^{B_1}}$)

$$\begin{aligned}
\textit{Correct for } x \sim \mathcal{D}_{y^{B_1}}\textit{:} \qquad \Pr[T^{\text{tr}}(x) = 1] \;&\ge\; \Pr[T(x) = 1] \\
&\ge\; 4/5. && (6)
\end{aligned}$$

$$\begin{aligned}
\textit{Correct for } x \sim \mathcal{D}_y\textit{:} \qquad \Pr[T^{\text{tr}}(x) = 0] \;&\ge\; \Pr[T(x) = 0] \\
&\quad - \Pr[T(x) \text{ makes} > 5q_1 \text{ queries to } B_1] && (7)\\
&\ge\; 4/5 - 1/5 && (8)\\
&=\; 3/5, && (9)
\end{aligned}$$

where (7) uses the Union Bound and (8) uses the Markov Bound.

Algorithm *T′*. We are ready to define the algorithm T' for the bi-correlated samples problem for $(g, \mathcal{D})$. The random input to this problem is $z = (z_{ij})$, $(i,j) \in [n] \times \{0,1\}$, sampled either from *(i)* $\mathcal{D}_{01}^n$ or *(ii)* $\mathcal{D}_{10}^n$. On input z the algorithm T' simply runs T^{tr} on the input $(x_1, \ldots, x_n) \in (\{0,1\}^m)^n$ defined by

$$x_i \;\coloneqq\; \begin{cases} z_{iy_i} & \text{for } i \in B_1, \\ \sim \mathcal{D}_{y_i} & \text{for } i \notin B_1. \end{cases}$$

That is, for $i \in B_1$ the algorithm T' simply copies its input bits in z to the bits of x. For $i \notin B_1$ the algorithm T' uses its own randomness to generate an independent sample from either $\mathcal{D}_0$ or $\mathcal{D}_1$. The key observation is that in case *(i)* we have $x \sim \mathcal{D}_y$, and in case *(ii)* we have $x \sim \mathcal{D}_{y^{B_1}}$. But T^{tr} can distinguish these two cases to within bounded error by (6) and (9). Hence T' is a bounded-error algorithm for bi-correlated samples with query cost $5q_1 \le O(q/\mathsf{fbs}(f))$. This completes the proof of Theorem 1.6.

Abstract

The median of a set of vertices P of a graph G is the set of all vertices x of G minimizing the sum of distances from x to all vertices of P. In this paper, we present a linear time algorithm to compute medians in median graphs, improving over the existing quadratic time algorithm. We also present a linear time algorithm to compute medians in the ℓ_1-cube complexes associated with median graphs. Median graphs constitute the principal class of graphs investigated in metric graph theory and have a rich geometric and combinatorial structure. Our algorithm is based on the majority rule characterization of medians in median graphs and on a fast computation of parallelism classes of edges (Θ-classes or hyperplanes) via Lexicographic Breadth First Search (LexBFS). To prove the correctness of our algorithm, we show that any LexBFS ordering of the vertices of G satisfies the following *fellow traveler property* of independent interest: the parents of any two adjacent vertices of G are also adjacent.

1 Introduction

The median problem (also called the Fermat-Torricelli problem or the Weber problem) is one of the oldest optimization problems in Euclidean geometry [43]. The *median problem* can be defined for any metric space (X, d): given a finite set $P \subset X$ of points with positive weights, compute the points x of X minimizing the sum of the distances from x to the points

of P multiplied by their weights. The median problem in graphs is one of the principal models in network location theory [35, 62] and is equivalent to finding nodes with largest closeness centrality in network analysis [14, 15, 57]. It also occurs in social group choice as the Kemeny median. In the consensus problem in social group choice, given individual rankings one has to compute a consensual group decision. By Arrow's impossibility theorem, there is no consensus function satisfying natural "fairness" axioms. It is also well-known that the majority rule leads to Condorcet's paradox, i.e., to the existence of cycles in the majority relation. In this respect, the Kemeny median [39, 40] is an important consensus function and corresponds to the median problem in graphs of permutahedra.

The median problem in Euclidean spaces cannot be solved in a symbolic form [6], but it can be solved numerically by Weiszfeld's algorithm [66] and its convergent modifications (see e.g. [51]) and can be approximated in nearly linear time with arbitrary precision [26]. For the ℓ_1-metric the median problem becomes much easier and can be solved by the majority rule on coordinates, i.e., by taking as median a point whose ith coordinate is the median of the list consisting of ith coordinates of the points of P. This kind of majority rule was used in [38] to define centroids of trees (which coincide with their medians [32, 62]). For graphs with n vertices, m edges, and standard graph distance, the median problem can be trivially solved in $O(nm)$ time by solving the All Pairs Shortest Paths (APSP) problem. One may ask if APSP is necessary to compute the median. However, by [1] APSP and median problem are equivalent under subcubic reductions. It was also shown in [2] that computing the medians of sparse graphs in subquadratic time refutes the HS (Hitting Set) conjecture.

In this paper, we show that the medians in median graphs can be computed in optimal $O(m)$ time (i.e., without solving APSP). Median graphs are the graphs in which each triplet u, v, w of vertices has a unique median, i.e., a vertex metrically lying between u and v, v and w, and w and u. They originally arise in universal algebra [4, 18] and their properties have been first investigated in [45, 49]. It was shown in [24, 54] that the cube complexes of median graphs are exactly the CAT(0) cube complexes, i.e., cube complexes of global non-positive curvature. CAT(0) cube complexes, introduced and nicely characterized in [33] in a local-to-global way, are now one of the principal objects of investigation in geometric group theory [59]. Median graphs also occur in Computer Science: by [3, 13] they are exactly the domains of event structures (one of the basic abstract models of concurrency) [50] and median-closed subsets of hypercubes are exactly the solution sets of 2-SAT formulas [48, 60]. The bijections between median graphs, CAT(0) cube complexes, and event structures have been used in [20, 21, 25] to disprove three conjectures in concurrency [56, 63, 64]. Finally, median graphs, viewed as median closures of sets of vertices of a hypercube, contain all most parsimonious (Steiner) trees [12] and as such have been extensively applied in human genetics. For a survey on median graphs and their connections with other discrete and geometric structures, see the books [36, 42], the surveys [10, 41], and the paper [22].

As we noticed, median graphs have strong geometric and metric properties. For the median problem, the concept of Θ-classes is essential. Two edges of a median graph G are called opposite if they are opposite in a common square of G. The equivalence relation Θ is the reflexive and transitive closure of this oppositeness relation. Each equivalence class of Θ is called a Θ-class (Θ-classes correspond to hyperplanes in CAT(0) cube complexes [58] and to events in event structures [50]). Removing the edges of a Θ-class, the graph G is split into two connected components which are convex and gated. Thus they are called halfspaces of G. The convexity of halfspaces implies via [29] that any median graph G isometrically embeds into a hypercube of dimension equals to the number q of Θ-classes of G.

Our results and motivation. In this paper, we present a linear time algorithm to compute medians in median graphs and in ℓ_1-cube complexes associated to median graphs. Our main motivation and technique stem from the majority rule characterization of medians in median graphs and the unimodality of the median function [8, 61]. Even if the majority rule is simple to state and is a commonly approved consensus method, its algorithmic implementation is less trivial if one has to avoid the computation of the distance matrix. On the other hand, the unimodality of the median function implies that one may find the median set by using local search. More generally, consider a partial orientation of the input median graph G, where an edge uv is transformed into the arc $\overrightarrow{uv}$ iff the median function at u is larger than the median function at v (in case of equality we do not orient the edge uv). Then the median set is exactly the set of all the sinks in this partial orientation of G. Therefore, it remains to compare for every edge uv the median function at u and at v in constant time. For this we use the partition of the edge-set of a median graph G into Θ-classes and; for every Θ-class, the partition of the vertex-set of G into complementary halfspaces. It is easy to notice that all edges of the same Θ-class are oriented in the same way because for any such edge uv the difference between the median functions at u and at v, respectively, can be expressed as the sum of weights of all vertices in the same halfspace as v minus the sum of weights of all vertices in the same halfspace as u.

Our main technical contribution is a new method for computing the Θ-classes of a median graph G with n vertices and m edges in linear $O(m)$ time. For this, we prove that Lexicographic Breadth First Search (LexBFS) [55] produces an ordering of the vertices of G satisfying the following *fellow traveler property*: for any edge uv, the parents of u and v are adjacent. With the Θ-classes of G at hand and the majority rule for halfspaces, we can compute the weights of halfspaces of G in optimal time $O(m)$, leading to an algorithm of the same complexity for computing the median set. We adapt our method to compute in linear time the median of a finite set of points in the ℓ_1-cube complex associated with G. The method can be applied to compute the total distance (the Wiener index) in optimal $O(m)$ time and the distance matrix of G in optimal $O(n^2)$ time (see the full version [16]).

Related work. The study of medians in median graphs originated in [8, 61] and continued in [7, 44, 46, 47, 53]. Using different techniques and extending the majority rule for trees [32], the following *majority rule* has been established in [8, 61]: a halfspace H of a median graph G contains at least one median iff H contains at least one half of the total weight of G; moreover, the median of G coincides with the intersection of halfspaces of G containing strictly more than half of the total weight. Hence the median set is always convex. It was shown in [61] that the median function of a median graph is weakly convex (an analog of a discrete convex function). This convexity property characterizes all graphs in which all local medians are global [9]. A nice axiomatic characterization of medians of median graphs via three basic axioms has been obtained in [47]. More recently, [53] characterized median graphs as *closed Condorcet domains*, i.e., as sets of linear orders with the property that, whenever the preferences of all voters belong to the set, their majority relation has no cycles and also belongs to the set. In the full version [16] we show that the median graphs are the bipartite graphs in which the medians are characterized by the majority rule.

Prior to our work, the best algorithm to compute the Θ-classes of a median graph G has complexity $O(m \log n)$ [34]. It was used in [34] to recognize median graphs in subquadratic time. The previous best algorithm for the median problem in a median graph G with n vertices and q Θ-classes has complexity $O(qn)$ [7] which is quadratic in the worst case. Indeed q may be linear in n (as in the case of trees) and is always at least $d(\sqrt[d]{n}-1)$ as shown below

(d is the largest dimension of a hypercube which is an induced subgraph of G). Additionally, [7] assumes that an isometric embedding of G in a q-hypercube is given. The description of such an embedding has already size $O(qn)$. The Θ-classes of a median graph G correspond to the coordinates of the smallest hypercube in which G isometrically embeds (this is called the *isometric dimension* of G [36]). Thus one can define Θ-classes for all partial cubes, i.e., graphs isometrically embeddable into hypercubes. An efficient computation (in $O(n^2)$ time) of all Θ-classes was the main step of the $O(n^2)$ algorithm of [30] for recognizing partial cubes. The fellow-traveler property (which is essential in our computation of Θ-classes) is a notion coming from geometric group theory [31] and is a main tool to prove the (bi)automaticity of a group. In a slightly stronger form it allows to establish the dismantlability of graphs (see [19, 23, 24] for examples of classes of graphs in which a fellow traveler order was obtained by BFS or LexBFS). LexBFS has been used to solve optimally several algorithmic problems in different classes of graphs, in particular for their recognition (for a survey, see [28]).

Cube complexes of median graphs with ℓ_1-metric have been investigated in [65]. The same complexes but endowed with the ℓ_2-metric are exactly the CAT(0) cube complexes. As we noticed above, they are of great importance in geometric group theory [59]. The paper [17] established that the space of trees with a fixed set of leaves is a CAT(0) cube complex. A polynomial-time algorithm to compute the ℓ_2-distance between two points in this space was proposed in [52]. This result was recently extended in [37] to all CAT(0) cube complexes. A convergent numerical algorithm for the median problem in CAT(0) spaces was given in [5].

2 Preliminaries

All graphs $G = (V, E)$ in this paper are finite, undirected, simple, and connected; V is the vertex-set and E is the edge-set of G. We write $u \sim v$ if $u, v \in V$ are adjacent. The *distance* $d(u, v) = d_G(u, v)$ between two vertices u and v is the length of a shortest (u, v)-path, and the *interval* $I(u, v) = \{x \in V : d(u, x) + d(x, v) = d(u, v)\}$ consists of all the vertices on shortest (u, v)–paths. A set H (or the subgraph induced by H) is *convex* if $I(u, v) \subseteq H$ for any two vertices u, v of H; H is a *halfspace* if H and $V \setminus H$ are convex. Finally, H is *gated* if for every vertex $v \in V$, there exists a (unique) vertex $v' \in V(H)$ (the *gate* of v in H) such that for all $u \in V(H)$, $v' \in I(u, v)$. The *k-dimensional hypercube* Q_k has all subsets of $\{1, \dots, k\}$ as the vertex-set and $A \sim B$ iff $|A \triangle B| = 1$. A graph G is called *median* if $I(x, y) \cap I(y, z) \cap I(z, x)$ is a singleton for each triplet x, y, z of vertices; this unique intersection vertex $m(x, y, z)$ is called the *median* of x, y, z. Median graphs are bipartite and do not contain induced $K_{2,3}$. The *dimension* $d = \dim(G)$ of a median graph G is the largest dimension of a hypercube of G. In G, we refer to the 4-cycles as *squares*, and the hypercube subgraphs as *cubes*.

A map $w : V \to \mathbb{R}^+ \cup \{0\}$ is called a *weight function*. For a vertex $v \in V$, $w(v)$ denotes the weight of v (for a set $S \subseteq V$, $w(S) = \sum_{x \in S} w(x)$ denotes the weight of S). Then $F_w(x) = \sum_{v \in V} w(v) d(x, v)$ is called the *median function* of the graph G and a vertex x minimizing F_w is called a *median vertex* of G. Finally, $\mathrm{Med}_w(G) = \{x \in V : x \text{ is a median of } G\}$ is called the *median set* (or simply, the *median*) of G with respect to the weight function w.

3 Facts about median graphs

We recall the principal properties of median graphs used in the algorithms. Some of those results are a part of folklore for the people working in metric graph theory and some other results can be found in the papers [45, 46] by Mulder.

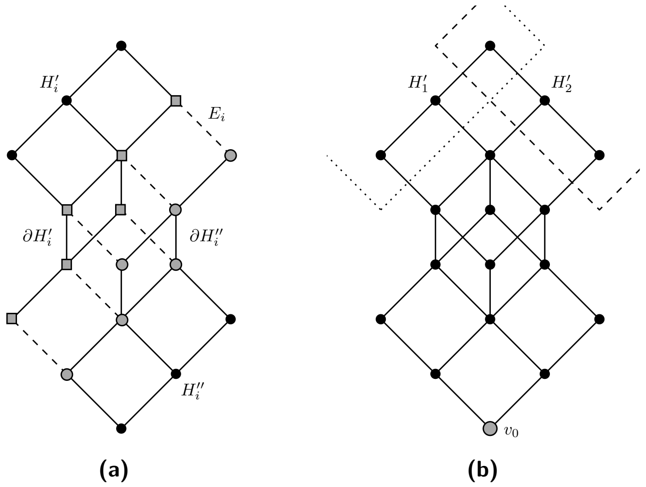

Figure 1 (a) In dashed, the Θ-class E_i of D, its two complementary halfspaces H'_i and H''_i and their boundaries $\partial H'_i$ and $\partial H''_i$, (b) two peripheral halfspaces of D, and (c) a LexBFS ordering of D.

From now on, $G = (V, E)$ is a median graph with n vertices and m edges. The first three properties follow from the definition.

▶ **Lemma 1** (Quadrangle Condition). *For any vertices u, v, w, z of G such that $v, w \sim z$ and $d(u, v) = d(u, w) = d(u, z) - 1 = k$, there is a unique vertex $x \sim v, w$ such that $d(u, x) = k - 1$.*

▶ **Lemma 2** (Cube Condition). *Any three squares of G, pairwise intersecting in three edges and all three intersecting in a single vertex, belong to a 3-dimensional cube of G.*

▶ **Lemma 3** (Convex=Gated). *A subgraph of G is convex if and only if it is gated. Each convex subgraph S of G is the intersection of all halfspaces containing S.*

Two edges uv and $u'v'$ of G are in relation Θ_0 if $uvv'u'$ is a square of G and uv and $u'v'$ are opposite edges of this square. Let Θ denote the reflexive and transitive closure of Θ_0. Denote by $E_1, \ldots, E_q$ the equivalence classes of Θ and call them Θ-*classes* (see Fig. 1(a)).

▶ **Lemma 4.** [45] (Halfspaces and Θ-classes). *For any Θ-class E_i of G, the graph $G_i = (V, E \setminus E_i)$ consists of exactly two connected components H'_i and H''_i that are halfspaces of G; all halfspaces of G have this form. If $uv \in E_i$, then H'_i and H''_i are the subgraphs of G induced by $W(u, v) = \{x \in V : d(u, x) < d(v, x)\}$ and $W(v, u) = \{x \in V : d(v, x) < d(u, x)\}$.*

Two Θ-classes E_i and E_j are *crossing* if each halfspace of the pair $\{H'_i, H''_i\}$ intersects each halfspace of the pair $\{H'_j, H''_j\}$; otherwise, E_i and E_j are called *laminar*.

▶ **Lemma 5** (Crossing Θ-classes). *Any vertex $v \in V(G)$ and incident edges $vv_1 \in E_1, \ldots, vv_k \in E_k$ belong to a single cube of G if and only if $E_1, \ldots, E_k$ are pairwise crossing.*

The *boundary* $\partial H'_i$ of a halfspace H'_i is the subgraph of H'_i induced by all vertices v' of H'_i having a neighbor v'' in H''_i. A halfspace H'_i of G is *peripheral* if $\partial H'_i = H'_i$ (See Fig. 1(b)).

▶ **Lemma 6** (Boundaries). *For any Θ-class E_i of G, $\partial H'_i$ and $\partial H''_i$ are isomorphic and gated.*

From now on, we suppose that G is rooted at an arbitrary vertex v_0 called the *basepoint*. For any Θ-class E_i, we assume that v_0 belongs to the halfspace H''_i. Let $d(v_0, H'_i) = \min\{d(v_0, x) : x \in H'_i\}$. Since H'_i is gated, the gate of v_0 in H'_i is the unique vertex of H'_i

at distance $d(v_0, H_i')$ from v_0. Since median graphs are bipartite, the choice of v_0 defines a canonical orientation of the edges of G: $uv \in E$ is oriented from u to v (notation $\overrightarrow{uv}$) if $d(v_0, u) < d(v_0, v)$. Let $\overrightarrow{G}_{v_0}$ denote the resulting oriented pointed graph.

▶ **Lemma 7.** [46] (Peripheral Halfspaces). *Any halfspace H_i' maximizing $d(v_0, H_i')$ is peripheral.*

For a vertex v, all vertices u such that $\overrightarrow{uv}$ is an edge of $\overrightarrow{G}_{v_0}$ are called *predecessors* of v and are denoted by $\Lambda(v)$. Equivalently, $\Lambda(v)$ consists of all neighbors of v in the interval $I(v_0, v)$. A median graph G satisfies the *downward cube property* if any vertex v and all its predecessors $\Lambda(v)$ belong to a single cube of G.

▶ **Lemma 8.** [45] (Downward Cube Property). *G satisfies the downward cube property.*

Lemma 8 immediately implies the following upper bound on the number of edges of G:

▶ **Corollary 9.** *If G has dimension d, then $m \leq dn \leq n \log n$.*

We give a sharp lower bound on the number q of Θ-classes, which is new to our knowledge.

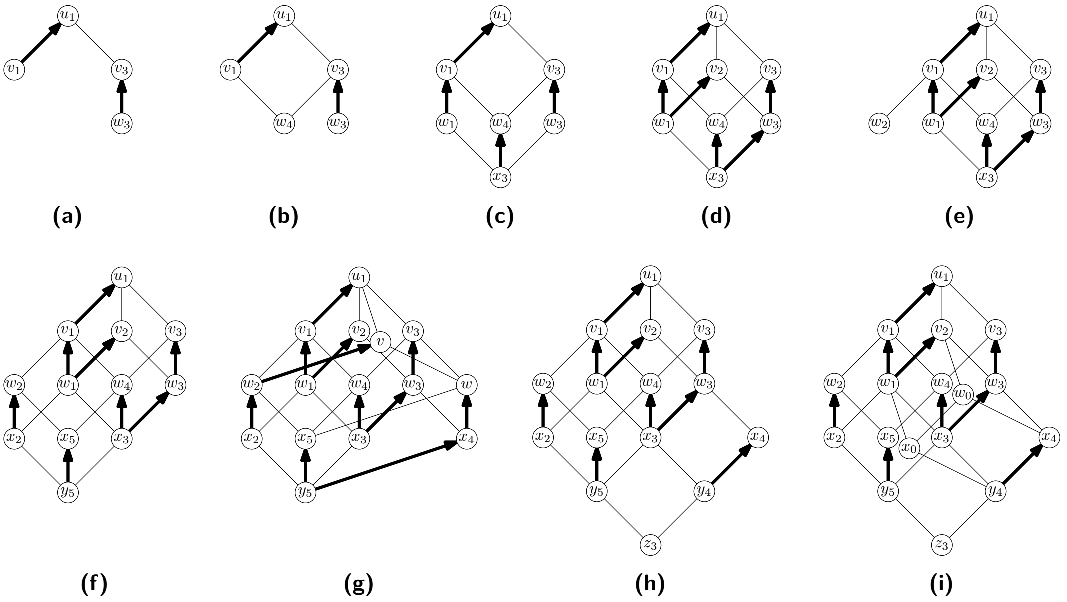
▶ **Proposition 10.** *If G has q Θ-classes and dimension d, then $q \geq d(\sqrt[d]{n} - 1)$ and this bound is tight.*

Proof. Let $\Gamma(G)$ be the crossing graph $\Gamma(G)$ of G: $V(\Gamma(G))$ is the set of Θ-classes of G and two Θ-classes are adjacent in $\Gamma(G)$ if they are crossing. Note that $|V(\Gamma(G))| = q$. Let $X(\Gamma(G))$ be the clique complex of $\Gamma(G)$. By the characterization of median graphs among ample classes [11, Proposition 4], the number of vertices of G is equal to the number $|X(\Gamma(G))|$ of simplices of $X(\Gamma(G))$. Since G is of dimension d, by [11, Proposition 4], $\Gamma(G)$ does not contain cliques of size $d + 1$. By Zykov's theorem [68] (see also [67]), the number of k-simplices in $X(\Gamma(G))$ is at most $\binom{d}{k}\left(\frac{q}{d}\right)^k$. Hence $n = |V(G)| = |X(\Gamma(G))| \leq \sum_{k=0}^{d} \binom{d}{k}\left(\frac{q}{d}\right)^k = \left(1 + \frac{q}{d}\right)^d$ and thus $q \geq d(\sqrt[d]{n} - 1)$. Let now G be the Cartesian product of d paths of length $(\sqrt[d]{n} - 1)$. Then G has $(\sqrt[d]{n} - 1 + 1)^d = n$ vertices and $d(\sqrt[d]{n} - 1)$ Θ-classes (each Θ-class of G corresponds to an edge of one of factors). ◀

4 Computation of the Θ-classes via LexBFS

The *Breadth-First Search (BFS)* refines the basepoint order and defines the same orientation $\overrightarrow{G}_{v_0}$ of G. BFS uses a queue Q and the insertion in Q defines a total order $<$ on the vertices of G: $x < y$ iff x is inserted in Q before y. When a vertex u arrives at the head of Q, it is removed from Q and all not yet discovered neighbors v of u are inserted in Q; u becomes the *parent* $f(v)$ of v; for any vertex $v \neq v_0$, $f(v)$ is the smallest predecessor of v. The arcs $\overrightarrow{f(v)v}$ define the *BFS-tree* of G. The *Lexicographic Breadth-First Search (LexBFS)*, proposed in [55], is a refinement of BFS. In BFS, if u and v have the same parent, then the algorithm order them arbitrarily. Instead, the LexBFS chooses between u and v by considering the ordering of their second-earliest predecessors. If only one of them has a second-earliest predecessor, then that one is chosen. If both u and v have the same second-earliest predecessor, then the tie is broken by considering their third-earliest predecessor, and so on (See Fig. 1(c)). The LexBFS uses a set partitioning data structure and can be implemented in linear time [55]. In median graphs, the next lemma shows that it suffices to consider only the earliest and second-earliest predecessors, leading to a simpler implementation of LexBFS:

▶ **Lemma 11.** *If u and v are two vertices of a median graph G, then $|\Lambda(u) \cap \Lambda(v)| \leq 1$.*



(a) **(b)** **(c)** **(d)** **(e)**

(f) **(g)** **(h)** **(i)**

Figure 2 Animated proof of Theorem 13.

During the execution of BFS (or LexBFS), one can assume that for each vertex v the set $\Lambda(v)$ of its predecessors is computed as an ordered list $\Lambda_<(v)$ (ordered by $<$). By Lemma 8, $|\Lambda_<(v)| \leq d := \dim(G)$. Note that $<$ also gives rise to a total order on the edges of G: for two edges uv and $u'v'$ with $u < v$ and $u' < v'$ we have $uv < u'v'$ iff $u < u'$ or if $u = u'$ and $v < v'$. The next lemma characterizes the first edge in the order $<$ of each Θ-class E_i.

▶ **Lemma 12.** *An edge $uv \in E_i$ with $d(v_0, u) < d(v_0, v)$ is the first edge of E_i iff $\Lambda_<(v) = \{u\}$.*

A graph G satisfies the *fellow-traveler property* if for any LexBFS ordering of the vertices of G, for any edge uv with $v_0 \notin \{u, v\}$, the parents $f(u)$ and $f(v)$ are adjacent.

▶ **Theorem 13.** *Any median graph G satisfies the fellow-traveler property.*

Proof. Let $<$ be an arbitrary LexBFS order of the vertices of G and f be its parent map. Since any LexBFS order is a BFS order, $<$ and f satisfy the following properties of BFS:

(BFS1) if $u < v$, then $f(u) \leq f(v)$;
(BFS2) if $f(u) < f(v)$, then $u < v$;
(BFS3) if $v \neq v_0$, then $f(v) = \min_<\{u : u \sim v\}$;
(BFS4) if $u < v$ and $v \sim f(u)$, then $f(v) = f(u)$.

Notice also the following simple but useful property:

▶ **Lemma 14.** *If $abcd$ is a square of G with $d(v_0, c) = k$, $d(v_0, b) = d(v_0, d) = k+1$, $d(v_0, a) = k + 2$ and $f(a) = b$, and the edge ad satisfies the fellow-traveler property, then $f(d) = c$.*

We prove the fellow-traveler property by induction on the total order on the edges of G defined by $<$. The proof is illustrated by several figures (the arcs of the parent map are represented in bold). We use the following convention: all vertices having the same distance to the basepoint v_0 will be labeled by the same letter but will be indexed differently; for example, w_1 and w_2 are two vertices having the same distance to v_0.

Suppose by way of contradiction that $e = u_1v_3$ with $v_3 < u_1$ is the first edge in the order $<$ such that the parents $f(u_1)$ and $f(v_3)$ of u_1 and v_3 are not adjacent. Then necessarily $f(u_1) \neq v_3$. Set $v_1 = f(u_1)$ and $w_3 = f(v_3)$ (Fig. 2a). Since $d(v_0, v_1) = d(v_0, v_3)$ and $u_1 \sim v_1, v_3$, by the quadrangle condition v_1 and v_3 have a common neighbor at distance

$d(v_0, v_1) - 1$ from v_0. This vertex cannot be w_3, otherwise $f(u_1)$ and $f(v_3)$ would be adjacent. Therefore there is a vertex $w_4 \sim v_1, v_3$ at distance $d(v_0, v_1) - 1$ from v_0 (Fig. 2b). By induction hypothesis, the parent $x_3 = f(w_4)$ of w_4 is adjacent to $w_3 = f(v_3)$. Since $u_1 \sim v_1 = f(u_1), v_3$ and $v_3 \sim w_3 = f(v_3), w_4$, by (BFS3) we conclude that $v_1 < v_3$ and $w_3 < w_4$. By (BFS2), $f(v_1) \leq f(v_3)$, whence $f(v_1) \leq w_3$ and since $f(v_1) \neq f(v_3)$ (otherwise, $f(u_1) \sim f(v_3)$), we deduce that $f(v_1) < w_3 < w_4$. Hence $f(v_1) \neq w_4$. Set $w_1 = f(v_1)$. By the induction hypothesis, $f(v_1) = w_1$ is adjacent to $f(w_4) = x_3$ (Fig. 2c). By the cube condition applied to the squares $w_4v_1w_1x_3$, $w_4v_1u_1v_3$, and $w_4v_3w_3x_3$ there is a vertex v_2 adjacent to u_1, w_1, and w_3. Since $u_1 \sim v_2$ and $f(u_1) = v_1$, by (BFS3) we obtain $v_1 < v_2$. Since v_2 is adjacent to w_1 and $w_1 = f(v_1)$, by (BFS4) we obtain $f(v_2) = f(v_1) = w_1$, and by (BFS2), $v_2 < v_3$. Since $f(v_2) = w_1$, by Lemma 14 for $v_2w_1x_3w_3$, we obtain $f(w_3) = x_3$ (Fig. 2d). Since $v_1 < v_2$, $f(v_1) = f(v_2) = w_1$, and $v_2 \sim w_1, w_3$, by LexBFS v_1 is adjacent to a predecessor different from w_1 and smaller than w_3. Since $w_3 < w_4$, this predecessor cannot be w_4. Denote by w_2 the second smallest predecessor of v_1 (Fig. 2e) and note that $w_1 < w_2 < w_3 < w_4$.

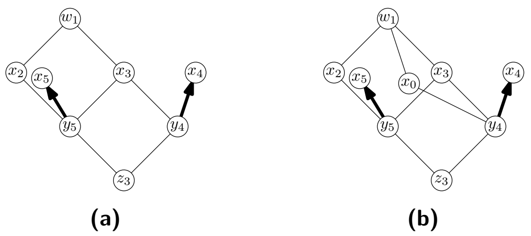
By the quadrangle condition, w_2 and w_4 are adjacent to a vertex x_5, which is necessarily different from x_3 because G is $K_{2,3}$-free. By the induction hypothesis, $f(w_2)$ and $f(v_1) = w_1$ are adjacent. Then $f(w_2) \neq x_3, x_5$, otherwise we obtain a forbidden $K_{2,3}$. Set $f(w_2) = x_2$. Analogously, $f(x_5) = y_5$ and $f(w_2) = x_2$ are adjacent as well as $f(x_5) = y_5$ and $f(w_4) = x_3$ (Fig. 2f). By (BFS1), $x_2 = f(w_2) < f(w_3) = x_3$ and by (BFS3), $x_3 = f(w_4) < x_5$. Since $w_3 < w_4$ with $f(w_3) = f(w_4)$ and w_4 is adjacent to x_5, by LexBFS w_3 must have a predecessor different from x_3 and smaller than x_5. This vertex cannot be x_2 by (BFS3) since $f(w_3) = x_3$. Denote this predecessor of w_3 by x_4 and observe that $x_2 < x_3 < x_4 < x_5$. By the induction hypothesis, the parent of x_4 is adjacent to $f(w_3) = x_3$. Let $y_4 = f(x_4)$.

If $y_4 = y_5$, applying the cube condition to the squares $x_3w_3x_4y_5$, $x_3w_4x_5y_5$, and $x_3w_4v_3w_3$ we find a vertex w adjacent to x_4, v_3, and x_5. Applying the cube condition to the squares $w_4v_3wx_5$, $w_4v_1w_2x_5$, and $w_4v_1u_1v_3$ we find a vertex v adjacent to u_1, w_2, and w. Since $v \sim w_2$, by (BFS3) $f(v) \leq w_2 < w_3 = f(v_3)$, hence by (BFS2) we obtain $v < v_3$. Therefore we can apply the induction hypothesis, and by Lemma 14 for $u_1v_1w_2v$, we deduce that $f(v) = w_2$. By Lemma 14 for $v_3w_3x_4w$, we deduce that $f(w) = x_4$ (Fig. 2g). Applying the induction hypothesis to the edge vw we have that $f(v) = w_2$ is adjacent to $f(w) = x_4$, yielding a forbidden $K_{2,3}$ induced by v, x_5, x_4, w, w_2 (Fig. 2g). All this shows that $y_4 \neq y_5$. By the quadrangle condition, y_5 and y_4 have a common neighbor z_3 (Fig. 2h).

Recall that $x_2 < x_3 < x_4 < x_5$, and note that by (BFS1), $y_4 = f(x_4) < f(x_5) = y_5$. We denote by H the subgraph of G induced by the vertices $V' = \{w_1, x_2, x_3, x_4, x_5, y_4, y_5, z_3\}$. The set of edges of H is $E' = \{z_3y_4, z_3y_5, y_4x_3, y_4x_4, y_5x_2, y_5x_3, y_5x_5, x_2w_1, x_3w_1\}$. To conclude the proof, we use the following technical lemma.

▶ **Lemma 15.** *Let $H = (V', E')$ (Fig. 3a) be an induced graph of G, where $d(v_0, w_1) = d(v_0, x_2) + 1 = \cdots = d(v_0, x_5) + 1 = d(v_0, y_4) + 2 = d(v_0, y_5) + 2 = d(v_0, z_3) + 3$ and $f(x_5) = y_5$ and $f(x_4) = y_4$, such that $x_2 < x_3 < x_4 < x_5$ and $y_4 < y_5$. If G satisfies the fellow-traveler property up to distance $d(v_0, w_1)$, then there exists a vertex x_0 such that $x_0 < x_2$ and $x_0 \sim w_1, y_4$ (Fig. 3b).*

Since G contains a subgraph H satisfying the conditions of Lemma 15, there exists a vertex x_0 such that $x_0 < x_2$ and $x_0 \sim w_1, y_4$ (Fig. 2i). By the cube condition applied to the squares $x_3w_1x_0y_4$, $x_3w_1v_2w_3$, and $x_3w_3x_4y_4$, there exists $w_0 \sim x_0, v_2, x_4$ (Fig. 2i). Since x_0 is adjacent to w_0, by (BFS3) $f(w_0) \leq x_0 < x_2 = f(w_2)$. By (BFS2), $w_0 < w_2$. Recall that $f(v_1) = w_1 = f(v_2)$ and that w_2 is the second-earliest predecessor of v_1. Since $w_0 < w_2$ and w_0 is a predecessor of v_2, by LexBFS we deduce that $v_2 < v_1$. Since v_1 and v_2 are



(a) **(b)**

Figure 3 The induced subgraph H in Lemma 15.

both adjacent to u_1 we obtain a contradiction with $f(u_1) = v_1$. This contradiction shows that any median graph G satisfies the fellow-traveller property. This finishes the proof of Theorem 13. ◀

Now we use Theorem 13 to compute the Θ-classes of G. We run LexBFS and return a LexBFS-ordering of $V(G)$ and $E(G)$ and the ordered lists $\Lambda_<(v), v \in V$. Then consider the edges of G in the LexBFS-order. Pick the first unprocessed edge uv and suppose that $u \in \Lambda_<(v)$. If $\Lambda_<(v) = \{u\}$, by Lemma 12, uv is the first edge of its Θ-class, thus we create a new Θ-class E_i and insert uv as the first edge of E_i. We call uv the *root* of E_i and keep $d(v_0, v)$ as the distance from v_0 to H'_i. Now suppose $|\Lambda_<(v)| \geq 2$. We consider two cases: (i) $u \neq f(v)$ and (ii) $u = f(v)$. For (i), by Theorem 13, uv and $f(u)f(v)$ are opposite edges of a square. Therefore uv belongs to the Θ-class of $f(u)f(v)$ (which was already computed because $f(u)f(v) < uv$). In order to recover the Θ-class of the edge $f(u)f(v)$ in constant time, we use a (non-initialized) matrix A whose rows and columns correspond to the vertices of G such that $A[x, y]$ contains the Θ-class of the edge xy when x and y are adjacent and the Θ-class of xy has already been computed and $A[x, y]$ is undefined if x and y are not adjacent or if the Θ-class of xy has not been computed yet. For (ii), pick any $x \in \Lambda_<(v), x \neq u$. By Theorem 13, $uv = f(v)v$ and $f(x)x$ are opposite edges of a square. Since $f(x)x$ appears before uv in the LexBFS order, the Θ-class of $f(x)x$ has already been computed, and the algorithm inserts uv in the Θ-class of $f(x)x$. Each Θ-class E_i is totally ordered by the order in which the edges are inserted in E_i. Consequently, we obtain:

▶ **Theorem 16.** *The Θ-classes of a median graph G can be computed in $O(m)$ time.*

5 The median of G

We use Theorem 16 to compute the median set $\text{Med}_w(G)$ of a median graph G in $O(m)$ time. We also use the existence of peripheral halfspaces and the majority rule.

5.1 Peripheral peeling

The order $E_1, E_2, \ldots, E_q$ in which the Θ-classes E_i of G are constructed corresponds to the order of the distances from v_0 to H'_i: if $i < j$ then $d(v_0, H'_i) \leq d(v_0, H'_j)$ (recall that $v_0 \in H''_i$). By Lemma 7, the halfspace H'_q of E_q is peripheral. If we contract all edges of E_q (i.e., we identify the vertices of $H'_q = \partial H'_q$ with their neighbors in $\partial H''_q$) we get a smaller median graph $\widetilde{G} = H''_q$; $\widetilde{G}$ has $q-1$ Θ-classes $\widetilde{E}_1, \ldots, \widetilde{E}_{q-1}$, where $\widetilde{E}_i$ consists of the edges of E_i in $\widetilde{G}$. The halfspaces of $\widetilde{G}$ have the form $\widetilde{H}'_i = H'_i \cap H''_q$ and $\widetilde{H}''_i = H''_i \cap H''_q$. Then $\widetilde{E}_1, \ldots, \widetilde{E}_{q-1}$ corresponds to the ordering of the halfspaces $\widetilde{H}'_1, \ldots, \widetilde{H}'_{q-1}$ of $\widetilde{G}$ by their distances to v_0. Hence the last halfspace $\widetilde{H}'_{q-1}$ is peripheral in $\widetilde{G}$. Thus the ordering $E_q, E_{q-1}, \ldots, E_1$ of the Θ-classes of G provides us with a set $G_q = G, G_{q-1} = \widetilde{G}, \dots, G_0$ of median graphs such that G_0 is a single vertex and for each $i \geq 1$, the Θ-class E_i defines a peripheral halfspace in the graph G_i obtained after the successive contractions of the peripheral halfspaces of $G_q, G_{q-1}, \dots, G_{i+1}$ defined by $E_q, E_{q-1}, \dots, E_{i+1}$. We call $G_q, G_{q-1}, \dots, G_0$ a *peripheral peeling* of G. Since each vertex of G and each Θ-class is contracted only once, we do not need to explicitly compute the restriction of each Θ-class of G to each G_i. For this it is enough to keep for each vertex v a variable indicating whether this vertex belongs to an already contracted peripheral halfspace or not. Hence, when the ith Θ-class must be contracted, we simply traverse the edges of E_i and select those edges whose both ends are not yet contracted.

5.2 Computing the weights of the halfspaces of G

We use a peripheral peeling $G_q, G_{q-1}, \dots, G_0$ of G to compute the weights $w(H'_i)$ and $w(H''_i)$, $i = 1, \dots, q$ of all halfspaces of G. As above, let $\widetilde{G}$ be obtained from G by contracting the Θ-class E_q. Consider the weight function $\widetilde{w}$ on $\widetilde{G} = H''_q$ defined as follows:

$$\widetilde{w}(v'') = \begin{cases} w(v'') + w(v') & \text{if } v'' \in \partial H''_q, v' \in H'_q, \text{ and } v'' \sim v', \\ w(v'') & \text{if } v'' \in H''_q \setminus \partial H''_q. \end{cases} \tag{5.1}$$

▶ **Lemma 17.** *For any Θ-class $\widetilde{E}_i$ of $\widetilde{G}$, $\widetilde{w}(\widetilde{H}'_i) = w(H'_i)$ and $\widetilde{w}(H''_i) = w(H''_i)$.*

By Lemma 17, to compute all $w(H'_i)$ and $w(H''_i)$, it suffices to compute the weight of the peripheral halfspace of E_i in the graph G_i, set it as $w(H'_i)$, and set $w(H''_i) := w(G) - w(H'_i)$.

Let G be the current median graph, let H'_q be a peripheral halfspace of G, and $\widetilde{G} = H''_q$ be the graph obtained from G by contracting the edges of E_q. To compute $w(H'_q)$, we traverse the vertices of H'_q (by considering the edges of E_q). Set $w(H''_q) = w(G) - w(H'_q)$. Let $\widetilde{w}$ be the weight function on $\widetilde{G}$ defined by Equation 5.1. Clearly, $\widetilde{w}$ can be computed in $O(|V(H'_q)|) = O(|E_q|)$ time. Then by Lemma 17 it suffices to recursively apply the algorithm to the graph $\widetilde{G}$ and the weight function $\widetilde{w}$. Since each edge of G is considered only when its Θ-class is contracted, the algorithm has complexity $O(m)$.

5.3 The median $\mathrm{Med}_w(G)$

We start with a simple property of the median function F_w that follows from Lemma 4:

▶ **Lemma 18.** *If $xy \in E_i$ with $x \in H'_i$ and $y \in H''_i$, then $F_w(x) - F_w(y) = w(H''_i) - w(H'_i)$.*

A halfspace H of G is *majoritary* if $w(H) > \frac{1}{2}w(G)$, *minoritary* if $w(H) < \frac{1}{2}w(G)$, and *egalitarian* if $w(H) = \frac{1}{2}w(G)$. Let $\mathrm{Med}^{\mathrm{loc}}_w(G) = \{v \in V : F_w(v) \leq F_w(u), \forall u \sim v\}$ be the set of local medians of G. We continue with the majority rule:

▶ **Proposition 19.** [8, 61]. *$\mathrm{Med}_w(G)$ is the intersection of all majoritary halfspaces and $\mathrm{Med}_w(G)$ intersects all egalitarian halfspaces. If H'_i and H''_i are egalitarian halfspaces, then $\mathrm{Med}_w(G)$ intersects both H'_i and H''_i. Moreover, $\mathrm{Med}_w(G) = \mathrm{Med}^{\mathrm{loc}}_w(G)$.*

We use Proposition 19 and the weights of halfspaces computed above to derive $\mathrm{Med}_w(G)$. For this, we define a new orientation of the edges $v'v''$ of each Θ-class E_i of G as follows. If $v' \in H'_i$ and $v'' \in H''_i$, then we direct $v'v''$ from v' to v'' if $w(H''_i) > w(H'_i)$ and from v'' to v' if $w(H'_i) > w(H''_i)$. If $w(H'_i) = w(H''_i)$, then the edge $v'v''$ is not directed. We denote this partially directed graph by $\overrightarrow{G}$. A vertex u of G is a *sink* of $\overrightarrow{G}$ if there is no edge uv directed in $\overrightarrow{G}$ from u to v. From Lemma 18, u is a sink of $\overrightarrow{G}$ if and only if u is a local median of G.

By Proposition 19, $\mathrm{Med}^{\mathrm{loc}}_w(G) = \mathrm{Med}_w(G)$ and thus $\mathrm{Med}_w(G)$ coincides with the set $S(\overrightarrow{G})$ of sinks of $\overrightarrow{G}$. Note that in the graph induced by $\mathrm{Med}_w(G)$, all edges are non-oriented in $\overrightarrow{G}$. Once all $w(H'_i)$ and $w(H''_i)$ have been computed, the orientation $\overrightarrow{G}$ of G can be constructed in $O(m)$ by traversing all Θ-classes E_i of G. The graph induced by $S(\overrightarrow{G})$ can then be found in $O(m)$.

▶ **Theorem 20.** *The median* $\mathrm{Med}_w(G)$ *of a median graph* G *can be computed in* $O(m)$ *time.*

▶ **Corollary 21.** *If* $w(G) > 0$*, we can find* $u, v \in V(G)$ *in* $O(m)$ *such that* $\mathrm{Med}_w(G) = I(u, v)$*.*

6 The median problem in the cube complex of G

We describe a linear time algorithm to compute medians in cube complexes of median graphs.

6.1 The main result

The problem. Let $\mathcal{G}$ be the *cube complex* of a median graph G obtained by replacing each graphic cube of G by a unit solid cube and by isometrically identifying common subcubes. We refer to $\mathcal{G}$ as to the *geometric realization* of G (see Fig. 4(a)). We suppose that $\mathcal{G}$ is endowed with the intrinsic ℓ_1-metric d_1. Let P be a finite set of points of $(\mathcal{G}, d_1)$ (called *terminals*) and let w be a weight function on $\mathcal{G}$ such that $w(p) > 0$ if $p \in P$ and $w(p) = 0$ if $p \notin P$. The goal of the *median problem* is to compute the set $\mathrm{Med}_w(\mathcal{G})$ of median points of $\mathcal{G}$, i.e., the set of all points $x \in \mathcal{G}$ minimizing the function $F_w(x) = \sum_{p\in\mathcal{G}} w(p)d_1(x, p) = \sum_{p\in P} w(p)d_1(x, p)$.

The input. The cube complex $\mathcal{G}$ is given by its 1-skeleton G. Each terminal $p \in P$ is given by its coordinates in the smallest cube $Q(p)$ of $\mathcal{G}$ containing p. Namely, we give a vertex $v(p)$ of $Q(p)$ together with its neighbors in $Q(p)$ and the coordinates of p in the embedding of $Q(p)$ as a unit cube in which $v(p)$ is the origin of coordinates. Let δ be the sum of the sizes of the encodings of the points of P. Thus the input of the median problem has size $O(m + \delta)$.

The output. Unlike $\mathrm{Med}_w(G)$ (which is a gated subgraph of G), $\mathrm{Med}_w(\mathcal{G})$ is not a subcomplex of $\mathcal{G}$. Nevertheless we show that $\mathrm{Med}_w(\mathcal{G})$ is a subcomplex of the box complex $\widehat{\mathcal{G}}$ obtained by subdividing $\mathcal{G}$, using the hyperplanes passing via the terminals of P. The output is the 1-skeleton $\widehat{M}$ of $\mathrm{Med}_w(\widehat{G})$ and $\mathrm{Med}_w(\widehat{\mathcal{G}})$, and the local coordinates of the vertices of $\widehat{M}$ in $\mathcal{G}$. We show that the output has linear size $O(m)$.

▶ **Theorem 22.** *The 1-skeleton* $\widehat{M}$ *of* $\mathrm{Med}_w(\mathcal{G})$ *can be computed in linear time* $O(m + \delta)$*.*

6.2 Geometric halfspaces and hyperplanes

In the following, we fix a basepoint v_0 of G. For each point x of $\mathcal{G}$, let $Q(x)$ be the smallest cube of $\mathcal{G}$ containing x and let $v(x)$ be the gate of v_0 in $Q(x)$. For each Θ-class E_i defining a dimension of $Q(x)$, let $\epsilon_i(x)$ be the coordinate of x along E_i in the embedding of $Q(x)$ as a unit cube in which $v(x)$ is the origin. For a Θ-class E_i and a cube Q having E_i as a dimension, the *i-midcube* of Q is the subspace of Q obtained by restricting the E_i-coordinate of Q to $\frac{1}{2}$. A *midhyperplane* $\mathfrak{h}_i$ of $\mathcal{G}$ is the union of all i-midcubes. Each $\mathfrak{h}_i$ cuts $\mathcal{G}$ in two components [58] and the union of each of these components with $\mathfrak{h}_i$ is called a *geometric halfspace* (see Fig. 4(b)). The *carrier* $\mathcal{N}_i$ of E_i is the union of all cubes of $\mathcal{G}$ intersecting $\mathfrak{h}_i$; $\mathcal{N}_i$ is isomorphic to $\mathfrak{h}_i \times [0, 1]$. For a Θ-class E_i and $0 < \epsilon < 1$, the *hyperplane* $\mathfrak{h}_i(\epsilon)$ is the set of all points $x \in \mathcal{N}_i$ such that $\epsilon_i(x) = \epsilon$. Let $\mathfrak{h}_i(0)$ and $\mathfrak{h}_i(1)$ be the respective geometric

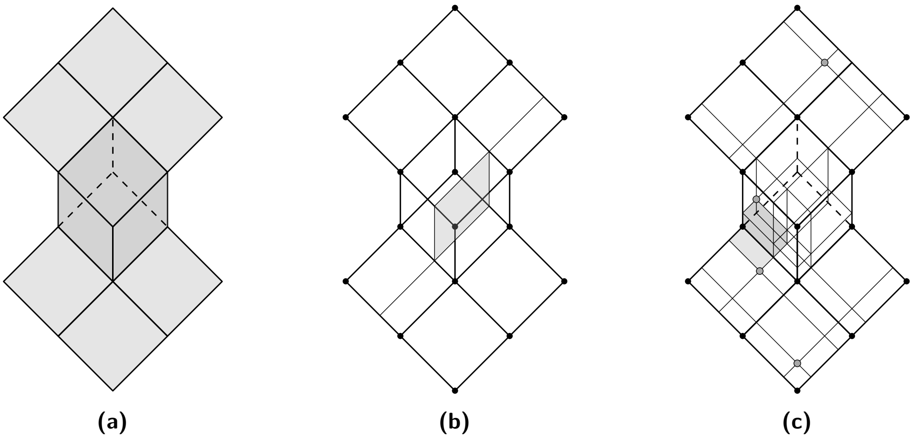


Figure 4 (a) The cube complex $\mathcal{D}$ of D, (b) a hyperplane of $\mathcal{D}$, and (c) the box complex $\widehat{\mathcal{D}}$ and $\mathrm{Med}_w(\mathcal{D})$ (in gray) defined by 4 terminals of weight 1.

realizations of $\partial H''_i$ and $\partial H'_i$. Note that $\mathfrak{h}_i(\epsilon)$ is obtained from $\mathfrak{h}_i$ by a translation. The *open carrier* $\mathcal{N}^\circ_i$ is $\mathcal{N}_i \setminus (\mathfrak{h}_i(0) \cup \mathfrak{h}_i(1))$. We denote by $\mathcal{H}'_i(\epsilon)$ and $\mathcal{H}''_i(\epsilon)$ the geometric halfspaces of $\mathcal{G}$ defined by $\mathfrak{h}_i(\epsilon)$. Let $\mathcal{H}''_i := \mathcal{H}''_i(0)$ and $\mathcal{H}'_i := \mathcal{H}'_i(1)$; they are the geometric realizations of H'_i and H''_i. Note that $\mathcal{G}$ is the disjoint union of $\mathcal{H}'_i$, $\mathcal{H}''_i$, and $\mathcal{N}^\circ_i$.

6.3 The majority rule for $\mathcal{G}$

The box complex $\widehat{\mathcal{G}}$. By [65, Theorem 3.16], $(\mathcal{G}, d_1)$ is a median metric space (i.e., $|I(x,y) \cap I(y,z) \cap I(z,x)| = 1$ $\forall x,y,z \in \mathcal{G}$). For each $p \in P$ and each coordinate $\epsilon_i(p)$, consider the hyperplane $\mathfrak{h}_i(\epsilon_i(p))$. All such hyperplanes subdivide $\mathcal{G}$ into a box complex $\widehat{\mathcal{G}}$ (see Fig. 4(c)). Clearly, $(\widehat{\mathcal{G}}, d_1)$ is a median space. By [65, Theorem 3.13], the 1-skeleton $\widehat{G}$ of $\widehat{\mathcal{G}}$ is a median graph and each point of P corresponds to a vertex of $\widehat{G}$. The Θ-classes of $\widehat{G}$ are subdivisions of the Θ-classes of G. In $\widehat{\mathcal{G}}$, all edges of a Θ-class of $\widehat{G}$ have the same length. Let $\widehat{G}_l$ be the graph $\widehat{G}$ in which the edges have these lengths. $\widehat{G}_l$ is a median space, thus $\mathrm{Med}_w(\widehat{G}_l) = \mathrm{Med}_w(\widehat{G})$ by [61]. By Proposition 19, $\mathrm{Med}_w(\widehat{G}_l)$ is the intersection of the majoritary halfspaces of $\widehat{G}$.

▶ **Proposition 23.** *$\mathrm{Med}_w(\mathcal{G})$ is the subcomplex of $\widehat{\mathcal{G}}$ defined by $\widehat{M} := \mathrm{Med}_w(\widehat{G}_l)$.*

The E_i-median problems. We adapt now Proposition 19 to the continuous setting. For a Θ-class of G, the *E_i-median* is the median of the multiset of points of the segment $[0,1]$ weighted as follows: the weight $w_i(0)$ of 0 is $w(\mathcal{H}''_i)$, the weight $w_i(1)$ of 1 is $w(\mathcal{H}'_i)$, and for each $p \in P \cap \mathcal{N}^\circ_i$, there is a point $\epsilon_i(p)$ of $[0,1]$ of weight $w_i(\epsilon_i(p)) = w(p)$. It is well-known that this median is a segment $[\varrho''_i, \varrho'_i]$ defined by two consecutive points $\varrho''_i \le \varrho'_i$ of $[0,1]$ with positive weights, and for any $p \in P$, $\epsilon_i(p) \le \varrho''_i$ or $\epsilon_i(p) \ge \varrho'_i$. *Majoritary*, *minoritary*, and *egalitarian* geometric halfspaces of $\mathcal{G}$ are defined in the same way as the halfspaces of G.

▶ **Proposition 24.** *Let E_i be a Θ-class of G. Then the following holds:*

1. *$\mathrm{Med}_w(\mathcal{G}) \subseteq \mathcal{H}''_i$ (resp., $\mathrm{Med}_w(\mathcal{G}) \subseteq \mathcal{H}'_i$) if and only if $\mathcal{H}''_i$ is majoritary (resp., $\mathcal{H}'_i$ is majoritary), i.e., $\rho''_i = \rho'_i = 0$ (resp. $\rho''_i = \rho'_i = 1$);*
2. *$\mathrm{Med}_w(\mathcal{G}) \subseteq \mathcal{H}''_i \cup \mathcal{N}^\circ_i$ (resp., $\mathrm{Med}_w(\mathcal{G}) \subseteq \mathcal{H}'_i \cup \mathcal{N}^\circ_i$) and $\mathrm{Med}_w(\mathcal{G})$ intersects each of the sets $\mathcal{H}''_i$ (resp., $\mathcal{H}'_i$) and $\mathcal{N}^\circ_i$ if and only if $\mathcal{H}''_i$ (resp. $\mathcal{H}'_i$) is egalitarian and $\mathcal{H}'_i$ (resp., $\mathcal{H}''_i$) is minoritary, i.e., $0 = \rho''_i < \rho'_i < 1$ (resp. $0 < \rho''_i < \rho'_i = 1$);*
3. *$\mathrm{Med}_w(\mathcal{G}) \subseteq \mathcal{N}^\circ_i$ if and only if $\mathcal{H}'_i$ and $\mathcal{H}''_i$ are minoritary, i.e., $0 < \rho''_i \le \rho'_i < 1$;*
4. *$\mathrm{Med}_w(\mathcal{G})$ intersects the three sets $\mathcal{H}_i, \mathcal{H}''_i$, and $\mathcal{N}^\circ_i$ if and only if $\mathcal{H}'_i$ and $\mathcal{H}''_i$ are egalitarian, i.e., $0 = \rho''_i \le \rho'_i = 1$ (and thus $w(\mathcal{N}^\circ_i) = 0$).*

6.4 The algorithm

Preprocessing the input. We first compute the Θ-classes $E_1, E_2, \ldots, E_q$ of G ordered by increasing distance from v_0 to H_i'. Using this, we can modify the input of the median problem in linear time $O(m+\delta)$ in such a way that for each terminal $p \in P$, $v(p)$ is the gate of v_0 in $Q(p)$. In this way, the local coordinates of the terminals of P coincide with the coordinates $\epsilon_i(p)$ defined in Section 6.2. For each Θ-class E_i, let $P_i = P \cap \mathcal{N}_i^\circ = \{p \in P : 0 < \epsilon_i(p) < 1\}$, and for each point $v \in V(G)$, let $P_v = \{p \in P : v(p) = v\}$. By traversing the points of P, we can compute all sets P_i, $1 \leq i \leq q$ and P_v, $v \in V$ and the weights of these sets in time $O(\delta)$.

Computing the E_i-medians. We first compute the weights $w_i(0) = w(\mathcal{H}_i'')$ and $w_i(1) = w(\mathcal{H}_i')$ of the geometric halfspaces $\mathcal{H}_i'', \mathcal{H}_i'$ of G. For each vertex v of G, let $w_*(v) = w(P_v)$. Note that $w_*(V) = w(P)$. Since $v_0 \in H_i''$, $w_*(H_i') = w(\mathcal{H}_i')$ and $w_*(H_i'') = w(\mathcal{H}_i'') + w(\mathcal{N}_i^o)$ for each Θ-class E_i. We apply the algorithm of Section 5.2 to G with the weight function w_* to compute the weights $w_*(H_i')$ and $w_*(H_i'')$ of all halfspaces of G. Since $w(\mathcal{N}_i^o) = w(P_i)$ is known, we can compute $w(\mathcal{H}_i') = w_*(H_i')$ and $w(\mathcal{H}_i'') = w_*(H_i'') - w(P_i)$. This allows us to complete the definition of each E_i-median problem which altogether can be solved linearly in the size of the input [27, Problem 9.2], i.e., in time $O(\Sigma_{i=1}^q(|P_i|+2)) = O(\delta+m)$.

Computing $\widehat{M}$. To compute the 1-skeleton $\widehat{M}$ of $\mathrm{Med}_w(\mathcal{G})$ in $\widehat{G}$, we orient the edges of E_i according to the weights of $\mathcal{H}_i'$ and $\mathcal{H}_i''$: $v'v'' \in E_i$ with $v' \in \mathcal{H}_i'$ and $v'' \in \mathcal{H}_i''$ is directed from v'' to v' if $\varrho_i' = \varrho_i'' = 1$ ($\mathcal{H}_i'$ is majoritary) and from v' to v'' if $\varrho_i' = \varrho_i'' = 0$ ($\mathcal{H}_i''$ is majoritary), otherwise the edges of E_i are not oriented. Denote this partially directed graph by $\overrightarrow{G}$ and let $S(\overrightarrow{G})$ be the set of sinks of $\overrightarrow{G}$. A non-directed edge $v'v'' \in E_i$ defines a *half-edge with origin* v'' if $\varrho_i'' > 0$ and a *half-edge with origin* v' if $\varrho_i' < 1$ (an edge $v'v''$ such that $0 < \varrho_i'' \leq \varrho_i' < 1$ defines two half-edges).

▶ **Proposition 25.** *For any vertex v of $\overrightarrow{G}$, all half-edges with origin v define a cube Q_v of $\mathcal{G}$.*

Proof. For any vertex v and two Θ-classes E_i, E_j defining half-edges with origin v, let v_i and v_j be the respective neighbors of v in $\widehat{G}$ along the directions E_i and E_j. By Proposition 24, vv_i and vv_j point to two majoritary halfspaces of $\widehat{G}$ (and $\mathcal{G}$). Since those two halfspaces cannot be disjoint, E_i and E_j are crossing. The proposition then follows from Lemma 5. ◀

For any cube Q of $\mathcal{G}$, let $B(Q) \subseteq Q$ be the subcomplex of $\widehat{\mathcal{G}}$ that is the Cartesian product of the E_i-medians $[\varrho_i'', \varrho_i']$ over all Θ-classes E_i wich define dimensions of Q. By the definition of the E_i-medians, $B(Q)$ is a single box of $\widehat{\mathcal{G}}$ and its vertices belong to $\widehat{G}$.

▶ **Proposition 26.** *For any cube Q of $\mathcal{G}$, if $Q \cap \mathrm{Med}_w(\mathcal{G}) \neq \emptyset$, then $B(Q) = \mathrm{Med}_w(\mathcal{G}) \cap Q$.*

Proof. If a vertex x of $B(Q)$ is not a median of $\widehat{G}$, by Proposition 19, x is not a local median of $\widehat{G}$. Thus $F_w(x) > F_w(y)$ for an edge xy of $\widehat{G}$. Suppose that xy is parallel to the edges of E_i of G. Then $\epsilon_i(x)$ coincides with ϱ_i'' or ϱ_i'. Since $F_w(x) > F_w(y)$, the halfspace $W(y,x)$ of $\widehat{G}$ is majoritary, contrary to the assumption that $\epsilon_i(x)$ is an E_i-median point. Thus all vertices of $B(Q)$ belong to $\widehat{M}$ and by Proposition 23, $B(Q) \subseteq \mathrm{Med}_w(\mathcal{G})$. It remains to show that any point of $Q \setminus B(Q)$ is not median. Otherwise, by Proposition 23 and since $\widehat{M}$ is convex, there exists a vertex $y \notin B(Q)$ of $(\widehat{M} \cap Q) \setminus B(Q)$ adjacent to a vertex x of $B(Q)$. Let xy be parallel to E_i. Then $\epsilon_i(x)$ coincides with ϱ_i'' or ϱ_i' and $\epsilon_i(y)$ does not belong to the E_i-median $[\varrho_i'', \varrho_i']$. Hence the halfspace $W(y,x)$ of $\widehat{G}$ is minoritary, contrary to $F_w(y) = F_w(x)$. ◀

For a sink v of $\overrightarrow{G}$, let $g(v)$ be the point of Q_v such that for each Θ-class E_i of Q_v, $\epsilon_i(g(v)) = \varrho'$ if $v \in \mathcal{H}'_i$ and $\epsilon_i(g(v)) = \varrho''$ if $v \in \mathcal{H}''_i$. Note that $g(v)$ is the gate of v in $B(Q_v)$ and $g(v)$ is a vertex of $\widehat{M}$. Conversely, let $x \in \widehat{M}$ and consider the cube $Q(x)$. Since $B(Q(x))$ is a cell of $\widehat{\mathcal{G}}$, for each Θ-class E_i of $Q(x)$, we have $\epsilon_i(x) \in \{\varrho'_i, \varrho''_i\}$. Let $f(x)$ be the vertex of $Q(x)$ such that $f(x) \in \mathcal{H}''_i$ if $\epsilon_i(x) = \varrho''_i$ and $f(x) \in \mathcal{H}'_i$ otherwise.

▶ **Proposition 27.** *For any $v \in S(\overrightarrow{G})$, $g(v)$ is the gate of v in $\widehat{M}$ and* $\mathrm{Med}_w(\mathcal{G})$*. For any $x \in \widehat{M}$, $x = g(f(x))$ is the gate of $f(x)$ in $\widehat{M}$ and* $\mathrm{Med}_w(\mathcal{G})$.

Furthermore, for any edge uv of G with $u, v \in S(\overrightarrow{G})$, either $g(u) = g(v)$ or $g(u)g(v)$ is an edge of $\widehat{M}$. Conversely, for any edge xy of $\widehat{M}$, $f(x)f(y)$ is an edge of G.

Proof. By Proposition 24 applied to $\mathcal{G}$, Proposition 19 applied to $\widehat{G}$, and the definition of sinks of $\overrightarrow{\widehat{G}}$, $g(v)$ is a sink of $\overrightarrow{\widehat{G}}$, thus $g(v)$ is a median of $\widehat{G}$ and $\mathcal{G}$. Since $B(Q_v) = \mathrm{Med}_w(\mathcal{G}) \cap Q_v$ is gated and non-empty, the gate of v in $\mathrm{Med}_w(\mathcal{G})$ belongs to $B(Q_v)$ and thus the gate of v in $\mathrm{Med}_w(\mathcal{G})$ is the gate of v on $B(Q_v)$. Conversely, $\epsilon_i(x) \notin \{0, 1\}$ for any E_i defining a dimension of $Q(x)$, thus there is an E_i-half-edge with origin $f(x)$. Pick now any E_j-edge incident to v such that E_j does not define a dimension of $Q(x)$. Without loss of generality, assume that $f(x) \in \mathcal{H}'_j$. Then $x \in \mathcal{H}'_j$, yielding $w(\mathcal{H}'_j) \geq \frac{1}{2}w(P)$. By Proposition 24, $\varrho'_j = 1$ and thus $f(x)$ is not the origin of an E_j-edge or E_j-half-edge. Consequently, $Q_{f(x)} = Q(x)$ by Proposition 25 and by the definition of $f(x)$ and $g(f(x))$, we have $x = g(f(x))$.

Let $v'v''$ be an E_i-edge between two sinks of $\overrightarrow{G}$ with $v' \in \mathcal{H}'_i$ and $v'' \in \mathcal{H}''_i$. Let $x' = g(v')$ and $x'' = g(v'')$ and assume that $x' \neq x''$. Let u', u'' be the points of $v'v''$ such that $\epsilon_i(u') = \varrho'_i$ and $\epsilon_i(u'') = \varrho''_i$. Note that u' and u'' are adjacent vertices of $\widehat{G}$ and that $u' \in I_{\widehat{G}}(v', x')$ and $u'' \in I_{\widehat{G}}(v'', x'')$. In $\widehat{G}$, x'' is the gate of u'' (and x' is the gate of u') in $\widehat{M}$. Since $d_{\widehat{G}}(u', x') + d_{\widehat{G}}(x', x'') = d_{\widehat{G}}(u', x'') \leq d_{\widehat{G}}(u'', x'') + 1$ and $d_{\widehat{G}}(u'', x'') + d_{\widehat{G}}(x', x'') = d_{\widehat{G}}(u'', x') \leq d_{\widehat{G}}(u', x') + 1$, we obtain that $d_{\widehat{G}}(x', x'') \leq 1$.

Any edge $x'x''$ of $\widehat{M}$ is parallel to a Θ-class E_i of G. For any Θ-class E_j of $Q(x')$ (resp. $Q(x'')$) with $j \neq i$, E_j is a Θ-class of $Q(x'')$ (resp. $Q(x')$) and $\epsilon_j(x') = \epsilon_j(x'')$. By their definition, $f(x')$ and $f(x'')$ can be separated only by E_i, i.e., $d_G(f(x'), f(x'')) \leq 1$. Since f is an injection from $V(\widehat{M})$ to $S(\overrightarrow{G})$, necessarily $f(x')$ and $f(x'')$ are adjacent. ◀

The algorithm computes the set $S(\overrightarrow{G})$ of all sinks of $\overrightarrow{G}$ and for each sink $v \in S(\overrightarrow{G})$, it computes the gate of $g(v)$ of v in $\widehat{M}$ and the local coordinates of $g(v)$ in $\mathcal{G}$. The algorithm returns $\left\{g(v) : v \in S(\overrightarrow{G})\right\}$ as $V(\widehat{M})$ and $\left\{g(u)g(v) : uv \in E \text{ and } u, v \in S(\overrightarrow{G})\right\}$ as $E(\widehat{M})$. Proposition 27 implies that $V(\widehat{M})$ and $E(\widehat{M})$ are correctly computed and that $\widehat{M}$ contains at most n vertices and m edges. Moreover each vertex x of $\widehat{M}$ is the gate $g(f(x))$ of the vertex $f(x)$ of $Q(x)$ that has dimension at most $\deg(f(x))$. Hence the size of the description of the vertices of $\widehat{M}$ is at most $O(m)$. This finishes the proof of Theorem 22.

Abstract

We study the problem of coloring a given graph using a small number of colors in several well-established models of computation for big data. These include the data streaming model, the general graph query model, the massively parallel communication (MPC) model, and the CONGESTED-CLIQUE and the LOCAL models of distributed computation. On the one hand, we give algorithms with sublinear complexity, for the appropriate notion of complexity in each of these models. Our algorithms color a graph G using $\kappa(G) \cdot (1 + o(1))$ colors, where $\kappa(G)$ is the degeneracy of G: this parameter is closely related to the arboricity $\alpha(G)$. As a function of $\kappa(G)$ alone, our results are close to best possible, since the optimal number of colors is $\kappa(G) + 1$. For several classes of graphs, including real-world "big graphs," our results improve upon the number of colors used by the various $(\Delta(G) + 1)$-coloring algorithms known for these models, where $\Delta(G)$ is the maximum degree in G, since $\Delta(G) \geqslant \kappa(G)$ and can in fact be arbitrarily larger than $\kappa(G)$.

On the other hand, we establish certain lower bounds indicating that sublinear algorithms probably cannot go much further. In particular, we prove that any randomized coloring algorithm that uses at most $\kappa(G) + O(1)$ colors would require $\Omega(n^2)$ storage in the one pass streaming model, and $\Omega(n^2)$ many queries in the general graph query model, where n is the number of vertices in the graph. These lower bounds hold even when the value of $\kappa(G)$ is known in advance; at the same time, our upper bounds do not require $\kappa(G)$ to be given in advance.

1 Introduction

Graph coloring is a fundamental topic in combinatorics and the corresponding algorithmic problem of coloring an input graph with a small number of colors is a basic and heavily studied problem in computer science. It has numerous applications, e.g., in scheduling [67, 49, 48], air traffic flow management [15], frequency assignment in wireless networks [8, 56], and register allocation [21, 26, 22]. More recently, vertex coloring has been used to compute seed vertices in social networks that are then expanded to detect community structures in the network [54].

Given an n-vertex graph $G = (V, E)$, the task is to assign colors to the vertices in V so that no two adjacent vertices get the same color. Doing so with the minimum possible number of colors – called the chromatic number, $\chi(G)$ – is famously hard: it is NP-hard to even approximate $\chi(G)$ to a factor of $n^{1-\varepsilon}$ for any constant $\varepsilon > 0$ [31, 68, 45]. In the face of this hardness, it is algorithmically interesting to color G with a possibly suboptimal number of colors depending upon tractable parameters of G. One such simple parameter is Δ, the maximum degree: a trivial greedy algorithm colors G with $\Delta + 1$ colors in linear time.

We study graph coloring in a number of space-constrained and data-access-constrained settings, including the data streaming model, a query model, and certain distributed computing models. As expected, coloring using the optimal number of colors is hard in these models. Abboud et al. [1] show that coloring an n-vertex graph G with $\chi(G)$ colors in the p-pass streaming setting requires $\Omega(n^2/p)$ space, and checking c-colorability for $3 \leqslant c < n$ requires $\Omega((n-c)^2/p)$ space. In such constrained settings, even finding a coloring with "about Δ" colors is a fairly nontrivial problem that has been studied from various angles in a flurry of research over the last decade [5, 10, 23, 24, 40, 59]. In a recent breakthrough (awarded Best Paper at SODA 2019), Assadi, Chen, and Khanna [5] gave sublinear algorithms for $(\Delta + 1)$-coloring an input graph in such models.

In this work, we focus on colorings that use "about κ" colors, where $\kappa = \kappa(G)$ is the *degeneracy* of G, a parameter that improves upon Δ. It is defined as follows: $\kappa = \min\{k :$ every induced subgraph of G has a vertex of degree at most $k\}$. Every graph is $(\kappa + 1)$-colorable. Clearly, $\kappa \leqslant \Delta$ and can be much smaller than Δ for sparse graphs and real-world graphs; see Table 2. Thus, our aim is to use fewer colors when $(\Delta + 1)$-coloring might be wasteful. A closely related parameter is $\alpha(G)$, the arboricity of the graph, which is the minimum number of forests into which the set of edges of G can be partitioned. It is known that $\alpha \leqslant \kappa < 2\alpha$. A number of works has studied the $O(\alpha)$-coloring problem in distributed computing models [11, 12, 35, 36, 47]. However, to the best of our knowledge, such coloring algorithms were unknown in the data streaming and graph query models.

There is a simple greedy algorithm that runs in linear time and produces a $(\kappa+1)$-coloring; see Section 3. However, just as before, when processing a massive graph under the constraints of either the space-bounded streaming model or certain distributed computing models, the inherently sequential nature of the greedy algorithm makes it infeasible. We overcome this barrier with a very simple framework: decompose the graph into smaller subgraphs so as to store all the blocks in our limited memory, and then run the greedy algorithm on each block. We show that this basic framework (with careful implementation in the respective models) suffices for obtaining the colorings we seek.

On the other hand, we give a number of lower bounds showing that, despite its simplicity, our algorithmic framework does about as good a job as sublinear algorithms can. In particular, no randomized algorithm can achieve $(\kappa + O(1))$-colorings without spending $\Omega(n^2)$ space in the streaming model or $\Omega(n^2)$ queries in the query model.

1.1 Our Results and Techniques

Algorithms. We give new graph coloring algorithms, parametrized by the degeneracy κ, in the following models:

(1) the data streaming model, where the input is a stream of edge insertions and deletions (i.e., a dynamic graph stream) resulting in the eventual graph to be colored and we are limited to a work space of $\widetilde{O}(n)$ bits[1], the so-called semi-streaming setting [32];

(2) the general graph query model [38], where we may access the graph using only neighbor queries (what is the ith neighbor of x?) and pair queries (are x and y adjacent?);

(3) the massively parallel communication (MPC) model, where each of a large number of memory-limited processors holds a sublinear-sized portion of the input data and computation proceeds using rounds of communication;

(4) the congested clique model of distributed computation, where there is one processor per vertex holding that vertex's neighborhood information and each round allows each processor to communicate $O(\log n)$ bits to a specific other processor; and

(5) the LOCAL model of distributed computation, where there is one processor per vertex holding that vertex's neighborhood information and each round allows each processor to send an arbitrary amount of information to all its neighbors.

Table 1 Summary of our algorithmic results and basic comparison with most related previous work. In the result marked ($\star$), we require that $\kappa = \omega(\log^2 n)$.

Model	Colors	Complexity Parameters		Reference
Streaming	$\Delta + 1$	$\widetilde{O}(n)$ space,	$\widetilde{O}(n\sqrt{\Delta})$ post-processing time	[5]
(one pass)	$\kappa + o(\kappa)$	$\widetilde{O}(n)$ space,	$\widetilde{O}(n)$ post-processing time	this paper
Query	$\Delta + 1$		$\widetilde{O}(n^{3/2})$ queries	[5]
	$\kappa + o(\kappa)$		$\widetilde{O}(n^{3/2})$ queries	this paper
MPC	$\Delta + 1$	$O(1)$ rounds,	$O(n \log^3 n)$ bits per processor	[5]
	$\kappa + o(\kappa)$	$O(1)$ rounds,	$O(n \log^2 n)$ bits per processor	this paper
Congested	$\Delta + 1$		$O(1)$ rounds	[23]
Clique	$O(\kappa)$		$O(1)$ rounds	[36]
	$\kappa + o(\kappa)^\star$		$O(1)$ rounds	this paper
LOCAL	$O(\kappa n^{1/k})$	$O(k)$ rounds,	for $k \in \left[\omega(\log\log n),\, O(\sqrt{\log n})\right]$	[47]
	$O(\kappa n^{1/k} \log n)$	$O(k)$ rounds,	for $k \in \left[\omega(\sqrt{\log n}),\, o(\log n)\right]$	this paper

Table 1 summarizes our algorithmic results and provides, in each case, a basic comparison with the most related result from prior work. We give an elaborate account of the related works in Section 2.

As we have noted, $\kappa \leqslant \Delta$ in every case; indeed, κ could be arbitrarily better than Δ as shown by the example of a star graph, where $\kappa = 1$ whereas $\Delta = n - 1$. From a practical standpoint, it is notable that in many real-world large graphs drawn from various application domains – such as social networks, web graphs, and biological networks – the parameter κ is often *significantly* smaller than Δ. See Table 2 for some concrete numbers. That said, $\kappa + o(\kappa)$ is, in general, mathematically incomparable with $\Delta + 1$.

[1] The $\widetilde{O}(\cdot)$ notation hides factors polylogarithmic in n.

Table 2 Statistics of several large real-world graphs taken from the application domains of social networks, web graphs, and biological networks, showing that the degeneracy, κ, is often significantly smaller than the maximum degree, Δ. Source: `http://networkrepository.com` [61].

A key contribution here is a conceptual idea and a corresponding technical lemma underlying all our algorithms. We show that every graph admits a “small” sized *low degeneracy partition* (LDP), which is a partition of its vertex set into “few” blocks such that the subgraph induced by each block has low degeneracy, roughly logarithmic in n. Moreover, such an LDP can be computed by a very simple and distributed randomized algorithm: for each vertex, choose a “color” independently and uniformly at random from a suitable-sized palette (this is not to be confused with the eventual graph coloring we seek; this random assignment is most probably not a proper coloring of the graph). The resulting color classes define the blocks of such a partition, with high probability. Theorem 8, the LDP Theorem, makes this precise. Given an LDP, a generic graph coloring algorithm is to run the aforementioned greedy algorithm on each block, using distinct palettes for the distinct blocks. We obtain algorithms achieving our claimed results by suitably implementing this generic algorithm in each computational model.

Lower Bounds. Recall that a graph with degeneracy κ admits a proper $(\kappa + 1)$-coloring. As Table 1 makes clear, there are several space-conscious $(\Delta + 1)$-coloring algorithms known; perhaps we could aim for improved algorithms that provide $(\kappa + 1)$-colorings? We prove that this is not possible in sublinear complexity in either the streaming or the query model. In fact, we prove more. We show that distinguishing n-vertex graphs of degeneracy κ from those with chromatic number $\kappa + 2$ requires $\Omega(n^2)$ space in the streaming model and $\Omega(n^2)$ queries in the general graph query model. This shows that it is hard to produce a $(\kappa + 1)$-coloring and in fact even to determine the value of κ. These results generalize to the problems of producing a $(\kappa + \lambda)$-coloring or estimating the degeneracy up to $\pm\lambda$; the corresponding lower bounds are $\Omega(n^2/\lambda^2)$. Furthermore, the streaming lower bounds hold even in the insertion-only model, where the input stream is simply a listing of the graph’s edges in some order; compare this with our upper bound, which works even for dynamic graph streams.

A possible criticism of the above lower bounds for coloring is that they seem to depend on it being hard to *estimate* the degeneracy κ. Perhaps the coloring problem could become easier if κ was given to the algorithm in advance? We prove two more lower bounds showing that this is not so: the same $\Omega(n^2/\lambda^2)$ bounds hold even with κ known *a priori.*

In the full version of this paper [18], we present a “combinatorial” lower bound that addresses a potential criticism of our main algorithmic technique: the LDP. Perhaps a more sophisticated graph-theoretic result, such as the Palette Sparsification Theorem of Assadi et al. (see Section 2), could improve the quality of the colorings obtained? We prove that this is not so: there is no analogous theorem for colorings with “about κ” colors.

2 Related Work and Comparisons

Streaming and Query Models. Assadi et al. [5] give a one-pass streaming $(\Delta+1)$-coloring algorithm that uses $\widetilde{O}(n)$ space (i.e., is semi-streaming) and works on dynamic graph streams. They also give a $(\Delta+1)$-coloring algorithm in the general graph query model that makes $\widetilde{O}(n^{3/2})$ queries. For these, they establish a beautiful *Palette Sparsification Theorem*: a combinatorial result saying that choosing a random $O(\log n)$-sized palette from $\{1,\ldots,\Delta+1\}$ for each vertex allows a compatible list coloring. While we do not get a similarly tight combinatorial result – there isn't one, as we just noted – we do achieve faster post-processing time ($\widetilde{O}(n)$ versus their $\widetilde{O}(n\sqrt{\Delta})$) in the streaming setting and have a simpler post-processing algorithm (greedy offline versus matching-based) in the query setting, while keeping other complexity parameters the same (Table 1). These wins come at the price of a less tight result – $(1+o(1))\kappa$ colors instead of the combinatorially optimal $\kappa+1$ – but of course our streaming and query lower bounds show that such slack is necessary. Also, as noted before, we often have $\kappa \ll \Delta$ (Table 2).

For streaming lower bounds, Abboud et al. [1] show that coloring a graph G with $\chi(G)$ colors requires $\Omega(n^2/p)$ space in p passes. They also show that deciding c-colorability for $3 \leqslant c < n$ (that might be a function of n) takes $\Omega((n-c)^2/p)$ space in p passes. Furthermore, any streaming algorithm that distinguishes between $\chi(G) \leqslant 3c$ and $\chi(G) \geqslant 4c$ must use $\Omega(n^2/pc^2)$ space. Another recent work on coloring in the streaming model is Radhakrishnan et al. [60], which studies the problem of 2-coloring an n-uniform hypergraph.

In the query model, there are a number of works studying basic graph problems [39, 57, 25] but, to the best of our knowledge, Assadi et al. were the first to study graph coloring in this sense. Also, to the best of our knowledge, there was no previously known algorithm for $O(\alpha)$-coloring in the semi-streaming and graph query settings, whereas here we obtain $(\kappa+o(\kappa))$-colorings; recall the bound $\kappa \leqslant 2\alpha-1$.

MPC and Congested Clique Models. The MapReduce framework [27] is extensively used in distributed computing to process massive data sets. Beame, Koutris, and Suciu [16] defined the Massively Parallel Communication (MPC) model to abstract out key theoretical features of MapReduce; it has since become a widely used setting for designing and analyzing big data algorithms, especially for graph problems. Another well studied model for distributed graph algorithms is Congested Clique [50]. Behnezhad et al. [17] show that Congested Clique is equivalent to the "semi-MPC model," defined as MPC with $O(n\log n)$ bits of memory per machine, thanks to simulations in both directions preserving the round complexity.

Harvey et al. [41] gave a $(\Delta+o(\Delta))$-coloring algorithm in the MapReduce model; it can be simulated in MPC using $O(1)$ rounds and $O(n^{1+c})$ space per machine for some constant $c>0$. The aforementioned paper of Assadi et al. [5] gives an $O(1)$-round MPC algorithm for $(\Delta+1)$-coloring using $O(n\log^3 n)$ bits of space per machine. Because this space usage is $\omega(n\log n)$, the equivalence result of Behnezhad et al. [17] does not apply and this doesn't lead to an $O(1)$-round Congested Clique algorithm. In contrast, our MPC algorithm can be made to use only $O(n\log n)$ bits per machine and $\kappa+o(\kappa)$ colors for graphs with $\kappa=\omega(\log^2 n)$, and therefore leads to such a Congested Clique algorithm. Chang et al. [23] gave an $O(\sqrt{\log\log n})$-round MPC algorithm with $o(n)$ space per machine and $\widetilde{O}(m)$ space in total. Using the improved network decomposition results by Rozhon and Ghaffari [62], this round complexity can be reduced to $O(\log\log\log n)$. We, however, focus on the quasi-linear memory per machine regime.

Graph coloring has recently garnered considerable attention in the Congested Clique model. Parter [58] gave a $(\Delta+1)$-coloring algorithm using $O(\log\log\Delta \cdot \log^\star \Delta)$ rounds, later improved to $O(\log^\star \Delta)$ by Parter and Su [59]. Chang et al. [23] have recently improved this to $O(1)$ rounds. They use similar but more involved graph partitioning techniques than us, as is probably necessary for a stringent $(\Delta+1)$-coloring. For low-degeneracy graphs, our algorithm uses fewer colors than all these algorithms while achieving the best possible asymptotic round complexity ($O(1)$). Parallel to our work, Ghaffari and Sayyadi [36] gave an $O(1)$-round algorithm for the $O(\alpha)$-coloring problem. Their analysis suggests that they obtain a $(c\alpha)$-coloring algorithm, where the constant $c > 10$. On the other hand, we get a tight $(1+o(1))\kappa$-coloring. Recall, again, that $\kappa \leqslant 2\alpha - 1$ (Fact 2). Hence, we have an arguably simpler algorithmic framework achieving better results. The main novelty in our techniques lies in choosing degeneracy as the key parameter (instead of arboricity, which could lead to results looser by a factor of 2) and in the careful analysis that gives very sharp – not just asymptotic – bounds on the number of colors. Our algorithm (only the Congested Clique implementation), however, needs $\kappa = \omega(\log^2 n)$ or $\kappa = O(1)$ to keep the round complexity constant.

The LOCAL Model. There is a deep body of work on graph coloring in this model. Indeed, graph coloring is one of *the* most central "symmetry breaking" problems in distributed computing. We refer the reader to the monograph by Barenboim and Elkin [13] for an excellent overview of the state of the art. Here, we shall briefly discuss only a few results closely related to our contribution.

There is a long line of work on fast $(\Delta+1)$-coloring in the LOCAL model, in the deterministic as well as the randomized setting [55, 10, 33, 51, 44, 3, 63, 14] culminating in sublogarithmic time solutions due to Harris [40] and Chang et al. [24]. Barenboim and Elkin [11, 12] studied fast distributed coloring algorithms that may use far fewer than Δ colors: in particular, they gave algorithms that use $O(\alpha)$ colors and run in $O(\alpha^\varepsilon \log n)$ time on graphs with arboricity at most α. Recall again that $\kappa \leqslant 2\alpha - 1$, so that a 2α-coloring always *exists*. They also gave a faster $O(\log n)$-time algorithm using $O(\alpha^2)$ colors. Further, they gave a family of algorithms that produce an $O(t\alpha^2)$-coloring in $O(\log_t n + \log^\star n)$, for every t such that $2 \leqslant t \leqslant O(\sqrt{n/\alpha})$. Our algorithm for the LOCAL model builds on this latter result.

Kothapalli and Pemmaraju [47] focused on arboricity-dependant coloring using very few rounds. They gave a randomized $O(k)$-round algorithm that uses $O(\alpha n^{1/k})$ colors for $2\log\log n \leqslant k \leqslant \sqrt{\log n}$ and $O(\alpha^{1+1/k} n^{1/k+3/k^2} 2^{-2^k})$ colors for $k < 2\log\log n$. We extend their result to the range $k \in \left[\omega(\sqrt{\log n}),\, o(\log n)\right]$, using $O(\alpha n^{1/k} \log n)$ colors.

Ghaffari and Lymouri [35] gave a randomized $O(\alpha)$-coloring algorithm that runs in time $O(\log n \cdot \min\{\log\log n, \log\alpha\})$ as well as an $O(\log n)$-time algorithm using $\min\{(2+\varepsilon)\alpha + O(\log n \log\log n),\, O(\alpha\log\alpha)\}$ colors, for any constant $\varepsilon > 0$. However, their technique does not yield a sublogarithmic time algorithm, even at the cost of a larger palette.

The LDP Technique. As mentioned earlier, our algorithmic results rely on the concept of a low degeneracy partition (LDP) that we introduce in this work. Some relatives of this idea have been considered before. Specifically, Barenboim and Elkin [13] define a d-defective (resp. b-arbdefective) c-coloring to be a vertex coloring using palette $[c]$ such that every color class induces a subgraph with maximum degree at most d (resp. arboricity at most b). Obtaining such improper colorings is a useful first step towards obtaining proper colorings. They give deterministic algorithms to obtain good arbdefective colorings [12]. However, their algorithms are elaborate and are based on construction of low outdegree acyclic partial orientations of the graph's edges: an expensive step in our space-conscious models.

Elsewhere (Theorem 10.5 of Barenboim and Elkin [13]), they note that a useful defective (not arbdefective) coloring is easily obtained by randomly picking a color for each vertex; this is then useful for computing an $O(\Delta)$-coloring.

Our LDP technique can be seen as a simple randomized method to produce an arbdefective coloring. Crucially, we parametrize our result using degeneracy instead of arboricity and give sharp – not just asymptotic – bounds on the degeneracy of each color class.

The Degeneracy Parameter. The parameter has been studied under several other names, such as *width* [34], *linkage* [46] and *Szekeres-Wilf number* [66]. For a graph G, the number $\kappa(G) + 1$ is often called the *coloring number* of G [28, 65]. It has also been extensively studied as *k-core number* in different areas such as data streaming and parallel computing [29], distributed systems [4], data mining [53], protein networks [6], and social networks[20]. Farach-Colton and Tsai [30] studied the parameter in the streaming model, and gave a one-pass semi-streaming algorithm that approximates the degeneracy of an input graph within a multiplicative factor of $1 + \varepsilon$. Our lower bounds complement this result as we show that computing the degeneracy κ exactly or more generally within a multiplicative factor of $(1 + \kappa^{-(1/2+\gamma)})$, for some constant γ, is not possible in the one-pass semi-streaming setting.

Other Related Work. Other work considers coloring in the setting of *dynamic graph algorithms*: edges are inserted and deleted over time and the goal is to *maintain* a valid vertex coloring of the graph that must be updated quickly after each modification. Unlike in the streaming setting, there is no space restriction. Bhattacharya et al. [19] gave a randomized algorithm that maintains a $(\Delta + 1)$-coloring with $O(\log \Delta)$ expected amortized update time, later improved to $O(1)$ by Henzinger and Peng [43]. Solomon and Wein [64] studied the problem for low-arboricity graphs and gave an $O(\alpha \log^2 n)$-coloring algorithm with $O(\text{poly}(\log \log n))$ update time. Recently, Henzinger et al. [42] designed an $O(\alpha \log n)$-coloring algorithm with $O(\log^2 n)$ update time. Barba et al. [9] gave tradeoffs between the number of colors used and update time. However, the techniques in these works do not seem to apply in the streaming setting due to fundamental differences in the models.

Estimating the arboricity of a graph in the streaming model is a well studied problem. McGregor et al. [52] gave a one pass $(1+\varepsilon)$-approximation algorithm to estimate the arboricity of graph using $\widetilde{O}(n)$ space. Bahmani et al. [7] gave a matching lower bound. Our lower bounds for estimating degeneracy are quantitatively much larger but they call for much tighter estimates.

3 Preliminaries

Throughout this paper, graphs are simple, undirected, and unweighted. In considering a graph coloring problem, the input graph will usually be called G and we will put $n = |V(G)|$. The notation "$\log x$" stands for $\log_2 x$. For an integer k, we denote the set $\{1, 2, \ldots, k\}$ by $[k]$.

For a graph G, we define $\Delta(G) = \max\{\deg(v) : v \in V(G)\}$. We say that G is k-degenerate if every induced subgraph of G has a vertex of degree at most k. For instance, every forest is 1-degenerate and an elementary theorem says that every planar graph is 5-degenerate. The *degeneracy* $\kappa(G)$ is the smallest k such that G is k-degenerate. The *arboricity* $\alpha(G)$ is the smallest r such that the edge set $E(G)$ can be partitioned into r forests. When the graph G is clear from the context, we simply write Δ, κ, and α, instead of $\Delta(G)$, etc.

We note two useful facts: the first is immediate and the second is an easy exercise.

▶ **Fact 1.** *If an n-vertex graph has degeneracy κ, then it has at most κn edges.*

▶ **Fact 2.** *In every graph, the degeneracy κ and arboricity α satisfy $\alpha \leqslant \kappa \leqslant 2\alpha - 1$.*

In analyzing our algorithms, it will be useful to consider certain *vertex orderings* of graphs and their connection with the notion of degeneracy, given by Lemma 5 below. Although the lemma is folklore, it is crucial to our analysis, so we include a proof for completeness.

▶ **Definition 3.** *An* ordering *of G is a list consisting of all its vertices (equivalently, a total order on $V(G)$). Given an ordering $\lhd$, for each $v \in V(G)$, the* ordered neighborhood *$N_{G,\lhd}(v) := \{w \in V(G) : \{v, w\} \in E(G), v \lhd w\}$, i.e., the set of neighbors of v that appear* after *v in the ordering. The* ordered degree *$\operatorname{odeg}_{G,\lhd}(v) := |N_{G,\lhd}(v)|$.*

▶ **Definition 4.** *A* degeneracy ordering *of G is an ordering produced by the following algorithm: starting with an empty list, pick a minimum degree vertex v (breaking ties arbitrarily), append v to the end of the list, and recurse on $G - v$ if it is nonempty.*

▶ **Lemma 5.** *G is k-degenerate iff there exists an ordering $\lhd$ such that $\operatorname{odeg}_{G,\lhd}(v) \leqslant k$ for all $v \in V(G)$.*

Proof. Suppose that G is k-degenerate. Let $\lhd = (v_1, \ldots, v_n)$ be a degeneracy ordering. Then, for each i, $\operatorname{odeg}_{G,\lhd}(v_i)$ is the degree of v_i in the induced subgraph $H := G \setminus \{v_1, \ldots, v_{i-1}\}$. By definition, H has a vertex of degree at most k, so v_i, being a minimum degree vertex in H, must have degree at most k.

On the other hand, suppose that G has an ordering $\lhd$ such that $\operatorname{odeg}_{G,\lhd}(v) \leqslant k$ for all $v \in V(G)$. Let H be an induced subgraph of G. Let v be the leftmost (i.e., smallest) vertex in $V(H)$ according to $\lhd$. Then all neighbors of v in H in fact lie in $N_{G,\lhd}(v)$, so $\deg_H(v) \leqslant \operatorname{odeg}_{G,\lhd}(v) \leqslant k$. Therefore, G is k-degenerate. ◀

A c-coloring of a graph G is a mapping $\psi\colon V(G) \to [c]$; it is said to be a *proper coloring* if it makes no edge monochromatic: $\psi(u) \neq \psi(v)$ for all $\{u, v\} \in E(G)$. The smallest c such that G has a proper c-coloring is called the *chromatic number* $\chi(G)$. By considering the vertices of G one at a time and coloring greedily, we immediately obtain a proper $(\Delta + 1)$-coloring. This idea easily extends to degeneracy-based coloring.

▶ **Lemma 6.** *Given unrestricted ("offline") access to an input graph G, we can produce a proper $(\kappa + 1)$-coloring of G in linear time.*

Proof. Construct a degeneracy ordering $(v_1, \ldots, v_n)$ of G and then greedily color the vertices one by one in the order $(v_n, \ldots, v_1)$. Given a palette of size $\kappa + 1$, by the "only if" direction of Lemma 5, there will always be a free color for a vertex. ◀

Of course, the simple algorithm above is not implementable directly in "sublinear" settings, such as space-bounded streaming algorithms, query models, or distributed computing models. Nevertheless, we shall use it on suitably constructed subgraphs of our input graph.

We shall use the following form of the Chernoff bound.

▶ **Fact 7.** *Let X be a sum of mutually independent indicator random variables. Let μ and δ be real numbers such that $\mathbb{E}X \leqslant \mu$ and $0 \leqslant \delta \leqslant 1$. Then, $\Pr[X \geqslant (1 + \delta)\mu] \leqslant \exp(-\mu\delta^2/3)$.*

4 A Generic Framework for Coloring Algorithms

In this section, we give a generic framework for graph coloring that we later instantiate in various computational models. As a reminder, our focus is on graphs G with a nontrivial upper bound on the degeneracy $\kappa = \kappa(G)$. Each such graph *admits* a proper $(\kappa + 1)$-coloring; our focus will be on obtaining a proper $(\kappa + o(\kappa))$-coloring efficiently.

As a broad outline, our framework calls for coloring G in two phases. The first phase produces a *low degeneracy partition* (LDP) of G: it partitions $V(G)$ into a "small" number of parts, each of which induces a subgraph that has "low" degeneracy. This step can be thought of as preprocessing and it is essentially free (in terms of complexity) in each of our models. The second phase properly colors each part, using a small number of colors, which is possible because the degeneracy is low. In later sections, we shall see that the low degeneracy allows this second phase to be efficient in each of the models we consider.

4.1 A Low Degeneracy Partition

In this phase of our coloring framework, we assign each vertex a color chosen uniformly at random from $[\ell]$, these choices being mutually independent, where ℓ is a suitable parameter. For each $i \in [\ell]$, let G_i denote the subgraph of G induced by vertices colored i. We shall call each G_i a *block* of the vertex partition given by $(G_1, \ldots, G_\ell)$. The next theorem, our main technical tool, provides certain guarantees on this partition given a suitable choice of ℓ.

▶ **Theorem 8** (LDP Theorem). *Let G be an n-vertex graph with degeneracy κ. Let $k \in [1, n]$ be a "guess" for the value of κ and let $s \geqslant Cn \log n$ be a sparsity parameter, where C is a sufficiently large universal constant. Put*

$$\ell = \left\lceil \frac{2nk}{s} \right\rceil , \qquad \lambda = 3\sqrt{\kappa \ell \log n}\,, \tag{1}$$

and let $\psi\colon V(G) \to [\ell]$ be a uniformly random coloring of G. For $i \in [\ell]$, let G_i be the subgraph induced by $\psi^{-1}(i)$. Then, the partition $(G_1, \ldots, G_\ell)$ has the following properties.

(i) *If $k \leqslant 2\kappa$, then w.h.p., for each i, the degeneracy $\kappa(G_i) \leqslant (\kappa + \lambda)/\ell$.*

(ii) *W.h.p., for each i, the block size $|V(G_i)| \leqslant 2n/\ell$.*

(iii) *If $\kappa \leqslant k \leqslant 2\kappa$, then w.h.p., the number of monochromatic edges $|E(G_1) \cup \cdots \cup E(G_\ell)| \leqslant s$.*

In each case, "w.h.p." means "with probability at least $1 - 1/\operatorname{poly}(n)$."

Proof. Notice that when $k \leqslant (C/2) \log n$, the condition $s \geqslant Cn \log n$ results in $\ell = 1$, so the vertex partition is the trivial one-block partition, which obviously satisfies all the properties in the theorem. Thus, in our proof, we may assume that $k > (C/2) \log n$.

We start with Item ii, which is the most straightforward. From Equation (1), we have $\ell \leqslant 4nk/s$, so

$$\frac{n}{\ell} \geqslant \frac{s}{4k} \geqslant \frac{Cn \log n}{4k} \geqslant \frac{C \log n}{4}\,.$$

Each block size $|V(G_i)|$ has binomial distribution $\operatorname{Bin}(n, 1/\ell)$, so a Chernoff bound gives

$$\Pr\left[|V(G_i)| > \frac{2n}{\ell}\right] \leqslant \exp\left(-\frac{n}{3\ell}\right) \leqslant \exp\left(-\frac{C \log n}{12}\right) \leqslant \frac{1}{n^2}\,,$$

for sufficiently large C. By a union bound over the at most n blocks, Item ii fails with probability at most $1/n$.

Items i and iii include the condition $k \leqslant 2\kappa$, which we shall assume for the rest of the proof. By Equation (1) and the bounds $s \geqslant Cn \log n$ and $k > (C/2) \log n$,

$$\ell \leqslant \left\lceil \frac{2k}{C \log n} \right\rceil \leqslant \frac{4k}{C \log n} \leqslant \frac{8\kappa}{C \log n}\,,$$

whence, for sufficiently large C,

$$\lambda \leqslant 3\sqrt{\kappa \cdot \frac{8\kappa}{C \log n} \cdot \log n} \leqslant \kappa \,. \tag{2}$$

We now turn to establishing Item i. Let $\lhd$ be a degeneracy ordering for G. For each $i \in [\ell]$, let $\lhd_i$ be the restriction of $\lhd$ to $V(G_i)$. Consider a particular vertex $v \in V(G)$ and let $j = \psi(v)$ be its color. We shall prove that, w.h.p., $\operatorname{odeg}_{G,\lhd_j}(v) \leqslant (\kappa+\lambda)/\ell$.

By the "only if" direction of Lemma 5, we have $\operatorname{odeg}_{G,\lhd}(v) = |N_{G,\lhd}(v)| \leqslant \kappa$. Now note that

$$\operatorname{odeg}_{G_j,\lhd_j}(v) = \sum_{u \in N_{G,\lhd(v)}} \mathbb{1}_{\{\psi(u)=\psi(v)\}}$$

is a sum of mutually independent indicator random variables, each of which has expectation $1/\ell$. Therefore, $\mathbb{E}\operatorname{odeg}_{G_j,\lhd_j}(v) = \operatorname{odeg}_{G,\lhd}(v)/\ell \leqslant \kappa/\ell$. Since $\lambda \leqslant \kappa$ by Equation (2), we may use the form of the Chernoff bound in Fact 7, which gives us

$$\Pr\left[\operatorname{odeg}_{G_j,\lhd_j}(v) > \frac{\kappa+\lambda}{\ell}\right] \leqslant \exp\left(-\frac{\kappa}{\ell}\frac{\lambda^2}{3\kappa^2}\right) = \exp\left(-\frac{9\kappa\ell\log n}{3\kappa\ell}\right) \leqslant \frac{1}{n^3}\,,$$

where the equality follows from Equation (1). In words, with probability at least $1-1/n^3$, the vertex v has ordered degree at most $(\kappa+\lambda)/\ell$ within its own block. By a union bound, with probability at least $1-1/n^2$, all n vertices of G satisfy this property. When this happens, by the "if" direction of Lemma 5, it follows that $\kappa(G_i) \leqslant (\kappa+\lambda)/\ell$ for every i.

Finally, we take up Item iii, which is now straightforward. Assume that the high probability event in Item i occurs. Then, by Fact 1,

$$|E(G_1) \cup \cdots \cup E(G_\ell)| \leqslant \sum_{i=1}^{\ell} \kappa(G_i)\,|V(G_i)| \leqslant \frac{\kappa+\lambda}{\ell}\sum_{i=1}^{\ell}|V(G_i)| = \frac{n(\kappa+\lambda)}{\ell} \leqslant \frac{2n\kappa}{\ell} \leqslant s\,,$$

where the final inequality uses the condition $\kappa \leqslant k$ and Equation (1). ◀

It will be convenient to encapsulate the guarantees of this theorem in a definition.

▶ **Definition 9.** *Suppose graph G has degeneracy κ. A vertex partition $(G_1,\ldots,G_\ell)$ simultaneously satisfying the degeneracy bound in Item i, the block size bound in Item ii, and the (monochromatic) edge sparsity bound in Item iii in Theorem 8 is called an (ℓ,s,λ)-LDP of G.*

It will turn out that an (ℓ,s,λ)-LDP leads to a proper coloring of G using at most $\kappa+\lambda+\ell$ colors. An instructive setting of parameters is $s = \Theta((n\log n)/\varepsilon^2)$, where ε is either a small constant or a slowly vanishing function of n, such as $1/\log n$. Then, a quick calculation shows that when an accurate guess $k \in [\kappa, 2\kappa]$ is made, Theorem 8 guarantees an LDP that has edge sparsity $s = \widetilde{O}(n)$ and that leads to an eventual proper coloring using $(1+O(\varepsilon))\kappa$ colors. When $\varepsilon = o(1)$, this number of colors is $\kappa + o(\kappa)$.

Recall that the second phase of our coloring framework involves coloring each G_i separately, exploiting its low degeneracy. Indeed, given an (ℓ,s,λ)-LDP, each block G_i *admits* a proper $(\kappa(G_i)+1)$-coloring. Suppose we use a distinct palette for each block; then the total number of colors used is

$$\sum_{i=1}^{\ell}(\kappa(G_i)+1) \leqslant \ell\left(\frac{\kappa+\lambda}{\ell}+1\right) = \kappa+\lambda+\ell\,, \tag{3}$$

as claimed above. Of course, even if our first phase random coloring ψ yields a suitable LDP, we still have to collect each block G_i or at least enough information about each block so as to produce a proper $(\kappa(G_i) + 1)$-coloring. How we do this depends on the precise model of computation; see Sections 5 and 6 here and the full version [18] for further instantiations.

4.2 Applications in Various Models

We now turn to the application of the framework in designing graph coloring algorithms in specific models of computation for big data, where the focus is on utilizing space sublinear in the size of the massive input graph. Such models are sometimes termed *space-conscious*.

In Section 5, we discuss the simulation of our framework in the streaming model. We present a semi-streaming algorithm in the dynamic model, meaning that edges can be both inserted and deleted. Our main result is captured in Theorem 10.

▶ **Theorem 10.** *Set $s = \lceil \varepsilon^{-2} n \log n \rceil$, where $\varepsilon > 0$ is a parameter. There is a one-pass algorithm that processes a dynamic (i.e., turnstile) graph stream using $O(\varepsilon^{-2} n \log^4 n)$ bits of space and, with high probability, produces a proper coloring using at most $(1 + O(\varepsilon))\kappa$ colors. In particular, taking $\varepsilon = 1/\log n$, it produces a $(\kappa + o(\kappa))$-coloring using $\widetilde{O}(n)$ space. Each edge update is processed in $\widetilde{O}(1)$ time and end-of-stream post-processing takes $\widetilde{O}(n)$ time.*

In Section 6, applying our framework to the general graph query model, we obtain:

▶ **Theorem 11.** *Given query access to a graph G, there is a randomized algorithm that, with high probability, produces a proper coloring of G using $\kappa + o(\kappa)$ colors. The algorithm's worst-case query complexity, running time, and space usage are all $\widetilde{O}(n^{3/2})$.*

Besides this, we obtain algorithmic results in certain distributed models of computation, namely MPC, Congested-Clique, and LOCAL models, where graph coloring is one of the most heavily studied problems. Our results are stated below. See the full version of our paper [18] for the corresponding discussions and proofs.

▶ **Theorem 12.** *There is a randomized $O(1)$-round MPC algorithm that, given an n-vertex graph G, outputs a $(\kappa + o(\kappa))$-coloring of G with high probability. The algorithm uses n processors, each with $O(n \log^2 n)$ bits of memory.*

▶ **Theorem 13.** *There is a randomized $O(1)$-round algorithm in the Congested Clique model that, given a graph G, w.h.p. finds a $(\kappa + O(\kappa^{3/4} \log^{1/2} n))$-coloring. For $\kappa = \omega(\log^2 n)$, this gives a $(\kappa + o(\kappa))$-coloring.*

▶ **Theorem 14.** *There is a randomized distributed algorithm in the LOCAL model that, given an n-vertex graph G, an estimate of its arboricity α up to a constant factor, and a parameter t such that $2 < t \leqslant O(\sqrt{n/\log n})$, produces an $O(t\alpha \log n)$-coloring of G in time $O(\log_t n + \log^\star n)$.*

5 Streaming Model

We turn to the most intensely studied space-conscious model: the data streaming model. For graph problems, in the basic model, the input is a stream of non-repeated edges that define the input graph G: this is called the *insertion-only* model, since it can be thought of as building up G through a sequence of edge insertions. In the more general *dynamic graph model* or *turnstile model*, the stream is a sequence of edge updates, each update being either an insertion or a deletion: the net effect is to build up G. Our algorithm below will work in this more general model. Later, in we shall give a corresponding lower bound that will hold even in the insertion-only model (for a lower bound, this is a strength).

We assume that the vertex set $V(G) = [n]$ and the input is a stream σ of at most $m = \text{poly}(n)$ updates to an initially empty graph. An update is a triple (u, v, c), where $u, v \in V(G)$ and $c \in \{-1, 1\}$: when $c = 1$, this token represents an insertion of edge $\{u, v\}$ and when $c = -1$, it represents a deletion. Let $N = \binom{n}{2}$ and $[[m]] = \mathbb{Z} \cap [-m, m]$. It is convenient to imagine a vector $\mathbf{x} \in [[m]]^N$ of edge multiplicities that starts at zero and is updated entrywise with each token. The input graph G described by the stream will be the underlying simple graph, i.e., $E(G)$ will be the set of all edges $\{u, v\}$ such that $x_{u,v} \neq 0$ at the end. We shall say that σ *builds up* $\mathbf{x}$ and G.

Our algorithm makes use of two data streaming primitives, each a *linear sketch*. (We can do away with these sketches in the insertion-only setting; see the end of this section.) The first is a sketch for *sparse recovery* given by a matrix A (say): given a vector $\mathbf{x} \in [[m]]^N$ with sparsity $\|\mathbf{x}\|_0 \leqslant t$, there is an efficient algorithm to reconstruct $\mathbf{x}$ from $A\mathbf{x}$. The second is a sketch for ℓ_0 *estimation* given by a random matrix B (say): given a vector $\mathbf{x} \in [[m]]^N$, there is an efficient algorithm that takes $B\mathbf{x}$ and computes from it an estimate of $\|\mathbf{x}\|_0$ that, with probability at least $1 - \delta$, is a $(1 + \gamma)$-multiplicative approximation. It is known that there exists a suitable $A \in \{0, 1\}^{d \times N}$, where $d = O(t \log(N/t))$, where A has column sparsity $O(\log(N/t))$; see, e.g., Theorem 9 of Gilbert and Indyk [37]. It is also known that there exists a suitable distribution over matrices giving $B \in \{0, 1\}^{d' \times N}$ with $d' = O(\gamma^{-2} \log \delta^{-1} \log N(\log \gamma^{-1} + \log \log m))$. Further, given an update to the ith entry of $\mathbf{x}$, the resulting updates in $A\mathbf{x}$ and $B\mathbf{x}$ can be effected quickly by generating the required portion of the ith columns of A and B.

Algorithm 1 One-Pass Streaming Algorithm for Graph Coloring via Degeneracy.

```
procedure COLOR(stream $\sigma$, integer $k$)   ▷ $\sigma$ builds up $\mathbf{x}$ and $G$;  $k \in [1, n]$ is a guess for $\kappa(G)$
    choose $s$, $\ell$ as in Equation (1) and $t, d, d', A, B$ as in the above discussion
    initialize $\mathbf{y} \in [[m]]^d$ and $\mathbf{z} \in [[m]]^{d'}$ to zero
    foreach $u \in [n]$ do $\psi(u) \leftarrow$ uniform random color in $[\ell]$
    foreach token $(u, v, c)$ in $\sigma$ do
        if $\psi(u) = \psi(v)$ then $\mathbf{y} \leftarrow \mathbf{y} + cA_{u,v}$;  $\mathbf{z} \leftarrow \mathbf{z} + cB_{u,v}$
    if estimate of $\|\mathbf{w}\|_0$ obtained from $\mathbf{z}$ is $> 5s/4$ then abort
    $\mathbf{w}' \leftarrow$ result of $t$-sparse recovery from $\mathbf{y}$                ▷ we expect that $\mathbf{w}' = \mathbf{w}$
    foreach $i \in [\ell]$ do
        $G_i \leftarrow$ simple graph induced by $\{\{u, v\} : w'_{u,v} \neq 0$ and $\psi(u) = \psi(v) = i\}$
        color $G_i$ using palette $\{(i, j) : 1 \leqslant j \leqslant \kappa(G_i) + 1\}$; cf. Lemma 6 ▷ net effect is to color $G$
```

In our description of Algorithm 1, we use $A_{u,v}$ (resp. $B_{u,v}$) to denote the column of A (resp. B) indexed by $\{u, v\}$. The algorithm's logic results in sketches $\mathbf{y} = A\mathbf{w}$ and $\mathbf{z} = B\mathbf{w}$, where $\mathbf{w}$ corresponds to the subgraph of G consisting of ψ-monochromatic edges only (cf. Theorem 8), i.e., $\mathbf{w}$ is obtained from $\mathbf{x}$ by zeroing out all entries except those indexed by $\{u, v\}$ with $\psi(u) = \psi(v)$. We choose the parameter $t = 2s$, where $s \geqslant Cn \log n$ is the sparsity parameter from Theorem 8, which gives $d = O(s \log n)$; we choose $\gamma = 1/4$ and $\delta = 1/n$, giving $d' = O(\log^3 n)$.

Notice that Algorithm 1 requires a guess for $\kappa := \kappa(G)$, which is not known in advance. Our final one-pass algorithm runs $O(\log n)$ parallel instances of COLOR(σ, k), using geometrically spaced guesses $k = 2, 4, 8 \ldots$. It outputs the coloring produced by the non-aborting run that uses the smallest guess. This leads to this section's main result (restated from Section 4.2).

▶ **Theorem 10.** *Set $s = \lceil \varepsilon^{-2} n \log n \rceil$, where $\varepsilon > 0$ is a parameter. There is a one-pass algorithm that processes a dynamic (i.e., turnstile) graph stream using $O(\varepsilon^{-2} n \log^4 n)$ bits of space and, with high probability, produces a proper coloring using at most $(1 + O(\varepsilon))\kappa$ colors. In particular, taking $\varepsilon = 1/\log n$, it produces a $(\kappa + o(\kappa))$-coloring using $\widetilde{O}(n)$ space. Each edge update is processed in $\widetilde{O}(1)$ time and end-of-stream post-processing takes $\widetilde{O}(n)$ time.*

Proof. The coloring produced is obviously proper. Let us bound the number of colors used. One of the parallel runs of Color(σ, k) in Algorithm 1 will use a value $k = k^\star \in (\kappa, 2\kappa]$. We shall prove that, w.h.p., (a) every non-aborting run with $k \leqslant k^\star$ will use at most $(1 + O(\varepsilon))\kappa$ colors, and (b) the run with $k = k^\star$ will not abort.

We start with (a). Consider a particular run using $k \leqslant k^\star$. By Item i of Theorem 8, each G_i has degeneracy at most $(\kappa + \lambda)/\ell$; so if $\mathbf{w}$ is correctly recovered by the sparse recovery sketch (i.e., $\mathbf{w}' = \mathbf{w}$ in Algorithm 1), then each G_i is correctly recovered and the run uses at most $\kappa + \lambda + \ell$ colors, as in Equation (3). Using the values from Equation (1), this number is at most $(1 + O(\varepsilon))\kappa$. Now, if the run does not abort, then the estimate of the sparsity $\|\mathbf{w}\|_0$ is at most $5s/4$. By the guarantees of the ℓ_0-estimation sketch, the true sparsity is at most $(5/4)(5s/4) < 2s = t$, so, w.h.p., $\mathbf{w}$ is indeed t-sparse and, by the guarantees of the sparse recovery sketch, $\mathbf{w}' = \mathbf{w}$. Taking a union bound over all $O(\log n)$ runs, the bound on the number of colors holds for all required runs simultaneously, w.h.p..

We now take up (b). Note that $\|\mathbf{w}\|_0$ is precisely the number of ψ-monochromatic edges in G. By Item iii of Theorem 8, we have $\|\mathbf{w}_0\| \leqslant s$ w.h.p. By the accuracy guarantee of the ℓ_0-estimation sketch, in this run the estimate of $\|\mathbf{w}\|_0$ is at most $5s/4$ w.h.p., so the run does not abort.

The space usage of each parallel run is dominated by the computation of $\mathbf{y}$, so it is $O(d \log m) = O(s \log n \log m) = O(\varepsilon^{-2} n \log^3 n)$, using our setting of s and the assumption $m = \text{poly}(n)$. The claims about the update time and post-processing time follow directly from the properties of a state-of-the-art sparse recovery scheme, e.g., the scheme based on expander matching pursuit given in Theorem 9 of Gilbert and Indyk [37]. ◀

6 Query Model

We now turn to the *general graph query model*, a standard model of space-conscious algorithms for big graphs where the input graph is random-accessible but the emphasis is on the examining only a tiny (ideally, sublinear) portion of it; for general background see Chapter 10 of Goldreich's book [38]. In this model, the algorithm starts out knowing the vertex set $[n]$ of the input graph G and can access G only through the following types of queries.

- A *pair query* Pair$(\{u, v\})$, where $u, v \in [n]$. The query returns 1 if $\{u, v\} \in E(G)$ and 0 otherwise. For better readability, we shall write this query as Pair(u, v).
- A *neighbor query* Neighbor(u, j), where $u \in [n]$ and $j \in [n-1]$. The query returns $v \in [n]$ where v is the jth neighbor of u in some underlying fixed ordering of vertex adjacency lists; if $\deg(v) < j$, so that there does not exist a jth neighbor, the query returns $\perp$.

Naturally, when solving a problem in this model, the goal is to do so while minimizing the number of queries.

6.1 Sublinear Algorithm

By adapting the combinatorial machinery from their semi streaming algorithm, Assadi et al. [5] gave an $\widetilde{O}(n^{3/2})$-query algorithm for finding a $(\Delta + 1)$-coloring. Our LDP framework gives a considerably simpler algorithm using $\kappa + o(\kappa)$ colors, where $\kappa := \kappa(G)$. We remark here that $\widetilde{O}(n^{3/2})$ query complexity is optimal (up to polylogarithmic actors), as Assadi et al. [5] proved a matching lower bound for any $(c \cdot \Delta)$-coloring algorithm, for any constant $c > 1$.

▶ **Theorem 11.** *Given query access to a graph G, there is a randomized algorithm that, with high probability, produces a proper coloring of G using $\kappa + o(\kappa)$ colors. The algorithm's worst-case query complexity, running time, and space usage are all $\widetilde{O}(n^{3/2})$.*

Proof. The algorithm proceeds in two stages. In the first stage, it attempts to extract all edges in G through neighbor queries alone, aborting when "too many" queries have been made. More precisely, it loops over all vertices v and, for each v, issues queries $\mathrm{Neighbor}(v, 1), \mathrm{Neighbor}(v, 2), \ldots$ until a query returns $\perp$. If this stage ends up making $3n^{3/2}$ queries (say) without having processed every vertex, then it aborts and the algorithm moves on to the second stage. By Fact 1, if $\kappa \leqslant \sqrt{n}$, then this stage will not abort and the algorithm will have obtained G completely; it can then $(\kappa + 1)$-color G (as in Lemma 6) and terminate, skipping the second stage.

In the second stage, we know that $\kappa > \sqrt{n}$. The algorithm now uses a random coloring ψ to construct an (ℓ, s, λ)-LDP of G using the "guess" $k = \sqrt{n}$, with $s = \Theta(\varepsilon^{-2} n \log n)$ and ℓ, λ given by Equation (1). To produce each subgraph G_i in the LDP, the algorithm simply makes all possible queries $\mathrm{Pair}(u, v)$ where $\psi(u) = \psi(v)$. W.h.p., the number of queries made is at most

$$\frac{1}{2} \sum_{i \in [\ell]} |V(G_i)|^2 \leqslant \frac{\ell}{2} \left(\frac{2n}{\ell} \right)^2 \leqslant \frac{2n^2 s}{4nk} = \Theta\left(\frac{n^{3/2} \log n}{\varepsilon^2} \right),$$

where the first inequality uses Item ii of Theorem 8. We can enforce this bound in the worst case by aborting if it is violated.

Clearly, $k \leqslant 2\kappa$, so Item i of Theorem 8 applies and by the discussion after Definition 9, the algorithm uses $(1 + O(\varepsilon))\kappa$ colors. Setting $\varepsilon = 1/\log n$, this number is at most $\kappa + o(\kappa)$ and the overall number of queries remains $\widetilde{O}(n^{3/2})$, as required. ◀

7 Lower Bounds

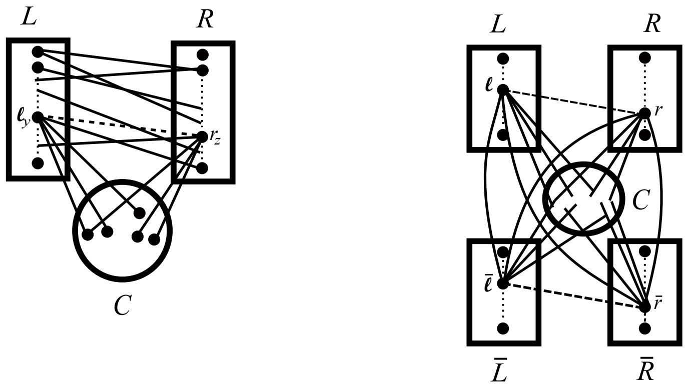
Can we improve the guarantees of our algorithms so that they use at most $\kappa + 1$ colors, rather than $\kappa + o(\kappa)$? After all, every graph G does have a proper $(\kappa(G) + 1)$-coloring. Our lower bounds answer this with a strong "No" in the data streaming and query models. If we insist on a coloring that good, we would incur the worst possible space or query complexity: $\Omega(n^2)$. In fact, this holds even if κ is known to the algorithm in advance. Moreover, all our streaming lower bounds hold even if the input stream consists of edge insertions alone.

Our lower bounds generalize to the problem of producing a $(\kappa + \lambda)$-coloring. We show that this requires $\Omega(n^2/\lambda^2)$ space or query complexity. Such generalizations are based on the following Blow-Up Lemma.

▶ **Definition 15.** *Let G be a graph and λ a positive integer. The* blow-up graph *G^λ is obtained by replacing each vertex of G with a copy of the complete graph K_λ and replacing each edge of G with a complete bipartite graph between the copies of K_λ at its endpoints. More succinctly, G^λ is the lexicographical product $G[K_\lambda]$.*

▶ **Lemma 16** (Blow-Up Lemma). *For all graphs G and positive integers λ, c, if G has a c-clique, then G^λ has a $(c\lambda)$-clique. Also, $\kappa(G^\lambda) \leqslant (\kappa(G) + 1)\lambda - 1$.*

Proof. The claim about cliques is immediate. The bound on $\kappa(G^\lambda)$ follows by taking a degeneracy ordering of G and replacing each vertex v by a list of vertices of the clique that replaces v in G^λ, ordering vertices within the clique arbitrarily. ◀



(a) Gadget graph for Lemma 19. **(b)** Gadget graph for Theorem 21.

Figure 1 Gadget constructions for lower bounds.

Streaming Lower Bounds. Our streaming lower bounds use reductions from the INDEX problem in communication complexity. In the INDEX_N problem, Alice is given a vector $\mathbf{x} = (x_1, \ldots, x_N) \in \{0,1\}^N$ and Bob is given an index $k \in [N]$. The goal is for Alice to send Bob a (possibly random) c-bit message that enables Bob to output x_k with probability at least $2/3$. The smallest c for which such a protocol exists is called the one-way randomized communication complexity, $\mathrm{R}^{\to}(\text{INDEX}_N)$. As is well known, $\mathrm{R}^{\to}(\text{INDEX}_N) = \Omega(N)$ [2].

We shall in fact consider instances of INDEX_N where $N = p^2$, for an integer p. Using a canonical bijection between $[N]$ and $[p] \times [p]$, we reinterpret $\mathbf{x}$ as a matrix with entries $(x_{ij})_{i,j \in [p]}$, and Bob's input as $(y, z) \in [p] \times [p]$. We further interpret this matrix $\mathbf{x}$ as the bipartite adjacency matrix of a $(2p)$-vertex balanced bipartite graph $H_{\mathbf{x}}$. Such graphs $H_{\mathbf{x}}$ will be key gadgets in the reductions to follow.

▶ **Definition 17.** *For $\mathbf{x} \in \{0,1\}^{p \times p}$, a realization of $H_{\mathbf{x}}$ on a list $(\ell_1, \ldots, \ell_p, r_1, \ldots, r_p)$ of distinct vertices is a graph on these vertices whose edge set is $\{\{\ell_i, r_j\} : x_{ij} = 1\}$.*

First Flavor: Degeneracy Not Known in Advance. To prove lower bounds of the first flavor, we start by demonstrating the hardness of the abstract problem GRAPH-DIST.

▶ **Definition 18** (GRAPH-DIST **problem**)**.** *Consider two graph families: $\mathcal{G}_1 := \mathcal{G}_1(n, q, \lambda)$, consisting of n-vertex graphs with chromatic number $\chi \geqslant (q+1)\lambda$, and $\mathcal{G}_2 := \mathcal{G}_2(n, q, \lambda)$, consisting of n-vertex graphs with $\kappa \leqslant q\lambda - 1$. Then GRAPH-DIST$(n, q, \lambda)$ is the problem of distinguishing $\mathcal{G}_1$ from $\mathcal{G}_2$ (note that $\mathcal{G}_1 \cap \mathcal{G}_2 = \varnothing$): given an input graph G on n vertices, the problem is to decide whether $G \in \mathcal{G}_1$ or $G \in \mathcal{G}_2$, with success probability at least $2/3$.*

We shall prove that GRAPH-DIST is "hard" in the insertion-only streaming setting and in the query setting, thereby establishing that in these models it is hard to produce a $(\kappa+\lambda)$-coloring. In fact, our proofs will show that it is just as hard to estimate the parameter κ; this goes to show that the hardness of the coloring problem is not just because of the large output size.

▶ **Lemma 19.** *Solving GRAPH-DIST(n, q, λ) in one pass requires $\Omega(n^2/\lambda^2)$ space. More precisely, there is a constant $c > 0$ such that for every integer $\lambda \geqslant 1$ and every sufficiently large integer q, there is a setting $n = n(q, \lambda)$ for which every randomized one-pass streaming algorithm for GRAPH-DIST(n, q, λ) requires at least cn^2/λ^2 bits of space.*

Proof. Put $p = q - 1$. We reduce from INDEX_N, where $N = p^2$, using the following plan. Starting with an empty graph on $n = 3\lambda p$ vertices, Alice adds certain edges based on her input $\mathbf{x} \in \{0,1\}^{p \times p}$ and then Bob adds certain other edges based on his input

$(y, z) \in [p] \times [p]$. By design, solving GRAPH-DIST(n, q, λ) on the resulting final graph reveals the bit x_{yz}, implying that a one-pass streaming algorithm for GRAPH-DIST requires at least $\mathrm{R}^{\to}(\text{INDEX}_N) = \Omega(N) = \Omega(p^2) = \Omega(n^2/\lambda^2)$ bits of memory. The details follow.

First, consider $\lambda = 1$. We use the vertex set $L \uplus R \uplus C$ ("$\uplus$" denotes a disjoint union), where $L = \{\ell_1, \ldots, \ell_p\}$, $R = \{r_1, \ldots, r_p\}$, and $|C| = p$. Alice introduces the edges of the gadget graph $H_{\mathbf{x}}$ (from def. 17), realized on the vertices $(\ell_1, \ldots, \ell_p, r_1, \ldots, r_p)$. Bob introduces all possible edges within $C \cup \{\ell_y, r_z\}$, except for $\{\ell_y, r_z\}$. Let G be the resulting graph (see Figure 1a).

If $x_{yz} = 1$, then G contains a clique on $C \cup \{\ell_y, r_z\}$, whence $\chi(G) \geqslant p + 2$. If, on the other hand, $x_{yz} = 0$, then we claim that $\kappa(G) \leqslant p$. By Lemma 5, the claim will follow if we exhibit a vertex ordering $\lhd$ such that $\mathrm{odeg}_{G,\lhd}(v) \leqslant p$ for all $v \in V(G)$. We use an ordering where $L \cup R \setminus \{\ell_y, r_z\} \lhd \ell_y \lhd \{r_z\} \cup C$ and the ordering within each set is arbitrary. By construction of $H_{\mathbf{x}}$, each vertex in $L \cup R \setminus \{\ell_y, r_z\}$ has *total* degree at most p. For each vertex $v \in \{r_z\} \cup C$, we trivially have $\mathrm{odeg}_{G,\lhd}(v) \leqslant p$ because $|C| = p$. Finally, since $x_{yz} = 0$, the vertex r_z is not a neighbor of ℓ_y; so $\mathrm{odeg}_{G,\lhd}(\ell_y) = |C| = p$. This proves the claim.

When $\lambda \geqslant 1$, Alice and Bob introduce edges so as to create the blow-up graph G^λ, as in Definition 15. By Lemma 16, if $x_{yz} = 1$, then G^λ has a $(p + 2)\lambda$-clique, whereas if $x_{yz} = 0$, then $\kappa(G^\lambda) \leqslant (p+1)\lambda - 1$. In the former case, $\chi(G^\lambda) \geqslant (p+2)\lambda = (q+1)\lambda$, so that $G^\lambda \in \mathcal{G}_1(n, q, \lambda)$; cf. Definition 18. In the latter case, $\kappa(G^\lambda) \leqslant q\lambda - 1$, so that $G^\lambda \in \mathcal{G}_2(n, q, \lambda)$. Thus, solving GRAPH-DIST(n, q, λ) on G^λ reveals x_{yz}. ◀

Our coloring lower bounds are straightforward consequences of the above lemma.

▶ **Theorem 20.** *Given a single randomized pass over a stream of edges of an n-vertex graph G, succeeding with probability at least $2/3$ at either of the following tasks requires $\Omega(n^2/\lambda^2)$ space, where $\lambda \geqslant 1$ is an integer parameter:*

(i) *produce a proper $(\kappa + \lambda)$-coloring of G;*

(ii) *produce an estimate $\hat{\kappa}$ such that $|\hat{\kappa} - \kappa| \leqslant \lambda$.*

Furthermore, if we require $\lambda = O\big(\kappa^{\frac{1}{2}-\gamma}\big)$, where $\gamma > 0$, then neither task admits a semi-streaming algorithm.

Proof. An algorithm for either task i and or task ii immediately solves GRAPH-DIST with appropriate parameters, implying the $\Omega(n^2/\lambda^2)$ bounds, thanks to Lemma 19. For the "furthermore" statement, note that the graphs in the family $\mathcal{G}_2$ constructed in the proof of Lemma 19 have $\kappa = \Theta(n)$, so performing either task with the stated guarantee on λ would require $\Omega(n^{1+2\gamma})$ space, which is not in $\widetilde{O}(n)$. ◀

▶ Remark. Together, Theorem 10 and Theorem 20 say that producing a $(\kappa + \kappa/\log^{O(1)} n)$-coloring is possible in semi-streaming space whereas producing a $(\kappa + O\big(\kappa^{\frac{1}{2}-O(1)}\big))$-coloring is not. We leave open the question of whether this gap can be tightened.

Second Flavor: Degeneracy Known in Advance. We now show that the coloring problem remains just as hard even if the algorithm knows the degeneracy of the graph before seeing the edge stream.

▶ **Theorem 21.** *Given as input an integer κ, followed by a stream of edges of an n-vertex graph G with degeneracy κ, a randomized one-pass algorithm that produces a proper $(\kappa + \lambda)$-coloring of G requires $\Omega(n^2/\lambda^2)$ bits of space. Furthermore, if we require $\lambda = O\big(\kappa^{\frac{1}{2}-\gamma}\big)$, where $\gamma > 0$, then the task does not admit a semi-streaming algorithm.*

Proof. We reduce from $\textsc{index}_N$, where $N = p^2$, using a plan analogous to the one used in proving Lemma 19. Alice and Bob will construct a graph on $n = 5\lambda p$ vertices, using their respective inputs $\mathbf{x} \in \{0,1\}^{p\times p}$ and $(y, z) \in [p] \times [p]$.

First, we consider the case $\lambda = 1$. We use the vertex set $L \uplus R \uplus \overline{L} \uplus \overline{R} \uplus C$, where $L = \{\ell_1, \dots \ell_p\}$, $R = \{r_1, \dots, r_p\}$, $\overline{L} = \{\overline{\ell}_1, \dots, \overline{\ell}_p\}$, $\overline{R} = \{\overline{r}_1, \dots, \overline{r}_p\}$, and $|C| = p$. Let $\overline{\mathbf{x}}$ be the bitwise complement of $\mathbf{x}$. Alice introduces the edges of the gadget graph $H_{\mathbf{x}}$ (from Definition 17), realized on $L \cup R$, and the edges of $H_{\overline{\mathbf{x}}}$ realized on $\overline{L} \cup \overline{R}$. For ease of notation, put $\ell := \ell_y$, $r := r_z$, $\overline{\ell} := \overline{\ell}_y$, $\overline{r} := \overline{r}_z$, and $S := C \cup \{\ell, r, \overline{\ell}, \overline{r}\}$. Bob introduces all possible edges within S, except for $\{\ell, r\}$ and $\{\overline{\ell}, \overline{r}\}$. Let G be the resulting graph (see Figure 1b).

We claim that the degeneracy $\kappa(G) = p + 2$. To prove this, we consider the case $x_{yz} = 1$ (the other case, $x_{yz} = 0$, is symmetric). By construction, G contains a clique on the $p + 3$ vertices in $C \cup \{\ell, r, \overline{\ell}\}$; therefore, by definition of degeneracy, $\kappa(G) \geqslant p + 2$. To show that $\kappa(G) \leqslant p + 2$, it will suffice to exhibit a vertex ordering $\lhd$ such that $\mathrm{odeg}_{G,\lhd}(v) \leqslant p + 2$ for all $v \in V(G)$. To this end, consider an ordering where $V(G) \setminus S \lhd \overline{\ell} \lhd S \setminus \{\overline{\ell}\}$ and the ordering within each set is arbitrary. Each vertex $v \in V(G) \setminus S$ has $\mathrm{odeg}_{G,\lhd}(v) \leqslant \deg(v) \leqslant p$ and each vertex $v \in S \setminus \{\overline{\ell}\}$ has $\mathrm{odeg}_{G,\lhd}(v) \leqslant \big|S \setminus \{\overline{\ell}\}\big| - 1 = p + 2$. As for the vertex $\overline{\ell}$, since $\overline{x}_{yz} = 1 - x_{yz} = 0$, by the construction in Definition 17, $\overline{r}$ is not a neighbor of $\overline{\ell}$; therefore, $\mathrm{odeg}_{G,\lhd}(\overline{\ell}) \leqslant \big|S \setminus \{\overline{\ell}, \overline{r}\}\big| = p + 2$.

Let $\mathcal{A}$ be a streaming algorithm that behaves as in the theorem statement. Recall that we are considering $\lambda = 1$. Since $\kappa(G) = p + 2$ for every instance of $\textsc{index}_N$, Alice and Bob can simulate $\mathcal{A}$ on their constructed graph G by first feeding it the number $p + 2$, then Alice's edges, and then Bob's. When $\mathcal{A}$ succeeds, the coloring it outputs is a proper $(p + 3)$-coloring; therefore it must repeat a color inside S, as $|S| = p + 4$. But S has exactly one pair of non-adjacent vertices: the pair $\{\ell, r\}$ if $x_{yz} = 0$, and the pair $\{\overline{\ell}, \overline{r}\}$ if $x_{yz} = 1$. Thus, an examination of which two vertices in S receive the same color reveals x_{yz}, solving the $\textsc{index}_N$ instance. It follows that $\mathcal{A}$ must use at least $\mathrm{R}^{\to}(\textsc{index}_N) = \Omega(N) = \Omega(p^2)$ bits of space.

Now consider an arbitrary λ. Alice and Bob proceed as above, except that they simulate $\mathcal{A}$ on the blow-up graph G^λ. Since G always has a $(p + 3)$-clique and $\kappa(G) = p + 2$, the two halves of Lemma 16 together imply $\kappa(G^\lambda) = (p + 3)\lambda - 1$. So, when $\mathcal{A}$ succeeds, it properly colors G^λ using at most $(p + 4)\lambda - 1$ colors. For each $A \subseteq V(G)$, abusing notation, let A^λ denote its corresponding set of vertices in G^λ (cf. Definition 15). Since $|S^\lambda| = (p + 4)\lambda$, there must be a color repetition within S^λ. Reasoning as above, this repetition must occur within $\{\ell, r\}^\lambda$ when $x_{yz} = 0$ and within $\{\overline{\ell}, \overline{r}\}^\lambda$ when $x_{yz} = 1$. Therefore, Bob can examine the coloring to solve $\textsc{index}_N$, showing that $\mathcal{A}$ must use $\Omega(N) = \Omega(p^2) = \Omega(n^2/\lambda^2)$ space.

The "furthermore" part follows by observing that $\kappa(G^\lambda) = \Theta\big(|V(G^\lambda)|\big)$. ◀

Query Lower Bounds. We prove lower bounds of the above two flavors for the graph query model as well. We describe the proofs in the full version of the paper [18].

▶ **Theorem 22.** *Given query access to an n-vertex graph G, succeeding with probability at least $2/3$ at either of the following tasks requires $\Omega(n^2/\lambda^2)$ queries, where $\lambda \geqslant 1$ is an integer:*

(i) *produce a proper $(\kappa + \lambda)$-coloring of G;*

(ii) *produce an estimate $\hat{\kappa}$ such that $|\hat{\kappa} - \kappa| \leqslant \lambda$.*

▶ **Theorem 23.** *Given an integer κ and query access to an n-vertex graph G with $\kappa(G) = \kappa$, an algorithm that, with probability $2/3$, produces a proper $(\kappa + \lambda)$-coloring of G must make $\Omega(n^2/\lambda^2)$ queries.*

Combinatorial Lower Bound. Finally, we prove a combinatorial result that shows that unlike $(\Delta + 1)$-coloring, an analogous Palette Sparsification Theorem (as in Assadi et al. [5]) doesn't exist for degeneracy-based coloring. Moreover, our result implies that an algorithm based on such a technique must use at least as many colors as Algorithm 1. We discuss this in detail in the full version of our paper [18].

Improved Bounds for Matching in Random-Order Streams

Abstract

We study the problem of computing an approximate maximum cardinality matching in the semi-streaming model when edges arrive in a *random* order. In the semi-streaming model, the edges of the input graph $G = (V, E)$ are given as a stream $e_1, \ldots, e_m$, and the algorithm is allowed to make a single pass over this stream while using $O(n\text{polylog}(n))$ space ($m = |E|$ and $n = |V|$). If the order of edges is adversarial, a simple single-pass greedy algorithm yields a 1/2-approximation in $O(n)$ space; achieving a better approximation in adversarial streams remains an elusive open question.

A line of recent work shows that one can improve upon the 1/2-approximation if the edges of the stream arrive in a random order. The state of the art for this model is two-fold: Assadi et al. [SODA 2019] show how to compute a $\frac{2}{3}(\sim .66)$-approximate matching, but the space requirement is $O(n^{1.5}\text{polylog}(n))$. Very recently, Farhadi et al. [SODA 2020] presented an algorithm with the desired space usage of $O(n\text{polylog}(n))$, but a worse approximation ratio of $\frac{6}{11}(\sim .545)$, or $\frac{3}{5}(= .6)$ in bipartite graphs.

In this paper, we present an algorithm that computes a $\frac{2}{3}(\sim .66)$-approximate matching using only $O(n\log(n))$ space, improving upon both results above. We also note that for adversarial streams, a lower bound of Kapralov [SODA 2013] shows that any algorithm that achieves a $1 - \frac{1}{e}(\sim .63)$-approximation requires $(n^{1+\Omega(1/\log\log(n))})$ space. Our result for random-order streams is the first to go beyond the adversarial-order lower bound, thus establishing that computing a maximum matching is provably easier in random-order streams.

1 Introduction

Computing a maximum cardinality matching is a classical problem in combinatorial optimization, with a large number of algorithms and applications. Motivated by the rise of massive graphs, much of the recent research on this problem has focused on sub-linear algorithms that are able to compute a matching without storing the entire graph in memory. One of the standard sub-linear models for processing graphs is known as the *semi-streaming* model [17]: the algorithm has access to a sequence of edges (the stream), and is allowed to make a single pass over this sequence while only using only $O(n\text{polylog}(n))$ internal memory, where n is the number of vertices in the graph. Note that the memory used is still significantly smaller than the number of edges in the graph, and that $O(n)$ memory is also necessary if we want the algorithm to output the actual edges of the matching. (One typically assume

Table 1 Single-pass semi-streaming algorithms known for the maximum matching when edges arrive in a random order. The space bounds are expressed in terms of $O(\log(n))$-size words, though many existing results do not state the exact polylog(n) term. The result of Gamlath et al. [18] works in weighted graphs; all others are restricted to unweighted graphs.

	Approximation Factor		
	Bipartite graphs	**General graphs**	**Space**
Konrad et al. [28]	0.5005	0.5003	$O(n)$
Gamlath et al. [18]	0.512	0.506	$O(n \cdot \text{polylog}(n))$
Konrad [27]	0.539	-	$O(n \cdot \text{polylog}(n))$
Assadi et al. [3]	0.666	0.666	$O(n^{1.5} \cdot \text{polylog}(n))$
Farhadi et al. [16]	0.6	0.545	$O(n \cdot \text{polylog}(n))$
This paper	**0.666**	**0.666**	$O(n\log(n))$

$O(\log(n))$-size words, so that a single edge can be stored in $O(1)$ space; if one were to express space in terms of the number of bits, all the space bounds in this paper would increase by a $O(\log(n))$ factor.)

If the edges of the stream arrive in an arbitrary order, a simple greedy algorithm can compute a maximal matching – and hence a 1/2-approximate maximum matching – in a single streaming pass and $O(n)$ space. Going beyond a 1/2-approximation with a single pass is considered one of the main open problems in the area. The strongest lower bound is by Kapralov [23], who build upon an earlier lower bound of Goel et al. [20]: any algorithm with approximation ratio $\geq 1 - 1/e \sim .63$ requires $n^{1+\Omega(1/\log\log(n))})$ space [23]. But we still do not know where the right answer lies between $1/2$ and $1 - 1/e$.

To make progress on this intriguing problem, several recent papers studied a more relaxed model, where the graph is still arbitrary, but the edges are assumed to arrive in a *uniformly random* order. Konrad et al. were the first to go beyond a 1/2-approximation in this setting: they showed that in random-order streams, there exists an $O(n)$-space algorithm that computes an .5003-approximate matching, or .5005-approximate for bipartite graphs [28]. This was later improved to .506 in general graphs [18] and .539 in bipartite graphs [27]. Assadi et al. then showed an algorithm with an approximation ratio of $(2/3 - \epsilon) \sim .66$, but their algorithm had a significantly larger space requirement of $O(n^{1.5}\text{polylog}(n))$ [3]. Finally, very recently (SODA 2020), Farhadi et al. achieved the current state of the art for $O(n\text{polylog}(n))$ space; their algorithm achieves an approximation ratio of $6/11 \sim .545$ for general graphs and $3/5 = .6$ for bipartite graphs [16]. A summary of these results can be found in Table 1.

Although this line of work suggests that computing a maximum matching might be fundamentally easier in random-order streams, we note that even in bipartite graphs, none of the previous results go beyond the best known lower bound for adversarial streams mentioned above [23]: the algorithm of Assadi et al. uses too much space ($n^{1.5} \gg n^{1+1/\log\log(n)}$), while the result of Farhadi et al. has an approximation ratio of $.6 < 1 - 1/e$.

Our result is the first to go beyond the adversarial-order lower bound, thus establishing that computing a matching is provably easier in random-order streams.

▶ **Theorem 1** (Our Result). *Given any (possibly non-bipartite) graph G and any approximation parameter $1 > \epsilon > 0$, there exists a deterministic single-pass streaming algorithm that with high probability computes a $(2/3 - \epsilon)$-approximate matching if the edges of G arrive in a uniformly random order. The space usage of the algorithm is $O(n\log(n)poly(\epsilon^{-1}))$.*

Our result significantly improves upon the space requirement of Assadi et al. [3] and the approximation ratio of Farhadi et al. [16]. In fact, our algorithm achieves the best of both those results (see Table 1). On top of that, our result is quite simple; given that it improves upon a sequence of previous results, we see this simplicity as a plus.

Related Work

If the only requirement is to return an approximate estimate of the *size* of the maximum matching, rather than the actual edges, a surprising result by Kapralov et al. shows that one can get away with very little space: given a single pass over a random-order stream, it is possible to estimate the size within a $1/\text{polylog}(n)$ factor using only $\text{polylog}(n)$ space [24]; a very recent improvement reduces the polylog factors to $O(\log^2(n))$ [25]. There is also a line of work that estimates the size of the matching in $o(n)$ space in *adversarial* streams for special classes of graphs as such planar graphs or low-arboricity graphs [14, 8, 30, 11, 31].

There are many one-pass streaming algorithms for computing a maximum matching in *weighted* graphs. For adversarial-order streaming, a long line of work culminated in a $(1/2-\epsilon)$-approximation using $O(n)$ space [17, 29, 13, 12, 32, 19]. Gamlath et al. recently showed that for random-order streams, one can achieve an approximation ratio of $1/2 + \Omega(1)$, [18]. See also other related work on weighted graphs in [8].

There are several results on upper and lower bounds for computing a maximum matching in dynamic streams (where edges can also be deleted) [26, 10, 6, 9, 5]. Finally, there are several results that are able to achieve better bounds by allowing the algorithm to make multiple passes over the stream: some results focus on just two or three passes [28, 15, 22, 27], while others seek to compute a $(1-\epsilon)$-approximate matching by allowing a large constant number (or even $\log(n)$) passes [29, 1, 21, 2].

Overview of Techniques

The basic greedy algorithm trivially achieves a 1/2-approximate matching in adversarial streams; in fact, Konrad et al later showed that the ratio remains $1/2 + o(1)$ even in random-order streams [28]. Existing algorithms for improving the 1/2 ratio in random-order streams generally fall into two categories. The algorithms in [28, 27, 18, 16] use the randomness of the stream to compute some fraction of short augmenting paths, thus going beyond the 1/2-approximation of a maximal matching. The result in [3] instead shows that one can obtain a large matching by constructing a subgraph that obeys certain degree-properties.

Our result follows the framework of [3]. Given any graph G, an earlier result of Bernstein and Stein for fully dynamic matching defined the notion of an edge-degree constrainted subgraph (denoted EDCS), which is a sparse subgraph $H \subseteq G$ that obeys certain degree-properties [7]. They showed that any EDCS H always contains a $(2/3-\epsilon)$-approximate matching. The streaming result of Assadi et al. [3] then showed that given a random-order stream, it is possible to compute an EDCS H in $O(n^{1.5})$ space; returning the maximum matching in H yields a $(2/3-\epsilon)$-approximate matching in G.

Our result also takes the EDCS as its starting point, but it is unclear how to compute an EDCS H of G using less than $O(n^{1.5})$ space. Our algorithm requires two new contributions. Firstly, we show that it is sufficient for H to satisfy a somewhat relaxed set of properties. Our main contribution is then to use an entirely different construction of this relaxed subgraph, which uses the randomness of the stream more aggressively to compute H using low space.

2 Notation and Preliminaries

Consider any graph $H = (V_H, E_H)$. We define $\deg_H(v)$ to be the degree of v in H and we define the degree of an edge (u, v) to be $\deg_H(u) + \deg_H(v)$. A matching M in H is a set of vertex-disjoint edges. All graphs in this paper are unweighted and undirected. We use $\mu(H)$ to denote the size of the maximum matching in H. Unless otherwise indicated, we let $G = (V, E)$ refer to the input graph and let $n = |V|$ and $m = |E|$. We note that every graph referred to in the paper has the same vertex V as the input graph; when we refer to subgraphs, we are always referring to a subset of edges on this same vertex set.

The input graph $G = (V, E)$ is given as a stream of edges $S = \langle e_1, \dots, e_m \rangle$. We assume that the permutation $(e_1, \dots, e_m)$ of the edges is chosen *uniformly at random* among all permutations of E. We use $S_{[i,j]}$ to denote the substream $\langle e_i, \dots, e_j \rangle$, and we use $G_{>i} \subseteq G$ to denote the subgraph of G containing all edges in $\{e_{i+1}, \dots, e_m\}$.

Our analysis will apply concentration bounds to segments $S_{[i,j]}$ of the stream. Observe that because the stream is a random permutation, any segment $S_{[i,j]}$ is equivalent to sampling $j - 1 + 1$ edges from the stream without replacement. We can thus apply the Chernoff bound for negatively associated variables (see e.g. the primer in [33]).

▶ **Theorem 2** (Chernoff). *Let $X_1, \dots X_n$ be negatively associated random variables taking values in $[0, 1]$. Let $X = \sum X_i$ and let $\mu = \mathbb{E}[X]$. Then, for any $0 < \delta < 1$ we have*

$$\Pr[X \le \mu(1-\delta)] \le \exp(\frac{-\mu \cdot \delta^2}{2}),$$

and

$$\Pr[X \ge \mu(1+\delta)] \le \exp(\frac{-\mu \cdot \delta^2}{3})$$

The early and late sections of the stream

Our algorithm will use the first ϵm edges of the stream to learn about the graph and will effectively ignore them for the purposes of analyzing the maximum matching. Thus, we only approximate the maximum matching in the later $(1-\epsilon)m$ edges of stream; because the stream is random, these edges still contain a large fraction of the maximum matching. We use the following definitions and lemmas to formalize this intuition.

▶ **Definition 3.** *We Let E^{early} denote the first ϵm edges of the stream, and E^{late} denote the rest: that is, $E^{early} = \{e_1, \dots, e_{\epsilon m}\}$, and $E^{late} = \{e_{\epsilon m+1}, \dots, e_m\}$. Define $G^{early} = (V, E^{early})$ and $G^{late} = (V, E^{late}) = G_{>\epsilon m}$.*

For the probability bounds to work out, we need to assume that $\mu(G) \ge 20 \log(n)\epsilon^{-2}$. We justify this assumption by observing that every graph G satisfies $m \le 2n\mu(G)$, so if $\mu(G) < 20\log(n)\epsilon^{-2}$, then the algorithm can trivially return an exact maximum matching by simply storing every edge using only $O(m) = O(\log(n)\epsilon^{-2})$ space. This justifies the following:

▷ Claim 4 (Assumption). We can assume for the rest of the paper that $\mu(G) \ge 20\log(n)\epsilon^{-2}$.

Combining Claim 4 with Chernoff bound we get the following lemma, which allows us to focus our analysis on the edges in G^{late}.

▶ **Lemma 5.** *Assuming that $\epsilon < 1/2$, we have that $\Pr[\mu(G^{late}) \ge (1-2\epsilon)\mu(G)] \ge 1 - n^{-5}$.*

Proof. Fix some maximum matching $M = (f_1, ..., f_{\mu(G)})$ of G. Define X_i to be the indicator variable that edge $f_i \in M$ appears in G^{late}. Since the stream is random, and since G^{late} contains exactly $(1-\epsilon)m$ edges, we have that $\mathbb{E}[X_i] = (1-\epsilon)$ and $\sum \mathbb{E}[X_i] = (1-\epsilon)\mu(G)$. It is also easy to see that the X_i are negatively associated, since these variables correspond to sampling $(1-\epsilon)m$ edges without replacement. Recall from Claim 4 that we assume $\mu(G) \geq 20\log(n)\epsilon^{-2}$. Applying the Chernoff Bound in Theorem 2 completes the proof. ◀

Existing Work on EDCS

We now review the basic facts about the edge-degree constrained subgraph (EDCS), which was first introduced in [7].

▶ **Definition 6.** *Let $G = (V, E)$ be a graph, and $H = (V, E_H)$ a subgraph of G. Given any parameters $\beta \geq 2$ and $\lambda < 1$, we say that H is a (β, λ)-EDCS of G if H satisfies the following properties:*

- [Property P1]. *For any edge $(u, v) \in H$, $\deg_H(u) + \deg_H(v) \leq \beta$*
- [Property P2]. *For any edge $(u, v) \in G \setminus H$, $\deg_H(u) + \deg_H(v) \geq \beta(1-\lambda)$.*

The crucial fact about the EDCS is that it always contains a (almost) 2/3-approximate matching. The simplest proof of Lemma 7 below is in Lemma 3.2 of [4].

▶ **Lemma 7** ([4])**.** *Let $G(V, E)$ be any graph and $\epsilon < 1/2$ be some parameter. Let λ, β be parameters with $\lambda \leq \frac{\epsilon}{64}$, $\beta \geq 8\lambda^{-2}\log(1/\lambda)$. Then, for any $(\beta, \lambda) - EDCS$ H of G, we have that $\mu(H) \geq (\frac{2}{3} - \epsilon)\mu(G)$. (Note that the final guarantee is stated slightly differently than in Lemma 3.2 of [4], and to ensure the two are equivalent, we set λ to be a factor of two smaller than in Lemma 3.2 of [4].)*

3 Our Modified Subgraph

Unlike the algorithm of [3], we do not actually construct an EDCS of G, as we do not know how to do this in less than $O(n^{1.5})$ space. We instead rely on a more relaxed set of properties, which we analyze using Lemma 7 as a black-box. We now introduce some of the basic new tools used by our algorithm. Note that graph G in the lemma and definitions below crucially refers to any arbitrary graph G, and not necessarily the main input graph of the streaming algorithm.

▶ **Definition 8.** *We say that a graph H has bounded edge-degree β if for every edge $(u, v) \in H$, $\deg_H(u) + \deg_H(v) \leq \beta$.*

▶ **Definition 9.** *Let G be any graph, and let H be a subgraph of G with bounded edge-degree β. For any parameter $\lambda < 1$, we say that an edge $(u, v) \in G \setminus H$ is (G, H, β, λ)-underfull if $\deg_H(u) + \deg_H(v) < \beta(1-\lambda)$*

The two definitions above effectively separate the two EDCS properties: any subgraph H of G with bounded edge-degree β automatically satisfies property P1 of an EDCS, and underfull edges are then those that violate property P2. We now show that one can always construct a large matching from the combination of these two parts.

▶ **Lemma 10.** *Let $\epsilon < 1/2$ be any parameter, and let λ, β be parameters with $\lambda \leq \frac{\epsilon}{128}$, $\beta \geq 16\lambda^{-2}\log(1/\lambda)$. Consider any graph G, and any subgraph H with bounded edge-degree β. Let X contain all edges in $G \backslash H$ that are (G, H, β, λ)-underfull. Then $\mu(X \cup H) \geq (2/3 - \epsilon)\mu(G)$*

Proof. Note that it is NOT necessarily the case that $H \cup X$ is an EDCS of G, because adding the edges of X to H will increase vertex and edge degrees in H, so $H \cup X$ might not satisfy property P1 of an EDCS. We thus need a more careful argument.

Let M_G be the maximum matching in G, let $M_G^H = M_G \cap H$ and let $M_G^{G \setminus H} = M_G \cap (G \setminus H)$. Let $X^M = X \cap M_G^{G \setminus H}$. Note that by construction, $M_G \subseteq H \cup M_G^{G \setminus H}$, so $\mu(H \cup M_G^{G \setminus H}) = \mu(G)$.

We now complete the proof by showing that $H \cup X^M$ is a $(\beta + 2, 2\lambda)$-EDCS of $H \cup M_G^{G \setminus H}$. Let us start by showing property P2. Recall that X contains all edges (u, v) in $G \setminus H$ for which $\deg_H(u) + \deg_H(v) < \beta(1 - \lambda)$, so by construction X^M contains all such edges in $M_G^{G \setminus H}$. Thus, every edge $(u, v) \in (H \cup M_G^{G \setminus H}) \setminus (H \cup X^M) = M_G^{G \setminus H} \setminus X^M$ must have $\deg_H(u) + \deg_H(v) \geq \beta(1 - \lambda) \geq (\beta + 2)(1 - 2\lambda)$, where the last inequality is just rearranging the algebra to fit Property P2 for our new EDCS parameters of $\beta + 2, 2\lambda$.

For property P1, note that $X^M \subseteq M_G^{G \setminus H}$ is a matching, so for every vertex v we have $\deg_H(v) \leq \deg_{H \cup X^M}(v) \leq \deg_H(v) + 1$. Now, for $(u, v) \in H$ we had $\deg_H(u) + \deg_H(v) \leq \beta$ (by property P1 of H), and for $(u, v) \in X^M \subseteq X$ we had $\deg_H(u) + \deg_H(v) < \beta$ (by definition of X). Thus, for every $(u, v) \in H \cup X^M$ we have that $\deg_{H \cup X^M}(u) + \deg_{H \cup X^M}(v) \leq \deg_H(u) + \deg_H(v) + 2 \leq \beta + 2$.

Note that because of how we set the parameters, $\beta' = \beta + 2 < 2\beta$ and $\lambda' = 2\lambda$ satisfy the requirements of Lemma 7. We thus have that $\mu(H \cup X) \geq \mu(H \cup X^M) \geq (2/3 - \epsilon)\mu(H \cup M_G^{G \setminus H}) = (2/3 - \epsilon)\mu(G)$. ◀

4 The Algorithm

4.1 The Two Phases

Our algorithm will proceed in two phases. Once phase I terminates, the algorithm proceeds to phase II and never returns to phase I. The goal of phase I is to construct a suitable subgraph H of G. We now state the formal properties that will be guaranteed by phase I.

▶ **Definition 11** (parameters). *Throughout this section we use the following parameters. Let $\epsilon < 1/2$ be the final approximation parameter we are aiming for. Set $\lambda = \frac{\epsilon}{128}$ and set $\beta = 16\lambda^{-2} \log(1/\lambda)$; note that λ and β are $O(poly(1/\epsilon))$. Set $\alpha = \frac{\epsilon m}{n\beta^2 + 1} = O(\frac{m}{n} poly(1/\epsilon))$ and $\gamma = 5 \log(n) \frac{m}{\alpha} = O(n \log(n) poly(1/\epsilon))$.*

▶ **Lemma 12.** *Phase I uses $O(n\beta) = O(npoly(1/\epsilon))$ space and constructs a subgraph H of G. The phase satisfies the following properties:*

1. *Phase I terminates within the first ϵm edges of the stream. That is, Phase I terminates at the end of processing some edge e_i with $i \leq \epsilon m$.*
2. *When Phase I terminates at the end of processing some edge e_i, the subgraph $H \subseteq G$ constructed during this phase satisfies the following properties:*
   a. *H has bounded edge-degree β. As a corollary, H has $O(n\beta)$ edges.*
   b. *With probability at least $1 - n^{-3}$, the total number of $(G_{>i}, H, \beta, \lambda)$-underfull edges in $G_{>i} \setminus H$ is at most γ. (Recall that $G_{>i}$ denotes the subgraph of G that contains all edges in $\{e_{i+1}, \ldots, e_m\}$.)*

We now show that if we can ensure the properties of Lemma 12, our main result follows.

Proof of Theorem 1. Let us say that Phase I terminates after edge e_i and let H be the subgraph constructed by Phase I. Phase II of the algorithm proceeds as follows. It initializes an empty set X. Then, for every edge (u, v) in $S_{[i+1,m]}$, if $\deg_H(u) + \deg_H(v) < \beta(1 - \lambda)$ (that is, if (u, v) is $(G_{>i}, H, \beta, \lambda)$-underfull), the algorithm adds edge (u, v) to X. After the algorithm completes the stream, it then returns the maximum matching in $H \cup X$.

Let us now analyze the approximation ratio. By property 1 of Lemma 12, $G_{>i} \subseteq G^{late}$; thus, X contains all $(G^{late}, H, \beta, \lambda)$-underfull edges. By property 2a, H has bounded edge-degree β. Thus, applying Lemma 10, we have that $\mu(H) \geq (2/3 - \epsilon)\mu(G^{late})$. Combining this with Lemma 5, we get that $\mu(H) \geq (2/3 - \epsilon)(1 - 2\epsilon)\mu(G) \geq (2/3 - 3\epsilon)\mu(G)$; using $\epsilon' = \epsilon/3$ thus yields the desired approximation ratio.

For the space analysis, we know from Lemma 12 that Phase I requires $O(n\beta)$ space, which is the space needed to store subgraph H. By Property 2b, the size of X in Phase II is at most $O(n \log(n))$. The overall space is thus $O(n\log(n) + n\beta) = O(n\log(n) + n\text{poly}(1/\epsilon))$.

Finally, note that the only two probabilistic claims are Lemma 5 and Property 2b of Lemma 12, both of which hold with probability $\geq 1 - n^{-3}$. A union bound thus yields an overall probability of success $\geq 1 - 2n^{-3}$. ◀

4.2 Description of Phase I

All we have left is to describe Phase I and prove Lemma 12. See Algorithm 1 for pseudocode of the entire algorithm. Recall the parameters $\epsilon, \beta, \lambda, \alpha, \gamma$ from Definition 11. Phase I is split into epochs, each containing exactly α edges from the stream. So in epoch i, the algorithm looks at $S_{[(i-1)\alpha+1, i\alpha]}$.

Phase I initializes the graph $H = \emptyset$. In epoch i, the algorithm goes through the edges of $S_{[(i-1)\alpha+1,i\alpha]}$ one by one. For edge (u,v), if $\deg_H(u) + \deg_H(v) < (1-\lambda)\beta$, then the algorithm adds edge (u,v) to H (Line 5). (Note that the algorithm changes H over time, so $\deg_H(u)+\deg_H(v)$ always refers to the degrees in H at the time edge (u,v) is being examined.) After each edge insertion to H, the algorithm runs procedure *RemoveOverfullEdges(H)* (Line 7); this procedure repeatedly picks an edge (x,y) with $\deg_H(x) + \deg_H(y) > \beta$ until no such edge remains. Note that as a result, our algorithm preserves the invariant that H always has bounded edge-degree β.

In each epoch, the algorithm also has a single boolean FoundUnderfull, which is set to True if the algorithm ever adds an edge to H during that epoch. At the end of the epoch, if FoundUnderfull is set to True, then the algorithm simply proceeds to the next epoch. If FoundUnderfull is False, then the algorithm permanently terminates Phase I and proceeds to Phase II. (The intuition is that since the ordering of the stream is random, if the algorithm failed to find an underfull edge in an entire epoch, then there must be relatively few underfull edges left in the stream, so Property 2b of Lemma 12 will be satisfied.)

Note that FoundUnderfull being false is the only way Phase I can terminate (Line 9); we prove in the analysis that this deterministically occurs within the first ϵm edges of the stream.

4.3 Analysis

We now turn to proving Lemma 12. The hardest part is proving Property 1. Observe that every epoch that doesn't terminate Phase I must add at least one edge to H. To prove Property 1, we use an auxiliary lemma that bounds the total number of changes made to H.

▶ **Lemma 13.** *Fix any parameter $\beta > 2$. Let $H = (V_H, E_H)$ be a graph, with E_H initially empty. Say that an adersary adds and removes edges from H using an arbitrary sequence of two possible moves*

- [Deletion Move]. *Remove an edge (u,v) from H for which $\deg_H(u) + \deg_H(v) > \beta$*
- [Insertion Move]. *Add an edge (u,v) to H for some pair $u,v \in V$ for which $\deg_H(u) + \deg_H(v) < \beta - 1$.*

Then, after $n\beta^2$ moves, no legal move remains.

Algorithm 1 The algorithm for computing a matching in a random-order stream. After initialization, the algorithm goes to Phase I. Once the algorithm exits Phase I, it moves on to Phase II and never returns to Phase I. Line 9 is the only place where the algorithm can exit Phase I.

```
Procedure Initilization
    Initialize $H = \emptyset$        /* $H$ is a global variable modified by Phase I */
    Let $\epsilon < 1/2$ be the main approximation parameter
    Set $\lambda = \frac{\epsilon}{128}$, $\beta = 16\lambda^{-2}\log(1/\lambda)$, $\alpha = \frac{\epsilon m}{n\beta^2+1}$, $\gamma = 5\log(n)\frac{m}{\alpha}$ (Definition 11).
    Go To Phase I
Procedure Phase I
    Do Until Termination  /* each iteration corresponds to one epoch */
        (1) FoundUnderfull ← FALSE
        (2) for $\alpha$ Iterations: do  /* each epoch looks at exactly $\alpha$ edges.  */
            (3) Let $(u, v)$ be the next edge in the stream
            (4) if $\deg_H(u) + \deg_H(v) < \beta(1-\lambda)$ then
                (5) Add edge $(u, v)$ to $H$   /* note: this increases $\deg_H(u)$ and
                  $\deg_H(v)$.  */
                (6) FoundUnderfull ← TRUE
                (7) RemoveOverfullEdges(H)
        (8) if FoundUnderfull = FALSE then
            (9) Go To Phase II        /* permanently exit Phase I. */ ;
        /* Else, will move on to the next epoch of Phase I.          */
Procedure RemoveOverfullEdges(H)
    (1) while there exists $(u, v) \in H$ such that $\deg_H(u) + \deg_H(v) > \beta$ do
        (2) Remove $(u, v)$ from $H$         /* note: this decreases $\deg_H(u)$ and
          $\deg_H(v)$ */
     /* note: when the while loop terminates, $H$ is guaranteed to have
    bounded edge-degree $\beta$.  */
Procedure Phase II
    (1) Initialize $X \leftarrow \emptyset$       /* all underfull edges will be added to $X$ */ ;
    (2) foreach remaining edge $(u, v)$ in the stream do
        (3) if $\deg_H(u) + \deg_H(v) < \beta(1-\lambda)$ then
            (4) Add edge $(u, v)$ to $X$        /* note: this does NOT change any
              $\deg_H(v)$.  */
    (5) Return the maximum matching in $H \cup X$ ;
```

Proof. The proof is similar to that of Proposition 2.4 in [4]. Define the following potential functions $\Phi_1(H) = (\beta - 1/2) \cdot \sum_{v \in V_H} \deg_H(v)$, $\Phi_2(H) = \sum_{(u,v) \in E_H} \deg_H(u) + \deg_H(v)$, and the main potential function $\Phi(H) = \Phi_1(H) - \Phi_2(H)$. Note that initially H is empty so $\Phi(H) = 0$. We claim that at all times $\Phi(H) \leq \Phi_1(H) \leq n\beta^2$. To see this, note that every vertex $v \in V_H$ always has $\deg_H(v) \leq \beta$, because as long as $\deg_H(v) = \beta$, the adversary cannot perform any insertion moves incident to v. In the rest of the proof, we show that every Insertion/Deletion move increases $\Phi(H)$ by at least 1; combined with the fact that at all times $0 \leq \Phi(H) \leq n\beta^2$, we get that there are at most $n\beta^2$ moves in total.

Consider any Deletion Move of edge (u,v). Clearly $\Phi_1(v)$ decreases by exactly $2\beta - 1$. We now show that $\Phi_2(v)$ decreases by at least 2β. One the one hand, $\Phi_2(v)$ decreases by at least $\beta + 1$ because edge (u,v) no longer participates in the sum, and $\deg_H(u) + \deg_H(v)$ was $> \beta$ before the deletion. But at the same time, since $\deg_H(u) + \deg_H(v) \geq \beta + 1$ before the deletion, there are at least $\beta - 1$ edges other than (u,v) incident to u or v, and each of their edge degrees decrease by 1 in the sum for $\Phi_2(H)$. Thus, $\Phi_2(H)$ decreases by at least $\beta + 1 + (\beta - 1) = 2\beta$, while $\Phi_1(H)$ decreases by exactly $2\beta - 1$, so overall $\Phi(H) = \Phi_1(H) - \Phi_2(H)$ increases by at least one.

Similarly, consider any Insertion Move of edge (u,v). Clearly $\Phi_1(v)$ increases by exactly $2\beta-1$. We now show that $\Phi_2(v)$ increases by at most $2\beta-2$. Recall that $\deg_H(u)+\deg_H(v) \leq \beta - 2$ before the insertion, so after the insertion we have that $\deg_H(u) + \deg_H(v) \leq \beta$, so the edge (u,v) itself contributes at most β to the sum in Φ_2. There are also at most $\beta - 2$ edges other than (u,v) incident to u or v, each of whose edge degrees increases by 1. Thus, overall, $\Phi_2(H)$ increases by at most $\beta + (\beta - 2) = 2\beta - 2$, so $\phi(H)$ increases by at least $(2\beta - 1) - (2\beta - 2) = 1$. ◀

Proof of Lemma 12. Property 2a is clearly satisfied by construction, because after any insertion to H the algorithm runs *RemoveOnderfullEdges(H)* (line 7) to ensure that H has bounded edge-degree β. As a result, we clearly have that every *vertex* degree is at most β, so Phase I needs only $O(n\beta)$ space to store H.

For the proof of Property 1, observe that any changes the algorithm makes to H follow the rules for Insertion/Deletion moves from Lemma 13, so Algorithm 1 makes at most $n\beta^2$ changes to H. (Line 5 of Phase I corresponds to deletion moves in Lemma 13, while line 2 of *RemoveOverfullEdges(H)* corresponds to insertion moves. Note that line 5 of phase I actually obeys an even stronger inequality than deletion moves, since $\beta(1-\lambda) < \beta - 1$.) Each epoch that does not terminate Phase I makes at least one change to H, so phase I goes through at most $n\beta^2 + 1$ epochs before termination. Each epoch contains α edges, so overall Phase I goes through at most $\alpha(n\beta^2 + 1) = \epsilon m$ edges, as desired.

All that remains is to prove Property 2b. As mentioned above, the intuition is simple: the algorithm only exits Phase I if it fails to find a single underfull edge in the entire epoch (Line 9), and since the stream is random, such an event implies that there are probably relatively few underfull edges left in the stream. We now formalize this intuition.

Let $\mathcal{A}_i$ be the event that FoundUnderfull is set to FALSE in epoch i. Recall that epoch i ends on edge $e_{i\alpha}$; let $\mathcal{B}_i$ be the event that the number of $(G_{>i\alpha}, H, \beta, \lambda)$-underfull edges is more than γ. Note that Property 2b fails to hold if and only if we have $\mathcal{A}_i \wedge \mathcal{B}_i$ for some i, so we now upper bound $\Pr[A_i \wedge B_i]$. Our bound relies on the randomness of the stream. Let E_i^r contain all edges in the graph that have not yet appeared in the stream at the *beginning* of epoch i (r for remaining). Let E_i^e be the edges that appear in epoch i (e for epoch), and note that E_i^e is a subset of size α chosen uniformly at random from E_i^r. Define H_i to be the subgraph H at the beginning of epoch i, and define $E_i^u \subseteq E_i^r$ to be the set $\{(u,v) \in E_i^r \mid \deg_{H_i}(u) + \deg_{H_i}(v) < \beta(1-\lambda)\}$ (u for underfull). Observe that because of event $\mathcal{A}_i$, the graph H does not change throughout epoch i, so an edge that is underfull at any point during the epoch will be underfull at the end as well. Thus, $\mathcal{A}_i \wedge \mathcal{B}_i$ is equivalent to the event that $|E_i^u| > \gamma$ but $E_i^u \cap E_i^e = \emptyset$.

Let $\mathcal{A}_i^k$ be the event that the kth edge of epoch i is not in E_i^u. We have that

$$\Pr[\mathcal{B}_i \wedge \mathcal{A}_i] \leq \Pr[\mathcal{A}_i \mid \mathcal{B}_i] = \Pr[\mathcal{A}_i^1 \mid \mathcal{B}_i] \prod_{k=2}^{\alpha} \Pr[\mathcal{A}_i^k \mid \mathcal{B}_i, \mathcal{A}_i^1, \ldots, \mathcal{A}_i^{k-1}].$$

Now, observe that

$$\Pr[\mathcal{A}_i^1 \mid \mathcal{B}_i] < 1 - \frac{\gamma}{m}$$

because the first edge of the epoch is chosen uniformly at random from the set of $\leq m$ remaining edges, and the event fails if the chosen edge is in E_i^u, where $|E_i^u| > \gamma$ by definition of $\mathcal{B}_i$. Similarly, for any k,

$$\Pr[\mathcal{A}_i^k \mid \mathcal{B}_i, \mathcal{A}_i^1, \ldots, \mathcal{A}_i^{k-1}] < 1 - \frac{\gamma}{m}$$

because conditioning on the previous events $\mathcal{A}_i^j$ implies that no edge from E_i^u has yet appeared in this epoch, so there are still at least γ edges from E_i^u left in the stream.

Recall from Definition 11 that $\gamma = 5\log(n) \cdot \frac{m}{\alpha}$. Combining the three above equations yields that $\Pr[\mathcal{B}_i \wedge \mathcal{A}_i] \leq (1 - \frac{\gamma}{m})^\alpha = (1 - \frac{5\log(n)}{\alpha})^\alpha \leq n^{-5}$. There are clearly at most n^2 epochs, so union bounding over all of them shows that Property 2b fails with probability at most n^{-3}, as desired. ◀

5 Open Problems

We presented a new single-pass streaming algorithm for computing a maximum matching in a *random-order* stream. The algorithm achieves a $(2/3 - \epsilon)$-approximation using $O(n\log(n))$ space; these bounds improve upon all previous results for the problem.

But while 2/3 is a natural boundary, there is no reason to believe it is the best possible. Is there an algorithm with approximation ratio $2/3 + \Omega(1)$? Is it possible to compute a $(1 - \epsilon)$-approximate matching in random-order streams? A lower bound of $1 - \Omega(1)$ in this setting would also be extremely interesting.

Another natural open problem is get improved bounds for weighted graphs. Gamlath et al. [18] recently broke through the barrier of 1/2 and presented an algorithm for weighted graphs that computes a .506-approximation (or .512 in bipartite graphs) in random-order streams. Can we improve the approximation ratio to 2/3 in weighted graphs? To $(1 - \epsilon)$?

Abstract

In the online multiple knapsack problem, an algorithm faces a stream of items, and each item has to be either rejected or stored irrevocably in one of n bins (knapsacks) of equal size. The gain of an algorithm is equal to the sum of sizes of accepted items and the goal is to maximize the total gain.

So far, for this natural problem, the best solution was the 0.5-competitive algorithm FirstFit (the result holds for any $n \geq 2$). We present the first algorithm that beats this ratio, achieving the competitive ratio of $1/(1 + \ln(2)) - O(1/n) \approx 0.5906 - O(1/n)$. Our algorithm is deterministic and optimal up to lower-order terms, as the upper bound of $1/(1 + \ln(2))$ for randomized solutions was given previously by Cygan et al. [TOCS 2016].

1 Introduction

Knapsack problems have been studied in theoretical computer science for decades [13, 14]. In particular, in the *multiple knapsack* problem [2, 5, 6, 7, 10, 12, 18], items of given sizes and profits have to be stored in n bins (knapsacks), each of capacity 1. The goal is to find a subset of all items that maximizes the total profit and can be feasibly packed into bins without exceeding their capacities. We consider an *online scenario*, where an online algorithm is given a sequence of items of unknown length. When an item is presented to an algorithm, it has to either irrevocably reject the item or accept it to a chosen bin (which cannot be changed in the future). The actions of an online algorithm have to be made without the knowledge of future items.

Proportional case. In this paper, we focus on the most natural, *proportional variant* (sometimes called *uniform*), where item profits are equal to item sizes and the goal is to maximize the sum of profits of all accepted items.

The single-bin case ($n = 1$) has been fully resolved: no deterministic online algorithm can be competitive [16], and the best randomized algorithm ROne by Böckenhauer et al. [4] achieves the optimal competitive ratio of 0.5.[1]

Less is known for multiple-bin case ($n \geq 2$). Cygan et al. [7] showed that the FirstFit algorithm is 0.5-competitive and proved that no algorithm (even a randomized one) can achieve a competitive ratio greater than R, where

$$R = 1/(1 + \ln 2) \approx 0.5906.$$

Other variants. Some authors focused on the variant, where the goal is to maximize the *maximum* profit over all bins, instead of the sum of the profits. For this objective, optimal competitive ratios are already known: 0.5-competitive deterministic algorithm was given by Böckenhauer et al. [4], and the upper bound of 0.5 holding even for randomized solutions were presented by Cygan et al. [7].

The multiple knapsack problem can be generalized in another direction: profits and sizes may be unrelated. However, already *the unit variant*, where the profit of each item is equal to 1, does not admit any competitive solutions (even randomized ones) [5].

These results together mean that the proportional case studied in this paper is the only variant, whose online complexity has not been fully resolved yet.

1.1 Our results

The main result of this paper is an $(R - O(1/n))$-competitive deterministic online algorithm for the proportional variant of the multiple knapsack problem. We give insights for our construction in Section 1.3 below and the definition of our algorithm later in Section 2. Given the upper bound of R for randomized solutions [7], our result is optimal up to lower-order terms also for the class of randomized solutions.

It is possible to show that for deterministic algorithms, the term $O(1/n)$ in the competitive ratio is inevitable: in the full version of the paper, we show how the upper bound construction given in [7] can be tweaked and extended to show that the competitive ratio of any deterministic algorithm is at most $R - O(1/n)$.

1.2 Related work

Some previous papers focused on a *removable* scenario, where an accepted item can be removed afterwards from its bin [2, 7, 8, 10, 11]. Achievable competitive ratios are better than their non-removable counterparts; in particular, the proportional variant admits constant-competitive deterministic algorithms even for a single bin [10].

The online knapsack problem has been also considered in relaxed variants: with resource augmentation, where the bin capacities of an online algorithm are larger than those of the optimal offline one [11, 17], with a resource buffer [9], or in the variant where an algorithm may accept fractions of items [17].

The hardness of the variants with arbitrary profits and sizes as well as applications to online auctions motivated another strand of research focused on the so-called random-order model [1, 3, 15, 19]. There, the set of items is chosen adversarially, but the items are presented to an online algorithm in random order.

[1] An online algorithm is called α-competitive if, for any input instance, its total profit is at least fraction α of the optimal (offline) solution. While many papers use the reciprocal of α as the competitive ratio, the current definition is more suited for accounting arguments in our proofs.

1.3 Algorithmic challenges and ideas

Our algorithm splits items into three categories: large (of size greater than 1/2), medium (of size from the interval $[\phi, 1/2]$) and small (of size smaller than ϕ). We defer the actual definition of ϕ.

First, we explain what an online algorithm should do when it faces a stream of large items. Note that no two large items can fit together in a single bin. If an algorithm greedily collects all large items, then the adversary may give n items of size $1/2 + \epsilon$ (accepted by an online algorithm) followed by n items of size 1 (accepted by an optimal offline algorithm Opt), and the resulting competitive ratio is then 0.5. On the other hand, if an algorithm stops after accepting some number of large items, Opt may collect all of them.

Our Rising Threshold Algorithm (Rta) balances these two strategies. It chooses a non-decreasing threshold function $\mathsf{f} : [0, 1] \to [1/2, 1]$ and ensures that the size of the i-th accepted large item is at least $\mathsf{f}(i/n)$. While an actual definition of f is given later, to grasp a general idea, it is worth looking at its plot in Figure 1 (left). A natural adversarial strategy is to give large items meeting these thresholds, and once Rta fills k bins, present n items of sizes slightly smaller than the next threshold $\mathsf{f}((k + 1)/n)$. These items will be rejected by Rta but can be accepted by Opt. Analyzing this strategy and ensuring that the ratio is at least R for any choice of k yields boundary conditions. Analyzing these conditions for n tending to infinity, we obtain a differential equation, whose solution is the function f used in our algorithm.

The actual difficulty, however, is posed by medium items. Rta never proactively rejects them and it keeps a subset of *marked* medium items in their own bins (one item per one bin), while it stacks the remaining, non-marked ones (places them together in the same bin, possibly combining items of similar sizes). This strategy allows Rta to combine a large item with marked medium items later. However, the amount of marked items has to be carefully managed as they do not contribute large gain alone. A typical approach would be to partition medium items into discrete sub-classes, control the number of items in each class, and analyze the gain on the basis of the *minimal* size item in a particular subclass. To achieve optimal competitive ratio, we however need a more fine-grained approach: we use a carefully crafted continuous function ξ to control the number of marked items larger than a given value. Analyzing all possible adversarial strategies gives boundary conditions for ξ. In particular, the value ϕ that separates medium items from small ones was chosen as the minimum value that ensures the existence of function ξ satisfying all boundary conditions.

Finally, we note that simply stacking small items in their own bins would not lead to the desired competitive ratio. Instead, Rta tries to stack them in a single bin, but whenever its load exceeds ϕ, Rta tries to merge them into a single medium item and verify whether such an item could be marked. This allows for combining them in critical cases with large items.

1.4 Preliminaries

We have n bins of capacity 1, numbered from 1 to n. An input is a stream of items from $(0, 1]$, defined by their sizes. Upon seeing an item, an online algorithm has to either reject it or place it in an arbitrary bin without violating the bin's capacity. The *load* of a bin b, denoted $\mathsf{load}(b)$, is the sum of item sizes stored in bin b. We define the load of a set of items as the sum of their sizes and the total load as the load of all items collected by an algorithm. Additionally, for any $x \leq 1/2$, we define $\mathsf{pile}(x) = \max\{2/3, 2x\}$. Note that if we put medium items of sizes at least x (till it is possible) into a bin b, then $\mathsf{load}(b) \geq \mathsf{pile}(x)$.

To simplify calculations, for any set Z of items, we define the *gain* of Z, denoted $\mathsf{g}(Z)$, as their load divided by n; similarly, the total gain is the total load divided by n. Furthermore, we use $\mathsf{min}(Z)$ to denote the minimum size of an item in set Z. If Z is accepted by our online algorithm, $\mathsf{b}(Z)$ denotes the number of bins our algorithm uses to accommodate these items, divided by n. For any value $x \in [0, 1]$, $Z^{\geq x}$ is the set of all items from Z of size greater or equal x. Whenever we use terms $\mathsf{g}(Z)$, $\mathsf{min}(Z)$ or $\mathsf{b}(Z)$ for a set Z that varies during runtime, we mean these values for the set Z after an online algorithm terminates its execution.

For any input sequence σ and an algorithm A, we use $A(\sigma)$ to denote the total gain of A on sequence σ. We denote the optimal offline algorithm by Opt.

1.5 Neglecting lower-order terms

As our goal is to show the competitive ratio $R - O(1/n)$, we introduce a notation that allows to neglect terms of order $1/n$. We say that x is *approximately equal* to y (we write $x \eqsim y$) if $|x - y| = O(1/n)$. Furthermore, we say that x is *approximately greater* than y (we write $x \gtrsim y$) if $x \geq y$ or $x \eqsim y$; we define relation $\lesssim$ analogously. Each of these relations is transitive when composed a constant number of times.

In our analysis, we are dealing with Lipschitz continuous functions (their derivative is bounded by a universal constant). For such function h, (i) the relation $\eqsim$ is preserved after application of h, and (ii) an integral of h can be approximated by a sum, as stated in the following facts, used extensively in the paper.

▶ **Fact 1.** *Fix any Lipschitz continuous function h and values $x \eqsim y$ from its domain. Then, $h(x) \eqsim h(y)$. Furthermore, if h is non-decreasing, then $x \lesssim y$ implies $h(x) \lesssim h(y)$ and $x \gtrsim y$ implies $h(x) \gtrsim h(y)$.*

▶ **Fact 2.** *For any Lipschitz continuous function h and integers a, b satisfying $1 \leq a \leq b \leq n$, it holds that $(1/n) \cdot \sum_{i=a+1}^{b} h(i/n) \eqsim \int_{a/n}^{b/n} h(x)\,\mathrm{d}x$.*

1.6 Roadmap of the proof

We present our algorithm in Section 2. Its analysis consists of three main parts.

- In Section 3, we investigate the gain of Rta on large items and explain the choice of the threshold function f.
- In Section 4, we study properties of medium items, marking routine, function ξ and show how the marked items influence the gain on other non-large items.
- In Section 5, we study the impact of marked items on bins containing large items.

Each of these parts is concluded with a statement that, under certain conditions, Rta is $(R - O(1/n))$-competitive (cf. Lemma 5, Lemma 15, Lemma 20 and Lemma 21). In Section 6, we argue that these lemmas cover all possible outcomes. For succinctness, some technical claims have been moved to Section 7.

2 Rising Threshold Algorithm

We arrange items into three categories: small, medium and large. We say that an item is *large* if its size is in the range $(1/2, 1]$, *medium* if it is in the range $[\phi, 1/2]$, and otherwise it is *small*, where we define

$$\xi_\mathrm{c} = (1 + (2/3) \cdot \ln(4/3)) \cdot R - 2/3 \approx 0.0372 \quad \text{and} \tag{1}$$

$$\phi = (2/3) \cdot \xi_\mathrm{c} \,/\, (2/3 - R + \xi_\mathrm{c}) \approx 0.2191. \tag{2}$$

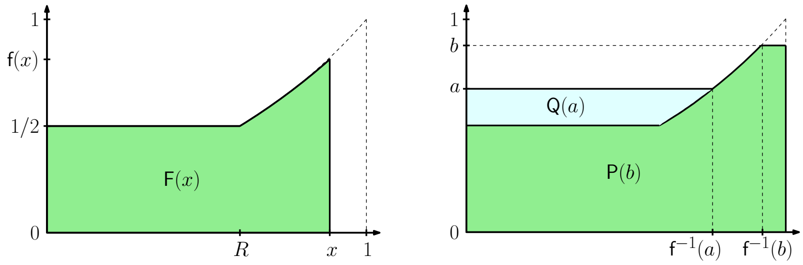

Figure 1 Left: function f and its integral F. The value of $\mathsf{F}(x)$ roughly corresponds to our lower bound on the gain of Rta when it collects $n \cdot x$ large items. Right: functions P and Q used in estimating the gain in Section 4 and Section 5; note that their arguments are marked at Y axis.

We further arrange medium items into subcategories M_2, M_3 and M_4: a medium item belongs to M_i if its size is from range $(1/(i+1), 1/i]$. As we partition only medium items this way, M_4 contains items of sizes from $[\phi, 1/4]$. Note that at most i items of category M_i fit in a single bin.

At some times (defined precisely later) a group of small items of a total load from $[\phi, 2\phi)$ stored in a single bin may become *merged*, and from that point is treated as a single medium item. We ensure that such merging action does not violate invariants of our algorithm.

Our algorithm Rta applies labels to bins; the possible labels are E, A, S_*, M_S, M_2, M_3, M_4 and L_+. Each bin starts as an E-bin, and Rta can relabel it later. The label determines the content of a given bin:

- an E-bin is empty,
- an A-bin (an *auxiliary bin*) contains small items of a total load smaller than ϕ and at most one A-bin exists at any time,
- an S_*-bin contains one or multiple small items,
- an M_S-bin contains a single marked medium item,
- an M_i-bin contains one or more medium items of category M_i,
- an L_+-bin contains a single large item and possibly some other non-large ones.

For any label C, we define a corresponding set, also denoted C, containing all items stored in bins of label C. For instance, L_+ is a set containing all items stored in L_+-bins. Furthermore, we define L as the set of all large items (clearly $L \subseteq L_+$ and $\mathsf{b}(L) = \mathsf{b}(L_+)$) and the set $M_* = M_2 \uplus M_3 \uplus M_4$.

Rta processes a stream of items, and it operates until the stream ends or there are no more empty bins (even if an incoming item could fit in some partially filled bin). Upon the arrival of an item, Rta classifies it by its size and proceeds as described below.

Large items. Whenever a large item arrives, Rta compares its size with the threshold $\mathsf{f}(\mathsf{b}(L) + 1/n)$, and if the item is smaller, Rta rejects it. The function $\mathsf{f} : [0,1] \to [1/2, 1]$ is defined as

$$\mathsf{f}(x) = \begin{cases} 1/2 & \text{if } x \leq R, \\ (2\mathrm{e})^{x-1} & \text{otherwise,} \end{cases} \tag{3}$$

and depicted in Figure 1 (left). If the item meets the threshold, Rta attempts to put it in an M_S-bin with sufficient space left (relabeling it to L_+), and if no such bin exists, Rta puts the item in any empty bin.

Medium items. We fix a continuous and decreasing function ξ that maps medium item sizes to $[0, \xi_c/\phi]$:

$$\xi(x) = \begin{cases} \xi_c/x & \text{if } x \in [\phi, 1/3], \\ 9\xi_c \cdot (1-2x) & \text{if } x \in (1/3, 1/2]. \end{cases} \tag{4}$$

We say that the subset Z of medium items is ξ-dominated if $|Z^{\geq x}|/n \leq \xi(x)$ for any $x \in Z$. Intuitively, it means that if we sort items of Z from largest to smallest, then all points $(i/n, x_i)$ are under or at the plot of ξ^{-1}, see Figure 3 (left).

Rta never proactively rejects medium items, i.e., it always accepts them if it has an empty bin. Some medium items become *marked* upon arrival; we denote the set of medium marked items by D. Large or small items are never marked. Marked medium items are never combined in a single bin with other marked medium items. At all times, Rta ensures that the set D is ξ-dominated. As no two items from D are stored in a single bin, this corresponds to the condition $\mathsf{b}(D^{\geq x}) \leq \xi(x)$ for any $x \in D$. Each marked item is stored either in an M_S-bin (alone) or in an L_+-bin (together with a large item and possibly some other non-marked items). That is, $M_S \subseteq D \subseteq M_S \uplus L_+$.

Whenever a medium item arrives, Rta attempts to put it in an L_+-bin. If it does not fit there, Rta verifies whether marking it (including it in the set D) preserves ξ-domination of D. If so, Rta marks it and stores it in a separate M_S-bin. Otherwise, Rta *fails to mark* the item and the item is stored in an M_i-bin (where i depends on the item size): it is added to an existing bin whenever possible and a new M_i-bin is opened only when necessary.

We emphasize that if Rta puts a large item in an M_S-bin later (and relabel it to L_+), the sole medium item from this bin remains marked (i.e., in the set D). However, if a medium item fits in an L_+-bin at the time of its arrival, it avoids being marked, even though its inclusion might not violate ξ-dominance of the set D. Note also that M_* contains medium items Rta failed to mark.

Small items. Rta never proactively rejects any small item. Whenever a small item arrives, Rta attempts to put this item in an L_+-bin, in an S_*-bin, and in the A-bin, in this exact order. If the item does not fit in any of them (this is possible only if the A-bin does not exist), Rta places it in an empty bin and relabels this bin to A.

If Rta places the small item in an already existing A-bin and in effect its load reaches or exceeds ϕ, Rta attempts to *merge* all its items into a single medium marked item. If the resulting medium item can be marked and included in D without violating its ξ-dominance, Rta relabels the A-bin to M_S and treats its contents as a single marked medium item from now on. Otherwise, it simply changes the label of the A-bin to S_*.

3 Gain on large items

In this section, we analyze the gain of Rta on large items. To this end, we first calculate the integral of function f, denoted F (see Figure 1, left) and list its properties that can be verified by routine calculations.

$$\mathsf{F}(x) = \int_0^x \mathsf{f}(y)\, dy = \begin{cases} x/2 & \text{if } x \leq R, \\ R \cdot (2e)^{x-1} & \text{otherwise.} \end{cases} \tag{5}$$

▶ **Lemma 3.** *The following properties hold for function* F.

1. $\mathsf{f}^{-1}(c) = 1 + R \cdot \ln c$ *and* $\mathsf{F}(\mathsf{f}^{-1}(c)) = R \cdot c$ *for any* $c \in (1/2, 1]$.
2. $\mathsf{F}(x)/\mathsf{f}(x) = \min\{x, R\}$ *for any* $x \in [0, 1]$.
3. $(1/n) \cdot \sum_{i=1}^{\ell} \mathsf{f}(i/n) \approx \int_0^{\ell/n} \mathsf{f}(x)\, dx = \mathsf{F}(\ell/n)$ *for any* $\ell \in \{0, \ldots, n\}$.

Using Lemma 3, we may bound on the gain of Rta on large items L and use this bound to estimate its competitive ratio when it terminates with empty bins.

▶ **Lemma 4.** *It holds that $\mathsf{g}(L) \gtrsim \mathsf{F}(\mathsf{b}(L)) = \mathsf{F}(\mathsf{b}(L_+))$. Moreover, $\mathsf{g}(L) \gtrsim \mathsf{F}(\mathsf{b}(L)) + \mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x})$ for any $x \geq \mathsf{f}(\mathsf{b}(L))$.*

Proof. For the first part of the lemma, we sort large items from L in the order they were accepted by Rta. The size of the i-th large item is at least the threshold $f(i/n)$. Hence, by Lemma 3, $\mathsf{g}(L) \geq (1/n) \cdot \sum_{i=1}^{|L|} f(i/n) \approx \mathsf{F}(|L|/n) = \mathsf{F}(\mathsf{b}(L))$.

To show the second part, we fix any $x \geq \mathsf{f}(\mathsf{b}(L))$ and for each large item of size greater than x we reduce its size to x. The total gain of the removed parts is exactly $\mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x})$. The resulting large item sizes still satisfy acceptance thresholds, and thus the gain on the remaining part of L is approximately greater than $\mathsf{F}(\mathsf{b}(L))$. Summing up yields $\mathsf{g}(L) \gtrsim \mathsf{F}(\mathsf{b}(L)) + \mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x})$. ◀

3.1 When RTA terminates with some empty bins

▶ **Lemma 5.** *If Rta terminates with some empty bins, then it is $(R - O(1/n))$-competitive.*

Proof. Fix an input sequence σ. As Rta terminates with empty bins, it manages to accept all medium and small items from σ. Furthermore, it accepts large items from σ according to the thresholds given by function f. Recall that f is non-decreasing: at the beginning it is equal to $1/2$ (Rta accepts any large item) and the acceptance threshold grows as Rta accepts more large items. Let $x = \mathsf{f}(\mathsf{b}(L) + 1/n)$ be the value of the acceptance threshold for large items when Rta terminates. We consider two cases.

- $\mathsf{b}(L) \leq R - 1/n$. The threshold used for each large item is at most $x \leq \mathsf{f}(R) = 1/2$, i.e., Rta accepts all large items. Then, Rta accepts all items and is 1-competitive.
- $\mathsf{b}(L) > R - 1/n$. Let N be the set of all non-large items accepted by Rta. By Lemma 4,

$$\begin{aligned}\textsc{Rta}(\sigma) = \mathsf{g}(L) + \mathsf{g}(N) &\gtrsim \mathsf{F}(\mathsf{b}(L)) + \mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x}) + \mathsf{g}(N) \\ &\approx R \cdot x + \mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x}) + \mathsf{g}(N).\end{aligned}$$

where for the last relation we used $\mathsf{F}(\mathsf{b}(L)) \approx \mathsf{F}(\mathsf{f}^{-1}(x)) = R \cdot x$ (by Lemma 3).
As Rta takes all non-large items and all large items that are at least x, the input sequence σ contains items taken by Rta and possibly some large items smaller than x. Thus, the gain of Opt on large items is maximized when it takes $L^{\geq x}$ and fills the remaining $n - |L^{\geq x}|$ bins with large items from σ smaller than x. The total gain of Opt is thus at most

$$\textsc{Opt}(\sigma) \leq \mathsf{g}(L^{\geq x}) + x \cdot (1 - \mathsf{b}(L^{\geq x})) + \mathsf{g}(N) = x + \mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x}) + \mathsf{g}(N).$$

Comparing the bounds on gains of Rta and Opt and observing that the term $\mathsf{g}(L^{\geq x}) - x \cdot \mathsf{b}(L^{\geq x}) + \mathsf{g}(N)$ is non-negative, yields $\textsc{Rta}(\sigma) \geq R \cdot \textsc{Opt}(\sigma) - O(1/n)$. As $\textsc{Opt}(\sigma) \geq \mathsf{g}(L) = \Omega(1)$, we obtain $\textsc{Rta}(\sigma) \geq (R - O(1/n)) \cdot \textsc{Opt}(\sigma)$. ◀

As an immediate corollary, we observe that if σ contains large items only, then Rta is $(R - O(1/n))$-competitive: If it terminates with empty bins, then its competitive ratio follows by Lemma 5. Otherwise, it terminates with n large items, and hence, by Lemma 4, $\textsc{Rta}(\sigma) \gtrsim \mathsf{F}(\mathsf{b}(L)) = \mathsf{F}(1) = R$. On the other hand, $\textsc{Opt}(\sigma) \leq 1$, and therefore the competitive ratio is at most $R - O(1/n)$ also in this case.

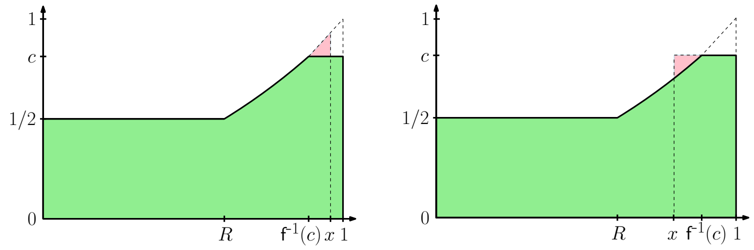

Figure 2 A geometric interpretation of the second property of Lemma 6: using P to lower-bound the sum of $\mathsf{F}(x)$ and the rectangle $c \cdot (1 - x)$ for the case $\mathsf{f}^{-1}(c) \le x$ (left) and $\mathsf{f}^{-1}(c) > x$ (right).

4 Gain on medium items

In the remaining part of the analysis, we make use of the following functions. For any $c \in (1/2, 1]$, let $\mathsf{P}(c) = \int_0^1 \min\{\mathsf{f}(y), c\} \,\mathrm{d}y$ and $\mathsf{Q}(c) = \int_0^1 \max\{c - \mathsf{f}(y), 0\} \,\mathrm{d}y$. Both functions are increasing and depicted in Figure 1 (right). As we show below (cf. the last property of Lemma 6), $\mathsf{P}(c)$ lower-bounds the gain of RTA in the case when its load on non-L_+ bins is at least c.

▶ **Lemma 6.** *Fix any $c \in (1/2, 1]$ and any $x \in [0, 1]$. It holds that*

1. $\mathsf{P}(c) = c - R \cdot c \cdot \ln(2c)$*,*
2. $\mathsf{Q}(c) = R \cdot c \cdot \ln(2c)$*,*
3. $\mathsf{P}(c) + \mathsf{Q}(c) = c$*,*
4. $\mathsf{F}(x) + c \cdot (1 - x) \ge \mathsf{P}(c)$*.*

Proof of Lemma 6. We fix any $c \in (1/2, 1]$ and any $x \in [0, 1]$. For the first property, observe that

$$\mathsf{P}(c) = \int_0^{\mathsf{f}^{-1}(c)} \mathsf{f}(y) \,\mathrm{d}y + \int_{\mathsf{f}^{-1}(c)}^1 c \,\mathrm{d}y = \mathsf{F}(\mathsf{f}^{-1}(c)) + c \cdot (1 - \mathsf{f}^{-1}(c)) = c - R \cdot c \cdot \ln(2c),$$

where for the last equality we used Lemma 3. Similarly, the second property follows as

$$\mathsf{Q}(c) = \int_0^{\mathsf{f}^{-1}(c)} c - \mathsf{f}(y) \,\mathrm{d}y = c \cdot \mathsf{f}^{-1}(c) - \mathsf{F}(\mathsf{f}^{-1}(c)) = R \cdot c \cdot \ln(2c).$$

The third relation, $\mathsf{P}(c) + \mathsf{Q}(c) = c$, follows immediately by the first two. Finally, for the last relation, we use

$$\mathsf{F}(x) + c \cdot (1 - x) = \int_0^x \mathsf{f}(y) \,\mathrm{d}y + \int_x^1 c \,\mathrm{d}y \ge \int_0^x \min\{\mathsf{f}(y), c\} \,\mathrm{d}x + \int_x^1 \min\{f(y), c\} \,\mathrm{d}y = \mathsf{P}(c).$$

See also Figure 2 for a geometric argument. ◀

4.1 Boundary conditions on function ξ

We start with a shorthand notation. Let $\mathsf{T}(a, b) = (a + b - 1/2) \cdot (\xi(b) - \xi(a))$, where $a, b \in [\phi, 1/2]$ (so that the values of $\xi(a)$ and $\xi(b)$ are well defined).

Our choice of function ξ satisfies the conditions below. In fact, for our analysis to hold, function ξ could be replaced by any Lipschitz continuous and non-increasing function mapping $[\phi, 1/2]$ to $[0, 1]$ satisfying these properties.

▶ **Lemma 7.** *The following properties hold for function ξ:*

1. $x \cdot \xi(x)$ *is a non-increasing function of* $x \in [\phi, 1/2]$,
2. $\mathsf{P}(\mathsf{pile}(x)) + x \cdot \xi(x) \geq R$ *for* $x \in [\phi, 1/2]$,
3. $\mathsf{P}(1-\phi) + 2\phi \cdot \xi(2\phi) \geq R$,
4. $2/3 - (2/3 - \phi) \cdot \xi(x) \geq R$ *for* $x \in [\phi, 1/3]$,
5. $\mathsf{P}(1-\phi) + \mathsf{Q}(1-x) + (x+\phi-1) \cdot \xi(x) + \max\{T(x,y), 0\} \geq R$ *for* $x \in [1/3, 1/2]$ *and* $y \in [\phi, 2\phi]$,
6. $\mathsf{P}(\mathsf{pile}(y)) + \mathsf{Q}(1-x) + (x - \mathsf{pile}(y)) \cdot \xi(x) + T(x,y) \geq R$ *for* $x \in [1/3, 1/2]$ *and* $y \in [\phi, x]$,
7. $\mathsf{P}(2x) + \mathsf{Q}(1-x) - x \cdot \xi(x) \geq R$ *for* $x \in [1/3, 1/2]$.

4.2 Marked and tight items

We start with a simple bound on the gain of Rta on M_S-bins. Recall that these bins store single marked items.

▶ **Lemma 8.** *If* Rta *terminates with at least one* M_S*-bin, then* $\mathsf{g}(M_\mathrm{S}) \geq \mathsf{min}(M_\mathrm{S}) \cdot \mathsf{b}(M_\mathrm{S})$*, and* $\mathsf{b}(M_\mathrm{S}) \leq \xi(\mathsf{min}(M_\mathrm{S}))$.

Proof. The first condition follows trivially as each M_S-bin contains a single medium item of size at least $\mathsf{min}(M_\mathrm{S})$. For the second condition, note that $M_\mathrm{S} \subseteq D$, and thus also $M_\mathrm{S} \subseteq D^{\geq \min(M_\mathrm{S})}$. As D is ξ-dominated, $\mathsf{b}(M_\mathrm{S}) \leq \mathsf{b}(D^{\geq \min(M_\mathrm{S})}) \leq \xi(\min(M_\mathrm{S}))$. ◀

We now take a closer look at the marked items and their influence on the gain on other sets of items. We say that a medium marked item $x \in D$ is *tight* if it is on the verge of violating ξ-domination invariant.

▶ **Definition 9.** *An item* $x \in D$ *is tight if* $\mathsf{b}(D^{\geq x}) > \xi(x) - 1/n$.

If an item $x \in D$ is tight, then another item of size x or greater cannot be included in D without violating ξ-domination invariant. Figure 3 (left) illustrates this concept. As D can only grow, once an item becomes tight, it remains tight till the end. We emphasize that items smaller than x are not relevant for determining whether x is tight. If D contains a tight item, then $\mathsf{mt}(D)$ denotes the size of the minimum tight item in D. This important parameter influences the gain both on set D and also on stacking bins M_* and S_*.

▶ **Lemma 10.** *If* D *contains a tight item, then* $\mathsf{g}(D) \gtrsim \mathsf{mt}(D) \cdot \xi(\mathsf{mt}(D))$.

Proof. Fix a tight item $d \in D$ of size $\mathsf{mt}(D)$. By Definition 9, $\mathsf{b}(D^{\geq d}) > \xi(d) - 1/n$, and thus $\mathsf{g}(D) \geq \mathsf{g}(D^{\geq d}) \geq d \cdot \mathsf{b}(D^{\geq d}) \gtrsim d \cdot \xi(d)$. ◀

4.3 Impact of tight items on stacking bins

By Property 1 of Lemma 7, $x \cdot \xi(x)$ is a non-increasing function of x. Therefore, the smaller $\mathsf{mt}(D)$ is, the larger is the lower bound on $\mathsf{g}(D)$ guaranteed by Lemma 10. Now we argue that the larger $\mathsf{mt}(D)$ is, the better is the gain on stacking bins M_* and S_*.

▶ **Lemma 11.** *Assume* Rta *failed to mark a medium item* y*. Then, a tight item exists and* $\mathsf{mt}(D) \lesssim y$.

Proof. Let $D_\mathrm{ext} = D \cup \{y\}$. By the lemma assumption, D_ext is not ξ-dominated, i.e., there exists an item $x \in D_\mathrm{ext}$ such that $\mathsf{b}(D_\mathrm{ext}^{\geq x}) > \xi(x)$. Note that $x \leq y$, as otherwise we would have $D^{\geq x} = D_\mathrm{ext}^{\geq x}$, and thus $\mathsf{b}(D^{\geq x}) > \xi(x)$, which would contradict ξ-domination of D.

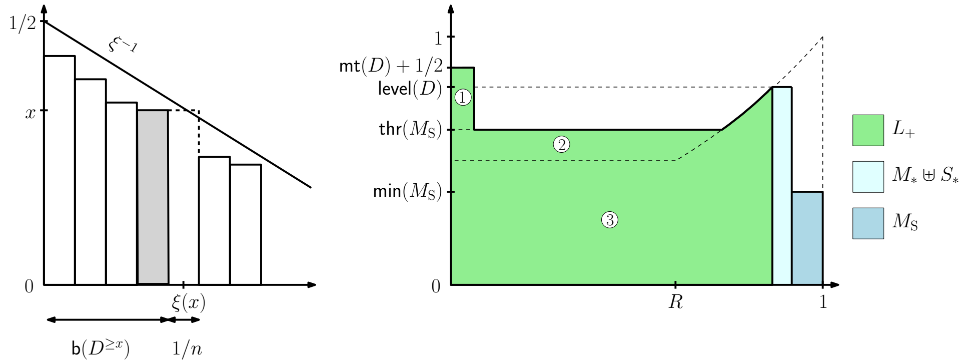

Figure 3 Left: set D of marked items with a tight (gray) item of size x. As x is tight, insertion of another item of size x (with a dashed border) would violate ξ-domination of D. Right: items collected by Rta, when it terminates without empty bins and with M_{S}-bins. Gain on L_+-sets is split into three parts, where the first part corresponds to the gain of T^* (cf. Lemma 17). The minimum guaranteed load in M_{S}-bins is given by Lemma 8 and in the bins of $M_* \uplus S_*$ by Lemma 13.

Let $d \geq x$ be the minimum size of an item from $D^{\geq x}$. Then, $D^{\geq d} = D^{\geq x}$, and thus

$$\mathsf{b}(D^{\geq d}) = \mathsf{b}(D^{\geq x}) = \mathsf{b}(D^{\geq x}_{\text{ext}}) - 1/n > \xi(x) - 1/n \geq \xi(d) - 1/n, \tag{6}$$

where in the last inequality we used monotonicity of ξ. By (6), d is tight. On the other hand, ξ-domination of D implies that $\mathsf{b}(D^{\geq d}) \leq \xi(d)$. This, combined with (6), yields $\xi(d) \approx \xi(x)$, and thus $d \approx x \leq y$. Note that d remains tight till the end of the execution. This concludes the lemma, as the minimum tight item, $\mathsf{mt}(D)$, can be only smaller than d. ◀

▶ **Lemma 12.** *If* Rta *finishes*

- *with at least one M_*-bin, then $\mathsf{mt}(D)$ is defined and $\mathsf{mt}(D) \lesssim \mathsf{min}(M_*)$;*
- *with at least one S_*-bin, then $\mathsf{mt}(D)$ is defined and $\mathsf{mt}(D) \lesssim 2\phi$.*

Proof. For the first part of the lemma, fix a medium item from M_* of size $\mathsf{min}(M_*)$. By the definition of Rta, it failed to mark this item. Hence, by Lemma 11, $\mathsf{mt}(D)$ is defined and $\mathsf{mt}(D) \lesssim \mathsf{min}(M_*)$.

Assume now that Rta finishes with at least one S_*-bin. When the first such S_*-bin was created, Rta placed a small item $s < \phi$ in the already existing A-bin of load $r < \phi$, and the merge action failed, because Rta failed to mark the resulting item of size $s + r$. Thus, again by Lemma 11, $\mathsf{mt}(D)$ is defined and $\mathsf{mt}(D) \lesssim s + r < 2\phi$. ◀

To estimate the gain on M_*-bins and S_*-bins, we define

$$\mathsf{level}_* = \begin{cases} \min\{\mathsf{pile}(\mathsf{mt}(D)), 1-\phi\} & \text{if } D \text{ contains a tight item and } S_* \neq \emptyset, \\ \mathsf{pile}(\mathsf{mt}(D)) & \text{if } D \text{ contains a tight item and } S_* = \emptyset, \\ 1 & \text{if } D \text{ does not contain any tight item.} \end{cases} \tag{7}$$

▶ **Lemma 13.** *It holds that $\mathsf{g}(M_* \uplus S_*) \gtrsim \mathsf{level}_* \cdot \mathsf{b}(M_* \uplus S_*)$.*

Proof. If D does not contain a tight item, then, by Lemma 12, both M_* and S_* are empty, and the lemma follows trivially. Thus, in the following we assume that D contains a tight item and we take a closer look at the contents of S_*-bins and M_*-bins.

Assume that M_* is non-empty. RTA creates a new M_i-bin (for $i \in \{2,3,4\}$) if the incoming medium item of category M_i (of size $(1/(i+1), 1/i]$) does not fit in any of the existing M_i bins. Hence, each M_i-bin (except at most one) has exactly i items, and therefore its load is greater than $i/(i+1) \geq 2/3$ and is also at least $i \cdot \min(M_i) \geq 2 \cdot \min(M_*)$. Thus,

$$\mathsf{g}(M_*) \gtrsim \max\{2/3, 2 \cdot \min(M_*)\} \cdot \mathsf{b}(M_*) = \mathsf{pile}(\min(M_*)) \cdot \mathsf{b}(M_*) \gtrsim \mathsf{pile}(\mathsf{mt}(D)) \cdot \mathsf{b}(M_*), \quad (8)$$

where the second inequality follows by Lemma 12 and by monotonicity of function pile. Note that (8) holds trivially also when there are no M_*-bins.

If there are no S_*-bins, then, $\mathsf{g}(M_* \uplus S_*) = \mathsf{g}(M_*) \gtrsim \mathsf{pile}(\mathsf{mt}(D)) \cdot \mathsf{b}(M_*) = \mathsf{level}_* \cdot \mathsf{b}(M_* \uplus S_*)$, and the lemma follows.

If there are some S_*-bins, recall that RTA creates a new S_*-bin only if the considered small item does not fit in any existing S_*-bin. Thus, the load of each S_*-bin (except at most one) is at least $1 - \phi$, and therefore $\mathsf{g}(S_*) \gtrsim (1-\phi) \cdot \mathsf{b}(S_*)$. Combining this with (8) implies $\mathsf{g}(M_* \uplus S_*) \gtrsim \mathsf{pile}(\mathsf{mt}(D)) \cdot \mathsf{b}(M_*) + (1-\phi) \cdot \mathsf{b}(S_*) \geq \min\{\mathsf{pile}(\mathsf{mt}(D)), 1-\phi\} \cdot \mathsf{b}(M_* \uplus S_*)$. ◀

4.4 When RTA terminates without empty bins and without M_S-bins

Using tight items, we may analyze the case when RTA terminates without empty bins and without M_S-bins, and show that in such case its gain is approximately greater than R. As the gain of OPT is at most 1, this yields the desired competitive ratio.

▶ **Lemma 14.** *If RTA terminates without empty bins, then $\mathsf{b}(L) + \mathsf{b}(M_\mathrm{S}) + \mathsf{b}(M_*) + \mathsf{b}(S_*) \approx 1$.*

Proof. There is at most one A-bin. The remaining bins (at least $n-1$ many) are of classes L_+, M_S, M_* or S_*, and thus $\mathsf{b}(L) + \mathsf{b}(M_\mathrm{S}) + \mathsf{b}(M_*) + \mathsf{b}(S_*) \approx 1$. ◀

▶ **Lemma 15.** *If on input σ, RTA terminates without empty bins and without M_S-bins, then RTA$(\sigma) \gtrsim R$.*

Proof. We analyze the gain of RTA on three disjoint sets: L, D and $M_* \uplus S_*$.

$$\begin{aligned} \textsc{Rta}(\sigma) &\geq \mathsf{g}(L) + \mathsf{g}(M_* \uplus S_*) + \mathsf{g}(D) \\ &\gtrsim \mathsf{F}(\mathsf{b}(L)) + \mathsf{level}_* \cdot (1 - \mathsf{b}(L)) + \mathsf{g}(D) && \text{(by L. 4, L. 13 and L. 14)} \\ &\gtrsim \mathsf{P}(\mathsf{level}_*) + \mathsf{g}(D) && \text{(by L. 6)} \end{aligned}$$

If D does not contain a tight item, then $\mathsf{level}_* = 1$, and thus RTA$(\sigma) \gtrsim \mathsf{P}(1) = R$.

If D contains a tight item, then by Lemma 10, $\mathsf{g}(D) \geq \mathsf{mt}(D) \cdot \xi(\mathsf{mt}(D))$, and therefore RTA$(\sigma) \gtrsim \mathsf{P}(\mathsf{level}_*) + \mathsf{mt}(D) \cdot \xi(\mathsf{mt}(D))$. We consider two cases.

- If $\mathsf{level}_* \geq \mathsf{pile}(\mathsf{mt}(D))$, then RTA$(\sigma) \gtrsim \mathsf{P}(\mathsf{pile}(\mathsf{mt}(D))) + \mathsf{mt}(D) \cdot \xi(\mathsf{mt}(D)) \geq R$, where the last inequality follows by Property 2 of Lemma 7.
- The opposite case, $\mathsf{level}_* < \mathsf{pile}(\mathsf{mt}(D))$, is possible only if S_*-bins exist and $\mathsf{level}_* = 1 - \phi$. By Lemma 12, the existence of S_*-bins implies $\mathsf{mt}(D) \lesssim 2\phi$. As the function $x \cdot \xi(x)$ is non-increasing (cf. Property 1 of Lemma 7), RTA$(\sigma) \gtrsim \mathsf{P}(1-\phi) + 2\phi \cdot \xi(2\phi) \geq R$. The last inequality follows by Property 3 of Lemma 7. ◀

5 Gain on large items revisited

In this section, we assume that RTA terminates without empty bins and with at least one M_S-bin. Recall that Lemma 4 allows us to estimate $\mathsf{g}(L_+)$ by calculating the gain on *large* items alone. Now we show how to improve this bound by taking into account non-large items in L_+. First, we leverage the fact that if a (marked) medium item is in M_S, then Rta must have failed to combine it with a large item, and we obtain a better lower bound on the size of each large item. Second, we show that in some cases marked medium items must be in L_+ which increases its load. If an M_S-bin exists, we define

$$\mathsf{T}^* = \begin{cases} \mathsf{T}(\mathsf{min}(M_\mathrm{S}), \mathsf{mt}(D)) & \text{if } \mathsf{mt}(D) \text{ is defined and } \mathsf{min}(M_\mathrm{S}) > \max\{\mathsf{mt}(D), 1/3\} \\ 0 & \text{otherwise,} \end{cases}$$

$$\mathsf{thr}(M_\mathrm{S}) = \min\{1 - \mathsf{min}(M_\mathrm{S}), 1/2 + \phi\}.$$

Note that T^* is always non-negative. In particular, $\mathsf{T}(\mathsf{min}(M_\mathrm{S}), \mathsf{mt}(D)) = (\mathsf{min}(M_\mathrm{S}) + \mathsf{mt}(D) - 1/2) \cdot (\xi(\mathsf{mt}(D)) - \xi(\mathsf{min}(M_\mathrm{S})) \geq 0$ because $\mathsf{min}(M_\mathrm{S}) + \mathsf{mt}(D) \geq 1/2$ for $\mathsf{min}(M_\mathrm{S}) > 1/3$ and $\mathsf{mt}(D) \geq \phi$.

▶ **Lemma 16.** *Assume Rta terminates with at least one M_S-bin. Then, the load of any L_+-bin is at least $\mathsf{thr}(M_\mathrm{S})$.*

Proof. Consider any L_+-bin b and let y be the large item contained in this bin. If b contains an additional medium item, then its load is greater than $1/2 + \phi$, and the lemma follows. Hence, in the following, we assume that y was not combined with a medium item in a single bin. As Rta finishes with an M_S-bin, we fix a medium item x of size $\mathsf{min}(M_\mathrm{S})$. We consider three cases.

- Item x arrived (or was created by merging some small items) before the arrival of y. Rta did not place y in the M_S-bin containing x, because $y + x > 1$. Thus, $\mathsf{load}(b) \geq y \geq 1 - x = 1 - \min(M_\mathrm{S})$.
- Item x arrived after the arrival of y. (Some small items might be placed together with y prior to the arrival of x.) As Rta placed x in a separate bin, it did not fit in b, i.e., the load of b at the time of the arrival of x was greater than $1 - x = 1 - \min(M_\mathrm{S})$.
- Item x was created by merging small items after the arrival of y. Let $s < x$ be the small item that caused the creation of x. Rta placed s in A-bin, because s did not fit in b, i.e., the load of b at that time was greater than $1 - s > 1 - x = 1 - \min(M_\mathrm{S})$. ◀

▶ **Lemma 17.** *Assume that Rta terminates with at least one M_S-bin. Then, $\mathsf{g}(L_+) \gtrsim \mathsf{T}^* + \int_0^{\mathsf{b}(L)} \max\{\mathsf{f}(y), \mathsf{thr}(M_\mathrm{S})\}\,\mathrm{d}y$.*

Proof. We sort accepted large items by their arrival time and denote the bin containing the i-th large item by b_i. The bin b_i contains a large item of size at least $\mathsf{f}(i/n)$ because of the acceptance threshold, and its load is at least $\mathsf{thr}(M_\mathrm{S})$ by Lemma 16, i.e., $\mathsf{load}(b_i) \geq \max\{\mathsf{f}(i/n), \mathsf{thr}(M_\mathrm{S})\}$.

We now show how to decrease the load in L_+-bins, so that the remaining load in bin b_i remains at least $\max\{\mathsf{f}(i/n), \mathsf{thr}(M_\mathrm{S})\}$ and the change in the total gain is approximately equal to T^*. This claim is trivial for $\mathsf{T}^* = 0$, so we assume $\mathsf{T}^* > 0$. This is possible only if a tight item exists, $\mathsf{min}(M_\mathrm{S}) > \mathsf{mt}(D)$ and $\mathsf{min}(M_\mathrm{S}) > 1/3$. As $\mathsf{min}(M_\mathrm{S}) > \mathsf{mt}(D)$, every marked medium item of size from the interval $[\mathsf{mt}(D), \mathsf{min}(M_\mathrm{S}))$ is in (a separate) L_+-bin; let $\tilde{L}$ be the set of these bins. As $M_\mathrm{S} \subseteq D^{\geq \mathsf{mt}(D)}$, $n \cdot \mathsf{b}(\tilde{L}) = |D^{\geq \mathsf{mt}(D)} \setminus M_\mathrm{S}| = |D^{\geq \mathsf{mt}(D)}| - |M_\mathrm{S}|$. Using the tightness of $\mathsf{mt}(D)$ and Lemma 8, $\mathsf{b}(\tilde{L}) = \mathsf{b}(D^{\geq \mathsf{mt}(D)}) - \mathsf{b}(M_\mathrm{S}) \gtrsim \xi(\mathsf{mt}(D)) - \xi(\mathsf{min}(M_\mathrm{S}))$. From each bin of $\tilde{L}$ we remove a load of $\mathsf{mt}(D) + \mathsf{min}(M_\mathrm{S}) - 1/2$. The induced change in the total gain is then approximately equal to $\mathsf{b}(\tilde{L}) \cdot (\mathsf{mt}(D) + \mathsf{min}(M_\mathrm{S}) - 1/2) = \mathsf{T}^*$.

We now analyze the load of bin b_i after the removal. The original load of bin b_i was at least $\mathsf{f}(i/n) + \mathsf{mt}(D)$, and after removal it is at least $\mathsf{f}(i/n) + \mathsf{min}(M_\mathrm{S}) - 1/2$. This amount is at least $\mathsf{f}(i/n)$ (as $\mathsf{min}(M_\mathrm{S}) \leq 1/2$) and at least $1 - \mathsf{min}(M_\mathrm{S}) \geq \mathsf{thr}(M_\mathrm{S})$ (as $\mathsf{f}(i/n) \geq 1/2$). Hence, the remaining load of b_i is at least $\max\{\mathsf{f}(i/n), \mathsf{thr}(M_\mathrm{S})\}$.

Thus, $\mathsf{g}(L_+) - \mathsf{T}^* \geq \frac{1}{n}\sum_{i=1}^{n\cdot\mathsf{b}(L)} \max\{\mathsf{f}(i/n), \mathsf{thr}(M_\mathrm{S})\} \approx \int_0^{\mathsf{b}(L)} \max\{\mathsf{f}(y), \mathsf{thr}(M_\mathrm{S})\}\,\mathrm{d}y$. Particular subsets of L_+ are depicted in Figure 3 (right); the removed part of gain T^* is depicted as (1). ◀

▶ **Lemma 18.** *Assume that* Rta *terminates with at least one* M_S*-bin. Then,* $\mathsf{g}(L_+) + \eta \cdot (1 - \mathsf{b}(L)) \gtrsim \mathsf{P}(\eta) + \mathsf{Q}(\min\{\mathsf{thr}(M_\mathrm{S}), \eta\}) + \mathsf{T}^*$ *for any* $\eta \in (1/2, 1]$.

Proof. We fix any $\eta \in (1/2, 1]$ and define $h = \min\{\mathsf{thr}(M_\mathrm{S}), \eta\}$. By Lemma 17, $\mathsf{g}(L_+) - \mathsf{T}^* + \eta \cdot (1 - \mathsf{b}(L)) \gtrsim \int_0^{\mathsf{b}(L)} \max\{\mathsf{f}(y), h\}\,\mathrm{d}y + \int_{\mathsf{b}(L)}^1 \eta\,\mathrm{d}y$. We denote this lower bound by $A(\mathsf{b}(L))$ and we analyze it as a function of $\mathsf{b}(L)$. When $\mathsf{b}(L) < \mathsf{f}^{-1}(h)$, then using $h \leq \eta$ we obtain $A(\mathsf{b}(L)) = \int_0^{\mathsf{b}(L)} h\,\mathrm{d}y + \int_{\mathsf{b}(L)}^1 \eta\,\mathrm{d}y \geq \int_0^{\mathsf{f}^{-1}(h)} h\,\mathrm{d}y + \int_{\mathsf{f}^{-1}(h)}^1 \eta\,\mathrm{d}y = A(\mathsf{f}^{-1}(h))$. Therefore, we need to lower-bound the value of $A(\mathsf{b}(L))$ only for $\mathsf{b}(L) \geq \mathsf{f}^{-1}(h)$. In such case,

$$\begin{aligned}
A(\mathsf{b}(L)) &= \int_0^{\mathsf{b}(L)} \max\{h, \mathsf{f}(y)\}\,\mathrm{d}y + \int_{\mathsf{b}(L)}^1 \eta\,\mathrm{d}y \\
&= \int_0^{\mathsf{b}(L)} \mathsf{f}(y)\,\mathrm{d}y + \int_{\mathsf{b}(L)}^1 \eta\,\mathrm{d}y + \int_0^{\mathsf{b}(L)} \max\{h - \mathsf{f}(y), 0\}\,\mathrm{d}y \\
&\geq \int_0^1 \min\{\mathsf{f}(y), \eta\} + \int_0^1 \max\{h - \mathsf{f}(y), 0\}\,\mathrm{d}y = \mathsf{P}(\eta) + \mathsf{Q}(h).
\end{aligned}$$ ◀

5.1 When RTA terminates without empty bins and with some M_S-bins

The following lemma combines our bounds on gains on L_+, M_*, S_* and M_S.

▶ **Lemma 19.** *Assume that* Rta *run on input* σ *terminates without empty bins and with at least one* M_S*-bin. Then, for any* $\eta \in (1/2, \mathsf{level}_*]$,

$$\textsc{Rta}(\sigma) \gtrsim \mathsf{P}(\eta) + \mathsf{Q}(\min\{\eta, \mathsf{thr}(M_\mathrm{S})\}) + \mathsf{T}^* + (\mathsf{min}(M_\mathrm{S}) - \eta) \cdot \xi(\mathsf{min}(M_\mathrm{S})).$$

Proof. By the lemma assumptions,

$$\begin{aligned}
\textsc{Rta}(\sigma) &\geq \mathsf{g}(L_+) + \mathsf{g}(M_* \uplus S_*) + \mathsf{g}(M_\mathrm{S}) \\
&\gtrsim \mathsf{g}(L_+) + \eta \cdot \mathsf{b}(M_* \uplus S_*) + \mathsf{min}(M_\mathrm{S}) \cdot \mathsf{b}(M_\mathrm{S}) && \text{(by L. 13 and L. 8)} \\
&\approx \mathsf{g}(L_+) + \eta \cdot (1 - \mathsf{b}(L_+)) + (\mathsf{min}(M_\mathrm{S}) - \eta) \cdot \mathsf{b}(M_\mathrm{S}). && \text{(by L. 14)}
\end{aligned}$$

Applying the guarantee of Lemma 18 to $\mathsf{g}(L_+) + \eta \cdot (1 - \mathsf{b}(L_+))$ concludes the proof. ◀

▶ **Lemma 20.** *Assume that* Rta *run on input* σ *terminates without empty bins and with at least one* M_S*-bin. If* $\mathsf{min}(M_\mathrm{S}) \leq 1/3$*, then* $\textsc{Rta}(\sigma) \gtrsim R$.

Proof. As $\mathsf{level}_* \geq 2/3$, we may apply Lemma 19 with $\eta = 2/3$. Note that $\mathsf{thr}(M_\mathrm{S}) \geq 2/3$ for $\min(M_\mathrm{S}) \leq 1/3$. Then,

$$\begin{aligned}
\textsc{Rta}(\sigma) &\gtrsim \mathsf{P}(2/3) + \mathsf{Q}(2/3) + (\mathsf{min}(M_\mathrm{S}) - 2/3) \cdot \xi(\mathsf{min}(M_\mathrm{S})) \\
&= 2/3 + (\phi - 2/3) \cdot \xi(\mathsf{min}(M_\mathrm{S})) \geq R. && \text{(by L. 6)}
\end{aligned}$$

The last inequality follows by Property 4 of Lemma 7. ◀

▶ **Lemma 21.** *Assume that* Rta *run on input* σ *terminates without empty bins and with at least one* M_S*-bin. If* $\mathsf{min}(M_\mathrm{S}) > 1/3$*, then* $\textsc{Rta}(\sigma) \gtrsim R$.

Proof. As $\mathsf{min}(M) > 1/3$, $\mathsf{thr}(M_\mathrm{S}) < 1 - \mathsf{min}(M_\mathrm{S}) \geq 2/3$. Lemma 19 applied with any $\eta \in [2/3, \mathsf{level}_*]$ yields

$$\textsc{Rta}(\sigma) \gtrsim \mathsf{P}(\eta) + \mathsf{Q}(1 - \mathsf{min}(M_\mathrm{S})) + \mathsf{T}^* + (\mathsf{min}(M_\mathrm{S}) - \eta) \cdot \xi(\mathsf{min}(M_\mathrm{S})). \tag{9}$$

First, we assume that D has no tight items. Then, $\mathsf{level}_* = 1$, and we may use (9) with $\eta = 2 \cdot \mathsf{min}(M_\mathrm{S})$ obtaining $\textsc{Rta}(\sigma) \geq \mathsf{P}(2 \cdot \mathsf{min}(M_\mathrm{S})) + \mathsf{Q}(1 - \mathsf{min}(M_\mathrm{S})) - \mathsf{min}(M_\mathrm{S}) \cdot \xi(\mathsf{min}(M_\mathrm{S})) \geq R$, where the last inequality follows by Property 7 of Lemma 7.

Second, we assume that D contains a tight item and we consider three cases.

- $\mathsf{level}_* < \mathsf{pile}(\mathsf{mt}(D))$. This relation is possible only when $\mathsf{level}_* = 1 - \phi$ and $\textsc{Rta}$ terminates with at least one S_*-bin. In this case, Lemma 12 implies that $\mathsf{mt}(D) \leq 2\phi$. We apply (9) with $\eta = 1 - \phi$ obtaining $\textsc{Rta}(\sigma) \geq \mathsf{P}(1 - \phi) + \mathsf{Q}(1 - \mathsf{min}(M_\mathrm{S})) + \mathsf{T}^* + (\mathsf{min}(M_\mathrm{S}) + \phi - 1) \cdot \xi(\mathsf{min}(M_\mathrm{S}))$, which is at least R by Property 5 of Lemma 7.
- $\mathsf{level}_* \geq \mathsf{pile}(\mathsf{mt}(D))$ and $\mathsf{min}(M_\mathrm{S}) \leq \mathsf{mt}(D)$. Using monotonicity of pile, $\mathsf{level}_* \geq \mathsf{pile}(\mathsf{min}(M_\mathrm{S})) = 2 \cdot \mathsf{min}(M_\mathrm{S})$. Applying (9) with $\eta = 2 \cdot \mathsf{min}(M_\mathrm{S})$ yields $\textsc{Rta}(\sigma) \gtrsim R$ by Property 7 of Lemma 7.
- $\mathsf{level}_* \geq \mathsf{pile}(\mathsf{mt}(D))$ and $\mathsf{min}(M) > \mathsf{mt}(D)$. In this case, $\mathsf{T}^* = \mathsf{T}(\min(M_\mathrm{S}), \mathsf{mt}(D))$. Applying (9) with $\eta = \mathsf{pile}(\mathsf{mt}(D))$ yields $\textsc{Rta}(\sigma) \gtrsim \mathsf{P}(\mathsf{pile}(\mathsf{mt}(D))) + \mathsf{Q}(1 - \mathsf{min}(M_\mathrm{S})) + \mathsf{T}(\min(M_\mathrm{S}), \mathsf{mt}(D)) + (\mathsf{min}(M_\mathrm{S}) - \mathsf{pile}(\mathsf{mt}(D)) \cdot \xi(\mathsf{min}(M_\mathrm{S}))$, which is at least R by Property 6 of Lemma 7. ◀

6 Competitive ratio of RTA

▶ **Theorem 22.** *The competitive ratio of* $\textsc{Rta}$ *for the multiple knapsack problem is at least* $R - O(1/n)$.

Proof. Fix an input σ. If $\textsc{Rta}(\sigma)$ terminates with some empty bins, then its competitive ratio follows by Lemma 5.

Hence, below we assume that $\textsc{Rta}$ terminates without empty bins. We presented three lemmas that cover all possible cases: there are no M_S-bins (Lemma 15), there are M_S-bins and $\mathsf{min}(M_\mathrm{S}) \leq 1/3$ (Lemma 20), and there are M_S-bins and $\mathsf{min}(M_\mathrm{S}) > 1/3$ (Lemma 21). In all these cases, we proved $\textsc{Rta}(\sigma) \gtrsim R$. As $\textsc{Opt}(\sigma) \leq 1$, the theorem follows. ◀

7 Proof of Lemma 7

We start with technical helper claims.

▶ **Fact 23.** *The functions below are the derivatives of functions* P, Q *and* ξ, *respectively.*

$$\mathsf{P}'(x) = -R \cdot \ln x$$
$$\mathsf{Q}'(x) = 1 + R \cdot \ln x$$
$$\xi'(x) = \begin{cases} -\xi_\mathrm{c}/x^2 & \textit{if } x < 1/3, \\ -18\xi_\mathrm{c} & \textit{if } x > 1/3 \end{cases}$$

▶ **Lemma 24.** $\mathsf{T}(x,y)$ *is a non-increasing function of* y *in the interval* $[\phi, 1/2]$.

Proof. Recall that $\mathsf{T}(x,y) = (x + y - 1/2) \cdot (\xi(y) - \xi(x))$ is defined for $x, y \in [\phi, 1/2]$. As the function $\mathsf{T}(x,y)$ is continuous and differentiable everywhere except $y = 1/3$, it suffices to show that its partial derivative $\partial_y \mathsf{T}(x,y)$ is non-positive (except $y = 1/3$). We have

$$\partial_y \mathsf{T}(x,y) = \xi(y) - \xi(x) + (x + y - 1/2) \cdot \xi'(y) \leq \xi(y) + y \cdot \xi'(y),$$

where for the inequality we used $\xi(x) \geq 0$ and $(x - 1/2) \cdot \xi'(y) \geq 0$.

If $y \leq 1/3$, then $\partial_y \mathsf{T}(x,y) \leq \xi_{\mathrm{c}}/y + y \cdot (-\xi_{\mathrm{c}}/y^2) = 0$. If $y > 1/3$, then $\partial_y \mathsf{T}(x,y) \leq 9\xi_{\mathrm{c}} \cdot (1-2y) - 18\xi_{\mathrm{c}} \cdot y = 9\xi_{\mathrm{c}} \cdot (1-4y) < 0$, which concludes the proof. ◀

▶ **Lemma 25.** *$P(2/3) = R - \xi_{\mathrm{c}}$ and for any $y \in [2/3, 1]$ it holds that $\mathsf{P}(y) \geq R + 3\xi_{\mathrm{c}} \cdot y - 3\xi_{\mathrm{c}}$.*

Proof. For the first part of the lemma, observe that by the definition of ξ_{c} (see (1)),

$$\mathsf{P}(2/3) + \xi_{\mathrm{c}} = 2/3 - R \cdot (2/3) \cdot \ln(4/3) + (1 + (2/3) \cdot \ln(4/3)) \cdot R - 2/3 = R.$$

To show the second relation, note that $\mathsf{P}(2/3) = R - \xi_{\mathrm{c}}$ and $\mathsf{P}(1) = R$. Let $h(y) = R + 3\xi_{\mathrm{c}} \cdot y - 3\xi_{\mathrm{c}}$ be the linear function that coincides with $\mathsf{P}(y)$ for $y = 2/3$ and $y = 1$. As the function P is concave on its whole domain (its second derivative $\mathsf{P}''(y) = -R/y$ is negative), we have $\mathsf{P}(y) \geq h(y)$ for any $y \in [2/3, 1]$. ◀

Proof of Lemma 7. Note that $\xi(1/3) = 3 \cdot \xi_{\mathrm{c}}$ and $\xi(1/2) = 0$, For each property, we define an appropriate function G_i that we analyze; for all properties except the first one, we show that the function value is at least R for an appropriate range of arguments.

Property 1. Let $G_1(x) = x \cdot \xi(x)$. Then $G_1(x) = \xi_{\mathrm{c}}$ for $x \in [\phi, 1/3]$, and for $x \in [1/3, 1/2]$ it holds that $G_1(x) = 9\xi_{\mathrm{c}} \cdot x \cdot (1-2x)$, i.e., the function $G_1(x)$ is decreasing. Hence, $G_1(x)$ is non-increasing in the whole domain $[\phi, 1/2]$.

Property 2. Let $G_2(x) = \mathsf{P}(\mathsf{pile}(x)) + x \cdot \xi(x)$; we want to show that $G_2(x) \geq R$ for any $x \in [\phi, 1/2]$. For $x \in [\phi, 1/3]$, it holds that $G_2(x) = \mathsf{P}(2/3) + \xi_{\mathrm{c}} = R$ (by Lemma 25). For $x \in [1/3, 1/2]$, $G_2(x) = \mathsf{P}(2x) + x \cdot \xi(x)$. Using Lemma 25, we obtain $G_2(x) \geq R + 6\xi_{\mathrm{c}} \cdot x - 3\xi_{\mathrm{c}} + 9\xi_{\mathrm{c}} \cdot (x - 2x^2) = R - 18\xi_{\mathrm{c}} \cdot (x - 1/2) \cdot (x - 1/3) \geq R$. The last inequality follows as for any $x \in [1/3, 1/2]$ the term $(x - 1/2) \cdot (x - 1/3)$ is non-positive.

Property 3. Let $G_3 = \mathsf{P}(1-\phi) + 2\phi \cdot \xi(2\phi)$. It can be verified numerically that $G_3 > 0.593 > R$.

Property 4. Let $G_4(x) = 2/3 - (2/3 - \phi) \cdot \xi(x)$. As the function $\xi(x)$ is decreasing, for any $x \in [\phi, 1/3]$ it holds that $G_4(x) \geq G_4(\phi) = 2/3 - (2/3) \cdot \xi_{\mathrm{c}}/\phi + \xi_{\mathrm{c}}$. Substituting the definition of ϕ (see (2)), we obtain $G_4(x) \geq G_4(\phi) \geq 2/3 - 2/3 + R - \xi_{\mathrm{c}} + \xi_{\mathrm{c}} = R$.

Property 5. Let $G_5(x,y) = \tilde{G}_5(x) + \max\{\mathsf{T}(x,y), 0\}$, where $\tilde{G}_5(x) = \mathsf{P}(1-\phi) + \mathsf{Q}(1-x) + (x + \phi - 1) \cdot \xi(x)$. We want to show that $G_5(x,y) \geq R$ for any $x \in [1/3, 1/2]$ and $y \in [\phi, 2\phi]$.

- If $x \in [1/3, 2\phi]$, then already $\tilde{G}_5(x) \geq R$. To show this relation, we estimate its derivative in the interval $[1/3, 2\phi]$:

$$\begin{aligned}\tilde{G}_5'(x) &= -1 - R \cdot \ln(1-x) + (x + \phi - 1) \cdot \xi'(x) + \xi(x) \\ &= -1 - R \cdot \ln(1-x) - 36\xi_{\mathrm{c}} \cdot x - 18\xi_{\mathrm{c}} \cdot \phi + 27\xi_{\mathrm{c}} \\ &\leq -1 - R \cdot \ln(1-2\phi) - 36\xi_{\mathrm{c}} \cdot (1/3) - 18\xi_{\mathrm{c}} \cdot \phi + 27\xi_{\mathrm{c}} < -0.2479 < 0.\end{aligned}$$

  Hence, $\tilde{G}_5$ is decreasing in the interval $[1/3, 2\phi]$, and thus for any $x \in [1/3, 2\phi]$ it holds that $G_5(x,y) \geq \tilde{G}_5(x) \geq \tilde{G}_5(2\phi) > 0.5997 > R$.
- If $x \in (2\phi, 1/2]$, then $\mathsf{T}(x,y) \geq 0$. As $\mathsf{T}(x,y)$ is a non-increasing function of y in the interval $[\phi, 2\phi]$ (by Lemma 24), it holds that $\mathsf{T}(x,y) \geq \mathsf{T}(x, 2\phi)$. Therefore,

$$G_5(x,y) \geq G_5(x, 2\phi) = \mathsf{P}(1-\phi) + \mathsf{Q}(1-x) - (\phi + 1/2) \cdot \xi(x) + (x + 2\phi - 1/2) \cdot \xi(2\phi).$$

We now estimate its partial derivative for $x \in [2\phi, 1/2]$:

$$\begin{aligned}\partial_x G_5(x, 2\phi) &= -1 - R \cdot \ln(1-x) - (\phi + 1/2) \cdot \xi'(x) + \xi(2\phi) \\ &\le -1 - R \cdot \ln(1/2) + 18\xi_{\mathrm{c}} \cdot (\phi + 1/2) + 9\xi_{\mathrm{c}} \cdot (1 - 4\phi) < -0.0673 < 0.\end{aligned}$$

Therefore $G_5(x, 2\phi)$ is decreasing as a function of x in the interval $[2\phi, 1/2]$. Thus, for the considered range of arguments, $G_5(x, y) \ge G_5(x, 2\phi) \ge G_5(1/2, 2\phi) > 0.5934 > R$.

Property 6. Let

$$G_6(x, y) = \mathsf{P}(\mathsf{pile}(y)) + \mathsf{Q}(1-x) + (x - \mathsf{pile}(y)) \cdot \xi(x) + \mathsf{T}(x, y)$$

Fix any pair $(x, y) \in [1/3, 1/2] \times [\phi, 1/2]$, such that $y \le x$. We prove that $G_6(x, y) \ge R$, by showing each of the following inequalities

$$G_6(x, y) \ge G_6(x, y') \ge \tilde{G}_6(x, y') \ge \tilde{G}_6(1/2, y'') \ge R, \tag{10}$$

where $y' = \max\{y, 1/3\}$ and $y'' = y' + 1/2 - x$. The function $\tilde{G}_6$ is a lower bound on function G_6 created by using Lemma 25 (and defined formally later).

The first inequality of (10) is trivial for $y \ge 1/3$, hence we assume that $y < 1/3$. In such case, using the definition of function pile, we get $G_6(x, y) = \mathsf{P}(2/3) + \mathsf{Q}(1-x) + (x - 2/3) \cdot \xi(x) + \mathsf{T}(x, y)$. As $\mathsf{T}(x, y)$ is a decreasing function of y, we obtain that $\mathsf{T}(x, y) \ge \mathsf{T}(x, y')$ and thus also $G_6(x, y) \ge G_6(x, y')$.

To show the second inequality of (10), we first simplify $G_6(x, y)$ using that $y \ge 1/3$ and the definition of pile:

$$G_6(x, y) = \mathsf{P}(2y) + \mathsf{Q}(1-x) + (x - 2y) \cdot \xi(x) + (x + y - 1/2) \cdot (\xi(y) - \xi(x))$$

Now, using Lemma 25, we have

$$G_6(x, y) \ge R + \mathsf{Q}(1-x) + 6\xi_{\mathrm{c}} \cdot y - 3\xi_{\mathrm{c}} + (1/2 - 3y) \cdot \xi(x) + (x + y - 1/2) \cdot \xi(y).$$

We denote the estimate above by $\tilde{G}_6(x, y)$ and we inspect its two partial derivatives.

$$\begin{aligned}\partial_x \tilde{G}_6(x, y) &= -1 - R \cdot \ln(1-x) + (1/2 - 3y) \cdot \xi'(x) + \xi(y) \\ \partial_y \tilde{G}_6(x, y) &= 6\xi_{\mathrm{c}} - 3 \cdot \xi(x) + \xi(y) + (x + y - 1/2) \cdot \xi'(y)\end{aligned}$$

The directional derivative along the vector $\mathbf{v} = (1, 1)$ is then equal to

$$\begin{aligned}\partial_{\mathbf{v}} \tilde{G}_6(x, y) &= \partial_x \tilde{G}_6(x, y) + \partial_y \tilde{G}_6(x, y) \\ &= -1 - R \cdot \ln(1-x) + 6\xi_{\mathrm{c}} - 3 \cdot \xi(x) + 2 \cdot \xi(y) - 18\xi_{\mathrm{c}} \cdot (x - 2y) \\ &= -1 - R \cdot \ln(1-x) + 36\xi_{\mathrm{c}} \cdot x - 3\xi_{\mathrm{c}} \\ &\le -1 - R \cdot \ln(1/2) + 36\xi_{\mathrm{c}} \cdot (1/2) - 3\xi_{\mathrm{c}} < -0.0322 < 0.\end{aligned}$$

This means that if we take any point $(x, y') \in [1/3, 1/2] \times [1/3, 1/2]$, where $y' \le x$, and move along vector $\mathbf{v}$, to point $(1/2, y'') = (1/2, y + 1/2 - x)$, the value of the function $\tilde{G}_6$ can only decrease. This concludes the proof of the third inequality of (10).

To show the final inequality of (10), we fix any $y'' \in [1/3, 1/2]$. Then $\tilde{G}_6(1/2, y'') = R + 6\xi_{\mathrm{c}} \cdot y - 3\xi_{\mathrm{c}} + y'' \cdot \xi(y'') = R - 18\xi_{\mathrm{c}} \cdot (y'' - 1/2) \cdot (y'' - 1/3) \ge R$, where the last inequality holds as $(y'' - 1/2) \cdot (y'' - 1/3)$ is non-positive.

Property 7. Let $G_7(x) = \mathsf{P}(2x) + \mathsf{Q}(1-x) - x \cdot \xi(x)$. For $x \in [1/3, 1/2]$, it holds that $G_7(x) = G_6(x, x)$. Hence $G_7(x) \ge R$ for $x \in [1/3, 1/2]$ follows by Property 6. ◀

Abstract

Given a string S of length n, its *Lyndon array* identifies for each suffix $S[i..n]$ the next lexicographically smaller suffix $S[j..n]$, i.e. the minimal index $j > i$ with $S[i..n] \succ S[j..n]$. Apart from its plain $(n \log_2 n)$-bit array representation, the Lyndon array can also be encoded as a succinct parentheses sequence that requires only $2n$ bits of space. While linear time construction algorithms for both representations exist, it has previously been unknown if the same time bound can be achieved with less than $\Omega(n \lg n)$ bits of additional working space. We show that, in fact, $o(n)$ additional bits are sufficient to compute the succinct $2n$-bit version of the Lyndon array in linear time. For the plain $(n \log_2 n)$-bit version, we only need $\mathcal{O}(1)$ additional words to achieve linear time. Our space efficient construction algorithm makes the Lyndon array more accessible as a fundamental data structure in applications like full-text indexing.

1 Introduction & Related Work

The Lyndon array [5] is a well-known combinatorial object on strings and has gained renewed attention [6, 7, 14, 18, 19, 23] due to its recently discovered central role in combinatorics on strings, e.g., when computing all the runs in a string [2]. It is known [18, 13] that the Lyndon array can be computed in linear time from the list of lexicographically sorted suffixes (the *suffix array*). Baier [1] introduced the first *direct* algorithm for computing the Lyndon array – interestingly as a *preliminary* step for his new suffix sorting algorithm. However, it requires $\Theta(n \lg n)$ bits of additional working space even for just computing the Lyndon array. Other Lyndon array construction algorithms have been introduced [13, 19, 20], but they all have the same space bounds.

The Lyndon array has some structural properties that allow for a more space efficient representation, namely using only $2n + 2$ bits [19]. Thus, it would be desirable to compute this succinct representation using less than $\Theta(n \lg n)$ bits of working space, without sacrificing the linear running time. Previously, no such algorithm was known.

Our Contributions. We introduce the first algorithm that computes the succinct Lyndon array in $\mathcal{O}(n)$ time, using only $\mathcal{O}(n \lg\lg n/ \lg n)$ bits of additional working space. Alternatively, our algorithm can construct the plain ($\mathcal{O}(n \lg n)$-bits) Lyndon array using only $\mathcal{O}(1)$ words of additional working space, i.e., directly without precomputing the suffix array. In practice, our approach is up to 10 times faster than previous algorithms for the Lyndon array.

The rest of the paper is organized as follows: In Section 2 we introduce the notation and definitions that we use throughout the paper. Section 3 provides a new intuitive definition of the succinct Lyndon array. We introduce our construction algorithm for the succinct Lyndon array in Sections 4 and 5, and adapt it such that it computes the plain ($\mathcal{O}(n \lg n)$-bits) Lyndon array in Section 6. Finally, we present experimental results for both versions (Section 7), and summarize our findings (Section 8).

2 Preliminaries

We write $\lg x$ for $\log_2 x$. For $i, j \in \mathbb{N}$, the interval $[i, j]$ represents $\{x \mid x \in \mathbb{N} \wedge i \leq x \leq j\}$. We use the notation $[i, j + 1) = (i - 1, j] = (i - 1, j + 1) = [i, j]$ for open and half-open discrete intervals. Our analysis is performed in the word RAM model [17], where we can perform fundamental operations (logical shifts, basic arithmetic operations etc.) on words of size w bits in constant time. For the input size n of our problems we assume $\lceil \lg n \rceil \leq w$.

A *string* (also called *text*) over the *alphabet* Σ is a finite sequence of *symbols* from the finite and totally ordered set Σ. We say that a string $\mathcal{S}$ has length n and write $|\mathcal{S}| = n$, iff $\mathcal{S}$ is a sequence of exactly n symbols. The i-th symbol of a string $\mathcal{S}$ is denoted by $\mathcal{S}[i]$, while the *substring* from the i-th to the j-th symbol is denoted by $\mathcal{S}[i..j]$. For convenience we use the interval notations $\mathcal{S}[i..j + 1) = \mathcal{S}(i - 1..j] = \mathcal{S}(i - 1..j + 1) = \mathcal{S}[i..j]$. The i-th *suffix* of $\mathcal{S}$ is defined as $\mathcal{S}_i = \mathcal{S}[i..n]$, while the substring $\mathcal{S}[1..i]$ is called *prefix* of $\mathcal{S}$. A prefix or suffix of $\mathcal{S}$ is called *proper*, iff its length is at most $n - 1$. The concatenation of two strings $\mathcal{S}$ and $\mathcal{T}$ is denoted by $\mathcal{S} \cdot \mathcal{T}$. The length of the *longest common prefix (LCP)* between $\mathcal{S}$ and $\mathcal{T}$ is defined as $\textsc{lcp}(\mathcal{S}, \mathcal{T}) = \max\{\ell \mid \mathcal{S}[1..\ell] = \mathcal{T}[1..\ell]\}$. The *longest common extension (LCE)* of indices i and j is the length of the LCP between $\mathcal{S}_i$ and $\mathcal{S}_j$, i.e. $\textsc{lce}(i, j) = \textsc{lcp}(\mathcal{S}_i, \mathcal{S}_j)$. We can simplify the description of our algorithm by introducing a special symbol $\$ \notin \Sigma$ that is smaller than all symbols from Σ. For a string $\mathcal{S}$ of length n we define the 0-*th suffix* $\mathcal{S}_0 = \$$ as well as the $(n + 1)$-*st suffix and position* $\mathcal{S}_{n+1} = \mathcal{S}[n + 1] = \$$. The total order on Σ

induces a total order on the set Σ^* of strings over Σ. Let $\mathcal{S}$ and $\mathcal{T}$ be strings over Σ, and let $\ell = \textsc{lcp}(\mathcal{S}, \mathcal{T})$. We say that $\mathcal{S}$ is lexicographically smaller than $\mathcal{T}$ and write $\mathcal{S} \prec \mathcal{T}$, iff we have $\mathcal{S} \neq \mathcal{T}$ and $\mathcal{S}[\ell+1] < \mathcal{T}[\ell+1]$. Analogously, we say that $\mathcal{S}$ is lexicographically larger than $\mathcal{T}$ and write $\mathcal{S} \succ \mathcal{T}$, iff we have $\mathcal{S} \neq \mathcal{T}$ and $\mathcal{S}[\ell+1] > \mathcal{T}[\ell+1]$.

2.1 The Lyndon Array & Nearest Smaller Suffixes

A *Lyndon word* is a string that is lexicographically smaller than all of its proper suffixes, i.e. $\mathcal{S}$ is a Lyndon word, iff $\forall i \in [2..n] : \mathcal{S}_i \succ \mathcal{S}$ holds [8]. For example, the string `northamerica` is not a Lyndon word because its suffix `america` is lexicographically smaller than itself. On the other hand, its substring `americ` is a Lyndon word. The Lyndon array of $\mathcal{S}$ identifies the longest Lyndon word at each position of $\mathcal{S}$:

▶ **Definition 1** (Lyndon Array). *Given a string $\mathcal{S}$ of length n, the Lyndon array is an array λ of n integers with $\lambda[i] = \max\{\ell \mid \mathcal{S}[i..i+\ell)$ is a Lyndon word$\}$.*

▶ **Definition 2** (Nearest Smaller Suffixes). *Given a string $\mathcal{S}$ and a suffix $\mathcal{S}_i$, the* next smaller suffix of $\mathcal{S}_i$ *is $\mathcal{S}_j$, where j is the smallest index that is larger than i and satisfies $\mathcal{S}_i \succ \mathcal{S}_j$. The* previous smaller suffix of $\mathcal{S}_i$ *is defined analogously. The* next-smaller-suffix array (NSS array) and previous-smaller-suffix array (PSS array) *are arrays of size n defined as follows:*

$$\mathsf{nss}[i] = \min\{j \mid j \in (i, n+1] \wedge \mathcal{S}_i \succ \mathcal{S}_j\} \qquad \mathsf{pss}[i] = \max\{j \mid j \in [0, i) \wedge \mathcal{S}_j \prec \mathcal{S}_i\}$$

The Lyndon array and nearest smaller suffixes are highly related to each other. In fact, the NSS array is merely a different representation of the Lyndon array (Lemma 3), as visualized in Figure 1a. We conclude the preliminaries by showing a slightly weaker connection between the PSS array and Lyndon words (Lemma 4).

▶ **Lemma 3** (Lemma 15 [13]). *The longest Lyndon word at position i ends at the starting position of the NSS of $\mathcal{S}_i$, i.e. $\lambda[i] = \mathsf{nss}[i] - i$.*

▶ **Lemma 4.** *Let $\mathsf{pss}[j] = i > 0$, then $\mathcal{S}[i..j)$ is a Lyndon word.*

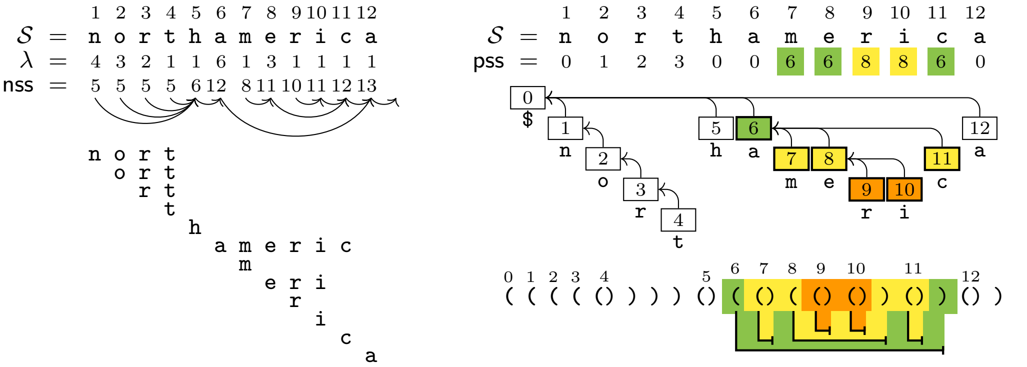
Proof. By definition, the string $\mathcal{S}[i..j)$ is a Lyndon word iff there exists no $k \in (i, j)$ with $\mathcal{S}[k..j) \prec \mathcal{S}[i..j)$. Assume that such a k exists. Since $i = \mathsf{pss}[j]$, we know that (a) $\mathcal{S}_k \succ \mathcal{S}_i$. Now assume there is a mismatching character between $\mathcal{S}[k..j)$ and $\mathcal{S}[i..j)$. Then appending $\mathcal{S}_j$ to both strings preserves this mismatch. This implies that we have $\mathcal{S}[k..j) \prec \mathcal{S}[i..j) \iff \mathcal{S}[k..j) \cdot \mathcal{S}_j \prec \mathcal{S}[i..j) \cdot \mathcal{S}_j$, and thus $\mathcal{S}_k \prec \mathcal{S}_i$, which contradicts (a). Therefore, we know that (b) $\mathcal{S}[k..j) = \mathcal{S}[i..i+(j-k))$. Then

$$\mathcal{S}_k \overset{(a)}{\succ} \mathcal{S}_i \quad \iff \quad \mathcal{S}[k..j) \cdot \mathcal{S}_j \succ \mathcal{S}[i..i+(j-k)) \cdot \mathcal{S}_{i+(j-k)} \quad \overset{(b)}{\iff} \quad \mathcal{S}_j \succ \mathcal{S}_{i+(j-k)}$$

which contradicts the fact that $\mathsf{pss}[j] = i < i + (j-k)$. Hence, the described k cannot exist, and $\mathcal{S}[i..j)$ must be a Lyndon word. ◀

3 Previous-Smaller-Suffix Trees

In this section we introduce the *previous-smaller-suffix tree*, which simulates access to the Lyndon array, the NSS array, and the PSS array. The PSS array inherently forms a tree in which each index i is represented by a node whose parent is $\mathsf{pss}[i]$. The root is the artificial index 0, which is parent of all indices that do not have a PSS (see Figure 1b for an example).



(a) Lyndon array, NSS array, and maximal Lyndon words at all indices of $\mathcal{S}$.

(b) PSS array, PSS tree, and BPS representation of the PSS tree of $\mathcal{S}$. (Best viewed in color.)

Figure 1 Data structures for $\mathcal{S} = \texttt{northamerica}$.

▶ **Definition 5** (Previous-Smaller-Suffix Tree $\mathcal{T}_{\mathsf{pss}}$). *Let $\mathcal{S}$ be a string of length n. The* previous-smaller-suffix tree (PSS tree) *of $\mathcal{S}$ is an ordinal tree $\mathcal{T}_{\mathsf{pss}}$ with nodes $[0, n]$ and root 0. For $i \in [1, n]$, we define* Parent$(i) = \mathsf{pss}[i]$. *The children are arranged in ascending order, i.e. if i is a left-side sibling of j, then $i < j$ holds.*

The PSS tree is highly similar to the Left-to-Right-Minima (LRM) tree [3, 9, 22], which we will briefly explain now. Given an array $A[1, n]$ with artificial minimum $A[0] = -\infty$, let $\mathsf{psv}[i] = \max\{j \mid j \in [0, i) \wedge A[j] < A[i]\}$ be the index of the *previous smaller value (PSV)* of $A[i]$. The LRM tree of A is an ordinal tree in which each index i is a child of $\mathsf{psv}[i]$, and the children are ordered ascendingly (i.e. the only difference to the PSS tree is that we consider previous smaller *values* instead of previous smaller *suffixes*). If A is the inverse suffix array of $\mathcal{S}$, then by definition of the inverse suffix array we have $\forall i, j \in [1, n] : \mathcal{S}_i \prec \mathcal{S}_j \Leftrightarrow A[i] < A[j]$. It follows that the PSS tree of a string is identical to the LRM tree of its inverse suffix array. Consequently, an important property of the LRM tree also applies to the PSS tree:

▶ **Corollary 6** (Lemma 1 [9]). *The nodes of the PSS tree directly correspond to the preorder-numbers, i.e. node i has preorder-number i (if the first preorder-number is 0).*

The corollary allows us to simulate the NSS array with the PSS tree:

▶ **Lemma 7.** *Given the PSS tree, NSS array and Lyndon array of the same string we have* $\mathsf{nss}[i] = i + \textsc{SubtreeSize}(i)$ *and thus* $\lambda[i] = \textsc{SubtreeSize}(i)$.[1]

Proof. Since the nodes directly correspond to the preorder-numbers (Corollary 6), it follows that the descendants of i form a consecutive interval $(i, r]$. Since $i + \textsc{SubtreeSize}(i) = i + (r - i + 1) = r + 1$ holds, we only have to show $\mathsf{nss}[i] = r + 1$. Assume $r = n$, then there is no index larger than i that is not a descendant of i. Clearly, in this case i does not have an NSS, and thus it follows $\mathsf{nss}[i] = n + 1 = r + 1$. Assume $r < n$ instead, then $\mathcal{S}_{r+1}$ must be lexicographically smaller than all suffixes that begin at positions from $[i, r]$, since otherwise $r + 1$ would be a descendant of i. Therefore, $\mathcal{S}_{r+1}$ is the first suffix that starts right of i and is lexicographically smaller than $\mathcal{S}_i$, which means $\mathsf{nss}[i] = r + 1$. ◀

[1] $\textsc{SubtreeSize}(i)$ denotes the number of nodes in the subtree that is rooted in i, including i itself.

3.1 Storing the PSS Tree as a BPS

We store the PSS tree as a balanced parentheses sequence (BPS, [21]) of length $2n+2$, which takes $2n+2$ bits. Note that this is less than the $\approx 2.54n$ bits that are necessary to encode previous and next smaller *values* [10] because different suffixes of a text cannot be equal. As a shorthand for the BPS of the PSS tree we write $\mathcal{B}_{\mathsf{pss}}$. The sequence is algorithmically defined by a preorder-traversal of the PSS tree, where we write an opening parenthesis whenever we *walk down* an edge, and a closing one whenever we *walk up* an edge. An example is provided in Figure 1b. Note that the BPS of the PSS tree is identical to the succinct Lyndon array presentation from [19]. While the BPS itself does not support fast tree operations, it can be used to construct the data structure from [22], which takes $\mathcal{O}(n)$ time and $\mathcal{O}(n)$ bits of working space. This data structure is of size $2n + \mathcal{O}(n/\lg^c n)$ bits (for any $c \in \mathbb{N}^+$ of our choice) and supports $\textsc{Parent}(\cdot)$ and $\textsc{SubtreeSize}(\cdot)$ operations in $\mathcal{O}(c^2)$ time, and thus allows us to simulate access to the Lyndon array in $\mathcal{O}(c^2)$ time using Lemma 7.

Operations on a BPS Prefix. Since we will be building $\mathcal{B}_{\mathsf{pss}}$ from left to right, at any given point of the algorithm execution we know a prefix of $\mathcal{B}_{\mathsf{pss}}$. It is crucial that we maintain support for the following queries in constant time:

- Given the index o_i of an opening parenthesis in $\mathcal{B}_{\mathsf{pss}}$, determine the node i that belongs to the parenthesis. We have $i = \text{rank}_{\text{open}}(o_i) - 1$, where $\text{rank}_{\text{open}}(o_i)$ is the number of opening parentheses in $\mathcal{B}_{\mathsf{pss}}[1..o_i]$.
- Given a preorder-number i, find the index o_i of the corresponding opening parenthesis in $\mathcal{B}_{\mathsf{pss}}$. We have $o_i = \text{select}_{\text{open}}(i) = \min\{o \mid \text{rank}_{\text{open}}(o) > i\}$.
- Given an integer $k \geq 1$, find the index $o_{\text{uncl}(k)} = \text{select}_{\text{uncl}}(k)$ of the k-th *unclosed* parenthesis in $\mathcal{B}_{\mathsf{pss}}$. An opening parenthesis is called unclosed, if we have not written the matching closing parenthesis yet. For example, there are five opening parentheses in (()((), but only the first and the third one are unclosed.

There are support data structures of size $\mathcal{O}(n \lg\lg n / \lg n)$ bits that answer $\text{rank}_{\text{open}}$ and $\text{select}_{\text{open}}$ queries in constant time [16]. Since these data structures can be constructed in linear time by scanning the BPS from left to right, clearly we can maintain them with no significant time overhead when writing the BPS in an append-only manner. The structure for $\text{select}_{\text{uncl}}$ is a simple modification of the structure for $\text{select}_{\text{open}}$. Consider the (not necessarily balanced) parentheses sequence $\hat{\mathcal{B}}$ with $\hat{\mathcal{B}}[i] =$ (, iff $\mathcal{B}_{\mathsf{pss}}[i]$ is an unclosed parenthesis, and otherwise $\hat{\mathcal{B}}[i] =$). Clearly, answering $\text{select}_{\text{uncl}}$ on $\mathcal{B}_{\mathsf{pss}}$ is equivalent to answering $\text{select}_{\text{open}}$ on $\hat{\mathcal{B}}$. Thus, if we construct the $\text{select}_{\text{open}}$ data structure by Golynski [16, Section 2.1] for $\hat{\mathcal{B}}$, then we already have a working index for $\text{select}_{\text{uncl}}$ on $\mathcal{B}_{\mathsf{pss}}$. However, this approach comes at the cost of additional $2n$ bits of space because we need to explicitly store $\hat{\mathcal{B}}$. In the following paragraph, we outline how to modify the index such that queries can be answered directly on $\mathcal{B}_{\mathsf{pss}}$, i.e. without $\hat{\mathcal{B}}$. The reader should be familiar with [16, Section 2.1].

Assume that we want to answer $\text{select}_{\text{open}}(i)$ on $\hat{\mathcal{B}}$. Golynski's index conceptually splits $\hat{\mathcal{B}}$ into chunks of size $\lg n - 3\lg\lg n$. At the time we actually need to access $\hat{\mathcal{B}}$, we have already identified the chunk $\hat{C} = \hat{\mathcal{B}}[c_x..c_x + \lg n - 3\lg\lg n)$ and the value p such that the i-th opening parenthesis in $\hat{\mathcal{B}}$ is exactly the p-th opening parenthesis in $\hat{C}$. Answering the query is realized by simply retrieving the index j of the p-th opening parenthesis within $\hat{C}$ from a precomputed lookup table. Then, the result of the query is $c_x + j - 1$. We can answer the query without $\hat{\mathcal{B}}$, if we retrieve the chunk $C = \mathcal{B}_{\mathsf{pss}}[c_x..c_x + \lg n - 3\lg\lg n)$ directly from $\mathcal{B}_{\mathsf{pss}}$ (instead of retrieving the chunk $\hat{C}$ from $\hat{\mathcal{B}}$). We only need to change the precomputed lookup table such that it returns the index of the p-th unclosed parenthesis within the chunk instead of the index of the p-th opening parenthesis.

(a) Before.

(b) After.

Figure 2 The partial PSS tree before and after processing index 11 of $\mathcal{S} = \texttt{northamerica}$ during the execution of Algorithm 1. We have $p_1 = 10$, $p_2 = 8$, $p_3 = 6$, $p_4 = 0$, and $p_m = p_3$. (Best viewed in color.)

Appending parentheses to $\mathcal{B}_{\mathsf{pss}}$ may invalidate parts of the support data structure for $\text{select}_{\text{uncl}}$. The reason for this is that we essentially emulate $\text{select}_{\text{uncl}}$ on $\mathcal{B}_{\mathsf{pss}}$ by answering $\text{select}_{\text{open}}$ on $\hat{\mathcal{B}}$. Appending a closing parenthesis to $\mathcal{B}_{\mathsf{pss}}$ not only translates to appending a closing parenthesis to $\hat{\mathcal{B}}$, but also means that we have to replace the rightmost opening parenthesis in $\hat{\mathcal{B}}$ with a closing one. Thus, we may have to change previously computed parts of the support data structure. This can easily be handled without significant time overhead by only periodically updating the data structure, and naively keeping track of newly appended parentheses in between updates. We omit the details.

4 Constructing the PSS Tree

In this section we introduce our construction algorithm for the BPS of the PSS tree, which processes the indices of the input text in left-to-right order. Processing index i essentially means that we attach i to a partial PSS tree that is induced by the nodes from $[0, i)$. An example is provided in Figure 2a. But how can we efficiently determine i's parent $\mathsf{pss}[i]$? Consider the nodes on the rightmost path of the partial tree, which starts at $i-1$ and ends at the root 0. We call the set of these nodes *PSS closure* $\mathcal{P}_{i-1}$ of $i-1$ because it contains exactly the nodes that can be obtained by repeated application of the PSS function on $i-1$. For $j \in [1, n]$ we recursively define $\mathcal{P}_0 = \{0\}$ and $\mathcal{P}_j = \{j\} \cup \mathcal{P}_{\mathsf{pss}[j]}$. Interestingly, $\mathsf{pss}[i]$ is a member of $\mathcal{P}_{i-1}$:

▶ **Lemma 8.** *For any index $i \in [1, n]$ we have* $\mathsf{pss}[i] = \max\{j \mid j \in \mathcal{P}_{i-1} \wedge \mathcal{S}_j \prec \mathcal{S}_i\}$.

Proof. If we show $\mathsf{pss}[i] \in \mathcal{P}_{i-1}$, then the correctness of the lemma follows from Definition 2. Assume $\mathsf{pss}[i] \notin \mathcal{P}_{i-1}$, then there is some index $j \in \mathcal{P}_{i-1}$ with $\mathsf{pss}[i] \in (\mathsf{pss}[j], j)$. By Definition 2, this implies $\mathcal{S}_{\mathsf{pss}[i]} \succ \mathcal{S}_j$. However, we also have $j \in (\mathsf{pss}[i], i)$, which leads to the contradiction $\mathcal{S}_{\mathsf{pss}[i]} \prec \mathcal{S}_j$. ◀

Let $p_1 = i - 1, p_2, \ldots, p_k = 0$ be the elements of $\mathcal{P}_{i-1}$ in descending order, then it follows from Lemma 8 that there is some $m \in [1, k]$ with $\mathsf{pss}[i] = p_m$, i.e. node i has to become a child of p_m in the partial PSS tree. In terms of the BPS, we have to append $m - 1$ closing parentheses to the BPS prefix. Then, we can simply write the opening parenthesis of node i. Once again, an example is provided in Figure 2b.

Algorithm 1 BuildPssBps.

```
Input: String $\mathcal{S}$ of length $n$
Output: BPS of the PSS Tree of $\mathcal{S}$
1: $\mathcal{B}_{\mathsf{pss}} \leftarrow ($                                        ▷ Open node 0
2: for $i = 1$ to $n$ do
3:     Let $\mathcal{P}_{i-1} = \{p_1, \dots, p_k\}$ with $\mathsf{pss}[p_x] = p_{x+1}$
4:     Determine $p_m = \mathsf{pss}[i]$
5:     Append $m - 1$ closing parentheses to $\mathcal{B}_{\mathsf{pss}}$      ▷ Close nodes $p_1, \dots, p_{m-1}$
6:     Append one opening parenthesis to $\mathcal{B}_{\mathsf{pss}}$          ▷ Open node $i$
7: Append $|\mathcal{P}_n|$ closing parentheses to $\mathcal{B}_{\mathsf{pss}}$          ▷ Close rightmost path
```

Our construction algorithm for $\mathcal{B}_{\mathsf{pss}}$ is based on this simple idea, as outlined by Algorithm 1. Initially, the BPS only contains the opening parenthesis of the root 0 (line 1). Then, whenever we process an index i, we use $\mathcal{P}_{i-1}$ to determine p_m (lines 3–4) and extend $\mathcal{B}_{\mathsf{pss}}$ by appending $m-1$ closing parentheses and one opening one (lines 5–6). Finally, once all nodes have been added to the PSS tree, we only have to close all remaining unclosed parentheses (line 7). The algorithm has two black boxes: How do we determine $\mathcal{P}_{i-1}$ (line 3), and how do we use it to find p_m (line 4)? The first question is easily answered, since the operations that we support on the BPS prefix at all times (see Section 3.1) are already sufficient to access each element of $\mathcal{P}_{i-1}$ in constant time. Let $p_1, \dots, p_k$ be exactly these elements in descending order. As explained earlier, they directly correspond to the unclosed parentheses of the BPS prefix, such that p_k corresponds to the leftmost unclosed parenthesis, and p_1 to the rightmost one. Therefore, we have $p_x = \text{rank}_{\text{open}}(\text{select}_{\text{uncl}}(k - x + 1)) - 1$. It remains to be shown how to efficiently find p_m.

4.1 Efficiently Computing p_m

Consider the following naive approach for computing p_m: Iterate over the indices $p_1, \dots, p_k$ in descending order (i.e. p_1 first, p_k last). For each index p_x, evaluate whether $\mathcal{S}_{p_x} \prec \mathcal{S}_i$ holds. As soon as this is the case, we have found p_m. The cost of this approach is high: A naive suffix comparison between $\mathcal{S}_{p_x}$ and $\mathcal{S}_i$ takes $\textsc{lce}(p_x, i) + 1$ individual character comparisons, which means that we spend $\mathcal{O}(m + \sum_{x=1}^{m} \textsc{lce}(p_x, i))$ time to determine m. However, the following property will allow us to decrease this time bound significantly:

▶ **Corollary 9** (Bitonic LCE Values). *Let $p_1, \dots, p_k$ be exactly the elements of $\mathcal{P}_{i-1}$ in descending order and let $p_m = \mathsf{pss}[i]$. Furthermore, let $\ell_x = \textsc{lce}(p_x, i)$ for all $x \in [1, k]$. We have $\ell_1 \leq \ell_2 \leq \cdots \leq \ell_{m-1}$ as well as $\ell_m \geq \ell_{m+1} \geq \cdots \geq \ell_k$.*

Proof. Follows from $\mathcal{S}_{p_1} \succ \ldots \succ \mathcal{S}_{p_{m-1}} \succ \mathcal{S}_i \succ \mathcal{S}_{p_m} \succ \ldots \succ \mathcal{S}_{p_k}$ and simple properties of the lexicographical order. ◀

From now on, we continue using the notation $\ell_x = \textsc{lce}(p_x, i)$ from the corollary. Note that the longest LCE between i and any of the p_x occurs either with p_m or with p_{m-1}. Let $\ell_{\max} = \max(\ell_{m-1}, \ell_m)$ be this largest LCE value, then our more sophisticated approach for determining m only takes $\mathcal{O}(m + \ell_{\max})$ time. It consists of two steps: First, we determine a candidate interval $(u, w] \subseteq [1, k]$ of size at most $\ell_{\max}$ that contains m. In the second step we gradually narrow down the borders of the candidate interval until the exact value of m is known.

Figure 3 Matching character comparisons when determining p_m. On the left we have the suffix $\mathcal{S}_i$ as well as $\mathcal{S}_{p_1}, \mathcal{S}_{p_2}, \ldots, \mathcal{S}_{p_w}$, which are relevant for the first step. Each prefix $\alpha, \beta, \gamma, \delta$ highlights the LCP between the respective suffix $\mathcal{S}_{p_x}$ and $\mathcal{S}_i$. On the right side we have the suffixes $\mathcal{S}_{p_u}, \mathcal{S}_{p_{u+1}}, \ldots, \mathcal{S}_{p_w}$, which are relevant for the second step. (Best viewed in color.)

Step 1: Find a candidate interval. Our goal is to find $(u, w] = (u, u + \ell_u + 1]$ with $m \in (u, w]$. Initially, we naively compute $\ell_1 = \text{LCE}(p_1, i)$, allowing us to evaluate $\mathcal{S}_{p_1} \prec \mathcal{S}_i$ in constant time. If this holds, then we have $m = 1$ and no further steps are necessary. Otherwise, let $u \leftarrow 1$ and (i) let $w \leftarrow u + \ell_u + 1$. We already know that $u < m$ holds. Now we have to evaluate if $m \leq w$ also holds. Therefore, we compute $\ell_w = \text{LCE}(p_w, i)$ naively, which allows us to check in constant time if $\mathcal{S}_{p_w} \prec \mathcal{S}_i$ and decide if $m \leq w$ holds. If this is not the case, then we assign $u \leftarrow w$ as well as $\ell_u \leftarrow \ell_w$ and continue at (i). If however $\mathcal{S}_{p_w} \prec \mathcal{S}_i$ holds, then we have $m \leq w$ and therefore $m \in (u, w]$. Figure 3 (left) outlines the procedure.

Step 2: Narrow down $(u, w]$ to the exact value of m. Now we gradually tighten the borders of the candidate interval. If ℓ_u is smaller than ℓ_w, then we try to increase u by one. Otherwise, we try to decrease w by one.

Assume that we have $\ell_u < \ell_w$, then it follows from Corollary 9 that $\ell_{u+1} \geq \ell_u$ holds. Therefore, when computing ℓ_{u+1} we can simply skip the first ℓ_u character comparisons. Now we use ℓ_{u+1} to evaluate in constant time if $\mathcal{S}_{p_{u+1}} \succ \mathcal{S}_i$ holds. If that is the case, then we have $u + 1 < m$ and thus we can assign $u \leftarrow u + 1$ and start Step 2 from the beginning. If however $\mathcal{S}_{p_{u+1}} \prec \mathcal{S}_i$ holds, then we have $m = u + 1$ and no further steps are necessary. In case of $\ell_u \geq \ell_w$ we proceed analogously. Once again, Figure 3 (right) visualizes the procedure.

Time Complexity. Step 1 is dominated by computing LCE values. Determining the final LCE value ℓ_w takes $\ell_w + 1$ individual character comparisons and thus $\Theta(\ell_w + 1)$ time. Whenever we compute any previous value of ℓ_w, we increase w by $\ell_w + 1$ afterwards. Therefore, the time for computing all LCE values is bound by $\Theta(w + \ell_w) = \Theta(u + \ell_u + \ell_w) \subseteq \mathcal{O}(m + \ell_{\max})$. Since initially $(u, w]$ has size at most $\ell_{\max}$, we call Step 2 at most $\mathcal{O}(\ell_{\max})$ times. With every call we increase ℓ_u or ℓ_w by exactly the number of matching character comparisons that we perform. Therefore, the total number of matching character comparisons is bound by $2\ell_{\max}$.

Thus, the total time needed for Step 2 is bound by $\mathcal{O}(\ell_{\max})$. In sum, processing index i takes $\mathcal{O}(m + \ell_{\max})$ time. For the total processing time of all indices (and thus the execution time of Algorithm 1) we get:

$$\begin{aligned} &\sum_{i=1}^{n} \mathcal{O}(\overbrace{|\mathcal{P}_{i-1} \cap [\mathsf{pss}[i], i]|}^{m}) + \sum_{i=1}^{n} \mathcal{O}(\overbrace{\max_{p_x \in \mathcal{P}_{i-1}} \mathrm{LCE}(p_x, i)}^{\ell_{\max}}) \\ = \quad &\mathcal{O}(n) \qquad\qquad\qquad + \qquad \mathcal{O}(n^2) \end{aligned}$$

(The $\mathcal{O}(m)$-terms sum to $\mathcal{O}(n)$ since $m - 1$ is exactly the number of closing parentheses that we write while processing i, and there are exactly $n+1$ closing parentheses in the entire BPS.) As it appears, the total time bound of the algorithm is still far from linear time. However, it is easy to identify the crucial time component that makes the algorithm too expensive. From now on we call the $\mathcal{O}(m)$ term of the processing time *negligible*, while the $\mathcal{O}(\ell_{\max})$ term is called *critical*.

Clearly, if we could somehow remove the critical terms, we would already achieve linear time. There exists a variety of data structures that could help us to achieve this goal by accelerating suffix comparisons, e.g. the (compressed or sparse) suffix tree, the (compressed) suffix array, or dedicated data structures for fast LCE queries. However, all of theses data structures either require more than $\mathcal{O}(n)$ bits of construction space, or more than $\mathcal{O}(n)$ construction time, or they are non-deterministic, or their efficiency depends on the alphabet or the compressability of the text. For example, there exists a linear time construction algorithm for the sparse suffix tree [15], but it is non-deterministic. This motivates the techniques that we describe in the following sections, which directly remove the critical terms without relying on any of the aforementioned data structures. This way, the execution time of Algorithm 1 decreases to $\mathcal{O}(n)$, while the additional working space remains unchanged.

5 Achieving Linear Time

The critical time component for processing index i is $\ell_{\max} = \max_{p_x \in \mathcal{P}_{i-1}} \mathrm{LCE}(p_x, i)$. When processing i with the technique from Section 4.1, we inherently find out the exact value of $\ell_{\max}$, and we also discover the index $p_{\max}$ for which we have $\mathrm{LCE}(p_{\max}, i) = \ell_{\max}$. From now on, we simply use $\ell = \ell_{\max}$ and $j = p_{\max}$. While discovering a large LCE value ℓ is costly, it yields valuable structural information about the input text: There is a repeating substring of length ℓ with occurrences $\mathcal{S}[j..j + \ell)$ and $\mathcal{S}[i..i + \ell)$. Intuitively, there is also a large repeating structure in the PSS tree, and consequently a repeating substring in $\mathcal{B}_{\mathsf{pss}}$. This motivates the techniques shown in this section, which conceptually alter Algorithm 1 as follows: Whenever we finish processing an index i with critical cost ℓ, we skip the next $\Omega(\ell)$ iterations of the loop by simply extending the BPS prefix with the copy of an already computed part, which means that the amortized critical cost per index becomes constant.

Depending on j and ℓ we choose either the *run extension* (Section 5.1) or the *amortized look-ahead* (Section 5.2) to perform the extension. Algorithm 2 outlines our final construction algorithm on a higher level, and complements the written description by showing when the special cases arise. Before going into detail, we point out that $\mathcal{S}[j..i)$ is a Lyndon word. As mentioned earlier, it follows from Corollary 9 that j equals p_m or p_{m-1}. Since i is the first node that is not a descendant of p_{m-1}, we have $\mathsf{nss}[p_{m-1}] = i$. Therefore, if $j = p_{m-1}$ holds, we have $\mathsf{nss}[j] = i$, which by definition implies that $\mathcal{S}[j..i)$ is a Lyndon word. If however $j = p_m = \mathsf{pss}[i]$ holds, then $\mathcal{S}[j..i)$ is a Lyndon word because of Lemma 4.

Algorithm 2 BuildPssBpsLinear.

```
Input: String $\mathcal{S}$ of length $n$
Output: BPS of the PSS Tree of $\mathcal{S}$
1: $\mathcal{B}_{\mathsf{pss}} \leftarrow$ (
2: for $i = 1$ to $n$ do
3:     Let $\mathcal{P}_{i-1} = \{p_1, \ldots, p_k\}$ with $\mathsf{pss}[p_x] = p_{x+1}$
4:     Determine $p_m = \mathsf{pss}[i]$,
           using the technique from Section 4.1, causing critical cost $\ell$ and
           discovering the index $j$ with $\textsc{lce}(j, i) = \ell$ as described in the
           beginning of Section 5.
5:     Append $m - 1$ closing parentheses to $\mathcal{B}_{\mathsf{pss}}$
6:     Append one opening parenthesis to $\mathcal{B}_{\mathsf{pss}}$
       (For any $x$, let $o_x$ be the opening parenthesis of node $x$.)
7:     if $\ell \geq 2(i - j)$ then
8:         Apply the run extension as described in Section 5.1.
               Let $t = \lfloor \ell/(i - j) \rfloor + 1$. Take $\mathcal{B}_{\mathsf{pss}}(o_j..o_i]$ and append it $(t - 2)$
               times to $\mathcal{B}_{\mathsf{pss}}$. Continue in line 2 with $i \leftarrow i + (t - 2) \cdot (i - j)$.
9:     else
10:        Apply the amortized look-ahead as described in Section 5.2.
               Using Lemma 13, find the largest value $\chi \in [1, \lfloor \ell/4 \rfloor]$ that sat-
               isfies $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\chi-1}] = \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\chi-1}]$, and append a copy of
               $\mathcal{B}_{\mathsf{pss}}(o_j..o_{j+\chi-1}]$ to $\mathcal{B}_{\mathsf{pss}}$. Continue in line 2 with $i \leftarrow i + \chi$. If
               $\chi < \lfloor \ell/4 \rfloor$, then iteration $i + \chi$ will automatically skip additional
               $\Omega(\ell)$ iterations by using the run extension.
11: Append $|\mathcal{P}_n|$ closing parentheses to $\mathcal{B}_{\mathsf{pss}}$
```

5.1 Run Extension

We apply the run extension iff we have $\ell \geq 2(i - j)$. It is easy to see that in this case $\mathcal{S}[j..j+\ell)$ and $\mathcal{S}[i..i+\ell)$ overlap such that the Lyndon word $\mu = \mathcal{S}[j..i)$ repeats itself at least three times, starting at index j. We call the substring $\mathcal{S}[j..i+\ell)$ *Lyndon run with period* $|\mu|$. The number of *repetitions* is $t = \lfloor \ell/|\mu| \rfloor + 1 \geq 3$, and the starting positions of the repetitions are $r_1, \ldots, r_t$ with $r_1 = j$, $r_2 = i$, and generally $r_x = r_{x-1} + |\mu|$. In a moment we will show that in this particular situation the following lemma holds:

▶ **Lemma 10.** *Let o_x be the index of the opening parenthesis of node x in $\mathcal{B}_{\mathsf{pss}}$. Then we have $\mathcal{B}_{\mathsf{pss}}[o_{r_1}..o_{r_2}] = \mathcal{B}_{\mathsf{pss}}[o_{r_2}..o_{r_3}] = \cdots = \mathcal{B}_{\mathsf{pss}}[o_{r_{t-1}}..o_{r_t}]$.*

Expressed less formally, each repetition of μ – except for the last one – induces the same substring in the BPS. Performing the run extension is as easy as taking the already written substring $\mathcal{B}_{\mathsf{pss}}(o_{r_1}..o_{r_2}] = \mathcal{B}_{\mathsf{pss}}(o_j..o_i]$, and appending it $t - 2$ times to $\mathcal{B}_{\mathsf{pss}}$. Afterwards, the last parenthesis that we have written is the opening parenthesis of node r_t, and we continue the execution of Algorithm 1 with iteration $r_t + 1$. Thus, we have skipped the processing of $r_t - i$ indices. Since

$$r_t - i \;=\; (t-2)\cdot|\mu| \;\geq\; \frac{(t-2)\cdot|\mu|}{t\cdot|\mu|}\cdot\ell \;\geq\; \frac{1}{3}\cdot\ell \;=\; \Omega(\ell)\ ,$$

it follows that the average critical cost per index from $[i, r_t]$ is constant.

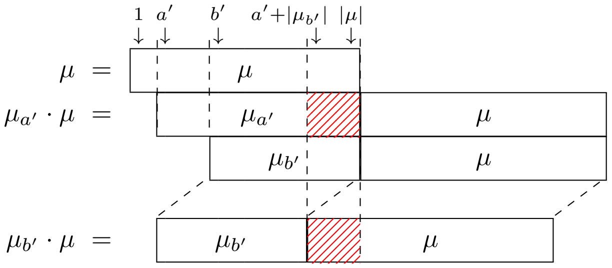
Proving the Lemma. It remains to be shown that Lemma 10 holds. It is sufficient to prove the correctness for $t = 3$, since the correctness for the general case follows by repeatedly applying the lemma with $t = 3$. Therefore, we only have to show $\mathcal{B}_{\mathsf{pss}}[o_{r_1}..o_{r_2}] = \mathcal{B}_{\mathsf{pss}}[o_{r_2}..o_{r_3}]$.

Isomorphic Subtrees. Since μ is a Lyndon word, it is easy to see that the suffixes at the starting positions of repetitions are lexicographically smaller than the suffixes that begin in between the starting positions of repetitions, i.e. we have $\forall x \in (r_1, r_2) : \mathcal{S}_{r_1} \prec \mathcal{S}_x$ and $\forall x \in (r_2, r_3) : \mathcal{S}_{r_2} \prec \mathcal{S}_x$. Consequently, the indices from (r_1, r_2) are descendants of r_1 in the PSS tree, and the indices from (r_2, r_3) are descendants of r_2 in the PSS tree, i.e. each of the intervals $[r_1, r_2)$ and $[r_2, r_3)$ induces a tree.

Next, we show that these trees are actually isomorphic. Clearly, the tree induced by $[r_1, r_2)$ solely depends on the lexicographical order of suffixes that begin within $[r_1, r_2)$, and the tree induced by $[r_2, r_3)$ solely depends on the lexicographical order of suffixes that begin within $[r_2, r_3)$. Assume that the trees are *not* isomorphic, then there must be a suffix comparison that yields different results in each interval, i.e. there must be offsets $a, b \in [0, |\mu|)$ with $a \neq b$ such that $\mathcal{S}_{r_1+a} \prec \mathcal{S}_{r_1+b} \iff \mathcal{S}_{r_2+a} \succ \mathcal{S}_{r_2+b}$ holds. However, this is impossible, as shown by the lemma below.

▶ **Lemma 11.** *For all $a, b \in [0, |\mu|)$ with $a \neq b$ we have $\mathcal{S}_{r_1+a} \prec \mathcal{S}_{r_1+b} \iff \mathcal{S}_{r_2+a} \prec \mathcal{S}_{r_2+b}$.*

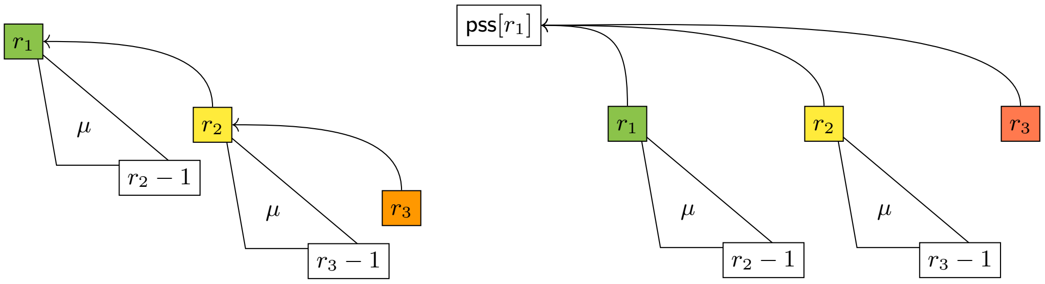
Proof. Assume w.l.o.g. $a < b$, and let $a' = a + 1$ and $b' = b + 1$. We can show that the strings $\mu_{a'} \cdot \mu$ and $\mu_{b'} \cdot \mu$ have a mismatch:



Consider the two hatched areas in the drawing above. The top area highlights the suffix $\mu_{a'+|\mu_{b'}|}$ of μ, which has length $c = |\mu| - (a' + |\mu_{b'}|) + 1$. The bottom area highlights the prefix $\mu[1..c]$ of μ. Since μ is a Lyndon word, there is no proper non-empty suffix of μ that is also a prefix of μ. It follows that the hatched areas cannot be equal, i.e. $\mu_{a'+|\mu_{b'}|} \neq \mu[1..c]$. This guarantees a mismatch between $\mu_{a'} \cdot \mu$ and $\mu_{b'} \cdot \mu$. Therefore, appending an arbitrary string to $\mu_{a'} \cdot \mu$ and $\mu_{b'} \cdot \mu$ does not influence the outcome of a lexicographical comparison. The statement of the lemma directly follows by appending $\mathcal{S}_{r_3}$ and $\mathcal{S}_{r_4}$ respectively:

$$\mu_{a'}\cdot\mu \prec \mu_{b'}\cdot\mu \iff \underbrace{\mu_{a'}\cdot\mu\cdot\mathcal{S}_{r_3}}_{=\ \mathcal{S}_{r_1+a}} \prec \underbrace{\mu_{b'}\cdot\mu\cdot\mathcal{S}_{r_3}}_{=\ \mathcal{S}_{r_1+b}} \iff \underbrace{\mu_{a'}\cdot\mu\cdot\mathcal{S}_{r_4}}_{=\ \mathcal{S}_{r_2+a}} \prec \underbrace{\mu_{b'}\cdot\mu\cdot\mathcal{S}_{r_4}}_{=\ \mathcal{S}_{r_2+b}}$$

◀



(a) Increasing run. **(b)** Decreasing run.

Figure 4 The run of the Lyndon word $\mu = \mathcal{S}[r_1, r_2) = \mathcal{S}[r_2, r_3) = \mathcal{S}[r_3, r_3{+}|\mu|)$ induces isomorphic subtrees in the PSS tree. If $\mathcal{S}_{r_1} \prec \mathcal{S}_{r_2}$, then the roots of the subtrees form a chain **(a)**. Otherwise, they are siblings **(b)**.

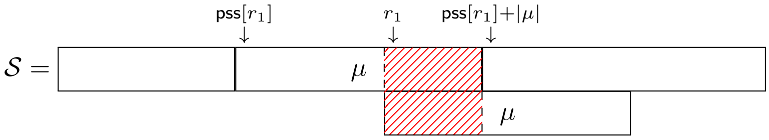
Finally, we show that in the PSS tree the induced isomorphic trees are connected in a way that ultimately implies $\mathcal{B}_{\mathsf{pss}}[o_{r_1}..o_{r_2}] = \mathcal{B}_{\mathsf{pss}}[o_{r_2}..o_{r_3}]$. There are two possible scenarios for this connection, which depend on the so called *direction* of the Lyndon run. We call a run *increasing* iff $\mathcal{S}_{r_1} \prec \mathcal{S}_{r_2}$ holds, and *decreasing* otherwise.

Increasing Runs. First, we focus on increasing runs. It follows from $\mathcal{S}_{r_1} \prec \mathcal{S}_{r_2} \iff \mu \cdot \mathcal{S}_{r_2} \prec \mu \cdot \mathcal{S}_{r_3} \iff \mathcal{S}_{r_2} \prec \mathcal{S}_{r_3}$ that $\mathcal{S}_{r_1} \prec \mathcal{S}_{r_2} \prec \mathcal{S}_{r_3}$. Since μ is a Lyndon word, we have $\forall x \in (r_1, r_2) : \mathcal{S}_{r_2} \prec \mathcal{S}_x$ as well as $\forall x \in (r_2, r_3) : \mathcal{S}_{r_3} \prec \mathcal{S}_x$. Therefore, we have $\mathsf{pss}[r_2] = r_1$ and $\mathsf{pss}[r_3] = r_2$, and the isomorphic subtrees are connected as visualized in Figure 4a. It is easy to see that a preorder-traversal from r_1 to r_2 yields the same sequence of parentheses as a preorder-traversal from r_2 to r_3. Therefore we have $\mathcal{B}_{\mathsf{pss}}[o_{r_1}..o_{r_2}] = \mathcal{B}_{\mathsf{pss}}[o_{r_2}..o_{r_3}]$, which means that Lemma 10 holds for increasing runs.

Decreasing Runs. With the same argument as for increasing runs, we have $\mathcal{S}_{r_1} \succ \mathcal{S}_{r_2} \succ \mathcal{S}_{r_3}$ in decreasing runs. We also have $\forall x \in (r_1, r_2) : \mathcal{S}_{r_2} \prec \mathcal{S}_x$ as well as $\forall x \in (r_2, r_3) : \mathcal{S}_{r_3} \prec \mathcal{S}_x$, which means that $\mathsf{pss}[r_2] \leq \mathsf{pss}[r_1]$ and $\mathsf{pss}[r_3] \leq \mathsf{pss}[r_1]$ hold. In Lemma 12 we will show that in fact $\mathsf{pss}[r_1] = \mathsf{pss}[r_2] = \mathsf{pss}[r_3]$ holds, such that the isomorphic subtrees are connected as visualized in Figure 4b. A preorder-traversal from r_1 to r_2 yields the same sequence of parentheses as a preorder-traversal from r_2 to r_3. Therefore we have $\mathcal{B}_{\mathsf{pss}}[o_{r_1}..o_{r_2}] = \mathcal{B}_{\mathsf{pss}}[o_{r_2}..o_{r_3}]$, which means that Lemma 10 holds for decreasing runs.

▶ **Lemma 12.** *In decreasing runs we have* $\mathsf{pss}[r_1] = \mathsf{pss}[r_2] = \mathsf{pss}[r_3]$.

Proof. As explained previously, we have $\mathsf{pss}[r_2] \leq \mathsf{pss}[r_1]$ and $\mathsf{pss}[r_3] \leq \mathsf{pss}[r_1]$, and thus only need to show $\mathcal{S}_{\mathsf{pss}[r_1]} \prec \mathcal{S}_{r_2}$ and $\mathcal{S}_{\mathsf{pss}[r_1]} \prec \mathcal{S}_{r_3}$. We will show below that μ cannot be a prefix of $\mathcal{S}_{\mathsf{pss}[r_1]}$, from which the statement of the lemma can be deduced easily since the suffixes $\mathcal{S}_{r_2}$ and $\mathcal{S}_{r_3}$ begin with the prefix μ. Assume for the sake of contradiction that μ is a prefix of $\mathcal{S}_{\mathsf{pss}[r_1]}$. If we also assume $\mathsf{pss}[r_1] + |\mu| > r_1$, we get:



As indicated by the hatched area, this implies that there is a proper non-empty suffix of μ that is also a prefix of μ, which is impossible because μ is a Lyndon word. Thus we have $\mathsf{pss}[r_1] + |\mu| \not> r_1$. Also, we cannot have $\mathsf{pss}[r_1] + |\mu| = r_1$, because then $\mathsf{pss}[r_1]$ would be the starting position of another repetition of μ, which would imply $\mathcal{S}_{\mathsf{pss}[r_1]} \succ \mathcal{S}_{r_1}$. It follows $\mathsf{pss}[r_1] + |\mu| < r_1$, i.e. $\mathsf{pss}[r_1] + |\mu| \in (\mathsf{pss}[r_1], r_1)$ and thus $\mathcal{S}_{\mathsf{pss}[r_1]+|\mu|} \succ \mathcal{S}_{r_1}$. However, this leads to a contradiction:

$$\begin{aligned} \mathcal{S}_{\mathsf{pss}[r_1]} \prec \mathcal{S}_{r_1} &\iff \mu \cdot \mathcal{S}_{\mathsf{pss}[r_1]+|\mu|} \prec \mu \cdot \mathcal{S}_{r_2} \\ &\iff \mathcal{S}_{\mathsf{pss}[r_1]+|\mu|} \prec \mathcal{S}_{r_2} \\ &\underset{\mathcal{S}_{r_1} \succ \mathcal{S}_{r_2}}{\implies} \mathcal{S}_{\mathsf{pss}[r_1]+|\mu|} \prec \mathcal{S}_{r_1} \end{aligned}$$ ◀

5.2 Amortized Look-Ahead

Finally, we show how to amortize the critical cost $\mathcal{O}(\ell)$ of processing index i if the run extension is not applicable, i.e. if we have $\ell < 2(i - j)$. Unfortunately, the trees induced by the nodes from $[j, j + \ell)$ and $[i, i + \ell)$ are not necessarily isomorphic. However, we can still identify a sufficiently large isomorphic structure. In a moment we will show that the following lemma holds:

▶ **Lemma 13.** *Let o_x be the index of the opening parenthesis of node x in $\mathcal{B}_{\mathsf{pss}}$. We either have $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}] = \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$, or there is an integer $\chi < \lfloor \ell/4 \rfloor$ with $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\chi-1}] = \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\chi-1}]$ and an index $h \in [i, i+\chi)$ such that $\mathcal{S}[h..i+\ell)$ is a Lyndon run of the Lyndon word $\mathcal{S}[h..i+\chi)$. We can determine which case applies, and also determine the value of χ (if applicable) in $\mathcal{O}(\ell)$ time and $\mathcal{O}(1)$ words of additional space.*

When performing the amortized look-ahead we first determine which case of the lemma applies. Then, if $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}] = \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$, we extend the known prefix of the BPS by appending a copy of $\mathcal{B}_{\mathsf{pss}}(o_j..o_{j+\lfloor \ell/4 \rfloor -1}]$, and continue the execution of Algorithm 1 with iteration $i + \lfloor \ell/4 \rfloor$. Since this way we skip the processing of $\lfloor \ell/4 \rfloor - 1 = \Omega(\ell)$ indices, the average critical cost per index from $[i, i + \lfloor \ell/4 \rfloor)$ is constant. If, however, the second case applies, then we determine the value of χ and extend the known prefix of the BPS by appending a copy of $\mathcal{B}_{\mathsf{pss}}(o_j..o_{j+\chi-1}]$, allowing us to continue the execution of Algorithm 1 with iteration $i+\chi$. We know that there is some $h \in [i, i+\chi)$ such that $\mathcal{S}[h..i+\ell)$ is a Lyndon run of the Lyndon word $\mu = \mathcal{S}[h..i+\chi)$. This run might even be longer: Let $\ell' = \textsc{lce}(h, i+\chi)$ (computed naively), then $\mathcal{S}[h..i + \chi + \ell')$ is the longest run of μ that starts at index h. If the run is increasing, then $\mathsf{pss}[i + \chi] = h$ holds (see Section 5.1), and the longest LCE that we discover when processing index $i + \chi$ is ℓ'. If the run is decreasing, then $\mathsf{pss}[i + \chi] = \mathsf{pss}[h]$ holds. Also in this case, the longest LCE that we discover when processing index $i + \chi$ is ℓ', since $\textsc{lce}(\mathsf{pss}[i + \chi], i + \chi)$ is less than $|\mu|$ (see proof of Lemma 12). Therefore, the critical cost of processing index $i + \chi$ will be $\mathcal{O}(\ell')$. However, since the Lyndon run has at least three repetitions, we will also skip the processing of $\Omega(\ell')$ indices by using the run extension. The algorithmic procedure for the second case can be summarized as follows: We process index i with critical cost $\mathcal{O}(\ell)$ and skip $\chi - 1$ indices afterwards. Then we process index $i + \chi$ with critical cost $\mathcal{O}(\ell')$ and skip another $\Omega(\ell')$ indices by using the run extension. Since we have $\ell' = \Omega(\ell)$, the total critical cost is $\mathcal{O}(\ell')$, and the total number of processed or skipped indices is $\Omega(\ell')$. Thus, the average critical cost per index is constant.

Proving Lemma 13. It remains to be shown that Lemma 13 holds. For this purpose, assume $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}] \neq \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$. From now on we refer to $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}]$ and $\mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$ as *left* and *right side*, respectively. Consider the first mismatch between the two, where w.l.o.g. we assume that the mismatch has an opening parenthesis on the left

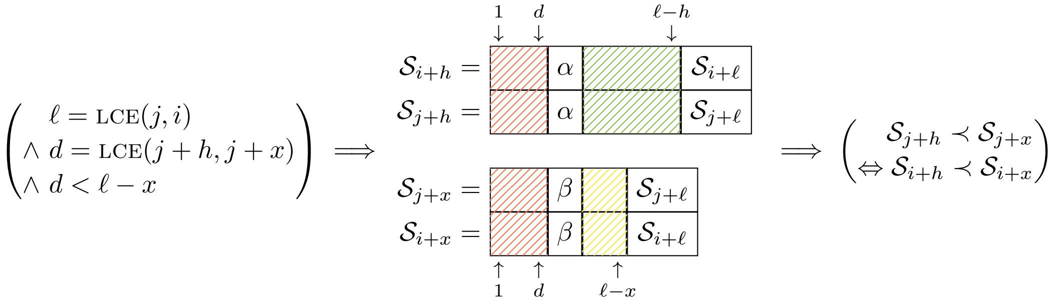


Figure 5 Proving Lemma 13. Equal colors indicate equal substrings. (Best viewed in color.)

side, and a closing one on the right side. On the left side, the opening parenthesis corresponds to a node $j+x$ with $x \in [1, \lfloor \ell/4 \rfloor)$ that is a child of another node $j+h$. Since $\mathcal{S}[j..j+\ell)$ is a Lyndon word, all nodes from $(j, j+\ell)$ are descendants of j. Consequently, we have $h \in [0,x)$. Now we look at the right side: Since we have a closing parenthesis instead of an opening one, we know that $i+x$ is not attached to $i+h$, but to a smaller node, i.e. we have $\mathsf{pss}[i+x] < i+h$. It follows that $\mathcal{S}_{j+h} \prec \mathcal{S}_{j+x}$ and $\mathcal{S}_{i+h} \succ \mathcal{S}_{i+x}$ hold. Let $d = \text{LCE}(j+h, j+x)$ and assume $d \leq \ell - x$. Then due to $\mathcal{S}_{j+h} \prec \mathcal{S}_{j+x}$ we have $\mathcal{S}[j+h+d] < \mathcal{S}[j+x+d]$. However, since we have $\mathcal{S}[j..j+\ell] = \mathcal{S}[i..i+\ell]$, it follows $\text{LCE}(i+h, i+x) = d$ and $\mathcal{S}[i+h+d] < \mathcal{S}[i+x+d]$, which contradicts $\mathcal{S}_{i+h} \succ \mathcal{S}_{i+x}$ (see Figure 5). Thus, it holds $d = \text{LCE}(j+h, j+x) \geq \ell - x$, allowing us to show that $\mathcal{S}[j+h..j+\ell)$ is a Lyndon run with period $x-h$. Since $\mathsf{pss}[j+x] = j+h$ holds, it follows from Lemma 4 that $\mathcal{S}[j+h..j+x)$ is a Lyndon word. Due to $\text{LCE}(j+h, j+x) > \ell - x \geq 3(\ell/4) \geq 3(x-h)$ we know that the Lyndon word repeats at least four times, and the run extends all the way to the end of $\mathcal{S}[j..j+\ell)$. Note that since the opening parenthesis of node $j+x$ causes the first mismatch between $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}]$ and $\mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$, we have $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+x-1}] = \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+x-1}]$. Therefore, $\chi \leftarrow x$ already satisfies Lemma 13.

Finally, we explain how to determine $\chi = x$ in $\mathcal{O}(\ell)$ time. As described above, if $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}] \neq \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$, then there is some offset $h < \lfloor \ell/4 \rfloor$ such that $\mathcal{S}[j+h..j+\ell)$ is a Lyndon run of at least four repetitions of a Lyndon word μ. Consequently, $\mathcal{S}[j+\lfloor \ell/4 \rfloor..j+\ell)$ has the form $\text{suf}(\mu) \cdot \mu^t \cdot \text{pre}(\mu)$ with $t \geq 2$, where $\text{suf}(\mu)$ and $\text{pre}(\mu)$ are a proper suffix and a proper prefix of μ. A string of this form is called *extended Lyndon run*. In Section 5.2.1 we propose an algorithm that checks whether or not $\mathcal{S}[j+\lfloor \ell/4 \rfloor..j+\ell)$ is an extended Lyndon run in $\mathcal{O}(\ell)$ time and constant additional space. If $\mathcal{S}[j+\lfloor \ell/4 \rfloor..j+\ell)$ is not an extended Lyndon run, then we have $\mathcal{B}_{\mathsf{pss}}[o_j..o_{j+\lfloor \ell/4 \rfloor -1}] = \mathcal{B}_{\mathsf{pss}}[o_i..o_{i+\lfloor \ell/4 \rfloor -1}]$ and no further steps are needed to satisfy Lemma 13. Otherwise, the algorithm from Section 5.2.1 also provides the period $|\mu|$ of the run, as well as $|\text{suf}(\mu)|$. In this case, we try to extend the extended Lyndon run to the left: We are now not only considering $\mathcal{S}[j+\lfloor \ell/4 \rfloor..j+\ell)$, but $\mathcal{S}[j..j+\ell)$. We want to find the leftmost index $j+h$ that is the starting position of a repetition of μ. Given $|\mu|$ and $|\text{suf}(\mu)|$, this can be done naively by scanning $\mathcal{S}[j..j+\lfloor \ell/4 \rfloor]$ from right to left, which takes $\mathcal{O}(\ell)$ time. If we have $h \geq \lfloor \ell/4 \rfloor - |\mu|$, then the first case of Lemma 13 applies and no further steps are necessary. Otherwise, we let $\chi \leftarrow h + |\mu|$. This concludes the proof of Lemma 13 and the description of our construction algorithm.

5.2.1 Detecting Extended Lyndon Runs

In this section, we propose a linear time algorithm that identifies extended Lyndon runs, i.e. strings of the form $\text{suf}(\mu) \cdot \mu^t \cdot \text{pre}(\mu)$ with $t \geq 2$, where $\text{suf}(\mu)$ and $\text{pre}(\mu)$ are a proper suffix and a proper prefix of μ. Our approach exploits properties of the Lyndon factorization, which is defined as follows:

▶ **Lemma 14** (Lyndon Factorization [5]). *Every non-empty string $\mathcal{S}$ can be decomposed into non-empty Lyndon words $s_1, s_2, \dots, s_m$ such that $\mathcal{S} = s_1 \cdot s_2 \cdot \ldots \cdot s_m$ and $\forall i \in [2, m] : s_{i-1} \succeq s_i$. There is exactly one such factorization for each string.*

▶ **Lemma 15.** *Let $\mathcal{S} = \mathrm{suf}(\mu) \cdot \mu^t \cdot \mathrm{pre}(\mu)$ be an extended Lyndon run. Let $x_1, \dots, x_{k_1}$ be the Lyndon factorization of $\mathrm{suf}(\mu)$, and let $y_1, \dots, y_{k_2}$ be the Lyndon factorization of $\mathrm{pre}(\mu)$. Then the Lyndon factorization of $\mathcal{S}$ is $x_1, \dots, x_{k_1}, \underbrace{\mu, \mu, \dots, \mu}_{t \text{ times}}, y_1, \dots, y_{k_2}$.*

Proof. Clearly, the factorization given by the lemma consists solely of Lyndon words. Thus, we only have to show $x_1 \succeq \ldots \succeq x_{k_1} \succeq \mu \succeq y_1 \succeq \ldots \succeq y_{k_2}$. Since we defined $x_1, \dots, x_{k_1}$ and $y_1, \dots, y_{k_2}$ to be the Lyndon factorizations of $\mathrm{suf}(\mu)$ and $\mathrm{pre}(\mu)$ respectively, we already know that $\forall i \in [2, k_1] : x_{i-1} \succeq x_i$ and $\forall i \in [2, k_2] : y_{i-1} \succeq y_i$ hold. It remains to be shown that $x_{k_1} \succeq \mu \succeq y_1$ holds. Since x_{k_1} is a non-empty suffix of $\mathrm{suf}(\mu)$ and thus also a non-empty proper suffix of μ, it follows that $x_{k_1} \succ \mu$ holds. Since y_1 is a prefix of $\mathrm{pre}(\mu)$ and thus also a prefix of μ, it follows (by definition of the lexicographical order) that $\mu \succ y_1$ holds. ◀

Lemma 15 implies that the longest factor of the Lyndon factorization of an extended Lyndon run is exactly the repeating Lyndon word μ. This is the key insight that we use to detect extended Lyndon runs:

▶ **Lemma 16.** *Let $\mathcal{S}$ be a string of length n. If $\mathcal{S}$ is an extended Lyndon run of the form $\mathcal{S} = \mathrm{suf}(\mu) \cdot \mu^t \cdot \mathrm{pre}(\mu)$, then we can determine $|\mu|$ and $|\mathrm{suf}(\mu)|$ in $\mathcal{O}(n)$ time and $\mathcal{O}(1)$ words of additional space.*

Proof. Using Duval's algorithm [8, Algorithm 2.1], we compute the Lyndon factorization of $\mathcal{S}$ in $\mathcal{O}(n)$ time and $\mathcal{O}(1)$ words of additional space. The algorithm computes and outputs the factors one-at-a time and in left-to-right order. Whenever it outputs a factor that is longer than all previous ones, we store its length l and its starting position d. Note that since we investigate each factor individually and then immediately discard it, we never need to store the entire factorization in memory. If $\mathcal{S}$ is an extended Lyndon run, then following Lemma 15 it must have the form $\mathcal{S} = \mathrm{suf}(\mu) \cdot \mu^t \cdot \mathrm{pre}(\mu)$ with $|\mathrm{suf}(\mu)| = d - 1$ and $|\mu| = l$. Since we know d and l, checking whether $\mathcal{S} = \mathrm{suf}(\mu) \cdot \mu^t \cdot \mathrm{pre}(\mu)$ holds can be achieved by performing a simple scan over $\mathcal{S}$. ◀

6 Algorithmic Summary & Adaptation to the Lyndon Array

We now summarize our construction algorithm for the PSS tree. We process the indices from left to right using the techniques from Section 4.1, where processing an index means attaching it to the PSS tree. Whenever the critical time of processing an index is $\mathcal{O}(\ell)$, we skip the next $\Omega(\ell)$ indices by using the run extension (Section 5.1) or the amortized look-ahead (Section 5.2). Thus, the critical time per index is constant, and the total worst-case execution time is $\mathcal{O}(n)$. In terms of working space, we only need $\mathcal{O}(n \lg\lg n / \lg n)$ bits to support the operations described in Section 3.1. The correctness of the algorithm follows from the description. We have shown:

▶ **Theorem 17.** *For a string $\mathcal{S}$ of length n we can compute its succinct Lyndon array $\mathcal{B}_{\mathsf{pss}}$ in $\mathcal{O}(n)$ time using $\mathcal{O}(n \lg\lg n / \lg n)$ bits of working space apart from the space needed for $\mathcal{S}$ and $\mathcal{B}_{\mathsf{pss}}$.*

The algorithm can easily be adapted to compute the Lyndon array instead of the PSS tree. For this purpose, we use a single array $\mathcal{A}$ (which later becomes the Lyndon array), and no further auxiliary data structures. We maintain the following invariant: At the time we start processing index i, we have $\mathcal{A}[j] = \mathsf{pss}[j]$ for $j \in \mathcal{P}_{i-1}$, and $\mathcal{A}[j] = \lambda[j]$ for $j \in [1, i) \setminus \mathcal{P}_{i-1}$. As before, we determine $p_m = \mathsf{pss}[i]$ with the techniques from Section 4.1. In Step 1 and Step 2 we require some access on elements of $\mathcal{P}_{i-1}$, which we can directly retrieve from $\mathcal{A}$. Apart from that, the algorithm remains unchanged. Once we computed p_m, we set $\mathcal{A}[i] \leftarrow p_m$ ($= \mathsf{pss}[i]$). Additionally, it follows that i is the first node that is not a descendant of any of the nodes $p_1, \ldots, p_{m-1}$, which means that we have $\mathsf{nss}[p_x] = i$ for any such node. Therefore, we assign $\mathcal{A}[p_x] \leftarrow i - p_x$ ($= \lambda[p_x]$). The run extension and the amortized look-ahead remain essentially unchanged, with the only difference being that we copy and append respective array intervals instead of BPS substrings (some trivial shifts on copied values are necessary). Once we have processed index n, we have $\mathcal{A}[j] = \mathsf{pss}[j]$ for $j \in \mathcal{P}_n$, and $\mathcal{A}[j] = \lambda[j]$ for $j \in [1, n] \setminus \mathcal{P}_n$. Clearly, all indices $p_x \in \mathcal{P}_n$ do not have a next smaller suffix, and we set $\mathcal{A}[p_x] \leftarrow n - p_x + 1 = \lambda[p_x]$. After this, we have $\mathcal{A} = \lambda$. Since at all times we only use $\mathcal{A}$ and no auxiliary data structures, the additional working space needed (apart from input and output) is constant. The linear execution time and correctness of the algorithm follow from the description. Thus we have shown:

▶ **Theorem 18.** *Given a string $\mathcal{S}$ of length n, we can compute its Lyndon array λ in $\mathcal{O}(n)$ time using $\mathcal{O}(1)$ words of working space apart from the space needed for $\mathcal{S}$ and λ.*

7 Experimental Results

We implemented our construction algorithm for both the succinct and the plain Lyndon array (LA-Succ and LA-Plain). The C++ implementation is publicly available at GitHub[2]. As a baseline we compared the throughput of our algorithms with the throughput of DivSufSort[3], which is known to be the fastest suffix array construction algorithm in practice [12]. Thus, it can be seen as a natural lower bound for any Lyndon array construction algorithm that depends on the suffix array. Additionally we consider LA-ISA-NSV, which builds the Lyndon array by computing next smaller values on the inverse suffix array (see [13], we use DivSufSort to construct the suffix array). For LA-Succ we only construct the succinct Lyndon array without the support data structure for fast queries. All experiments were conducted on the LiDO3 cluster[4], using an Intel Xeon E5-2640v4 processor and 64GiB of memory. We repeated each experiment five times and use the median as the final result. All texts are taken from the Pizza & Chili text corpus[5].

Table 1 shows the throughput of the different algorithms, i.e. the number of input bytes that can be processed per second. We are able to construct the plain Lyndon array at a speed of between 41 MiB/s (`fib41`) and 82 MiB/s (`xml`), which is on average 9.9 times faster than LA-ISA-NSV, and 8.1 times faster than DivSufSort. Even in the worst case, LA-Plain is still 6.8 times faster than LA-ISA-NSV, and 5.2 times faster than DivSufSort (`pitches`). When constructing the succinct Lyndon array we achieve around 86% of the throughput of LA-Plain on average, but never less than 81% (`pitches`). In terms of memory usage, we measured the additional working space needed apart from the space for the text and the

(succinct) Lyndon array. Both LA-Plain and LA-Succ never needed more than 0.002 bytes of additional memory per input character (or 770 KiB of additional memory in total), which is why we do not list the results in detail.

8 Summary

We showed how to construct the succinct Lyndon array in linear time using $\mathcal{O}(n \lg\lg n/\lg n)$ bits of working space. The construction algorithm can also produce the (non-succinct) Lyndon array in linear time using only $\mathcal{O}(1)$ words of working space. There are no other linear time algorithms achieving these bounds. Our algorithm performs also extremely well in practice. We envision applications of these practical algorithms in full-text indexing, such as an improved implementation of Baier's suffix array construction algorithm [1], or as a first step in sparse suffix sorting [11, 4].

Abstract

Fault tolerant distance preservers are sparse subgraphs that preserve distances between given pairs of nodes under edge or vertex failures. In this paper, we present the first non-trivial constructions of subset distance preservers, which preserve all distances among a subset of nodes S, that can handle either an edge *or* a vertex fault.

- For an n-vertex undirected weighted graph or weighted DAG $G = (V, E)$ and $S \subseteq V$, we present a construction of a subset preserver with $\widetilde{O}(|S|n)$ edges that is resilient to a single fault. In the single pair case ($|S| = 2$), the bound improves to $O(n)$. We further provide a nearly-matching lower bound of $\Omega(|S|n)$ in either setting, and we show that the same lower bound holds conditionally even if attention is restricted to unweighted graphs.
- For an n-vertex directed unweighted graph $G = (V, E)$ and $r \in V, S \subseteq V$,we present a construction of a preserver of distances in $\{r\} \times S$ with $\widetilde{O}(n^{4/3}|S|^{5/6})$ edges that is resilient to a single fault. In the case $|S| = 1$ the bound improves to $O(n^{4/3})$, and for this case we provide another matching conditional lower bound.
- For an n-vertex directed weighted graph $G = (V, E)$ and $r \in V, S \subseteq V$, we present a construction of a preserver of distances in $\{r\} \times S$ with $\widetilde{O}(n^{3/2}|S|^{3/4})$ edges that is resilient to a single vertex fault. (It was proved in [14] that the bound improves to $O(n^{3/2})$ when $|S| = 1$, and that this is conditionally tight.)

1 Introduction

Distance Preservers. This paper is about *distance preservers*, a graph-theoretic primitive that appears in work on spanners [16, 32, 23, 17, 2, 1, 24], hopsets [2, 28, 27], shortcutting [27, 2], shortest path algorithms [5, 4, 21, 18], etc.; recently, distance preservers have also been a popular topic in their own right [17, 20, 16, 12, 25, 18].

▶ **Definition 1** (Distance Preservers). *For a graph $G = (V, E)$ and a set $P \subseteq V \times V$ of "demand pairs", a subgraph $H = (V, E_H \subseteq E)$ is a distance preserver of G, P if*

$$\texttt{dist}_G(s,t) = \texttt{dist}_H(s,t) \text{ for all } (s,t) \in P.$$

When $P = S \times S$ for some $S \subseteq V$, we say that H is a subset distance preserver of G, S.

Most often, the goal is to determine the worst-case tradeoff between the number of demand pairs and the number of edges needed for a distance preserver. For example, a classic result in the area is that any p demand pairs in an n-node graph have a distance preserver on $O(np^{1/2})$ edges [20].

The subset distance preserver structure $P = S \times S$ is quite common in the known applications of distance preservers (e.g. [4, 21, 18]), and one of the primary reasons distance preservers were first developed was to address this setting [22]. Despite this, our understanding of subset distance preservers lags far behind our understanding of the general case. There is *no* graph setting in which the structure $P = S \times S$ is known to be useful towards proving sparser distance preservers, and yet our lower bounds get much worse when they are required to have this structure. To illustrate, one of the main questions in the area is whether one can generally have a subset preserver with only a constant number of edges per demand pair:

Is there an absolute constant $c > 0$ such that, for any $|P| = n^{2-c}$ demand pairs in an n-node graph, there is always a distance preserver on $O(|P|)$ edges?

In the *sourcewise* setting $P = S \times V$, the answer is clearly yes (build a shortest path tree rooted at each $s \in S$). In the *pairwise* setting, i.e. P is arbitrary, it was proved by Coppersmith and Elkin [20] that the answer is no (even if attention is restricted to undirected unweighted graphs). But in the intermediate *subset* setting $P = S \times S$, the question is completely open: we can neither prove it for undirected unweighted graphs, nor refute it for directed weighted graphs; all we know is that $c \leq \frac{2}{3}$ [12].

Fault Tolerance. Distance preservers and friends are often applied to networks or distributed systems where parts can spontaneously fail. A natural additional requirement for these applications is *fault-tolerance*, meaning roughly that the preserver is robust to these failures:

▶ **Definition 2** (Fault Tolerant Distance Preservers). *For a graph $G = (V, E)$ and demand pairs P, a distance preserver H of G, P is* fault tolerant (FT) *if for any vertex or edge x we have that $H \setminus \{x\}$ is still a distance preserver of $G \setminus \{x\}$.*[1] *We say H is* vertex (edge) fault tolerant*, abbreviated VFT (EFT), to indicate that x must specifically be a vertex (edge).*

The current literature reflects a world in which vertex faults are harder to analyze than edge faults; many basic questions in the area are closed for EFT but open for (V)FT [19, 9, 8, 13, 15]. To highlight one example:

For a single demand pair (s, t) in an undirected (possibly weighted) graph G, is there always an FT distance preserver on $O(n)$ edges?

In [14], it is proved that the answer is *yes* for the special case of edge failures. The argument leverages a convenient structural fact about edge failures, which may generally explain some of the EFT/VFT discrepancy: a shortest path in $G \setminus \{x\}$ is always the union of two shortest paths in G when x is an edge [3], but nothing like this seems to hold when x is a vertex. Accordingly, the above question is open when the failures can be vertices.

[1] One can also consider a version where several nodes/edges fail at once. However, recent lower bounds have proved that the available preserver quality is quite poor already for $f = 2$ faults [30, 14], so $f = 1$ may be the more applicable setting.

1.1 Our Results

In this work, we show that the $P = S \times S$ structure does actually seem to be useful in the FT setting. For background, it was proved by Bilo et al. [8] that any $|S|$ source nodes in an n-node undirected weighted graph has an EFT preserver on $\widetilde{O}(n|S|)$ edges. Our main results fill in several gaps around this result, extending to the general FT setting and providing corresponding lower bounds.

▶ **Theorem 3** (Undirected Graphs)**.** *For any undirected weighted n-node graph $G = (V, E, w)$ and set of source nodes $S \subseteq V$, there is a general FT subset distance preserver on $\widetilde{O}(n|S|)$ edges. When $|S| = 2$, the bound improves to $O(n)$. Moreover, for any given value of $|S|$ there are examples where $\Omega(n|S|)$ edges are needed.*

We note that Theorem 3 positively resolves the latter open question mentioned above. We think this bound $\widetilde{O}(n|S|)$ is surprising; to explain why, let us compare to the corresponding bounds in the non-faulty setting. Here the current state-of-the-art [20] is that $|S| = \sigma$ source nodes in an n-node graph have a subset distance preserver of size

$$O\left(\min\left\{n + n^{1/2}\sigma^2, n\sigma\right\}\right).$$

In particular, when $\sigma \geq \sqrt{n}$ the bound is $O(n\sigma)$. In other words, following Theorem 3, one can tolerate a fault in this parameter regime essentially *for free*. It is more likely that this reflects the weakness of our current understanding of non-faulty subset distance preservers, rather a world in which fault tolerance is actually free. Still, the non-faulty subset distance preserver bounds have resisted improvement for the last 15 years, so the unintuitive hypothesis of free fault tolerance suggested by Theorem 3 may be hard to refute.

Since Theorem 3 is essentially best possible, for the rest of the paper we investigate to what extent it extends to other graph settings. For example, what if attention is restricted to unweighted graphs? Our lower bound construction fundamentally relies on the use of edge weights, and thus it does not constrain this setting. However, we show that it can be replaced with a *conditional* lower bound: it will not be possible to meaningfully improve Theorem 3 for unweighted graphs without first improving on the non-faulty setting. This result will use a new parameter for distance preservers that we call the *gap*. For a graph G and demand pairs P, the gap is

$$\gamma(P) := \max_{(s,t),(s',t') \in P} \mathtt{dist}_G(s, t) - \mathtt{dist}_G(s', t').$$

Intuitively, the gap measures how close G, P are to a “layered” instance: except for a few degenerate cases, the gap is 0 if and only if G is a layered graph, P is a subset of the first × last layer, and the shortest paths for P cross the layers directly without backtracking. We use the following technical hypothesis for our unweighted lower bound:

▶ **Hypothesis 4.** *For any $\sigma = \sigma_n$, there is an n-node undirected unweighted graph G and demand pairs $P = S \times T$ with*

$$|S| \leq \sigma \qquad \textit{and} \qquad |T| \leq \sqrt{\frac{n\sigma}{(\gamma(P) + 1)}}$$

such that any distance preserver has $\Omega(n\sigma)$ edges.

We remark that this hypothesis is only plausible when $|T| = \Omega(\sigma)$, and hence we need $\gamma(P) = O(n/\sigma)$. But the current understanding of non-faulty distance preservers is compatible with the bounds in Hypothesis 4, even if we were to assume more strongly that $\gamma(P) = 0$.

▶ **Theorem 5.** *Assuming Hypothesis 4, for any $\sigma = \sigma_n$, there are examples of undirected unweighted n-node graphs and node subsets of size $|S| = \sigma$ where any FT distance preserver needs $\Omega(n\sigma)$ edges.*

Thus Theorem 3 is conditionally tight even for unweighted graphs. Next, we ask if it extends to directed graphs. For the special case of DAGs, we observe that any replacement path avoiding a failure can be represented by concatenation of two original shortest paths linked together by an edge (much like the EFT setting). This allows the above content to extend directly to preservers for DAGs.

▶ **Theorem 6** (DAGs)**.** *The upper and lower bound of Theorem 3 both still hold when the input graph G is a weighted DAG. If G is an unweighted DAG, then the lower bound of Theorem 5 still holds as well, assuming that Hypothesis 4 also holds for unweighted DAGs.*

The general directed setting is trickier. The question of single-pair FT preservers for directed weighted graphs was settled in [14]; these need at least $\Omega(n^{4/3})$ and at most $O(n^{3/2})$ edges,[2] and hence Theorem 3 does not extend to this setting. For directed unweighted graphs, we provide the first improvements on this upper bound:

▶ **Theorem 7** (Directed Unweighted Graphs)**.** *For any directed unweighted n-node graph $G = (V, E)$, and demand pairs $(r, S) \in V \times 2^V$ there is an FT distance preserver on $\widetilde{O}(n^{4/3}|S|^{5/6})$ edges. When $|S| = 1$, the bound improves to $O(n^{4/3})$.*

Like before, we show conditional tightness of this bound, although here only in the single-pair setting. Our lower bound needs the following hypothesis:

▶ **Hypothesis 8.** *There is an n-node directed unweighted graph G and demand pairs $P = S \times T$ with*

$$|S|, |T|, \gamma(P) = O(n^{1/3})$$

such that any distance preserver has $\Omega(n^{4/3})$ edges.

Hypothesis 8 is more tenuous than Hypothesis 4, as it is right on the boundary of current techniques. We will discuss the interpretation of these hypotheses more shortly. Still, the point is that one cannot meaningfully improve our single-fault distance preservers without first gaining an improved understanding of the non-faulty case:

▶ **Theorem 9.** *Assuming Hypothesis 8, there are examples of directed unweighted n-node graphs and single demand pairs where any FT distance preserver needs $\Omega(n^{4/3})$ edges.*

We remark that if the goal is just to refute the extension of Theorem 3 to directed graphs, rather than to show exact tightness of Theorem 7, then one can get by with a weaker assumption than Hypothesis 8 (e.g. the preserver lower bound can be $\Omega(n^{1.01})$, or one can trade this off with a relaxation of $|S|, |T|, \gamma(P)$).

Lastly, we mention that our techniques give a nontrivial extension of the single-pair result in [14] to the multi-target setting.

[2] More specifically, it was proved that the correct size bound is exactly that of a non-faulty distance preserver of n demand pairs in an n-node directed weighted graph. Due to [20], this is at least $\Omega(n^{4/3})$ and at most $O(n^{3/2})$.

▶ **Theorem 10** (Directed Weighted Graphs). *For any directed weighted n-node graph $G = (V, E)$ and demand pairs $(r, S) \in V \times 2^V$, there is an FT distance preserver on $\widetilde{O}(n^{3/2}|S|^{3/4})$ edges.*

We recall from [14] that the bound improves to $O(n^{3/2})$ when $|S| = 1$, and that this single-pair bound is unimprovable under the hypothesis that the current bounds for non-faulty distance preservers of directed weighted graphs are tight.

1.2 Interpretation of Hypotheses

Since our lower bounds rely on Hypotheses 4 and 8, we will give them some more context here and discuss how likely they are to be true. Currently, except for a certain tiny range of parameters [12], the state-of-the-art upper bounds for non-faulty $S \times T$ preservers are based entirely on a property called *consistency*:

▶ **Definition 11** (Consistency). *A set of paths Π in a (possibly directed) graph G are* consistent *if, for any $\pi_1, \pi_2 \in \Pi$ with nodes $u < v \in \pi_1, u < v \in \pi_2$, the subpaths $\pi_1[u \rightsquigarrow v], \pi_2[u \rightsquigarrow v]$ are equal.*

In other words, given any set of consistent paths with endpoints in $S \times T$, one can exploit the consistency property to prove upper bounds on the total number of edges contained in the union of all these paths [20, 12]. Interpreting $S \times T$ as demand pairs for a preserver, it is not hard to break shortest path ties in such a way that the chosen paths are consistent, and so these "consistency bounds" yield preserver upper bounds, which are essentially state-of-the-art.

With this in mind, let us imagine a weaker version of Hypotheses 4, where we hypothesize a *consistent* set of $S \times T$ paths with $\Omega(n\sigma)$ edges in their union, the gap $\gamma(S \times T)$ defined as the maximum difference between any two path lengths, and $|S|, |T|$ are bounded as before. From a construction in [16], this hypothesis is true. The similar "consistency-weakened" version of Hypothesis 8 is also true, from an unpublished construction of Bodwin and Reingold.

So, the truth of Hypotheses 4 and 8 essentially depends on how smoothly one can pass from consistent paths to unique shortest paths without destroying the other important properties of the construction, like the edge density and the gap. It is hard to say for sure whether this will be possible. Our guess is that the consistency bounds can be improved – and thus Hypotheses 4, 8 are false – but that this will require major new technical ideas that are not currently in the literature. The main evidence for this is that the consistency bounds have been polynomially improved for general *pairwise* preservers, which do not require the structure $P = S \times T$ [16]. But in the $P = S \times T$ setting the consistency bounds have resisted improvement for the last 15 years [20], despite significant research effort, so we feel that Hypotheses 4, 8 accurately mark the boundaries of current knowledge. Thus we interpret these hypotheses, and the corresponding lower bounds, as proof that no more progress can really be made in the FT setting until the non-faulty setting is understood first.

1.3 Related Work

For an n-vertex unweighted graph G and a set of sources S, Parter and Peleg [31] showed that there exists an $S \times V$ FTP with $O\left(n^{3/2}|S|^{1/2}\right)$ edges. This bound holds also for the case of a single node failure and when the graph is directed. They also showed that this result is existentially optimal, namely, there exist n-vertex graphs and a set of sources S such that any $S \times V$ FTP has at least $\Omega\left(n^{3/2}|S|^{1/2}\right)$ edges.

For the more general case of $P = S \times T$, [8] showed an FTP of size $\widetilde{O}\left(n^{4/3}|S|^{1/3}|T|^{1/3}\right)$ under edge failure. An FTP for a single pair in undirected (possibly weighted) graph of linear size was explicitly presented in [14], but was also implied by previous replacement-paths algorithms, e.g., [29].

Considerably much less is known for the multiple fault setting (even for edges faults). Parter [30] showed an upper bound of $O(n^{5/3})$ edges for $\{s\} \times V$ (edge) f-FTP with $f = 2$, in undirected unweighted graphs. A matching lower bound of $\Omega\left(|S|^{1/(f+1)} \cdot n^{2-1/(f+1)}\right)$ for sourcewise ($P = S \times V$) f-FTP was also provided in [30], for any f. Gupta and Khan [26] extended this result, providing a tight upper bound for sourcewise ($S \times V$) f-FTP with $f = 2$. This bound holds also for the case of a two vertex failures and when the graph is directed. For the more general case of f failures, Bodwin et al. [14] showed an upper bound of$\widetilde{O}(f \cdot |S|^{1/2^f} \cdot n^{2-1/2^f})$ edges for a $S \times V$ f-FTP. This result holds under both edge and vertex faults, and in directed graphs. For weighted graphs, [14] showed that even a single pair f-FTP with $f \geq 2$ has $\Theta(n^2)$ edges.

Baswana and Khanna [7] proved the existence of a $(1+\epsilon)$ multiplicative vertex FT spanner for $P = \{s\} \times V$, with $O(n/\epsilon^3 + n\log n)$ edges, for any $\epsilon > 0$. Recently, Bilo et al. [11] improved this result to $O(n \log n/\epsilon^2)$, for both edge and vertex single failure. In [10], Bilò et al. showed construction of approximate FTP to handle multiple edge failures. They showed that for any $f \geq 1$ and for $P = \{s\} \times V$, we can compute an FTP $O(fn)$ size that after failure of f edge preserves distance up to a multiplicative stretch of $(2f + 1)$.

1.4 Preliminaries and Tools

Graph Notations. We use the following graph notations and definitions in the context of a given undirected graph $G = (V, E, w)$ with $n = |V|$, $m = |E|$ and a weight function $w : E \to \mathbb{R}^+$. To avoid complications due to shortest-paths of the same length, we assume throughout that all shortest path are computed with a consistent tie-breaking function π that guarantees the uniqueness of the shortest-paths[3]. For every $x, y \in V$, and a subgraph $G' \subseteq G$, let $\pi(x, y, G')$ be the (unique) x-y shortest path in G', when $G' = G$ we may simply write $\pi(x, y)$. For any path P, let $P[x, y]$ be the subpath of P between x and y and let $P(x, y) = P[x, y] \setminus \{x, y\}$. For a node $v \in V$, let T_v be the shortest path tree rooted at v. For $v, x \in V$, let $T_v(x)$ the subtree of T_v rooted at x.

For $s, t \in V$ and a failure $x \in V$, the *replacement path* $P_{s,t,x}$ is the unique s-t shortest path in $G \setminus \{x\}$. To avoid cumbersome notation, when s or t are clear from context, we may omit them from the notation. Let $D_{s,t,x}$ be the *detour* segment of the replacement path defined by $P_{s,t,x} \setminus \pi(s, t)$.

For a path P, let $E(P)$ denote its edges and $V(P)$ denote its vertices. Similarly, for a collection of paths $\mathcal{P}$, we denote their edges and vertices with $E(\mathcal{P}) = \bigcup_{P \in \mathcal{P}} E(P)$ and $V(\mathcal{P}) = \bigcup_{P \in \mathcal{P}} V(P)$ respectively. We denote the first and last vertex of a path P by $\mathrm{first}(P)$ and $\mathrm{last}(P)$ respectively. Similarly, for a collection of path $\mathcal{P}$, we denote their sources and terminals with $\mathrm{first}(\mathcal{P}) = \bigcup_{P \in \mathcal{P}} \mathrm{first}(P)$ and $\mathrm{last}(\mathcal{P}) = \bigcup_{P \in \mathcal{P}} \mathrm{last}(P)$. For a tree T and vertices u, v let $\mathrm{LCA}(u, v)$ denote the *least common ancestor* of u and v in T.

Heavy Path Decomposition. For a shortest path tree T_s rooted at s, we use the *heavy-path decomposition* technique devised by Sleator and Tarjan [33] in order to break the tree T_s into vertex-disjoint paths with several desired properties. The following lemma summarizes the main properties of this partitioning scheme (proof can be also found in [7]).

[3] See Def. 11 for a formal definition of a consistent tie-breaking.

▶ **Lemma 12** ([33]). *There exist a linear time algorithm that given an n-vertex tree T computes a path Q in T whose removal breaks T into vertex-disjoint subtrees $T_1, ..., T_\ell$ such that for each $i \leq \ell$:*

- *$|V(T_i)| \leq n/2$ and $V(Q) \cap V(T_i) = \emptyset$,*
- *T_i is connected to Q through some edge.*

The desired decomposition is obtained by recursively applying Lemma 12 (on each of the subtrees T_i), getting a partition of T into vertex disjoint paths $\mathcal{HP}(T)$. A useful property of the decomposition is that for every edge $(u, v) \in T$ that does not appear in any of the paths $\mathcal{HP}(T)$, it holds that $|V(T_s(v))| \leq |V(T_s(u))|/2$. This yields the following useful lemma.

▶ **Lemma 13** ([7]). *For any vertex v, its path to the root in T intersects at most $\log n$ paths in $\mathcal{HP}(T)$.*

2 Fault Tolerant Preservers for Undirected Graphs

2.1 Preservers for Undirected Weighted Graphs

▶ **Theorem 14.** *Any undirected (possibly weighted) $G = (V, E, w)$ and a set $S \subseteq V$ of sources has a $S \times S$ subset (vertex) fault tolerant preserver H with $O(n|S| \log n)$ edges.*

The subgraph H simply contains all the $S \times S$ replacement paths, that is,

$$H = \{P_{s,t,x} \mid s, t \in S,\ x \in \pi(s, t)\}.$$

To prove Theorem 14, we will provide a bound on the size of H.

Size Analysis. A replacement path $P_{s,t,x}$ is *short* if it has at most $n/|S|$ edges; otherwise it is *long*. Throughout this section, we mainly focus on bounding the number of edges in the collection of all short replacement paths, denoted throughout by $\mathcal{P}_{short}$:

▶ **Lemma 15.** $|E(\mathcal{P}_{short})| = O(n|S| \log n)$.

We start by observing that to prove Theorem 14 it is indeed sufficient to consider only the short replacement paths.

▷ Claim 16. Lemma 15 implies Theorem 14.

Proof. Let S^* be a sample of nodes obtained by including each node independently with probability $p = |S|/n$, and let $S' = S^* \cup S$. For each edge e in a long replacement path $P = P_{s,t,x}$, by standard Chernoff bounds, with constant probability there are nodes $s_1, s_2 \in S' \cap P$, separated by $\leq n/|S|$ edges in P, such that e comes between s_1 and s_2 in P. We thus have $e \in P_{s_1,s_2,x}$, so e is now part of a short replacement path. Hence e is counted in Lemma 15 with at least constant probability. Since only $O(n|S| \log n)$ edges may be counted in this way, by linearity of expectation it follows that there are $O(n|S| \log n)$ total edges in long replacement paths. ◁

Road-Map for Proving Lemma 15. From now on, we focus on the collection of short replacement paths, $\mathcal{P} = \mathcal{P}_{short}$. We will show the existence of a subgraph H' with $\widetilde{O}(|S|n)$ edges that contains all the edges of $\mathcal{P}$. This subgraph will be the union of three auxiliary sub-graphs each containing a different subset of replacement paths. For any source $s \in S$, we first show the existence of a subgraph H_s of size $\widetilde{O}(n)$ such that $H_s \cup T(S)$ include *most* of the replacement paths which originate at s, where $T(S) = \cup_s T_s$. Then, letting $H_2 = \bigcup_{s \in S} H_s$, we have that $|H_2| = \widetilde{O}(n|S|)$. Finally, the third subgraph H_3 will include a collection of left-over $O(|S|^2 \log n)$ (short) replacement paths, and thus its size will be bounded by $O(n|S| \log n)$ as well.

Partitioning of Replacement Paths based on Heavy-Path Decomposition. Throughout, we consider a fixed source node $s \in S$ and the set $\mathcal{P}_s = \{P_{s,t,x} \mid P_{s,t,x} \in \mathcal{P}, t \in S\}$ of all its short replacement paths. We then divide these replacement paths into several subsets based on the heavy-path decomposition $\mathcal{HP}(T_s)$ of the shortest-path tree T_s as follows. For every path $Q \in \mathcal{HP}(T_s)$, let

$$\mathcal{P}_s(Q) := \{P_{s,t,x} \mid x \in Q \text{ and } x \neq \mathrm{LCA}(t, \mathrm{last}(Q))\} \quad \text{and} \quad \mathcal{P}'_s = \bigcup_{Q \in \mathcal{HP}(T_s)} \mathcal{P}_s(Q) \ .$$

We will also define a small subset of the *left-over* replacement paths $\mathcal{L}_s = \mathcal{P}_s \setminus \mathcal{P}'_s$. The analysis shows that $|\mathcal{L}_s| = O(|S| \log n)$, and since all these replacement paths are short, the total number of edges in these left-over replacement paths can be bounded by $O(|S| n \log n)$. We next bound the number of edges in each of the subsets $\mathcal{P}_s(Q)$, enjoying the fact that the failures of all the replacement paths in these sets lie on a *single* path.

Bounding the number of edges in $\mathcal{P}_s(Q)$ (failure on a single path). Let $Q = \langle x_0, ..., x_k \rangle$. Following Baswana and Khanna [7], for every $x_i \in Q$, we define the vertex partition of $T_s \setminus \{x_i\}$ into

$$U_i : V(T_s \setminus T_s(x_i)), \quad D_i := V(T_s(x_{i+1})) \text{ and } O_i := V(T_s) \setminus (U_i \cup D_i \cup \{x_i\}).$$

Note that for any $i \neq j$, O_i and O_j are pairwise disjoint. This property is crucial for our construction.

▶ **Observation 17.** *Fix $x_i \in Q$. If $P_{s,t,x_i} \in \mathcal{P}_s(Q)$ and $P_{s,t,x_i} \neq \pi(s,t)$ then $t \in D_i$.*

Proof. Since $U_i \cup O_i \cup D_i = V \setminus \{x_i\}$, we need to rule out two cases. (i) Assume that $t \in U_i$. In this case $x_i \notin \pi(s,t)$, and thus $P_{s,t,x_i} = \pi(s,t)$. (ii) Assume that, $t \in O_i$. In this case, we must also have that $x_i = \mathrm{LCA}(t, \mathrm{last}(Q))$ and thus $P_{s,t,x_i} \notin \mathcal{P}_s(Q)$ (this path will be included in the left-over set $\mathcal{L}_s$). As $U_i \cup O_i \cup D_i = V$, we conclude that $t \in D_i$. ◀

▶ **Lemma 18.** *Fix $x_i \in Q$ and $t \in S \cap D_i$. The replacement path $P = P_{s,t,x_i}$ is of the form $p_1(P) \circ e_1(P) \circ p_2(P) \circ e_2(P) \circ p_3(P)$ where $e_1(P), e_2(P)$ are edges, $p_1(P) \subseteq T_s$, $p_3(P) \subseteq T_t$ and $V(p_2(P)) \subseteq O_i$. Each of the edges $e_1(P), e_2(P)$ (but not both) and some of the paths $p_i(P)$, $i \in \{1,2,3\}$ might be empty.*

Proof. Let $P_i = p_i(P)$ for $i \in \{1,2,3\}$, and $e_j = e_j(P)$ for $j \in \{1,2\}$. Let z be the *first* vertex of the path P (i.e., closest to s) that belongs to D_i. Let u be the *last* vertex of the path P (i.e., closest to t) that belongs to U_i. Let $P_1 = P[s,u]$ and $P_3 = P[z,t]$. We first claim that $P_1 \subset T_s$. To see this, observe that since $u \in U_i$, $x_i \notin \pi(s,u)$ and thus $P_1 = \pi(s,u) \subseteq T_s$. Since $P_1 = \pi(s,u)$, it also implies that u appears strictly before z on the path P.

Next, we show that $P_3 \subset T_t$ by proving that $x_i \notin \pi(z,t)$. Assume towards contradiction otherwise, i.e., that $x_i \in \pi(z,t)$. We have that $\pi(z,t) = \pi(z,x_i) \circ \pi(x_i,t)$. Since (x_i, x_{i+1}) appears on both of the paths $\pi(z,x_i)$ and $\pi(x_i,t)$, we get an alternative z-t path $\pi(z,x_{i+1}) \circ \pi(x_{i+1},t)$ that is strictly shorter, leading to a contradiction. As $x_i \notin \pi(z,t)$, we get that $P_3 = \pi(z,t) \subset T_t$ as required. It remains to consider the path $P(u,z)$. If $P \cap O_i = \emptyset$ then

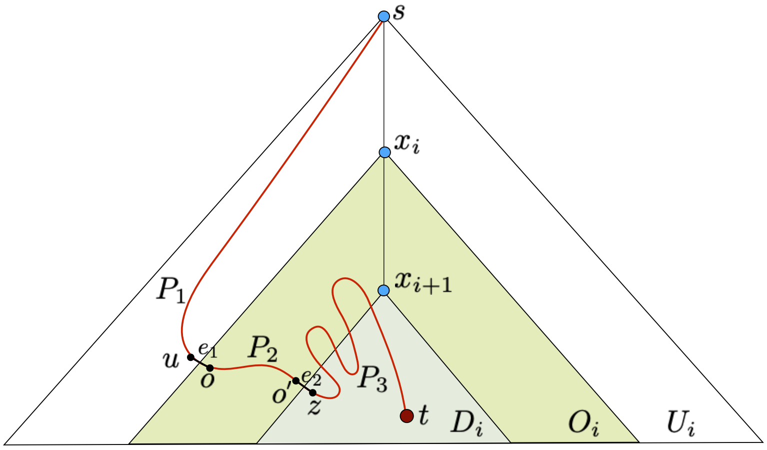

Figure 1 The partition of the path $P = P_{s,t,x_i}$ suggested in Lemma 18 is presented. $P_1 = p_1(P)$ is the portion of P that appears before o, $P_3 = p_3(P)$ is the portion of P from z, and the remaining portion is $P_2 = p_2(P)$. In the figure, $e_1 = e_1(P)$ and $e_2 = e_2(P)$.

we are done. Otherwise, Let o, o' be the first (resp. last) vertices in O_i on the path P. Note that it might be the case that $o = o'$. Letting $e_1 = (u, o)$, $e_2 = (o', z)$, and $P_2 = P[o, o']$, we get that $P = P_1 \circ e_1 \circ P_2 \circ e_2 \circ P_3$ and by definition $V(P_2) \subseteq O_i$. The claim follows. ◀

From now on, for any path $P \in \mathcal{P}_s(Q)$, let $p_i(P), e_j(P)$ denote the partition defined in Lemma 18 (for $i \in [3], j \in [2]$). As $p_1(P), p_3(P) \subseteq T(S)$, it remains to mainly bound the edges contributed by $p_2(P)$ for every $P \in \mathcal{P}_s(Q)$. To do that, we focus on a fixed failure $x_i \in Q$ and define a special graph G_i (which is not necessarily a sub-graph of G) in which $p_2(P)$ is a shortest path. A similar approach has been taken in [7]. For every $x_i \in Q$, define the graph $G_i = (V_i, E_i)$ such that $V_i = O_i \cup \{s\}$ and E_i includes the edges of $G[O_i]$ and the following additional edges. For each $o \in O_i$ with a neighbor in U_i, E_i contains the edge (s, o) with weight $\min_{(u,o)\in E, u\in U_i}\{w(\pi(s, u, G)) + w((u, o))\}$. Letting τ_i denote the shortest paths tree rooted at s in G_i, define

$$H(s, Q) := \left(\bigcup_{i<k}(\tau_i \cap G)\right) \cup \left(\bigcup_{P\in\mathcal{P}_s(Q), j\in\{1,2\}} e_j(P)\right).$$

We show the following:

▶ **Lemma 19.**
(i) *For every $P_{s,t,x_i} \in \mathcal{P}_s(Q)$, it holds that $P_{s,t,x_i} \subseteq T(S) \cup H(s, Q)$.*
(ii) $|E(H(s, Q))| = O(|T_s(\text{first}(Q))| + |\mathcal{P}_s(Q)|)$.

Proof. (i) Since $p_1(P_{s,t,x_i}), p_3(P_{s,t,x_i}) \subseteq T(S)$ and $e_1(P_{s,t,x_i}), e_2(P_{s,t,x_i}) \in H(s, Q)$, it is sufficient to show that $p_2(P_{s,t,x_i}) \subseteq \tau_i \cap G$. Specifically, we show that $p_2(P_{s,t,x_i})$ is a suffix of a shortest path rooted in s in the graph G_i.

Let o, o' be the first (resp., last) nodes in $P_{s,t,x_i} \cap O_i$. First, observe that the existence of an edge $e = (s, o) \in G_i$ with weight $w(e)$ implies that there exists a path in $G[U_i \cup O_i]$ of weight $w(e)$ from s to o, such that all of its vertices are in U_i except the last one. Thus, if there exists a path of weight W from s to $o \in O$ in G_i, it implies that there exists a path in $G[U_i \cup O_i]$ of weight W from s to o. We now claim $p_2(P_{s,t,x_i}) \subseteq \tau_i \cap G$. Let $u \in U_i$ be the vertex preceding o on the path P_{s,t,x_i} such that $e_1(P_{s,t,x_i}) = (u, o)$ (i.e., alternatively, u is the last vertex in U_i on the path P_{s,t,x_i}). By the optimal subpath property,

$P_{s,t,x_i}[s,o']$ is a shortest path in $G \setminus \{x_i\}$, and by Lemma 18 it is in the subgraph $G[U_i \cup O_i]$. Recall that $V(P_{s,t,x_i}[s,u]) \subseteq U_i$ and $V(P_{s,t,x_i}[o,o']) \subseteq O_i$. Thus $e_1(P_{s,t,x_i})$ is the edge that minimizes $w(\pi(s,u,G)) + w((u,o))$, namely, $w((s,o)) = w(\pi(s,u,G)) + w((u,o))$. Therefore $(s,o) \circ P_{s,t,x_i}[o,o']$ is a shortest path from s to o' in G_i, and $p_2(P_{s,t,x_i}) \subseteq \tau_i \cap G$.

We proceed with (ii). As $V(\tau_i \cap G) \subseteq O_i$, by the mutual disjointness of O_i's, it follows that

$$\sum_{i<k} |\tau_i \cap G| \leq \sum_{i<k} |O_i| \leq |T_s(\text{first}(Q))| \ .$$

The claim follows by noting that contribution of $e_1(P)$ and $e_2(P)$ for every $P \in \mathcal{P}_s(Q)$ is at most $2|\mathcal{P}_s(Q)|$. ◀

Interestingly, Lemma 19(ii) yields an immediate linear upper bound for single pair preservers. That is, in the case where $S = \{s,t\}$ and $Q = \pi(s,t)$, the set $\mathcal{P}_s(Q)$ contains all the replacement paths. As $|\mathcal{P}_s(Q)|$ includes at most one path for each failure, its size is bounded by $|\pi(s,t)| = O(n)$.

▶ **Corollary 20** (Single-Pair FT Preservers). *Any undirected (possibly weighted) graph $G = (V,E)$, and a pair of nodes $s,t \in V$ has a single-pair FT Preserver of linear size.*

Bounding the set $\mathcal{P}'_s$. So far, we assume that the failing vertex appears on a fixed path $Q \in \mathcal{HP}(T_s)$. We next bound the total number of edges in the union of all paths $\mathcal{P}'_s = \bigcup_{Q \in \mathcal{HP}(T_s)} \mathcal{P}_s(Q)$. By Lemma 19, every $P_{s,t,x_i} \in \mathcal{P}_s(Q)$ is contained in $T(S) \cup H(s,Q)$. Therefore, it remains to bound the number of edges in the subgraph $H_s = \cup_{Q \in \mathcal{HP}(T_s)} H(s,Q)$.

▶ **Lemma 21.** *$|E(H_s)| = O(n \log n)$.*

Proof. Since $H_s = \cup_{Q \in \mathcal{HP}(T_s)} H(s,Q)$, by Lemma 19 it is sufficient to show that:

- (i) $\Sigma_{Q \in \mathcal{HP}(T_s)} |T_s(\text{first}(Q))| = O(n \log n)$ and
- (ii) $\Sigma_{Q \in \mathcal{HP}(T_s)} |\mathcal{P}_s(Q)| = O(n \log n)$.

Begin with (i). By Lemma 13, for every $t \in S$, the s-t path in T_s intersects with at most $\log n$ paths $Q \in \mathcal{HP}(T_s)$. Since a vertex t appears in $T_s(\text{first}(Q))$ only if $\text{first}(Q) \in \pi(s,t)$, it holds that each vertex belongs to at most $\log n$ such subtrees.

We proceed with (ii) and first show that $\Sigma_{Q \in \mathcal{HP}(T_s)} |\mathcal{P}_s(Q)| \leq |\mathcal{P}'_s|$. Recall that $\mathcal{P}_s(Q)$ includes the replacement paths of $\mathcal{P}'_s$ whose failure appears in Q. Since $\mathcal{HP}(T_s)$ is a partition of T_s, every two paths $Q \neq Q'$ in this partitioning are vertex disjoint. Thus for $Q \neq Q' \in \mathcal{HP}(T_s)$, $\mathcal{P}'_s(Q) \cap \mathcal{P}'_s(Q') = \emptyset$, implying that $\{\mathcal{P}'_s(Q)\}_{Q \in \mathcal{HP}(T_s)}$ is a partition of $\mathcal{P}'_s$ and the claim follows.

Next, we show that $|\mathcal{P}'_s| = O(n \log n)$ by claiming that for every $t \in S$, there are at most $O(n \log n/|S|)$ replacement paths between s and t in $\mathcal{P}'_s$. Fix $t \in S$ and let $\mathcal{P}'_s(t) = \{P_{s,t,x} \mid P_{s,t,x} \in \mathcal{P}'_s\}$. Our goal is to show that $|\mathcal{P}'_s(t)| \leq O(n \log n/|S|)$. Note that in the case where G is unweighted, for every short replacement path $P_{s,t,x}$ with hop-length of $O(n \log n/|S|)$, it holds that the original shortest path $\pi(s,t)$ is short as well, and thus it has at most $O(n \log n/|S|)$ vertex failures that require a replacement path. Consider a shortest path $\pi(s,t)$ in a weighted graph and let $\ell := c \cdot n \log n/|S|$. In the case that $\pi(s,t)$ has hop-length less than 2ℓ, the lemma trivially holds. Otherwise, we assume $|\pi(s,t)| > 2\ell$. Let s' be the ℓ'th vertex on the path from s, namely $\pi(s,s')$ has hop-length of ℓ. Similarly, let t' be the ℓ'th vertex on the path from t, namely $\pi(t',t)$ has hop-length of ℓ. Observe that any short replacement path $P \in \mathcal{P}'_s(t)$ avoids both s', t', otherwise its length is larger than ℓ. This implies that the starting point of any detour of a path in $\mathcal{P}'_s(t)$ is before s' and its ending point is after t'. We show that there is at most one replacement path $P \in \mathcal{P}'_s(t)$ for all the failures in $\pi(s',t')$. Assume towards contradiction that there are two replacement paths $P_v, P_u \in \mathcal{P}'_s(t)$, and $u, v \in \pi(s',t')$. As both P_v, P_u avoid $\pi(s',t')$, both avoid u, v. Thus, we get that both paths are shortest paths in $G \setminus \{u, v\}$, which is a contradiction to the uniqueness of the shortest paths. As any other shortest path must have a failure on $\pi(s,s')$ or $\pi(t',t)$, we have that $|\mathcal{P}'_s(t)| \leq 1 + 2\ell$. Thus, for any $t \in S$, we have that $|\mathcal{P}'_s(t)| = O(n \log n/|S|)$, and $|\mathcal{P}'_s| = O(n \log n)$, as desired. ◀

Bounding the number of edges in the left-over subset $\mathcal{L}_s$. It remains to bound the number of edges contributed by the left-over replacement paths.

▷ Claim 22. $|\mathcal{L}_s| = O(|S| \log n)$ and thus $|E(\mathcal{L}_s)| = O(n \log n)$.

Proof. We first claim that for every fixed $t \in S$, $\mathcal{L}_s$ contains $O(\log n)$ replacement paths between s and t. Thus, $|\mathcal{L}_s| = O(|S| \log n)$. Recall that $P_{s,t,x} \in \mathcal{L}_s$ if and only if there exists a path $Q \in \mathcal{HP}(T_s)$ such that $x \in Q$ and $x = \mathrm{LCA}(t, \mathrm{last}(Q))$. Thus, we have that $x \in \pi(s,t) \cap Q$. According to Lemma 13, there are at most $\log n$ paths from $\mathcal{HP}(T_s)$ intersecting with $\pi(s,t)$ in T_s. Since an LCA is unique for every pair of nodes, for each such path Q there is only one failure x such that $x = \mathrm{LCA}(t, \mathrm{last}(Q))$. Since each path in $\mathcal{L}_s$ is short, i.e., has at most $O(n/|S|)$ edges, the total number of edges in the paths of $\mathcal{L}_s$ is bounded by $O(n|S| \log n)$ as desired. ◁

We are now ready to complete the proof of Lemma 15.

Proof of Lemma 15. The collection of all short replacement paths $\mathcal{P}$ is divided into $\bigcup_s \mathcal{P}'_s$ and the left-over sets $\bigcup_s \mathcal{L}_s$. By Lemma 19(i), $E(\mathcal{P}'_s) \subseteq H_s \cup T(S)$. By Lemma 21, $|E(H_s)| = O(n \log n)$ and thus the total number of edges in $\bigcup_s \mathcal{P}'_s$ is bounded by $O(n|S| \log n)$. By Claim 22, $|E(\mathcal{L}_s)| = O(n \log n)$ and thus $E(\bigcup_s \mathcal{L}_s) = O(n|S| \log n)$. The lemma follows. ◀

2.2 Preservers for Undirected Unweighted Graphs

We next extend our constructions to the $S \times T$ setting. In [8], such an extension has been provided for the case of the single edge failure. We obtain the following theorem.

▶ **Theorem 23.** *For any undirected unweighted $G = (V, E)$ and subsets $S, T \subseteq V$, one can compute a (vertex) fault tolerant $S \times T$ preserver H with $\widetilde{O}(n^{4/3}|S|^{1/3}|T|^{1/3})$ edges.*

Proof. The subgraph H simply contains all the $S \times T$ replacement paths, i.e., $H = \{P_{s,t,x} \mid s, t \in S, \ x \in \pi(s,t)\}$. We will bound size the size of this subgraph, by bounding the size of subgraph H' that contains H. Let R be a random subset of $O(n/L)$ nodes where L is a parameter to be optimized later. Let $\ell = \lceil L \log n \rceil$. The subgraph $H' = H_1 \cup H_2$ is defined as follows.

1. Let H_1 be an $W \times W$ FPT for $W = R \cup S$ obtained by Theorem 14.
2. Let $H_2 = \{\ell\text{-length suffix of } P_{s,t,x} \mid s, t \in S \times T, x \in \pi(s,t), \mathtt{dist}_G(x,t) \leq \ell\}$.

Correctness. Fix $\{s,t\} \in S \times T$ and $x \in \pi(s,t)$. First assume that $|P_{s,t,x}| \leq \ell$. It then implies that also $|\pi(s,t)| \leq \ell$ and thus also that $\mathtt{dist}(x,t) \leq \ell$. Concluding that $P_{s,t,x} \subseteq H_2$. Next, assume that $|P_{s,t,x}| > \ell$. By Chernoff bound, w.h.p. it holds that $|P_{s,t,x} \cap R| \neq \emptyset$. Let $r \in R$ be the closest vertex to t from R on $\pi(s,t)$, we then have that $P_{s,t,x} = P_{s,r,x} \circ P_{r,t,x}$, and $|P_{r,t,x}| \leq \ell$ (as r is the closest vertex to t from R). Since H_1 is an $W \times W$ FPT, we have that $P_{s,r,x} \subset H_1$. It is left to show that $P_{r,t,x}$ is included in either H_1 or H_2. First, assume that $\texttt{dist}(x,t) > \ell$. As $\ell \geq |P_{r,t,x}| \geq |\pi(r,t)|$, it holds that $x \notin \pi(r,t)$ and thus $P_{r,t,x} = \pi(r,x)$. Since the $W \times W$ preservers of Theorem 14 contains all BFS trees of the W nodes, it includes the BFS tree T_r, and $P_{r,t,x} \subset H_1$. Next, assume that $\texttt{dist}(x,t) \leq \ell$. By construction, as $|P_{r,t,x}| \leq \ell$, it holds that $P_{r,t,x} \subset H_2$.

Size Analysis. By Theorem 14, $|E(H_1)| = O\left(n(|S| + n/\ell)\log^2 n\right)$. In addition, $|E(H_2)| = O(|S||T|\ell^2)$ as it includes ℓ edges of ℓ s-t replacement paths for every s,t pair. Letting $\ell = n^{2/3}(|S||T|)^{-1/3}$ gives $O(n^{4/3}(|S||T|)^{1/3}\log^2 n)$. This bound matches the state of the art bound known for one edge failure by [8] (Theorem 11). ◀

3 Fault Tolerant Preservers for General Directed Graphs

We start by defining a couple of notations needed for our constructions. Recall the for each pair of vertices $s,t \in V$, and a node fault $x \in \pi(s,t)$, the detour of replacement path $P_{s,t,x}$ is represented as $D_{s,t,x}$. We denote $\partial D_{s,t,x}$ to denote the partial subpath of $D_{s,t,x}$ obtained by removing the first and last vertex from $D_{s,t,x}$.

Any partial detour $\partial D_{s,t,x}$ is a shortest path in the graph $G \setminus \pi(s,t)$, so we have following lemma.

▶ **Lemma 24.** *For any $s,t \in V$, and $x \in \pi(s,t)$, the path $\partial D_{s,t,x}$ is a shortest path in $G \setminus \pi(s,t)$.*

We now describe the fault-tolerant distance preservers with respect to pair-set $\{r\} \times S$, for a given choice of a root node $r \in V$ and a set $S \subseteq V$. Let T represent the shortest path tree rooted at r in G. We initialize H_0 to T. Further for each $s \in S$ and failure $x \in \pi(r,s)$, we add the two edge present in $E(D_{s,t,x}) \setminus E(\partial D_{s,t,x})$ to H_0. In the process, we add at most $O(n|S|)$ edges to H.

For a directed path Q, we use "H_Q" to represent the minimal sub-graph such that $H_0 + H_Q$ is a 1-FT distance preserver for pairs in $(r \times S)$ when vertex-faults in G are *restricted* to path Q. One of our main-contributions in achieving sparseness for (non-acyclic graphs) is in obtaining tight bound over the size of H_Q. This is captured in the Proposition 25 and Proposition 29.

3.1 Preservers for Directed Weighted Graphs

We obtain the following bound on H_Q for directed weighted graphs.

▶ **Proposition 25.** *For any directed path $Q = (y \rightsquigarrow z)$ in T (between two vertices y, z with y being ancestor of z in T), the graph H_Q, for a directed possibly weighted graph G, requires at most $O(|T(y)|\ |S|^{3/4}\ \sqrt{|Q|})$ edges, where $|Q|$ denotes the number of vertices in path Q.*

Proof. Let Q be a directed $y \rightsquigarrow z$ tree-path in T, for some $y,z \in V$ with y being ancestor of z. Let $k = |S \cap T(y)|$, and α be an integer parameter to be decided later on. For simplicity we assume $K = k/\alpha$ is integer. Let $S_1, \ldots, S_\alpha$ be an arbitrary partition of $S \cap T(y)$, each of size K, satisfying the constraint that for each $(s,s') \in S_i \times S_{i+1}$, LCA$(s,z)$ is either equal to or an ancestor of LCA(s',z). Further let $w_0 = y$, w_i be LCA$(S_i \cup \{z\})$ for $1 \leq i \leq \alpha$, and $w_{\alpha+1} = z$. Observe that for $i \in [1,\alpha]$, w_i is either equal to, or a ancestor of w_{i+1}. Partition Q in consecutive segments (blocks): $B_0 = Q[w_0,w_1]$, $B_1 = Q[w_1,w_2]$, $\ldots$, $B_\alpha = Q[w_\alpha,w_{\alpha+1}]$. Further, let L_i be the number of vertices in B_i, for $0 \leq i \leq \alpha$. (See Figure 2).

We will analyze the failures in each block separately. Fix an index $1 \leq i \leq K$. We distinguish two cases as below.

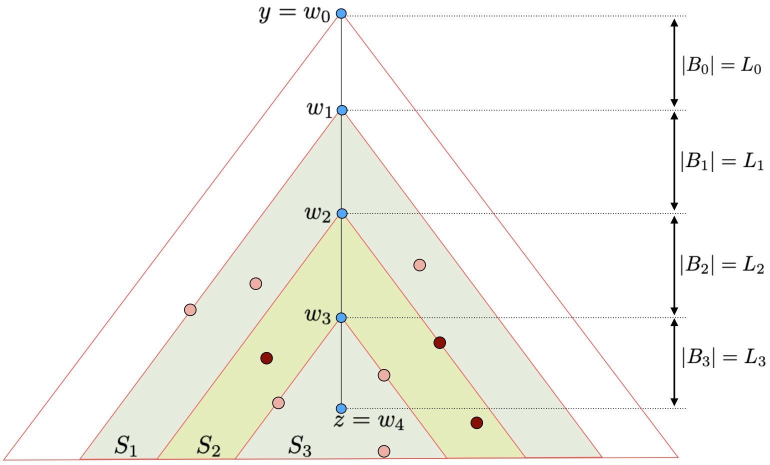

Figure 2 Depiction of block-partitioning of $y \rightsquigarrow z$ tree-path, for $K = \alpha = 3$. Observe that the sets $S_1, S_2, \ldots, S_\alpha$ are each of size $K = 3$.

Analysis of replacement path to vertices in S_i on vertex failure in B_i. Consider a pair $(f, s) \in B_i \times S_i$. Observe that on failure of f, the partial detour $\partial D_{r,s,f}$ (of replacement path $P_{r,s,f}$) is a shortest path in $G \setminus B_i[w_i, \mathrm{LCA}(s, z)]$. (Recall $B_i[w_i, \mathrm{LCA}(s, z)]$ is the sub-path of B_i comprising of those vertices that are ancestor of s in T). Furthermore, it follows from our tie-breaking scheme that none of the vertices of $\partial D_{r,s,f}$ can lie outside $T(y)$. So, for a fixed $s \in S_i$, to compute an (r, s) FT-preserver containing partial-detours corresponding to $f \in B_i$, we can simply use Coppersmith-Elkin's [20] pairwise-distance preserver over graph $G[T(y)] \setminus B_i[w_i, \mathrm{LCA}(s, z)]$, where, $G[T(y)]$ is the graph induced by vertices in subtree $T(y)$.

Since fault f has L_i choices, this gives a bound of $O(|T(y)| \cdot \sqrt{L_i})$ edges, for a single $s \in S_i$. On summing over $|S_i| = K = k/\alpha$ nodes in S_i, and each of the α blocks, we get a bound (say X_1):

$$X_1 = O\Big(|T(y)| \cdot \frac{k}{\alpha} \cdot \sum_{i\in[1,\alpha]} \big(\sqrt{L_i}\big)\Big) \tag{1}$$

Analysis of replacement path to vertices in $\cup_{j>i} S_j$ on vertex failure in B_i. Consider a pair $(f, s) \in B_i \times \cup_{j>i} S_j$. Observe that on failure of f, the partial detour $\partial D_{r,s,f}$ is a shortest path in $G \setminus B_i$, since all the vertices in B_i are ancestor of s. So here we will use a distance preserver over graph $G[T(y)] \setminus B_i$, and the number of pairs (as well as partial-detours) is at most $|S \cap T(y)| \cdot L_i$. Hence, handling failures on B_i incurs us $O(|T(y)| \cdot \sqrt{k\ L_i})$ cost. On summing over all blocks, we get a bound (say X_2):

$$X_2 = O\Big(|T(y)| \cdot \sum_{i\in[0,\alpha]} \big(\sqrt{k \cdot L_i}\big)\Big) \tag{2}$$

For a given α, we have $X_1 \leq O(|T(y)| \cdot (k^2/\alpha)^{1/2} \cdot \sqrt{|Q|})$ and $X_2 \leq O(|T(y)| \cdot (k\alpha)^{1/2} \cdot \sqrt{|Q|})$, where $|Q|$ denotes the number of vertices on path Q. Optimizing over α, we get α must be $\Theta(\sqrt{k})$. This provides a bound of at most $O(|T(y)|k^{3/4}\sqrt{|Q|})$ edges on the size of H_Q. ◀

We are now ready to prove our results for directed weighted graphs. Previously it was know by Bodwin et al. [14] that for a single-pair $(r, s) \in V \times V$, we can compute a FTP with at most $O(n^{1.5})$ edges. A direct implementation of this result over pairs in $\{r\} \times S$ would result in a bound of $O(n^{1.5}|S|)$ edges. However using Proposition 25 and heavy-path decomposition, we are able to obtain a better bound of $o(n^{1.5}|S|)$ size for the $\{r\} \times S$ setting.

Let $Q_1 = (y_1 \rightsquigarrow z_1), \ldots, Q_\gamma = (y_\gamma \rightsquigarrow z_\gamma)$ be the paths in the heavy-path decomposition of T (i.e. $\mathcal{HP}(T)$). Then $\sum_{i=1}^{\gamma} |T(y_i)|$ is $O(n \log n)$ (see Lemma 13). Since $\cup_{i=1}^{\gamma} V(Q_i) = V(T)$, it follows that to handle all failures in T we incur at most $O(n|S|^{3/4}\sqrt{n}\log n)$ cost.

Thus our $\{r\}\times S$ 1-FT distance-preserver for weighted directed graphs require $\widetilde{O}(n^{3/2}|S|^{3/4})$ edges.

▶ **Theorem 26.** *For any n-node directed weighted graph $G = (V, E)$, $(r, S) \in V \times 2^V$, there is a 1-VFT $(r \times S)$ distance preserver H on $\widetilde{O}(n^{3/2}|S|^{3/4})$ edges.*

3.2 Preservers for Directed Unweighted Graphs

Using Proposition 25, together with a deeper insight into shortest-path's structure in unweighted graphs, we provide an alternative and better bound on H_Q.

Let Q be a directed $y \rightsquigarrow z$ tree-path in T, with y being ancestor of z. Let ℓ (a function of Q) be a parameter to be chosen later. For a triplet (r, s, x) we say that $D_{r,s,x}$ is *long* if the partial detour $\partial D_{r,s,x}$ has at least ℓ nodes, and *short* otherwise. We separately analyse the short and long detours.

Long Detours. Let us fix a node $s \in S \cap T(y)$. Let $W_s \subseteq V(T(y))$ be a random sample of nodes obtained by including each node in $T(y) \setminus \pi(r, s)$ independently with probability ℓ^{-1}. For each long detour $D_{r,s,x}$, for $x \in \pi(r, s)$, with constant probability or higher we sample a node $w \in W_s$. Edges of corresponding partial-detour intersecting a node $w \in W_s$ is contained in the union of an in- and out-BFS tree rooted at w. Hence they contain $O(|T(y)|)$ edges. Unioning over all $w \in W_s$, all long detours that intersect W_s contain $O(|T(y)|^2/\ell)$ edges in total. Finally, we note that since each long detour is counted with at least constant probability, there are at most $O(|T(y)|^2/\ell)$ total edges contained in *all* long detours, for a single node s. Summing this over $s \in S$ gives a bound of $O(|S| \cdot |T(y)|^2/\ell)$.

Short Detours. Let $w_0 = y$, and for $i = 1$ to $\alpha = \lfloor |Q|/\ell \rfloor$, let w_i be the descendant of w_{i-1} on Q at a distance ℓ from it. We partition Q into blocks: $B_0, B_1, \ldots, B_\alpha$ such that B_i includes w_i but excludes w_{i+1}, for $i \in [0, \alpha]$. The following lemma presents the disjointness relation for short detours corresponding to non-consecutive blocks.

▶ **Lemma 27.** *For each $s \in S \cap T(y)$ and $x \in B_i$, a short partial detour $\partial\mathcal{D}_{r,s,x}$ lies in $T(w_i) \setminus T(w_{i+2})$.*

Proof. Consider a fault $x \in B_i$ and a node $s \in S \cap T(y)$. Let a, b be respectively the first and last vertices on $\mathcal{D}_{r,s,x}$. As $x \in B_i = Q[w_i, w_{i+1}] \setminus \{w_{i+1}\}$, node a must be at least the grand parent of w_{i+1}. Thus $\texttt{dist}(a, w_{i+2}) \geq \ell + 2$, and moreover, distance from a to all nodes in $T(w_{i+2})$ is also at least $\ell + 2$. Since distance from a to all vertices in $\partial\mathcal{D}_{r,s,x}$ is at most $\ell + 1$, this completes the proof that $\partial\mathcal{D}_{r,s,x}$ is disjoint with $T(w_{i+2})$. ◀

From a more careful implementation of Proposition 29, it follows that the $T(y)$ term in its bound can in-fact be replaced by $T(w_i) \setminus T(w_{i+2})$ term when faults are restricted to B_i (see Lemma 27). Thus the next lemma follows.

▶ **Lemma 28.** *To handle short detours for faults on B_i, for $i \in [0, \alpha]$, we require at most*

$$O\big(|T(w_i) \setminus T(w_{i+2})| \; |S|^{3/4} \; \sqrt{\ell}\big)$$

edges to be added to H_0.

Since $\sum_{i=0}^{\alpha} |T(w_i) \setminus T(w_{i+2})| = O(T(y))$, the total cost of the construction of H_Q is

$$O\big(|S| \cdot |T(y)|^2/\ell + |T(y)|\ |S|^{3/4}\ \sqrt{\ell}\big)\ .$$

Setting $\ell := |S|^{1/6}|T(y)|^{2/3}$ thus proves the following.

▶ **Proposition 29.** *For any directed path $Q = (y \rightsquigarrow z)$ in T (between two vertices y, z with y being ancestor of z in T), the graph H_Q, for a directed unweighted graph G, requires at most $O(|T(y)|^{4/3}\ |S|^{5/6})$ edges.*

As a direct corollary of Proposition 29, we obtain an $O(n^{4/3})$ upper bound for single node-pair preserver. If the input pair is $(r, s) \in V \times V$, then taking $Q = \pi(r, s)$, provides us the following.

▶ **Corollary 30.** *For any n-node directed unweighted graph $G = (V, E)$, $r, s \in V$, there is a 1-VFT (r, s) distance preserver H on $O(n^{4/3})$ edges.*

We now use the technique of heavy path decomposition. Let $Q_i = (y_i \rightsquigarrow z_i)$, $1 \leq i \leq \gamma$ be the paths in the heavy-path decomposition of T (i.e. $\mathcal{HP}(T)$). Then $\sum_{i=1}^{\gamma} |T(y_i)|$ is $O(n \log n)$. So Proposition 29 directly proves the following.

▶ **Theorem 31.** *For any n-node directed unweighted graph $G = (V, E)$, $(r, S) \in V \times 2^V$, there is a 1-VFT $(r \times S)$ distance preserver H on $\widetilde{O}(n^{4/3}|S|^{5/6})$ edges.*

4 Fault Tolerant Preservers for Directed Acyclic Graphs

For DAGs, we first present our result for single node-pair case.

▶ **Theorem 32.** *For every n-node directed graph $G = (V, E)$ and a pair $p \in V \times V$, there exists a FT-vertex preserver $H \subseteq G$ for p with $O(n)$ edges.*

Proof. Let $p = (s, t)$, and $Q = \pi(s, t)$ denote the s-t shortest path. Let T_1 (T_2) be an outgoing (incoming) shortest path tree rooted at s (t) in G such that the s-t path in it overlaps with Q; and let H be initialized to $T_1 \cup T_2$. Consider a vertex failure x on Q. Let y_x be the last vertex on the replacement path $P_{s,t,x}$ lying outside subtree $T_1(x)$, and let z_x be its successor. As G is acyclic the z_x to t shortest path in G cannot pass through x. Thus we may assume $Q[s, y_x]$ is contained in T_1, and $Q[z_x, t]$ is contained in T_2. So, for each $x \in Q$, it only remains to add edge (y_x, z_x) to H, thereby proving the linear size bound. ◀

In above theorem, we showed that for each $x \in \pi(s, t)$, there is exists an edge $e_{x,s,t} = (y_x, z_x)$ such that

1. $\textsc{treepath}_{T_s}(s, y_x)$ doesn't contains x,
2. no shortest-path from z_x to t can contain x, and
3. the concatenated path $\textsc{treepath}_{T_s}(s, y_x) \cdot (y_x, z_x) \cdot \pi_G(z_x, t)$ is an s-t shortest path in $G \setminus x$,

where T_s, for $s \in S$, denotes the shortest path tree rooted at s.

To extend our construction to $S \times S$ setting we proceed as follows. We choose a uniformly random set $\widetilde{S}$ of $\Theta(|S|)$ vertices, and let $R = S \cup \widetilde{S}$ and $L = \frac{n \log n}{|S|}$. Initialize H to $\cup_{r \in R}(T_r)$. Next, for each $s, t \in R$ satisfying $\texttt{dist}_G(s, t) \leq L$ and each $x \in \pi_G(s, t)$, add the edge $e_{x,s,t}$ to H. Observe that in this process, we include at most $O(n|S| \log n)$ edges to H. Thus the size of H is at most $O(n|S| \log n)$.

It remains to prove the correctness of H. Consider a pair $(s,t) \in S \times S$, and a vertex $x \in \pi_G(s,t)$. Let $(s = r_0, r_1, r_2, \ldots, r_\ell = t)$ be the vertices in R lying on $P_{s,t,x}$, in the order they appear. (Recall $P_{s,t,x}$ denote the s to t replacement path in $G \setminus x$). With high probability, length between consecutive r_i's in $P_{s,t,x}$ is at most L. This shows that with high probability each segment $P_{s,t,x}[r_i, r_{i+1}]$, for $i < \ell$, is present in $G \setminus x$.

Therefore, with high probability, H is a $S \times S$ fault-tolerant preserver for the input DAG G, and it comprises of at most $O(n|S|\log n)$ edges.

▶ **Theorem 33.** *Any DAG (possibly weighted) $G = (V, E, w)$ and a set $S \subseteq V$ of sources has a $S \times S$ sourcewise (vertex) fault tolerant preserver H with $O(n|S|\log n)$ edges.*

Using the same analysis as in Theorem 23, the above result can be extended to obtain a $S \times T$ preserver for unweighted DAGs with $O(n^{4/3}(|S||T|)^{1/3}\log^2 n)$ edges.

▶ **Theorem 34.** *For any unweighted DAG $G = (V, E)$ and subsets $S, T \subseteq V$, one can compute a (vertex) fault tolerant $S \times T$ preserver H with $\widetilde{O}(n^{4/3}|S|^{1/3}|T|^{1/3})$ edges.*

5 Lower Bounds for FT Preservers

5.1 Unconditional Lower-Bounds for Weighted Graphs

We show here a construction of a graph G on $O(n)$ vertices with integral edge weights in range $[1, n^c]$ (for some constant c) such that its $(\{s\} \times S)$-distance preserver requires at least $\Omega(n|S|)$ edges. Our lower bound construction is an adaption of $\{s\} \times V$ $(1+\epsilon)$-FTP by [6] to the $\{s\} \times S$ exact-FTP setting.

The vertex set of $V(G)$ constitutes $n + \sigma$ vertices, and is union of disjoint sets $U = \{u_1, u_2, \ldots, u_n\}$ and $W = \{w_1, w_2, \ldots, w_\sigma\}$. The edge set of $E(G)$ (in both directed as well as undirected scenario) is the union of the following two sets.

- $E_U = \{(u_n, u_{n-1}), \ldots, (u_i, u_{i-1}), \ldots, (u_2, u_1)\}$, with $wt(u_i, u_{i-1}) = 1$.
- $E_{U,W} = \{(u_i, w_j) \mid i \in [1, n], j \in [1, \sigma]\}$, with $wt(u_i, w_j) = (i \cdot n^4)$.

Say that $S = W$, and let $s = u_n$ be the designated source vertex. Let T_s be the shortest path tree rooted at s in G. It is easy to verify the set $E_U \cup (\{u_1\} \times W)$ constitute the edges of T_s. Now for any $i \in [1, n]$ and $j \in [1, \sigma]$, let $P_{i,j}$ denote the path $(u_n, u_{n-1}, \ldots, u_i) \circ (u_i, w_j)$. Then for any i, j, $wt(P_{i,j}) = i \cdot n^4 + (n - i)$.

If vertex u_{i-1} fails then the shortest path from s to vertex w_j $(j \in [1, \sigma])$ in G is path $P_{i,j}$. Hence each w_j must keep all its incoming edges in the FT-preserver. This shows there exists graphs whose $\{s\} \times S$ FT-preserver must contain $\Omega(n|S|)$ edges, thereby, implying the following result.

▶ **Theorem 35.** *For any positive integers n and σ $(\leq n)$, there exists an n-vertex (un)directed weighted graph $G = (V, E)$ with pair $(s, S) \in V \times 2^V$ satisfying $|S| = \sigma$ whose $\{s\} \times S$ 1-FT-distance-preserver must contain $\Omega(n|S|)$ edges.*

5.2 Conditional Lower-Bounds for Undirected Unweighted Graphs

▶ **Hypothesis 36** (Gap $S \times T$ Distance Preserver Lower Bounds)**.** *For any $\sigma = \sigma_n$, there is an n-node undirected unweighted graph $G = (V, E)$ and demand pairs $P = S \times T$ with $|S| \leq \sigma, |T| \leq \sqrt{n\sigma/\gamma(P)}$ such that any distance preserver of P has $\Omega(n\sigma)$ edges.*

▶ **Theorem 37.** *Assuming Hypothesis 36, for any $\sigma = \sigma_n$, there are examples of n-node undirected unweighted graphs $G = (V, E)$ and node subsets of size $|S| = \sigma$ where $\Omega(n\sigma)$ edges are needed for an $S \times S$ FT preserver of an undirected unweighted graph.*

We first say the construction, which uses ideas from [31]. Let $\gamma = \gamma(P)$ be the gap of an instance from Hypothesis 36. For $i \in [\sigma]$, we create identical disjoint trees T_i, each on $O(n/\sigma)$ nodes, computed as follows. Let

$$\beta := \sqrt{\frac{n}{\sigma\gamma}},$$

and start with β disjoint paths $L_{i,1}, \dots, L_{i,\beta}$, where $L_{i,j}$ is path on $2j\gamma$ nodes with endpoints $(q_{i,j}, s_{i,j})$. For $j \in [\beta - 1]$, the parent of $q_{i,j}$ is set to $q_{i,j+1}$ by adding an edge; thus the node $q_{i,\beta} =: r_i$ is naturally viewed as the root of T_i, and $\{s_{i,1}, \dots, s_{i,\beta}\}$ are then the leaves. We set

$$\widetilde{T} = \{s_{i,j} \mid i \in [\alpha],\ j \in [\beta]\}$$

and take $\widetilde{S}$ to be a set of $|\widetilde{S}| = \sigma$ new nodes. Noting that $\left|\widetilde{T}\right| = \sigma\beta = \sqrt{n\sigma/\gamma}$, between $\widetilde{S}$ and $\widetilde{T}$ we may plug in an n-node distance preserver lower bound graph H from Hypothesis 36. We then let

$$S := \widetilde{S} \cup \{r_1, \dots, r_\alpha\}.$$

This completes the construction. One immediately counts that the number of vertices is

$$n + \left|\bigcup_{i=1}^{\alpha} T_i\right| = O(n),$$

and $|S| = 2\sigma$, so it remains to argue that an FT subset distance preserver must contain a non-faulty $\widetilde{S} \times \widetilde{T}$ preserver in the copy of H, which thus has $\Omega(n\sigma)$ edges. Consider nodes $t_{i,j} \in \widetilde{T}, s \in \widetilde{S}$. Following the argument in [31], one can verify that on failure of $q_{i,j-1}$, every shortest $r_i \rightsquigarrow s$ path has the form

$$(q_{i,\beta}, \dots, q_{i,j}) \circ L_{i,j} \circ \pi(t_{i,j}, s)$$

where $\pi(t_{i,j}, s)$ is a shortest $t_{i,j} \rightsquigarrow s$ path in H.

5.3 Conditional Lower-Bounds for Directed Unweighted Graphs

For directed unweighted graphs, we prove:

▶ **Hypothesis 38** (Layered $S \times T$ Directed Distance Preserver Lower Bounds). *There is an n-node directed unweighted graph $G = (V, E)$ and demand pairs $S \times T$ with $|S|, |T|, \gamma(S \times T) \leq O(n^{1/3})$ such that any distance preserver of P has $\Omega(n^{4/3})$ edges.*

▶ **Theorem 39.** *Assuming Hypothesis 38, there are examples where $\Omega(n^{4/3})$ edges are needed for a single-pair 1-VFT preserver of a directed unweighted graph.*

To prove Theorem 39, we start with an $s \rightsquigarrow t$ shortest path π of length $\Theta(n^{2/3})$ and an n-node distance preserver lower bound H from Hypothesis 38, and then we add some additional nodes and edges to the graph to carefully connect these two parts of the construction. Then, similar in spirit to our previous lower bounds, we prove that for each $s' \in S, t' \in T$ pair one can fault a particular node on π so that every shortest $s \rightsquigarrow t$ path passes through s', t'. This means one must implicitly keep a (non-faulty) distance preserver of H, which thus has $\Omega(n^{4/3})$ nodes.

Abstract

We study the kernelization complexity of structural parameterizations of the Vertex Cover problem. Here, the goal is to find a polynomial-time preprocessing algorithm that can reduce any instance (G, k) of the Vertex Cover problem to an equivalent one, whose size is polynomial in the size of a pre-determined complexity parameter of G. A long line of previous research deals with parameterizations based on the number of vertex deletions needed to reduce G to a member of a simple graph class $\mathcal{F}$, such as forests, graphs of bounded tree-depth, and graphs of maximum degree two. We set out to find the most general graph classes $\mathcal{F}$ for which Vertex Cover parameterized by the vertex-deletion distance of the input graph to $\mathcal{F}$, admits a polynomial kernelization. We give a complete characterization of the minor-closed graph families $\mathcal{F}$ for which such a kernelization exists. We introduce a new graph parameter called *bridge-depth*, and prove that a polynomial kernelization exists if and only if $\mathcal{F}$ has bounded bridge-depth. The proof is based on an interesting connection between bridge-depth and the size of minimal blocking sets in graphs, which are vertex sets whose removal decreases the independence number.

1 Introduction

Background and motivation. The NP-complete Vertex Cover problem is one of the most prominent problems in the field of kernelization [3, 8, 13, 16, 26], which investigates provably efficient and effective preprocessing for parameterized problems. A *parameterized problem* is a decision problem in which a positive integer k, called the *parameter*, is associated with every instance x. A *kernelization* for a parameterized problem is a polynomial-time algorithm that reduces any parameterized instance (x, k) to an equivalent instance (x', k') of the same problem whose size is bounded by $f(k)$ for some function f, which is the *size* of the kernelization. Hence a kernelization guarantees that instances which are large compared to their parameter, can be efficiently reduced without changing their answer. Of particular interest are *polynomial kernelizations*, whose size bound f is polynomial.

An instance (G, k) of Vertex Cover asks whether the undirected graph G has a vertex set S of size at most k that contains at least one endpoint of every edge. Using the classic Nemhauser-Trotter theorem [28], one can reduce (G, k) in polynomial time to an instance (G', k') with the same answer, such that $|V(G')| \leq 2k$. Hence when using the size of the desired solution as the parameter, Vertex Cover has a kernelization that reduces to instances of $2k$ vertices, which can be encoded in $\mathcal{O}(k^2)$ bits. While the bitsize of this kernelization is known to be essentially optimal [10] assuming the established conjecture $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$, this result does not guarantee any effect of the preprocessing for instances whose solution has size at least $|V(G)|/2$. In particular, it does not promise any size reduction when G is simply a path.

To be able to give better preprocessing guarantees, one can use *structural parameters* which take on smaller values than the size of a minimum vertex cover, a quantity henceforth called the *vertex cover number*. Such structural parameterizations can conveniently be described in terms of the vertex-deletion distance to certain graph families $\mathcal{F}$. Note that the vertex cover number $\textsc{vc}(G)$ of G can be defined as the minimum number of vertex deletions needed to reduce G to an edgeless graph. Hence this number will always be at least as large as the *feedback vertex number* $\textsc{fvs}(G)$ of G, which is the vertex-deletion distance of G to a forest. In 2011, it was shown that Vertex Cover even admits a polynomial kernelization when parameterized by the feedback vertex number [21, 22]. This triggered a long line of follow-up research, which aimed to find the most general graph families $\mathcal{F}$ such that Vertex Cover admits a polynomial kernelization when parameterized by vertex-deletion distance to $\mathcal{F}$. Polynomial kernelizations were obtained for the families $\mathcal{F}$ of graphs of maximum degree two [27], of graphs of constant *tree-depth* [5, 23], of the *pseudo-forests* where each connected component has at most one cycle [17], and for *d-quasi-forests* in which each connected component has a feedback vertex set of size at most $d \in \mathcal{O}(1)$ [18]. Note that all these target graph classes are *closed under taking minors*. Using *randomized algorithms* with a small error probability, polynomial kernelizations are also known for several parameterizations by vertex-deletion distance to graph classes that are not minor-closed, such as Kőnig graphs [25], bipartite graphs [25], and parameterizations based on the linear-programming relaxation of Vertex Cover [19, 24]. On the negative side, it is known that Vertex Cover parameterized by the vertex-deletion distance to a graph of treewidth two [9] does *not* have a polynomial kernel, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. This long line of research into kernelization for structural parameterizations raises the following question:

> How can we characterize the graph families $\mathcal{F}$ for which Vertex Cover parameterized by vertex-deletion distance to $\mathcal{F}$ admits a polynomial kernel?

We answer this question for all minor-closed families $\mathcal{F}$, by introducing a new graph parameter.

Our results. We introduce a new graph parameter that we call *bridge-depth.* It has a recursive definition similar to that of tree-depth [30] (full definitions follow in Section 3), but deals with bridges in a special way. A graph without vertices has bridge-depth zero. The bridge-depth $\mathsf{bd}(G)$ of a disconnected graph G is simply the maximum bridge-depth of its connected components. The bridge-depth of a connected nonempty graph G is defined as follows. Let G_{CB} denote the graph obtained from G by contracting each edge that is a bridge in G; the order does not matter. Then $\mathsf{bd}(G) := 1 + \min_{v \in V(G_{\text{CB}})} \mathsf{bd}(G_{\text{CB}} \setminus v)$. Intuitively, the bridge-depth of G is given by the depth of an elimination process [6] that reduces G to the empty graph. One step consists of contracting all bridges and removing a vertex; each of the remaining connected components is then recursively eliminated in parallel. From this definition, it is not difficult to see that $\mathsf{bd}(G)$ is at least as large as the *tree-width* of G, but never larger than the tree-depth or feedback vertex number of G. In particular, any forest has bridge-depth one.

Using the notion of bridge-depth, we characterize the minor-closed families $\mathcal{F}$ for which Vertex Cover parameterized by vertex-deletion distance to $\mathcal{F}$ admits a polynomial kernel.

▶ **Theorem 1.1.** *Let $\mathcal{F}$ be a minor-closed family of graphs, and assume $\mathsf{NP} \nsubseteq \mathsf{coNP/poly}$. Vertex Cover parameterized by vertex-deletion distance to $\mathcal{F}$ has a polynomial kernelization if and only if $\mathcal{F}$ has bounded bridge-depth.*

Theorem 1.1 gives a clean and unified explanation for all the minor-closed families $\mathcal{F}$ that were previously considered individually [5, 17, 18, 22, 27], and generalizes these results as far as possible. To the best of our knowledge, Theorem 1.1 captures all known (deterministic) kernelizations for structural parameterizations of Vertex Cover. (There are *randomized* kernelizations [19, 24, 25] which apply for distance to classes $\mathcal{F}$ that are *not* minor-closed, such as bipartite graphs.) For example, we capture the case of $\mathcal{F}$ being a forest [22] since forests have bridge-depth one, and the case of $\mathcal{F}$ being graphs of constant tree-depth [5, 23] since bridge-depth does not exceed tree-depth. In this sense, bridge-depth can be seen as the ultimate common generalization of feedback vertex number and tree-depth (which are incomparable parameters) in the context of polynomial kernels for Vertex Cover.

We consider it one of our main contributions to identify the graph parameter bridge-depth as the right way to capture the kernelization complexity of Vertex Cover parameterizations.

Techniques. To describe our techniques, we introduce some terminology. Let $\alpha(G)$ denote the independence number of graph G, i.e., the maximum size of a set of pairwise nonadjacent vertices. A *blocking set* in a graph G is a vertex set $Y \subseteq V(G)$ such that $\alpha(G \setminus Y) < \alpha(G)$. Hence if Y is a blocking set, then every maximum independent set in G contains a vertex from Y. Earlier kernelizations for Vertex Cover parameterized by distance to a graph class $\mathcal{F}$, starting with the work of Jansen and Bodlaender [22], all rely, either implicitly or explicitly, on having upper-bounds on the size of (inclusion-)minimal blocking sets for graphs in $\mathcal{F}$ [5, 17, 18, 22, 27]. For example, it is known that minimal blocking sets in a bipartite graph have size at most two [18, Cor. 11], while minimal blocking sets in graphs of tree-depth c have size at most 2^c [5, Lemma 1]. Similarly, all the existing superpolynomial kernelization lower bounds for parameterizations by distance to $\mathcal{F}$, rely on $\mathcal{F}$ having minimal blocking sets of arbitrarily large size. Indeed, if $\mathcal{F}$ is closed under disjoint union and has arbitrarily large blocking sets, it is easy to prove a superpolynomial lower bound (cf. [19, Thm. 1]).

Since all positive cases for kernelization are when minimal blocking sets of graphs in $\mathcal{F}$ have bounded size, while one easily obtains lower bounds when the size of minimal blocking sets of graphs in $\mathcal{F}$ is unbounded, the question rises whether a bound on the size of minimal blocking sets is a necessary and sufficient condition for the existence of polynomial kernels. To our initial surprise, we show that for minor-closed families $\mathcal{F}$, this is indeed the case: the purely structural property of having bounded-size minimal blocking sets can always be leveraged into preprocessing algorithms.

For an insight into our techniques, consider an instance (G,k) of Vertex Cover, together with a vertex set $X \subseteq V(G)$ such that $G \setminus X \in \mathcal{F}$ for some minor-closed family $\mathcal{F}$ that has bounded-size minimal blocking sets. The goal of the kernelization is then to reduce to an equivalent instance of size $|X|^{\mathcal{O}(1)}$ in polynomial time. Using ideas of the previous kernelizations [5,22], it is quite simple to reduce the *number of connected components* of $G \setminus X$ to size $|X|^{\mathcal{O}(1)}$. To obtain a polynomial kernel, the challenge is therefore to bound the size of each such component C of $G \setminus X$ to $|X|^{\mathcal{O}(1)}$, so that the overall instance size becomes polynomial in $|X|$. However, the non-existence of large minimal blocking sets does not seem to offer any handle for reducing the size of individual components of $G \setminus X$. The route to the kernelization therefore goes via the detour of bridge-depth. We prove the following relation between the sizes of minimal blocking sets and bridge-depth.

▶ **Theorem 1.2.** *Let $\mathcal{F}$ be a minor-closed family of graphs. Then $\mathcal{F}$ has bounded bridge-depth if and only if the size of minimal blocking sets of graphs in $\mathcal{F}$ is bounded.*

Using this equivalence, we can exploit the fact that all minimal blocking sets of $\mathcal{F}$ are of bounded size, through the fact that the bridge-depth of $G \setminus X \in \mathcal{F}$ is small. This means that there is a bounded-depth elimination process to reduce $G \setminus X$ to the empty graph. We use this bounded-depth process in a technical kernelization algorithm following a recursive scheme, inspired by the earlier kernelization for the parameterization by distance to bounded tree-depth [5].

Let us now discuss the ideas behind the equivalence of Theorem 1.2. We prove that the bridge-depth of graphs in a minor-closed family $\mathcal{F}$ is upper-bounded in terms of the maximum size of minimal blocking sets for graphs in $\mathcal{F}$, by exploiting the Erdős-Pósa property in an interesting way. We analyze an elementary graph structure called *necklace of length t*, which is essentially the multigraph formed by a path of t double-edges. If a simple graph $G \in \mathcal{F}$ contains a necklace of length t as a minor, then there is a minor G' of G (which therefore also belongs to $\mathcal{F}$) that has a minimal blocking set of size $\Omega(t)$. Hence to show that bridge-depth is upper-bounded in terms of the size of minimal blocking sets of graphs in $\mathcal{F}$, it suffices to show that bridge-depth is upper-bounded by the maximum length of a necklace minor of graphs in $\mathcal{F}$. Since the definition of bridge-depth allows for the contraction of all bridges in a single step, it suffices to consider bridgeless graphs. Then we argue that in a bridgeless graph, any pair of maximum-length necklace minor models intersects at a vertex (cf. Lemma 4.6). By the Erdős-Pósa property, this implies that there is a constant-size vertex set that hits all maximum-length necklace minor models, and whose removal therefore strictly decreases the maximum length of a necklace minor. If the length of necklace minor models is bounded, then after a bounded number of steps of this process (interleaved with contracting all bridges) we reduce the maximum length of necklace minor models to zero, which is equivalent to breaking all cycles of the graph. At that point, the bridge-depth is one by definition, and we have obtained the desired upper-bound on the bridge-depth in terms of the length of the longest necklace minor, and therefore blocking set size.

For the other direction of Theorem 1.2, we prove (cf. Theorem 5.4) the tight bound that a minimal blocking set in a graph G has size at most $2^{\mathsf{bd}(G)}$. We use induction to prove this statement, together with an analysis of the structure of a tree of bridges whose removal decreases the bridge-depth. The fact that bipartite graphs have minimal blocking sets of size at most two, allows for an elegant induction step.

Related work. In a recent paper, Hols, Kratsch, and Pieterse [19] also analyze the role of blocking sets in the existence of polynomial kernels for structural parameterizations of Vertex Cover. Note that our paper is independent from, and orthogonal to [19]: we consider the setting of *deterministic* kernelization algorithms for parameterizations to *minor-closed* families $\mathcal{F}$, and obtain an exact characterization of which $\mathcal{F}$ allow for a polynomial kernelization. Hols et al. [19] consider hereditary families $\mathcal{F}$ and give kernelizations for several such parameterizations, without arriving at a complete characterization. Some of the randomized kernelizations they provide do not fit into our framework, but all the deterministic kernelizations they present are captured by Theorem 1.1. Another contribution of [19] is to prove that there is a class $\mathcal{F}$ with minimal blocking sets of size one where Vertex Cover cannot be solved in polynomial time. In particular, there is no polynomial kernel parameterized by the distance to this family $\mathcal{F}$, and thus bounded minimal blocking set size is not sufficient to get a polynomial kernel. This implies that our minor-closed assumption of Theorem 1.1 cannot be dropped.

We refer to the survey by Fellows et al. [13] for an overview of classic results and new research lines concerning kernelization for Vertex Cover. Additional relevant work includes the work by Kratsch [24] on a randomized polynomial kernel for a parameterization related to the difference between twice the cost of the linear-programming relaxation of Vertex Cover and the size of a maximum matching.

Organization. Preliminaries on graphs and complexity are presented in Section 2. Section 3 introduces bridge-depth and its properties. In Section 4 we prove one direction of Theorem 1.2, showing that large bridge-depth implies the existence of large minimal blocking sets. In Section 5 we handle the other direction, proving a tight upper-bound on the size of minimal blocking sets in terms of the bridge-depth. We discuss the kernelization algorithm exploiting bridge-depth in Section 6, with the technical content being available in the full version of the article [4] due to space limitations. We conclude the article in Section 7. The proofs of the results marked with "($\star$)" have been also deferred to the full version [4].

2 Preliminaries

Graphs. We use standard graph-theoretic notation, and we refer the reader to Diestel [11] for any undefined terms. All graphs we consider are finite and undirected. Graphs are simple, unless specifically stated otherwise. A graph G has vertex set $V(G)$ and edge set $E(G)$. Given a graph G and a subset $S \subseteq V(G)$, we say that S is *connected* if $G[S]$ is connected, and we use the shorthand $G \setminus S$ to denote $G[V(G) \setminus S]$. For a single vertex $v \in V(G)$, we use $G \setminus v$ as a shorthand for $G \setminus \{v\}$. Similarly, for a set of edges $T \subseteq E(G)$ we denote by $G \setminus T$ the graph on vertex set $V(G)$ with edge set $E(G) \setminus T$. A cycle on three vertices is called a *triangle*. For a positive integer i, we denote by $[i]$ the set of all integers j such that $1 \leq j \leq i$. Given $v \in V(G)$, we denote $N_G(v) = \{u \mid \{u, v\} \in E(G)\}$, $d_G(v) = |N_G(v)|$ and given $X \subseteq V(G)$, we denote $N_G(X) = \bigcup_{v \in X} N_G(v) \setminus X$. Given $X, Y \subseteq V(G)$, we denote by $N_G^Y(X) = N_G(X) \cap Y$. We may omit the subscript G when it is clear from the context. For distinct vertices u and v of a graph G, the graph G' obtained by *identifying* u and v is defined by removing vertices u and v from G, adding a new vertex uv with $N_{G'}(uv) = N_G(\{u, v\})$, and keeping the other vertices and edges unchanged. Given two adjacent vertices u and v, we define the *contraction* of the edge $\{u, v\}$ as the identification of u and v.

Given a graph G, we denote by $\alpha(G)$ the size of a maximum independent set in G, by $\#\textsc{cc}(G)$ the number of connected components of G, by $\mathsf{diam}(G)$ the diameter of G, and by $\Delta(G)$ the maximum degree of G. Given a graph G and a set $S \subseteq V(G)$, we say that S is a *blocking set* in G if $\alpha(G \setminus S) < \alpha(G)$. The maximum size of an inclusion-wise minimal blocking set of a graph G is denoted by $\mathsf{mbs}(G)$.

A graph H is a minor of graph G if H can be obtained from G by a sequence of edge deletions, edge contractions, and removals of isolated vertices. Let us also recall the definition of minor in the context of multigraphs. Let H be a loopless multigraph. An *H-model M* in a simple graph G is a collection $\{S_x^M \mid x \in V(H)\}$ of pairwise disjoint subsets of $V(G)$ such that $G[S_x^M]$ is connected for every $x \in V(H)$, and such that for every pair of distinct vertices x, y of H, the quantity $|\{\{u,v\} \in E(G) \mid u \in S_x^M, v \in S_y^M\}|$ is at least the number of edges in H between x and y. The vertex set $V(M)$ of M is the union of the vertex sets of the subgraphs in the collection. We say that a graph G contains a loopless multigraph H as a *minor* if G has an H-model.

For the following definitions, we refer the reader to [29] for more details and we only recall here some basic notations and facts. The *tree-depth* of a graph G, denoted by $\mathsf{td}(G)$, is defined recursively. The empty graph without vertices has tree-depth zero. The tree-depth of a disconnected graph is the maximum tree-depth of its connected components. Finally, if G is a nonempty connected graph then $\mathsf{td}(G) = 1 + \min_{v \in V(G)} \mathsf{td}(G \setminus v)$. Equivalent definitions exist in terms of the minimum height of a rooted forest whose closure is a supergraph of G. The tree-width of G is denoted $\mathsf{tw}(G)$ (cf. [2]).

Given a graph family $\mathcal{F}$, an *$\mathcal{F}$-modulator* in a graph G is a subset of vertices $X \subseteq V(G)$ such that $G \setminus X \in \mathcal{F}$. We denote by $\mathsf{dist\text{-}to\text{-}}\mathcal{F}(G)$ the size of a smallest $\mathcal{F}$-modulator in G. For a graph measure f that associates an integer with each graph, and an integer c, a *c-f-modulator* is a modulator to $\mathcal{F}_c^{\mathsf{f}} := \{G \mid \mathsf{f}(G) \leq c\}$. We denote by $c\text{-}\mathsf{f}\text{-}\mathsf{mod}(G) := \mathsf{dist\text{-}to\text{-}}\mathcal{F}_c^{\mathsf{f}}(G)$, that is, the size of a smallest c-f-modulator of G. Typical measures f that we consider here are tree-width, tree-depth, and bridge-depth. Notice that $0\text{-}\mathsf{tw}\text{-}\mathsf{mod}(G)$ corresponds to the minimum size of a vertex cover of G, and $1\text{-}\mathsf{tw}\text{-}\mathsf{mod}(G)$ corresponds to the minimum size of a feedback vertex set of G. Finally, IS (resp. VC) denotes the Maximum Independent Set (resp. Minimum Vertex Cover) problem.

Parameterized complexity. A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, for some finite alphabet Σ. For an instance $(x,k) \in \Sigma^* \times \mathbb{N}$, the value k is called the *parameter*. For a computable function $g \colon \mathbb{N} \to \mathbb{N}$, a *kernelization algorithm* (or simply a *kernel*) for a parameterized problem L of *size* g is an algorithm A that given any instance (x,k) of L, runs in polynomial time and returns an instance (x',k') such that $(x,k) \in L \Leftrightarrow (x',k') \in L$ with $|x'|, k' \leq g(k)$. Consult [8,12,14,16,31] for background on parameterized complexity.

3 An introduction to bridge-depth

Let G be a graph. An edge $e \in E(G)$ is a *bridge* if its removal increases the number of connected components of G. We define $G_{\textsc{cb}}$ as the simple graph obtained from G by contracting all bridges of G (the order does not matter.) Observe that, as contracting an edge cannot create a new bridge, $G_{\textsc{cb}}$ has no bridges, implying that $(G_{\textsc{cb}})_{\textsc{cb}} = G_{\textsc{cb}}$. Given a subgraph T of a graph G, we say that T is a *tree of bridges* if T is a tree and, for every $e \in E(T)$, e is a bridge in G. Note that a single vertex is, by definition, a tree of bridges. Note also that with any vertex $v \in V(G_{\textsc{cb}})$ we can associate, in a bijective way, an inclusion-wise maximal tree of bridges T_v of G. The set $\{T_v \mid v \in V(G_{\textsc{cb}})\}$ is a minor model of $G_{\textsc{cb}}$ in G (a

G_{CB}-model, from now on). For any $u, v \in V(G_{\text{CB}})$ such that $\{u, v\} \in E(G_{\text{CB}})$, there is exactly one edge $\{u', v'\} \in E(G)$ with $u' \in T_u$ and $v' \in T_v$. The latter claim can be easily verified by supposing that there are two such edges, implying that some edge in T_u or T_v is involved in a cycle, which contradicts the fact that all the edges in T_u and T_v are bridges.

▶ **Definition 3.1.** *The* bridge-depth $\mathsf{bd}(G)$ *of a graph* G *is recursively defined as follows:*

- *If G is the empty graph without any vertices, then $\mathsf{bd}(G) = 0$.*
- *If G has $\ell > 1$ connected components $\{G_i \mid i \in [\ell]\}$, then $\mathsf{bd}(G) = \max_{i\in[\ell]} \mathsf{bd}(G_i)$.*
- *If G is connected, then $\mathsf{bd}(G) = 1 + \min_{v\in V(G_{\text{CB}})} \mathsf{bd}(G_{\text{CB}} \setminus v)$.*

Informally, bd behaves like tree-depth except that at each step of the recursive definition we are allowed to delete trees of bridges instead of just single vertices, as proved in Item 4 of the following proposition. The following properties of bridge-depth follow from the definitions in an elementary way, often exploiting the fact that if e is a bridge in G, then e is also a bridge in any minor of G that still contains e.

▶ **Proposition 3.2.** *For any graph G the following claims hold:*

1. *$\mathsf{bd}(G) = 1$ if and only if G is a forest with at least one vertex.*
2. *$\mathsf{bd}(G_{\text{CB}}) = \mathsf{bd}(G)$.*
3. *The parameter bd is minor-closed: if G' is a minor of G then $\mathsf{bd}(G') \le \mathsf{bd}(G)$.*
4. *If G is connected, then $\mathsf{bd}(G) = 1 + \min_T \mathsf{bd}(G \setminus V(T))$, where the minimum is taken over all trees of bridges T of G.*
5. *For any $X \subseteq V(G)$, we have $\mathsf{bd}(G) \le |X| + \mathsf{bd}(G \setminus X)$.*
6. *$\mathsf{tw}(G) \le \mathsf{bd}(G)$.*

Proof. The first item follows easily from the definition, while the second one uses that $(G_{\text{CB}})_{\text{CB}} = G_{\text{CB}}$.

Proof of 3: We prove the claim by induction on $|V(G)| + |E(G)|$. Suppose that G has multiple connected components $\{G_i \mid i \in [\#\text{CC}(G)]\}$, and let $\{G'_i \mid i \in [\#\text{CC}(G')]\}$ be the connected components of the minor G' of G. Then each connected component G'_j is a minor of some component G_i of G on fewer than $|V(G)|$ vertices, which gives $\mathsf{bd}(G'_j) \le \mathsf{bd}(G_i)$ by induction. Hence we have $\mathsf{bd}(G') = \max_{j\in[\#\text{CC}(G')]} \mathsf{bd}(G'_j) \le \max_{i\in[\#\text{CC}(G)]} \mathsf{bd}(G_i) = \mathsf{bd}(G)$.

We now deal with the case that G is connected. In general, if some graph G^* is a minor of G, then G^* is a minor of a graph G' obtained from G by removing an edge, contracting an edge, or removing an isolated vertex. Since G is assumed to be connected, the third case cannot occur here. Then by induction, we have $\mathsf{bd}(G^*) \le \mathsf{bd}(G')$, so it suffices to prove that $\mathsf{bd}(G') \le \mathsf{bd}(G)$ for any graph G' obtained by removing or contracting an edge. Let us first prove that if G'_{CB} is a minor of G_{CB}, then $\mathsf{bd}(G') \le \mathsf{bd}(G)$. Indeed, let $v^* \in V(G_{\text{CB}})$ such that $\mathsf{bd}(G) = 1 + \mathsf{bd}(G_{\text{CB}} \setminus v^*)$, and consider an arbitrary component G'_i of G'. Note that $(G'_i)_{\text{CB}}$ is a component of $(G')_{\text{CB}}$, and therefore a minor of G_{CB} by hypothesis. If $(G'_i)_{\text{CB}}$ is a minor of the graph $G_{\text{CB}} \setminus v^*$, then by induction and Item 2 we have $\mathsf{bd}(G'_i) = \mathsf{bd}((G'_i)_{\text{CB}}) \le \mathsf{bd}(G_{\text{CB}} \setminus v^*) < \mathsf{bd}(G)$. Otherwise, any minor model $\{S_x \mid x \in V((G'_i)_{\text{CB}})\}$ of $(G'_i)_{\text{CB}}$ in G_{CB} contains a branch set S_{x^*} with $v^* \in S_{x^*}$. But then $\mathsf{bd}((G'_i)_{\text{CB}}) \le 1 + \mathsf{bd}((G'_i)_{\text{CB}} \setminus x^*)$ by definition, and $(G'_i)_{\text{CB}} \setminus x^*$ is a minor of $G_{\text{CB}} \setminus v^*$, and therefore has bridge-depth at most $\mathsf{bd}(G) - 1$, so that $\mathsf{bd}((G'_i)_{\text{CB}}) \le \mathsf{bd}(G)$. Hence for each component G'_i of G' we have $\mathsf{bd}(G'_i) = \mathsf{bd}((G'_i)_{\text{CB}}) \le \mathsf{bd}(G)$, implying $\mathsf{bd}(G') \le \mathsf{bd}(G)$.

Thus, it only remains to prove that G'_{CB} is a minor of G_{CB}. Let us first assume that G' is obtained from G by removing an edge e. Let $\{T_v \mid v \in V(G_{\text{CB}})\}$ be the G_{CB}-model in G given by the trees of bridges. If e is not a bridge, then e is an edge between T_u and T_v for some vertices $u, v \in V(G_{\text{CB}})$. To obtain G'_{CB} as a minor, we start from G_{CB}, remove edge $\{u, v\}$, and for any edge e' between $T_{u'}$ and $T_{v'}$ (for any $u', v' \in V(G_{\text{CB}})$) that has become a bridge in G' because of the removal of e, we contract $\{u', v'\}$. This implies that G'_{CB} is a minor of G_{CB}. Otherwise, if e is a bridge, then there exists $u \in V(G_{\text{CB}})$ such that $e \in E(T_u)$, and G' has two connected components G'_1 and G'_2. To obtain $(G'_i)_{\text{CB}}$ as a minor, for $i \in [2]$, we start from G_{CB} and remove any vertex v such that $T_v \cap V(G'_i) = \emptyset$ (notice that u appears both in $(G'_1)_{\text{CB}}$ and $(G'_2)_{\text{CB}}$). Thus, both $(G'_1)_{\text{CB}}$ and $(G'_2)_{\text{CB}}$ are minors of G_{CB}, hence G'_{CB} as well. The case where G' is obtained from G by contracting an edge e can be proved using similar but simpler arguments. Indeed, if e is a bridge in G, then we have that $G'_{\text{CB}} = G_{\text{CB}}$, and if it is not, if suffices to contract in G_{CB} the edge $\{u, v\}$ with $u, v \in V(G_{\text{CB}})$ such that e is an edge between T_u and T_v.

Proof of 4: Let $v \in V(G_{\text{CB}})$ and T_v be its associated tree of bridges in G. Observe first that we may have $(G \setminus V(T_v))_{\text{CB}} \neq G_{\text{CB}} \setminus v$. Indeed, if for example we consider G composed of two vertex-disjoint triangles $\{a, b, c\}$, $\{a', b', c'\}$ and an edge $e = \{a, a'\}$, and if we consider $T_v = \{e\}$, then $G_{\text{CB}} \setminus v$ is composed of two disjoint edges, whereas $(G - V(T_v))_{\text{CB}}$ is composed of two isolated vertices. However, it is easy to verify that $(G \setminus V(T_v))_{\text{CB}} = (G_{\text{CB}} \setminus v)_{\text{CB}}$. Let us now prove that $\min_T \mathsf{bd}(G \setminus V(T)) \leq \min_{v \in V(G_{\text{CB}})} \mathsf{bd}(G_{\text{CB}} \setminus v)$. Let v^* be a vertex minimizing $\mathsf{bd}(G_{\text{CB}} \setminus v)$. We have $\min_T \mathsf{bd}(G \setminus V(T)) \leq \mathsf{bd}(G \setminus V(T_{v^*})) = \mathsf{bd}((G \setminus V(T_{v^*})_{\text{CB}})$ using Item 2 in the last equality, and $\mathsf{bd}((G \setminus V(T_{v^*})_{\text{CB}}) = \mathsf{bd}((G_{\text{CB}} \setminus v^*)_{\text{CB}}) = \mathsf{bd}(G_{\text{CB}} \setminus v^*)$ using again Item 2.

For the other inequality, let T^0 be a tree of bridges that minimizes $\mathsf{bd}(G \setminus V(T))$. If T^0 is not inclusion-wise maximal, let T^* be any inclusion-wise maximal tree of bridges containing T^0. Note that as $G \setminus V(T^*)$ is a subgraph of $G \setminus V(T^0)$, by Item 3 we get that $\mathsf{bd}(G \setminus V(T^*)) \leq \mathsf{bd}(G \setminus V(T^0))$, implying that T^* also minimizes $\mathsf{bd}(G \setminus V(T))$. Let $v^* \in V(G_{\text{CB}})$ such that $T_{v^*} = T^*$. We have $\min_{v \in V(G_{\text{CB}})} \mathsf{bd}(G_{\text{CB}} \setminus v) \leq \mathsf{bd}(G_{\text{CB}} \setminus v^*) = \mathsf{bd}((G \setminus T_{v^*})_{\text{CB}}) = \mathsf{bd}(G \setminus T_{v^*})$.

Proof of 5: We use induction on $|X|$, the base case $X = \emptyset$ being trivial. For the induction step, pick an arbitrary $v \in X$, let $X' := X \setminus \{v\}$, and $G' := G \setminus X'$. By induction we have $\mathsf{bd}(G) \leq |X'| + \mathsf{bd}(G')$. Let G'_i be the connected component of G' containing v. Using v as a singleton tree of bridges in G'_i, Item 4 shows that $\mathsf{bd}(G'_i) \leq 1 + \mathsf{bd}(G'_i \setminus v) \leq 1 + \mathsf{bd}(G' \setminus v)$. Since all other components G'_j of G' also occur as components of $G' \setminus v$, it follows that $\mathsf{bd}(G'_j) \leq \mathsf{bd}(G' \setminus v)$, implying $\mathsf{bd}(G') \leq 1 + \mathsf{bd}(G' \setminus v) = 1 + \mathsf{bd}(G \setminus X)$ since $G' \setminus v = G \setminus X$. Hence $\mathsf{bd}(G) \leq |X'| + 1 + \mathsf{bd}(G \setminus X)$.

Proof of 6: We use induction on $|V(G)|$; the base case follows directly from the definitions. It is well-known (cf. [2, Lemma 6]) that the tree-width of G is the maximum tree-width of its biconnected components. Hence it suffices to prove that for an arbitrary biconnected component G' of G, we have $\mathsf{tw}(G') \leq \mathsf{bd}(G')$. If G' consists of a single edge, then $\mathsf{tw}(G') = \mathsf{bd}(G') = 1$. Otherwise, G' is a connected bridgeless graph. This implies $(G')_{\text{CB}} = G'$, so by Definition 3.1 there is a vertex $v \in V(G')$ such that $\mathsf{bd}(G') = 1 + \mathsf{bd}(G' \setminus v)$. Since G' is a minor of G, we have $\mathsf{bd}(G') \leq \mathsf{bd}(G)$ by Item 3. By induction, the tree-width of $G' \setminus v$ is at most $\mathsf{bd}(G' \setminus v) \leq \mathsf{bd}(G) - 1$. Adding vertex v to all bags of a tree decomposition of this width, gives a valid tree decomposition of G' of width at most $\mathsf{bd}(G' \setminus v) + 1 \leq \mathsf{bd}(G')$. Hence $\mathsf{tw}(G') \leq \mathsf{bd}(G')$ for all biconnected components of G. ◀

A $(c+1) \times (c+1)$-grid is a planar graph of tree-width exactly $c+1$ [2, Cor. 89], which implies by Item 6 of Proposition 3.2 that its bridge-depth is larger than c. This gives the following consequence of Proposition 3.2, which will be useful when invoking algorithmic meta-theorems.

▶ **Observation 3.3.** *For each $c \in \mathbb{N}$, the graphs of bridge-depth at most c form a minor-closed family that excludes a planar graph. By the Graph Minor Theorem [35], there is a finite set of forbidden minors $\mathcal{H}_c$ such that $\mathsf{bd}(G) \leq c$ if and only if G excludes all graphs of $\mathcal{H}_c$ as a minor. The set $\mathcal{H}_c$ contains a planar graph, since some planar graphs have bridge-depth $> c$.*

Observation 3.3, together with known results on minor testing, imply the following.

▶ **Proposition 3.4** (Follows from [1, Thm. 7.1])**.** *For each constant $c \in \mathbb{N}$, there is a linear-time algorithm to test whether the bridge-depth of a given graph G is at most c.*

Fomin et al. [15, Thm. 1.3] gave a generic approximation algorithm for finding a small vertex set that hits forbidden minors from a finite forbidden set containing a planar graph. By Observation 3.3, deleting vertices to obtain a graph of bounded bridge-depth fits into their framework.

▶ **Proposition 3.5** (Follows from [15, Thm. 1.3])**.** *For each fixed $c \in \mathbb{N}$ there is a polynomial-time algorithm that, given a graph G, outputs a set $X \subseteq V(G)$ such that $\mathsf{bd}(G \setminus X) \leq c$ and $|X| \leq \mathcal{O}(|X_{\text{opt}}| \log^{2/3} |X_{\text{opt}}|)$, where $|X_{\text{opt}}|$ is the minimum size of such a set.*

The following concept will be crucial to facilitate a recursive approach for reducing graphs of bounded bridge-depth.

▶ **Definition 3.6.** *A* lowering tree *T of a graph G is a tree of bridges (possibly consisting of a single vertex and no bridges) such that $\mathsf{bd}(G \setminus V(T)) = \mathsf{bd}(G) - 1$.*

Item 4 of Proposition 3.2 implies that any connected graph G has a lowering tree.

▶ **Proposition 3.7.** *For each fixed $c \in \mathbb{N}$ there is an algorithm that, given a connected graph G on n vertices of bridge-depth c, computes a lowering tree in $\mathcal{O}(n^2)$ time.*

Proof. Given G, we compute its decomposition into biconnected components, which can be done in linear time taking into account that having bounded bridge-depth implies a linear number of edges [20]. From this decomposition, it is straightforward to identify the inclusion-maximal trees of bridges in G. For each tree of bridges T in G, we can test whether $\mathsf{bd}(G \setminus V(T)) < c = \mathsf{bd}(G)$ in linear time using Proposition 3.4, and we output T if this is the case. By Proposition 3.2, such a tree T exists. Since G is decomposed into at most n trees of bridges, and we need a linear-time computation for each T, this results in an $\mathcal{O}(n^2)$-time algorithm. ◀

4 Bounded minimal blocking sets imply bounded bridge-depth

The goal of this section is to prove one direction of Theorem 1.2, showing that if $\mathcal{F}$ has bounded-size minimal blocking sets, then $\mathcal{F}$ has bounded bridge-depth. As explained in Section 1, we prove this via the intermediate structure of *necklace minors* and show that the bridge-depth of a graph G can be upper-bounded in terms of the longest necklace contained in it as a minor.

This result can be seen as an analog to the fact that the tree-depth of a graph can be bounded in terms of the length of the longest simple path it contains (as a subgraph or as a minor, which is equivalent for paths). A classical proof of this fact (see [29]) is to consider a depth-first search tree of G, bounding the tree-depth of G by the depth of this tree. However, it does not seem immediate to find a similar bound for bridge-depth.

We therefore follow another approach, inspired by the following alternative proof that the tree-depth is upper-bounded by the length of the longest path (which gives a worse bound). Observe that in a connected graph G, any two longest paths intersect at a vertex. (If they did not, one could combine them to make an even longer path.) Given a connected graph G whose longest path has t vertices, we can bound its tree-depth by $f(t) := \sum_{i=1}^{t} i$ as follows. Let P be a longest path in G. Then the longest path in $G \setminus V(P)$ has strictly fewer than t vertices, and by induction the tree-depth of $G \setminus V(P)$ is at most $f(t-1)$. From the definition of tree-depth, it follows that the tree-depth of G is at most $|V(P)| = t$ larger than that of $G \setminus V(P)$, so the tree-depth of G is at most $f(t)$.

In the case of bridge-depth, where paths are replaced with necklaces contained as minors, we cannot afford to remove the entire set of vertices of the corresponding model of a longest necklace, as the size of this set cannot be bounded in terms of the length t of the necklace. To overcome this problem, we will prove in Lemma 4.6, similarly to the case of paths, that there cannot be two vertex-disjoint longest necklaces. Then we resort to the Erdős-Pósa property, which gives us a set of vertices of size $f(t)$ whose removal decreases the maximum length of a longest necklace. We now formalize these ideas.

▶ **Definition 4.1.** *For $t \in \mathbb{N}$, the* necklace of length t*, denoted by N_t, is the multigraph having $t+1$ vertices $\{v_i \mid i \in [t+1]\}$ and two parallel edges between v_i and v_{i+1} for $i \in [t]$.*

▶ **Observation 4.2.** *A simple graph G contains N_t as a minor if and only if G contains $t+1$ vertex-disjoint sets $S_i \subseteq V(G)$ such that each S_i is connected and, for $i \in [t]$, there are at least two edges between S_i and S_{i+1}.*

▶ **Definition 4.3.** *The* necklace-minor length *of a graph G, denoted by $\mathsf{nm}(G)$, is the largest length of a necklace contained in G as a minor, or zero if G contains no such minor.*

We need to introduce the Erdős-Pósa property for packing and covering minor models. Let $\mathcal{F}$ be a finite collection of simple graphs. An *$\mathcal{F}$-model* is an H-model for some $H \in \mathcal{F}$. Two $\mathcal{F}$-models M_1 and M_2 are *disjoint* if $V(M_1) \cap V(M_2) = \emptyset$. Let $\nu_{\mathcal{F}}(G)$ be the maximum cardinality of a packing of pairwise disjoint $\mathcal{F}$-models in G, and let $\tau_{\mathcal{F}}(G)$ be the minimum size of a subset $X \subseteq V(G)$ such that $G \setminus X$ has no $\mathcal{F}$-model. Clearly, $\nu_{\mathcal{F}}(G) \leq \tau_{\mathcal{F}}(G)$. We say that the *Erdős-Pósa property* holds for $\mathcal{F}$-models if there exists a bounding function $f\colon \mathbb{N} \to \mathbb{N}$ such that, for every graph G, $\tau_{\mathcal{F}}(G) \leq f(\nu_{\mathcal{F}}(G))$.

In the case where $\mathcal{F} = \{H\}$ contains a single connected graph H, Robertson and Seymour [34] proved the following result.

▶ **Theorem 4.4** (Robertson and Seymour [34])**.** *Let H be a connected graph. The Erdős-Pósa property holds for H-models if and only if H is planar.*

It is worth mentioning that a tight bounding function when H is planar has been recently obtained by van Batenburg et al. [36]. Theorem 4.4 easily implies the following corollary.

▶ **Corollary 4.5.** *For every $t \geq 1$, the Erdős-Pósa property holds for N_t-models.*

Proof. For $t \geq 1$, let $\mathcal{F}_t$ be the set containing all minor-minimal *simple* graphs that contain the necklace N_t as a minor. By definition, a simple graph G contains an N_t-model if and only if it contains an $\mathcal{F}_t$-model. Clearly, all the graphs in $\mathcal{F}_t$ are connected and planar, and it is easy to see that $|\mathcal{F}_t|$ is bounded by a function of t. For each $F \in \mathcal{F}_t$, by Theorem 4.4 there is a function f_F such that if G does not contain k vertex-disjoint models of F, then all the F-models of G can be hit by at most $f_F(k)$ vertices. This implies that if G does not contain k models of any graph in $\mathcal{F}_t$, then the union of all hitting sets has size bounded by $\sum_{F \in \mathcal{F}_t} f_F(k)$, and since $\mathcal{F}_t$ is finite this is a valid bounding function for N_t-models. ◀

We denote by f_{N_t} the bounding function for N_t-models given by Corollary 4.5. In a connected bridgeless graph, each pair of maximum-length necklace models intersect at a vertex:

▶ **Lemma 4.6.** *If G is a connected bridgeless simple graph with $\mathsf{nm}(G) = t$, then $\nu_{N_t}(G) = 1$.*

Proof. Suppose for contradiction that G contains two disjoint models M^1 and M^2 of N_t. For $i \in [t+1]$ and $\ell \in [2]$, let S_i^ℓ be the vertex set of M^ℓ given by Observation 4.2. Note that these $2t+2$ subsets of vertices of G are pairwise disjoint, and that for any $i \in [t]$, there are at least two edges between S_i^ℓ and S_{i+1}^ℓ. Since G is bridgeless and connected, it is 2-edge-connected and by Menger's theorem [11, § 3.3] G contains two edge-disjoint paths between any pair of vertices. Pick two arbitrary vertices $x_1 \in M^1, x_2 \in M^2$, and let P^1, P^2 be two edge-disjoint paths between them. Consider the subpath Q^ℓ of P^ℓ between the last vertex of M^1 that is visited, until the first vertex of M^2. Let $Q^\ell = (v_1^\ell, \dots, v_{q_\ell}^\ell)$ where $v_1^\ell \in M^1$ and $v_{q_\ell}^\ell \in M^2$. Let a_ℓ such that $v_1^\ell \in S_{a_\ell}^1$ and b_ℓ such that $v_{q_\ell}^\ell \in S_{b_\ell}^2$.

Let us first show that if t is odd, then we can use Q^1 to find an $N_{t'}$-model M' for some $t' > t$ by "gluing" M^1 and M^2, leading to a contradiction. Let $S = S_{a_1}^1 \cup V(Q^1) \cup S_{b_1}^2$. If $a_1 > \frac{t+1}{2}$ define $A = \{S_1^1, \dots, S_{a_1-1}^1\}$, and otherwise define $A = \{S_{a_1+1}^1, \dots, S_{t+1}^1\}$. Similarly, if $b_1 > \frac{t+1}{2}$ define $B = \{S_1^2, \dots, S_{b_1-1}^2\}$, and otherwise define $B = \{S_{b_1+1}^2, \dots, S_{t+1}^2\}$. Note that the sets A, S, B are pairwise disjoint. Since t is odd, it can be easily checked that $M' = A \cup \{S\} \cup B$ is an $N_{t'}$-model in G for some $t' > t$; see Figure 1(a) for an illustration.

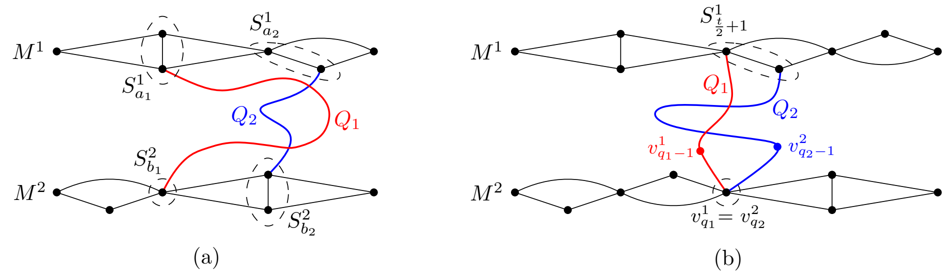

Figure 1 (a) Example with $t = 3$ and $a_1 = b_1 = 2$. (b) Example with $t = 4$.

Let us now consider the case where t is even. Note first that if there exists $\ell \in [2]$ such that $a_\ell \neq \frac{t}{2} + 1$ or $b_\ell \neq \frac{t}{2} + 1$, then we can use Q^ℓ to find an $N_{t'}$-model for some $t' > t$ as in the previous case. Hence, it only remains to consider the case where $a_1 = b_1 = a_2 = b_2 = \frac{t}{2} + 1$, meaning that Q^1 and Q^2 are two edge-disjoint paths, both between $S^1_{\frac{t}{2}+1}$ and $S^2_{\frac{t}{2}+1}$. Let $A = \{S_1^1, \dots, S^1_{\frac{t}{2}}\}$, $B = \{S_1^2, \dots, S^2_{\frac{t}{2}}\}$, and $S = S^1_{a_1} \cup (V(Q^1) \setminus \{v^1_{q_1}\}) \cup (V(Q^2) \setminus \{v^2_{q_2}\})$. We claim that $M' = A \cup \{S, S^2_{\frac{t}{2}+1}\} \cup B$ is an N_{t+1}-model. Indeed, note in particular there are two edges between S and $S^2_{\frac{t}{2}+1}$ as we cannot have $v^1_{q_1-1} = v^2_{q_2-1}$ and $v^1_{q_1} = v^2_{q_2}$ because Q^1 and Q^2 are edge-disjoint and G is a simple graph; see Figure 1(b) for an illustration. ◀

By combining Corollary 4.5 with Lemma 4.6 we easily get the following corollary.

▶ **Corollary 4.7.** *Let G be a connected bridgeless graph and $t = \mathsf{nm}(G)$. Then G contains a set of vertices X with $|X| \leq f_{N_t}(1)$ such that $\mathsf{nm}(G \setminus X) < \mathsf{nm}(G)$, where $f_{N_t} : \mathbb{N} \to \mathbb{N}$ is the bounding function given by Corollary 4.5.*

Proof. By Lemma 4.6, it follows that $\nu_{N_t}(G) = 1$, and therefore by Corollary 4.5

$$\tau_{N_t}(G) \;\le\; f_{N_t}(\nu_{N_t}(G)) \;=\; f_{N_t}(1).$$

Thus, there exists a set $X \subseteq V(G)$ with $|X| \le f_{N_t}(1)$ such that $G \setminus X$ has no N_t-model, implying that $\mathsf{nm}(G \setminus X) < t$. ◀

We are finally in position to prove the following theorem.

▶ **Theorem 4.8.** *There is a function $f\colon \mathbb{N} \to \mathbb{N}$ such that $\mathsf{bd}(G) \le f(\mathsf{nm}(G))$ for all graphs G.*

Proof. We prove the statement by induction on $\mathsf{nm}(G)$, for the function f defined by $f(t) := 1 + \sum_{i=1}^{t} f_{N_i}(1)$. If $\mathsf{nm}(G) = 0$, then G is a forest, and by definition of bridge-depth we get $\mathsf{bd}(G) = 1 = f(0)$. Suppose now that $\mathsf{nm}(G) = t$ with $t > 0$.

Consider the case that G is connected. Then G_{CB} is also connected and has no bridge, and thus we can apply Corollary 4.7 and get a set $X \subseteq V(G_{\text{CB}})$ with $|X| \le f_{N_t}(1)$ such that $\mathsf{nm}(G') < t$, where $G' = G_{\text{CB}} \setminus X$. By Item 5 of Proposition 3.2, we get that $\mathsf{bd}(G) = \mathsf{bd}(G_{\text{CB}}) \le |X| + \mathsf{bd}(G')$. Let $G'_1, \ldots, G'_\ell$ be the connected components of G'. As $\mathsf{nm}(G') < t$, we get that $\mathsf{nm}(G'_i) < t$ for every $i \in [\ell]$. Then, by induction hypothesis it follows that, for every $i \in [\ell]$, $\mathsf{bd}(G'_i) \le f(t-1) = 1 + \sum_{i=1}^{t-1} f_{N_i}(1)$. Thus, as $\mathsf{bd}(G') = \max_{i\in[\ell]} \mathsf{bd}(G'_i) \le 1 + \sum_{i=1}^{t-1} f_{N_i}(1)$, we get that

$$\mathsf{bd}(G) \;\le\; |X| + \mathsf{bd}(G') \;\le\; f_{N_t}(1) + 1 + \sum_{i=1}^{t-1} f_{N_i}(1) \;=\; 1 + \sum_{i=1}^{t} f_{N_i}(1) \;=\; f(\mathsf{nm}(G)).$$

Finally, if G is disconnected, let $G_1, \ldots, G_\ell$ be its connected components, and note that $\mathsf{bd}(G) = \max_{i\in[\ell]} \mathsf{bd}(G_i)$. Since for every $i \in [\ell]$ it holds that $\mathsf{nm}(G_i) \le \mathsf{nm}(G)$, and since the function f is non-decreasing, by applying the above case to each connected component of G we get that

$$\mathsf{bd}(G) \;=\; \max_{i\in[\ell]} \mathsf{bd}(G_i) \;\le\; \max_{i\in[\ell]} f(\mathsf{nm}(G_i)) \;\le\; \max_{i\in[\ell]} f(\mathsf{nm}(G)) \;=\; f(\mathsf{nm}(G)).$$ ◀

Now that we established a relation between bridge-depth and necklace minors, our next step is to relate necklace minors to blocking sets. For this purpose, we use the known triangle-path gadget.

▶ **Definition 4.9.** *A* triangle-path of length t *is the graph consisting of t vertex-disjoint triangles, with vertex sets $\{\{a_i, b_i, c_i\} \mid i \in [t]\}$, together with the $t-1$ edges $\{\{b_i, a_{i+1}\} \mid i \in [t-1]\}$. The* triangle-path-minor length *of a graph G, denoted by $\mathsf{tpm}(G)$, is the largest length of a triangle-path contained in G as a minor, or zero if no such minor exists.*

A slight variation of this gadget was used by Fomin and Strømme [17, Def. 6]. We observe the following (cf. [17, Obs. 3–5]).

▶ **Observation 4.10.** *Let G be a triangle-path of length $t \ge 2$. Then $\mathsf{mbs}(G) \ge t+2$, as $\{a_1, c_1\} \cup \{b_t, c_t\} \cup \{c_i \mid i \in [2, t-1]\}$ is a minimal blocking set.*

▶ **Lemma 4.11.** *For any graph G, $\mathsf{tpm}(G) \ge \lfloor \frac{\mathsf{nm}(G)+1}{2} \rfloor$.*

Proof. Let $t = \mathsf{nm}(G)$, and let $\{S_i \mid i \in [t+1]\}$ be an N_t-model in G. Let $i \in [\lfloor \frac{t+1}{2} \rfloor]$ and let $e_1 = \{u_1, v_1\}$ and $e_2 = \{u_2, v_2\}$ be the two edges between S_{2i-1} and S_{2i}, with $u_\ell \in S_{2i-1}$ and $v_\ell \in S_{2i}$. If $u_1 \neq u_2$ then there is a partition A_1, A_2 of S_{2i-1} such that $u_i \in A_i$ and A_i is connected for $i \in [2]$, and we define $L_i = \{A_1, A_2\}$, $R_i = \{S_{2i}\}$. Otherwise, if $u_1 = u_2$, then necessarily $v_1 \neq v_2$, and we define symmetrically $L_i = \{S_{2i-1}\}$ and $R_i = \{A_1, A_2\}$. In both cases we get that $L_i \cup R_i$ is a model of a triangle, and moreover there is an edge between a vertex in R_i and a vertex in L_{i+1} for every $i \in [\lfloor \frac{t+1}{2} \rfloor - 1]$. This implies that $\bigcup_{i \in [\lfloor \frac{t+1}{2} \rfloor]} (L_i \cup R_i)$ is a model of a triangle-path of length $\lfloor \frac{t+1}{2} \rfloor$ in G. ◀

▶ **Corollary 4.12.** *There is a function $g \colon \mathbb{N} \to \mathbb{N}$ such that $\mathsf{bd}(G) \leq g(\mathsf{tpm}(G))$ for all graphs G.*

Proof. By Lemma 4.11, we have that $\mathsf{tpm}(G) \geq \mathsf{nm}(G)/2$. By letting $g(t) := f(2t)$, where f is the function given by Theorem 4.8, we get the desired result. ◀

▶ **Corollary 4.13.** *Let $\mathcal{F}$ be a minor-closed family of graphs. If $\mathcal{F}$ has unbounded bridge-depth then it contains the family $\mathcal{F}^{\mathsf{tp}}$ of all triangle-paths.*

Using this corollary, we can prove one direction of Theorem 1.2.

▶ **Theorem 4.14.** *Let $\mathcal{F}$ be a minor-closed family of graphs of unbounded bridge-depth. Then there are graphs in $\mathcal{F}$ that have arbitrarily large minimal blocking sets.*

Proof. By Corollary 4.13, $\mathcal{F}$ contains all triangle-paths. Since a triangle-path of length t contains a minimal blocking set of size $t + 2$ by Observation 4.10, the theorem follows. ◀

Theorem 4.14 is phrased for graph families, rather than individual graphs. There is no function h such that $\mathsf{bd}(G) \leq h(\mathsf{mbs}(G))$ for all G: a bipartite grid graph can have arbitrarily large tree-width and therefore bridge-depth, but its minimal blocking sets have size at most two (cf. Lemma 5.2).

5 Bounded bridge-depth implies bounded-size blocking sets

In this section we prove the other direction of Theorem 1.2: minimal blocking sets in a graph G have size at most $2^{\mathsf{bd}(G)}$. We need the following consequence of Kőnig's theorem.

▶ **Lemma 5.1.** *Let G be a bipartite graph and let M be a maximum matching in G. Every maximum independent set of G contains all vertices that are not saturated by M, and exactly one endpoint of each edge in M.*

Proof. Consider a maximum independent set S in G. Then $\overline{S} := V(G) \setminus S$ is a minimum vertex cover of G. By Kőnig's theorem (cf. [11, Thm. 2.1.1]) we have $|\overline{S}| = |M|$. Since $\overline{S}$ is a vertex cover it contains at least one endpoint of each edge of M; since $|\overline{S}| = |M|$ it contains exactly one endpoint of each edge of M, and no other vertices of G. So the complement S contains all vertices that are not saturated by M, and exactly one endpoint of each edge in M. ◀

The next lemma shows that minimal blocking sets in a bipartite graph have at most two vertices. This was known before, see for example [18, Thm. 14]. Our self-contained proof highlights an additional property of such minimal blocking sets: the two vertices of minimal blocking sets of size two belong to opposite partite sets. This will be crucial later on.

▶ **Lemma 5.2.** *Let G be a bipartite graph with partite sets A and B. If $Y \subseteq V(G)$ is a blocking set in G, then there is a blocking set $Y' \subseteq Y$ in G such that one of the following holds:*

- *$|Y'| = 1$, or*
- *$Y' = \{a, b\}$ for some $a \in A$ and $b \in B$.*

Proof. Let M be a maximum matching in G, let $V(M)$ be the saturated vertices, and let $U := V(G) \setminus V(M)$ be the unsaturated vertices. Let $R_{A \cap U}$ be the vertices that can be reached by an M-alternating path from $A \cap U$ (which necessarily starts with a non-matching edge). Let $R_{B \cap Y}$ be the vertices that can be reached by an M-alternating path that starts with a *matching edge* from a vertex of $B \cap Y$. Note that both types of alternating paths move from A to B over non-matching edges, and move from B to A over matching edges.

We first deal with some cases in which we easily obtain a blocking set Y' as desired.

Case 1: $A \cap Y \cap R_{A \cap U} \neq \emptyset$. Let $a \in A \cap Y \cap R_{A \cap U}$. Then $a \in A$ can be reached by an M-alternating path P that starts in an unsaturated vertex in the same partite set, implying that P has even length and ends with a matching edge into a. Hence $M' := M \oplus E(P)$, where $\oplus$ denotes the symmetric difference, is a new maximum matching, and it does not saturate $a \in A \cap Y$. Lemma 5.1 applied to M' implies that all maximum independent sets of G contain a, showing that $Y' := \{a\}$ is a blocking set of size one.

Case 2: $B \cap U \cap R_{B \cap Y} \neq \emptyset$. By definition, some $u \in B \cap U$ can be reached by an M-alternating path P that starts in some vertex $b \in B \cap Y$ that belongs to the same partite set. Similarly as in the previous case, $M' := M \oplus E(P)$ is a new maximum matching that does not saturate b, so by Lemma 5.1 applied to M' we conclude that $Y' := \{b\}$ is a blocking set of size one.

Case 3: $A \cap Y \cap R_{B \cap Y} \neq \emptyset$. By definition, some $a \in A \cap Y$ is reachable by an M-alternating path P from some $b \in B \cap Y$, and P starts with a matching edge. Since it ends in the other partite set, it ends with a matching edge as well; hence both a and b are saturated. We claim that $Y' := \{a, b\}$ is a blocking set in G, as desired. Let $a = a_1, b_1, \ldots, a_k, b_k = b$ be the vertices on P, so that $\{a_i, b_i\} \in M$ for all $i \in [k]$ and $\{b_i, a_{i+1}\} \in E(G) \setminus M$ for $i \in [k-1]$. By Lemma 5.1, a maximum independent set in G contains one endpoint of each of the edges $\{a_i, b_i\} \in M$. A maximum independent set avoiding a_1 therefore has to contain b_1, preventing it from containing a_2, forcing it to contain b_2, and so on. Hence a maximum independent set avoiding a_1 contains b_k, proving that $Y' := \{a, b\} = \{a_1, b_k\}$ is a blocking set in G.

Case 4: $B \cap U \cap R_{A \cap U} \neq \emptyset$. Then some unsaturated vertex of A can reach an unsaturated vertex of B by an M-alternating path P. But then M is not a maximum matching since $M \oplus E(P)$ is larger; a contradiction. Hence this case cannot occur.

Assume now that none of the cases above hold. We will conclude the proof of the lemma by deriving a contradiction. Let $R := R_{A \cap U} \cup R_{B \cap Y}$. The following will be useful.

▷ Claim 5.3. If $a \in A \cap R$ and $\{a, b\} \in E(G)$, then $b \in B \cap R$.

Proof. By definition, $a \in A \cap R$ implies a is reachable by some M-alternating path P that moves to A over matching edges and moves to B over non-matching edges, such that P starts in a vertex $v \in (A \cup U) \cup (B \cap Y)$. But then b is also reachable by such an alternating path from v: if $\{a, b\} \in M$ then, since P ends at a, edge $\{a, b\}$ must be the last edge of P, so a prefix of P is an M-alternating path reaching b; if $\{a, b\} \notin M$ then appending $\{a, b\}$ to P yields such an M-alternating path. Hence $b \in R$, and $b \in B$ follows since G is bipartite. ◁

Now consider the following set: $S := (A \cap R) \cup (B \setminus R)$.

We will prove that S is a maximum independent set of G disjoint from Y, contradicting the assumption that Y is a blocking set. To see that S is indeed an independent set, consider any vertex from $A \cap S$, which belongs to $A \cap R$. By Claim 5.3 all neighbors of a belong to $B \cap R$, and are therefore not contained in S. Hence S is indeed an independent set. To see that it is maximum, by Lemma 5.1 it suffices to argue it contains all of U and one endpoint of each edge in M.

To see that S contains all vertices of $A \cap U$, note that all such vertices are trivially in $R_{A \cap U}$ and therefore in R, implying their presence in $A \cap R$ and therefore in S. To see that S contains all vertices of $B \cap U$, it suffices to show that $B \cap U \cap R = \emptyset$, which follows from the fact that neither Case 2 nor Case 4 is applicable. Hence S contains all vertices of U.

To see that S contains an endpoint of each edge of M, let $\{a, b\} \in M$ be arbitrary with $a \in A$ and $b \in B$. If $b \notin R$ then clearly $b \in S$, as desired. If $b \in R$, then this is witnessed by an alternating path P that reaches b and ends with a non-matching edge. Extending P with the edge $\{a, b\} \in M$ then shows that $a \in R$, so that $a \in A \cap R$ is an endpoint of the edge contained in S.

Hence S is a maximum independent set in G. Since Case 1 and Case 3 do not apply, it follows that $A \cap R \cap Y = \emptyset$, so that $S \cap A$ contains no vertex from Y. Since all vertices of $B \cap Y$ are trivially in $R_{B \cap Y}$ and therefore in R, it follows that $B \setminus R$ contains no vertex from Y. Hence S is a maximum independent set in G disjoint from Y, contradicting the assumption that Y is a blocking set. ◀

We will use Lemma 5.2 to power the induction step in the proof of the next theorem, which gives the desired upper-bound on the size of minimal blocking sets in terms of bridge-depth. The main idea in the induction step is as follows. For a connected graph G, we consider a tree of bridges T for which $\mathsf{bd}(G \setminus V(T)) < \mathsf{bd}(G)$. We can summarize the relevant ways in which a maximum independent set in G can be composed out of maximum independent sets for the connected components of $G \setminus E(T)$, into a weighted tree T' that is obtained from T by adding a pendant leaf to each vertex. In turn, maximum-weight independent sets in T' correspond to maximum independent sets a bipartite graph obtained from T' by replacing each vertex by a set of false twins. Applying Lemma 5.2 to this bipartite graph points to two vertices that form a blocking set. We can translate this back into two components of $G \setminus E(T)$ that are sufficient for constructing a blocking set in G, and apply induction using the fact that $\mathsf{bd}(G \setminus V(T)) < \mathsf{bd}(G)$.

▶ **Theorem 5.4** ($\star$). *Let G be a graph and $Y_G \subseteq V(G)$ a blocking set in G. There is a blocking set $Y'_G \subseteq Y_G$ in G of size at most $2^{\mathsf{bd}(G)}$.*

Note that Theorem 5.4 and Theorem 4.14 together prove Theorem 1.2. We finish the section by showing that the upper-bound of $2^{\mathsf{bd}(G)}$ on the size of minimal blocking sets is tight.

▶ **Theorem 5.5.** *For every $c \in \mathbb{N}$, there is a graph G with $\mathsf{bd}(G) \leq c$ that contains a minimal blocking set of size 2^c.*

Proof. Recall the notion of triangle-path from Definition 4.9. For $t \geq 2$, let a *truncated triangle-path of length t* be the graph U_t obtained from a triangle-path of length t by removing vertices a_1 and b_t; see Figure 2. Analogously to Observation 4.10, we show that $Y_t := \{c_i \mid i \in [t]\}$ is a minimal blocking set in U_t. Since Y_t is an independent set of size t, while (the remainders of) the triangles in U_t partition the vertices of U_t into t cliques, it follows that $\alpha(U_t) = t$. The set Y_t is a blocking set, since $U_t \setminus Y_t$ is a path on $2(t-1)$ vertices, whose independence number is only $t - 1$. Finally, it is easy to see that for any $y \in Y_t$, there is a size-t independent set in $U_t \setminus (Y_t \setminus y)$ that consists of the vertex y and, for every (remainder of a) triangle in U_t, the vertex closest to y.

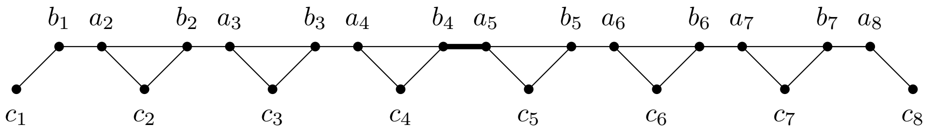

Figure 2 Truncated triangle path U_8 of length 8, illustrating Theorem 5.5. Removing the fat middle bridge and its incident vertices, leaves two connected components isomorphic to U_4.

Hence U_t has a minimal blocking set of size t, for all $t \geq 2$. To prove the theorem, it therefore suffices to show that $\mathsf{bd}(U_{2^c}) \leq c$ for all $c \in \mathbb{N}$. We prove this by induction on c. For $c = 1$, note that the graph U_2 is just the four-vertex path. Hence it is a forest, implying $\mathsf{bd}(U_2) = 1$ by Proposition 3.2. For $c > 1$, consider the graph U_{2^c}. By construction, the middle edge $e = \{b_{2^{c-1}}, a_{2^{c-1}+1}\}$ is a bridge in U_{2^c}. Let T be the tree in U_{2^c} consisting of the single bridge e. Note that removing $V(T)$ splits U_{2^c} evenly, into two connected components that are both isomorphic to $U_{2^{c-1}}$. By induction, $\mathsf{bd}(U_{2^{c-1}}) \leq c - 1$. Then Proposition 3.2 shows that $\mathsf{bd}(U_{2^c}) \leq 1 + \mathsf{bd}(U_t \setminus V(T)) = 1 + (c - 1) = c$. ◀

6 Kernelization for modulators to bounded bridge-depth

To establish the positive direction of Theorem 1.1, we develop a polynomial kernel for Vertex Cover parameterized by the size of a modulator X whose removal leaves a graph of constant bridge-depth; an approximately optimal such set X can be computed using Proposition 3.5. As the kernelization is technical and consists of many different reduction rules, with a nontrivial size analysis, the material is deferred to the full version [4]. In this limited space, we present the high-level idea behind the kernelization and the role of bridge-depth.

Consider an instance (G, k) of Vertex Cover with a modulator X such that $\mathsf{bd}(G \setminus X) \in \mathcal{O}(1)$. As explained in the introduction, using the fact that minimal blocking sets for the components C of $G \setminus X$ have bounded size, the number of such components can easily be bounded by $|X|^{\mathcal{O}(1)}$. To bound the size of individual components, the definition of bridge-depth ensures that in each connected component C of $G \setminus X$ there is a tree of bridges $T \subseteq E(C)$ (called a *lowering tree*) such that removing the vertex set $V(T)$ from C decreases the bridge-depth of C. By designing new problem-specific reduction rules, we shrink the tree of bridges to size polynomial in the parameter. This is where the main technical work of the kernelization step lies. It properly subsumes the earlier kernelization for the parameterization by distance to a forest, which is imported as a black box in all previous works [5, 17–19, 27]. Having bounded the number of components of $G \setminus X$, together with the size of a lowering tree of bridges in each component, we now proceed as follows: in each component C of $G \setminus X$ we move the vertices from a lowering tree of bridges into the set X. This blows up $|X|$ by a polynomial factor, but strictly decreases the bridge-depth of the graph $G \setminus X$. We then recursively kernelize the resulting instance. When the bridge-depth of $G \setminus X$ reaches zero, the graph $G \setminus X$ is empty and the kernelization is completed. Full details can be found in the full version [4].

The negative direction of Theorem 1.1 is much easier to establish. Using the fact that a minor-closed family $\mathcal{F}$ of unbounded bridge-depth contains all triangle paths, a kernelization lower bound for modulators to such $\mathcal{F}$ follows easily using known gadgets.

7 Conclusion

In this paper we introduced the graph parameter bridge-depth and used it to characterize the minor-closed graph classes $\mathcal{F}$ for which Vertex Cover parameterized by $\mathcal{F}$-modulator has a polynomial kernel. It would be interesting to see whether the characterization can be extended to subgraph-closed or even hereditary graph classes. If a characterization exists of the hereditary graph classes whose modulators lead to a polynomial kernel, it will likely not be as clean as Theorem 1.1: it will have to deal with the fact that bipartite graphs can be arbitrarily complex in terms of width parameters, while bipartite modulators allow for a polynomial kernel. Hence such a characterization has to capture parity conditions of $\mathcal{F}$.

A natural attempt to generalize our approach to deal with bipartite graphs is to consider the following parameter, which we call *bipartite-contraction-depth*: we mimic the definition of bridge-depth (cf. Definition 3.1), except that we redefine the graph G_{CB} to be the graph obtained from G by *simultaneously* contracting all edges that do *not* lie on an odd cycle. Note that bipartite-contraction-depth generalizes bridge-depth, in the sense that bridges do not lie on an odd cycle, and that the bipartite-contraction-depth of a graph with an odd cycle transversal of size k is at most $k+1$. Having defined this parameter, we would need, in order to obtain a statement similar to Theorem 4.14, that large bipartite-contraction-depth implies the existence of structures that allow to obtain kernel lower bounds, similarly to the fact that large bridge-depth implies the existence of large triangle-paths (cf. Corollary 4.13). The appropriate structure here seems to be an *odd-cycle-path of length t*, defined as a set of t vertex-disjoint odd cycles $C_1, \ldots, C_t$, and a set of $t-1$ vertex-disjoint paths (of any length) connecting C_i to C_{i+1} for $i \in [t-1]$, in such a way that for every $i \in \{2, \ldots, t-1\}$, the two attachment vertices in C_i are distinct. Now the expected property would be that large bipartite-contraction-depth forces long odd-cycle-paths. Unfortunately, this is not true. Indeed, consider the *Escher wall of size h* depicted in [33, Fig. 3]. It is proved in [33] that this graph does not contain two vertex-disjoint odd cycles, but a smallest hitting set for odd cycles has size h. Since there are no two vertex-disjoint cycles, a longest odd-cycle-path has length one. On the other hand, it can be easily verified that an Escher wall of size h has bipartite-contraction-depth $\Omega(h)$. Informally, this can be seen by noting that, initially, all edges lie on an odd cycle, hence a vertex removal is required, and that each such removal cascades in a constant number of contractions until all edges lie again on an odd cycle. Since a smallest hitting set for odd cycles of an Escher wall of size h has size h, the claimed bound follows. Therefore, summarizing this discussion, if one aims at a result similar to Theorem 1.1 that also applies to families $\mathcal{F}$ containing bipartite graphs, it seems that significant new ideas are required.

Another open research direction consists of a further algorithmic exploration of the merits of bridge-depth. We expect that several polynomial-space fixed-parameter tractable algorithms that work for graphs of bounded tree-depth [7, 32] can be extended to work with bridge-depth instead. Which other ways to enrich the recursive definition of tree-depth lead to novel algorithmic insights? As for kernelization purposes, it is plausible that bridge-depth also characterizes the existence of polynomial kernels for other problems other than Vertex Cover, parameterized by the vertex-deletion distance of the input graph to a minor-closed graph class.

Abstract

While 3-SAT is NP-hard, 2-SAT is solvable in polynomial time. Austrin, Guruswami, and Håstad [FOCS'14/SICOMP'17] proved a result known as "$(2+\varepsilon)$-SAT is NP-hard". They showed that the problem of distinguishing k-CNF formulas that are g-satisfiable (i.e. some assignment satisfies at least g literals in every clause) from those that are not even 1-satisfiable is NP-hard if $\frac{g}{k} < \frac{1}{2}$ and is in P otherwise. We study a generalisation of SAT on arbitrary finite domains, with clauses that are disjunctions of unary constraints, and establish analogous behaviour. Thus we give a dichotomy for a natural fragment of promise constraint satisfaction problems (PCSPs) on arbitrary finite domains.

1 Introduction

It is a classic result that while 3-SAT is NP-hard [12, 22], 2-SAT can be solved in polynomial-time [21]. Austrin, Guruswami, and Håstad [2] considered the promise problem $(1, g, k)$-SAT (for integers $1 \le g \le k$): given a k-CNF formula with the promise that there is an assignment that satisfies at least g literals in each clause, find an assignment that satisfies at least one literal in each clause. They showed that the problem is NP-hard if $\frac{g}{k} < \frac{1}{2}$ and in P otherwise. Viewing k-SAT as $(1, 1, k)$-SAT, this shows that, in a natural sense, the transition from tractability to hardness occurs just after 2 and not just before 3.

The *set-satisfiability* (SetSAT) problem generalises the Boolean satisfiability problem to larger domains and we prove that it exhibits an analogous hardness transition. As in (a, g, k)-SAT, for integer constants $1 \leq a \leq g \leq k$ and $1 \leq s < d$, an instance of the (a, g, k)-SetSAT problem is a conjunction of clauses, where each clause is a disjunction of k literals. However, variables $x_1, \ldots, x_n$ can take values in a larger domain $[d] = \{1, \ldots, d\}$, while literals take the form "$x_i \in S$", where S is any subset of the domain $[d]$ of size s. As in the Boolean case, an assignment $\sigma\colon \{x_1, \ldots, x_n\} \to [d]$ is g-satisfying if it satisfies at least g literals in every clause. In (a, g, k)-SetSAT with set size s and domain size d, given an instance promised to be g-satisfiable, we are to find an a-satisfying assignment. When $s = 1$ and $d = 2$ we recover Boolean promise SAT, whereas when $a = g = 1$ we recover the non-promise version of SetSAT.

The most natural case of SetSAT is when we allow *all* nontrivial unary constraints (sets) as literals, i.e., the case $s = d - 1$. (While we defined sets defining literals to have size exactly s, one can simulate sets of size at most s by replacing them with all possible supersets of size s; see the proof of [9, Proposition A.5]). More generally one could consider the problem restricted to any family of literals. Our work deals with the "folded" case: if a set S is available as a literal, then for all permutations of the domain π, $\pi(S)$ is also available as a literal. In this case only the cardinality of S matters, and in fact only the maximum available cardinality matters, so all such problems are equivalent to (a, g, k)-SetSAT, for some constants a, g, k, s, d.

1.1 Related work

Our main motivation to study SetSAT as a promise problem is the fact that it constitutes a natural fragment of so-called promise constraint satisfaction problems (PCSPs), which are problems defined by homomorphisms between relational structures (see Section 2 for more details). PCSPs were studied as early as in the classic work of Garey and Johnson [16] on approximate graph colouring, but a systematic study originated in the paper of Austrin et al. [2]. In a series of papers [5, 6, 7], Brakensiek and Guruswami linked PCSPs to the universal-algebraic methods developed for the study of non-uniform CSPs [4]. In particular, the notion of (weak) polymorphisms, formulated in [2], allowed some ideas developed for CSPs to be used in the context of PCSPs. The algebraic theory of PCSPs was then lifted to an abstract level by Barto, Bulín, Krokhin, and Opršal in [10, 3]. Consequently, this theory was used by Ficak, Kozik, Olšák, and Stankiewicz to obtain a dichotomy for symmetric Boolean PCSPs [15], thus improving on an earlier result from [6], which gave a dichotomy for symmetric Boolean PCSPs with folding. Further resent results on PCSPs include the work of Krokhin and Opršal [20], Brakensiek and Guruswami [8], and Austrin, Bhangale, and Potukuchi [1].

Variants of the Boolean satisfiability problem over larger domains have been defined using CNFs by Gil, Hermann, Salzer, and Zanuttini [17] and DNFs by Chen and Grohe [11] but, as far as we are aware, have not been studied as promise problems before.

1.2 Results

We completely resolve the complexity of (a, g, k)-SetSAT. As our main result, we show that the complexity of $(1, g, k)$-SetSAT depends only on the ratio $\frac{g}{k}$.

▶ **Theorem 1.** *$(1, g, k)$-SetSAT with set size s and domain size $s+1$ is solvable in polynomial time if $\frac{g}{k} \geq \frac{s}{s+1}$ and is NP-hard otherwise.*

Our result generalises the case of $(1, g, k)$-SAT, where $s = 1$ and the hardness threshold is $\frac{1}{2}$. The general case, when $a \neq 1$ or $d > s + 1$, follows by simple reductions (cf. [9, Corollary A.4]). The positive side of the theorem is proved by a simple randomised algorithm based on classical work of Papadimitriou [23], just as in the Boolean case. The main difficulty is in proving NP-hardness when the ratio $\frac{g}{k}$ is close to, but below $\frac{s}{s+1}$.

Following [2] and the more abstract algebraic framework of [3], the hardness proof relies on understanding polymorphisms, i.e., high-arity functions $f\colon [d]^n \to [d]$ which describe the symmetries of our computational problem. In the Boolean case, the proof of [2] relies on showing that every polymorphism depends on only a few variables (in other words, is a junta), and that this condition suffices for a reduction from the gap label cover problem. In our case, this condition does not hold, and neither do the various generalisations of it used in later work on PCSPs [15, 3, 20]. In fact, we show in [9, Section 6] that SetSAT has significantly richer, more robust polymorphisms, which makes the application of many such conditions impossible. Our main technical contribution is a new condition that guarantees an NP-hardness reduction from a multilayered variant of the gap label cover problem.

As in previous work, the combinatorial core of our NP-hardness results for SetSAT relies on identifying, in every polymorphism $f\colon [d]^n \to [d]$, a small set of distinguished coordinates. The rough idea is that a polymorphism encodes a 1-in-n choice analogously to the long code, and the reduction relies on being able to decode f with small ambiguity.

The set of distinguished coordinates could be, in the simplest case, those on which f depends (called *essential coordinates*) and, as shown in [2], a small set of essential coordinates is sufficient for hardness of $(1, g, k)$-SAT if $\frac{g}{k} < \frac{1}{2}$. More generally, the distinguished set S could be such that some partial assignment to S makes f constant (as a function of its remaining coordinates), or restricts the range of f (called *fixing* [2, 15] and *avoiding* [3] sets, respectively). As shown in [9, Section 6], the polymorphisms of SetSAT on non-Boolean domains do not have small sets of coordinates that are essential, fixing, or avoiding. Instead, in this paper we introduce the notion of a *smug set* of f. We say that a set $S \subseteq [n]$ is smug if for some input $(a_1, \dots, a_n)$ to f, the coordinates i whose values a_i agree with the output $f(a_1, \dots, a_n)$ are exactly those in S. We show that every polymorphism of SetSAT has a smug set of constant size (independent of n) and cannot have many disjoint smug sets.

In previous work, it was crucial that essential coordinates respect minors. We say that (an m-ary function) g is a *minor* of (an n-ary function) f if $g(x_1, \dots, x_m) \approx f(x_{\pi(1)}, \dots, x_{\pi(n)})$ for some $\pi\colon [n] \to [m]$ (that is, g is obtained from f by identifying or permuting coordinates of f, or introducing inessential coordinates). In that case, if S contains all essential coordinates of f, then $\pi(S)$ contains all essential coordinates of g. This does not hold for smug sets; instead, if S is a smug set of g, then its pre-image $\pi^{-1}(S)$ is a smug set of f. The pre-image may however be much larger. Still, these properties of smug sets are enough to guarantee that, in any sufficiently long chain of minors, if one chooses a random coordinate in a small smug set from each function in the chain, then for some two functions in the chain the choices will agree, respecting the minor relation between them with constant probability. We show that this condition is sufficient to obtain NP-hardness from a layered gap label cover problem. See Section 4 for details.

We note that several other properties of label cover variants were used before in the context of polymorphisms. Guruswami and Sandeep [18] use "smoothness" of NP-hard label cover instances (introduced by Khot [19]) so that a minor relation π needs to be respected only if it is injective on a small set S. This allows them to use sets S which are *weakly fixing*, i.e. the partial assignment to S which makes f constant does not necessarily have to assign the same value to all coordinates in S. Layered label cover was introduced by Dinur, Guruswami, Khot, and Regev [13] to tighten the approximation hardness for hypergraph vertex cover. In the proof of hardness of hypergraph colouring by Dinur, Regev, and Smyth [14], as reinterpreted in [3], layered label cover is used to partition polymorphisms into an arbitrary constant number L of parts, so that only minors within one part need to be respected. This implies that in any chain of minors with $L + 1$ functions, some two functions will be in the same part and hence the minor between them will be respected; our approach is hence similar, though apparently more general, in this aspect. Another feature used in [14, 3] is that the bound on the size of a set of special coordinates or on the number of disjoint such sets may be any subpolynomial function in n, not necessarily a constant. These different features of NP-hard label cover instances can be combined; however, this is not necessary for our result.

2 Preliminaries

Let $[n] = \{1, 2, \dots, n\}$. For a set A, we call $R \subseteq A^k$ a *relation* of arity $\mathrm{ar}(R) = k$ and $f\colon A^k \to B$ a function of arity $\mathrm{ar}(f) = k$.

We take the domain of the variables in SetSAT to be $[d]$ and for a fixed $s < d$ we identify each literal with the indicator function of some $S \subseteq [d], |S| = s$: $S(x) = \mathbb{1}[x \in S]$. For a SetSAT instance (or *formula*) with n variables $x_1, \dots, x_n$, an assignment to the variables is a function $\sigma : \{x_1, \dots, x_n\} \to [d]$. An assignment σ is called a g-satisfying assignment for an instance ϕ if σ satisfies at least g literals in every clause of ϕ. A 1-satisfying assignment is usually simply called a satisfying assignment. A formula is called g-satisfiable if there exists a g-satisfying assignment to its variables, and satisfiable if there exists a 1-satisfying assignment.

The SAT problem corresponds to the SetSAT problem with $d = 2$ and $s = 1$, so SetSAT does indeed generalise SAT. Note that every SetSAT instance is trivially unsatisfiable when $s = 0$ and satisfiable when $s = d$, so we exclude these cases in our analysis. We now give the formal definition of (a, g, k)-SetSAT.

▶ **Definition 2.** *Let $1 \leq s < d$ and $1 \leq a \leq g \leq k$. The (a, g, k)-SetSAT problem is the following promise problem. In the decision version, given a SetSAT instance where each clause has k literals, accept the instance if it is g-satisfiable and reject it if it is not a-satisfiable. In the search version, given a g-satisfiable SetSAT instance, find an a-satisfying assignment.*

We will prove hardness only for the decision version of (a, g, k)-SetSAT and tractability only for the search version. This suffices since the decision version of (a, g, k)-SetSAT is polynomial-time reducible to the corresponding search problem. This is discussed in [9, Appendix A], where it is also shown how to obtain simple hardness results for SetSAT. In particular, [9, Propositions A.1 and A.3] show that we can focus on the case of $(1, g, k)$-SetSAT with $d = s + 1$.

Promise CSPs

We describe how the SetSAT problem fits into the general framework of promise CSPs (PCSPs). For a more in-depth algebraic study of PCSPs, we refer the reader to [3].

A *relational structure* $\mathbf{A}$ is a tuple $(A; R_1, \dots, R_m)$ where each R_i is a relation on A. We say that two relational structures are *similar* if their relations have the same sequence of arities. A *homomorphism* between similar relational structures $\mathbf{A} = (A; R_1^{\mathbf{A}}, \dots, R_m^{\mathbf{A}})$ and $\mathbf{B} = (B; R_1^{\mathbf{B}}, \dots, R_m^{\mathbf{B}})$ is a function $h : A \to B$ such that $(a_1, \dots, a_{\mathrm{ar}(R_i^{\mathbf{A}})}) \in R_i^{\mathbf{A}}$ implies $(h(a_1), \dots, h(a_{\mathrm{ar}(R_i^{\mathbf{A}})})) \in R_i^{\mathbf{B}}$ for all i. We denote this by $\mathbf{A} \to \mathbf{B}$.

▶ **Definition 3.** *Let* $(\mathbf{A}, \mathbf{B})$ *be a pair of similar relational structures such that there is a homomorphism* $\mathbf{A} \to \mathbf{B}$*. The pair* $(\mathbf{A}, \mathbf{B})$ *is called the* template *of the* promise constraint satisfaction problem $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$*. The decision version of* $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ *is as follows: given as input a relational structure* $\mathbf{C}$ *similar to* $\mathbf{A}$ *and* $\mathbf{B}$*, decide whether* $\mathbf{C}$ *admits a homomorphism to* $\mathbf{A}$*, or does not even admit a homomorphism to* $\mathbf{B}$*. The* promise *is that it is never the case that* $\mathbf{C} \to \mathbf{B}$ *but* $\mathbf{C} \not\to \mathbf{A}$*. The search problem asks to find a homomorphism* $\mathbf{C} \to \mathbf{B}$*, given that there exists a homomorphism* $\mathbf{C} \to \mathbf{A}$*.*

Since (a, g, k)-SetSAT is a PCSP where all relations have fixed arity k, it is possible to transform SetSAT instances from their CNF representation into the PCSP representation of Definition 3. Let f be a bijection between $[d^k]$ and the set of clauses containing k literals (ignoring the variables they contain). We can represent each SetSAT instance Ψ as a relational structure $\mathbf{C} = (C; R_1^{\mathbf{C}}, \ldots, R_{d^k}^{\mathbf{C}})$, where $C = \{x_1, \ldots, x_n\}$ is the set of variables appearing in Ψ and $R_i^{\mathbf{C}}$ is a k-ary relation corresponding to the clause $f(i)$. For each clause $(S_1(x_1) \vee \ldots \vee S_k(x_k))$ of type $f(i)$ in Ψ, we add the tuple $(x_1, \ldots, x_k)$ to $R_i^{\mathbf{C}}$, so that each $R_i^{\mathbf{C}}$ collects the tuples of variables appearing in clauses of type $f(i)$.

Now define $R_i^{\mathbf{A}}$ (respectively $R_i^{\mathbf{B}}$) to be the k-ary relation over $[d]$ containing $(a_1, \ldots, a_k)$ if and only if $(a_1, \ldots, a_k)$ g-satisfies (respectively a-satisfies) the clause $f(i)$ when the variable of the j-th literal of $f(i)$ is set to a_j, for $1 \leq j \leq k$. Let $\mathbf{A} = ([d], R_1^{\mathbf{A}}, \ldots, R_{d^k}^{\mathbf{A}})$ and $\mathbf{B} = ([d], R_1^{\mathbf{B}}, \ldots, R_{d^k}^{\mathbf{B}})$. Then (a, g, k)-SetSAT is precisely $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$: the identity function is a homomorphism from $\mathbf{A}$ to $\mathbf{B}$, a homomorphism $\mathbf{C} \to \mathbf{A}$ represents a g-satisfying assignment to Ψ, and a homomorphism $\mathbf{C} \to \mathbf{B}$ represents an a-satisfying assignment to Ψ.

Polymorphisms

The following concept from the algebraic study of PCSPs is central to our hardness result.

Let $f : A^m \to B$ be a function. We say that f is a *polymorphism* of the template $(\mathbf{A}, \mathbf{B})$ if, for $\bar{a}^1, \ldots, \bar{a}^m \in R_i^{\mathbf{A}}$, we have that $f(\bar{a}^1, \ldots, \bar{a}^m) \in R_i^{\mathbf{B}}$; here f is applied componentwise. We will denote by $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ the set of all polymorphisms of the template $(\mathbf{A}, \mathbf{B})$. A simple example of a polymorphism of every template with $A = B$ is a *projection*, which is a function $p_i^{(m)} : A^m \to B$ of the form $p_i^{(m)}(x_1, \ldots, x_m) = x_i$. More generally, for every template, trivial polymorphisms are given by *dictators*, which are functions p of the form $p(x_1, \ldots, x_m) = f(x_i)$, where f is a homomorphism from A to B.

In particular, $f : [d]^m \to [d]$ is a polymorphism of (a, g, k)-SetSAT if for every SetSAT clause C of width k and for every tuple $\bar{v}^1, \ldots, \bar{v}^m \in [d]^k$ of g-satisfying assignments to C, we have that $f(\bar{v}^1, \ldots, \bar{v}^m)$ is an a-satisfying assignment to C.

3 Tractability

How big must one make the fraction of satisfied literals in order for the SetSAT problem to become tractable? The following proposition shows that $\frac{s}{s+1}$ is sufficient.

▶ **Proposition 4.** *For* $1 \leq s < d$ *and* $\frac{g}{k} \geq \frac{s}{s+1}$*,* $(1, g, k)$*-SetSAT is solvable in expected polynomial time.*

Proof. Algorithm 1 finds a satisfying assignment to a g-satisfiable formula in expected polynomial time. The algorithm and its analysis are based on [2, Proposition 6.1], which in turn is based on Papadimitriou's randomised algorithm for 2-SAT [23].

Algorithm 1 Randomised algorithm for $(1, g, k)$-SetSAT with $\frac{g}{k} \ge \frac{s}{s+1}$.

```
1: $x \leftarrow$ arbitrary assignment
2: while $x$ does not satisfy input formula $\phi$ do
3:     Arbitrarily pick a falsified clause $C$
4:     Randomly choose from $C$ a literal $S(x_i)$
5:     Randomly choose a value for $x_i$ so that $S(x_i)$ is satisfied
   return $x$
```

Suppose that ϕ has a g-satisfying assignment x^*. Let x^t be the assignment obtained in iteration t of the algorithm, and let $D_t = \text{dist}(x^t, x^*)$, where $\text{dist}(x, y)$ is the Hamming distance between x and y. Since $D_t - D_{t-1} \in \{-1, 0, 1\}$ for every t, we have

$$\begin{aligned}\mathbb{E}(D_t - D_{t-1}) &= \mathbb{P}(D_t - D_{t-1} = 1) - \mathbb{P}(D_t - D_{t-1} = -1)\\ &\le \frac{k-g}{k} - \frac{g}{k}\frac{1}{s} \le 0 \quad \text{if and only if} \quad \frac{g}{k} \ge \frac{s}{s+1}.\end{aligned}$$

The sequence $D_0, D_1, \ldots$ is a random walk starting between 0 and n with steps either unbiased or biased toward 0. With constant probability, such a walk hits 0 within n^2 steps and so the probability that the algorithm fails to find a satisfying assignment within crn^2 steps is at most 2^{-r} for some constant c. ◀

▶ Remark 5. The proof of Proposition 4 can be modified to show that Algorithm 1 also finds a satisfying assignment when each literal corresponds to a set of size *at most* s. This makes sense intuitively, as smaller literals give the algorithm a better chance of setting x_i equal to x_i^* in Step 5.

We show that if $\frac{g}{k} \ge \frac{s}{s+1}$ then $(1, g, k)$-SetSAT has a specific family of polymorphisms that leads to a *deterministic* algorithm based on linear programming.

A function $f : A^m \to B$ is *symmetric* if $f(a_1, \ldots, a_m) = f(a_{\pi(1)}, \ldots, a_{\pi(m)})$ for all $a_1, \ldots, a_m \in A$ and all permutations π on $[m]$.

▶ **Definition 6.** *A symmetric function $f : [d]^m \to [d]$ is a* plurality *if*

$$f(x_1, \ldots, x_m) = \mathit{argmax}_{a \in [d]}\{\#\ \mathit{of\ occurrences\ of}\ a\ \mathit{in}\ (x_1, \ldots, x_m)\},$$

with ties broken in such a way that f is symmetric.

We will also use the fact that all polymorphisms of SetSAT are *conservative*; i.e., they always return one of their input values, as the following proposition shows.

▶ **Proposition 7.** *All polymorphisms of $(1, g, k)$-SetSAT are conservative.*

Proof. Let $f : [d]^m \to [d]$ be such that $f(a_1, \ldots, a_m) = b$ and $b \notin \{a_1, \ldots, a_m\}$. If S is a literal not containing b, then the clause $(S(x_1) \vee \ldots \vee S(x_k))$ is g-satisfied (even k-satisfied) by setting all x_i equal to any one of the a_j. Thus taking the m assignments $(x_1 = \cdots = x_k = a_j)_{1 \le j \le m}$ and applying f to each component, we get the assignment $x_1 = \cdots = x_k = b$ which clearly does not 1-satisfy the clause, and so f cannot be a polymorphism. ◀

▶ **Proposition 8.** *Let $s \ge 1$. If $\frac{g}{k} > \frac{s}{s+1}$ then every plurality function is a polymorphism of $(1, g, k)$-SetSAT. If $\frac{g}{k} = \frac{s}{s+1}$ then every plurality function of arity $m \not\equiv 0 \mod s+1$ is a polymorphism of $(1, g, k)$-SetSAT, and no symmetric function of arity $m \equiv 0 \mod s+1$ is a polymorphism of $(1, g, k)$-SetSAT.*

Proof. Let f be a plurality function of arity m. Given m g-satisfying assignments to a clause of width k, we are guaranteed to have at least mg satisfying values among the mk total values. Therefore there is a coordinate i, $1 \leq i \leq k$, containing at least $\lceil \frac{mg}{k} \rceil$ satisfying values, that is, at least $\lceil \frac{mg}{k} \rceil$ values not equal to the value b forbidden by the i-th literal of the clause. In order for f to be a polymorphism it suffices that $\lceil \frac{mg}{k} \rceil > \frac{s}{s+1}m$, since then b will appear fewer than $\frac{m}{s+1}$ times and will never be returned using the plurality rule. But $\frac{g}{k} > \frac{s}{s+1}$ is equivalent to $\frac{mg}{k} > \frac{s}{s+1}m$, and the latter implies that $\lceil \frac{mg}{k} \rceil > \frac{s}{s+1}m$, so f is a polymorphism.

In the case that $\frac{g}{k} = \frac{s}{s+1}$, the same argument works so long as $\frac{mg}{k}$ is not an integer, since by taking the ceiling we obtain a value strictly greater than $\frac{s}{s+1}m$. Since $\frac{g}{k} = \frac{s}{s+1}$, we have $\frac{g}{k}m = \frac{s}{s+1}m$ and this is an integer only if m is a multiple of $s+1$.

To show that there are no symmetric polymorphisms when $\frac{g}{k} = \frac{s}{s+1}$ and m is a multiple of $s+1$, note that this equality implies that k is divisible by $s+1$. Let M be the $(s+1) \times (s+1)$ matrix whose first row is $12 \cdots s+1$ and whose i-th row for $2 \leq i \leq s+1$ is obtained from the $(i-1)$-st row by shifting it cyclically to the left by one coordinate. We stack $\frac{k}{s+1}$ copies of M on top of each other and take $\frac{m}{s+1}$ copies of this stack side-by-side to form the $k \times m$ matrix M'. If f is symmetric, it returns the same value b when applied to each row of M'. Every column of M' satisfies exactly an $\frac{s}{s+1}$-fraction of the literals in a clause whose k literals all forbid b. On the other hand, the assignment produced by applying f to each row of M' does not even 1-satisfy this clause, so f is not a polymorphism. ◀

Proposition 8 has interesting consequences for solvability of $(1, g, k)$-SetSAT via linear programming relaxations. By [3, Theorem 7.9], $(1, g, k)$-SetSAT is solvable by the basic linear programming relaxation if $\frac{g}{k} > \frac{s}{s+1}$ (since there exist symmetric polymorphisms of all arities) but not solvable by the basic linear programming relaxation if $\frac{g}{k} = \frac{s}{s+1}$ (since there do not exist symmetric polymorphisms of all arities). By [8, Theorem 3.1], $(1, g, k)$-SetSAT is solvable by the combined basic linear programming and affine relaxation if $\frac{g}{k} \geq \frac{s}{s+1}$ (since there exist symmetric polymorphisms of infinitely many arities). We note that iterative rounding of the basic linear relaxation could also be used to get a deterministic algorithm as in [2].

4 Layered label cover and smug sets

An *ℓ-layered label cover* instance is a sequence of $\ell + 1$ sets $X_0, \ldots, X_\ell$ (called *layers*) of variables with range $[m]$, for some *domain size* $m \in \mathbb{N}$, and a set of constraints Φ. Each constraint is a function (often called a projection constraint) from a variable $x \in X_i$ to a variable in a further layer $y \in X_j$, $i < j$: that is, a function denoted $\phi_{x \to y}$ which is satisfied by an assignment $\sigma\colon X_0 \cup \cdots \cup X_\ell \to [m]$ if $\sigma(y) = \phi_{x \to y}(\sigma(x))$. A *chain* is a sequence of variables $x_i \in X_i$ for $i = 0, \ldots, \ell$ such that there are constraints $\phi_{x_i \to x_j}$ between them, for $i < j$. A chain is *weakly satisfied* if at least one of these constraints is satisfied.

The basis for our hardness result is the hardness of distinguishing fully satisfiable instances from those where no constant fraction of chains can be weakly satisfied. This follows by a simple adaptation of a reduction from the work of Dinur, Guruswami, Khot, and Regev [13], which we defer to the full version [9, Appendix B].

▶ **Theorem 9.** *For every $\ell \in \mathbb{N}$ and $\varepsilon > 0$, there is an $m \in \mathbb{N}$ such that it is NP-hard to distinguish ℓ-layered label cover instances with domain size m that are fully satisfiable from those where not even an ε-fraction of all chains is weakly satisfied.*

In order to use Theorem 9 to derive hardness for PCSPs, we use the algebraic approach: every PCSP is equivalent to a promise problem about satisfying minor conditions with polymorphisms. We give definitions first, following [3], to where we refer the reader for a more detailed exposition.

For $f\colon A^n \to B$, $g\colon A^m \to B$ and $\pi\colon [n] \to [m]$, we say that g is the *minor* of f obtained from π if

$$g(x_1, \dots, x_m) \approx f(x_{\pi(1)}, \dots, x_{\pi(n)}), \tag{1}$$

where $g \approx f$ means that the values of g and f agree on every input in A^m. We write $f \xrightarrow{\pi} g$ as a shorthand for (1). For $\pi\colon [n] \to [m]$, the expression $f \xrightarrow{\pi} g$ is called a *minor identity.*

A *minion* on a pair of sets (A, B) is a non-empty set of functions from A^n to B (for $n \in \mathbb{N}$) that is closed under taking minors.

A *bipartite minor condition* is a finite set Σ of minor identities where the sets of function symbols used on the left- and right-hand sides are disjoint. More precisely, Σ is a pair of disjoint sets U and V of function symbols of arity n and m, respectively, and a set of minor identities of the form $f \xrightarrow{\pi} g$, where $g \in U$, $f \in V$ and $\pi : [n] \to [m]$. A bipartite minor condition Σ is *satisfied* in a minion $\mathcal{M}$ if there is an assignment $\xi : U \cup V \to \mathcal{M}$ that assigns to each function symbol a function from $\mathcal{M}$ of the corresponding arity so that for every identity $f \xrightarrow{\pi} g$ in Σ, we have $\xi(f) \xrightarrow{\pi} \xi(g)$ in $\mathcal{M}$. A bipartite minor condition is called *trivial* if it is satisfied in every minion, or equivalently, in the minion consisting of all projections on $\{0, 1\}$. Since choosing a projection of arity n is the same as choosing an element of $[n]$, deciding whether a bipartite minor condition is trivial is the same as standard label cover.

We can now define the *promise satisfaction of a minor condition* problem. For a minion $\mathcal{M}$ and an integer m, $\mathrm{PMC}_{\mathcal{M}}(m)$ is the following promise problem: given a bipartite minor condition Σ that involves only symbols of arity at most m, the answer should be YES if Σ is trivial and NO if Σ is not satisfiable in $\mathcal{M}$ (the promise is that either of those two cases holds, i.e. an algorithm can behave arbitrarily otherwise). Barto et al. [3] show that $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ is log-space equivalent to $\mathrm{PMC}_{\mathcal{M}}(m)$, for $\mathcal{M} = \mathrm{Pol}(\mathbf{A}, \mathbf{B})$ and m a constant depending on $\mathbf{A}$ only.

A final piece of notation before we prove a corollary of Theorem 9. A *chain of minors* is a sequence of the form $f_0 \xrightarrow{\pi_{0,1}} f_1 \xrightarrow{\pi_{1,2}} \dots \xrightarrow{\pi_{\ell-1,\ell}} f_\ell$. We shall then write $\pi_{i,j}\colon [\mathrm{ar}(f_i)] \to [\mathrm{ar}(f_j)]$ for the composition of $\pi_{i,i+1}, \dots, \pi_{j-1,j}$, for any $0 \le i < j \le \ell$. Note that $f_i \xrightarrow{\pi_{i,j}} f_j$.

▶ **Corollary 10** (of Theorem 9). *Let $\mathcal{M}$ be a minion. Suppose there are constants $k, \ell \in \mathbb{N}$ and an assignment of a set of at most k coordinates $\mathrm{sel}(f) \subseteq [\mathrm{ar}(f)]$ to every $f \in \mathcal{M}$ such that for every chain of minors $f_0 \xrightarrow{\pi_{0,1}} f_1 \xrightarrow{\pi_{1,2}} \dots \xrightarrow{\pi_{\ell-1,\ell}} f_\ell$, there are $0 \le i < j \le \ell$ such that $\pi_{i,j}(\mathrm{sel}(f_i)) \cap \mathrm{sel}(f_j) \neq \emptyset$. Then $\mathrm{PMC}_{\mathcal{M}}(m)$ is NP-hard, for m large enough. In particular, if $\mathcal{M} = \mathrm{Pol}(\mathbf{A}, \mathbf{B})$, then $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ is NP-hard.*

Proof. For ℓ, k as in the assumption, let $\varepsilon := \frac{1}{k}$ and let m be as given by Theorem 9. We reduce an ℓ-layered label cover instance by replacing each variable x with a symbol f_x of arity m and each constraint $\phi_{x\to y}\colon [m] \to [m]$ by the minor condition $f_x \xrightarrow{\phi_{x\to y}} f_y$. If the original instance was fully satisfiable, the new instance is trivial (i.e., fully satisfiable by projections).

If the constructed instance is satisfied by functions in the minion $\mathcal{M}$, we define an assignment to the original instance by selecting, for each variable x, a random coordinate from $\mathrm{sel}(f_x) \subseteq [m]$ (uniformly, independently). The assumption guarantees a set of constraints $\phi_{x\to y}$ such that (1) each chain contains at least one and (2) for each such constraint $\phi_{x\to y}$, we have $\phi_{x\to y}(\mathrm{sel}(f_x)) \cap \mathrm{sel}(f_y) \neq \emptyset$. The random choice then satisfies each of these constraints, and hence weakly satisfies each chain, with probability at least $\frac{1}{k} = \varepsilon$. The expected fraction of weakly satisfied chains is thus at least ε and a standard maximisation-of-expectation procedure deterministically finds an assignment which certifies this. ◀

The following definition is crucial to our results.

▶ **Definition 11.** *For a function $f\colon A^{\mathrm{ar}(f)} \to B$ we say that a set of coordinates $S \subseteq [\mathrm{ar}(f)]$ is a* smug *set if there is an input vector $\bar{v} \in A^{\mathrm{ar}(f)}$ such that $S = \{i \mid v_i = f(\bar{v})\}$.*

We will use the following to prove hardness of $(1, g, k)$-SetSAT.

▶ **Corollary 12.** *Let $\mathcal{M}$ be a minion. Suppose there are constants $k, \ell \in \mathbb{N}$ such that the following holds, for every $f \in \mathcal{M}$:*

- *f has a smug set of at most k coordinates,*
- *f has no family of more than ℓ (pairwise) disjoint smug sets,*
- *if $f \xrightarrow{\pi} g$ and S is a smug set of g, then $\pi^{-1}(S)$ is a smug set of f.*

Then $\mathrm{PMC}_{\mathcal{M}}(m)$ is NP-hard, for m large enough. In particular, if $\mathcal{M} = \mathrm{Pol}(\mathbf{A}, \mathbf{B})$, then $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ is NP-hard.

Proof. For each $f \in \mathcal{M}$, we define $\mathrm{sel}(f)$ as a smug set of at most k coordinates, arbitrarily chosen (some such set exists by the first condition). Consider a chain $f_0 \xrightarrow{\pi_{0,1}} f_1 \xrightarrow{\pi_{1,2}} \dots \xrightarrow{\pi_{\ell-1,\ell}} f_\ell$. Suppose to the contrary that for each $0 \le i < j \le \ell$, $\pi_{i,j}(\mathrm{sel}(f_i))$ is disjoint from $\mathrm{sel}(f_j)$, or equivalently, that $\mathrm{sel}(f_i)$ is disjoint from $\pi_{i,j}^{-1}(\mathrm{sel}(f_j))$. This implies that $\pi_{0,i}^{-1}(\mathrm{sel}(f_i))$ is disjoint from $\pi_{0,i}^{-1}(\pi_{i,j}^{-1}(\mathrm{sel}(f_j))) = \pi_{0,j}^{-1}(\mathrm{sel}(f_j))$. That is, the sets $\pi_{0,i}^{-1}(\mathrm{sel}(f_i))$ for $i = 0 \dots \ell$ are pairwise disjoint. By the third condition they are smug sets of f_0. But by the second condition this is impossible. ◀

We note that in the proof of Corollary 12, the exact definition of "smug" is irrelevant, as long as it satisfies the above three conditions.

It is easy to check that the definition of "smug" satisfies the third condition for any functions $f \xrightarrow{\pi} g$, not necessarily polymorphisms. Indeed, if an input $\bar{v} \in A^{\mathrm{ar}(g)}$ to g gives a smug set $S = \{j \mid v_j = g(\bar{v})\}$, then the corresponding input $\bar{u} \in A^{\mathrm{ar}(f)}$ to f defined as $u_i := v_{\pi(i)}$ satisfies $f(\bar{u}) = g(\bar{v})$ and hence gives a smug set $\{i \mid u_i = f(\bar{u})\} = \{i \mid v_{\pi(i)} = g(\bar{v})\} = \{i \mid \pi(i) \in S\} = \pi^{-1}(S)$.

The definition of "smug" is particularly well-suited to our problem, because whether f is a polymorphisms or not depends only on its family of smug sets.

▶ **Lemma 13.** *Let $1 \le s$ and $1 \le g < k$. A function $f\colon [s+1]^m \to [s+1]$ is a polymorphism of $(1, g, k)$-SetSAT if and only if there is no multiset $S_1, \dots, S_k$ of smug sets of f, such that each coordinate $\ell \in [m]$ is contained in at most $k - g$ of them.*

$\bar{o}$
$\bar{b}$

Figure 1 Illustration of Lemma 13. Smug sets $S \subseteq [m]$ are highlighted in each row.

Proof. A function $f\colon [s+1]^m \to [s+1]$ is not a polymorphism if and only if there is a clause of the form $x_1 \neq b_1 \vee \dots \vee x_k \neq b_k$ (for some column vector $\bar{b} \in [s+1]^k$) and a sequence of m column vectors $\bar{v}^1, \dots, \bar{v}^m \in [s+1]^k$ each of which g-satisfies the clause, but for which the vector $\bar{o} = f(\bar{v}^1, \dots, \bar{v}^m)$ (with f applied coordinatewise) does not even 1-satisfy the clause. The latter is equivalent to saying that $o_i = b_i$ for $i \in [k]$, that is, applying f to the i-th row gives $f(v_i^1, \dots, v_i^m) = b_i$. The former is equivalent to saying that for each column $\bar{v}$ in $\bar{v}^1, \dots, \bar{v}^m$, the condition $v_i \neq b_i$ holds for at least g indices $i \in [k]$ of that column. The two are hence equivalent to saying that for each column $\bar{v}^\ell$, $\ell \in [m]$, the condition $v_i^\ell = f(v_i^1, \dots, v_i^m)$ holds for at most $k - g$ indices $i \in [k]$ in that column. In other words, the k row vectors $(v_i^1, \dots, v_i^m)$ for $i \in [k]$ have smug sets such that ℓ is contained in at most $k - g$ of these sets, for each coordinate $\ell \in [m]$. ◀

Checking the second condition for polymorphisms of our SetSAT problem is easy.

▶ **Lemma 14.** *For every polymorphism f of $(1, g, k)$-SetSAT with domain size $s + 1$, if $S_1, \dots, S_n$ are disjoint smug sets of f, then $n < \frac{k}{k-g}$.*

Proof. Suppose to the contrary that $n \geq \frac{k}{k-g}$. Then we can build a multiset containing each S_i up to $k - g$ times until we have exactly k in total. We thus obtain a multiset of k smug sets such that every coordinate is contained in at most $k - g$ of them. ◀

5 Finding small smug sets

It is easy to show NP-hardness when $\frac{g}{k} \leq \frac{1}{2}$ (cf. [9, Proposition A.8]). We now show a general reduction by finding a small smug set for $(1, g, k)$-SetSAT whenever $\frac{g}{k} < \frac{s}{s+1}$.

Consider a polymorphism $f \colon [s + 1]^m \to [s + 1]$ of $(1, g, k)$-SetSAT (with set size s and domain size $s + 1$).

▶ **Lemma 15.** *There exists a smug set of size at most $s - 1$, or a family of s disjoint minimal smug sets $S_1, \dots, S_s$.*

Proof. Suppose that every smug set has size at least s. We show by induction on t that there is a family of t disjoint minimal smug sets $S_1, \dots, S_t$. Suppose we found $S_1, \dots, S_t$ for some $0 \leq t < s$ and we want to find S_{t+1}. Let T be a set containing one arbitrary coordinate from each S_i, $i = 1 \dots t$. Let $\bar{v} \in [s + 1]^m$ be the input vector with values $t + 2$ on T, i on $S_i \setminus T$ (for $i = 1 \dots t$) and $t + 1$ on the remaining coordinates $R := [m] \setminus (S_1 \cup \dots \cup S_t)$. Since $|T| \leq t < s$, T is not smug, so $f(\bar{v}) \neq t + 2$. By minimality, $S_i \setminus T$ are not smug for $i = 1 \dots t$, so $f(\bar{v}) \neq i$. Therefore, by conservativity of f (Proposition 7), the only remaining option is $f(\bar{v}) = t + 1$. Thus R is smug and disjoint from S_i. Taking S_{t+1} to be a minimal smug set contained in R proves the induction step. ◀

Together with Lemma 14, Lemma 15 already establishes (via Corollary 12) NP-hardness when $s \geq \frac{k}{k-g} = \frac{g}{k-g} + 1$ (equivalently, $\frac{g}{k} \leq \frac{s-1}{s}$): since there cannot be s disjoint smug sets, every polymorphism has a smug set of size at most $s - 1$. The proof in the general case, when $\frac{g}{k} < \frac{s}{s+1}$, extends this approach by first finding (assuming there are no small smug sets) disjoint minimal smug sets $S_1, \dots, S_s$, then exploiting the fact that each has a special coordinate whose removal makes it not smug, and using these coordinates to find further variants of each S_i with new special coordinates.

▶ **Lemma 16.** *Let $\frac{g}{k} < \frac{s}{s+1}$ (equivalently, $s > \frac{g}{k-g}$). Every polymorphism of $(1, g, k)$-SetSAT on s has a smug set of size at most g.*

Proof. Consider a polymorphism $f \colon [s + 1]^m \to [s + 1]$ of $(1, g, k)$-SetSAT. We prove by induction on t that there is a smug set of size at most $t - 1$, or there is a sequence of smug sets $S_1, \dots, S_t$ and a set T such that (see Figure 2):

(i) $|T| = t$ and $|T \cap S_i| = 1$ for $i = 1 \dots t$ (hence $S_i \cap T \neq S_{i'} \cap T$ for $i \neq i'$);
(ii) $S_i \setminus T$ is not smug for $i = 1 \dots t$;
(iii) $S_i \cap S_{i'} = \emptyset$ if $i \not\equiv i' \mod s$;
(iv) $S_i \supseteq S_{i-s} \setminus T$ for $i > s$.

Figure 2 Illustration of smug sets obtained in the proof of Lemma 16. Each row represents one of the sets in the sequence $S_1, \dots, S_t$. The set T is formed by coordinates with a T and get values $s+1$. The vector $\bar{v}$ is used to find the next row S_{t+1}.

By Lemma 15 we can start with $t = s$ (by taking any T containing one coordinate from each S_i). Suppose the above is true for $t \geq s$ and let us prove the same for $t+1$. If there is a smug set of size at most t then we are done, so assume that T is not smug. Let $\bar{v} \in [s+1]^m$ be the input vector with value $s+1$ on T and different values from $\{1, \dots, s\}$ on $S_{t-i} \setminus T$ for $i = 0 \dots s-2$ and on the set of remaining coordinates $R := [m] \setminus (S_t \cup \dots \cup S_{t-s+2} \cup T)$. Then by (ii), R is smug.

Observe that R contains $S_{t-s+1} \setminus T$, because $S_t, \dots, S_{t-s+2}, T$ are disjoint from that set by (iii). We define S_{t+1} to be a minimal subset of R among smug sets containing $S_{t-s+1} \setminus T$. By (ii) $S_{t-s+1} \setminus T$ itself is not smug, so there exists some coordinate ℓ in $S_{t+1} \setminus S_{t-s+1}$. We choose it arbitrarily and set $T' := T \cup \{\ell\}$.

We claim that the sequence of smug sets $S_1, \dots, S_{t+1}$ and the set T' satisfy the above conditions. By minimality $S_{t+1} \setminus T'$ is not smug, so it satisfies (ii) and by definition it satisfies (iv). The set S_{t+1} is disjoint from $S_t, \dots, S_{t-s+2}, T$, because R was. It is also disjoint from S_i for $i \not\equiv t+1 \mod s$, because for every such i, $S_i \setminus T$ is contained in one of $S_t, \dots, S_{t-s+2}$; this proves (iii). In particular ℓ is not contained in any of these sets, and since it is not contained in S_{t-s+1}, it is in fact not contained in any S_i with $i < t+1$. Hence $|T'| = t$ and $|T' \cap S_i| = |T \cap S_i| = 1$ for $i < t+1$. Clearly also $|T' \cap S_{t+1}| = |\{\ell\}| = 1$. Therefore, (i) is satisfied, concluding the inductive proof.

Let us now consider sets as guaranteed above for $t = g+1$ (assuming there is no smug set of size at most g). Let $\bar{v} \in [s+1]^m$ be the input vector with value $i+1$ on $S_{t-i} \setminus T$ for $i = 0 \dots s-1$, and value $s+1$ on the remaining coordinates $R := ([m] \setminus (S_t \cup \dots \cup S_{t-s+1})) \cup T$. By (ii) the sets $S_{t-i} \setminus T$ are not smug, so R is smug. We claim that the multiset obtained from $\{S_1, \dots, S_t\}$ by adding $(k-g-1)$ copies of the set R contradicts Lemma 13: that is, each coordinate in $[m]$ is covered at most $k-g$ times by this multiset.

Consider first the coordinates contained in R. By definition of R, they are disjoint from $S_{t-i} \setminus T$ for $i = 0 \dots s-1$. By (iv), they are also disjoint from all sets $S_i \setminus T$ for $i = 0 \dots t$, because every such set is contained in one of the former. Hence if a coordinate in R is also contained in one of $S_1, \dots, S_t$, then it is contained in T and therefore in at most one of $S_1, \dots, S_t$, by (i). In total, it is thus covered at most $(k-g-1)+1 = k-g$ times.

Consider now coordinates outside of R. By (iii), they can be covered only by sets S_i with congruent indices $i \mod s$. Since $s > \frac{g}{k-g}$, we have $s(k-g) > g$, so there are $t = g+1 \leq s(k-g)$ distinct indices in total in $\{1, \ldots, t\}$. Hence at most $k-g$ of them can be pairwise congruent to each other $\mod s$. Thus coordinates outside of R are also covered at most $k-g$ times. ◀

This concludes the proof that smug sets satisfy the first condition of Corollary 12 for polymorphisms of $(1, g, k)$-SetSAT with set size s and domain size $s+1$, assuming $\frac{g}{k} < \frac{s}{s+1}$. Therefore, the problem is NP-hard. The full dichotomy then follows by simple reductions, see [9, Corollary A.4].

Abstract

We study how to dynamize the Trapezoidal Search Tree (TST) – a well known randomized point location structure for planar subdivisions of kinetic line segments.

Our approach naturally extends incremental leaf-level insertions to recursive methods and allows adaptation for the online setting. The dynamization carries over to the Trapezoidal Search DAG (TSD), which has linear size and logarithmic point location costs with high probability. On a set S of non-crossing segments, each TST update performs expected $\mathcal{O}(\log^2 |S|)$ operations and each TSD update performs expected $\mathcal{O}(\log |S|)$ operations.

We demonstrate the practicality of our method with an open-source implementation, based on the Computational Geometry Algorithms Library, and experiments on the update performance.

1 Introduction

Our results on vertical ray shooting in dynamic planar subdivisions and dynamic order maintenance originate from the search for a simple and practical data structure, with guarantees, that facilitate building the intersection graph of thin geometric objects, which is a natural precursor in meshing fracture networks [14]. This note studies how to structure 2D kinetic and non-kinetic line segment data in a fully-dynamic online setting that supports

intersection reporting. Beside sweeping plane applications, such data structures are also of interest for map matching problems [22] and for point location queries in dynamic, constrained Delaunay triangulations [4].

Most works term the "dynamic point location problem" as to quickly find the first edge directly above or below a query point, which is vertical ray shooting queries over a dynamic set of edges. We also use this unfortunate terminology throughout, though there are works (e.g. [18]) that solve the seemingly more complicated problem of deciding if two query points are in the same face of the dynamic subdivision. Planar subdivisions are often categorized by additional geometric properties on the subdivisions' faces. Authors frequently consider cases where all faces are convex, or all faces intersect horizontal lines at most twice (monotone faces). Clearly, monotone faces and faces' boundaries formed by monotone curves (e.g. line segments) are distinct properties.

Trapezoids are a key ingredient to simplify the study of geometric problems concerning sets of line segments S. We use three well known [2, 11, 15, 20] and closely related [13] structures. These are (i) the trapezoidal decomposition $\mathcal{A}(S)$ of a plane induced by S, (ii) the Trapezoidal Search Tree (TST), and (iii) the Trapezoidal Search DAG (TSD) (see Section 2). TST $\mathcal{T}(S,\pi)$ and TSD $\mathcal{D}(S,\pi)$ stem from deterministic algorithms, that incrementally insert the segments in S according to a, typically random, permutation π over S. Decomposition $\mathcal{A}(S)$ has size $\mathcal{O}(|S|+k)$, where k denotes the number of *crossing pairs* of segments in S. Since segment boundaries of a general planar subdivision are non-crossing ($k=0$), the refined decomposition $\mathcal{A}(S)$ of the boundary segments S is within a constant of the subdivision's size, regardless of the face shape.

Chiang and Tamassia's 1992 survey [9, Chapter 6] reviews several dynamizations for planar subdivisions. In [10], the two authors describe a dynamization for the special case of a trapezoidal decomposition $\mathcal{A}$ of monotone subdivisions. Using several tree structures, they achieve $\mathcal{O}(\log|S|)$ point location query time within an $\mathcal{O}(|S|\log|S|)$ size structure, which allows fully-dynamic updates in amortized $\mathcal{O}(\log^2|S|)$ operations. Also for monotone subdivisions, Goodrich and Tamassia show with [12] how to maintain interlaced, monotone spanning trees over the edges of the planar graph and its dual graph. This leads to an $\mathcal{O}(|S|)$ sized structure with an update time of $O(\log|S|+m)$, for insertion of a monotone chain of length m, but point location queries take $\mathcal{O}(\log^2|S|)$ operations. Cheng and Janardan [8] show how to achieve equal bounds for more general, connected subdivisions.

Most recent approaches that achieve *online, fully-dynamic updates* within $\mathcal{O}(|S|)$ size and $\mathcal{O}(\log|S|)$ query time are extensions of the works of Baumgarten et al. [5] that uses dynamic fractional cascading to enable vertical ray shooting queries. Arge et al. [3] show a trade-off improvement, i.e. raising the fan-out of tree nodes to $\Theta(\log^{\varepsilon}|S|)$ allows to lower the point location query time bound to $\mathcal{O}(\log|S|)$. However, insertions take $\mathcal{O}(\log^{1+\varepsilon}|S|)$ amortized time and deletions take $\mathcal{O}(\log^{2+\varepsilon}|S|)$ amortized time per update. Chan and Nekrich [7] added Multi-Colored Segment Trees to the approach and applied de-randomization and de-amortization techniques to finally derive update bounds of $\mathcal{O}(\log^{1+\varepsilon}|S|)$ for both, insertions and deletions. To our knowledge, these are currently the best bounds on the pointer machine (see Table 1 in [7] for an overview). Refining this approach, Munro and Nekrich [17] recently analyzed the I/O counts in an external memory model with block sizes of $\Omega(\log^8 n)$.

The *Randomized Incremental Construction (RIC)* of TSDs provides simple, and thereby practical, point location structures of expected $\mathcal{O}(|S|)$ size whose longest search path is with high probability also in $\mathcal{O}(\log|S|)$. Their analysis is a celebrated result of Mulmuley [15], who argues on a random experiment that draws geometric objects, and Seidel [20], who uses a backward-analysis to bound the expected costs. Vastly unmentioned is Mulmuley's book [16], which extends TSDs to a specialized (offline) dynamic setting of a random insert/delete string for a fixed set of segments S, in which each element has a probability of $1/|S|$ to appear in each update request. The approach thrives on a randomly chosen, fixed order on S, rotations in the structure, and regular leaf-level insertions and deletions. Several distributed book chapters finally show that executing such a (+/-)-sequence of m updates has a total expected cost of $\mathcal{O}(m \log m + k \log m)$, where k is the number of intersections in the fixed set S. Schwarzkopf [19] independently describes a similar update model that also leads to a dynamization. His analysis provides an expected $\mathcal{O}(\log^2 n)$ time bound for update operations from the sequence, where n denotes the current number of non-crossing segments, but the expected point location query bound is w.h.p. in $\mathcal{O}(\log^2 n)$.

In [2], Agarwal et al. describe a TST over a static set of segments, that move over time. Their approach is based on a RIC of TSTs with expected $\mathcal{O}(|S| \log |S| + k)$ size whose depth is w.h.p in $\mathcal{O}(\log |S|)$. The authors mention a bound on the expected construction time of $\mathcal{O}(|S| \log^2 |S| + k \log |S|)$ and show that randomization is crucial to resolve a structural change, due to kinetic (adversarial) movement of the line segments, in expected $\mathcal{O}(\log |S|)$ operations. One may, however, form constant velocity trajectories for (point-like) segments that lead to $\Omega(n\sqrt{n})$ many topological updates for any binary space partition method [1].

Insightful work of Hemmer et al. [13] recently revealed a certain bijection between the search paths of $\mathcal{T}(S, \pi)$ and the "un-folded" search paths of $\mathcal{D}(S, \pi)$ by means of a structural induction argument (along fixed π) on the two incremental algorithms. The authors show Las Vegas type point location guarantees for the RIC of TSDs by bounding computation time of the length of a longest search path in a TSD by means of *the size* of the related TST.

1.1 Paper Organization and Section Contributions

Our surprisingly simple, thereby practical (c.f. Section 6), approach uses only one search structure and performs insertions and deletions directly on higher levels of it. Since we maintain randomness of the priority orders on the segment sets, the expected size and expected point location query bounds are retained for each state of the structures. Section 2 reviews the basic RIC of TSTs and TSDs in a unified notation and we introduce our natural, recursive extensions of those basic primitives in Section 3.

Our algorithms therein enable fully-dynamic updates in both data structures in the offline setting, i.e. the complete ground set of segments S is known in advance. Our extension to the online setting provides a simpler, randomized solution to the dynamic order-maintenance problem with expected update cost of $\mathcal{O}(\log |S|)$ based on an arithmetic coding scheme on Treaps (c.f. Section 5). Known solutions to this problem provide $\mathcal{O}(1)$ amortized update costs [24] or deterministic worst case $\mathcal{O}(\log^2 n)$ update cost based on de-amortization techniques [6]. Our algorithms are suitable for pointer machines with arithmetic since they only compare the spatial location of the input points, intersection points, and priority values. Our need of constant time arithmetic operations on fixed-point numbers with $\mathcal{O}(\log |S|)$-bits is solely due to the online order-maintanance problem. In particular, the method does not require indirect addressing of Random Access Memory.

To our knowledge, we provide the first analysis for the update costs of an *online fully-dynamic* data structure that originates from the classic RIC method. Though our Section 4 argues for non-crossing segments only, our geometric interpretation of TST nodes provides a 4-ply covering property that enables new proof methods. We show a new form of Backward-Analysis on the permutation space and a bound on simple "segment searches" for affected search nodes in the structure (avoiding maintenance of so-called conflict lists or $\mathcal{A}$). For TSTs, we obtain expected update costs of $\mathcal{O}(\log^2 |S|)$ for insertion and deletion. Which we

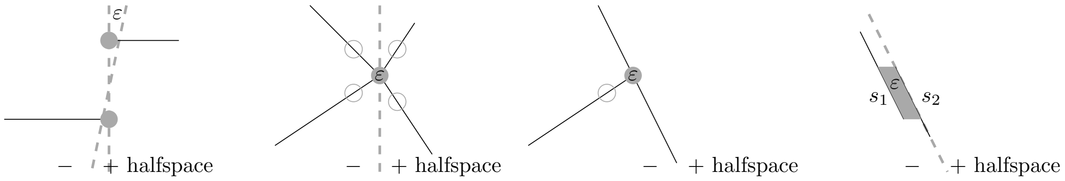

Figure 1 Standard shear transformation (left) and three refined tie-breaking rules for point/point meets, point/segment meets (geometric), and segment/segment overlaps (lexicographic).

can improve further for TSDs to an expected update cost of $\mathcal{O}(\log|S|)$ for insertion and deletion. Hence randomization allows improvements on the amortized deletion bound of $\mathcal{O}(\log^{2+\varepsilon}|S|)$ in [3] and on the $\mathcal{O}(\log^{1+\varepsilon}|S|)$ deterministic update bounds in [7], without losing the size or the point location query bounds.

2 Basic Definitions, Algorithms and Properties

A segment $s = \overline{pq}$ between two distinct points $p, q \in \mathbb{R}^2$ is the set $\{p + \alpha(q - p) : \alpha \in [0, 1]\}$ of points in the Euclidean plane. Two segments are called disjoint if $s \cap s' = \emptyset$ and *overlapping* if $s \cap s'$ contains more than one point. For the case of one common point, we say that two segments *meet* if it is an endpoint that is contained in the other segment and otherwise they are called *intersecting* (or *crossing*). The segment boundaries of a general planar subdivision, for example, have no intersections, but may well contain points in which arbitrarily many segments meet. A line, parallel to the y-axis, through a point is called a *vertical-cut* (e.g. through an end or intersection point) and the line through the endpoints of a segment is called an *edge-cut*. To avoid ambiguity, we denote the open halfspaces of a cut with "$-$" and "$+$". For vertical-cuts $-$ denotes the one with lower x-coordinates and for edge-cuts $-$ denotes the one with the lower values of the y-axis.

As in [11, Chapter 6], our presentation assumes that no two distinct points (end or intersection) have exactly the same x-coordinate, unless they are a common endpoint in which the segments meet. As usual, this assumption is resolved by an implicit, infinitesimal shear transformation which translates to a tie-breaking rule in the geometric orientation predicate that resolves to comparing the y-coordinates. A simple extension of the halfspace partitioning for the remaining cases (of segments and cuts due to a segment) conceptually moves the points infinitesimally away from the degeneracy along their segment for a consistent decision. To also assign co-linear cases consistently we finally resolve to lexicographic comparison (c.f. Figure 1). We also assume that the whole domain is bounded by a very large rectangle, which is also a trapezoid. Extensions to unbounded problems are commonly achieved by careful case treatment of unbounded faces of arrangements (e.g. in [23]).

Our combinatorial analysis (c.f. Section 4) of the proposed dynamization requires more precise terms to establish a geometric correspondence, which we introduce now in a unified review of the well known incremental algorithms. We frequently identify a permutation π from the set of permutations $\mathbf{P}(S)$ over S as bijection $\pi : S \to \{1, \ldots, |S|\}$ and call $\pi(s)$ the *priority* of a segment $s \in S$.

2.1 Trapezoidal Search Trees $\mathcal{T}(S, \pi)$

A TST over a trapezoidal domain $\Delta \subseteq \mathbb{R}^2$ is a certain hierarchical Binary Space Partition with vertical cuts and edge cuts induced by the segments in S. These rooted trees are defined by inductively applying the deterministic insertion algorithm for the segments of S in *ascending priority* order. Hence, the structure is uniquely determined by (S, π).

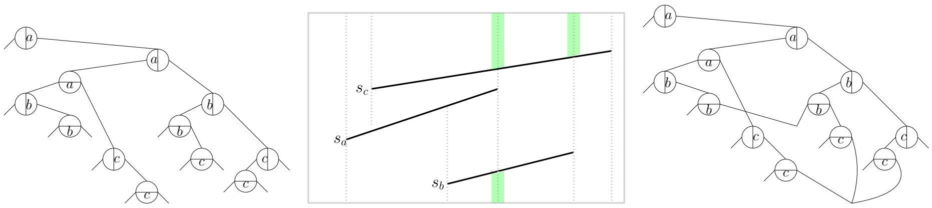

Figure 2 Example of TST Leaf-Insert (left) and TSD Leaf-Insert (right) for segments with priority order $s_a < s_b < s_c$ (middle). The vertical merges of Algorithm 2 are indicated in green.

Every node v of the binary tree is associated with a trapezoidal region $\Delta(v) \subseteq \Delta$ and, on the empty set of segments, $\mathcal{T}(\{\}, ())$ contains only the root r with $\Delta(r) = \Delta$. In TSTs, every non-leaf node v has two child nodes v^-, v^+ and stores a cut that signifies the halfspace partition of $\Delta(v)$ in $\Delta(v^-)$ and $\Delta(v^+)$, which enables point-location search descents. We say that this cut *destroys* the trapezoidal region $\Delta(v)$ and use this to extend the priority assignment to also comprise tree nodes.

We denote the priority of node v with $p(v)$. More precisely, leaves have priority $+\infty$ and non-leaf nodes have the priority of the segment whose cut insertion destroys the node. E.g. the cuts that constitute the (3 or 4) boundaries of $\Delta(v)$ have smaller priorities than $p(v)$.

Algorithm 1 Leaf-Insert($\mathcal{T}, s$).

1. Search for the leaf nodes $L = \{u_1, \dots, u_l\} \subseteq \mathcal{T}$ with $\Delta(u_i) \cap s \neq \emptyset$.
2. Create refined slabs of these regions by vertically partitioning each $\Delta(u_i)$ with cuts due to endpoints of s or intersection points of s with edge-cuts bounding $\Delta(u_i)$.
3. Partition the intersected slab regions further with the edge cut through s.

See Algorithm 1 for the steps to insert the next segment s in a TST $\mathcal{T}$. Note that nodes' priorities are monotonically increasing on paths from the root. Procedure Leaf-Insert inserts $3, 2$ or 1 cuts on the region of a leaf and the edge-cut is always the last cut that is performed. We refer to these patterns as vertical-vertical-edge (VVE), vertical-edge (VE), and edge (E) destruction. To remove unnecessary ambiguity in the tree structure, we use the additional convention that in a VVE-destruction, the left of the two vertical cuts is inserted first (e.g. as parent of the right vertical cut). See Figure 2 for an example.

▶ **Theorem 2.1** (TST size and depth [2]). *Let S be a set of segments and k_S the number of intersecting pairs among them. The expected size of a TST over S is bounded by*

$$\mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S)} |\mathcal{T}(S, \pi)| = \mathcal{O}(|S| \log |S| + k_S) \ .$$

The expected leaf depth is $\mathcal{O}(\log |S|)$ and the maximum leaf depth of $\mathcal{T}$ is w.h.p. $\mathcal{O}(\log |S|)$.

Clearly, any TST over a set of segments S contains at least $\Omega(|S| + k_S)$ nodes and there are certain instances that may have size $\Omega(|S|^3)$. Agarwal et al. [2] mention an upper bound of $\mathcal{O}(|S| \log^2 |S| + k_S \log |S|)$ expected time for the purely incremental construction.

2.2 Trapezoidal Decomposition $\mathcal{A}(S)$ and Search DAG $\mathcal{D}(S, \pi)$

One may save space in such a search structure by considering a certain planar subdivision $\mathcal{A}(S)$ that is induced from a set of segments S. Given aforementioned discussion of degeneracies, this subdivision is defined by emitting two vertical rays (in negative and positive y-direction) from each end or intersection point until the ray meets the first segment or the bounding rectangle. Each face of $\mathcal{A}(S)$ is a trapezoid with 3 or 4 boundary edges and standard double counting establishes a size of $\mathcal{O}(|S| + k_S)$ for these planar decompositions. Note that $\mathcal{A}(S)$ is independent of segment priorities.

Mulmuley [15] and Seidel [20] consider the incremental process of inserting an additional segment s and obtaining $\mathcal{A}(S \cup \{s\})$ from $\mathcal{A}(S)$. Algorithm 2 shows the additional merging phase, to "contract" pre-existing vertical-cuts (between the regions of the nodes in L) towards their emission point until they meet s, to maintain the property that the leaf regions coincide with $\mathcal{A}(S)$. Hence, the planar subdivision of the leaves of a TST, i.e. $\{\Delta(v) \subseteq \mathbb{R}^2 : v \in \mathcal{T}(S, \pi), v \text{ is leaf}\}$, is a *refinement* of $\mathcal{A}(S)$, regardless of π.

Algorithm 2 Leaf-Insert($\mathcal{D}, s$).

```
1. Search for the leaf nodes $L = \{u_1, \dots, u_l\} \subseteq \mathcal{D}$ with $\Delta(u_i) \cap s \neq \emptyset$.
2. Create refined slabs of these regions by vertically partitioning each $\Delta(u_i)$ with cuts due
   to endpoints of $s$ or the intersection points of $s$ with edge-cuts bounding $\Delta(u_i)$.
3. Partition the intersected slab regions further with the edge cut through $s$.
4. Scan over the vertical cuts between nodes in $L$ that cross $s$.
   Merge the vertical cuts of the refined regions whose emission point is now blocked by $s$.
```

Though the resulting search graph is a DAG (also known as History DAG), the basic data stored with a node is still identical with the binary TST tree nodes (e.g. Figure 2). One key ingredient for the well known, expected construction time of $\mathcal{O}(|S| \log |S| + k_S)$, is to perform the search for affected leaves (c.f. Step 1) quickly. A way to achieve this, without prior knowledge of all future segment insertions, is to also maintain an explicit graph representation of the planar subdivision $\mathcal{A}(S)$ of the segments S that are currently contained in the structure. This trick allows to perform only one point location query for, e.g., the left endpoint of s, followed by a walk along s through $\mathcal{A}(S)$. Our Section 3.1 solves this differently. We summarize the well known aspects of this incremental algorithm in the following statement.

▶ **Theorem 2.2** (TSD size and depth [11, 15, 20]). *Let S be a set of segments and k_S the number of intersecting pairs among them. The expected size of a TSD over S is bounded by*

$$\mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S)} |\mathcal{D}(S, \pi)| = \mathcal{O}(|S| + k_S) \ .$$

The expected search path length is $\mathcal{O}(\log |S|)$ and the maximum search path length of $\mathcal{D}$ is w.h.p. $\mathcal{O}(\log |S|)$.

The TST and TSD structure also allow simple deletions of segments in a certain decremental setting, that deletes all segments in *descending* priority order. That is, the modifications that the structure undergoes in the steps of Algorithm 2 are simply undone in exactly the reverse order (steps 4 to 2), causing the same amount of work. This is what Seidel's classic backward-analysis, that analyses dropping the last element instead of appending it, exploits.

The insightful work of [13], recently revealed a certain bijection between the search paths of $\mathcal{T}(S, \pi)$ and the (valid) search paths in $\mathcal{D}(S, \pi)$ by means of a structural induction argument (along fixed π) on the two incremental algorithms. This allows them to bound the runtime of computing the length of a longest search path in a TSD $\mathcal{D}(S, \pi)$ by means of the size of the related TST $\mathcal{T}(S, \pi)$. Based on this technique, our analysis of the update time in TSTs (c.f. Section 4) carries over to an upper bound in TSDs as well.

The main geometric difference between the structures is that in TSTs the region of a node is always a subset of its parents' region, whereas in TSDs the region of a node may extend further to the left and right, due to vertical merges, but not across the top and bottom boundaries. We now describe our recursive algorithms for vertical partitions, vertical merges, edge partitions, and edge merges that operate on intermediary priority levels.

3 Recursive Primitives for Dynamic Updates

Characteristic for our approach is that insertions and deletions are performed directly on higher levels of the search structures rather than solely on leaves. We first describe the recursive primitives for inserting a new segment s in the structure of $\mathcal{T}(S, \pi)$.

We choose a random position $p \in \{1, \dots, |S| + 1\}$ uniformly in which we emplace the element s, between $(p-1)$ and p, in the sequence π, calling the resulting priority order π'. Our recursive algorithms then update the structure $\mathcal{T}(S, \pi)$ exactly to $\mathcal{T}(S \cup \{s\}, \pi')$. More precisely, we restrict the search (c.f. Step 1 of Algorithms 1 and 2) to those nodes with priority smaller than p, which leads to a set L of affected subtree roots whose priorities are larger than p in π'. We conceptually "hang out" these nodes by creating a copy L' of them and reverting those in L to leaves, temporarily. The insertion then proceeds in the same sequence as on regular leaves, but every binary space partition on nodes of L is accompanied by a matching call with the recursive primitive on the respective subtree of the node's copy in L'. After this process, we have a matching root in L' for each leaf that was created below L, which we then "hang in" instead of the simple leaf. Given the close relation of the two structures, it turns out that our recursive primitives, with few changes, already provide the necessities for dynamic updates of TSDs.

This and the following section assume that priority value comparisons, i.e. $\pi'(s') > \pi'(s)$, are decidable in constant time. Section 5 shows a new and simple solution, based on Treaps, to solve the dynamic order maintenance problem sufficiently fast for the online setting. Given the discussion above on the possible E-, VE- and VVE-destruction patterns, we simplify notation in this section by denoting with Descend(v) the tuple of $0, 2, 3$, or 4 descendants with the next higher priority value than $p(v)$. E.g. Descend$(v) = ()$ if v is a leaf, Descend$(v) = (v_a, v_b)$ if v underwent an E-destruction, Descend$(v) = (v_l, v_a, v_b)$ or Descend$(v) = (v_a, v_b, v_r)$ if v underwent a VE-destruction, and Descend$(v) = (v_l, v_a, v_b, v_r)$ if v underwent a VVE-destruction. With v_l, v_a, v_b and v_r we denote the respective left, above, below and right child of the node's destruction (e.g. Figure 3).

3.1 Priority Restricted Searches

We use the following top-down refinement process to derive the node set L, such that its nodes u_i are sorted by the sequence in which s stabs $\Delta(u_i)$ from left-to-right: First locate the search node u, with maximal $p(u) < p(s)$, that fully contains s in $\Delta(u)$. Place u in an initially empty list. Successively replace the leftmost node u in the list with $p(u) < p(s)$ with the nodes of Descend(u), whose region intersects s, until all node priorities exceed $p(s)$.

Note that nodes with priority larger than $p(s)$ are not refined and the spatial location of the regions of the nodes in Descend$(\cdot)$ allows us to easily keep the set L sorted by left-to-right stabbing sequence of s.

3.2 Recursive Vertical Partitions and Merges

Our methods are inspired by sorting algorithms on lists of integers, though they move cuts and child relations among nodes based on the nodes' priorities. We first introduce the recursive primitive V-Partition(u, q, v^-, v^+), where $q \in \mathbb{R}^2$ denotes the point that induces the vertical cut $c(q)$, u is an affected tree node, and v^-, v^+ the roots of the respective, initially empty, result trees. As outlined above, the primitives update the search structure to the state that regular leaf insertion (in ascending priority order) would have created under the presence of vertical cut $c(q)$ splitting $\Delta(u)$ in $\Delta^- \cup \Delta^+$. (A lengthy, rigorous proof fixes $\Delta(u)$ and performs a structural induction argument over the sequence of successive cuts that destroy the region.) See Figure 3 for the recursive cases by destruction patterns and Algorithm 3.

The recursive node visits are similar to a search for points on $c(q)$ and V-Partition performs at most two recursive calls per node in TSTs. Reverting these steps in exactly the reverse order provides the inverse operation V-Merge(u^-, u^+, q, v) on two trees with adjacent search regions (c.f. Algorithm 4). Note that the TSD primitives actually perform *fewer* recursive calls, since vertical cuts are contracted in this structure.

3.3 Recursive Edge Partitions and Merges

Based on the recursive primitives for vertical cuts, we now introduce the recursive edge partition Partition(u, c, v^-, v^+) on regions $\Delta(u)$ that are fully crossed by the edge cut c (c.f. Algorithm 5). As above, v^- and v^+ denote the initially empty result trees for the respective partition of $\Delta(u)$ in $\Delta^- \cup \Delta^+$.

If the edge cut c does not intersect the edge cut that destroys u, the recursive results on nodes of Descend(u) only need V-Merge calls on one side of c to produce the result. E.g. the left case in the figure of Algorithm 5: First a V-Merge call on (v_a^+, v_r^+) and then with v_l^+. For new intersections with c, let i denote the intersection point. We first use V-Partition(u_a, i, v_{al}, v_{ar}) and V-Partition(u_b, i, v_{bl}, v_{br}) to create trees v_{al}, v_{bl} and v_{ar}, v_{br} for the respective left and right sides of i, prior to the edge partition with c. Finally, we use V-Merge to combine those results properly. E.g. the two gray areas in right case in the figure of Algorithm 5.

Note that for segments from a planar subdivision, the treatment of intersections is not necessary. The inverse primitive for edge cut merges (of two adjacent regions) can be derived analogously, by executing the inverse primitives in exactly the reverse order.

4 Counting Search Nodes in Affected Regions

To improve readability in this section, we denote for singleton elements the set union $S \cup \{s\}$ with $S + s$ and the set difference $S \setminus \{s\}$ with $S - s$. With $\mathbf{P}(S)$ we denote the set of bijective mappings $\pi : S \to \{1, \ldots, |S|\}$. For $S' \subseteq S$ we use the predicate "$\pi(S') \leq |S'|$" to abbreviate that $\pi(s) \leq |S'|$ holds for each $s \in S'$, i.e. the permutation begins with the elements of S'.

The following definitions concern sets of segments and their (deterministic) induced trapezoidal subdivision $\mathcal{A}$ of the plane. For $s \in S \setminus B$, we define $F_B(s) \subseteq \mathbb{R}^2$ to denote the region of the faces in $\mathcal{A}(B)$ that are intersected by s, that is $F_B(s) = \bigcup_{\{f \in \mathcal{A}(B): f \cap s \neq \emptyset\}} f$. Moreover, for $s \in B$ we define the neighborhood zone $N_B(s) \subseteq \mathbb{R}^2$ to be the union of all faces of $\mathcal{A}(B)$ that are adjacent to s (e.g. s contributes as edge, vertex or intersection cut). Note that every point in $\mathbb{R}^2$ is in at most 4 neighborhood zones and $N_{B+s}(s) = F_B(s)$.

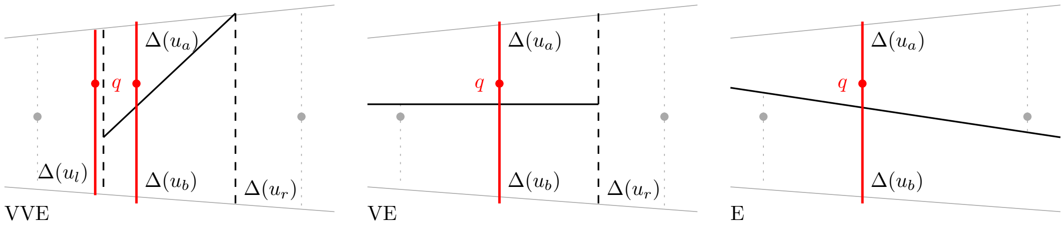

Figure 3 Cases during recursions of V-Partition(u, q, v^-, v^+) and V-Merge(u^-, u^+, q, v).

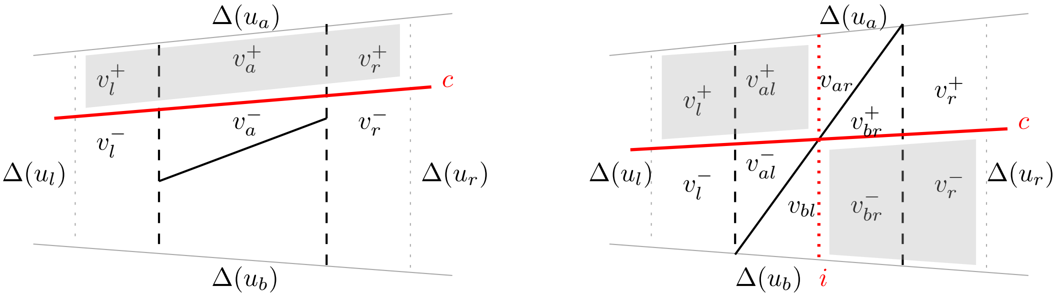
Algorithm 3 V-Partition(u, q, v^-, v^+): Assertion: $c(q)$ intersects $\Delta(u)$.

```
      Stop if $u$ is a leaf; Let $(u_l, u_a, u_b, u_r) := \text{Descend}(u)$.
TST:  IF $c(q)$ intersects $\Delta(u_a)$ and $\Delta(u_b)$
TSD:  IF $q \in \Delta(u_a)$                                    "$q \in \Delta(u_b)$" analogue
        If present, move $u_l$ and its parent's vertical cut in $v^-$.
        If present, move $u_r$ and its parent's vertical cut in $v^+$.
        Cut both unoccupied leaves, that is one child of $v^-$ and one of $v^+$, with the edge
        cut. Let $v_a^-, v_b^-, v_a^+, v_b^+$ denote these leaves.
        V-Partition$(u_a, q, v_a^-, v_a^+)$
  TST:  V-Partition$(u_b, q, v_b^-, v_b^+)$
  TSD:  Set both below pointers on $u_b$ instead of $v_b^-$ and $v_b^+$.
      ELSE IF $c(q)$ intersects $\Delta(u_l)$           "$c(q)$ intersects $\Delta(u_r)$" symmetrically
        Move $u_r$ (if present) , $u_a, u_b$ and their parents' cuts in $v^+$.
        Let $v_l^+$ denote the unoccupied leaf.
        V-Partition$(u_l, q, v^-, v_l^+)$
```

Algorithm 4 V-Merge(u^-, u^+, q, v): Assertion: $c(q)$ bounds $\Delta(u^-)$ and $\Delta(u^+)$.

```
      IF $u^-$ is leaf THEN Move contents of $u^+$ in $v$ and stop.      "$u^+$ leaf" analogue
      Let $(u_l^-, u_a^-, u_b^-, u_r^-) := \text{Descend}(u^-)$ and $(u_l^+, u_a^+, u_b^+, u_r^+) := \text{Descend}(u^+)$.
TST:  IF $p(u^-) = p(u^+)$
TSD:  IF $p(u^-) = p(u^+)$ and $u_b^- = u_b^+$                           "$u_a^- = u_a^+$" analogue
        If present, move $u_l^-$ and its parent's vertical cut in $v$.
        If present, move $u_r^+$ and its parent's vertical cut in the unoccupied leaf of $v$.
        Cut the new unoccupied leaf of $v$ with the edge cut. Let $v_a, v_b$ denote these
        leaves.
        V-Merge$(u_a^-, u_a^+, q, v_a)$
  TST:  V-Merge$(u_b^-, u_b^+, q, v_b)$
  TSD:  Set the below pointer on $u_b^-$ instead of $v_b$.
      ELSE IF $p(u^-) < p(u^+)$                                          "$>$" symmetrically
        Move $u_l^-$ (if present) , $u_a^-, u_b^-$ and their parents' cuts in $v$.
        Let $v_r$ denote the unoccupied leaf.
        V-Merge$(u_r^-, u^+, q, v_r)$
```

Algorithm 5 Partition(u, c, v^-, v^+): Assertion: c crosses $\Delta(u)$ entirely.



```
Stop if $u$ is a leaf.
Let $(u_l, u_a, u_b, u_r) :=$ Descend$(u)$ and $l_1, l_2$ denote the vertical cuts destroying $\Delta(u)$.
IF $c$ does not intersect $\Delta(u_b)$ properly                     "not $\Delta(u_a)$" analogue
    Allocate new nodes $v_l^-, v_l^+, v_a^-, v_a^+, v_r^-, v_r^+, v_{ar}^+$.
    Partition$(u_l, c, v_l^-, v_l^+)$; Partition$(u_a, c, v_a^-, v_a^+)$; Partition$(u_r, c, v_r^-, v_r^+)$
    V-Merge$(v_a^+, v_r^+, l_2, v_{ar}^+)$
    V-Merge$(v_l^+, v_{ar}^+, l_1, v^+)$
    Place $v_l^-, v_a^-, u_b, v_r^-$ below respective cuts under $v^-$.
ELSE IF edge cut of $u$ is steeper than $c$                  "less steep" symmetrically
    Let $i$ denote the vertical cut (induced by the intersection of the edge-cut and $c$).
    Allocate new nodes $v_l^-, v_l^+, v_r^-, v_r^+$ as well as $v_{ar}, v_{al}, v_{al}^-, v_{al}^+$ and $v_{bl}, v_{br}, v_{br}^-, v_{br}^+$.
    Partition$(u_l, c, v_l^+, v_l^-)$; Partition$(u_r, c, v_r^+, v_r^-)$
    V-Partition$(u_a, i, v_{al}, v_{ar})$; V-Partition$(u_b, i, v_{bl}, v_{br})$
    Partition$(v_{al}, c, v_{al}^-, v_{al}^+)$; Partition$(v_{br}, c, v_{br}^-, v_{br}^+)$

    Place V-Merge$(v_l^+, v_{al}^+, l_1, \cdot)$ as left child under cut $i$ below $v^+$.
    Place $v_r^+$ and its parent's cut in the unoccupied leaf of $v^+$.
    Cut the unoccupied leaf of $v^+$ with the edge cut of $u$.
    Place $v_{ar}$ and $v_{br}^+$ in these leaves.

    Place $v_l^-$ and its parent's cut in $v^-$.
    Place V-Merge$(b_{br}^-, v_r^-, l_2, \cdot)$ as right child under cut $i$ in $v^-$.
    Cut the unoccupied leaf of $v^-$ with the edge cut of $u$.
    Place $v_{al}^-$ and $v_{bl}$ in these leaves.
```

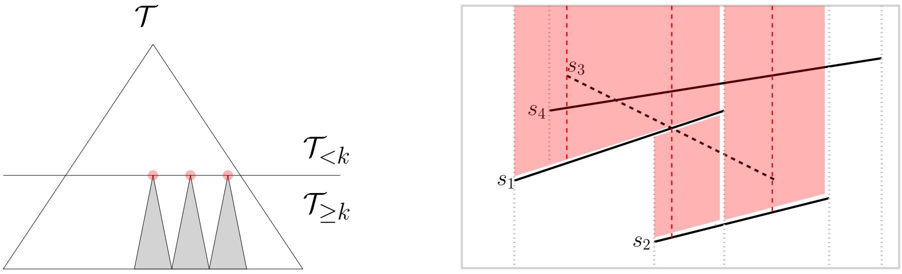
Given a TST $\mathcal{T}(S, \pi)$ and some priority value $r \in \{1, \ldots, |S|\}$, we consider partitions of its nodes in classes $\mathcal{T}_{<r}, \mathcal{T}_{=r}$, and $\mathcal{T}_{>r}$, having priority less, equal or larger than r. E.g. $\mathcal{T}_{<1} = \emptyset$ and $\mathcal{T}_{>r}$ always contains the leaf nodes. As introduced in Section 2.1, we identify every node v in $\mathcal{T}$ with its associated search region $\Delta(v) \subseteq \mathbb{R}^2$.

From the refinement property (c.f. Section 2.2), we have that the leaves' partition $\{\Delta(v) \subseteq \mathbb{R}^2 : v \in \mathcal{T}(S, \pi),\ p(v) = \infty\}$ of the domain is a (set theoretic) refinement of $\mathcal{A}(S)$, for any S and $\pi \in \mathbf{P}(S)$. This applies in particular for a set of segments $S_{\leq r} = \{s \in S : \pi(s) \leq r\}$. Since additional leaf-insertions only refine further, we have that the region $\Delta(v)$ of a node $v \in \mathcal{T}_{>r}$ is either contained in or disjoint from neighborhood zone $N_{S_{\leq r}}(s)$ for any $s \in S_{\leq r}$.

This provides the following 4-ply covering property. For any $B \subseteq S$ with a $\pi \in \mathbf{P}(S)$ such that $\pi(B) \leq |B|$, we have that

$$\sum_{s \in B} \Big| \{ v \in \mathcal{T}_{=l}(S, \pi) \ : \ \Delta(v) \subseteq N_B(s) \} \Big| \ \leq \ 4 \Big| \mathcal{T}_{=l}(S, \pi) \Big| \ , \tag{1}$$

for each $l > |B|$.



(a) Partition of nodes in $\mathcal{T}$ in $\mathcal{T}_{<k}$ and $\mathcal{T}_{\geq k}$ due to node priority. Affected nodes are in red and their subtrees in gray.

(b) The neighborhood zone of s_3 (shaded in red) is $F_{\{s_1,s_2\}}(s_3) = N_{\{s_1,s_2,s_3\}}(s_3)$.

Figure 4 Illustration of affected subtrees (left) and neighborhood zone refinement (right).

▶ **Definition 4.1** (Affected Nodes). *Given a segment $s \in S$ of designated priority rank $r \in \{1, \dots, |S|\}$, we call a node v of $\mathcal{T}_{\geq r}$ over $S - s$ affected if and only if $\Delta(v) \cap s \neq \emptyset$ and it is topmost in $\mathcal{T}$. That is, v has no parent u in $\mathcal{T}_{\geq r}$ with $p(u) \leq p(v)$.*

Clearly, for every $v \in \mathcal{T}_{\geq r}$ whose region $\Delta(v)$ intersects s, we have $\Delta(v) \subseteq F_{S_{<r}}(s)$ as well. In other words, the affected nodes correspond precisely to the leaves of $\mathcal{T}(S_{<r}, \pi)$, the tree over the first $r-1$ segments, that are intersected by s. See Figure 4a for an illustration and Figure 4b for an example. In this example, decomposition $\mathcal{A}(\{s_1, s_2\})$ has 7 faces of which s_3 intersects 3. The neighborhood region of s_3 is $F_{\{s_1,s_2\}}(s_3) = N_{\{s_1,s_2,s_3\}}(s_3)$ and shaded in red. The TST for $\left(\{s_1, s_2, s_4\}, \left(\begin{smallmatrix} s_1 & s_2 & s_4 \\ 1 & 2 & 3 \end{smallmatrix}\right)\right)$ has 13 leaf regions and the TSD has 10 leaves. Note that for TST nodes v with priority $p(v) \geq 3$, the region $\Delta(v)$ is either fully contained or outside the red zone.

Given a $\pi \in \mathbf{P}(S-s)$ and a value $p \in \{1, \dots, |S|\}$, we call the region $F_{\{s' \in (S-s)\ :\ \pi(s') < p\}}(s)$ the *p-neighborhood of s*.

▶ **Lemma 4.2** (Zone Covering). *Let S be a set of non-crossing segments, $p \in \{1, \dots, |S|\}$ a fixed value, and $s \in S$. For any $l \geq p$, the expected number of priority l nodes of a random TST over $S - s$ that are in the p-neighborhood of s is upper bounded with*

$$\mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left| \left\{ v \in \mathcal{T}_{=l}(S-s, \pi) \ : \Delta(v) \subseteq F \right\} \right| \ \leq \ \frac{4}{p} \mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left| \mathcal{T}_{=l}(S-s, \pi) \right| ,$$

where F denotes the p-neighborhood of s.

On a sequence of elements, we call the process to place a new element between the elements of positions $p-1$ and p *emplacing* at p and *dropping* is the reverse operation. E.g. old elements of index less than p remain and those of at least p are moved one position to the right. We perform a backward analysis and consider dropping the element at position p in sequences of $\mathbf{P}(S)$ instead of emplacing a $s \in S$ at position p in sequences of $\mathbf{P}(S-s)$.

Proof. The main idea is to group the sequences in $\mathbf{P}(S)$ by those having the same cardinality p subsets $B \in \binom{S}{p}$ in the first p entries to use that $\bigcup_{s \in B} N_B(s) = \mathbb{R}^2$, as in Eq. 1.

For $\pi \in \mathbf{P}(S)$, we denote with $\pi^{-1}(p) \in S$ the element that π maps to position p and with $\pi - s$ we denote the sequence of $\mathbf{P}(S-s)$ that results from dropping element s. To shorten notation, we define a random variable γ that counts the relevant nodes of a tree within a certain region $N \subseteq \mathbb{R}^2$, that is $\gamma(S, \pi, N) = |\{v \in \mathcal{T}_{=l}(S, \pi) \ : \ \Delta(v) \subseteq N\}|$.

We count the expected number of nodes within $\mathcal{T}(S - \pi^{-1}(p), \pi - \pi^{-1}(p))$, that fall into the region $N_{\{s \in S\ :\ \pi(s) \leq p\}}\left(\pi^{-1}(p)\right)$, which is the neighborhood zone of the element at position p among those with priority at most p.

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S)} \gamma\left(S - \pi^{-1}(p), \pi - \pi^{-1}(p), N_{\{s \in S\ :\ \pi(s) \leq p\}}\left(\pi^{-1}(p)\right)\right) && (2)\\
=&\frac{1}{|S|!} \sum_{B \in \binom{S}{p}} \sum_{s \in B} \sum_{\substack{\pi \in \mathbf{P}(S)\ :\\ \pi(B) \leq p,\ \pi(s) = p}} \gamma(S - s, \pi - s, N_B(s)) && (3)\\
\leq&\frac{1}{|S|!} \sum_{B \in \binom{S}{p}} \sum_{s \in B} \frac{4}{p} \sum_{\substack{\pi \in \mathbf{P}(S)\ :\\ \pi(B) \leq p,\ \pi(s) = p}} \gamma(S - s, \pi - s, \mathbb{R}^2) && (4)\\
=&\frac{4}{|S|!\ p} \sum_{s \in S} \sum_{B \in \binom{S-s}{p-1}} \sum_{\substack{\pi \in \mathbf{P}(S-s)\ :\\ \pi(B) < p}} \gamma(S - s, \pi, \mathbb{R}^2) && (5)\\
=&\frac{1}{|S|} \sum_{s \in S} \frac{4}{p} \frac{1}{|S - s|!} \sum_{\pi \in \mathbf{P}(S-s)} \gamma(S - s, \pi, \mathbb{R}^2) && (6)\\
=&\frac{1}{|S|} \sum_{s \in S} \ \frac{4}{p} \mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \gamma(S - s, \pi, \mathbb{R}^2) && (7)
\end{aligned}
$$

Equation (3) is due to regrouping the summation terms by the sequences that have the same sets of elements B in the first p positions, (4) due to the ordinary[1] "camel trick" of the form $\sum_{s \in B} f(s) = \sum_{s \in B} \frac{1}{|B|} \sum_{s \in B} f(s)$ and the 4-ply covering. Equation (5) uses the combinatorial identity $\binom{n}{k}\binom{k}{1} = \binom{n}{1}\binom{n-1}{k-1}$ to first choose $s \in S$ for position p. Since the terms in (7) do not depend on the spatial location of s, the bound holds for any $s \in S$. ◀

We now bound the expected total size of subtrees below affected nodes (c.f. Figure 4a).

▶ **Lemma 4.3** (Subtree Sizes). *Let S be a set of non-crossing segments, $p \in \{1, \ldots, |S|\}$ uniformly at random, and $s \in S$. The expected total size of affected subtrees in a random TST over $(S - s)$ is $\mathcal{O}\left(\log^2 |S|\right)$.*

Proof. We use Lemma 4.2 to bound the number of nodes in $\mathcal{T}(S - s, \pi)$ that have a priority of at least p and have a region that is in the p-neighborhood of s.

$$
\begin{aligned}
&\frac{1}{|S|} \sum_{p=1}^{|S|} \mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left|\left\{ v \in \mathcal{T}_{\geq p}(S - s, \pi)\ :\ \Delta(v) \subseteq F_{\{s' \in (S-s)\ :\ \pi(s') < p\}}(s) \right\}\right| && (8)\\
\leq\ & \frac{1}{|S|} \sum_{p=1}^{|S|} \frac{4}{p} \mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left|\mathcal{T}_{\geq p}(S - s, \pi)\right| && (9)\\
\leq\ & \frac{1}{|S|} \sum_{p=1}^{|S|} \frac{4}{p} \mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left|\mathcal{T}(S - s, \pi)\right| && (10)\\
\leq\ & \frac{1}{|S|} \sum_{p=1}^{|S|} \frac{4}{p} \mathcal{O}\left(|S - s| \log |S - s|\right) \leq \mathcal{O}\left(\log^2 |S|\right) && (11)
\end{aligned}
$$

Bound (11) is due to the expected size of the whole tree (c.f. Theorem 2.1). ◀

[1] E.g. proof of Theorem 3.1.4 in [16, p. 90] or proof of Theorem 6.3 in [11, p. 136].

With a slightly more advanced application of our arguments presented thus far, we now bound the cost for simple iterated ray-shooting search to find the affected subtree roots for a query segment that has a designated random priority rank (c.f. Section 3.1).

▶ **Lemma 4.4** (Segment Search). *Let S be a set of non-crossing segments, $p \in \{1, \dots, |S|\}$ uniformly at random, and $s \in S$. The expected time to find the affected nodes within a random TST over $(S - s)$ is $\mathcal{O}\left(\log^2 |S|\right)$.*

Proof. The search visits only nodes v with regions $\Delta(v) \cap s \neq \emptyset$. Since Lemma 4.3 bounds the size of the result set, we only need to bound the number of nodes with priority smaller p. We do so by invoking Lemma 4.2 $\lceil \log_2 p \rceil$ times.

$$\frac{1}{|S|}\sum_{p=1}^{|S|} \mathop{\mathbb{E}}_{\pi\in\mathbf{P}(S-s)} \left|\left\{v \in \mathcal{T}_{<p}(S-s,\pi) \ : \ \Delta(v)\cap s \neq \emptyset\right\}\right| \tag{12}$$

$$\leq \frac{1}{|S|}\sum_{p=1}^{|S|}\sum_{j=1}^{\lceil \log_2 p\rceil} \mathop{\mathbb{E}}_{\pi\in\mathbf{P}(S-s)} \left|\left\{v \in \mathcal{T}(S-s,\pi) : 2^{j-1} < p(v) \leq 2^j, \ \Delta(v)\cap s \neq \emptyset\right\}\right| \tag{13}$$

$$= \frac{1}{|S|}\sum_{p=1}^{|S|}\sum_{j=1}^{\lceil \log_2 p\rceil} \frac{4}{2^{j-1}} \mathop{\mathbb{E}}_{\pi\in\mathbf{P}(S-s)} \left|\left\{v \in \mathcal{T}(S-s,\pi) \ : \ 2^{j-1} < p(v) \leq 2^j\right\}\right| \tag{14}$$

$$\leq \frac{1}{|S|}\sum_{p=1}^{|S|}\sum_{j=1}^{\lceil \log_2 p\rceil} \frac{4}{2^{j-1}} \mathcal{O}\left(2^j \log(2^j)\right) \tag{15}$$

$$= \frac{1}{|S|}\sum_{p=1}^{|S|}\sum_{j=1}^{\lceil \log_2 p\rceil} \mathcal{O}\left(j\right) \leq \frac{1}{|S|}\sum_{p=1}^{|S|} \mathcal{O}(\log^2 p) \leq \mathcal{O}\left(\log^2 |S|\right) \tag{16}$$

In (13), we use "linearity of expectation" to count search nodes of $\mathcal{T}_{<p}$ in batches of priority intervals of the form $(2^{j-1}, 2^j]$. Bound (14) is due to invoking Lemma 4.2 for s according to the priority interval. To bound a batch j in (15) we use Theorem 2.1 on the whole TST size over the first 2^j segments. ◀

Now we have all necessary arguments for our bound on dynamic update costs in TSTs.

▶ **Theorem 4.5.** *Let S be a set of non-crossing segments and $s \in S$. The expected cost of inserting s in a random TST over $(S - s)$ is $\mathcal{O}(\log^2 |S|)$.*

Proof. Let $1 \leq m \leq |\mathcal{T}|$ denote the total number of nodes within affected subtrees of $\mathcal{T}$, prior to the insertion call. We argue that the total number of nodes visited by the insertion procedure is $\mathcal{O}(m)$, which establishes the result based on Lemma 4.3 and 4.4 for non-crossing segments.

For each root of an affected subtree, we have at most 2 calls of V-Partition to slab the subtree. After the slabbing stage of the insertion, we have at most $3m$ nodes in total.

The edge Partition calls on one slab are independent from those of another slab in $\mathcal{T}$. Neglecting node removals due to V-Merge briefly, the total number of temporarily created nodes of Partition increases at most by a factor of 2. Since we cannot remove more than what was created, the total number of nodes that V-Merge may visit is bounded by $6m$. ◀

Given the duality of the update procedures, deletion of a $s \in S$ having priority $p(s)$ visits exactly the same nodes as insertion of s among $(S - s)$ with priority value $p(s)$. Hence the expected node visits are equal as well. Since our bound on expected update operations counts TST search nodes, we may employ the method of Hemmer et al. [13], on the bijection between TST and TSD search paths, to obtain equal asymptotic bounds for the expected update costs in TSDs. A more detailed consideration, however, allows an improvement.

4.1 Improved Update Bounds For TSDs

The region of each TSD node may be represented by its top, bottom and vertical boundary cuts. To use "linearity of expectation", we decompose the random variable $|\mathcal{D}(S,\pi)|$ in a sum of $\mathcal{O}(|S|^5)$ binary indicator variables $\mathcal{N}_{i,i',i'',i''',j}$ that are 1 if and only if $\mathcal{D}(S,\pi)$ contains a node whose boundary is constituted by cuts with the priorities i, i', i'', i''' and gets destroyed by the segment with priority j. That is $|\mathcal{D}_{=l}| = \sum_{i,i',i'',i'''} \mathcal{N}_{i,i',i'',i''',l}$. The number of these indicator variables only depends on $|S|$, but not on π or the spatial location of the segments.

▶ **Lemma 4.6** (Overlap into Zones). *Let S be a set of non-crossing segments, $p \in \{1, \ldots, |S|\}$ a fixed value, and $s \in S$. For any $l \geq p$, the expected number of priority l nodes of a random TSD over $S - s$ that overlap the p-neighborhood of s is upper bounded with*

$$\mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left| \left\{ v \in \mathcal{D}_{=l}(S-s,\pi) \ : \Delta(v) \cap F \neq \emptyset \right\} \right| \ \leq \ \frac{\mathcal{O}(1)}{p} \mathop{\mathbb{E}}_{\pi \in \mathbf{P}(S-s)} \left| \mathcal{D}_{=l}(S-s,\pi) \right| \ ,$$

where F denotes the p-neighborhood of s.

For the proof recall that, for any subset $C \subseteq S$ and its maximum priority element $m \in C$, classic Backward Analysis (e.g. Chapter 6 in [11]) shows that the number d_C, denoting the number of faces in $\mathcal{A}(C - m)$ that segment m intersects (a.k.a destroys), is expected $\mathcal{O}(1)$. Since the neighborhood zones are a union of faces of $\mathcal{A}(C - m)$, element m also intersects no more than $4 \cdot d_C$ of the neighborhood zones in N_{C-m}.

Proof. The proof is analogue to Lemma 4.2, except from Eq. 4 which uses that every TST node is in at most 4 neighborhood zones. Given the refined decomposition of $|\mathcal{D}_{=l}|$, showing that *each* of the priority l nodes intersects at most $\mathcal{O}(1)$ zones of N_B gives the statement due to linearity of expectation.

A priority $l < \infty$ node, i.e. a non-leaf node, is either fully crossed by the segment $\pi^{-1}(l)$ or contains an endpoint of it. In the first case, the number of N_B zones that the node region intersects is bounded by $4 \cdot d_C$, where $C = B + \pi^{-1}(l)$. For the endpoint case, let $|B| < l', l'' < l$ denote the priorities of the top and bottom segment that bound the node's trapezoidal region. Hence, the node does not intersect more than $4(d_{C'} + d_{C''})$ neighborhood zones where $C' = B + \pi^{-1}(l')$ and $C'' = B + \pi^{-1}(l'')$. The argument for a leaf node, i.e. $l = \infty$, is analogue to the endpoint case. ◀

▶ **Corollary 4.7.** *Let S be a set of non-crossing segments and $s \in S$. The expected cost of inserting s in a random TSD over $(S - s)$ is $\mathcal{O}(\log |S|)$.*

Proof. Using Lemma 4.6, Equation 11 improves to $\frac{1}{|S|} \sum_{p=1}^{|S|} \mathcal{O}(\frac{1}{p}|S - s|)$, which evaluates to an expected number of $\mathcal{O}(\log |S|)$ TSD nodes to overlap into the affected zone. Moreover, Equation 15 improves to $\frac{1}{|S|} \sum_{p=1}^{|S|} \sum_{j=1}^{\lceil \log_2 p \rceil} \mathcal{O}\left(\frac{1}{2^{j-1}} 2^j\right)$, which evaluates to an expected number of $\mathcal{O}(\log |S|)$ TSD nodes that are visited in the segment search. Since our recursive update primitives visit a TSD node at most once, using the same arguments as in the proof of Theorem 4.5 on TSDs provides the expected update cost as stated. ◀

5 Offline vs Online – Maintaining Small Codes For Dynamic Orders

To support online emplacement and dropping of additional elements in a sequence $\pi \in \mathbf{P}(S)$, we use a more flexible representation than standard bijections $\pi : S \to \{1, \dots, |S|\}$. We represent sequences as injective mappings $\tau : S \to (0,1) \subseteq \mathbb{R}$. If the values of τ are stored with the elements of S, we can evaluate the required $\pi(s) < \pi(s')$ predicates with comparison on τ in constant time. However, dynamically extending τ for a new element $s \notin S$ such that $\tau(s)$ falls with equal probability in the intervals between $\{\tau(s') : s' \in S\}$ is challenging. E.g. simple random sampling of $\tau(s)$ uniformly out of $(0,1)$ does not provide this. Since single registers of the pointer machine model are confined to numbers with only $\mathcal{O}(\log |S|)$ bits, simple interval halving strategies may well produce inefficiently long codes for τ as well.

We solve this problem using one additional randomized data structure to maintain orders among n elements of a totally ordered set of "keys'. Treaps are a conceptual fusion of Binary Search Trees (BSTs), over the nodes' key values, and (Min-)Heaps, over the nodes' priority values. Insertions and deletions are performed similarly to BSTs and additionally standard tree rotations are used to maintain the heap property on the randomly chosen priority values. Seidel and Aragon [21] show not only that Treaps achieve $\mathcal{O}(\log n)$ depth with high probability but also that, even if the cost of a rotation is proportional to the whole subtree size, insertions and deletions still perform expected $\mathcal{O}(\log n)$ operations.

For our simple in-order numbering scheme in a fixed BST, we consider an injective mapping from root-to-node paths, which we read as smaller/larger strings over the alphabet $\{s, l\}$, to binary fractional number from $(0,1) \subseteq \mathbb{Q}$ coded as "1"-terminated strings over the alphabet $\{0, 1\}$. More precisely, for the empty path string (the root node r) the associated value is $\gamma(r) = 0.1_{(2)}$, s-edges are coded as 0 and l-edges are coded as 1. E.g. the left child node v_s of the root has code $\gamma(v_s) = 0.01_{(2)}$, the right child node v_l of the root has code $\gamma(v_l) = 0.11_{(2)}$, and we have $\gamma(v_s) < \gamma(r) < \gamma(v_l)$. On paths of a BST, the search tree property extends to the order of these γ values of the nodes. This allows us to check if u is before v in the in-order sequence by comparing the values of $\gamma(u)$ and $\gamma(v)$. Moreover, this recursive code definition can be assigned in a top-down fashion for all nodes in a subtree under v, once $\gamma(v)$ is assigned.

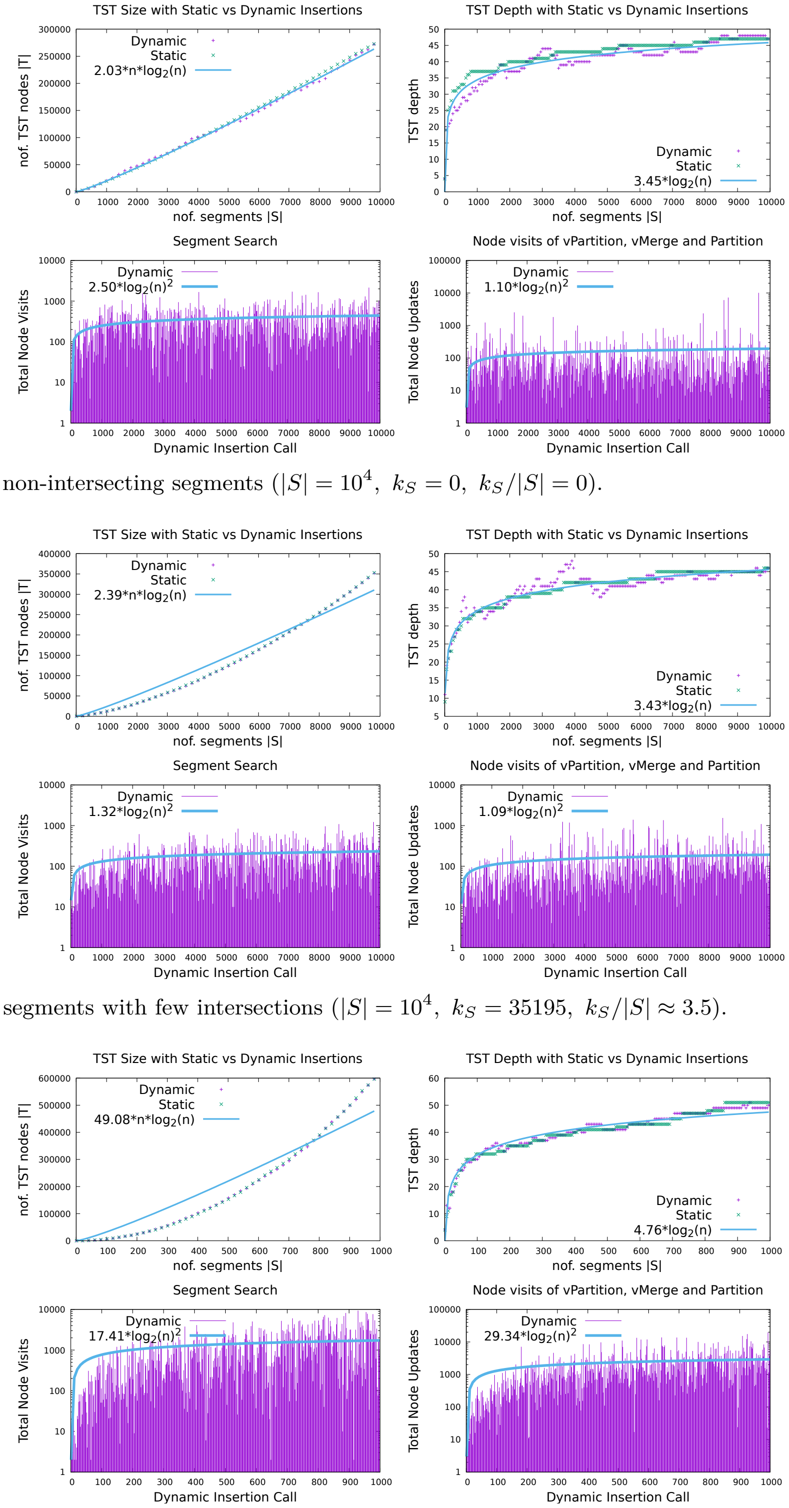
In order to maintain the proper values τ for a set S, we augment the Treap nodes to also store the total number of nodes in their subtree. To emplace a new element, we first choose an integer $1 \leq p \leq |S| + 1$ uniformly at random. Next we use the standard Treap insertion to add a new node resembling the p-smallest key-value as a new leaf. After the bottom-up re-balancing rotations are finished, we simply re-visit the whole rotated subtree in a top-down fashion to overwrite the key value of each node v with the new value $\gamma(v)$. The deletion of an element is handled analogously. To evaluate an order predicate between two elements, we simply compare the current key values due to the Treap, which are stored with the elements of S. We summarize this with the following statement.

▶ **Observation 5.1.** *Representation of sequences $\pi \in \mathbf{P}(S)$ requires no more than $\mathcal{O}(|S|)$ space and dynamic updates take expected $\mathcal{O}(\log |S|)$ operations. After successful updates, evaluation of a $\pi(s) < \pi(s')$ predicate on $s, s' \in S$ takes $\mathcal{O}(1)$ operations.*

6 Implementation and Experiments

We implemented[2] our fully-dynamic approach for TSTs based on the exact predicates and exact construction for line segments of the Computational Geometry Algorithms Library [23].

[2] `https://github.com/milutinB/dynamic_trapezoidal_map_impl`



(a) Random non-intersecting segments ($|S| = 10^4,\ k_S = 0,\ k_S/|S| = 0$).

(b) Random segments with few intersections ($|S| = 10^4,\ k_S = 35195,\ k_S/|S| \approx 3.5$).

(c) Random segments with many intersections ($|S| = 10^3,\ k_S = 120730,\ k_S/|S| \approx 120.7$).

Figure 5 Experimental results on TST size (top left), TST depth (top right), and node visits of the segment search (bottom left) and updates (bottom right) for RIC TSTs (green) and Dynamic TSTs (purple). The blue curve indicates the respective function fit on the data of Dynamic TSTs.

Our experiments focus on evaluating the practicality of the approach and the tightness of the analysis. We use the standard RIC of TSTs as verification and baseline comparison. To measure the performance of our segment search and dynamic updates, we count the total number of node visits during recursions of the update and the search. To capture the asymptotic behavior in the experiments, we perform many insertion calls, with either ascending segment priority values (static TST) or a random shuffle of them (dynamic TST).

We created random sets of segments with varying numbers of intersections based on the 64-bit Mersenne Twister random number generator of the C++ Standard Library. The experiment without intersections is comprised of horizontal segments, for which we first chose a y-coordinate uniformly (from the domain range) and then two x-coordinates uniformly (see Figure 5a). The experiment with few intersections is comprised of short segments, for which we chose a point, a direction, and a length uniformly at random (on average 3% of the domain boundary length; see Figure 5b). The experiment on many intersections are generated by choosing the coordinates of both endpoints uniformly at random (see Figure 5c).

Figure 5 shows the results on the segment search and recursive node visits of updates. For ease of comparison, we also plot a function fit[3] (thick blue lines) of the well known size and depth bounds (top rows) and our new segment search and update bounds (bottom rows) as overlay on the experimental data. Note that only on the non-intersecting data set a comparison of function fit and bounds is meaningful. We do however also provide it for the other experiments as a "trend line" that indicates the additional costs due to segment intersections. To allow a better visual perception of the average cost per insertion, Figures 5a and 5b show every 20th data point and Figure 5c shows every 2nd data point as impulse.

The experiment on non-intersecting segments matches with our analysis of segment search and update operations on TSTs. As anticipated, TST updates on segments with many intersections are more expensive.

Abstract

This paper is concerned with the $1||\sum p_j U_j$ problem, the problem of minimizing the total processing time of tardy jobs on a single machine. This is not only a fundamental scheduling problem, but also a very important problem from a theoretical point of view as it generalizes the Subset Sum problem and is closely related to the 0/1-Knapsack problem. The problem is well-known to be NP-hard, but only in a weak sense, meaning it admits pseudo-polynomial time algorithms. The fastest known pseudo-polynomial time algorithm for the problem is the famous Lawler and Moore algorithm which runs in $O(P \cdot n)$ time, where P is the total processing time of all n jobs in the input. This algorithm has been developed in the late 60s, and has yet to be improved to date.

In this paper we develop two new algorithms for $1||\sum p_j U_j$, each improving on Lawler and Moore's algorithm in a different scenario:

- Our first algorithm runs in $\tilde{O}(P^{7/4})$ time[1], and outperforms Lawler and Moore's algorithm in instances where $n = \tilde{\omega}(P^{3/4})$.
- Our second algorithm runs in $\tilde{O}(\min\{P \cdot D_\#, P + D\})$ time, where $D_\#$ is the number of *different* due dates in the instance, and D is the sum of all different due dates. This algorithm improves on Lawler and Moore's algorithm when $n = \tilde{\omega}(D_\#)$ or $n = \tilde{\omega}(D/P)$. Further, it extends the known $\tilde{O}(P)$ algorithm for the single due date special case of $1||\sum p_j U_j$ in a natural way.

Both algorithms rely on basic primitive operations between sets of integers and vectors of integers for the speedup in their running times. The second algorithm relies on fast polynomial multiplication as its main engine, while for the first algorithm we define a new "skewed" version of $(\max, \min)$-convolution which is interesting in its own right.

1 Introduction

In this paper we consider the problem of minimizing the total processing times of tardy jobs on a single machine. In this problem we are given a set of n jobs $J = \{1, \ldots, n\}$, where each job j has a *processing time* $p_j \in \mathbb{N}$ and a *due date* $d_j \in \mathbb{N}$. A *schedule* σ for J is a permutation $\sigma : \{1, \ldots, n\} \to \{1, \ldots, n\}$. In a given schedule σ, the *completion time* C_j of a job j under σ is given by $C_j = \sum_{\sigma(i) \leq \sigma(j)} p_i$, that is, the total processing time of jobs preceding j in σ (including j itself). Job j is *tardy* in σ if $C_j > d_j$, and *early* otherwise. Our goal is find a schedule with minimum total processing time of tardy jobs. If we assign a binary indicator variable U_j to each job j, where $U_j = 1$ if j is tardy and otherwise $U_j = 0$, our objective function can be written as $\sum p_j U_j$. In the standard three field notation for scheduling problems of Graham [5], this problem is denoted as the $1||\sum p_j U_j$ problem (the 1 in the first field indicates a single machine model, and the empty second field indicates there are no additional constraints).

The $1||\sum p_j U_j$ problem is a very natural and fundamental scheduling problem, which models a very basic scheduling scenario. As it includes Subset Sum as a special case (see below), the $1||\sum p_j U_j$ problem is NP-hard. However, it is only hard in the weak sense, meaning it admits pseudo-polynomial time algorithms. The focus of this paper is on developing fast pseudo-polynomial time algorithms for $1||\sum p_j U_j$, improving in several settings on the best previously known solution from the late 60s. Before we describe our results, we discuss the previously known state of the art of the problem, and describe how our results fit into this line of research.

1.1 State of the Art

A famous generalization of the $1||\sum p_j U_j$ problem is the $1||\sum w_j U_j$ problem. Here, each job j also has a weight w_j in addition to its processing time p_j and due date d_j, and the goal is to minimize the total weight (as opposed to total processing times) of tardy jobs. This problem has already been studied in the 60s, and even appeared in Karp's fundamental paper from 1972 [6]. The classical algorithm of Lawler and Moore [10] for the problem is one of the earliest and most prominent examples of pseudo-polynomial algorithms, and it is to date the fastest known algorithm even for the special case of $1||\sum p_j U_j$. Letting $P = \sum_{j \in J} p_j$, their result can be stated as follows:

▶ **Theorem 1.1** ([10]). *$1||\sum w_j U_j$ and $1||\sum p_j U_j$ can both be solved in $O(P \cdot n)$ time.*

Note that as we assume that all processing times are integers, we have $n \leq P$, and so the running time of the algorithm in Theorem 1.1 can be bounded by $O(P^2)$. In fact, it makes perfect sense to analyze the time complexity of a pseudo-polynomial time algorithm for either problems in terms of P, as P directly corresponds to the total input length when integers are encoded in unary. Observe that while the case of $n = P$ (all jobs have unit processing times) essentially reduces to sorting, there are several non-trivial cases where n is smaller than P yet still quite significant in the $O(P \cdot n)$ term of Theorem 1.1. The fundamental question this paper addresses is:

> *"Can we obtain algorithms with running times $O(P^{2-\varepsilon})$, for any fixed $\varepsilon > 0$, for either $1||\sum w_j U_j$ or $1||\sum p_j U_j$?"*

For $1||\sum w_j U_j$ there is some evidence that the answer to this question should be no. Karp [6] observed that the special case of the $1||\sum w_j U_j$ problem where all jobs have the same due date d, the $1|d_j = d|\sum w_j U_j$ problem, is essentially equivalent to the classical 0/1-Knapsack problem. Cygan *et al.* [4] and Künnemann *et al.* [9] studied the $(\min, +)$-Convolution problem (see Section 2), and conjectured that the $(\min, +)$-convolution between two vectors of length n cannot be computed in $\tilde{O}(n^{2-\varepsilon})$ time, for any $\varepsilon > 0$. Under this $(\min, +)$-Convolution Conjecture, they obtained lower bounds for several Knapsack related problems. In our terms, their result can be stated as follows:

▶ **Theorem 1.2** ([4, 9])**.** *There is no $\tilde{O}(P^{2-\varepsilon})$ time algorithm for the $1|d_j = d|\sum w_j U_j$ problem, for any $\varepsilon > 0$, unless the $(\min, +)$-Convolution Conjecture is false. In particular, $1||\sum w_j U_j$ has no such algorithm under this conjecture.*

Analogous to the situation with $1||\sum w_j U_j$, the special case of $1||\sum p_j U_j$ where all jobs have the same due date d (the $1|d_j = d|\sum p_j U_j$ problem) is equivalent to the classical Subset Sum problem. Recently, there has been significant improvements for Subset Sum resulting in algorithms with $\tilde{O}(T + n)$ running times [2, 7], where n is number of integers in the instance and T is the target. Due to the equivalence between the two problems, this yields the following result for the $1|d_j = d|\sum p_j U_j$ problem:

▶ **Theorem 1.3** ([2, 7])**.** *$1|d_j = d|\sum p_j U_j$ can be solved in $\tilde{O}(P)$ time.*

On the other hand, due to equivalence of $1|d_j = d|\sum p_j U_j$ and Subset Sum, we also know that Theorem 1.3 above cannot be significantly improved unless the Strong Exponential Time Hypothesis (SETH) fails. Specifically, combining a recent reduction from k-SAT to Subset Sum [1] with the equivalence of Subset Sum and $1|d_j = d|\sum p_j U_j$, yields the following:

▶ **Theorem 1.4** ([1])**.** *There is no $\tilde{O}(P^{1-\varepsilon})$ time algorithm for the $1|d_j = d|\sum p_j U_j$ problem, for any $\varepsilon > 0$, unless SETH fails.*

Nevertheless, Theorem 1.4 still leaves quite a big gap for the true time complexity of $1||\sum p_j U_j$, as it can potentially be anywhere between the $\tilde{O}(P)$ time known already for the special case of $1|d_j = d|\sum p_j U_j$ (Theorem 1.3), and the $O(Pn) = O(P^2)$ time of Lawler and Moore's algorithm (Theorem 1.1). This is the starting point of our paper.

1.2 Our Results

The main contribution of this paper is two new pseudo-polynomial time algorithms for $1||\sum p_j U_j$, each improving on Lawler and Moore's algorithm in a different sense. Our algorithms take a different approach to that of Lawler and Moore in that they rely on fast operators between sets and vectors of numbers.

Our first algorithm improves Theorem 1.1 in case there are sufficiently many jobs in the instance compared to the total processing time. More precisely, our algorithm has a running time of $\tilde{O}(P^{7/4})$, and so it is faster than Lawler and Moore's algorithm in case $n = \tilde{\omega}(P^{3/4})$.

▶ **Theorem 1.5.** *$1||\sum p_j U_j$ can be solved in $\tilde{O}(P^{7/4})$ time.*

The algorithm in Theorem 1.5 uses a new kind of convolution which we coined "Skewed Convolution" and is interesting in its own right. In fact, one of the main technical contributions of this paper is a fast algorithm for the $(\max, \min)$-Skewed-Convolution problem (see definition in Section 2).

Our second algorithm for $1||\sum p_j U_j$ improves Theorem 1.1 in case there are not too many different due dates in the problem instance; that is, $D_\# = |\{d_j : j \in J\}|$ is relatively small when compared to n. This is actually a very natural assumption, for instance in cases where delivery costs are high and products are batched to only few shipments. Let D denote the sum of the different due dates in our instance. Then our second result can be stated as follows:

▶ **Theorem 1.6.** *$1||\sum p_j U_j$ can all be solved in $\tilde{O}(\min\{P \cdot D_\#, P + D\})$ time.*

The algorithm in Theorem 1.6 uses basic operations between sets of numbers, such as the sumset operation (see Section 2) as basic primitives for its computation, and ultimately relies on fast polynomial multiplication for its speedup. It should be noted that Theorem 1.6 includes the $\tilde{O}(P)$ result of Theorem 1.3 for $1|d_j = d|\sum p_j U_j$ as a special case where $D_\# = 1$ or $D = d$.

1.3 Roadmap

The paper is organized as follows. In Section 2 we discuss all the basic primitives that are used by our algorithms, including some basic properties that are essential for the algorithms. We then present our second algorithm in Section 3, followed by our first algorithm in Section 4. Section 5 describes our fast algorithm for the skewed version of $(\max, \min)$-convolution, and is the main technical part of the paper. Finally, we conclude with some remarks and open problems in Section 6.

2 Preliminaries

In the following we discuss the basic primitives and binary operators between sets/vectors of integers that will be used in our algorithms. In general, we will use the letters X and Y to denote sets of non-negative integers (where order is irrelevant), and the letters A and B to denote vectors of non-negative integers.

Sumsets

The most basic operation used in our algorithms is computing the sumset of two sets of non-negative integers:

▶ **Definition 2.1** (Sumsets). *Given two sets of non-negative integers X_1 and X_2, the* sumset *of X_1 and X_2, denoted $X_1 \oplus X_2$, is defined by*

$$X_1 \oplus X_2 = \{x_1 + x_2 : x_1 \in X_1, x_2 \in X_2\}.$$

Clearly, the sumset $X_1 \oplus X_2$ can be computed in $O(|X_1| \cdot |X_2|)$ time. However, in certain cases we can do better using fast polynomial multiplication. Consider the two polynomials $p_1[\alpha] = \sum_{x \in X_1} \alpha^x$ and $p_2[\beta] = \sum_{x \in X_2} \beta^x$. Then the exponents of all terms in $p_1 \cdot p_2$ with non-zero coefficients correspond to elements in the sumset $X_1 \oplus X_2$. Since multiplying two polynomials of maximum degree d can be done in $O(d \log d)$ time [3], we have the following:

▶ **Lemma 2.2.** *Given two sets of non-negative integers $X_1, X_2 \subseteq \{0, \ldots, P\}$, one can compute the sumset $X_1 \oplus X_2$ in $O(P \log P)$ time.*

Set of all Subset Sums

Given set of non-negative integers X, we will frequently be using the set of all sums generated by subsets of X:

▶ **Definition 2.3** (Subset Sums). *For a given set of non-negative integers X, define the set of all subset sums $\mathcal{S}(X)$ as the set of integers given by*

$$\mathcal{S}(X) = \Big\{ \sum_{x \in Y} x : Y \subseteq X \Big\}.$$

Here, we always assume that $0 \in \mathcal{S}(X)$ (as it is the sum of the empty set).

We can use Lemma 2.2 above to compute $\mathcal{S}(X)$ from X rather efficiently: First, split X into two sets X_1 and X_2 of roughly equal size. Then recursively compute $\mathcal{S}(X_1)$ and $\mathcal{S}(X_2)$. Finally, compute $\mathcal{S}(X) = \mathcal{S}(X_1) \oplus \mathcal{S}(X_2)$ via Lemma 2.2. The entire algorithm runs in $\tilde{O}(\sum_{x \in X} x)$ time.

▶ **Lemma 2.4** ([7]). *Given a set of non-negative integers X, with $P = \sum_{x \in X} x$, one can compute $\mathcal{S}(X)$ in $\tilde{O}(P)$ time.*

Convolutions

Given two vectors $A = (A[i])_{i=0}^{n}$, $B = (B[j])_{j=0}^{n}$, the $(\circ, \bullet)$-Convolution problem for binary operators $\circ$ and $\bullet$ is to compute a vector $C = (C[k])_{k=0}^{2n}$ with

$$C[k] = \bigcirc_{i+j=k} A[i] \bullet B[j].$$

A prominent example of a convolution problem is $(\min, +)$-Convolution discussed above; another similarly prominent example is $(\max, \min)$-Convolution which can be solved in $\tilde{O}(n^{3/2})$ time [8]. For our purposes, it is convenient to look at a *skewed* variant of this problem:

▶ **Definition 2.5** (Skewed Convolution). *Given two vectors $A = (A[i])_{i=0}^{n}$, $B = (B[j])_{j=0}^{n}$, we define the $(\max, \min)$-Skewed-Convolution problem to be the problem of computing the vector $C = (C[k])_{k=0}^{2n}$ where the kth entry in C equals*

$$C[k] = \max_{i+j=k} \min\{A[i], B[j] + k\}$$

for each $k \in \{0, \ldots, 2n\}$.

The main technical result of this paper is an algorithm for $(\max, \min)$-Skewed-Convolution that is significantly faster than the naive $O(n^2)$ time algorithm.

▶ **Theorem 2.6.** *The $(\max, \min)$-Skewed-Convolution problem for vectors of length n can be solved in $\tilde{O}(n^{7/4})$ time.*

3 Algorithm via Sumsets and Subset Sums

In the following section, we provide a proof of Theorem 1.6 by presenting an algorithm for $1||\sum p_j U_j$ running in $\tilde{O}(\min\{P \cdot D_\#, P + D\})$ time. Recall that $J = \{1, \ldots, n\}$ denotes our input set of jobs, and p_j and d_j respectively denote the processing time and due date of job $j \in \{1, \ldots, n\}$. Our goal is to determine the minimum total processing time of tardy jobs in any schedule for J. Throughout the section we let $d^{(1)} < \cdots < d^{(D_\#)}$ denote the $D_\# \leq n$ *different* due dates of the jobs in J.

A key observation for the $1||\sum p_jU_j$ problem, used already by Lawler and Moore, is that any instance of the problem always has an optimal schedule of a specific type, namely an Earliest Due Date schedule. An Earliest Due Date (EDD) schedule is a schedule $\pi : J \to \{1, \ldots, n\}$ such that

- any early job precedes all late jobs in π, and
- any early job precedes all early jobs with later due dates.

In other words, in an EDD schedule all early jobs are scheduled before all tardy jobs, and all early jobs are scheduled in non-decreasing order of due dates.

▶ **Lemma 3.1** ([10]). *Any $1||\sum p_jU_j$ instance has an optimal schedule which is EDD.*

The $D_\#$-many due dates in our instance partition the input set of job J in a natural manner: Define $J_i = \{j : d_j = d^{(i)}\}$ for each $i \in \{1, \ldots, D_\#\}$. Furthermore, let $X_i = \{p_j : j \in J_i\}$ the processing-times of job in J_i. According to Lemma 3.1 above, we can restrict our attention to EDD schedules. Constructing such a schedule corresponds to choosing a subset $E_i \subseteq J_i$ for each due date $d^{(i)}$ such that $\sum_{j \in E_\ell, \ell \leq i} p_j \leq d^{(i)}$ holds for each $i \in \{1, \ldots, D_\#\}$. Moreover, the optimal EDD schedule maximizes the total sum of processing times in all selected E_i's.

Our algorithm is given in Algorithm 1. It successively computes sets $S_1, \ldots, S_{D_\#}$, where set S_i corresponds to the set of jobs $J_1 \cup \cdots \cup J_i$. In particular, S_i includes the total processing-time of any possible set-family of early jobs $\{E_1, \ldots, E_i\}$. Thus, each $x \in S_i$ corresponds to the total processing time of early jobs in a subset of $J_1 \cup \cdots \cup J_i$. The maximum value $x \in S_{D_\#}$ therefore corresponds to the maximum total processing time of early jobs in any schedule for J. Thus, the algorithm terminates by returning the optimal total weight of tardy jobs $P - x$.

Algorithm 1 SumsetScheduler(J).

```
Let $d^{(1)} < \ldots < d^{(D_\#)}$ denote the different due dates of jobs in $J$.
Compute $X_i = \{p_j : d_j = d^{(i)}\}$ for each $i \in \{1, \ldots, D_\#\}$.
Compute $\mathcal{S}(X_1), \ldots, \mathcal{S}(X_{D_\#})$.
Let $S_0 = \emptyset$.
for $i = 1, \ldots, D_\#$ do
    – Compute $S_i = S_{i-1} \oplus \mathcal{S}(X_i)$.
    – Remove any $x \in S_i$ with $x > d^{(i)}$.
Return $P - x$, where $x$ is the maximum value in $S_{D_\#}$.
```

Correctness of our algorithm follows immediately from the definitions of sumsets and subset sums, and from the fact that we prune out elements $x \in S_i$ with $x > d^{(i)}$ at each step of the algorithm. This is stated more formally in the lemma below.

▶ **Lemma 3.2.** *Let $i \in \{1, \ldots, D_\#\}$, and let S_i be the set of integers at the end of the second step of $5(i)$. Then $x \in S_i$ if and only if there are sets of jobs $E_1 \subseteq J_1, \ldots, E_i \subseteq J_i$ such that*

- $\sum_{j \in \bigcup_{\ell=1}^{i} E_\ell} p_j = x$, *and*
- $\sum_{j \in E_\ell, \ell \leq i_0} p_j \leq d^{(i_0)}$ *holds for each $i_0 \in \{1, \ldots, i\}$.*

Proof. The proof is by induction on i. For $i = 1$, note that $S_1 = \mathcal{S}(X_1) \setminus \{x : x > d^{(1)}\}$ at the end of step $5(1)$. Since $\mathcal{S}(X_1)$ includes the total processing time of any subset of jobs in J_1, the first condition of the lemma holds. Since $\{x : x > d^{(1)}\}$ includes all integers violating the second condition of the lemma, the second condition holds.

Let $i > 1$, and assume the lemma holds for $i - 1$. Consider some $x \in S_i$ at the end of the second step of $5(i)$. Then by Definition 2.1, we have $x = x_1 + x_2$ for some $x_1 \in S_{i-1}$ and $x_2 \in \mathcal{S}(X_i)$ due the first step of $5(i)$. By definition of $\mathcal{S}(X_i)$, there is some $E_i \subseteq J_i$ with total processing time x_2. By our inductive hypothesis there is $E_1 \subseteq J_1, \ldots, E_{i-1} \subseteq J_{i-1}$ such that $\sum_{j \in \bigcup_{\ell=1}^{i} E_\ell} p_j = x_1$, and $\sum_{j \in E_\ell, \ell \le i_0} p_j \le d^{(i_0)}$ holds for each $i_0 \in \{1, \ldots, i-1\}$. Furthermore, by the second step of $5(i)$, we know that $\sum_{j \in E_\ell, \ell \le i} p_j = x \le d^{(i)}$. Thus, $E_1, \ldots, E_i$ satisfy both conditions of the lemma. ◀

Let us next analyze the time complexity of the SumsetScheduler algorithm. Steps 1 and 2 can be both performed in $\tilde{O}(n) = \tilde{O}(P)$ time. Next observe that step 3 can be done in total $\tilde{O}(P)$ time using Lemma 2.4, as $X_2, \ldots, X_{D_\#}$ is a partition of the set of all processing times of J, and these all sum up to P. Next, according to Lemma 2.2, each sumset operation at step 5 can be done in time proportional to the largest element in the two sets, which is always at most P. Thus, since we perform at most $D_\#$ sumset operations, the merging step requires $\tilde{O}(D_\# \cdot P)$ time, which gives us the total running time of the algorithm above.

Another way to analyze the running time of SumsetScheduler is to observe that the maximum element participating in the ith sumset is bounded by $d^{(i+1)}$. It follows that we can write the running time of the merging step as $\tilde{O}(D)$, where $D = \sum_{i=1}^{D_\#} d^{(i)}$. Thus, we have just shown that $1||\sum p_j U_j$ can be solved in $\tilde{O}(\min\{D_\# \cdot P, D + P\})$ time, completing the proof of Theorem 1.6.

4 Algorithm via Fast Skewed Convolutions

We next present our $\tilde{O}(P^{7/4})$ time algorithm for $1||\sum p_j U_j$, providing a proof of Theorem 1.5. As in the previous section, we let $d^{(1)} < \cdots < d^{(D_\#)}$ denote the $D_\# \le n$ different due dates of the input jobs J, and $J_i = \{j : d_j = d^{(i)}\}$ and $X_i = \{p_j : j \in J_i\}$ as in Section 3 for each $i \in \{1, \ldots, D_\#\}$.

For a consecutive subset of indices $I = \{i_0, i_0 + 1, \ldots, i_1\}$, with $i_0, \ldots, i_1 \in \{1, \ldots, D_\#\}$, we define a vector $M(I)$, where $M(I)[x]$ equals the latest (that is, maximum) time point x_0 for which there is a subset of the jobs in $\bigcup_{i \in I} J_i$ with total processing time equal to x that can all be scheduled early in an EDD schedule starting at x_0. If no such subset of jobs exists, we define $M(I)[x] = +\infty$.

For a singleton set $I = \{i\}$, the vector $M(I)$ is easy to compute once we have computed the set $\mathcal{S}(X_i)$:

$$M(\{i\})[x] = \begin{cases} d^{(i)} - x & \text{if } x \in \mathcal{S}(X_i) \text{ and } x \le d^{(i)}, \\ +\infty & \text{otherwise.} \end{cases} \tag{1}$$

For larger sets of indices, we have the following lemma.

▶ **Lemma 4.1.** *Let $I_1 = \{i_0, i_0 + 1, \ldots, i_1\}$ and $I_2 = \{i_1 + 1, i_1 + 2, \ldots, i_2\}$ be any two sets of consecutive indices with $i_0, \ldots, i_1, \ldots, i_2 \in \{1, \ldots, D_\#\}$. Then for any value x we have:*

$$M(I_1 \cup I_2)[x] = \max_{x_1 + x_2 = x} \min\{M(I_1)[x_1], M(I_2)[x_2] - x_1\}.$$

Proof. Let $I = I_1 \cup I_2$. Then $M(I)[x]$ is the latest time point after which a subset of jobs $J^* \subseteq \bigcup_{i \in I} J_i$ of total processing time x can be scheduled early in an EDD schedule. Let x_1 and x_2 be the total processing times of jobs in $J_1^* = J^* \cap \left(\bigcup_{i \in I_1} J_i\right)$ and $J_2^* = J^* \cap \left(\bigcup_{i \in I_2} J_i\right)$, respectively. Then $x = x_1 + x_2$. Clearly, $M(I)[x] \le M(I_1)[x_1]$, since we have to start scheduling the jobs in J_1^* at time $M(I_1)[x_1]$ by latest. Similarly, it holds that

$M(I)[x] \leq M(I_2)[x_2] - x_1$ since the jobs in J_2^* are scheduled at latest at $M(I_2)[x_2]$ and the jobs in J_1^* have to be processed before that time point in an EDD schedule. In combination, we have shown that LHS $\leq$ RHS in the equation of the lemma.

To prove that LHS $\geq$ RHS, we construct a feasible schedule for jobs in $\bigcup_{i \in I} J_i$ starting at RHS. Let x_1 and x_2 be the two values with $x_1 + x_2 = x$ that maximize RHS. Then there is a schedule which schedules some jobs $J_1^* \subseteq \bigcup_{i \in I_1} J_i$ of total processing time x_1 beginning at time $\min\{M(I_1)[x_1], M(I_2)[x_2] - x_1\} \leq M(I_1)[x_1]$, followed by a another subset of jobs $J_2^* \subseteq \bigcup_{i \in I_2} J_i$ of total processing time x_2 starting at time $\min\{M(I_1)[x_1], M(I_2)[x_2] - x_1\} + x_1 \leq M(I_2)[x_2]$. This is a feasible schedule starting at time RHS for a subset of jobs in $\bigcup_{i \in I} J_i$ which has total processing time x. ◀

Note that the equation given in Lemma 4.1 is close but not precisely the equation defined in Definition 2.5 for the $(\min, \max)$-Skewed-Convolution problem. Nevertheless, the next lemma shows that we can easily translate between these two concepts.

▶ **Lemma 4.2.** *Let A and B be two integer vectors of P entries each. Given an algorithm for computing the* $(\max, \min)$*-Skewed-Convolution of A and B in $T(P)$ time, we can compute in $T(P) + O(P)$ time the vector $C = A \otimes B$ defined by*

$$C[x] = \max_{x_1 + x_2 = x} \min\{A[x_1], B[x_2] - x_1\}.$$

Proof. Given A and B, construct two auxiliary vectors A_0 and B_0 defined by $A_0[x] = B[x] + x$ and $B_0[x] = A[x]$ for each entry x. Compute the $(\max, \min)$-Skewed-Convolution of A_0 and B_0, and let C_0 denote the resulting vector. We claim that the vector C defined by $C[x] = C_0[x] - x$ equals $A \otimes B$. Indeed, we have

$$\begin{aligned} C_0[x] - x &= \max_{x_1 + x_2 = x} \min\{A_0[x_1], B_0[x_2] + x\} - x \\ &= \max_{x_1 + x_2 = x} \min\{A_0[x_1] - x, B_0[x_2]\} \\ &= \max_{x_1 + x_2 = x} \min\{B[x_1] + x_1 - x, A[x_2]\} \\ &= \max_{x_1 + x_2 = x} \min\{B[x_1] - x_2, A[x_2]\} \\ &= \max_{x_1 + x_2 = x} \min\{A[x_1], B[x_2] - x_1\}, \end{aligned}$$

where in the third step we expanded the definition of A_0 and B_0 and in the last step we used the symmetry of x_1 and x_2. ◀

We are now in position to describe our algorithm called ConvScheduler which is depicted in Algorithm 2. The algorithm first computes the subset sums $\mathcal{S}(X_1), \ldots, \mathcal{S}(X_{D_\#})$, and the set of vectors $\mathcal{M} = \{M_1, \ldots, M_{D_\#}\}$. Following this, it iteratively combines every two consecutive vectors in $\mathcal{M}$ by using the $\otimes$ operation. The algorithm terminates when $\mathcal{M} = \{M_1\}$, where at this stage M_1 corresponds to the entire set of input jobs J. It then returns $P - x$, where x is the maximum value with $M_1[x] < \infty$; by definition, this corresponds to a schedule for J with $P - x$ total processing time of tardy jobs. For convenience of presentation, we assume that $D_\#$ is a power of 2.

Correctness of this algorithm follows directly from Lemma 4.1. To analyze its time complexity, observe that steps 1–4 can be done in $\tilde{O}(P)$ time (using Lemma 2.4). Step 5 is performed $O(\log D_\#) = O(\log P)$ times, and each step requires a total of $\tilde{O}(P^{7/4})$ time according to Theorem 2.6, as the total sizes of all vectors at each step is $O(P)$. Finally, step 6 requires $O(P)$ time. Summing up, this gives us a total running time of $\tilde{O}(P^{7/4})$, and completes the proof of Theorem 1.5 (apart from the proof of Theorem 2.6).

Algorithm 2 ConvScheduler(J).

```
Let $d^{(1)} < \ldots < d^{(D_\#)}$ denote the different due dates of jobs in $J$.
Compute $X_i = \{p_j : d_j = d^{(i)}\}$ for each $i \in \{1, \ldots, D_\#\}$.
Compute $\mathcal{S}(X_1), \ldots, \mathcal{S}(X_{D_\#})$.
Compute $\mathcal{M} = \{M_1 = M(1), \ldots, M_{D_\#} = M(D_\#)\}$.
while $|\mathcal{M}| > 1$ do
    – Compute $M_i = M_{2i-1} \otimes M_{2i}$ for each $i \in \{1, \ldots, |\mathcal{M}|/2\}$.
Return $P - x$, where $x$ is the maximum value with $M_1[x] < \infty$.
```

5 Fast Skewed Convolutions

In the following section we present our algorithm for $(\max, \min)$-Skewed-Convolution, and provide a proof for Theorem 2.6. Let $A = (A[i])_{i=0}^n$ and $B = (B[j])_{j=0}^n$ denote the input vectors for the problem throughout the section.

We begin by first defining the problem slightly more generally, in order to facilitate our recursive strategy later on. For this, for each integer $\ell \in \{0, \ldots, \log n\}$, let $A^\ell = \lfloor A/2^\ell \rfloor$ and $B^\ell = \lfloor B/2^\ell \rfloor$, where rounding is done component-wise. We will compute vectors $C^\ell = (C^\ell[k])_{k=0}^{2n}$ defined by:

$$C^\ell[k] = \max_{i+j=k} \min\{A^\ell[i], B^\ell[j] + \lfloor k/2^\ell \rfloor\}.$$

Observe that a solution for $\ell = 0$ yields a solution to the original $(\max, \min)$-Skewed-Convolution problem, and for $\ell \geq \log 2n$ the problem degenerates to $(\max, \min)$-Convolution.

We next define a particular kind of additive approximation of vectors C^ℓ. We say that a vector D^ℓ is a *good approximation* of C^ℓ if $C^\ell[k] - 2 \leq D^\ell[k] \leq C^\ell[k]$ for each $k \in \{0, \ldots, 2n\}$. Now, the main technical part of our algorithm is encapsulated in the following lemma.

▶ **Lemma 5.1.** *There is an algorithm that computes C^ℓ in $\tilde{O}(n^{7/4})$ time, given A^ℓ, B^ℓ, and a good approximation D^ℓ of C^ℓ.*

We postpone the proof of Lemma 5.1 for now, and instead show that it directly yields our desired algorithm for $(\max, \min)$-Skewed-Convolution:

Proof of Theorem 2.6. In order to compute $C = C^0$, we perform an (inverse) induction on ℓ: As mentioned before, if $\ell \geq \log 2n$, then we can neglect the "$+ \lfloor k/2^\ell \rfloor$" term and compute C^ℓ in $\tilde{O}(n^{3/2}) = \tilde{O}(n^{7/4})$ time using a single $(\max, \min)$-Convolution computation [8].

For the inductive step, let $\ell < \log 2n$ and assume that we have already computed $C^{\ell+1}$. We construct the vector $D^\ell = 2C^{\ell+1}$, and argue that it is a good approximation of C^ℓ. Indeed, for each entry k, on the one hand, we have:

$$\begin{aligned} D^\ell[k] &= 2C^{\ell+1}[k] = 2 \cdot \max_{i+j=k} \min\{\lfloor A^\ell[i]/2 \rfloor, \lfloor B^\ell[j]/2 \rfloor + \lfloor k/2^{\ell+1} \rfloor\} \\ &\leq \max_{i+j=k} \min\{A^\ell[i], B^\ell[j] + \lfloor k/2^\ell \rfloor\} = C^\ell[k]; \end{aligned}$$

and on the other hand, we have:

$$\begin{aligned} D^\ell[k] &= 2C^{\ell+1}[k] = 2 \cdot \max_{i+j=k} \min\{\lfloor A^\ell[i]/2 \rfloor, \lfloor B^\ell[j]/2 \rfloor + \lfloor k/2^{\ell+1} \rfloor\} \\ &\geq \max_{i+j=k} \min\{A^\ell[i] - 1, B^\ell[j] + \lfloor k/2^\ell \rfloor - 2\} \geq C^\ell[k] - 2. \end{aligned}$$

Thus, using D^ℓ we can apply Lemma 5.1 above to obtain C^ℓ in $\tilde{O}(n^{7/4})$ time. Since there are $O(\log n)$ inductive steps overall, this is also the overall time complexity of the algorithm. ◀

It remains to prove Lemma 5.1. Recall that we are given A^ℓ, B^ℓ, and D^ℓ, and our goal is to compute the vector C^ℓ in $\tilde{O}(n^{7/4})$ time. We construct two vectors L^ℓ and R^ℓ with $2n$ entries each, defined by

$$L^\ell[k] = \max\left\{A^\ell[i_0] : \begin{array}{c} A^\ell[i_0] \le B^\ell[k-i_0] + \lfloor k/2^\ell \rfloor \text{ and} \\ D^\ell[k] \le A^\ell[i_0] \le D^\ell[k]+2 \end{array}\right\},$$

and

$$R^\ell[k] = \max\left\{B^\ell[j_0] + \lfloor k/2^\ell \rfloor : \begin{array}{c} B^\ell[j_0] + \lfloor k/2^\ell \rfloor \le A^\ell[k-j_0] \text{ and} \\ D^\ell[k] \le B^\ell[j_0] + \lfloor k/2^\ell \rfloor \le D^\ell[k]+2 \end{array}\right\}$$

for $k \in \{0, \dots, 2n\}$. That is, $L^\ell[k]$ and $R^\ell[k]$ respectively capture the largest value attained as the left-hand side or right-hand side of the inner min-operation in $C^\ell[k]$, as long as that value lies in the feasible region approximated by $D^\ell[k]$. Since D^ℓ is a good approximation, the following lemma is immediate from the definitions:

▶ **Lemma 5.2.** *$C^\ell[k] = \max\{L^\ell[k], R^\ell[k]\}$ for each $k \in \{0, \dots, 2n\}$.*

According to Lemma 5.2, it suffices to compute L^ℓ and R^ℓ. We focus on computing L^ℓ as the algorithm for computing R^ℓ follows after applying minor modifications.

Let $0 < \delta < 1$ be a fixed constant to be determined later. We say that an index $k \in \{0, \dots, n\}$ is *light* if

$$|\{i : D^\ell[k] \le A^\ell[i] \le D^\ell[k]+2\}| \le n^\delta.$$

Informally, k is light if the number of candidate entries $A^\ell[i]$ which can equal $C^\ell[k]$ is relatively small (recall that $D^\ell[k] \le C^\ell[k] \le D^\ell[k]+2$, as D^ℓ is a good approximation of C^ℓ). If k is not light then we say that it is *heavy.*

Our algorithm for computing L^ℓ proceeds in three main steps: In the first step it handles all light indices, in the second step it sparsifies the input vector, and in the third step it handles all heavy indices:

- *Light indices:* We begin by iterating over all light indices $k \in \{0, \dots, 2n\}$. For each light index k, we iterate over all entries $A^\ell[i]$ satisfying $D^\ell[k] \le A^\ell[i] \le D^\ell[k]+2$, and set $L^\ell[k]$ to be the maximum $A^\ell[i]$ among those entries with $A^\ell[i] \le B^\ell[k-i] + \lfloor k/2^\ell \rfloor$. Note that after this step, we have

  $$L^\ell[k] = \max\{A^\ell[i_0] : A^\ell[i_0] \le B^\ell[k-i_0] + \lfloor k/2^\ell \rfloor \text{ and } D^\ell[k] \le A^\ell[i_0] \le D^\ell[k]+2\}$$

  for each light index k.

- *Sparsification step:* After dealing with the light indices, several entries of A^ℓ become redundant. Consider an entry $A^\ell[i]$ for which $|\{i_0 : A^\ell[i]-2 \le A^\ell[i_0] \le A^\ell[i]+2\}| \le n^\delta$. Then all indices k for which $L^\ell[k]$ might equal $A^\ell[i]$ must be light, and are therefore already dealt with in the previous step. Consequently, it is safe to replace $A^\ell[i]$ by $-\infty$ so that $A^\ell[i]$ no longer plays a role in the remaining computation.

- *Heavy indices:* After the sparsification step A^ℓ contains few distinct values. Thus, our approach is to fix any such value v and detect whether $L^\ell[k] \ge v$. To that end, we translate the problem into an instance of $(\max, \min)$-Convolution: Let $(A^\ell_v[i])_{i=0}^n$ be an be an indicator-like vector defined by $A^\ell_v[i] = +\infty$ if $A^\ell[i] = v$, and otherwise $A^\ell_v[i] = -\infty$. We next compute the vector L^ℓ_v defined by $L^\ell_v[k] = \lfloor k/2^\ell \rfloor + \max_{i+j=k} \min\{A^\ell_v[i], B^\ell[j]\}$ using a single computation of $(\max, \min)$-Convolution.

We choose

$$L^\ell[k] = \max\{v : L^\ell_v[k] \geq v \text{ and } D^\ell[k] \leq v \leq D^\ell[k] + 2\}$$

for any heavy index k and claim that $L^\ell[k]$ equals $\max\{A^\ell[i_0] : A^\ell[i_0] \leq B^\ell[k-i_0]+\lfloor k/2^\ell \rfloor\}$. On the one hand, if $L^\ell_v[k] \geq v$ then there are indices i and j with $i + j = k$ for which $A^\ell[i] = v$ and $B^\ell[j] + \lfloor k/2^\ell \rfloor \geq A^\ell[i] = v$. Thus, the computed value $L^\ell[k]$ is not greater than

$$L^\ell[k] \leq \max\{A^\ell[i_0] : A^\ell[i_0] \leq B^\ell[k - i_0] + \lfloor k/2^\ell \rfloor \text{ and } D^\ell[k] \leq A^\ell[i_0] \leq D^\ell[k] + 2\}.$$

On the other hand, for all values v for which $A^\ell[i] = v$ for some $i \in \{0, \dots, n\}$, we have if $v = A^\ell[i] \leq B^\ell[k - i] + \lfloor k/2^\ell \rfloor$ then $A^\ell_v[i] = -\infty$, which in turn implies that $A^\ell_v[i] \geq B^\ell[k - i] + \lfloor k/2^\ell \rfloor \geq A^\ell[i] = v$. Thus, our selection of $L^\ell[k]$ is also at least as large as

$$L^\ell[k] \geq \max\{A^\ell[i_0] : A^\ell[i_0] \leq B^\ell[k - i_0] + \lfloor k/2^\ell \rfloor \text{ and } D^\ell[k] \leq A^\ell[i_0] \leq D^\ell[k] + 2\},$$

and hence, these two values must be equal.

This completes the description of our algorithm. As we argued its correctness above, what remains is to analyze its time complexity. Note that we can determine in $O(\log n)$ time whether an index k is light or heavy, by first sorting the values in A^ℓ. For each light index k, determining $L^\ell[k]$ can be done in $O(n^\delta)$ time (on the sorted A^ℓ), giving us a total of $\tilde{O}(n^{1+\delta})$ time for the first step. For the second step, we can determine whether a given entry $A^\ell[i]$ can be replaced with $-\infty$ in $O(\log n)$ time, giving us a total of $\tilde{O}(n)$ time for this step.

Consider then the final step of the algorithm. Observe that after exhausting the sparsification step, A^ℓ contains at most $O(n^{1-\delta})$ many distinct values: For any surviving value v, there is another (perhaps different) value v' of difference at most 2 from v that occurs at least n^δ times in A^ℓ, and so there can only be at most $O(n^{1-\delta})$ such distinct values. Thus, the running time of this step is dominated by the running time of $O(n^{1-\delta})$ (max, min)-Convolution computations, each requiring $\tilde{O}(n^{3/2})$ time using the algorithm of [8], giving us a total of $\tilde{O}(n^{5/2-\delta})$ time for this step.

Thus, the running time of our algorithm is dominated by the $\tilde{O}(n^{1+\delta})$ running time of its first step, and the $\tilde{O}(n^{5/2-\delta})$ running time of its last step. Choosing $\delta = 3/4$ gives us $\tilde{O}(n^{7/4})$ time for both steps, which is the time promised by Lemma 5.1. Thus, Lemma 5.1 holds.

6 Discussion and Open Problems

In this paper we presented two algorithms for the $1||\sum p_j U_j$ problem; the first running in $\tilde{O}(P^{7/4})$ time, and the second running in $\tilde{O}(\min\{P \cdot D_\#, P + D\})$ time. Both algorithms provide the first improvements over the classical Lawler and Moore algorithm in 50 years, and use more sophisticated tools such as polynomial multiplication and fast convolutions. Moreover, both algorithms are very easy to implement given a standard ready made FFT implementation for fast polynomial multiplication. Nevertheless, there are still a few ways which our results can be improved or extended:

- *Multiple machines:* A natural extension of the $1||\sum p_j U_j$ problem is to the setting of multiple parallel machines, the $Pm||\sum p_j U_j$. Lawler and Moore's algorithm can be used to solve $Pm||\sum p_j U_j$ in $O(P^m \cdot n)$ time, where m is the number of machines. A priori, there is no reason to believe that this cannot be improved to $\tilde{O}(P^m)$, or even better. It is not hard to extend the algorithm in Theorem 1.6 to an algorithm with running time $\tilde{O}(P^m \cdot D_\#)$ for the m parallel machine setting, by using m-variate polynomials for implementing sumsets in Lemma 2.2. However, a similar extension for the algorithm in Theorem 1.5 is far less direct.

- *Even faster skewed convolutions:* We have no indication that our algorithm for $(\max, \min)$-Skewed-Convolution is the fastest possible. It would interesting to see whether one can improve its time complexity, say to $\tilde{O}(P^{3/2})$. Naturally, any such improvement would directly improve Theorem 1.5.

  Conversely, one could try to obtain some sort of lower bound for the problem, possibly in the same vein as Theorem 1.2. Improving the time complexity beyond $\tilde{O}(P^{3/2})$ seems difficult as this would directly imply an improvement to the $(\max, \min)$-Convolution problem. Indeed, let A, B be a given $(\max, \min)$-Convolution instance and construct vectors A_0, B_0 with $A_0[i] = N \cdot A[i]$ and $B_0[j] = N \cdot B[j]$ for $N = 2n + 1$. If C_0 is the $(\max, \min)$-Skewed-Convolution of A_0 and B_0 (that is, $C_0[k] = \max_{i+j=k} \min\{A_0[i], B_0[j] + k\}$), then the vector C with $C[k] = \lfloor C_0[k]/N \rfloor$ is the $(\max, \min)$-Convolution of A and B.

- *Other scheduling problems:* Finally, it will be interesting to see other scheduling problems where the techniques used in this paper can be applied. A good first place to start might be to look at other problems which directly generalize Subset Sum.

Abstract

In this paper we study a wide range of variants for computing the (discrete and continuous) Fréchet distance between uncertain curves. We define an uncertain curve as a sequence of *uncertainty regions*, where each region is a disk, a line segment, or a set of points. A *realisation* of a curve is a polyline connecting one point from each region. Given an uncertain curve and a second (certain or uncertain) curve, we seek to compute the lower and upper bound Fréchet distance, which are the minimum and maximum Fréchet distance for any realisations of the curves.

We prove that both problems are NP-hard for the continuous Fréchet distance, and the upper bound problem remains hard for the discrete Fréchet distance. In contrast, the lower bound discrete Fréchet distance can be computed in polynomial time using dynamic programming. Furthermore, we show that computing the expected discrete or continuous Fréchet distance is #P-hard when the uncertainty regions are modelled as point sets or line segments.

On the positive side, we argue that in any constant dimension there is a FPTAS for the lower bound problem when Δ/δ is polynomially bounded, where δ is the Fréchet distance and Δ bounds the diameter of the regions. We then argue there is a near-linear-time 3-approximation for the decision problem when the regions are convex and roughly δ-separated. Finally, we study the setting with Sakoe–Chiba bands, restricting the alignment of the two curves, and give polynomial-time algorithms for upper bound and expected (discrete) Fréchet distance for point-set-modelled uncertainty regions.

1 Introduction

In this paper we investigate the well-studied topic of curve similarity in the context of the burgeoning area of geometric computing under uncertainty. While classical algorithms in computational geometry typically assume the input point locations are known exactly, in recent years there has been a concentrated effort to adapt these algorithms to uncertain inputs, which can more faithfully model real-world inputs. The need to model such uncertain inputs is perhaps no more clear than for the location data of a moving object obtained from physical devices, which is inherently imprecise due to issues such as measurement error, sampling error, and network latency [42, 43]. Moreover, to ensure location privacy, one may purposely add uncertainty to the data by adding noise or reporting positions as geometric regions rather than points. (See the survey by Krumm [35] and the references therein.)

Here we consider both the continuous and discrete Fréchet distance for uncertain curves. Given the applications above, our uncertain input is given as a sequence of compact regions, from which a polygonal curve is *realised* by selecting one point from each region. Our goal is to find, for a given pair of uncertain curves, the upper bound, lower bound, and expected Fréchet distance, where the upper (resp. lower) bound Fréchet distance is the maximum (resp. minimum) distance over any realisation. For the expected Fréchet distance we assume a probability distribution is provided that describes how each vertex on a curve is chosen from the compact region. Previously, Ahn et al. [5] considered the lower bound problem for the discrete Fréchet distance, giving a polynomial-time algorithm for points in constant dimension. The authors also gave efficient approximation algorithms for the discrete upper bound Fréchet distance for uncertain inputs, where the approximation factor depends on the spread of the region diameters or how well-separated they are. Subsequently, Fan and Zhu showed that the discrete upper bound Fréchet distance is NP-hard for uncertain inputs modelled as thin rectangles [25]. To our knowledge, we are the first to consider either variant for the continuous Fréchet case, and the first to consider the expected Fréchet distance.

1.1 Previous Work

Geometric computing under uncertainty. The two most common models of geometric uncertainty are the locational model [36] and the existential model [46, 48]. In the existential model the location of an uncertain point is known, but the point may not be present; in the locational model we know that each uncertain point exists, but not its exact location.

In this paper we consider the locational model. Each uncertain point is a set of potential locations. We call an uncertain point *indecisive* if the set of potential locations is finite, or *imprecise* if the set is not finite but is a convex region. A *realisation* of a set of uncertain points is a selection of one point from each uncertain point. The goal is typically to compute the realisation of a set of uncertain points that minimises or maximises some quantity (e.g. area, distance, perimeter) of some underlying geometric structure (e.g. convex hull, MST) [1, 7, 14, 17, 21, 23, 28, 34, 37, 38, 39, 45, 47]. By assigning a probability distribution to uncertain points, one can also consider the expectation or distribution of various measures [2, 4, 32, 41].

Fréchet distance. Computing the Fréchet distance between two precise curves can be done in near-quadratic time [3, 6, 12], and assuming the Strong Exponential Time Hypothesis (SETH) it cannot be computed or even approximated well in strongly subquadratic time [9, 15]. However, for several restricted versions the Fréchet distance can be calculated more quickly, for example for c-packed curves [20], when the edges are long [29], or when the alignment of

Table 1 Hardness results for the decision problems in this paper. Ahn et al. [5] solve the lower bound problem for disks, but their algorithm extends to the indecisive curves as well as line segment imprecision.

curves is restricted [11, 40]. Many variants of the problem have been considered: Fréchet distance with shortcuts [16, 19], weak Fréchet distance [6], discrete Fréchet distance [3, 22], Fréchet gap distance [24], Fréchet distance under translations [10, 26], and more.

1.2 Our Contributions

In this paper we present an extensive study of the Fréchet distance for uncertain curves. We provide a wide range of hardness results and present several approximations and polynomial-time solutions to restricted versions. We are the first to consider the continuous Fréchet distance in the uncertain setting, as well as the first to consider the expected Fréchet distance.

On the negative side, we present a plethora of hardness results (Table 1; details follow in Section 2). The hardness of the lower bound case is curious: while the variants discrete Fréchet distance on imprecise inputs [5] and, as we prove, continuous Fréchet distance on indecisive inputs both permit a simple dynamic programming solution, the variant continuous Fréchet distance on imprecise input has just enough (literal) wiggle room to show NP-hardness by reduction from SubsetSum.

We complement the lower bound hardness result by two approximation algorithms (Section 3). The first is a FPTAS for general uncertain curves in constant dimension when the ratio between the diameter of the uncertain points and the lower bound Fréchet distance is polynomially bounded. The second is a 3-approximation for separated imprecise curves, but uses a simpler greedy approach that runs in near-linear time.

The NP-hardness of the upper bound by a reduction from CNF-SAT is less surprising, but requires a careful set-up and analysis of the geometry to then extend it to a reduction from #CNF-SAT to the expected (discrete or continuous) Fréchet distance. However, by adding the common constraint that the alignment between the curves needs to stay within a Sakoe–Chiba [44] band of constant width (see Section 4 for definition and results), we can solve these problems in polynomial time for indecisive curves. Sakoe–Chiba bands are frequently used for time-series data [8, 33, 44] and trajectories [11, 18], when the alignment should (or is expected to) not vary too much from a certain "natural" alignment.

1.3 Preliminaries

Curves. Denote $[n] \equiv \{1, 2, \dots, n\}$. Consider a *sequence* of d-dimensional points $\pi = \langle p_1, p_2, \dots, p_n \rangle$. A *polygonal curve* π is defined by these points by linearly interpolating between the successive points and can be seen as a continuous function: $\pi(i + \alpha) = (1 - \alpha)p_i + \alpha p_{i+1}$ for $i \in [n-1]$ and $\alpha \in [0, 1]$. The *length* of such a curve is the number of

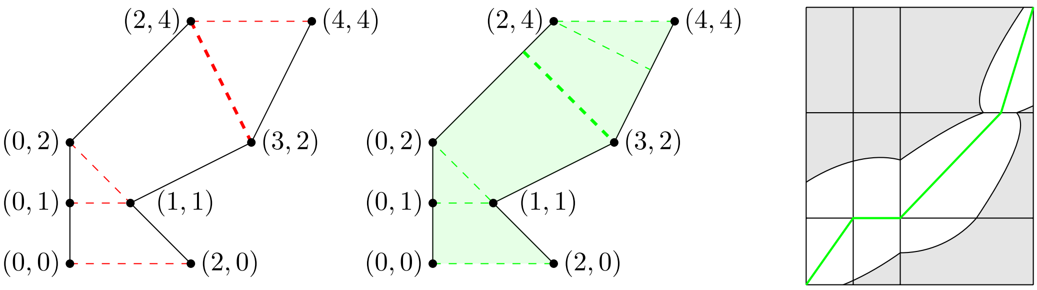

Figure 1 Left: Discrete Fréchet distance, where an optimal coupling is shown in dashed red lines. Middle: Fréchet distance, dashed green lines indicate specific values for δ for optimal functions ϕ_1, ϕ_2. Right: Free-space diagram for threshold $\delta = 2.15$. One can draw a monotonous path from the lower left corner to the upper right corner of the diagram, so the Fréchet distance between trajectories is below the threshold.

its vertices, $|\pi| = n$. Where we deem important to distinguish between points that are a part of the curve and other points, we denote the polygonal curve by $\pi = \langle \pi_1, \pi_2, \ldots, \pi_n \rangle$. We denote the *concatenation* of two polygonal curves π and σ of lengths n and m by $\pi \parallel \sigma$; the new curve follows π, then has a segment between $\pi(n)$ and $\sigma(1)$, and then follows σ. Similarly, $p \parallel q$ (or simply pq) denotes the line segment between points p and q. We can generalise this notation:

$$\Big\|_{i\in[n]} p_i \equiv p_1 \parallel p_2 \parallel \cdots \parallel p_n \equiv \pi \,.$$

We denote a *subcurve* from vertex i to j of curve π as $\pi[i : j] \equiv p_i \parallel p_{i+1} \parallel \cdots \parallel p_j$.

Metrics definitions. Given two points $x, y \in \mathbb{R}^d$, denote their Euclidean distance by $\|x - y\|$. For two compact sets $X, Y \subset \mathbb{R}^d$, denote their distance by $\|X - Y\| = \min_{x\in X, y\in Y} \|x - y\|$. Throughout we treat the dimension d as a small constant.

Let Φ_n denote the set of all *reparametrisations* of length n, defined as continuous non-decreasing functions $\phi : [0, 1] \to [1, n]$ where $\phi(0) = 1$ and $\phi(1) = n$. Given a pair of curves π and σ of lengths n and m, respectively, and corresponding reparametrisations $\phi_1 \in \Phi_n$ and $\phi_2 \in \Phi_m$, define $\text{width}_{\phi_1,\phi_2}(\pi, \sigma) = \max_{t\in[0,1]} \|\pi(\phi_1(t)) - \sigma(\phi_2(t))\|$.

The width represents the maximum distance between two points traversing the curves from start to end according to ϕ_1 and ϕ_2 (which allow varying speed, but no backtracking). The *Fréchet distance* $d_{\mathrm{F}}(\pi, \sigma)$ is defined as the minimum possible width over all such traversals:

$$d_{\mathrm{F}}(\pi, \sigma) = \inf_{\phi_1\in\Phi_n, \phi_2\in\Phi_m} \text{width}_{\phi_1,\phi_2}(\pi, \sigma) = \inf_{\phi_1\in\Phi_n, \phi_2\in\Phi_m} \max_{t\in[0,1]} \|\pi(\phi_1(t)) - \sigma(\phi_2(t))\| \,.$$

The *discrete Fréchet distance* $d_{\mathrm{dF}}(\pi, \sigma)$ is defined similarly, except that we do not traverse edges of the curves, but must jump from one vertex to the next on either or both curves. We define a valid *coupling* as a sequence $c = \langle (p_1, q_1), \ldots, (p_r, q_r) \rangle$ of pairs from $[n] \times [m]$ where $(p_1, q_1) = (1, 1)$, $(p_r, q_r) = (n, m)$, and, for any $i \in [r - 1]$ we have $(p_{i+1}, q_{i+1}) \in \{(p_i + 1, q_i), (p_i, q_i + 1), (p_i + 1, q_i + 1)\}$. Let $\mathcal{C}$ be the set of all valid couplings on curves of lengths n and m, then

$$d_{\mathrm{dF}}(\pi, \sigma) = \inf_{c\in\mathcal{C}} \max_{s\in[|c|]} \|\pi(p_s) - \sigma(q_s)\| \,,$$

where $c_s = (p_s, q_s)$ for all $s \in [|c|]$. Both distances, as well as a common approach to computing Fréchet distance, are illustrated in Figure 1.

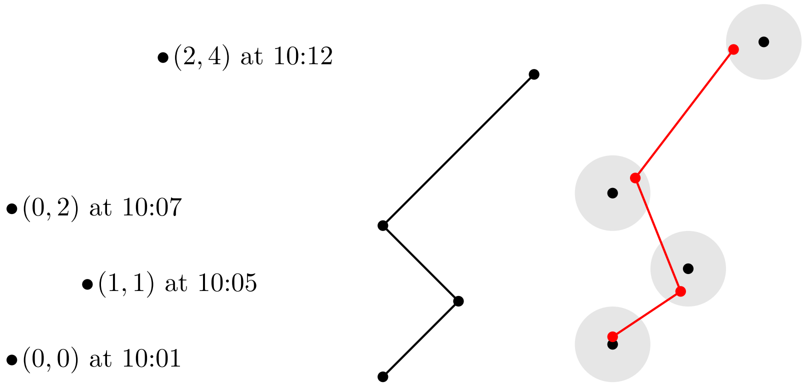

Figure 2 Left: Trajectory data. Middle: Polygonal curve on the data. Right: Imprecise curve with disks as imprecision regions and real curve.

Uncertainty model. An *uncertain* point is commonly represented as a compact region $U \subset \mathbb{R}^d$. Usually, it is a finite set of points, a disk, a rectangle, or a line segment. The intuition is that only one point from this region represents the true location of the point; however, we do not know which one. A *realisation* p of such a point is one of the points from the region U. When needed we assume the realisations are drawn from U according to a known probability distribution $\mathbb{P}$. We denote the diameter of any compact set (e.g. an uncertain point) $U \subset \mathbb{R}^d$ by $\operatorname{diam}(U) = \max_{p,q \in U} \|p - q\|$. An *indecisive* point is a special case of an uncertain point: it is a set of points $U = \{p_1, \dots, p_k\}$, where each point $p_i \in \mathbb{R}^d$ for $i \in [k]$. Similarly, an *imprecise* point is a compact convex region $U \subset \mathbb{R}^d$. We will often use disks or line segments as such regions. Note that a precise point is a special case of an indecisive point (set of size one) and an imprecise point (disk of radius zero).

Uncertain curves and distances. Define an *uncertain curve* as a sequence of uncertain points $\mathcal{U} = \langle U_1, \dots, U_n \rangle$. A *realisation* $\pi \Subset \mathcal{U}$ of an uncertain curve is a polygonal curve $\pi = \langle p_1, \dots, p_n \rangle$, where each p_i is a realisation of the corresponding uncertain point U_i. We denote the set of all realisations of an uncertain curve $\mathcal{U}$ by $\operatorname{Real}(\mathcal{U})$ (see Figure 2). In a probabilistic setting, we write $\pi \Subset_{\mathbb{P}} \mathcal{U}$ to denote that each point of π gets drawn from the corresponding uncertainty region independently according to distribution $\mathbb{P}$.

For uncertain curves $\mathcal{U}$ and $\mathcal{V}$, define the upper bound, lower bound, and expected discrete Fréchet distance (and extend to continuous Fréchet distance $d_{\mathrm{F}}^{\max}$, $d_{\mathrm{F}}^{\min}$, $d_{\mathrm{F}}^{\mathbb{E}(\mathbb{P})}$ using d_{F}) as:

$$d_{\mathrm{dF}}^{\max}(\mathcal{U}, \mathcal{V}) = \max_{\pi \Subset \mathcal{U}, \sigma \Subset \mathcal{V}} d_{\mathrm{dF}}(\pi, \sigma)\,, \qquad d_{\mathrm{dF}}^{\min}(\mathcal{U}, \mathcal{V}) = \min_{\pi \Subset \mathcal{U}, \sigma \Subset \mathcal{V}} d_{\mathrm{dF}}(\pi, \sigma)\,,$$

$$d_{\mathrm{dF}}^{\mathbb{E}(\mathbb{P})}(\mathcal{U}, \mathcal{V}) = \mathbb{E}_{\pi \Subset_{\mathbb{P}} \mathcal{U}, \sigma \Subset_{\mathbb{P}} \mathcal{V}}[d_{\mathrm{dF}}(\pi, \sigma)]\,.$$

If the distribution is clear from the context, we write $d_{\mathrm{F}}^{\mathbb{E}}$ and $d_{\mathrm{dF}}^{\mathbb{E}}$. The definitions above also apply if one of the curves is precise, as a precise curve is a special case of an uncertain curve.

2 Hardness Results

In this section, we first discuss the hardness results for the upper bound and expected value of the continuous and discrete Fréchet distance for indecisive and imprecise curves. We then show hardness of finding the lower bound continuous Fréchet distance on imprecise curves.

2.1 Upper Bound and Expected Fréchet Distance

We present proofs of NP-hardness and #P-hardness for the upper bound and expected Fréchet distance for both indecisive and imprecise curves by showing polynomial-time reductions from CNF-SAT and #CNF-SAT (counting version). We consider the upper bound problem for indecisive curves and then illustrate how the construction can be used to show #P-hardness for the expected Fréchet distance (both discrete and continuous). We then illustrate how the construction can be adapted to show hardness for imprecise curves. All our constructions are in two dimensions. The missing proofs can be found in the full version [13].

2.1.1 Upper Bound Fréchet Distance on Indecisive Curves

Define the following problem and its continuous counterpart, using $d_{\mathrm{F}}^{\max}$ instead:

▶ **Problem 1.** *Upper Bound Discrete Fréchet: Given two uncertain curves $\mathcal{U}$ and $\mathcal{V}$ and a threshold $\delta \in \mathbb{R}^+$, decide if $d_{\mathrm{dF}}^{\max}(\mathcal{U}, \mathcal{V}) > \delta$.*

Suppose we are given a CNF-SAT formula C with n clauses, C_1 to C_n, on m boolean variables, x_1 to x_m. We pick some value $0.12 \le \varepsilon < 0.25$.[1] Construct a *variable* curve, where each variable corresponds to an indecisive point with locations $(0, 0.5 + \varepsilon)$ and $(0, -0.5 - \varepsilon)$; the locations are interpreted as assigning the variable True and False. Any realisation of the curve corresponds to a variable assignment. Each indecisive point is followed by a precise point that is far away, to force synchronisation with the other curve:

$$\mathrm{VG}_j = \{(0, 0.5 + \varepsilon), (0, -0.5 - \varepsilon)\} \parallel (2, 0)\,.$$

Consider a specific clause C_i of the formula. We define an *assignment gadget* $\mathrm{AG}_{i,j}$ for each variable x_j and clause C_i depending on how the variable occurs in the clause.

$$\mathrm{AG}_{i,j} = \begin{cases} (0, -0.5) \parallel (1, 0) & \text{if } x_j \text{ is a literal of } C_i, \\ (0, 0.5) \parallel (1, 0) & \text{if } \neg x_j \text{ is a literal of } C_i, \\ (0, 0) \parallel (1, 0) & \text{otherwise.} \end{cases}$$

Note that if assignment $x_j = \text{True}$ makes a clause C_i true, then the first precise point of the corresponding assignment gadget appears at distance $1 + \varepsilon$ from the realisation corresponding to setting $x_j = \text{True}$ of the indecisive point in VG_j. We can repeat the construction, yielding a *variable clause gadget* and an *assignment clause gadget:*

$$\mathrm{VCG} = (-2, 0) \parallel \mathop{\Big\|}_{j \in [m]} \mathrm{VG}_j\,, \qquad \mathrm{ACG}_i = (-1, 0) \parallel \mathop{\Big\|}_{j \in [m]} \mathrm{AG}_{i,j}\,.$$

Consider the Fréchet distance between the two gadgets. Observe that matching a synchronisation point from one gadget with a non-synchronisation point in the other yields a distance more than $1 + \varepsilon$, whereas matching synchronisation points pairwise and non-synchronisation points pairwise will yield the distance at most $1 + \varepsilon$. So we only consider one-to-one couplings, i.e. we match point i on one curve to point i on the other curve, for all i.

Now, if a realisation corresponds to a satisfying assignment, then for some x_j we have picked the realisation that is opposite from the coupled point on the clause curve, yielding the bottleneck distance of $1 + \varepsilon$. If the realisation corresponds to a non-satisfying assignment, then the synchronisation points establish the bottleneck, yielding the distance 1. So, we can clearly distinguish between a satisfying and a non-satisfying assignment for a clause.

[1] This range is determined by the relative distances in the construction.

Next, we define the *variable curve* and the *clause curve* as follows:

$$\mathrm{VC} = (0,0) \parallel \mathrm{VCG} \parallel (0,0)\,, \qquad \mathrm{CC} = \mathop{\Big\Vert}_{i\in[n]} \mathrm{ACG}_i\,.$$

Observe that the synchronisation points at $(-2,0)$ and $(-1,0)$ ensure that for any optimal coupling we match up VCG with some ACG_i as described before. Also note that all the points on CC are within distance 1 from $(0,0)$. Therefore, we can always pick any one of n clauses to align with VCG, and couple the remaining points to $(0,0)$; the bottleneck distance will then be determined by the distance between VCG and the chosen ACG_i.

Now consider a specific realisation of VCG. If the corresponding assignment does not satisfy C, then we can synchronise VCG with a clause that is false to obtain a distance of 1. If the assignment corresponding to the realisation satisfies all clauses, we must synchronise VCG with a satisfied clause, which yields a distance of $1+\varepsilon$. The construction is shown in Figures 3 and 4.

We can use similar reasoning to arrive at the same conclusion if we compute the Fréchet distance instead. The necessary adaptations are presented in the full version [13].

▶ **Theorem 2.** *The problems* Upper Bound Discrete Fréchet *and* Upper Bound Continuous Fréchet *for indecisive curves are NP-hard.*

2.1.2 Expected Fréchet Distance on Indecisive Curves

We show that finding expected discrete Fréchet distance is #P-hard by providing a polynomial-time reduction from #CNF-SAT, i.e. the problem of finding the number of satisfying assignments to a CNF-SAT formula. Missing details can be found in the full version [13]. Define the following problem and its continuous counterpart:

▶ **Problem 3.** Expected Discrete Fréchet: *Find* $d_{\mathrm{dF}}^{\mathbb{E}(\mathbb{U})}(\mathcal{U},\mathcal{V})$ *for uncertain curves* $\mathcal{U},\mathcal{V}$.

The main idea is to derive an expression for the number of satisfying assignments in terms of $d_{\mathrm{dF}}^{\mathbb{E}(\mathbb{U})}(\mathrm{VC},\mathrm{CC})$. This works, since there is a one-to-one correspondence between boolean variable assignment and a choice of realisation of VC, so counting the number of satisfying assignments corresponds to finding the proportion of realisations yielding large Fréchet distance. We can establish the result for Expected Continuous Fréchet similarly.

▶ **Theorem 4.** *The problems* Expected Discrete Fréchet *and* Expected Continuous Fréchet *for indecisive curves are #P-hard.*

2.1.3 Imprecise Curves

We have so far considered indecisive points; instead, we can look at imprecise points, namely, line segments or disks. We can show similar hardness results in that setting. We alter the construction – instead of the point $\{(0,0.5+\varepsilon),(0,-0.5-\varepsilon)\}$, we either have the disk centred at $(0,0)$ with radius $0.5+\varepsilon$ or the line segment connecting $(0,-0.5-\varepsilon)$ and $(0,0.5+\varepsilon)$. Observe that the locations of the indecisive point are still on the disk or the line segment. We can show that the upper bound decision problem is NP-hard by showing that we can always consider only the extreme locations on the imprecise points that coincide with the locations of the indecisive points.

▶ **Theorem 5.** *The problems* Upper Bound Discrete Fréchet *and* Upper Bound Continuous Fréchet *for imprecise curves modelled as line segments or disks are NP-hard.*

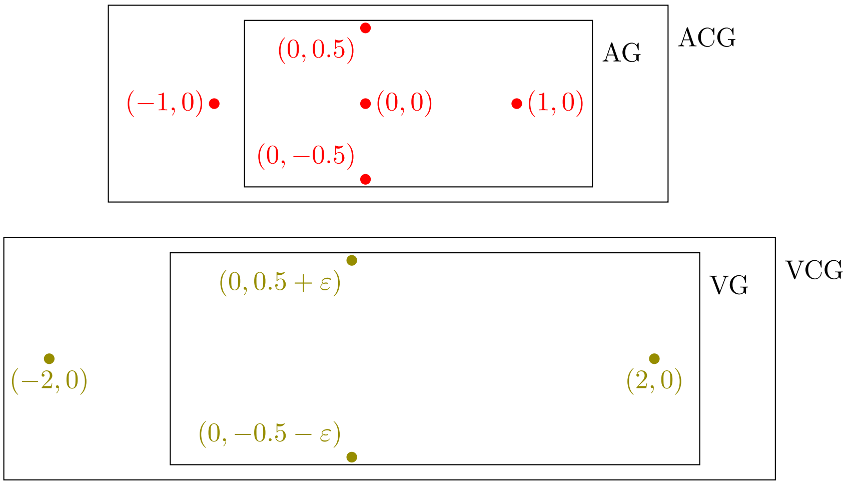

Figure 3 Illustration of gadgets used in the basic construction.

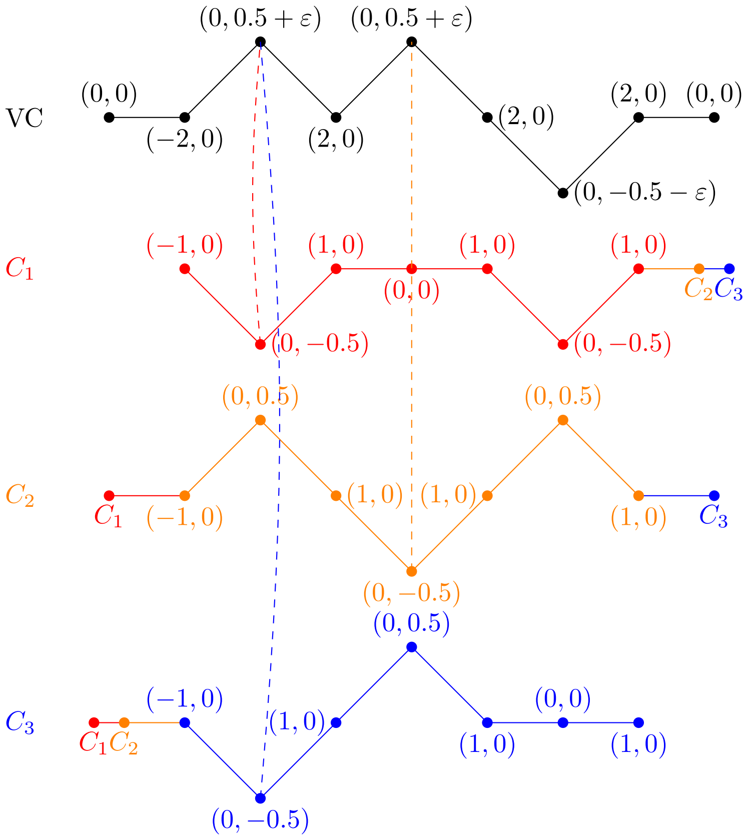

Figure 4 Realisation of VC for assignment $x_1 = \text{TRUE}$, $x_2 = \text{TRUE}$, $x_3 = \text{FALSE}$ and the CC for formula $C = (x_1 \vee x_3) \wedge (\neg x_1 \vee x_2 \vee \neg x_3) \wedge (x_1 \vee \neg x_2)$. Note that $C = \text{TRUE}$ with the given variable assignment. Also note that we can choose any of C_1, C_2, C_3 to align with VC; we always get the bottleneck distance of $1 + \varepsilon$, as all three are satisfied, so here $d_{\text{dF}}(\text{VC}, \text{CC}) = 1 + \varepsilon$.

We can also consider the value of expected Fréchet distance on imprecise points. We show the result only for points modelled as line segments; in principle, we believe that for disks a similar result holds, but the specifics of our reduction do not allow for clean computations.

We cannot immediately use our construction: we treat subsegments at the ends of the imprecision segments as TRUE and FALSE, but we have no interpretation for points in the centre part of a segment. So, we want to separate the realisations that pick any such invalid points. To that aim, we introduce extra gadgets to the clause curve that act as clauses, but catch these invalid realisations, so each of them yields the distance of 1. Now we have three distinct cases: realisation is satisfying, non-satisfying, or invalid. We can derive the expression connecting $d_{\mathrm{dF}}^{\mathbb{E}(\mathbb{U})}$ and the number of satisfying assignments.

▶ **Theorem 6.** *The problem* EXPECTED DISCRETE FRÉCHET *for imprecise curves modelled as line segments is #P-hard.*

2.2 Lower Bound Fréchet Distance

In this section, we prove that computing the lower bound Fréchet distance is NP-hard. The missing proofs can be found in the full version [13]. Unlike the upper bound proofs, this reduction uses the NP-hard problem SUBSET-SUM. Consider the following problems.

▶ **Problem 7.** LOWER BOUND CONTINUOUS FRÉCHET: *Given a polygonal curve π with n vertices, an uncertain curve $\mathcal{U}$ with m vertices, and a threshold $\delta > 0$, decide if $d_{\mathrm{F}}^{\min}(\pi, \mathcal{U}) \leq \delta$.*

▶ **Problem 8.** SUBSET-SUM: *Given a set $S = \{s_1, \ldots, s_n\}$ of n positive integers and a target integer τ, decide if there exists an index set I such that $\sum_{i \in I} s_i = \tau$.*

2.2.1 An Intermediate Problem

We start by reducing SUBSET-SUM to a more geometric intermediate curve-based problem.

▶ **Definition 9.** *Let $\alpha > 0$ be some value, and let $\sigma = \langle \sigma_1, \ldots, \sigma_{2n+1} \rangle$ be a polygonal curve. Call σ an* α-regular curve *if for all $1 \leq i \leq 2n+1$, the x-coordinate of σ_i is $i \cdot \alpha$. Let $Y = \{y_1, \ldots, y_n\}$ be a set of n positive integers. Call σ a* Y-respecting curve *if:*

1. *For all $1 \leq i \leq n$, σ passes through the point $((2i + 1/2)\alpha, 0)$.*
2. *For all $1 \leq i \leq n$, σ either passes through the point $((2i - 1/2)\alpha, 0)$ or $((2i - 1/2)\alpha, -y_i)$.*

Intuitively, the above definition requires σ to pass through $((2i + 1/2)\alpha, 0)$ as it reflects the y-coordinate about the line $y = 0$ (see Figure 5). Thus, if the curve also passes through $((2i - 1/2)\alpha, 0)$, the two reflections cancel each other. If it passes through $((2i - 1/2)\alpha, -y_i)$, the lemma below argues that y_i shows up in the final vertex height.

▶ **Lemma 10.** *Let σ be a Y-respecting α-regular curve, and let I be the subset of indices i such that σ passes through $((2i - 1/2)\alpha, -y_i)$. If $\sigma_1 = (\alpha, 0)$, then $\sigma_{2n+1} = ((2n+1)\alpha, 2\sum_{i \in I} y_i)$.*

The following is needed in the next section, and follows from the proof of the above.

▶ **Corollary 11.** *For a set $Y = \{y_1, \ldots, y_n\}$, let $M = \sum_{i=1}^{n} y_i$. For any vertex σ_i of a Y-respecting α-regular curve, its y-coordinate is at most $2M$ and at least $-2M$.*

▶ **Problem 12.** RR-CURVE: *Given a set $Y = \{y_1, \ldots, y_n\}$ of n positive integers, a value $\alpha = \alpha(Y) > 0$, and an integer τ, decide if there is a Y-respecting α-regular curve $\sigma = \langle \sigma_1, \ldots, \sigma_{2n+1} \rangle$ such that $\sigma_1 = (\alpha, 0)$ and $\sigma_{2n+1} = ((2n+1)\alpha, 2\tau)$.*

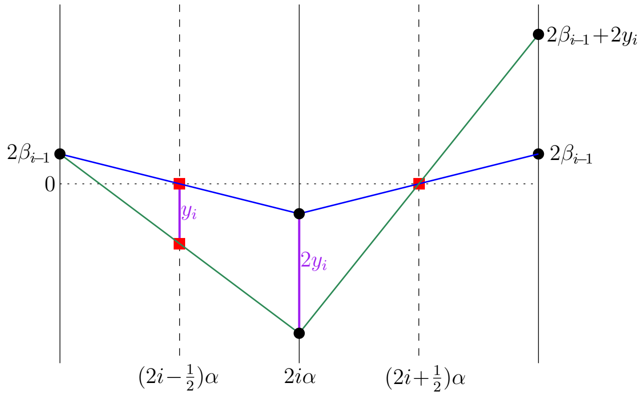

Figure 5 Passing through $((2i-1/2)\alpha,0)$ does not change the height, and passing through $((2i-1/2)\alpha,-y_i)$ adds $2y_i$.

By Lemma 10, Subset-Sum immediately reduces to the above problem by setting $Y=S$. Note that for this reduction it suffices to use any positive constant for α; however, we allow α to depend on Y, as this will ultimately be needed in our reduction to Problem 7.

▶ **Theorem 13.** *For any $\alpha(Y)>0$, RR-Curve is NP-hard.*

2.2.2 Reduction to Lower Bound Fréchet Distance

Let α, τ, $Y=\{y_1,\dots,y_n\}$ be an instance of RR-Curve. In this section, we show how to reduce it to an instance δ, π, $\mathcal{U}$ of Problem 7, where the uncertain regions in $\mathcal{U}$ are vertical line segments. The main idea is to use $\mathcal{U}$ to define an α-regular curve, and use π to enforce that it is Y-respecting. Specifically, let $M=\sum_{i=1}^{n} y_i$. Then $\mathcal{U}=\langle v_1,\dots,v_{2n+1}\rangle$, where each v_i is a vertical segment whose horizontal coordinate is $i\alpha$ and whose vertical extent is given by the interval $[-2M,2M]$. By Corollary 11, we have the following simple observation.

▶ **Observation 14.** *The set of all Y-respecting α-regular curves is a subset of* $\mathrm{Real}(\mathcal{U})$.

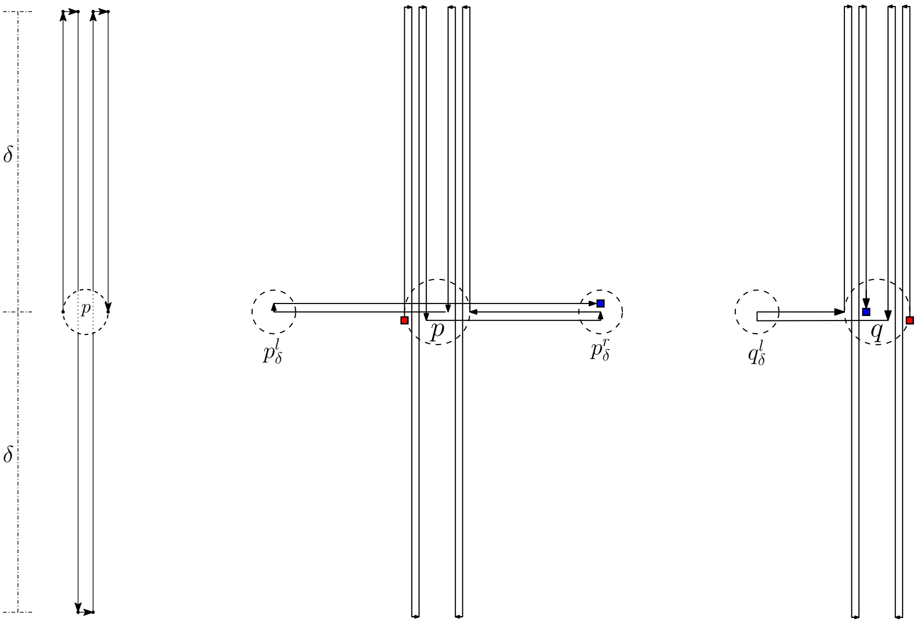
Thus, the main challenge is to define π to enforce that the realisation is Y-respecting. To that end, we first describe a gadget forcing the realisation to pass through a specified point.

▶ **Definition 15.** *For any point $p=(x,y)\in\mathbb{R}^2$ and value $\delta>0$, let the δ* gadget *at p, denoted $\mathrm{g}_\delta(p)$, be the curve: $(x,y)\parallel(x,y+\delta)\parallel(x,y-\delta)\parallel(x,y+\delta)\parallel(x,y)$. See Figure 6a.*

▶ **Lemma 16.** *Let $p=(x,y)\in\mathbb{R}^2$ be a point, and let ℓ be any line segment. Then if $d_\mathrm{F}(\ell,\mathrm{g}_\delta(p))\le\delta$, then ℓ must pass through p.*

For our uncertain curve to be Y-respecting, it must pass through all points of the form $((2i+1/2)\alpha,0)$. This condition is satisfied by the lemma above by placing a δ gadget at each such point. The second condition of a Y-respecting curve is that it passes through $((2i-1/2)\alpha,0)$ or $((2i-1/2)\alpha,-y_i)$. This condition is much harder to encode, and requires putting several δ gadgets together to create a composite gadget, which we now describe.

▶ **Definition 17.** *For any point $p=(x,y)\in\mathbb{R}^2$ and value $\delta>0$, let $p^l_\delta=(x-\delta/2,y)$ and $p^r_\delta=(x+\delta/2,y)$. Define the δ* lower composite gadget *at p, denoted $\mathrm{lcg}_\delta(p)$, to be the curve $\mathrm{g}_\delta(p)\parallel p^r_\delta\parallel\mathrm{g}_\delta(p)\parallel p^l_\delta\parallel p^r_\delta$. See Figure 6b. Define the δ* upper composite gadget *at q, denoted $\mathrm{ucg}_\delta(q)$, to be the curve $\mathrm{g}_\delta(q)\parallel q^l_\delta\parallel\mathrm{g}_\delta(q)$. See Figure 6c. Define the δ* composite gadget *of p and q, denoted $\mathrm{cg}_\delta(p,q)$, to be the curve $\mathrm{lcg}_\delta(p)\parallel\mathrm{ucg}_\delta(q)$.*



(a) $\mathrm{g}_\delta(p)$. **(b)** $\mathrm{lcg}_\delta(p)$. **(c)** $\mathrm{ucg}_\delta(q)$.

Figure 6 Depiction of gadgets $\mathrm{g}_\delta(p)$, $\mathrm{lcg}_\delta(p)$, and $\mathrm{ucg}_\delta(p)$. Circles represent zero-area points. For the right two figures, the red / blue square represents the starting / ending point.

To use this composite gadget, we centre the lower gadget at height $-y_i$ and the upper gadget directly above it at height zero. As the two gadgets are on top of each other, ultimately we require our uncertain curve to go back and forth once between consecutive vertical line segments, for which we have the following key property.

▶ **Lemma 18.** *Let $p = (x_p, -y_p)$ and $q = (x_p, 0)$ be points in $\mathbb{R}^2$. Let $\sigma = \langle a, b, c, d\rangle$ be a three-segment curve such that $b_x > x_p + \delta$ and $c_x < x_p - \delta$. If $d_\mathrm{F}(\sigma, \mathrm{cg}_\delta(p, q)) \le \delta$, then:*

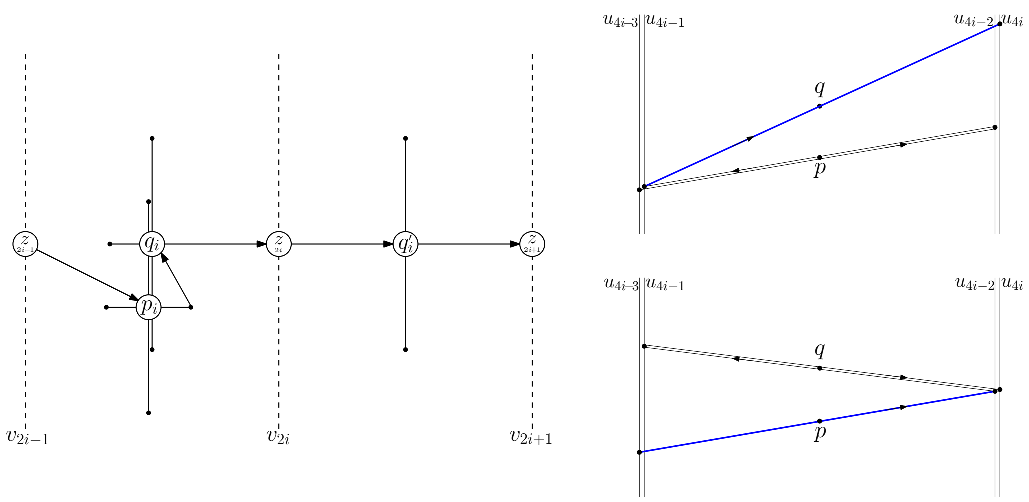
(i) *the segment ab must pass through p,*
(ii) *the segment cd must pass through q, and*
(iii) *the segment bc must either pass through p or through q.*

In particular, either ab and bc are on the same line, or cd and bc are on the same line.

Let v_l, v_r be vertical segments lying to the left and right of $\mathrm{cg}_\delta(p, q)$ further than δ away, and let z_l, z_r be the points on v_l and v_r at the same height as q. Consider the uncertain curve $\mathcal{U} = \langle U_1, U_2, U_3, U_4\rangle$, where $U_1 = U_3 = v_l$ and $U_2 = U_4 = v_r$. By Lemma 18, if there is a curve $\sigma \Subset \mathcal{U}$ such that $d_\mathrm{F}(\sigma, z_l \parallel \mathrm{cg}_\delta(p, q) \parallel z_r) \le \delta$, then implicitly it defines a single edge from v_l to v_r either passing through p or passing through q (see Figure 7b, whose notation is defined below). The following lemma acts as a rough converse of Lemma 18.

▶ **Lemma 19.** *Let $p = (x_p, -y_p)$ and $q = (x_p, 0)$ be points in $\mathbb{R}^2$, with $y_p \le \delta/4$. Let $\sigma = \langle p, b, c, q\rangle$ be a curve such that $x_p + \delta < b_x \le x_p + 1.1\delta$, $x_p - 1.1\delta \le c_x < x_p - \delta$, and $-\delta/2 \le b_y, c_y \le \delta/2$. If bc passes through either p or q, then $d_\mathrm{F}(\sigma, \mathrm{cg}_\delta(p, q)) \le \delta$.*

We now give the reduction from RR-Curve to Problem 7, whose correctness follows from the lemmas and discussion above. (See the full version [13] for details.) Let $\alpha(Y)$, τ, $Y = \{y_1, \dots, y_n\}$ be an instance of RR-Curve. For the reduction to Problem 7, we set $\delta = 4M$, where $M = \sum_{i=1}^n y_i$. Theorem 13 allows us to choose how to set $\alpha(Y)$, and we



(a) Pictorial representation of λ_i.

(b) The two solutions.

Figure 7 On the left, λ_i. On the right, the two possible solutions with Fréchet distance at most δ. The top (resp. bottom) corresponds to an α-regular curve passing through q (resp. p).

set $\alpha = 2.1\delta = 8.4M$. Let $V = \{v_1, \dots, v_{2n+1}\}$ be a set of vertical line segments where all upper (resp. lower) endpoints of the segments have height $2M$ (resp. $-2M$), and for all i, the x-coordinate of v_i is $i\alpha$. Let $\mathcal{U} = \langle U_1, \dots, U_{4n+1}\rangle$ be the uncertain curve such that $U_{4n+1} = v_{2n+1}$, and for all $1 \le i \le n$, $U_{4i-3} = v_{2i-1}$, $U_{4i-2} = v_{2i}$, $U_{4i-1} = v_{2i-1}$, and $U_{4i} = v_{2i}$. For $1 \le i \le 2n+1$, define the points $z_i = (i\alpha, 0)$, and for $1 \le i \le n$, define $q_i = ((2i - 1/2)\alpha, 0)$, $q'_i = ((2i + 1/2)\alpha, 0)$, and $p_i = ((2i - 1/2)\alpha, -y_i)$. For a given value $1 \le i \le n$, consider the curve $\lambda_i = z_{2i-1} \parallel \mathrm{cg}_\delta(p_i, q_i) \parallel z_{2i} \parallel \mathrm{g}_\delta(q'_i)$ (see Figure 7a). Let $s = (\alpha, 0)$ and $t = ((2n+1)\alpha, 2\tau)$. Then $\pi = \mathrm{g}_\delta(s) \parallel \lambda_1 \parallel \lambda_2 \parallel \cdots \parallel \lambda_{n-1} \parallel \lambda_n \parallel \mathrm{g}_\delta(t)$.

▶ **Theorem 20.** *Lower Bound Continuous Fréchet (Problem 7) is NP-hard, even when the uncertain regions are all equal-length vertical segments with the same height and the same horizontal distance (to the left or right) between adjacent uncertain regions.*

3 Algorithms for Lower Bound Fréchet Distance

In the previous section, we have shown that the decision problem for $d_F^{\min}$ is hard, given a polygonal curve and an uncertain curve with line-segment-based imprecision model. Interestingly, the same problem is solvable in polynomial time for indecisive curves. The key idea is that we can use a dynamic programming approach similar to that for computing Fréchet distance [6] and only keep track of realisations of the last indecisive point considered so far. (Note that one can also reduce the problem to Fréchet distance between paths in *DAG complexes,* studied by Har-Peled and Raichel [31], but this yields a slower running time.)

Consider the setting with an indecisive curve $\mathcal{V} = \langle V_1, \dots, V_n\rangle$ of n points and a precise curve $\pi = \langle p_1, \dots, p_m\rangle$ with m points; each indecisive point has k possible realisations, $V_i = \{q_i^1, \dots, q_i^k\}$. We can propagate reachability column by column. Define $\mathrm{Feas}(i, \ell)$ to be the *feasibility column* for realisation q_i^ℓ of U_i. This is a set of intervals on the vertical cell boundary line in the free-space diagram (see Figure 1), corresponding to the subintervals of one curve within distance δ from a point on the other curve. It is computed exactly the same way as for the precise Fréchet distance – it depends on the distance between a point and a line segment and gives a single interval on each vertical cell boundary.

Represent the standard dynamic program for computing Fréchet distance so that it operates column by column, grouping propagation of reachable intervals between vertically aligned cells. Call that procedure $\mathrm{Prop}(R)$, where R is the *reachability column* for point i and the result is the reachability column for point $i+1$ on one of the curves. The reachability column is a set of intervals on a vertical line, indicating the points in the free-space diagram that are reachable from the lower left corner with a monotone path.

Define $\mathrm{Reach}(i,s)$ to be the reachability column induced by q_i^s, where a point is in a reachability interval if it can be reached by a monotone path for some realisation of the previous points. Then we iterate over all the realisations of the previous column, getting precise cells, and propagate the reachable intervals as in the precise Fréchet distance algorithm:

$$\mathrm{Reach}(i+1,\ell) = \mathrm{Feas}(i+1,\ell) \cap \bigcup_{\ell' \in [k]} \mathrm{Prop}(\mathrm{Reach}(i,\ell'))\,.$$

For the column corresponding to U_1, we set one reachable interval of a single point at the bottom for all realisations p_1^s for which $\|q_1^s - p_1\| \le \delta$.

▶ **Theorem 21.** *Given an indecisive curve $\mathcal{V} = \langle V_1, \dots, V_n \rangle$ with k options per point, a precise curve $\pi = \langle p_1, \dots, p_m \rangle$, and a threshold $\delta > 0$, we can decide if $d_{\mathrm{F}}^{\min}(\pi, \mathcal{V}) \le \delta$ in time $\Theta(mnk^2)$ in the worst case, using $\Theta(mk)$ space. We can also report the realisation of $\mathcal{V}$ realising Fréchet distance at most δ, using $\Theta(mnk)$ space instead. Call the algorithm that solves the problem and reports a fitting realisation* $\textsc{Decider}(\delta, \pi, \mathcal{V})$.

We can extend this result to two indecisive curves. This result highlights a distinction between $d_{\mathrm{F}}^{\min}$ and $d_{\mathrm{F}}^{\max}$ and between different uncertainty models. To tackle $d_{\mathrm{F}}^{\min}$ with general uncertain curves, we develop approximation algorithms.

3.1 Approximation by Grids

Given a polygonal curve π and a general uncertain curve $\mathcal{U}$, in this section we show how to find a curve $\sigma \Subset \mathcal{U}$ such that $d_{\mathrm{F}}(\pi, \sigma) \le (1+\varepsilon) d_{\mathrm{F}}^{\min}(\pi, \mathcal{U})$. This is accomplished by carefully discretising the regions, in effect approximately reducing the problem to the indecisive case, for which we then can use Theorem 21. Missing proofs can be found in the full version [13].

For simplicity we assume the uncertain regions have constant complexity. Throughout, we assume $d_{\mathrm{F}}^{\min}(\pi, \mathcal{U}) > 0$, as justified by the following lemma.

▶ **Lemma 22.** *Let π be a polygonal curve with n vertices, and $\mathcal{U}$ an uncertain curve with m vertices. Then one can determine whether $d_{\mathrm{F}}^{\min}(\pi, \mathcal{U}) = 0$ in $O(mn)$ time.*

We call an algorithm a $(1+\varepsilon)$-*decider* for Problem 7, if when $d_{\mathrm{F}}^{\min}(\pi, \mathcal{U}) \le \delta$, it returns a curve $\sigma \Subset \mathcal{U}$ such that $d_{\mathrm{F}}(\pi, \sigma) \le (1+\varepsilon)\delta$, and when $d_{\mathrm{F}}^{\min}(\pi, \mathcal{U}) > (1+\varepsilon)\delta$, it returns $\textsc{False}$ (in between either answer is allowed). In this section, we present a $(1+\varepsilon)$-*decider* for Problem 7. We make use of the following standard observation.

▶ **Observation 23.** *Given a curve $\pi = \langle \pi_1, \dots, \pi_n \rangle$, call a curve $\sigma = \langle \sigma_1, \dots, \sigma_n \rangle$ an r-perturbation of π if $\|\pi_i - \sigma_i\| \le r$ for all i. Since $\|\pi_i - \sigma_i\|, \|\pi_{i+1} - \sigma_{i+1}\| \le r$, all points of the segment $\sigma_i\sigma_{i+1}$ are within distance r of $\pi_i\pi_{i+1}$. For segments this implies that $d_{\mathrm{F}}(\pi_i\pi_{i+1}, \sigma_i\sigma_{i+1}) \le r$, which implies that $d_{\mathrm{F}}(\pi, \sigma) \le r$ by composing the mappings for all i.*

The high-level idea is to replace $\mathcal{U}$ with the set of grid points it intersects, however, as our uncertain regions may avoid the grid points, we need to include a slightly larger set of points.

▶ **Definition 24.** *Let U be a compact subset of $\mathbb{R}^d$. We now define the set of points* $\mathrm{EG}_r(U)$ *which we call the* expanded r-grid points *of U.*

Let $B(\sqrt{d}r)$ denote the ball of radius $\sqrt{d}r$, centred at the origin. Let $\mathrm{Thick}(U, r) = U \oplus B(\sqrt{d}r)$*, where $\oplus$ denotes Minkowski sum. Let G_r be the regular grid of side length r, and let* $\mathrm{GT}_r(U)$ *be the subset of grid vertices from G_r that fall in* $\mathrm{Thick}(U, r)$*. Finally, define*

$$\mathrm{EG}_r(U) = \{p \mid p = \arg\min_{q \in U} \|q - x\| \textit{ for } x \in \mathrm{GT}_r(U)\} .$$

The following lemma argues that one can build a decider by using grids as hinted above. Using this decider, we can solve the corresponding optimisation problem.

▶ **Lemma 25.** *There is a $(1+\varepsilon)$-decider for Problem 7 with running time $O(mn \cdot (1 + (\Delta/(\varepsilon\delta))^{2d}))$, for $1 \geq \varepsilon > 0$, where $\Delta = \max_i \mathrm{diam}(U_i)$ is the maximum diameter of an uncertain region.*

▶ **Theorem 26.** *Let π be a polygonal curve with n vertices, $\mathcal{U}$ an uncertain curve with m vertices, and $\delta = d_{\mathrm{F}}^{\min}(\pi, \mathcal{U})$. Then for any $1 \geq \varepsilon > 0$, there is an algorithm which returns a curve $\sigma \Subset \mathcal{U}$ such that $d_{\mathrm{F}}(\pi, \sigma) \leq (1+\varepsilon)\delta$, whose running time is $O(mn(\log(mn) + (\Delta/(\varepsilon\delta))^{2d}))$, where $\Delta = \max_i \mathrm{diam}(U_i)$ is the maximum diameter of an uncertain region.*

If the polygonal curve π is replaced with an uncertain curve $\mathcal{W}$, it easy to argue that this approach extends to approximating $d_{\mathrm{F}}^{\min}(\mathcal{W}, \mathcal{U})$.

3.2 Greedy Algorithm

Here we argue that there is a simple 3-decider for Problem 7, running in near-linear time in the plane. The idea is to greedily and iteratively pick $\sigma_i \in U_i$ so as to allow us to get as far as possible along π. Without any assumptions on $\mathcal{U}$, this greedy procedure may walk too far ahead and get stuck. Thus, here we assume that consecutive U_i are separated to ensure that optimal solutions do not lag too far behind. Here we also assume the U_i are convex, i.e. imprecise, and have constant complexity, as it simplifies certain definitions. In this section, let $\pi = \langle \pi_1, \ldots, \pi_n \rangle$ be a polygonal curve and let $\mathcal{U} = \langle U_1, \ldots, U_m \rangle$ be an imprecise curve.

▶ **Definition 27.** *Call $\mathcal{U}$* γ-separated *if for all $1 \leq i < m$, $\|U_i - U_{i+1}\| > \gamma$ and each U_i is convex. Define an* r-visit *of U_i to be any maximal-length contiguous portion of $\pi \cap (U_i \oplus B(2r))$ which intersects $U_i \oplus B(r)$, where $\oplus$ denotes Minkowski sum. If $\mathcal{U}$ is γ-separated for $\gamma \geq 4r$, then any r-visit of U_i is disjoint from any r-visit of U_j for $i \neq j$, in which case define the* true r-visit *of U_i to be the first visit of U_i which occurs after the true r-visit of U_{i-1}. (For U_1 it is the first r-visit.)*

▶ **Lemma 28.** *If $\mathcal{U}$ is γ-separated for $\gamma \geq 4r$, then for any curve $\sigma \Subset \mathcal{U}$ and any reparametrisations f and g such that $\mathrm{width}_{f,g}(\pi, \sigma) \leq r$, σ_i must map to a point on the true r-visit of U_i for all i.*

For two points α and β on π, let $\alpha \leq \beta$ denote that α occurs before β, and for any points $\alpha \leq \beta$ let $\pi(\alpha, \beta)$ denote the subcurve between α and β.

▶ **Definition 29.** *The* δ-greedy sequence *of π with respect to $\mathcal{U}$, denoted* $\mathrm{gs}(\pi, \mathcal{U}, \delta)$*, is the longest possible sequence $\alpha = \langle \alpha_1, \ldots, \alpha_k \rangle$ of points on π, where $\alpha_1 = \pi_1$, and for any $i > 1$, α_i is the point furthest along π such that $\|\alpha_i - U_i\| \leq \delta$ and $d_{\mathrm{F}}(\alpha_{i-1}\alpha_i, \pi(\alpha_{i-1}, \alpha_i)) \leq 2\delta$.*

▶ **Observation 30.** *For any $i \leq k$, let $\alpha^i = \langle \alpha_1, \ldots, \alpha_i \rangle$ be the ith prefix of* $\mathrm{gs}(\pi, \mathcal{U}, \delta)$*. Then $d_{\mathrm{F}}(\alpha^i, \pi(\alpha_1, \alpha_i)) \leq 2\delta$, and $\alpha^i \Subset \mathcal{U}_i \oplus B(\delta)$, where $\mathcal{U}_i \oplus B(\delta) = \langle U_1 \oplus B(\delta), \ldots, U_i \oplus B(\delta) \rangle$.*

The following is the main lemma used to argue the correctness of our greedy approach, and it makes use of helper Lemma 28.

▶ **Lemma 31.** *If $\mathcal{U}$ is 10δ-separated and $d_{\mathrm{F}}^{\min}(\pi,\mathcal{U}) \leq \delta$, then $\mathrm{gs}(\pi,\mathcal{U},\delta)$ has length m and $\alpha_m = \pi_n$.*

The following lemma is the only place where we require the points to be in $\mathbb{R}^2$. The proof is interesting and uses a result from Guibas et al. [30].

▶ **Lemma 32.** *For π and $\mathcal{U}$ in $\mathbb{R}^2$, where $\mathcal{U}$ is 10δ-separated, $\mathrm{gs}(\pi,\mathcal{U},\delta)$ is computable in $O(m + n\log n)$ time.*

▶ **Theorem 33.** *Let $\mathcal{U}$ be $10r$-separated for some $r > 0$. There is a 3-decider for Problem 7 with running time $O(m + n\log n)$ in the plane that works for any query value $0 < \delta \leq r$.*

Proof. Compute $\mathrm{gs}(\pi,\mathcal{U},\delta)$. If it has length m, then let $\sigma = \langle \sigma_1, \dots, \sigma_m\rangle$ be any curve in $\mathrm{Real}(\mathcal{U})$ such that $\|\sigma_i - \alpha_i\| \leq \delta$ for all i. If this occurs and if $\alpha_m = \pi_n$, we output σ as our solution, and otherwise we output FALSE. Thus, the running time follows from Lemma 32.

Observe that if we output a curve σ, then $d_{\mathrm{F}}(\sigma,\pi) \leq 3\delta$, using the triangle inequality:

$$d_{\mathrm{F}}(\sigma,\pi) \leq d_{\mathrm{F}}(\sigma,\alpha) + d_{\mathrm{F}}(\alpha,\pi) \leq \delta + 2\delta = 3\delta\,.$$

Thus, we only need to argue that when $d_{\mathrm{F}}^{\min}(\pi,\mathcal{U}) \leq \delta$, a curve is produced, which is immediate from Lemma 31. ◀

4 Algorithms for Upper Bound and Expected Fréchet Distance

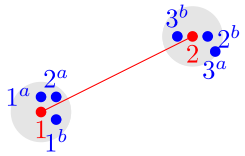
As shown in Section 2.1, finding the upper bound and expected discrete and continuous Fréchet distance is hard even for simple uncertainty models. However, restricting the possible couplings between the curves makes the problem solvable in polynomial time. In this section, we use *indecisive* curves. Define a Sakoe–Chiba time band [44] in terms of reparametrisations of the curves: for a band of width w and all $t \in [0,1]$, if $\phi_1(t) = x$, then $\phi_2(t) \in [x - w, x + w]$. In the discrete case we only couple point i on one curve to points $i \pm w$ on the other curve.

4.1 Upper Bound Discrete Fréchet Distance

First of all, let us discuss a simple setting. Suppose we are given a curve $\sigma = \langle q_1, \dots, q_n\rangle$ of n precise points and $\mathcal{U} = \langle U_1, \dots, U_n\rangle$ of n indecisive points, each of them having ℓ options, so for all $i \in [n]$ we have $U_i = \{p_i^1, \dots, p_i^\ell\}$. We would like to answer the following decision problem: *"If we restrict the couplings to a Sakoe–Chiba band of width w, is it true that $d_{\mathrm{dF}}^{\max}(\mathcal{U},\sigma) \leq \delta$ for some given threshold $\delta > 0$?"* So, we want to solve the decision problem for the upper bound discrete Fréchet distance between a precise and an indecisive curve.

In a fully precise setting the discrete Fréchet distance can be computed using dynamic programming [22]. We create a table where the rows correspond to vertices of one curve, say σ, and columns correspond to vertices of the other curve, say π. Each table entry (i,j) then contains a TRUE or FALSE value indicating if there is a coupling between $\sigma[1:j]$ and $\pi[1:i]$ with maximum distance at most δ. We use a similar approach.

Suppose we position $\mathcal{U}$ to go horizontally along the table, and σ to go vertically. Consider an arbitrary column in the table and suppose that we fix the realisation of $\mathcal{U}$ up to the previous column. Then we can simply consider the new column ℓ times, each time picking a different realisation for the new point on $\mathcal{U}$, and compute the resulting reachability. As we do this for the entire column at once, we can ensure consistency of our choice of realisation.



F F	F T	T T
T T	T F	F F

$$\begin{array}{|c|}\hline F\\\hline T\\\hline\end{array} \to \begin{array}{|c|c|}\hline F & T\\\hline T & F\\\hline\end{array} \to \begin{array}{|c|}\hline T\\\hline F\\\hline\end{array}$$

Figure 8 Left: An indecisive and a precise curve. Middle: Distance matrix. "T T" in the bottom left cell means $\|1 - 1^a\| \leq \delta$ and $\|1 - 1^b\| \leq \delta$. Right: Computing reachability matrix, column by column. Note two reachability vectors for the second column.

This procedure will give us a set of binary reachability vectors for the new column, each vector corresponding to a realisation. The *reachability vector* is a boolean vector that, for the cell (i, j) of the table, states whether for a particular realisation π of $\mathcal{U}[1 : i]$ the discrete Fréchet distance between π and $\sigma[1 : j]$ is below some threshold δ.

An important observation is that we do not need to distinguish between the realisations that give the same reachability vector: once we start filling out the next column, all we care about is the existence of some realisation leading to that particular reachability vector. So, we can keep a *set* of binary vectors corresponding to reachability in the column.

This procedure was suggested for a specific realisation. However, we can also repeat this for each previous reachability vector, only keeping the unique results. As all the realisation choices happen along $\mathcal{U}$, by treating the table column-by-column we ensure that we do not have issues with inconsistent choices. Therefore, repeating this procedure n times, we fill out the last column of the table. At that point, if any vector has False in the top right cell, then there is some realisation $\pi \Subset \mathcal{U}$ such that $d_{\mathrm{dF}}(\pi, \sigma) > \delta$, and hence $d_{\mathrm{dF}}^{\max}(\mathcal{U}, \sigma) > \delta$.

In more detail, we use two tables, distance matrix D and reachability matrix R. First of all, we initialise the distance matrix D and the reachability of the first column for all possible locations of U_1. Then we fill out R column-by-column. We take the reachability of the previous column and note that any cell can be reached either with the horizontal step or with the diagonal step. We need to consider various extensions of the curve $\mathcal{U}$ with one of the ℓ realisations of the current point: the distance matrix should allow the specific coupling. Assume we find that a certain cell is reachable; if allowed by the distance matrix, we can then go upwards, marking cells above the current cell reachable, even if they are not directly reachable with a horizontal or diagonal step. Then we remember the newly computed vector; we only add distinct vectors. The computation is illustrated in Figure 8; missing details can be found in the full version [13]. We use the following loop invariant to show correctness.

▶ **Lemma 34.** *Consider column i. Every reachability vector of this column corresponds to at least one realisation of $\mathcal{U}[1 : i]$ and the discrete Fréchet distance between that realisation and $\sigma[1 : \min(n, i + w)]$; and every realisation corresponds to some reachability vector.*

▶ **Theorem 35.** *Problem Upper Bound Discrete Fréchet restricted to a Sakoe–Chiba time band of width w on a precise curve and an uncertain curve on indecisive points with ℓ options, both of length n, can be solved in time $\Theta(4^w \ell n \sqrt{w})$ in the worst case.*

Now we extend our previous result to the setting where both curves are indecisive, so instead of σ we have $\mathcal{V} = \langle V_1, \ldots, V_n \rangle$, with, for each $j \in [n]$, $V_j = \{q_j^1, \ldots, q_j^\ell\}$. Suppose we pick a realisation for curve $\mathcal{V}$. Then we can apply the algorithm we just described. We cannot run it separately for every realisation; instead, note that the part of the realisation that matters for column i is the points from $i - w$ to $i + w$, since any previous or further points are outside the time band. So, we can fix these $2w + 1$ points and compute the column. We do so for each possible combination on these $2w + 1$ points.

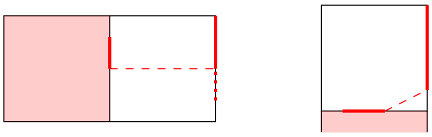


Figure 9 Reachability adjustments. Left: Although the dotted interval is free according to the distance matrix, only the solid interval is reachable from the cell on the left with a monotone path, assuming the cell on the left is free. Right: The full interval that is marked as free is reachable.

▶ **Theorem 36.** *Suppose we are given two indecisive curves of length n with ℓ options per indecisive point. Then we can compute the upper bound discrete Fréchet distance restricted to a Sakoe–Chiba band of width w in time $\Theta(4^w \ell^{2w+1} n\sqrt{w})$.*

4.2 Expected Discrete Fréchet Distance

To compute the expected discrete Fréchet distance with time bands, we need two observations:

1. For any two precise curves, there is a single threshold δ where the answer to the decision problem changes – a *critical value*; it is the distance between two points on the curves.
2. We can modify our algorithm to store associated counts with each reachability vector, obtaining the fraction of realisations that yield the answer TRUE for a given threshold δ.

We can execute our algorithm for each critical value and get the cumulative distribution function $\mathbb{P}(d_{\text{dF}}(\pi, \sigma) > \delta)$ for $\pi, \sigma \Subset_{\mathbb{U}} \mathcal{U}, \mathcal{V}$. Using the fact that the cumulative distribution function is a step function, we compute $d_{\text{dF}}^{\mathbb{E}}$.

▶ **Theorem 37.** *Suppose we are given two indecisive curves of length n with ℓ options per indecisive point. Then we can compute the expected discrete Fréchet distance when constrained to a Sakoe–Chiba band of width w in time $\Theta(4^w \ell^{2w+3} n^2 w^2)$ in the worst case.*

4.3 Continuous Fréchet Distance

We can adapt our time band algorithms to handle continuous Fréchet distance. Instead of the boolean reachability vectors, we use vectors of *free space* cells, introduced by Alt and Godau [6, 27]. We need to now store reachability intervals on cell borders (see Figure 9). The number of these intervals is limited: for any cell, the upper value of the interval is defined by the distance matrix, so yielding at most ℓ^2 values; the lower value of the interval is defined by the distance matrix or by one of the cells from the same row, yielding exponential dependency on w. However, the algorithm is still polynomial-time in n.

We can also store the associated counts. We then find critical values, in line with those arising in precise curve Fréchet distance [6]. This way we adapt our algorithm for computing expected distance to continuous case, and it runs in time polynomial in n for fixed w and ℓ, as desired. Further details are provided in the full version [13].

▶ **Theorem 38.** *Suppose we are given two indecisive curves of length n with ℓ options per indecisive point. Then we can compute upper bound Fréchet distance and expected Fréchet distance restricted to a Sakoe–Chiba band of fixed width w in time polynomial in n.*

Abstract

In the counting Graph Homomorphism problem (#GraphHom) the question is: Given graphs G, H, find the number of homomorphisms from G to H. This problem is generally #P-complete, moreover, Cygan et al. proved that unless the Exponential Time Hypothesis fails there is no algorithm that solves this problem in time $O(|V(H)|^{o(|V(G)|)})$. This, however, does not rule out the possibility that faster algorithms exist for restricted problems of this kind. Wahlström proved that #GraphHom can be solved in plain exponential time, that is, in time $O((2k+1)^{|V(G)|+|V(H)|}\mathrm{poly}(|V(H)|, |V(G)|))$ provided H has clique width k. We generalize this result to a larger class of graphs, and also identify several other graph classes that admit a plain exponential algorithm for #GraphHom.

1 Introduction

The Exponential Time Hypothesis (ETH) [16] essentially suggests that the Satisfiability problem does not admit an algorithm that is significantly faster than the straightforward brute force algorithm. The ETH has been widely used to obtain (conditional) lower bounds on the complexity of various problems, see [18] for a fairly recent survey. It however does not rule out nontrivial algorithms for many other hard problems.

One of such problems is the Graph Homomorphism problem (GraphHOM for short). A homomorphism from a graph G to a graph H is a mapping $\varphi\colon V(G) \to V(H)$ such that for any edge $ab \in E(G)$ the pair $\varphi(a)\varphi(b)$ is an edge of H. GraphHOM asks, given graphs G and H, whether or not there exists a homomorphism from G to H [14]. In the counting version of this problem, denoted #GraphHOM, the goal is to find the number of homomorphisms from G to H. These two problems can be solved just by checking all possible mappings from a given graph G to a given graph H, which takes time $O^*(|V(H)|^{|V(G)|})$, where O^* denotes asymptotics up to a polynomial factor. Assuming the ETH Cygan et al. [6] proved that the general GraphHom and therefore #GraphHom cannot be solved in time $O(|V(H)|^{o(|V(G)|)})$. A similar bound for the more general Constraint Satisfaction Problem (CSP) was established in [22], and some related hardness results have also been obtained in [5].

In spite of these results, there are several ways to restrict GraphHom which sometimes result in a problem admitting a faster algorithm. For graph classes $\mathcal{G}, \mathcal{H}$, GraphHom$(\mathcal{G}, \mathcal{H})$ denotes the problem GraphHom in which the input graphs G, H belong to $\mathcal{G}, \mathcal{H}$, respectively. #GraphHOM can be restricted in the same way. Both problems have received much attention in their own right and as a special case of the general CSP, and much is known about their computational complexity. We will use the symbol $-$ to indicate that an input graph is not restricted. In particular, it is known that GraphHom$(-, \mathcal{H})$ is solvable in polynomial time only if every graph in $\mathcal{H}$ contains a loop or is bipartite [15]. It is also known that #GraphHom$(-, \mathcal{H})$ is solvable in polynomial time only if every graph in $\mathcal{H}$ is complete with all the loops present or is complete bipartite [9]. In the remaining cases these problems are shown to be NP- and #P-complete, respectively. Similarly, it is known that GraphHom$(\mathcal{G}, -)$ [13] and #GraphHom$(\mathcal{G}, -)$ [8] are solvable in polynomial time if and only if the class of cores of the graphs from $\mathcal{G}$ in the former case, and the class $\mathcal{G}$ itself in the latter case have bounded tree width, respectively.

Here we focus on such restrictions that give rise to problems solvable still in exponential time but much faster than brute force. Specifically, GraphHom$(\mathcal{G}, \mathcal{H})$ or #GraphHom$(\mathcal{G}, \mathcal{H})$ are said to be solvable in *plain exponential* time if there is a solution algorithm running in time $O^*(c^{|V(G)|+|V(H)|})$, where c is a constant. In this paper we study problems of the form #GraphHom$(-, \mathcal{H})$, however, clearly, all the easiness results for #GraphHom$(-, \mathcal{H})$ also hold for GraphHom$(-, \mathcal{H})$. If the problem #GraphHom$(-, \mathcal{H})$ is solvable in plain exponential time, we call the class $\mathcal{H}$ a *plain exponential class*.

Plain exponential classes of graphs have received substantial attention in the literature. The most well known such class is $\mathcal{K}$, the class of all cliques. Note that #GraphHom$(-, \mathcal{K})$ is equivalent to the #Graph Colouring problem, in which the problem is, given a graph G and a number k, to find the number of k-colourings of G. A fairly straightforward dynamic programming algorithm solves this problem in time $O^*(3^{|V(G)|})$; we outline this algorithm in Example 8. A more sophisticated algorithm [17] solves #GraphHom$(-, \mathcal{K})$ in time $O^*(2^{|V(G)|})$. If $\mathcal{H}$ is a class of graphs of tree width k then #GraphHom$(-, \mathcal{H})$ is solvable in time $O^*((k+3)^{|V(G)|})$, see [11]. For the class $\mathcal{D}_c$ of graphs of degree at most c the problem #GraphHom$(-, \mathcal{D}_c)$ can be solved in time $O^*(c^{|V(G)|})$ by a minor modification of the brute force enumeration algorithm, see Example 7. Finally, Wahlström [23] obtained probably the most general result so far on plain exponential graph classes, proving that if $\mathcal{H}$ only contains graphs of clique width at most k then #GraphHom$(-, \mathcal{H})$ can be solved in time $O^*((2k+1)^{|V(G)|+|V(H)|})$. The algorithm from [23] is also dynamic programming and uses the representation of (labeled) graphs of bounded clique width through a sequence of operations such as disjoint union, connecting vertices with certain labels, and relabeling vertices. Such sequences are called *k-expressions*.

In this paper we aim at a systematic study of plain exponential classes of graphs. As the first step we further expand the class of graphs for which plain exponential counting algorithms are possible by adding one more operation to the construction of graphs of bounded clique width. In a nutshell, the new operation expands a graph H to a graph H' in such a way that H is a retract of H', and the preimages of vertices of H are connected in a regular way. The new class of graphs includes families of graphs of unbounded clique width, for instance, hypercubes, grids, cliques with subdivided edges, and therefore is strictly larger than the class of graphs of bounded clique width. By means of this new set of operations one can define a new graph "width" measure that we call *extended clique width*, only this new measure involves two parameters rather than one. Graphs of extended clique width (k, r) can also be represented by *extended (k, r)-expressions*. Let $\mathcal{X}_{k,r}$ denote the class of graphs whose extended width parameters are at most k, r, respectively. (In this case we will say that such a graph has extended clique width *at most* (k, r).) Although in most cases in this paper the only parameter that matters is $\max\{k, r\}$, we think that further stratification is useful for a number of more precise results.

We then show that given an arbitrary graph G, a graph H of extended clique width (k, r), and an extended (k, r)-expression Φ representing H, the number $\mathsf{hom}(G, H)$ of homomorphisms from G to H can be found in time $O^*((2\max(k, r) + 1)^{2|V(G)|})$. Similar to [23], the algorithm is dynamic programming and iteratively computes numbers $\mathsf{hom}(G', H')$, where G' is an induced subgraph of G and H' is a graph represented by a subexpression of Φ. Clearly, as one cannot assume that an extended (k, r)-expression representing H is known in advance, this algorithm alone does not guarantee that $\mathcal{X}_{k,r}$ is plain exponential. However, we also show that given a graph H of extended clique width at most (k, r), an extended (k, r)-expression representing H can be found in time $O^*((4\max(k, r) + 4)^{|V(H)|})$. Combined with the previous result we thus obtain the following

▶ **Theorem 1.** *For any fixed k, r the class of graphs of extended clique width at most (k, r) is plain exponential.*

Next, we show that the classes of graphs of bounded extended clique width are quite general. Let $\mathsf{Hypercubes}$ denote the class of all hypercubes and let Grids denote the class of all rectangular grids. Also, for a class $\mathcal{H}$ of graphs, $\mathcal{K}(\mathcal{H})$ denotes the class of graphs H obtained as follows. Take $H' \in \mathcal{H}$, a clique on vertices $\{v_1, \dots, v_n\}$, and for every edge v_iv_j of the clique, $i \neq j$, replace this edge with a copy of H', that is, connect v_i, v_j to all vertices of H' and include all the edges of H'. It is known that all three classes have unbounded clique width [20, 3], and $\mathcal{K}(\mathcal{H})$ has unbounded clique width even when $\mathcal{H}$ contains just one graph with one vertex.

▶ **Theorem 2.** $\mathsf{Hypercubes}$ *has extended clique width at most (2,1),* Grids *has extended clique width at most (6,1). For any class $\mathcal{H}$ of extended clique width (k, r), the class $\mathcal{K}(\mathcal{H})$ has extended clique width at most $(k + 5, \max(r, 1))$.*

By Theorem 1 this immediately implies that classes $\mathsf{Hypercubes}$ and Grids are plain exponential. For subdivisions of cliques we prove a stronger result.

▶ **Proposition 3.** *For any plain exponential class $\mathcal{H}$ of graphs (not necessarily of bounded extended clique width), the class $\mathcal{K}(\mathcal{H})$ is also plain exponential.*

It seems that there are two general reasons for a class of graphs to be plain exponential: to have bounded (extended) clique width or to have bounded degree. Classes $\mathsf{Hypercubes}$ and $\mathcal{K}(\mathcal{H})$ witness that bounded extended clique width (and in fact even bounded clique width) does not imply bounded degree. By proving that graphs from $\mathcal{X}_{k,r}$ satisfy certain nontrivial property and showing that a random c-regular graph for $c > 3$ (unsurprisingly) does not satisfy this property with high probability, we show that $\mathcal{D}_c$ does not have bounded extended clique width. The two types of classes can be combined together to obtain new plain exponential classes. Let G, H be graphs. The Cartesian product $G\Box H$ of G and H is defined to be the graph with vertex set $V(G) \times V(H)$ and edges $(u_1, v_1)(u_2, v_2)$ such that either $u_1 = u_2$ and $v_1v_2 \in E(H)$, or $v_1 = v_2$ and $u_1u_2 \in E(G)$.

▶ **Theorem 4.** *Let $\mathcal{G}$ be a plain exponential class of graphs and $\mathcal{H}$ of bounded degree. Then $\mathcal{G}\Box\mathcal{H} = \{G\Box H \mid G \in \mathcal{G}, H \in \mathcal{H}\}$ is plain exponential.*

Note that for another standard graph product, $G \times H$, where edges are given by the rule: $(u_1, v_1)(u_2, v_2)$ is an edge if and only if $u_1u_2 \in E(G)$ and $v_1v_2 \in E(H)$, a similar result is almost trivial, as we observe in Example 9.

There is no doubt that plain exponential classes are much more diverse than what is shown above. For instance, for a class $\mathcal{G}$ of graphs, let $\mathcal{G}^{+d}$ denote the class of graphs G such that it is possible to remove up to d vertices from G to obtain a graph from $\mathcal{G}$. Then as is easily seen, $\mathcal{G}^{+d}$ is plain exponential whenever $\mathcal{G}$ is plain exponential. Also, there are some odd plain exponential class of graphs (odd in the sense we could not fit it into any of the types above). Let Kneser_k denote the well studied class of Kneser graphs, see, e.g. [19]: Kneser_k is the class of graphs, whose vertices are the k-element subsets of a certain set, and two vertices are connected if and only if the corresponding subsets are disjoint. A plain exponential algorithm for Kneser_k (for a fixed k) exists, see [2, 21]. We find an alternative algorithm for this class of graphs.

▶ **Theorem 5.** *For every k the class Kneser_k is plain exponential.*

The class Kneser_k however does not fit in any of the more general classes of plain exponential graphs.

Due to space restrictions not all proofs are included in this paper. For the missing proofs the reader is referred to the full version of the paper [7].

2 Preliminaries: Homomorphisms and Clique width

2.1 Homomorphisms, plain exponential time

By $[n]$ we denote the set $\{1, \dots, n\}$ and by $[[n]]$ the set $\{0, 1, \dots, n\}$. As always we denote the vertex set of a graph G by $V(G)$, and its edge set by $E(G)$. A *homomorphism* of a graph G to a graph H is a mapping $\varphi\colon V(G) \to V(H)$ such that $\varphi(u)\varphi(v) \in E(H)$ for any $uv \in E(G)$. By $\mathsf{hom}(G, H)$ we denote the number of homomorphisms from G to H. The *Counting Graph Homomorphism* problem, #GraphHom, is defined as follows: given graphs G, H, find the number of homomorphisms from G to H. Its decision version – does there exist a homomorphism from G to H? – is denoted by GraphHom. For more on graph homomorphisms see [14]. If H is allowed only from a class $\mathcal{H}$ of graphs, the resulting counting and decision problems are denoted #GraphHom$(-, \mathcal{H})$ and GraphHom$(-, \mathcal{H})$, respectively.

We will be concerned with the complexity and the best running time of algorithms for #GraphHom$(-, \mathcal{H})$. In particular, we say that a class $\mathcal{H}$ of graphs is *plain exponential* if there is an algorithm that solves the problem #GraphHom$(-, \mathcal{H})$ in *plain exponential time*: there exists a constant c such that on input G, H, $H \in \mathcal{H}$, the algorithm runs in time $O^*(c^{|V(G)|+|V(H)|})$, where O^* means asymptotics up to a factor polynomial in $|V(G)|, |V(H)|$. Note that we will always assume that G and H are connected, since otherwise the existence or the number of homomorphisms from G to H can be deduced from those of their connected components.

▶ **Example 6.** (H-Colouring.) If $\mathcal{H}$ consists of just one graph, H, the problems #GraphHom$(-, \mathcal{H})$, GraphHom$(-, \mathcal{H})$ are known as #H-Colouring and H-Colouring, respectively. The #H-Colouring problem is solvable in polynomial time if H is a complete graph with all loops present, or is a complete bipartite graph [9]. The H-Colouring problem is solvable in polynomial time if H contains a loop or is bipartite [15]. Otherwise these problems are #P- and NP-complete, respectively. Since the brute force algorithm for this problems runs in $O(|V(H)|^{|V(G)|})$ time, #H-Colouring and H-Colouring are always solvable in plain exponential time. Also, by inspecting the solution algorithms from [9, 15] these results can be slightly generalized: #GraphHom$(-,\mathcal{H})$ is solvable in polynomial time whenever every graph from $\mathcal{H}$ is a complete graph with all loops, or a complete bipartite graph. Similarly GraphHom$(-,\mathcal{H})$ is polynomial time solvable if every graph from H contains a loop or is bipartite.

▶ **Example 7.** (Graphs of bounded degree.) As is mentioned in the introduction, if the degrees of graphs from $\mathcal{H}$ are bounded by a number c, the (improved) brute force algorithm solves #GraphHom$(-,\mathcal{H})$, GraphHom$(-,\mathcal{H})$ in time $O^*(c^{|V(G)|})$. Let G, H be input graphs, $H \in \mathcal{H}$. Recall that we assume G is connected; otherwise the procedure below has to be performed for each connected component, and the results multiplied. Order the vertices $v_1, \dots, v_n$ of G in such a way that each vertex except for the first one is adjacent to one of the preceding vertices. Then the brute force algorithm is organized as follows: Assign images to $v_1, \dots, v_n$ in turn. There are $|V(H)|$ possibilities to map v_1, but then if v_i is adjacent to v_j, $j < i$, the image of v_j is fixed, and therefore there are at most c possibilities for the image of v_i. Thus, the algorithm runs in $O^*(c^n)$. This approach also allows H to have a bounded number of vertices of high degree.

▶ **Example 8.** (Graphs of bounded clique width.) Let $\mathcal{C}_k$ denote the class of all graphs of clique width at most k (to be defined in Section 2.2). Then #GraphHom$(-,\mathcal{C}_k)$, GraphHom$(-,\mathcal{C}_k)$ can be solved in time $O^*((2k+1)^{|V(G)|+|V(H)|})$, implying that $\mathcal{C}_k$ is plain exponential [23].

Here we briefly describe the simple algorithm solving #GraphHom$(-,\mathcal{K})$, where $\mathcal{K}$ is the class of cliques. Given a graph G and a number s (or, equivalently, the clique K_s) the solution algorithm maintains an array $N(S,\ell)$ for $S \subseteq V$ and $\ell \le s$, which contains the number of homomorphisms from the subgraph of G induced by S to an ℓ-element clique. To compute each $N(S,\ell)$ we go over all subsets $S' \subseteq S$, consider the vertices from S' to be mapped to the ℓ-th vertex of the ℓ-clique. Then there are $N(S-S', \ell-1)$ ways to map the remaining vertices, and $N(S,\ell)$ is the sum of all numbers like this. It is not hard to see that the running time of this algorithm is $O^*(3^{|V(G)|})$. It can be improved to run in time $O^*(2^{|V(G)|})$ [17], and some further improvements are possible in certain cases [10].

▶ **Example 9.** Often plain exponential classes can be combined to obtain a new plain exponential class. For graphs G, H let $G \times H$ denote their product, the graph with vertex set $V(G) \times V(H)$ and edges $(u_1, v_2)(u_2, v_2)$ whenever $u_1u_2 \in E(G)$ and $v_1v_2 \in E(H)$. Also, for graph classes $\mathcal{G}, \mathcal{H}$, let $\mathcal{G} \times \mathcal{H}$ denote the class $\{G \times H \mid G \in \mathcal{G}, H \in \mathcal{H}\}$. If $\mathcal{G}, \mathcal{H}$ are plain exponential, then so is $\mathcal{G} \times \mathcal{H}$. Indeed, let π_1, π_2 denote the projection homomorphisms of $G \times H$ onto G and H, respectively; that is, $\pi_1 : (u,v) \mapsto u$ and $\pi_2 : (u,v) \mapsto v$. For any graph T a mapping $\varphi : V(T) \to V(G) \times V(H)$ is a homomorphism if and only if the mappings $\varphi_1 = \pi_1 \circ \varphi_1 : V(T) \to V(G)$ and $\varphi_2 = \pi_2 \circ \varphi : V(T) \to V(H)$ are homomorphisms. In this case $\varphi(u,v) = (\varphi_1(u), \varphi_2(v))$. This immediately implies that $\mathsf{hom}(T, G \times H) = \mathsf{hom}(T, G) \cdot \mathsf{hom}(T, \mathcal{H})$, and the result follows.

We will often deal with vertex labeled graphs. It will be convenient to represent labels on vertices of a graph G as a *label function* $\pi \colon V(G) \to [k]$, in which case we say that G is *k-labeled.* The graph $G = (V, E)$ equipped with a label function π will be denoted by $\mathbb{G} = (V, E, \pi)$. The k-labeled graph $\mathbb{G}$ is then called a *k-labeling* of G. Let $\mathbb{G}_1 = (V_1, E_1, \pi_1)$ and $\mathbb{G}_2 = (V_2, E_2, \pi_2)$ be k-labeled graph. A mapping $\varphi \colon V_1 \to V_2$ is a *homomorphism* of k-labeled graph $\mathbb{G}_1$ to k-labeled graph $\mathbb{G}_2$ if it is a homomorphism of graph $G_1 = (V_1, E_1)$ to $G_2 = (V_2, E_2)$ respecting the labeling, that is, $\pi_2(\varphi(v)) = \pi_1(v)$ for every $v \in V_1$.

The following notation will also be useful. Let again $\mathbb{G}_1, \mathbb{G}_2$ be k-labeled graphs, such that V_1, V_2 are disjoint. Then $\mathbb{G}_1 \bigoplus \mathbb{G}_2 = (V_1 \uplus V_2, E_1 \uplus E_2, \pi_1 \uplus \pi_2)$, where $\pi_1 \uplus \pi_2(v) = \pi_1(v)$, if $v \in V_1$, and $\pi_1 \uplus \pi_2(v) = \pi_2(v)$, if $v \in V_2$.

Finally, the subgraph of a graph $G = (V, E)$ induced by a set $S \subseteq V$ is denoted by $G[S]$. For a k-labeled graph $\mathbb{G} = (V, E, \pi)$, by $\mathbb{G}[S]$ we denote the k-labeled subgraph induced by $S \subseteq V$. Note that the label function of $\mathbb{G}[S]$ is $\pi|_S$, i.e., the restriction of π on the set S.

2.2 Clique width and k-expressions

The simplest way to introduce clique width of a graph is through k-expressions.

▶ **Definition 10.** *The following operators are defined on k-labeled graphs.*

- $\cdot_i$: *Construct a graph with one vertex, which is labeled $i \in [k]$.*
- $\rho_{i \to j}(\mathbb{G})$: *Relabel all vertices with label $i \in [k]$ of a k-labeled graph $\mathbb{G}$ to label $j \in [k]$.*
- $\eta_{ij}(\mathbb{G})$, *for $i \neq j$: Add an edge from every vertex labeled i to every vertex labeled j in $\mathbb{G}$, i.e. add edges uv for any vertices u, v where u has label i and v has label j.*
- $\mathbb{G}_1 \bigoplus \mathbb{G}_2$: *The disjoint union of k-labeled graphs $\mathbb{G}_1$ and $\mathbb{G}_2$.*

*A k-*expression *is any (properly formed) formula using the above operators.*

Every k-expression represents a k-labeled graph. We say that a graph $G = (V, E)$ is represented by k-expression Φ, if there exists a k-labeling π of the vertices of G such that Φ represents $\mathbb{G} = (V, E, \pi)$. A graph has clique width *k if k is minimal so that the graph is represented by a k-expression. The class of all graphs of clique width at most k is denoted by $\mathcal{C}_k$.*

Wahlström in [23] used k-expressions of graphs to show that $\mathcal{C}_k$ is plain exponential. However, k-expressions suitable for his plain exponential algorithm must satisfy an extra condition. Let Φ be a k-expression representing a k-labeled graph $\mathbb{G}$. Note that any subexpression of Φ represents a subgraph of $\mathbb{G}$. We say that k-expression Φ is *safe* if for every its subexpression $\Phi_1 \bigoplus \Phi_2$ such that Φ_1, Φ_2 represent graphs $\mathbb{G}_1, \mathbb{G}_2$, respectively, the graph $\mathbb{G}_i$ equals $\mathbb{G}[V(\mathbb{G}_i)]$ for $i = 1, 2$. In other words all edges of $\mathbb{G}$ between vertices of $\mathbb{G}_i$, $i = 1, 2$, are already edges of $\mathbb{G}_i$.

▶ **Lemma 11** ([23]).

(1) *Every graph of clique width k can be represented by a safe k-expression.*

(2) *A safe k-expression for a graph of clique width k can be found in plain exponential time.*

A class $\mathcal{G}$ of graphs has bounded clique width if $\mathcal{G} \subseteq \mathcal{C}_k$ for some k. Classes of bounded clique width include cliques, cographs, and distance-hereditary graphs [12, 4]. We will also be interested in nice graph classes that do not have bounded clique width. These include classes Hypercubes of hypercubes, Grids of rectangular grids, and subdivisions of cliques $\mathcal{K}(\mathcal{H})$ (introduced in Section 1) [20, 3].

3 Extended clique width

3.1 Extended k-expressions

In this section we introduce a more general version of k-expressions, and accordingly a more general version of clique width. New k-expressions require two more operators on k-labeled graphs. The first one does not have analogues in k-expressions. Let $\mathbb{G}$ be a k-labeled graph and r a positive integer parameter. The idea behind the *inflation* operator is the following. For each vertex v of $\mathbb{G}$ we add up to r new copies of v. The set of new copies of v depends only on the label of v, and is given by the vector $\overrightarrow{M}$ defined below. Let $v_{i_1}, \dots, v_{i_\ell}$ be the added copies of v, and v itself is considered as v_0. Next, some new edges are introduced: whether or not edge $v_i w_j$ is added depends only on whether $vw \in V(\mathcal{G})$, the labels of v, w, and the numbers i, j. These connections are given by the set $\mathcal{S}$ defined below. Finally, the new copies obtain labels, and the label of v_i only depends on the label of v in $\mathbb{G}$ and i. This step is governed by the vector $\overrightarrow{\sigma}$ in the definition below.

We now proceed to a formal definition. Fix natural k, r. By $\overrightarrow{M}$ we denote a vector $(M_1, \dots, M_k)$ where each M_i is a subset of $[[r]]$ containing 0. For such a vector $\overrightarrow{M}$, let

$$\mathcal{L}(\overrightarrow{M}) = \{(i_1, j_1, i_2, j_2) \mid i_1, i_2 \in [k], j_1 \in M_{i_1}, j_2 \in M_{i_2}\}.$$

▶ **Definition 12.** *Let $\overrightarrow{M} = (M_1, \dots, M_k)$, $\{0\} \subseteq M_i \subseteq [[r]]$ for $i \in [k]$, $\sigma_j : [k] \to [k]$ for $j \leq [[r]]$, where σ_0 is the identity mapping, and $\mathcal{S} \subseteq \mathcal{L}(\overrightarrow{M})$. Also, $\mathcal{S}$ is required to be a symmetric set, that is, if $(i_1, j_1, i_2, j_2) \in \mathcal{S}$ then $(i_2, j_2, i_1, j_1) \in \mathcal{S}$. Operator $\beta_{\overrightarrow{M}, \overrightarrow{\sigma}, \mathcal{S}}$ transforms a k-labeled graph $\mathbb{G} = (V, E, \pi)$ to a k-labeled graph $\mathbb{G}' = (V', E', \pi')$ as follows:*

- *$V' = \bigcup_{i=1}^{k} C_i$, where $C_i = \{a_j | j \in M_i,\ a \in V \text{ and } \pi(a) = i\}$. The vertices a_0, $a \in V$, are called original vertices of $\mathbb{G}' = \beta_{\overrightarrow{M}, \overrightarrow{\sigma}, \mathcal{S}}(\mathbb{G})$ and are identified with their corresponding vertices from V;*
- *$a_j b_{j'} \in E'$ if and only if $ab \in E$, and $(\pi(a), j, \pi(b), j') \in \mathcal{S}$ or $j = j' = 0$;*
- *$\pi'(a_j) = \sigma_j(\pi(a))$*

The second operator combines disjoint union with a sequence of adding edges operators.

▶ **Definition 13.** *Let $\mathcal{T} \subseteq [k] \times [k]$. Operator $\eta_{\mathcal{T}}$ takes two k-labeled graphs as input and produces a k-labeled graph as output. For k-labeled graphs $\mathbb{G}_1 = (V_1, E_1, \pi_1)$, and $\mathbb{G}_2 = (V_2, E_2, \pi_2)$, V_1, V_2 disjoint, the k-labeled graph $\eta_{\mathcal{T}}(\mathbb{G}_1, \mathbb{G}_2) = (V, E, \pi)$, is defined as follows:*

- *$V = V_1 \cup V_2$;*
- *$E = E_1 \cup E_2 \cup \{(a, b) \mid a \in V_1, b \in V_2, \pi_1(a) = i, \pi_2(b) = j,\ (i, j) \in \mathcal{T}\}$;*
- *$\pi(a) = \pi_1(a)$ if $a \in V_1$ and $\pi(a) = \pi_2(a)$ if $a \in V_2$.*

We refer to this operator as the connect operator.

An *extended* (k, r)*-expression* is a (properly formed) expression that involves operators $\cdot_i$ $(i \in [k])$, $\rho_{i \to j}$ $(i, j \in [k])$, $\beta_{\overrightarrow{M}, \overrightarrow{\sigma}, \mathcal{S}}$, and $\eta_{\mathcal{T}}$, where $\overrightarrow{M}, \overrightarrow{\sigma}, \mathcal{S}, \mathcal{T}$ are as in Definitions 12, 13. Similar to k-expressions, extended (k, r)-expressions represent k-labeled graphs, as well as usual graphs. For an example of extended (k, r)-expression see the construction of hypercubes in Section 3.2.

Note that if $\mathbb{G}_1$ and $\mathbb{G}_2$ are two isomorphic k-labeled graphs, and $\mathbb{G}_1$ is represented by an extended (k, r)-expression Φ, then Φ is an extended (k, r)-expression representing $\mathbb{G}_2$ as well.

A graph $G = (V, E)$ is said to have *extended clique width* (k, r) if the pair (k, r) is minimal such that there is a k-labeling π of G and an extended (k, r)-expression Φ that represents $\mathbb{G} = (V, E, \pi)$. If such a π exists we also say that Φ represents G. Note that an extended clique width of a graph is not unique, as pairs of numbers can be incomparable. However, for our purposes it will usually be enough to assume that $k = r$: just replace both parameters with $\max(k, r)$. The class of all graphs of extended clique width at most (k, r) is denoted by $\mathcal{X}_{k,r}$. A class $\mathcal{G}$ of graphs has bounded extended clique width if $\mathcal{G} \subseteq \mathcal{X}_{k,k}$ for some k.

The connect operator is clearly a substitute for the operator η_{ij} from Definition 10 of clique width. In particular, graphs of extended clique width $(k, 0)$ are very close to graphs of clique width k.

▶ **Proposition 14.** *Any graph G that can be represented by a k-expression, can also be represented by an extended $(k,0)$-expression. Therefore, $\mathcal{C}_k \subseteq \mathcal{X}_{k,0}$, that is, every graph that has clique width k also has extended clique width at most $(k,0)$.*

As is easily seen, the connect operator can be expressed through disjoint union and adding edges. However, we will need properties similar to the safety of k-expressions. Unfortunately, the inflation operator does not allow for an equally clean and easy definition of safety, as in the case of k-expressions, and we use the connect operator instead.

Let $\mathbb{G} = \eta_{\mathcal{T}}(\mathbb{G}_1, \mathbb{G}_2)$. It is straightforward from the definition that $\mathbb{G}[V(\mathbb{G}_1)]$ is equal to $\mathbb{G}_1$ and $\mathbb{G}[V(\mathbb{G}_2)]$ is equal to $\mathbb{G}_2$, that is, $\eta_{\mathcal{T}}$ does not add edges inside $\mathbb{G}_1, \mathbb{G}_2$. Also, if $\mathbb{G} = \beta_{\overrightarrow{M},\overrightarrow{\sigma},\mathcal{S}}(\mathbb{G}_1)$, then again $\mathbb{G}[V(\mathbb{G}_1)]$ is equal to $\mathbb{G}_1$. Similar to k-expressions we say that an extended (k,r)-expression Φ is *safe* if for each of its subexpressions $\eta_{\mathcal{T}}(\Phi_1, \Phi_2)$ and $\beta_{\overrightarrow{M},\overrightarrow{\sigma},\mathcal{S}}(\Phi_1)$ such that Φ_1, Φ_2 represent graphs $\mathbb{G}_1, \mathbb{G}_2$, respectively, it holds $\mathbb{G}_i = \mathbb{G}[V(\mathbb{G}_i)]$ for $i = 1, 2$. The following property is straightforward.

▶ **Lemma 15.** *Any extended (k,r)-expression is safe.*

An extended (k,r)-expression representing G (if one exists) can be found in plain exponential time.

▶ **Theorem 16.** *There is an algorithm running in time $O^*((4\max(k,r)+4)^{|V(G)|})$ that given a graph G outputs an extended (k,r)-expression for G if one exists, or reports "NO" otherwise.*

Proof (Sketch). One of the ingredients of our algorithm is the problem of deciding whether two k-labeled graphs are isomorphic. k-labeled graphs $\mathbb{G} = (V_1, E_1, \pi_1), \mathbb{H} = (V_2, E_2, \pi_2)$ are isomorphic if there exists an isomorphism φ from the graph $G = (V_1, E_1)$ to $H = (V_2, E_2)$ such that $\pi_1(a) = \pi_2(\varphi(a))$ for $a \in V_1$. We show that this problem can be reduced to the ordinary Graph Isomorphism problem and use the celebrated result by Babai [1] that there is an algorithm that, given graphs G and H, decides whether there exists an isomorphism between G and H in time $O(2^{\log(|V(G)|)^{O(1)}})$.

▶ **Lemma 17.** *There is a polynomial time reduction from the problem of deciding the isomorphism of k-labeled graphs to Graph Isomorphism.*

We now describe the main part of the algorithm. Create an array N of size $(k+1)^n$ whose entries $N(\mathbb{G}')$ are labeled with a k-labeling $\mathbb{G}'$ of a subgraph G' of G. For every entry $N(\mathbb{G}')$ the k-labeled graph $\mathbb{G}'$ either has an extended (k,r)-expression or it does not. The goal is to set the value of each entry $N(\mathbb{G}')$ to some extended (k,r)-expression for $\mathbb{G}'$ if it has one and to "no" otherwise. Then either for some labeling $\mathbb{G}$ of G the entry $N(\mathbb{G})$ contains a (k,r)-expression for G, or G does not have extended clique width at most (k,r).

Now we consider more detailed possibilities for each $\mathbb{G}'$. There are four cases. Case 1 takes place if $\mathbb{G}'$ has an extended (k,r)-expression that ends with an inflation operator; Case 2 takes place if $\mathbb{G}'$ has an extended (k,r)-expression that ends with a connect operator; Case 3 takes place if $\mathbb{G}'$ has an extended (k,r)-expression that ends with a sequence of relabeling operators; and, finally, Case 4 takes place if $\mathbb{G}'$ does not have an extended (k,r)-expression.

All one-element k-labeled graphs are obviously represented by an extended (k,r)-expression. Let us suppose the values of each entry $N(\mathbb{G}')$, where $\mathbb{G}'$ contains at most $n-1$ vertices is set correctly. Then, we want to set the correct values for entries of the array whose associated k-labeled graph has exactly n vertices. We use the dynamic programming approach that consists of two phases. In Phase 1, for each entry $N(\mathbb{G}')$ such that $\mathbb{G}'$ has n vertices, we check if $\mathbb{G}'$ satisfies the conditions of Case 1. Then for each k-labeled graph like this that does not satisfy the conditions of Case 1 we check if it falls in Case 2. In Phase 2, by relabeling $\mathbb{G}'$ for which $N(\mathbb{G}')$ is assigned a value, we find a new extended (k,r)-expression for $\mathbb{G}'$ that do not satisfy the conditions of Cases 1 and 2, but satisfy the conditions of Case 3. In the end, for each $\mathbb{G}'$ that belongs to none of Cases 1, 2, or 3, we set the value $N(\mathbb{G}')$ to "no" because it does not have an extended (k,r)-expression. In the rest of this proof, for a k-labeled graph $\mathbb{G}'$, we show how to check if it satisfies the conditions of each of Cases 1 and 2.

Let $\mathbb{G}' = (V', E', \pi')$ be a k-labeled graph with $|V'| = n$ and it has an extended (k,r)-expression that ends with an inflation operator. Then there is an induced subgraph $\mathbb{G}'_1$ of $\mathbb{G}'$ such that the result of application of an inflation operator to $\mathbb{G}'_1$ is isomorphic to $\mathbb{G}'$, and $\mathbb{G}'_1$ has an extended (k,r)-expression. Thus, there exist $\sigma_i : [k] \to [k]$, $i \in [[r]]$, $\overrightarrow{M}$, $M_i \subseteq [[r]]$, $i \in [k]$, $\mathcal{S} \subseteq \mathcal{L}(\overrightarrow{M})$, and a set $V'_1 \subset V'$, such that

(A) $\mathbb{G}'_2 = (V'_2, E'_2, \pi'_2) = \beta_{\overrightarrow{M},\overrightarrow{\sigma},\mathcal{S}}(\mathbb{G}'[V'_1])$ is isomorphic to $\mathbb{G}'$, and

(B) $\mathbb{G}'[V'_1]$ has an extended (k,r)-expression.

Conversely, if there exist $V'_1 \subset V'$, $\sigma_i : [k] \to [k]$, $i \in [[r]]$, $\overrightarrow{M}$, $M_i \subseteq [[r]]$, $i \in [k]$, $\mathcal{S} \subseteq \mathcal{L}(\overrightarrow{M})$ satisfying conditions (A),(B), then $\mathbb{G}'_2$ has an extended (k,r)-expression that ends with an inflation operator. As $\mathbb{G}'_2$ and $\mathbb{G}'$ are isomorphic, $\mathbb{G}'$ has an extended k-expression that ends with an inflation operator as well. Thus, the sufficient and necessary conditions for $\mathbb{G}'$ to have an extended (k,r)-expression that ends with an inflation operator, is that there exist $V'_1 \subset V'$, $\sigma_i : [k] \to [k]$, $i \in [[r]]$, $\overrightarrow{M}$, $M_i \subseteq [[r]]$, $i \in [k]$, $\mathcal{S} \subseteq \mathcal{L}(\overrightarrow{M})$ satisfying (A),(B).

The algorithm now searches through all possible selection of V'_1, $\overrightarrow{\sigma}$, $\mathcal{S}$, to check if conditions (A),(B) satisfied for any of them. Let us evaluate the running time of this procedure. Checking condition (A) takes time $O(2^{log((k+2)n)^{O(1)}})$ by Lemma 17, while condition (B) can be verified by looking up the existing entry $N(\mathbb{G}'[V'_1])$ in $O(1)$ time. There are 2^n choices for V'_1 and k^{rk} choices for $\overrightarrow{\sigma}$. Vector $\overrightarrow{M}$ can be chosen in 2^{rk} ways, and so $\mathcal{L}(\overrightarrow{M})$ has at most $2^{2rk}k^2$ elements. Thus, $\mathcal{S}$ can be chosen in at most $2^{2^{2rk}k^2}$ ways. Thus, the total running time of filling up $N(\mathbb{G}')$ in this case is upper bounded by

$$2^{|V(G)|} \times k^{rk} \times 2^{2rk}k^2 \times 2^{2^{2rk}k^2} \times O(2^{log((k+2)n)^{O(1)}}) = O^*(2^{2|V(G)|}).$$

Now let us suppose that $\mathbb{G}' = (V', E', \pi')$ has an extended (k,r)-expression that ends with a connect operator. Then due to the safety of extended (k,r)-expressions there exist two induced subgraphs $\mathbb{G}'_1$ and $\mathbb{G}'_2$ of $\mathbb{G}'$ such that, first, they both are represented by extended (k,r)-expressions, and, second, there is $\mathcal{T} \subseteq [k]^2$, such that $\eta_{\mathcal{T}}(\mathbb{G}'_1, \mathbb{G}'_2)$ is identical to $\mathbb{G}'$. Thus to find an extended (k,r)-expression for $\mathbb{G}'$ it suffices to go through all partitions of V' into sets V'_1 and V'_2 and for each partition check the following two conditions. First, check if $\mathbb{G}'_1 = \mathbb{G}'[V'_1]$ and $\mathbb{G}'_2 = \mathbb{G}'[V'_2]$ have an extended (k,r)-expression by looking up the entries $N(\mathbb{G}'_1), N(\mathbb{G}'_2)$. Second, check if there is $\mathcal{T} \subseteq [k]^2$ such that $\eta_{\mathcal{T}}(\mathbb{G}'_1, \mathbb{G}'_2)$ is identical to $\mathbb{G}$. Since there are at most $2^{|V(G)|}$ ways to partition V' into V'_1 and V'_2, takes time $O(2^{|V(G)|})$ to check if $\mathbb{G}'$ falls into Case 2.

So far we have registered an extended (k,r)-expression for every $\mathbb{G}'$ that satisfies the conditions of Case 1 or Case 2. Now, start Phase 2 and check whether any of the remaining k-labeled graphs $\mathbb{G}'$ satisfies the conditions of Case 3. In order to do that we go through all k-labeled graphs $\mathbb{G}'$ with n vertices and such that $N(\mathbb{G}')$ contains an extended (k,r)-expression Φ, that is initially for all $\mathbb{G}'$ that fall into Cases 1,2. Then we consider every possible relabeling ρ_{ij} in turn. If $\rho_{ij}(\mathbb{G}')$ is a k-labeled graph such that $N(\mathbb{G}')$ does not have an extended (k,r)-expression, then we set $N(\rho_{ij}(\mathbb{G}')) = \rho_{ij}(\Phi)$. We repeat this process for each k-labeled graph $\mathbb{G}'$, until no new entries can be filled. The time required for Phase 2 in total, for all $\mathbb{G}'$, not only those with n vertices is bounded by number of all k-labelings of all subgraphs of G times the number of possible operators ρ_{ij}. As is easily seen, the time required for Phase 2 in total is

$$(k+1)^{|V(G)|} \times k^2 = O^*((k+1)^{|V(G)|})$$

Time complexity: The array we construct has $(k+1)^{|V(G)|}$ entries. The time required to complete Phase 1 for all the entries is bounded by $O^*(4^{|V(G)|} \times (k+1)^{|V(G)|})$. The time to complete Phase 2 for all entries is bounded by $O^*((k+1)^{|V(G)|})$. Thus the total running time is $O^*((4k+4)^{|V(G)|})$. ◀

Next we explore what kind of graphs and k-labeled graphs can be represented by extended (k,r)-expressions.

3.2 Graph classes of bounded extended but not regular clique width

In this section we show that not all graphs of bounded extended clique width also have bounded clique width. Specifically, we consider the classes Hypercubes of hypercubes, Grids of rectangular grids, and $\mathcal{K}(\mathcal{H})$ of sudivisions of cliques by graphs from a class $\mathcal{H}$. All these classes have unbounded clique width, as mentioned in Section 2.2.

▶ **Theorem 18.**
(1) Hypercubes *has extended clique width at most (2,1).*
(2) Grids *has extended clique width at most (6,1).*
(3) *If $\mathcal{H}$ is a class of graphs of extended clique width (k,r), then $\mathcal{K}(\mathcal{H})$ has extended clique width at most $(k+5, \max(r,1))$.*

Proof. We present extended (2,1)-expressions for hypercubes and extended (6,1)-expressions for grids. Extended expressions for subdivide cliques are more involved, and the reader is referred to the full version of the paper [7].

(1) Let HC_n denote an n-dimensional hypercube. An extended (2,1)-expression Φ_n representing HC_n is constructed by induction on the dimensionality of the hypercube. The base cases of induction are HC_0 and HC_1. An extended (2,1)-expression for HC_0 is $\cdot_1$, and an extended (2,1)-expression for HC_1 is $\eta_{\{(1,2)\}}(\cdot_1, \cdot_2)$.

Suppose that for $m \le n$ the graph HC_m has an extended (2,1)-expression. Let Φ_n be an extended (2,1)-expression for HC_n. Let $\overrightarrow{M} = (\{0,1\},\{0,1\})$, let σ_0 be the identity mapping on [2], let $\sigma_1 : [2] \to [2]$ be given by $\sigma_1(1) = 2, \sigma_1(2) = 1$, and let $\mathcal{S} = \{(1,1,1,1),(2,1,2,1),(1,1,2,1),(2,1,1,1),(1,0,2,1),(2,1,1,0),(2,0,1,1),(1,1,2,0)\}$. Then it is not hard to see that $\beta_{\overrightarrow{M},\vec{\sigma},\mathcal{S}}\Phi_n$ is an extended (2,1)-expression for HC_{n+1}.

(2) Let us denote the vertex set of an $n \times m$-grid by $G_{n,m} = [n] \times [m]$. We proceed by induction on n, m. First, observe that a 2×2-grid labeled in an arbitrary way with 4 labels can be represented by a 4-expression in a straightforward manner. We choose the labeling π_{22} of $G_{2,2}$ given by $\pi_{22}(1,1) = 1, \pi_{22}(2,1) = 2, \pi_{22}(2,1) = 3, \pi_{22}(2,2) = 4$.

Next, we construct a 6-expression (not an extended one) for a $2 \times m$-grid labeled in a specific way. The labeling π'_{2m} of $G_{2,m}$ we achieve is given by $\pi'_{2m}(1,1) = \cdots = \pi'_{2m}(1,m-1) = 1$, $\pi'_{2m}(2,1) = \cdots = \pi'_{2m}(2,m-1) = 2$, $\pi'_{2m}(1,m) = 3$, $\pi'_{2m}(2,m) = 4$. Suppose we have constructed a 6-expression representing a $2 \times (m-1)$-grid labeled this way. Then add vertices $(1,m)$ and $(2,m)$ labeled 5 and 6, respectively, and apply operators $\eta_{53}, \eta_{56}, \eta_{64}$, and $\rho_{3\to1}, \rho_{4\to2}, \rho_{5\to3}, \eta_{6\to4}$. It is straightforward that the resulting labeled graph is a $2 \times m$-grid labeled in the required way.

Now starting with the labeled $2 \times m$-grid constructed in the previous step we show by induction that a $n \times m$-grid with labeling π_{nm} can be represented by an extended (4,1)-expression, where π_{nm} is given by $\pi_{nm}(i,j) = 3$ for $i \leq n-2$ and $j \in [m]$, $\pi_{nm}(n-1,j) = 1, \pi_{nm}(n,j) = 2$ for $j \in [m]$. The base case for induction, the grid $G_{2,m}$ labeled with π_{2m} can be obtained from the labeled grid constructed in the previous paragraph by applying operators $\rho_{3\to1}$ and $\rho_{4\to2}$. Suppose that an extended (4,1)-expression representing $G_{n-1,m}$ labeled with π_{n-1m} exists. For the induction step we consider inflation operator with the following parameters: $k = 4$, $r = 1$, $\overrightarrow{M} = (\{0,1\},\{0\},\{0\},\{0\})$, $\mathcal{S} = \{(1,1,2,0),(2,0,1,1),(1,1,1,1)\}$, σ_0 is the identity mapping on [4] and $\sigma_1(i) = i$, except $\sigma_1(1) = 4$. The operator $\beta_{\overrightarrow{M},\overrightarrow{\sigma},\mathcal{S}}$ applied to $G_{n-1,m}$ labeled with π_{n-1m} works as follows: it creates an extra copy of each vertex with label 1, that is, of $n-2$-nd row, and connects each new vertex a_1 to every vertex with label 2, a is connected to. In other words, if $a = (n-2,i)$, then a_1 plays the role of (n,i) and is properly connected to the only vertex with label 2 vertex $(n-2,i)$ is connected to, that is, $(n-1,i)$. Also, $\beta_{\overrightarrow{M},\sigma,\mathcal{S}}$ connects vertices $(n,i),(n,i+1)$. Finally, the vertices of the form (n,i) are assigned label 4. In order to obtain a grid labeled with π_{nm} it suffices to apply operators $\rho_{1\to3}$, $\rho_{2\to1}$ and $\rho_{4\to2}$. ◀

4 Counting homomorphism to labeled graphs given an extended k-expression

In this section we prove our main result.

▶ **Theorem 19.** *Let G and H be two graphs, and let k-labeled graph $\mathbb{H}$ be a k-labeling of graph H. Given an extended (k,r)-expression Φ for $\mathbb{H}$,* $\mathsf{hom}(G,H)$ *can be found in time $O^*((2(\max(k,r)+1))^{2|V(G)|})$*

The following notation and terminology will be used throughout this section. Let $\mathsf{HOM}(G,H)$ denote the set of all homomorphisms from G to H. Let $X \subseteq V(G)$, and let $\chi : X \to [k]$ be a label function. A mapping φ from X to k-labeled graph $\mathbb{H} = (V,E,\pi)$ is said to be consistent with χ if for every $x \in X$ it holds $\pi(\varphi(x)) = \chi(x)$. Let $\mathsf{hom}_\chi(G[X],\mathbb{H})$, $\mathsf{HOM}_\chi(G[X],\mathbb{H})$, $\mathsf{map}_\chi(G[X],\mathbb{H})$, and $\mathsf{MAP}_\chi(G[X],\mathbb{H})$, denote the number of homomorphisms from $G[X]$ to $\mathbb{H}$ consistent with χ, the set of all homomorphisms from $G[X]$ to $\mathbb{H}$ consistent with χ, the number of all mappings from $G[X]$ to $\mathbb{H}$ consistent with χ, and the set of all mappings from $G[X]$ to $\mathbb{H}$ consistent with χ, respectively.

Observing that an extended (k,r)-expression can be naturally viewed as an extended $(\max(k,r),\max(k,r))$-expression, in what follows we assume $k = r$. Let Φ be an extended (k,k)-expression for a k-labeling $\mathbb{H}$ of the graph H. We proceed by induction on the structure of Φ. More precisely, our algorithm will compute entries of an array $\mathsf{hom}(\mathbb{G}[X],\mathbb{H}')$, where $X \subseteq V(G)$ and $\mathbb{G}[X]$ is a k-labeling of $G[X]$, and $\mathbb{H}'$ is the k-labeled graph represented by a subexpression of Φ. Since the labeling of $\mathbb{H}'$ is important in this inductive process, we also cannot avoid labeling the graph $\mathbb{G}$. Operator $\cdot_i$ creating a graph $\mathbb{H}'$ with a single vertex labeled i gives the base case of induction. In this case $\mathsf{hom}(\mathbb{G}[X],\mathbb{H}') = 1$ if all vertices of X are labeled i and $\mathbb{G}[X]$ has no edges; otherwise $\mathsf{hom}(\mathbb{G}[X],\mathbb{H}') = 0$. Finally, after computing the numbers $\mathsf{hom}(\mathbb{G},\mathbb{H})$ for all the k-labelings $\mathbb{G}$ of G, we complete using the following observation.

▶ **Observation 20.** *Let G and H be graphs, and let k-labeled graph $\mathbb{H}$ be a k-labeling of H. Then*

$$\mathsf{hom}(G,H) = \sum_{\chi:V(G)\to[k]} \mathsf{hom}_\chi(G,\mathbb{H})$$

It therefore suffices to show how to compute $\mathsf{hom}(\mathbb{G}[X], \mathbb{H}')$, where $\mathbb{G}[X]$ is an arbitrary k-labeling of $G[X]$, $X \subseteq V(G)$, and $\mathbb{H}'$ is represented by a subexpression Φ' of Φ, provided $\mathsf{hom}(\mathbb{G}[Y], \mathbb{H}'')$ is known for all $Y \subset X$, all labelings $\mathbb{G}[Y]$ of $G[Y]$, and $\mathbb{H}''$ represented by a subexpression Φ'' of Φ' with $\Phi'' \neq \Phi'$. We consider 3 cases depending on the last operator of Φ'. In the cases of the relabeling and connect operators the argument is similar to that for k-expressions. Here we only consider the inflation operator.

4.1 Inflation operator

In this part, we show how to make a recursive step in the case when the last operator of Φ' is an inflation operator. Before explaining this step, we need several definitions.

A *retraction* is a homomorphism ψ from a graph G_2 to its subgraph G_1 such that $\psi(v) = v$ for each vertex v of G_1. In this case the subgraph G_1 is called a *retract* of G_2. A retraction from a k-labeled graph $\mathbb{G}_2 = (V_2, E_2, \pi_2)$ to a k-labeled graph $\mathbb{G}_1 = (V_1, E_1, \pi_1)$ is defined to be a retraction from $G_2 = (V_2, E_2)$ to $G_1 = (V_1, E_1)$ preserving the label function π_2, that is, $\pi_2(v) = \pi_1(\psi(v))$ for all $v \in V_2$.

It will be convenient for us to subdivide operator $\beta_{\overrightarrow{M},\overrightarrow{\sigma},\mathcal{S}}$ into two steps: the first one is expansion of the original graph using $\overrightarrow{M}$ and $\mathcal{S}$, and the second is relabeling of some vertices of the resulting graph using $\overrightarrow{\sigma}$. More specifically, let $\mathbb{H} = (V, E, \pi)$ be a k-labeled graph, $\overrightarrow{M}$, $M_i \subseteq [[k]]$ for $i \in [k]$ (recall that we assume $k = r$), $\mathcal{S} \subseteq \mathcal{L}(\overrightarrow{M})$, and $\sigma_i : [k] \to [k]$, $i \in [[k]]$. Then $\mathbb{H}' = (V', E', \pi') = \alpha_{\overrightarrow{M},\mathcal{S}}(\mathbb{H})$ is given by

- $V' = \bigcup_{i=1}^{k} C_i$, where $C_i = \{a_j | j \in M_i,\ a \in V \text{ and } \pi_1(a) = i\}$. The vertices a_0, $a \in V$, are called original vertices of $\mathbb{H}' = \alpha_{\overrightarrow{M},\mathcal{S}}(\mathbb{H})$ and are identified with their corresponding vertices from V;
- $(a_j, b_{j'}) \in E'$ if and only if $(a, b) \in E$, and $(\pi(a), j, \pi(b), j') \in \mathcal{S}$ or $j = j' = 0$;
- $\pi'(a_j) = \pi(a)$.

Then, $\mathbb{H}'' = (V'', E'', \pi'') = \beta_{\overrightarrow{M},\overrightarrow{\sigma},\mathcal{S}}(\mathbb{H})$, that is, $V'' = V'$, $E'' = E'$, and $\pi''(a_j) = \sigma_j(\pi(a))$ for $a \in V''$ and $j \in M_{\pi(a)}$.

As is easily seen, $\mathbb{H}$ is an induced subgraph of $\mathbb{H}'$, and a retract. Indeed, the mapping μ that maps every $a_j \in V(\mathbb{H}')$ to a (recall that a_j is a "copy" of some $a \in V(\mathbb{H})$) is a retraction.

The objective is to find a method to express the number of homomorphisms from induced subgraphs of G to $\mathbb{H}''$ given those from induced subgraphs of G to $\mathbb{H}$.

▶ **Lemma 21.** *Let $Y \subseteq V(G)$ and let γ be a function $Y \to [k]$. There is an algorithm that given $\mathsf{hom}_\zeta(G[X], \mathbb{H})$ for all functions ζ from a subset $X \subset Y$ to $[k]$ as input, finds $\mathsf{hom}_\gamma(G[Y], \mathbb{H}'')$ in time $O((2(k+1))^{|V(G)|})$.*

We break this down into two steps. The main result of Step I, which is summarized in Lemma 22, finds an equality for the number of homomorphisms from G to $\mathbb{H}'$. Then, the result for Step II analogous to Lemma 22 finds the number of homomorphisms from induced subgraphs of G to $\mathbb{H}''$ given those for G and $\mathbb{H}'$. As Step II is substantially simpler than Step I, we omit it here.

Step I

Let $\mathbb{H}' = (V', E', \pi') = \alpha_{\overrightarrow{M},\mathcal{S}}(\mathbb{H})$ and $\mathbb{H} = (V, E, \pi)$. Let Y be a subset of $V(G)$ and γ a function $Y \to [k]$. Also, set

$$\mathbb{W}(\gamma) = \{\omega |\ \omega : Y \to [[k]] \text{ and } \forall a \in Y,\ \omega(a) \in M_{\gamma(a)}\}.$$

For $\omega \in \mathbb{W}(\gamma)$, let

$$\mathsf{HOM}_\gamma(G[Y], \mathbb{H}', \omega) = \{\varphi \mid \ \varphi \in \mathsf{HOM}_\gamma(G[Y], \mathbb{H}') \text{ and } \forall a \in Y, \exists b \in V(\mathbb{H}) \ \text{ s. t. } \varphi(a) = b_{\omega(a)}\}.$$

For the rest of Step I, let X' and X'' be two disjoint subsets of $V(G)$ and let $\chi' : X' \to [k]$ and $\chi'' : X'' \to [k]$ be arbitrary functions. Also let $X = X' \uplus X''$ and let $\chi = \chi' \uplus \chi''$.

Let $\mathsf{HOM}_{\chi',\chi''}(G[X], \mathbb{H}')$ denote the set of all elements of $\mathsf{HOM}_\chi(G[X], \mathbb{H}')$ that map a vertex a from X to an original vertex of $\mathbb{H}'$ (recall that any vertex of $\mathbb{H}$ is called an original vertex of $\mathbb{H}'$) if and only if $a \in X'$.

For any $\varphi \in \mathsf{HOM}_{\chi',\chi''}(G[X], \mathbb{H}')$, there is a unique $\omega \in \mathbb{W}(\chi)$ such that φ is also an element of $\mathsf{HOM}_\chi(G[X], \mathbb{H}', \omega)$. Let us call ω the *consistent function* of φ. We then partition $\mathsf{HOM}_{\chi',\chi''}(G[X], \mathbb{H}')$ into smaller subsets and count the elements in each smaller subset. The partition splits $\mathsf{HOM}_{\chi',\chi''}(G[X], \mathbb{H}')$ into sets of homomorphisms that all share the same consistent function $\omega \in \mathbb{W}(\chi)$. As is easily seen, $\mathsf{HOM}_\chi(G[X], \mathbb{H}', \omega) \cap \mathsf{HOM}_{\chi',\chi''}(G[X], \mathbb{H}')$ is such a subset.

Let $\mathcal{B}(\chi', \chi'')$ be the set of all $\omega \in \mathbb{W}(\chi)$ such that ω satisfies the following properties:

(b.1) $\omega \in \mathbb{W}(\chi)$ and $\omega(x) = 0$ if and only if $x \in X'$.

(b.2) For every $a, b \in X$ such that at least one of them is not an element of X', and $ab \in E(G)$ it holds that $(\chi(a), \omega(a), \chi(b), \omega(b)) \in \mathcal{S}$.

Now, as the set of homomorphisms is subdivided into sufficiently small fragments, it is possible to show that the number of elements in $HOM_\chi(G[X], \mathbb{H}')$ such that ω is their consistent function is the same for any $\omega \in \mathcal{B}(\chi', \chi'')$ and it is zero otherwise.

▶ **Lemma 22.** *Let G, $\mathbb{H}$, $\mathbb{H}'$, X', X'', $X = X' \uplus X''$, χ', χ'', and $\chi = \chi' \uplus \chi''$ be defined as above, then*

$$|\mathsf{HOM}_{\chi',\chi''}(G[X], \mathbb{H}')| = |\mathcal{B}(\chi', \chi'')| \times \mathsf{hom}_\chi(G[X], \mathbb{H}).$$

To evaluate the running time of this procedure, note that the algorithm has to enumerate all possible partitions X', X'' of X, and all mappings that can be in $\mathbb{W}(\chi)$. Overall, it amounts to the number of mappings from X to a $k+1$ element set. The number of choices of X is $2^{|V(G)|}$. Thus the running time is bounded by $O((2(k+1))^{|V(G)|})$. Lemma 21 now follows from Lemma 22 and a similar result for Step II.

4.2 Putting pieces together

We are now in a position to prove Theorem 19.

Proof of Theorem 19. By Observation 20, $\mathsf{hom}(G, H)$ equals the sum of $\mathsf{hom}_\chi(G, \mathbb{H})$ over all k-label functions $\chi : V(G) \to [k]$. For each χ we need to compute $\mathsf{hom}_\chi(G, \mathbb{H})$. This computation is done through dynamic programming and requires finding all the numbers of the form $\mathsf{hom}_\chi(G[X], \mathbb{H}')$, where $X \subseteq V(G)$ and $\mathbb{H}'$ is a graph represented by a subexpression of Φ. By Lemma 21 and similar results for relabeling and connect operators computing each such value from the previous values takes $O((2k+1)^{|V(G)|})$ time. There are $k^{|V(G)|}$ label functions χ, and $2^{|V(G)|}$ subsets of $V(G)$. As the number of subexpressions of Φ introduces only a polynomial factor, the running time of the algorithm is $O^*((2(k+1)^{2|V(G)|})$. ◀

5 Beyond bounded extended clique width

In this section we study plain exponential classes that do not have bounded extended clique width. We start with showing that the class of all graphs with degrees less than a constant does not have bounded extended clique width, and how it can be combined with any plain exponential class to produce a new plain exponential class. Then we present two more plain exponential classes of graphs that so far not representable as derivatives of graph with bounded degree and/or bounded extended clique width.

5.1 Bounded degrees

To prove that some graph class does not have bounded extended clique width we first identify two nontrivial properties of graphs whose extended clique width is at most (k, k). Let G be a graph and $\mathcal{N}(v)$ denote the neighborhood of $v \in V(G)$. Also, let H be an induced subgraph of G, and $\mathcal{N}_H(v) = \mathcal{N}(v) \cap H$ for $v \in V(G)$.

▶ **Lemma 23.** *Let G be a connected graph and $|V(G)| = n$. If G has extended clique width at most (k, k) then the following two conditions hold:*

(1) *For any $\frac{k^2}{n} < \alpha \leq \frac{1}{2}$, there exists a subset $W \subseteq V(G)$ with $\frac{\alpha n}{k+1} \leq |W| \leq \alpha n$ such that there are at most 2^k subsets $U_1, \ldots, U_\ell$ of W with the following property: for every $v \in V(G) - W$ either $\mathcal{N}_H(v) = U_i$ for some $i \in [\ell]$, or $\mathcal{N}_H(v) = \mathcal{N}_H(w) \cap U_i$ for some $w \in V(H)$ and $i \in [\ell]$.*

(2) *If in addition the maximal degree of G is d, there is a constant $\delta(d, k)$ that only depends on d and k, such that for any β, $\delta(d, k) < \beta < \frac{1}{2}$, there are subsets $U \subseteq W \subseteq V$ such that $|W| \geq d|U|$, and $\frac{\beta n}{k+1} < |W| \leq \beta n$. Also, there is a partition Π of W into $|U|$ classes such that every vertex from $W - U$ only has neighbors in at most d blocks of Π.*

Then to prove that the class of all graphs whose degrees are bounded by a constant, does not have bounded extended clique width, we prove that a random d-regular graph does not satisfy the property from Lemma 23(2) with high probability, concluding that $\mathcal{D}_d$ does not have bounded extended clique width.

▶ **Lemma 24.** *Let $d > 3$. The probability that a random d-regular graph with n vertices satisfies the condition of Lemma 23(2) is $o(1)$.*

Classes of bounded degree can be combined with any plain exponential class to form another plain exponential class, as the following theorem shows. Let G_1 and G_2 be graphs. The *Cartesian product* of G_1 and G_2, denoted by $G_1 \square G_2$, is the graph whose vertex set is $V(G_1) \times V(G_2)$, and vertices (u_1, v_1) and (u_2, v_2) of $G_1 \square G_2$ are connected with an edge if and only if $u_1 = u_2$ and $v_1 v_2 \in E(G_2)$, or $v_1 = v_2$ and $u_1 u_2 \in E(G_1)$. For classes $\mathcal{G}, \mathcal{H}$ of graphs $\mathcal{G} \square \mathcal{H}$ denotes the class $\{G \square H \mid G \in \mathcal{G}, H \in \mathcal{H}\}$.

▶ **Theorem 25.** *If $\mathcal{D}$ is in plain exponential class of graphs and $\mathcal{B}$ has bounded degree, then $\mathcal{B} \square \mathcal{D}$ is also plain exponential.*

Proof. Let d be a bound on the degree of graphs from $\mathcal{B}$. Let $H = B \square D$, $B \in \mathcal{B}$, $D \in \mathcal{D}$, and let G be a graph. We are concerned with the number $\mathsf{hom}(G, H)$. Without loss of generality assume $V(B) = [r]$. Let P be a r-partition of $V(G)$. Then a mapping $h : V(G) \to V(H)$ is said to be consistent with P if for every $v \in V(G)$ such that $v \in P_i$ it holds $h(v) \in \{(i, e) | e \in V(D)\}$. In other words, h maps vertices of each set $P_i \in V(G)$ to vertices of the same copy of D in the Cartesian product.

Our algorithm will find a set $\mathcal{P}$ of r-partitions of $V(G)$ such that if a homomorphism $h : G \to H$ is consistent with an r-partition P, then $P \in \mathcal{P}$. Every r-partition can be viewed as a mapping from $V(G)$ to $V(B)$. Since B has degree at most d, partitions from $\mathcal{P}$ can be enumerated using a process similar to that in Example 7. Order the vertices $v_1, \dots, v_n$ of G in such a way that each vertex except for the first one is adjacent to one of the preceding vertices. Then a brute force algorithm is organized as follows: Assign images from $V(B)$ to $v_1, \dots, v_n$ in turn. Clearly, there are $V(B)$ possibilities to map v_1. Suppose that images from $V(B)$ are assigned to $v_1, \dots, v_{j-1}$ by a mapping $\pi : \{v_1, \dots, v_{j-1}\} \to V(B)$. We claim that there are just $d + 1$ possibilities to extend π on v_j if we want to keep the possibility that a homomorphism consistent with the obtained r-partition exists. By the choice of the order $v_1, \dots, v_n$, there is v_i, $i < j$, adjacent with v_j. It is possible to assing $\pi(v_j) = \pi(v_i)$. In this case a consistent homomorphism may map the edge v_iv_j to an edge of the form $(\pi(v_i), e_1)(\pi(v_i), e_2)$ for some $e_1e_2 \in E(D)$. Otherwise v_iv_j should be mapped to an edge of the form $(\pi(v_i), e)(\pi(v_j), e)$. In this case there are at most d possibilities for $\pi(v_j)$. Thus, the algorithm enumerates all the required r-partitions in time $O^*((d + 1)^n)$.

Now, let P be one of the r-partitions of $V(G)$ generated in the previous step. Let G'_P be a graph that is obtained by contracting every edge of $V(G)$ whose ends are in different blocks of P. We claim that $\mathsf{hom}(G'_P, D)$ is equal to the number of homomorphisms of G to $B\square D$ that are consistent with P.

Let $x \in V(G)$ and let $y \in V(G'_P)$. We use the notation $x \in y$, if y is the result of contraction of x with 0 or more other vertices of G. Also, the set of all homomorphism from G to $H = B\square D$ that are consistent with P is denoted by $HOM(P, G, H)$. We define a mapping φ from elements of $\mathsf{HOM}(G'_P, D)$ to elements of $\mathsf{HOM}(P, G, H)$ as follows: for every $h' \in \mathsf{HOM}(G'_P, D)$ set $\varphi(h') = h$, where h is given by $h(x) = (i, e)$, for $x \in P_i$ and $e = h'(y)$, $x \in y$.

We show that φ is bijective. First, we show that it is injective. If $h'_1, h'_2 \in \mathsf{HOM}(G'_P, D)$ are two different mappings, there is an element $y \in V(G'_P)$ such that $h'_1(y) \neq h'_2(y)$. Therefore, for every $x \in V(G)$ with $x \in y$, $\varphi(h'_1)(x) \neq \varphi(h'_2)(x)$.

Next we prove that φ is also surjective. We define a function $\varphi^{-1} : \mathsf{HOM}(P, G, H) \to \mathsf{MAP}(G'_P, E)$ such that $(\varphi^{-1} \circ \varphi)$ is the identity mapping. Then to complete the proof of surjectivity it only remains to show that the range of φ^{-1} is $\mathsf{HOM}(G'_P, D)$.

Note that for any homomorphism from G to H consistent with P, any $y \in V(G'_P)$, and any $w_1, w_2 \in y$, if $h(w_1) = (i, e)$, then $h(w_2) = (j, e)$ for some $j \in [r]$. We define φ^{-1} as follows. For $h \in \mathsf{HOM}(P, G, H)$ set $\varphi^{-1}(h) = h'$ such that h' is given by $h'(y) = e$, where y is such that for every $x \in y$, $h(x) = (j, e)$ for some $j \in [r]$.

It is straightforward that $(\varphi^{-1} \circ \varphi)$ is the identity function. Now observe that for any $y_1, y_2 \in V(G'_P)$ with $y_1y_2 \in E(G'_P)$ there are $x_1 \in y_1$ and $x_2 \in y_2$ such that $x_1x_2 \in E(G)$. Since y_1 and y_2 are not contracted in G'_P, x_1, x_2 are in the same block P_j of P for some $j \in [r]$. Therefore, $h(x_1) = (j, e_1)$, $h(x_2) = (j, e_2)$, and $e_1e_2 \in E(D)$. Hence $h'(y_1)h'(y_2) = e_1e_2$ is an edge of E. Thus, h' maps an edge of G to an edge of H, and it is a homomorphism. The surjectivity of φ follows.

Finally, since all the r-partitions of G for which there may exist a consistent homomorphism can be enumerated in plain exponential time, and $\mathsf{hom}(G'_P, D)$ can also be found in plain-exponential time for each such partition P, the overall algorithm runs in plain exponential time. ◀

5.2 Subdivided Cliques

Recall that the *subdivision* of an edge uv by a graph H is a graph with vertex set $V(H) \cup \{u, v\}$ and edge set $E(H) \cup \bigcup\limits_{t \in V(H)} \{ut, vt\}$. The subdivision of a graph G by a graph H is the graph obtained by replacing every edge uv of G with its subdivision by a copy of H (a disjoint copy for each edge). Let $\mathcal{K}(\mathcal{H})$ denote the class of subdivisions of cliques by graphs from a class $\mathcal{H}$.

The following theorem is the main result of this section.

▶ **Theorem 26.** *Let $\mathcal{H}$ be a plain exponential class of graphs. Then $\mathcal{K}(\mathcal{H})$ is also plain exponential.*

More precisely, if $\#\textsc{GraphHom}(-, \mathcal{H})$ can be solved in time $O^*(c^{|V(G)|+|V(H)|})$, c constant, for any given graphs G and $H \in \mathcal{H}$, then $\#\textsc{GraphHom}(-, \mathcal{K}(\mathcal{H}))$ can be solved in time $O^*(c_1^{2(|V(G)|+|V(H)|})$, where $c_1 = \max(c, 2)$.

Theorem 18(3) claims that if $\mathcal{H}$ is of bounded extended clique width, then so is $\mathcal{K}(\mathcal{H})$, and then that $\mathcal{K}(\mathcal{H})$ is plain exponential follows from Theorem 19. However, in Theorem 26 $\mathcal{H}$ does not have to be of bounded extended clique width.

5.3 Kneser Graphs

Kneser graphs give another example of a plain exponential class of graphs.

The *Kneser graph* $\mathrm{KG}_{n,k}$ is the graph whose vertex set is the set of k-element subsets of a set with n elements, and two vertices are adjacent if and only if the two corresponding sets are disjoint. By Kneser_k we denote the class of all Kneser graphs for a fixed k. The class Kneser_k is plain exponential, as it follows from the results of [2, 21]. Here we give an alternative algorithm for $\textsc{GraphHom}(-, \mathsf{Kneser}_k)$.

Let G be a graph, and $G^{(k)}$ denote the graph obtained by replacing each of its vertices with a clique of size k and replacing each of its edges with a complete bipartite graph on $k + k$ vertices. For $a \in V(G)$ let $\psi(a)$ denote the set of vertices of the clique replacing v in $G^{(k)}$.

First, we introduce a many to one correspondence between elements of $\mathsf{HOM}(G^{(k)}, K_n)$ and $\mathsf{HOM}(G, \mathrm{KG}_{n,k})$. Let $\tau : \mathsf{HOM}(G^{(k)}, K_n) \to \mathsf{HOM}(G, \mathrm{KG}_{n,k})$ be defined by setting $\tau(\varphi) : V(G) \to \mathrm{KG}_{n,k}$ to be the mapping $v \mapsto \{\varphi(u) | u \in \psi(v)\}$. Notice that the cardinality of $\{\varphi(u) | u \in \psi(v)\}$ equals k because $G^{(k)}[\psi(v)]$ is a k-clique and φ is a homomorphism from $G^{(k)}$ to K_n. Therefore $\tau(\varphi)(v)$ is always a vertex of $\mathrm{KG}_{n,k}$.

It can be shown that for $\varphi \in \mathsf{HOM}(G^{(k)}, K_n)$, $\tau(\varphi)$ is a homomorphism, and moreover for any element σ of $\mathsf{HOM}(G, \mathrm{KG}_{n,k})$, $\tau(\varphi) = \sigma$ for exactly $(k!)^{|V(G)|}$ homomorphisms $\varphi \in \mathsf{HOM}(G^{(k)}, K_n)$. Therefore

$$|\mathsf{HOM}(G, \mathrm{KG}_{n,k})| = \frac{\mathsf{HOM}(G^{(k)}, K_n)}{(k!)^{|V(G)|}}.$$

Since there is an algorithm that computes $\mathsf{hom}(G^{(k)}, K_n)$ in time $O^*(2^{k|V(G)|})$, there is an algorithm that computes $\mathsf{hom}(G, \mathrm{KG}_{n,k})$ in the same time.

▶ Remark 27. The running time of the algorithm above is not plain exponential if k is not a constant. Bonamy et al. [2] proved that the class $\mathsf{Kneser} = \bigcup_{k \in \mathbb{N}} \mathsf{Kneser}_k$ is not plain exponential unless the ETH fails.

Interestingly, the class of Kneser graphs does not have bounded extended clique width.

▶ **Theorem 28.** *The class* Kneser$_2$ *does not have bounded extended clique width.*

To prove this result we use the property of graphs with bounded extended clique width from Lemma 23 (1).

Abstract

Holant problems are intimately connected with quantum theory as tensor networks. We first use techniques from Holant theory to derive new and improved results for quantum entanglement theory. We discover two particular entangled states $|\Psi_6\rangle$ of 6 qubits and $|\Psi_8\rangle$ of 8 qubits respectively, that have extraordinary closure properties in terms of the Bell property. Then we use entanglement properties of constraint functions to derive a new complexity dichotomy for all real-valued Holant problems containing a signature of odd arity. The signatures need not be symmetric, and no auxiliary signatures are assumed.

1 Introduction

1.1 Holant problems

Holant problems are a broad class of sum-of-products computations. It generalizes other frameworks such as counting constraint satisfaction problems (#CSP) and counting graph homomorphisms (#GH). Both have been well studied and full complexity dichotomies have been established [9, 26, 7, 13, 11, 25, 8, 31, 12]. On the other hand, the understanding of Holant problems, even restricted to the Boolean domain, is still limited. In this paper, we focus on Holant problems defined over the Boolean domain.

Holant problems are parameterized by a set of constraint functions, also called signatures. A signature (over the Boolean domain) of arity $n > 0$ is a map $\mathbb{Z}_2^n \to \mathbb{C}$. Let $\mathcal{F}$ be any fixed set of signatures. A signature grid $\Omega = (G, \pi)$ over $\mathcal{F}$ is a tuple, where $G = (V, E)$ is a graph without isolated vertices, π labels each $v \in V$ with a signature $f_v \in \mathcal{F}$ of arity $\deg(v)$, and labels the incident edges $E(v)$ at v with input variables of f_v. We consider all 0-1 edge assignments σ, and each gives an evaluation $\prod_{v\in V} f_v(\sigma|_{E(v)})$, where $\sigma|_{E(v)}$ denotes the restriction of σ to $E(v)$.

▶ **Definition 1** (Holant problems). *The input to the problem* $\operatorname{Holant}(\mathcal{F})$ *is a signature grid* $\Omega = (G, \pi)$ *over* $\mathcal{F}$*. The output is the partition function*

$$\operatorname{Holant}_\Omega = \sum_{\sigma: E(G)\to\{0,1\}} \prod_{v\in V(G)} f_v(\sigma|_{E_{(v)}}).$$

Bipartite Holant problems $\operatorname{Holant}(\mathcal{F} \mid \mathcal{G})$ *are Holant problems over bipartite graphs* $H = (U, V, E)$*, where each vertex in* U *or* V *is labeled by a signature in* $\mathcal{F}$ *or* $\mathcal{G}$ *respectively. We say* $\mathcal{F}$ *is on the left hand side* (LHS) *and* $\mathcal{G}$ *is on the right hand side* (RHS)*.*

Weighted #CSP is a special class of Holant problems. So are all weighted #GH. Other problems expressible as Holant problems include counting matchings and perfect matchings [43], counting weighted Eulerian orientations [38, 15], computing the partition functions of six-vertex models [41, 16] and eight-vertex models [4, 14], and a host of other vertex models from statistical physics [5]. It is proved that counting perfect matchings cannot be expressed by #GH [28, 17]. Thus, Holant problems are provably more expressive.

Progress has been made in the complexity classification of Holant problems. When all signatures are restricted to be symmetric, a full dichotomy is proved [18]. When asymmetric signatures are allowed, some dichotomies are proved for special families of Holant problems by assuming that certain auxiliary signatures are available, e.g., Holant^*, Holant^+ and Holant^c [20, 2, 22, 3]. Without assuming auxiliary signatures a Holant dichotomy is established only for non-negative real-valued signatures [37].

1.2 Quantum entanglement theory

Holant problems can be viewed as tensor networks in quantum theory. The partition function $\operatorname{Holant}_\Omega$ can be used in a (strong) simulation of quantum circuits [44]. A signature grid is just a tensor network, where each signature is a tensor with its inputs associated with its incident edges and the Holant value of the signature grid is obtained by contracting all edges. In this sense, a signature of arity n represents a state of n *qubits*. In quantum theory, the basic component of a system is a qubit. The (pure) state $|\Psi\rangle$ of n qubits is described by a vector in $\mathbb{C}^{2^n}$. (The standard notion requires quantum states to have norm 1, but in this paper, normalization by a nonzero scalar makes no difference for complexity, so we work with states having arbitrary nonzero norms.) A nonzero n-ary signature f is synonymous with an n-qubit state $|f\rangle = \sum_{x\in\{0,1\}^n} f(x)|x\rangle$. In this paper, we use them interchangeably. When f is a zero signature (i.e., $f \equiv 0$), we agree that $|f\rangle$ is a null state, denoted by $\mathfrak{N}$.

A core concept in quantum theory is *entanglement*. It is perhaps the most distinguishing characteristic feature separating quantum and classical physics.

▶ **Definition 2** (Quantum entanglement). *A state of n qubits (*$n > 1$*, representing a multiple system) is* entangled *if it cannot be decomposed as a tensor product of single-qubit states (individual systems). It is* genuinely entangled *if it cannot be decomposed as a tensor product of states of proper subsystems. It exhibits* multipartite entanglement *if it involves a genuinely entangled state of subsystem of more than two qubits (i.e., it cannot be decomposed as a tensor product of single-qubit states and 2-qubit states).*

Today, entanglement is recognized as an important resource in quantum computing and quantum information theory. It has been shown that quantum computing speedups essentially depend on unbounded entanglement [34]. While in quantum information theory, an entangled state is shared by several parties, one can perform operations on a subsystem locally without access to the other subsystems. This set-up is commonly used in quantum teleportation and quantum key distribution [27, 6]. For different information-theoretic tasks, different types of entanglement can be used [40]. The classification of them under *stochastic local operation with classical communication* (SLOCC) equivalence was proposed in 2000 by Dür et al. [24], and is an area of active research [46, 39, 36, 35, 1, 30]. Yet so far, even the classification of entangled 4-qubit states is not completely settled. For more about quantum entanglement theory, we refer to the survey [33].

1.3 Existing dichotomies inspired by entanglement theory

There are many natural connections between Holant problems and quantum theory. The introduction of Holant problems is inspired by holographic transformations [45]. Such a holographic transformation applied separately on each qubit i with a matrix A_i is just a SLOCC in quantum theory. Also, many known P-time computable signature sets for Holant problems can be clearly described in the quantum literature [19, 2] and they correspond directly to sets of states that are of independent interest in quantum theory [23, 32].

Going beyond that, Backens recently applied knowledge from the theory of quantum entanglement, directly to the study of Holant problems and derived new dichotomy results [2, 3]. We give a short description for these results in this subsection. We use $\langle\Phi|$ to denote the Hermitian adjoint (complex conjugate) of $|\Phi\rangle$, and $\langle\Phi|\Psi\rangle$ to denote the (complex) inner product of two n-qubit states.

▶ **Definition 3** (Projection). *The projection of the i-th qubit of an n-qubit ($n \geqslant 2$) state $|\Psi\rangle$ onto a single-qubit state $|\theta\rangle = a|0\rangle + b|1\rangle$ is defined as $\langle\theta|_i|\Psi\rangle = \bar{a}|\Psi_i^0\rangle + \bar{b}|\Psi_i^1\rangle$ where $\bar{a}$ and $\bar{b}$ are complex conjugates of a and b, and $|\Psi_i^0\rangle$ and $|\Psi_i^1\rangle$ are states of the remaining $n-1$ qubits when the i-th qubit of $|\Psi\rangle$ is set to 0 and 1 respectively.*

▶ **Theorem 4** ([42, 29]). *Let $|\Psi\rangle$ be a genuinely entangled n-qubit ($n \geqslant 3$) state. For any two qubits of $|\Psi\rangle$, there exist projections of the other $n-2$ qubits onto $n-2$ many single-qubit states that result in an entangled 2-qubit state.*

This result was presented to show that any pure entangled multipartite quantum state violates some Bell's inequality [42]. The original proof [42] was flawed and was corrected recently [29]. Theorem 4 shows that two particle entanglement can be realized via performing local projections on a genuinely entangled multiparticle state. It is observed in [2] that the theorem holds even when restricted to only local projections onto computational or Hadamard basis states, i.e., $|0\rangle$, $|1\rangle$, $|+\rangle = |0\rangle + |1\rangle$ and $|-\rangle = |0\rangle - |1\rangle$.

Based on Theorem 4 and the inductive entanglement classification under SLOCC equivalence [36, 35, 1], Backens showed that beyond entangled 2-qubit states, genuinely entangled 3-qubit states can be realized via local projections onto computational or Hadamard basis states (Theorem 12 in [2]). This theorem is equivalent to the following inductive statement.

▶ **Theorem 5** ([2]). *Let $|\Psi\rangle$ be an n-qubit ($n \geqslant 4$) state exhibiting multipartite entanglement. Then, there exists some i and some $|\theta\rangle \in \{|0\rangle, |1\rangle, |+\rangle, |-\rangle\}$ such that $\langle\theta|_i|\Psi\rangle$ exhibits multipartite entanglement.*

▶ Remark 6. This result shows that multipartite entanglement of an n-qubit ($n \geqslant 4$) state can be *preserved* under projections onto states $|0\rangle$, $|1\rangle$, $|+\rangle$ and $|-\rangle$.

The Holant$^+(\mathcal{F})$ problem is defined as Holant$(\mathcal{F} \cup \{|0\rangle, |1\rangle, |+\rangle, |-\rangle\})$, where single qubit states $|0\rangle, |1\rangle, |+\rangle$ and $|-\rangle$ represent unary signatures $\Delta_0 = (1, 0)$, $\Delta_1 = (0, 1)$, $\Delta_+ = (1, 1)$ and $\Delta_- = (1, -1)$ in the Holant framework. According to Theorem 5, we know that in the framework of Holant$^+$ problems, a genuinely entangled 3-qubit state can always be realized from an n-qubit ($n \geqslant 4$) state exhibiting multipartite entanglement. Then, using a genuinely entangled 3-qubit state, a full dichotomy was proved for Holant$^+$ problems [2]. Later, it was generalized to Holant^c problems [22, 3] where Holant$^c(\mathcal{F})$ is defined as Holant$(\mathcal{F} \cup \{|0\rangle, |1\rangle\})$.

1.4 Our results

In this paper, we consider when multipartite entanglement can be preserved under projections onto only computational basis states, i.e., $|0\rangle$ or $|1\rangle$. We have the following result.

▶ **Theorem 7.** *Let $|\Psi\rangle$ be an n-qubit ($n \geqslant 4$) state exhibiting multipartite entanglement and $\langle 0^n|\Psi\rangle \neq 0$. If $n \geqslant 5$ and $|\Psi\rangle$ is not of the form $a|0^n\rangle + b|1^n\rangle$, or $n = 4$ and $|\Psi\rangle$ is not of the form $a|0000\rangle + b|1111\rangle + c|0011\rangle + d|1100\rangle$ (up to a permutation of the four qubits) where a, b, c and d can possibly be zero, then there exists some i such that $|\Psi_i^0\rangle$ or $|\Psi_i^1\rangle$ exhibits multipartite entanglement.*

Under SLOCC equivalence, without loss of generality, we may assume that $\langle 0^n|\Psi\rangle \neq 0$. The other conditions are all necessary to ensure the preservation of multipartite entanglement under projections to $|0\rangle$ and $|1\rangle$. Thus Theorem 7 is a strengthening of Theorem 5. More importantly, our approach is in the opposite direction to Backens'. While Backens proved results in quantum entanglement theory to apply it to the complexity classification of Holant problems, we prove new results in quantum entanglement theory by employing the machinery from Holant problems. We prove Theorem 7 using a technique developed for Holant problems called the interplay between the *unique prime factorization* of signatures and *gadget constructions*. This technique is at the heart of a standard approach (arity reduction) to build inductive arguments for Holant problems [15]. The new result in quantum entanglement theory sheds light on the classification of entanglement under SLOCC equivalence.

Going one step further, we ask whether we can restrict projections onto only one state $|0\rangle$, while multipartite entanglement is still preserved. The answer is no. Then, one way to salvage the situation is to consider the self-loop gadget using one of the Bell states, $|\phi^+\rangle = |00\rangle + |11\rangle$ together with projections onto $|0\rangle$.

▶ **Definition 8** (Self-loop). *The self-loop on the i-th and j-th qubits of a state $|\Psi\rangle$ by the Bell state $|\phi^+\rangle = |00\rangle + |11\rangle$ is defined as $\langle \phi^+|_{ij}|\Psi\rangle = |\Psi_{ij}^{00}\rangle + |\Psi_{ij}^{11}\rangle$, where $|\Psi_{ij}^{00}\rangle$ and $|\Psi_{ij}^{11}\rangle$ are states of $n-2$ qubits when setting the i-th and j-th qubits of $|\Psi\rangle$ to 00 and 11 respectively.*

▶ **Lemma 9.** *Let $|\Psi\rangle$ be an n-qubit ($n \geqslant 4$) state exhibiting multipartite entanglement. There exists some choice of three or four of the n qubits such that by performing self-loops by $|\phi^+\rangle$ and projections onto $|0\rangle$ of the other qubits, we get*

- *a 3-qubit state exhibiting multipartite entanglement, or*
- *a* GHZ *type 4-qubit state, i.e.,* $|\mathrm{GHZ}_4\rangle = |0000\rangle + |1111\rangle$, *or*
- *the state $|1\rangle$.*

Why do we consider $|\phi^+\rangle$ and $|0\rangle$? The state $|\phi^+\rangle$ is synonymous with the binary EQUALITY signature $=_2$. It is always available in the Holant framework as it means *merging* two dangling edges in a graph. Moreover, we can show that $|0\rangle$ is realizable from any state of odd number of qubits under some mild assumptions. Then, we can apply Lemma 9 to get a new dichotomy for Holant problems where at least one signature of odd arity is present.

▶ **Theorem 10.** *Let $\mathcal{F}$ be a set of real-valued signatures containing at least one signature of odd arity. If $\mathcal{F}$ satisfies the tractability condition* (T) *in Theorem 21, then* $\mathrm{Holant}(\mathcal{F})$ *is polynomial-time computable; otherwise,* $\mathrm{Holant}(\mathcal{F})$ *is #P-hard.*

▶ Remark 11. Theorem 7 and Lemma 9 hold for complex-valued n-qubit states. However, Theorem 10 is restricted to real-valued signatures, in which the Hermitian conjugate and the complex inner product can be represented by a *mating* gadget in the Holant framework.

1.5 Surprising discovery of two extraordinary quantum states

What about signature sets containing only signatures of even arity, in which $|0\rangle$ cannot be realized. Since $|\phi^+\rangle$ is always available, we consider whether multipartite entanglement is preserved under self-loops by $|\phi^+\rangle$ alone. Given an n-qubit ($n \geqslant 6$ is even) state $|\Psi\rangle$ exhibiting multipartite entanglement, are there some i and j such that performing a self-loop by $|\phi^+\rangle$ on the i-th and j-th qubits of $|\Psi\rangle$ results in an $(n-2)$-qubit state exhibiting multipartite entanglement? (By the definition of multipartite entanglement, for even n it must be $n \geq 6$.)

The answer is no. Here we made a quite surprising discovery: There *exist* genuinely entangled 6-qubit and 8-qubit states such that multipartite entanglement is *not* preserved under self-loops. Furthermore, it is not preserved under self-loops not only by $|\phi^+\rangle$, but also by all four Bell states, $|\phi^+\rangle, |\psi^+\rangle = |01\rangle + |10\rangle, |\phi^-\rangle = |00\rangle - |11\rangle$, and $|\psi^-\rangle = |01\rangle - |10\rangle$. The self loop of the i-th and j-th qubits of $|\Psi\rangle$ by $|\psi^+\rangle$ is defined as $\langle\psi^+|_{ij}|\Psi\rangle = |\Psi^{01}_{ij}\rangle + |\Psi^{10}_{ij}\rangle$. Similarly, we can define $\langle\phi^-|_{ij}|\Psi\rangle$ and $\langle\psi^-|_{ij}|\Psi\rangle$.

▶ **Definition 12** (Bell property). *Let $|\Psi\rangle$ be a genuinely entangled state. We say that it satisfies the Bell property if for any two qubits i and j of $|\Psi\rangle$ and any Bell state $|\phi\rangle$, $\langle\phi|_{ij}|\Psi\rangle$ is a tensor product of Bell states. It satisfies the strong Bell property if for any i and j and any Bell state $|\phi\rangle$, $\langle\phi|_{ij}|\Psi\rangle$ is a tensor product of the Bell state $|\phi\rangle$, i.e., $\langle\phi|_{ij}|\Psi\rangle = |\phi\rangle \otimes \cdots \otimes |\phi\rangle$.*

▶ **Theorem 13.** *There exist genuinely entangled 6-qubit states that satisfy the Bell property, and genuinely entangled 8-qubit states that satisfy the strong Bell property.*

We first give an 8-qubit state $|\Psi_8\rangle$ that satisfies the strong Bell property.

$$\begin{aligned}|\Psi_8\rangle =& |00000000\rangle + |00001111\rangle + |00110011\rangle + |00111100\rangle + |01010101\rangle + |01011010\rangle + |10011001\rangle + |10010110\rangle \\ &+ |01101001\rangle + |01100110\rangle + |10100101\rangle + |10101010\rangle + |11000011\rangle + |11001100\rangle + |11110000\rangle + |11111111\rangle.\end{aligned}$$

$|\Psi_8\rangle$ can be represented by an 8-ary signature Ψ_8. Let $\mathcal{S}(\Psi_8)$ be the support of Ψ_8, i.e., $\mathcal{S}(\Psi_8) = \{\alpha \in \mathbb{Z}_2^8 \mid \Psi_8(\alpha) \neq 0\}$. $\mathcal{S}(\Psi_8)$ has the following structure: the sums of the first four variables, and the last four variables are both even; the assignment of the first four variables are either identical to, or complement of the assignment of the last four variables. While it is not obvious from this description that the support set is an affine subspace of $\mathbb{Z}_2^8$, but *it is*.

$$\begin{aligned}\mathcal{S}(\Psi_8) = \big\{(x_1, x_2, \ldots, x_8) \in \mathbb{Z}_2^8 \,|& x_1 + x_2 + x_3 + x_4 \equiv 0,\ x_1 + x_2 + x_5 + x_6 \equiv 0, \\ & x_1 + x_3 + x_5 + x_7 \equiv 0,\ x_2 + x_3 + x_5 + x_8 \equiv 0,\ \bmod 2\big\}.\end{aligned}$$

In other words, take 4 variables x_1, x_2, x_3, x_5, (these are not the first 4 variables in the description above), then on the support the remaining 4 variables are mod 2 sums of $\binom{4}{3}$ subsets of $\{x_1, x_2, x_3, x_5\}$. This will imply that $|\Psi_8\rangle$ is genuinely entangled. Also, one can check that $\langle\phi|_{12}|\Psi_8\rangle = |\phi\rangle^{\otimes 3}$ for any Bell state $|\phi\rangle$. Due to the symmetry of $|\Psi_8\rangle$, the same result holds by replacing $\{1, 2\}$ with any $\{i, j\}$. Thus, $|\Psi_8\rangle$ satisfies the strong Bell property.

The 6-qubit state $|\Psi_6\rangle$ satisfying the Bell property has 32 nonzero coefficients. We give it in the signature form.

$$\Psi_6(x_1, \ldots, x_6) = \chi_{\mathcal{S}(\Psi_6)} \cdot (-1)^{x_1x_4 + x_2x_5 + x_3x_6 + x_4x_5 + x_5x_6 + x_4x_6},$$

where $\chi_{\mathcal{S}(\Psi_6)}$ is the indicator function on the support $\mathcal{S}(\Psi_6) = \{(x_1, \ldots, x_6) \in \mathbb{Z}_2^6 \mid \sum_{i=1}^6 x_i = 0 \bmod 2\}$ (even parity). Such a support will imply that $|\Psi_6\rangle$ is genuinely entangled. We can write Ψ_6 as the following 8-by-8 matrix where the assignment of the first three variables in lexicographic order (from 000 to 111) is the row index and the assignment of the last three variables in lexicographic order is the column index.

$$M_{123,456}(\Psi_6) = \begin{bmatrix} 1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & -1 & 1 & 0 & 1 & 0 & 0 & -1 \\ 0 & 1 & -1 & 0 & 1 & 0 & 0 & -1 \\ -1 & 0 & 0 & -1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & -1 & 0 & 0 & -1 \\ -1 & 0 & 0 & 1 & 0 & -1 & 1 & 0 \\ -1 & 0 & 0 & 1 & 0 & 1 & -1 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 & 1 \end{bmatrix}.$$

By the symmetry of $|\Psi_6\rangle$, one can check that $|\Psi_6\rangle$ satisfies the Bell property by verifying $\langle\phi|_{12}|\Psi_6\rangle$, $\langle\phi|_{45}|\Psi_6\rangle$ and $\langle\phi|_{14}|\Psi_6\rangle$ are tensor products of Bell states for any bell state $|\phi\rangle$.

We can use Pauli operations to generate more states satisfying the Bell property. Consider the following four Pauli operators

$$I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Y = \begin{bmatrix} 0 & -\mathfrak{i} \\ \mathfrak{i} & 0 \end{bmatrix} \quad \text{and} \quad Z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

A Pauli operation on an n-qubit state $|\Psi\rangle$ is defined as $P_1 \otimes P_2 \otimes \ldots \otimes P_n|\Psi\rangle$ (which produces another n-qubit state) where each P_i is a Pauli operator. Let $|\Psi_6\rangle$ and $|\Psi_8\rangle$ be states described above. Let $\mathfrak{P}_6$ and $\mathfrak{P}_8$ denote the sets of states realized by performing Pauli operations on $|\Psi_6\rangle$ and $|\Psi_8\rangle$ respectively.

▶ **Theorem 14.** *Every state in $\mathfrak{P}_6$ or $\mathfrak{P}_8$ satisfies the Bell property.*

Due to the existence of these 6-qubit and 8-qubit states with such extraordinary properties, it remains as a difficult task to achieve a full dichotomy for real-valued Holant problems. On the other hand, we hope such states can be further investigated and perhaps applied to quantum computing or quantum information theory.

The paper is organized as follows. In Section 2, we give a proof of our main quantum entanglement result (Theorem 7) by using the theory of signatures. Then we give some preliminaries for Holant problems in Section 3, and a proof sketch for our dichotomy result (Theorem 10) in Section 4.

2 Preservation of Multipartite Entanglement under Projections

We use the theory of signatures to prove Theorem 7. Recall that by our definition, a signature always has arity at least one. A nonzero signature g *divides* f denoted by $g \mid f$, if there is a signature h such that $f = g \otimes h$ (with possibly a permutation of variables) or there is a constant λ such that $f = \lambda \cdot g$. In the latter case, if $\lambda \neq 0$, then we also have $f \mid g$ since $g = \frac{1}{\lambda} \cdot f$. For nonzero signatures f and g, we use $f \sim g$ to denote both $g \mid f$ and $f \mid g$. A nonzero signature f is irreducible if f cannot be written as $g \otimes h$ for some signatures g and h. This is equivalent to saying that $|f\rangle$ is a genuinely entangled state of multiple qubits or $|f\rangle$ is a single-qubit state. Let $\mathcal{T}_1$ denote the set of tensor products of unary signatures and $\mathcal{T}$ denote the set of tensor products of unary and binary signatures. Then a state $|f\rangle$ of multiple qubits is entangled iff $f \notin \mathcal{T}_1$, and $|f\rangle$ exhibits multipartite entanglement iff $f \notin \mathcal{T}$. In terms of the above division relation, the unique prime factorization (UPF) of signatures is established (see Lemma 2.13 of [15]). The following result is a direct corollary.

▶ **Corollary 15.** *Let f be a nonzero n-ary signature. Suppose that there are two irreducible signatures g on variables in $A \subseteq [n]$ and h on variables in $B \subseteq [n]$ such that $g \mid f$ and $h \mid f$. Then, either A is disjoint with B, or $A = B$ and $g \sim h$.*

We use f_i^0 and f_i^1 to denote the signature forms of quantum states $|f_i^0\rangle$ and $|f_i^1\rangle$ realized by projections onto $|0\rangle$ and $|1\rangle$. In the Holant framework, these signatures are realized by a *pinning* gadget, i.e., connecting the variable x_i of f with unary signatures $\Delta_0 = (1, 0)$ and $\Delta_1 = (0, 1)$ respectively. We may further pick a variable x_j of f_i^c and pin it to the value d ($c, d \in \{0, 1\}$). Obviously, the pinning gadgets on different variables x_i and x_j commute. Thus, we have $(f_i^c)_j^d = (f_j^d)_i^c$. We denote it by f_{ij}^{cd}.

Suppose that $g \mid f$ where g is on variables in A. Then for any variable x_i of f that is not in A, we have $g \mid f_i^0$ and $g \mid f_i^1$ (By definition, the division relation holds even if f_i^0 or f_i^1 is a zero signature). Thus, the division relation is unchanged under pinning gadgets on variables out of A. The following lemma shows that a stronger converse is also true.

▶ **Lemma 16.** *Let f be a signature of arity $n \geqslant 2$. If there exists a signature g on variables in $A \subsetneq [n]$ and some x_i not in A such that $g \mid f_i^0$ and $g \mid f_i^1$, then $g \mid f$.*

Now, we are ready to prove Theorem 7. We restate it in terms of signatures. We use 0^n and 1^n to denote the n-bit all-0 and all-1 strings, and $\mathcal{S}(f)$ to denote the support of f.

▶ **Theorem 17.** *Let f be an n-ary ($n \geqslant 4$) signature, $f \notin \mathcal{T}$ and $f(0^n) \neq 0$. If $n \geqslant 5$ and $\mathcal{S}(f) \not\subseteq \{0^n, 1^n\}$, or $n = 4$ and $\mathcal{S}(f) \not\subseteq \{0000, 1111, 0011, 1100\}$ up to any permutation of four variables, then there exists some i such that f_i^0 or f_i^1 is not in $\mathcal{T}$.*

Proof. Since $f(0^n) \neq 0$, we have $f_i^0 \not\equiv 0$ and $f_{ij}^{00} \not\equiv 0$ (not identically 0) for all indices i and j. Also, since the support $\mathcal{S}(f) \not\subseteq \{0^n, 1^n\}$, there exist some s and t such that $f_{st}^{01} \not\equiv 0$. For a contradiction, we assume $f_i^0, f_i^1 \in \mathcal{T}$ for all i. We consider the following two possible cases.

Case 1. For all indices i, $f_i^0 \in \mathcal{T}_1$ (i.e., tensor product of unary signatures).

We will show that in this case, there is a unary signature $a(x_u)$ on some variable x_u, such that $a(x_u) \mid f$. This will lead to a contradiction.

Recall that there exist some s and t such that $f_{st}^{01} \not\equiv 0$. Then, clearly $f_t^1 \not\equiv 0$. Since $f_t^1 \in \mathcal{T}$, in the UPF of f_t^1, the variable x_s may appear in a unary signature or an irreducible binary signature. In both cases, since f has arity at least 4, we can pick a variable x_u such that x_u and x_s appear in two distinct irreducible signatures in the UPF of f_t^1 (i.e., x_u and x_s are not entangled in f_t^1). Then, we show that x_u must appear in a unary signature in the UPF of f_t^1. Otherwise, there is an irreducible binary signature $b(x_u, x_v)$ such that $b(x_u, x_v) \mid f_t^1$. Since x_u is not entangled with x_s in f_t^1, we have $v \neq s$. Then, $b(x_u, x_v) \mid f_{st}^{01}$. On the other hand, we consider f_s^0. By our assumption, $f_s^0 \in \mathcal{T}_1$ and hence there exists some unary signature $a'(x_u)$ such that $a'(x_u) \mid f_s^0$. Then, $a'(x_u) \mid f_{st}^{01}$. Since $f_{st}^{01} \not\equiv 0$, by Corollary 15, $b(x_u, x_v) \sim a'(x_u)$. Contradiction. Thus, there exists some $a(x_u)$ such that $a(x_u) \mid f_t^1$.

Now we show that $a(x_u) \mid f_t^0$. First, we show that $a(x_u) \mid f_s^0$. Since $f_s^0 \in \mathcal{T}_1$, there exists some unary signature $a'(x_u)$ such that $a'(x_u) \mid f_s^0$, and then $a'(x_u) \mid f_{st}^{01}$. Also, we have $a(x_u) \mid f_{st}^{01}$ since $a(x_u) \mid f_t^1$. Since $f_{st}^{01} \not\equiv 0$, by Corollary 15, we have $a(x_u) \sim a'(x_u)$. Thus, $a(x_u) \mid f_s^0$. Since $f_t^0 \in \mathcal{T}_1$, there exists a unary signature $a''(x_u)$ such that $a''(x_u) \mid f_t^0$, and then $a''(x_u) \mid f_{st}^{00}$. Also, we have $a(x_u) \mid f_{st}^{00}$ since $a(x_u) \mid f_s^0$. Remember that $f_{st}^{00} \not\equiv 0$. Then, by Corollary 15, we have $a(x_u) \sim a''(x_u)$. Thus, $a(x_u) \mid f_t^0$.

Since $a(x_u) \mid f_t^0$ and $a(x_u) \mid f_t^1$, by Lemma 16, we have $a(x_u) \mid f$. In other words, $f = a(x_u) \otimes g$ where g is a nonzero signature of arity $n - 1$ on variables other than x_u. Since $f \notin \mathcal{T}$, we have $g \notin \mathcal{T}$. Consider f_u^0. We know that it is a nonzero signature and hence $f_u^0 \sim g$. Thus, $f_u^0 \notin \mathcal{T}$. We have reached a contradiction.

Case 2. There exists some index k and an irreducible binary signature $b(x_v, x_w)$ such that $b(x_v, x_w) \mid f_k^0$.

We will show that in this case, $b(x_v, x_w) \mid f$. First, we show that $b(x_v, x_w) \mid f_i^0$ for all $i \notin \{v, w\}$. We already have $b(x_v, x_w) \mid f_k^0$. Consider f_i^0 for all indices $i \notin \{v, w, k\}$. Since $f_i^0 \in \mathcal{T}$ and $f_i^0 \not\equiv 0$, there is either a unary signature $a(x_v)$ or an irreducible binary signature $b'(x_v, x_{w'})$ for some $w' \notin \{i, v\}$ that appears in the UPF of f_i^0, i.e., $a(x_v) \mid f_i^0$ or $b'(x_v, x_{w'}) \mid f_i^0$. In the former case, we have $a(x_v) \mid f_{ik}^{00}$. In the latter case and if $w' \neq k$, we have $b'(x_v, x_{w'}) \mid f_{ik}^{00}$. In the latter case and if $w' = k$, then let $a'(x_v)$ be the unary signature realized from $b'(x_v, x_{w'})$ by pinning $x_{w'} = x_k$ to 0, we get $a'(x_v) \mid f_{ik}^{00}$. On the other hand, since $b(x_v, x_w) \mid f_k^0$, we have $b(x_v, x_w) \mid f_{ik}^{00}$. Since $f_{ik}^{00} \not\equiv 0$, by Corollary 15, we know that the two cases that $a(x_v) \mid f_{ik}^{00}$ and $a'(x_v) \mid f_{ik}^{00}$ cannot occur. Thus, $w' \neq k$ and $b'(x_v, x_{w'}) \mid f_{ik}^{00}$. By Corollary 15, $w' = w$, and $b(x_v, x_w) \sim b'(x_v, x_{w'})$. Thus, $b(x_v, x_w) \mid f_i^0$ for all $i \notin \{v, w\}$.

Then we want to show that there exists some $j \notin \{v, w\}$ such that $b(x_v, x_w) \mid f_j^1$.

- We first consider the case that there exist some indices i and j where $\{i, j\}$ is disjoint with $\{v, w\}$ such that $f_{ij}^{01} \not\equiv 0$. We show that $b(x_v, x_w) \mid f_j^1$. Since $b(x_v, x_w) \mid f_i^0$, we have $b(x_v, x_w) \mid f_{ij}^{01}$. By assumption $f_{ij}^{01} \not\equiv 0$, and then clearly $f_j^1 \not\equiv 0$. Recall that $f_j^1 \in \mathcal{T}$. Again, there is either a unary signature $a(x_v)$ or an irreducible binary signature $b'(x_v, x_{w'})$ that appears in the UPF of f_j^1, i.e., $a(x_v) \mid f_j^1$ or $b'(x_v, x_{w'}) \mid f_j^1$. In the first case since $i \neq v$, we can pin x_i of f_j^1 to 0, and we get $a(x_v) \mid f_{ij}^{01}$. In the second case and if $w' = i$, again we can get $a'(x_v) \mid f_{ij}^{01}$, where $a'(x_v) = b'(x_v, 0)$, obtained from pinning x_i to 0. But $f_{ij}^{01} \not\equiv 0$ and $b(x_v, x_w) \mid f_{ij}^{01}$. Then, in the UPF of f_{ij}^{01}, it does not have a unary signature on x_v as a factor. Thus, it must be the case that $b'(x_v, x_{w'}) \mid f_j^1$ where $w' \neq i$. Then, we have $b'(x_v, x_{w'}) \mid f_{ij}^{01}$. Since $b(x_v, x_w) \mid f_{ij}^{01}$ and $f_{ij}^{01} \not\equiv 0$, by Corollary 15, $w' = w$ and $b'(x_v, x_{w'}) \sim b(x_v, x_w)$, and thus $b(x_v, x_w) \mid f_j^1$. Then, by Lemma 16, we have $b(x_v, x_w) \mid f$. In other words, $f = b(x_v, x_w) \otimes h$ where h is a nonzero signature of arity $n - 2$ on variables other than x_v and x_w. Since $f \notin \mathcal{T}$, we have $h \notin \mathcal{T}$. Then consider f_v^0. We know that it is a nonzero signature and $h \mid f_v^0$. Thus, $f_v^0 \notin \mathcal{T}$. Contradiction.
- Then we consider the case that $f_{ij}^{01} \equiv 0$ for all indices $\{i, j\}$ that are disjoint with $\{v, w\}$. Consider an n-bit input α of f. We write α as $\alpha_v \alpha_w \beta$ where α_v is the input on variable x_v, α_w is the input on variable x_w, and β is the input on the other $n - 2$ variables. Then, $f(\alpha) = 0$ if β is not the all-0 or all-1 bit string in $\{0, 1\}^{n-2}$. It follows that f has at most eight nonzero entries. We list all its entries by the following 4-by-2^{n-2} matrix $M_{vw}(f)$ with $(x_v, x_w) \in \{0, 1\}^2$ as the row index (in the order 00, 01, 10, 11) and the assignment of the other variables in lexicographic order as the column index.

$$M_{vw}(f) = \begin{bmatrix} c_1 & 0 & \dots & \dots & 0 & c_2 \\ c_3 & 0 & \dots & \dots & 0 & c_4 \\ c_5 & 0 & \dots & \dots & 0 & c_6 \\ c_7 & 0 & \dots & \dots & 0 & c_8 \end{bmatrix}.$$

Here, $c_1 = f(0^n) \neq 0$. Consider signatures f_v^0 and f_v^1. They have the following matrix forms with the variable $x_w \in \{0, 1\}$ as the row index.

$$M_w(f_v^0) = \begin{bmatrix} c_1 & 0 & \dots & \dots & 0 & c_2 \\ c_3 & 0 & \dots & \dots & 0 & c_4 \end{bmatrix} \quad \text{and} \quad M_w(f_v^1) = \begin{bmatrix} c_5 & 0 & \dots & \dots & 0 & c_6 \\ c_7 & 0 & \dots & \dots & 0 & c_8 \end{bmatrix}.$$

Also consider signatures f_w^0 and f_w^1. They have the following matrix forms with the variable $x_v \in \{0, 1\}$ as the row index.

$$M_v(f_w^0) = \begin{bmatrix} c_1 & 0 & \dots & \dots & 0 & c_2 \\ c_5 & 0 & \dots & \dots & 0 & c_6 \end{bmatrix} \quad \text{and} \quad M_v(f_w^1) = \begin{bmatrix} c_3 & 0 & \dots & \dots & 0 & c_4 \\ c_7 & 0 & \dots & \dots & 0 & c_8 \end{bmatrix}.$$

Consider f_v^0. Since f has arity at least 4, f_v^0 has arity at least 3. Since $f_v^0 \in \mathcal{T}$, the variable x_w either appears in a unary factor $a(x_w)$ of f_v^0 or an irreducible binary factor $b(x_w, x_{w'})$ of f_v^0. In the latter case, we can pick another variable x_r of f_v^0 where $r \neq w$ or w', and we consider f_{vr}^{00}. We know that $f_{vr}^{00} \not\equiv 0$ since $c_1 \neq 0$ and $b(x_w, x_{w'}) \mid f_{vr}^{00}$ since $b(x_w, x_{w'}) \mid f_v^0$. Notice that the column with c_2 and c_4 does not appear in $M_w(f_{vr}^{00})$. Thus, the signature f_{vr}^{00} is of the form $(c_1, c_3) \otimes (1,0)^{\otimes(n-2)}$ which is a tensor product of unary signatures. Contradiction. Thus, there is a unary signature $a(x_w)$ such that $a(x_w) \mid f_v^0$. Then, we have $c_1c_4 = c_2c_3$. Similarly by considering f_w^0, we have $c_1c_6 = c_2c_5$. Now, we consider f_v^1, and prove $c_5c_8 = c_6c_7$. If $c_5 = c_7 = 0$, then clearly we have $c_5c_8 = c_6c_7 = 0$. Otherwise, for any $r \neq w$ or v, we have $f_{vr}^{10} = (c_5, c_7) \otimes (1,0)^{\otimes(n-2)} \not\equiv 0$ which is a tensor product of unary signatures. If there is a binary signature $b(x_w, x_{w'})$ such that $b(x_w, x_{w'}) \mid f_v^1$, then we can find some $r \neq w, w'$ such that $b(x_w, x_{w'}) \mid f_{vr}^{10}$. Contradiction. Thus, there is a unary signature $a(x_w)$ such that $a(x_w) \mid f_v^1$. Then, we have $c_5c_8 = c_6c_7$. Similarly by considering f_w^1, we have $c_3c_8 = c_4c_7$.

- Suppose $n \geqslant 5$. Then f_v^0 has arity at least 4. We first show that $c_2 = 0$. We consider $f_{vw}^{00} = [c_1, 0, \ldots\ldots, 0, c_2]$. Since $f_v^0 \in \mathcal{T}$, we have $f_{vw}^{00} \in \mathcal{T}$. Note that f_{vw}^{00} has arity at least 3. Since $c_1 \neq 0$, the only possible value of c_2 to make $f_{vw}^{00} \in \mathcal{T}$ is 0. Thus, $c_2 = 0$. Since $c_1c_4 = c_2c_3 = 0$ and $c_1 \neq 0$, we have $c_4 = 0$. Also, since $c_1c_6 = c_2c_5 = 0$ and $c_1 \neq 0$, we have $c_6 = 0$. If $c_8 = 0$, then $f = b(x_v, x_w) \otimes (1,0)^{\otimes(n-2)} \in \mathcal{T}$. A contradiction with $f \notin \mathcal{T}$. Thus, we have $c_8 \neq 0$. Since $c_5c_8 = c_6c_7 = 0$ and $c_8 \neq 0$, we have $c_5 = 0$. Also since $c_3c_8 = c_4c_7 = 0$ and $c_8 \neq 0$, we have $c_3 = 0$. Consider $f_{vw}^{11} = [c_7, 0, \ldots\ldots, 0, c_8]$. Since $f_{vw}^{11} \in \mathcal{T}$ and it has arity at least 3, and $c_8 \neq 0$, we have $c_7 = 0$. Thus, f has only two nonzero entries that are on the all-0 input and the all-1 input. A contradiction with our assumption that $\mathcal{S}(f) \nsubseteq \{0^n, 1^n\}$.
- Suppose $n = 4$. If $c_2 = 0$, then with the same proof as in the case that $n \geqslant 5$, we have $c_4 = c_6 = 0$, $c_8 \neq 0$ and then $c_3 = c_5 = 0$. Thus, $\mathcal{S}(f) \subseteq \{0000, 1111, 1100\}$. Contradiction. Otherwise, $c_2 \neq 0$. Suppose that $c_2 = kc_1$. Then $c_4 = kc_3$ since $c_1c_4 = c_2c_3$ and $c_6 = kc_5$ since $c_1c_6 = c_2c_5$. If c_3 and c_4 are not zero, then $c_8 = kc_7$ since $c_3c_8 = c_4c_7$. Then, $f = b(x_v, x_w) \otimes (1,0,0,k) \in \mathcal{T}$. Contradiction. Thus, $c_3 = c_4 = 0$. Similarly, if c_5 and c_6 are not zero, then we still have $c_8 = kc_7$ since $c_5c_8 = c_6c_7$. Then, we have $f \in \mathcal{T}$. Contradiction. Thus, $c_5 = c_6 = 0$. Then, $\mathcal{S}(f) \subseteq \{0000, 1111, 0011, 1100\}$. Contradiction.

Therefore, there exists some i such that f_i^0 or f_i^1 is not in $\mathcal{T}$. ◀

Our result can be used in the classification of entanglement under SLOCC equivalence. An n-qubit state $|\Psi\rangle$ is equivalent to another n-qubit state $|\Phi\rangle$ under SLOCC if there exist some invertible 2-by-2 matrices M_1, M_2, …, M_n such that $|\Psi\rangle = M_1 \otimes M_2 \otimes \ldots \otimes M_n|\Phi\rangle$. Physicists are interested in the classification of SLOCC equivalence classes. For 2-qubit states there are two SLOCC classes, and for 3-qubit states there are six SLOCC classes [24]. However, for states of 4 or more qubits there are infinitely many SLOCC classes [24]. Then, the goal is to categorize these classes into some finitely many families with common physical or mathematical properties. Depending on which properties are used, there are different approaches. One powerful approach that can possibly handle states of a high number of qubits is by induction [36, 35, 1, 30]. In this approach, the classification of n-qubit states relies on the classification of $(n-1)$-qubit states.

Consider an n-qubit state $|\Psi\rangle$. We can pick some index i and write $|\Psi\rangle$ as $|\Psi\rangle = |0\rangle|\Psi_i^0\rangle + |1\rangle|\Psi_i^1\rangle$. Families of entanglement classes of $|\Psi\rangle$ can be defined according to the types of entanglements found in the linear span$\{|\Psi_i^0\rangle, |\Psi_i^1\rangle\}$ which is related to the entanglement types of $|\Psi_i^0\rangle$ and $|\Psi_i^1\rangle$ themselves. Theorem 7 gives a direct relation between the entanglement types of $|\Psi\rangle$ and $\{|\Psi_i^0\rangle, |\Psi_i^1\rangle\}$. For example, consider a 5-qubit state exhibiting multipartite entanglement. First, by performing SLOCC using the matrix $N_2 = \left[\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right]$ on this state, we can always get a state $|\Psi\rangle$ where the coefficient of $|0^5\rangle$ is nonzero. If $|\Psi\rangle$ has the form $a|0^5\rangle + b|1^5\rangle$, then it is equivalent to $|\mathrm{GHZ}_5\rangle = |0^5\rangle + |1^5\rangle$. Otherwise, we can apply Theorem 7. There exists some i such that $|\Psi_i^0\rangle$ or $|\Psi_i^1\rangle$ exhibits multipartite entanglement. Then, in order to classify the state $|\Psi\rangle$, we only need to consider possible entanglement types of $\{|\Psi_i^0\rangle, |\Psi_i^1\rangle\}$ where at least one state exhibits multipartite entanglement. This eliminates many cases compared to considering all entanglement types of $\{|\Psi_i^0\rangle, |\Psi_i^1\rangle\}$.

3 Preliminaries for Holant Problems

3.1 Definitions and Notations

Let f be a complex-valued signature. If $\overline{f(\alpha)} = f(\overline{\alpha})$ for all α where $\overline{f(\alpha)}$ denotes the complex conjugation of $f(\alpha)$ and $\overline{\alpha}$ denotes the bit-wise complement of α, we say f satisfies *arrow reversal symmetry* (ARS). We may use f^α to denote $f(\alpha)$.

We use $=_n$ to denote the EQUALITY signature of arity n, which takes value 1 on the all-0 or all-1 inputs and 0 elsewhere. Note that $=_2$ represents the Bell state $|\phi^+\rangle$. Let $\mathcal{EQ} = \{=_1, =_2, \ldots, =_n, \ldots\}$ denote the set of all EQUALITY signatures. Then $\#\mathrm{CSP}(\mathcal{F})$ is exactly $\mathrm{Holant}(\mathcal{EQ} \mid \mathcal{F})$. Also, let $\mathcal{EQ}_k = \{=_k, =_{2k}, \ldots, =_{nk}, \ldots\}$, and we define $\#\mathrm{CSP}_k(\mathcal{F})$ to be $\mathrm{Holant}(\mathcal{EQ}_k \mid \mathcal{F})$. The following two reductions are known [10]:

$$\#\mathrm{CSP}(\mathcal{F}) \leqslant_T \mathrm{Holant}(=_3, \mathcal{F}) \quad \text{and} \quad \#\mathrm{CSP}_2(\mathcal{F}) \leqslant_T \mathrm{Holant}(=_4, \mathcal{F}).$$

Here, $\leqslant_T$ denotes P-time Turing reduction. We use $\neq_2$ to denote the binary DISEQUALITY signature with truth table $(0,1,1,0)$. It represents the Bell state $|\psi^+\rangle$.

A signature f of arity $n \geqslant 2$ can be expressed as a $2 \times 2^{n-1}$ matrix $M_i(f)$, which lists the 2^n entries of f with variable $x_i \in \{0,1\}$ as row index and the assignments of the other $n-1$ variables in lexicographic order as column index, i.e. $M_i(f) = \left[\begin{smallmatrix} f^{0,00\ldots0} & f^{0,00\ldots1} & \ldots & f^{0,11\ldots1} \\ f^{1,00\ldots0} & f^{1,00\ldots1} & \ldots & f^{1,11\ldots1} \end{smallmatrix}\right] = \left[\begin{smallmatrix} \mathbf{f}_i^0 \\ \mathbf{f}_i^1 \end{smallmatrix}\right]$, where $\mathbf{f}_i^a$ denotes the row vector indexed by $x_i = a$ in $M_i(f)$. For $=_2$, it has the 2-by-2 signature matrix $M(=_2) = I_2 = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$. For $\neq_2$, $M(\neq_2) = N_2 = \left[\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right]$.

3.2 Holographic Transformation

For an invertible matrix $T \in \mathbf{GL}_2(\mathbb{C})$ and a signature f of arity n, written as a column vector $f \in \mathbb{C}^{2^n}$, we denote by $Tf = T^{\otimes n} f$ the transformed signature. For a signature set $\mathcal{F}$, define $T\mathcal{F} = \{Tf \mid f \in \mathcal{F}\}$ to be the set of transformed signatures. For signatures written as row vectors we define fT^{-1} and $\mathcal{F}T^{-1}$ similarly.

Let $T \in \mathbf{GL}_2(\mathbb{C})$. The holographic transformation defined by T is the following operation: given a signature grid $\Omega = (H, \pi)$ of $\mathrm{Holant}(\mathcal{F} \mid \mathcal{G})$, for the same bipartite graph H, we get a new signature grid $\Omega' = (H, \pi')$ of $\mathrm{Holant}\left(\mathcal{F}T^{-1} \mid T\mathcal{G}\right)$ by replacing each signature in $\mathcal{F}$ or $\mathcal{G}$ with the corresponding signature in $\mathcal{F}T^{-1}$ or $T\mathcal{G}$.

▶ **Theorem 18** (Valiant's Holant Theorem [45]). *For any $T \in \boldsymbol{GL}_2(\mathbb{C})$,*

$$\mathrm{Holant}(\mathcal{F} \mid \mathcal{G}) \equiv_T \mathrm{Holant}(\mathcal{F}T^{-1} \mid T\mathcal{G}).$$

$\mathrm{Holant}(\mathcal{F})$ is equivalent to its bipartite form $\mathrm{Holant}\,(=_2\mid \mathcal{F})$. A particular holographic transformation that will be commonly used is the transformation defined by $Z^{-1} = \frac{1}{\sqrt{2}} \left[\begin{smallmatrix} 1 & -\mathfrak{i} \\ 1 & \mathfrak{i} \end{smallmatrix}\right]$, with $Z = \frac{1}{\sqrt{2}} \left[\begin{smallmatrix} 1 & 1 \\ \mathfrak{i} & -\mathfrak{i} \end{smallmatrix}\right]$. Since $(=_2)Z = (\neq_2)$, we have $\mathrm{Holant}\,(=_2\mid \mathcal{F}) \equiv_T \mathrm{Holant}\left(\neq_2\mid Z^{-1}\mathcal{F}\right)$. We denote $Z^{-1}\mathcal{F}$ by $\widehat{\mathcal{F}}$ and $Z^{-1}f$ by $\widehat{f}$. The following relation between f and $\widehat{f}$ is known.

▶ **Lemma 19** (Lemma A.2 in [15]). *f is a real valued signature iff $\widehat{f}$ satisfies* ARS.

3.3 Gadget Construction

One basic reduction for Holant problems is gadget construction. We say a signature f is *realizable* from a signature set $\mathcal{F}$ (by gadget construction) if there is a graph $G = (V, E, D)$ with internal edges E and dangling edges D where each vertex $v \in V$ is labeled by a signature f_v from $\mathcal{F}$, and the graph defines the signature f by its sum-of-products with inputs on the dangling edges. If f is realizable from a set $\mathcal{F}$, then $\text{Holant}(f, \mathcal{F}) \equiv_T \text{Holant}(\mathcal{F})$.

A basic gadget construction is *merging*; we connect two variables x_i and x_j of f using $=_2$. We use $\partial_{ij} f = f_{ij}^{00} + f_{ij}^{11}$ to denote a signature realized by merging, where f_{ij}^{ab} denotes the signature obtained by setting $(x_i, x_j) = (a, b) \in \{0,1\}^2$. The merging operation using $=_2$ is synonymous with performing a self-loop by the Bell state $|\phi^+\rangle$.

A gadget construction often used in this paper is *mating*. Given a *real*-valued signature f of arity $n > m \geqslant 1$, we connect two copies of f in the following manner: Fix a set S of $n - m$ variables among all n variables of f. For each $x_k \in S$, connect x_k of one copy of f with x_k of the other copy using $=_2$. The variables that are not in S are called dangling variables. For $m = 1$, there is one dangling variable x_i. Then, the mating construction realizes a binary signature, denoted by $\mathfrak{m}_i f$. It can be represented by matrix multiplication. We have

$$M(\mathfrak{m}_i f) = M_i(f) I_2^{\otimes(n-1)} M_i^{\mathrm{T}}(f) = \begin{bmatrix} \mathbf{f}_i^0 \\ \mathbf{f}_i^1 \end{bmatrix} \begin{bmatrix} \mathbf{f}_i^{0\mathrm{T}} & \mathbf{f}_i^{1\mathrm{T}} \end{bmatrix} = \begin{bmatrix} |\mathbf{f}_i^0|^2 & \langle \mathbf{f}_i^0, \mathbf{f}_i^1 \rangle \\ \langle \mathbf{f}_i^0, \mathbf{f}_i^1 \rangle & |\mathbf{f}_i^1|^2 \end{bmatrix}. \tag{3.1}$$

The (complex) inner product $\langle \cdot, \cdot \rangle$ uses complex conjugation. But since f is real-valued, this is the same as the usual dot product. $|\mathbf{f}|$ denotes its 2-norm. In the setting of $\text{Holant}(\neq_2 | \widehat{\mathcal{F}})$, the above mating operation is equivalent to connecting variables in S using $\neq_2$. We denote the resulting signature by $\widehat{\mathfrak{m}}_i \widehat{f} = \widehat{\mathfrak{m}_i f}$. Note that $\widehat{f}$ satisfies ARS since f is real. Thus,

$$N_2^{\otimes(n-1)} \widehat{\mathbf{f}}_i^{0\,\mathrm{T}} = (\widehat{f}^{0,11\ldots1}, \widehat{f}^{0,11\ldots0}, \ldots, \widehat{f}^{0,00\ldots0})^{\mathrm{T}} = (\overline{\widehat{f}^{1,00\ldots0}}, \overline{\widehat{f}^{1,00\ldots1}}, \ldots, \overline{\widehat{f}^{1,11\ldots1}})^{\mathrm{T}} = \overline{\widehat{\mathbf{f}}_i^1}^{\mathrm{T}}.$$

Then, we have

$$M(\widehat{\mathfrak{m}}_i \widehat{f}) = \begin{bmatrix} \widehat{\mathbf{f}}_i^0 \\ \widehat{\mathbf{f}}_i^1 \end{bmatrix} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}^{\otimes(n-1)} \begin{bmatrix} \widehat{\mathbf{f}}_i^{0\,\mathrm{T}} & \widehat{\mathbf{f}}_i^{1\,\mathrm{T}} \end{bmatrix} = \begin{bmatrix} \widehat{\mathbf{f}}_i^0 \\ \widehat{\mathbf{f}}_i^1 \end{bmatrix} \begin{bmatrix} \overline{\widehat{\mathbf{f}}_i^1}^{\mathrm{T}} & \overline{\widehat{\mathbf{f}}_i^0}^{\mathrm{T}} \end{bmatrix} = \begin{bmatrix} \langle \widehat{\mathbf{f}}_i^0, \widehat{\mathbf{f}}_i^1 \rangle & |\widehat{\mathbf{f}}_i^0|^2 \\ |\widehat{\mathbf{f}}_i^1|^2 & \langle \widehat{\mathbf{f}}_i^1, \widehat{\mathbf{f}}_i^0 \rangle \end{bmatrix}. \tag{3.2}$$

Here, due to ARS, the complex inner product can also be represented by mating using $\neq_2$.

3.4 Known results

We give some known signature sets that define tractable, i.e., polynomial time computable, counting problems. There are three families: product-type signatures, affine signatures and local affine signatures denoted by $\mathscr{P}$, $\mathscr{A}$ and $\mathscr{L}$ respectively. Please see the full paper or [22] for definitions and more details. Problems defined by $\mathscr{T}$ are also tractable.

▶ **Definition 20.** *We say a signature set $\mathcal{F}$ is $\mathscr{C}$-transformable if there exists a $T \in \mathbf{GL}_2(\mathbb{C})$ such that $(=_2)(T^{-1})^{\otimes 2} \in \mathscr{C}$ and $T\mathcal{F} \subseteq \mathscr{C}$.*

By Theorem 18, if $\text{Holant}(\mathscr{C})$ is tractable, then $\text{Holant}(\mathcal{F})$ is tractable for any $\mathscr{C}$-transformable set $\mathcal{F}$. The following tractable results are known [22, 3].

▶ **Theorem 21.** *For any complex-valued signature set $\mathcal{F}$,* Holant$(\mathcal{F})$ *is P-time computable if*

$$\mathcal{F} \subseteq \mathscr{T}, \quad \mathcal{F} \text{ is } \mathscr{P}\text{-transformable}, \quad \mathcal{F} \text{ is } \mathscr{A}\text{-transformable}, \quad \text{or } \mathcal{F} \text{ is } \mathscr{L}\text{-transformable}. \tag{T}$$

Based on dichotomy results of #CSP and Holant^c [21, 22, 3], the following #P-hardness results are known.

▶ **Theorem 22.** *Let $\mathcal{F}$ be a set of real-valued signatures. If $\mathcal{F}$ does not satisfy condition* (T)*, then* $\#\mathrm{CSP}(\mathcal{F})$*,* $\#\mathrm{CSP}_2(\mathcal{F})$ *and* $\mathrm{Holant}^c(\mathcal{F})$ *are #P-hard.*

For reducible signatures, the following reduction was proved by Lin and Wang [37].

▶ **Lemma 23.** *If a nonzero real-valued signature f has a factorization $g \otimes h$ where g and h are also real-valued signatures, then* $\mathrm{Holant}(g, h, \mathcal{F}) \equiv_T \mathrm{Holant}(f, \mathcal{F})$*. In this case, we say that g and h are realizable from f by factorization.*

4 Proof Sketch for Theorem 10

We give a proof sketch for Theorem 10.

By Theorem 21, if $\mathcal{F}$ satisfies condition (T), then $\mathrm{Holant}(\mathcal{F})$ is tractable. We prove #P-hardness when $\mathcal{F}$ does not satisfy condition (T). First, we show that under some holographic transformations, either one can use a signature of odd arity in $\mathcal{F}$ to realize the unary signature $\Delta_0 = (1, 0)$, or one can realize an equality signature $=_k$ for some $k \geqslant 3$.

▶ **Lemma 24.** *Let $\mathcal{F}$ be a set of real-valued signatures containing a signature of odd arity. Then* $\mathrm{Holant}(\neq_2|=_k, \widehat{\mathcal{F}}) \leqslant_T \mathrm{Holant}(\mathcal{F})$ *for some $k \geqslant 3$, or* $\mathrm{Holant}(\Delta_0, Q\mathcal{F}) \leqslant_T \mathrm{Holant}(\mathcal{F})$ *for some real orthogonal 2-by-2 matrix $Q \in \mathbf{O}_2(\mathbb{R})$.*

We first prove the #P-hardness of $\mathrm{Holant}(\neq_2|=_k, \widehat{\mathcal{F}})$ given $k \geqslant 3$ and $\mathcal{F}$ does not satisfy condition (T). We give the following reduction.

▶ **Lemma 25.** *If $k \geqslant 3$, then* $\#\mathrm{CSP}_k(\neq_2, \mathcal{G}) \equiv_T \mathrm{Holant}(\mathcal{EQ}_k\ |\neq_2, \mathcal{G}) \leqslant_T \mathrm{Holant}(\neq_2|=_k, \mathcal{G})$*.*

Proof. The first equivalence is by definition. For the second reduction, we show that $=_{nk}$ can be realized on the LHS by induction on n. First, we connect one variable of each of k copies of $\neq_2$ on the LHS with the k variables of $=_k$ on the RHS (Figure 1a). This gadget realizes $=_k$ on the LHS.

Then, suppose that $=_{nk}$ is realizable on the LHS. We take one copy of $=_{nk}$ and two copies of $=_k$ on the LHS, and one copy of $=_k$ on the RHS. Remember that $k \geqslant 3$. We connect two variables of $=_k$ on the RHS with one variable of each of the two copies of $=_k$ on the LHS, and connect the other $k - 2$ variables of $=_k$ on the RHS with $k - 2$ variables of $=_{nk}$ on the LHS (Figure 1b). This gadget realizes $=_{(n+1)k}$ on the LHS.

Also, connecting $k - 1$ variables of one copy of $=_k$ on the RHS with $k - 1$ variables of another copy of $=_k$ on the RHS using $\neq_2$ on the LHS realizes $\neq_2$ on the RHS. ◀

Then, we give a dichotomy of $\#\mathrm{CSP}_k(\neq_2, \mathcal{G})$ for any *complex*-valued signature set $\mathcal{G}$. This result should be of independent interest. Let $\rho_k = e^{\frac{\mathrm{i}\pi}{2k}}$ be a $4k$-th primitive root of unity, $T_k = \left[\begin{smallmatrix} 1 & 0 \\ 0 & \rho_k \end{smallmatrix}\right]$, and $\mathcal{A}_k^d = T_k^d \mathcal{A} = \{T_k^d f \mid f \in \mathcal{A}\}$ where $d \in [k]$.

▶ **Theorem 26.** *Let $\mathcal{G}$ be a set of complex-valued signatures. If $\mathcal{G} \subseteq \mathcal{P}$ or $\mathcal{G} \subseteq \mathcal{A}_k^d$ for some $d \in [k]$. then* $\#\mathrm{CSP}_k(\neq_2, \mathcal{G})$ *is tractable; otherwise,* $\#\mathrm{CSP}_k(\neq_2, \mathcal{G})$ *is* # P*-hard.*

When $\mathcal{F}$ does not satisfy condition (T), we can show that $\widehat{\mathcal{F}} \notin \mathcal{P}$ and $\widehat{\mathcal{F}} \notin \mathcal{A}_k^d$ for any $d \in [k]$. Combining with Lemma 25 and Theorem 26, we have the following result.

▶ **Lemma 27.** *Let $\mathcal{F}$ be a set of complex-valued signatures. If $\mathcal{F}$ does not satisfy condition* (T) *and $k \geqslant 3$, then* $\mathrm{Holant}(\neq_2|=_k, \widehat{\mathcal{F}})$ *is #P-hard.*

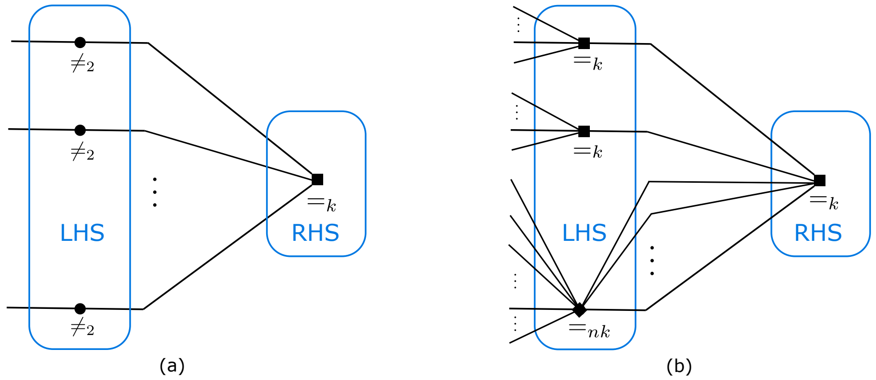

Figure 1 Gadgets realizing $=_k$ and $=_{(n+1)k}$ on the LHS.

Next, we prove the #P-hardness of Holant$(\Delta_0, Q\mathcal{F})$ given $\mathcal{F}$ is a real-valued signature set not satisfying condition (T) and $Q \in \mathbf{O}_2(\mathbb{R})$. Under this condition, we can show that $Q\mathcal{F}$ is also a real-valued signature set not satisfying condition (T). Thus, in order to prove Holant$(\Delta_0, Q\mathcal{F})$ is #P-hard, it suffices to show that Holant$(\Delta_0, \mathcal{F})$ is #P-hard for any real-valued signature set $\mathcal{F}$ not satisfying condition (T). Here, we will apply our entanglement result (Lemma 9) to the proof of #P-hardness. If Δ_1 is realizable from Holant$(\Delta_0, \mathcal{F})$, then we reduce Holant$(\Delta_0, \mathcal{F})$ from Holant$^c(\mathcal{F})$ and we are done by the dichotomy of Holant$^c(\mathcal{F})$. By using Δ_0, we first give two conditions that Δ_1 can be easily realized by pinning or interpolation. We show that either Holant$^c(\mathcal{F}) \leqslant_T$ Holant$(\Delta_0, \mathcal{F})$, or every irreducible $f \in \mathcal{F}$ satisfies the following important *first order orthogonality* condition.

▶ **Definition 28** (First order orthogonality). *Let f be a complex-valued signature of arity $n \geqslant 2$, we say that it satisfies* first order orthogonality (1st-Orth) *if there exists some $\mu \neq 0$ such that for all indices $i \in [n]$, the entries of f satisfy the following equations*

$$|\boldsymbol{f}_i^0|^2 = |\boldsymbol{f}_i^1|^2 = \mu, \text{ and } \langle \boldsymbol{f}_i^0, \boldsymbol{f}_i^1 \rangle = 0.$$

To restate it in the quantum terminology, let $|\Psi\rangle$ be a normalized n-qubit ($n \geqslant 2$) state, i.e., $\langle \Psi|\Psi\rangle = 1$. Then it satisfies first order orthogonality if for every i-th qubit of $|\Psi\rangle$, $\langle \Psi_i^0|\Psi_i^0\rangle = \langle \Psi_i^1|\Psi_i^1\rangle = 1/2$ and $\langle \Psi_i^0|\Psi_i^1\rangle = 0$.

▶ Remark 29. When f is a real-valued signature, the inner product is just the ordinary dot product which can be represented by mating using $=_2$. Thus, f satisfies 1st-Orth iff there is some real $\mu \neq 0$ such that for all indices i, $M(\mathfrak{m}_i f) = \mu I_2$. On the other hand, when $\widehat{f}$ is a signature with ARS, by equation (3.2), the complex inner product can also be represented by mating using $\neq_2$. Thus, $\widehat{f}$ satisfies 1st-Orth iff there is some real $\mu \neq 0$ such that for all i, $M(\widehat{\mathfrak{m}}_i \widehat{f}) = \mu N_2$. Moreover, f satisfies 1st-Orth iff $\widehat{f}$ satisfies it. Although 1st-Orth is well-defined for any complex-valued signature, the properties of $\mathfrak{m}_i f$ and $\widehat{\mathfrak{m}}_i \widehat{f}$ crucially depend on f being real (equivalently $\widehat{f}$ satisfying ARS).

Back to the proof of the #P-hardness of Holant$(\Delta_0, \mathcal{F})$. Since $\mathcal{F}$ does not satisfy condition (T), $\mathcal{F} \not\subseteq \mathscr{T}$. Hence, there is a signature $f \in \mathcal{F}$ of arity $n \geqslant 3$ such that $f \notin \mathscr{T}$. In other words, $\mathcal{F}$ contains an n-qubit state exhibiting multipartite entanglement. We will prove #P-hardness by induction on n. We first consider the base case that $n = 3$. We show that an irreducible ternary signature (a genuinely entangled 3-qubit state) satisfying first order orthogonality has some special forms, from which one can realize $=_3$ or $=_4$ after some holographic transformations. Then, we can reduce the problem from #CSP$(\mathcal{F})$, or

#CSP$_2(\mathcal{F})$, or Holant$(\neq_2|=_3, \widehat{\mathcal{F}})$, to Holant$(\Delta_0, \mathcal{F})$. This allows us to finish the proof by invoking existing dichotomy results for #CSP$(\mathcal{F})$, or #CSP$_2(\mathcal{F})$, or the #P-hardness result we showed above for Holant$(\neq_2|=_k, \widehat{\mathcal{F}})$ where $k \geqslant 3$.

▶ **Lemma 30.** *Let $\mathcal{F}$ be a set of real-valued signatures containing a ternary signature $f \notin \mathfrak{T}$. If $\mathcal{F}$ does not satisfy condition* (T)*, then* Holant$(\Delta_0, \mathcal{F})$ *is #P-hard.*

Then, we consider the inductive step. The general strategy is that we start with a signature $f \in \mathcal{F}$ of arity $n \geqslant 4$ that is not in $\mathfrak{T}$, and realize a signature g of arity $n-1$ or $n-2$ also not in $\mathfrak{T}$, by pinning or merging. (By the definition of $\mathfrak{T}$, when $n = 4$, this g must have arity 3.) By a sequence of reductions (that is constant in length independent of the problem instance size), we can realize a signature h of arity 3 that is not in $\mathfrak{T}$. Then we are done. In other words, given an n-qubit state with multipartite entanglement, we want to show that multipartite entanglement is preserved under projections onto $|0\rangle$ and self-loops by $|\phi^+\rangle$. Lemma 9 says that the preservation holds, or $|1\rangle$ or $|\mathrm{GHZ}_4\rangle$ is realizable. We give an inductive restatement of Lemma 9 in the Holant framework.

▶ **Lemma 31.** *Let $f \in \mathcal{F}$ be a signature of arity $n \geqslant 4$ and $f \notin \mathfrak{T}$. Then one of the following alternatives must hold:*

- Δ_1 *is realizable:* Holant$(\Delta_0, \Delta_1, \mathcal{F}) \leqslant_T$ Holant$(\Delta_0, \mathcal{F})$*, or*
- $=_4$ *is realizable:* Holant$(=_4, \mathcal{F}) \leqslant_T$ Holant$(\Delta_0, \mathcal{F})$*, or*
- *a signature $g \notin \mathfrak{T}$ of arity $n-1$ or $n-2$ is realizable:* Holant$(\Delta_0, g, \mathcal{F}) \leqslant_T$ Holant$(\Delta_0, \mathcal{F})$.

Proof Sketch. For all indices i and all pairs of indices $\{j, k\}$, consider f_i^0 and $\partial_{jk} f$. If there exists i or $\{j, k\}$ such that f_i^0 or $\partial_{jk} f \notin \mathfrak{T}$, then we can realize $g = f_i^0$ or $\partial_{jk} f$ which has arity $n-1$ or $n-2$, and we are done. Otherwise, f_i^0 and $\partial_{jk} f \in \mathfrak{T}$ for all i and all $\{j, k\}$. Under this assumption, our goal is to show that we can realize Δ_1, or there is a unary signature $a(x_u)$ or a binary signature $b(x_v, x_w)$ such that $a(x_u) \mid f$ or $b(x_v, x_w) \mid f$. Then, we have $f = a(x_u) \otimes g$ or $f = b(x_v, x_w) \otimes g$ for some g of arity $n-1$ or $n-2$. We know g can be realized from f by factorization. By the definition of $\mathfrak{T}$, we have $g \notin \mathfrak{T}$ since $f \notin \mathfrak{T}$, and we are done. When $n \geqslant 5$, the above induction proof can be achieved by the interplay of the unique prime factorization, and the commutivity of f_i^0 (pinning) and $\partial_{jk} f$ (merging) gadgets on disjoint indices. For $n = 4$, there is the additional case that $=_4$ can be realized. Thus for $n = 4$, it requires more work; we need to combine the induction proof and first order orthogonality to handle it. ◀

Remember that Holant$(\Delta_0, \Delta_1, \mathcal{F})$ is just Holant$^c(\mathcal{F})$ and #CSP$_2(\mathcal{F}) \leqslant_T$ Holant$(=_4, \mathcal{F})$. By Theorem 22, #CSP$_2(\mathcal{F})$ and Holant$^c(\mathcal{F})$ are both #P-hard when $\mathcal{F}$ does not satisfy condition (T). Combining with Lemmas 30 and 31, we have the following result.

▶ **Lemma 32.** *Let $\mathcal{F}$ be a set of real-valued signatures. If $\mathcal{F}$ does not satisfy condition* (T)*, then* Holant$(\Delta_0, \mathcal{F})$ *is #P-hard.*

Finally, combining Theorem 21 and Lemmas 24, 27 and 32, we finished the proof of Theorem 10.

Abstract

We study the approximation complexity of the partition function of the eight-vertex model on general 4-regular graphs. For the first time, we relate the approximability of the eight-vertex model to the complexity of approximately counting perfect matchings, a central open problem in this field. Our results extend those in [8].

In a region of the parameter space where no previous approximation complexity was known, we show that approximating the partition function is at least as hard as approximately counting perfect matchings via approximation-preserving reductions. In another region of the parameter space which is larger than the region that is previously known to admit Fully Polynomial Randomized Approximation Scheme (FPRAS), we show that computing the partition function can be reduced to counting perfect matchings (which is valid for both exact and approximate counting). Moreover, we give a complete characterization of nonnegatively weighted (not necessarily planar) 4-ary matchgates, which has been open for several years. The key ingredient of our proof is a *geometric* lemma.

We also identify a region of the parameter space where approximating the partition function on *planar* 4-regular graphs is feasible but on *general* 4-regular graphs is equivalent to approximately counting perfect matchings. To our best knowledge, these are the first problems that exhibit this dichotomic behavior between the planar and the nonplanar settings in approximate counting.

1 Introduction

The eight-vertex model is defined over 4-regular graphs, the states of which are the set of *even orientations*, i.e. those with an even number of arrows into (and out of) each vertex. There are eight permitted types of local configurations around a vertex – hence the name eight-vertex model (see Figure 1).

Classically, the eight-vertex model is defined by statistical physicists on a square lattice region where each vertex of the lattice is connected by an edge to four nearest neighbors. In general, the eight configurations 1 to 8 in Figure 1 are associated with eight possible weights $w_1, \ldots, w_8$. By physical considerations, the total weight of a state remains unchanged if all arrows are flipped, assuming there is no external electric field. In this case we write $w_1 = w_2 = a$, $w_3 = w_4 = b$, $w_5 = w_6 = c$, and $w_7 = w_8 = d$. This complementary invariance is known as *arrow reversal symmetry* or *zero field assumption*.

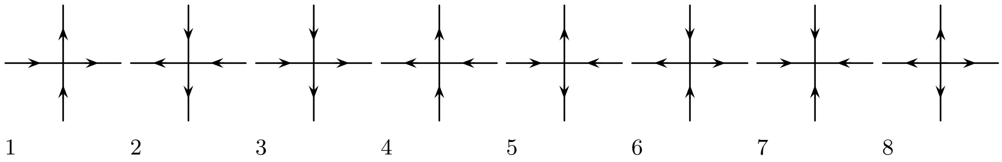

Figure 1 Valid configurations of the eight-vertex model.

Even in the zero-field setting, this model is already enormously expressive: the special case when $d = 0$ is the zero-field six-vertex model which has sub-models such as the ice ($a = b = c$), KDP, and Rys F models; on the square lattice, some other important models such as the dimer and zero-field Ising models can be reduced to the eight-vertex model [2]. After it was introduced in 1970 by Sutherland [19] and by Fan and Wu [9], Baxter [1, 2] achieved a good understanding of the zero-field case in the thermodynamic limit on the square lattice (in physics it is called an "exactly solved model").

In this paper, we assume the arrow reversal symmetry and further assume that $a, b, c, d \geq 0$, as is the case in *classical* physics. Given a 4-regular graph G, we label four incident edges of each vertex from 1 to 4. The *partition function* of the eight-vertex model with parameters (a, b, c, d) on G is defined as

$$Z_{\mathrm{EV}}(G; a, b, c, d) = \sum_{\tau \in \mathcal{O}_{\mathbf{e}}(G)} a^{n_1+n_2} b^{n_3+n_4} c^{n_5+n_6} d^{n_7+n_8}, \tag{1}$$

where $\mathcal{O}_{\mathbf{e}}(G)$ is the set of all even orientations of G, and n_i is the number of vertices in type i in G ($1 \leq i \leq 8$, locally depicted as in Figure 1 where the 4 edges are oriented counterclockwise starting from the edge on the left) under an even orientation $\tau \in \mathcal{O}_{\mathbf{e}}(G)$.

In terms of the exact computational complexity, a complexity dichotomy is given for the eight-vertex model on 4-regular graphs for all eight parameters [6]. This is studied in the context of a classification program for the complexity of counting problems [5], where the eight-vertex model serves as important basic cases for Holant problems defined by not necessarily symmetric constraint functions. It is shown that every setting is either P-time computable (and some are surprising) or #P-hard. However, most cases for P-time tractability are due to nontrivial cancellations. In our setting where a, b, c, d are nonnegative, the problem of computing the partition function of the eight-vertex model exactly is #P-hard unless: (1) $a = b = c = d$ (this is equivalent to the unweighted case); (2) at least three of a, b, c, d are zero; or (3) two of a, b, c, d are zero and the other two are equal. In addition, on planar graphs it is also P-time computable for parameter settings (a, b, c, d) with $a^2 + b^2 = c^2 + d^2$, using the *FKT algorithm*.

Since exact computation is hard in most cases, one natural question is what is the approximate complexity of counting and sampling of the eight-vertex model. To our best knowledge, prior to [8], there is only one previous result in this regard due to Greenberg and Randall [12]. They showed that on square lattice regions a specific Markov chain (which flips the orientations of all four edges along a uniformly picked face at each step) is torpidly mixing when d is large. This means that when sinks and sources have large weights, this particular chain *cannot* be used to approximately count or sample eight-vertex configurations on the square lattice according to the Gibbs measure. Recently, similar torpid mixing results have been achieved for the six-vertex model on the square lattice [17].

The paper [8] gave the first classification results for the approximate complexity of the eight-vertex model on general and planar 4-regular graphs, and they conform to phase transition in physics. In order to state the results, we adopt the following notations assuming $a, b, c, d \geq 0$.

- $\mathcal{X} = \{\ (a,b,c,d) \mid a \le b+c+d,\ \ b \le a+c+d,\ \ c \le b+c+d,\ \ d \le a+b+c\}$;
- $\mathcal{Y} = \{\ (a,b,c,d) \mid a+d \le b+c,\ \ b+d \le a+c,\ \ c+d \le a+b\}$;
- $\mathcal{Z} = \{\ (a,b,c,d) \mid a^2 \le b^2+c^2+d^2,\ \ b^2 \le a^2+c^2+d^2,\ \ c^2 \le a^2+b^2+d^2,\ \ d^2 \le a^2+b^2+c^2\}$.

▶ Remark 1. $\mathcal{Y} \subset \mathcal{X}$. $\mathcal{Z} \subset \mathcal{X}$.

Physicists have shown an *order-disorder phase transition* for the eight-vertex model on the square lattice between parameter settings outside $\mathcal{X}$ and those inside $\mathcal{X}$ (see Baxter's book [3] for more details). In [8], it was shown that: (1) approximating the partition function of the eight-vertex model on general 4-regular graphs outside $\mathcal{X}$ is NP-hard, (2) there is an FPRAS[1] for general 4-regular graphs in the region $\mathcal{Y} \bigcap \mathcal{Z}$, and (3) there is an FPRAS for planar 4-regular graphs in the extra region $\{(a,b,c,d) \mid a+d \le b+c,\ \ b+d \le a+c,\ \ c+d \ge a+b\} \bigcap \mathcal{Z}$.

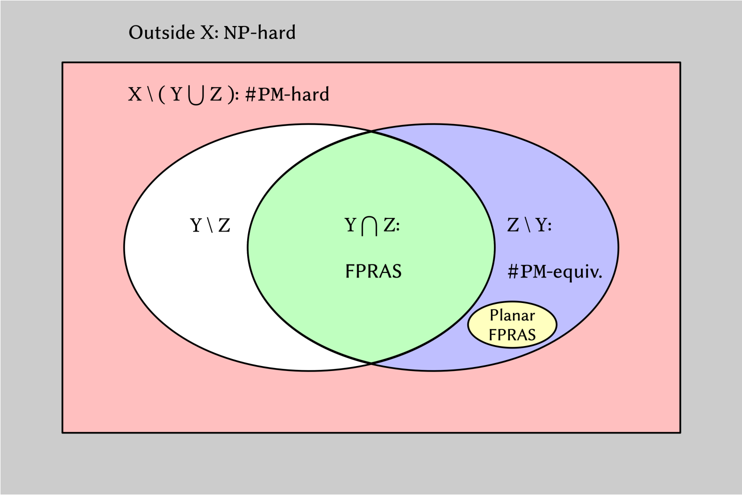

Figure 2 A Venn diagram of the approximation complexity of the eight-vertex model.

In this paper we make further progress in the classification of the approximate complexity of the eight-vertex model on 4-regular graphs in terms of the parameters (see Figure 2). For the first time, the complexity of approximating the partition function of the eight-vertex model ($\#\mathrm{EV}(a,b,c,d)$) is related to that of approximately counting perfect matchings ($\#\mathrm{PM}$).

▶ **Theorem 2.** *For any four positive numbers $a,b,c,d > 0$ such that $(a,b,c,d) \notin \mathcal{Y}$, the problem $\#\mathrm{EV}(a,b,c,d)$ is at least as hard to approximate as counting perfect matchings:*

$$\#\mathrm{PM} \le_{\mathrm{AP}} \#\mathrm{EV}(a,b,c,d).$$

▶ Remark 3. The theorem is stated for the case where all four parameters are positive. The same proof also works for the case when there is exactly one zero among the nonnegative values $\{a,b,c\}$. A complete account for four nonnegative values $\{a,b,c,d\}$ is given in the Table 1. There is a symmetry among a,b,c for the eight-vertex model on general (not necessarily planar) 4-regular graphs, so for simplicity in this table we assume $a \le b \le c$.

[1] Suppose $f : \Sigma^* \to \mathbb{R}$ is a function mapping problem instances to real numbers. A *fully polynomial randomized approximation scheme (FPRAS)* [14] for a problem is a randomized algorithm that takes as input an instance x and $\varepsilon > 0$, running in time polynomial in n (the input length) and ε^{-1}, and outputs a number Y (a random variable) such that $\Pr\left[(1-\varepsilon)f(x) \le Y \le (1+\varepsilon)f(x)\right] \ge \frac{3}{4}$.

Table 1 Approximation complexity of the eight-vertex model with $(a, b, c, d) \notin d\text{-}\mathtt{SUM}^2$.

	$d = 0$	$d > 0$
$a = b = c = 0$	P-time computable (trivial)	P-time computable (trivial)
$a = b = 0, c > 0$	P-time computable (trivial)	$c = d$: P-time computable [6] $c \neq d$: NP-hard [8]
$a = 0, b, c > 0$	NP-hard [8]	#PM-hard (in this paper)
$a, b, c > 0$	NP-hard [7]	#PM-hard (in this paper)

The proof of Theorem 2 is in Section 3. Our proof for the hardness result has several ingredients:

1. We express the eight-vertex model on a 4-regular graph G as an edge-2-coloring problem on G using Valiant's *holographic transformation* [22].
2. We show that a modified version of the edge-2-coloring problem on G is equivalent to the zero-field Ising model on its *crossing-circuit graph* denoted by $\widetilde{G}$. Thus known #PM-equivalence result for the Ising model [11, Lemma 7] directly transfers to the modified version of the edge-2-coloring problem under certain parameter settings.
3. We further show that for any parameter setting outside $\mathcal{Y}$, approximating the partition function of the eight-vertex model is at least as hard as the #PM-equivalent modified edge-2-coloring problem via approximation-preserving reductions.

▶ **Theorem 4.** *For any* $(a, b, c, d) \in \mathcal{Z}$*,*

$$\#\mathrm{EV}(a, b, c, d) \leq_{\mathrm{AP}} \#\mathrm{PM}.$$

The proof of Theorem 4 is in Section 4. To prove the #PM-easiness result, we again express the eight-vertex model in the Holant framework (see Section 2) and show that the constraint functions of the eight-vertex model in $\mathcal{Z}$ can be implemented by constant-size *matchgates* with nonnegatively weighted edges (Definition 13). We note that allowing nonnegative edge-weights does not add more computational power to the unweighted #PM [18, Proposition 5]. The crucial ingredient of our proof is a *geometric* lemma (Lemma 18) in 3-dimensional space.

This matchgate expressibility is tight: no constraint functions of the eight-vertex model with parameter settings outside the region $\mathcal{Z}$ can be implemented by a matchgate (Lemma 19). Moreover, the general version of our result also works for the eight-vertex model without the arrow reversal symmetry. It is open if approximately computing the partition function in $\mathcal{X} \setminus (\mathcal{Y} \bigcup \mathcal{Z})$ is #PM-equivalent or not.

As part of this work, we give a complete characterization of the constraint functions that can be expressed by 4-ary matchgates in Theorem 15. This solves an important question that has been open for several years [18, 4]. We believe it is of independent interest.

▶ **Corollary 5.** *For any four positive numbers* $a, b, c, d > 0$ *such that* $(a, b, c, d) \in \mathcal{Z} \setminus \mathcal{Y}$*,*

$$\#\mathrm{EV}(a, b, c, d) \equiv_{\mathrm{AP}} \#\mathrm{PM}.$$

Note that for the eight-vertex model in the region[3] $\{(a,b,c,d) \mid a+d \le b+c, \;\; b+d \le a+c, \;\; c+d > a+b\} \bigcap \mathcal{Z}$, computing $Z_{\mathrm{EV}}(a,b,c,d)$ is (1) #P-complete in exact computation [6], (2) #PM-equivalent in approximate computation on general 4-regular graphs (Corollary 5), and (3) admits an FPRAS in approximate computation on planar 4-regular graphs [8]. To our best knowledge, these are the first identified problems having these three properties. Previously the combined results of [10] and [13] proved that counting k-colorings for certain range of parameters is FPRASable on general graphs but NP-hard in approximate complexity. The complexity result in this paper is different because the complexity we described in item (2) above is #PM-equivalent (neither harder nor easier). We note that the complexity status of #PM is a long standing open problem in the field (neither known to be FPRASable nor known to be NP-hard to approximate). These results contrast with, in the setting of approximately counting, the FKT algorithm for exact counting which shows that the #P-hard problem #PM can be computed in polynomial time on planar graphs.

2 Preliminaries

Given a 4-regular graph $G=(V,E)$, the *edge-vertex incidence graph* $G'=(U_E,U_V,E')$ is a bipartite graph where $(u_e,u_v) \in U_E \times U_V$ is an edge in E' iff $e \in E$ in G is incident to $v \in V$. We model an orientation $(w \to v)$ on an edge $e=\{w,v\} \in E$ from w into v in G by assigning 1 to $(u_e,u_w) \in E'$ and 0 to $(u_e,u_v) \in E'$ in G'. A configuration of the eight-vertex model on G is an *edge-2-coloring* on G', namely $\sigma : E' \to \{0,1\}$, where for each $u_e \in U_E$ its two incident edges are assigned 01 or 10, and for each $u_v \in U_V$ the sum of values $\sum_{i=1}^{4} \sigma(e_i) \equiv 0 \pmod 2$, over the four incident edges of u_v. Thus we model the even orientation rule of G on all $v \in V$ by requiring “two-0-two-1/four-0/four-1” locally at each vertex $u_v \in U_V$.

The “one-0-one-1” requirement on the two edges incident to a vertex in U_E is a binary Disequality constraint, denoted by $(\neq_2)$. The values of a 4-ary *constraint function*, or a *signature* f can be listed in a matrix $M(f) = \begin{bmatrix} f_{0000} & f_{0010} & f_{0001} & f_{0011} \\ f_{0100} & f_{0110} & f_{0101} & f_{0111} \\ f_{1000} & f_{1010} & f_{1001} & f_{1011} \\ f_{1100} & f_{1110} & f_{1101} & f_{1111} \end{bmatrix}$, called the *constraint matrix* of f. For the eight-vertex model satisfying the even orientation rule and arrow reversal symmetry, the signature f at every vertex $v \in U_V$ in G' has the form $M(f) = \begin{bmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{bmatrix}$, if we draw a vertex with incident edges labeled 1, 2, 3, and 4 locally as the left, down, right, and up edges respectively according to Figure 1. Thus computing the partition function $Z_{\mathrm{EV}}(G;a,b,c,d)$ is equivalent to evaluating

$$Z'(G';f) := \sum_{\sigma : E' \to \{0,1\}} \prod_{u \in U_E} (\neq_2)\left(\sigma|_{E'(u)}\right) \prod_{u \in U_V} f\left(\sigma|_{E'(u)}\right).$$

where $E'(u)$ denotes the incident edges of $u \in U_E \cup U_V$. In fact, in this way we express the partition function of the eight-vertex model as the Holant sum in the framework for Holant problems:

$$Z_{\mathrm{EV}}(G;a,b,c,d) = \mathrm{Holant}\left(G'; \neq_2 \mid f\right)$$

where we use $\mathrm{Holant}(H; g \mid f)$ to denote the sum $\sum_{\sigma : E \to \{0,1\}} \prod_{u \in U} g\left(\sigma|_{E(u)}\right) \prod_{u \in V} f\left(\sigma|_{E(u)}\right)$ on a bipartite graph $H=(U,V,E)$. Each vertex in U (or V) is assigned the signature g (or f, respectively). The signature g is considered as a row vector (or covariant tensor),

[3] This region is the intersection of $\overline{\mathcal{Y}}$ and the extra region $\{(a,b,c,d) \mid a+d \le b+c, \;\; b+d \le a+c, \;\; c+d \ge a+b\}$ where there is an FPRAS for planar graphs. Note that the strict inequality $c+d > a+b$ is needed.

whereas the signature f is considered as a column vector (or contravariant tensor). (See [5] for more on Holant problems.) The following proposition says that an invertible holographic transformation does not change the complexity of the Holant problem in the bipartite setting.

▶ **Proposition 6** ([22]). *Suppose $T \in \mathbb{C}^2$ is an invertible matrix. Let $d_1 = \operatorname{arity}(g)$ and $d_2 = \operatorname{arity}(f)$. Define $g' = g\left(T^{-1}\right)^{\otimes d_1}$ and $f' = T^{\otimes d_2} f$. Then for any bipartite graph H, $\operatorname{Holant}(H; g \mid f) = \operatorname{Holant}(H; g' \mid f')$.*

We denote $\operatorname{Holant}(G; f) = \operatorname{Holant}(G'; =_2 \mid f)$ and use $\operatorname{Holant}(f)$ to denote the problem whose input is a graph G and output is $\operatorname{Holant}(G; f)$; this is equivalent to the usual definition.

3 #PerfectMatchings-hardness

Our proof strategy for Theorem 2 is as follows. In Lemma 7, we express the eight-vertex model on a 4-regular graph G as a Holant problem; this is an equivalent form of the orientation problem expressed as an edge-2-coloring problem on G, and is achieved using a holographic transformation. In Lemma 8, we give an approximation-preserving reduction to show that this edge-2-coloring problem is at least as hard as a modified version of the edge-2-coloring problem where weights at some input originally in the support are dropped off. In Lemma 9, we establish the equivalence between this modified version of the edge-2-coloring problem and the zero-field Ising model. Thus a known result for the Ising model (Proposition 11) indicates the #PM-equivalence of this modified version of the edge-2-coloring problem under certain parameter settings (Corollary 12). It can be deduced from Lemma 7, Lemma 8, and Corollary 12 that for any (a, b, c, d) with $a + d > b + c$ (and symmetrically $b + d > a + c$ or $c + d > a + b$), approximately computing the partition function is at least as hard as the #PM-equivalent modified edge-2-coloring problem under approximation-preserving reductions.

▶ **Lemma 7.**

$$2^{|V(G)|} \cdot Z_{\mathrm{EV}}(G; a, b, c, d) = \operatorname{Holant}\left(G; \begin{bmatrix} a{+}b{+}c{+}d & 0 & 0 & -a{+}b{+}c{-}d \\ 0 & a{-}b{+}c{-}d & a{+}b{-}c{-}d & 0 \\ 0 & a{+}b{-}c{-}d & a{-}b{+}c{-}d & 0 \\ -a{+}b{+}c{-}d & 0 & 0 & a{+}b{+}c{+}d \end{bmatrix}\right).$$

Proof. Using the binary disequality function ($\neq_2$) for the orientation of any edge, we can express the partition function of the eight-vertex model G as a Holant problem on its edge-vertex incidence graph G',

$$Z_{\mathrm{EV}}(G; a, b, c, d) = \operatorname{Holant}\left(G'; \neq_2 \mid f\right),$$

where f is the 4-ary signature with $M(f) = \left[\begin{smallmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{smallmatrix}\right]$. Note that, writing the truth table of $(\neq_2) = (0, 1, 1, 0)$ as a vector and multiplied by a tensor power of the matrix Z^{-1}, where $Z = \frac{1}{\sqrt{2}}\left[\begin{smallmatrix} 1 & 1 \\ i & -i \end{smallmatrix}\right]$ we get $(\neq_2)(Z^{-1})^{\otimes 2} = (1, 0, 0, 1)$, which is exactly the truth table of the binary equality function ($=_2$). Then according to Proposition 6, by the Z-transformation, we get

$$\begin{aligned} \operatorname{Holant}\left(G'; \neq_2 \mid f\right) &= \operatorname{Holant}\left(G'; \neq_2 \cdot \left(Z^{-1}\right)^{\otimes 2} \mid Z^{\otimes 4} \cdot f\right) \\ &= \operatorname{Holant}\left(G'; =_2 \mid Z^{\otimes 4} f\right) \\ &= \operatorname{Holant}\left(G;\ Z^{\otimes 4} f\right), \end{aligned}$$

and a direct calculation shows that $M(Z^{\otimes 4} f) = \frac{1}{2}\begin{bmatrix} a{+}b{+}c{+}d & 0 & 0 & -a{+}b{+}c{-}d \\ 0 & a{-}b{+}c{-}d & a{+}b{-}c{-}d & 0 \\ 0 & a{+}b{-}c{-}d & a{-}b{+}c{-}d & 0 \\ -a{+}b{+}c{-}d & 0 & 0 & a{+}b{+}c{+}d \end{bmatrix}$. ◀

▶ **Lemma 8.** *Suppose $d > 0$ and at most one of a, b, c is zero. Then*

$$\operatorname{Holant}\left(\begin{bmatrix} a+b+c+d & 0 & 0 & -a+b+c-d \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -a+b+c-d & 0 & 0 & a+b+c+d \end{bmatrix}\right) \leq_{\mathrm{AP}} \operatorname{Holant}\left(\begin{bmatrix} a+b+c+d & 0 & 0 & -a+b+c-d \\ 0 & a-b+c-d & a+b-c-d & 0 \\ 0 & a+b-c-d & a-b+c-d & 0 \\ -a+b+c-d & 0 & 0 & a+b+c+d \end{bmatrix}\right).$$

Proof. This task can be reduced to

$$\operatorname{Holant}\left(\neq_2 \mid \begin{bmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{bmatrix}, \begin{bmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix}\right) \leq_{\mathrm{AP}} \operatorname{Holant}\left(\neq_2 \mid \begin{bmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{bmatrix}\right) \tag{2}$$

and the analysis can be found in the full version of this paper.

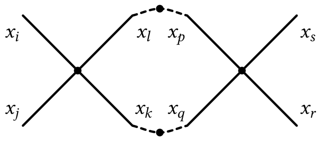

Figure 3 A gadget construction.

Next we show how to get (2). Given the signature f with matrix $\begin{bmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{bmatrix}$ in #EV(a,b,c,d), we construct a 4-ary signature $\check{f}$ with constraint matrix $\begin{bmatrix} \check{d} & 0 & 0 & \check{a} \\ 0 & \check{b} & \check{c} & 0 \\ 0 & \check{c} & \check{b} & 0 \\ \check{a} & 0 & 0 & \check{d} \end{bmatrix}$ using a polynomial number of vertices and edges such that $\check{a}$, $\check{b}$, $\check{c}$, and $\check{d}$ are all exponentially close to 1 after normalization, i.e., to be 2^{-n^C} close to 1, for any $C > 0$, with a construction of $n^{O(1)}$ size in polynomial time.

We assume we start with the following condition:

$$0 < d \leq a \leq b \leq c. \tag{3}$$

If this is not the case, we can obtain a 4-ary construction that realizes this condition using constantly many vertices. With some preliminary construction we can further assume $1 \leq d \leq a \leq b \leq c \leq \frac{3}{2}d$ initially. (See the full version of this paper for details.) Note that starting with the signature f with matrix $M(f) = \begin{bmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{bmatrix}$, we can arbitrarily permute a, b, c by relabeling the edges, and so we get signatures f_1 with $M(f_1) = \begin{bmatrix} d & 0 & 0 & b \\ 0 & a & c & 0 \\ 0 & c & a & 0 \\ b & 0 & 0 & d \end{bmatrix}$ and f_2 with $M(f_2) = \begin{bmatrix} d & 0 & 0 & c \\ 0 & a & b & 0 \\ 0 & b & a & 0 \\ c & 0 & 0 & d \end{bmatrix}$. There are two constructions G_1 and G_2 which we use as basic steps; both constructions start with a signature f with parameters satisfying (3).

1. $\boldsymbol{G_1}$: connect two vertices with signatures f_1 and f_2 respectively as in Figure 3. Since we are in the orientation view, we place the signature $(\neq_2)$ on the two degree 2 vertices connecting the two degree 4 vertices. Then the signature g_1 of the construction G_1 is obtained by matrix multiplication $M(g_1) = M_{x_i x_j, x_s x_r}(g_1) = M(f_1) \cdot N \cdot M(f_2)$, where $N = \begin{bmatrix} & & & 1 \\ & & 1 & \\ & 1 & & \\ 1 & & & \end{bmatrix}$. Thus

$$M(g_1) = \begin{bmatrix} (b+c)d & 0 & 0 & bc+d^2 \\ 0 & a(b+c) & a^2+bc & 0 \\ 0 & a^2+bc & a(b+c) & 0 \\ bc+d^2 & 0 & 0 & (b+c)d \end{bmatrix}.$$

The signature g_1 has four new parameters, denoted by

$$(a_1,\ b_1,\ c_1,\ d_1) = (a(b+c),\ bc+d^2,\ a^2+bc,\ (b+c)d).$$

We make the following observations and all of them can be easily verified using (3):

- d_1 is the weight on sink and source and $0 < d_1 \leq a_1, b_1, c_1$.
- $c_1 = \max(a_1, b_1, c_1, d_1)$.
- $\frac{a_1}{d_1} = \frac{a}{d}, \frac{b_1}{d_1} \leq \frac{b}{d}, \frac{c_1}{d_1} \leq \frac{c}{d}$.
- $c_1 d_1 \leq a_1 b_1$ because $c_1 d_1 - a_1 b_1 = -(b+c)(a-d)(bc-ad) \leq 0$.

2. ***G*$_2$**: connect two vertices with signatures f_2 as in Figure 3. Denote the signature of G_2 by g_2. We have

$$M(g_2) = M(f_2) \cdot N \cdot M(f_2) = \begin{bmatrix} 2cd & 0 & 0 & c^2+d^2 \\ 0 & 2ab & a^2+b^2 & 0 \\ 0 & a^2+b^2 & 2ab & 0 \\ c^2+d^2 & 0 & 0 & 2cd \end{bmatrix}.$$

The signature g_2 has four new parameters, denoted by

$$(a_2,\ b_2,\ c_2,\ d_2) = (2ab,\ a^2+b^2,\ c^2+d^2,\ 2cd).$$

The following observations can also be easily verified using (3):

- d_2 is the weight on sink and source and if $cd \leq ab$, then $0 < d_2 \leq a_2, b_2, c_2$.
- $\frac{a_2}{d_2} \leq \frac{a}{d}, \frac{b_2}{d_2} \leq \frac{b}{d}, \frac{c_2}{d_2} \leq \frac{c}{d}$.
- $\frac{c_2 - d_2}{d_2} = \frac{(c-d)^2}{2cd} \leq \frac{1}{2}\left(\frac{c-d}{d}\right)^2 \leq \left(\frac{c-d}{d}\right)^2$.

Based on the two basic constructions above, we construct the signature $\check{f}$ in logarithmically many rounds recursively, each of the $O(\log n)$ rounds uses the signature constructed in the previous round. We now describe a single round in this construction, which consists of two steps. In step 1 we use a signature with some parameter setting (a, b, c, d) satisfying (3) and apply G_1 to two copies of the signature. If the resulting parameter $b_1 < a_1$ we switch the roles of a_1 and b_1, and obtain $(a'_1, b'_1, c'_1, d'_1) = (b_1, a_1, c_1, d_1)$, again satisfying (3), as well as $c_1 d_1 \leq a_1 b_1$. In step 2, we apply G_2 to two copies of the signature constructed in step 1 (with the switching of the roles of a_1 and b_1 if it is needed). Denote the parameters of the resulting signature by (a^*, b^*, c^*, d^*). Altogether each round uses four copies of the signature from the previous round, starting with the initial given signature. Therefore in polynomial time we can afford to carry out $C \log n$ rounds for any constant C. Note that, if we consider the normalized quantities $(\frac{a}{d}, \frac{b}{d}, \frac{c}{d}, \frac{d}{d})$, then the respective quantities in each step G_1 and G_2 do not increase their distances to 1, i.e.,

$$0 \leq \frac{a^*}{d^*} - 1 \leq \frac{a}{d} - 1, \quad 0 \leq \frac{b^*}{d^*} - 1 \leq \frac{b}{d} - 1, \quad 0 \leq \frac{c^*}{d^*} - 1 \leq \frac{c}{d} - 1.$$

This is true even if the G_2 construction in step 2 is applied in the case when the roles of a_1 and b_1 are switched for the signature from step 1, when that switch is required $(b_1 < a_1)$ as described. More importantly, based on the properties of G_1 and G_2, we know that the (normalized) gap between d and the previous largest entry c shrinks quadratically fast, as measured by the new c^* normalized with d^*. More precisely,

$$0 \leq \frac{c^*}{d^*} - 1 \leq \left(\frac{c}{d} - 1\right)^2.$$

Note that c^* may no longer be the largest among a^*, b^*, c^*; however we will permute them to get $\widetilde{a}, \widetilde{b}, \widetilde{c}$ so that (3) is still satisfied before proceeding to the next round. This completes the description of our construction in one round which obtains $(\widetilde{a}, \widetilde{b}, \widetilde{c}, \widetilde{d})$ from (a, b, c, d).

We will construct the final signature $\check{f}$ by $O(\log n)$ rounds of this construction. Also we will follow each value a, b, c individually as they get transformed through each round. To state it formally, starting with the normalized triple $(\frac{a}{d}, \frac{b}{d}, \frac{c}{d})$, we define a successor triple $(\frac{a^*}{d^*}, \frac{b^*}{d^*}, \frac{c^*}{d^*})$, so that each entry has the respective successor (e.g., the entry $\frac{a}{d}$ has successor $\frac{a^*}{d^*}$). This is well-defined because (a_1, b_1, c_1, d_1) and (a_2, b_2, c_2, d_2) are homogeneous functions of (a, b, c, d). Note that even though from one round to the next, we may have to rename a^*, b^*, c^* so that the permutated triple $\widetilde{a}, \widetilde{b}, \widetilde{c}$ satisfies (3), the successor sequence as the rounds progress stays with an individual value. E.g., starting from (a, b, c, d), if after one round $a^* = \max(a^*, b^*, c^*, d^*) = \widetilde{c}$, then the successor of $\frac{a}{d}$ after two rounds is $\frac{(\widetilde{c})^*}{(d^*)^*}$. Now define $(\alpha_k, \beta_k, \gamma_k)$ to be the (ordered) triple $(\frac{a}{d}, \frac{b}{d}, \frac{c}{d})$ for $k = 1$, or its successor triple, at the beginning of the k-th round for $k > 1$.

Let $\check{f}$ be the 4-ary signature constructed after $3(k+1)$ rounds. By the *Pigeonhole Principle*, after $3(k+1)$ rounds, at least one of a, b, c has the property that in at least $k+1$ many rounds (let $1 \le i_0 < i_1 < \ldots < i_k \le 3(k+1)$ be $k+1$ such rounds) the corresponding $\frac{a}{d}, \frac{b}{d}, \frac{c}{d}$ or its successors are the maximum (normalized) value in that round, and thus its next successor gets shrunken quadratically in that round. Suppose this is a; the same proof works if it is b or c. Let α_i be the maximum (normalized) value at the beginning of round i in $k+1$ rounds, where $i \in \{i_0, \ldots, i_k\}$. Since initially we have $1 \le d \le a \le b \le c \le \frac{3}{2}d$,

$$0 \le \alpha_{i_1} - 1 \le \alpha_{i_0+1} - 1 \le (\alpha_{i_0} - 1)^2 \le \frac{1}{2^2}.$$

Then

$$0 \le \alpha_{i_2} - 1 \le \alpha_{i_1+1} - 1 \le (\alpha_{i_1} - 1)^2 \le \frac{1}{2^{2^2}}.$$

By induction $0 \le \alpha_{i_k} - 1 \le \frac{1}{2^{2^k}}$. At the end of $3(k+1)$ rounds, if $\check{f}$ has parameters $(\check{a}, \check{b}, \check{c}, \check{d})$, then

$$0 \le \frac{\max(\check{a}, \check{b}, \check{c})}{\check{d}} - 1 \le \alpha_{i_k} - 1 \le \frac{1}{2^{2^k}}.$$

Therefore, after logarithmically many rounds, using polynomially many vertices, we can get a 4-ary construction with parameters $\check{a}$, $\check{b}$, $\check{c}$, and $\check{d}$ that are exponentially close to 1 after normalizing by $\check{d}$. Thus (2) is proved. ◀

Problem : ISING(β).
Instance : Graph $G = (V, E)$.
Output: $Z_{\text{ISING}}(G; \beta) := \sum_{\sigma: V \to \{0,1\}} \beta^{\text{mono}(\sigma)}$, where mono($\sigma$) denotes the number of edges $\{u, v\}$ such that $\sigma(u) = \sigma(v)$.

▶ **Lemma 9.** *The Ising problem* ISING $\left(\frac{w}{x}\right)$ *is equivalent to the Holant problem* Holant $\left(\begin{bmatrix} w & 0 & 0 & x \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ x & 0 & 0 & w \end{bmatrix}\right)$. *In particular,* ISING $\left(\frac{w}{x}\right) \equiv_{\text{AP}}$ Holant $\left(\begin{bmatrix} w & 0 & 0 & x \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ x & 0 & 0 & w \end{bmatrix}\right)$.

▶ Remark 10. A non-homogenized form of the Ising model is $\widetilde{Z}_{\text{ISING}}(G; x, w) := \sum_{\sigma: V \to \{0,1\}} w^{\text{mono}(\sigma)} x^{|E| - \text{mono}(\sigma)}$. If $x \neq 0$ then $\widetilde{Z}_{\text{ISING}}(G; x, w) = x^{|E|} Z_{\text{ISING}}(G; \frac{w}{x})$. If $x = 0$ then in $\widetilde{Z}_{\text{ISING}}$ all vertices in each component must take the same assignment (all 0 or all 1). In this case both $\widetilde{Z}_{\text{ISING}}(G; x, w)$ and the Holant problem in Lemma 9 are trivially solvable in polynomial time.

Proof. For the problem Holant $\left(\begin{bmatrix} w & 0 & 0 & x \\ 0 & y & z & 0 \\ 0 & z & y & 0 \\ x & 0 & 0 & w \end{bmatrix}\right)$, the roles of x, y, z are interchangeable by relabeling the edges. For example, if the signature $f(x_1, x_2, x_3, x_4)$ has the constraint matrix $\begin{bmatrix} w & 0 & 0 & x \\ 0 & y & z & 0 \\ 0 & z & y & 0 \\ x & 0 & 0 & w \end{bmatrix}$, then the signature $f(x_1, x_3, x_2, x_4)$ has the constraint matrix $\begin{bmatrix} w & 0 & 0 & z \\ 0 & y & x & 0 \\ 0 & x & y & 0 \\ z & 0 & 0 & w \end{bmatrix}$. It follows that

$$\text{Holant}\left(\begin{bmatrix} w & 0 & 0 & x \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ x & 0 & 0 & w \end{bmatrix}\right) \quad \text{and} \quad \text{Holant}\left(\begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & x & 0 \\ 0 & x & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right)$$

are exactly the same problem. So to prove the lemma it suffices to prove the equivalence of

$$\textsc{Ising}\left(\frac{w}{z}\right) \quad \text{and} \quad \text{Holant}\left(\begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & z & 0 \\ 0 & z & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right).$$

First we show that Holant $\left(\begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & z & 0 \\ 0 & z & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right)$ can be expressed as $\textsc{Ising}\left(\frac{w}{z}\right)$.

Given a 4-regular graph $G = (V, E)$ as an instance of Holant $\left(\begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & z & 0 \\ 0 & z & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right)$, we can partition E into a set $\mathcal{C}$ of *circuits* (in which vertices may repeat but edges cannot) in the following way: at every vertex $v \in V$, denote the four edges incident to v by e_1, e_2, e_3, e_4 in a cyclic order according to the local labeling of the signature function; we make e_1 and e_3 into adjacent edges in a single circuit, and similarly we make e_2 and e_4 into adjacent edges in a single circuit (note that these may be the same circuit). We say each circuit in $\mathcal{C}$ is a *crossing circuit* of G. For the graph G, we define its *crossing-circuit graph* $\widetilde{G} = (\mathcal{C}, \widetilde{E})$, with possible multiloops and multiedges, as follows: its vertex set $\mathcal{C}$ consists of the crossing circuits; for every $v \in V$, if circuits C_1 and C_2 intersect at v, then there is an edge $\widetilde{e}_v \in \widetilde{E}$ labeled by v. Note that it is possible that $C_1 = C_2$, and for such a self-intersectison point the edge $\widetilde{e}_v$ is a loop. Each $C \in \mathcal{C}$ may have multiple loops, and for distinct circuits C_1 and C_2 there may be multiple edges between them. The edge set $\widetilde{E}$ of $\widetilde{G}$ is in 1-1 correspondence with V of G.

Observe that the problem Holant $\left(\begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & z & 0 \\ 0 & z & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right)$ requires that every valid configuration σ (that contributes a non-zero term) obeys the following rule at each vertex v:

- Assuming e_1, e_2, e_3, e_4 are the four edges incident to v in cyclic order, then $\sigma(e_1) = \sigma(e_3)$ (denoted by b_1) and $\sigma(e_2) = \sigma(e_4)$ (denoted by b_2). That is to say, all edges in a crossing circuit must have the same assignment (either all 0 or all 1). Therefore, the valid configurations σ on the edges of G are in 1-1 correspondence with $0, 1$-assignments σ' on the vertices of $\widetilde{G}$.
- Under σ, the local weight on v is w if $b_1 = b_2$ and is z otherwise. Suppose crossing circuits C_1 and C_2 intersect at v (they could be identical). Then in $\widetilde{G}$, σ' has local weight w on the edge $\widetilde{e}_v$ if $\sigma'(C_1) = \sigma'(C_2)$ and has local weight z otherwise.

This means

$$\text{Holant}\left(G; \begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & z & 0 \\ 0 & z & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right) = z^{|V(G)|} \cdot Z_{\textsc{Ising}}\left(\widetilde{G}; \frac{w}{z}\right).$$

Next we show that $\textsc{Ising}\left(\frac{w}{z}\right)$ can be expressed as Holant $\left(\begin{bmatrix} w & 0 & 0 & 0 \\ 0 & 0 & z & 0 \\ 0 & z & 0 & 0 \\ 0 & 0 & 0 & w \end{bmatrix}\right)$. Note that every graph $G = (V, E)$ (without isolated vertices) is the crossing-circuit graph of some 4-regular graph $\overline{G}$. To define $\overline{G}$ from G, one only needs to do the following: (1) transform each vertex $v \in V$ into a closed cycle C_v; (2) for each loop at $v \in V$, make a self-intersection on C_v; and (3) for each non-loop edge $\{u, v\} \in E$ (u and v are two distinct vertices), make C_u and C_v

intersect in a "crossing" way at a vertex in $\overline{G}$ (by first creating a vertex p on C_u and another vertex p' on C_v, then merging p and p' with local labeling $1, 3$ on C_u and $2, 4$ on C_v). Then the above proof holds for the reverse direction. ◀

▶ **Proposition 11** ([11, Lemma 7]). *Suppose $\beta < -1$. Then $\#\mathrm{PM} \equiv_{\mathrm{AP}} \textsc{Ising}(\beta)$.*

▶ **Corollary 12.** *Suppose $x \neq 0$ and $\frac{w}{x} < -1$. Then $\#\mathrm{PM} \equiv_{\mathrm{AP}} \mathrm{Holant}\left(\left[\begin{smallmatrix} w & 0 & 0 & x \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ x & 0 & 0 & w \end{smallmatrix}\right]\right)$.*

When $a+d > b+c$ we have $\frac{a+b+c+d}{-a+b+c-d} < -1$, so by Corollary 12, Lemma 8, and Lemma 7,

$$\begin{aligned}
\#\mathrm{PM} &\equiv_{\mathrm{AP}} \mathrm{Holant}\left(\left[\begin{smallmatrix} a+b+c+d & 0 & 0 & -a+b+c-d \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -a+b+c-d & 0 & 0 & a+b+c+d \end{smallmatrix}\right]\right) \\
&\leq_{\mathrm{AP}} \mathrm{Holant}\left(\left[\begin{smallmatrix} a+b+c+d & 0 & 0 & -a+b+c-d \\ 0 & a-b+c-d & a+b-c-d & 0 \\ 0 & a+b-c-d & a-b+c-d & 0 \\ -a+b+c-d & 0 & 0 & a+b+c+d \end{smallmatrix}\right]\right) \\
&\equiv_{\mathrm{AP}} \#\mathrm{EV}(a, b, c, d).
\end{aligned}$$

By the symmetry of a, b, c, we have proved Theorem 2.

4 #PerfectMatchings-easiness

In this section, we address two problems:

1. What are the signatures that can be realized by 4-ary matchgates (Definition 13)?
   Although the set of signatures that can be realized by planar matchgates with complex edge weights have been completely characterized [5], the set of signatures that can be realized by general (not necessarily planar) matchgates with nonnegative real edge weights is not fully understood, even for matchgates of arity 4. This type of matchgates plays a crucial role in the study of the approximate complexity of counting problems [18, 4], as we will see in this paper.
   In Theorem 15, we give a complete characterization of signatures of arity 4 that can be realized by matchgates with nonnegative real edges. Our method is primarily geometric.
2. Theorem 2 shows that for positive parameters $(a, b, c, d) \notin \mathcal{Y}$ the problem $\#\mathrm{EV}(a, b, c, d)$ is at least as hard as counting perfect matchings approximately. Here we ask the reverse question: For what parameter settings (a, b, c, d) does $\#\mathrm{EV}(a, b, c, d) \leq_{\mathrm{AP}} \#\mathrm{PM}$?
   We know that

   $$Z_{\mathrm{EV}}(G; a, b, c, d) = \mathrm{Holant}\left(G'; {\neq_2} \mid f\right),$$

   where f is the 4-ary signature with $M(f) = \left[\begin{smallmatrix} d & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & d \end{smallmatrix}\right]$. Considering the fact that $(\neq_2)$ can be easily realized by a matchgate (a vertex with two dangling edges), Theorem 4 is a direct consequence of Lemma 17 which says that any signature in $\mathscr{Z}$ is realizable by some *4-ary matchgate* of constant size (with nonnegative edge weights, but not necessarily planar) (see Definition 13). Our theorem works for the eight-vertex model with parameter settings $\mathcal{S}^{\mathrm{E}}_{\leq 2}$ (defined below) not necessarily satisfying the arrow reversal symmetry.
   Moreover, Lemma 19 indicates that our result is tight in the sense that $\mathcal{S}^{\mathrm{E}}_{\leq 2}$ captures precisely the set of all signatures that can be realized by 4-ary matchgates (with even support, i.e., nonzero only on inputs of even Hamming weight). A similar statement holds for $\mathcal{S}^{\mathrm{O}}_{\leq 2}$. the corresponding set with odd support.

▶ **Definition 13.** *We use the term* a k-ary matchgate *to denote a graph* Γ *having* k *"dangling" edges, labelled* $i_1, \ldots, i_k$*. Each dangling edge has weight* 1 *and each non-dangling edge* e *is equipped with a nonnegative weight* w_e*. A configuration is a* $0,1$*-assignment to the edges. A configuration is a perfect matching if every vertex has exactly one incident edge assigned* 1*. A* k*-ary matchgate implements the signature* f*, where* $f(b_1, \ldots, b_k)$ *for* $(b_1, \ldots, b_k) \in \{0,1\}^k$ *is the sum, over perfect matchings, of the product of the weight of edges with assignment* 1*, where the dangling edge* i_j *is assigned* b_j*, and the empty product has weight* 1*.*

▶ Remark 14. Contrary to Definition 13 which does not require planarity, planar matchgates with complex edge weights has been completely characterized [21, 5]. As computing the weighted sum of perfect matchings is in polynomial time over planar graphs by the *FKT algorithm* [20, 15, 16], problems that can be locally expressed by planar matchgates are tractable over planar graphs.

▶ **Notation.**

$$\mathcal{S}^{\mathrm{E}}_{\leq^2} = \{f \mid M(f) = \begin{bmatrix} d_1 & 0 & 0 & a_1 \\ 0 & b_1 & c_1 & 0 \\ 0 & c_2 & b_2 & 0 \\ a_2 & 0 & 0 & d_2 \end{bmatrix} \textit{ satisfying } \begin{cases} a_1a_2 \leq b_1b_2 + c_1c_2 + d_1d_2 \\ b_1b_2 \leq a_1a_2 + c_1c_2 + d_1d_2 \\ c_1c_2 \leq a_1a_2 + b_1b_2 + d_1d_2 \\ d_1d_2 \leq a_1a_2 + b_1b_2 + c_1c_2 \end{cases}, a_1, \cdots, d_2 \geq 0.\},$$

$$\mathcal{S}^{\mathrm{O}}_{\leq^2} = \{f \mid M(f) = \begin{bmatrix} 0 & d_1 & a_1 & 0 \\ b_1 & 0 & 0 & c_1 \\ c_2 & 0 & 0 & b_2 \\ 0 & a_2 & d_2 & 0 \end{bmatrix} \textit{ satisfying } \begin{cases} a_1a_2 \leq b_1b_2 + c_1c_2 + d_1d_2 \\ b_1b_2 \leq a_1a_2 + c_1c_2 + d_1d_2 \\ c_1c_2 \leq a_1a_2 + b_1b_2 + d_1d_2 \\ d_1d_2 \leq a_1a_2 + b_1b_2 + c_1c_2 \end{cases}, a_1, \cdots, d_2 \geq 0.\}.$$

▶ **Theorem 15.** *Denote by* $\mathcal{M}$ *the set of signatures that can be realized by 4-ary matchgates. Then* $\mathcal{M} = \mathcal{S}^{\mathrm{E}}_{\leq^2} \bigcup \mathcal{S}^{\mathrm{O}}_{\leq^2}$.

▶ Remark 16. Note that any signature in $\mathcal{M}$ must satisfy either *even parity* (nonzero only on inputs of even Hamming weight) or *odd parity* (nonzero only on inputs of odd Hamming weight). Theorem 15 for the even parity part ($\mathcal{S}^{\mathrm{E}}_{\leq^2}$) is a combination of Lemma 17 and Lemma 19. The odd parity part can be proved similarly.

▶ **Lemma 17.** *Suppose* $f \in \mathcal{S}^{\mathrm{E}}_{\leq^2}$*. Then there is a 4-ary matchgate of constant size whose signature is* f*.*

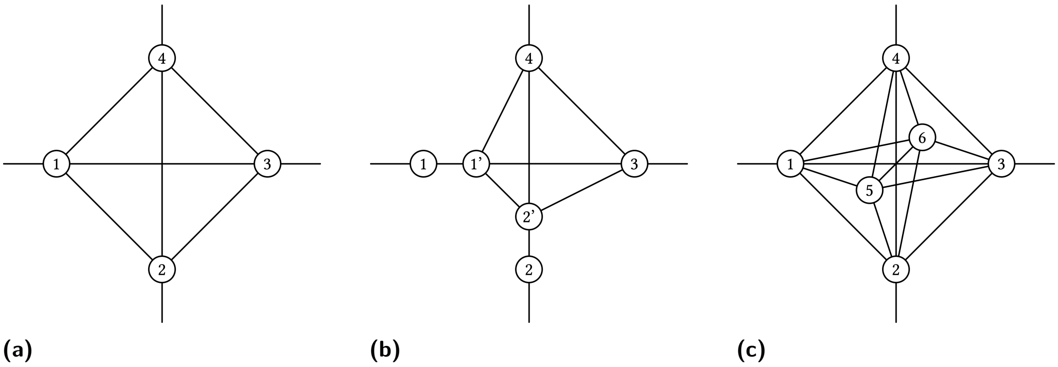

Figure 4 4-ary matchgates.

Proof. We first note that if any of the four inequalities in the definition of $\mathcal{S}_{\leq^2}$ is an equality, then the remaining three inequalities automatically hold, since the 8 values $a_1, \ldots, d_2$ are all nonnegative.

Given a signature $\begin{bmatrix} d_1 & 0 & 0 & a_1 \\ 0 & b_1 & c_1 & 0 \\ 0 & c_2 & b_2 & 0 \\ a_2 & 0 & 0 & d_2 \end{bmatrix}$, first we construct a matchgate for $d_1d_2 = a_1a_2+b_1b_2+c_1c_2$. If $d_1d_2 = 0$ then all four products $a_1a_2 = b_2b_2 = c_1c_2 = d_1d_2 = 0$, and one can easily adapt from the following proof to show that the signature is realizable as a matchgate signature. So it suffices to implement the normalized version $\begin{bmatrix} a_1a_2+b_1b_2+c_1c_2 & 0 & 0 & a_1 \\ 0 & b_1 & c_1 & 0 \\ 0 & c_2 & b_2 & 0 \\ a_2 & 0 & 0 & 1 \end{bmatrix}$. Our construction is a weighted K_4 depicted in Figure 4a. Let e_1, e_2, e_3, e_4 be the dangling edges incident to vertices $1, 2, 3, 4$, respectively. Denote by w_{ij} the weight on the edge between vertex i and vertex j. One can check that the following weight assignment meets our need: $w_{12} = a_1, w_{34} = a_2, w_{14} = b_1, w_{23} = b_2, w_{13} = c_1, w_{24} = c_2$.

For $a_1a_2 = b_1b_2 + c_1c_2 + d_1d_2$, without loss of generality we assume $a_1a_2 \neq 0$ and we normalize $a_1 = 1$. Then our construction is shown in Figure 4b where we set $w_{11'} = 1, w_{22'} = 1, w_{1'2'} = d_2, w_{34} = d_1, w_{1'4} = c_2, w_{2'3} = c_1, w_{1'3} = b_2, w_{2'4} = b_1$. One can verify that it realizes the normalized signature $\begin{bmatrix} d_1 & 0 & 0 & 1 \\ 0 & b_1 & c_1 & 0 \\ 0 & c_2 & b_2 & 0 \\ b_1b_2+c_1c_2+d_1d_2 & 0 & 0 & d_2 \end{bmatrix}$. The construction for $b_1b_2 = a_1a_2 + c_1c_2 + d_1d_2$ and $c_1c_2 = a_1a_2 + b_1b_2 + d_1d_2$ are symmetric to the above case.

It remains to show that the interior

$$\begin{cases} a_1a_2 & < & b_1b_2 + c_1c_2 + d_1d_2 \\ b_1b_2 & < & a_1a_2 + c_1c_2 + d_1d_2 \\ c_1c_2 & < & a_1a_2 + b_1b_2 + d_1d_2 \\ d_1d_2 & < & a_1a_2 + b_1b_2 + c_1c_2 \end{cases} \tag{4}$$

can all be reached. We first deal with the case when all eight parameters are strictly positive and leave the other cases to the end of this proof. We use a weighted K_6 to be our matchgate depicted in Figure 4c, and set $w_{12} = r_1, w_{34} = r_2, w_{14} = s_1, w_{23} = s_2, w_{13} = t_1, w_{24} = t_2, w_{15} = p_1, w_{25} = p_2, w_{35} = p_3, w_{45} = p_4, w_{16} = q_1, w_{26} = q_2, w_{36} = q_3, w_{46} = q_4, w_{56} = 1$. Then the matchgate has a singature with the following parameters

$$\begin{aligned} a'_1 &= r_1 + p_1q_2 + p_2q_1, & a'_2 &= r_2 + p_3q_4 + p_4q_3, \\ b'_1 &= s_1 + p_1q_4 + p_4q_1, & b'_2 &= s_2 + p_2q_3 + p_3q_2, \\ c'_1 &= t_1 + p_1q_3 + p_3q_1, & c'_2 &= t_2 + p_2q_4 + p_4q_2, \\ d'_1 &= (r_1r_2 + s_1s_2 + t_1t_2)+ & d'_2 &= 1, \\ &\quad (p_3q_4 + p_4q_3)r_1 + (p_1q_2 + p_2q_1)r_2+ \\ &\quad (p_2q_3 + p_3q_2)s_1 + (p_1q_4 + p_4q_1)s_2+ \\ &\quad (p_2q_4 + p_4q_2)t_1 + (p_1q_3 + p_3q_1)t_2. \end{aligned}$$

Note that all the edge weights have to be nonnegative. By properly setting the edge weights in the matchgate, we show that we can achieve any relative ratios among the eight given positive values $a_1, a_2, b_1, b_2, c_1, c_2, d_1, d_2$ that satisfy (4). Our first step is to achieve any relative ratios among the four product values a_1a_2, b_1b_2, c_1c_2, d_1d_2 satisfying (4); and the second step is to adjust the relative ratio within the pairs $\{a_1, a_2\}$, $\{b_1, b_2\}$, $\{d_1, d_2\}$ and $\{c_1, c_2\}$ without affecting the product values. This can be justified by the observation that, by a scaling a global positive constant can be easily achieved, and all appearances of a_1 and a_2 in (4) are as a product a_1a_2, and similarly for $b_1, b_2, c_1, c_2, d_1, d_2$.

For the fourteen edge weights $r_1, \ldots, q_4$ to be determined, let

$$\begin{cases} A' = p_1p_2q_3q_4 + p_3p_4q_1q_2, & R = r_1r_2 + r_1(p_3q_4 + p_4q_3) + r_2(p_1q_2 + p_2q_1), \\ B' = p_1p_4q_2q_3 + p_2p_3q_1q_4, & S = s_1s_2 + s_1(p_2q_3 + p_3q_2) + s_2(p_1q_4 + p_4q_1), \\ C' = p_1p_3q_2q_4 + p_2p_4q_1q_3, & T = t_1t_2 + t_1(p_2q_4 + p_4q_2) + t_2(p_1q_3 + p_3q_1), \end{cases} \tag{5}$$

and define

$$\begin{cases} A & = & A' + S + T \\ B & = & B' + R + T \\ C & = & C' + R + S \\ D & = & A' + B' + C'. \end{cases} \tag{6}$$

Note that A', B', C', R, S, T are all nonnegative and so are A, B, C, D.

Our goal is to choose the fourteen edge weights $r_1, \ldots, q_4$ so that A, B, C, D are all positive and satisfy

$$\begin{cases} A & = \frac{1}{2}(b_1b_2 + c_1c_2 + d_1d_2 - a_1a_2) \\ B & = \frac{1}{2}(a_1a_2 + c_1c_2 + d_1d_2 - b_1b_2) \\ C & = \frac{1}{2}(a_1a_2 + b_1b_2 + d_1d_2 - c_1c_2) \\ D & = \frac{1}{2}(a_1a_2 + b_1b_2 + c_1c_2 - d_1d_2). \end{cases} \tag{7}$$

Note that, by definition, the left-side of (7) is precisely the right-side of (7) when $a_1, \ldots, d_2$ are replaced by $a'_1, \ldots, d'_2$ respectively. Denote the products $a_1a_2, b_1b_2, c_1c_2, d_1d_2$ by a^{**}, b^{**}, c^{**}, d^{**} respectively. Then (7) is a set of four linear equations $M \cdot \begin{bmatrix} a^{**} \\ b^{**} \\ c^{**} \\ d^{**} \end{bmatrix} = \begin{bmatrix} A \\ B \\ C \\ D \end{bmatrix}$, where $M = \frac{1}{2}\begin{bmatrix} -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 \end{bmatrix}$. Note that M is invertible and $M^{-1} = M$, so (7) is equivalent to $M \cdot \begin{bmatrix} A \\ B \\ C \\ D \end{bmatrix} = \begin{bmatrix} a^{**} \\ b^{**} \\ c^{**} \\ d^{**} \end{bmatrix}$, having an identical form. Since the requirement (4) in terms of $a^{**}, b^{**}, c^{**}, d^{**}$ translates into the requirement A, B, C, D being strictly positive via M, it is not surprising that the requirement $a^{**}, b^{**}, c^{**}, d^{**}$ being strictly positive translates into the requirement

$$\begin{cases} A < B + C + D \\ B < A + C + D \\ C < A + B + D \\ D < A + B + C, \end{cases} \tag{8}$$

and that A, B, C, D are positive is the same as (4).

Furthermore, let $\begin{cases} X=S+T \\ Y=R+T \\ Z=R+S \end{cases}$, then the requirement R, S, T being positive is equivalent to the requirement $\begin{cases} Y+Z>X \\ X+Z>Y \\ X+Y>Z \end{cases}$. This is because $\begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{bmatrix} \cdot \begin{bmatrix} R \\ S \\ T \end{bmatrix} = \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}$ is the same as $\frac{1}{2}\begin{bmatrix} -1 & 1 & 1 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \end{bmatrix} \cdot \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} R \\ S \\ T \end{bmatrix}$.

The crucial ingredient of our proof is a *geometric* lemma in 3-dimensional space. Suppose $a^{**}, b^{**}, c^{**}, d^{**}$ are positive and they satisfy (4). This defines $\begin{bmatrix} \tilde{A} \\ \tilde{B} \\ \tilde{C} \\ \tilde{D} \end{bmatrix} = M \cdot \begin{bmatrix} a^{**} \\ b^{**} \\ c^{**} \\ d^{**} \end{bmatrix}$. By a scaling we may assume $\tilde{D} = 1$. Hence $(\tilde{A}, \tilde{B}, \tilde{C}, \tilde{D})$ are positive and satisfy (8). Thus $(\tilde{A}, \tilde{B}, \tilde{C})$ belongs to the set U in the statement of Lemma 18.

By Lemma 18, there exist (strictly) positive tuples $(\tilde{A}', \tilde{B}', \tilde{C}')$ and $(\tilde{X}, \tilde{Y}, \tilde{Z})$ such that

$$(\tilde{A}, \tilde{B}, \tilde{C}) = (\tilde{A}', \tilde{B}', \tilde{C}') + (\tilde{X}, \tilde{Y}, \tilde{Z}),$$

satisfying $\tilde{A}' + \tilde{B}' + \tilde{C}' = 1$ and $\begin{cases} \tilde{Y}+\tilde{Z}>\tilde{X} \\ \tilde{X}+\tilde{Z}>\tilde{Y} \\ \tilde{X}+\tilde{Y}>\tilde{Z} \end{cases}$. By the previous observation this indicates that there exist (strictly) positive $\tilde{A}', \tilde{B}', \tilde{C}', \tilde{R}, \tilde{S}, \tilde{T}$ such that $\begin{cases} \tilde{A}=\tilde{A}'+\tilde{S}+\tilde{T} \\ \tilde{B}=\tilde{B}'+\tilde{R}+\tilde{T} \\ \tilde{C}=\tilde{C}'+\tilde{R}+\tilde{S} \\ \tilde{D}=\tilde{A}'+\tilde{B}'+\tilde{C}' \end{cases}$.

We first set p_i, q_i $(1 \le i \le 4)$ so that $(A', B', C') = c \cdot (\tilde{A}', \tilde{B}', \tilde{C}')$ for some constant c. To achieve this, set $q_1 = q_2 = q_3 = q_4 = 1$, and let o_1, o_2, o_3 be positive, and then set $p_1 = \sqrt{\frac{o_2 o_3}{o_1}}$, $p_2 = \sqrt{\frac{o_3 o_1}{o_2}}$, $p_3 = \sqrt{\frac{o_1 o_2}{o_3}}$, and $p_4 = \frac{1}{p_1 p_2 p_3}$. We have $p_1 p_2 p_3 p_4 = 1$, and $p_2 p_3 = o_1, p_3 p_1 = o_2, p_1 p_2 = o_3$. Then set $\begin{cases} A'=p_1p_2+\frac{1}{p_1p_2}=o_3+\frac{1}{o_3} \\ B'=p_2p_3+\frac{1}{p_2p_3}=o_1+\frac{1}{o_1} \\ C'=p_3p_1+\frac{1}{p_3p_1}=o_2+\frac{1}{o_2} \end{cases}$, which can be independently any positive numbers at least 2, by choosing o_1, o_2, o_3 to be suitable positive numbers. This allows us to get A', B', C' such that $(A', B', C') = c \cdot (\tilde{A}', \tilde{B}', \tilde{C}')$ for some constant c. Then it is obvious that $r_1, r_2, s_1, s_2, t_1, t_2$ can be set so that $(R, S, T) = c \cdot (\tilde{R}, \tilde{S}, \tilde{T})$. Compute A, B, C, D according to (6). As a consequence, $(A, B, C, D) = c \cdot (\tilde{A}, \tilde{B}, \tilde{C}, \tilde{D})$ is a valid solution.

To adjust the relative ratio between $\{d_1, d_2\}$, say increasing $\frac{d_2}{d_1}$ by δ, while keeping all product values and the relative ratios within the other three pairs, just increase $r_1, r_2, s_1, s_2, t_1, t_2$ by $\delta^{1/2}$ and increase p_i, q_i $(1 \le i \le 4)$ by $\delta^{1/4}$. Similarly, to increase $\frac{a_2}{a_1}$ by δ alone without affecting the other products and ratios, just increase r_2 by $\delta^{1/2}$ and p_3, p_4, q_3, q_4 by $\delta^{1/4}$, and decrease r_1 by $\delta^{1/2}$ and p_1, p_2, q_1, q_2 by $\delta^{1/4}$. The other cases are symmetric.

Finally we deal with the cases when there are zeros among the eight parameters. Note that at most one of $a_1a_2, b_1b_2, c_1c_2, d_1d_2$ is zero, because if at least two products are zero, say $a_1a_2 = b_1b_2 = 0$, then (4) forces a contradiction that $c_1c_2 < d_1d_2$ and $d_1d_2 < c_1c_2$. In the case $d_1d_2 = 0$:

- $d_1 = 0, d_2 \ne 0$: We make the modification that $w_{12} = w_{34} = w_{14} = w_{23} = w_{13} = w_{24} = 0$, i.e. $r_1, r_2, s_1, s_2, t_1, t_2 = 0$.
- $d_1 = d_2 = 0$: We make the further modification that $w_{56} = 0$.
- $d_1 \ne 0, d_2 = 0$: We connect the four dangling edges in Figure 4c to four degree 2 vertices, respectively. This switches the role of d_1 and d_2 in the previous proof.

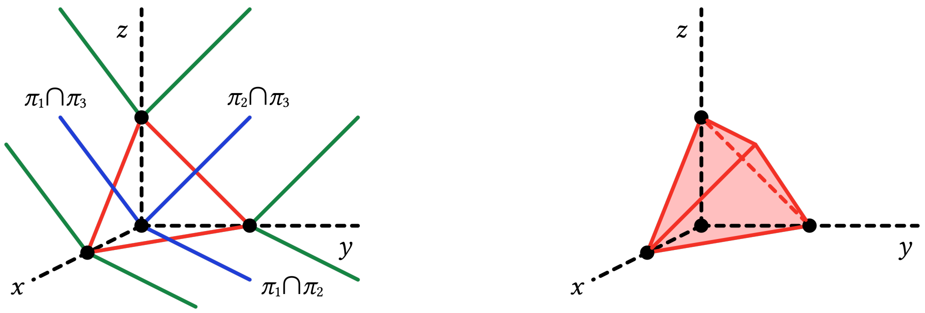
One can check our proof is still valid in the above three cases. If $a_1a_2 = 0$, then we connect the dangling edges on vertices 1, 2 to two degree 2 vertices (similar to the operation from Figure 4a to Figure 4b). This switches the role of d_1, d_2 with a_2, a_1 and the proof folllows. The proofs for $b_1b_2 = 0$ and $c_1c_2 = 0$ are symmetric. ◀

Now we give the crucial geometric lemma.

▶ **Lemma 18.** *Let* $U = \{(x, y, z) \in \mathbb{R}^3_{>0} \mid x < y+z+1, y < x+z+1, z < x+y+1, 1 < x+y+z\}$, $V = \{(x, y, z) \in \mathbb{R}^3_{>0} \mid x + y + z = 1\}$, *and* $W = \{(x, y, z) \in \mathbb{R}^3_{>0} \mid y + z > x, x + z > y, x + y > z\}$. *Then* U *is the Minkowski sum of* V *and* W, *namely,* U *consists of precisely those points* $\boldsymbol{u} \in \mathbb{R}^3$, *such that* $\boldsymbol{u} = \boldsymbol{v} + \boldsymbol{w}$ *for some* $\boldsymbol{v} \in V$ *and* $\boldsymbol{w} \in W$. *The same statement is true for the closures of* U, V *and* W *(in the topology of Euclidean space).*

Proof. Observe that U, V, and W are the interiors of a polyhedron with 7 facets, a regular triangle, and a polyhedron with 3 facets, respectively.

The polyhedron for W is the intersection of three half spaces bounded by three planes, $\begin{cases} (\pi_1): y+z \ge x \\ (\pi_2): x+z \ge y \\ (\pi_3): x+y \ge z \end{cases}$, where the planes are defined by equalities. Note that these inequalities imply that $x, y, z \ge 0$, thus this polyhedron has only three facets. We can find the intersection of each pair of the three planes for W as $\begin{cases} \pi_1 \cap \pi_2 : x=y \ge 0, z=0 \\ \pi_1 \cap \pi_3 : x=z \ge 0, y=0 \\ \pi_2 \cap \pi_3 : y=z \ge 0, x=0 \end{cases}$. Note that these intersections lie on the planes $z = 0$, $y = 0$, and $x = 0$, respectively.



(a) The blue rays are the intersections of the three facets for W. The red triangle is the boundary for V. The green rays together with the red triangle are the intersections of the seven facets for U.

(b) The tetrahedron in U that is left uncovered by sliding W along the boundary of V, but is covered by the rays from the simplex V in the direction of $(1,1,1)$.

Figure 5

Let $\boldsymbol{e}_1 = (1,0,0), \boldsymbol{e}_2 = (0,1,0), \boldsymbol{e}_3 = (0,0,1)$. Then the triangle for V is just the convex hull of $\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3$. Suppose we shift the origin of W from $\boldsymbol{0}$ to $\boldsymbol{e}_1$ and denote the resulting (interior of a) polyhedron by $W^{\boldsymbol{e}_1}$, then we have the defining inequalities $\begin{cases} (\pi_1^{\boldsymbol{e}_1}): y+z \geq (x-1) \\ (\pi_2^{\boldsymbol{e}_1}): (x-1)+z \geq y \\ (\pi_3^{\boldsymbol{e}_1}): (x-1)+y \geq z \end{cases}$, where the shifted planes are defined by the corresponding equalities. By symmetry, if we shift the origin of W to $\boldsymbol{e}_2$ and to $\boldsymbol{e}_3$, we have respectively $W^{\boldsymbol{e}_2}$ with $\begin{cases} (\pi_1^{\boldsymbol{e}_2}): (y-1)+z \geq x \\ (\pi_2^{\boldsymbol{e}_2}): x+z \geq (y-1) \\ (\pi_3^{\boldsymbol{e}_2}): x+(y-1) \geq z \end{cases}$, and $W^{\boldsymbol{e}_3}$ with $\begin{cases} (\pi_1^{\boldsymbol{e}_3}): y+(z-1) \geq x \\ (\pi_2^{\boldsymbol{e}_3}): x+(z-1) \geq y \\ (\pi_3^{\boldsymbol{e}_3}): x+y \geq (z-1) \end{cases}$. Note that the shifted planes $\pi_1^{\boldsymbol{e}_1}$, $\pi_2^{\boldsymbol{e}_2}$, and $\pi_3^{\boldsymbol{e}_3}$ contain three distinct facets of U, and they coincide exactly with a facet of $W^{\boldsymbol{e}_1}$, $W^{\boldsymbol{e}_2}$, and $W^{\boldsymbol{e}_3}$, respectively.

By sliding W with its origin along the line $x+y=1, z=0$ from $\boldsymbol{e}_1$ to $\boldsymbol{e}_2$, we have a partial coverage of U by the shifting copies of W from $W^{\boldsymbol{e}_1}$ and $W^{\boldsymbol{e}_2}$:

- The shifted ray of $\pi_1 \cap \pi_2 : x = y \geq 0, z = 0$ moves from $\pi_1^{\boldsymbol{e}_1} \cap \pi_2^{\boldsymbol{e}_1} : (x-1) = y \geq 0, z = 0$ to $\pi_1^{\boldsymbol{e}_2} \cap \pi_2^{\boldsymbol{e}_2} : x = (y-1) \geq 0, z = 0$. Notice that this is a parallel transport, and stays on the plane $z = 0$, and thus it swipes another facet of U on $z = 0$ bounded by the two lines $x - y = -1$ and $x - y = 1$.
- The shifted ray of $\pi_1 \cap \pi_3 : x = z \geq 0, y = 0$ moves from $\pi_1^{\boldsymbol{e}_1} \cap \pi_3^{\boldsymbol{e}_1} : (x-1) = z \geq 0, y = 0$ to $\pi_1^{\boldsymbol{e}_2} \cap \pi_3^{\boldsymbol{e}_2} : x = z \geq 0, (y-1) = 0$; the shifted ray of $\pi_2 \cap \pi_3 : y = z \geq 0, x = 0$ moves from $\pi_2^{\boldsymbol{e}_1} \cap \pi_3^{\boldsymbol{e}_1} : y = z \geq 0, (x-1) = 0$ to $\pi_2^{\boldsymbol{e}_2} \cap \pi_3^{\boldsymbol{e}_2} : (y-1) = z \geq 0, x = 0$. Notice that both stay on the plane $x + y - z = 1$ which is $\pi_3^{\boldsymbol{e}_1} = \pi_3^{\boldsymbol{e}_2}$.

It follows that the part of U satisfying $x + y - z > 1$ is covered by the Minkowski sum of W and the line segment on $x + y = 1, z = 0$ from $\boldsymbol{e}_1$ to $\boldsymbol{e}_2$ (which is a side of the triangle V).

Symmetrically, after sliding W with its origin from $\boldsymbol{e}_2$ to $\boldsymbol{e}_3$ along the line $y+z = 1, x = 0$ we get the parallel tranport from $W^{\boldsymbol{e}_2}$ to $W^{\boldsymbol{e}_3}$. Also after sliding W with its origin from $\boldsymbol{e}_3$ back to $\boldsymbol{e}_1$ along the line segment $x + z = 1, y = 0$ we get the parallel tranport from $W^{\boldsymbol{e}_3}$ to $W^{\boldsymbol{e}_1}$. After these, the only subset in U that is left uncovered by shifting copies of W is $U \cap \{(x,y,z) \mid \begin{cases} -x+y+z \leq 1 \\ x-y+z \leq 1 \\ x+y-z \leq 1 \end{cases} \} = \{(x,y,z) \in \mathbb{R}^3_{>0} \mid \begin{cases} x+y+z \geq 1 \\ -x+y+z \leq 1 \\ x-y+z \leq 1 \\ x+y-z \leq 1 \end{cases} \}$ – a *tetrahedron* (Figure 5b). However this subset can be covered by the rays $\{\boldsymbol{v} + \lambda(1,1,1) \mid \boldsymbol{v} \in V, \lambda > 0\}$. Note that $\lambda(1,1,1) \in W$ for all $\lambda > 0$.

Finally regarding the closures $\overline{U}, \overline{V}$ and $\overline{W}$, for $v_n \in V$ and $w_n \in W$, if $v_n \to v \in \overline{V}$ and $w_n \to w \in \overline{W}$, then $u_n = v_n + w_n \in U$, and $u_n \to v + w$. So $v + w \in \overline{U}$. Conversely, if $u_n \to u \in \overline{U}$, where $u_n \in U$, then $u_n = v_n + w_n$ for some $v_n \in V$ and $w_n \in W$. As V is bounded, there is a convergent subsequence $\{v_{n_k}\}$, such that $v = \lim_{k\to\infty} v_{n_k} \in \overline{V}$. Then $w_{n_k} = u_{n_k} - v_{n_k}$ also converges to some $w \in \overline{W}$, and then $u = \lim_{k\to\infty}(v_{n_k} + w_{n_k}) = v + w$, is a sum of points from $\overline{V}$ and $\overline{W}$.

This completes the proof. ◀

▶ **Lemma 19.** *Suppose f is the signature of a 4-ary matchgate with* $M(f) = \begin{bmatrix} d_1 & 0 & 0 & a_1 \\ 0 & b_1 & c_1 & 0 \\ 0 & c_2 & b_2 & 0 \\ a_2 & 0 & 0 & d_2 \end{bmatrix}$. *Then $f \in \mathcal{S}^{\mathrm{E}}_{\leq 2}$. In particular, if f satisfies arrow reversal symmetry, $f \in \mathcal{Z}$.*

▶ Remark 20. The last part $d_1 d_2 \ \leq\ a_1 a_2 + b_1 b_2 + c_1 c_2$ was proved in [4, Lemma 56]. The proofs for other three parts are symmetric and similar to the proof for the last part. For completeness, here we give the proof for the first part $a_1 a_2 \ \leq\ b_1 b_2 + c_1 c_2 + d_1 d_2$.

Proof. Consider a 4-ary matchgate Γ with signature f. Given that $M(f) = \begin{bmatrix} d_1 & 0 & 0 & a_1 \\ 0 & b_1 & c_1 & 0 \\ 0 & c_2 & b_2 & 0 \\ a_2 & 0 & 0 & d_2 \end{bmatrix}$, $a_1 a_2 \ \leq\ b_1 b_2 + c_1 c_2 + d_1 d_2$ is equivalent as

$$f(0011)f(1100) \leq f(0110)f(1001) + f(0101)f(1010) + f(0000)f(1111). \tag{9}$$

Let $I = \{i_1, i_2, i_3, i_4\}$ be the set of dangling edges of Γ. For $X \subseteq I$, let M_X denote the set of perfect matchings that include dangling edges in X (by assigning them 1) and exclude dangling edges in $I \setminus X$ (by assigning them 0). We exhibit an injective map

$$\mu : M_{\{i_1,i_2\}} \times M_{\{i_3,i_4\}} \to [M_{\{i_2,i_3\}} \times M_{\{i_1,i_4\}}] \bigcup [M_{\{i_2,i_4\}} \times M_{\{i_1,i_3\}}] \bigcup [M_{\emptyset} \times M_I]$$

which is weight-preserving in the sense that for matchings m_1, m_2, m_3, m_4 with $\mu(m_1, m_2) = (m_3, m_4)$, we have $w(m_1)w(m_2) = w(m_3)w(m_4)$. The existence of μ implies (9).

Given $(m_1, m_2) \in M_{\{i_1,i_2\}} \times M_{\{i_3,i_4\}}$, consider $m_1 \oplus m_2$ and note that this is a collection of cycles together with two paths. Let π be the path connecting the dangling edge i_1 to some other dangling edge; let π' be the path connecting the remaining two dangling edges. Let $m_3 := m_1 \oplus \pi$ and $m_4 := m_2 \oplus \pi$. Then we have the following

- If π connects i_1 to i_2, then $m_3 \in M_{\emptyset}$ and $m_4 \in M_I$;
- If π connects i_1 to i_3, then $m_3 \in M_{\{i_2,i_3\}}$ and $m_4 \in M_{\{i_1,i_4\}}$;
- If π connects i_1 to i_4, then $m_3 \in M_{\{i_2,i_4\}}$ and $m_4 \in M_{\{i_1,i_3\}}$.

The construction is invertible, since if (m_3, m_4) is in the image of the above mapping, then $m_3 \oplus m_4 = m_1 \oplus m_2$. From $m_1 \oplus m_2$, we can recover π (as the unique path that connects i_1 to one of the other dangling edges in $\{i_2, i_3, i_4\}$). Then we can recover m_1 and m_2 as $m_3 \oplus \pi$ and $m_4 \oplus \pi$ respectively. Therefore, $\mu : (m_1, m_2) \to (m_3, m_4)$ is an injection.

To see that μ is weight-preserving, observe that the each of the edges in π appears in exactly one of m_1 and m_2 and in exactly one of m_3 and m_4 and that $m_i \setminus \pi = m_{i+2} \setminus \pi$ for $i \in \{1, 2\}$. Hence,

$$w(m_1)w(m_2) = \prod_{e \in m_1 \setminus \pi} w_e \cdot \prod_{e \in m_2 \setminus \pi} w_e \cdot \prod_{e \in \pi} w_e = \prod_{e \in m_3 \setminus \pi} w_e \cdot \prod_{e \in m_4 \setminus \pi} w_e \cdot \prod_{e \in \pi} w_e = w(m_3)w(m_4).$$

Abstract

A roundtrip spanner of a directed graph G is a subgraph of G preserving roundtrip distances approximately for all pairs of vertices. Despite extensive research, there is still a small stretch gap between roundtrip spanners in directed graphs and undirected graphs. For a directed graph with real edge weights in $[1, W]$, we first propose a new deterministic algorithm that constructs a roundtrip spanner with $(2k-1)$ stretch and $O(kn^{1+1/k}\log(nW))$ edges for every integer $k > 1$, then remove the dependence of size on W to give a roundtrip spanner with $(2k-1)$ stretch and $O(kn^{1+1/k}\log n)$ edges. While keeping the edge size small, our result improves the previous $2k+\epsilon$ stretch roundtrip spanners in directed graphs [Roditty, Thorup, Zwick'02; Zhu, Lam'18], and almost matches the undirected $(2k-1)$-spanner with $O(n^{1+1/k})$ edges [Althöfer et al. '93] when k is a constant, which is optimal under Erdös conjecture.

1 Introduction

A t-spanner of a graph G is a subgraph of G in which the distance between every pair of vertices is at most t times their distance in G, where t is called the stretch of the spanner. Sparse spanner is an important choice to implicitly representing all-pair distances [19], and spanners also have application backgrounds in distributed systems (see [14]). For undirected graphs, $(2k-1)$-spanner with $O(n^{1+1/k})$ edges is proposed and conjectured to be optimal [2, 17]. However, directed graphs may not have sparse spanners with respect to the normal distance measure. For instance, in a bipartite graph with two sides U and V, if there is a directed edge from every vertex in U to every vertex in V, then removing any edge (u, v) in this graph will destroy the reachability from u to v, so its only spanner is itself, which has $O(n^2)$ edges. To circumvent this obstacle, one can approximate the optimal spanner in terms of edge size (e.g. in [9, 3]), or one can define directed spanners on different distance measures. This paper will study directed sparse spanners on roundtrip distances.

Roundtrip distance is a natural metric with good property. Cowen and Wagner [7, 8] first introduce it into directed spanners. Formally, roundtrip distance between vertices u, v in G is defined as $d_G(u \leftrightarrows v) = d_G(u \to v) + d_G(v \to u)$, where $d_G(u \to v)$ is the length of shortest path from u to v in G. For a directed graph $G = (V, E)$, a subgraph $G' = (V, E')$ $(E' \subseteq E)$ is called a t-roundtrip spanner of G if for all $u, v \in G$, $d_{G'}(u \leftrightarrows v) \le t \cdot d_G(u \leftrightarrows v)$, where t is called the stretch of the roundtrip spanner.

In a directed graph $G=(V,E)$ ($n=|V|, m=|E|$) with real edge weights in $[1,W]$, Roditty et al. [16] give a $(2k+\epsilon)$-spanner of $O(\min\{(k^2/\epsilon)n^{1+1/k}\log(nW),\ (k/\epsilon)^2 n^{1+1/k}(\log n)^{2-1/k}\})$ edges. Recently, Zhu and Lam [18] derandomize it and improve the size of the spanner to $O((k/\epsilon)n^{1+1/k}\log(nW))$ edges, while the stretch is also $2k+\epsilon$. We make a step further based on these works and reduce the stretch to $2k-1$. Formally, we state our main results in the following theorems.

▶ **Theorem 1.** *For any directed graph G with real edge weights in $[1,W]$ and integer $k \geq 1$, there exists a $(2k-1)$-roundtrip spanner of G with $O(kn^{1+1/k}\log(nW))$ edges, which can be constructed in $\tilde{O}(kmn\log W)$ time*[1]*.*

By a similar scaling method in [16], we can make the size of the spanner independent of the maximum edge weight W to obtain a $(2k-1)$-spanner with strongly subquadratic space.

▶ **Theorem 2.** *For any directed graph G with real edge weights in $[1,W]$ and integer $k \geq 1$, there exists a $(2k-1)$-roundtrip spanner of G with $O(kn^{1+1/k}\log n)$ edges, which can be constructed in $\tilde{O}(kmn\log W)$ time.*

Actually, our result almost matches the lower bound following girth conjecture. The girth conjecture, implicitly mentioned by Erdös [11], says that for any k, there exists a graph with n vertices and $\Omega(n^{1+1/k})$ edges whose girth (minimum cycle) is at least $2k+2$. This conjecture implies that no algorithm can construct a spanner of $O(n^{1+1/k})$ size and less than $2k-1$ stretch for all undirected graph with n vertices [17]. This lower bound also holds for roundtrip spanners on directed graphs.

Our approach is based on the scaling constructions of the $(2k+\epsilon)$-stretch roundtrip spanners in [16, 18]. To reduce the stretch, we construct inward and outward shortest path trees from vertices in a hitting set [1, 10] of size $O(n^{1/k})$, and carefully choose the order to process vertices in order to make the stretch exactly $2k-1$. To further make the size of the spanner strongly subquatratic, we use a similar approach as in [16] to contract small edges in every scale, and treat vertices with different radii of balls of size $n^{1-1/k}$ differently.

1.1 Related Works

The construction time in this paper is $\tilde{O}(kmn\log W)$. However, there exist roundtrip spanners with $o(mn)$ construction time but larger stretches. Pachoci et al. [13] proposes an algorithm which can construct $O(k\log n)$-roundtrip spanner with $O(n^{1+1/k}\log^2 n)$ edges. Its construction time is $O(mn^{1/k}\log^5 n)$, which breaks the cubic time barrier. Very recently, Chechik et al. [6] give an algorithm which constructs $O(k\log\log n)$-roundtrip spanners with $\tilde{O}(n^{1+1/k})$ edges in $\tilde{O}(m^{1+1/k})$ time.

For spanners defined with respect to normal directed distance, researchers aim to approximate the k-spanner with minimum number of edges. Dinitz and Krauthgamer [9] achieve $\tilde{O}(n^{2/3})$ approximation in terms of edge size, and Bermen et al. [3] improves the approximation ratio to $\tilde{O}(n^{1/2})$.

Another type of directed spanners is transitive-closure spanner, introduced by Bhattacharyya et al. [5]. In this setting the answer may not be a subgraph of G, but a subgraph of the transitive closure of G. In other words, selecting edges outside the graph is permitted. The tradeoff is between diameter (maximum distance) and edge size. One of Bhattacharyya et al.'s results is spanners with diameter k and $O((n\log n)^{1-1/k})$ approximation of optimal edge size [5], using a combination of linear programming rounding and sampling. Berman et al. [4] improves the approximation ratio to $O(n^{1-1/\lceil k/2\rceil}\log n)$. We refer to Raskhodnikova [15] as a review of transitive-closure spanners.

[1] $\tilde{O}(\cdot)$ hides $\log n$ factors.

1.2 Organization

In Section 2, the notations and basic concepts used in this paper will be discussed. In Section 3 we describe the construction of the $(2k-1)$-roundtrip spanner with $O(kn^{1+1/k}\log(nW))$ edges, thus proving Theorem 1. Then in Section 4 we improve the size of the spanner to $O(kn^{1+1/k}\log n)$ and still keep the stretch to $(2k-1)$, thus proving Theorem 2. The conclusion and further direction are discussed in Section 5.

2 Preliminaries

In this paper we consider a directed graph $G=(V,E)$ with non-negative real edge weights w where $w(e)\in[1,W]$ for all $e\in E$. Denote $G[U]$ to be the subgraph of G induced by $U\subseteq V$, i.e. $G[U]=(U,E\cap(U\times U))$. A roundtrip path between nodes u and v is a cycle (not necessarily simple) passing through u and v. The roundtrip distance between u and v is the minimum length of roundtrip paths between u and v. Denote $d_U(u\leftrightarrows v)$ to be the roundtrip distance between u and v in $G[U]$. (Sometimes we may also use $d_U(u\leftrightarrows v)$ to denote a roundtrip shortest path between u,v in $G[U]$.) It satisfies:

- For $u,v\in U$, $d_U(u\leftrightarrows u)=0$ and $d_U(u\leftrightarrows v)=d_U(v\leftrightarrows u)$.
- For $u,v\in U$, $d_U(u\leftrightarrows v)=d_U(u\to v)+d_U(v\to u)$.
- For $u,v,w\in U$, $d_U(u\leftrightarrows v)\le d_U(u\leftrightarrows w)+d_U(w\leftrightarrows v)$.

Here $d_U(u\to v)$ is the one-way distance from u to v in $G[U]$. We use $d(u\leftrightarrows v)$ to denote the roundtrip distance between u and v in the original graph $G=(V,E)$.

In G, a t-roundtrip spanner of G is a subgraph H of G on the same vertex set V such that the roundtrip distance between any pair of $u,v\in V$ in H is at most $t\cdot d(u\leftrightarrows v)$. t is called the *stretch* of the spanner.

For a subset of vertices $U\subseteq V$, given a center $u\in U$ and a radius R, define roundtrip ball $Ball_U(u,R)$ to be the set of vertices whose roundtrip distance on $G[U]$ to center u is strictly smaller than the radius R. Formally, $Ball_U(u,R)=\{v\in U: d_U(u\leftrightarrows v)<R\}$. Then the size of the ball, denoted by $|Ball_U(u,R)|$, is the number of vertices in it. Similarly we define $\overline{Ball}_U(u,R)=\{v\in U: d_U(u\leftrightarrows v)\le R\}$. Subroutine $\texttt{InOutTrees}(U,u,R)$ calculates the edge set of an inward and an outward shortest path tree centered at u spanning vertices in $Ball_U(u,R)$ on $G[U]$. (That is, the shortest path tree from u to all vertices in $Ball_U(u,R)$ and the shortest path tree from all vertices in $Ball_U(u,R)$ to u.) It is easy to see that the shortest path trees will not contain vertices outside $Ball_U(u,R)$:

▶ **Lemma 3.** *The inward and outward shortest path trees returned by* $\texttt{InOutTrees}(U,u,R)$ *only contain vertices in* $Ball_U(u,R)$*.*

Proof. For any $v\in Ball_U(u,R)$, let C be a cycle containing u and v such that the length of C is less than R. Then for any vertex $w\in C$, $d_U(u\leftrightarrows w)<R$, so w must be also in the trees returned by $\texttt{InOutTrees}(U,u,R)$. ◀

For all notations above, we can omit the subscript V when the roundtrip distance is considered in the original graph $G=(V,E)$. Our algorithm relies on the following well-known theorem to calculate hitting sets deterministically.

▶ **Theorem 4** (Cf. Aingworth et al. [1], Dor et al. [10]). *For universe V and its subsets $S_1,S_2,\ldots,S_n$, if $|V|=n$ and the size of each S_i is greater than p, then there exists a hitting set $H\subseteq V$ intersecting all S_i, whose size $|H|\le(n\ln n)/p$, and such a set H can be found in $O(np)$ time deterministically.*

3 A $(2k-1)$-Roundtrip Spanner Algorithm

In this section we introduce our main algorithm constructing a $(2k-1)$-roundtrip spanner with $O(kn^{1+1/k}\log(nW))$ edges for any G. We may assume $k \geq 2$ in the following analysis, since the result is trivial for $k=1$.

Our approach combines the ideas of [16] and [18]. In [18], given a length L, we pick an arbitrary vertex u and find the smallest integer h such that $|\overline{Ball}(u,(h+1)L)| < n^{1/k}|\overline{Ball}(u,h\cdot L)|$, then we include the inward and outward shortest path tree centered at u spanning $\overline{Ball}(u,(h+1)L)$ and remove vertices in $\overline{Ball}(u,h\cdot L)$ from V. We can see that $h \leq k$, so the stretch is $2k$ for u,v with roundtrip distance L, and by a scaling approach the final stretch is $2k+\epsilon$. We observe that if $h=k-1$, $|\overline{Ball}(u,(k-1)L)| \geq n^{(k-1)/k}$, so by Theorem 4 we can preprocess the graph by choosing a hitting set H with size $O(n^{1/k}\log n)$ and construct inward and outward shortest path trees centered at all vertices in H, then we do not need to include the shortest path trees spanning $\overline{Ball}(u,k\cdot L)$. The stretch can then be decreased to $2k-1+\epsilon$. To make the stretch equal $2k-1$, instead of arbitrarily selecting u each time, we carefully define the order to select u.

3.1 Preprocessing

We first define a radius $R(u)$ for each vertex u. It is crucial for the processing order of vertices.

▶ **Definition 5.** *For all $u \in V$, we define $R(u)$ to be the maximum length R such that $|Ball(u,R)| < n^{1-1/k}$, that is, if we sort the vertices by their roundtrip distance to u in G by increasing order, $R(u)$ is the roundtrip distance from u to the $\lceil n^{1-1/k}\rceil$-th vertex.*

For any $u \in V$, $|\overline{Ball}(u,R(u))| \geq n^{1-1/k}$. By Theorem 4, we can find a hitting set H intersecting all sets in $\{\overline{Ball}(u,R(u)) : u \in V\}$, such that $|H| = O(n^{1/k}\log n)$. For all $t \in H$, we build an inward and an outward shortest path tree of G centered at t, and denote the set of edges of these trees by E_0 and include them in the final spanner. This step generates $O(n^{1+1/k}\log n)$ edges in total, and it is easy to obtain the following statement:

▶ **Lemma 6.** *For $u,v \in V$ such that $d(u \leftrightarrows v) \geq R(u)/(k-1)$, the roundtrip distance between u and v in the graph (V,E_0) is at most $(2k-1)d(u \leftrightarrows v)$.*

Proof. Find the vertex $t \in H$ such that $t \in \overline{Ball}(u,R(u))$, that is, $d(u \leftrightarrows t) \leq R(u)$. Then the inward and outward shortest path trees from t will include $d(u \leftrightarrows t)$ and $d(t \leftrightarrows v)$. By $R(u) \leq (k-1)d(u \leftrightarrows v)$, we have $d(u \leftrightarrows t) \leq (k-1)d(u \leftrightarrows v)$ and $d(t \leftrightarrows v) \leq d(t \leftrightarrows u) + d(u \leftrightarrows v) \leq k \cdot d(u \leftrightarrows v)$. So the roundtrip distance of u and v in E_0 is at most $d(u \leftrightarrows t) + d(t \leftrightarrows v) \leq (2k-1)d(u \leftrightarrows v)$. ◀

3.2 Approximating a Length Interval

Instead of approximating all roundtrip distances at once, we start with an easier subproblem of approximating all pairs of vertices whose roundtrip distances are within an interval $[L/(1+\epsilon), L)$. Parameter ϵ is a real number in $(0, 1/(2k-2)]$. The procedure $\texttt{Cover}(G,k,L,\epsilon)$ described in Algorithm 1 will return a set of edges which gives a $(2k-2)(1+\epsilon)$-approximation of roundtrip distance $d(u \leftrightarrows v)$ if $R(u)/(k-1) > d(u \leftrightarrows v)$, for $d(u \leftrightarrows v) \in [L/(1+\epsilon), L)$.

Note that in Algorithm 1, initially $U = V$ and the balls are considered in $G[U] = G$. In the end of every iteration we remove a ball from U, and the following balls are based on the roundtrip distances in $G[U]$. However, $R(u)$ does not need to change during the algorithm and can still be based on roundtrip distances in the original graph G. The analysis for the size of the returned set $\hat{E}$ and the stretch are as follows.

Algorithm 1 Cover$(G(V,E),k,L,\epsilon)$.

```
1: $U \leftarrow V, \hat{E} = \emptyset$
2: while $U \neq \emptyset$ do
3:     $u \leftarrow \arg\max_{u \in U} R(u)$
4:     $step \leftarrow \min\{R(u)/(k-1), L\}$
5:     $h \leftarrow$ minimum positive integer satisfying $|Ball_U(u, h \cdot step)| < n^{h/k}$
6:     Add InOutTrees$(U, u, h \cdot step)$ to $\hat{E}$
7:     Remove $\overline{Ball}_U(u,(h-1)step)$ from $U$
8: end while
9: return $\hat{E}$
```

▶ **Lemma 7.** *The returned edge set of* `Cover`*(G,k,L,ϵ) has $O(n^{1+1/k})$ size.*

Proof. When processing a vertex u, by the selection of h in line 5, $|Ball_U(u, h \cdot step)| < n^{h/k}$ and $|\overline{Ball}_U(u,(h-1)step)| \geq n^{(h-1)/k}$. When $h \geq 2$ it is because of h's minimality, and when $h = 1$ it is because $u \in \overline{Ball}_U(u, 0)$. So each time `InOutTrees` is called, the size of ball to build shortest path trees is no more than $n^{1/k}$ times the size of ball to remove. During an execution of `Cover`(G,k,L,ϵ), each vertex is removed once from U. Therefore the total number of edges added in $\hat{E}$ is $O(n^{1+1/k})$. ◀

We can also see that if the procedure `Cover`$(G[U],k,L,\epsilon)$ is run on a subgraph $G[U]$ induced on a subset $U \subseteq V$, then the size of $\hat{E}$ is bounded by $O(|U|n^{1/k})$. It is also easy to see that h is at most $k-1$:

▶ **Lemma 8.** *The h selected at line 5 in* `Cover`*(G,k,L,ϵ) satisfies $h \leq k-1$.*

Proof. In $G[U]$, the ball $Ball_U(u,(k-1)step)$ must have size no greater than $Ball(u,(k-1)step)$ since the distances in $G[U]$ cannot decrease while some vertices are removed. Since $|Ball(u, R(u))| < n^{1-1/k}$ and $step \leq R(u)/(k-1)$, we get $|Ball_U(u,(k-1)step)| \leq |Ball(u,(k-1)step)| < n^{1-1/k}$, thus $h \leq k-1$. ◀

Next we analyze the roundtrip distance stretch in $\hat{E}$. Note that in order to make the final stretch $2k-1$, for the roundtrip distance approximated by edges in $\hat{E}$ we can make the stretch $(2k-2)(1+\epsilon)$, but for the roundtrip distance approximated by E_0 we need to make the stretch at most $2k-1$ as E_0 stays the same.

▶ **Lemma 9.** *For any pair of vertices u, v such that $d(u \leftrightarrows v) \in [L/(1+\epsilon), L)$, either* `Cover`*$(G,k,L,\epsilon)$'s returned edge set $\hat{E}$ can form a cycle passing through u, v with length at most $(2k-2)(1+\epsilon)d(u \leftrightarrows v)$, or $R(u) \leq (k-1)d(u \leftrightarrows v)$, in which case the E_0 built in Section 3.1 can form a detour cycle with length at most $(2k-1)d(u \leftrightarrows v)$ by Lemma 6.*

Proof. Consider any pair of vertices u, v with roundtrip distance $d = d(u \leftrightarrows v) \in [L/(1+\epsilon), L)$, and a shortest cycle P going through u, v with length d.

During `Cover`(G,k,L,ϵ), consider the vertices on P that are first removed from U. Suppose w is one of the first removed vertices, and w is removed as a member of $\overline{Ball}_{U_c}(c,(h_c-1)step_c)$ centered at c. This is to say $d_{U_c}(c \leftrightarrows w) \leq (h_c-1)step_c$.

Case 1: $step_c > d$. Then

$$d_{U_c}(c \leftrightarrows u) \leq d_{U_c}(c \leftrightarrows w) + d_{U_c}(w \leftrightarrows u) \leq (h_c-1)step_c + d < h_c step_c,$$

and $u \in Ball_{U_c}(c, h_c step_c)$. The second inequality holds because U_c is the remaining vertex set before removing w, so by definition of w, all vertices on P are in U_c. Symmetrically

$v \in Ball_{U_c}(c, h_c step_c)$. `InOutTrees`$(U_c, c, h_c step_c)$ builds a detour cycle passing through u, v with length $< 2h_c step_c$. By Lemma 8, we have $h_c \le k-1$. Also $step_c \le L \le (1+\epsilon)d$, therefore we build a detour of length $< 2(k-1)step_c \le (2k-2)(1+\epsilon)d$ in $\hat{E}$.

Case 2: $step_c \le d$. Because $d < L$, this case can only occur when $step_c = R(c)/(k-1)$. Because c is chosen before u, $R(u) \le R(c) = (k-1)step_c \le (k-1)d$. By Lemma 6, E_0 can give a $(2k-1)$-approximation of d. ◀

3.3 Main Construction

Now we can proceed to prove the main theorem based on a scaling on lengths of the cycles from 1 to $2nW$.

▶ **Theorem 10.** *For any directed graph G with real edge weights in $[1, W]$, there exists a polynomial time constructible $(2k-1)$-roundtrip spanner of G with $O(kn^{1+1/k}\log(nW))$ edges.*

Proof. Note that the roundtrip distance between any pair of vertices must be in the range $[1, 2(n-1)W]$. First do the preprocessing in Section 3.1. Then divide the range of roundtrip distance $[1, 2nW)$ into intervals $[(1+\epsilon)^{p-1}, (1+\epsilon)^p)$, where $\epsilon = 1/(2k-2)$. Call `Cover`$(G, k, (1+\epsilon)^p, \epsilon)$ for $p = 0, \cdots, \lfloor \log_{1+\epsilon}(2nW) \rfloor + 1$, and merge all returned edges with E_0 to form a spanner.

First we prove that the edge size is $O(kn^{1+1/k}\log(nW))$. Preprocessing adds $O(n^{1+1/k} \cdot \log n)$ edges. `Cover`$(G, k, (1+\epsilon)^p, \epsilon)$ is called for $\log_{1+1/(2k-2)}(2nW) = O(k\log(nW))$ times. By Lemma 7, each call generates $O(n^{1+1/k})$ edges. So the total number of edges in the roundtrip spanner is $O(kn^{1+1/k}\log(nW))$.

Next we prove the stretch is $2k-1$. For any pair of vertices u, v with roundtrip distance d, let $p = \lfloor \log_{1+\epsilon} d \rfloor + 1$, then $d \in [(1+\epsilon)^{p-1}, (1+\epsilon)^p)$. By Lemma 9, either the returned edge set of `Cover`$(G, k, (1+\epsilon)^p, \epsilon)$ can form a detour cycle passing through u, v of length at most $(2k-2)(1+\epsilon)d = (2k-1)d$, or the edges in E_0 can form a detour cycle passing through u, v of length at most $(2k-1)d$.

In conclusion this algorithm can construct a $(2k-1)$-roundtrip spanner with $O(kn^{1+1/k} \cdot \log(nW))$ edges. ◀

3.4 Construction Time

The running time of the algorithm in the proof of Theorem 10 is $O(kn(m + n\log n)\log(nW))$. It is also easy to see that the algorithm is deterministic. Next we analyze construction time in detail.

In preprocessing, for any $u \in V$, $R(u)$ can be calculated by running Dijkstra searches with Fibonacci heap [12] starting at u, so calculating $R(\cdot)$ takes $O(n(m + n\log n))$ time. Finding H takes $O(n^{2-1/k})$ time by Theorem 4. Building E_0 takes $O(n^{1/k}\log n \cdot (m + n\log n))$ time.

A `Cover` call's while loop runs at most n times since each time at least one node is removed. In a loop, u can be found in $O(n)$ time, and all other operations regarding roundtrip balls can be done in $O(m + n\log n)$ time by Dijkstra searches starting at u on $G[U]$. Therefore a `Cover` call takes $O(n(m + n\log n))$ time.

`Cover` is called $O(k\log(nW))$ times. Combined with the preprocessing time, the total construction time is $O(kn(m + n\log n)\log(nW))$.

4 Removing the Dependence on W

In this section we prove Theorem 2. The size of the roundtrip spanner in Section 3 is dependent on the maximum edge weight W. In this section we remove the dependence by designing the scaling approach more carefully. Our idea is similar to that in [16]. When we consider the roundtrip distances in the range $[L/(1+\epsilon), L)$, all cycles with length $\leq L/n^3$ have little effect so we can contract them into one node, and all edges with length $> (2k-1)L$ cannot be in any $(2k-1)L$ detour cycles, so they can be deleted. Thus, an edge with length l can only be in $O(\log_{1+\epsilon} n)$ iterations for L between $l/(2k-1)$ and $l \cdot n^3$ (based on the girth of this edge). However, the stretch will be a little longer if we directly apply the algorithm in Section 3 on the contracted graph.

To overcome this obstacle, we only apply the vertex contraction when $R(u)$ is large (larger than $2(k-1)L$). By making the "step" a little larger than L and ϵ smaller, when $d < L < step$, the stretch is still bounded by $(2k-1)$. When $R(u) \leq 2(k-1)L$, we first delete all node v with $R(v) < L/8$, then simply apply the algorithm in Section 3 in the original graph. Since every node u can only be in the second part when $R(u)/2(k-1) \leq L \leq 8R(u)$, the number of edges added in the second part is also strongly polynomial.

First we define the girth of an edge:

▶ **Definition 11.** *We define the* girth of an edge e *in* G *to be the length of shortest directed cycle containing* e*, and denote it by* $g(e)$*.*

It is easy to see that for $e = (u, v)$, $d(u \leftrightarrows v) \leq g(e)$. In $O(n(m + n \log n))$ time we can compute $g(e)$ for all edges e in G [12].

Algorithm 2 approximates roundtrip distance $d(u \leftrightarrows v) \in [L/(1+\epsilon), L)$. In the p-th iteration of the algorithm, $G_p[U_p]$ is always the subgraph contracted from the subgraph $G[U]$. Given $v_p \in U_p$, let $C(v_p)$ be the set of vertices in U that are contracted into v_p. We can see the second part of this algorithm (after line 12) is the same as Algorithm 1 in Section 3.

For the contracted subgraph $G_p[U_p]$, we give new definitions for balls and `InOutTrees`. Given two vertices $u_p, v_p \in U_p$, define

$$\hat{d}_{U_p}(u_p, v_p) = \min_{u \in C(u_p), v \in C(v_p)} d_U(u, v)$$

Balls in $G_p[U_p]$ are defined as follows.

$$Ball_{U_p}(u_p, r) = \{v_p \in U_p : \hat{d}_{U_p}(u_p, v_p) < r\}$$

$$\overline{Ball}_{U_p}(u_p, r) = \{v_p \in U_p : \hat{d}_{U_p}(u_p, v_p) \leq r\}$$

In Line 9, `NewInOutTrees`$(U_p, u_p, h \cdot step)$ is formed by only keeping the edges between different contracted vertices in `InOutTrees`$(U, u, h \cdot step)$ from u (see Line 6). In the inward tree or outward tree of `InOutTrees`$(U, u, h \cdot step)$, if after contraction there are multiple edges from or to a contracted vertex, respectively, only keep one of them. We can see the number of edges added to $\hat{E}$ is bounded by $O(|Ball_{U_p}(u_p, h \cdot step)|)$. Also in U_p, the roundtrip distance from u_p to vertices in $Ball_{U_p}(u_p, h \cdot step)$ by edges in `NewInOutTrees`$(U_p, u_p, h \cdot step)$ is at most $h \cdot step$.

In line 3, we can delete long edges since obviously they cannot be included in $\hat{E}$.

The main algorithm is shown in Algorithm 3.

▶ **Lemma 12.** *For* $k \leq n$ *and* $n \geq 12$*, Algorithm* Spanner(G, k) *constructs a* $(2k-1)$*-roundtrip spanner of* G*.*

Algorithm 2 Cover2(G, k, p, ϵ).

```
1:  $L \leftarrow (1+\epsilon)^p$
2:  Contract all edges $e$ with $g(e) \le L/n^3$ in $G$ to form a graph $G_p$, let its vertex set be $V_p$
3:  (Delete edges $e$ with $g(e) > 2(k-1)L$ from $G_p$)
4:  $U \leftarrow V, U_p \leftarrow V_p, \hat{E} \leftarrow \emptyset$
5:  while $U \neq \emptyset$ and $\max_{u \in U} R(u) \ge 2(k-1)L$ do
6:      $u \leftarrow \arg\max_{u \in U} R(u)$, let $u_p$ be the corresponding vertex in $U_p$
7:      $step \leftarrow (1+1/n^2)L$
8:      $h \leftarrow$ minimum positive integer satisfying $|Ball_{U_p}(u_p, h \cdot step)| < n^{h/k}$
9:      Add NewInOutTrees$(U_p, u_p, h \cdot step)$ to $\hat{E}$
10:     Remove $\overline{Ball}_{U_p}(u_p, (h-1)step)$ from $U_p$, remove corresponding vertices from $U$
11: end while
12: Remove all vertices $u$ from $U$ with $R(u) < L/8$
13: while $U \neq \emptyset$ do
14:     $u \leftarrow \arg\max_{u \in U} R(u)$
15:     $step \leftarrow \min\{R(u)/(k-1), L\}$
16:     $h \leftarrow$ minimum positive integer satisfying $|Ball_U(u, h \cdot step)| < n^{h/k}$
17:     Add InOutTrees$(U, u, h \cdot step)$ to $\hat{E}$
18:     Remove $\overline{Ball}_U(u, (h-1)step)$ from $U$
19: end while
20: return $\hat{E}$
```

Algorithm 3 Spanner$(G(V, E), k)$.

```
Do the preprocessing in Section 3.1. Let $E_0$ be the added edges
$\epsilon \leftarrow \frac{1}{4(k-1)}$.
$\hat{E} \leftarrow E_0$
for $p \leftarrow 0$ to $\lfloor \log_{1+\epsilon}(2nW) \rfloor + 1$ do
    $\hat{E} \leftarrow \hat{E} \cup$ Cover2$(G, k, p, \epsilon)$
end for
return $H(V, \hat{E})$
```

Proof. For any pair of vertices u, v with roundtrip distance $d = d(u \leftrightarrows v)$ on G, there exists a p, such that $d \in [(1+\epsilon)^{p-1}, (1+\epsilon)^p)$. Let $L = (1+\epsilon)^p$. If $R(u) \le (k-1)d$ or $R(v) \le (k-1)d$, by Lemma 6, E_0 contains a roundtrip cycle between u and v with length at most $(2k-1)d$. So we assume $R(u) > (k-1)d$ and $R(v) > (k-1)d$. Also, if there is a vertex w on the shortest cycle containing u and v with $R(w) < L/8$, then there will be a vertex $t \in H$ so that $d(w \leftrightarrows t) < L/8$, so the roundtrip distance in E_0 will be $d(u \leftrightarrows t) + d(t \leftrightarrows v) < L/4 + 2d \le (1+\epsilon)d/4 + 2d < (2k-1)d$ for $k \ge 2$, so Line 12 cannot impact the correctness.

Consider the iteration p of Algorithm 2, let u_p, v_p be the contracted vertices of u, v respectively. Let P be a shortest cycle going through u, v in G and P' be the contracted cycle going through u_p, v_p in G_p. It is easy to see that each vertex on P corresponds to some vertex on P'. Similar as Lemma 8, in Line 8 and Line 16, we have $(k-1) \cdot step \le R(u)$. It is easy to see that $|Ball_{U_p}(u_p, (k-1) \cdot step)| \le |Ball_U(u, (k-1) \cdot step)| < n^{1-1/k}$, which implies $h \le k-1$.

We prove it by the induction on p. When p is small, there is no contracted vertex in G_p. By the same argument as in Lemma 9, either $\texttt{Cover2}(G, k, L, \epsilon)$'s returned edge set $\hat{E}$ contains a roundtrip cycle between u and v with length at most

$$2h_c \cdot \mathit{step}_c \le 2(k-1)(1+1/n^2)(1+\epsilon)d = (2k-3/2)(1+1/n^2)d \le (2k-1)d$$

($k \ge 2$, $k \le n$ and $n \ge 12$) since $\mathit{step}_c \le (1+1/n^2)L$ in Line 7 and Line 15 and $h_c \le k-1$, or E_0 contains a cycle between u and v with length at most $(2k-1)d$. Next we assume that vertices of G contracted in the same vertex in G_p are already connected in $\hat{E}$, and has the $(2k-1)$-stretch.

During $\texttt{Cover2}(G, k, p, \epsilon)$, if some vertices in P' are removed from U_p in Line 10, like Lemma 9, suppose $w_p \in U_p$ is one of the first removed vertices, and w_p is removed as a member of $\overline{\mathit{Ball}}_{U_c}(c, (h_c-1)\mathit{step}_c)$ centered at c. Let $w' \in C(w_p)$ be one vertex on P, since there are at most n original vertices contracted and $\mathit{step}_c = (1+1/n^2)L$, we have $d_U(c \leftrightarrows u) \le d_{U_p}(c \leftrightarrows w_p) + d_U(w' \leftrightarrows u) + n \cdot L/n^3 \le (h_c-1)\mathit{step}_c + d_U(u \leftrightarrows v) + L/n^2 < (h_c-1)\mathit{step}_c + L + L/n^2 = h_c\mathit{step}_c$, and symmetrically $d_U(c \leftrightarrows v) < h_c\mathit{step}_c$. Thus $\texttt{NewInOutTrees}(U_c, c, h_c\mathit{step}_c)$ builds a roundtrip cycle passing through u_p, v_p of length $< 2h_c\mathit{step}_c$ in current contracted graph. It follows that $d_{G_p[\hat{E}]}(u_p, v_p) < 2h_c\mathit{step}_c \le 2(k-1)(1+1/n^2)L$. Since there are at most n contracted vertices in the roundtrip cycle between u_p and v_p, and $w(e) \le g(e)$ for every contracted edge e, we have

$$d_{G[\hat{E}]}(u,v) \le 2(k-1)(1+1/n^2)L + n \cdot (2k-1)L/n^3 \le (2k-3/2)(1+3/n^2)d \le (2k-1)d.$$

($k \ge 2$, $k \le n$ and $n \ge 12$.)

If there is no vertex in P' removed from U_p in Line 10 and Line 12, then all vertices w in P have $L/8 \le R(w) < 2(k-1)L$. By the same argument as in Lemma 9, the second part of Algorithm 2 also ensures that $\hat{E} \cup E_0$ contains a roundtrip cycle passing through u, v with length at most $(2k-1)d$. ◀

▶ **Lemma 13.** *The subgraph returned by algorithm* Spanner(G, k) *has* $O(kn^{1+1/k} \log n)$ *edges.*

Proof. Preprocessing adds $O(n^{1+1/k} \log n)$ edges as in Section 3.1. The edges added in Line 17 is bounded as follows. Consider Algorithm 2, after Line 12, the subgraph only consists of vertices with $R(u) \in [L/8, 2(k-1)L]$, so each vertex belongs to at most $\log_{1+\epsilon} 16k$ such iterations. Thus the total number of edges added after Line 12 is at most $n^{1+1/k} \log_{1+\epsilon} 16k = O(kn^{1+1/k} \log k)$ edges. Next we count the edges added in Line 9.

We remove the directions of all edges in G to get an undirected graph G', and remove the directions of all edges in every G_p to get an undirected graph G'_p, but define the weight of an edge e in G' and every G'_p to be the girth $g(e)$ in G. Let F be a minimum spanning forest of G' w.r.t. the girth $g(e)$. We can see that in iteration p, if we remove edges in F with $g(e) > 2(k-1)(1+\epsilon)^p$ and contract edges e with $g(e) \le (1+\epsilon)^p/n^3$ in F, then the connected components in F will just be the connected components in G'_p, which are the strongly connected components in G_p. This is because of the cycle property of MST: If an edge $e = (u,v)$ in G'_p has $g(e) \le (1+\epsilon)^p/n^3$, then in F all edges f on the path connecting u, v have $g(f) \le (1+\epsilon)^p/n^3$, thus u, v are already contracted in F; If an edge $e = (u,v)$ in G'_p has $g(e) \le 2(k-1)(1+\epsilon)^p$, then in F all edges f on the path connecting u, v have $g(f) \le 2(k-1)(1+\epsilon)^p$, so u, v are in the same component in F.

So the total size of connected components $\{C : |C| \ge 2\}$ in G'_p is at most 2 times the number of edges e in F with $(1+\epsilon)^p/n^3 < g(e) \le 2(k-1)(1+\epsilon)^p$, and every edge in F can be in at most $\log_{1+\epsilon} 2(k-1)n^3 = O(k \log n)$ number of different G'_p. Thus, the total size of connected components with size at least 2 in all G'_p is bounded by $O(kn \log n)$. By a similar argument of Lemma 7, in each call of Cover2(G, k, p, ϵ), line 9 will add $|C|n^{1/k}$ new edges to $\hat{E}$, for every connected component C with $|C| \geq 2$ in G'_p. Thus the total number of edges in the subgraph returned by Spanner(G, k) is bounded by $O(kn^{1+1/k}\log n)$. ◀

Construction Time

The analysis of Spanner's running time is similar to Section 3.4. Compared with Cover, Cover2 adds operations of building G_p. We also need to calculate $g(\cdot)$ in preprocessing, which can done by n Dijkstra searches. G_p can be built in $O(m)$ time. Cover2 is called $\log_{1+\epsilon'}(2nW) = O(k\log(nW))$ times. Therefore the total construction time is still $O(kn(m+n\log n)\log(nW))$.

5 Conclusion

In this paper we discuss the construction of $(2k-1)$-roundtrip spanners with $O(kn^{1+1/k}\log n)$ edges. An important and interesting further direction is whether we can find truly subcubic algorithm constructing such spanners.

Abstract

In this paper, we consider the question of computing sparse subgraphs for any input directed graph $G = (V, E)$ on n vertices and m edges, that preserves reachability and/or strong connectivity structures.

- We show $O(n + \min\{|\mathcal{P}|\sqrt{n}, n\sqrt{|\mathcal{P}|}\})$ bound on a subgraph that is an 1-fault-tolerant reachability preserver for a given vertex-pair set $\mathcal{P} \subseteq V \times V$, i.e., it preserves reachability between any pair of vertices in $\mathcal{P}$ under single edge (or vertex) failure. Our result is a significant improvement over the previous best $O(n|\mathcal{P}|)$ bound obtained as a corollary of single-source reachability preserver construction. We prove our upper bound by exploiting the special structure of single fault-tolerant reachability preserver for any pair, and then considering the interaction among such structures for different pairs.
- In the lower bound side, we show that a 2-fault-tolerant reachability preserver for a vertex-pair set $\mathcal{P} \subseteq V \times V$ of size $\Omega(n^{\epsilon})$, for even any arbitrarily small ϵ, requires at least $\Omega(n^{1+\epsilon/8})$ edges. This refutes the existence of linear-sized dual fault-tolerant preservers for reachability for any polynomial sized vertex-pair set.
- We also present the first sub-quadratic bound of at most $\widetilde{O}(k\ 2^k\ n^{2-1/k})$ size, for strong-connectivity preservers of directed graphs under k failures. To the best of our knowledge no non-trivial bound for this problem was known before, for a general k. We get our result by adopting the color-coding technique of Alon, Yuster, and Zwick [JACM'95].

1 Introduction

One of the major problems in computer science, especially in the era of big data, is to *sparsify* input graph while preserving certain properties of it. Let $\wp$ be any property defined over a graph. Given a graph $G = (V, E)$, a subgraph $H = (V, E_H)$, where $E_H \subseteq E$, is said to preserve property $\wp$ if the property $\wp$ is satisfied by the subgraph H if and only if it is satisfied

by graph G. Reachability and strong-connectivity are two fundamental graph properties that we consider in this paper. In case of reachability, given a directed graph G and a set $\mathcal{P}$ of vertex-pairs the objective is to find a subgraph H with as few edges as possible, so that for any pair $(s, t) \in \mathcal{P}$ there is a path from s to t in H iff so is in G. This problem has been studied extensively [16, 10, 1]. In case of strong-connectivity, given a directed graph G the objective is to find a subgraph H with as few edges as possible so that the strongly-connected components in G and H are identical. A folklore result shows that for any n-node graph we can have a strong-connectivity preserving subgraph with at most $2n$ edges.

In this paper we study the above two problems under the possibility of edge or vertex failures. In the real world networks are prone to failures. Most of the time such failures are unavoidable and also unpredictable in physical systems like communication or road networks. Due to this reason edge (or vertex) failure model draws a huge attention of the researchers in the recent past. In most of the scenarios such failures are much smaller in number in comparison to the size of the graph. Thus it is natural to associate a parameter to capture the number of edge (or vertex) failures, and then try to build fault-tolerant data-structures of size depending on this failure parameter for various graph theoretic problems. Many natural graph theoretic questions like connectivity [30, 28, 5, 25], finding shortest paths [18], graph-structures preserving approximate distances [26, 17, 13, 19, 7, 8, 11, 4] etc. have been studied in the presence of edge (or vertex) failures.

The main focus of this paper is to understand the extremal structure of paths in directed graphs under possible (bounded) edge failures. More specifically, our goal is to show existence (or non-existence) of subgraphs of certain size[1] that preserves reachability and strong-connectivity in the presence of a small number of edge failures.

▶ **Definition 1** (Fault-tolerant Strong-Connectivity Preserver (FT-SCC Preserver)). *For any graph $G = (V, E)$, a subgraph H of G is said to be k-fault-tolerant strong-connectivity preserver (k-FT-SCC preserver) if for each set F $(\subseteq E)$ of k edge failures, the strongly-connected components in $G - F$ and $H - F$ are identical.*

We would like to emphasize that so far there is no non-trivial bound on the size of k-FT-SCC preserver. In this paper we show an upper bound of $\widetilde{O}(k\ 2^k\ n^{2-1/k})$ on k-FT-SCC preserver of any n-node (directed) graph. Moreover we show that we can find such a subgraph efficiently.

▶ **Theorem 2.** *There is a polynomial time (randomized) algorithm that given any directed graph $G = (V, E)$ on n vertices and $k \geq 1$, computes a k-FT-SCC preserver of G containing at most $\widetilde{O}(k\ 2^k\ n^{2-1/k})$ edges with probability at least $1 - 1/n^4$.*

As a direct application we get a data-structure (oracle) of size sub-quadratic in n, for reporting strongly-connected components after k failures. The best earlier known bound for $k > 1$ failures was $\Omega(2^k n^2)$ [6], whereas for $k = 1$ it was known by Georgiadis, Italiano, and Parotsidis [24] that $O(n)$ space and query-time bound is achievable. So ours is the first truly sub-quadratic (i.e., $O(n^{2-\epsilon})$ for some $\epsilon > 0$) sized strong-connectivity oracle for any constant number of failures. One may observe that there are graphs with n nodes for which any k-FT-SCC preserver must be of size $\Omega(2^k n)$.

Next we study the extremal bounds of fault-tolerant reachability preserving subgraphs.

[1] Throughout this paper by *size* of a subgraph we mean the number of edges present in that subgraph.

▶ **Definition 3** (Fault-tolerant Pairwise Reachability Preserver). *For any graph $G = (V, E)$ and a set $\mathcal{P}$ of vertex-pairs, a subgraph H of G is said to be k-fault-tolerant pairwise reachability preserver for $\mathcal{P}$, denoted by $FTRS(\mathcal{P}, G)$, if for each F $(\subseteq E)$ of k edge failure, the reachability relations between pairs in $\mathcal{P}$ agree on $G - F$ and $H - F$.*

Baswana, Choudhary and Roditty [5] provided a polynomial time algorithm that given any n-node directed graph constructs an $O(2^k n)$-sized subgraph that preserves reachability from a fixed source vertex to all other vertices under k edge failures. As a corollary, to preserve reachability between arbitrary $\mathcal{P}$ pairs, we get an $O(2^k n|\mathcal{P}|)$-sized k-fault-tolerant pairwise reachability preserver. Clearly the bound is extremely bad for large sized set $\mathcal{P}$. So far we do not know any better bound even for small values of k. On the other hand in standard static setting (i.e., when $k = 0$) we know existence of $O\big(n + (n|\mathcal{P}|)^{2/3}\big)$-sized pairwise reachability preserver [1].

An important question is how much the size of a reachability preserver varies when we go from standard static (i.e., without any failure) setting to single failure setting, and then further from single failure to dual failure setting. It is also natural to ask the following question: What is the bound on the number of pairs in $\mathcal{P}$ so that it is possible to obtain linear sized single-fault-tolerant pairwise reachability preservers. Here we show that this is possible as long as $|\mathcal{P}| = O(\sqrt{n})$. Note that this is also the current best known limit for the standard static setting [1]. So one cannot hope to improve our bound without improving the bound for static setting. Below we state our upper bound result.

▶ **Theorem 4.** *For any directed graph $G = (V, E)$ with n vertices, and a set $\mathcal{P}$ of vertex-pairs, there exists a single-fault pairwise reachability preserver $FTRS(\mathcal{P}, G)$ having at most $O\big(n + \min(|\mathcal{P}|\sqrt{n},\ n\sqrt{|\mathcal{P}|})\big)$ edges. Furthermore, we can find such a subgraph in polynomial time.*

Our construction of SCC preservers plays a significant role in obtaining such a sparse reachability preserver. One may wonder whether the above result can be generalized to multiple failures, at least for constantly many failures. Unfortunately, we observe a striking difference between single and multiple (even for two) failures scenario in the context of pairwise reachability preservers.

▶ **Theorem 5.** *For every n, p with $p = O(n^{2/3})$, there is an infinite family of n-node directed graphs and pair-sets $\mathcal{P}$ of size p, for which a dual fault-tolerant pairwise reachability preserver requires at least $\Omega(n|\mathcal{P}|^{\frac{1}{8}})$ edges.*

This shows linear size reachability preserver is not possible under dual failures in general pairwise setting with the number of pairs being $\Omega(n^\epsilon)$ for any small $\epsilon > 0$. As a consequence we get a polynomial separation in size of a pairwise reachability preserver between single and dual failures. This is in sharp contrast with single-source all destinations setting, wherein, the size only doubles each time we increase the count of failure by value one [5].

It is worth mentioning that in this paper we show fault-tolerant structures with respect to edge failures only, however, all our results hold for vertex-failures as well.

1.1 Related Work

A simple version of reachability preserver is when there is a single source vertex s and we would like to preserve reachability from s to all other vertices. Baswana et al. [5] provided an efficient construction of a k-fault-tolerant single-source reachability preserver of size $O(2^k n)$. Further they showed that this upper bound on size of a preserver is tight up to some constant factor. As an immediate corollary of their result, we get a k-fault-tolerant pairwise reachability preserver of size $O(2^k n|\mathcal{P}|)$ (by applying the algorithm of [5] to find subgraph for each source vertex in pairs of $\mathcal{P}$, and then taking the union of all these subgraphs). We do not know whether this bound is tight for general k. However for standard static (with no faulty edges) setting much better bound is known. We know that even to preserve all the pairwise distances, not just reachability, there is a subgraph of size $O\big(n + \min(n^{2/3}|\mathcal{P}|, n\sqrt{|\mathcal{P}|})\ \big)$ [16, 10]. Later Abboud and Bodwin [1] showed that for any directed graph $G = (V, E)$ given a set S of source vertices and a pair-set $\mathcal{P} \subseteq S \times V$ we can construct a pairwise reachability preserver of size $O\big(n + \min(\sqrt{n|\mathcal{P}||S|}, (n|\mathcal{P}|)^{2/3})\ \big)$. It is further shown that for any integer $d \geq 2$ there is an infinite family of n-node graphs and vertex-pair sets $\mathcal{P}$ for which any pairwise reachability preserver must be of size $\Omega\big(n^{2/(d+1)}|\mathcal{P}|^{(d-1)/d}\big)$. Note, for undirected graph storing spanning forests is sufficient to preserve pairwise reachability information, and thus we can always get a linear size reachability preserver for undirected graphs. We would like to emphasize that all the results provided in this paper hold for directed graphs. A problem similar to constructing reachability preserver is to construct a data-structure (aka. oracle) that can answer queries of the form whether a vertex is reachable from a fixed source vertex s after multiple edge (or vertex) failures. As an application of [5] we get such an oracle of size $O(2^k n)$ for k edge (or vertex) failures with query time $O(2^k n)$. For just dual failures we have an $O(n)$ size oracle with $O(1)$ query time due to [15]. In a recent work, Brand and Saranurak [31] obtained a k-fault-tolerant $\mathcal{O}(n^2)$ sized reachability oracle that has $O(k^\omega)$ query time, where ω is the constant of matrix-multiplication.

Finding strongly connected components (SCCs) under edge failures is another important problem. One specific problem is given a directed graph G to build a data-structure (oracle) that for any vertices u, v and a set of edges F of size k can answer whether u and v are in the same SCC in $G - F$. Using k-fault-tolerant reachability preserver of [5] we can get such an oracle of size $O(2^k n^2)$ with query time $O(2^k n)$ (see [6]). Moreover, [6] provides us an algorithm that computes all the SCCs in $G - F$ in time $O(2^k n \log^2 n)$ by using a data-structure of size $O(2^k n^2)$. Georgiadis, Italiano and Parotsidis [24] also studied this problem of computing all the SCCs under single edge failure, and gave a solution with $O(n)$ query time using a data-structure of size only $O(n)$. However so far we do not know any solution for computing all the SCCs after more than one edge failures using a data structure of size $O(n^{2-\epsilon})$ for any $\epsilon > 0$. In this paper we give construction of first such truly sub-quadratic sized data-structure as long as there are only constantly many failures. For undirected graphs, the optimal bound of $O(kn)$ edges for k-fault-tolerant connectivity preserver directly follows from k-edge (vertex) connectivity certificate constructions provided by Nagamochi and Ibaraki [27]. In contrast, for directed graphs, the only known result for "sparse" certificate of k-edge (vertex) strong-connectivity is for $k = 2$, due to a series of works by Georgiadis et al. [22, 23, 21]. Our truly sub-quadratic sized k-FT-SCC preservers also in turn provides the *first* truly sub-quadratic sized k-edge (vertex) strong-connectivity certificates for directed graphs, for $k \geq 3$ (see Section 6).

Other closely related problems that have been studied in the fault-tolerant model include computing distance preservers [18, 29, 28], depth-first-search tree [3], spanners [13, 19], approximate distance preservers [7, 30, 9], approximate distance oracles [20, 14], compact routing schemes [14, 12].

1.2 Technical Overview

SCC preserver. Our starting point is a simple construction, which is motivated from some of the techniques used in [24], of linear (in number of vertices) sized single fault-tolerant SCC oracle. Then by using that construction as a basic building block we provide a construction of fault-tolerant SCC preserver for k edge failures. Using the ideas inspired by color-coding technique of Alon, Yuster and Zwick [2], we show a generic procedure that converts any r-fault-tolerant (or even non-fault-tolerant) SCC preserver construction into a $(k+r)$-FT-SCC preserver construction. Our technique, especially the first step of our conversion procedure, is quite similar to that used in [19] to convert any spanner to a r-fault-tolerant spanner with the same *stretch*. The first step alone cannot serve our purpose fully, mostly because it could work (with high probability) only when the SCCs after k faults are of "small size". To mitigate this issue we have to handle the large sized SCCs (after k failures) with a completely different technique. As a consequence our whole proof becomes slightly more intricate than that in [19].

Our conversion procedure works as follows. In the first step, we sample a set J of edges and treat J as failure set, and then compute r-fault-tolerant SCC preserver of $G - J$ (residual graph after removing edges in J). Do this multiple times and take union of all those r-FT SCC preservers for different random choices of J. Now in the second step, we sample a set W of "a few" vertices of G, and then for each $w \in W$ compute single-source FTRS with w as the source and single-destination FTRS by treating w as the destination. Then take union of all these FTRS subgraphs. Finally we claim that with high probability the union of subgraphs produced by first and the second step is a $(k + r)$-FT-SCC preserver.

Our correctness proof proceeds as a win-win analysis. For the sake of simplicity let us provide a high level proof sketch for the case when $r = 0$. For any set F of edge failures, we distinguish two cases depending on whether a SCC C in $G - F$ is small or not. Our choice on size of J ensures that we over-samples F during the first step. Hence if C is of small size with high probability at least for one random choice of J, C will be completely inside one strongly connected component after removing J (that also includes F) from G (in other words, J "separates" C from F), leading to C also being a SCC in the final subgraph (after failure of edges in F). Next we turn to the case when C is of large size. In that scenario it is not difficult to show that with high probability W (chosen at random during second step) and C have some common vertex, and hence C will be preserved due to inclusion of single-source and single-destination FTRS structure. Our techniques hold even when we are able to "partially separate" C from F, and that helps us in proving our result for any r (see Section 3 for the details). So we get that any improvement in size of r-FT-SCC preserver will directly improve the size of $(k + r)$-FT-SCC preserver.

FT-Reachability-Preserver. The construction of $O(n + \sqrt{n}|\mathcal{P}|)$-sized reachability-preserver for a pair-set $\mathcal{P}$ uses the fact the preservers on general digraphs are reducible to preserver on DAGs (since the SCCs can always be compressed into "supernodes", and there is a linear size certificate for strong-connectivity). In a DAG, it is not very difficult to ensure that paths between two given pairs meet and diverge only once, which in turn provides a cap on the maximum number of edges in a preserver. Our approach to FT-reachability is to try to adapt the constructions for non-faulty setting [1]. However, one major hindrance we face is that we cannot directly compress SCCs into "supernodes" as they can destroy 2-connectivity structures, and thus the problem is not reducible to DAGs. We start by observing that FTRS(p) for a pair $p = (s, t)$ is just union of two "maximally disjoint" $s - t$ paths. The interactions between FTRS(p) for different pairs p help us in achieving our bound of $O(n + \sqrt{n}|\mathcal{P}|)$. Our second upper bound of $O(n\sqrt{|\mathcal{P}|})$ is much simpler than the first one. Again we consider union of FTRS(p) structures for all $p \in \mathcal{P}$, and then consider all the vertices that appear in more than $\sqrt{|\mathcal{P}|}$ "maximally disjoint" paths in total (in all FTRS structures). Next we remove all those paths and add single-source and single-destination FTRS structure from those selected vertices. Then we use the properties of single-source and single-destination FTRS to show that the final subgraph will be a FTRS for the pair-set $\mathcal{P}$.

These structures as well as linear bound on preserver size for small sized $\mathcal{P}$ (at most $O(\sqrt{n})$ pairs), is not expendable beyond single failure due to the fact that k-FTRS(p) for any $k > 1$ cannot be represented as union of $o(n)$ paths (see [15]). In the latter part of this paper we also show that this is not a drawback of our approach, instead in some sense it is unavoidable, by proving a size lower bound of any k-fault-tolerant pairwise preserver, for $k \geq 2$. Our lower bound for dual failure is inspired by the following observation: If for a pair $p = (s, t)$, $Q_p = (q_1, \dots, q_\ell)$ and $R_p = (r_1, \dots, r_t)$ are two vertex-disjoint paths from s to t. Then by playing with failures on Q and R, we can force multiple paths originating from Q and terminating to R to be present in our 2-FTRS for p. Note that a 2-FTRS, for a single pair p, would still be linear in size. However, as the number of pairs increases achieving sparsity is tricky. To obtain a 2-FTRS lower-bound for multiple pairs we embed in between the paths Q_p and R_p, the "hard" distance preserver graph given by Coppersmith and Elkin [16]. We start with a lower bound distance preserver graph G over pair-set $\mathcal{P}$, and perform its layering L number of times, for some parameter L. Inspired by techniques of Bodwin et al. [10, 1], we are able to show that all the paths in the "hard" instance graph from [16] can be assumed to have equal distance between the relevant pairs. Thus our layered embedded structure also acts as a non-faulty reachability preserver among pairs with end-points respectively on paths Q_p and R_p.

2 Preliminaries and Tools

Given a directed graph $G = (V, E)$ on $n = |V|$ vertices and $m = |E|$ edges, the following notations will be used throughout the paper.

- $H[A]$: The subgraph of H induced by vertices in set A.
- G^R : The graph obtained by reversing all the edges in graph G.
- $H - F$: For a set of edges F, the graph obtained by deleting the edges in F from graph H.
- $\pi(x, y, H)$: The shortest path from x to y in graph H.
- $P \circ Q$: The concatenation of two paths P and Q, i.e., a path that first follows P and then Q.
- $T(v)$: The subtree of a directed tree T rooted at a vertex $v \in T$.
- $cert(C, H)$: An arbitrarily chosen certificate of at most $2(|C| - 1)$ edges corresponding to a strongly connected component C in H.

Our algorithm for computing *pairwise-reachability* and *strong-connectivity* preservers in a fault tolerant environment employs the concept of a *single-source* FTRS which is a sparse subgraph that preserves reachability from a designated source vertex even after the failure of at most k edges in G. Observe that in case of no failure, a directed reachability tree has $n - 1$ edges and is able to preserve reachability from the source which is a also the root. An FTRS with respect to a given source is formally defined as follows.

▶ **Definition 6** (FTRS). *Let $\mathcal{P} \subseteq V \times V$ be any set of pairs of vertices. A subgraph H of G is said to be a k-Fault-Tolerant Reachability-Subgraph of G for $\mathcal{P}$ if for any pair $(s, t) \in \mathcal{P}$ and for any subset $F \subseteq E$ of k edges, t is reachable from s in $G - F$ if and only if t is reachable from s in $H - F$. Such a subgraph H is denoted by k-FTRS$(\mathcal{P}, G)$, or simply FTRS$(\mathcal{P}, G)$ when $k = 1$.*

Baswana et al. [5] provide a construction of sparse FTRS for any general $k \geq 1$ when there is a designated source vertex.

▶ **Theorem 7** ([5]). *For any directed graph $G = (V, E)$, a designated source vertex $s \in V$, and an integer $k \geq 1$, there exists a (sparse) subgraph H of G which is a k-FTRS$(\{s\} \times V, G)$ and contains at most $2^k n$ edges. Moreover, such a subgraph is computable in $O(2^k mn)$ time, where n and m are respectively the number of vertices and edges in graph G.*

Our constructions will require the knowledge of the vertices reachable from a vertex s as well as the vertices that can reach s. So we will be using FTRS defined with respect to a source vertex ($\{s\} \times V$ case), as well as FTRS defined with respect to a destination vertex ($V \times \{s\}$ case).

In this paper, we consider fault-tolerant structures with respect to edge failures only. Vertex failures can be handled by simply splitting a vertex v into an edge (v_{in}, v_{out}), where the incoming and outgoing edges of v are respectively directed into v_{in} and directed out of v_{out}.

3 Strong-connectivity Preservers

We show a construction of strong-connectivity preservers that are able to preserve strong-connectivity relation between vertices in $G = (V, E)$ as long as the number of failures are bounded by k. For our convenience, we assume that G is strongly connected, if not, we may apply our construction to each strongly-connected component (SCC) of G. Although the main contribution of this section is to get a fault-tolerant SCC preserver for general k failures, let us start with the case when there can be at most one edge failure.

3.1 Construction for single failure

We first give a simple construction of an $O(n)$ size FT-SCC preserver for the scenario of $k = 1$. Let s be an arbitrary vertex in G. We initialize H_1 to union of subgraphs FTRS$(\{s\} \times V, G)$ and FTRS$(V \times \{s\}, G)$. The following simple observation describes the significance of H_1 in preserving strong connectivity information.

▶ **Observation 8.** *Given a directed graph G, let H_1 be the union of subgraphs FTRS$(\{s\} \times V, G)$ and FTRS$(V \times \{s\}, G)$. For any vertex x and any edge-failure e, if x and s are strongly connected in $G - \{e\}$, then they are also strongly connected in $H_1 - \{e\}$.*

We now introduce a lemma that will be crucial in preserving strong-connectivity between vertices not (strongly) connected to s after failure.

▶ **Lemma 9.** *For any n-vertex directed graph $G = (V, E)$ and an ordered list $L = (v_1, v_2, \ldots, v_n)$ of vertices of G, in polynomial time we can compute a subgraph $H_0 = H_0(L)$ of G with at most $2n$ edges satisfying the condition that the SCCs of $G[v_1 \cdots v_i]$ are identical to those in $H_0[v_1 \cdots v_i]$, for $1 \leq i \leq n$.*

Proof. For any $i \in \{1, \cdots, n\}$, let $V_i = \{v_1, \ldots, v_i\}$ be the subset of V comprising of first i vertices, and G_i be the subgraph of G induced by the set V_i. We initialize H_0 to be an empty graph on n vertices. The edges of H_0 are incrementally computed in n rounds, wherein, in the i^{th} round we add edges to H_0, so as to ensure that the SCCs of $H_0[v_1 \cdots v_i]$ are identical to those in G_i.

For any $i \in \{1, \cdots, n\}$, let γ_i denote the number of SCCs in graph G_i, and let C_i be the SCC of v_i in graph G_i. Observe that $\gamma_i \leq 1 + \gamma_{i-1}$, where the equality holds for index i if and only if $C_i = \{v_i\}$. If $C_{i,1}, C_{i,2}, \ldots, C_{i,\ell_i}$ is a decomposition of SCC C_i in $G_{i-1} (= G_i - v_i)$, then in round i it suffices to add at most $2\ell_i$ edges corresponding to an out-reachability and an in-reachability tree rooted at v_i and spanning the "super-nodes" (that is obtained by contracting all the edges in a component $C_{i,j}$) $C_{i,1}, C_{i,2}, \ldots, C_{i,\ell_i}$. Now $\ell_i = 1 + \gamma_{i-1} - \gamma_i$. Thus the number of edges in H_0 is at most $2(\ell_2 + \ldots + \ell_n) = 2(n - 1 + \gamma_1 - \gamma_n) \leq 2n$. ◀

Construction procedure of 1-FT-SCC preserver

Consider an arbitrarily chosen vertex s in G. Then by treating s as a source vertex, we compute the directed reachability-tree T rooted at s for graph G. Similarly we compute a reachability-tree T' for reverse graph G^R. Let L (resp. L') represent an ordered list containing the vertices of T (resp. T') sorted in the decreasing order of their depth (where vertices in the same depth are in an arbitrary order). Next we compute the subgraphs $H_0(L)$ and $H_0(L')$ with the property mentioned in Lemma 9, and finally set H to be the union of graphs H_1 (as defined in Observation 8), $H_0(L)$, and $H_0(L')$.

It is easy to see that H contains $O(n)$ edges. We now prove the correctness.

Consider a vertex x in G and a failing edge $e = (a, b)$ such that x and s are not strongly-connected in $G - \{e\}$. Let C_x be the SCC of x in $G - \{e\}$. We will show that C_x must be an SCC in at least one of the graphs: $H_0(L) - \{e\}$ or $H_0(L') - \{e\}$.

Observe that x is either not reachable from s in $G - \{e\}$, or does not have a path to s in $G - \{e\}$. Without loss of generality, we assume that the first case holds. Thus $e = (a, b)$ must lie on the tree-path from s to x in T. Then a is a parent of b in T. Observe that since none of the vertices of C_x can be reachable from s in $G - \{e\}$, the entire SCC C_x must lie in the subtree rooted at b, denoted by T_b. Since L stores vertices of T sorted in the decreasing order of depth, the vertices of subtree T_b (and hence also C_x) appears before a in the list L. This implies that C_x must be an SCC in $H_0(L) - \{(a, b)\}$. This completes the correctness.

So we conclude with the following theorem.

▶ **Theorem 10.** *There is a polynomial time (deterministic) algorithm that given any directed graph $G = (V, E)$ on n vertices, computes an 1-FT-SCC preserver of G with at most $O(n)$ edges.*

3.2 A generic construction

In this section we provide a construction for general k failures.

▶ **Lemma 11.** *If there is an algorithm $\mathcal{A}$ that on every n-node directed graph builds a r-fault-tolerant SCC preserver of size $f(n, r)$, then for any $k = \Omega(r)$, there is a randomized algorithm $\mathcal{B}$ that given a directed graph G and a parameter $\alpha \in [0, 1]$, computes a $(k + r)$-FT-SCC preserver of size $O(k2^{k+r} \cdot n^{2-\alpha} \log n + n^{k\alpha} \cdot \log n \cdot f(n, r))$ with high probability. Moreover, if $\mathcal{A}$ runs in time $T(n)$ then the algorithm $\mathcal{B}$ runs in time poly$(n)T(n)$.*

Description of Procedure $\mathcal{B}$ to compute $(k + r)$-FT-SCC preserver

Let $\alpha \in [0, 1]$ be the input parameter. Procedure $\mathcal{B}$ constructs two graphs H_1 and H_2 as follows.

- $\boldsymbol{H_1}$ **:** Repeat the following for $L = 16 \cdot n^{k\alpha} \cdot \log n$ number of iterations: Independently add each edge of G to a set J with probability $p = \frac{2}{n^\alpha}$, and then use the given algorithm $\mathcal{A}$ to compute a r-FT-SCC preserver of the remaining graph $G - J$. Set H_1 to be union of these r-FT-SCC preservers, taken over all L iterations.
- $\boldsymbol{H_2}$ **:** Let $q = 16(k + r) \cdot n^{-\alpha} \log n$, and W be a uniformly random set of $nq = \big(16(k + r) \cdot n^{1-\alpha} \log n\big)$ vertices in G. Initialize H_2 to be union of $(k + r)$-FTRS$(\{w\} \times V, G)$ and $(k + r)$-FTRS$(V \times \{w\}, G)$, taken over all $w \in W$.

Finally procedure $\mathcal{B}$ outputs a new subgraph H which is union of H_1 and H_2.

Correctness of Procedure $\mathcal{B}$

For a set F of edge failures and a vertex x in G, let $C_{x,F}$ be the SCC containing x in $G-F$. We say that the SCC $C_{x,F}$ is small if it contains at most $\frac{n^\alpha}{4}$ vertices, and large otherwise.

First we will consider the scenario that $C_{x,F}$ is small. Let F_1 and F_2 be any two disjoint subsets of E of size respectively k and r, and let $F = F_1 \cup F_2$. (Observe that C_{x,F_1} might be large even though $C_{x,F}$ is small). Let $cert(C_{x,F}, G-F)$ be an arbitrary certificate of at most $2(|C_{x,F}|-1)$ edges corresponding to a strongly connected component of $C_{x,F}$. We say an iteration *separates* $C_{x,F}$ from F_1 if at that iteration none of the edges of $cert(C_{x,F}, G-F)$ is selected in J, but all the edges of F_1 lie in J. The probability that a particular iteration separates $C_{x,F}$ from F_1 is:

$$(1-p)^{|cert(C_{x,F},G-F)|} \cdot p^{|F_1|} \geq \left(1-\frac{2}{n^\alpha}\right)^{2(n^\alpha/4)} \cdot \left(\frac{2}{n^\alpha}\right)^k \geq \frac{1}{4} \cdot \frac{2^k}{n^{k\alpha}} \ .$$

The probability that none of the iterations is able to separate $C_{x,F}$ from F_1 is at most

$$\left(1-\frac{2^k}{4n^{k\alpha}}\right)^{16n^{k\alpha}\cdot \log n} \leq \frac{1}{n^{4(2^k)}} \ .$$

Now, there are $n^{O(k)}$ (assuming $k = \Omega(r)$) choices for pair (F_1, F_2), and n choices for x, thus a total of $n^{O(k)}$ different choices for the triplet $(C_{x,F}, F_1, F_2)$. By union bound, the probability that none of the L iterations are able to separate $C_{x,F}$ from F_1, for at least one choice of $(C_{x,F}, F_1, F_2)$, is at most: $\frac{n^{O(k)}}{n^{4(2^k)}} \leq \frac{1}{n^5}$.

The next claim is immediate from definition of FT-SCC preserves.

▷ Claim 12. Let $F_1, F_2, J \subseteq E$ where J contains F_1, F be $F_1 \cup F_2$, and C be an SCC in $G-F$ whose certificate is disjoint with J. Further let $\widetilde{H}$ be a r-FT-SCC preserver of $G-J$. Then C is also an SCC in $\widetilde{H} - F_2$ if $|F_2| \leq r$.

The above discussion together with Claim 12 completes the analysis of the scenario when the SCCs are small, and we obtain the following lemma.

▶ **Lemma 13.** *H_1 with high probability preserves small SCCs after $k+r$ failures.*

Next, we consider the scenario that $C_{x,F}$ is large, i.e, contains more than $\frac{n^\alpha}{4}$ vertices. Let F be a set of $k+r$ edge failures, and $C_{x,F}$ be the SCC of x in $G-F$. In order to ensure that the SCC $C_{x,F}$ is preserved in $H_2 - F$ it suffices to ensure that $C_{x,F}$ has non-empty intersection with W. This is because we include in H_2 the $(k+r)$-fault-tolerant in-and-out-reachability preserves of each of the vertices of W in H_2. The probability[2] that none of the vertices of $C_{x,F}$ lie in random set W is at most:

$$(1-q)^{|C_{x,F}|} \leq \left(1-\frac{16(k+r)\log n}{n^\alpha}\right)^{n^\alpha/4} \leq \frac{1}{n^{4(k+r)}} \ .$$

Again, there are a total of $n^{2(k+r)+1}$ different choices for the pair $(C_{x,F}, F)$. By union bound, the probability that for at least one choice of (F, x), there is some large SCC $C_{x,F}$ having empty intersection with W is at most: $\frac{n^{2(k+r)+1}}{n^{4(k+r)}} \leq \frac{1}{n^5}$. This completes the analysis of the scenario when the SCCs are large.

[2] It is easy to verify that the bound of $\frac{1}{n^{4(k+r)}}$ holds for both the scenarios: sampling with replacement by probability q, or just taking W to be a uniformly random subset of vertices of nq size.

▶ **Lemma 14.** *H_2 with high probability preserves large SCCs after $k+r$ failures.*

Now we are ready to prove Lemma 11.

Proof of Lemma 11. Recall, H is the graph obtained by taking the union of the graphs H_1 and H_2. From Lemma 13 and Lemma 14, it follows that our construction results in a valid $(k+r)$-fault-tolerant SCC preserver. The total number of edges in H is $O(k2^{k+r} \cdot n^{2-\alpha}\log n + n^{k\alpha} \cdot \log n \cdot f(n,r))$. ◀

Now as a corollary of Lemma 11, we directly obtain a k-FT-SCC preserver with sub-quadratic in n edges, since we know $f(n,0) = O(n)$. However to get even better bound we use $f(n,1) = O(n)$ by Theorem 10. On substituting $r = 1$ and $\alpha = 1/(k+1)$ in Lemma 11, we obtain that a $(k+1)$-FT-SCC preserver has at most $\widetilde{O}(k\ 2^k\ n^{2-1/(k+1)})$ edges. Thus the following theorem is immediate.

▶ **Theorem 15.** *For every digraph $G = (V,E)$ on n vertices and every $k \geq 1$, there is a polynomial time (randomized) algorithm that with probability at least $1 - 1/n^4$ computes a k-fault-tolerant SCC preserver of G with at most $\widetilde{O}(k\ 2^k\ n^{2-1/k})$ edges.*

4 Reachability Preservers

In this section we will focus on finding a sparse pairwise reachability preserver. Recall that, for a directed graph $G = (V,E)$ and a set $\mathcal{P}$ of vertex-pairs, a 1-fault tolerant reachability subgraph of G is a subgraph H that preserves the reachability information between all pairs of vertices in $\mathcal{P}$ under single edge failure. We denote such a subgraph by FTRS($\mathcal{P}, G$), or simply FTRS($\mathcal{P}$) if the underlying graph G is clear from the context.

4.1 Upper Bound I

Let us start by showing an existential upper-bound on the number of edges present in an optimum sized FTRS.

▶ **Theorem 16.** *For any directed graph $G = (V,E)$ with n vertices, m edges, and a set $\mathcal{P}$ of vertex-pairs, there exists a FTRS($\mathcal{P}, G$) (or simply FTRS($\mathcal{P}$)) that contains $O(n + |\mathcal{P}|\sqrt{n})$ edges.*

As a corollary of the above theorem we get a FTRSof linear (in number of vertices) size whenever number of pairs for which we have to preserve reachability is at most $O(\sqrt{n})$. Note, for each of $O(\sqrt{n})$ pairs if we use Theorem 7 separately we get a FTRSof size $O(n^{3/2})$. Hence our result improves the size of a FTRSby a factor of $\sqrt{n}$. We devote this subsection to prove the above theorem.

Let H_{scc} be an 1-fault tolerant SCC preserver of G as obtained by Theorem 10, and H_{opt} be an optimum sized subgraph of G such that $H := H_{scc} \cup H_{opt}$ is a FTRS($\mathcal{P}$).

For a pair $p = (s,t) \in \mathcal{P}$ let H_p denote an optimum (minimum) sized subgraph of H that is a FTRS(p), i.e., after any single edge failure e, t is reachable from s in $H_p - e$ if and only if that is also the case in $G - e$. An optimum sized subgraph of H that is a FTRS(p), may not be unique. However we arbitrarily choose one such subgraph, and throughout this section refer to that as H_p. The following proposition is immediate from the definition of optimum sized FTRS.

▶ **Proposition 17.** *For any pair $p = (s,t) \in \mathcal{P}$, H_p is union of two $s - t$ paths intersecting only at (s,t)-cut-edges and (s,t)-cut-vertices in H.*

It directly follows from the above proposition that, any *minimal* (s,t)-cut[3] in H_p is of size at most 2. The following property of any (simple) $s-t$ path in H_p will be useful in studying the structure of H (especially in proving Claim 21).

▶ **Observation 18.** *For any pair $p=(s,t)\in\mathcal{P}$ consider a (simple) $s-t$ path Q in H_p. Let C be any minimal (s,t)-cut in H_p. Then Q takes exactly one edge from the set C.*

Proof. The result trivially holds for a minimal (s,t)-cut of size one. Moreover, by minimality of H_p, there cannot exists (s,t)-cut of size three or larger in H_p. So we are left to consider minimal cuts of size two.

Consider a simple $s-t$ path Q in H_p, and let $C=(e,e')$ be a minimal (s,t)-cut of size two in H_p. Let $Z_p=(v_0=s,v_1,\ldots,v_\ell=t)$ be the (s,t)-cut-vertices in H_p, in the order they appear on Q. Let $\mathcal{I}\subseteq[1,\ell]$ be those indices for which (v_{i-1},v_i) is a cut-edge in H_p, and $\mathcal{J}$ be $[1,\ell]\setminus\mathcal{I}$. So for each $i\in\mathcal{J}$, there exists 2-edge-disjoint paths from v_{i-1} to v_i, in H_p; let these be respectively denoted by R_i^0 and R_i^1. By definition of cut-vertices, it is easy to observe that none of the internal vertices of R_i^0 and R_i^1 can lie in Z_p, for $i\in\mathcal{J}$.

Obtain $\widetilde{Q}$ from Q by replacing $R_i^{z_i}$ with $R_i^{1-z_i}$, for $z_i\in\{0,1\}$ and $i\in\mathcal{J}$. So Q and $\widetilde{Q}$, both lie in H_p, and intersect only at (s,t)-cut-edges and cut-vertices. Now for the minimal (s,t)-cut $C=\{e,e'\}$, Q will contain one of the cut-edges, say e, and $\widetilde{Q}$ will contain the other cut edge, i.e. e'. This shows that any simple $s-t$ path in H_p contains exactly one of the edges of a minimal (s,t)-cut of size two. ◀

For each pair $p\in\mathcal{P}$ we define *critical-edge-set* for p, denoted by C_p, as the set of all edges e in H such that $H-e$ is not a FTRS(p). Sometimes we will also use the notation C_p to denote the underlying subgraph formed by edges present in C_p. Note, all the edges of H_{opt} must be in $\cup_{p\in\mathcal{P}}C_p$. Otherwise, if there exists an edge $e\in H_{opt}$ that is not in any of C_p's then we can remove e from H while preserving 1-fault tolerant reachability for all pairs $p\in\mathcal{P}$, leading to a contradiction on the optimality of the size of H_{opt}. So we can deduce the following observation.

▶ **Observation 19.** *For any edge $e\in H$, either $e\in C_p$ for some pair $p\in\mathcal{P}$, or $e\in H_{scc}$.*

Let d_{avg} be the average in-degree of H, i.e., $d_{avg}=|E(H)|/n$. Recall that we use $E(H)$ to denote the set of edges in the subgraph H. Now partition the set of vertices V into two subsets:

1. The set of *light* vertices V_ℓ containing all the vertices whose in-degree in H_{opt} is (strictly) less than $d_{avg}/2$; and
2. The set of *heavy* vertices V_h containing all the vertices whose in-degree in H_{opt} is at least $d_{avg}/2$.

Let E_ℓ and E_h respectively be the set of incoming edges to the vertices in V_ℓ and V_h, in graph H_{opt}. Clearly, $|E_\ell|<(\frac{d_{avg}}{2})n=|E(H)|/2$.

▶ **Lemma 20.** *If $d_{avg}>12$, then for each $p\in\mathcal{P}$, $|E_h\cap C_p|\leq 16|\mathcal{P}|/d_{avg}$.*

We defer the proof of the above lemma to the end of this section. Now assuming the above we show the desired bound on $|E(H)|$, as stated in Theorem 16. First of all, if $d_{avg}\leq 12$ then $E(H)$ is of size $O(n)$. So from now on we assume that $d_{avg}>12$. Note that $|E(H)|=|E(H_{opt})|+|E(H_{scc})|$. By the result of the previous section (see Theorem 10) we know that the graph H_{scc} has at most $O(n)$ edges. Observe that,

[3] A set of edges is said to be an *minimal* (s,t)-cut if and only if it is a valid (s,t)-cut and any of its proper subset is not an (s,t)-cut.

$$
\begin{aligned}
&|E(H_{opt})| = |E_\ell| + |E_h| \leq \frac{|E(H_{opt})|}{2} + |E_h| \\
\Rightarrow &|E(H)| \leq 2(|E_h| + |E(H_{scc})|). \qquad (1)
\end{aligned}
$$

We bound the size of E_h as follows,

$$
\begin{aligned}
|E_h| &\leq \sum_{p\in\mathcal{P}} |E_h \cap C_p| && \text{(since for all } e \in H_{opt},\ e \in C_p \text{ for some } p \in \mathcal{P} \text{ by Observation 19)} \\
&\leq \sum_{p\in\mathcal{P}} \frac{16|\mathcal{P}|}{d_{avg}} && \text{(by Lemma 20)} \\
&= \frac{16|\mathcal{P}|^2 n}{|E(H)|}. && (2)
\end{aligned}
$$

By combining inequalities (1) and (2) we get that $|E(H)| \leq O(n + |\mathcal{P}|\sqrt{n})$.

Now it only remains to prove Lemma 20. Before going into the proof we would first like to make a few important observations regarding the structure of H, which will eventually help us to bound its size. Consider a (simple) path Q from s to t where $(s,t) = p \in \mathcal{P}$, such that all the edges on Q are in H_p. Since Q is a simple path it gives a natural ordering among the vertices present on it. Let us denote this ordering relationship by $<_Q$ ($\leq_Q$ and $>_Q$).

▷ Claim 21. Consider a pair $p = (s,t) \in \mathcal{P}$, and let Q be a (simple) $s - t$ path in H_p. For an edge $e = (u,v) \in C_p$ on Q, suppose there are two vertices $u_1, u_2 <_Q v$, and let Q_1 and Q_2 be (any arbitrary) $u_1 - v$ and $u_2 - v$ path respectively, in $H - \{e\}$. Then Q_1 and Q_2 must share an edge.

Proof. Since $e \in C_p$ if we exclude e from H, the remaining subgraph $H' = H - \{e\}$ will not be a FTRS(p). Observe that e cannot be an (s,t)-cut-edge in H as it violates the existence of paths Q_1 and Q_2 in $H - \{e\}$. So there must exist an edge $f = (u_f, v_f)$ on failure of which there is an $s - t$ path, in $H - \{f\}$, but there is no such path in $H' - \{f\} = H - \{e, f\}$. Since there is no $s - t$ path in $H - \{e, f\}$, $C = \{e, f\}$ must be an (s,t)-cut in H (and also in H_p). Further, since e is not an (s,t)-cut-edge in H, C is a minimal (s,t)-cut in H_p. Let (A, B) be a partition of V induced by the cut C in H such that $s \in A$ and $t \in B$. As Q is a simple $s - t$ path in H_p, by Observation 18 it passes through cut C only once, thereby implying $u_1, u_2 \in A$. Thus, the path Q_i from u_i to v must pass through an edge in C, for $i = 1, 2$. As Q_1 and Q_2 lie in $H - \{e\}$, they both must pass through the edge f, thereby proving the claim. ◁

Now using the above claim we prove the following.

▷ Claim 22. For any pair $p = (s,t) \in \mathcal{P}$, let Q be a (simple) $s - t$ path in H_p. For a vertex v on Q, suppose there are two incoming edges h_1 and h_2 incident on v, which are not part of Q. Further, for $i = 1, 2$, let $p_i = (s_i, t_i)$ be a pair satisfying $h_i \in C_{p_i}$, and let $Q_i \in H_{p_i}$ be an $s_i - t_i$ path containing h_i. If v_i ($\neq v$) is the last vertex in $Q_i[s_i, v]$ that also lies on Q, for $i = 1, 2$, then we cannot simultaneously have $v_1 <_Q v$ as well as $v_2 <_Q v$.

Proof. Let us assume on contrary that $v_1, v_2 <_Q v$. Without loss of generality, we can assume $v_1 \leq_Q v_2$. Let f be an edge on whose failure, any $s_2 - t_2$ path must pass through the edge h_2. Observe h_2 cannot be an (s_2, t_2) cut-edge, as $Q[v_2, v]$ is a $v_2 - v$ path avoiding h_2, thus $C = \{f, h_2\}$ is a minimal (s_2, t_2) cut in H. Note, f must be on $Q[v_2, v]$.

By Claim 21, $Q_1[v_1, v]$ and $Q_2[v_2, v]$ must share an edge. Let $e = (x, y)$ be the last such shared edge. Now even if we exclude h_2 from H we still get the following $s_2 - t_2$ path: $Q_2[s_2, y] \circ Q_1[y, v] \circ Q_2[v, t_2]$ in $H - C$. Since, $C = \{f, h_2\}$ is an (s_2, t_2) cut, this contradicts the assumption that $v_1, v_2 <_Q v$. ◁

▷ Claim 23. For any pair $p = (s, t) \in \mathcal{P}$, let Q be a (simple) $s - t$ path in H_p. For a vertex v on Q, suppose there are two incoming edges h_1 and h_2 incident on v, which are not part of Q. Consider the sets $B_{h_i} := \{q \in \mathcal{P} | h_i \in C_q\}$, for $i \in \{1, 2\}$. Further, for each $i \in \{1, 2\}$, suppose for every pair $p' = (s', t') \in B_{h_i}$, the following holds:

1. Neither there is an $s' - v$ path in $H_{p'}$ with h_i as its last edge, that is internally vertex-disjoint with Q,
2. Nor there exists a vertex, say $v_i <_Q v$, with a $v_i - v$ path in $H_{p'}$ with h_i as its last edge that is edge-disjoint with Q.

Then either $h_1 \notin H_{opt}$ or $h_2 \notin H_{opt}$. (Recall, $H_{opt} = H - H_{scc}$.)

Proof. For $i = 1, 2$, consider a pair $(s_i, t_i) \in B_{h_i}$. Let $Q_i \in H_i$ be an $s_i - t_i$ path containing h_i. Let $u_i \in V - \{v\}$ be the last vertex in $Q_i[s_i, v]$ that also lies on Q. Due to the preconditions mentioned in the statement of the claim, such a u_i must exists, and is necessarily contained in segment $Q[v, t]$. Observe $Q_i[u_i, v]$ is internally vertex disjoint with Q. Next we show that if $u_2 \leq_Q u_1$, $h_2 \notin H_{opt}$.

Suppose $u_2 \leq_Q u_1$. Let f be an edge on whose failure, any $s_2 - t_2$ path must pass through the edge h_2. Observe h_2 cannot be an (s_2, t_2) cut-edge, as $Q[u_2, u_1] \circ Q_1[u_1, v]$ is a $u_2 - v$ path avoiding h_2, thus $C = \{f, h_2\}$ is a minimal (s_2, t_2) cut in H. Observation 18 implies $f \notin Q_2$. Note, f must be either on $Q[u_2, u_1]$ or on $Q_1[u_1, v]$, thereby implying $f \notin Q[v, u_2]$. Thus u_2 and v are strongly connected in $H - \{f\}$ as the cycle $Q_2[u_2, v] \circ Q[v, u_2]$ is intact $H - \{f\}$. Hence H_{scc} contains a $u_2 - v$ path even after the failure of f, and let R' be such a path. Thus even if we exclude h_2 from H_{opt} we still get the following $s_2 - t_2$ path: $Q_2[s_2, u_2] \circ R \circ Q_2[v, t_2]$ in $H - \{f\}$. So due to optimality of H_{opt}, the edge h_2 cannot be in H_{opt} $(= H - H_{scc})$. Similarly when $u_1 <_Q u_2$, $h_1 \notin H_{opt}$, and this completes the proof. ◁

Now we are ready to prove Lemma 20.

Proof of Lemma 20. For the sake of contradiction let us assume that for some pair $p = (s, t) \in \mathcal{P}$, $|E_h \cap C_p| > \frac{16|\mathcal{P}|}{d_{avg}}$. Recall, by Proposition 17 H_p is union of two (simple) $s - t$ paths, say Q and $\widetilde{Q}$, intersecting only at (s, t)-cut-edges in H. At least one of these two paths, say Q, must contain at least $\frac{8|\mathcal{P}|}{d_{avg}}$ edges from $|E_h \cap C_p|$. Now consider the following vertex set

$$Q_h := \{v \in V_h | \text{ there exists an edge } (u, v) \in Q \text{ that is also in } E_h \cap C_p\}.$$

Clearly, $|Q_h| \geq \frac{8|\mathcal{P}|}{d_{avg}}$. Let Q_e denote the subset of edges in $E(H_{opt})$ that are incident on the vertices in Q_h and not part of the path Q. Next consider the following edge-set

$$A := \{(u, v) \in Q_e | \text{ for some } (s', t') \in \mathcal{P} \text{ there exists an } s' - v \text{ path in } H$$
$$\text{with } (u, v) \text{ as its last edge, that is internally vertex-disjoint with } Q\}.$$

Observe, it follows from Proposition 17 that $|A| \leq 2|\mathcal{P}|$. Assuming $d_{avg} > 12$, a simple counting argument shows that there exists a vertex $v \in Q_h$ such that number of edges from $Q_e - A$ that are incident on v is at least 3. If not, then since each vertex in Q_h is by definition heavy, $|A| \geq |Q_h|(\frac{d_{avg}}{2} - 2) \geq \frac{8|\mathcal{P}|}{3}$ assuming $d_{avg} > 12$, which leads to a contradiction.

It implies that there must exist two vertices u_1, u_2 on Q where $u_1 <_Q u_2$, and two edges $h_1, h_2 \in Q_e - A$ (incident on v) such that there are $u_1 - v$ path, say Q_1, with h_1 as its last edge and $u_2 - v$ path, say Q_2, with h_2 as its last edge in H, where both Q_1, Q_2 are edge-disjoint with Q. Now either $u_1, u_2 <_Q v$, or $u_1, u_2 >_Q v$.

Since due to optimality of H_{opt}, $h_2 \in C_{p'}$ for some $p' = (s', t') \in \mathcal{P}$, without loss of generality we can further assume that the path Q_2 is in the subgraph $H_{p'}$. Now if $u_1, u_2 <_Q v$, by Claim 22 there must be an $s' - v$ path in H with h_2 as its last edge that is internally vertex-disjoint with $Q[s, v]$. Thus by the definition of set A, $h_2 \in A$, leading to a contradiction. Now consider the other alternative, i.e., when $u_1, u_2 >_Q v$. In this case without loss of generality we can assume that for $i = 1, 2$ there exists no vertex, say $v_i <_Q v$, with a $v_i - v$ path in H with h_i as its last edge, that is edge-disjoint with Q. Then by Claim 23 either $h_1 \notin H_{opt}$ or $h_2 \notin H_{opt}$, which again leads to a contradiction.

Hence we conclude that for all pairs $p \in \mathcal{P}$, $|E_h \cap C_p| \leq \frac{16|\mathcal{P}|}{d_{avg}}$ for $d_{avg} > 12$. ◀

A Constructive Algorithm. Observe that the size of an minimal subgraph H which is an FTRS$(\mathcal{P}, G)$, must have size at most $O(n + |\mathcal{P}|\sqrt{n})$. Now, a simple constructive algorithm is as follows: We initialize H to G. Next for each pair $(s, t) \in \mathcal{P}$ for each $e \in E(H)$ check if the (s, t)-cut-edges in G and $G - \{e\}$ are identical, if so, remove e from H. The process terminates in polynomial time and results in a graph which is a minimal FTRS$(\mathcal{P}, G)$.

4.2 Upper Bound II

In this subsection, we present our second construction for pairwise reachability preservers.

▶ **Theorem 24.** *For any directed graph $G = (V, E)$ with n vertices, m edges, and a set $\mathcal{P}$ of vertex-pairs, there exists a poly-time computable FTRS$(\mathcal{P}, G)$ containing at most $O(n\sqrt{|\mathcal{P}|})$ edges.*

By Proposition 17, for any pair $p = (s, t) \in \mathcal{P}$, FTRS$(p)$ is union of two $s - t$ paths intersecting only at (s, t) cut-edges and cut-vertices. Let these paths be respectively denoted by $Q_{s,t}$ and $\widetilde{Q}_{s,t}$.

Let $\mathcal{C}$ be the collection $\mathcal{C} = \bigcup_{(s,t)\in\mathcal{P}} \{Q_{s,t}, \widetilde{Q}_{s,t}\}$, and W be initialized to $\emptyset$. For each vertex v, let $\text{FREQ}(v, \mathcal{C})$ denote the total number of paths in $\mathcal{C}$ that contains v. Now we use the following procedure:

1. While there is a vertex w with $\text{FREQ}(w, \mathcal{C}) > \sqrt{|\mathcal{P}|}$, we add w to W, and remove all those paths from $\mathcal{C}$ that contains w.
2. Initialize H to union of subgraphs FTRS(w, G) and FTRS(w, G^R), taken over all $w \in W$.
3. Also add to H the union of edges lying in paths remaining in $\mathcal{C}$.

The size of set W is at most $2\sqrt{|\mathcal{P}|}$ since each time a vertex is added to W at least $\sqrt{|\mathcal{P}|}$ paths are eliminated from $\mathcal{C}$. By Theorem 7 we can bound the size of both FTRS(w, G) and FTRS(w, G^R) by $O(n)$ for each $w \in W$. After step 2, since for each $v \in V$, $\text{FREQ}(v, \mathcal{C})$ is bounded by $\sqrt{|\mathcal{P}|}$, the number of edges in H is at most $O(n\sqrt{|\mathcal{P}|})$. The correctness follows from the following claim.

▷ Claim 25. The subgraph H computed by above process is a FTRS$(\mathcal{P}, G)$.

Proof. Consider a pair $(s, t) \in \mathcal{P}$ and an edge failure $e \in E$. Observe that if e lies in both $Q_{s,t}$ and $\widetilde{Q}_{s,t}$, then e must be an (s, t)-cut. In such a scenario there will be no path from s to t in $G - \{e\}$ as well as in $H - \{e\}$. So let us assume e does not lie in at least one of the paths, $Q_{s,t}$ or $\widetilde{Q}_{s,t}$. Without loss of generality, we assume $Q_{s,t}$ will remain intact in $G-\{e\}$. We will show that there is an $s-t$ path in $H-\{e\}$ even when $Q_{s,t} \notin H$. Recall that if $Q_{s,t} \notin H$, then $Q_{s,t}$ must contain a vertex from set W, let this vertex be w. Since there is a path from s to t in $G-\{e\}$ containing w, there must exists an $s-w$ path, say R_1, in $\mathrm{FTRS}(V \times \{w\}, G) - \{e\}$, and a $w-t$ path, say R_2, in $\mathrm{FTRS}(\{w\} \times V, G) - \{e\}$. The concatenated path $R_1 \circ R_2$ is an $s-t$ path avoiding e. Also $R_1 \circ R_2$ lies in H as we include in H a $\mathrm{FTRS}(\{x\} \times V, G)$ as well as a $\mathrm{FTRS}(V \times \{x\}, G)$, for each $x \in W$. It thus follows that H is a fault-tolerant reachability preserver for the pair (s,t). ◁

5 Lower Bounds for Pairwise Reachability Preserver under Dual Failures

In this section, we provide several lower bound results. In our constructions, we will employ the following lower bound for pairwise distance preservers that was established by Coppersmith and Elkin in [16], and later reformulated in [1] using standard tricks in [10].

▶ **Theorem 26** ([16, 10, 1]). *For any integer $d \geq 2$ there are infinitely many $n \in \mathbb{N}$ such that for any $p \in [n^{f(d)}, n^{f(d+1)}]$, where $f(d) = \frac{2d^2-2d-2}{(d^2+d-2)}$, there exists an n-node undirected unweighted graph $G=(V,E)$ and a pair-set $\mathcal{P} \subseteq V \times V$ of size $|\mathcal{P}| = O(p)$, such that*

- *For each pair $(s,t) \in \mathcal{P}$ there is a unique shortest path in G between s and t,*
- *These paths are all edge-disjoint and have identical length (which we denote by L), and*
- *The edge set of G is precisely the union of these paths and has size $\Omega\big(n^{2d/(d^2+1)}p^{(d^2-d)/(d^2+1)}\big)$.*

Throughout this section, we will reserve $f(d)$ to refer to the function $\frac{2(d^2-d-1)}{(d^2+d-2)}$.

The construction of our lower-bound graph $G=(V_G,E_G)$ is as follows. Let $H = (V_H, E_H)$, $\mathcal{P}_H$ be an instance drawn from Theorem 26. Let L be the common distance between all the pairs in $\mathcal{P}_H$, and $K = L^r$ for some parameter $r \geq 1$ to be fixed later on. For each node u in H, add $2K$ copies of u to G, namely, $u_1, \ldots, u_{2K}$. For each edge (u,v) in H and $i \geq 2$, add edges (u_i, v_{i-1}) and (v_i, u_{i-1}) to G.

Next, for each node $v \in V_H$, add two paths $v_{\text{LEFT}} := (v_{\text{LEFT},1}, \ldots, v_{\text{LEFT},2K})$ and $v_{\text{RIGHT}} := (v_{\text{RIGHT},1}, \ldots, v_{\text{RIGHT},2K})$, each on a set of $2K$ new nodes to G. Also, add an edge from $v_{\text{LEFT},i}$ to v_i, and v_i to $v_{\text{RIGHT},i}$ to G, for $i \in [1, 2K]$.

Finally, for each $(x,y) \in \mathcal{P}_H$, create two new vertices $s_{x,y}$ and $t_{x,y}$, and include $(s_{x,y}, t_{x,y})$ in pair-set $\mathcal{P}_G$; add directed edges from $s_{x,y}$ to $x_{\text{LEFT},1}, y_{\text{RIGHT},1}$ and add directed edges from $x_{\text{LEFT},2K}, y_{\text{RIGHT},2K}$ to $t_{x,y}$. This completes the description of G, and pair-set $\mathcal{P}_G$.

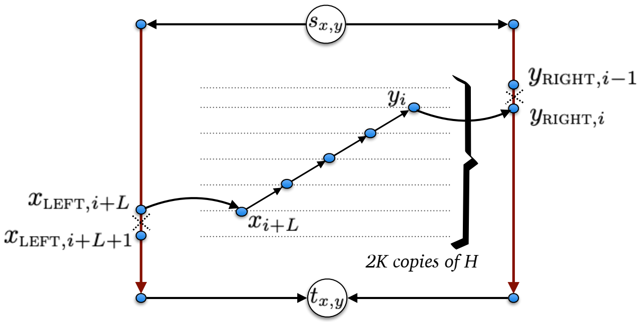

Figure 1 Dual fault-tolerant reachability preserver: depiction of graph G and pair $(s_{x,y}, t_{x,y}) \in \mathcal{P}_G$.

Observe that

1. $|\mathcal{P}_G| = |\mathcal{P}_H|$;
2. $|V_G| = \Theta(|\mathcal{P}_H| + L^r|V_H|) = \Theta(L^r|V_H|)$, whenever $|\mathcal{P}_H| \leq O(L^r|V_H|)$; and
3. $|E_G| = \Theta(|\mathcal{P}_H| + L^r|E_H|) = \Theta(L^{r+1}|\mathcal{P}_H|)$ (since $|E_H| = L|\mathcal{P}_H|$ by the description of H given in Theorem 26).

We first analyze the size of E_G. By Theorem 26, we have

$$L = \frac{|E_H|}{|\mathcal{P}_H|} = \Theta(|V_H|^{\frac{2d}{d^2+1}}\ |\mathcal{P}_H|^{\frac{-(d+1)}{d^2+1}}). \tag{3}$$

Let $n := |V_G| = \Theta(|V_H| \cdot L^r)$ and $m := |E_G| = \Theta(|\mathcal{P}_H| \cdot L^{r+1})$. On multiplying $L^{\frac{2dr}{d^2+1}}$ on both sides of Equation 3, we obtain

$$\begin{aligned} L^{1+\frac{2dr}{d^2+1}} &= \Theta\Big(|V_G|^{\frac{2d}{d^2+1}}\ |\mathcal{P}_G|^{\frac{-(d+1)}{d^2+1}}\Big) \\ \text{or, } L^{r+1} &= \Theta\Big(|V_G|^{\frac{2d(r+1)}{d^2+2rd+1}}\ |\mathcal{P}_G|^{\frac{-(d+1)(r+1)}{d^2+2rd+1}}\Big) \end{aligned}$$

$$\text{Thus, } |E_G| = \Theta(|\mathcal{P}_G|L^{r+1}) = \Theta\Big(|V_G|^{\frac{2d(r+1)}{d^2+2rd+1}}\ |\mathcal{P}_G|^{\frac{d^2+dr-(d+r)}{d^2+2rd+1}}\Big) \tag{4}$$

The size of V_H is given by $|V_H| = \Theta\Big(\frac{|V_G|}{L^r}\Big) = \Theta\Big(n^{\frac{d^2+1}{d^2+2rd+1}}|\mathcal{P}_G|^{\frac{(d+1)r}{d^2+2rd+1}}\Big)$.
So, the condition $|V_H|^{f(d)} \leq |\mathcal{P}_H| \leq |V_H|^{f(d+1)}$ translates to

$$\Big(n^{\frac{d^2+1}{d^2+2rd+1}}|\mathcal{P}_G|^{\frac{(d+1)r}{d^2+2rd+1}}\Big)^{f(d)} \leq |\mathcal{P}_G| \leq \Big(n^{\frac{d^2+1}{d^2+2rd+1}}|\mathcal{P}_G|^{\frac{(d+1)r}{d^2+2rd+1}}\Big)^{f(d+1)}$$

which can be re-stated as: $n^{\frac{(d^2+1)f(d)}{d^2+2rd+1-(d+1)rf(d)}} \leq |\mathcal{P}_G| \leq n^{\frac{(d^2+1)f(d+1)}{d^2+2rd+1-(d+1)rf(d+1)}}$
and on simplification is equivalent to

$$n^{\frac{2(d^2-d-1)}{(d^2+d+2r-2)}} \leq |\mathcal{P}_G| \leq n^{\frac{2(d^2+d-1)}{(d^2+3d+2r)}}. \tag{5}$$

We now prove that a dual fault-tolerant reachability preserver of G requires $\Omega(|E_G|)$ edges. Consider pair $(s_{x,y}, t_{x,y})$ in set $\mathcal{P}_G$, for a pair $(x, y) \in \mathcal{P}_H$. Let $\pi(x, y, H) = (x = w^0, w^1, \ldots, w^L = y)$ be the shortest path between x and y in the undirected graph H.

By construction of G and uniqueness of $\pi(x, y, H)$, it follows that for any $i \in [1, K]$, there exists a unique path from x_{i+L} to y_i in G. Indeed $\pi(x_{i+L}, y_i, G) = (w^0_{i+L}, w^1_{i+L-1}, w^2_{i+L-2}, \ldots, w^L_i)$, is the shortest and the only path starting from $x_{i+L} = w^0_{i+L}$ and terminating to $y_i = w^L_i$ in G. Moreover, there is no path from $x_{i-\alpha+L}$ that terminates to $y_{i+\beta}$ for non-negative integers α, β if at least one of them is greater than 0.

On failures of edges $(x_{\text{LEFT},i+L}, x_{\text{LEFT},i+L+1})$ and $(y_{\text{RIGHT},i-1}, y_{\text{RIGHT},i})$, the concatenated path

$$(s_{x,y}, x_{\text{LEFT},1}, \ldots, x_{\text{LEFT},i+L}) \circ \pi(x_{i+L}, y_i, G) \circ (y_{\text{RIGHT},i}, \ldots, y_{\text{RIGHT},2L}, t_{x,y})$$

is the only path from $s_{x,y}$ to $t_{x,y}$ in the surviving part of G.

Thus, a dual fault-tolerant reachability preserver of G must contain $\pi(x_{i+L}, y_i, G)$, for each $i \in [1, K]$ and $(x, y) \in \mathcal{P}_H$. From the fact that the shortest path between pairs in $\mathcal{P}_H$ are all edge-disjoint in H, it directly follows, a dual fault-tolerant reachability preserver of G must contain $\Omega(KL|\mathcal{P}_H|) = \Omega(K|E_H|) = \Omega(|E_G|)$ edges. The above analysis along with Eq. 4 and Eq. 5 proves our main result, Theorem 27, on dual failure.

▶ **Theorem 27.** *For any integer $d \geq 2$, any real $r \geq 1$, any real $c \in (0,1)$, there are infinitely many $n \in \mathbb{N}$ such that for any $p \in [n^{f(d,r)}, \min\{cn, n^{f(d+1,r)}\}]$, where $f(d,r) = \frac{2d^2-2d-2}{(d^2+d+2r-2)}$, there exists an n-node directed graph $G = (V,E)$ and pair-set $\mathcal{P} \subseteq V \times V$ of size $|\mathcal{P}| = O(p)$, such that any dual fault-tolerant reachability preserver of G for $\mathcal{P}$, must have $\Omega\left(n^{\frac{2d(r+1)}{d^2+2rd+1}} |\mathcal{P}|^{\frac{(d-1)(d+r)}{d^2+2rd+1}}\right)$ edges.*

Note, in the above theorem we need $p \leq cn$ for $c < 1$, to ensure that $|\mathcal{P}_H| \leq O(L^r|V_H|)$ (See the construction of G from H). Some instances of the above theorem are as below.

- $\Omega(n^{8/9}|\mathcal{P}|^{1/3})$ edges for $n^{1/3} \leq |\mathcal{P}| \leq n^{5/6}$ (when $d = 2, r = 1$).
- $\Omega(n^{12/13}|\mathcal{P}|^{4/13})$ edges for $n^{1/4} \leq |\mathcal{P}| \leq n^{5/7}$ (when $d = 2, r = 2$).

Non-existence of Linear-sized Dual Fault-Tolerant Preservers. For $d = 2$, the lower bound turns to be $\Omega\left(n^{\frac{4r+4}{4r+5}} |\mathcal{P}|^{\frac{r+2}{4r+5}}\right)$ on the size of preserver, and bound on $\mathcal{P}$ becomes $[n^{\frac{1}{r+2}}, n^{\frac{5}{r+5}}]$. Let $\epsilon = \frac{2}{(r+2)}$, so $\epsilon \leqslant 2/3$ for $r \geqslant 1$. Now for $|\mathcal{P}| = n^{\epsilon}$, observe $|\mathcal{P}| = n^{\frac{2}{r+2}}$ which lies in range $[n^{\frac{1}{r+2}}, n^{\frac{5}{r+5}}]$, the lower bound on the size of preserver becomes $\Omega(n^{1+\frac{1}{4r+5}})$ which is $\Omega(n^{1+\epsilon/8})$. Thus the following non-linearity result is immediate.

▶ **Theorem 28.** *For every $p = n^{\epsilon}$, for $\epsilon \leq 2/3$, there is an infinite family of n-node directed graphs and pair-sets $\mathcal{P}$ of size $|\mathcal{P}| = p$, for which every dual fault-tolerant reachability preserver of G for $\mathcal{P}$ requires at least $\Omega(n|\mathcal{P}|^{\frac{1}{8}})$ edges.*

Recall, Theorem 7 implies that for any $\mathcal{P}$ of size p there exists a dual fault-tolerant reachability preserver with at most $O(np)$ edges. Our result proves a wide separation in the size pairwise 1-fault-tolerant and 2-fault-tolerant reachability preservers.

6 Application of FT-SCC Preserver in Connectivity Certificates

In this section we present an application of k-FT-SCC preserver for vertex and edge connectivity certificates for digraphs.

▶ **Definition 29** (k-connectivity certificate)**.** *For a graph $G = (V,E)$, a subgraph $H = (V, E_H)$ of G is said to be a k-Edge (Vertex) Connectivity Certificate of G if for each pair of vertices $x, y \in V$, if there are are at least k-edge (vertex) disjoint paths from x to y, and vice versa in G, then the same holds true for graph H as well.*

Georgiadis et al. [22, 23] showed that for any strongly-connected graph we can compute a sparse certificate for 2-vertex connectivity and 2-edge-connectivity comprising of just $O(n)$ edges. However, little is known about extremal size bound of k-connectivity certificates in *digraphs*, for a general k.

We below present a generic reduction from $(k-1)$-FT-SCC preserver to k-connectivity in digraphs.

▶ **Lemma 30.** *Let H be a $(k-1)$-FT-SCC preserver of a digraph G, for some integer $k \geq 1$. Then, H is a k-Edge (Vertex) Connectivity Certificate for G.*[4]

[4] Note that reverse is not always true, i.e. a k-edge(vertex) connectivity certificate is not a $(k-1)$-FT-SCC preserver.

Proof. Let H be a $(k-1)$-FT-SCC preserver of G. Consider a pair of vertices $x, y \in V$, that are at least k-edge (vertex) connected in G.

By Menger's theorem, it follows that for x and y to be k-edge (vertex) connected in G it holds that on removal of any set $F \subseteq E$ of $k-1$ edges (resp. $F \subseteq V$ of $k-1$ vertices) from G, the surviving graph $G-F$ still contains a path from x to y, and a path from y to x, i.e. x and y are strongly connected in $G-F$. Now by definition of $(k-1)$-FT-SCC preserver, we have that on removal of any set F of $k-1$ edges or vertices from H, x and y must be strongly connected in $H-F$. So another application of Menger's theorem, proves that x and y to be k-edge (vertex) connected in H. ◀

Thus, Lemma 30 together with the FT-SCC preserver construction presented in Theorem 15 provides us a k-connectivity certificate of size sub-quadratic in n, for any $k \geq 3$, as follows.

▶ **Theorem 31.** *There is a polynomial time (randomized) algorithm that given any directed graph $G = (V, E)$ on n vertices and $k \geq 2$, computes a k-Edge (Vertex) Connectivity Certificate of G containing at most $\widetilde{O}(k\ 2^k\ n^{2-\frac{1}{k-1}})$ edges with probability at least $1 - 1/n^4$.*

7 Conclusion

In this paper we discuss the problem of sparsifying a directed graph while preserving its strong-connectivity and pairwise reachability structure under edge failures. For SCC preservers, we provide a construction of a truly sub-quadratic (in number of vertices) sized subgraph that preserves SCC components under constantly many edge failures. More specifically, we show an upper bound of $\tilde{O}(k2^k n^{2-1/k})$ on the size for any n-node graph with k faulty edges, whereas we show a lower bound of $\Omega(2^k n)$. We would like to pose the problem of closing this gap between upper and lower bound as an open problem.

In case of reachability preserver, we show an upper bound of $O\big(n+\min(|\mathcal{P}|\sqrt{n},\ n\sqrt{|\mathcal{P}|})\ \big)$ for any n-node graph and a vertex-pair set $\mathcal{P}$ with one faulty edge. This implies linear sized preserver for $O(\sqrt{n})$ many vertex-pairs, which is also known to be the limit for standard non-fault tolerant static setting. Unfortunately we do not know how to generalize our single fault-tolerant pairwise reachability preserver construction to dual fault-tolerant setting. On the contrary, we show a striking difference between single and dual fault tolerant setting by proving a super linear lower bound on dual fault-tolerant reachability preserver for $\Omega(n^\epsilon)$ (for some $\epsilon > 0$) vertex-pairs. One extremely interesting open problem is to get any non-trivial (better than $O(n|\mathcal{P}|)$) upper bound on size of a multiple fault-tolerant pairwise reachability preserver. Other future work lies in improving our size bounds, extending our result to bi-connectivity and other pairwise structures.

Abstract

A long line of research on fixed parameter tractability of integer programming culminated with showing that integer programs with n variables and a constraint matrix with tree-depth d and largest entry Δ are solvable in time $g(d,\Delta)\text{poly}(n)$ for some function g, i.e., fixed parameter tractable when parameterized by tree-depth d and Δ. However, the tree-depth of a constraint matrix depends on the positions of its non-zero entries and thus does not reflect its geometric structure. In particular, tree-depth of a constraint matrix is not preserved by row operations, i.e., a given integer program can be equivalent to another with a smaller dual tree-depth.

We prove that the *branch-depth* of the matroid defined by the columns of the constraint matrix is equal to the minimum tree-depth of a row-equivalent matrix. We also design a fixed parameter algorithm parameterized by an integer d and the entry complexity of an input matrix that either outputs a matrix with the smallest dual tree-depth that is row-equivalent to the input matrix or outputs that there is no matrix with dual tree-depth at most d that is row-equivalent to the input matrix. Finally, we use these results to obtain a fixed parameter algorithm for integer programming parameterized by the branch-depth of the input constraint matrix and the entry complexity. The parameterization by branch-depth cannot be replaced by the more permissive notion of branch-width.

1 Introduction

Integer programming is a fundamental problem of importance in both theory and practice. It is well-known that integer programming in fixed dimension, i.e., with a bounded number of variables, is polynomially solvable since the work of Lenstra and Kannan [21, 26] from the 1980's. Much subsequent research has focused on studying extensions and speed-ups of the results of Kannan and Lenstra. However, on the side of integer programs with many variables, research has been sparser. Until relatively recently, the most prominent tractable case is that of totally unimodular constraint matrices, i.e., matrices with all subdeterminants equal to 0 and ±1; in this case, all vertices of the feasible region are integral and algorithms for linear programming can be applied.

Besides total unimodularity, many recent results [1, 2, 5, 6, 9, 10, 14, 15] on algorithms for integer programming exploited various structural properties of the constraint matrix yielding efficient algorithms for n-fold IPs, tree-fold IPs, multi-stage stochastic IPs, and IPs with bounded fracture number and bounded tree-width. This research culminated with an algorithm by Levin, Onn and the third author [25] who constructed a fixed parameter algorithm for integer programs with bounded (primal or dual) tree-depth and bounded coefficients. We remark that it is possible to show that the problem is W[1]-hard when parameterized by tree-depth only [10, 24] and NP-hard even for instances with coefficients and tree-width (even path-width) bounded by two [7, Lemma 102] (also cf. [10, 25]).

The tree-depth of a constraint matrix depends on the position of its non-zero entries and thus does not properly reflect the true geometric structure of the integer program. In particular, a matrix with a large (dual) tree-depth may be row-equivalent to another matrix with small (dual) tree-depth that is susceptible to efficient algorithms. We will overcome this drawback with tools from matroid theory. To do so, we consider the branch-depth of the matroid defined by the columns of the constraint matrix and refer to this parameter as to the *branch-depth* of the matrix. Since this matroid is invariant under row operations, the branch-depth of a matrix is *row-invariant*, i.e., preserved by row operations, and captures the true simplicity of the geometric structure of the problem, which can be obfuscated in the case of tree-depth by the choice of the basis.

Our main results can be summarized as follows (we state the results exactly in the next subsection).

- The branch-depth of a matrix A is equal to the minimum dual tree-depth of a matrix row-equivalent to A (Theorem 1).
- There exists a fixed parameter algorithm for computing a matrix with minimum tree-depth that is row-equivalent to an input matrix (Theorem 32).

Our second result is based on a fixed parameter algorithm for computing the branch-depth of a vector matroid represented over a finite field (Theorem 28). Computing decompositions of such matroids is of interest in relation to model checking, in particular monadic second order model checking is fixed parameter tractable for matroids with bounded branch-width that are representable over finite fields [16–18], also see [11]. The existing fixed parameter algorithm [19, 20] for computing the branch-width of such matroids relies on the upper bound on the size of excluded minors for branch-width by Geelen et al. [12] and needs to precompute the (likely very large) list of excluded minors. We could follow a similar path in the setting of branch-depth, however, we decided to design a completely explicit algorithm. While this turned out surprisingly challenging, the hidden constants are significantly better, and we hope that our techniques can be extended to the even more challenging setting of branch-width.

We remark that our first result in conjunction with existing results on approximating branch-depth of a matroid (Theorem 6) yields a fixed parameter algorithm for integer programs with bounded branch-depth (Corollary 4). Since the branch-depth of the constraint matrix is always at most its dual tree-depth (Proposition 12), our algorithm extends the algorithm presented in [25] for integer programs with small dual tree-depth. Since the algorithm from our second result (Theorem 32) preserves that the entry complexity is bounded (cf. Theorem 3), it can also be used a preprocessing step for the algorithm presented in [25], which gives another proof of Corollary 4. Our results on fixed parameter tractability of integer programming cannot be extended to constraint matrices with bounded branch-width (see the discussion at the end of this section); however, Cunningham and Geelen [3] (also cf. [27] for detailed proofs and implementation) provided a slicewise pseudopolynomial algorithm for IPs with non-negative matrices with bounded branch-width, i.e., the problem belongs to the complexity class XP for unary encoding of input.

1.1 Exact statement of our results

To state our results precisely, we need to fix some notation. We consider the general integer programming (IP) problem in the standard form:

$$\min\left\{f(\mathbf{x})\ \middle|\ A\mathbf{x}=\mathbf{b}\,,\ \mathbf{l}\le\mathbf{x}\le\mathbf{u}\,,\ \mathbf{x}\in\mathbb{Z}^n\right\}, \tag{1}$$

where $A\in\mathbb{Z}^{m\times n}$ is an integer $m\times n$ matrix, $\mathbf{b}\in\mathbb{Z}^m$, $\mathbf{l},\mathbf{u}\in(\mathbb{Z}\cup\{\pm\infty\})^n$, and $f:\mathbb{Z}^n\to\mathbb{Z}$ is a separable convex function, i.e., $f(\mathbf{x})=\sum_{i=1}^{n}f_i(x_i)$ where $f_i:\mathbb{Z}\to\mathbb{Z}$ are convex functions. In particular, each $f_i(x_i)$ can be a linear function of x_i. We remark that integer programming is well-known to be NP-hard even when $f(\mathbf{x})\equiv 0$, or when the largest coefficient $\Delta:=\|A\|_\infty$ is 1 (by a reduction from the Vertex Cover problem), or when $m=1$ (by a reduction from the Subset Sum problem). We refer the reader to Section 2 for the definitions of the primal and dual tree-depth of a matrix A and the branch-depth of A.

We now demonstrate the drawback of the parameterization of integer programs by tree-depth that we have mentioned earlier. Consider the following matrices A and A'.

$$A=\begin{pmatrix}1&1&\cdots&1&1\\2&1&\cdots&1&1\\1&2&\ddots&1&1\\\vdots&\ddots&\ddots&\ddots&1\\1&1&\ddots&2&1\\1&1&\cdots&1&2\end{pmatrix}\quad\text{and}\quad A'=\begin{pmatrix}1&1&\cdots&1&1\\1&0&\cdots&0&0\\0&1&\ddots&0&0\\\vdots&\ddots&\ddots&\ddots&0\\0&0&\ddots&1&0\\0&0&\cdots&0&1\end{pmatrix}.$$

The dual tree-depth of the matrix A is equal to the number of its rows while the dual tree-depth of A' is two (its dual graph is a star); we remark that the branch-depth of both matrices A and A' is also equal to two. Since the matrices A and A' are row-equivalent, the integer programs determined by them ought to be of the same computational difficulty. More precisely, consider the following matrix B:

$$B = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 & 0 \\ -1 & 1 & 0 & \cdots & 0 & 0 \\ -1 & 0 & 1 & \ddots & 0 & 0 \\ -1 & \vdots & \ddots & \ddots & \ddots & 0 \\ -1 & 0 & 0 & \ddots & 1 & 0 \\ -1 & 0 & 0 & \cdots & 0 & 1 \end{pmatrix} .$$

Since $A' = BA$, it is possible to replace an integer program of the form (1) with an integer program with a constraint matrix $A' = BA$, right hand side $\mathbf{b}' = B\mathbf{b}$, and bounds $\mathbf{l}' = \mathbf{l}$ and $\mathbf{u}' = \mathbf{u}$, and attempt to solve this new instance of IP which has dual tree-depth two.

In Section 4, we first observe that the branch-depth of a matrix A is at most its dual tree-depth, and prove that the branch-depth of a matrix A is actually equal to the minimum dual tree-depth of a matrix A that is row-equivalent to A:

▶ **Theorem 1.** *Let A be a matrix over a field $\mathbb{F}$. The branch-depth of A is equal to the minimum dual tree-depth of a matrix A' that is row-equivalent to A, i.e., that can be obtained from A by row operations.*

The tools developed to prove Theorem 1 together with existing results on matroid branch-depth yield an algorithm that given a matrix A of small branch-depth yields a matrix B that transforms the matrix A to a row-equivalent matrix with small dual tree-depth. Recall that the *entry complexity of a matrix A*, denoted by $\mathrm{ec}(A)$, is the maximum length of the binary encoding of an entry $A_{i,j}$ (the length of binary encoding a rational number $r = p/q$ with p and q being coprime is $\lceil \log_2 p \rceil + \lceil \log_2 q \rceil + 1$).

▶ **Theorem 2.** *There exist a computable function $g : \mathbb{N} \to \mathbb{N}$ and an FPT-parameter algorithm parameterized by d with running time polynomial in $\mathrm{ec}(A)$, n and m that for an input $m \times n$ integer matrix A and an integer d*

1. *outputs that the branch-depth of A is larger than d, or*
2. *outputs an invertible rational matrix $B \in \mathbb{Q}^{m \times m}$ such that the dual tree-depth of BA is at most 4^d and the entry complexity of BA is $O(g(d)\,\mathrm{ec}(A))$.*

However, we go further and design a fixed parameter algorithm for computing the branch-depth of a vector matroid (Theorem 32) and use this algorithm to prove the following strengthening of Theorem 2.

▶ **Theorem 3.** *There exist a computable function $g' : \mathbb{N}^2 \to \mathbb{N}$ and an FPT-parameter algorithm parameterized by d with running time polynomial in $\mathrm{ec}(A)$, n and m that for an input $m \times n$ integer matrix A and an integer d*

1. *outputs that the branch-depth of A is larger than d, or*
2. *outputs an invertible rational matrix $B \in \mathbb{Q}^{m \times m}$ such that the dual tree-depth of BA is equal to the branch-depth of A and the entry complexity of BA is at most $g'(d, \mathrm{ec}(A))$.*

As explained above, Theorems 2 and 3 allow us to perform row operations to obtain an equivalent integer program with small dual tree-depth from an integer program with small branch-depth. In particular, if the instance of an integer program described as in (1) has bounded branch-depth, then Theorem 3 yields a matrix B such that the instance with $A' = BA$, $\mathbf{b}' = B\mathbf{b}$, $\mathbf{l}' = \mathbf{l}$ and $\mathbf{u}' = \mathbf{u}$ has dual tree-depth equal to branch-depth. To apply the algorithm from [25], we need to transform the matrix A' into an integer matrix. We do so by multiplying each row by the least common multiple of the denominators of the fractions in this row; note that the value of this least common multiple is at most $2^{2^{\mathrm{ec}(A')}}$ since there can be at most $2^{\mathrm{ec}(A')}$ different denominators appearing in the row. In particular, the entry complexity of the resulting integer matrix is bounded by a function of the entry complexity of A'. Also note that since the parameter dependence in the algorithm of [7] is roughly $\mathrm{ec}(A)^{\mathrm{td}_D(A)^2 \cdot 2^{\mathrm{td}_D(A)}}$, improving the exponent by replacing A with a row-equivalent matrix with smaller dual tree-depth likely outweighs the increase in the coefficients, which enters as the base of the exponent. Hence, we obtain the following corollary of the theorem.

▶ **Corollary 4.** *There exists a computable function $g'' : \mathbb{N}^2 \to \mathbb{N}$ such that integer programs with n variables and a constraint matrix A can be solved in time polynomial in $g''(\mathrm{bd}(A), \mathrm{ec}(A))$ and n, where $\mathrm{bd}(A)$ and $\mathrm{ec}(A)$ are the branch-depth and the entry complexity of the matrix A, i.e., integer programming is fixed parameter tractable when parameterized by branch-depth and entry complexity.*

We note that the results of [7,25] give a strongly fixed-parameter algorithm (i.e., an algorithm whose number of arithmetic operations does not depend on the size of the numbers involved) for integer programming in the regimes discussed above if the objective function f is a linear function (i.e., $f(\mathbf{x}) = \mathbf{w}\mathbf{x}$ for some $\mathbf{w} \in \mathbb{Z}^n$). Hence, the corollary above also gives a strongly-polynomial algorithm when f is a linear function.

We also remark that existing hardness results imply that the parameterization both by branch-depth and entry complexity in Corollary 4 is necessary unless FPT =W[1], i.e., it is not sufficient to parameterize instances only by one of the two parameters. Likewise, it is not possible to replace the branch-depth parameter by the more permissive notion of branch-width [3]. In fact, even solving integer programs with constant dual tree-width and constant entry complexity is NP-hard [25] (the dual tree-width of A is an upper bound on the branch-width of the vector matroid formed by columns of A). Let us also mention that Fomin et al. [8] proved lower bounds on the complexity of integer programming parameterized by branch-width under the exponential-time hypothesis.

The algorithm given in Corollary 4 is parameterized by the branch-depth of the vector matroid formed by the columns of the matrix A, i.e., it corresponds to the dual tree-depth of A. It is natural to ask whether the tractability also holds in the setting dual to this one, i.e., when the branch-depth of the vector matroid formed by the rows of the matrix A is bounded. This hope is dismissed in Proposition 14.

2 Notation

In this section, we fix the notation used throughout the paper and present the notions of tree-depth of a graph and of branch-depth of a matroid, including the results concerning them that we will need further. To avoid our presentation becoming cumbersome through adding or subtracting one at various places, we define the *depth* of a rooted tree to be the maximum number of edges on a path from the root to a leaf, and define the *height* of a rooted tree to be the maximum number of vertices on a path from the root to a leaf, i.e., the height of a rooted tree is always equal to its depth increased by one. The *depth of a vertex* in a rooted tree is the number of edges on the path from the root to that particular vertex. The height of a rooted forest F is the maximum height of a rooted tree in F. The *closure* $\mathrm{cl}(F)$ of a rooted forest is the graph obtained by adding edges from each vertex to all its descendants. Finally, the *tree-depth* $\mathrm{td}(G)$ of a graph G is the minimum height of a rooted forest F such that the closure $\mathrm{cl}(F)$ of the rooted forest F contains G as a subgraph. It can be shown that the path-width of a graph G is at most its tree-depth $\mathrm{td}(G)$ decreased by one, and in particular, the tree-width of G is at most its tree-depth decreased by one (in this extended abstract, we do not give the definitions of path-width and tree-width here due to space limitations). We would like to note that the tree-depth as used in [23] is equal to the minimum depth of a rooted tree F such that $G \subseteq \mathrm{cl}(F)$, however, we here follow the definition of tree-depth that is standard; still, we wish to highlight this subtle difference since [23] is one of our main references.

The *primal graph* of an $m \times n$ matrix A is the graph $G_P(A)$ with vertices $\{1, \dots, n\}$, i.e., its vertices correspond to the columns of A, where vertices i and j are connected if A contains a row whose i-th and j-th entries are non-zero. The *primal tree-depth* $\mathrm{td}_P(A)$ of a matrix A is the tree-depth of its primal graph. Analogously, the *dual graph* of A is the graph $G_D(A)$ with vertices $\{1, \dots, m\}$, i.e., its vertices correspond to the rows of A, where vertices i and j are connected if A contains a column whose i-th and j-th entries are non-zero, i.e., the dual graph $G_D(A)$ is isomorphic to the primal graph of the matrix A^T. Finally, the *dual tree-depth* of A, which is denoted by $\mathrm{td}_D(A)$, is the tree-depth of the dual graph $t_D(A)$.

We next introduce the notion of branch-depth of a matroid. To keep our presentation self-contained, we start by recalling the definition of a matroid. A *matroid* M is a pair $(X, \mathcal{I})$, where $\mathcal{I}$ is a non-empty hereditary collection of subsets of X that satisfies the *augmentation axiom*. The collection $\mathcal{I}$ is hereditary if for every $X' \in \mathcal{I}$, $\mathcal{I}$ contains all subsets of X'. The augmentation axiom asserts that for all $X' \in \mathcal{I}$ and $X'' \in \mathcal{I}$ with $|X'| < |X''|$, there exists an element $x \in X'' \setminus X'$ such that $X' \cup \{x\} \in \mathcal{I}$. The sets contained in $\mathcal{I}$ are referred to as *independent*. The *rank* $r(X')$ of a set $X' \subseteq X$ is the size of the maximum independent subset of X'; the rank $r(M)$ of a matroid $M = (X, \mathcal{I})$ is the rank of X and an independent set of size $r(M)$ is a *basis* of M. A *circuit* is a set $X' \subseteq X$ such that X' is not independent but every proper subset of X' is. Two elements of x and x' are said to be *parallel* if $r(\{x\}) = r(\{x'\}) = r(\{x, x'\}) = 1$, and an element x of M is a *loop* if $r(\{x\}) = 0$.

Two particular examples of matroids are graphic matroids and vector matroids. If G is a graph, then the pair $(E(G), \mathcal{I})$ where $\mathcal{I}$ contains all acyclic subsets of edges of G is a matroid and is denoted by $M(G)$; matroids of this kind are called *graphic matroids*. If X is a set of vectors of a vector space and $\mathcal{I}$ contains all subsets of X that are linearly independent, then the pair $(X, \mathcal{I})$ is a matroid; matroids of this kind are *vector matroids*. In the setting of vector matroids, the rank of $X' \subseteq X$ is the dimension of the linear hull of X'. If $(X, \mathcal{I})$ is a vector matroid, we write $\mathcal{L}(X')$ for the linear hull of the vectors contained in $X' \subseteq X$ and abuse the notation by writing $\dim X'$ for $\dim \mathcal{L}(X')$.

In what follows, we will need a notion of a quotient of a vector space, which we now recall. If A is a vector space and K a subspace of A, the *quotient space* A/K is a vector space of dimension $\dim A - \dim K$ obtained from A by considering cosets of A given by K and inheriting addition and scalar multiplication from A; see e.g. [13] for further details if needed. One can show show for every subspace K of A, there exists a subspace B of A with dimension $\dim A - \dim K$ such that each coset contains a single vector from B, i.e., every vector w of A can be uniquely expressed as the sum of a vector w_B of B and a vector w_K of K. We call the vector w_B to be the *quotient* of w by K. Note that the quotient of a vector is not uniquely defined by K, however, it becomes uniquely defined when the subspace B is fixed.

A *depth-decomposition* of a matroid $M = (X, \mathcal{I})$ is a pair (T, f), where T is a rooted tree and f is a mapping from X to the leaves of T such that the number of edges of T is the rank of M and the following holds for every subset $X' \subseteq X$: the rank of X' is at most the number of edges contained in the paths from the root to the vertices $f(x)$, $x \in X'$. If the matroid M contains two parallel elements x and x', we will always assume that $f(x) = f(x')$. The *branch-depth* $\mathrm{bd}(M)$ of a matroid M is the smallest depth of a tree T that forms a depth-decomposition of M. For example, if $M = (X, \mathcal{I})$ is a matroid of rank r, T is a path with r edges rooted at one of its end vertices, and f is a mapping such that $f(x)$ is equal to the non-root end vertex of T for all $x \in X$, then the pair (T, f) is a depth-decomposition of M. In particular, the branch-depth of any matroid M is well-defined and is at most the rank of M. We remark that the notion of branch-depth of a matroid given here is the one defined in [22,23]; another matroid parameter, which is also called branch-depth but is different from the one that we use here, is defined in [4]. Finally, the *branch-depth* $\mathrm{bd}(A)$ of a matrix A is the branch-depth of the vector matroid formed by the columns of A. Since the vector matroid formed by the columns of A and the vector matroid formed by the columns of any matrix row-equivalent to A are the same, the branch-depth of A is invariant under row operations.

An *extended depth-decomposition* of a vector matroid $M = (X, \mathcal{I})$ is a triple (T, f, g) such that (T, f) is a depth-decomposition of M and g is a bijective mapping from the non-root vertices of T to a basis of the linear hull of X that satisfies that every element $x \in X$ is contained in the linear hull of the g-image of the non-root vertices on the path from $f(x)$ to the root of T. We next state and prove a simple proposition on the way that the vectors forming M are expressed as linear combinations of the vectors of the base formed by the g-image.

▶ **Proposition 5.** *Let (T, f, g) be an extended depth-decomposition of a vector matroid M. Let X' be a subset of elements of M and let X'' be an independent subset of X' with $r(X')$ elements. Then for every vector $x' \in X'$, there is a vector $x'' \in X''$ such that x' is contained in the linear hull of the g-images of the vertices on the path from $f(x'')$ to the root.*

If (T, f, g) is an extended depth-decomposition of a matroid M and all g-images are elements of the matroid M, then we say that the extended depth-decomposition is *principal*. Kardoš et al. [23, Corollary 3.17] designed an algorithm that outputs an approximation of an optimal depth-decomposition; we state the result here for the case of vector matroids.

▶ **Theorem 6.** *There exists a polynomial-time algorithm that given a vector matroid M and an integer d, either outputs that the branch-depth of M is larger than d or outputs a principal extended depth-decomposition of M of depth at most 4^d.*

If (T, f, g) is an extended depth-decomposition and u is a vertex of T, then K_u is the linear hull of the g-images of the vertices on the path from u to the root of T; in particular, if u is the root, then K_u contains the zero vector only. It will always be clear from the context for which extended depth-decomposition of M the spaces K_u are defined since the vertex u determines which rooted tree T is considered.

A *branch* of a rooted tree T is a subtree S rooted at a vertex u of T, with u having at least two children, such that S contains exactly u, one child u' of u, and all descendants of u'. In particular, a rooted tree has a branch if and only if it has a vertex with at least two children. A branch S is *primary* if every ancestor of the root of S has exactly one child. Every rooted tree T that is not a rooted path has at least two primary branches and all primary branches are rooted at the same vertex. We write $\widehat{S}$ for the set of elements of the matroid M mapped by f to the leaves of S and $\|S\|$ for the number of edges of S. Let S be a branch of T and $S_1, \ldots, S_k$ be the other branches with the same root. The branch S is *at capacity* if

$$r\left(X \setminus \left(\widehat{S}_1 \cup \cdots \cup \widehat{S}_k\right)\right) = r(M) - \|S_1\| - \|S_2\| - \cdots - \|S_k\|,$$

where X is the set of all elements of the matroid M. Note that if S is primary, then the left side of the equality is $r(\widehat{S})$ and the right side is $h + \|S\|$ in this case, where h is the depth of the root of S In particular, a primary branch S is *at capacity* if and only if the rank of

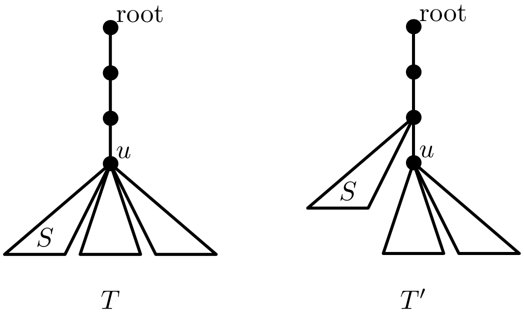

Figure 1 The trees T and T' from the statement of Lemma 8.

$\widehat{S}$ is equal to the sum of $\|S\|$, i.e., if and only if the rank inequality from the definition of a depth-decomposition holds with equality for the set $\widehat{S}$. Finally, a branch S rooted at a vertex u is *solid* if the matroid $(M/K_u)\left[\widehat{S}\right]$ is connected.

3 Optimal extended depth-decompositions

The goal of this section is to show that every vector matroid has an extended depth-decomposition with depth equal to its branch-depth. To do so, we start with noting that branches rooted at the root of the decomposition tree are always at capacity; the proof is left due to space limitations.

▶ **Lemma 7.** *Let (T, f) be a depth-decomposition of a vector matroid M. If T has a branch S rooted at the root of T, then S is at capacity.*

The following lemma is a core of an argument that every matroid has a depth-decomposition of optimal depth such that each primary branch is at capacity. See Figure 1 for the illustration of the operation described in the statement of the lemma.

▶ **Lemma 8.** *Let (T, f) be a depth-decomposition of a vector matroid M. Assume that T contains a primary branch S that is not at capacity. Let u be the root of S, and let T' be the rooted tree obtained from T by changing the root of S to be the parent of u. Then, (T', f) is a depth-decomposition of M.*

Proof. Let X be all elements of M and fix a subset X' of X. We need to show that $\dim X'$ is at most the number e_0 of edges on the paths in T' from the vertices in the f-image of X' to the root. If X' contains an element of $X \setminus \widehat{S}$, then the number of such edges is the same in the trees T and T' and the inequality follows from the fact that (T, f) is a depth-decomposition of M. Hence, we will assume that X' is a subset of $\widehat{S}$. Observe that collectively the primary branches of T different from S contain $r - h - \|S\|$ edges, where h is the depth of the root of S. We derive using the fact that (T, f) is a depth-decomposition the following:

$$\begin{aligned} e_0 + 1 + (r - h - \|S\|) &\geq \dim X' \cup (X \setminus \widehat{S}) \\ &= \dim X' + \dim X \setminus \widehat{S} - \dim \mathcal{L}(X') \cap \mathcal{L}\left(X \setminus \widehat{S}\right) \\ &\geq \dim X' + \dim X \setminus \widehat{S} - \dim \mathcal{L}\left(\widehat{S}\right) \cap \mathcal{L}\left(X \setminus \widehat{S}\right) \\ &= \dim X' + \dim X \setminus \widehat{S} - (\dim \widehat{S} + \dim X \setminus \widehat{S} - \dim X) \\ &= \dim X' - \dim \widehat{S} + r. \end{aligned}$$

This implies that $\dim X'$ is at most

$$e_0 + \dim \widehat{S} + 1 - h - \|S\| \leq e_0,$$

where the inequality follows using that S is not at capacity, i.e., $\dim \widehat{S} < h + \|S\|$. Hence, (T', f) is a depth-decomposition of M. ◀

We can obtain the following by iteratively applying Lemma 8.

▶ **Lemma 9.** *Let (T, f) be a depth-decomposition of a vector matroid $M = (X, \mathcal{I})$ of depth d. There exists a depth-decomposition of M of depth at most d such that every primary branch is at capacity.*

The following lemma describes the way how the structure of the vector matroids is captured by depth-decompositions such that each primary branch is at capacity.

▶ **Lemma 10.** *Let (T, f) be a depth-decomposition of a vector matroid $M = (X, \mathcal{I})$ such that T is not a rooted path and each primary branch of T is at capacity. Let $S_1, \dots, S_k$ be the primary branches of T, and let $A_1, \dots, A_k$ be the linear hulls of $\widehat{S_1}, \dots, \widehat{S_k}$, respectively. Further, let h be the depth of the common root of $S_1, \dots, S_k$ in T. There exists a subspace K of dimension h such that $A_i \cap A_j = K$ for all $1 \leq i < j \leq k$.*

We are now ready to prove the main theorem of this section.

▶ **Theorem 11.** *Let (T, f) be a depth-decomposition of a vector matroid $M = (X, \mathcal{I})$ of depth d. There exists an extended depth-decomposition of M of depth at most d.*

Proof. The proof proceeds by induction on the rank of M. By Lemma 9, we can assume that all primary branches of T are at capacity. If T is a rooted path, we assign elements of a basis of $\mathcal{L}(X)$ to the non-root vertices of T arbitrarily, i.e., we choose g to be any bijection to a basis of $\mathcal{L}(X)$, which yields an extended depth-decomposition (T, f, g) of M. Note that if the rank of M is one, then T is the one-edge rooted path, i.e., this case covers the base of the induction in particular.

We next assume that T is not a rooted path for the rest of the proof. Let $S_1, \dots, S_k$ be the primary branches of T, and let h be the depth of the common root of $S_1, \dots, S_k$. By Lemma 10, there exists a subspace K of dimension h such that the intersection of linear hulls of $\widehat{S_i}$ and $\widehat{S_j}$ is K for all $1 \leq i < j \leq k$; let $b_1, \dots, b_h$ be an arbitrary basis of K.

We define M_i, $i = 1, \dots, k$, to be the matroid such that the elements of M_i are $\widehat{S_i}$ and $X' \subseteq \widehat{S_i}$ is independent if and only if the elements $X' \cup \{b_1, \dots, b_h\}$ are linearly independent. In particular, the rank of $X' \subseteq \widehat{S_i}$ in M_i is equal to $\dim X' \cup K - h$. The matroid M_i can be viewed as obtained by taking the vector matroid with the elements $\widehat{S_i} \cup \{b_1, \dots, b_h\}$ and contracting the elements $b_1, \dots, b_h$. In particular, M_i is a vector matroid, and the vector representation of M_i can be obtained from $\widehat{S_i}$ by taking quotients by K. Note that the rank of M_i is $\dim \widehat{S_i} \cup K - h$, i.e., its rank is smaller than the rank of M and we will be able to eventually apply induction to it.

Let f_i be the restriction of f to $\widehat{S_i}$. We claim that (S_i, f_i) is a depth-decomposition of M_i. Let X' be a subset of $\widehat{S_i}$, and let e_i be the number of edges contained in the union of paths from the elements $f(x)$, $x \in X'$, to the root of S_i. By the definition of M_i, the rank of X' in M_i is equal to $\dim X' \cup K - h$. Choose an arbitrary $j \neq i$, $1 \leq j \leq k$. Since (T, f) is a depth-decomposition of M, the intersection of linear hulls of $\widehat{S_i}$ and $\widehat{S_j}$ is K, and the branch S_j is at capacity, i.e., $\dim \widehat{S_j} = \|S_j\| + h$, we obtain that the rank of X' in M_i is equal to

$$\begin{aligned}\dim X' \cup K - h &= \dim X' \cup \widehat{S_j} - \dim \widehat{S_j}\\ &\le e_i + \|S_j\| + h - \dim \widehat{S_j} = e_i.\end{aligned}$$

Hence, (S_i, f_i) is a depth-decomposition of M_i.

We now apply induction to each matroid M_i and its depth-decomposition (S_i, f_i), $i = 1, \ldots, k$, to obtain extended depth-decompositions (S'_i, f'_i, g_i) of M_i such that the depth of S'_i is at most the depth of S_i. Let T' be a rooted tree obtained from a rooted path of length h by identifying its non-root end with the roots of $S'_1, \ldots, S'_k$. Note that the depth of T' does not exceed the depth of T. Further, let f' be the unique function from X to the leaves of T such that the restriction of f' to the elements of M_i is f_i. Finally, let g be any function from the non-root vertices of T such that the h non-root vertices of the path from the root are mapped to the vectors $b_1, \ldots, b_h$ by g and $g(v) = g_i(v)$ for every non-root vertex v of S_i.

We claim that (T', f', g) is an extended depth-decomposition of M. We first verify that, for every $x \in X$, $f'(x)$ is contained in the linear hull of the g-image of the non-root vertices on the path from $f'(x)$ to the root. Fix $x \in X$ and let i be such that $x \in \widehat{S}_i$. Since (S'_i, f'_i, g_i) is an extended depth-decomposition of M_i, x is contained in the linear hull of K and the g_i-images of the non-root vertices on the path from $f'(x) = f_i(x)$ to the root of S'_i. Hence, x is contained in the linear hull of the g-image of the non-root vertices on the path from $f'(x)$ to the root of T'.

Consider now an arbitrary subset $X' \subseteq X$. We have already established that all elements of X' are contained in the linear hull of the g-image of the non-root vertices on the paths from $f'(x)$, $x \in X'$, to the root of T'. Since the dimension of this linear hull is equal to the number of non-root vertices on such paths, which is equal to the number of edges of the paths, it follows that (T', f') is a depth-decomposition of M. ◀

4 Optimal tree-depth of a matrix

In this section, we relate the optimal dual tree-depth of a matrix A to its branch-depth. We start with observing that the branch-depth of a matrix A is at most its dual tree-depth; the proof is left due to space limitations.

▶ **Proposition 12.** *If A is an $m \times n$ matrix, then $\mathrm{bd}(A) \le \mathrm{td}_D(A)$.*

We next establish the main theorem of this section.

▶ **Theorem 13.** *Let A be an $m \times n$ matrix of rank m, M the vector matroid formed by columns of A, and (T, f, g) an extended depth-decomposition of M. Further, let $\mathrm{Im}(g) = \{w_1, \ldots, w_m\}$. The dual tree-depth of the $m \times n$ matrix A' such that the j-th column of A is equal to*

$$\sum_{i=1}^{m} A'_{ij} w_i$$

is at most the depth of the tree T.

Proof. Let F be the rooted forest obtained from T by removing the root and associate the i-th row of A' with the vertex v of F such that $g(v) = w_i$. Note that the height of F is the depth of T. We will establish that the dual graph $G_D(A')$ is contained in the closure $\mathrm{cl}(F)$ of F. Let i and i', $1 \le i, i' \le m$, be such that the vertices of F associated with the i-th and i'-th rows of A' are adjacent in $G_D(A')$. This means that there exists j, $1 \le j \le n$, such that $A'_{ij} \ne 0$ and $A'_{i'j} \ne 0$. Let v be the leaf of T such that the j-th column of A is mapped by f

to v. The definition of an extended depth-decomposition yields that the j-th column is a linear combination of the g-image of the non-root vertices on the path from v to the root of T. In particular, the path contains the two vertices of T mapped by g to w_i and $w_{i'}$; these two vertices are associated with the i-th and i'-th rows of A'. Hence, the vertices associated with the i-th and i'-th rows are adjacent in $\mathrm{cl}(F)$. We conclude that $G_D(A')$ is a subgraph of $\mathrm{cl}(F)$. ◀

Proposition 12 and Theorem 11 combine to a proof of Theorem 1.

5 Parameterized algorithms for integer programming

The main purpose of this section is to combine Theorem 1 with the existing approximation algorithm for branch-depth (Theorem 6) to obtain an approximation algorithm for computing a row-equivalent matrix with small dual tree-depth if it exists.

Proof of Theorem 2. Let A be an $m \times n$ matrix. Without loss of generality, we can assume that the rows of A are linearly independent, i.e., the rank of A is m. This also implies that the rank of the column space of A is m, in particular, $n \geq m$.

We apply the approximation algorithm described in Theorem 6 to the vector matroid M formed by the columns of the matrix A, and we obtain an extended depth-decomposition (T, f, g) of M. If the depth of T is larger than 4^d, then the branch-depth of A is larger than d; we report this and stop. Let B_g be the matrix with the columns formed by the vectors in $\mathrm{Im}(g)$ and let $B = B_g^{-1}$. Note that the matrix A' from the statement of Theorem 13 is equal to BA. By Theorem 13, the dual tree-depth of A' is at most 4^d. The proof that the entry complexity of A' is at most $O(d \cdot 4^d \cdot \mathrm{ec}(A))$ is left due to space limitations. ◀

Theorem 2 yields Corollary 4, which asserts that integer programming is fixed parameter tractable when parameterized by the branch-depth and the entry complexity of the constraint matrix. We complement this corollary by showing that integer programming is not fixed parameter tractable when parameterized by the "primal" branch-depth.

▶ **Proposition 14.** *Integer programming is* NP*-hard for instances with constraint matrices A satisfying $\mathrm{bd}(A^T) = 1$ and $\mathrm{ec}(A) = 1$, i.e., for instances such that the vector matroid formed by rows of the constraint matrix has branch-depth one.*

6 Structure of extended depth-decompositions

In this section, we present structural results on extended depth-decompositions that we need to design a fixed parameter algorithm to compute a depth-decomposition of a vector matroid with an optimal depth. The proofs of the next two lemmas are left due to space limitations; we note that the first of the two lemmas can be viewed as a generalization of Lemma 10.

▶ **Lemma 15.** *Let (T, f) be a depth-decomposition of a vector matroid M and let U be a set of vertices of T such that every vertex contained in U has at least two children and every ancestor of a vertex in U with at least two children is contained in U. Assume that every branch of T rooted at a vertex from U is at capacity. Every vertex $u \in U$ can be associated with a subspace L_u of the linear hull of the elements of M such that the dimension of L_u is the depth of u and the following holds. Let u be a vertex of U, let $S_1, \ldots, S_k$ be all branches rooted at u, and let $A_1, \ldots, A_k$ be the linear hulls of $\widehat{S_1}, \ldots, \widehat{S_k}$, respectively. If each ancestor of u has a single child, let L_0 be the vector space containing the zero vector only; otherwise, let u' be the nearest ancestor of u with at least two children, and let L_0 be the space $L_{u'}$. It holds that $\mathcal{L}(A_i \cup L_0) \cap \mathcal{L}(A_j \cup L_0) = L_u$ for all $1 \leq i < j \leq k$.*

▶ **Lemma 16.** *Let (T, f) be a depth-decomposition of a vector matroid M, u_1 a vertex of T with at least 2 children, and $u_2, \ldots, u_k$ all ancestors of u_1 with at least two children (listed in the increasing distance from u_1). Assume that every branch rooted at one the vertices $u_1, \ldots, u_k$ is at capacity, and let L_1 be the space L_{u_1} from the statement of Lemma 15 applied with $U = \{u_1, \ldots, u_k\}$. Further, let S_1 be any branch rooted at u_1 and f_1 the restriction of f to S_1. The pair (S_1, f_1) is a depth-decomposition of the vector matroid $(M/L_1)\left[\widehat{S_1}\right]$ and a branch of (S_1, f_1) is at capacity if and only if it is at capacity in (T, f). In addition, if (S_1', f_1') is another depth-decomposition of the vector matroid $(M/L_1)\left[\widehat{S_1}\right]$, then (T', f') is a depth-decomposition of the vector matroid M, where T' is obtained from T by replacing S_1 with S_1', and the function f' is defined as $f'(x) = f_1'(x)$ for $x \in \widehat{S_1}$, and $f'(x) = f(x)$ otherwise.*

Lemmas 15 and 16 allow to extend Lemma 8 to all branches.

▶ **Lemma 17.** *Let (T, f) be a depth-decomposition of a vector matroid M, and S_0 a branch of T rooted at a vertex u_0 such that S_0 is not at capacity. Suppose that every branch rooted at an ancestor of u_0 is at capacity. Let T' be the rooted tree obtained from T by changing the root of S_0 to be the parent of u_0. Then, (T', f) is a depth-decomposition of M.*

Lemmas 15–17 yield an iterative algorithm described in the next theorem.

▶ **Theorem 18.** *There exists a polynomial time algorithm that given a vector matroid M and a depth-decomposition (T, f) of M outputs an extended depth-decomposition (T', f', g) of M such that the depth of T' is at most the depth of T and every branch of T' is at capacity.*

We obtain the following two statements as corollaries of Theorem 18.

▶ **Corollary 19.** *Every vector matroid M has a depth-decomposition (T, f) with depth $\mathrm{bd}(M)$ such that every branch of T is at capacity.*

▶ **Corollary 20.** *If (T, f) is a depth-decomposition of a vector matroid M, then there exists g such that (T, f, g) is an extended depth-decomposition of M.*

We conclude this section with a theorem that asserts that every vector matroid has a depth-decomposition of minimum depth that has a special structure. We need three auxiliary lemmas.

▶ **Lemma 21.** *Let M be a vector matroid and $M_1, \ldots, M_k$ be its components. Further, let (T_i, f_i, g_i) be an extended depth-decomposition of M_i. Let T be the rooted tree obtained from the trees $T_1, \ldots, T_k$ by identifying the roots of the trees, let f be the mapping from the elements of M to the leaves of T such that $f(x) = f_i(x)$ if x belongs to M_i, and let g be the mapping such that $g(v) = g_i(v)$ if v is a non-root vertex of T_i. The triple (T, f, g) is an extended depth-decomposition of M.*

▶ **Lemma 22.** *Let (T, f, g) be an extended depth-decomposition of a vector matroid M, and let u be a vertex with at least two children. If S is a branch rooted at u, then $\widehat{S}$ is a union of components of M/K_u.*

▶ **Lemma 23.** *Let (T, f, g) be an extended depth-decomposition of a vector matroid M, and let u be a vertex with at least two children. Further, let S be a branch rooted at u and (T', f', g') be an extended depth-decomposition of the matroid $(M/K_u)\left[\widehat{S}\right]$. Let T'' be the rooted tree obtained by removing from T the branch S and identifying the root of T' with*

u, setting $f''(x) = f'(x)$ for elements $x \in \widehat{S}$ and $f''(x) = f(x)$ for other elements x of M, and setting $g''(v) = g(v)$ for vertices of T not contained in S and $g''(v) = g'(v) + K_u$ for non-root vertices of T'. The triple (T'', f'', g'') is an extended depth-decomposition of M.

We are now ready to prove the final theorem of this section.

▶ **Theorem 24.** *Every vector matroid M has an extended depth-decomposition (T, f, g) of depth $\mathrm{bd}(M)$ such that every branch of T is both at capacity and solid.*

Proof. We start with a depth-decomposition (T, f, g) of M with depth $\mathrm{td}(M)$ and modify it iteratively as follows. At each iteration, we first apply Theorem 18 to obtain a depth-decomposition such that every branch is at capacity. If every branch is solid, we stop. If there is a branch S that is not solid, we proceed as follows. Since S is not solid, the matroid $(M/K_u)\left[\widehat{S}\right]$ is not connected, where u is the root of S. Let $M_1, \ldots, M_k$ be the components of the matroid $(M/K_u)\left[\widehat{S}\right]$ and let X_u be the set containing all loops of the matroid $(M/K_u)\left[\widehat{S}\right]$. Let (S_i, f_i, g_i) be an extended depth-decomposition of M_i, $i = 1, \ldots, k$, with depth $\mathrm{bd}(M_i)$. Since the branch-depth $\mathrm{bd}(M_i)$ of M_i is at most the branch-depth of $(M/K_u)\left[\widehat{S}\right]$, the depth of each of the trees $S_1, \ldots, S_k$ is at most the depth of S. By Lemmas 21 and 23, it is possible to replace the branch S with the branches $S_1, \ldots, S_k$ rooted at the root of S and assigning the elements of X_u to arbitrary leaves of the branches $S_1, \ldots, S_k$. Note that the depth of the new rooted tree does not exceed the depth of the original rooted tree. In this way, we obtain a new extended depth-decomposition of M, and we proceed to the next iteration. The proof that the procedure described above terminates after at most $r^{\mathrm{bd}(M)+1}$ iterations is left due to space limitations. ◀

7 Algorithm for finite fields

In this section, we design a fixed parameter algorithm for computing a depth-decomposition of a vector matroid over a fixed finite field. To do so, we need to introduce additional notation. Let (T, f, g) be an extended depth-decomposition of a vector matroid M, and let r be the rank of M. Let $u_0, \ldots, u_{2r}$ be a depth-first-search transversal of the tree T (see Figure 2 for illustration). For $i \in \{0, \ldots, 2r\}$, we define A_i to be the linear hull of K_{u_i} and the f-preimage of the leaves among the vertices $u_0, \ldots, u_i$. Similarly, we define B_i to be the linear hull of K_{u_i} and the f-preimage of the leaves among the vertices $u_i, \ldots, u_{2r}$. The sequence $(u_i, A_i, B_i)_{i\in\{0,\ldots,2r\}}$ is called a *transversal sequence* for (T, f, g). Note that $A_i \cap B_i = K_{u_i}$ by the fact that $\mathrm{Im}(g)$ is a basis of the linear hull of elements of M. If (T, f, g) is principal and (T', f', g') is another extended depth-decomposition of M, we say that a branch S of T' is *i-crossed* if $\widehat{S}$ contains the g-image of a vertex on the path from u_i to the root of T.

▶ **Lemma 25.** *Let M be a vector matroid, (T, f, g) a principal extended depth-decomposition of M, and (T', f', g') an extended depth-decomposition of M such that every branch is solid. Further, let $(u_i, A_i, B_i)_{i\in\{0,\ldots,2r\}}$ be a transversal sequence for (T, f, g). If S is a branch of (T', f', g') that is not i-crossed, then $\widehat{S}$ is a subset of A_i or B_i.*

We will design a dynamic programming algorithm, which will be constructing an optimal depth-decomposition of a vector matroid M using the information on the structure of M captured by an extended depth-decomposition of M produced by an approximation algorithm

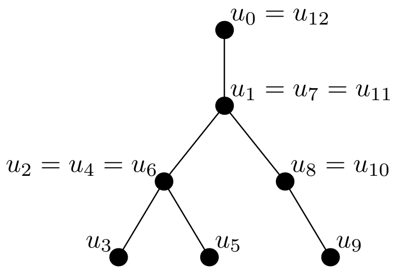

Figure 2 An example of a depth-first-search transversal of a rooted tree.

given in Theorem 6. The depth-decomposition will be constructed iteratively for elements of M in the order in that the leaves that they are assigned to appear in the transversal sequence of the depth-decomposition produced by the approximation algorithm. Since it would not be feasible to store all possible "partial" depth-decompositions, we need a more succinct way of representing an already constructed part of a depth-decomposition, which we now formally introduce.

Let (T, f, g) be a principal extended depth-decomposition of a vector matroid M with rank r over a field $\mathbb{F}$, $(u_i, A_i, B_i)_{i\in\{0,\dots,2r\}}$ a transversal sequence for (T, f, g), and (T', f', g') another extended depth-decomposition of a matroid M. A *frontier* is a tuple (T_0, d, a, b, h) such that d, a, and b are non-negative integers, T_0 is a rooted tree of depth with at most d leaves, and h is a mapping from non-root vertices of T_0 to $\mathbb{F}^{d+a+b}$ such that $\mathrm{Im}(h)$ is a set of linearly independent vectors and for every $j = 1, \dots, d$, there is a leaf of T_0 for which the j-th unit vector is contained in the linear hull of the h-image of the vertices on the path from the leaf to the root of T_0. We will refer the middle a coordinates of images of h as *A-coordinates* and to the last b coordinates as *B-coordinates*.

The *i-frontier* of (T', f', g') with respect to (T, f, g) and $(u_i, A_i, B_i)_{i\in\{0,\dots,2r\}}$ is the frontier (T_0, d, a, b, h) such that

- T_0 is the rooted subtree of T' formed by the paths from the f'-images of U to the root, where U is the set of g-images of the vertices on the path from u_i to the root of T.
- The integer d is the depth of u_i in T.
- The integers a and b are the smallest integers for that there exists an a-dimensional subspace L_A of A_i and a b-dimensional subspace L_B of B_i such that the linear hull of the g'-images of the vertices of T_0 (note that T_0 is a subtree of T') is a subspace of the linear hull of $v^u_1, \dots, v^u_d$, L_A and L_B, where $v^u_1, \dots, v^u_d$ are g-images of the vertices on the path from the root of T to u_i (in this order).
- Finally, h is a mapping from the non-root vertices of T_0 to $\mathbb{F}^{d+a+b}$ that satisfies the following. Let $v^A_1, \dots, v^A_a$ be vectors such that $v^u_1, \dots, v^u_d, v^A_1, \dots, v^A_a$ form a basis of L_A, and let $v^B_1, \dots, v^B_b$ be vectors such that $v^u_1, \dots, v^u_d, v^B_1, \dots, v^B_b$ form a basis of L_B. The value $h(v)$ for a non-root vertex v of T_0 is equal to the coordinates of $f'(v)$ with respect to the (linearly independent) vectors $v^u_1, \dots, v^u_d, v^A_1, \dots, v^A_a, v^B_1, \dots, v^B_a$.

The following lemma justifies the definition of an *i-frontier*. Informally speaking, the lemma says that two depth-decompositions of a vector matroid M can be combined along the same i-frontier, i.e., the i-frontier contains all information that needs to be stored when iteratively constructing a depth-decomposition of M in a dynamic way for the elements of contained in $A_0, A_1, \dots, A_{2r}$.

▶ **Lemma 26.** *Let (T, f, g) be a principal extended depth-decomposition of a vector matroid M, $(u_i, A_i, B_i)_{i\in\{0,\dots,2r\}}$ a transversal sequence for (T, f, g), and (T', f', g') and (T'', f'', g'') two solid extended depth-decompositions of M. Suppose that the i-frontiers of (T', f', g') and (T'', f'', g'') with respect to (T, f, g) and $(u_i, A_i, B_i)_{i\in\{0,\dots,2r\}}$ are the same, and let T_0 be the rooted tree of the i-frontier. Obtain T'_A from T' by removing all branches S with $\widehat{S} \subseteq B_i$ that are not i-crossed, T''_B from T'' by removing all branches S with $\widehat{S} \subseteq A_i$ that are not i-crossed, and T''' by gluing T'_A and T''_B together on the vertices that correspond to each vertex of T_0. Finally, let f''' be a function from the elements of M to the leaves of T''' defined as follows. If $x \in A_i \setminus B_i$, then $f'''(x) = f'(x)$. If $x \in B_i \setminus A_i$, then $f'''(x) = f''(x)$. Lastly, if $x \in A_i \cap B_i = K_{u_i}$, then $f'''(x)$ is any leaf u of T_0 such that $x \in \mathcal{L}(g'(P_u))$. Then (T''', f''') is a depth-decomposition of M.*

Before stating the main result of this section, we need to observe that the number of frontiers for any fixed d is bounded.

▶ **Lemma 27.** *For every integer d and any finite field $\mathbb{F}$, there exist at most $d^{2d+4}|\mathbb{F}|^{2d^4}$ choices of a rooted tree T of depth at most d, integers $d' \le d$, a and b and a mapping h to $\mathbb{F}^{d'+a+b}$ such that (T, d', a, b, h) is a frontier.*

We can now design a dynamic programming algorithm for computing the branch-depth of a matroid represented over a fixed finite field. While there are many technical details that needs to be taken care of, the basic idea of the algorithm is simple: we first obtain an approximate depth-decomposition using Theorem 6 and then proceed computing along its depth-first-search transversal possible frontiers; Lemma 26 guarantees that frontiers capture all information that needs to be carried through dynamic programming, and their number of frontiers is bounded by Lemma 27.

▶ **Theorem 28.** *For the parameterization by a positive integer d and a prime power q, there exists a fixed parameter algorithm that for a vector matroid M over the q-element field either outputs that $\mathrm{bd}(M)$ is larger than d, or outputs a depth-decomposition of M with depth d.*

Proof. We first apply the algorithm from Theorem 6. The algorithm either outputs that the branch-depth of M is larger than d or outputs a principal extended depth-decomposition (T, f, g) of a vector matroid M with depth at most 4^d. For the purpose of the analysis of the algorithm that we present, fix a solid extended depth-decomposition (T_s, f_s, g_s) of M with depth $\mathrm{bd}(M)$, which exists by Theorem 24.

Let r be the rank of the matroid M, and let $(u_i, A_i, B_i)_{i\in\{0,\dots,2r\}}$ be a transversal sequence for (T, f, g). The algorithm then iteratively for $j = 0, \dots, 2r$ computes a list of all frontiers (T_0, d', a, b, h), $d' \le d$ for which there there exists a vector matroid M' with rank $\dim A_i + b$ such that the restrictions of M and M' to the elements contained in the subspace A_i are the same, and a solid extended depth-decomposition (T', f', g') of M' of depth at most d such that (T, d', a, b, h) is the i-frontier of (T', f', g') with respect to (T, f, g) and its transversal sequence.

Note that the number of such frontiers is bounded by a function of d and q only by Lemma 27; the number of edges of T can be shown to be $d' + a + b$. If the branch-depth of M is at most d, then the set of such frontiers is non-empty for every $j = 0, \dots, 2r$: the matroid M' in the i-th iteration can be chosen to be the the union of the restriction of the matroid M to the elements of A_i and the elements of K_u, where u ranges over all the vertices on the path from u_i to the root of T. A solid extended depth-decomposition (T', f', g') can be obtained from (T_s, f_s, g_s) by removing all branches S with $\widehat{S} \subseteq B_i$ that are not i-crossed. So, if the set of the frontiers becomes empty at any of the iterations, the algorithm can stop and output that the branch-depth of M is larger than d.

We now describe the iterations of the algorithm in detail. For $j = 0$, the list of frontiers contains a single element $(R, 0, 0, 0, h)$, where R is the rooted tree that contains the root only and h is the null mapping. We now describe how the algorithm computes the list for $j > 0$ assuming that the list is already available for $j - 1$. The iteration of the algorithm differs according to whether u_j is a parent of u_{j-1} and u_j is a child of u_{j-1}.

We start with describing the case that u_j is a parent of u_{j-1}. Let $d' < d$ be the depth of u_j. Then the depth of u_{j-1} is $d' + 1$. The following is performed for every frontier of the form $(T_0, d' + 1, a, b, h)$ in the list from the previous iteration, and every leaf u of T_0 such that the linear hull of the h-image of the vertices from u to the root contains the $(d' + 1)$-th unit vector. If the leaves of T_0 can be assigned distinct indices $i' = 1, \ldots, d'$ such that the linear hull of the h-image of the vertices from each leaf to the root contains contains the i'-th unit vector, where i' is the index assigned to the leaf, then we include $(T_0, d', a + 1, b, h')$ to the list from the j-th iteration, where h' is a mapping from the non-root vertices of T_0 obtained from h by turning the $(d' + 1)$-th coordinate to be one of the A-coordinates and applying any invertible linear transformation to the $a + 1$ A-coordinates, i.e., we fix such a linear transformation L and set $h'(v) = L(h(v))$ for all vertices v of T_0. If there exists $i' = 1, \ldots, d'$ such that u is the only leaf for which the linear hull of the h-image of the vertices from it to the root contains the i'-th unit vector, we continue with the next choice of (T_0, d', a, b, h') and u. Otherwise, for every $i' = 1, \ldots, d'$ there exists another leaf for which the linear hull of the h-image of the vertices from it to the root contains the i'-th unit vector, which means that we may be able to remove u from T_0. So, let T_0' be the tree obtained from T_0 by removing the path from u to the nearest ancestor with at least two children and turn the $(d' + 1)$-th coordinate to an A-coordinate. If the linear hull of the h-images of the vertices of T_0' restricted to their B-coordinates does not have dimension b, then it is not possible to modify this frontier by removing u and we continue with the next choice of (T_0, d', a, b, h') and u. Otherwise, let a' be the dimension of the linear hull of the h-images of the vertices of T_0' restricted to their A-coordinates and include (T_0, d', a', b, h') to the list from the j-th iteration, where h' is a mapping obtained from h by mapping its A-coordinates by a linear transformation L such that L maps a-dimensional vector space to a'-dimensional vector space and its image has dimension a'.

We next describe the case that u_j is a child of u_{j-1}. Again, let $d' \leq d$ be the depth of u_j. Then the depth of u_{j-1} is $d' - 1$. The following is performed for every frontier of the form $(T_0, d' - 1, a, b, h)$ in the list from the previous iteration. For every leaf u and every $i' = 1, \ldots, b$ such that the unit vector for the i'-th B-coordinate is contained in the linear hull of the h-image of the vertices from u to the root, we turn the i'-th B-coordinate to the d'-th coordinate to obtain h' and include $(T_0, d', a, b - 1, h')$ to the list from the j-th iteration. In addition, we perform the following. For every $\ell = 1, \ldots, d$, we consider a rooted path of length ℓ and identify its root with a vertex T_0 in all possible ways that the depth of the resulting tree T' does not exceed d. Let u be the new leaf of T_0' and let h' be a mapping obtained from h by assigning each of the ℓ new vertices one of the unit vectors for the i'-th B-coordinates for $i' = b + 1, \ldots, b + \ell$. For every invertible linear transformation L to the $b + \ell$ B-coordinates that yields h'' such that the linear hull of the h''-images of the vertices on the path from u to the root of T_0' contains the unit vector for the $(b + \ell)$-th B-coordinate, we turn the $(b + \ell)$-th B-coordinate to the d'-th coordinate to obtain h''' and include $(T_0, d', a', b + \ell - 1, h''')$ to the list from the j-th iteration.

Assume that all the iterations of the algorithm have been performed. If the list of frontiers is empty after any iteration, the branch-depth of M exceeds d and the algorithm reports this. Otherwise, the final list (for $j = 2r$) contains a single element $(R, 0, 0, 0, h)$ where R is the rooted tree that contains the root only. Tracing back to the list for $j = 0$, we obtain a series of frontiers $(T_i, d_i, a_i, b_i, h_i)$, $i = 0, \ldots, 2r$, such that the i-th one can be obtained from the $(i-1)$-th by the operations explained earlier. Note that d_i is the depth of u_i in T. In the frontier $(T_i, d_i, a_i, b_i, h_i)$, the first d_i coordinate of the h-image correspond to the g-image of the vertices on the path from the root of T to u_i (in this order). The way the frontiers were constructed guarantees consistency between the shape of the frontiers and the basis elements displayed by frontiers; in particular, the mappings h_i are projections of the linear hull of elements of M to the subspace corresponding to the i-frontier and the linear transformations used in the steps of the algorithm provides a consistent way of relating these projections with each other. Hence, there exists an extended depth-decomposition (T', f', g') such that $(T_i, d_i, a_i, b_i, h_i)$ is the i-frontier of (T', f', g') with respect to (T, f, g) and $(u_i, A_i, B_i)_{i\in\{0,\ldots,j\}}$. The algorithm computes this extended depth-decomposition (T', f', g') and outputs it. ◀

Theorems 18 and 28 yield the following corollary.

▶ **Corollary 29.** *For the parameterization by a positive integer d and a prime power q, there exists a fixed parameter algorithm that for a vector matroid M over the q-element field either outputs that $\mathrm{bd}(M)$ is larger than d, or computes $\mathrm{bd}(M)$ and outputs an extended depth-decomposition of M with depth $\mathrm{bd}(M)$ such that every branch of the depth-decomposition is at capacity.*

8 Algorithm for rational matrices

In this section, we adopt the algorithm presented in Section 7 to matroids over rationals; the proofs are left due to space limitations. We start with two auxiliary lemmas. We remark that the bound of 2^{2d-1} in Lemma 30 can be replaced with $d \cdot 2^{d-1}$ using a more careful analysis.

▶ **Lemma 30.** *Let M be a vector matroid and (T, f) a depth-decomposition of M with depth d such that every branch is at capacity. There exists a mapping g such that (T, f, g) is an extended depth-decomposition of M and every element of $\mathrm{Im}(g)$ is a linear combination of at most 2^{2d-1} elements of M.*

▶ **Lemma 31.** *Let A be an integer matrix of branch-depth (over $\mathbb{Q}$) at most d such that all its entries are between $-K$ and $+K$. Further, let q be a prime larger than $(K2^{2d})^{2^{2d}}$. The following holds for any subset X of the columns of A: the vectors contained in X are linearly independent over $\mathbb{Q}$ if and only they are independent over the q-element field.*

We derive the following using Theorem 28, Corollary 29, and Lemmas 30 and 31.

▶ **Theorem 32.** *For the parameterization by positive integers d and K, there exists a fixed parameter algorithm that for a vector matroid M over $\mathbb{Q}$ such that the entries of all vectors in M have complexity at most K either outputs that $\mathrm{bd}(M)$ is larger than d, or computes $\mathrm{bd}(M)$ and outputs an extended depth-decomposition (T, f, g) of M with depth $\mathrm{bd}(M)$. Moreover, the entry complexity of the vectors in $\mathrm{Im}(g)$ is bounded by a function of d and K.*

Theorem 32 yields Theorem 3.

Abstract

The longest common substring problem consists in finding a longest string that appears as a (contiguous) substring of two input strings. We consider the dynamic variant of this problem, in which we are to maintain two dynamic strings S and T, each of length at most n, that undergo substitutions of letters, in order to be able to return a longest common substring after each substitution. Recently, Amir et al. [ESA 2019] presented a solution for this problem that needs only $\tilde{\mathcal{O}}(n^{2/3})$ time per update. This brought the challenge of determining whether there exists a faster solution with polylogarithmic update time, or (as is the case for other dynamic problems), we should expect a polynomial (conditional) lower bound. We answer this question by designing a significantly faster algorithm that processes each substitution in amortized $\log^{\mathcal{O}(1)} n$ time with high probability. Our solution relies on exploiting the local consistency of the parsing of a collection of dynamic strings due to Gawrychowski et al. [SODA 2018], and on maintaining two dynamic trees with labeled bicolored leaves, so that after each update we can report a pair of nodes, one from each tree, of maximum combined weight, which have at least one common leaf-descendant of each color. We complement this with a lower bound of $\Omega(\log n / \log \log n)$ for the update time of any polynomial-size data structure that maintains the LCS of two dynamic strings, even allowing amortization and randomization.

1 Introduction

The well-known longest common substring (LCS) problem, formally stated below, was conjectured by Knuth to require $\Omega(n \log n)$ time. However, in his seminal paper that introduced suffix trees, Weiner showed how to solve it in linear time (for constant alphabets) [29]. Since then, this classical question was considered in many different versions, such as obtaining a tradeoff between the time and the working space [21, 27], or computing an approximate LCS under either the Hamming or the edit distance (see [9, 20, 28] and references therein), to name a few.

Problem: Longest Common Substring
Input: Two strings S and T of length at most n over an alphabet Σ.
Output: A longest substring X of S that is a substring of T.

We consider the dynamic version of this problem where the strings are updated and we are to report an LCS after each update. That is, we return the length of an LCS and a pair of starting positions of its occurrences in the strings. The allowed update operations are substitutions of single letters in either S or T. In fact, with due care, our algorithms can be adapted to handle all edit operations, i.e. insertions and deletions as well, but we only allow substitutions for the sake of a clearer exposition of the main ideas.

Dynamic problems on strings are of wide interest. Maybe the most basic question in this direction is that of maintaining a dynamic text while enabling efficient pattern matching queries. This is clearly motivated by, say, the possible application in a text editor. The first structure achieving polylogarithmic update time and optimal query time for this problem was designed by Sahinalp and Vishkin [26]. Later, the update time was improved to $\mathcal{O}(\log^2 n \log\log n \log^* n)$ at the cost of $\mathcal{O}(\log n \log\log n)$ additional time per query by Alstrup et al. [2]. Recently, Gawrychowski et al. [15] presented a data structure that requires $\mathcal{O}(\log^2 n)$ time per update and allows for time-optimal queries. Other problems on strings that have been studied in the dynamic setting include maintaining repetitions, such as the set of square substrings [5] or a longest palindromic substring [4, 7].

As for the LCS problem itself, Amir et al. [6] initiated the study of this question in the dynamic setting by considering the problem of constructing a data structure over two strings that returns the LCS after a single edit operation in one of the strings. However, in their solution, after each edit operation, the string is immediately reverted to its original version. Abedin et al. [1] improved the tradeoffs for this problem by designing a more efficient solution for the so-called heaviest induced ancestors problem. Amir and Boneh [3] investigated some special cases of the *partially dynamic LCS* problem (in which one of the strings is assumed to be static); namely, the case where the static string is periodic and the case where the substitutions in the dynamic string are substitutions with some letter $\# \notin \Sigma$. Finally, Amir et al. [7] presented the first algorithm for the *fully dynamic LCS* problem (in which both strings are subject to updates) that needs only sublinear time per edit operation (insertion or deletion of a letter) in either string, namely $\tilde{\mathcal{O}}(n^{2/3})$. As a stepping stone towards this result, they designed an algorithm for the partially dynamic LCS problem that takes $\tilde{\mathcal{O}}(\sqrt{n})$ time per edit operation.

For some natural dynamic problems, the best known bounds on the query and the update time are of the form $\mathcal{O}(n^\alpha)$, where n is the size of the input and α is some constant. Henzinger et al. [16] introduced the online Boolean matrix-vector multiplication conjecture that can be used to provide some justification for the polynomial time hardness of many such dynamic problems in a unified manner. This brings the question of determining if the bound on the update time in the dynamic LCS problem should be polynomial or subpolynomial.

We answer this question by significantly improving on the bounds presented by Amir et al. [7] and presenting a solution for the fully dynamic LCS problem that handles each update in amortized polylogarithmic time with high probability. As a warm-up, we present a (relatively simple) deterministic solution for the partially dynamic LCS problem that handles each update in amortized $\mathcal{O}(\log^2 n)$ time.

After having determined that the complexity of fully dynamic LCS is polylogarithmic, the next natural question is whether we can further improve the bound to polyloglogarithmic. By now we have techniques that can be used to not only distinguish between these two situations but (in some cases) also provide tight bounds. As a prime example, static predecessor for a set of n numbers from $[n^2]$ requires $\Omega(\log\log n)$ time for structures of size $\tilde{\mathcal{O}}(n)$ [25], and dynamic connectivity for forests requires $\Omega(\log n)$ time [24], with both bounds being asymptotically tight. In some cases, seemingly similar problems might have different complexities, as in the orthogonal range emptiness problem: Nekrich [22] showed a data structure of size $\mathcal{O}(n\log^4 n)$ with $\mathcal{O}(\log^2\log n)$ query time for 3 dimensions, while for the same problem in 4 dimensions Pătraşcu showed that any polynomial-size data structure requires $\Omega(\log n/\log\log n)$ query time [23]. In the full version of this work, we show the following results, each obtained through a series of reductions, starting from the problem of answering reachability queries in butterfly graphs that was considered in the seminal paper of Pătraşcu [23].

▶ **Theorem 1.** *Any structure of $\tilde{\mathcal{O}}(n)$ size for maintaining an LCS of a dynamic string S and a static string T, each of length at most n, requires $\Omega(\log n/\log\log n)$ time per update operation.*

▶ **Theorem 2.** *Any polynomial-size structure for maintaining the LCS of two dynamic strings of length n requires $\Omega(\log n/\log\log n)$ time per update operation.*

Finally, we demonstrate that the difference in the allowed space in the above two lower bounds is indeed needed. To this end, we show that partially dynamic LCS admits an $\mathcal{O}(n^{1+\epsilon})$-space, $\mathcal{O}(\log\log n)$-update time solution, for any $\epsilon > 0$.

Techniques and roadmap. We first consider the partially dynamic version of the problem where updates are only allowed in one of the strings, say S, in Section 3. This problem is easier as we can use the static string T as a reference point. We maintain a partition of S into blocks (i.e. substrings of S whose concatenation equals S), such that each block is a substring of T, but the concatenation of any two consecutive blocks is not. This is similar to the approach of [8] and other works that consider one dynamic and one static string. The improvement upon the $\tilde{\mathcal{O}}(\sqrt{n})$-time algorithm presented in [7] comes exactly from imposing the aforementioned maximality property, which guarantees that the sought LCS is a substring of the concatenation of at most three consecutive blocks and contains the first letter of one of these blocks. The latter property allows us to anchor the LCS in S. Upon an update, we can maintain the block decomposition, by updating a constant number of blocks. It then suffices to show how to efficiently compute the longest substring of T that contains the first letter of a given block. We reduce this problem to answering a *heaviest induced ancestors* (HIA) query. This reduction was also presented in [1, 6], but we describe the details to make following the more involved solution of fully dynamic LCS easier.

In Section 4 we move to the fully dynamic LCS problem. We try to anchor the LCS in both strings as follows. For each of the strings S and T we show how to maintain, in $\log^{\mathcal{O}(1)} n$ time, a collection of pairs of adjacent fragments (e.g. $(S[i\mathinner{.\,.} j-1], S[j\mathinner{.\,.} k])$), denoted by J_S for S and J_T for T, with the following property. For any common substring X of S and T there exists a partition $X = X_\ell X_r$ for which there exists a pair $(U_\ell, U_r) \in J_S$ and a pair $(V_\ell, V_r) \in J_T$ such that X_ℓ is a suffix of both U_ℓ and V_ℓ, while X_r is a prefix of both U_r and V_r. We can maintain this collection by exploiting the properties of the locally consistent parsing previously used for maintaining a dynamic collection of strings [15]. We maintain tries for fragments in the collections and reduce the dynamic LCS problem to a problem on dynamic bicolored trees, which we solve by using dynamic heavy-light decompositions and 2D range trees.

2 Preliminaries

We use $[n]$ to denote the set $\{1, 2, \ldots, n\}$. Let $S = S[1]S[2] \cdots S[n]$ be a *string* of length $|S| = n$ over an integer alphabet Σ. For two positions i and j on S, we denote by $S[i\,..\,j] = S[i] \cdots S[j]$ the *fragment* of S that starts at position i and ends at position j (it is the empty string ε if $j < i$). A string Y, of length m with $0 < m \leq n$, is a *substring* of S if there exists a position i in S such that $Y = S[i\,..\,i+m-1]$. The prefix of S ending at the i-th letter of S is denoted by $S[..\,i]$ and the suffix of S starting at the i-th letter of S is denoted by $S[i\,..]$. The reverse string of S is denoted by S^R. The concatenation of strings S and T is denoted by ST, and the concatenation of k copies of string S is denoted by S^k. By $\mathsf{lcp}(S, T)$ we denote the length of the longest common prefix of strings S and T.

We define the trie of a collection of strings $C = \{S_1, S_2, \ldots, S_k\}$ as follows. It is a rooted tree with edges labeled by single letters. Every string S that is a prefix of some string in C is represented by exactly one path from the root to some node v of the tree, such that the concatenation of the labels of the edges of the path, the *path-label* of v, is equal to S. The compacted trie of C is obtained by contracting maximal paths consisting of nodes with one child to an edge labeled by the concatenation of the labels of the edges of the path. Usually, the label of the new edge is stored as the start/end indices of the corresponding fragment of some S_i. The *suffix tree* of a string T is the compacted trie of all suffixes of $T\$$ where \$ is a letter smaller than all letters of the alphabet Σ. It can be constructed in $\mathcal{O}(|T|)$ time for linear-time sortable alphabets [11]. For a node u in a (compacted) trie, we define its *depth* as the number of edges on the path from the root to u. Analogously, we define the *string-depth* of u as the total length of labels along the path from the root to u.

We say that a tree is weighted if there is a weight $w(u)$ associated with each node u of the tree, such that weights along the root-to-leaf paths are increasing, i.e. for any node u other than the root, $w(u) > w(\text{parent}(u))$. Further, we say that a tree is labeled if each of its leaves is given a distinct label.

▶ **Definition 3.** *For rooted, weighted, labeled trees $\mathcal{T}_1$ and $\mathcal{T}_2$, two nodes $u \in \mathcal{T}_1$ and $v \in \mathcal{T}_2$, are* induced *(by ℓ) if and only if there are leaves x and y with the same label ℓ, such that x is a descendant of u and y is a descendant of v.*

Problem: Heaviest Induced Ancestors
Input: Two rooted, weighted, labeled trees $\mathcal{T}_1$ and $\mathcal{T}_2$ of total size n.
Query: Given a pair of nodes $u \in \mathcal{T}_1$ and $v \in \mathcal{T}_2$, return a pair of nodes u', v' such that u' is ancestor of u, v' is ancestor of v, u' and v' are induced and they have the largest total combined weight $w(u') + w(v')$.

This problem was introduced in [14], with the last advances made in [1]. The next lemma encapsulates one of the known trade-offs.

▶ **Lemma 4** ([14]). *There is a data structure for the Heaviest Induced Ancestors problem, that can be built in $\mathcal{O}(n \log^2 n)$ time and answers queries in $\mathcal{O}(\log^2 n)$ time.*

3 Partially Dynamic LCS

In this section, we describe an algorithm for solving the partially dynamic variant of the LCS problem, where updates are only allowed on one of the strings, say S, while T is given in advance and is not subject to change.

Let us assume for now that all the letters of S throughout the execution of the algorithm occur at least once in T; we will waive this assumption later. Also, for simplicity, we assume that S is initially equal to $\$^{|S|}$, for $\$ \notin \Sigma$. We can always obtain any other initial S by performing an appropriate sequence of updates in the beginning.

▶ **Definition 5.** *A* block decomposition *of string S with respect to string T is a sequence of strings $(s_1, s_2, \dots, s_k)$ such that $S = s_1 s_2 \dots s_k$ and every s_i is a fragment of T. An element of the sequence is called a* block *of the decomposition. A decomposition is* maximal *if and only if $s_i s_{i+1}$ is not a substring of T for every $i \in [k-1]$.*

Maximal block decompositions are not necessarily unique and may have different lengths, but all admit the following useful property.

▶ **Lemma 6.** *For any maximal block decomposition of S with respect to T, any fragment of S that occurs in T is contained in at most three consecutive blocks. Furthermore, any occurrence of an LCS of S and T in S must contain the first letter of some block.*

Proof. We prove the first claim by contradiction. If $(s_1, s_2, \dots, s_k)$ is a maximal block decomposition of S with respect to T and a fragment of S that occurs in T spans at least four consecutive blocks $s_i, s_{i+1}, s_{i+2}, \dots, s_j$, then $s_{i+1}s_{i+2}$ is a substring of T, a contradiction.

As for the second claim, it is enough to observe, that if an occurrence of an LCS in S starts in some other than the first position of a block b, then it must contain the first letter of the next block, as otherwise its length would be smaller than the length of block b, which is a common substring of S and T. ◀

We will show that an update in S can be processed by considering a constant number of blocks in a maximal block decomposition of S with respect to T. We first summarize the basic building block needed for efficiently maintaining such a maximal block decomposition.

▶ **Lemma 7.** *Let T be a string of length at most n. After $\mathcal{O}(n \log^2 n)$-time and $\mathcal{O}(n)$-space preprocessing, given two fragments U and V of T, one can compute a longest fragment of T that is equal to a prefix of UV in $\mathcal{O}(\log\log n)$ time.*

Proof. We build a weighted ancestor queries structure over the suffix tree of T. A weighted ancestor query (ℓ, u) on a (weighted) tree $\mathcal{T}$, asks for the deepest ancestor of u with weight at most ℓ. Such queries can be answered in $\mathcal{O}(\log\log n)$ time after an $\mathcal{O}(n)$-time preprocessing of $\mathcal{T}$ if all weights are polynomial in n [12], as is the case for suffix trees with the weight of each node being its string-depth. We also build a data structure for answering unrooted LCP queries over the suffix tree of T. In our setting, such queries can be defined as follows: given nodes u and v of the suffix tree of T, we want to compute the (implicit or explicit) node where the search for the path-label of v starting from node u ends. Cole et al. [10] showed how to construct in $\mathcal{O}(n \log^2 n)$ time a data structure of size $\mathcal{O}(n \log n)$ that answers unrooted LCP queries in $\mathcal{O}(\log\log n)$ time. With these data structures at hand, the longest prefix of UV that is a fragment of T can be computed as follows. First, we retrieve the nodes of the suffix tree of T corresponding to U and V using weighted ancestor queries in $\mathcal{O}(\log\log n)$ time. In more detail, if $U = T[i\mathinner{.\,.} j]$ then we access the leaf of the suffix tree corresponding to $T[i\mathinner{.\,.}]$ and access its ancestor at string-depth $|U|$, and similarly for V. Second, we ask an unrooted LCP query to obtain the node corresponding to the sought prefix of UV. ◀

▶ **Lemma 8.** *A maximal block decomposition of a dynamic string S, with respect to a static string T, can be maintained in $\mathcal{O}(\log\log n)$ time per substitution operation with a data structure of size $\mathcal{O}(n \log n)$ that can be constructed in $\mathcal{O}(n \log^2 n)$ time.*

Proof. We keep the blocks on a doubly-linked list and we store the starting positions of blocks in an $\mathcal{O}(n)$-size predecessor/successor data structure over $[n]$ that supports $\mathcal{O}(\log\log n)$-time queries and updates [30]. This allows us to navigate in the structure of blocks, and in particular to be able to compute the block in which the edit occurred and its neighbors.

Suppose that we have a maximal block decomposition $B = (s_1, \ldots, s_k)$ of S with respect to T. Consider an operation which updates the letter x located in block s_i to y, so that $s_i = s_i^{\mathrm{l}} x s_i^{\mathrm{r}}$. Consider a block decomposition $B' = (s_1, s_2, \ldots, s_{i-1}, s_i^{\mathrm{l}}, y, s_i^{\mathrm{r}}, s_{i+1}, \ldots, s_k)$ of string S' after the update. Note that both s_i^{l} and s_i^{r} may be empty. This block decomposition does not need to be maximal. However, since B is a maximal block decomposition of S, none of the strings s_1s_2, s_2s_3, $\ldots$, $s_{i-2}s_{i-1}$, $s_{i+1}s_{i+2}$, $s_{i+2}s_{i+3}$, $\ldots$, $s_{k-1}s_k$ occurs in T. Thus, given B', we repeatedly merge any two consecutive blocks from $(s_{i-1}, s_i^{\mathrm{l}}, y, s_i^{\mathrm{r}}, s_{i+1})$ whose concatenation is a substring of T into one, until this is no longer possible. We have at most four merges before obtaining a maximal block decomposition B' of string S'. Each merge is implemented with Lemma 7 in $\mathcal{O}(\log\log n)$ time. ◀

As for allowing substitutions of letters that do not occur in T, we simply allow blocks of length 1 that are not substrings of T in block decompositions, corresponding to such letters. It is readily verified that all the statements above still hold.

Due to Lemma 6, for a maximal block decomposition $(s_1, s_2, \ldots, s_k)$ of S with respect to T, we know that any occurrence of an LCS of S and T in S must contain the first letter of some block of the decomposition and cannot span more than three blocks. In other words, it is the concatenation of a potentially empty suffix of $s_{i-1}s_i$ and a potentially empty prefix of $s_{i+1}s_{i+2}$ for some $i \in [k]$ (for convenience we consider the non-existent s_is to be equal to ε). We call an LCS that can be decomposed in such way a candidate of s_i. Our goal is to maintain the candidate proposed by each s_i in a max-heap with the length as the key. We also store a pointer to it from block s_i. The max-heap is implemented with an $\mathcal{O}(n)$-size predecessor/successor data structure over $[n]$ that supports $\mathcal{O}(\log\log n)$-time queries and updates [30]. We assume that each block s_i stores a pointer to its candidate in the max-heap.

After an update, the candidate of each block b that satisfies the following two conditions remains unchanged: (a) b did not change and (b) neither of b's neighbors at distance at most 2 changed. For the $\mathcal{O}(1)$ blocks that changed, we proceed as follows. First, in $\mathcal{O}(\log\log n)$ time, we remove from the max-heap any candidates proposed by the deleted blocks or blocks whose neighbors at distance at most 2 have changed. Then, for each new block and for each block whose neighbors at distance at most 2 have changed, we compute its candidate and insert it to the max-heap. To compute the candidate of a block s_i, we proceed as follows. We first compute the longest suffix U of $s_{i-1}s_i$ and the longest prefix V of $s_{i+1}s_{i+2}$ that occur in T in $\mathcal{O}(\log\log n)$ time using Lemma 7. Then, the problem in scope can be restated as follows: given two fragments U and V of T compute the longest fragment of UV that occurs in T. This problem can be reduced to a single HIA query over the suffix trees of T and T^R as shown in [1, 6] and we provide a brief overview at the end of this section. Combining the above discussion with Lemmas 4 and 8 we obtain that an LCS can be maintained after an $\mathcal{O}(n\log^2 n)$ time preprocessing in $\mathcal{O}(\log^2 n)$ time per update. In fact, the bottleneck in the update time in this approach is in Lemma 4, that is, the HIA structure, as the additional time in the update is only $\mathcal{O}(\log\log n)$. We can thus obtain a faster data structure at the expense of slower preprocessing using the following lemma.

▶ **Lemma 9.** *For any $\varepsilon > 0$, there is a structure for the* Heaviest Induced Ancestors *problem, that can be built in $\mathcal{O}(n^{1+\varepsilon})$ time and answers queries in constant time.*

Proof. Consider an instance of HIA on two trees $\mathcal{T}_1$ and $\mathcal{T}_2$ of total size m containing at most ℓ leaves, and let b be a parameter to be chosen later. We will show how to construct a structure of size $\mathcal{O}(b^2 m)$ that allows us to reduce in constant time a query concerning two nodes $u \in \mathcal{T}_1$ and $v \in \mathcal{T}_2$ to two queries to smaller instances of HIA. In each of the smaller instances the number of leaves will shrink by a factor of b, and the total size of all smaller instances will be $\mathcal{O}(m)$. Let $b = n^{\delta}$, where n is the total size of the original trees. We recursively repeat the construction always choosing b according to the formula. Because the depth of the recursion is at most $\log_b n = \mathcal{O}(1)$, this results in a structure of total size $\mathcal{O}(n^{1+\varepsilon})$ for $\varepsilon = 2\delta$ and allows us to answer any query in a constant number of steps, each taking constant time.

We select b evenly-spaced (in the order of in-order traversal) leaves of $\mathcal{T}_1$ and $\mathcal{T}_2$ and call them marked. Consider a query concerning a pair of nodes $u \in \mathcal{T}_1$ and $v \in \mathcal{T}_2$. Let u'', v'' be the nearest ancestors of u and v, respectively, that contain at least one marked leaf in their subtrees. u'' and v'' can be preprocessed in $\mathcal{O}(m)$ space and accessed in constant time. We have three possibilities concerning the sought ancestors u', v':

1. u' is an ancestor of u'' and v' is an ancestor of v'' (not necessarily proper),
2. u' is a descendant of u'',
3. v' is a descendant of v''.

To check the first possibility, we preprocess every pair of marked leaves x, y. Both u'' and v'' store pointers to some marked leaves in their subtrees, so it is enough to consider a query concerning two ancestors of marked leaves x, y. This can be solved similarly as preprocessing two heavy paths for HIA queries in $\mathcal{O}(\log^2 n)$ time [14], except that now we can afford to preprocess the predecessor for every possible depth on both paths in $\mathcal{O}(m)$ space, which decreases the query time to constant. The overall space is $\mathcal{O}(b^2 m)$.

The second and the third possibility are symmetric, so we focus on the second. By removing all marked leaves and their ancestors from $\mathcal{T}_1$ we obtain a collection of smaller trees, each containing less than n/b leaves. Because u' is below u'', u and u' belong to the same smaller tree. For technical reasons, we want to work with $\mathcal{O}(b)$ smaller trees, so we merge all smaller trees between two consecutive marked leaves by adding the subtree induced by their roots in $\mathcal{T}_1$. Now consider the smaller tree $\mathcal{T}_1^i$ containing u (and, by assumption, also u''). We extract the subtree of $\mathcal{T}_2$ induced by the leaves of $\mathcal{T}_1^i$, call it $\mathcal{T}_2^i$, and build a smaller instance of HIA for $\mathcal{T}_1^i$ and $\mathcal{T}_2^i$. To query the smaller instance, we need to replace v by its nearest ancestor that belong to $\mathcal{T}_2^i$. This can be preprocessed for each i and v in $\mathcal{O}(bm)$ space. By construction, $\mathcal{T}_1^i$ and $\mathcal{T}_2^i$ contain less than n/b leaves, and each node of $\mathcal{T}_1$ shows up in at most two trees $\mathcal{T}_1^i$. Each node of $\mathcal{T}_2$ might appear in multiple trees $\mathcal{T}_2^i$, but the number of non-leaf nodes in $\mathcal{T}_2^i$ is smaller than its number of leaves, so the overall number of non-leaf nodes is smaller than m, and consequently the overall number of nodes is smaller than $2m$.

The construction time can be verified to be at most the size of the structure. ◀

▶ **Theorem 10.** *It is possible to maintain an LCS of a dynamic string S and a static string T, each of length at most n, (i) after an $\mathcal{O}(n \log^2 n)$-time preprocessing in $\mathcal{O}(\log^2 n)$ time per substitution operation, or (ii) after an $\mathcal{O}(n^{1+\varepsilon})$-time preprocessing in $\mathcal{O}(\log\log n)$ time per substitution operation.*

We now briefly explain the reduction to HIA in the interests of self-containment and developing intuition in a relatively easier setting before we move on to the harder problem of maintaining an LCS of two dynamic strings.

Let $\mathcal{T}_1$ and $\mathcal{T}_2$ be the suffix trees of $T\$$ and $T^R\#$, respectively, where \$ and # are sentinel letters not in the alphabet and lexicographically smaller than all other letters. Note that each suffix of $T\$$ corresponds to a leaf in $\mathcal{T}_1$; similarly for $\mathcal{T}_2$. We label a leaf v of $\mathcal{T}_1$ with the starting position of the suffix of $T\$$ that it represents. For $\mathcal{T}_2$, however, we label the leaf corresponding to $T^R[i\,..]\#$ with $n-i+2$. Intuitively, if we consider a split $T = T[..\,i-1]T[i\,..]$, the leaves corresponding to $T[i\,..]\$$ in $\mathcal{T}_1$ and $T[..\,i-1]^R\#$ in $\mathcal{T}_2$ get the same label. Further, let the weight of each node in $\mathcal{T}_1$ and $\mathcal{T}_2$ be its string-depth. Upon query, we first compute the node p corresponding to V in $\mathcal{T}_1$ and the node q corresponding to U^R in $\mathcal{T}_2$ using weighted ancestor queries in $\mathcal{O}(\log\log n)$ time. Then the length of the longest substring of UV is exactly the sum of the weights of the nodes returned by a HIA query for p and q. (Some technicalities arise when p or q are implicit nodes, which can be overcome straightforwardly.)

4 Fully Dynamic LCS

In this section, we prove our main result.

▶ **Theorem 11.** *We can maintain an LCS of two dynamic strings, each of length at most n, in $\log^{\mathcal{O}(1)} n$ time per substitution operation.*

We start with some intuition. Let us suppose that we can maintain a decomposition of each string in blocks of length roughly 2^k for each level $k = 0, 1, \dots, \log n$ with the following property: any two equal fragments $U = S[i\,..\,j]$ and $V = T[i'\,..\,j']$ are "aligned" by a pair of equal blocks B_1 in S and B_2 in T at some level k such that $2^k = \Theta(|U|)$. In other words, the decomposition of U (resp. V) at level k consists of a constant number of blocks, where the first and last blocks are potentially trimmed, including B_1 (resp. B_2), and the distance of the starting position of B_1 from position i in S equals the distance of the starting position of B_2 from position i' in T. The idea is that we can use such blocks as anchors for the LCS. For each level, for each string B appearing as a block in this level, we would like to design a data structure that:

a) supports insertions/deletions of strings corresponding to sequences of a constant number of level-k blocks, each containing a specified block equal to B and a boolean variable indicating the string this sequence originates from (S or T), and

b) can return the longest common substring among pairs of elements originating from different strings that is aligned by a pair of specified blocks (that are equal to B).

For each substitution in either of the strings, we would only need to update $\mathcal{O}(\log n)$ entries in our data structures – a constant number of them per level.

Unfortunately, it is not clear how to maintain a decomposition with these properties. We resort to the dynamic maintenance of a *locally consistent parsing* of the two strings, due to Gawrychowski et al. [15]. We exploit the structure of this parsing in order to apply the high-level idea outlined above in a much more technically demanding setting.

4.1 Locally Consistent Parsing

The authors of [15] settled the time complexity of maintaining a collection of strings $\mathcal{W}$ under the following operations: $\mathsf{makestring}(W)$ (insert a non-empty string W), $\mathsf{concat}(W_1, W_2)$ (insert W_1W_2 to $\mathcal{W}$, for $W_1, W_2 \in \mathcal{W}$), $\mathsf{split}(W, i)$ (split the string W at position i and insert both resulting strings to $\mathcal{W}$, for $W \in \mathcal{W}$), $\mathsf{lcp}(W_1, W_2)$ (return the length of the longest common prefix of W_1 and W_2, for $W_1, W_2 \in \mathcal{W}$). Let us note that operations concat and split do not remove their arguments from $\mathcal{W}$. A substitution can be implemented with a constant number of calls to such operations.

▶ **Theorem 12** (Gawrychowski et al. [15]). *A collection $\mathcal{W}$ of strings of total length n can be dynamically maintained under operations $\mathsf{makestring}(W)$, $\mathsf{concat}(W_1, W_2)$, $\mathsf{split}(W, i)$, and $\mathsf{lcp}(W_1, W_2)$ with the operations requiring time $\mathcal{O}(\log n + |W|)$, $\mathcal{O}(\log n)$, $\mathcal{O}(\log n)$ worst-case time with high probability and $\mathcal{O}(1)$ worst-case time, respectively.*

At the heart of Theorem 12 lies a locally consistent parsing of the strings in the collection that can be maintained efficiently while the strings undergo updates. It can be interpreted as a dynamic version of the recompression method of Jeż [18, 19] (see also [17]) for a static string T. As such, we first describe the parsing of Theorem 12 for a static string T and then extend the description to the dynamic variant for a collection of strings.

A *run-length straight line program* (*RLSLP*) is a context-free grammar which generates exactly one string and contains two kinds of non-terminals: *concatenations* with production rule of the form $A \rightarrow BC$ (for symbols B, C) and *powers* with production rule of the form $A \rightarrow B^k$ (for a symbol B and an integer $k \geq 2$), where a *symbol* can be a non-terminal or a letter in Σ. Every symbol A generates a unique string denoted by $\mathsf{gen}(A)$.

Let $T = T_0$. We can compute strings $T_1, \ldots, T_H$, where $H = \mathcal{O}(\log n)$ and $|T_H| = 1$ in $\mathcal{O}(n)$ time using interleaved calls to the following two auxiliary procedures:

RunCompress applied if h is even: for each B^r, $r > 1$, replace all occurrences of B^r as a run by a new letter A. There are no runs after an application of this procedure.[1]

HalfCompress applied if h is odd: first partition Σ into Σ_ℓ and Σ_r; then, for each pair of letters $B \in \Sigma_\ell$, $C \in \Sigma_r$ such that BC occurs in T_h replace all occurrences of BC by a new letter A.

We can interpret strings $T = T_0, T_1, \ldots, T_H$ as an *uncompressed parse tree* $\mathsf{PT}(T)$, by considering their letters as nodes, so that the parent of $T_h[i]$ is the letter of T_{h+1} that either (a) corresponds to $T_h[i]$ or (b) replaced a fragment of T_h containing $T_h[i]$. We say that the node representing $T_h[i]$ is the node left (resp. right) of the node representing $T_h[i+1]$ (resp. $T_h[i-1]$). Every node v of $\mathsf{PT}(T)$ is labeled with the symbol it represents, denoted by $\mathcal{L}(v)$. For a node v corresponding to a letter of T_h, we say that the level of v, denoted by $\mathsf{lev}(v)$, is h. The *value* $\mathsf{val}(v)$ of a node v is defined as the fragment of T corresponding to the leaf descendants of v and it is an occurrence of $\mathsf{gen}(A)$ for $A = \mathcal{L}(v)$.

We define a *layer* to be any sequence of nodes $v_1 v_2 \cdots v_r$ in $\mathsf{PT}(T)$ whose values are consecutive fragments of T, i.e. $\mathsf{val}(v_j) = T[r_{j-1}+1 \mathinner{.\,.} r_j]$ for some increasing sequence of r_i's. The value of a layer C is the concatenation of the values of its elements and is denoted by $\mathsf{val}(C)$. We similarly use $\mathsf{gen}(\cdot)$ for sequences of symbols, to denote the concatenation of the strings generated by them. We call a layer $v_1 v_2 \cdots v_r$ an *up-layer* when $\mathsf{lev}(v_i) \leq \mathsf{lev}(v_{i+1})$ for all i, and a *down-layer* when $\mathsf{lev}(v_i) \geq \mathsf{lev}(v_{i+1})$ for all i.

In [15], the authors show how to maintain an RLSLP for each string in the collection, each with at most $c \log n$ levels for some global constant c with high probability. Let T be a string in the collection. For each fragment $U = T[a \mathinner{.\,.} b]$ of T, one can compute in $\mathcal{O}(\log n)$ time a *context insensitive decomposition* that consists in a layer $\mathsf{C}(U)$ of nodes in $\mathsf{PT}(T)$ with value $T[a \mathinner{.\,.} b]$ and has the following property. It can be decomposed into an up-layer $\mathsf{C}_{\mathsf{up}}(U)$ and a down-layer $\mathsf{C}_{\mathsf{down}}(U)$ such that:

- The sequence of the labels of the nodes in $\mathsf{C}_{\mathsf{up}}(U)$ can be expressed as a sequence of at most $c \log n$ symbols and powers of symbols $\mathsf{d}_{\mathsf{up}}(U) = A_0^{r_0} A_1^{r_1} \cdots A_m^{r_m}$ such that, for all i, $A_i^{r_i}$ corresponds to r_i consecutive nodes at level i of $\mathsf{PT}(T)$; r_i can be 0 for $i < m$.

[1] A fragment $T[i \mathinner{.\,.} j] = B^r$ is a run if it is a maximal fragment consisting of Bs.

- Similarly, the sequence of the labels of the nodes in $\mathsf{C}_{\mathsf{down}}(U)$ can be expressed as a sequence of at most $c \log n$ symbols and powers of symbols $\mathsf{d}_{\mathsf{down}}(U) = B_m^{t_m} B_{m-1}^{t_{m-1}} \cdots B_0^{t_0}$ such that, for all i, $B_i^{t_i}$ corresponds to t_i consecutive nodes at level i of $\mathsf{PT}(T)$; t_i can be equal to 0.

We denote by $\mathsf{d}(U)$ the concatenation of $\mathsf{d}_{\mathsf{up}}(U)$ and $\mathsf{d}_{\mathsf{down}}(U)$. Note that $U = \mathsf{gen}(\mathsf{d}(U)) = \mathsf{gen}(A_0)^{r_0} \cdots \mathsf{gen}(A_m)^{r_m} \mathsf{gen}(B_m)^{t_m} \cdots \mathsf{gen}(B_0)^{t_0}$. See Figure 1 for a visualization. The parsing of the strings enjoys local consistency in the following way: $\mathsf{d}(U) = \mathsf{d}(V)$ for any fragment V of any string in the collection such that $U = V$. We will slightly abuse notation and use the term "context insensitive decomposition" to refer to both $\mathsf{d}(U)$ and $\mathsf{C}(U)$. In addition, we also use $\mathsf{d}(\cdot)$ for substrings and not just for fragments.

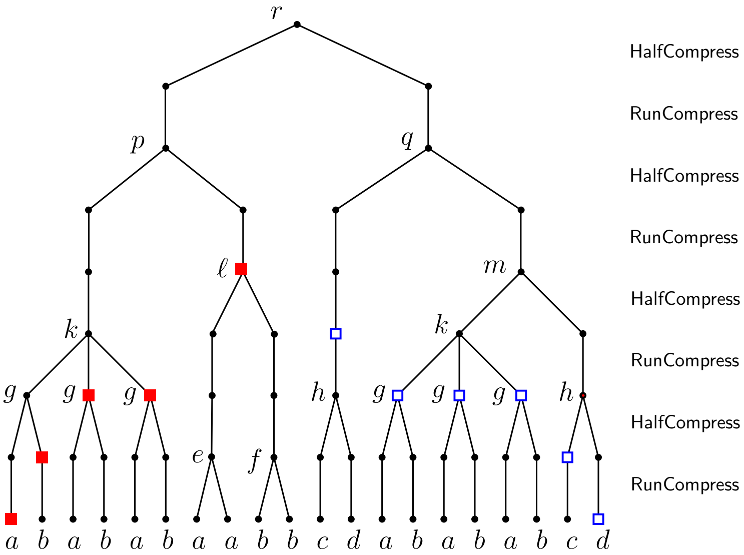

Figure 1 An example $\mathsf{PT}(T)$ for $T = T_0 = abababaabbcdababababcd$. We omit the label of each node v with a single child u; $\mathcal{L}(v) = \mathcal{L}(u)$. $T_3 = kefhkh$ and $T_6 = pq$. We denote the nodes $\mathsf{C}_{\mathsf{up}}(T)$ by red (filled) squares and the nodes of $\mathsf{C}_{\mathsf{down}}(T)$ with blue (unfilled) squares. $\mathsf{d}_{\mathsf{up}}(T) = abg^2\ell$, $\mathsf{d}_{\mathsf{down}}(T) = hg^3cd$ and hence $\mathsf{d}(T) = abg^2\ell hg^3cd$.

Let us consider any sequence of nodes corresponding, for some $j < m$, to $A_j^{r_j}$ with $r_j > 1$ or $B_j^{t_j}$ with $t_j > 1$. We note that T_j must have been obtained from T_{j-1} by an application of $\mathsf{HalfCompress}$, since there are no runs after an application of procedure $\mathsf{RunCompress}$. Thus, at level $j+1$ in $\mathsf{PT}(T)$, i.e. the one corresponding to T_{j+1}, all of these nodes collapse to a single one: their parent in $\mathsf{PT}(T)$. Hence, we have the following lemma.

▶ **Lemma 13.** *Let U be a fragment of T with $\mathsf{d}_{\mathsf{up}}(U) = A_0^{r_0} A_1^{r_1} \cdots A_m^{r_m}$ and $\mathsf{d}_{\mathsf{down}}(U) = B_m^{t_m} B_{m-1}^{t_{m-1}} \cdots B_0^{t_0}$. Then we have the following:*

- *The value of $\mathsf{C}_{\mathsf{up}}(U)$ is a suffix of the value of a layer L_{up} of (at most) $c \log n + r_m - 1$ level-m nodes, such that the two layers have the same rightmost node. The last r_m nodes are consecutive siblings with label A_m.*
- *The value of $\mathsf{C}_{\mathsf{down}}(U)$ is a prefix of the value of the layer L_{down} consisting of the subsequent (at most) $c \log n + \max(t_m - 1, 0)$ level-m nodes. If $t_m \neq 0$, then the first t_m nodes of L_{down} are consecutive siblings with label $B_m \neq A_m$.*

The parse trees of the strings in the collection are not maintained explicitly. However, we have access to the following pointers and functions, among others, which allow us to efficiently navigate through them. First, we can get a pointer to the root of $\mathsf{PT}(T)$ for any string T in the collection. Given a pointer P to some node v in $\mathsf{PT}(T)$ we can get $\deg(v)$ and pointers to the parent of v, the k-th child of v and the nodes to the left/right of v.

Let us now briefly explain how the dynamic data structure of [15] processes a substitution in T at some position i, that yields a string T'. First, the context insensitive decompositions of $T[\,..\,i-1]$ and $T[i+1\,..\,]$ are retrieved. These, together with the new letter at position i form a layer of $\mathsf{PT}(T')$. The sequence of the labels of the nodes of this layer can be expressed as a sequence of $\mathcal{O}(\log n)$ symbols and powers of symbols. Then, only the portion of $\mathsf{PT}(T)$ that lies above this layer needs to be (implicitly) computed, and the authors of [15] show how to do this in $\mathcal{O}(\log n)$ time. In total, we get $\mathsf{PT}(T')$ from $\mathsf{PT}(T)$ through $\mathcal{O}(\log^2 n)$ insertions and deletions of nodes and layers that consist of consecutive siblings.

4.2 Anchoring the LCS

We will rely on Lemma 13 in order to identify an LCS $S[i\,..\,j] = T[i'\,..\,j']$ at a pair of topmost nodes of the context insensitive decompositions of $S[i\,..\,j]$ and $T[i'\,..\,j']$ in $\mathsf{PT}(S)$ and $\mathsf{PT}(T)$, respectively. In order to develop some intuition, let us first sketch a solution for the case that $\mathsf{PT}(S)$ and $\mathsf{PT}(T)$ do not contain any power symbols throughout the execution of our algorithm. For each node v in one of the parse trees, let $\mathsf{Z}_\ell(v)$ be the value of the layer consisting of the (at most) $c\log n$ level-$\mathsf{lev}(v)$ nodes, with v being the layer's rightmost node, and $\mathsf{Z}_\mathsf{r}(v)$ be the value of the layer consisting of the (at most) $c\log n$ subsequent level-$\mathsf{lev}(v)$ nodes. Now, consider a common substring X of S and T and partition it into the prefix $X_\ell = \mathsf{gen}(\mathsf{d}_\mathsf{up}(X))$ and the suffix $X_r = \mathsf{gen}(\mathsf{d}_\mathsf{down}(X))$. For any fragment U of S that equals X, $\mathsf{C}_\mathsf{up}(U)$ is an up-layer of the form $v_1 \cdots v_m$. Hence, by Lemma 13, X_ℓ is a suffix of $\mathsf{Z}_\ell(v_m)$. Similarly, X_r is a prefix of $\mathsf{Z}_\mathsf{r}(v_m)$. Thus, it suffices to maintain pairs $(\mathsf{Z}_\ell(v), \mathsf{Z}_\mathsf{r}(v))$ for all nodes v in $\mathsf{PT}(S)$ and $\mathsf{PT}(T)$, and, in particular, a pair of nodes $u \in \mathsf{PT}(S)$ and $v \in \mathsf{PT}(T)$ that maximizes $\mathsf{lcp}(\mathsf{Z}_\ell(u)^R, \mathsf{Z}_\ell(v)^R) + \mathsf{lcp}(\mathsf{Z}_\mathsf{r}(u), \mathsf{Z}_\mathsf{r}(v))$. The existence of power symbols poses some technical challenges which we overcome below.

For each node of $\mathsf{PT}(T)$, we consider at most one pair consisting of an up-layer and a down-layer. The treatment of nodes differs, based on their parent. We have two cases.

1. For each node z with $\deg(z) = 2$ and $\mathcal{L}(z)$ being a concatenation symbol, for each child v of z, we consider the following layers:
   - The up-layer $\mathsf{J}_\mathsf{up}(v)$ of the (at most) $c\log n$ level-$\mathsf{lev}(v)$ consecutive nodes of $\mathsf{PT}(T)$ with v a rightmost node.
   - The down-layer $\mathsf{J}_\mathsf{down}(v)$ of the (at most) p level-$\mathsf{lev}(v)$ subsequent level-$\mathsf{lev}(v)$ nodes of $\mathsf{PT}(T)$. If the node to the right of v is a child of a node w with more than two children, then $p = c\log n + \deg(w)$. Otherwise $p = c\log n$.
2. For each node z of $\mathsf{PT}(T)$ whose label is a power symbol and has more than one child, we will consider $\mathcal{O}(\log n)$ pairs of layers. In particular, for each v, being one of the $c\log n + 1$ leftmost or $c\log n + 1$ rightmost children of z, we consider the following layers:
   - The up-layer $\mathsf{J}_\mathsf{up}(v)$ defined as the concatenation of (a) the (at most) $c\log n$ level-$\mathsf{lev}(v)$ consecutive nodes of $\mathsf{PT}(T)$ preceding the leftmost child of z and (b) all the children of z that lie weakly to the left of v, i.e. including v.
   - The down-layer $\mathsf{J}_\mathsf{down}(v)$ of the (at most) $c\log n$ subsequent level-$\mathsf{lev}(v)$ nodes of $\mathsf{PT}(T)$ – with one exception. If v is the rightmost child of z and the node to its right is a child of a node w with more than two children, then $\mathsf{J}_\mathsf{down}(v)$ consists of the $c\log n + \deg(w)$ subsequent level-$\mathsf{lev}(v)$ nodes.

In particular, we create at most one pair $(\mathsf{J}_{\mathsf{up}}(v), \mathsf{J}_{\mathsf{down}}(v))$ of layers for each node v of $\mathsf{PT}(T)$. Let $\mathsf{Y}_\ell(v) = \mathsf{val}(\mathsf{J}_{\mathsf{up}}(v))$ and $\mathsf{Y}_\mathsf{r}(v) = \mathsf{val}(\mathsf{J}_{\mathsf{down}}(v))$. Given a pointer to a node z in $\mathsf{PT}(T)$, we can compute the indices of the fragments corresponding to those layers with straightforward use of the pointers at hand in $\mathcal{O}(\log n)$ time. With a constant number of split operations, we can then add the string $\mathsf{Y}_\mathsf{r}(v)$ to our collection within $\mathcal{O}(\log n)$ time. Similarly, if we also maintain T^R in our collection of strings, we can add the reverse of $\mathsf{Y}_\ell(v)$ to the collection within $\mathcal{O}(\log n)$ time. We maintain pointers between v and these strings. Note that each node of $\mathsf{PT}(T)$ takes part in $\mathcal{O}(\log n)$ pairs of layers and these pairs can be retrieved in $\mathcal{O}(\log n)$ time. Similarly, for each node whose label is a power symbol, subsets of its children appear in $\mathcal{O}(\log n)$ pairs of layers; these can also be retrieved in $\mathcal{O}(\log n)$ time. Thus, throughout the updates on T, which delete/insert $\mathcal{O}(\log^2 n)$ nodes and layers of consecutive siblings, we can maintain the pairs of layers in $\tilde{\mathcal{O}}(1)$ time. These pairs of layers (or rather the pairs of their corresponding strings maintained in a dynamic collection) will be stored in an abstract structure presented in the next section. In order to keep the space occupied by our data structure $\tilde{\mathcal{O}}(n)$, after every n updates to the collection we delete our data structure, and initialize a new instance of it for an empty collection, on which we call $\mathsf{makestring}(S)$ and $\mathsf{makestring}(T)$. The cost of this reinitialization can be deamortized using standard techniques. We summarize the above discussion in the following lemma.

▶ **Lemma 14.** *We can maintain pairs* $(\mathsf{Y}_\ell(v)^R, \mathsf{Y}_\mathsf{r}(v))$ *for all* v *in* $\mathsf{PT}(T)$ *and* $\mathsf{PT}(S)$*, with each string given as a handle from the dynamic collection, in* $\tilde{\mathcal{O}}(1)$ *time per substitution, using* $\tilde{\mathcal{O}}(n)$ *space.*

▶ Remark 15. Note that the above lemma holds in the case that insertions and deletions are also allowed in S and T, as each such update operation is processed similarly to substitution and affects $\tilde{\mathcal{O}}(1)$ pairs $(\mathsf{Y}_\ell(v)^R, \mathsf{Y}_\mathsf{r}(v))$. Everything that follows in this section is oblivious to the kind of operations allowed in S and T.

The following lemma gives us an anchoring property, which is crucial for our approach.

▶ **Lemma 16.** *For any common substring* X *of* S *and* T*, there exists a partition* $X = X_\ell X_r$ *for which there exist nodes* $u \in \mathsf{PT}(S)$ *and* $v \in \mathsf{PT}(T)$ *such that:*

1. X_ℓ *is a suffix of* $\mathsf{Y}_\ell(u)$ *and* $\mathsf{Y}_\ell(v)$*, and*
2. X_r *is a prefix of* $\mathsf{Y}_\mathsf{r}(u)$ *and* $\mathsf{Y}_\mathsf{r}(v)$*.*

Proof. Let $\mathsf{d}_{\mathsf{up}}(X) = A_0^{r_0} A_1^{r_1} \cdots A_m^{r_m}$ and $\mathsf{d}_{\mathsf{down}}(X) = B_m^{t_m} B_{m-1}^{t_{m-1}} \cdots B_0^{t_0}$.

▷ Claim 17. Either $r_m > 1$, $t_m = 0$ and $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is not a suffix of $A_m^{c \log n + r_m}$ or there exists a node $v \in \mathsf{PT}(T)$ such that:

1. $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is a suffix of $\mathsf{Y}_\ell(v)$, and
2. $\mathsf{gen}(\mathsf{d}_{\mathsf{down}}(X))$ is a prefix of $\mathsf{Y}_\mathsf{r}(v)$.

Proof. We assume that $r_m = 1$ or $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is a suffix of $A_m^{c \log n + r_m}$ or $t_m \neq 0$ and distinguish between the following cases.

Case 1. There exists an occurrence Y of X in T, where the label of the parent of the rightmost node u of $\mathsf{C}_{\mathsf{up}}(Y)$ is not a power symbol. (In this case $r_m = 1$.) Recall here, that we did not construct any pairs of layers for nodes whose parent has a single child. Let v be the highest ancestor of u with label A_m. If $u \neq v$ then all nodes that are descendants of v and strict ancestors of u have a single child, while the parent of v does not. In addition, the label of the parent of v must be a concatenation symbol, since only new letters are introduced at each level and thus we cannot have new nodes with label A_m appearing to the left/right of any strict ancestor of u. Finally, note that a layer of k level-$\mathsf{lev}(v)$ nodes with v a leftmost (resp. rightmost) node contains an ancestor of each of the nodes in a layer of k level-$\mathsf{lev}(u)$ nodes with u a leftmost (resp. rightmost) node. Thus, an application of Lemma 13 for u straightforwardly implies our claim for v.

Case 2. There exists an occurrence Y of X in T, where the label of the parent z of the rightmost node u of $\mathsf{C}_{\mathsf{up}}(Y)$ is a power symbol. Let W be the rightmost occurrence of X in T such that the rightmost node w of $\mathsf{C}_{\mathsf{up}}(W)$ is a child of z. We have three subcases.

a) We first consider the case $r_m = 1$. Let us assume towards a contradiction that u is not one of the $c\log n+1$ leftmost or the $c\log n+1$ rightmost children of z. Then, by Lemma 13 we have that $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is a suffix of $A_m^{c\log n}$ and $\mathsf{gen}(\mathsf{d}_{\mathsf{down}}(X))$ is a prefix of $A_m^{c\log n}$. Hence, there is another occurrence of X $|\mathsf{gen}(A_m)|$ positions to the right of Y, contradicting our assumption that Y is a rightmost occurrence.

b) In the case that $t_m \neq 0$, u must be the rightmost child of z since $A_m \neq B_m$.

c) In the remaining case that $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is a suffix of $A_m^{c\log n+r_m}$, either $t_m > 0$ and we are done, or $\mathsf{gen}(\mathsf{C}_{\mathsf{down}}(Y))$ is a prefix of the value of the (at most) $c\log n$ level-m nodes to the right of u. In the latter case, either u is already among the rightmost $c\log n+1$ children of z or there is another occurrence of X $|\mathsf{gen}(A_m)|$ positions to the right of Y, contradicting our assumptions on Y. ◁

We have to treat a final case.

▷ Claim 18. If $r_m > 1$, $t_m = 0$ and $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is not a suffix of $A_m^{c\log n+r_m}$ then there exists a node $v \in \mathsf{PT}(T)$ such that:

1. $\mathsf{gen}(A_0^{r_0}A_1^{r_1}\cdots A_{m-1}^{r_{m-1}}A_m)$ is a suffix of $\mathsf{Y}_\ell(v)$, and
2. $\mathsf{gen}(A_m)^{r_m-1}\mathsf{gen}(\mathsf{d}_{\mathsf{down}}(X))$ is a prefix of $\mathsf{Y}_\mathsf{r}(v)$.

Proof. In any occurrence of X in T, the label of the parent z of the rightmost node of $\mathsf{C}_{\mathsf{up}}(Y)$ is a power symbol. Let u be the r_m-th rightmost node of $\mathsf{C}_{\mathsf{up}}(Y)$. By the assumption that $\mathsf{gen}(\mathsf{d}_{\mathsf{up}}(X))$ is not a suffix of $A_m^{c\log n+r_m}$ and Lemma 13, u must be one of the $c\log n$ leftmost children of z. ◁

The combination of the two claims applied to both S and T yields the lemma. ◀

4.3 A Problem on Dynamic Bicolored Trees

Due to Lemmas 14 and 16, our task reduces to solving the problem defined below in polylogarithmic time per update, as we can directly apply it to $\mathcal{R} = \{(\mathsf{Y}_\ell(u)^R, \mathsf{Y}_\mathsf{r}(u)) : u \in \mathsf{PT}(S)\}$ and $\mathcal{B} = \{(\mathsf{Y}_\ell(v)^R, \mathsf{Y}_\mathsf{r}(v)) : v \in \mathsf{PT}(T)\}$. Note that $|\mathcal{R}| + |\mathcal{B}| = \tilde{\mathcal{O}}(n)$ throughout the execution of our algorithm.

Problem: LCP for Two Families of Pairs of Strings
Input: Two families $\mathcal{R}$ and $\mathcal{B}$, each consisting of pairs of strings, where each string is given as a handle from a dynamic collection.
Update: Insertion or deletion of an element in $\mathcal{R}$ or $\mathcal{B}$.
Query: Return $(P,Q) \in \mathcal{R}$ and $(P',Q') \in \mathcal{B}$ that maximize $\mathsf{lcp}(P,P') + \mathsf{lcp}(Q,Q')$.

Each element of $\mathcal{B}$ and $\mathcal{R}$ is given a unique identifier. We maintain two compacted tries $\mathcal{T}_P$ and $\mathcal{T}_Q$. By appending unique letters, we can assume that no string is a prefix of another string. $\mathcal{T}_P$ (resp. $\mathcal{T}_Q$) stores the string P (resp. Q) for every $(P,Q) \in \mathcal{R}$, with the corresponding leaf colored red and labeled by the identifier of the pair and the string P' (resp. Q') for every $(P',Q') \in \mathcal{B}$, with the corresponding leaf colored blue and labeled by the identifier of the pair. Then, the sought result corresponds to a pair of nodes $u \in \mathcal{T}_P$ and $v \in \mathcal{T}_Q$ returned by a query to a data structure for the Dynamic Bicolored Trees Problem defined below for $\mathcal{T}_1 = \mathcal{T}_P$ and $\mathcal{T}_2 = \mathcal{T}_Q$, with node weights being their string-depths.

Problem: Dynamic Bicolored Trees Problem
Input: Two weighted trees $\mathcal{T}_1$ and $\mathcal{T}_2$ of total size at most m, whose leaves are bicolored and labeled, so that each label corresponds to exactly one leaf of each tree.
Update: Split an edge into two / attach a new leaf to a node / delete a leaf.
Query: Return a pair of nodes $u \in \mathcal{T}_1$ and $v \in \mathcal{T}_2$ with the maximum combined weight that have at least one red descendant with the same label, and at least one blue descendant with the same label.

To complete the reduction, we have to show how to translate an update in $\mathcal{R}$ or $\mathcal{B}$ into updates in $\mathcal{T}_P$ and $\mathcal{T}_Q$. Let us first explain how to represent $\mathcal{T}_P$ and $\mathcal{T}_Q$. For each edge, we store a handle to a string from the dynamic collection, and indices for a fragment of this string which represents the edge's label. For each explicit node, we store edges leading to its children in a dictionary structure indexed by the first letters of the edges' labels. For every leaf, we store its label and color. An insert operation receives a string (given as a handle from a dynamic collection), together with its label and color, and should create its corresponding leaf. A delete operation does not actually remove a leaf, but simply removes its label. However, in order to not increase the space complexity, we rebuild the whole data structure from scratch after every m updates. This rebuilding does not incur any extra cost asymptotically; the time required for it can be deamortized using standard techniques.

▶ **Lemma 19.** *Each update in $\mathcal{R}$ or $\mathcal{B}$ implies $\mathcal{O}(1)$ updates in $\mathcal{T}_P$ and $\mathcal{T}_Q$ that can be computed in $\mathcal{O}(\log n)$ time.*

Proof. Inserting a new leaf, corresponding to string U, to $\mathcal{T}_P$ requires possibly splitting an edge into two by creating a new explicit node, and then attaching a new leaf to an explicit node. To implement this efficiently, we maintain the set C of path-labels of explicit nodes of $\mathcal{T}_P$ in a balanced search tree, sorted in lexicographic order. Using lcp queries (cf. Theorem 12), we binary search for the longest prefix U' of U that equals the path-label of some implicit or explicit node of $\mathcal{T}_P$. If this node is explicit, then we attach a leaf to it. Otherwise, let the successor of U' in C be the path-label of node v. We split the edge $(\mathsf{parent}(v), v)$ appropriately and attach a leaf to the newly created node. This allows us to maintain $\mathcal{T}_P$ after each insert operation in $\mathcal{O}(\log n)$ time.

For a delete operation, we can access the leaf corresponding to the deleted string in $\mathcal{O}(\log n)$ time using the balanced search tree. ◀

It thus suffices to show a solution for the Dynamic Bicolored Trees Problem that processes each update in polylogarithmic time.

We will maintain a heavy-light decomposition of both $\mathcal{T}_1$ and $\mathcal{T}_2$. This can be done by using a standard method of rebuilding as used by Gabow [13]. Let $L(u)$ be the number of leaves in the subtree of u, including the leaves without labels, when the subtree was last rebuilt. Each internal node u of a tree selects at most one child v and the edge (u, v) is *heavy*. All other edges are *light*. Maximal sequences of consecutive heavy edges are called *heavy paths*. The node $r(p)$ closest to the root of the tree is called the *root* of the heavy path p and the node $e(p)$ furthest from the root of the tree is called the *end* of the heavy path. The following procedure receives a node u of the tree and recursively rebuilds its subtree.

```
function DECOMPOSE($u$, $r$)                    ▷ $r$ is the root of the heavy path containing $u$.
    $S \leftarrow \text{children}(u)$
    $v \leftarrow \text{argmax}_{v \in S} L(v)$
    if $L(v) \geq \frac{5}{6} \cdot L(u)$ then
        edge $(u, v)$ is heavy
        DECOMPOSE($v$, $r$)
        $S \leftarrow S \setminus \{v\}$
    for $v \in S$ do
        DECOMPOSE($v$, $v$)
```

Every root u of a heavy path maintains the number of insertions $I(u)$ in its subtree since it was last rebuilt. When $I(u) \geq \frac{1}{6} \cdot L(u)$, we recalculate the values of $L(v)$ for nodes v in the subtree of u and call DECOMPOSE(u, u). This maintains the property that $L(e(p)) \geq \frac{2}{3} L(r(p))$ for each heavy path p and leads to the following.

▶ **Proposition 20.** *There are $\mathcal{O}(\log m)$ heavy paths above any node.*

As rebuilding a subtree of size s takes $\mathcal{O}(s)$ time, by a standard potential argument, we get the following.

▶ **Lemma 21.** *The heavy-light decompositions of $\mathcal{T}_1$ and $\mathcal{T}_2$ can be maintained in $\mathcal{O}(\log m)$ amortized time per update.*

The main ingredient of our structure is a collection of additional structures, each storing a dynamic set of points. Each such point structure sends its current result to a max-heap, and after each update we return the largest element stored in the heap. The problem each of these point structures are designed for is the following.

Problem: Dynamic Best Bichromatic Point
Input: A multiset of at most m bicolored points from $[m] \times [m]$.
Update: Insertions and deletions of points from $[m] \times [m]$.
Query: Return a pair of points $R = (x, y)$ and $B = (x', y')$ such that R is red, B is blue, and $\min(x, x') + \min(y, y')$ is as large as possible.

We call the pair of points sought in this problem the *best bichromatic pair of points*. In Section 4.4 we explain how to modify range trees in order to obtain the following result.

▶ **Lemma 22.** *There is a data structure for Dynamic Best Bichromatic Point that processes each update in $\mathcal{O}(\log^2 m)$ amortized time.*

Conceptually, we maintain a point structure for every pair of heavy paths from $\mathcal{T}_P$ and $\mathcal{T}_Q$. However, the total number of points stored in all structures at any moment is only $\mathcal{O}(m \log^2 m)$ and the empty structures are not actually created. Consider heavy paths p of $\mathcal{T}_1$ and q of $\mathcal{T}_2$. Let ℓ be a label such that there are leaves u in the subtree of $r(p)$ in $\mathcal{T}_1$ and v in the subtree of $r(q)$ in $\mathcal{T}_2$ with the same color and both labeled by ℓ. Then, the point structure should contain a point (x, y) with this color, where x and y are the string-depths of the nodes of p and q containing u and v in their light subtrees, respectively. It can be verified that then the answer extracted from the point structure is equal to the sought result, assuming that the corresponding pair of nodes belongs to p and q, respectively. It remains to explain how to maintain this invariant when both trees undergo modifications.

Splitting an edge does not require any changes to the point structures. Each label appears only once in $\mathcal{T}_1$ and $\mathcal{T}_2$, and hence by Proposition 20 contributes to only $\mathcal{O}(\log^2 m)$ point structures. Furthermore, by navigating the heavy path decompositions we can access these structures efficiently. This allows us to implement each deletion in $\mathcal{O}(\log^4 m)$ amortized time, employing Lemma 22. To implement the insertions, we need to additionally explain what to do after rebuilding a subtree of u. In this case, we first remove all points corresponding to leaves in the subtree of u, then rebuild the subtree, and then proceed to insert points to existing and potentially new point structures. This can be amortized by the same standard potential argument if we add another factor of $\mathcal{O}(\log^2 n)$ in the analysis to account for the fact that we add a point in $\mathcal{O}(\log^2 n)$ point structures for each leaf in the subtree of u. Thus, insertions require $\mathcal{O}(\log^5 n)$ amortized time as well.

Wrap-up. Lemma 16 reduces our problem to the LCP for Two Families of Pairs of Strings problem for sets $\mathcal{R}$ and $\mathcal{B}$ of size $\tilde{\mathcal{O}}(n)$, so that each substitution in S or T yields $\tilde{\mathcal{O}}(1)$ updates to $\mathcal{R}$ and $\mathcal{B}$, which can be computed in $\tilde{\mathcal{O}}(1)$ time due to Lemma 14. The LCP for Two Families of Pairs of Strings problem is then reduced to the Dynamic Bicolored Trees Problem for trees $\mathcal{T}_1$ and $\mathcal{T}_2$ of size $\tilde{\mathcal{O}}(n)$, so that each update in $\mathcal{R}$ or $\mathcal{B}$ yields $\mathcal{O}(1)$ updates to the trees, which can be computed in $\mathcal{O}(\log n)$ time (Lemma 19). We solve the latter problem by maintaining a heavy-light decomposition of each of the trees in $\mathcal{O}(\log n)$ amortized time per update (Lemma 21), and an instance of a data structure for the Dynamic Best Bichromatic Point problem for each pair of heavy paths. For each update to the trees, we spend $\mathcal{O}(\log^5 n)$ amortized time to update the point structures.

4.4 Dynamic Best Bichromatic Point

In this section we prove Lemma 22, i.e. design an efficient data structure for the Dynamic Best Bichromatic Point problem.

With standard perturbation, we can guarantee that all x and y coordinates of points are distinct. We maintain an augmented dynamic 2D range tree [31] over the multiset of points. This is a balanced search tree $\mathcal{T}$ (called primary) over the x coordinates of all points in the multiset in which every x coordinate corresponds to a leaf and, more generally, every node $u \in \mathcal{T}$ corresponds to a range of x coordinates denoted by $x(u)$. Additionally, every $u \in \mathcal{T}$ stores another balanced search tree $\mathcal{T}_u$ (called secondary) over the y coordinates of all points $(x, y) \in S$ such that $x \in x(u)$. Thus, the leaves of $\mathcal{T}_u$ correspond to y coordinates of such points, and every $v \in \mathcal{T}_u$ corresponds to a range of y coordinates denoted by $y(v)$. We interpret every $v \in \mathcal{T}_u$ as the rectangular region of the plane $x(u) \times y(v)$, and, in particular, each leaf $v \in \mathcal{T}_u$ corresponds to a single point in the multiset. Each node $v \in \mathcal{T}_u$ will be augmented with some extra information that can be computed in constant time from the extra information stored in its children. Similarly, each node $u \in \mathcal{T}$ will be augmented with some extra information that can be computed in constant time from the extra information stored in its children together with the extra information stored in the root of the secondary tree $\mathcal{T}_u$. Irrespectively of what this extra information is, as explained by Willard and Lueker [31], if we implement the primary tree as a $BB(\alpha)$ tree and each secondary tree as a balanced search tree, each insertion and deletion can be implemented in $\mathcal{O}(\log^2 m)$ amortized time.

Before we explain what is the extra information, we need the following notion. Consider a non-leaf node $u \in \mathcal{T}$ and let $u_\ell, u_r \in \mathcal{T}$ be its children. Let $v \in \mathcal{T}_u$ be a non-leaf node with children $v_\ell, v_r \in \mathcal{T}_u$. The regions $A = x(u_\ell) \times y(v_\ell)$, $B = x(u_\ell) \times y(v_r)$, $C = x(u_r) \times y(v_\ell)$ and $D = x(u_r) \times y(v_r)$ partition $x(u) \times y(v)$ into four parts. We say that two points $p = (x, y)$

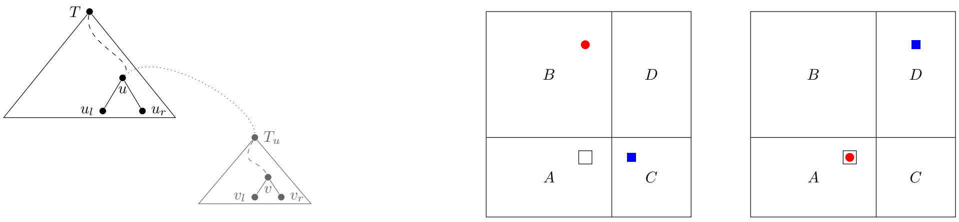

Figure 2 Left: A 2D range tree. Right: Node representing regions A, B, C, D. The best pair for each case is denoted by a small square.

and $q = (x', y')$ with $x < x'$ are shattered by $v \in \mathcal{T}_u$ if and only if $p \in A$ and $q \in D$ or $p \in B$ and $q \in C$ (note that the former is only possible when $y < y'$ while the latter can only hold when $y > y'$).

▶ **Proposition 23.** *Any pair of points in the multiset is shattered by a unique $v \in \mathcal{T}_u$ (for a unique u).*

Now we are ready to describe the extra information. Each node $u \in \mathcal{T}$ stores the best bichromatic pair with x coordinates from $x(u)$. Each node $v \in \mathcal{T}_u$ stores the best bichromatic pair shattered by one of its descendants $v' \in \mathcal{T}_u$ (possibly v itself). Additionally, each node $v \in \mathcal{T}_u$ stores the following information about points of each color in its region:

1. the point with the maximum x,
2. the point with the maximum y,
3. a point with the maximum $x + y$.

We need to verify that such extra information can be indeed computed in constant time from the extra information stored in the children.

▶ **Lemma 24.** *Let $v \in \mathcal{T}_u$ be a non-leaf node, and v_ℓ, v_r be its children. The extra information of v can be computed in constant time given the extra information stored in v_ℓ and v_r.*

Proof. This is clear for the maximum x, y and $x + y$ of each color, as we can take the maximum of the corresponding values stored in the children. For the best bichromatic pair shattered by a descendant v' of v, we start with considering the best bichromatic pair shattered by a descendant v'_ℓ of v_ℓ and v'_r of v_r. The remaining case is that the best bichromatic pair is shattered by v itself. Let A, B, C, D be as in the definition of shattering. Without losing generality we assume that the sought pair is $p = (x, y)$ and $q = (x', y')$ with $x < x'$, red p and blue q. We consider two cases:

1. $p \in A$ and $q \in D$: the best such pair is obtained by taking p with the maximum $x + y$ and any q,
2. $p \in B$ and $q \in C$: the best such pair is obtained by taking p with the maximum x and q with the maximum y.

In both cases, we are able to compute the best bichromatic pair shattered by v using the extra information stored at the children of v. See Figure 2. ◀

▶ **Lemma 25.** *Let $u \in \mathcal{T}$ be a non-leaf node, and u_ℓ, u_r be its children. The extra information of v can be computed in constant time given the extra information stored in v_ℓ, v_r and the root of $\mathcal{T}_u$.*

Proof. We seek the best bichromatic pair with x coordinates from $x(u)$. If the x coordinates are in fact from $x(u_\ell)$ or $x(u_r)$, we obtain the pair from the children of u. Otherwise, the pair must be shattered by some $v \in \mathcal{T}_u$ that is a descendant of the root of $\mathcal{T}_u$, so we obtain the pair from the root of $\mathcal{T}_u$. ◀

Abstract

We close the gap between black-box and non-black-box constructions of *composable* secure multiparty computation in the plain model under the *minimal assumption* of semi-honest oblivious transfer. The notion of protocol composition we target is *angel-based* security, or more precisely, security with super-polynomial helpers. In this notion, both the simulator and the adversary are given access to an oracle called an *angel* that can perform some predefined super-polynomial time task. Angel-based security maintains the attractive properties of the universal composition framework while providing meaningful security guarantees in complex environments without having to trust anyone.

Angel-based security can be achieved using non-black-box constructions in $\max(R_{\mathsf{OT}}, \widetilde{O}(\log n))$ rounds where R_{OT} is the round-complexity of semi-honest oblivious transfer. However, current best known *black-box* constructions under the same assumption require $\max(R_{\mathsf{OT}}, \widetilde{O}(\log^2 n))$ rounds. If R_{OT} is a constant, the gap between non-black-box and black-box constructions can be a multiplicative factor $\log n$. We close this gap by presenting a $\max(R_{\mathsf{OT}}, \widetilde{O}(\log n))$ round black-box construction. We achieve this result by constructing constant-round 1-1 CCA-secure commitments assuming only black-box access to one-way functions.

1 Introduction

Secure multiparty computation (MPC) [79, 24] enables two or more mutually distrustful parties to compute any functionality without compromising the privacy of their inputs. These early results [79, 24], along with a rich body of followup work that refined and developed the concept [25, 5, 65, 7, 73, 8], demonstrated the feasibility of general secure computation and its significance to secure protocol design. The existence of semi-honest oblivious transfer (OT) was established by Kilian [49] as the minimal, i.e., necessary and sufficient, assumption for general secure computation. The focus of this work is on *black-box constructions* of *composable* MPC protocols. We discuss these two aspects.

Black-Box constructions. A construction is black-box if it does not refer to the code of any cryptographic primitive it uses, and only depends on their input/output behavior. Such constructions are usually preferable since their efficiency is not affected by the implementation details of the underlying cryptographic primitives; moreover, they remain valid and applicable if the code of the underlying primitives is simply not available, e.g., in case of constructions based on hardware tokens [64, 23, 46, 28, 38].

Early constructions of general-purpose MPC were non-black-box in nature particularly due to NP-reductions required by underlying zero-knowledge proofs [24]. Ishai et al. [41] presented the first black-box construction of general purpose MPC based on enhanced trapdoor permutations or homomorphic public-key encryption schemes. Together with the subsequent work of Haitner [36], this provided a black-box construction of a general MPC protocol under minimal assumptions (i.e., semi-honest OT). The round complexity of black-box MPC was improved to $O(\log^* n)$ rounds by Wee [78], and to constant rounds by Goyal [26]. In the two party setting, a constant round construction was first obtained by Pass and Wee [72], and subsequently a 5-round construction was given by Ostrovsky, Richelson, and Scafuro [68], which is known to be optimal by the results of Katz and Ostrovsky [47].

Composable security. The notion of security considered in early MPC works is called *standalone security* since it only considers a single execution of the protocol. Stronger notions of security are required for complex environments such as the Internet where several MPC protocols may run *concurrently.* This setting is often referred to as the *concurrent* setting, and unfortunately, as shown by Feige and Shamir [19], stand-alone security does not necessarily imply security in the concurrent setting.

To address this issue, Canetti [8] proposed the notion of *universally composable* (UC) security which has two important properties: *concurrent security* and *modular analysis.* The former means that UC secure protocols maintain their security in the presence of other *concurrent* protocols and the latter means that the security of a larger protocol in the UC framework can be derived from the UC security of its component protocols. This latter property is stated as a composition theorem which, roughly speaking, states that UC is closed under composition [8]. Unfortunately, UC security turns out to be impossible in the plain model for most tasks [8, 9, 11]. Relaxations of UC that consider composing the same protocol were also ruled out by Lindell [59, 60].

These strong negative results motivated the search for alternative notions of concurrent security in the plain model by endowing more power to the simulator such as super-polynomial resources [69, 75, 6], ability to receive multiple outputs [30, 29], or resorting to weaker notions such as bounded concurrency [1, 70], input indistinguishability [63], or a combination thereof [27]. While all of these notions were (eventually) achieved under polynomial hardness assumptions [75, 4, 62, 12, 21, 55, 71, 52, 50, 32, 6, 22], only angel-based security by Prabhakaran and Sahai [75] (including its extension to interactive angels by Canetti, Lin, and Pass [12]) and shielded-oracle security by Broadnax et al. [6] are known to have the modular analysis property, i.e., admitting a composition theorem along the lines of UC. We focus on angel-based security in this work since it arguably has somewhat better composition properties than shielded oracles.[1]

[1] As noted in [6], shielded oracle security does not technically have the modular analysis property and is actually strictly weaker than angel-based. Nevertheless, it is still "compatible" with the UC framework – the security of a composed protocol can be derived from that of its components.

Angel based security is similar to UC except that it allows the simulator as well as the adversary access to a super-polynomial resource called an "angel" which can perform a pre-defined task such as inverting a one-way function. Early constructions of angel-based security were based on non-standard assumptions [75, 4, 62]. The beautiful work of Canetti et al. [12] presented the first construction under polynomial hardness assumptions, and the subsequent work of Goyal et al. [32] improved the round complexity to $\widetilde{O}(\log \lambda)$ under general assumptions.

The first *black-box construction* of angel-based security was obtained by Lin and Pass [55], under the minimal assumption of semi-honest OT. The main drawback of [55] is that it requires *polynomially many* rounds even if the underlying OT protocol has constant rounds. To address this situation, Kiyoshima [50] presented a $\widetilde{O}(\log^2 \lambda)$-round construction assuming constant-round semi-honest OT (or alternatively, $\max(\widetilde{O}(\log^2 \lambda), O(\mathrm{R}_{\mathsf{OT}}))$ rounds where R_{OT} is OT's round-complexity). We remark that Broadnax et al. [6] present a constant-round black-box construction for (the weaker but still composable) shielded-oracle security (utilizing prior work by Hazay and Venkitasubramaniam [39] who provide a constant-round protocol in the CRS-hybrid model); however, they require stronger assumptions, specifically, homomorphic commitments and public-key encryption with oblivious public-key generation.

State of the art. To summarize our discussion above, under the *minimal assumption* of polynomially secure semi-honest OT, the best known round complexity of *black-box constructions* for angel-based security, and in fact any composable notion with modular analysis property, is due to Kiyoshima [50] which requires $\max(\widetilde{O}(\log^2 \lambda), O(\mathrm{R}_{\mathsf{OT}}))$ rounds. This is in contrast to the non-black-box construction of Goyal et al. [32] which requires only $\max(\widetilde{O}(\log \lambda), O(\mathrm{R}_{\mathsf{OT}}))$ rounds. Therefore, there is a multiplicative gap of $\widetilde{O}(\log \lambda)$ between the round-complexities of state-of-the-art black-box and non-black-box constructions of angel-based MPC if, e.g., semi-honest OT has at most logarithmic rounds.

1.1 Our Results

In this work, we prove the following theorem, thus closing the gap between the round complexity of black-box and non-black-box constructions of angel-based MPC under minimal assumptions:

▶ **Theorem 1** (Main). *Assume the existence of* R_{OT}*-round semi-honest oblivious transfer protocols. Then, there exists a* $\max(\widetilde{O}(\log \lambda), O(\mathrm{R}_{\mathsf{OT}}))$*-round black-box construction of a general MPC protocol that satisfies angel-based UC security in the plain model.*

Note that this yields a $\widetilde{O}(\log \lambda)$-round construction under the general assumption of enhanced trapdoor permutations since they imply constant-round semi-honest OT.

We follow the framework of [12] and its extensions in [55, 50]. The main building block [12] is a special commitment scheme called a CCA-Secure Commitment. Roughly speaking, a CCA-secure commitment is a tag-based commitment scheme that maintains hiding even in the presence of a decommitment oracle $\mathcal{O}$. More specifically, the adversary receives one commitment from an honest committer and may simultaneously make concurrently many commitments to $\mathcal{O}$ (similar to non-malleable commitments [17]). The oracle immediately extracts and sends back any value adversary commits successfully provided that it used a tag that is different from the one used by the honest committer. Lin and Pass [55] show that $O(\max(\mathrm{R}_{\mathsf{CCA}}, \mathrm{R}_{\mathsf{OT}}))$-round black-box angel-based MPC can be obtained from a $\mathrm{R}_{\mathsf{CCA}}$-round CCA commitment and a R_{OT}-round semi-honest OT protocol. Kiyoshima [50] demonstrated that $\widetilde{O}(k \cdot \log \lambda)$-round CCA-secure commitments can be obtained in a black-box manner from a k-round commitment scheme with slightly weaker security called "one-one CCA" where the adversary can open only one session each with the committer as well as the oracle; they further construct a $O(\log \lambda)$-round one-one CCA scheme from one-way functions in a black-box manner.

We instead present a *constant round* construction of one-one CCA, which implies $\widetilde{O}(\log \lambda)$-round (full) CCA commitments using [50] (and Theorem 1 using [55]):

▶ **Theorem 2** (CCA Secure Commitments). *Assume the existence of one-way functions. Then, there exists a $\widetilde{O}(\log \lambda)$-round black-box construction of a CCA-secure commitment scheme.*

1.2 Overview of Techniques

Current approaches. Let us briefly review the current approaches for constructing CCA secure commitments. The main difficulty in constructing CCA secure commitments under polynomial hardness is to move from the real world – which contains the exponential time decommitment oracle $\mathcal{O}$– to a hybrid where $\mathcal{O}$'s responses can be efficiently simulated. A standard way to do this is to use a argument-of-knowledge (AoK): the protocol should require the (man-in-the-middle) adversary, say $\mathcal{A}$, to give a AoK of the value it commits. The main difficulty in employing this is that $\mathcal{A}$ may open concurrently many sessions with $\mathcal{O}$ (referred here to as "right" side sessions), interleaved in an arbitrary manner; furthermore, these values have to be extracted *immediately* within each session irrespective of what happens in other sessions. This is precisely the issue in constructing (black-box simulatable) concurrent zero-knowledge (CZK) protocols [18] as well, and ideas from there are applied in this setting too. A second difficulty is that these extractions must happen without rewinding the commitment $\mathcal{A}$ *receives* (referred to as "left" side session).

It is worthwhile to quickly recall the (tag based) non-malleable commitment construction in the original work of [17]. In this construction, $\mathcal{A}$ has only one right session; to prove that the value on the right is (computationally) independent from that on the left, the value on the right is extracted without rewinding the sensitive parts of the left side commitments. This is done by creating two types of AoK– one each for two possible values of a bit. These AoK create rewinding "slots" for extraction such that if $\mathcal{A}$ uses a different bit in the tag, it risks the possibility of having to perform a AoK on its own – i.e., without any "dangerous" rewinding on the left – in one of the slots (called a "free" slot). These special AoK are performed for each bit of the tag *sequentially* so that at least one free slot is guaranteed since the left and right tags are different by definition. While this requires n rounds n-bit tags, it is possible to split the tag into n smaller tags of $\log n$ bits and run the protocol for each of them in parallel [17, 57]. Referred to as "LOG trick," this yields a $O(\log n)$-round protocol.

The key idea for CCA commitments in [12], at a high level, is to ensure that in the *concurrent* setting, many free slots exist for each session so that extraction succeeds before the end of that session. This is achieved by creating a polynomial round protocol consisting of sequential repetition of special AoK as above and then relying on an analysis that is, at a high level, similar to early rewinding techniques from CZK literature [76, 10]. Once the issue of concurrent extraction is handled, the additional ideas in [55] are (again, at a high level) to enforce this approach using cut-and-choose protocols to obtain a black-box construction. The work of Goyal et al. [32] shows how to separate the tasks of "concurrent extraction" and"non-malleability" in this approach by proving a "robust extraction lemma." This allows them to follow a structure similar to that of concurrent non-malleable zero-knowledge (CNMZK) from [3] which matches the round complexity of CZK, i.e., $\widetilde{O}(\log n)$. However, their approach requires non-black usage of one-way functions. Kiyoshima [50] shows that the robust-extraction lemma can actually be applied to the previous black-box protocol of [55] to get $\widetilde{O}(k\cdot\log n)$ rounds if one has a slightly stronger primitive than non-malleable commitments: namely k-round 1-1 CCA commitments. To build such commitments, Kiyoshima builds non-malleability "from scratch" by combining the DDN "LOG trick" with cut-and-choose components of [55] so that the extraction on right in the standalone setting, can be done without any dangerous rewinding on left. This however results in $O(\log n)$ rounds for 1-1 CCA and $\widetilde{O}(\log^2 n)$ for full CCA.

Our approach. We significantly deviate from current approaches for constructing 1-1 CCA commitments. Instead of attempting to build non-malleability *from scratch*, our goal is to have a generic construction built around existing non-malleable commitments. The resulting protocol will not only have a simpler and more modular proof of security, but will also benefit from the efficiency and assumptions of the underlying non-malleable commitment (NMCom). Towards this goal, we return to investigate the structure of CNMZK protocols even for the simpler case of 1-1 CCA.

Setting aside the issue of round-complexity for the moment, a key idea in the construction of CNMZK protocols [3, 56, 67, 54] is to have the prover give a non-malleable commitment (NMCom) which can later be switched to a "trapdoor value" set by the verifier; the non-malleability of NMCom ensures that $\mathcal{A}$ cannot switch his value to a trapdoor on the right (unless he did so in the real world, which can be shown to be impossible through other means). The prover later proves that either the statement is true or it committed the trapdoor. The main problem with this approach is that it requires us to prove a predicate over the value committed in NMCom which requires non-black-box use of cryptographic primitives.

Non-malleable commit-and-prove. One potential idea to avoid non-black-box techniques is to turn to black-box commit-and-prove protocols in the literature and try to re-develop them in the context of non-malleability. Commit-and-prove protocols allow a committer to commit to a value v so that later, it can prove a predicate ϕ over the committed value in zero-knowledge. These protocols can be constructed in constant rounds using the powerful "MPC-in-the-head" approach introduced by Ishai et al. [42]. The approach allows committing multiple values $v_1, \ldots, v_n$ and then proving a joint predicate ϕ over them. One such construction is implicit in the work of Goyal et al. [31]. Such commitments were also used extensively by Goyal et al. to build size-hiding commit-and-prove [33] and an optimal four round construction was obtained by Khurana, Ostrovsky, and Srinivasan [48]. As noted above, if we can develop an appropriate non-malleable version of such protocols, it is conceivable that they can yield constant-round 1-1 CCA commitment. However, that non-malleable commitments are not usually equipped to handle proofs. Thus, such an approach will necessarily have to "open up" the construction of non-malleable commitments. In particular, like previous constructions, this approach cannot be based on non-malleable commitments in a black-box manner.

Changing the direction of NMCcom. In order to rely on non-malleable commitments directly, it is essential that we do not prove anything about the values committed inside the NMCom. Instead, we should restrict all proofs to be performed only over standard commitments since for them we can use standard black-box commit-and-prove protocols. Towards building this property, what if we change the direction of NMCom and ask the receiver of 1-1 CCA to send non-malleable commitments, which, for example, can be opened later? More specifically, in our 1-1 CCA protocol, the receiver will send a NMCom to a random value σ which it will open subsequently. The committer will send a "trapdoor commitment" t before it sees σ opened. Later, the committer will commit to the desired value v and give a AoK that either it knows v or t is a commitment to σ (the "trapdoor"). Observe that this structure completely avoids any proof directly over non-malleable commitments; all proofs only need to be performed over ordinary commitments. Therefore, if we use the commit phase of black-box commit-and-prove protocols to commit to σ and v we can easily complete the AoK in a black-box manner: the predicate ϕ in the proof phase will simply test for the presence of trapdoor σ. Some standard soundness issues arise in this approach but they can be handled by ensuring that the commit phase is extractable.

Although this approach yields a black-box construction directly from NMCom, it is hard to prove the 1-1 CCA property. At a high level, this is because of the following: if in the 1-1 CCA game, $\mathcal{A}$ schedules the completion of the left NMCom *before* the right one[2], the simulator in the security proof must extract σ from this NMCom while the right NMCom is still in play (so that it can generate t to be a commitment to σ). This involves rewinding the left NMCom (assuming it is extractable) which in turn rewinds the right session.[3] A similar issue arises in the work of Jain and Pandey [44] on black-box non-malleable zero-knowledge where it is resolved by using a NMCom that is already 1-1 CCA secure. We do not have this flexibility in our setting.

A possible fix for this issue is to rely on some kind of "delayed input" property: i.e., the commitment to t will be an extractable commitment that does not require the message m to be committed until the last round. This property can be obtained by committing to a key k in an extractable manner and then in the last round committing to m by simply encrypting with k. This however will no longer be compatible with the black-box commit-and-prove strategy since we will now have to take encryption into account.

We overcome this issue by making extensive use of extractable commitments. More specifically, we first *prepend* the NMCom with a standard "slot-based" extractable commitment which commits to the same value σ as the NMCom. If the NMCom also has a slot like extractable structure (e.g., the *three round* scheme of [34]), we can argue that non-synchronous adversaries must always leave a free slot either on top or at the bottom of NMCom. For example, in the troublesome scheduling discussed above, $\mathcal{A}$ can be easily rewound in the last two messages of NMCom (if we use [34]) *without* rewinding the right NMCom. In other non-synchronous schedules it will have a free slot in the top extractable commitment on the left. On the other hand, synchronous adversaries will fail in the NMCom step (and synchronous non-malleability suffices for our purposes). In summary, this will suffice for us to show that even if our simulator sets up the trapdoor statement on the left (by committing σ in t), $\mathcal{A}$ cannot do the same on the right. Other NMCom, particularly public-coin extractable NMCom also seem sufficient.

A second issue here is the intertwining of the left AoK[4] with "extractable" components on the right, e.g., the right AoK (or extractable commitment steps). In order to prove that $\mathcal{A}$ cannot setup the trapdoor, extraction from right AoK will be necessary and this will be troublesome when changing the witness in the left AoK during hybrids. This issue can be handled using the sequential repetition technique from [53]: we use $k+1$ AoKs where k is the (constant) rounds in a single AoK. Also note that other common methods for handling this issue do not work: e.g., we cannot rely on *statistical* WI since it requires stronger assumptions

[2] Note that NMCom's direction is opposite to that of 1-1 CCA: the receiver of 1-1 CCA is the sender of right NMCom.

[3] This is not an issue in the synchronous schedule since in that case, the value $\mathcal{A}$ commits to in NMCom is provided to the distinguisher along with the joint view.

[4] Observe that the AoK will just be the proof part of appropriate black-box commit-and-prove with right parameters to ensure black-box property; they will also satisfy witness-indistinguishability [19].

for constant rounds; we also cannot use proofs that are secure against a fixed number of rewinds since they usually allow a noticeable probability of extraction which is insufficient for 1-1 CCA commitments, where extraction must succeed with overwhelming probability.

1.3 Other Related Works

The focus of our work is constructions in the plain model. Hazay and Venkitasubramaniam [40] gave a black-box construction of an MPC protocol without any setup assumptions that achieves composable security against an *adaptive* adversary. UC security can be achieved by moving to other trusted setup models such as the common reference string model [14, 9, 35], assuming an honest majority of parties [11], trusted hardware [64, 23, 46, 15], timing assumptions on the network [45], registered public-key model [2], setups that may be expressed as a hybrid of two or more of these setups [20], and so on. Lin, Pass, and Venkitasubramaniam [58, 71] show that a large number of these setup models could be treated in a unified manner, and black-box analogues of these results were obtained by Kiyoshima, Lin, and Venkitasubramaniam [51].

2 Preliminaries

Notation. We use λ for the security parameter. We use $\overset{\mathrm{c}}{\approx}$ to denote computational indistinguishability between two distributions. For a set S, we use $x \overset{\$}{\leftarrow} \mathsf{S}$ to mean x is sampled uniformly at random from S. PPT denotes probabilistic polynomial time and $\mathsf{negl}(\cdot)$ denotes negligible function.

We assume familiarity with standard concepts such as commitment schemes, witness indistinguishability. In the following, we recall the definitions for extractable commitments, non-malleable commitments and CCA commitments. Definitions for the more basic primitives and other constructs (such as MPC related definitions) can be found in the full version of the paper [16].

2.1 Extractable Commitments

▶ **Definition 3** (Extractable Commitment Schemes). *A commitment scheme* $\mathsf{ExtCom} = (S, R)$ *is extractable if there exists an expected polynomial-time probabilistic oracle machine (the extractor)* Ext *that given oracle access to any PPT cheating sender* S^* *outputs a pair* (τ, σ^*) *such that:*

- ***Simulation:*** *τ is identically distributed to the view of S^* at the end of interacting with an honest receiver R in commitment phase.*
- ***Extraction:*** *the probability that τ is accepting and $\sigma^* = \bot$ is negligible.*
- ***Binding:*** *if $\sigma^* \neq \bot$, then it is statistically impossible to open τ to any value other than σ^*.*

The above construction of ExtCom (Figure 1) is standard [17, 74, 77, 70]. We will refer to it as the *standard* ExtCom.

▶ Remark 4 (Regarding Over-Extraction). Intuitively, Definition 3 stipulates that if the committer indeed commits to some value, the extractor must be able to extract it. We remark that it does not rule out what is called the "over-extraction" issue – namely, the extractor may extract a valid looking value even though none actually exists.

However, this definition suffices for most ZK and MPC applications (e.g. [75, 70, 72]), including ours. In our arguments specifically, we will employ hybrids where we extract the value that the adversary commits to using these commitment schemes. Jumping ahead, in the security proof for our protocol, we will need successful extraction only if the adversary actually commits to some *valid* value; otherwise, completing the hybrids is trivial.

The extractable commitment scheme, based on any commitment scheme Com, works in the following way. The scheme has 3 rounds if Com is non-interactive.

Input:

- Both S and R get security parameter 1^λ as the common input.
- S gets a string σ as his private input.

Commitmment Phase:

- The sender (committer) S commits using Com to λ pairs of strings $\{(v_i^0, v_i^1)\}_{i=1}^{\lambda}$ where $(v_i^0, v_i^1) = (\eta_i, \sigma \oplus \eta_i)$ and η_i are random strings in $\{0,1\}^{\ell(\lambda)}$ for $1 \leq i \leq \lambda$.[a]
- Upon receiving a challenge $\overline{c} = (c_1, \dots, c_\lambda)$ from the receiver R, S opens the commitments to $(v_1^{c_1}, \dots, v_\lambda^{c_\lambda})$.
- R checks that the openings are valid.

Decommitment Phase:

- S sends σ and opens the commitments to all λ pairs of strings.
- R checks that all the openings are valid, and also that $\sigma = v_1^0 \oplus v_1^1 = \cdots = v_\lambda^0 \oplus v_\lambda^1$.

[a] The scheme supports extraction as long as $k = \omega(\log \lambda)$ pairs are used.

Figure 1 Extractable Commitment Scheme $\langle S, R \rangle$.

2.2 Non-Malleable Commitments

We follow the definition of non-malleability from [57, 34]. This definition is based on the comparison between a real execution with an ideal one. In the *real* interaction, we consider a man-in-the-middle adversary $\mathcal{A}$ interacting with a committer C in the *left* session, and a receiver R in the *right*. We denote the relevant entities used in the right interaction as "tilde'd" version of the corresponding entities on the left. In particular, suppose that C commits to v in the left interaction, and $\mathcal{A}$ commits to $\widetilde{v}$ on the right. Let MIM_v denote the random variable that is the pair $(\mathsf{view}, \widetilde{v})$, consisting of the adversary's entire view of the man-in-the-middle execution as well as the value committed to by $\mathcal{A}$ on the right (assuming C commits to v on the left). The *ideal* interaction is similar, except that C commits to some arbitrary fixed value (say 0) on the left. Let MIM_0 denote the pair $(\mathsf{view}, \widetilde{v})$ in the ideal interaction. We use a *tag-based* (or "identity-based") specification, and ensure that $\mathcal{A}$ uses a distinct tag $\widetilde{\mathsf{id}}$ on the right from the tag id it uses on the left. This is done by stipulating that MIM_v and MIM_0 both output a special value $\perp_{\mathsf{id}}$ when $\mathcal{A}$ uses the same tag in both the left and right executions. The reasoning is that this corresponds to the uninteresting case when $\mathcal{A}$ is simply acting as a channel, forwarding messages from C on the left to R on the right and vice versa. We let $\mathsf{MIM}_v(z)$ and $\mathsf{MIM}_0(z)$ denote the real and ideal interactions respectively when the adversary receives auxiliary input z.

▶ **Definition 5** (Non-Malleable Commitment Schemes). *A (tag-based) commitment scheme $\langle C, R \rangle$ is non-malleable if for every* PPT *man-in-the-middle adversary $\mathcal{A}$, and for all values v, we have $\{\mathsf{MIM}_v(z)\}_{z \in \{0,1\}^*} \overset{c}{\approx} \{\mathsf{MIM}_0(z)\}_{z \in \{0,1\}^*}$.*

Synchronizing Adversaries. This notion refers to man-in-the-middle adversaries who upon receiving a message in one session, immediately respond with the corresponding message in the other session. An adversary is said to be *non-synchronizing* if it is not synchronizing.

2.3 CCA Commitments

We define the notion of CCA-secure commitments (and 1-1 CCA security in particular). These definitions rely on the notion of a *decommitment oracle*, which provide decommitments given valid transcripts to a particular (tag based) commitment protocol. Specifically, a decommitment oracle $\mathcal{O}$ for a given commitment protocol acts as follows:

- $\mathcal{O}$ acts as an honest reciever against some committer C, participating faithfully according to the specified commitment scheme. C is allowed to pick a tag for this interaction adaptively.
- At the end of this interaction, if the honest reciever were to accept the transcript as containing a valid commitment with respect to the given tag, $\mathcal{O}$ returns the value v committed by C to it. Otherwise, it returns $\perp$.

We denote an adversary with access to the decommitent oracle as $\mathcal{A}^{\mathcal{O}}$. CCA security then essentially constitutes preservation of the hiding property even against adversaries enjoying such oracle access. More formally, we define the following game $\mathsf{IND}_b(\langle C, R\rangle, \mathcal{A}, \mathcal{O}, n, z)$ ($b \in \{0, 1\}$) as follows: given the public parameter 1^n and auxillary input z, the adversary $\mathcal{A}^{\mathcal{O}}$ adaptively generates two challenge values v_0, v_1 of length n, and a tag $\mathsf{tag} \in \{0, 1\}^n$. Then, $\mathcal{A}^{\mathcal{O}}$ receives a commitment to v_b with tag tag from the challenger. Let y be the output of $\mathcal{A}$ in this game. The output of the game is $\perp$ if during the game, $\mathcal{A}$ sends $\mathcal{O}$ any commitment using tag tag. Otherwise, the output of the game is y. We abuse notation to denote the output of the game $\mathsf{IND}_b(\langle C, R\rangle, \mathcal{A}, \mathcal{O}, n, z)$ by the same symbol $\mathsf{IND}_b(\langle C, R\rangle, \mathcal{A}, \mathcal{O}, n, z)$.

▶ **Definition 6** (CCA Commitment). *Let $\langle C, R\rangle$ be a tag-based commitment scheme, and $\mathcal{O}$ be an associated decommitment oracle. Then $\langle C, R\rangle$ is said to be* ***CCA secure w.r.t. $\mathcal{O}$****, if for every nonuniform P.P.T. machine $\mathcal{A}$, the following ensembles are computationally indistinguishable:*

- $\{\mathsf{IND}_0(\langle C, R\rangle, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$
- $\{\mathsf{IND}_1(\langle C, R\rangle, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$

It is customary to call any commitment scheme that is CCA secure with respect to some decommitment oracle as just CCA secure (but in general the oracle is usually also described, and is of course necessary to prove such security). It is also customary to call the interaction between the challenger and adversary as the *left* interaction, and that between adversary and oracle as the *right* interaction, in the fashion of non-malleable commitments, where the security property chiefly considers man in the middle attacks.

Finally, a scheme is *1-1 CCA secure* (denoted as $\mathrm{CCA}^{1:1}$) if the corresponding adversary is only allowed one interaction with the oracle.

3 A New $\mathrm{CCA}^{1:1}$ Commitment Scheme

We will require the following ingredients for our $\mathrm{CCA}^{1:1}$ protocol:

- A statistically-binding commitment Com. Naor's commitment works.
- A 3-round slot-based extractable commitment scheme ExtCom; for concreteness we will use the standard 3-round scheme, shown in Figure 1. based on Naor's commitment (the first message ρ of Naor's commitment is not counted in rounds and assumed to be available from other parts of the protocol).
- An (extractable) commitment scheme ENMC that is *non-malleable* against *synchronizing* adversaries. We will need this protocol to be "compatible with slots" of the ExtCom defined above. For concreteness, we assume that ENMC is the 3-round commitment scheme of [34] which satisfies all our requirements.
- A k round witness indistinguishable argument of knowledge WIAoK.

We stress that all of these ingredients have constant rounds, and can be constructed from standard OWFs in a black-box manner.

Our Protocol. We now describe our first protocol for $\mathrm{CCA}^{1:1}$ commitments. This protocol does not specifically try to achieve the black-box usage of cryptographic primitives. This allows us to focus on proving CCA security. However, it achieves two important properties: it is based on minimal assumptions, and it has a constant number of rounds. Moreover, the structure of this protocol is chosen in such a way that later, it will be possible to convert into a fully black-box construction. We remark that we also directly use identities of length λ directly (this is in keeping with the [34] construction which does the same).

The formal description of the protocol appears in Figure 2. At a high level, the protocol proceeds as follows. First, it requires the receiver to commit to a trapdoor string α using two extractable primitives: ExtCom as well as ENMC. Next, the committer will commit to an all zero-string β using ExtCom. Jumping ahead, in the security proof a "simulator machine" on left will set $\beta = \alpha$ and use it as a "fake witness" in a WIAoK; later we shall instantiate ExtCom with, roughly speaking, a "black-box commit-and-prove" to obtain a black-box construction. The receiver simply opens α in the next step, and the committer commits to the desired value, say v, followed by a proof of knowledge of v or that $\beta = \alpha$. A crucial observation here is that *the proofs are not required to deal with values inside* ENMC – by ensuring that ENMC values opened in the protocol execution.

▶ **Theorem 7.** *The protocol $\langle C, R\rangle_{\mathsf{CCA}}$ (described in Figure 2) is a 1-1 CCA commitment scheme for all polynomial time adversaries.*

The statistical-binding property of protocol $\langle C, R\rangle_{\mathsf{CCA}}$ is straightforward. The computational hiding property is implied by the 1-1 CCA security as per Definition 6. Due to lack of space, we present an outline of the proof for non-malleability below. The complete proof is given in the full version of our paper [16].

Proof for Non-Malleability (Sketch.) We start with a man-in-the-middle adversary $\mathcal{A}$ that participates in the CCA challenge outlined above. Consider any two arbitrary values v_0 and v_1 in the message space. We will now show indistinguishability between the games $\{\mathsf{IND}_0(\langle C, R\rangle_{\mathsf{CCA}}, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$ and $\{\mathsf{IND}_1(\langle C, R\rangle_{\mathsf{CCA}}, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$. To this end, we will use a hybrid argument:

Our proof proceeds as follows. We start with the honest committer on the left committing to some arbitrary value v_0. The overall idea is to move to an intermediate hybrid where the left challenger is able to "set the trapdoor" and go through the WIAoKs without using the commitment. This will allow us to then replace the initial commitment to v_0 to one to v_1 (and move back to doing everything on the left "honestly"). Further, we will also maintain the following invariant across all the hybrids:

▶ **Definition 8** (Invariant Condition (informal)). *In the right session, the adversary* MIM *cannot set $\tilde{\beta} = \tilde{\alpha}$ except with negligible probability.*

We outline the necessary hybrids to get to this stage below:

Hybrid H_0^0. This is just the original experiment with the honest committer on the left. In other words, this is the experiment $\{\mathsf{IND}_0(\langle C, R\rangle_{\mathsf{CCA}}, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$. It is straightforward to see that the invariant holds in this hybrid: if it does not, then MIM must break the hiding property of the commitments in Stage 1 or 2 in the right execution to learn $\tilde{\alpha}$.

We let $\lambda \in \mathbb{N}$ denote the security parameter. All primitives used in the protocol by default have 1^λ as part of their input. We omit this detail in the following. Further, we assume that the execution involves a tag or identity $\mathsf{id} \in \{0,1\}^\lambda$.
Input: The committer C and reciever R have common input as the security parameter 1^λ. Additionally, C has as private input a value v which it wishes to commit to.

Commit Phase: This proceeds as follows:

Stage 0: C commits to the value v using Com and sends the identity id to R.

Stage 1: This consists of the following steps:
(a) R picks a value $\alpha \xleftarrow{\$} \{0,1\}^\lambda$.
(b) R commits to $\alpha_1 = \alpha$ using ExtCom.

Stage 2: R commits to $\alpha_2 = \alpha$ using ENMC, using identity id.
For future reference, we denote by $\mathsf{CombinedCom}$ the joint execution of Stage 1 and 2 up to this point. Observe that $\mathsf{CombinedCom}$ is a statistically binding commitment scheme.

Stage 3: C now commits to $\beta = 0^\lambda$ using ExtCom.

Stage 4: This goes as follows:
1. R decommits to both its commitments so far, revealing α_1 and α_2.
2. C checks these decommitments, aborting if $\alpha_1 \neq \alpha_2$.

Stage 5: C and R engage in $k+1$ WIAoK protocols *sequentially*. We denote these WIAoK executions as WIAoK_i for $i = 1, \ldots, k+1$. In all these WIAoKs, C proves the *same* (compound) statement which is true if and only if:
(a) there exists randomness η s.t. $c = \mathsf{Com}(v;\eta)$; **or**
(b) $\beta = \alpha_1 = \alpha_2$, where β is the unique string committed in the transcript of Stage-3.

Note that an honest prover will always use the witness for part-(a) of the above compound statement, which we refer as the "original witness". We will refer the witness for part-(b) of the compound statement. Looking ahead, some hybrids will use the trapdoor witness to go through the WIAoKs.

Decommit Phase: The committer C decommits to v and β. R checks if these decommitments are valid, and accepts if so.

Figure 2 Protocol $\langle C, R\rangle_{\mathsf{CCA}}$: $\mathrm{CCA}^{1:1}$ Commitment Scheme.

Hybrid H_1^0. In this hybrid, the decommitment oracle on the right is removed. All messages are generated as an honest receiver, and the value $\tilde{v}$ committed by the adversary is obtained by extracting the witness from the final WIAoK on the right.

Hybrid H_2^0. This hybrids proceeds as the previous one except that on the left, we also extract the value α_2 from the stage 2 ENMC.

In these two hybrids, the adversary's view up to Stage 4 is identical to that in H_0. Therefore, the invariant must hold in these hybrids (by the same reasoning as in H_0^0). By the knowledge soundness of WIAoK, the extracted witness should be the same as the one returned by the oracle in H_0. The entire view of the adversary is therefore unaffected by these changes, and so is identical to that in H_0^0.

Hybrid $\boldsymbol{H_3^0}$. This hybrid also proceeds as the previous one except that the value β is now set to be the extracted value α_2.

While it is easy to argue that the adversary cannot detect this change, it may still be able to use the change in the left ExtCom to change its own ExtCom on the right (note that the ExtCom scheme is malleable)! This is the primary reason we need the invariant condition, as it explicitly prevents this exact occurrence. We argue that the invariant holds by considering separate cases for synchronous and nonsynchronous adversaries. For synchronous adversaries, we show roughly that if the adversary could identify any change in the left stage 3 ExtCom, then it must have been influencing the earlier two commitments it made in a malleable fashion - this is ruled out by the non-malleability of ENMC. *As mentioned in the Technical Overview, this is the most difficult case to deal with, and where our main contribution lies.* For nonsynchronous adversaries, we show instead that there are "extraction opportunities" on the left where no messages on the right are exchanged for the corresponding duration (and extraction on the left can be performed unhindered). This relies on carefully setting the appropriate round complexities for ExtCom and ENMC.

Hybrid $\boldsymbol{H_4^0}$. In this hybrid, we ask the left execution to use the *trapdoor witness* in the Stage 5 WIAoKs (the actual changes happen by constructing a sequence of intermediate hybrids where the witness is replaced one by one in each WIAoK execution on the left, in order of occurrence).

In this hybrid, we ensure that any change of witness on the left does not occur during the same time as extraction of the witness on the right, since the latter involves rewinding and that can interfere with the witness indistinguishability of the left proof. In the synchronizing case, it is easy to see the invariant holds in this hybrid since the corresponding changes all occur *after* the right stage 3 ExtCom is concluded. For nonsynchronous adversaries, this may not be the case, but we can use an argument very similar to that used to argue the invariant in H_3^0. We can also argue indistinguishability of (the view in) this hybrid using the witness indistinguishability of our WIAoK scheme and the fact that the change in witness on the left, and extraction of witness on the right, occur at different times.

Finally, we define H_3^1, H_2^1, H_1^1 to H_0^1, where for H_i^1 is just the analogue of H_i^0, but replacing the initial commitment to v_0 with one to v_1 on the left. Using the same arguments above, we can show that both the invariant condition and indistinguishability views holds among H_4^1, H_3^1 down to H_0^1. Note that H_0^1 is just the experiment $\{\mathsf{IND}_1(\langle C, R\rangle_{\mathsf{CCA}}, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$, and hence we show that this is computationally indistinguishable from $\{\mathsf{IND}_0(\langle C, R\rangle_{\mathsf{CCA}}, \mathcal{A}, \mathcal{O}, n, z)\}_{n\in\mathbb{N}, z\in\{0,1\}^*}$ to $\mathcal{A}$. ◀

4 Our Black-Box CCA Commitment

Our starting point is to determine how we can make our protocol (in Figure 2) fully black-box. In fact, we note that the only component that is not already so is our argument system. Note that we use the arguments to prove statements about the Com in **Stage 0** and the ExtCom in **Stage 3**. Thus, we look to change these components with a suitable "commit-and-prove" protocol that is fully black-box. Further, we will require the following properties from the protocol so that it works with our template:

1. It should provide us a Com, and an ExtCom scheme. Importantly, this "first part" of the protocol should alone serve as a valid commitment with desired properties, regardless of whether we perform a subsequent WIAoK or not. This is in contrast to the definition (and construction) in [48].
2. Later we should be able to perform WIAoK on a compound statement regarding the values committed in the above Com and ExtCom;
3. The WIAoK part should make use of Com and ExtCom only in a black-box manner.

We provide a definition of Commit-and-Prove WIAoK (actually ZKAoK) formally in the full version [16] that captures all the required properties.

We note that there are not many approaches in the literature that achieve what we want: the work of [48] constructed a round-optimal version of such a primitive, but their protocol does not fit our needs because we require some properties that are not immediately avaiable from their construction. We discuss the issues briefly. While their commit stage is a statistically binding commitment, it cannot be modified to be *extractable*, which we crucially need. Further, we will require a *multi-commitment* property for our proof, namely that the predicate to be proved can support values used in *multiple* commit stages; while it is possible that the [48] protocol can be modified to achieve this property, the modification is unclear. Yet another issue is that we will use multiple proof modules (for the same proof) in our final protocol. Again it is not clear how to modify their protocol so that we ensure consistency of openings while also ensuring extractability from every proof module (note that their protocol has a challenge-response format that can allow extraction from just two challenges even across different sessions). We remark however that their protocol does support the *delayed predicate* property, which we also rely on.

We therefore build a commit-and-prove protocol suitable to our purposes. Our starting point is the "MPC-in-the-head" technique from [42]. This approach was originally used to construct black-box zero-knowledge arguments, by having the prover run a virtual MPC execution "in its head" and committing to the views of the virtual parties. The verifier then asks for some of these views to be opened and checks that the opened views are consistent. This construction achieves honest-verifier ZKAoK.[5] To meet our requirements, we want to turn this construction into commit-and-prove form, and bolster the security to tolerate malicious verifiers.

There are a few previous works that already take this approach to create commit and prove protocols. There is the recent work of Hazay, Ishai and Venkitasubramaniam [37], who make use of a commit and prove style protocol constant round secure 2PC protocols against malicious adversaries. Their overall design of the construction utilizes the MPC-in-the-head idea, but by way of using *server watchlists* which is a slightly different implementation of this concept first used in [43]. Being a part of their overall 2PC compiler, their protocol is in the OT-hybrid model, which makes it difficult to adapt to our usage, which is in the plain model. It is also unclear how to modify their construction to have the *multi-commitment* property, as well as make it argument of knowledge, as there is no immediate extraction algorithm to extract the sender's committed value from the proof stage.

We instead follow the approach used in the older work of Goyal et al [31], who use two virtual MPC executions. The first execution is simply a verifiable secret sharing of the value to be committed (the commitment to all the views serves also to commit to this value), which

[5] The authors of [42] also showed how to make it secure against dishonest verifiers. But their technique results in a construction with polynomially-many rounds, because they employ sequential repetition.

is sent on to the verifier (we will call this the *commit phase*). The second execution continues on from the first, where the virtual parties use their shares to compute some predicate on the shared value that represents the statement to be proved over the commitment (we will call this the *proof phase*).

To obtain security against malicious verifiers, one idea is to have the verifier *commit to* its challenge *before* the prover sends its first message. However, we cannot resort to this since this would excise the argument of knowledge property from this construction. We therefore employ a different approach, by building in a *coin-tossing* protocol into the argument system, which only uses an extractable commitment scheme. This is similar to the construction used in [61] to convert ZK arguments to ZKAoKs. It allows the PPT simulator to bias the coin-tossing result, thus allowing for simulation against dishonest verifiers; meanwhile, the knowledge extraction strategy in [42] still works.

The remaining task is to build an extractable commitment scheme that is compatible with the above. To obtain this, we observe that if the predicate ϕ to be simply the identity predicate, then we can still extract the committed value (i.e., the “witness” in the proof phase) as outlined above. Therefore, we view an execution of the above commit-and-prove protocol (with the identity predicate) as an extractable commitment scheme: hiding follows from the hiding of the commit phase as well as zero knowledge of the proof phase, and extractability follows just as mentioned above (i.e., by the argument of knowledge property). We claim further that this commitment scheme is actually *compatible* with our commit-and-prove scheme; this is due to the property of *multiple proofs* mentioned earlier, wherein *separate* proof modules can be performed on the *same* commitments (by adjusting the parameters of verifiable secret sharing). In particular, this allows the prover to use this new extractable commitment scheme, then later perform (black-box) arguments of knowledge for some statement about the value committed to in this scheme. This suffices for our purposes. We provide more details and the formal construction in the full version of our paper [16].

Now we can simply integrate these components into our original 1-1 CCA commitment scheme to obtain a fully black-box instantiation. We present our final protocol and security proof in the full version [16]. Note that our commit-and-prove scheme is constant round, and therefore our final protocol is still constant rounds.

5 Angel-Based MPC in $\widetilde{O}(\log\lambda)$ Rounds

Kiyoshima [50] presents a black-box construction of a CCA-secure commitment scheme with the following ingredients: (a) a two-round statistically-binding commitment scheme, and a constant round “strongly extractable” commitment, both of which are known from (black-box) one-way functions, (b) a concurrently-extractable commitment (due to Micciancio et al., [66]), with a “robustness parameter” ℓ, and (c) an R-round 1-1 CCA-secure commitment provided that $\ell = O(R \cdot \log\lambda \cdot \log\log\lambda)$. The round-complexity of the resulting protocol is $O(\ell)$. If R is a constant, this yields a $\widetilde{O}(\log\lambda)$-round construction for CCA secure commitments.[6] This yields Theorem 2.

As mentioned in the introduction, the security model that we consider is *angel-based* security, or UC *security with superpolynomial helpers*. Very briefly, this is essentially the same as the UC model used in [8], except that the adversary (in the real world) and the

[6] More precisely, Kiyoshima states his results with a specific value of ℓ, namely, $O(\log^2\lambda \cdot \log\log\lambda)$, since $R = O(\log\lambda)$ in his case. However, his construction and proof work for any value of R if ℓ is as described above.

environment (in the ideal world) both have access to a superpolynomial time functionality that acts as an oracle or a *helper*. Formal definitions for this security model can be found in [12] and [55]. If there is a protocol Π that emulates a functionality $\mathcal{H}$ with helper $\mathcal{H}$ in this setting, we say that Π $\mathcal{H}$-EUC-realizes $\mathcal{F}$.

Now, as in [50], we combine Theorem 2 with the following two results due to Canetti et al. [12, 13] and Lin and Pass [55] respectively to obtain Theorem 1.

▶ **Theorem 9** ([55]). *Assume the existence of an R_{CCA}-round robust CCA-secure commitment scheme $\langle C, R\rangle$ and the existence of an R_{OT}-round semi-honest oblivious transfer protocol $\langle S, R\rangle$. Then, there is an $O(\max(R_{\mathsf{CCA}}, R_{\mathsf{OT}}))$-round protocol that $\mathcal{H}$-EUC-realizes $\mathcal{F}_{\mathsf{OT}}$. Furthermore, this protocol uses $\langle C, R\rangle$ and $\langle S, R\rangle$ only in a black-box way.*

▶ **Theorem 10** ([12, 13]). *For every well-formed functionality $\mathcal{F}$, there exists a constant-round $\mathcal{F}_{\mathsf{OT}}$-hybrid protocol that $\mathcal{H}$-EUC-realizes $\mathcal{F}_{OT}$.*

Abstract

In the replacement paths (RP) problem we are given a graph G and a shortest path P between two nodes s and t [1]. The goal is to find for every edge $e \in P$, a shortest path from s to t that avoids e. The first result of this paper is a simple reduction from the RP problem to the problem of computing shortest cycles for all nodes on a shortest path.

Using this simple reduction we unify and extremely simplify two state of the art solutions for two different well-studied variants of the RP problem.

In the first variant (*algebraic*) we show that by using at most n queries to the Yuster-Zwick distance oracle [FOCS 2005], one can solve the the RP problem for a given directed graph with integer edge weights in the range $[-M, M]$ in $\tilde{O}\left(Mn^{\omega}\right)$ time [2] [3] . This improves the running time of the state of the art algorithm of Vassilevska Williams [SODA 2011] by a factor of $\log^6 n$.

In the second variant (*planar*) we show that by using the algorithm of Klein for the multiple-source shortest paths problem ($MSSP$) [SODA 2005] one can solve the RP problem for directed planar graph with non negative edge weights in $O\left(n \log n\right)$ time. This matches the state of the art algorithm of Wulff-Nilsen [SODA 2010], but with arguably much simpler algorithm and analysis.

1 Introduction

The replacement paths problem is defined as follows. We are given a graph G and a shortest path P connecting two nodes s and t. The problem is to find for every edge $e \in P$ a shortest path from s to t in the graph $(V, E \backslash e)$. As in previous works, we focus on computing the lengths of the replacement paths instead of the paths itself. Our results can be modified to return the paths as well.

[1] For the rest of this paper we assume $G = (V, E)$, $n = |V|$, $m = |E|$.
[2] ω denotes the matrix multiplication exponent ($\omega < 2.373$).
[3] The $\tilde{O}$ notation suppresses polylogarithmic factors.

The motivation for studying replacement paths is rooted in the fact that real-world graphs are vulnerable and are subject to nodes and links failures and having backup paths is a desirable property. Replacement paths are also well motivated by other important applications. One application stems from auction theory, where we use replacement paths to compute the Vickrey pricing of edges owned by selfish agents [15, 7]. In addition, Replacement paths are also used to compute the k shortest simple paths between two given vertices, as one can compute the k shortest simple paths by k calls to the replacement paths algorithm. The k shortest simple paths has many applications in and of itself [4].

1.1 Upper bounds

For undirected graphs with arbitrary (non negative) edge weights, Malik et al. [12] gave an $O(m+n\log n)$ algorithm; Nardelli et al. [14] later improve the running time to $O(m\alpha(m,n))$[4] in the Word RAM model for positive edge weights. For directed graphs with arbitrary edge weights (possibly negative), Gotthilf and Lewenstein [5] gave an $O(mn+n^2\log\log n)$ algorithm. For unweighted directed graphs, Roditty and Zwick [16] gave a randomized combinatorial algorithm that solves the problem in $\tilde{O}(m\sqrt{n})$ time. For directed graphs with integer edge weights in the range $[-M,M]$, Weimann and Yuster [17] obtain a randomized algorithm that runs in $\tilde{O}(Mn^{1+\frac{2}{3}\omega})$ time. Vassilevska Williams [18] improved the latter by giving a randomized algorithm that runs in $\tilde{O}(Mn^{\omega})$ time for $w>2$ and in $O(Mn^{\omega+\epsilon})$ time for any $\epsilon>0$ for $\omega=2$. The replacement paths problem was also studied for special family of graphs. For planar directed graphs with non negative edge weights, Emek, Peleg, and Roditty [3] obtain a recursive algorithm that runs in $O(n\log^3 n)$ time. Klein, Mozes, and Weimann [10] improve the running time to $O(n\log^2 n)$. At last, Wulff-Nilsen [20] improved the latter by giving an $O(n\log n)$ time algorithm.

1.2 Lower bounds

Hershberger et al. [8] showed a $\Omega(m\sqrt{n})$ time lower bound for the replacement paths problem for directed graphs with non negative edge weights, in the $path-comparison$ model of Karger et al [9]. Vassilevska-Williams and Williams [19] showed that the replacement paths problem in directed graphs with arbitrary edge weights is equivalent to the all pairs shortest paths problem (APSP), under subcubic reductions. Agarwal and Ramachandran [1] showed that the All-Nodes Shortest Cycles problem (ANSC) for directed graph with arbitrary edge weights, in which we are required to find for every node a shortest cycle containing it, is at least as hard as computing the replacement paths problem in directed graphs. This reduction can be used to solve the replacement paths problem using an oracle to the ANSC problem. However, the reduction does not preserve the range of the weights. That is, the reduction they present increases the weights of the graph by a factor of n. This means that the reduction is not applicable in the algebraic variant, as it would lead to a $\tilde{O}\left((Mn)\,n^{\omega}\right)$ solution. Moreover, the reduction does not preserve planarity, and therefore is not applicable in the planar variant as well.

1.3 Our result

The first result of this paper is a simple linear time reduction from the RP problem to the problem of computing shortest cycles for all nodes on a shortest path. The reduction maps the graph G into a new graph G^r with the following properties; The mapping from

[4] $\alpha(m,n)$ is the functional inverse of the Ackermann function.

G to G^r is invertible and is the inverse of itself. i.e. $(G^r)^r = G$. The reduction preserves the range of the edge weights i.e. if G has integer weights in the range $[-M, M]$ then so does G^r. The reduction preserves planarity i.e. if G is planar then so does G^r. The first property implies that the problem of computing shortest cycles for all nodes on a shortest path is equivalent to the RP problem. The second property enable us to solve the RP problem for directed graphs with integer edge weights in the range $[-M, M]$ in $O(Preprocess_{\mathcal{A}}(n, m, M) + n \cdot Query_{\mathcal{A}}(n, m, M))$ time, where $\mathcal{A}$ is a distance oracle. In particular, using Yuster-Zwick distance oracle, we solve the problem in deterministic $\tilde{O}(Mn^{\omega})$ time. Vassilevska Williams solved the problem using few techniques such as; Node sampling, graph compression and recursion. The running time of Vassilevska Williams's algorithm is at least $\log^{\frac{\omega}{\omega-2}}(n) \cdot Preprocess_{\mathcal{A}}(n, m, M)$. Therefore, when considering polylogarithmic factors, our algorithm improves the running time of Vassilevska Williams's algorithm by a factor of $\log^{\frac{\omega}{\omega-2}}(n)$. Hence, for $\omega < 2.373$ we improve the running time by at least a factor of $\log^6(n)$. The third property enable us to solve the RP problem for directed planar graphs with non negative edge weights using an oracle to the $MSSP$ problem. In particular, using Klein algorithm for the $MSSP$ problem, we solve the problem in $O(n \log n)$ time. The $MSSP$ problem is as follows; Given a planar graph G, and a list of distance queries from a source to a target, such that all sources share the same face, answer all distance queries. In fact, our reduction is to a simpler problem than the $MSSP$ problem, that is, computing at most $O(n)$ distance queries where both the source and the target are on the given face. Moreover, the boundary of the face consists of two shortest paths. The fact that our reduction is to a simpler problem than the $MSSP$ problem gives additional insights on the RP problem that might lead to further improvements.

2 Preliminaries

2.1 General notations

Let $G = (V, E)$ be a directed graph with n vertices and m edges, and let w be a weight function over E.

Let P be a path in G. We denote by $w(P)$ the length of the path P which is defined as the sum of the weights of the edges along P, and by $|P|$ the number of edges in P. We assume G does not contain negative cycles, hence the distance between every two nodes $u, v \in V$ is well defined and denoted by $d(u, v)$.

Let $e \in E$, we denote by $G \backslash e$ the graph $(V, E \backslash \{e\})$, and by $d_e(u, v)$ the distance from u to v in the graph $G \backslash e$.

Path concatenation: Given two paths $\Omega_1 = \langle u, ..., v\rangle$ $\Omega_2 = \langle v, ..., w\rangle$ we denote by $\Omega_1 \cdot \Omega_2$ the concatenation of Ω_1 and Ω_2.

Path slicing: Given a path $\Omega = \langle x_0, x_1, ..., x_k\rangle$, we denote by $\Omega[x_i, ..., x_j]$ for $i \leq j$ the subpath of Ω connecting x_i to x_j.

We denote the set $\{0, 1, ..., N\}$ by $[N]$.

2.2 Distance oracle

▶ **Definition 1.** Distance product - Let A be an $m \times n$ matrix and B an $n \times p$ matrix, where A and B have entries from $\mathbb{Z} \cup \{\infty\}$. Then their distance product $A \star B$ is an $m \times p$ matrix defined as

$$(A \star B)_{ij} = \underset{k \in [n]}{min} A_{ik} + B_{kj}$$

▶ **Theorem 2** (Alon, Galil and Margalit [2]). *One can compute the distance product of two $n \times n$ matrices with entries in $[-M, M]$ in $\tilde{O}(Mn^\omega)$ time.*

▶ **Theorem 3** (Yuster-Zwick [21]). *Given a directed graph G with edge weights in $[-M, ..., M]$, one can compute in $\tilde{O}(Mn^\omega)$ time a $n \times n$ matrix A, so that the (i, j) entry of the distance product $A \star A$ is the distance between nodes i and j in G.*

By Theorem 3, there exists a distance oracle $\mathcal{A}$ with the following preprocessing and query time; $Preprocess_{\mathcal{A}}(n, m, M) = \tilde{O}(Mn^\omega)$ and $Query_{\mathcal{A}}(n, m, M) = O(n)$. At the preprocess step, we compute the matrix A, and we answer a distance query between two nodes, i and j, by computing the (i, j) entry of $A \star A$.

2.3 Replacement path

Let G be a weighted directed graph, and let $P = \langle v_0, ..., v_k\rangle$ be a shortest path in G from $s = v_0$ to $t = v_k$.

We think of the path $P = \langle v_0, .., v_k\rangle$ as going from left to right, so for $v_i, v_j \in P$ whenever we say v_i is to the left (respectively right) of v_j we mean $i \leq j$ (respectively $i \geq j$).

▶ **Definition 4.** Let D be simple path connecting v_i to v_j for $i < j$. We call D a detour from v_i to v_j for the path P, if $D \cap P = \{v_i, v_j\}$ and $E(D) \cap E(P) = \emptyset$ (note that we need the second requirement for the case that $j = i + 1$).

Let D be a detour for the path P, connecting v_i to v_j. We denote by $Prefix(P, D)$ the path $P[v_0, ..., v_i]$, by $Suffix(P, D)$ the path $P[v_j, ..., v_k]$, and by $S(P, D)$ (S for segment) the path $P[v_i, ..., v_j]$. We say the detour D is skipping $e = (u, v)$ if v_i is to the left of u and v_j is to the right of v.

When P is clear from the context we abbreviate $Prefix(P, D)$ and simply write $Prefix(D)$ instead, and similarly for $Suffix(D)$ and $S(D)$.

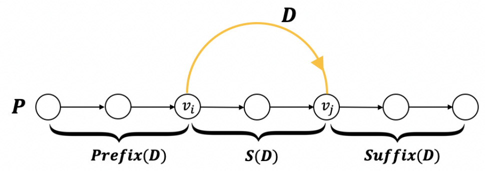

Figure 1 Partition of the path P, with respect to a detour D, into $Prefix(D)$, $S(D)$ and $Suffix(D)$.

The following Lemma is folklore.

▶ **Lemma 5.** *Let P be a shortest path in G connecting two nodes $s, t \in V$, and let $e \in P$. Suppose t is reachable from s in $G \backslash e$, then there exists a detour D skipping e s.t. $Prefix(D) \cdot D \cdot Suffix(D)$ is a shortest path from s to t in $G \backslash e$.*

In the next section we present the idea of reducing the RP problem to the problem of computing shortest cycles for all nodes on a shortest path. The results of this section are applicable for both the algebraic variant and the planar variant as well. In Section 4 we focus on directed graphs with integer weights in the range $[-M, M]$, and in section 5 we focus on directed planar graphs with non negative weights.

3 Replacement paths in weighted directed graphs

Let $s, t \in V$, and $P = \langle v_0 = s, v_1, ..., v_k = t\rangle$ be a shortest path connecting s to t in G.

We first start with two simple observations.

Observation 1. Let D be a detour of P. If we flip the orientation of P, i.e. replace every edge $e = (u, v)$ in P, with a new edge $e^r = (v, u)$, then in the new graph, the concatenation of D with $S(D)$ forms a directed cycle.

Observation 2. Let $e \in P$, and let D be a detour skipping e. D minimizes $w(Prefix(D)) + w(D) + w(Suffix(D))$ if and only if it minimizes $w(D) - w(S(D))$. This holds, as $P = Prefix(D) \cdot S(D) \cdot Suffix(D)$.

These two simple observations lead us to consider a new graph where we flip the orientation of P, and flip the sign of the weights of P. As we prove later, the minimal cycle containing e in the new graph, corresponds to some detour D skipping e, that minimize the expression $w(D) - w(S(D))$. The fact that the weight of the minimal cycle containing e is not smaller than what we are actually looking for $(\underset{D\,skip\,e}{min}\ w(D) - w(S(D)))$, requires some details.

▶ **Definition 6.** Let $Q = \langle u_0, u_1, .., u_N\rangle$ be a path in G, we denote by Q^r the path $\langle u_N, ..., u_1, u_0\rangle$ with new weights $w^r(u_{i+1}, u_i) = -w(u_i, u_{i+1})$.

In other words, we flip the orientation of Q and flip the sign of it's weights.

▶ **Definition 7.** (See Figure 2 for illustration) Denote by $G^r = (V^r, E^r)$ the following graph:

$V^r = V$

$E^r = E \cup E(P^r) \backslash E(P)$

and denote by $G^+ = (V^+, E^+)$ the following graph:

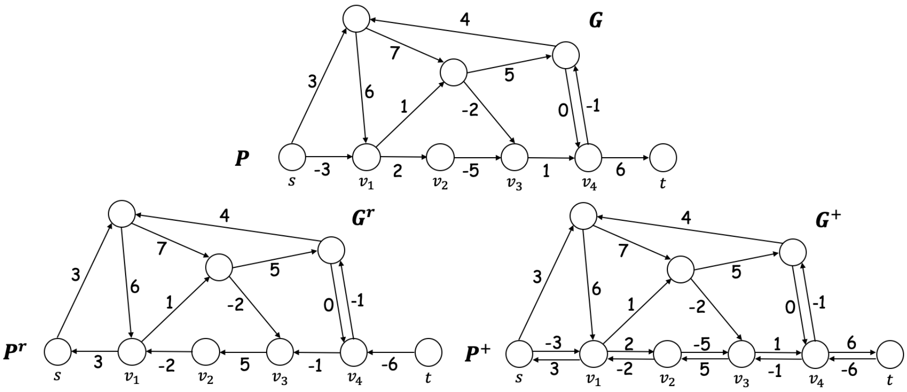
$V^+ = V$

$E^+ = E \cup E(P^r)$

Finally, let $P^+ = P \cup P^r$

▶ Remark 8. If there were already edges in the opposite direction of P then we disregard them. Notice $w(v, u) \geq -w(u, v)$ (as otherwise we would have a negative cycle), hence after adding an edge (v, u) with weight of $-w(u, v)$ there is no reason to keep the original weight of (v, u) when considering shortest paths.

In the following we show that G^+ does not contain negative cycles.



■ **Figure 2** An example of transformation of a graph G into G^r and G^+.

▶ **Lemma 9.** *Consider the graph G^+, and let $u, v \in P^+$. The simple path from u to v that lies in P^+ is a shortest path (notice u can be to the left of v, to the right of v, or even equal to v).*

Proof. We first show that there is a shortest path (not necessarily simple) from u to v that is fully contained in P^+. Let $P' = \langle x_0 = u, ..., x_N = v\rangle$ be a shortest path connecting u to v in G^+. The proof is by induction on the number of edges of P'. The base case, $|P'| = 0$ is clear, so we assume $|P'| \geq 1$. If the first edge of P' belongs to P^+, we can easily continue by induction over $P'[x_1, .., x_N]$ so we assume otherwise. Let $x_i \in P'$ be the first vertex except x_0 itself that belongs to P (x_i might be equal to x_N). We partition P' into two paths, $P'_1 = P'[x_1, .., x_i]$ $P'_2 = P'[x_i, .., x_N]$. Notice that the edges of P'_1 are not in P^+ (hence the edges of P'_1 belong to E). We separate to two cases:

1. x_i is to the right of x_0. In that case we replace P'_1 with the path $P_1 \coloneqq P[x_0, ..., x_i]$.

   $w(P'_1) \geq d(x_0, x_i) = w(P[x_0, ..., x_i])$, where the first inequality follows as P'_1 is edge disjoint from P^+ and therefore is contained in G.

2. x_i is to the left of x_0. In that case we replace P'_1 with the path $P_1 \coloneqq P^r[x_0, ..., x_i]$.

   Notice $P[x_i, ..., x_0] \cdot P'_1$ is a cycle in G hence its weight is non negative, so we have the following:
   $w(P'_1) + w(P[x_i, ..., x_0]) \geq 0 \implies w(P'_1) \geq -w(P[x_i, ..., x_0]) = w^r(P^r[x_0, ..., x_i])$.

Therefore we can replace P'_1 with P_1 without increasing the total weight of P'. By the induction hypothesis we can replace P'_2 with a path P_2 that lies in P^+ without increasing the total weight of P'. The concatenation of the paths P_1 and P_2 is a path from u to v that lies entirely in P^+ and it's length is at most $w(P')$.

Finally, notice we can assume the shortest path from u to v that lies in P^+, lies entirely in P or entirely in P^r, depending if u is to the left or to the right of v (there is no reason to go left and right over the same edge as the weights will cancel each other). ◀

▶ **Corollary 10.** *The graph G^+ does not contain negative cycles (hence G^r as well).*

Proof. Let C be a cycle in G^+. If C does not contain any vertex in P we are done (since the cycle C exists in G, and G does not contain negative cycles), so we assume otherwise. Let $v \in C \cap P$. Note that C is a path from v to itself. By Lemma 9 we can replace C with a simple path in P^+ from v to itself without increasing the cycle weight, that path is simply $\langle v\rangle$ with zero weight. ◀

▶ **Corollary 11.** *The path P^r is a shortest path in the graph G^r.*

Proof. By Lemma 9, P^r is a shortest path in G^+, hence it's also a shortest path in G^r (G^r is a subgraph of G^+ that contains P^r) ◀

▶ **Lemma 12.** *Let $e = (u, v) \in P$. Suppose that v is reachable from u in G^r, then there exists a shortest cycle in G^r containing e^r of the form $D \cdot S(D)^r$ where D is a detour skipping e.*

Proof. Let $C = \langle x_0, ..., x_N\rangle$ be a minimal cycle in G^r containing e^r s.t. $x_0 = v, x_1 = u$ and $x_N = v$.

Let $l \in [N]$ be the largest index s.t. $x_l \in P$ and x_l is to the left of u in P.

Let $r \in \{l+1, ..., N\}$ (i.e. r is greater than l) be the smallest index s.t. $x_r \in P$ (notice it implies that x_r is to the right of v in P). By Corollary 11 we can replace $C[x_0, ..., x_l]$ with $P^r[v, ..., x_l]$ and $C[x_r, ..., v]$ with $P^r[x_r, ..., v]$ without increasing the weight of the cycle. The middle part $D \coloneqq C[x_l, ..., x_r]$ is a detour skipping e, and $P^r[x_r, ..., x_l] = S(D)^r$. Hence $D \cdot S(D)^r$ is a cycle containing e^r with weight of at most $w^r(C)$. ◀

Notice the similarity of Lemma 5 and Lemma 12.

▶ **Definition 13.** Let $e \in P$. We denote by C_e the shortest cycle in G^r containing e^r. Moreover, by Lemma 12 we may assume that C_e is of the form $D \cdot S(D)^r$ for some detour D skipping e. If e^r is not contained in any cycle in G^r, then C_e is defined as having weight infinity (we define this to ease notation).

We denote by d^r the distance function over G^r.

▶ Remark 14. For any edge $e = (u, v) \in P$, $w^r(C_e) = d^r(u, v) - w(u, v)$.

▶ **Theorem 15.** *For any edge $e = (u, v) \in P$, $d_e(s, t) = w(P) + w^r(C_e)$ $(= w(P) - w(u, v) + d^r(u, v))$.*

Proof. From Lemma 5 it follows that $d_e(s,t) = \underset{D\,skip\,e}{min}\ w(Prefix(D)) + w(D) + w(Suffix(D))$ (where the right expression equals to ∞ if there is no such detour D).

From Lemma 12 it follows that $\underset{D\,skip\,e}{min}\ w(D) - w(S(D)) = \underset{C\,contain\,e^r}{min}\ w^r(C)$.

Hence in total we have:

$d_e(s,t) = \underset{D\,skip\,e}{min}\ w(Prefix(D)) + w(D) + w(Suffix(D)) = w(P) + \underset{D\,skip\,e}{min}\ w(D) - w(S(D)) = w(P) + \underset{C\,contain\,e^r}{min}\ w^r(C) = w(P) + w^r(C_e)$ ◀

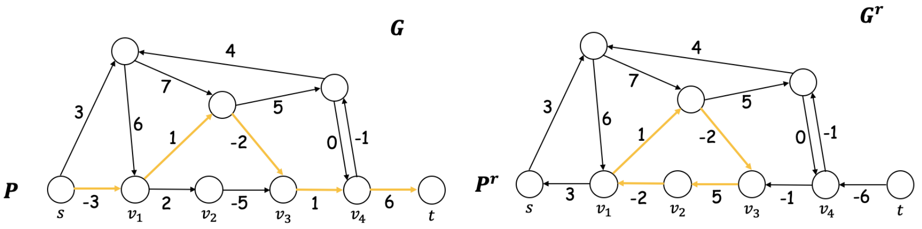


Figure 3 An example of a shortest path in $G \backslash (v_1, v_2)$ and the corresponding minimal cycle in G^r.

4 Replacement paths in graphs with integer weights

In this section, we aim to solve the replacement paths problem for directed graphs with integer weights in $[-M, M]$. Let $\mathcal{A}$ be a distance oracle for directed graphs with integer weights in $[-M, M]$. We let $Preprocess_{\mathcal{A}}(n, m, M)$ be the computation time of $\mathcal{A}$ to preprocess the graph and $Query_{\mathcal{A}}(n, m, M)$ be the computation time of $\mathcal{A}$ to answer a distance query. Finally, we denote by $d_{\mathcal{A}}(u, v)$ the answer of the oracle $\mathcal{A}$ to the query of the distance from u to v.

▶ **Theorem 16.** *Let $\mathcal{A}$ be a distance oracle for weighted directed graph with integer weights in $[-M, M]$. Then, there is an algorithm for the replacement paths problem that runs in $O(Preprocess_{\mathcal{A}}(n, m, M) + n \cdot Query_{\mathcal{A}}(n, m, M))$ time.*

Proof. We first compute G^r in linear time. Then we preprocess G^r to compute a distance oracle $\mathcal{A}$ in $Preprocess_{\mathcal{A}}(n, m, M)$ time, and finally for every edge $e = (u, v) \in P$ we compute $d^r(u, v)$ using the oracle $\mathcal{A}$ in $Query_{\mathcal{A}}(n, m, M)$ time, and store $d_e(s, t) \leftarrow d^r(u, v) - w(e) + w(P)$ $(= w^r(C_e) + w(P))$. The number of calls to the distance query is equal to the number of edges in P which is bounded by n. The correctness of the algorithm follows directly from Theorem 15. ◀

▶ **Theorem 17.** *The replacement paths problem for weighted directed graph, with integer weights in $[-M, M]$ can be solved in deterministic $\tilde{O}(Mn^{\omega})$ time.*

Proof. We denote by $\mathcal{A}$ the distance oracle of $Yuster-Zwick$ (recall Theorem 3). $Preprocess_{\mathcal{A}}(n, m, M) = \tilde{O}(Mn^{\omega})$ and $Query_{\mathcal{A}}(n, m, M) = O(n)$.

Hence, by Theorem 16 we can solve the replacement paths problem in total time of $\tilde{O}(Mn^{\omega}) + O(n^2) = \tilde{O}(Mn^{\omega})$. ◀

Algorithm 1 ReplacementPaths.

```
1. Input: $[G, P, s, t]$
2. Compute $G^r$ (for every edge in $P$, flip its orientation and its sign)
3. Compute a distance oracle $\mathcal{A}$ for the graph $G^r$
4. $d_e(s,t) \leftarrow d_{\mathcal{A}}(u,v) - w(e) + w(P)\ \ for\, e = (u,v) \in P$
5. Output: $[d_e(s,t)\ \ for\, e \in P]$
```

5 Replacement paths in planar graphs

In this section we aim to solve the replacement paths problem for directed planar graphs with non negative edge weights.

▶ **Definition 18** ($MSSP$ **problem).** Let G be a directed planar graph with arbitrary weights (possibly negative). Let $U = \{u_1, u_2, .., u_\ell\}$ be a set of nodes sharing the same face, T be a shortest path tree rooted at u_1, and $L \subseteq U \times V$ be a list of k pairs. The $MSSP$ (Multiple-source shortest paths) problem is as follows; Given G, T, L, output $d\,(u, v)$ for all $(u, v) \in L$.

Let $\mathcal{A}$ be an algorithm that solves the $MSSP$ problem. We denote by $T_{\mathcal{A}}(n, k)$ the running time of $\mathcal{A}$ to solve the $MSSP$ problem for a graph with n nodes, and a list of k pairs.

▶ **Theorem 19** (Klein [11]). *There exists an algorithm $\mathcal{A}$ that solves the $MSSP$ problem in time $T_{\mathcal{A}}(n, k) = O\,(n \log n + k \log n)$.*

Let $e = (u, v) \in P$. By Theorem 15, $d_e\,(s, t) = w\,(P) + d^r\,(u, v) - w\,(u, v)$. That is, in order to solve the RP problem we need to compute $d^r\,(u, v)$ for every $(u, v) \in P$. We will do so by invoking the $MSSP$ algorithm. However, there are two slight obstacles with this approach. The first obstacle is that the nodes of P^r are not necessarily belong to the same face. The second obstacle is that even though the $MSSP$ algorithm can handle negative weights, it requires a computation of a shortest path tree. The graph G^r contains negative weights, thus a naive computation of a shortest path tree would be too time consuming, as the best running time for computing $SSSP$ (single source shortest path) with negative weights in planar graphs is $O\left(n \log^2 n / \log\log n\right)$ [13]. We will face the first obstacle using a standard approach of creating a new planar graph, denoted as H_1, such that all nodes of P^r (more precisely a copy of them) belong to the same face in H_1. For tackling the second obstacle, notice that the only edges in G^r with negative weights belong to $E\,(P^r)$. We will see how we can utilize this to compute a shortest path tree rooted at t in time $O\,(n)$ by creating a new planar graph, denoted by H_2.

▶ **Definition 20.** Given three edges $e_1, e_2, e_3 \in E\,(G^r)$ incident with v, we say that e_2 is between e_1 and e_3 if a counterclockwise traversal of the edges incident with v that begins at e_1 reaches e_2 before it reaches e_3.

Let $v_i \in P^r \backslash \{s,t\}$, and let e be an edge incident with v_i such that $e \notin E(P^r)$. We say that e is to the right of P^r at v_i, if e is between the edge (v_{i+1}, v_i) and the edge (v_i, v_{i-1}). Otherwise, we say that e is to the left of P^r.

▶ **Definition 21** (See Figure 4 for illustration)**.** We define a new graph, denoted as H_1, obtained from G^r, with the following modifications;

1. For every node $v_i \in \{v_1, v_2, ..., v_{k-1}\}$, replace v_i with two new nodes v_i^l and v_i^r (l for left and r for right).
   Notice that we leave s and t as they are. To ease notations, whenever we write v_0^l or v_0^r we actually mean v_0 $(= s)$. Similarly whenever we write v_k^l or v_k^r we actually mean v_k $(= t)$.
2. For every $i \in [k-1], x \in \{l, r\}$, add an edge $\left(v_{i+1}^x, v_i^x\right)$ with weight $w^r(v_{i+1}, v_i)$.
3. Let $v \in \{v_1, v_2, ..., v_{k-1}\}$, and let e be an edge incident with v in G^r such that $e \notin E(P^r)$. If e is to the left of P^r at v, we modify e by substitute v with v^l . Otherwise, we modify e by substitute v with v^r.

▶ **Definition 22** (See Figure 4 for illustration)**.** We define a new graph, denoted as H_2, obtained from H_1, with the following modifications;

For every $i \in [k-1], x \in \{l, r\}$, remove the edge $\left(v_{i+1}^x, v_i^x\right)$ and add an edge (t, v_i^x) with weight $d^r(t, v_i)$.

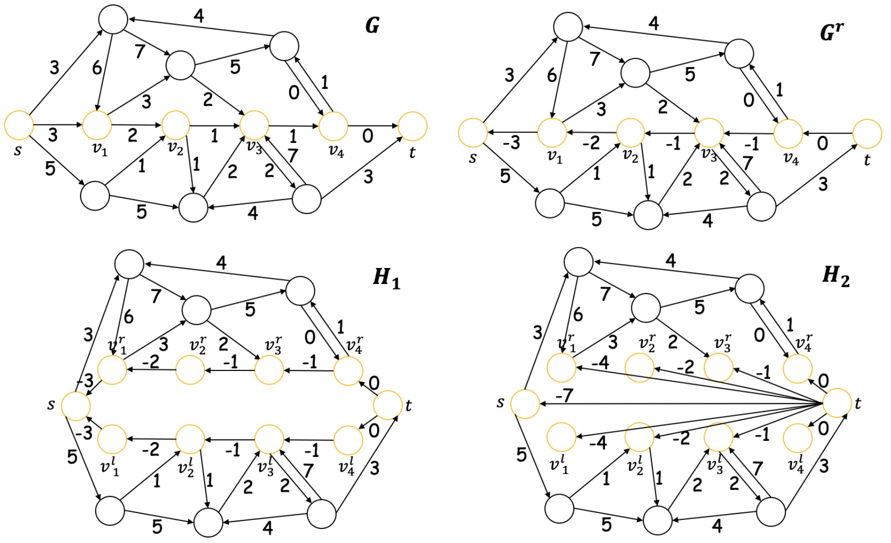

Figure 4 An example of transformation of a planar graph G into G^r,H_1 and H_2.

▶ Remark 23. H_1 and H_2 are planar graphs of size $O(n)$. Moreover, all nodes in the set $\left\{v_0^l, .., v_k^l, v_0^r, .., v_k^r\right\}$ share the same face in H_1.

Let us use the following notation; For every $i \in [k-1], x, y \in \{l, r\}$, $\rho_i^{xy} = d_{H_1}\left(v_i^x, v_{i+1}^y\right)$.

▶ **Lemma 24.** *For every $i \in [k-1]$ we have $d^r(v_i, v_{i+1}) = \min\left\{\rho_i^{ll}, \rho_i^{lr}, \rho_i^{rl}, \rho_i^{rr}\right\}$.*

Proof. Let Q be a path in H^1. We can simulate the path Q in the graph G^r, by replacing every instance of v_i^l and v_i^r with v_i. The resulting path has the same length of Q. In particular this holds for a path from v_i^x to v_{i+1}^y for any choice of $x, y \in \{l, r\}$. Therefore $d^r(v_i, v_{i+1}) \leq \min\left\{\rho_i^{ll}, \rho_i^{lr}, \rho_i^{rl}, \rho_i^{rr}\right\}$. Let P_i be a shortest path from v_i to v_{i+1} in G^r. By Lemma 12 we can assume P_i is of the form $P^r[v_i, ..., u] \cdot D_{uv} \cdot P^r[v, ..., v_{i+1}]$, where

$u \in P^r$ is to the left of v_i, $v \in P^r$ is to the right of v_{i+1}, and D_{uv} is a detour from u to v skipping the edge (v_i, v_{i+1}). The first and last edges of D_{uv} can either be to the left or to the right of P^r. Therefore there are four possible cases for the departure and entrance orientation of D_{uv} with respect to P^r. Let $x \in \{l, r\}$ be the orientation of the first edge of D_{uv}, and $y \in \{l, r\}$ be the orientation of the last edge of D_{uv}. We can simulate P_i in the graph H_1 by replacing all nodes $v_j \in P^r[v_i, ..., u]$ with v_j^x, and all nodes $v_j \in P^r[v, ..., v_{i+1}]$ with v_j^y. The resulting path is a path from v_i^x to v_{i+1}^y, and has the same length of P_i. Therefore $d^r(v_i, v_{i+1}) \geq \rho_i^{xy} \geq \min\left\{\rho_i^{ll}, \rho_i^{lr}, \rho_i^{rl}, \rho_i^{rr}\right\}$. It follows that $d^r(v_i, v_{i+1}) = \min\left\{\rho_i^{ll}, \rho_i^{lr}, \rho_i^{rl}, \rho_i^{rr}\right\}$. ◀

Our current goal is to compute a shortest path tree rooted at t in the graph H_1 in $O(n)$ time.

▶ **Lemma 25.** *For all $v \in V(H_1) (= V(H_2))$, $d_{H_1}(t, v) = d_{H_2}(t, v)$.*

Proof. For the first direction, let us prove $d_{H_1}(t, v) \leq d_{H_2}(t, v)$. Let Q_2 be a shortest path from t to v in H_2. We can simulate the path Q_2 in the graph H_1 as follows; If the first edge of the path Q_2 is of the form (t, v_i^x), then replace that edge with a path from t to v_i^x of length $d^r(t, v_i^x)$. The rest of the simulated path is identical to Q_2. The resulting path has the same length as Q_2. Therefore $d_{H_1}(t, v) \leq w(Q_2) = d_{H_2}(t, v)$. For the second direction, let us prove that $d_{H_2}(t, v) \leq d_{H_1}(t, v)$. Let Q_1 be a shortest path from t to v in H_1. The path $\langle t = v_k^x, ..., v_1^x, v_0^x = s\rangle$ is a shortest path in H_1 for $x \in \{l, r\}$. Let v_i^x be the last node in Q_1 that belongs to the set $\left\{v_k^l, ..., v_1^l, v_0^l, v_k^r, ..., v_1^r, v_0^r\right\}$. We can simulate the path Q_1 in the graph H_2 as follows; Replace the path $Q_1[t, ..., v_i^x]$ with a direct edge (t, v_i^x), and the rest of the simulated path is identical to Q_1. The resulting path is of the same length as Q_1. Therefore $d_{H_2}(t, v) \leq w(Q_1) = d_{H_1}(t, v)$. It follows that $d_{H_1}(t, v) = d_{H_2}(t, v)$. ◀

▶ **Theorem 26** (Henzinger, Klein, Rao and Subramanian [6]). *Let G be a directed planar graph with non negative weights, and let $s \in V(G)$. One can compute a shortest path tree rooted at s in $O(n)$ time.*

Notice that the only edges with negative weights in H_2 are incident with t. Let $c_0 = \min\{d^r(t, v_i) \mid i \in [k-1]\}$. We modify H_2 by increasing the weights of all edges going out from t by $-c_0$. The modified graph is a planar graph with non negative weights. Therefore by Theorem 26, we can compute a shortest path tree rooted at t, denoted as T_2, in the modified graph in $O(n)$ time. T_2 is a shortest path tree for the graph H_2.

Next we show how to modify T_2 to a shortest path tree in the graph H_1.

▶ **Definition 27.** Let $A = \left\{\left(v_{i+1}^x, v_i^x\right) \mid i \in [k-1], x \in \{l, r\}\right\}$. We define a new tree, denoted as T_1, obtained from T_2, with the following modifications;

For every edge $e = (u, v) \in A$, remove the edge $(p(v), v)$ from T_2, and insert the edge (u, v) with weight $d^r(u, v)$ to T_2, where $p(v)$ is the parent of v in T_2.

Note that for every node v_i^x for $x \in \{l, r\}$, the shortest path from t to v_i^x in T_1 is of the same length as in T_2. By Lemma 25, we conclude that T_1 is a shortest path tree in H_1.

▶ **Corollary 28.** *One can compute a shortest path tree T_1 rooted at t in H_1 in $O(n)$ time.*

▶ **Theorem 29.** *Let G be a directed planar graph with non negative weights. Let $\mathcal{A}$ be an algorithm that solves the MSSP problem on a graph with n nodes, and a list of k pairs, in time $T_{\mathcal{A}}(n, k)$. Then, there is an algorithm that solves the replacement paths problem on G, that runs in $O(T_{\mathcal{A}}(2n, 4n))$ time.*

Proof. By Corollary 28, we can compute H_1 and T_1 in $O(n)$ time.

Let $L_1 = \left\langle \left(v_i^x, v_{i+1}^y\right) | i \in [k-1], x \in \{l, r\} \right\rangle$ be a list of $4k$ pairs. By invoking $\mathcal{A}$ with (H_1, T_1, L_1) as an input, we have computed $\rho_i^{xy} = d_{H_1}\left(v_i^x, v_{i+1}^y\right)$ for all $i \in [k-1], x \in \{l, r\}$, in $T_{\mathcal{A}}(2n, 4n)$ time. Let $e = (v_i, v_{i+1}) \in P$. By Theorem 15, $d_e(s,t) = w(P) - w(e) + d^r(v_i, v_{i+1})$. By Lemma 24, $d^r(v_i, v_{i+1}) = \min\left\{\rho_i^{ll}, \rho_i^{lr}, \rho_i^{rl}, \rho_i^{rr}\right\}$. Thus for every edge $e = (v_i, v_{i+1}) \in P$, we store $d_e(s,t) \leftarrow w(P) - w(e) + \min\left\{\rho_i^{ll}, \rho_i^{lr}, \rho_i^{rl}, \rho_i^{rr}\right\}$. The total running time to solve the replacement paths problem is $O(n) + T_{\mathcal{A}}(2n, 4n) = O(T_{\mathcal{A}}(2n, 4n))$. ◀

▶ **Theorem 30.** *Let G be a directed planar graph with non negative weights. Then, there is an algorithm for the replacement paths problem over G that runs in $O(n \log n)$ time.*

Proof. We denote by $\mathcal{A}$ the algorithm of Klein for the $MSSP$ problem [11]. By Theorem 19, $T_{\mathcal{A}}(n, n) = O(n \log n)$. Hence by Theorem 29, we can solve the replacement paths problem in $O(2n \log(4n)) = O(n \log n)$ time. ◀

Abstract

We consider the problem of designing sublinear time algorithms for estimating the cost of minimum metric traveling salesman (TSP) tour. Specifically, given access to a $n \times n$ distance matrix D that specifies pairwise distances between n points, the goal is to estimate the TSP cost by performing only sublinear (in the size of D) queries. For the closely related problem of estimating the weight of a metric minimum spanning tree (MST), it is known that for any $\varepsilon > 0$, there exists an $\tilde{O}(n/\varepsilon^{O(1)})$ time algorithm that returns a $(1+\varepsilon)$-approximate estimate of the MST cost. This result immediately implies an $\tilde{O}(n/\varepsilon^{O(1)})$ time algorithm to estimate the TSP cost to within a $(2+\varepsilon)$ factor for any $\varepsilon > 0$. However, no $o(n^2)$ time algorithms are known to approximate metric TSP to a factor that is strictly better than 2. On the other hand, there were also no known barriers that rule out existence of $(1+\varepsilon)$-approximate estimation algorithms for metric TSP with $\tilde{O}(n)$ time for any fixed $\varepsilon > 0$. In this paper, we make progress on both algorithms and lower bounds for estimating metric TSP cost.

On the algorithmic side, we first consider the graphic TSP problem where the metric D corresponds to shortest path distances in a connected unweighted undirected graph. We show that there exists an $\tilde{O}(n)$ time algorithm that estimates the cost of graphic TSP to within a factor of $(2-\varepsilon_0)$ for some $\varepsilon_0 > 0$. This is the first sublinear cost estimation algorithm for graphic TSP that achieves an approximation factor less than 2. We also consider another well-studied special case of metric TSP, namely, $(1,2)$-TSP where all distances are either 1 or 2, and give an $\tilde{O}(n^{1.5})$ time algorithm to estimate optimal cost to within a factor of 1.625. Our estimation algorithms for graphic TSP as well as for $(1,2)$-TSP naturally lend themselves to $\tilde{O}(n)$ space streaming algorithms that give an 11/6-approximation for graphic TSP and a 1.625-approximation for $(1,2)$-TSP. These results motivate the natural question if analogously to metric MST, for any $\varepsilon > 0$, $(1+\varepsilon)$-approximate estimates can be obtained for graphic TSP and $(1,2)$-TSP using $\tilde{O}(n)$ queries. We answer this question in the negative – there exists an $\varepsilon_0 > 0$, such that any algorithm that estimates the cost of graphic TSP ($(1,2)$-TSP) to within a $(1+\varepsilon_0)$-factor, necessarily requires $\Omega(n^2)$ queries. This lower bound result highlights a sharp separation between the metric MST and metric TSP problems.

Similarly to many classical approximation algorithms for TSP, our sublinear time estimation algorithms utilize subroutines for estimating the size of a maximum matching in the underlying graph. We show that this is not merely an artifact of our approach, and that for any $\varepsilon > 0$, any algorithm that estimates the cost of graphic TSP or $(1,2)$-TSP to within a $(1+\varepsilon)$-factor, can also be used to estimate the size of a maximum matching in a bipartite graph to within an εn additive error. This connection allows us to translate known lower bounds for matching size estimation in various models to similar lower bounds for metric TSP cost estimation.

1 Introduction

In the metric traveling salesman problem (TSP), we are given n points in an arbitrary metric space with an $n \times n$ matrix D specifying pairwise distances between them. The goal is to find a simple cycle (a TSP tour) of minimum cost that visits all n points. An equivalent view of the problem is that we are given a complete weighted undirected graph $G(V, E)$ where the weights satisfy triangle inequality, and the goal is to find a Hamiltonian cycle of minimum weight. The study of metric TSP is intimately connected to many algorithmic developments, and the poly-time approximability of metric TSP and its many natural variants are a subject of extensive ongoing research (see, for instance, [3, 11, 14, 15, 17, 24–28] and references within for some relatively recent developments). In this paper, we consider the following question: can one design sublinear algorithms that can be used to obtain good estimates of the cost of an optimal TSP tour? Since the complete description of the input metric is of size $\Theta(n^2)$, the phrase sublinear here refers to algorithms that run in $o(n^2)$ time.

A standard approach to estimating the metric TSP cost is to compute the cost of a minimum spanning tree, and output two times this cost as the estimate of the TSP cost (since any spanning tree can be used to create a spanning simple cycle by at most doubling the cost). The problem of approximating the cost of the minimum spanning tree in sublinear time was first studied in the graph adjacency-list model by Chazelle, Rubinfeld, and Trevisan [7]. The authors gave an $\tilde{O}(dW/\varepsilon^2)$-time algorithm to estimate the MST cost to within a $(1+\varepsilon)$-factor in a graph where average degree is d, and all edge costs are integers in $[1..W]$. For certain parameter regimes this gives a sublinear time algorithm for estimating the MST cost but in general, this run-time need not be sublinear. Subsequently, in an identical setting as ours, Czumaj and Sohler [10] showed that for any $\varepsilon > 0$, there exists an $\tilde{O}(n/\varepsilon^{O(1)})$ time algorithm that returns a $(1 + \varepsilon)$-approximate estimate of the MST cost when the input is an n-point metric. This result immediately implies an $\tilde{O}(n/\varepsilon^{O(1)})$ time algorithm to estimate the TSP cost to within a $(2 + \varepsilon)$ factor for any $\varepsilon > 0$. However, no $o(n^2)$ query algorithms are known to approximate metric TSP to a factor that is strictly better than 2. On the other hand, there are also no known barriers that rule out existence of $(1 + \varepsilon)$-approximate estimation algorithms for metric TSP with $\tilde{O}(n)$ queries for any fixed $\varepsilon > 0$. In this paper, we make progress on both algorithms and lower bounds for estimating metric TSP cost.

On the algorithmic side, we first consider the *graphic TSP* problem, an important case of metric TSP that has been extensively studied in the classical setting – the metric D corresponds to the shortest path distances in a connected unweighted undirected graph [17, 18, 25]. We give the first $\tilde{O}(n)$ time algorithm for graphic TSP that achieves an approximation factor *strictly better* than 2.

▶ **Theorem 1.1.** *There is an $\tilde{O}(n)$ time randomized algorithm that estimates the cost of graphic TSP to within a factor of $2 - \varepsilon_0$ for some constant $\varepsilon_0 > 0$.*

On the other hand, if we are willing to allow a higher sublinear time, we can get a better approximation ratio.

▶ **Theorem 1.2.** *There is an* $\tilde{O}(n^{1.5})$ *time randomized algorithm that estimates the cost of graphic TSP to within a factor of* $(27/14)$.

At a high-level, our algorithm is based on showing the following: if a graph G either lacks a matching of size $\Omega(n)$ or has $\Omega(n)$ biconnected components (blocks), then the optimal TSP cost is not too much better than $2n$. Conversely, if the graph G has both a large matching and not too many blocks, then we can show that the optimal TSP cost is distinctly better than $2n$. Since we do not know an efficient sublinear algorithm to estimate the number of blocks in a graph G, we work with another quantity that serves as a proxy for this and can be estimated in $\tilde{O}(n)$ time. The main remaining algorithmic challenge then is to estimate sufficiently well the size of a largest matching. This problem is very important by itself, and has received much attention [13,19,20,23,30]; please see a detailed discussion of this problem, and relevant recent developments towards the end of this section. Our $\tilde{O}(n)$ query results utilize the recent result of Kapralov et al. [13] who give an algorithm to approximate the size of maximum matching to within a constant factor (for some very large constant) in $\tilde{O}(n)$ time in the *pair query* model (is there an edge between a given pair of vertices?). We also show that matching size can be estimated to within a factor of 2 in $\tilde{O}(n^{1.5})$ time, crucial to obtaining the approximation guarantee in Theorem 1.2.

Our approach for estimating graphic TSP cost in sublinear time also lends itself to an $\tilde{O}(n)$ space streaming algorithm that can obtain an even better estimate of the cost. To our knowledge, no estimate better than a 2-approximation was known previously. In the streaming model, we assume that the input to graphic TSP is presented as a sequence of edges of the underlying graph G. Any algorithm for this model, clearly also works if instead the entries of the distance matrix are presented in the stream – an entry that is 1 corresponds to an edge of G, and it can be ignored otherwise as a non-edge.

▶ **Theorem 1.3.** *There is an* $O(n)$ *space randomized streaming algorithm that estimates the cost of graphic TSP to within a factor of* $(11/6)$ *in insertion-only streams.*

We next consider another well-studied special case of metric TSP, namely, $(1,2)$-TSP where all distances are either 1 or 2 [2,5,22], and obtain the following result.

▶ **Theorem 1.4.** *There is an* $\tilde{O}(n^{1.5})$ *time randomized algorithm that estimates the cost of* $(1,2)$*-TSP to within a factor of* 1.625.

Throughout the paper, whenever we refer to a graph associated with a $(1,2)$-TSP instance, it refers to the graph G induced by edges of distance 1 in our $\{1,2\}$-metric. At a high-level, the idea underlying our algorithm is to analyze the structure of the graph G induced by edges of distance 1. We design an algorithm to estimate the size of a maximal "matching pair" of G which is defined to be a pair of edge-disjoint matchings. We show that whenever the size of a matching pair is large in a graph G, the TSP cost is distinctly smaller than $2n$, and conversely, if this quantity is not large, the TSP cost is close to $2n$. The main remaining algorithm challenge then is to estimate sufficiently well the size of a maximal matching pair, and we show that this can be done in $\tilde{O}(n^{1.5})$ time.

For $(1,2)$-TSP, an $\tilde{O}(n)$ query algorithm that estimates the cost of $(1,2)$-TSP to within a factor of 1.75 was claimed in [1] but this result is based on the matching size estimation results of [20]. Unfortunately, as confirmed by the authors [21], there is a problem with the proof of one of the statements in the paper – Observation 3.9 – which is crucial for the correctness of the main result. As a result, the $\tilde{O}(d)$ time result in the neighbor query model as well as the $\tilde{O}(n)$ time result in the adjacency matrix, claimed in [20] can no longer be relied upon, and we have chosen to make this paper independent of these results [20]. It is worth mentioning that if the $\tilde{O}(n)$-time matching estimation result of [20] can be shown to hold, then the run-time of both Theorems 1.2 and 1.4 can be improved to $\tilde{O}(n)$ time.

We note that it is easy to show that randomization is crucial to getting better than a 2-approximation in sublinear time for both graphic TSP and $(1, 2)$-TSP (we include the proof of these results in the full version of this paper). The algorithms underlying Theorems 1.2 and 1.4, lend themselves to $\tilde{O}(n)$ space single-pass streaming algorithms with identical approximation guarantees. These sublinear time algorithms motivate the natural question if analogously to metric MST, there exist sublinear time algorithms that for any $\varepsilon > 0$, output a $(1 + \varepsilon)$-approximate estimate of TSP cost for graphic TSP and $(1, 2)$-TSP in $\tilde{O}(n)$ time. We rule out this possibility in a strong sense for both graphic TSP and $(1, 2)$-TSP.

▶ **Theorem 1.5.** *There exists an $\varepsilon_0 > 0$, such that any algorithm that estimates the cost of graphic TSP ($(1, 2)$-TSP) to within a $(1 + \varepsilon_0)$-factor, necessarily requires $\Omega(n^2)$ queries.*

This lower bound result highlights a sharp separation between the behavior of metric MST and metric TSP problems. At a high-level, our lower bound is inspired by the work of Bogdanov et al. [6] who showed that any query algorithm that for any $\varepsilon > 0$ distinguishes between instances of parity equations (mod 2) that are either satisfiable (Yes) or at most $(1/2 + \varepsilon)$-satisfiable (No), requires $\Omega(n)$ queries where n denotes the number of variables. However, the query model analyzed in [6] is different from ours (see more details in Section 4). We first show that the lower bound of [6] can be adapted to an $\Omega(n^2)$ lower bound in our model, and then show that instances of parity equations can be converted into instances of graphic TSP (resp. $(1, 2)$-TSP) such that for some $\varepsilon_0 > 0$, any $(1 + \varepsilon_0)$-approximation algorithm for graphic TSP (resp. $(1, 2)$-TSP), can distinguish between the Yes and No instances of the parity equations, giving us the desired result.

Finally, similar to many classical approximation algorithms for TSP, our sublinear time estimation algorithms utilize subroutines for estimating the size of a maximum matching in the underlying graph. We show that this is not merely an artifact of our approach.

▶ **Theorem 1.6.** *For any $\varepsilon \in [0, 1/5)$, any algorithm that estimates the cost of an n-vertex instance of graphic TSP or $(1, 2)$-TSP to within a $(1 + \varepsilon)$-factor, can also be used to estimate the size of a maximum matching in an n-vertex bipartite graph to within an εn additive error, with an identical query complexity, running time, and space usage.*

This connection allows us to translate known lower bounds for matching size estimation in various models to similar lower bounds for metric TSP cost estimation. In particular, using the results of [4], we can show that there exists an ε_0 such that any randomized single-pass dynamic streaming algorithm for either graphic TSP or $(1, 2)$-TSP that estimates the cost to within a factor of $(1 + \varepsilon_0)$, necessarily requires $\Omega(n^2)$ space.

We conclude by establishing several additional lower bound results that further clarify the query complexity of approximating TSP cost. For instance, we show that if an algorithm can access an instance of graphic TSP by only querying the edges of the graph (via neighbor and pair queries), then any algorithm that approximates the graphic TSP cost to a factor better than 2, necessarily requires $\Omega(n^2)$ queries. This is in sharp contrast to Theorem 1.1, and shows that working with the distance matrix is crucial to obtaining sublinear time algorithms for graphic TSP. We also show that even in the distance matrix representation, the task of *finding a tour* that is $(2 - \varepsilon)$-approximate for any $\varepsilon > 0$, requires $\Omega(n^2)$ queries for both graphic TSP and $(1, 2)$-TSP.

Matching Size Estimation. As the problem of matching size estimation is intimately connected to metric TSP cost estimation, we briefly review some relevant work here. This line of research primarily assumes that we are given a graph $G(V, E)$ with maximum degree d, that can be accessed via *neighbor queries* [12]: (a) for any vertex v, we can query its degree, and (b) for any vertex v and an integer i, we can learn the i_{th} neighbor of v.

Parnas and Ron [23] initiated the study of matching size estimation in sublinear time and gave an $d^{O(\log(d/\varepsilon)}$ time algorithm that estimates the matching size to within a constant factor plus an additive εn error for any $\varepsilon > 0$. Nguyen and Onak [19] presented a new estimation algorithm and showed that it can estimate the matching size to within a factor of 2 plus an additive εn error in $2^{O(d)}/\varepsilon^2$ time. We will refer to this approximation guarantee as a $(2, \varepsilon)$-*approximation* of matching size. Yoshida et al. [30] strongly improved upon the performance guarantee obtained in [19], and showed that a $(2, \varepsilon)$-approximation to matching size can be accomplished in $O(d^4/\varepsilon^2)$ time (in fact, they obtain the stronger $(2 \pm \varepsilon)$-approximation guarantee). The analysis of [30] was further improved by Onak et al. [20] who showed that the state of the art for $(2, \varepsilon)$-approximation of matching size. We note that it is known that any $(O(1), \varepsilon)$-approximate estimate of matching size necessarily requires $\Omega(d)$ queries [23], so the result of [20] is essentially best possible. Unfortunately, as mentioned above, we recently discovered a subtle mistake in the analysis of Onak et al. [21]. Consequently, the best known time complexity for obtaining a $(2, \varepsilon)$-approximate estimate is $\tilde{O}(d^2/\varepsilon^2)$); this weaker result also follows from the work of [20], but does not rely on the incorrect observation in [20].

The difference between a linear dependence versus a quadratic dependence on degree d is however huge in the sublinear time applications when the graph is not very sparse. In particular, while an $\tilde{O}(d)$ query result translates into an $\tilde{O}(n)$ time algorithm in the adjacency matrix model, an $\tilde{O}(d^2)$ query result gives only an $\tilde{O}(n^2)$ time algorithm, which is clearly not useful. Very recently, Kapralov et al. [13] gave an alternate approach based on a vertex "peeling" strategy (originally proposed in [23]) that yields an $(O(1), \varepsilon)$-approximation of matching size in $\tilde{O}(d/\varepsilon^2)$ time. Unfortunately, the constant hidden in the $O(1)$ notation is very large, and efficiently obtaining a $(2, \varepsilon)$-approximation to matching size remains an important open problem. Meanwhile, by directly building on the work of [30], we obtain an $\tilde{O}(n^{1.5})$ time algorithm for a $(2, \varepsilon)$-approximation to matching size in the adjacency matrix model, and it is this algorithm that is used in the results of Theorem 1.2 and Theorem 1.4.

Other Related Work. We note here that there is an orthogonal line of research that focuses on computing an approximate solution in near-linear time when the input is presented as a weighted undirected graph, and the metric is defined by shortest path distances on this weighted graph. It is known that in this model, for any $\varepsilon > 0$, there is an $\tilde{O}(m/\varepsilon^2 + n^{1.5}/\varepsilon^3)$ time algorithm that computes a $(3/2 + \varepsilon)$-approximate solution; here n denotes the number of vertices and m denotes the number of edges [9], and that a $(3/2 + \varepsilon)$-approximate estimate of the solution cost can be computed in $\tilde{O}(m/\varepsilon^2)$ time [8]. It is not difficult to show that in this access model, even when the input graph is unweighted (i.e. a graphic TSP instance), any algorithm that outputs better than a 2-approximate estimate of the TSP cost, requires $\Omega(n + m)$ time even when $m = \Omega(n^2)$. Hence this access model does not admit sublinear time algorithms that beat the trivial 2-approximate estimate.

Organization. In Section 2, we present our algorithms for graphic TSP (Theorem 1.1 and Theorem 1.2). In section 3, we present the 1.625-approximation algorithm of (1, 2)-TSP (Theorem 1.4). In Section 4, we present our lower bound result that rules out possibility of a sublinear-time approximation scheme for both graphic TSP and (1, 2)-TSP (Theorem 1.5).

In Section 5, we present a strong connection between approximating metric TSP cost and estimating matching size (Theorem 1.6). We defer to the full version the proofs of several additional lower bound results on the complexity of approximating graphic TSP and $(1, 2)$-TSP cost.

2 Approximation for Graphic TSP Cost

In this section, we exploit well-known properties of biconnected graphs and biconnected components in graphs to give an algorithm that achieves a $(2 - \frac{1}{7c_0})$-approximation for graphic TSP if we have an efficient algorithm that approximates the maximum matching size within a factor of c_0. We first relate the cost of the TSP tour in a graph to the costs of the TSP tours in the biconnected components of the graph. Next we show that if the graph does not have a sufficiently big matching, it does not have a TSP tour whose length is much better than $2n$. We also show that if a graph has too many degree 1 vertices, or vertices of degree 2, both whose incident edges are bridges, then it does not have a TSP tour of cost much better than $2n$. We then establish the converse - a graph that has a good matching and not too many bad vertices (namely, vertices of degree 1 or articulation points of degree 2), then it necessarily has a TSP tour of cost much better than $2n$. We design $\tilde{O}(n)$ time test for the second condition, allowing us to approximate the cost of an optimal graphic TSP tour in sublinear time together with some known techniques for testing the first condition. In what follows, we first present some basic concepts and develop some tools that will play a central role in our algorithms.

2.1 Preliminaries

An unweighted graph $G = (V, E)$, defines a *graphic metric* in V, where the distance between any two vertices u and v is given by the length of the shortest path between u and v. The *graphic TSP* is the Traveling Salesman Problem defined on such a graphic metric. In this paper our goal is to find a non-trivial approximation to the length of the traveling salesman tour in sublinear time in a model where we are allowed to make *distance queries*. In the distance query model, the algorithm can make a query on a pair of vertices (u, v) and get back the answer $d(u, v)$, the distance between u and v in G.

In a connected graph G, an edge e is a *bridge* if the deletion of e would increase the number of connected components of G. A connected graph with no bridge is called a *2-edge-connected graph*. A maximal 2-edge-connected subgraph of G is called a *2-edge-connected component*. The *bridge-block tree* of a graph is a tree such that the vertex set contains the 2-edge-connected components and the edge set contains the bridges in the graph.

A connected graph G is called *2-vertex-connected* or *biconnected* if when any one vertex is removed, the resulting graph remains connected. In a graph which is not biconnected, a vertex v whose removal increases the number of components is called an *articulation point*. It is easy to prove that any biconnected graph with at least 3 vertices does not have degree 1 vertices. A well-known alternate characterization of biconnectedness is that, a graph G is biconnected if and only if for any two distinct edges, there is a simple cycle that contains them.

A *biconnected component* or *block* in a graph is a maximal biconnected subgraph. Any graph G can be decomposed into blocks such that the intersection of any two blocks is either empty, or a single articulation point. Each articulation point belongs to at least two blocks. If a block is a single edge, then we call this block a *trival block*; otherwise it is a *non-trivial* *block*. A trival block is also a bridge in the graph. The size of a block is the number of vertices in the block. The following lemma shows the relationship between the number of blocks and the sum of the sizes of the blocks.

▶ **Lemma 2.1.** *If a connected graph G has n vertices and k blocks, then the sum of the sizes of the blocks is equal to $n + k - 1$.*

Proof. We prove the lemma by induction on the number k of blocks. The base case is when $k = 1$. In this case, G itself is a block of size n.

For the induction step, we have $k > 1$ and thus the graph has at least one articulation point. Suppose v is an arbitrary articulation point in G. Let $V_1, V_2, \dots, V_j$ be the set of vertices in the connected components of $G \setminus \{v\}$. We have $\sum_{i=1}^{j} |V_i| = n - 1$. Let $G_1, G_2, \dots, G_j$ be the subgraphs of G induced by $V_1 \cup \{v\}, V_2 \cup \{v\}, \dots, V_j \cup \{v\}$. For any G_i, let k_i be the number of blocks in G_i, we have $\sum_{i=1}^{j} k_i = k$. By induction hypothesis, the sum of the sizes of blocks in G_i is $|V_i| + 1 + k_i - 1 = |V_i| + k_i$. So the sum of the sizes of blocks in G is $\sum_{i=1}^{j} |V_i| + k_i = n - 1 + k$. ◀

The block decomposition of a graph has a close relationship with the cost of graphic TSP of the graph.

▶ **Lemma 2.2** (Lemma 2.1 of [16]). *The cost of the graphic TSP of a connected graph $G = (V, E)$ is equal to the sum of the costs of the graphic TSP of all blocks in the graph.*

Together these two lemmas give us a simple lower bound on the cost of the graphic TSP of a graph G (using the fact that the cost of graphic TSP is at least the number of vertices in the graph).

▶ **Lemma 2.3.** *If a graph G has n vertices and k blocks, then the cost of graphic TSP of G is at least $n + k - 1$.*

An *ear* in a graph is a simple cycle or a simple path. An ear which is a path is also called an *open ear* and it has two endpoints, whereas for a cycle, one vertex is designated as the endpoint. An *ear decomposition* of a graph is a partition of a graph into a sequence of ears such the endpoint(s) of each ear (except for the first) appear on previous ears and the internal points (the points that are not endpoints) are not on previous ears. A graph G is biconnected if and only if G has an ear decomposition such that each ear but the first one is an open ear [29]. An ear is *nontrivial* if it has at least one internal point. The following lemma upper bounds the cost of graphic TSP of a biconnected graph.

▶ **Lemma 2.4** (Lemma 5.3 of [25], also a corollary of Lemma 3.2 of [17]). *Given a 2-vertex-connected graph $G = (V, E)$ and an ear-decomposition of G in which all ears are nontrivial, a graphic TSP tour of cost at most $\frac{4}{3}(|V| - 1) + \frac{2}{3}\pi$ can be found in polynomial-time, where π denotes the number of ears.*

We now prove an important lemma that gives an upper bound on the cost of graphic TSP in a biconnected graph in terms of the size of a matching in the graph.

▶ **Lemma 2.5.** *Suppose G is a biconnected graph with at least $n \geq 3$ vertices. If G has a matching M, then the cost of graphic TSP of G is at most $2n - 2 - \frac{2|M|}{3}$.*

Proof. We first find a spanning biconnected subgraph of G that only contains $2n - 2 - M$ edges, then use Lemma 2.4 to bound the cost of graphic TSP.

We construct a spanning biconnected subgraph $G^\star = P_0 \cup P_1 \cup \dots$ recursively: P_0 contains a single edge in M. If $G_{i-1} = P_0 \cup P_1 \cup \cdots \cup P_{i-1}$ is a spanning subgraph of G, let $G^\star = G_{i-1}$ and finish the construction. Otherwise we construct P_i as follows. Let e be an edge in M both whose endpoints are not in G_{i-1}. If there is no such edge, then let e be an arbitrary edge such that at least one of its endpoints is not in G_{i-1}. Let e' be an arbitrary edge in G_{i-1}. By the alternate characterization of biconnectedness, there is a simple cycle C_i that contains both e and e'. Let P_i be the path in C_i that contains e and exactly two vertices in G_{i-1}, which are the endpoints of P_i.

Since P_i contains at least one vertex not in G_{i-1}, the construction always terminates. Note that $P_0 \cup P_1$ is a cycle, and each P_i $(i > 1)$ is an open ear of $G^\star$. So, $(P_0 \cup P_1, P_2, \dots)$ is an open ear decomposition of $G^\star$, which means $G^\star$ is biconnected.

Now we prove that the number of edges in $G^\star$ is at most $2n - 2 - M$. Let n_i be the number of vertices in $G_i \backslash G_{i-1}$. Let G_{-1} be the empty graph, so that n_0=2. Let p_i be the number of edges in P_i and m_i be the number of edges e in M such that $e \cap G_i \neq \emptyset$ and $e \cap G_{i-1} = \emptyset$. (Here we view an edge as a 2-vertex set.) Note that $m_0 = 1$. Suppose $G^\star = G_k$. Then $\sum_{i=1}^k n_i = n$, $\sum_{i=1}^k p_i$ is the number of edges in $G^\star$ and $\sum_{i=1}^k m_i = |M|$. For any $i > 0$, P_i is an open ear whose internal points are not in G_{i-1}. So $n_i = p_i - 1$. If there is an edge $e \in M$ such that $e \cap G_{i-1} = \emptyset$, then P_i contains both endpoints of an edge in M, which means $m_i \leq n_i - 1$. If all edges in M already have an endpoint in G_{i-1}, $m_i = 0 \leq n_i - 1$. So in both cases, $p_i = n_i + 1 = 2n_i - (n_i - 1) \leq 2n_i - m_i$. Also, $p_0 = 1 = 2n_0 - 2 - m_0$. So the number of edges in $G^\star$ is $\sum_{i=0}^k p_i \leq 2n_0 - 2 - m_0 + \sum_{i=1}^k (2n_i - m_i) = 2n - 2 - |M|$.

As $(P_0 \cup P_1, P_2, P_3, \dots, P_k)$ is an open ear decomposition of $G^\star$, the number of ears in G is k. On the other hand, $\sum_{i=0}^k p_i = 1 + \sum_{i=1}^k (n_i + 1) = n - 1 + k$, we have $n - 1 + k \leq 2n - 2 - |M|$, which means $k \leq n - 1 - |M|$. By Lemma 2.4, the cost of graphic TSP of $G^\star$ is at most $\frac{4}{3}(n-1) + \frac{2}{3}k \leq 2(n-1) - \frac{2}{3}|M|$.

Since $G^\star$ is a subgraph of G that contains all the vertices in G, the cost of graphic TSP of G is at most the cost of graphic TSP of $G^\star$, which is at most $2n - 2 - \frac{2}{3}|M|$. ◀

2.2 Approximation Algorithm for Graphic TSP

We now give our sublinear-time algorithm for approximating the cost of graphic TSP of a graph G to within a factor strictly smaller than 2.

We call a vertex v a *bad* vertex if v has degree 1 or is an articulation point with degree 2.

For any given $\delta > 0$, the graphic TSP algorithm performs the following two steps.

1. Obtain an estimate $\hat{\alpha} n$ of the size of maximum matching αn.
2. Obtain an estimate $\hat{\beta} n$ of the number of bad vertices βn.

The algorithm then output $\min\{2n, (2 - \frac{2}{7}(\hat{\alpha} - 2\hat{\beta}))n\}$.

To perform the second step in $\tilde{O}(n)$ distance queries and time, we randomly sample $O(\frac{1}{\delta^2})$ vertices. For each sampled vertex, we can obtain the degree with n queries. The following lemma shows that we can also check whether a degree 2 vertex is an articulation point using distance queries in $O(n)$ time. Then by the Chernoff bound, we can approximate the number of bad vertices with additive error $O(\delta n)$ with a high constant probability.

▶ **Lemma 2.6.** *Suppose a vertex v in a connected graph G has only two neighbors u and w. The following three conditions are equivalent:*

1. *v is an articulation point.*
2. *The edges (u, v) and (v, w) are both bridges.*
3. *For any vertex $v' \neq v$, $|d(u, v') - d(w, v')| = 2$.*

Proof. We first prove the first two conditions are equivalent. If v is an articulation point, then v is in two different blocks. So edge (u, v) and (v, w) are in different blocks, which means v has degree 1 in both blocks. So both blocks are trivial, which means (u, v) and (v, w) are both bridges. If (u, v) and (v, w) are both bridges, then deleting either (u, v) or (v, w) will disconnect u and w, which means deleting v will also disconnect u and w.

Next we prove that the third condition is equivalent to the first two. Suppose v is an articulation point. Since v has degree 2, the graph $G \setminus \{v\}$ has only two components, one containing u and the other containing w. For any vertex $v' \neq v$, without loss of generality, suppose v' is in the same component as u in $G \setminus \{v\}$. Since (u, v) and (v, w) are both bridges in G, any path between v' and w contains u and v. So $d(v', w) = d(v', u) + 2$.

If v is not an articulation point, then u and w are connected in $G \setminus \{v\}$. Let $(u = v_0, v_1, v_2, \dots, v_k = w)$ be the shortest path between u and w in $G \setminus \{v\}$. For any vertex v_i on the path, the distance between v_i and u (resp. w) in $G \setminus \{v\}$ is i (resp. $k - i$). Consider the shortest path between u and v_i in G. If this path does not contain v, then it is the same as the path in $G \setminus \{v\}$. In this case, $d(u, v_i) = i$. If the shortest path contains v, then v must be the second last vertex on the path and w be the third last one. In this case, $d(u, v_i) = k - i + 2$. So $d(u, v_i) = \min\{i, k - i + 2\}$. Similarly, we also have $d(v_i, w) = \min\{i + 2, k - i\}$. Let $v' = v_{\lfloor k/2 \rfloor}$. Since $|i - (k - i)| \leq 1$, we have $i < k - i + 2$ and $k - i < i + 2$, which means $|d(u, v') - d(w, v')| = |i - (k - i)| \leq 2$. ◀

Next, we prove that if α is small or β is large, the cost of graphic TSP is bounded away from n. The following lemma shows that if the size of maximum matching of a graph is small, then the cost of the graphic TSP is large.

▶ **Lemma 2.7.** *For any $\varepsilon > 0$, if the maximum matching of a graph G has size at most $\frac{(1-\varepsilon)n}{2}$, then the cost of graphic TSP of G is at least $(1 + \varepsilon)n$.*

Proof. Suppose the optimal TSP tour is $(v_0, v_1, \dots, v_{n-1}, v_n = v_0)$. Since the size of maximum matching in G is at most $\frac{(1-\varepsilon)n}{2}$, there are at most $\frac{(1-\varepsilon)n}{2}$ edges between pairs (v_i, v_{i+1}) where i is even (resp. odd). So there are at least εn pairs of (v_i, v_{i+1}) that have distance at least 2, which means that the optimal cost of TSP tour of G is $\sum_{i=1}^{n-1} d(v_i, v_{i+1}) \geq n + \varepsilon n = (1 + \varepsilon)n$. ◀

The following lemma shows that if β is large, the cost of graphic TSP is large.

▶ **Lemma 2.8.** *For any $\varepsilon > 0$, if a connected graph G has εn bad vertices, then the cost of graph-TSP of G is at least $(1 + \varepsilon)n - 2$.*

Proof. We first prove by induction on the number of vertices that a graph with k bad vertices has $k - 1$ bridges. The base case is when $n = 2$, the graph has $k = 2$ bad vertices and $1 = k - 1$ bridge.

For the induction step, the graph has n vertices with $n \geq 3$. If G has no degree 1 vertices, then the graph has k articulation points with degree 2. By Lemma 2.6, any edge incident on a degree 2 articulation point is a bridge. So each bad vertex is incident on 2 bridges. On the other hand, a bridge is incident on at most 2 vertices. So there are at least $\frac{2k}{2} = k$ bridges in G. Next, suppose G has degree 1 vertices. Let v be an arbitrary such vertex and let u be its neighbor. Since G is connected and $n \geq 3$, u must has degree at least 2, since otherwise u and v are not connected to other vertices in G. Consider the graph $G \setminus \{v\}$, if u is a bad vertex in G, u has degree 1 in $G \setminus \{v\}$ and is still a bad vertex. So the number of bad vertices in $G \setminus \{v\}$ is $k - 1$. By induction hypothesis, $G \setminus \{v\}$ has at least $k - 2$ bridges. G has at least $k - 1$ bridges since (u, v) is also a bridge.

So G has at least $\varepsilon n - 1$ bridges, and the number of blocks in G is at least $\varepsilon n - 1$. By Lemma 2.3, the cost of graph-TSP of G is at least $n + \varepsilon n - 2 = (1 + \varepsilon)n - 2$. ◀

Finally, the following lemma shows that the cost of graphic TSP is at most $(2-\frac{2}{7}(\hat{\alpha}-2\beta))n$.

▶ **Lemma 2.9.** *If a graph has a matching M of size $\alpha' n$ and the graph has βn bad vertices, the cost of graphic TSP of G is at most $(2-\frac{2}{7}(\alpha'-2\beta))n$.*

Proof. Let $G_1, G_2, \dots, G_k$ be the block decomposition of G. Let n_i be the size of G_i. If $|n_i| \geq 3$, by Lemma 2.5, the cost of the graphic TSP of G_i is at most $2n_i - 3$ since any non-empty graph has a matching of size at least 1. If $|n_i| = 2$, then the graphic TSP of G_i is exactly $2 = 2n_i - 2$. Suppose G has ℓ non-trivial blocks. Then by Lemma 2.2 the cost of graphic TSP of G is at most $\sum_{i=1}^{k}(2n_i - 2) - \ell$, which equals to $2n - 2 - \ell$ by Lemma 2.1.

Let m_i be the size of maximum matching in G_i if G_i is a non-trivial block, and let $m_i = 0$ if G_i is a trivial block. By Lemma 2.5, the cost of the graphic TSP of G_i is at most $2n_i - 2 - \frac{2m_i}{3}$. For any non-trivial block G_i, $M \cap G_i$ is a matching in G_i. So the size of maximum matching in G_i is at least the number of edges in $M \cap G_i$. So by Lemma 2.2 and Lemma 2.1, the cost of graphic TSP of G is at most $\sum_{i=1}^{k}(2n_i - 2 - \frac{2}{3}m_i) = 2n - 2 - \frac{2}{3}|M'|$, where M' is the set of edges in M that are not bridges in G. Let B be the number of bridges in G. We have $2n - 2 - \frac{2}{3}|M'| \leq 2n - 2 - \frac{2}{3}(|M| - B)$.

So there are two upper bounds of the graphic TSP of G – $2n-2-\ell$ and $2n-2-\frac{2}{3}(|M|-B)$. Which bound is better depends on the number of bridges B.

If $B \leq (\frac{4}{7}\alpha' + \frac{6}{7}\beta)n$, the cost of graphic TSP of G is at most

$$2n - 2 - \frac{2}{3}(|M| - B) \leq 2n - \frac{2}{3}(\frac{3}{7}\alpha' - \frac{6}{7}\beta)n = (2 - \frac{2}{7}(\alpha' - 2\beta))n$$

If $B > (\frac{4}{7}\alpha' + \frac{6}{7}\beta)n$, consider the bridge-block tree T of G. T has at least B edges and at least $B + 1$ vertices. Since T is a tree, there are at least $\frac{B}{2}$ vertices of degree at most 2. For any vertex v_T of degree at most 2 in T, if the vertex v_T represents a single vertex v in G, then v is either a degree 1 vertex or a degree 2 articulation point in G, otherwise v_T represents a 2-edge-connected component of size at least 2 in G. So There are at least $\frac{B}{2} - \beta n \geq (\frac{2}{7}\alpha' - \frac{4}{7}\beta)n$ 2-edge-connected components of size at least 2. Since any 2-edge-connected component of size at least 2 has no bridge, each such component of G contains at least 1 non-trivial block in G, implying that $\ell \geq \frac{2}{7}(\alpha' - 2\beta)n$. So the cost of graphic TSP of G is at most $2n - 2 - \ell \leq (2 - \frac{2}{7}(\alpha' - 2\beta))n$. ◀

We summarize the ideas in this section and prove the following lemma.

▶ **Lemma 2.10.** *For any $c_0 > 1$ and $\delta > 0$, suppose $\hat{\alpha} \leq \alpha \leq c_0\hat{\alpha} + \delta$ and $\hat{\beta} - \delta \leq \beta \leq \hat{\beta}$. Then $(2 - \frac{2}{7}(\hat{\alpha} - 2\hat{\beta}))n$ is an approximation of the size of graphic TSP within a factor of $2 - \frac{1}{7c_0} + \delta$.*

Proof. Let $\hat{T} = (2 - \frac{2}{7}(\hat{\alpha} - 2\hat{\beta}))n$. Since $\hat{\beta} \geq \beta$ and $\hat{\alpha} \leq \alpha$, by Lemma 2.9, $T \leq \hat{T}$.

Then we prove that $\hat{T} \leq (2 - \frac{1}{7c_0} + \delta)T$. By Lemma 2.7 and Lemma 2.8, $T \geq \max\{(2 - 2\alpha)n, (1 + \beta)n - 2\}$, which means

$$(2 - \frac{1}{7c_0} + \delta)T \geq (2 - \frac{1}{7c_0})\max\{(2 - 2\alpha)n, (1 + \beta)n\} - 4 + \delta n$$

On the other hand, $\hat{T} \leq (2-\frac{2}{7}(\frac{\alpha}{c_0}-2\beta))n+\frac{6}{7}\delta n$ since $c_0\hat{\alpha}+\delta \leq \alpha$ and $\hat{\beta} \leq \beta+\delta$. For sufficient large n, we have $\delta n - 4 \geq \frac{6}{7}\delta n$, so it is sufficient to prove that $\frac{2-\frac{2}{7}(\frac{\alpha}{c_0}-2\beta)}{\max\{2-2\alpha,1+\beta\}} \leq 2 - \frac{1}{7c_0}$ for any $0 \leq \alpha, \beta \leq 1$ and $c_0 \geq 1$.

Let $\gamma = \frac{\alpha}{c_0} - 2\beta$, $1+\beta = 1 + (\frac{\alpha}{c_0} - \gamma)/2$, so if we fix γ, $\max\{2-2\alpha, 1+\beta\}$ is minimized when $2 - 2\alpha = 1 + (\frac{\alpha}{c_0} - \gamma)/2$. In this case $\alpha = \frac{(2+\gamma)c_0}{4c_0+1}$ and $\max\{2-2\alpha, 1+\beta\} = \frac{4c_0+2}{4c_0+1} - \frac{2c_0}{4c_0+1}\gamma$. If $\gamma \le \frac{1}{2c_0}$,

$$\begin{aligned}\frac{2-\frac{2}{7}(\alpha-2\beta)}{\max\{2-2\alpha,1+\beta\}} &\le \frac{2-\frac{2}{7}\gamma}{\frac{4c_0+2}{4c_0+1}-\frac{2c_0}{4c_0+1}\gamma} = \frac{4c_0+1}{7c_0} - \frac{2-\frac{4c_0+2}{7c_0}}{\frac{4c_0+2}{4c_0+1}-\frac{2c_0}{4c_0+1}\gamma} \\ &\le \frac{4c_0+1}{7c_0} + 2 - \frac{4c_0+2}{7c_0} = 2 - \frac{1}{7c_0}\end{aligned}$$

If $\gamma > \frac{1}{2c_0}$, $\frac{2-\frac{2}{7}(\alpha-2\beta)}{\max\{2-2\alpha,1+\beta\}} < \frac{2-\frac{1}{7c_0}}{1} = 2 - \frac{1}{7c_0}$ since $\beta \ge 0$. So $\hat{T} \le (2 - \frac{1}{7c_0} + \delta)T$. ◀

By Lemma 2.10, we immediately have the following theorem.

▶ **Theorem 2.11.** *For any $\delta > 0$ and $c_0 \ge 1$. Given a graph G with maximum matching size αn, suppose there is an algorithm that uses pair queries, runs in t time, and with probability at least $2/3$, outputs an estimate of the maximum matching size $\hat{\alpha} n$ such that $\hat{\alpha} \le \alpha \le c_0\hat{\alpha} + \delta$. Then there is an algorithm that approximates the cost of graphic TSP of G to within a factor of $2 - \frac{1}{7c_0} + \delta$, using distance queries, in $t + \tilde{O}(n/\delta^2)$ time with probability at least $3/5$.*

Proof. We first use the algorithm in the assumption to obtain an estimate $\hat{\alpha} n$ of the size of maximum matching αn. The following analysis is based on the event that this algorithm is run successfully, which has probability $2/3$.

We then sample $N = \frac{100}{\delta^2}$ vertices. For each sampled vertex v, we first query the distance between v and every vertex in G to obtain the degree of v. If v has degree 2, suppose u and w are the neighbors of v. We query the distance from u and w to every vertex in G. By Lemma 2.6, v is an articulation point if and only if there is no vertex v' such that $|d(u,v') - d(w,v')| \le 1$. So we can check if v is a bad vertex with $O(n)$ distance queries and time. Suppose there are βn bad vertices in G and $(\hat{\beta} - \delta/2)N$ sampled vertices are bad. By Chernoff bound, the probability that $\left|\beta - \hat{\beta} + \delta/2\right| > \delta/2$ is at most $2e^{\frac{\delta^2 N^2}{16}} < 1/15$. We analyze the performance based on the event that $\beta \le \hat{\beta} \le \beta + \delta$.

By Lemma 2.10, $(2 - \frac{2}{7}(\hat{\alpha} - 2\hat{\beta}))$ is a $(2 - \frac{1}{7c_0} + \delta)$ approximation of the size of graphic TSP of G. The probability of failure is at most $1/3 + 1/15 = 2/5$. ◀

Proof of Theorem 1.2. The following theorem whose proof appears in the full version, gives an algorithm for matching size estimation that only uses *pair queries* – given a pair of vertices, is there an edge between them? Note that any pair query can be simulated by a single query to the distance matrix in a graphic TSP instance. ◀

▶ **Theorem 2.12.** *For any $\varepsilon > 0$, there is an algorithm that uses pair queries, runs in $\tilde{O}(n^{1.5}/\varepsilon^2)$ time, and with probability $2/3$, outputs an estimate of the size of a maximal matching within an additive error εn.*

Substituting the above result in Theorem 2.11 and using the fact that a maximum matching has size at most twice the size of a maximal matching (setting $c_0 = 2$, and $\delta = \varepsilon$), we obtain Theorem 1.2.

Proof of Theorem 1.1. Kapralov et al. [13] give an algorithm that uses $\tilde{O}(d)$ queries to approximate the size of maximum matching in a graph with average degree d in the neighbor query model (the approximation ratio is a very large constant). Together with a reduction in [20], this implies a pair query algorithm that uses $\tilde{O}(n)$ queries to estimate matching size to a constant factor. Combined with Theorem 2.11, this implies Theorem 1.1. ◀

2.3 An $O(n)$ Space $(\frac{11}{6})$-Approximate Streaming Algorithm

We show here that our approach above can be extended to the insertion-only streaming model to obtain for any $\varepsilon > 0$, an $(\frac{11}{6} + \varepsilon)$-approximate estimate of the graphic TSP cost using $O(n/\varepsilon^2)$ space. Given a stream containing edges of a graph $G(V, E)$, our algorithm performs the following two tasks simultaneously:

- Find a maximal matching M in G – let αn denote its size.
- Estimate the number of bridges in the maximal matching M, say βn, to within an additive error of εn.

The algorithm outputs $(2 - \frac{2}{3}(\alpha - \beta))n$ as the estimated cost of graphic TSP of G.

In an insertion-only stream, it is easy to compute a maximal stream with $O(n)$ space, we start with M initialized as an empty set, and add a new edge (u, v) into the matching M iff neither u nor v are already in M. It is also easy to check if the edge is a bridge in insertion-only stream with $O(n)$ space. We can maintain a disjoint-set data structure. Whenever an edge arrives (other than e), we merge the connected components of its endpoints. If there is only one component remaining at the end of the stream, then e is not a bridge. Otherwise, e is a bridge.

To estimate the number of bridges in the maximal matching, we sample $N = 100/\varepsilon^2$ edges in the matching, and run in parallel N tests where each test determines whether or not the sampled edge is a bridge. We use $O(n/\varepsilon^2)$ space in total since we sample $N = O(1/\varepsilon^2)$ edges. Suppose there are $\bar{\beta}$ sampled edges are bridges, then by Chernoff bound, $\hat{\beta}n = \frac{\bar{\beta}|M|}{N}$ is an approximation of βn to within additive error εn with probability at least $9/10$.

As stated, this gives us a two-pass algorithm: the first pass for computing the matching M, and the second pass for estimating the number of bridges in M. However, we can do both these tasks simultaneously in a single pass as follows: at the beginning of the stream, we start the process of finding connected components of graph G. Whenever an edge e is added to M, if $|M| < N$, then we create a new instance I_e of the connectivity problem that ignores the edge e. This clearly allows us to test whether or not e is a bridge. Once $|M| > N$, then whenever an edge e is added to M, with probability $\frac{N}{|M|}$, we randomly drop an existing instance, say $I_{e'}$ of connectivity, and create a new instance I_e of connectivity that only ignores edge e (we insert back the edge e' into I_e). Since there are at most N instances of connectivity instance that are running in parallel, the algorithm uses $O(nN) = O(n/\varepsilon^2)$ space.

We defer to the full version the details of the analysis showing that the cost estimate output above is a $(\frac{11}{6} + \varepsilon)$-approximate estimate.

3 (1.625)-Approximation for (1, 2)-TSP Cost in $\tilde{O}(n^{1.5})$ Time

In this section, we give an algorithm that for any $\delta > 0$, approximates the cost of the minimum $(1, 2)$-TSP to within a factor of $1.625 + \delta$ with $\tilde{O}(n^{1.5}/\delta^2)$ queries. The idea of the algorithm is to approximate the size of a maximal "matching pair" of G. In a graph G, a *matching pair* (M_1, M_2) is a pair of edge-disjoint matchings. A *maximal* matching pair is a matching pair (M_1, M_2) such that for any edge $e \notin M_1 \cup M_2$, neither $M_1 \cup \{e\}$ nor $M_2 \cup \{e\}$ is a matching. The size of a matching pair (M_1, M_2) is the sum of the sizes of M_1 and M_2. The following lemma shows that the size of any maximal matching pair is lower bounded by the size of maximum matching in the graph.

▶ **Lemma 3.1.** *Suppose M is a matching in a graph G. Then any maximal matching pair (M_1, M_2) in G has size at least $|M|$.*

Proof. Let X_1 be the set of vertices matched in both M and M_1, and X_2 be the set of vertices matched in both M and M_2. We have $|X_1| + |X_2| \leq 2\,|M_1| + 2\,|M_2|$ since M_1 and M_2 are both matchings. On the other hand, for any edge $e \in M$, if e is either in M_1 or M_2, then both of its endpoints are in X_1 or X_2. If e is neither in M_1 or M_2, then there are edges $e_1 \in M_1$ and $e_2 \in M_2$ that share an endpoint with e since (M_1, M_2) is a maximal matching pair. So both X_1 and X_2 contain at least one endpoint of e. In both case e's endpoints appear twice in X_1 and X_2. So $|X_1| + |X_2| \geq 2\,|M|$, which means $|M_1| + |M_2| \geq |M|$. ◀

If a graph has a large sized matching pair, then the cost of $(1, 2)$-TSP is not very large.

▶ **Lemma 3.2.** *If a graph G with n vertices contains a matching pair (M_1, M_2) of size X, then the cost of $(1, 2)$-TSP of G is at most $2n - \frac{3}{4}X$.*

Proof. Since M_1 and M_2 are both matchings, $M_1 \cup M_2$ only contains paths and cycles of even length. We delete one edge from each cycle in $M_1 \cup M_2$, resulting in a graph that only contains paths. Since the cycles in $M_1 \cup M_2$ are of even length, the size of any cycle is at least 4. We deleted at most $\frac{1}{4}X$ edges, so G contains a set of vertex disjoint paths (including some of length 0, corresponding to isolated vertices), with total size at least $\frac{3}{4}X$. Construct a TSP tour by ordering the paths arbitrarily, orienting each one, and connecting the end of one path with the start of the next, cyclically. The tour contains at least $\frac{3}{4}X$ edges of weight 1, while the remaining edges are of weight 2. So the cost of the tour is at most $2n - \frac{3}{4}X$. ◀

By Lemma 3.1, the maximum matching size is upper bounded by the size of any maximal matching pair. It follows that if the maximum matching size is small, the cost of $(1, 2)$-TSP is large.

▶ **Lemma 3.3.** *For any $\varepsilon > 0$, if the maximum matching of a graph G has size at most $\frac{(1-\varepsilon)n}{2}$, then the cost of $(1, 2)$-TSP of G is at least $(1 + \varepsilon)n$.*

The proof of Lemma 3.3 is similar to the proof of Lemma 2.7 and we omit it here. By Lemma 3.2 and Lemma 3.3, if we can approximate the size of an arbitrary maximal matching pair, then we will get a good approximation of the cost of the $(1, 2)$-TSP.

▶ **Theorem 3.4.** *There is an algorithm that uses pair queries, with probability at least $2/3$, approximates the size of a maximal matching pair with additive error εn using $\tilde{O}(n^{1.5}/\varepsilon^2)$ time.*

The algorithm in Theorem 3.4 is given in the full verstion of this paper. With Theorem 3.4, we can approximate the cost of $(1, 2)$-TSP in a graph G by the size of maximal matching pair.

▶ **Theorem 3.5.** *For any $\delta > 0$, there is an algorithm that estimates the cost of $(1, 2)$-TSP of a graph G within a factor of $1.625 + \delta$ using $\tilde{O}(n^{1.5}/\delta^2)$ queries with probability at least $2/3$.*

Proof. Let $\varepsilon = \delta/2$. We use the algorithm in Theorem 3.4 that approximates the size of a maximal matching pair. Suppose the output of the algorithm is $\bar{X}$. Then, by Theorem 3.4, there is a maximal matching pair of size X such that $\left|X - \bar{X}\right| \leq \varepsilon n$. We output the cost of the $(1, 2)$-TSP of G to be $\bar{T} = 2n - \frac{3}{4}(\bar{X} - \varepsilon n)$. Suppose the optimal $(1, 2)$-TSP has cost T. By Lemma 3.2, $T \leq 2n - \frac{3}{4}X \leq 2n - \frac{3}{4}(\bar{X} - \varepsilon n) = \bar{T}$. On the other hand, by Lemma 3.3, the size of maximum matching in G is at least $(2n - T)/2$. So by Lemma 3.1, $X \geq (2n - T)/2$, which means $\bar{X} \geq (2n - T)/2 - \varepsilon n$. So $\bar{T} \leq 2n - \frac{3}{4}(n - T/2 - 2\varepsilon n) < 1.25n + 0.375T + \delta n$. Since T is the cost of $(1, 2)$-TSP of G, which is at least n, we have $\bar{T} \leq (1.625 + \delta)T$. ◀

▶ Remark 3.6. The algorithm can be generalized to insertion-only streaming model. In insertion-only streaming model, we can compute a maximal matching pair as follows: we set M_1 and M_2 as empty set before the stream. Whenever an edge e comes, we first check if there is an edge in M_1 that shares an endpoint with e. If not, then we add e into M_1. Otherwise, we check if there is an edge in M_2 that shares and endpoint with e. If not, then we add e into M_2. So we get an algorithm that only uses $O(n)$ space to compute a maximal matching pair. We have the following corollary.

▶ **Corollary 3.7.** *There is an insertion-only streaming algorithm that estimates the cost of $(1,2)$-TSP of a graph G within a factor of 1.625 using $O(n)$ space.*

4 An $\Omega(n^2)$ Query Lower Bound for Approximation Schemes

In this section, we prove that there exists an $\varepsilon_0 > 0$, such that any query algorithm for graphic or $(1,2)$-TSP that returns a $(1+\varepsilon_0)$-approximate estimate of optimal cost, requires $\Omega(n^2)$ queries. In order to prove this, we design a new query model for the 3SAT problem and show an $\Omega(n^2)$ query lower bound for 3SAT in this model. We then use a reduction from 3SAT to $(1,2)$-TSP in [22] to prove the lower bound for $(1,2)$-TSP; with some additional changes, we also get an identical lower bound for graphic TSP.

The idea of proving query lower bound for APX-hard problems by reduction from 3SAT is similar to the idea used in [6], and we follow their general approach. However, in [6], the authors study lower bounds for problems in sparse graphs and hence the query model uses only neighbor queries. So in their query model, the lower bound for 3SAT is $\Omega(n)$. In order to prove an $\Omega(n^2)$ query lower bound in the pair query model, we need to design a new query model for 3SAT.

In the 3SAT problem, we are given a 3CNF instance on n variables, and the goal is to estimate the largest fraction of clauses that can be satisfied by any assignment. The algorithm is allowed to perform only one kind of query: is a variable x present in a clause c? If the answer is yes, then the algorithm is given the full information about all variables that appear in the clause c. The proof of the next theorem is deferred to the full version of this paper.

▶ **Theorem 4.1.** *For any $\varepsilon > 0$, any algorithm that with probability at least $2/3$ distinguishes between satisfiable 3CNF instances and 3CNF instances where at most $(7/8+\varepsilon)$ fraction of clauses can be satisfied, needs $\Omega(n^2)$ queries.*

4.1 Reduction from 3SAT to $(1,2)$-TSP

We will utilize an additional property of the hard instances of 3SAT in Theorem 4.1, namely, each variable occurs the same constant number of times where the constant only depends on ε. We denote the number of variables by n, the number of clauses by m, and the number of occurrences of each variable by k; thus $m = kn/3$.

We use the reduction in [22] to reduce a 3SAT instance to a $(1,2)$-TSP instance. In this reduction, there is a gadget for each variable and for each clause. Each of these gadgets has size at most $L = \Theta(k^2)$. Thus the $(1,2)$-TSP contains N vertices where $N \leq L(n+m) = \frac{L(k+3)n}{3}$. Let G_{x_j} be the gadget of variable x_j and G_{c_i} be the gadget of clause c_i. There is a ground graph which is the same for each 3SAT instance. Each variable gadget is connected with the gadgets for clauses that contain that variable. The reduction satisfies the following property. If the 3SAT instance is satisfiable, then the $(1,2)$-TSP instance contains a Hamilton cycle supported only on the weight 1 edges. On the other hand, if at most $m-\ell$ clauses can be satisfied in the 3SAT instance, the $(1,2)$-TSP cost is at least $N + \lceil \ell/2 \rceil$. Thus there is a constant factor separation between the optimal $(1,2)$-TSP cost in the two cases. However, what remains to be shown is that any query algorithm for $(1,2)$-TSP can also be directly simulated on the underlying 3SAT instance with a similar number of queries. The theorem below now follows by establishing this simulation.

▶ **Theorem 4.2.** *There is a constant ε_0 such that any algorithm that approximates the $(1,2)$-TSP cost to within a factor of $(1+\varepsilon_0)$ needs $\Omega(n^2)$ queries.*

Proof. We consider the following stronger queries for $(1,2)$-TSP: for any query (u,v), if u is in a vertex gadget G_{x_j} and v is in a clause gadget G_{c_i} (or vice versa) and x_j occurs in c_i in the 3SAT instance, then the algorithm is given all the edges incident on G_{c_i}. Otherwise the algorithm just learns if the there is an edge between u and v.

Let $\varepsilon = 1/16$, and let the values of k, L and N correspond to this choice for ε according to the redution in Section 4.1. Let $\varepsilon_0 = \frac{k}{32(k+3)L}$. Consider the $(1,2)$-TSP instance reduced from the 3SAT instance generated by the hard distribution in Theorem 4.1 with $\varepsilon = 1/16$. If the 3SAT instance is perfectly satisfiable, then the $(1,2)$-TSP instance has a Hamilton cycle of cost N. If the 3SAT instance satisfies at most $(15/16)$-fraction of clauses, then each Hamilton cycle in the $(1,2)$-TSP instance has cost at least

$$N + (1/8 - \varepsilon)m/2 = N + (1/8 - \varepsilon)kn/6 \geq (1 + \frac{(1/8-\varepsilon)k}{2(k+3)L})N = (1+\varepsilon_0)N$$

For any query (u,v) in the $(1,2)$-TSP instance, we can simulate it by at most one query in the corresponding 3SAT instance as follows: if u is in a vertex gadget G_{x_j} and v is in a clause gadget G_{c_i} (or vice versa), then we make a query of x_j and c_i in the 3SAT instance. If the 3SAT query returns YES and the full information of c_i, then we return all the edges incident on G_{c_i} according to the reduction rule and the full information of c_i. If the 3SAT query returns NO or (u,v) are not in a vertex gadget and a clause gadget respectively, we return YES if (u,v) is an edge in the ground graph and NO otherwise.

By Theorem 4.1, any algorithm that distinguishes a perfectly satisfiable 3SAT instance from an instance where at most $(15/16)$-fraction of the clauses can be satisfied needs $\Omega(n^2)$ queries. So any algorithm that distinguishes a $(1,2)$-TSP instance containing a Hamilton cycle of length N from an instance that has minimum Hamilton cycle of cost $(1+\varepsilon_0)N$ needs $\Omega(n^2)$ queries. ◀

4.2 $\Omega(n^2)$ Lower Bound for Graphic TSP

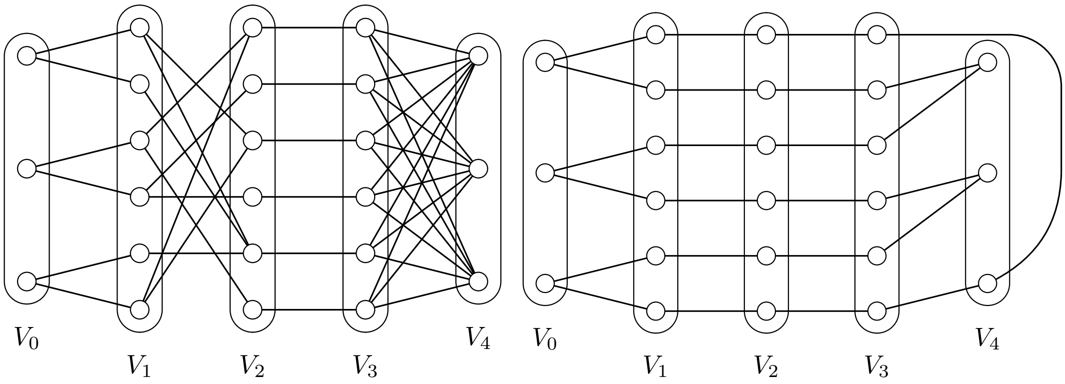
We can reduce an instance of $(1,2)$-TSP to an instance of graphic TSP by adding a new vertex that is adjacent to all other vertices. By doing so, any pair of vertices in the new graph has a distance at most 2. On the other hand, the cost of graphic TSP in the new graph differs by at most 1 from the cost of $(1,2)$-TSP in the old graph. So the $\Omega(n^2)$ query lower bound for $(1,2)$-TSP also holds for the graphic TSP problem.

5 A Reduction from Matching Size to TSP Cost Estimation

In this section, we give a reduction from the problem of estimating the maximum matching size in a bipartite graph to the problem of estimating the optimal $(1,2)$-TSP cost. An essentially identical reduction works for graphic TSP cost using the idea described in Section 4.2.

We will denote the size of the largest matching in a graph G by $\alpha(G)$. Given a bipartite graph $G(V, E)$ with n vertices on each side, we construct an instance $G'(V', E')$ of the $(1,2)$-TSP problem on $4n$ vertices such that the optimal TSP cost on G' is $5n - \alpha(G)$. Thus for any $\varepsilon \in [0, 1/5)$, any algorithm that can estimate $(1,2)$-TSP cost to within a $(1+\varepsilon)$-factor, also gives us an estimate of the matching size in G to within an additive error of $5\varepsilon n$.

We will now describe our construction of the graph G'. For clarity of exposition, we will describe G' as the graph that contains edges of cost 1 – all other edges have cost 2. Suppose the vertex set V of G consists of the bipartition $V_1 = \{v_1^1, v_2^1, \dots, v_n^1\}$ and $V_2 = \{v_1^2, v_2^2, \dots, v_n^2\}$. We construct the graph G' as follows: we start with the graph G, then add three sets of vertices V_0, V_3 and V_4, such that $V_0 = \{v_1^0, v_2^0, \dots, v_{n/2}^0\}$ with $n/2$ vertices, $V_3 = \{v_1^3, v_2^3, \dots, v_n^3\}$ with n vertices, and $V_4 = \{v_1^4, v_2^4, \dots, v_{n/2}^4\}$ with $n/2$ vertices. The graph G' will only have edges between V_j and V_{j+1} ($j = \{0, 1, 2, 3\}$). We will denote the set of edges between V_j and V_{j+1} as $E_{j,j+1}$. For any vertex $v_i^0 \in V_0$, it connects to v_{2i-1}^1 and v_{2i}^1 in V_1. $E_{1,2}$ has the same edges as the edges in G. Each vertex $v_i^2 \in V_2$ is connected to vertex v_i^3 in V_3, that is, vertices in V_2 and V_3 induce a perfect matching (identity matching). Finally, each vertex in V_3 is connected to all the vertices in V_4. See Figure 1(a) for an illustration.



(a) The illustration of G'.

(b) The illustration of tour T, where V_2 and V_3 are arranged with order $(v_{f(1)}^2, \dots, v_{f(6)}^2)$ and $(v_{f(1)}^3, \dots, v_{f(6)}^3)$.

Figure 1 An illustration of the reduction for $n = 6$.

The lemmas below relate matching size in G to $(1,2)$-TSP cost in G'.

▶ **Lemma 5.1.** *Let M be any matching in G. Then there is a $(1,2)$-TSP tour T in G' of cost at most $5n - |M|$.*

Proof. Let $f : [n] \to [n]$ be any bijection from $[n]$ to $[n]$ such that whenever a vertex v_i^1 is matched to a vertex v_j^2 in M, then $f(i) = j$. Consider the following $(1,2)$-TSP tour T: each vertex $v_i^0 \in V_0$ connects to v_{2i-1}^1 and v_{2i}^1 in T; each vertex $v_i^1 \in V_1$ connects to $v_{\lceil (i+1)/2 \rceil}^0$ and $v_{f(i)}^2$ in T. For any $v_{f(i)}^2 \in V_2$, it connects to v_i^1 and $v_{f(i)}^3$ in T. For any vertex $v_{f(i)}^3 \in V_3$, if $i > 1$, it connects to $v_{f(i)}^2$ and $v_{\lceil i/2 \rceil}^4$ in T; if $i = 1$, it connects to $v_{f(i)}^2$ and $v_{n/2}^4$ in T. See Figure 1(b) as an illustration. T is clearly a TSP-tour.

All edges in T are also edges in G' except for possibly some edges between V_1 and V_2. If v_i^1 is matched in M, then $(v_i^1, v_{f(i)}^2)$ is an edge in G', otherwise it is not in G' and thus has weight 2. So T only has $n - |M|$ weight 2 edges, which means T has cost at most $4n + n - |M| = 5n - |M|$. ◀

▶ **Lemma 5.2.** *For any $(1,2)$-TSP tour T in G, T has cost at least $5n - \alpha(G)$.*

To prove Lemma 5.2, we first prove an auxiliary claim.

▷ Claim 5.3. Suppose $G = (V_1, V_2, E)$ is a bipartite graph which has maximum size $\alpha(G)$. For any 2-degree subgraph H of G, if there are at most X vertices in V_1 has degree 2 in H, then there are at most $\alpha(G) + X$ vertices in V_2 which have degree at least 1 in H. Similarly, if there are at most X vertices in V_2 has degree 2 in H, then there are at most $\alpha(G) + X$ vertices in V_1 which have degree at least 1 in H.

Proof. If there are at most X vertices in V_1 has degree 2 in H. We construct H' by deleting an arbitrary edge on each degree 2 vertex in V_1, then construct H'' by deleing an arbitrary edge on each degree 2 vertex in V_2. Since H'' does not have degree two vertex, it is a matching of G. So the number of degree 1 vertices in V_2 in H'' is at most $\alpha(G)$. On the other hand, any vertex in V_2 which has degree at least 1 in H' also has degree 1 in H''. So there are at most $\alpha(G)$ vertices of degree at least 1 in V_2 in H'. Furthermore, since there are only X vertices of degree 2 in V_1 in H, we delete at most X edges in H when constructing H'. So H' has at most X more isolate vertices in V_2 than in H, which means H has at most $\alpha(G) + X$ vertices with degree at least 1 in V_2.

The second part of the claim follows via a similar argument as the first part of the claim. ◁

Proof of Lemma 5.2. Let a_{01} be the number of edges in $T \cap E_{0,1}$, $a_{2,3}$ be the number of edges in $T \cap E_{3,4}$. Let G^X be the intersection graph of G and T. Since the vertices in V_0 only connect to the vertices in V_1 in G', and any vertex in T has degree 2, there are at least $n - a_{01}$ edges incident on V_0 in T are not an edge in G'. On the other hand, since any vertex in V_1 is incident on at at most 1 edge in $E_{0,1}$, there are at least a_{01} vertices in V_1 is connected to a vertex in V_0 in T, which means there are at most $n - a_{01}$ vertices in V_1 has degree 2 in G^X. By Claim 5.3, there are at most $n - a_{01} + \alpha(G)$ vertices in V_2 has edge in G^X. For any isolate vertex in V_2 in T, it has only one edge in G' connecting to V_3, so this vertex must incident on an edge in T which is not in G'. So there are at least $n - (n - a_{01} + \alpha(G)) = \alpha(G) - a_{01}$ edges incident on V_2 in T which is not in G'.

There are $2n$ edges incident on V_3 in T, but among them, there are only a_{23} edges between V_2 and V_3 which is also in G', and there are at most n edges between V_3 and V_4 in T since each vertex has degree only 2. So there are at least $2n - n - a_{23} = n - a_{23}$ edges incident on V_3 which is not in G'. On the other hand, since any vertex in V_2 is incident on at at most 1 edge in $E_{2,3}$, there are at least a_{23} vertices in V_2 is connected to a vertex in V_3 in T, which means there are at most $n - a_{23}$ vertices in V_2 has degree 2 in G^X. By Claim 5.3, there are at most $n - a_{23} + \alpha(G)$ vertices in V_1 has edge in G^X. For any isolate vertex in V_1 in T, it has only one edge in G' connecting to V_0, so this vertex must incident on an edge in T which is not in G'. So there are at least $n - (n - a_{23} + \alpha(G)) = a_{23} - \alpha(G)$ edges incident on V_1 in T which is not in G'.

Since any edge has two endpoints, the number of edges in T but not in G' is at least $((n - a_{01}) + (a_{01} - \alpha(G)) + (n - a_{23}) + (a_{23} - \alpha(G)))/2 = n - \alpha(G)$, which means T has cost at least $4n + n - \alpha(G) = 5n - \alpha(G)$. ◀

▶ **Corollary 5.4.** *For any $\varepsilon \in [0, 1/5)$, any algorithm that can estimate $(1, 2)$-TSP cost to within a $(1 + \varepsilon)$-factor, can be used to estimate the size of a largest matching in a bipartite graph G on $2n$ vertices to within an additive error of $5\varepsilon n$.*

Proof. We use the reduction above to construct a $(1, 2)$-TSP instance G' on $4n$ vertices. By Lemmas 5.1 and 5.2, the optimal TSP cost for G' is $5n - \alpha(G)$. We now run the $(1 + \varepsilon)$-approximation algorithm for $(1, 2)$-TSP on graph G' (note that the reduction can be simulated in each of neighbor query model, pair query model, and the streaming model without altering the asymptotic number of queries used). Suppose the output is C which satisfies $(1-\varepsilon)(5n-\alpha(G)) \leq C \leq (1+\varepsilon)(5n-\alpha(G))$, which means $5n-\alpha(G)-5\varepsilon n < C < 5n-\alpha(G)+5\varepsilon n$. Let $\hat{\alpha} = 5n - C$, we have $\alpha(G) - 5\varepsilon n < \hat{\alpha} < \alpha(G) + 5\varepsilon n$. ◀

Abstract

The classic Ham-Sandwich theorem states that for any d measurable sets in $\mathbb{R}^d$, there is a hyperplane that bisects them simultaneously. An extension by Bárány, Hubard, and Jerónimo [DCG 2008] states that if the sets are convex and *well-separated*, then for any given $\alpha_1, \dots, \alpha_d \in [0, 1]$, there is a unique oriented hyperplane that cuts off a respective fraction $\alpha_1, \dots, \alpha_d$ from each set. Steiger and Zhao [DCG 2010] proved a discrete analogue of this theorem, which we call the *α-Ham-Sandwich theorem.* They gave an algorithm to find the hyperplane in time $O(n(\log n)^{d-3})$, where n is the total number of input points. The computational complexity of this search problem in high dimensions is open, quite unlike the complexity of the Ham-Sandwich problem, which is now known to be PPA-complete (Filos-Ratsikas and Goldberg [STOC 2019]).

Recently, Fearnley, Gordon, Mehta, and Savani [ICALP 2019] introduced a new sub-class of CLS (Continuous Local Search) called *Unique End-of-Potential Line* (UEOPL). This class captures problems in CLS that have unique solutions. We show that for the α-Ham-Sandwich theorem, the search problem of finding the dividing hyperplane lies in UEOPL. This gives the first non-trivial containment of the problem in a complexity class and places it in the company of classic search problems such as finding the fixed point of a contraction map, the unique sink orientation problem and the P-matrix linear complementarity problem.

1 Introduction

The Ham-Sandwich Theorem [41] is a classic result about partitioning sets in high dimensions: for any d measurable sets $S_1, \dots, S_d \subset \mathbb{R}^d$ in d dimensions, there is an oriented hyperplane H that simultaneously *bisects* $S_1, \dots, S_d$. More precisely, if H^+, H^- are the closed half-spaces bounded by H, then for $i = 1, \dots, d$, the measure of $S_i \cap H^+$ equals the measure of $S_i \cap H^-$. The traditional proof goes through the Borsuk-Ulam Theorem [30]. The Ham-Sandwich Theorem is a cornerstone of geometry and topology, and it has found applications in other areas of mathematics.

Let $[n] = \{1, \dots, n\}$. The *discrete* Ham-Sandwich Theorem [28,30] states that for any d finite point sets $P_1, \dots, P_d \subset \mathbb{R}^d$ in d dimensions, there is an oriented hyperplane H such that H bisects each P_i, i.e., for $i \in [d]$, we have $\min\{|P_i \cap H^+|, |P_i \cap H^-|\} \geq \lceil |P_i|/2 \rceil$. We denote the associated search problem as Ham-Sandwich. Lo, Matoušek, and Steiger [28] gave an $n^{O(d)}$-time algorithm for Ham-Sandwich. They also provided a linear-time algorithm for points in $\mathbb{R}^3$, under additional constraints.

There are many alternative and more general variants of both the continuous and the discrete Ham-Sandwich Theorem. For example, Bárány and Matoušek [5] derived a version where measures in the plane can be divided into any (possibly different) ratios by *fans* instead of hyperplanes (lines). A discrete variant of this result was given by Bereg [7]. Schnider [37] and Karasev [27] studied generalizations in higher dimensions. Recently Barba, Pilz, and Schnider [6] showed that four measures in the plane can be bisected with two lines. Higher dimensional generalizations of this result were presented in [9,25]. Zivaljević and Vrećica [44] and independently, Dol'nikov [19] proved a result called the Center Transversal Theorem that interpolates between the Ham-Sandwich Theorem and the Centerpoint Theorem [35]. There is also a no-dimensional version [14] for the Center Transversal Theorem. Schnider [38] presented a generalization based on this result among others.

Here, we focus on a version that allows for dividing the sets into arbitrary given ratios instead of simply bisecting them. The sets $S_1, \dots, S_d \subset \mathbb{R}^d$ are *well-separated* if every selection of them can be strictly separated from the others by a hyperplane. Bárány, Hubard, and Jerónimo [4] showed that if $S_1, \dots, S_d$ are well-separated and convex, then for any given reals $\alpha_1, \dots, \alpha_d \in [0, 1]$, there is a unique hyperplane that divides $S_1, \dots, S_d$ in the ratios $\alpha_1, \dots, \alpha_d$, respectively. Their proof goes through Brouwer's Fixed Point Theorem. Steiger and Zhao [40] formulated a discrete version. In this setup, $S_1, \dots, S_d$ are finite point sets. Again, we need that the (convex hulls of the) S_i are well-separated. Additionally, we require that the S_i follow a weak version of general position. Let $\alpha_1, \dots, \alpha_d \in \mathbb{N}$ be d integers with $1 \leq \alpha_i \leq |S_i|$, for $i \in [d]$. Then, there is a unique oriented hyperplane H that passes through one point from each S_i and has $|H^+ \cap S_i| = \alpha_i$, for $i \in [d]$ [40]. In other words, H simultaneously cuts off α_i points from S_i, for $i \in [d]$. This statement does not necessarily hold if the sets are not well-separated, see Figure 1 for an example.

Steiger and Zhao called their result the *Generalized Ham-Sandwich Theorem*, yet it is not a strict generalization of the classic Ham-Sandwich Theorem. Their result requires that the point sets obey well-separation and weak general position, while the classic theorem always holds without these assumptions. Therefore, we call this result the *α-Ham-Sandwich theorem*, for a clearer distinction. Set $n = \sum_{i \in [d]} |S_i|$. Steiger and Zhao gave an algorithm that computes the dividing hyperplane in $O\left(n(\log n)^{d-3}\right)$ time, which is exponential in d. Later, Bereg [8] improved this algorithm to achieve a running time of $n2^{O(d)}$, which is linear in n but still exponential in d. We denote the associated computational search problem of finding the dividing hyperplane as Alpha-HS.

No polynomial algorithms are known for Ham-Sandwich and for Alpha-HS if the dimension is not fixed, and the notion of approximation is also not well-explored. Despite their superficial similarity, it is not immediately apparent whether the two problems are comparable in terms of their complexity. Due to the additional requirements on an input for Alpha-HS, an instance of Ham-Sandwich may not be reducible to Alpha-HS in general.

A dividing hyperplane for Alpha-HS is guaranteed to exist if the sets satisfy the conditions of well-separation and (weak) general position. Therefore, the search problem Alpha-HS is total, that is, there is a solution for every valid instance. In general, such problems are modelled by the complexity class TFNP (Total Function Nondeterministic Polynomial) of

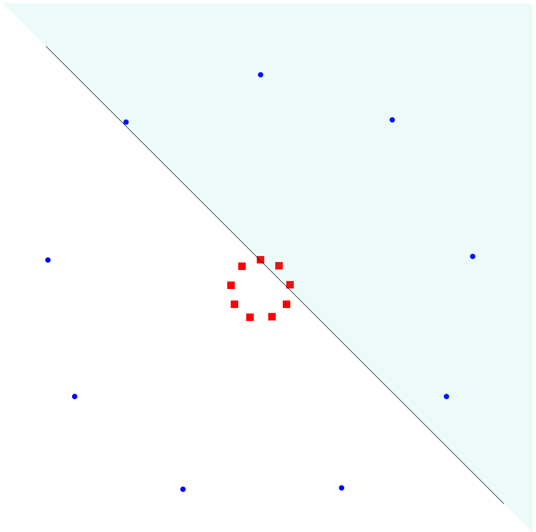

Figure 1 The red (square) and the blue (round) point sets are not well-separated. Every halfplane that contains three red points must contain at least five blue points. Thus, there is no halfplane that contains exactly three red and three blue points.

NP-search problems that always admit a solution. Two popular subclasses of TFNP, originally defined by Papadimitriou [34], are PPA (Polynomial Parity Argument) and its sub-class PPAD (Polynomial Parity Arguments on Directed graphs). These classes contain total search problems where the existence of a solution is based on a parity argument in an undirected or in a directed graph, respectively. Another sub-class of TFNP is PLS (polynomial local search). It models total search problems where the solutions can be obtained as minima in a local search process, while the number of steps in the local search may be exponential in the input size. The class PLS was introduced by Johnson, Papadimitriou, and Yannakakis [26]. A noteworthy sub-class of PPAD $\cap$ PLS is CLS (continuous local search) [18]. It models similar local search problems over a continuous domain using a continuous potential function.

Up to very recently, these complexity classes had mostly been studied in the context of algorithmic game theory. These classes have also found relevance in the study of fairness [33] and markets [10, 12]. However, there have been increasing efforts towards mapping the complexity landscape of existence theorems in high-dimensional discrete geometry. Computing an approximate solution for the search problem associated with the Borsuk-Ulam Theorem is in PPA. In fact, this problem is complete for this class. The discrete analogue of the Borsuk-Ulam Theorem, Tucker's Lemma [42], is also PPA-complete [1, 34]. Therefore, since the traditional proof of the Ham-Sandwich Theorem goes through the Borsuk-Ulam Theorem, it follows that Ham-Sandwich lies in PPA. In fact, Filos-Ratsikas and Goldberg [21] recently showed that Ham-Sandwich is complete for PPA. The (presumably smaller) class PPAD is associated with fixed-point type problems: computing an approximate Brouwer fixed point is a prototypical complete problem for PPAD. The discrete analogue of Brouwer's Fixed Point Theorem, Sperner's Lemma, is also complete for PPAD [34]. The computational version of the Hairy Ball Theorem has recently been shown to be PPAD-complete [24]. In a celebrated result, the relevance of PPAD for algorithmic game theory was made clear when it turned out that computing a Nash-equilibrium in a three player game is PPAD-complete [17]. Subsequently, this was also shown for the two player game [11]. In discrete geometry, finding a solution to the Colorful Carathéodory problem [3] was shown to lie in the intersection

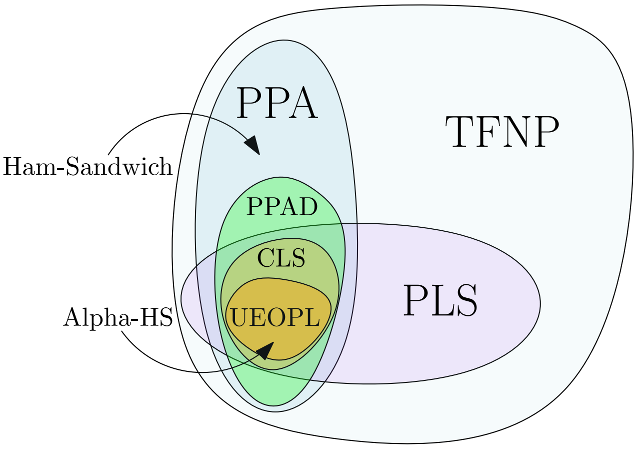

Figure 2 The hierarchy of complexity classes.

PPAD ∩ PLS [31,32]. This further implies that finding a *Tverberg* partition (and computing a centerpoint) also lies in the intersection [29,36,43]. The problem of computing the (unique) fixed point of a contraction map is known to lie in CLS [18].

Recently, at ICALP 2019, Fearnley, Gordon, Mehta, and Savani defined a sub-class of CLS that represents a family of total search problems with unique solutions [20]. They named the class *Unique End of Potential Line* (UEOPL) and defined it through the canonical complete problem UniqueEOPL. This problem is modelled as a directed graph. There are polynomially-sized Boolean circuits that compute the successor and predecessor of each node, and a potential value that always increases on a directed path. There is supposed to be only a single vertex with no predecessor (*start of line*). Under these conditions, there is a unique path in the graph that ends on a vertex (called *end of line*) with the highest potential along the path. This vertex is the solution to UniqueEOPL. Since the uniqueness of the solution is guaranteed only under certain assumptions, such a formulation is called a *promise* problem. Since there seems to be no efficient way to verify the assumptions, the authors allow two possible outcomes of the search algorithm: either report a correct solution, or provide any solution that was found to be in violation of the assumptions. This formulation turns UniqueEOPL into a *non-promise* problem and places it in TFNP, since a correct solution is bound to exist when there are no violations, and otherwise a violation can be reported as a solution. Fearnley et al. [20] also introduced the concept of a *promise-preserving* reduction between two problems A and B, such that if an instance of A has no violations, then the reduced instance of B is also free of violations. This notion is particularly meaningful for non-promise problems.

Contributions. We provide the first non-trivial containment in a complexity class for the α-Ham-Sandwich problem by locating it in UEOPL. More precisely, we formulate Alpha-HS as a non-promise problem in which we allow for both valid solutions representing the correct dividing hyperplane, as well as violations accounting for the lack of well-separation and/or (weak) general position of the input point sets. A precise formulation of the problem is given in Definition 4 in Section 2. We then show a promise-preserving reduction from Alpha-HS to UniqueEOPL. This implies that Alpha-HS lies in UEOPL, and hence in CLS $\subseteq$ PPAD ∩ PLS. See Figure 2 for a pictorial description.

It is not surprising to discover that Alpha-HS lies in PPAD, since the proof of the continuous version in [4] was based on Brouwer's Fixed Point Theorem. The observation that it also lies in PLS is new and noteworthy, putting Alpha-HS into the reach of local search algorithms. In contrast, given our current understanding of total search problems, it is unlikely that the problem Ham-Sandwich would be in PLS.

Since Alpha-HS lies in PPAD $\subseteq$ PPA, it is computationally easier than Ham-Sandwich, which is PPA-complete. This implies the existence of a polynomial-time reduction from Alpha-HS to Ham-Sandwich. A reduction in the other direction is unlikely. It thus turns out that well-separation brings down the complexity of the problem significantly.

Often, problems in TFNP come in the guise of a polynomial-size Boolean circuit with some property. In contrast, Alpha-HS is a purely geometric problem that has no circuit in its problem definition. Apart from the P-Matrix Linear complementarity problem, this is one of the few problems in UEOPL and hence in CLS that do not have a description in terms of circuits.

Our local-search formulation is based on the intuition of rotating a hyperplane until we reach the desired solution. We essentially start with a hyperplane that is tangent to the convex hull of each input set, and we deterministically rotate the hyperplane until it hits a new point. This rotation can be continued whenever the hyperplane hits a new point, until we reach the correct dividing hyperplane. In other words, we can follow a local-search argument to find the solution. We show that this sequence of rotations can be modelled as a canonical path in a grid graph, and we give a potential function that guides the rotation and always increases along this path. Every violation of well-separation and (weak) general position can destroy this path. Furthermore, no efficient methods to verify these two assumptions are known. This poses a major challenge in handling the violations. One of our main technical contributions is to handle the violation solutions concisely.

An alternative approach would have been to look at the dual space of points where we get an arrangement of hyperplanes. The dividing hyperplane could then be found by looking at the correct level sets of the arrangement. However, this approach has the problem that the orientations of the hyperplanes in the original space and the dual space are not consistent. This complicates the arguments on the level sets, so we found it more convenient to use our notion of rotating hyperplanes. We show that we can maintain a consistent orientation throughout the rotation, and an inconsistent rotation is detected as a violation of the promise.

Outline of the paper. We discuss the background about the α-Ham-sandwich Theorem and UniqueEOPL in Section 2. In Section 3, we describe our instance of Alpha-HS and give an overview of the reduction and violation-handling. We conclude in Section 4. The technical details of the reduction and some proofs can be found in the full version of the paper in [13].

2 Preliminaries

2.1 The α-Ham-Sandwich problem

For conciseness, we describe the discrete version of α-Ham-Sandwich Theorem [40] here. The continuous version [4] follows a similar formulation.

Let $P_1, \dots, P_d \subset \mathbb{R}^d$ be a collection of d finite point sets. Let $n_1, \dots, n_d$ denote the sizes of $P_1, \dots, P_d$, respectively. For each $i \in [d]$ we say that the point set P_i represents a unique color and let $P := P_1 \cup \cdots \cup P_d$ denote the union of all the points. A set of points $\{p_1, \dots, p_m\}$ is said to be *colorful* if there are no two points p_i, p_j both from the same color. Indeed a colorful point set can have size at most d.

Weak general position. We say that P has *very weak general position* [40], if for every choice of points $x_1 \in P_1, \ldots, x_d \in P_d$, the affine hull of the set $\{x_1, \ldots, x_d\}$ is a $(d-1)$-flat and does not contain any other point of P. This definition is sufficient for the result of Steiger and Zhao, where they simply call it as weak general position. Of course, this definition of weak general position has no restriction on sets $\{x_1, \ldots, x_d\}$ that contain multiple points from the same color. To simplify our proofs we need a slightly stronger form of general position. We discuss how to deal with very weak general position at the end of Section 3. We say that P has *weak general position* if the above restriction also applies to sets having exactly $d-1$ colors. That means, each color may contribute at most one point to the set, except perhaps one color which is allowed to contribute two points. A certificate for checking violations of weak general position is a set of $d+1$ points whose affine hull has dimension at most $d-1$, with at least $d-1$ colors in the set. Testing whether a point set is in general position can be shown to be NP-Hard, using the result in [23]. It is easy to see that when $d = 2$, weak general position is equivalent to general position.

Well-separation. The point set P is said to be *well-separated* [4, 40], if for every choice of points $y_1 \in \text{conv}(P_{i_1}), \ldots, y_k \in \text{conv}(P_{i_k})$, where $i_1, \ldots, i_k$ are distinct indices and $1 \leq k \leq d$, the affine hull of $\{y_1, \ldots, y_k\}$ is a $(k-1)$-flat. An equivalent definition is as follows: P is well-separated if and only if for every disjoint pair of index sets $I, J \subset [d]$, there is a hyperplane that separates the set $\{\cup_{i \in I} P_i\}$ from the set $\{\cup_{j \in J} P_j\}$ strictly. Formally:

▶ **Lemma 1.** *Let $y_1, \ldots, y_d$ be a colorful set of points in the corresponding $\text{conv}(P_i)$. The affine hull of $y_1, \ldots, y_d$ has dimension $d-2$ or less if and only if there is a partition of $[d]$ into index sets I, J such that $\text{conv}(\{\cup_{i \in I} P_i\}) \cap \text{conv}(\{\cup_{j \in J} P_j\}) \neq \emptyset$.*

Given such a colorful set, the partition of $[d]$ can be computed in $\text{poly}(n, d)$ time. Vice-versa, given such a partition, the colorful set can be computed in $\text{poly}(n, d)$ time.

A certificate for checking violations of well-separation is a colorful set $\{x_1, \ldots, x_d\}$ whose affine hull has dimension at most $d-2$. Another certificate is a partition $I, J \subset [d]$ such that the convex hulls of the indexed sets are not separable. Due to Lemma 1, both certificates are equivalent and either can be converted into the other in polynomial time. To the best of our knowledge, the complexity of testing well-separation is unknown.

Given any set of positive integers $\{\alpha_1, \ldots, \alpha_d\}$ satisfying $1 \leq \alpha_i \leq n_i$, $i \in [d]$, an $(\alpha_1, \ldots, \alpha_d)$*-cut* is an oriented hyperplane H that contains one point from each color and satisfies $|H^+ \cap P_i| = \alpha_i$ for $i \in [d]$, where H^+ is the closed positive half-space defined by H.

▶ **Theorem 2** (α-Ham-Sandwich Theorem [40]). *Let $P_1, \ldots, P_d$ be finite, well-separated point sets in $\mathbb{R}^d$. Let $\alpha = (\alpha_1, \ldots, \alpha_d)$ be a vector, where $\alpha_i \in [n_i]$ for $i \in [d]$.*

1. *If an α-cut exists, then it is unique.*
2. *If P has weak general position, then an α-cut exists for each choice of α.*

That means, every colorful d-tuple of P represents an oriented hyperplane that corresponds to exactly one α-vector. Steiger and Zhao [40] also presented an algorithm to compute the cut in $O(n(\log n)^{d-3})$ time, where $n = \sum_{i=1}^{d} n_i$. The algorithm proceeds inductively in dimension and employs a prune-and-search technique. Bereg [8] improved the pruning step to improve the runtime to $n2^{O(d)}$.

2.2 Unique End of Potential Line

We briefly explain the *Unique end of potential line* problem that was introduced in [20]. More details about the problem and the associated class can be found in the above reference.

▶ **Definition 3** (from [20]). *Let n, m be positive integers. The input consists of*

- *a pair of Boolean circuits $\mathbb{S}, \mathbb{P} : \{0,1\}^n \to \{0,1\}^n$ such that $\mathbb{P}(0^n) = 0^n \neq \mathbb{S}(0^n)$, and*
- *a Boolean circuit $\mathbb{V} : \{0,1\}^n \to \{0,1,\ldots,2^m - 1\}$ such that $\mathbb{V}(0^n) = 0$,*

each circuit having $\text{poly}(n,m)$ *size. The* UniqueEOPL *problem is to report one of the following:*

(U1). *A point $v \in \{0,1\}^n$ such that $\mathbb{P}(\mathbb{S}(v)) \neq v$.*

(UV1). *A point $v \in \{0,1\}^n$ such that $\mathbb{S}(v) \neq v$, $\mathbb{P}(\mathbb{S}(v)) = v$, and $\mathbb{V}(\mathbb{S}(v)) - \mathbb{V}(v) \leq 0$.*

(UV2). *A point $v \in \{0,1\}^n$ such that $\mathbb{S}(\mathbb{P}(v)) \neq v \neq 0^n$.*

(UV3). *Two points $v, u \in \{0,1\}^n$ such that $v \neq u$, $\mathbb{S}(v) \neq v$, $\mathbb{S}(u) \neq u$, and either $\mathbb{V}(v) = \mathbb{V}(u)$ or $\mathbb{V}(v) < \mathbb{V}(u) < \mathbb{V}(\mathbb{S}(v))$.*

The problem defines a graph G with up to 2^n vertices. Informally, $\mathbb{S}(\cdot), \mathbb{P}(\cdot), \mathbb{V}(\cdot)$ represent the *successor*, *predecessor* and *potential* functions that act on each vertex in G. The in-degree and out-degree of each vertex is at most one. There is an edge from vertex u to vertex v if and only if $\mathbb{S}(u) = v$, $\mathbb{P}(v) = u$ and $\mathbb{V}(u) < \mathbb{V}(v)$. Thus, G is a directed acyclic path graph (line) along which the potential strictly increases. The condition $\mathbb{S}(\mathbb{P}(x)) \neq x$ means that x is the start of the line, $\mathbb{P}(\mathbb{S}(x)) \neq x$ means that x is the end of the line, and $\mathbb{P}(\mathbb{S}(x)) = x$ occurs when x is neither. The vertex 0^n is a given start of the line in G.

(U1) is a solution representing the end of a line. **(UV1)**, **(UV2)** and **(UV3)** are violations. **(UV1)** gives a vertex v that is not the end of line, and the potential of $\mathbb{S}(v)$ is not strictly larger than that of v, which is a violation of our assumption that the potential increases strictly along the line. **(UV2)** gives a vertex that is the start of a line, but is not 0^n. **(UV3)** shows that G has more than one line, which is witnessed by the fact that v and u cannot lie on the same line if they have the same potential, or if the potential of u is sandwiched between that of v and the successor of v. Under the promise that there are no violations, G is a single line starting at 0^n and ending at a vertex that is the unique solution. UniqueEOPL is formulated in the non-promise setting, placing it in the class TFNP.

The complexity class UEOPL represents the class of problems that can be reduced in polynomial time to UniqueEOPL. This has been shown to lie in CLS and contains three classical problems in [20]: finding the fixed point of a piecewise-linear contraction map, solving the P-Matrix Linear complementarity problem, and finding the unique sink of a directed graph (with arbitrary edge orientations such that each face has a sink) on the 1-skeleton of a hypercube. Note that finding the fixed point of a contraction map is in CLS [18], but is not known to lie in UEOPL.

A notion of *promise-preserving* reductions is also defined in [20]. Let X and Y be two problems both having a formulation that allows for valid and violation solutions. A reduction from X to Y is said to be promise-preserving, if whenever it is promised that X has no violations, then the reduced instance of Y also has no violations. Thus a promise-preserving reduction to UniqueEOPL would mean that whenever the original problem is free of violations, then the reduced instance always has a single line that ends at a valid solution.

2.3 Formulating the search problem

We formalize the search problem for α-Ham-Sandwich in a non-promise setting:

▶ **Definition 4** (Alpha-HS). *Given d finite sets of points $P = P_1 \cup \ldots \cup P_d$ in $\mathbb{R}^d$ and a vector $(\alpha_1, \ldots, \alpha_d)$ of positive integers such that $\alpha_i \leq |P_i|$ for all $i \in [d]$, the* Alpha-HS *problem is to find one of the following:*

(G1). *An $(\alpha_1, \ldots, \alpha_d)$-cut.*

(GV1). *A subset of P of size $d+1$ and at least $d-1$ colors that lies on a hyperplane.*

(GV2). *A disjoint pair of sets $I, J \subset [d]$ such that $\text{conv}(\{\cup_{i\in I} P_i\}) \cap \text{conv}(\{\cup_{j\in J} P_j\}) \neq \emptyset$.*

Here a solution of type **(G1)** corresponds to a solution representing a valid cut, while solutions of type **(GV1)** and **(GV2)** refer to violations of weak general position and well-separation, respectively. From Theorem 2 we see that a valid solution is guaranteed if no violations are presented, which shows that Alpha-HS is a total search problem.

3 Alpha-HS is in UEOPL

In this section we describe our instance of Alpha-HS in more detail and briefly outline a reduction to UniqueEOPL.

Setup. The input consists of d finite point sets $P_1, \dots, P_d \subset \mathbb{R}^d$ each representing a unique color, of sizes $n_1, \dots, n_d$, respectively, and a vector of integers $\alpha = (\alpha_1, \dots, \alpha_d)$ such that $\alpha_i \in [n_i]$ for each $i \in [d]$. Let k denote the number of coordinates of α that are not equal to 1. Without loss of generality, we assume that $\{\alpha_1, \dots, \alpha_k\}$ are the non-unit entries in α. Let P denote the union $P_1 \cup \dots \cup P_d$. For each $i \in [d]$ we define an arbitrary order $\prec_i$ on P_i. Concatenating the orders $\prec_1, \prec_2, \dots, \prec_d$ in sequence gives a global order $\prec$ on P. That means, $p \prec q$ if $p \in P_i, q \in P_j$ and $i < j$ or $p, q \in P_j$ and $p \prec_j q$.

We follow the notation of [40] to define the orientation of a hyperplane in $\mathbb{R}^d$ that has a non-empty intersection with the convex hull of each P_i. For any hyperplane H passing via $\{x_1 \in \text{conv}(P_1), \dots, x_d \in \text{conv}(P_d)\}$, the normal is the unit vector $\hat{n} \in \mathbb{R}^d$ that satisfies $\langle x_i, \hat{n} \rangle = t$ for some fixed $t \in \mathbb{R}$ and each $i \in [d]$, and $\det \begin{vmatrix} x_1 & x_2 & \dots & x_d & \hat{n} \\ 1 & 1 & \dots & 1 & 0 \end{vmatrix} > 0$, where the columns of the matrix are determined using the order $\prec$. The positive and negative half-spaces of H are defined accordingly. In [4, Proposition 2], the authors show that the choice of $\hat{n}$ does not depend on the choice of $x_i \in \text{conv}(P_i)$ for any i, if the colors are well-separated. Notice that if the colors are not well-separated, then the dimension of the affine hull of $\{x_1, \dots, x_d\}$ may be less than $d - 1$. This makes the value of the determinant above to be zero, so the orientation is not well-defined.

We call a hyperplane *colorful* if it passes through a colorful set $\{p_1, \dots, p_d\} \subset P$. Otherwise, we call the hyperplane *non-colorful*. There is a natural orientation for colorful hyperplanes using the definition above. In order to define an orientation for non-colorful hyperplanes, one needs additional points from the convex hulls of unused colors on the hyperplane. Let H' denote a hyperplane that passes through points of $(d-1)$ colors. Let P_j denote the missing color in H'. To define an orientation for H', we choose a point from $\text{conv}(P_j)$ that lies on H' as follows. We collect the points of P_j on each side of H', and choose the highest ranked points under the order $\prec_j$. Let these points on opposite sides of H' be denoted by x and y. Let z denote the intersection of the line segment xy with H'. By convexity, z is a point in $\text{conv}(P_j)$, so we choose z to define the orientation of H'. The intersection point z does not change if x and y are interchanged, giving a valid definition of orientation for H'. We can also extend this construction to define orientations for hyperplanes containing points from fewer than $d - 1$ colors, but for our purpose this definition suffices. The *α-vector* of any oriented hyperplane H is a d-tuple $(\alpha_1, \dots, \alpha_d)$ of integers where α_i is the number of points of P_i in the closed halfspace H^+ for $i \in [d]$.

3.1 An overview of the reduction

We give a short overview of the ideas used in the reduction from Alpha-HS to UniqueEOPL. The details are technical and we encourage the interested reader to go through the details of our reduction in [13].

Our intuition is based on rotating a colorful hyperplane H to another colorful hyperplane H' through a sequence of local changes of the points on the hyperplanes such that the α-vector of H' increases in some coordinate by one from that of H. We next define the rotation operation in a little more detail. An *anchor* is a colorful $(d-1)$-tuple of P which spans a $(d-2)$-flat. The following procedure takes as input an anchor R and some point $p \in P \setminus R$ and determines the next hyperplane obtained by a rotation. The output is (R', p'), where R' is an anchor and $p' \in P \setminus R'$ is some point.

```
Procedure $(R', p') = NextRotate(R, p)$
1. Let $H$ denote the hyperplane defined by $R \cup \{p\}$ and $t_1$ be the missing color in $R$.
2. If the orientation of $H$ is not well-defined, report a violation of weak general position and well-separation.
3. Let $P_{t_1}^+$ be the subset of $P_{t_1}$ that lies in the closed halfspace $H^+$ and $P_{t_1}^-$ be the subset of $P_{t_1}$ that lies in the open halfspace $H^-$. Let $x \in P_{t_1}^+$ be the highest ranked point according to the order $\prec_{t_1}$ and $y \in P_{t_1}^-$ be the highest ranked point according to $\prec_{t_1}$.
4. If $p$ has color $t_1$ and $|P_{t_1}^+| = n_{t_1}$, report out of range.
5. We rotate $H$ around the anchor $R$ in a direction such that the hyperplane is moving away from $x$ along the segment $xy$ until it hits some point $q \in P$.
6. If the hyperplane hits multiple points at the same time, report a violation of weak general position.
7. If $q$ is not color $t_1$, set $R' := R \cup \{q\} \setminus \{r\}$ and $p' = r$, where $r$ is a point in $R$ with the same color as $q$. Otherwise, set $R' = R$ and $p' = q$.
8. Return $(R', p')$.
```

Figure 3 shows an application of this procedure, rotating H_0 to H_4 through H_1, H_2, H_3.

This rotation function can be interpreted as a function that assigns each hyperplane to the next hyperplane. The set of colorful hyperplanes can be interpreted as vertices in a graph with the rotation function determining the connectivity of the graph.

Canonical path. Each colorful hyperplane H is incident to a colorful set of d points. This set of points defines d possible anchors, and each anchor can be used to rotate H in a different fashion. To define a unique sequence of rotations, we pick a specific order as follows: first, we assume that the colorful hyperplane H whose α-vector is $(1, \ldots, 1)$ is given (we show later how this assumption can be removed). We start at H and pick the anchor that excludes the first color, then apply a sequence of rotations until we hit another colorful hyperplane with α-vector $(2, 1, \ldots, 1)$. Similarly, we move to a colorful hyperplane with α-vector $(3, 1, \ldots, 1)$ and so on until we reach $(\alpha_1, 1, \ldots, 1)$. Then, we repeat this for the other colors in order to reach $(\alpha_1, \alpha_2, 1, \ldots, 1)$ and so on until we reach the target α-vector. This pattern of α-vectors helps in defining a potential function that strictly increases along the path. We can encode this sequence of rotations as a unique path in the UniqueEOPL instance, and we call it *canonical path.*

A natural way to define the UniqueEOPL graph would be to consider hyperplanes as the vertices in the graph. However, this leads to complications. Figure 3 shows a rotation from H_0 to H_4, with α-vectors $(3, 2)$ and $(3, 3)$ respectively. During the rotation, we encounter a hyperplane H_2 for which its α-vector is $(4, 2)$, which differs from our desired sequence of $(3, 2), \ldots, (3, 2), (3, 3)$. This makes it difficult to define a potential function in the graph that strictly increases along the path $v_{H_0}, \ldots, v_{H_4}$ where v_{H_i} is the vertex representing hyperplane H_i. One way to alleviate this problem is to not use H_i as a vertex directly, but the *double-wedge* that is traced out by the rotation from H_i to H_{i+1}. If the α-vector is now measured using the hyperplane that bisects the double-wedge, then we get the desired sequence of $(3, 2), \ldots, (3, 2), (3, 3)$. See Figure 3 for an example.

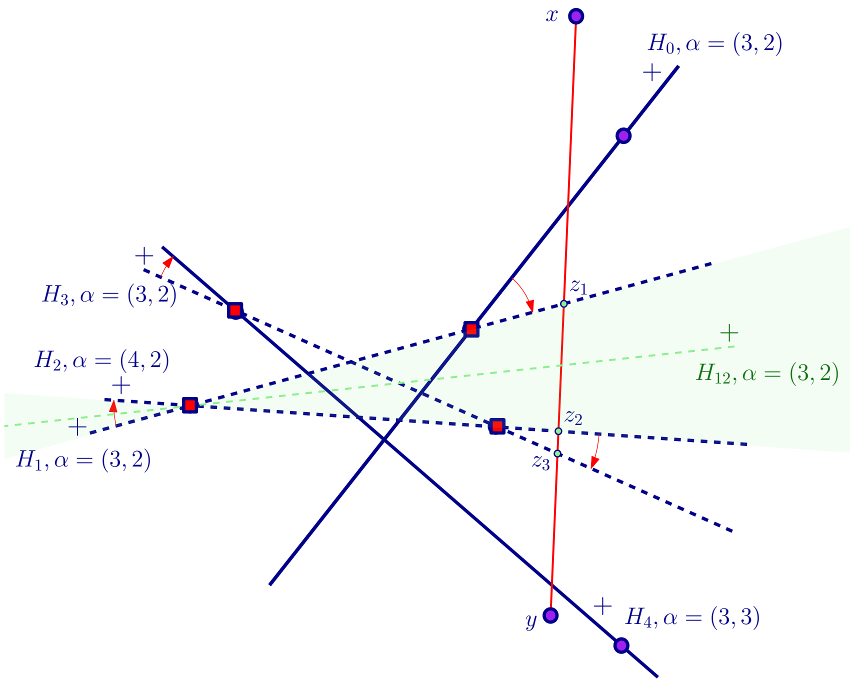

Figure 3 An example showing a sequence of rotations from H_0 to H_4 through H_1, H_2, H_3. Red (square) is the first color and purple (disk) is the second color. This sequence represents a path between two vertices in the UniqueEOPL graph that is generated in the reduction. The double-wedge is shaded and its angular bisector H_{12} has the desired α-vector.

With additional overhead, the rotation function can be extended to double-wedges. This in turn also leads to a neighborhood graph where the vertices are the double-wedges and the rotations can be used to define the edges. The graph is connected and has a grid-like structure that may be of independent interest. Due to lack of space, the description of double-wedges and the associated graph can be found in [13].

Distance parameter and potential function. The α-vector is not sufficient to define the potential function, since the sequence of rotations between two colorful hyperplanes may have the same α-vector. For instance, the bisectors of the rotations in $H_0, \ldots, H_3$ in Figure 3 all have the same α-vector. Hence, we need an additional measurement in order to determine the direction of rotation that increases the α-vector.

Similar to how we define the orientation for a non-colorful hyperplane, let H denote a hyperplane that passes through points of $(d-1)$ colors. Let P_j denote the missing color in H. Let $x, y \in P_j$ be the highest ranked points under $\prec_j$ in H^+ and H^- respectively. Let z denote the intersection of xy and H. We define a distance parameter called *dist-value* of H to be the distance $\|x - z\|$. In Figure 3, we can see that rotating from H_0 to H_4 sweeps the segment xy in one direction, with the dist-value of the hyperplanes increasing strictly. This is sufficient to break ties and hence determine the correct direction of rotation. The precise statement is given in Lemma 6. We can extend this definition to the domain of double-wedges. We define a potential value for each vertex on the canonical path in UniqueEOPL using the sum of weighed components of α-vector and dist-value for the tie-breaker.

Correctness. We show that if there are no violations, we can always apply **Procedure** *NextRotate* to increment the α-vector until we find the desired solution, which implies that the canonical path exists. If the input satisfies weak general position, we can see that the rotating hyperplane always hits a unique point in Step 5, which may be swapped to form a new anchor in Step 7.

The well-separation condition guarantees that the potential function always increases along the rotation. Let H_1, H_2 denote a pair of hyperplanes that are the input and output of **Procedure** *NextRotate* respectively. Let H denote any intermediate hyperplane during the rotation from H_1 to H_2 through the common anchor. Let P_j be the color missing from the anchor and x be the highest ranked point under $\prec_j$ in H_1^+. We say that the orientation of H_2 (resp. H) is *consistent* with that of H_1 if $x \in H_2^+$ (resp. $x \in H^+$). Lemma 5 shows that the orientations are always consistent when H_1 and H_2 are non-colorful hyperplanes even without the assumption of well-separation.

▶ **Lemma 5** (consistency of orientation). *Assume that weak general position holds. Let H_1, H_2 be the input and output of* ***Procedure*** *NextRotate respectively. Let H denote any intermediate hyperplane within the rotation. The orientations of H_1 (resp. H_2) and H are consistent when H_1 (resp. H_2) is a non-colorful hyperplane.*

Proof. Since H_1 is a non-colorful hyperplane, let P_j denote the color missing from H_1. H_1 and H give the same partition of P_j into two sets because the continuous rotation from H_1 to H does not hit any point in P_j. Let x and y be the highest ranked points under $\prec_j$ in each set. Since we have weak general position, the segment xy cannot pass through the anchor of the rotation so that the orientations of H_1 and H are well-defined by the $(d-1)$ colored points in the anchor and the intersections of the hyperplanes with the segment xy. Thus, the determinant defining the normal of the rotating hyperplane from H_1 to H for the orientation is always non-zero. Since the intersection of the rotating hyperplane from H_1 to H and the segment xy moves continuously along xy, by a continuity argument, the normal of the hyperplane does not flip during the rotation. Without loss of generality, assume that $x \in H_1^+$. This implies that x is always in the positive half-space of H and hence H has a consistent orientation as H_1. The same proof holds for H_2. ◀

Next, we show that the dist-value is strictly increasing for all the intermediate hyperplanes in the sequence of rotations from one colorful hyperplane to another colorful hyperplane.

▶ **Lemma 6.** *Assume that weak general position holds. Let H_0 be a colorful hyperplane and H_k be the first colorful hyperplane obtained by a sequence of rotations by* ***Procedure*** *NextRotate. We denote by $H_1, \dots, H_{k-1}$ the non-colorful hyperplanes obtained from the above sequence of rotations. The dist-values of $H_1, \dots, H_{k-1}$ are strictly increasing.*

Proof. Let P_j denote the color missing from H_1. Then, $H_2, \dots, H_{k-1}$ all miss the color P_j, otherwise H_k is not the first colorful hyperplane obtained by the rotations. Therefore, each H_i gives the same partition of P_j into two sets for $i = 1, \dots, k-1$ because the continuous rotations from H_1 to H_{k-1} does not hit any point in P_j. Let x and y be the highest ranked points under $\prec_j$ in each set. Without loss of generality, assume that $x \in H_1^+$. Since $H_1, \dots, H_{k-1}$ are non-colorful hyperplanes, by Lemma 5, the consistent of the orientation can carry from H_1 to H_2 and so on. Then we have $x \in H_1^+, \dots, x \in H_{k-1}^+$ and $y \in H_1^-, \dots, y \in H_{k-1}^-$. Let $z_1 = xy \cap H_1, \dots, z_{k-1} = xy \cap H_{k-1}$. According to Step 5 of **Procedure** *NextRotate*, each rotation is performed by moving away from x along the segment xy. Hence we have $\|x - z_1\| < \|x - z_2\| < \cdots < \|x - z_{k-1}\|$. ◀

The last step for proving that the potential function always increases along the canonical path is to show that the α-vector increases in some coordinate from one colorful hyperplane to another colorful hyperplane through **Procedure** *NextRotate*. This requires the assumption of well-separation. Lemma 7 shows that if the orientations of H_1, H_2 and H are inconsistent, then well-separation is violated. By the contrapositive, if well-separation is satisfied, then all hyperplanes in the rotation always give consistent orientations. Then, it implies that rotating from a colorful hyperplane H_0 to another colorful hyperplane H_k through a sequence of non-colorful hyperplanes that miss color P_j, we have $H_0^+ \cap P_j \subset H_k^+ \cap P_j$ and H_k contains one additional point in P_j that is hit by the last rotation. Therefore, α_j is increased by 1 and other α_is keep the same value because of the way we swap the point of repeated color with the one in the anchor and the direction of rotation.

▶ **Lemma 7.** *Assume that weak general position holds. Let H_1, H_2 be the input and output of* ***Procedure*** *NextRotate respectively. Let R denote the anchor of the rotation from H_1 to H_2, and P_j denote the color missing from R. Let H denote any intermediate hyperplane within the rotation. If the orientations of H_1 (resp. H_2) and H are inconsistent, then H_1 (resp. H_2) is a colorful hyperplane and we can find a colorful set $R \cup \{x'\}$ lying in a $(d-2)$-flat where $x' \in \operatorname{conv}(P_j)$, in $O(d^3)$ arithmetic operations. The set $R \cup \{x'\}$ witnesses the violation of well-separation.*

Proof. Since the orientations of H_1 and H are inconsistent, H_1 must be a colorful hyperplane by Lemma 5. Therefore, the point in H_1 that is not in the anchor is in P_j, denoted by p.

Let x and y be the points defined in Lemma 5 such that $x, y \in P_j$, and x and y are on different sides of H_1 and H. The $(d-2)$-flat containing R separates H_1 and H into two $(d-1)$-dimensional half-subspaces each. Let $H^+_{1,R}$ and H^+_R be the half-subspaces intersecting with xy on H_1 and H respectively, and let us denote the intersection points by z_p and z, respectively. The opposite half-subspaces are denoted by $H^-_{1,R}$ and H^-_R, respectively. By definition of the orientation for non-colorful hyperplanes, the orientation of H is defined by $R \cup \{z\}$. Although the orientation of H_1 is defined by $R \cup \{p\}$, if we consider the determinant defining the orientation using $R \cup \{z_p\}$, it gives an orientation consistent with that of H. Therefore, it must be that $p \in H^-_{1,R}$. Then, we can see that the line segment pz_p intersects the $(d-2)$-flat of R. We can compute z_p and also the intersection point x' of pz_p and the $(d-2)$-flat of R by solving systems of linear equations with d equations and d variables in $O(d^3)$ arithmetic operations. Since $x' \in \operatorname{conv}(P_j)$, $R \cup \{x'\}$ is a colorful set contained in the $(d-2)$-flat of R. ◀

In order to guarantee that there is no other path in UniqueEOPL apart from the canonical path, we introduce self-loops for vertices that are not on the canonical path. The detailed proof in [13] shows that if there are no violations, then the reduced instance of UniqueEOPL only gives a **(U1)** solution, which readily translates to a **(G1)** solution, so our reduction is promise-preserving, and this can be done in polynomial time.

Since we do not know the hyperplane with α-vector $(1, \ldots, 1)$ in advance, we split the problem into two sub-problems: in the first we start with any colorful hyperplane. We reverse the direction of the canonical path determined by the potential and construct an Alpha-HS instance for which the vertex with α-vector $(1, \ldots, 1)$ is the solution. In the second, we use this vertex as the input to the main Alpha-HS instance. If the input is free of violations, then both sub-problems give valid solutions and together they answer the original question. To merge the two sub-problems into one UniqueEOPL instance, we can make two layer copies of the vertices with an additional flag variable to indicate which copy is in the first layer. In the first layer, we build the canonical path from any colorful vertex to the colorful vertex with α-vector $(1,\ldots,1)$, which connects to the colorful vertex with α-vector $(1,\ldots,1)$ in the second layer. Similarly, in the second layer, we build the canonical path from the colorful vertex with α-vector $(1,\ldots,1)$ to the vertex with the target α-vector. Then, we can also easily modify the potential function accordingly.

An alternative approach is to define the canonical path directly from any colorful vertex to the target vertex. In this case, each coordinate of the current α-vector may increase or decrease depending on the signed distance to the target α-vector along the canonical path. However, the potential function can still be defined in a way that it is strictly increasing along the path.

Handling violations. The reduction maps violations of Alpha-HS to violations of the UniqueEOPL instance, and certificates for the violations can be recovered from additional processing. When a violation of weak general position is witnessed on a vertex that lies on the canonical path, a hyperplane incident to d colors may contain additional points. This in turn implies that some α-cut is missing, so that the correct solution for the target may not exist. For cuts that exist in spite of the violation, reporting either the correct solution or the violation are sufficient for Alpha-HS.

In addition, the (highest-ranked) points x, y from the missing color that we choose to define the orientation of a non-colorful hyperplane may form a segment xy that passes through the $(d-2)$-flat spanned by the anchor. In that case the orientation of the hyperplane is not well-defined. In the reduction, these problematic vertices are removed from the canonical path, thereby creating some additional starting points and end points in the reduced instance. These violations can be captured by **(U1)** with a wrong α-vector or **(UV2)**. Furthermore, the hyperplanes that contain the degenerate point sets could be represented by different choices of anchors and an additional point on the plane. Each such pair represents a vertex in the reduced instance. We join these vertices in the form of a cycle in the UniqueEOPL instance with all vertices having the same potential value, so that the violations can also be captured by **(UV1)** and **(UV3)**.

When a violation of well-separation is witnessed on a vertex on the canonical path, the orientations of the two hyperplanes paired by **Procedure** *NextRotate* may be inconsistent, which may not guarantee that the α-vector is incremented in one component by one (See Figure 4). Hence, the canonical path is split into two paths that can be captured by **(UV2)**. Furthermore, a violation of well-separation also creates multiple colorful hyperplanes with the same α-vector (See Figure 4, left). Two vertices in the UniqueEOPL graph with the same potential value, which could correspond to some colorful or non-colorful hyperplanes, can be reported by **(UV3)**. We show that this gives a certificate of violation of well-separation in the following lemmas, where m_0 is the number of bits used to represent each coordinate of points of P.

▶ **Lemma 8.** *Given two colorful hyperplanes H_p, H_q with the same α-vector, we can find a colorful set $\{x_1 \in \operatorname{conv}(P_1), \ldots, x_d \in \operatorname{conv}(P_d)\}$ that lies on a $(d-2)$-flat in $\operatorname{poly}(n, d, m_0)$ time.*

▶ **Lemma 9.** *Given two non-colorful hyperplanes that both contain $d-1$ points and have the same missing color, α-vector and dist-value, we can find a colorful set of points $\{x_1 \in \operatorname{conv}(P_1), \ldots, x_d \in \operatorname{conv}(P_d)\}$ that lies on a $(d-2)$-flat in $\operatorname{poly}(n, d, m_0)$ time.*

For the second output $(\mathbb{V}(v) < \mathbb{V}(u) < \mathbb{V}(\mathbb{S}(v)))$ of **(UV3)**, there are two cases to consider. In the first case, if both v and $\mathbb{S}(v)$ correspond to the same α-vector, then u also has the same α-vector and its dist-value is between that of v and $\mathbb{S}(v)$. Since rotating the hyperplane from

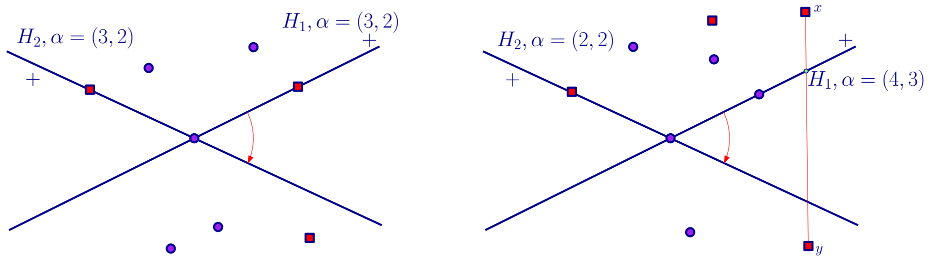

Figure 4 The examples show two sets of points that are not well-separated. Purple (circle) represents the first color and red (square) represents the second color. In both examples the rotation procedure does not increase the α-vector. Both examples show that the orientation of the hyperplane may be flipped after the rotation, so the resulting α-vector can go wrong.

v to $\mathbb{S}(v)$ does not pass through u, we can find a different hyperplane that is interpolated by v and $\mathbb{S}(v)$ and has the same dist-value as u. Hence, we apply Lemma 9 again to find a witness of the violation. For the second case that the α-vector of $\mathbb{S}(v)$ increases in one coordinate by one from that of v, since the role of dist-value is dominated by the role of α-vector in the potential function, the dist-value of u can be arbitrarily large. Therefore, we may not be able to apply the interpolation technique from the first again. We argue that we can transform P to a point set P' satisfying $\text{conv}(P'_i) \subseteq \text{conv}(P_i)$ for all $i \in [d]$, such that the hyperplanes of v and u become colorful. Then, we apply Lemma 8 to show that P' is not well-separated, which also implies that P is not well-separated. The precise statement and proof are given in [13]. We also show

- how to compute a **(GV1)** solution from a **(UV1)** solution,
- how to compute a **(GV1)** or **(GV2)** solution, given a **(UV2)** or **(UV3)** solution, and
- a **(GV1)** or **(GV2)** solution that can occur with a **(U1)** solution that has the incorrect α-vector.

We show that converting these solutions always takes $\text{poly}(n, d)$ time. The violations may be detected in either the first sub-problem or the second sub-problem. Our constructions thus culminate in the promised result:

▶ **Theorem 10.** *Alpha-HS* $\in$ UEOPL $\subseteq$ CLS.

Handling very weak general position. We have described our construction for the case when weak general position holds. If we only assume that very weak general position holds, then there may exist a hyperplane that passes through more than d points of at most $d-1$ colors. Therefore, in Step 5 of **Procedure** *NextRotate* the rotating hyperplane may hit more than one point so that it is not clear how to define the new anchor in Step 7. From the point of view of the reduction, there are many non-colorful vertices that represent the same hyperplane. We need a new approach to define a unique path to traverse these vertices with respect to this hyperplane. In other words, we charge the computational time of finding the new anchor to traversing these vertices on the path instead of considering it as one operation.

If we consider the space of all the points lying on the hyperplane, we have $d-1$ sets of points each representing a unique color in an affine subspace of $d-1$ dimensions. Thus, we can consider it as a new instance of Alpha-HS in one dimension lower. Let H be the rotating hyperplane that hits more than one point and contains $d-1$ colors. Without loss of generality, we assume that d is the missing color. We denote by $Q = Q_1 \cup Q_2 \cup \ldots \cup Q_{d-1}$ the $d-1$ sets of points in H such that $Q_i \subseteq P_i$ and denote by $\widehat{Q}_i$ the set of points represented in

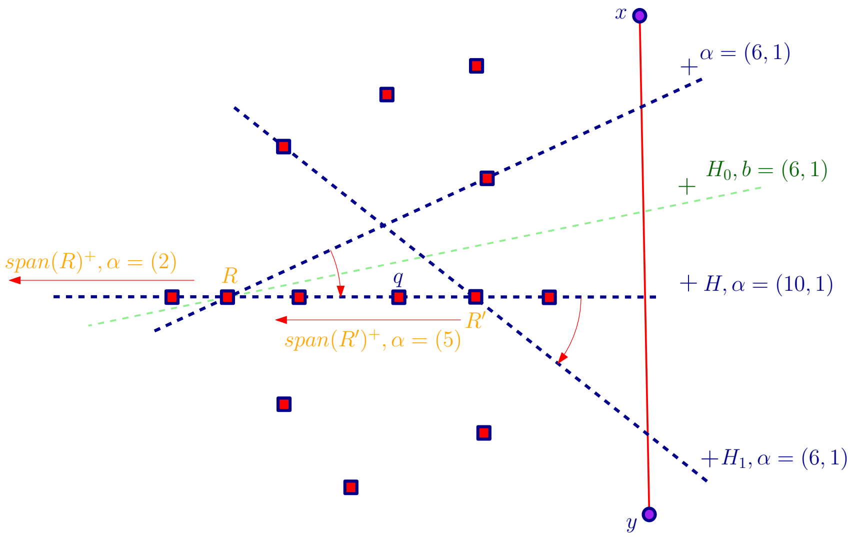

Figure 5 An example showing the relationship between the α-vector in a subproblem in $\mathbb{R}$ and the α-vector in the original problem in $\mathbb{R}^2$. Red (square) is the first color and purple (disk) is the second color. The orientation of $span(R)$ in H is defined such that it is consistent with H_0. $b = (6,1)$ is the α-vector of H_0. $k_1 = 4$ is the number of red points in $H^+ \setminus H$. The α-vector of the starting vertex (i.e., R) with respect to H is $(6-4=2)$. The α-vector of the end vertex is $(6+1-2=5)$. We can see that $q \in span(R')^+$ and q moves to the negative side of H_1 when rotating from H to H_1.

the new coordinate system in $\mathbb{R}^{d-1}$ for Q_i in H. First, we claim that if P is well-separated and in very weak general position, then $\widehat{Q}$ is also well-separated and in very weak general position. Since $Q \subset P$, it is clear that well-separation follows. Suppose that $\widehat{Q}$ violates very weak general position, then there exists a $(d-2)$-flat that contains more than $d-1$ points of $d-1$ colors in Q. In particular, any $(d-1)$-flat spanned by the $(d-2)$-flat and any point in P_d contains more than d points of d colors, which contradicts the fact that P is in very weak general position.

Suppose that P is well-separated and in very weak general position. Now we define what is the unique path with respect to $\widehat{Q}$. Let $b = (b_1, \dots, b_d)$ be the α-vector of the rotating hyperplane H_0 just before rotating to H at the anchor R. In the new instance of Alpha-HS, we would pick the orientation of $(d-2)$-flats in $\mathbb{R}^{d-1}$ such that every point $p \in Q$ lies in H_0^+ if and only if the corresponding point $\widehat{p} \in \widehat{Q}$ lies in $span(\widehat{R})^+$. Let $k_1, \dots k_{d-1}$ denote the number of points of $P_1, \dots, P_{d-1}$ in H^+, but not in Q_i. Then, we can see that the number of points in $\widehat{Q}_i$ lying in $span(\widehat{R})^+$ is equal to $b_i - k_i$. Thus, the α-vector of $span(\widehat{R})^+$ is $(b_1 - k_1, \dots, b_{d-1} - k_{d-1})$, which is the α-vector of the starting vertex of the path. On the other hand, the α-vector of the end vertex is $(|Q_1| + 1 - b_1 + k_1, \dots, |Q_{d-1}| + 1 - b_{d-1} + k_{d-1})$. It is because the points in $H_0^+ \setminus H_0$ become in the opposite side after the rotation passes through H. Therefore, if we rotate at the new anchor with α-vector $(|Q_1| + 1 - b_1 + k_1, \dots, |Q_{d-1}| + 1 - b_{d-1} + k_{d-1})$ in $\widehat{Q}$, then the α-vector of the new rotating hyperplane is still $(b_1, \dots, b_d)$. The next question is that if the vertex only stores any d points of H, we cannot recover b and H_0 so that the orientation cannot be defined consistently and the target α-vector for $\widehat{Q}$ is not known. To handle this problem, we need to redefine the double-wedge to be (R_1, p_1, R_2, p_2) instead of (R, p, q) in such a way that $R_1 = R_2$ if the double-wedge contains exactly $d+1$ points, otherwise $R_1 \subset span(R_2 \cup \{p_2\})$. For instance, if $(\widehat{R}_1, \widehat{q}_1) -> \dots -> (\widehat{R}_m, \widehat{q}_m)$ is the unique path in $\widehat{Q}$, where $\widehat{R}_i$ is an anchor of size $d-2$ so that $\widehat{R}_i$ and $\widehat{q}_i$ represent a $(d-2)$-flat in $\mathbb{R}^{d-1}$, then the corresponding path in the original problem is $(R, p, R_1 \cup \{q_1\}, p_1) -> (R, p, R_2 \cup \{q_2\}, p_2) -> \ldots -> (R, p, R_m \cup \{q_m\}, p_m)$, where p_i is some point in H that is picked under $\prec$ in a way that the tuple is uniquely defined in the path. Hence, b can be computed from the bisector of (R, p) and $(R_i \cup \{q_i\}, p_i)$, and the orientation of $(d-2)$-flats can also be defined by the bisector. There may exist some other double-wedge $(*, *, R_i \cup \{q_i\}, p_i)$ that is incident to H, but it will not have the same b.

In conclusion, the unique path in the reduction can be defined recursively as above in an Alpha-HS instance of one dimension lower. As a result, the representation of the double-wedges gets more complicated and the size is increased by a factor of $O(d)$. The potential function becomes a weighted sum of the potential function in each recursive level, but the number of bits is still in polynomial size. For handling violations, there are not many changes. Instead of reporting the violation of weak general position, we now report the violation of very weak general position when the rotating hyperplane in R^i contains more than i points of i colors. If any recursive subproblem violates very weak general position, it also implies that the original input P violates very weak general position.

4 Conclusion and future work

We gave a complexity-theoretic upper bound for Alpha-HS. No hardness results are known for this search problem, and the next question is determining if this is hard for UEOPL. One challenge is that UniqueEOPL is formulated as Boolean circuits, whereas Alpha-HS is purely geometric. Emulating circuits using purely geometric arguments is highly non-trivial. Filos-Ratsikas and Goldberg showed a reduction of this form in [21]. They reduced the PPA-complete 2D-Tucker circuit to Ham-Sandwich, going via the *Consensus-Halving* [39], and the *Necklace-splitting problems* [2]. A simplified argument was recently presented in [22]. It could be a worthwhile exercise to investigate if their techniques can provide insights for hardness of Alpha-HS.

Some related problems are determining the complexity of answering whether a point set is well-separated, whether it is in weak general position, or whether a given α-cut exists for the point set. A given α-cut may exist even when both assumptions are violated. On a related note, deciding whether the Linear Complementarity problem has a solution is NP-complete [15]. The solution is unique if the problem involves a P-matrix, but checking this condition is coNP-complete [16]. However, using witnesses to verify whether a matrix is P-matrix or not, a total search version is shown to be in UEOPL. Our result for Alpha-HS would go in a similar vein, if the complexities of the above problems were better determined.

Another line to work could be to determine the computational complexities of other extensions of the Ham-Sandwich theorem. For other geometric problems that are total and admit unique solutions, it could be worthwhile to explore their place in the class UEOPL. Faster algorithms for computing the α-cut can also be explored.

Abstract

We study the existence of approximate pure Nash equilibria (α-PNE) in weighted atomic congestion games with polynomial cost functions of maximum degree d. Previously it was known that d-approximate equilibria always exist, while nonexistence was established only for small constants, namely for 1.153-PNE. We improve significantly upon this gap, proving that such games in general do not have $\tilde{\Theta}(\sqrt{d})$-approximate PNE, which provides the first super-constant lower bound.

Furthermore, we provide a black-box gap-introducing method of combining such nonexistence results with a specific circuit gadget, in order to derive NP-completeness of the decision version of the problem. In particular, deploying this technique we are able to show that deciding whether a weighted congestion game has an $\tilde{O}(\sqrt{d})$-PNE is NP-complete. Previous hardness results were known only for the special case of *exact* equilibria and arbitrary cost functions.

The circuit gadget is of independent interest and it allows us to also prove hardness for a variety of problems related to the complexity of PNE in congestion games. For example, we demonstrate that the question of existence of α-PNE in which a certain set of players plays a specific strategy profile is NP-hard for any $\alpha < 3^{d/2}$, even for *unweighted* congestion games.

Finally, we study the existence of approximate equilibria in weighted congestion games with general (nondecreasing) costs, as a function of the number of players n. We show that n-PNE always exist, matched by an almost tight nonexistence bound of $\tilde{\Theta}(n)$ which we can again transform into an NP-completeness proof for the decision problem.

1 Introduction

Congestion games constitute the standard framework to study settings where selfish players compete over common resources. They are one of the most well-studied classes of games within the field of *algorithmic game theory* [32, 27], covering a wide range of applications, including, e.g., traffic routing and load balancing. In their most general form, each player has her own weight and the latency on each resource is a nondecreasing function of the total weight of players that occupy it. The cost of a player on a given outcome is just the total latency that she is experiencing, summed over all the resources she is using.

The canonical approach to analysing such systems and predicting the behaviour of the participants is the ubiquitous game-theoretic tool of equilibrium analysis. More specifically, we are interested in the *pure Nash equilibria (PNE)* of those games; these are stable configurations from which no player would benefit from unilaterally deviating. However, it is a well-known fact that such desirable outcomes might not always exist, even in very simple weighted congestion games. A natural response, especially from a computer science perspective, is to relax the solution notion itself by considering *approximate* pure Nash equilibria (α-PNE); these are states from which, even if a player could improve her cost by deviating, this improvement could not be by more than a (multiplicative) factor of $\alpha \geq 1$. Allowing the parameter α to grow sufficiently large, existence of α-PNE is restored. But how large does α really *need* to be? And, perhaps more importantly from a computational perspective, how hard is it to check whether a specific game has indeed an α-PNE?

1.1 Related Work

The origins of the systematic study of (atomic) congestion games can be traced back to the influential work of Rosenthal [30, 31]. Although Rosenthal showed the existence of congestion games without PNE, he also proved that *unweighted* congestion games always possess such equilibria. His proof is based on a simple but ingenious *potential function* argument, which up to this day is essentially still the only general tool for establishing existence of pure equilibria.

In follow-up work [20, 26, 17], the nonexistence of PNE was demonstrated even for special simple classes of (weighted) games, including network congestion games with quadratic cost functions and games where the player weights are either 1 or 2. On the other hand, we know that equilibria do exist for affine or exponential latencies [17, 28, 22], as well as for the class of singleton[1] games [16, 23]. Dunkel and Schulz [13] were able to extend the nonexistence instance of Fotakis et al. [17] to a gadget in order to show that deciding whether a congestion game with step cost functions has a PNE is a (strongly) NP-hard problem, via a reduction from 3-Partition.

Regarding approximate equilibria, Hansknecht et al. [21] gave instances of very simple, two-player polynomial congestion games that do not have α-PNE, for $\alpha \approx 1.153$. This lower bound is achieved by numerically solving an optimization program, using polynomial

[1] These are congestion games where the players can only occupy single resources.

latencies of maximum degree $d = 4$. On the positive side, Caragiannis et al. [4] proved that $d!$-PNE always exist; this upper bound on the existence of α-PNE was later improved to $\alpha = d + 1$ [21, 9] and $\alpha = d$ [3].

1.2 Our Results and Techniques

After formalizing our model in Section 2, in Section 3 we show the nonexistence of $\Theta(\frac{\sqrt{d}}{\ln d})$-approximate equilibria for polynomial congestion games of degree d. This is the first super-constant lower bound on the nonexistence of α-PNE, significantly improving upon the previous constant of $\alpha \approx 1.153$ and reducing the gap with the currently best upper bound of d. More specifically (Theorem 1), for any integer d we construct congestion games with polynomial cost functions of maximum degree d (and nonnegative coefficients) that do not have α-PNE, for any $\alpha < \alpha(d)$ where $\alpha(d)$ is a function that grows as $\alpha(d) = \Omega\left(\frac{\sqrt{d}}{\ln d}\right)$. To derive this bound, we had to use a novel construction with a number of players growing unboundedly as a function of d.

Next, in Section 4 we turn our attention to computational hardness constructions. Starting from a Boolean circuit, we create a gadget that transfers hard instances of the classic Circuit Satisfiability problem to (even unweighted) polynomial congestion games. Our construction is inspired by the work of Skopalik and Vöcking [34], who used a similar family of lockable circuit games in their PLS-hardness result. Using this gadget we can immediately establish computational hardness for various computational questions of interest involving congestion games (Theorem 3). For example, we show that deciding whether a d-degree polynomial congestion game has an α-PNE in which a specific set of players play a specific strategy profile is NP-hard, even up to exponentially-approximate equilibria; more specifically, the hardness holds for *any* $\alpha < 3^{d/2}$. Our investigation of the hardness questions presented in Theorem 3 (and later on in Corollary 7 as well) was inspired by some similar results presented before by Conitzer and Sandholm [11] (and even earlier in [19]) for *mixed* Nash equilibria in general (normal-form) games. To the best of our knowledge, our paper is the first to study these questions for *pure* equilibria in the context of congestion games. It is of interest to also note here that our hardness gadget is *gap-introducing*, in the sense that the α-PNE and exact PNE of the game coincide.

In Section 5 we demonstrate how one can combine the hardness gadget of Section 4, in a black-box way, with any nonexistence instance for α-PNE, in order to derive hardness for the decision version of the existence of α-PNE (Lemma 4, Theorem 5). As a consequence, using the previous $\Omega\left(\frac{\sqrt{d}}{\ln d}\right)$ lower bound construction of Section 3, we can show that deciding whether a (weighted) polynomial congestion has an α-PNE is NP-hard, for any $\alpha < \alpha(d)$, where $\alpha(d) = \Omega\left(\frac{\sqrt{d}}{\ln d}\right)$ (Corollary 6). Since our hardness is established via a rather transparent, "master" reduction from Circuit Satisfiability, which in particular is parsimonious, one can derive hardness for a family of related computation problems; for example, we show that computing the number of α-approximate equilibria of a weighted polynomial congestion game is #P-hard (Corollary 7).

In Section 6 we drop the assumption on polynomial cost functions, and study the existence of approximate equilibria under arbitrary (nondecreasing) latencies as a function of the number of players n. We prove that n-player congestion games always have n-approximate PNE (Theorem 8). As a consequence, one cannot hope to derive super-constant nonexistence lower bounds by using just simple instances with a fixed number of players (similar to, e.g., Hansknecht et al. [21]). In particular, this shows that the super-constant number of players in our construction in Theorem 1 is necessary. Furthermore, we pair this positive result with an almost matching lower bound (Theorem 9): we give examples of n-player congestion games (where latencies are simple step functions with a single breakpoint) that do not have α-PNE for all $\alpha < \alpha(n)$, where $\alpha(n)$ grows according to $\alpha(n) = \Omega\left(\frac{n}{\ln n}\right)$. Finally, inspired by our hardness construction for the polynomial case, we also give a new reduction that establishes NP-hardness for deciding whether an α-PNE exists, for any $\alpha < \alpha(n) = \Omega\left(\frac{n}{\ln n}\right)$. Notice that now the number of players n is part of the description of the game (i.e., part of the input) as opposed to the maximum degree d for the polynomial case (which was assumed to be fixed). On the other hand though, we have more flexibility on designing our gadget latencies, since they can be arbitrary functions.

Concluding, we would like to elaborate on a couple of points. First, the reader would have already noticed that in all our hardness results the (in)approximability parameter α ranges freely within an entire interval of the form $[1, \tilde{\alpha})$, where $\tilde{\alpha}$ is a function of the degree d (for polynomial congestion games) or of the number of players n; and that α, $\tilde{\alpha}$ are *not* part of the problem's input. It is easy to see that these features only make our results stronger, with respect to computational hardness, but also more robust. Secondly, although in this introductory section all our hardness results were presented in terms of NP-*hardness*, they immediately translate to NP-*completeness* under standard assumptions on the parameter α; e.g., if α is rational (for a more detailed discussion of this, see also the end of Section 2).

Due to space constraints we had to either fully omit, or just give very short sketches of, the proofs of our results. All proofs can be found in the full version of this paper [8].

2 Model and Notation

A (weighted, atomic) *congestion game* is defined by: a finite (nonempty) set of *resources* E, each $e \in E$ having a nondecreasing *cost (or latency) function* $c_e : \mathbb{R}_{>0} \longrightarrow \mathbb{R}_{\geq 0}$; and a finite (nonempty) set of *players* N, $|N| = n$, each $i \in N$ having a *weight* $w_i > 0$ and a set of *strategies* $S_i \subseteq 2^E$. If all players have the same weight, $w_i = 1$ for all $i \in N$, the game is called *unweighted.* A *polynomial congestion game* of degree d, for d a nonnegative integer, is a congestion game such that all its cost functions are polynomials of degree at most d with nonnegative coefficients.

A *strategy profile* (or *outcome*) $\mathbf{s} = (s_1, s_2, \dots, s_n)$ is a collection of strategies, one for each player, i.e. $\mathbf{s} \in \mathbf{S} = S_1 \times S_2 \times \cdots \times S_n$. Each strategy profile $\mathbf{s}$ induces a *cost* of $C_i(\mathbf{s}) = \sum_{e \in s_i} c_e(x_e(\mathbf{s}))$ to every player $i \in N$, where $x_e(\mathbf{s}) = \sum_{i:e \in s_i} w_i$ is the induced *load* on resource e. An outcome $\mathbf{s}$ will be called *α-approximate (pure Nash) equilibrium (α-PNE)*, where $\alpha \geq 1$, if no player can unilaterally improve her cost by more than a factor of α. Formally:

$$C_i(\mathbf{s}) \leq \alpha \cdot C_i(s_i', \mathbf{s}_{-i}) \qquad \text{for all } i \in N \text{ and all } s_i' \in S_i. \tag{1}$$

Here we have used the standard game-theoretic notation of $\mathbf{s}_{-i}$ to denote the vector of strategies resulting from $\mathbf{s}$ if we remove its i-th coordinate; in that way, one can write $\mathbf{s} = (s_i, \mathbf{s}_{-i})$. Notice that for the special case of $\alpha = 1$, (1) is equivalent to the classical definition of pure Nash equilibria; for emphasis, we will sometimes refer to such 1-PNE as *exact* equilibria.

If (1) does not hold, it means that player i could improve her cost by more than α by moving from s_i to some other strategy s_i'. We call such a move *α-improving.* Finally, strategy s_i is said to be *α-dominating* for player i (with respect to a fixed profile $\mathbf{s}_{-i}$) if

$$C_i(s_i', \mathbf{s}_{-i}) > \alpha \cdot C_i(\mathbf{s}) \qquad \text{for all } s_i' \neq s_i. \tag{2}$$

In other words, if a strategy s_i is α-dominating, every move from some other strategy s'_i to s_i is α-improving. Notice that each player i can have at most one α-dominating strategy (for $\mathbf{s}_{-i}$ fixed). In our proofs, we will employ a *gap-introducing* technique by constructing games with the property that, for any player i and any strategy profile $\mathbf{s}_{-i}$, there is always a (unique) α-dominating strategy for player i. As a consequence, the sets of α-PNE and exact PNE coincide.

Finally, for a positive integer n, we will use Φ_n to denote the unique positive solution of equation $(x+1)^n = x^{n+1}$. Then, Φ_n is strictly increasing with respect to n, with $\Phi_1 = \phi \approx 1.618$ (golden ratio) and asymptotically $\Phi_n \sim \frac{n}{\ln n}$ (see [9, Lemma A.3]).

Computational Complexity

Most of the results in this paper involve complexity questions, regarding the existence of (approximate) equilibria. Whenever we deal with such statements, we will implicitly assume that the congestion game instances given as inputs to our problems can be succinctly represented in the following way:

- all player have *rational* weights;
- the resource cost functions are "efficiently computable"; for polynomial latencies in particular, we will assume that the coefficients are *rationals*; and for step functions we assume that their values and breakpoints are *rationals*;
- the strategy sets are given *explicitly*.[2]

There are also computational considerations to be made about the number α appearing in the definition of α-PNE. For simplicity, throughout this paper we will assume that α is a rational number. However, all our hardness results are still valid for any real α, while for our completeness results one needs to assume that α is actually a *polynomial-time computable* real. For more details we refer to the full version of our paper [8].

3 The Nonexistence Gadget

In this section we give examples of polynomial congestion games of degree d, that do *not* have $\alpha(d)$-approximate equilibria; $\alpha(d)$ grows as $\Omega\left(\frac{\sqrt{d}}{\ln d}\right)$. Fixing a degree $d \geq 2$, we construct a family of games $\mathcal{G}^d_{(n,k,w,\beta)}$, specified by parameters $n \in \mathbb{N}, k \in \{1,\dots,d\}, w \in [0,1]$, and $\beta \in [0,1]$. In $\mathcal{G}^d_{(n,k,w,\beta)}$ there are $n+1$ players: a *heavy player* of weight 1 and n *light players* $1,\dots,n$ of equal weights w. There are $2(n+1)$ resources $a_0, a_1, \dots, a_n, b_0, b_1, \dots, b_n$ where a_0 and b_0 have the same cost function c_0 and all other resources $a_1,\dots,a_n,b_1,\dots,b_n$ have the same cost function c_1 given by

$$c_0(x) = x^k \quad \text{and} \quad c_1(x) = \beta x^d.$$

Each player has exactly two strategies, and the strategy sets are given by

$$S_0 = \{\{a_0,\dots,a_n\},\{b_0,\dots,b_n\}\} \quad \text{and} \quad S_i = \{\{a_0,b_i\},\{b_0,a_i\}\} \quad \text{for } i = 1,\dots,n.$$

The structure of the strategies is visualized in Figure 1.

[2] Alternatively, we could have simply assumed succinct representability of the strategies. A prominent such case is that of *network* congestion games, where each player's strategies are all feasible paths between two specific nodes of an underlying graph. Notice however that, since in this paper we are proving hardness results, insisting on explicit representation only makes our results even stronger.

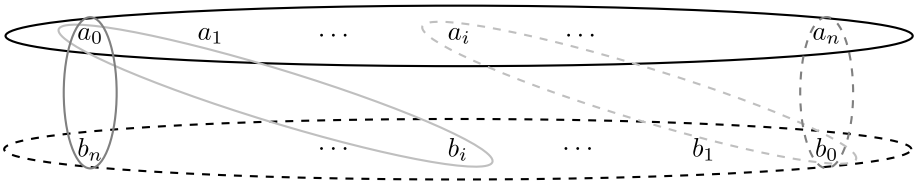

Figure 1 Strategies of the game $\mathcal{G}^d_{(n,k,w,\beta)}$. Resources contained in the two ellipses of the same colour correspond to the two strategies of a player. The strategies of the heavy player and light players n and i are depicted in black, grey and light grey, respectively.

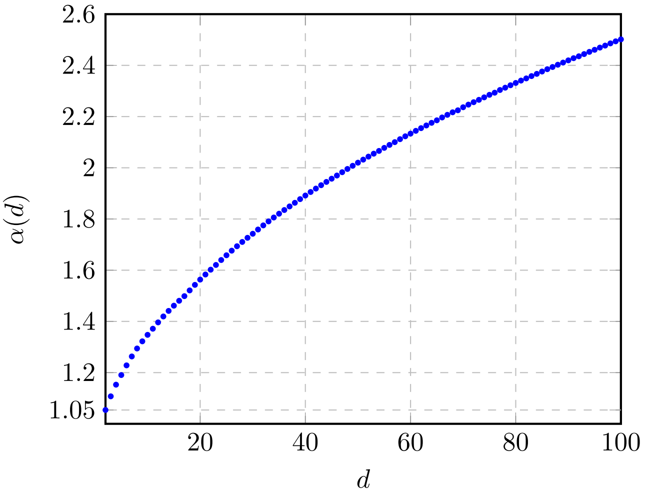

Figure 2 Nonexistence of $\alpha(d)$-PNE for weighted polynomial congestion games of degree d, as given by (3) in Theorem 1, for $d = 2, 3, \ldots, 100$. In particular, for small values of d, $\alpha(2) \approx 1.054$, $\alpha(3) \approx 1.107$ and $\alpha(4) \approx 1.153$.

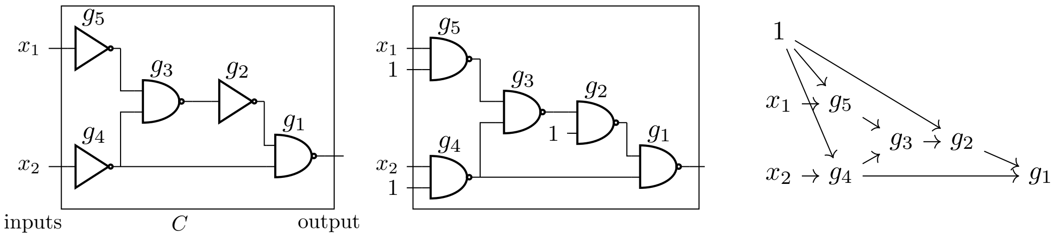
In the following theorem we give a lower bound on α, depending on parameters (n, k, w, β), such that games $\mathcal{G}^d_{(n,k,w,\beta)}$ do not admit an α-PNE. Maximizing this lower bound over all games in the family, we obtain a general lower bound $\alpha(d)$ on the inapproximability for polynomial congestion games of degree d (see (3) and its plot in Figure 2). Finally, choosing specific values for the parameters (n, k, w, β), we prove that $\alpha(d)$ is asymptotically lower bounded by $\Omega(\frac{\sqrt{d}}{\ln d})$.

▶ **Theorem 1.** *For any integer $d \geq 2$, there exist (weighted) polynomial congestion games of degree d that do not have α-approximate PNE for any $\alpha < \alpha(d)$, where*

$$\alpha(d) = \sup_{n,k,w,\beta} \min\left\{ \frac{1 + n\beta(1+w)^d}{(1+nw)^k + n\beta}, \frac{(1+w)^k + \beta w^d}{(nw)^k + \beta(1+w)^d} \right\} \qquad (3)$$
$$\text{s.t.} \quad n \in \mathbb{N}, k \in \{1, \ldots, d\}, w \in [0,1], \beta \in [0,1].$$

In particular, we have the asymptotics $\alpha(d) = \Omega\left(\frac{\sqrt{d}}{\ln d}\right)$ and the bound $\alpha(d) \geq \frac{\sqrt{d}}{2 \ln d}$, valid for large enough d. A plot of the exact values of $\alpha(d)$ (given by (3)*) for small degrees can be found in Figure 2.*

Interestingly, for the special case of $d = 2, 3, 4$, the values of $\alpha(d)$ (see Figure 2) yield *exactly* the same lower bounds with Hansknecht et al. [21]. This is a direct consequence of the fact that $n = 1$ turns out to be an optimal choice in (3) for $d \leq 4$, corresponding to an



(a) valid circuit C. **(b)** canonical form of C. **(c)** directed acyclic graph.

Figure 3 Example of a valid circuit C (having both NOT and NAND gates), its canonical form (having only NAND gates), and the directed acyclic graph corresponding to C.

instance with only $n+1 = 2$ players (which is the regime of the construction in [21]); however, this is not the case for larger values of d, where more players are now needed in order to derive the best possible value in (3). Furthermore, as we discussed also in Section 1.2, no construction with only 2 players can result in bounds larger than 2 (Theorem 8).

4 The Hardness Gadget

In this section we construct an unweighted polynomial congestion game from a Boolean circuit. In the α-PNE of this game the players emulate the computation of the circuit. This gadget will be used in reductions from CIRCUIT SATISFIABILITY to show NP-hardness of several problems related to the existence of approximate equilibria with some additional properties. For example, deciding whether a congestion game has an α-PNE where a certain set of players choose a specific strategy profile (Theorem 3).

Circuit Model

We consider Boolean circuits consisting of NOT gates and 2-input NAND gates only. We assume that the two inputs to every NAND gate are different. Otherwise we replace the NAND gate by a NOT gate, without changing the semantics of the circuit. We further assume that every input bit is connected to exactly one gate and this gate is a NOT gate. See Figure 3a for a *valid* circuit. In a valid circuit we replace every NOT gate by an equivalent NAND gate, where one of the inputs is fixed to 1. See the replacement of gates g_5, g_4 and g_2 in the example in Figure 3b. Thus, we look at circuits of 2-input NAND gates where both inputs to a NAND gate are different and every input bit of the circuit is connected to exactly one NAND gate where the other input is fixed to 1. A circuit of this form is said to be in *canonical form*. For a circuit C and a vector $x \in \{0,1\}^n$ we denote by $C(x)$ the output of the circuit on input x.

We model a circuit C in canonical form as a *directed acyclic graph*. The nodes of this graph correspond to the input bits $x_1, \dots, x_n$, the gates $g_1, \dots, g_K$ and a node 1 for all fixed inputs. There is an arc from a gate g to a gate g' if the output of g is input to gate g' and there are arcs from the fixed input and all input bits to the connected gates. We index the gates in reverse topological order, so that all successors of a gate g_k have a smaller index and the output of gate g_1 is the output of the circuit. Denote by $\delta^+(v)$ the set of the direct successors of node v. Then we have $|\delta^+(x_i)| = 1$ for all input bits x_i and $\delta^+(g_k) \subseteq \{g_{k'} \mid k' < k\}$ for every gate g_k. See Figure 3 for an example of a valid circuit, its canonical form and the corresponding directed acyclic graph.

Translation to Congestion Game

Fix some integer $d \geq 1$ and a parameter $\mu \geq 1 + 2 \cdot 3^{d+d/2}$. From a valid circuit in canonical form with input bits $x_1, \ldots, x_n$, gates $g_1, \ldots, g_K$ and the extra input fixed to 1, we construct a polynomial congestion game $\mathcal{G}_\mu^d$ of degree d. There are n *input players* $X_1, \ldots, X_n$ for every input bit, a *static player* P for the input fixed to 1, and K *gate players* $G_1, \ldots, G_K$ for the output bit of every gate. G_1 is sometimes called *output player* as g_1 corresponds to the output $C(x)$.

The idea is that every input and every gate player has a *zero* and a *one strategy*, corresponding to the respective bit being 0 or 1. In every α-PNE we want the players to emulate the computation of the circuit, i.e. the NAND semantics of the gates should be respected. For every gate g_k, we introduce two *resources* 0_k and 1_k. The zero (one) strategy of a player consists of the $0_{k'}$ ($1_{k'}$) resources of the direct successors in the directed acyclic graph corresponding to the circuit and its own 0_k (1_k) resource (for gate players). The static player has only one strategy playing all 1_k resources of the gates where one input is fixed to 1: $s_P = \{1_k \,|\, g_k \in \delta^+(1)\}$. Formally, we have

$$s_{X_i}^0 = \left\{0_k \,|\, g_k \in \delta^+(x_i)\right\} \text{ and } s_{X_i}^1 = \left\{1_k \,|\, g_k \in \delta^+(x_i)\right\}$$

for the zero and one strategy of an input player X_i. Recall that $\delta^+(x_i)$ is the set of direct successors of x_i, thus every strategy of an input player consists of exactly one resource. For a gate player G_k we have the two strategies

$$s_{G_k}^0 = \{0_k\} \cup \left\{0_{k'} \,|\, g_{k'} \in \delta^+(g_k)\right\} \text{ and } s_{G_k}^1 = \{1_k\} \cup \left\{1_{k'} \,|\, g_{k'} \in \delta^+(g_k)\right\}$$

consisting of at most k resources each. Notice that all 3 players related to a gate g_k (gate player G_k and the two players corresponding to the input bits) are different and observe that every resource 0_k and 1_k can be played by exactly those 3 players.

We define the cost functions of the resources using parameter μ. The cost functions for resources 1_k are given by c_{1_k} and for resources 0_k by c_{0_k}, where

$$c_{1_k}(x) = \mu^k x^d \qquad \text{and} \qquad c_{0_k}(x) = \lambda \mu^k x^d, \text{ with } \lambda = 3^{d/2}. \tag{4}$$

Our construction here is inspired by the lockable circuit games of Skopalik and Vöcking [34]. The key technical differences are that our gadgets use polynomial cost functions (instead of general cost functions) and only 2 resources per gate (instead of 3). Moreover, while in [34] these games are used as part of a PLS-reduction from Circuit/FLIP, we are also interested in constructing a gadget to be studied on its own, since this can give rise to additional results of independent interest (see Theorem 3).

Properties of the Gadget

For a valid circuit C in canonical form consider the game $\mathcal{G}_\mu^d$ as defined above. We interpret any strategy profile $\mathbf{s}$ of the input players as a bit vector $x \in \{0,1\}^n$ by setting $x_i = 0$ if $s_{X_i} = s_{X_i}^0$ and $x_i = 1$ otherwise. The gate players are said to *follow the NAND semantics* in a strategy profile, if for every gate g_k the following holds:

- if both players corresponding to the input bits of g_k play their one strategy, then the gate player G_k plays her zero strategy;
- if at least one of the players corresponding to the input bits of g_k plays her zero strategy, then the gate player G_k plays her one strategy.

We show that for the right choice of α, the set of α-PNE in $\mathcal{G}_\mu^d$ is the same as the set of all strategy profiles where the gate players follow the NAND semantics.

Define

$$\varepsilon(\mu) = \frac{3^{d+d/2}}{\mu - 1}. \tag{5}$$

From our choice of μ, we obtain $3^{d/2} - \varepsilon(\mu) \geq 3^{d/2} - \frac{1}{2} > 1$. For any valid circuit C in canonical form and a valid choice of μ the following lemma holds for $\mathcal{G}^d_\mu$.

▶ **Lemma 2.** *Let $\mathbf{s}_X$ be any strategy profile for the input players $X_1, \dots, X_n$ and let $x \in \{0,1\}^n$ be the bit vector represented by $\mathbf{s}_X$. For any $\mu \geq 1 + 2 \cdot 3^{d+d/2}$ and any $1 \leq \alpha < 3^{d/2} - \varepsilon(\mu)$, there is a unique α-approximate PNE*[3] *in $\mathcal{G}^d_\mu$ where the input players play according to $\mathbf{s}_X$. In particular, in this α-PNE the gate players follow the NAND semantics, and the output player G_1 plays according to $C(x)$.*

Proof sketch. We first fix the input players to the strategies given by $\mathbf{s}_X$ and show that then all gate players follow the NAND semantics (switching to the strategy corresponding to the NAND of their input bits is an α-improving move). Secondly, we argue that the input players have no incentive to change their strategy in any α-PNE where all gate players follow the NAND semantics. Hence, every strategy profile for the input players can be extended to an α-PNE in $\mathcal{G}^d_\mu$ that is uniquely defined by the NAND semantics. ◀

We are now ready to show our main result of this section; using the circuit game described above, we show NP-hardness of deciding whether approximate equilibria with additional properties exist.

▶ **Theorem 3.** *The following problems are NP-hard, even for* unweighted *polynomial congestion games of degree $d \geq 1$, for all $\alpha \in [1, 3^{d/2})$ and all $z > 0$:*

- *"Does there exist an α-approximate PNE in which a certain subset of players are playing a specific strategy profile?"*
- *"Does there exist an α-approximate PNE in which a certain resource is used by at least one player?"*
- *"Does there exist an α-approximate PNE in which a certain player has cost at most z?"*

Proof sketch. We use reductions from the NP-hard problem Circuit Satisfiability. For a circuit C we consider the game $\mathcal{G}^d_\mu$ as described above and focus on the output player G_1. Using Lemma 2 we get a one-to-one correspondence between satisfying assignments for C and α-PNE in $\mathcal{G}^d_\mu$ where G_1 plays her one strategy. ◀

5 Hardness of Existence

In this section we show that it is NP-hard to decide whether a polynomial congestion game has an α-PNE. For this we use a black-box reduction: our hard instance is obtained by combining any (weighted) polynomial congestion game $\mathcal{G}$ without α-PNE (i.e., the game from Section 3) with the circuit gadget of the previous section. To achieve this, it would be convenient to make some assumptions on the game $\mathcal{G}$, which however do not influence the existence or nonexistence of approximate equilibria.

[3] Which, as a matter of fact, is actually also an *exact* PNE.

Structural Properties of $\mathcal{G}$

Without loss of generality, we assume that a weighted polynomial congestion game of degree d has the following structural properties.

- *No player has an empty strategy.* If, for some player i, $\emptyset \in S_i$, then this strategy would be α-dominating for i. Removing i from the game description would not affect the (non)existence of (approximate) equilibria[4].
- *No player has zero weight.* If a player i had zero weight, her strategy would not influence the costs of the strategies of the other players. Again, removing i from the game description would not affect the (non)existence of equilibria.
- *Each resource e has a monomial cost function with a strictly positive coefficient*, i.e. $c_e(x) = a_e x^{k_e}$ where $a_e > 0$ and $k_e \in \{0, \dots, d\}$. If a resource had a more general cost function $c_e(x) = a_{e,0} + a_{e,1}x + \dots + a_{e,d}x^d$, we could split it into at most $d+1$ resources with (positive) monomial costs, $c_{e,0}(x) = a_{e,0}$, $c_{e,1}(x) = a_{e,1}x$, $\dots$, $c_{e,d}(x) = a_{e,d}x^d$. These monomial cost resources replace the original resource, appearing on every strategy that included e.
- *No resource e has a constant cost function.* If a resource e had a constant cost function $c_e(x) = a_{e,0}$, we could replace it by new resources having monomial cost. For each player i of weight w_i, replace resource e by a resource e_i with monomial cost $c_{e_i}(x) = \frac{a_{e,0}}{w_i}x$, that is used exclusively by player i on her strategies that originally had resource e. Note that $c_{e_i}(w_i) = a_{e,0}$, so that this modification does not change the player's costs, neither has an effect on the (non)existence of approximate equilibria. If a resource has cost function constantly equal to zero, we can simply remove it from the description of the game.

For a game having the above properties, we define the (strictly positive) quantities

$$a_{\min} = \min_{e\in E} a_e, \quad W = \sum_{i\in N} w_i, \quad c_{\max} = \sum_{e\in E} c_e(W). \tag{6}$$

Note that $c_{\max}$ is an upper bound on the cost of any player on any strategy profile.

Rescaling of $\mathcal{G}$

In our construction of the combined game we have to make sure that the weights of the players in $\mathcal{G}$ are smaller than the weights of the players in the circuit gadget. We introduce the following rescaling argument.

For any $\gamma \in (0, 1]$ define the game $\tilde{\mathcal{G}}_\gamma$, where we rescale the player weights and resource cost coefficients in $\mathcal{G}$ as

$$\tilde{a}_e = \gamma^{d+1-k_e} a_e, \quad \tilde{w}_i = \gamma w_i, \quad \tilde{c}_e(x) = \tilde{a}_e x^{k_e}. \tag{7}$$

This changes the quantities in (6) for $\tilde{\mathcal{G}}_\gamma$ to (recall that $k_e \geq 1$)

$$\begin{aligned}
\tilde{a}_{\min} &= \min_{e\in E} \tilde{a}_e = \min_{e\in E} \gamma^{d+1-k_e} a_e \geq \gamma^d \min_{e\in E} a_e = \gamma^d a_{\min},\\
\tilde{W} &= \sum_{i\in N} \tilde{w}_i = \sum_{i\in N} \gamma w_i = \gamma W,\\
\tilde{c}_{\max} &= \sum_{e\in E} \tilde{c}_e(\tilde{W}) = \sum_{e\in E} \tilde{a}_e(\gamma W)^{k_e} = \sum_{e\in E} \gamma^{d+1} a_e W^{k_e} = \gamma^{d+1} \sum_{e\in E} c_e(W) = \gamma^{d+1} c_{\max}.
\end{aligned}$$

In $\tilde{\mathcal{G}}_\gamma$ the player costs are all uniformly scaled as $\tilde{C}_i(\mathbf{s}) = \gamma^{d+1} C_i(\mathbf{s})$, so that the Nash dynamics and the (non)existence of equilibria are preserved.

[4] By this we mean, if $\mathcal{G}$ has (resp. does not have) α-PNE, then $\tilde{\mathcal{G}}$, obtained by removing player i from the game, still has (resp. still does not have) α-PNE.

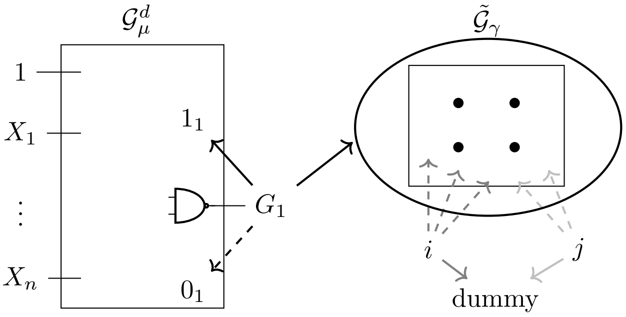


Figure 4 Combination of a circuit game (on the left) and a game without approximate equilibria (on the right). Changes to the subgames are indicated by solid arrows. The new one strategy of G_1 consists of 1_1 and all resources in $\tilde{\mathcal{G}}_\gamma$, while the zero strategy stays unchanged. The players of $\tilde{\mathcal{G}}_\gamma$ get a new strategy (the dummy resource), and keep their old strategies playing in $\tilde{\mathcal{G}}_\gamma$.

The next lemma formalizes the combination of both game gadgets and, furthermore, establishes the gap-introduction in the equilibrium factor. Using it, we will derive our key hardness tool of Theorem 5.

▶ **Lemma 4.** *Fix any integer $d \geq 2$ and rational $\alpha \geq 1$. Suppose there exists a weighted polynomial congestion game $\mathcal{G}$ of degree d that does* not *have an α-approximate PNE. Then, for any circuit C there exists a game $\tilde{\mathcal{G}}_C$ with the following property: the sets of α-approximate PNE and exact PNE of $\tilde{\mathcal{G}}_C$ coincide and are in one-to-one correspondence with the set of satisfying assignments of C. In particular, one of the following holds: either*

1. *C has a satisfying assignment, in which case $\tilde{\mathcal{G}}_C$ has an exact PNE (and thus, also an α-approximate PNE); or*
2. *C has no satisfying assignments, in which case $\tilde{\mathcal{G}}_C$ has no α-approximate PNE (and thus, also no exact PNE).*

Proof. Let $\mathcal{G}$ be a congestion game as in the statement of the theorem having the above mentioned structural properties. Recalling that weighted polynomial congestion games of degree d have d-PNE [3], this implies that $\alpha < d < 3^{d/2}$. Fix some $0 < \varepsilon < 3^{d/2} - \alpha$ and take $\mu \geq 1 + \frac{3^{d+d/2}}{\min\{\varepsilon,1\}}$; in this way $\alpha < 3^{d/2} - \varepsilon \leq 3^{d/2} - \varepsilon(\mu)$.

Given a circuit C we construct the game $\tilde{\mathcal{G}}_C$ as follows. We combine the game $\mathcal{G}_\mu^d$ whose Nash dynamics model the NAND semantics of C, as described in Section 4, with the game $\tilde{\mathcal{G}}_\gamma$ obtained from $\mathcal{G}$ via the aforementioned rescaling. We choose $\gamma \in (0, 1]$ sufficiently small such that the following three inequalities hold for the quantities in (6) for $\mathcal{G}$:

$$\gamma W < 1, \quad \gamma \sum_{e \in E} a_e < \frac{\mu}{\mu - 1}\left(\frac{3}{2}\right)^d, \quad \gamma\alpha^2 < \frac{a_{\min}}{c_{\max}}. \tag{8}$$

Thus, the set of players in $\tilde{\mathcal{G}}_C$ corresponds to the (disjoint) union of the static, input and gate players in $\mathcal{G}_\mu^d$ (which all have weights 1) and the players in $\tilde{\mathcal{G}}_\gamma$ (with weights $\tilde{w}_i$). We also consider a new dummy resource with constant cost $c_{\text{dummy}}(x) = \frac{\tilde{a}_{\min}}{\alpha}$. Thus, the set of resources corresponds to the (disjoint) union of the gate resources $0_k, 1_k$ in $\mathcal{G}_\mu^d$, the resources in $\tilde{\mathcal{G}}_\gamma$, and the dummy resource. We augment the strategy space of the players as follows:

- each input player or gate player of $\mathcal{G}_\mu^d$ that is *not* the output player G_1 has the same strategies as in $\mathcal{G}_\mu^d$ (i.e. either the zero or the one strategy);
- the zero strategy of the output player G_1 is the same as in $\mathcal{G}_\mu^d$, but her one strategy is augmented with *every* resource in $\tilde{\mathcal{G}}_\gamma$; that is, $s_{G_1}^1 = \{1_1\} \cup E(\tilde{\mathcal{G}}_\gamma)$;
- each player i in $\tilde{\mathcal{G}}_\gamma$ keeps her original strategies as in $\tilde{\mathcal{G}}_\gamma$, and gets a new dummy strategy $s_{i,\text{dummy}} = \{\text{dummy}\}$.

A graphical representation of the game $\tilde{\mathcal{G}}_C$ can be seen in Figure 4.

To finish the proof, we need to show that every α-PNE of $\tilde{\mathcal{G}}_C$ is an exact PNE and corresponds to a satisfying assignment of C; and, conversely, that every satisfying assignment of C gives rise to an exact PNE of $\tilde{\mathcal{G}}_C$ (and thus, an α-PNE as well).

Suppose that $\mathbf{s}$ is an α-PNE of $\tilde{\mathcal{G}}_C$, and let $\mathbf{s}_X$ denote the strategy profile restricted to the input players of $\mathcal{G}_\mu^d$. Then, as in the proof of Lemma 2, every gate player that is not the output player must respect the NAND semantics, and this is an α-dominating strategy. For the output player, either $\mathbf{s}_X$ is a non-satisfying assignment, in which case the zero strategy of G_1 was α-dominating, and this remains α-dominating in the game $\tilde{\mathcal{G}}_C$ (since only the cost of the one strategy increased for the output player); or $\mathbf{s}_X$ is a satisfying assignment. In the second case, we now argue that the one strategy of G_1 remains α-dominating. The cost of the output player on the zero strategy is at least $c_{0_1}(2) = \lambda\mu 2^d$, and the cost on the one strategy is at most

$$c_{1_1}(2)+\sum_{e\in E}\tilde{c}_e(1+\gamma W) = \mu 2^d+\sum_{e\in E}\gamma^{d+1-k_e}a_e(1+\gamma W)^{k_e} < \mu 2^d+\gamma\sum_{e\in E}a_e 2^d < \mu 2^d+\frac{\mu}{\mu-1}3^d,$$

where we used the first and second bounds from (8). Thus, the ratio between the costs is at least

$$\frac{\lambda\mu 2^d}{\mu 2^d+\frac{\mu}{\mu-1}3^d} = \lambda\left(\frac{1}{1+\frac{1}{\mu-1}\left(\frac{3}{2}\right)^d}\right) > 3^{d/2}\left(\frac{1}{1+\frac{1}{\mu-1}3^d}\right) > 3^{d/2}-\varepsilon(\mu) > \alpha.$$

Given that the gate players must follow the NAND semantics, the input players are also locked to their strategies (i.e. they have no incentive to change) due to the proof of Lemma 2. The only players left to consider are the players from $\tilde{\mathcal{G}}_\gamma$. First we show that, since $\mathbf{s}$ is an α-PNE, the output player must be playing her one strategy. If this was not the case, then each dummy strategy of a player in $\tilde{\mathcal{G}}_\gamma$ is α-dominated by any other strategy: the dummy strategy incurs a cost of $\frac{\tilde{a}_{\min}}{\alpha} \geq \gamma^d\frac{a_{\min}}{\alpha}$, whereas any other strategy would give a cost of at most $\tilde{c}_{\max} = \gamma^{d+1}c_{\max}$ (this is because the output player is not playing any of the resources in $\tilde{\mathcal{G}}_\gamma$). The ratio between the costs is thus at least

$$\frac{\gamma^d a_{\min}}{\gamma^{d+1}c_{\max}\alpha} = \frac{a_{\min}}{\gamma c_{\max}\alpha} > \alpha.$$

Since the dummy strategies are α-dominated, the players in $\tilde{\mathcal{G}}_\gamma$ must be playing on their original sets of strategies. The only way for $\mathbf{s}$ to be an α-PNE would be if $\mathcal{G}$ had an α-PNE to begin with, which yields a contradiction. Thus, the output player is playing the one strategy (and hence, is present in every resource in $\tilde{\mathcal{G}}_\gamma$). In such a case, we can conclude that each dummy strategy is now α-dominating. If a player i in $\tilde{\mathcal{G}}_\gamma$ is not playing a dummy strategy, she is playing at least one resource in $\tilde{\mathcal{G}}_\gamma$, say resource e. Her cost is at least $\tilde{c}_e(1+\tilde{w}_i) = \tilde{a}_e(1+\tilde{w}_i)^{k_e} > \tilde{a}_e \geq \tilde{a}_{\min}$ (the strict inequality holds since, by the structural properties of our game, all of $\tilde{a}_e$, $\tilde{w}_i$ and k_e are strictly positive quantities). On the other hand, the cost of playing the dummy strategy is $\frac{\tilde{a}_{\min}}{\alpha}$. Thus, the ratio between the costs is greater than α.

We have concluded that, if $\mathbf{s}$ is an α-PNE of $\tilde{\mathcal{G}}_C$, then $\mathbf{s}_X$ corresponds to a satisfying assignment of C, all the gate players are playing according to the NAND semantics, the output player is playing the one strategy, and all players of $\tilde{\mathcal{G}}_\gamma$ are playing the dummy strategies. In this case, we also have observed that each player's current strategy is α-dominating, so the strategy profile is an exact PNE. To finish the proof, we need to argue that every satisfying assignment gives rise to a unique α-PNE. Let $\mathbf{s}_X$ be the strategy profile corresponding to this assignment for the input players in $\mathcal{G}_\mu^d$. Then, as before, there is one and exactly one α-PNE $\mathbf{s}$ in $\tilde{\mathcal{G}}_C$ that agrees with $\mathbf{s}_X$; namely, each gate player follows the NAND semantics, the output player plays the one strategy, and the players in $\tilde{\mathcal{G}}_\gamma$ play the dummy strategies. ◀

By approximating all numbers occurring in the construction of Lemma 4 (weights, coefficients, approximation factor) by rationals, we obtain a polynomial-time reduction from Circuit Satisfiability, and thus the following theorem.

▶ **Theorem 5.** *For any integer $d \geq 2$ and rational $\alpha \geq 1$, suppose there exists a weighted polynomial congestion game which does not have an α-approximate PNE. Then it is NP-complete to decide whether (weighted) polynomial congestion games of degree d have an α-approximate PNE.*

Proof. Let $d \geq 2$ and $\alpha \geq 1$. Let $\mathcal{G}$ be a weighted polynomial congestion game of degree d that has no α-PNE; this means that for every strategy profile $\mathbf{s}$ there exists a player i and a strategy $s_i' \neq s_i$ such that $C_i(s_i, \mathbf{s}_{-i}) > \alpha \cdot C_i(s_i', \mathbf{s}_{-i})$. Note that the functions C_i are polynomials of degree d and hence they are continuous on the weights w_i and the coefficients a_e appearing on the cost functions. Hence, any arbitrarily small perturbation of the w_i, a_e does not change the sign of the above inequality. Thus, without loss of generality, we can assume that all w_i, a_e are rational numbers.

Next, we consider the game $\tilde{\mathcal{G}}_\gamma$ obtained from $\mathcal{G}$ by rescaling, as in the proof of Lemma 4. Notice that the rescaling is done via the choice of a sufficiently small γ, according to (8), and hence in particular we can take γ to be a sufficiently small rational. In this way, all the player weights and coefficients in the cost of resources are rational numbers scaled by a rational number and hence rationals.

Finally, we are able to provide the desired NP reduction from Circuit Satisfiability. Given a Boolean circuit C' built with 2-input NAND gates, transform it into a valid circuit C in canonical form. From C we can construct in polynomial time the game $\tilde{\mathcal{G}}_C$ as described in the proof of Lemma 4. The "circuit part", i.e. the game $\mathcal{G}_\mu^d$, is obtained in polynomial time from C, as in the proof of Theorem 3; the description of the game $\tilde{\mathcal{G}}_\gamma$ involves only rational numbers, and hence the game can be represented by a constant number of bits (i.e. independent of the circuit C). Similarly, the additional dummy strategy has a constant delay of ${}^{\tilde{a}_{\min}}/_{\alpha}$, and can be represented with a single rational number. Merging both $\mathcal{G}_\mu^d$ and $\tilde{\mathcal{G}}_\gamma$ into a single game $\tilde{\mathcal{G}}_C$ can be done in linear time. Since C has a satisfying assignment iff $\tilde{\mathcal{G}}_C$ has an α-PNE (or α-PNE), this concludes that the problem described is NP-hard.

The problem is clearly in NP: given a weighted polynomial congestion game of degree d and a strategy profile $\mathbf{s}$, one can check if $\mathbf{s}$ is an α-PNE by computing the ratios between the cost of each player in $\mathbf{s}$ and their cost for each possible deviation, and comparing these ratios with α. ◀

Combining the hardness result of Theorem 5 together with the nonexistence result of Theorem 1 we get the following corollary, which is the main result of this section.

▶ **Corollary 6.** *For any integer $d \geq 2$ and rational $\alpha \in [1, \alpha(d))$, it is NP-complete to decide whether (weighted) polynomial congestion games of degree d have an α-approximate PNE, where $\alpha(d) = \tilde{\Omega}(\sqrt{d})$ is the same as in Theorem 1.*

Notice that, in the proof of Lemma 4 and Theorem 5, we constructed a polynomial-time reduction from Circuit Satisfiability to the problem of determining whether a given congestion game has an α-PNE. Not only does this reduction map YES-instances of one problem to YES-instances of the other, but it also induces a bijection between the sets of satisfying assignments of a circuit C and α-PNE of the corresponding game $\tilde{\mathcal{G}}_C$. That is, this reduction is *parsimonious*. As a consequence, we can directly lift hardness of problems associated with counting satisfying assignments to Circuit Satisfiability into problems associated with counting equilibria in congestion games:

▶ **Corollary 7.** *Let $k \geq 1$ and $d \geq 2$ be integers and $\alpha \in [1, \alpha(d))$ where $\alpha(d) = \tilde{\Omega}(\sqrt{d})$ is the same as in Theorem 1. Then*

- *it is #P-hard to count the number of α-approximate PNE of (weighted) polynomial congestion games of degree d;*
- *it is NP-hard to decide whether a (weighted) polynomial congestion game of degree d has at least k distinct α-approximate PNE.*

Proof. The hardness of the first problem comes from the #P-hardness of the counting version of Circuit Satisfiability (see, e.g., [29, Ch. 18]). For the hardness of the second problem, it is immediate to see that the following problem is NP-complete, for any fixed integer $k \geq 1$: given a circuit C, decide whether there are at least k distinct satisfying assignments for C (simply add "dummy" variables to the description of the circuit). ◀

6 General Cost Functions

In this final section we leave the domain of polynomial latencies and study the existence of approximate equilibria in general congestion games having arbitrary (nondecreasing) cost functions. Our parameter of interest, with respect to which both our positive and negative results are going to be stated, is the number of players n. We start by showing that n-PNE always exist:

▶ **Theorem 8.** *Every weighted congestion game with n players and arbitrary (nondecreasing) cost functions has an n-approximate PNE.*

Proof. Fix a weighted congestion game with $n \geq 2$ players, some strategy profile $\mathbf{s}$, and a possible deviation s_i' of player i. First notice that we can write the change in the cost of any other player $j \neq i$ as

$$\begin{aligned} C_j(s_i', \mathbf{s}_{-i}) - C_j(\mathbf{s}) &= \sum_{e \in s_j} c_e(x_e(s_i', \mathbf{s}_{-i})) - \sum_{e \in s_j} c_e(x_e(\mathbf{s})) \\ &= \sum_{e \in s_j \cap (s_i' \setminus s_i)} [c_e(x_e(s_i', \mathbf{s}_{-i})) - c_e(x_e(\mathbf{s}))] \\ &+ \sum_{e \in s_j \cap (s_i \setminus s_i')} [c_e(x_e(s_i', \mathbf{s}_{-i})) - c_e(x_e(\mathbf{s}))] \qquad (9) \end{aligned}$$

Furthermore, we can upper bound this by

$$\begin{aligned} C_j(s'_i, \mathbf{s}_{-i}) - C_j(\mathbf{s}) &\leq \sum_{e \in s_j \cap (s'_i \setminus s_i)} [c_e(x_e(s'_i, \mathbf{s}_{-i})) - c_e(x_e(\mathbf{s}))] \\ &\leq \sum_{e \in s'_i} c_e(x_e(s'_i, \mathbf{s}_{-i})) \\ &= C_i(s'_i, \mathbf{s}_{-i}), \end{aligned} \tag{10}$$

the first inequality holding due to the fact that the second sum in (9) contains only nonpositive terms (since the latency functions are nondecreasing).

Next, define the social cost $C(\mathbf{s}) = \sum_{i \in N} C_i(\mathbf{s})$. Adding the above inequality over all players $j \neq i$ (of which there are $n-1$) and rearranging, we successively derive:

$$\begin{aligned} \sum_{j \neq i} C_j(s'_i, \mathbf{s}_{-i}) - \sum_{j \neq i} C_j(\mathbf{s}) &\leq (n-1) C_i(s'_i, \mathbf{s}_{-i}) \\ (C(s'_i, \mathbf{s}_{-i}) - C_i(s'_i, \mathbf{s}_{-i})) - (C(\mathbf{s}) - C_i(\mathbf{s})) &\leq (n-1) C_i(s'_i, \mathbf{s}_{-i}) \\ C(s'_i, \mathbf{s}_{-i}) - C(\mathbf{s}) &\leq n C_i(s'_i, \mathbf{s}_{-i}) - C_i(\mathbf{s}). \end{aligned} \tag{11}$$

We conclude that, if s'_i is an n-improving deviation for player i (i.e., $nC_i(s'_i, \mathbf{s}_{-i}) < C_i(\mathbf{s})$), then the social cost must strictly decrease after this move. Thus, any (global or local) minimizer of the social cost must be an n-PNE (the existence of such a minimizer is guaranteed by the fact that the strategy spaces are finite). ◀

The proof not only establishes the existence of n-approximate equilibria in general congestion games, but also highlights a few additional interesting features. First, due to the key inequality (11), n-PNE are reachable via sequences of n-improving moves, in addition to arising also as minimizers of the social cost function. These attributes give a nice "constructive" flavour to Theorem 8. Secondly, exactly because social cost optima are n-PNE, the *Price of Stability*[5] of n-PNE is optimal (i.e., equal to 1) as well. Another, more succinct way, to interpret these observations is within the context of *approximate potentials* (see, e.g., [6, 10, 9]); (11) establishes that the social cost itself is always an n-approximate potential of any congestion game.

Next, we design a family of games $\mathcal{G}_n$ that do not admit $\Theta\left(\frac{n}{\ln n}\right)$-PNE, thus nearly matching the upper bound Theorem 8. In the game $\mathcal{G}_n$ there are $n = m+1$ players $0, 1, \dots, m$, where player i has weight $w_i = 1/2^i$. In particular, this means that for any $i \in \{1, \dots, m\}$: $\sum_{k=i}^{m} w_k < w_{i-1} \leq w_0$. Furthermore, there are $2(m+1)$ resources $a_0, a_1, \dots, a_m, b_0, b_1, \dots, b_m$, where resources a_i and b_i have the same cost function c_i given by

$$c_{a_0}(x) = c_{b_0}(x) = c_0(x) = \begin{cases} 1, & \text{if } x \geq w_0, \\ 0, & \textit{otherwise}; \end{cases}$$

and for all $i \in \{1, \dots, m\}$,

$$c_{a_i}(x) = c_{b_i}(x) = c_i(x) = \begin{cases} \frac{1}{\xi}\left(1 + \frac{1}{\xi}\right)^{i-1}, & \text{if } x \geq w_0 + w_i, \\ 0, & \textit{otherwise}. \end{cases}$$

Where $\xi = \Phi_{n-1}$ is the positive solution of $(x+1)^{n-1} = x^n$.

[5] The Price of Stability (PoS) is a well-established and extensively studied notion in algorithmic game theory, originally studied in [2, 12]. It captures the minimum approximation ratio of the social cost between equilibria and the optimal solution (see, e.g., [7, 9]); in other words, it is the best-case analogue of the the Price of Anarchy (PoA) notion of Koutsoupias and Papadimitriou [25].

The strategy set of player 0 and of all players $i \in \{1, \dots, m\}$ are, respectively,

$$S_0 = \{\{a_0, \dots, a_m\}, \{b_0, \dots, b_m\}\}, \qquad \text{and} \qquad S_i = \{\{a_0, \dots, a_{i-1}, b_i\}, \{b_0, \dots, b_{i-1}, a_i\}\}.$$

Analysing the costs of strategy profiles in $\mathcal{G}_n$ (see [8]) we get the following theorem.

▶ **Theorem 9.** *For any integer $n \geq 2$, there exist weighted congestion games with n players and general cost functions that do not have α-approximate PNE for any $\alpha < \Phi_{n-1}$, where $\Phi_m \sim \frac{m}{\ln m}$ is the unique positive solution of $(x+1)^m = x^{m+1}$.*

Similar to the spirit of the rest of our paper so far, we'd like to show an NP-hardness result for deciding existence of α-PNE for general games as well. We do exactly that in the following theorem, where now α grows as $\tilde{\Theta}(n)$. Again, we use the circuit gadget and combine it with the game from the previous nonexistence Theorem 9. The main difference to the previous reductions is that now n is part of the input. On the other hand we are not restricted to polynomial latencies, so we use step functions having a single breakpoint.

▶ **Theorem 10.** *Let $\varepsilon > 0$, and let $\tilde{\alpha} : \mathbb{N}_{\geq 2} \longrightarrow \mathbb{Q}$ be any (polynomial-time computable) sequence such that $1 \leq \tilde{\alpha}(n) < \frac{\Phi_{n-1}}{1+\varepsilon} = \tilde{\Theta}(n)$, where $\Phi_m \sim \frac{m}{\ln m}$ is the unique positive solution of $(x+1)^m = x^{m+1}$. Then, it is NP-complete to decide whether a (weighted) congestion game with n players has an $\tilde{\alpha}(n)$-approximate PNE.*

7 Discussion and Future Directions

In this paper we showed that weighted congestion games with polynomial latencies of degree d do not have α-PNE for $\alpha < \alpha(d) = \Omega\left(\frac{\sqrt{d}}{\ln d}\right)$. For general cost functions, we proved that n-PNE always exist whereas α-PNE in general do not, where n is the number of players and $\alpha < \Phi_{n-1} = \Theta\left(\frac{n}{\ln n}\right)$. We also transformed the nonexistence results into complexity-theoretic results, establishing that deciding whether such α-PNE exist is itself an NP-hard problem.

We now identify two possible directions for follow-up work. A first obvious question would be to reduce the nonexistence gap between $\Omega\left(\frac{\sqrt{d}}{\ln d}\right)$ (derived in Theorem 1 of this paper) and d (shown in [3]) for polynomials of degree d; similarly for the gap between $\Theta\left(\frac{n}{\ln n}\right)$ (Theorem 9) and n (Theorem 8) for general cost functions and n players. Notice that all current methods for proving upper bounds (i.e., existence) are essentially based on potential function arguments; thus it might be necessary to come up with novel ideas and techniques to overcome the current gaps.

A second direction would be to study the complexity of *finding* α-PNE, when they are guaranteed to exist. For example, for polynomials of degree d, we know that d-improving dynamics eventually reach a d-PNE [3], and so finding such an approximate equilibrium lies in the complexity class PLS of local search problems (see, e.g., [24, 33]). However, from a complexity theory perspective the only known lower bound is the PLS-completeness of finding an *exact* equilibrium for *unweighted* congestion games [14] (and this is true even for $d = 1$, i.e., affine cost functions; see [1]). On the other hand, we know that $d^{O(d)}$-PNE can be computed in polynomial time (see, e.g., [5, 18, 15]). It would be then very interesting to establish a "gradation" in complexity (e.g., from NP-hardness to PLS-hardness to P) as the parameter α increases from 1 to $d^{O(d)}$.

Abstract

Edge connectivity of a graph is one of the most fundamental graph-theoretic concepts. The celebrated *tree packing* theorem of Tutte and Nash-Williams from 1961 states that every k-edge connected graph G contains a collection $\mathcal{T}$ of $\lfloor k/2 \rfloor$ edge-disjoint *spanning* trees, that we refer to as a *tree packing*; the *diameter* of the tree packing $\mathcal{T}$ is the largest diameter of any tree in $\mathcal{T}$. A desirable property of a tree packing for leveraging the high connectivity of a graph in distributed communication networks, is that its diameter is low. Yet, despite extensive research in this area, it is still unclear how to compute a tree packing of a low-diameter graph G, whose diameter is sublinear in $|V(G)|$, or, alternatively, how to show that such a packing does not exist.

In this paper, we provide first non-trivial upper and lower bounds on the diameter of tree packing. We start by showing that, for every k-edge connected n-vertex graph G of diameter D, there is a tree packing $\mathcal{T}$ containing $\Omega(k)$ trees, of diameter $O((101k \log n)^D)$, with edge-congestion at most 2.

Karger's edge sampling technique demonstrates that, if G is a k-edge connected graph, and $G[p]$ is a subgraph of G obtained by sampling each edge of G independently with probability $p = \Theta(\log n/k)$, then with high probability $G[p]$ is connected. We extend this result to show that the diameter of $G[p]$ is bounded by $O(k^{D(D+1)/2})$ with high probability. This immediately gives a tree packing of $\Omega(k/\log n)$ edge-disjoint trees of diameter at most $O(k^{D(D+1)/2})$. We also show that these two results are nearly tight for graphs with a small diameter: we show that there are k-edge connected graphs of diameter $2D$, such that any packing of k/α trees with edge-congestion η contains at least one tree of diameter $\Omega\left((k/(2\alpha\eta D))^D\right)$, for any k, α and η. Additionally, we show that if, for every pair u, v of vertices of a given graph G, there is a collection of k edge-disjoint paths connecting u to v, of length at most D each, then we can efficiently compute a tree packing of size k, diameter $O(D \log n)$, and edge-congestion $O(\log n)$. Finally, we provide several applications of low-diameter tree packing in the distributed settings of network optimization and secure computation.

1 Introduction

Edge connectivity of a graph is one of the most basic graph theoretic parameters, with various applications to network reliability and information dissemination. A key tool for leveraging high edge connectivity of a given graph is *tree packing*: a large collection of spanning trees that are (nearly) edge-disjoint. A celebrated result of Tutte [24] and Nash-Williams [19] shows that for every k-edge connected graph, there is a tree packing $\mathcal{T}$ containing $\lfloor k/2 \rfloor$ edge-disjoint trees. This beautiful theorem has numerous algorithmic applications, but unfortunately it provides no guarantee on the diameter of the individual trees in $\mathcal{T}$. In the worst case, trees in $\mathcal{T}$ may have diameter that is as large as $\Omega(|V(T)|)$, even if the diameter of the original graph is very small. Given a graph G and a collection $\mathcal{T}$ of trees in G, we say that the trees in $\mathcal{T}$ are *edge-disjoint* iff every edge of G lies in at most one tree of $\mathcal{T}$, and we say that they cause *edge-congestion* η iff every edge of G lies in at most η trees of $\mathcal{T}$. The *diameter* of a tree-packing $\mathcal{T}$ is the maximum diameter of any tree in $\mathcal{T}$.

The diameter of a graph is a central graph measure that determines the round complexity of distributed algorithms for various central graph problems, including minimum spanning tree, global minimum cut, shortest s-t path, and so on. All these problems admit a trivial lower bound of $\Omega(D)$ for the round complexity (where D is the diameter of the graph), and in fact a stronger lower bound of $\Omega(D + \sqrt{n})$, which is almost tight for general n-vertex graphs, that was shown by Das-Sarma et al. [23]. Despite attracting a significant amount of attention over the last decade (see e.g., [22, 10, 18, 2, 3, 16, 6, 1, 5, 4]), algorithms that exploit large edge connectivity of the input graph in the distributed setting are quite rare. The only examples that we are aware of are recent algorithms for minimum cut by Daga et al. [4] and by Ghaffari et al. [11].

Censor-Hillel et al. [2] presented several distributed algorithms, that, given a k-edge connected n-vertex graph of diameter D, computes a fractional tree packing of $\Omega(k/\log n)$ trees that are fractionally edge-disjoint[1] in $\widetilde{O}(D+\sqrt{n})$ rounds. These trees have been used to parallelize the flow of information, obtaining nearly optimal *throughput* for store-and-forward algorithms[2]. However, as these trees might have diameter as large as $\Omega(n)$ in the worst case, it is not clear how to use them in order to improve the *round complexity* of the problem at hand, as opposed to improving the throughput. In particular, in terms of optimizing the number of communication rounds, it may still be preferable to send the entire information over a single BFS tree rather than spreading it over *many* trees of potentially *large* diameter.

The problem of computing a low-diameter tree packing was studied later by Ghaffari [6] from the perspective of optimization. Specifically, he studied the multi-message broadcast problem, where a designated source vertex is required to send k messages to all other nodes in the network. Denoting by $\mathrm{OPT}(G)$ the minimum number of rounds required for the broadcast on an input graph G, he constructed a tree packing of size k, where both the diameter and the congestion are bounded by $\widetilde{O}(\mathrm{OPT}(G))$. While this approach provides a nearly optimal broadcast scheme, it does not provide absolute upper bounds on the diameter of the tree packing, and moreover, the congestion caused by the tree packing can be large.

[1] In the fractional setting, each tree T in the packing has a weight $w(T)$ and for each edge e, the sum of weights of all trees that contain e is at most 1.

[2] In this class of algorithms, the nodes can only forward the messages they receive (e.g., network coding is not allowed).

A recent work of Ghaffari and Kuhn [10] provides the following negative result for packing low-diameter trees into a graph: they show that for any large enough n and any $k \geq 1$, there is a k-edge-connected n-vertex graph of diameter $\Theta(\log n)$, such that, in any partitioning of the graph into spanning subgraphs, all but $O(\log n)$ of the subgraphs have diameter $\Omega(n/k)$. In light of this result, it is natural to consider the following key question:

(1) *Is it possible to compute a tree packing whose diameter is strongly* sublinear *in $|V(G)|$, provided that the diameter of the input graph G is* sublogarithmic *in $|V(G)|$?*

Our second key question aims at crystallizing the main challenge to computing low-diameter tree packing. So far, we have compared the diameter of the tree packing to the diameter of the original graph. However, as observed above, the results of [10] indicate that there may be a large gap between these two measures, even for graphs whose diameter is logarithmic in n. A more natural reference point is the following. We say that a graph G is (k, D)*-connected*, iff for every pair $u, v \in V(G)$ of distinct vertices, there are k edge-disjoint paths connecting u to v in G, such that the length of each path is bounded by D. Clearly, if there is a tree packing of edge-disjoint trees of diameter at most D into G, then G must be (k, D)-connected. The question is whether the reverse is also true, if we allow a small congestion and a small slack in the diameter of the trees. The celebrated result of Tutte and Nash-Williams shows that, if every pair of vertices in G has k edge-disjoint paths connecting them, then there are $\lfloor k/2 \rfloor$ edge-disjoint spanning trees in G. However, this result is not length-preserving, in the sense that the tree paths may be much longer than the original paths connecting pairs of vertices. Our goal is then to provide such a length-preserving transformation from collections of short edge-disjoint paths connecting pairs of nodes in G to a low-diameter tree packing.

(2) *Given a (k, D)-connected graph G, can one obtain a tree packing of $\widetilde{\Omega}(k)$ trees of diameter $\widetilde{O}(D)$ into G, with small edge-congestion?*

In this paper, we address both questions. For the first question, we show two efficient algorithms, that, given a k-edge connected n-vertex graph G of diameter at most D, construct a low-diameter tree packing. We complement this result by an almost matching lower bound. We address the second question by providing an efficient algorithm, that, given a (k, D)-connected graph G, computes a collection of k spanning trees of diameter at most $O(D \log n)$ each, that cause edge-congestion of $O(\log n)$.

Our Results

Our graph-theoretic results consider two main settings: in the first setting, the input graph is k-edge connected, and has diameter at most D; in the second setting, the input graph is (k, D)-connected. We only consider unweighted graphs, that is, all edge lengths are unit. Graphs are allowed to have parallel edges, unless we explicitly state that the graph is simple. Throughout the paper, we use the term *efficient algorithm* to refer to a sequential algorithm whose running time is polynomial in its input size.

Packing Trees into Low-Diameter Graphs. We prove the following two theorems that allow us to pack low-diameter trees into low-diameter graphs.

▶ **Theorem 1.** *There is an efficient randomized algorithm, that, given any positive integers D, n, k, and an n-vertex k-edge-connected graph G of diameter at most D, computes a collection $\mathcal{T}' = \{T'_1, \ldots, T'_{\lfloor k/2 \rfloor}\}$ of $\lfloor k/2 \rfloor$ spanning trees of G, such that each edge of G appears in at most two of the trees in $\mathcal{T}'$, and, with high probability, each tree $T'_i \in \mathcal{T}'$ has diameter $O((101k \ln n)^D)$.*

As we show later, the diameter bound of Theorem 1 is close to the best possible. Unfortunately, the trees in the packing provided by Theorem 1 may share edges. Next, we generalize the classical result of Karger [14] to obtain a packing of completely edge-disjoint trees of small diameter, in the following theorem.

▶ **Theorem 2.** *There is an efficient randomized algorithm that, given an n-vertex k-edge-connected graph G of diameter at most D, such that $k > 1000 \ln n$, computes a collection $\{T_1, \ldots, T_r\}$ of $r = \Omega(k/\ln n)$ edge-disjoint spanning trees of G, such that with probability $1 - 1/\mathsf{poly}(n)$, each resulting tree T_i has diameter $O(k^{D(D+1)/2})$.*

We note that while the diameter bound in Theorem 2 is slightly weaker than that obtained in Theorem 1, and the number of the spanning trees is somewhat lower, its advantage is that the resulting trees are guaranteed to be edge-disjoint. Moreover, the algorithm in Theorem 2 is very simple: we construct r graphs $G_1, \ldots, G_r$ with $V(G_i) = V(G)$ for all i, by sampling every edge of G into one of these graphs independently. We then compute a spanning tree T_i in each such graph G_i, and show that its diameter is suitably bounded. As such, this algorithm is easy to use in the distributed setting.

Lastly, we show that our upper bounds are close to the best possible if $k \gg D$, by proving the following lower bound.

▶ **Theorem 3.** *For all positive integers n, k, D, η, α such that $k/(4D\alpha\eta)$ is an integer and $n \geq 3k \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$, there exists a k-edge connected simple graph G on n vertices of diameter at most $2D+2$, such that, for any collection $\mathcal{T} = \{T_1, \ldots, T_{k/\alpha}\}$ of k/α spanning trees of G that causes edge-congestion at most η, some tree $T_i \in \mathcal{T}$ has diameter at least $\frac{1}{4} \cdot \left(\frac{k}{2D\alpha\eta}\right)^D$.*

Note that, in particular, any collection $\mathcal{T}$ of $\Omega(k)$ trees that are either edge-disjoint, or cause a constant edge-congestion, must contain a tree of diameter $\Omega\left(\left(\frac{k}{cD}\right)^D\right)$ for some constant c. Even if we are willing to allow a polylogarithmic edge-congestion, and to settle for $\Theta(k/\mathsf{poly}\log n)$ trees, at least one of the trees must have diameter $\Omega\left(\left(\frac{k}{D\mathsf{poly}\log n}\right)^D\right)$. Moreover, we show that the lower bound from Theorem 3 continues to hold even for the weaker notion of *edge-independent* trees[3], introduced in [12].

Packing Trees into (k, D)-connected Graphs. We next consider (k, D)-connected graphs and show an algorithm that computes a tree packing, that is near-optimal in both the number of trees and in the diameter.

▶ **Theorem 4.** *There is an efficient randomized algorithm, that, given any positive integers D, k, n with $k \leq n$, and a (k, D)-connected n-vertex graph G, computes a collection $\mathcal{T} = \{T_1, \ldots, T_k\}$ of k spanning trees of G, such that, for each $1 \leq \ell \leq k$, tree T_ℓ has diameter at most $O(D \log n)$, and with probability at least $1 - 1/\mathsf{poly}(n)$, each edge of G appears in $O(\log n)$ trees of $\mathcal{T}$.*

Improved Distributed Algorithms for Highly Connected Graphs. We present several applications of low-diameter tree packing in the standard CONGEST model of distributed computation [21]. By the proof of Theorem 2 and the $O(\log n)$-approximation algorithm for edge connectivity by [10], we obtain the following result.

[3] A collection $\mathcal{T}$ of spanning trees is edge-independent, iff all trees in $\mathcal{T}$ are rooted at the same vertex v^*, and for every vertex $v \in V(G)$, if we denote by $\mathcal{P}(v)$ the collection of paths that contains, for each tree $T \in \mathcal{T}$, the unique path connecting v to v^* in T, then all paths in $\mathcal{P}(v)$ are edge-disjoint.

▶ **Theorem 5.** *There is a randomized distributed algorithm, that, given an n-vertex graph G of constant diameter $D = O(1)$ and an integer λ, with high probability solves the problem of $O(\log n)$-approximate verification of λ-edge connectivity in G in $\mathsf{poly}(\lambda \cdot \log n)$ rounds.*

This improves upon the state of the art bound of $O(\sqrt{n})$ for graphs with constant diameter $D \geq 3$, and $\lambda \leq n^c$ for some positive constant $c < 1/(2D^2)$. From now on, we restrict our attention to k-edge connected graphs with a constant diameter $D = O(1)$. We employ the modular approach for distributed optimization introduced by Ghaffari and Haeupler in [8] which is based on the notion of *low-congestion shortcuts*. Roughly speaking, these shortcuts augment vertex-disjoint connected subgraphs by adding nearly-edge disjoint subsets of "shortcut" edges (that is, edges that reduce the diameter of each subgraph). Using our tree packing construction, we provide improved shortcuts for highly connected graphs of small diameter. This immediately leads to $o(\sqrt{n})$-round algorithms for several classical graph problems. For example, we prove the following:

▶ **Theorem 6.** *There is a randomized distributed algorithm, that, given a k-edge connected weighted n-vertex graph G of diameter D, such that the nodes know an $O(\log n)$ approximation of k, computes an MST of G in $\widetilde{O}(\min\{\sqrt{n/k}+n^{D/(2D+1)}, n/k\})$ rounds with high probability.*

If the nodes do not know an $O(\log n)$-approximation of the value of k, then such an approximation can be computed in $\mathsf{poly}(k \log n)$ rounds for $D = O(1)$ using Theorem 5, w.h.p. For general graphs (of an arbitrary connectivity) with diameter $D = 3, 4$, Kitamura et al. [15] showed nearly optimal constructions of MST's (based on shortcuts) with round complexities of $\widetilde{O}(n^{1/4})$ and $\widetilde{O}(n^{1/3})$ respectively. Turning to lower bounds, we slightly modify the construction of Lotker et al. [17] to obtain a lower bound of $\Omega((n/k)^{1/3})$ rounds for computing an MST in k-edge connected graphs of diameter 4, assuming that $k = O(n^{1/4})$.

Finally, we consider the basic task of *information dissemination*, where a given source vertex s is required to send N bits of information to the designated target vertex t in a k-edge connected n-vertex graph. This problem was first addressed in [10], who showed a lower bound of $\Omega(\min\{N/\log^2 n, n/k\})$ rounds, provided that the diameter of the graph is $\Theta(\log n)$. Using our low-diameter tree packing we obtain the first improved upper bounds for sublogarithmic diameter. We also show a new lower bound for simple store-and-forward algorithms, for the regime where $D = o(\log n)$.

▶ **Theorem 7.** *There is a randomized distributed algorithm, that, given any k-edge connected n-vertex graph G of diameter D with a source vertex s and a destination vertex t, sends an input sequence of N bits from s to t. The number of rounds is bounded by $\widetilde{O}(N^{1-1/(D+1)}+N/k)$ with high probability.*

In addition, for all integers n, N, D and $k \leq n$, there exists a k-edge connected n-vertex graph $G = (V, E)$ of diameter $2D$, and a pair s, t of its vertices, such that sending N bits from s to t in a store-and-forward manner requires at least $\Omega(\min\{(N/(D \log n))^{1-1/(D+1)}, n/k\} + N/k + D)$ rounds.

Applications to Secure Distributed Computation. Recently, Parter and Yogev [20] presented a general simulation result that converts any non-secure distributed algorithm to an equivalent secure algorithm, while paying a small overhead in the number of rounds. This transformation is based on the combinatorial graph structure of low-congestion cycle cover, namely, a collection of nearly edge-disjoint short cycles that cover all edges in the graph. The security provided by [20] was limited to adversaries who can manipulate at most one edge of the graph in a given round; in fact if the graph is only 2-edge connected, no stronger security guarantees, in terms of the number of edges that an adversary is allowed to corrupt is possible. In this paper we provide technical tools for handling stronger adversaries, who collude with $f(k)$ edges in a k-edge connected graph in each given round. In order to do so, we define a stronger variant of cycle cover that is adapted to the highly connected setting. This generalization is formalized by the notion of k-connected cycle cover, in which each edge in the graph is covered by k almost-disjoint cycles. Our key contribution is an algorithm that transforms any tree packing with k trees of diameter D into a $(k-1)$-connected cycle cover with cycle length $O(D \log n)$ and congestion $\widetilde{O}(k \log n)$. This yields a simple secure simulation of distributed algorithms in the presence of an adversary who colludes with $O(k/\log n)$ edges of the graph in each round[4]. Finally, we also use low-diameter tree packing to provide a simple store-and-forward algorithm for the problem of secure broadcast.

Organization. We provide the proof of Theorem 1 in Section 2, the proof of Theorem 2 in Section 3, the proof of Theorem 3 in Section 4, and the proof of Theorem 4 in Section 5. We discuss applications of our graph theoretic results to distributed computation in Section 6. Lastly, we discuss open problems in Section 7. Due to lack of space, some of the proofs are only sketched; the full formal proofs are deferred to the full version of the paper.

2 Low-Diameter Tree Packing with Small Edge-Congestion: Proof of Theorem 1

We start by showing that, if we are given a graph G, and a collection $\{T_1, \ldots, T_k\}$ of edge-disjoint spanning trees of G, such that the diameter of the tree T_k is at most $2D$ (but other trees may have arbitrary diameters), then we can efficiently compute another collection $\{T'_1, \ldots, T'_{k-1}\}$ of edge-disjoint spanning trees of G, such that the diameter of each resulting tree T'_i is bounded by $O((101k \ln n)^D)$ with high probability.

▶ **Theorem 8.** *There is an efficient randomized algorithm, that, given any positive integers D, k, n, an n-vertex graph G, and a collection $\{T_1, \ldots, T_k\}$ of k spanning trees of G, such that the trees $T_1, \ldots, T_{k-1}$ are edge-disjoint, and the diameter of T_k is at most $2D$, computes a collection $\{T'_1, \ldots, T'_{k-1}\}$ of edge-disjoint spanning trees of G, such that, with probability at least $1 - 1/\mathsf{poly}(n)$, for each $1 \leq i \leq k-1$, the diameter of tree T'_i is bounded by $O((101k \ln n)^D)$.*

Theorem 1 easily follows by combining Theorem 8 with the results of Kaiser [13], who gave a short elementary proof of the tree-packing theorem of Tutte [24] and Nash-Williams [19]. His proof directly translates into an efficient algorithm, that, given a k-edge connected graph G, computes a collection of $\lfloor k/2 \rfloor$ edge-disjoint spanning trees of G. In order to complete the proof of Theorem 1, we use the algorithm of Kaiser [13] to compute an arbitrary collection $\mathcal{T} = \{T_1, \ldots, T_{\lfloor k/2 \rfloor}\}$ of edge-disjoint spanning trees of G, and compute another arbitrary BFS tree T^* of G. Since the diameter of G is at most D, the diameter of T^* is at most $2D$. We then apply Theorem 8 to the collection $\{T_1, \ldots, T_{\lfloor k/2 \rfloor}, T^*\}$ of spanning trees, to obtain another collection $\mathcal{T}' = \{T'_1, \ldots, T'_{\lfloor k/2 \rfloor}\}$ of spanning trees, such that each edge of G belongs to at most 2 trees of $\mathcal{T}'$, and with high probability, the diameter of each tree in $\mathcal{T}'$ is at most $O((101k \ln n)^D)$. We note that, since we allow parallel edges, the trees in the set $\{T_1, \ldots, T_{\lfloor k/2 \rfloor}, T^*\}$ are edge-disjoint in graph $G \cup E(T^*)$.

[4] We note that an adversary may choose a different set of $O(k/\log n)$ edges to listen to or to corrupt in each round.

The main technical tool that we use in order to prove of Theorem 8 is the following theorem, that allows one to "fix" a diameter of a connected graph using a low-diameter tree.

▶ **Theorem 9.** *Let H be a connected graph with $|V(H)| \leq n$, and let T be a rooted tree of depth D, such that $V(T) = V(H)$. For a real number $0 < p < 1$, let R be a random subset of the edges of T, where each edge $e \in E(T)$ is added to R independently with probability p. Then with probability at least $1 - \frac{D}{n^{48}}$, the diameter of the graph $H \cup R$ is at most $(\frac{101 \ln n}{p})^D$.*

Theorem 8 easily follows from Theorem 9: For each $1 \leq i < k$, we construct a graph G_i as follows. Start with $G_i = T_i$ for all $1 \leq i \leq k$. Compute a random partition $E_1, \ldots, E_{k-1}$ of the edges of $E(T_k)$, by adding each edge $e \in E(T_k)$ to a set E_i chosen uniformly at random from $\{E_1, \ldots, E_{k-1}\}$ independently from other edges. Using Theorem 9 with $p = 1/(k-1)$, it is immediate to see that with high probability, the diameter of each resulting graph G_i is bounded by $O((101k \ln n)^D)$. We then let T'_i be a BFS tree of graph G_i, rooted at an arbitrary vertex. In order to complete the proof of Theorem 1, it is now enough to prove Theorem 9.

Proof of Theorem 9. Recall that we are given a connected graph H with $|V(H)| \leq n$, and a rooted tree T of depth D, such that $V(T) = V(H)$, together with a parameter $0 < p < 1$. We let R be a random subset of $E(T)$, where each edge $e \in E(T)$ is added to R independently with probability p. Our goal is to show that the diameter of the graph $H \cup R$ is at most $\left(\frac{101 \ln n}{p}\right)^D$ with probability at least $1 - \frac{D}{n^{48}}$. Denote $V = V(H) = V(T)$. For each $0 \leq i \leq D$, let V_i be the set of nodes lying at level i of the tree T (that is, at distance i from the tree root), and denote $V_{\leq i} = \bigcup_{t=0}^{i} V_t$. Let $H' = H \cup R$.

We say that a node $x \in V$ is *good* if either (i) $x \in V_{\leq D-1}$; or (ii) $x \in V_D$, and there is an edge in R connecting x to a node in V_{D-1}. We assume that $V = \{v_1, \ldots, v_{n'}\}$, where the vertices are indexed in an arbitrary order. Given an ordered pair (x, x') of vertices in H, and a path P connecting x to x', let $\sigma(P)$ be a sequence of vertices that lists all the vertices appearing on P in their natural order, starting from vertex x (so in a sense, we think of P as a directed path). For an ordered pair $(x, x') \in V$ of vertices, let $P_{x,x'}$ be shortest path connecting x to x' in H, and among all such paths P, choose the one whose sequence $\sigma(P)$ is smallest lexicographically. Observe that $P_{x,x'}$ is unique, and, moreover, if some pair u, u' of vertices lie on $P_{x,x'}$, with u lying closer to x than u' on $P_{x,x'}$, then the sub-path of $P_{x,x'}$ from u to u' is precisely $P_{u,u'}$.

Let $M = \frac{50 \ln n}{p}$. For a pair x, x' of vertices of V, we let $B(x, x')$ be the bad event that length of $P_{x,x'}$ is greater than M and there is no good internal node on $P_{x,x'}$. Notice that event $B(x, x')$ may only happen if every inner vertex on $P_{x,x'}$ lies in V_D, and for each such vertex, the unique edge of T that is incident to it was not added to R. Therefore, the probability that event $B(x, x')$ happens for a fixed pair x, x' of vertices is at most $(1-p)^M = (1-p)^{(50 \ln n)/p} \leq n^{-50}$. Let B be the bad event that $B(x, x')$ happens for some pair $x, x' \in V$ of nodes. From the union bound over all pairs of nodes in V, the probability of B is bounded by n^{-48}.

Recall that H is a subgraph of H' and $\mathrm{dist}_H(\cdot, \cdot)$ is the shortest-path distance metric on H. We use the following immediate observation.

▶ **Observation 10.** *If the event B does not happen, then for every node $x \in V$, there is a good node $x' \in V$ such that* $\mathrm{dist}_H(x, x') \leq M$*.*

We prove Theorem 9 by induction on D. The base of the induction is when $D = 1$. In this case, T is a star graph. Let c denote the vertex that serves as the center of the star. For any pair $x_1, x_2 \in V$ of vertices, we denote by x'_1 the good node that is closest to x_1 in H, and we define x'_2 similarly for x_2. Notice that, from the definition of good vertices, either $x'_1 = c$, or it is connected to c by an edge of R, and the same holds for x'_2. Therefore, $\text{dist}_{H'}(x'_1, x'_2) \le 2$ must hold. If the event B does not happen, then, since H is a subgraph of H', $\text{dist}_{H'}(x_1, x_2) \le \text{dist}_{H'}(x_1, x'_1) + \text{dist}_{H'}(x'_1, x'_2) + \text{dist}_{H'}(x_2, x'_2) \le \text{dist}_{H}(x_1, x'_1) + \text{dist}_{H'}(x'_1, x'_2) + \text{dist}_{H}(x_2, x'_2) \le 2M + 2 \le \frac{101 \ln n}{p}$. Therefore, with probability at least $1 - n^{-48}$, $\text{dist}_{H'}(x_1, x_2) \le \frac{101 \ln n}{p}$.

Assume now that Theorem 9 holds for every connected graph H and every tree T of depth at most $D - 1$, with $V(T) = V(H)$. Consider now some connected graph H, and a rooted tree T of depth D, with $V(T) = V(H)$. We partition the edges of $E(T)$ into two subsets: set E_1 contains all edges incident to the vertices of V_D, and set E_2 contains all remaining edges. Let $E'_1 = E_1 \cap R$, and let $E'_2 = E_2 \cap R$. Notice that the definition of good vertices only depends on the edges of E'_1, and so the event B only depends on the random choices made in selecting the edges of E'_1, and is independent from the random choices made in selecting the edges of E'_2.

Let L be a subgraph of H', obtained by starting with $L = H$, and then adding all edges of E'_1 to the graph. Finally, we define a new graph $\hat{H}$, whose vertex set is $V_{\le D-1}$, and there is an edge between a pair of nodes w, w' in $\hat{H}$ iff the distance between w and w' in L is at most $M + 2$. We also let $\hat{T}$ be the tree obtained from T, by discarding from it all vertices of V_D and all edges incident to vertices of V_D. Observe that $V(\hat{H}) = V(\hat{T}) = V_{\le D-1}$. The idea is to use the induction hypothesis on the graph $\hat{H}$, together with the tree $\hat{T}$. In order to do so, we need to prove that $\hat{H}$ is a connected graph, which we do next.

▶ **Observation 11.** *If the event B does not happen, then graph $\hat{H}$ is connected.*

Proof. Assume that the event B does not happen, and assume for contradiction that graph $\hat{H}$ is not connected. Let $\mathcal{C} = \{C_1, \dots, C_r\}$ be the set of all connected components of graph $\hat{H}$. For every pair C_i, C_j of distinct components of $\mathcal{C}$, consider the set $\mathcal{P}_{i,j} = \{P_{x,x'} \mid x \in V(C_i), x' \in V(C_j)\}$ of paths (recall that $P_{x,x'}$ is the shortest path connecting x to x' in H with $\sigma(P_{x,x'})$ lexicographically smallest among all such paths). We let $P_{i,j}$ be a shortest path in $\mathcal{P}_{i,j}$. Choose two distinct components $C_i, C_j \in \mathcal{C}$, whose path $P_{i,j}$ has the shortest length, breaking ties arbitrarily. Assume that $P_{i,j}$ connects a vertex $v \in C_i$ to a vertex $u \in C_j$, so $P_{i,j} = P_{v,u}$. Recall that $H \subseteq L$, and so the path $P_{i,j}$ is contained in graph L. Since we did not add edge (u, v) to $\hat{H}$, the length of $P_{i,j}$ is greater than $M + 2$. Since we have assumed that event B does not happen, there is at least one good inner vertex on path $P_{i,j}$. Let X be the set of all good vertices that serve as inner vertices of $P_{i,j}$.
